In addition to this approach, PGx should also be tailored to neonates and not only mirror observations initially described in adults. Pharmacogenetic studies may also provide information on the ontogeny of processes that have not yet been well described, such as transporter or receptor ontogeny (pharmacogenetic concordance). A recent illustration of such an exploration is the impact of polymorphisms on neonatal abstinence syndrome following maternal opioid intake. Specific catechol-*O*-methyltransferase (*COMT*, 158 adenine [A] > guanine [G]) and μ-opioid receptor (*OPRM1*, 118 A > G) polymorphisms influenced the extent and the duration of neonatal abstinence syndrome.[26] Pharmacogenetic studies may focus on the concordance between genotype and phenotype within cohorts of newborns and young infants. A structured approach to assess the contribution of genetic variation in addition to maturation to pharmacokinetic/pharmacodynamic variability has been suggested and is based on five questions:[23]

1. What gene products (if known) are relevant for the disposition of a given compound?
2. What is the developmental trajectory (if known) of functional (e.g., transporter, enzyme, or receptor) activity?
3. Does allelic variation affect the function(s) of a given compound?
4. Does allelic variation affect the developmental drug disposition phenotype?
5. What is the developmental context of the relevant genes?

Pharmacokinetic Principles

Pharmacokinetics describes the time course of changes in drug concentrations within the body. Although rates of change are often described with differential equations, concepts useful at the bedside are emphasized here.[27]

Compartment

In PK, *compartment* refers to fluid and tissue spaces into which drugs penetrate. These compartments may or may not be equivalent to anatomic or physiologic volumes. In the simplest case the compartment may correspond to the vascular space and equal the volume of a real body fluid, blood. Large or quite polar molecules may be confined to this central compartment until they are eliminated by elimination or metabolism. Many drugs, however, diffuse reversibly out of the central compartment into tissues or other fluid spaces, referred to generically as *peripheral or tissue compartments*. Diffusion can be driven, in part, by differences in concentration and protein binding between compartments or can be affected by active transport (influx/efflux) processes. These kinds of compartments are seldom sampled directly, but their involvement in kinetic processes may be recognized from the graphical or mathematical description of the kinetics of a drug. The number of exponential terms necessary to adequately describe the kinetic profile of a drug designates the number of compartments involved, recognizing that many more compartments may exist. For clinical application, rarely more than three compartments are required to describe the PK of any drug.[27–29]

The apparent volume of distribution might be better termed the *volume of dilution* because it is a mathematical description of the volume (L or L/kg) that dilutes a dose (mg or mg/kg) to produce the observed circulating drug concentration (mg/L or μg/mL). To simplify cancellation of units, concentrations are expressed here as milligrams per liter (mg/L), which is the same as micrograms per milliliter (μg/mL), the more conventional unit for drug concentrations in the US:

$$\text{concentration (mg/L)} = \frac{\text{Dose (mg/kg)}}{\text{Apparent Volume of Distribution (L/kg)}}$$

For many drugs the volume of distribution does not correspond to a specific physiologic body fluid or tissue, hence the term *apparent*. In fact, the volume of distribution for drugs that are bound extensively in tissues may exceed 1.0 L/kg, a physiologic impossibility that emphasizes the arithmetic, nonphysiologic nature of the apparent volume of distribution. The determination of the volume of distribution is described later.

First-Order Kinetics

Removal of most drugs from the body can be described by first-order (exponential or proportional) kinetics, in which a constant

proportion or percentage of a drug is removed per unit of time (e.g., 50% in one half-life interval), rather than a constant amount per unit of time (zero-order kinetics, see later in this chapter). Consequently, for drugs exhibiting first-order kinetics, the higher the concentration, the greater the amount removed during a time interval. The following equations describe the concentration (C) of a drug whose first-order kinetics has a rate constant, k (/hour), at time t and an initial concentration of C_0 achieved after administration of a dose.

In differential equation form, the change in concentration with time is:

$$\frac{dC}{dt} = -KC$$

The solution to this differential equation gives the exponential form, describing C at time t:

$$C_t = C_0 e^{-kt}$$

If this equation is transformed with use of the natural logarithm (ln), it becomes:

$$\ln C_t = \ln C_0 - kt$$

The last equation is the equation of a straight line, so a graph that plots ln C_t versus t has an intercept of ln C_0, the concentration at $t = 0$, and a slope of $-k$, the rate constant for the change in concentration. This can be used to calculate the half-life (see next section) and to estimate appropriate dosages. Multiple rate constants in more complex equations are distinguished with the letter k and numbered subscripts or with Greek letters.

Half-Life

The elimination half-life ($t_{1/2}$) of a drug is the time required for its concentration to decrease by 50%. Consequently, half-life is linked to a first-order kinetic process because the same proportion, 50%, of the drug is removed during equal periods. Half-life can be determined mathematically from the elimination rate constant, k, as:

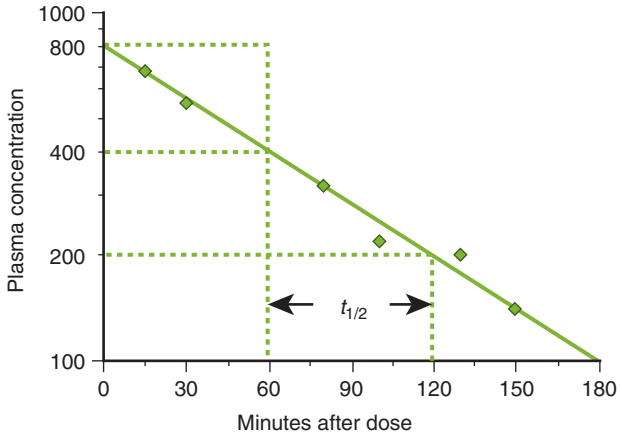
$$t_{1/2} = \frac{\text{Natural Logarithm 2}}{k} = \frac{0.693}{k}$$

Fig. 21.1 illustrates a graphical method for determination of half-life. Drug concentrations measured serially are graphed on semi-logarithmic axes, and the best-fit line is determined either visually or by linear regression analysis. In this illustration of first-order kinetics, the concentration decreases by 50% (from 800 to 400 mg/L) during the first hour and decreases by another 50% (from 400 to 200 mg/L) during the second hour. Thus the half-life is 1 hour. More drug is removed during one half-life at higher concentrations, although the proportion removed remains constant. The exponential equation for this graph is:

$$C = 800e^{-0.693t}$$

where $k = 0.693$/hour and $C_0 = 800$, allowing a mathematical calculation of half-life with use of the equation previously described:

$$t_{1/2} = \frac{0.693}{k\,(/\text{hour})} = \frac{0.693}{0.693/\text{hour}} = 1\,\text{hour}.$$



• **Fig. 21.1** Apparent single-compartment first-order plasma drug disappearance curve illustrating graphic determination of half-life from the best-fit line of serial plasma concentrations.

Multicompartment First-Order Kinetics

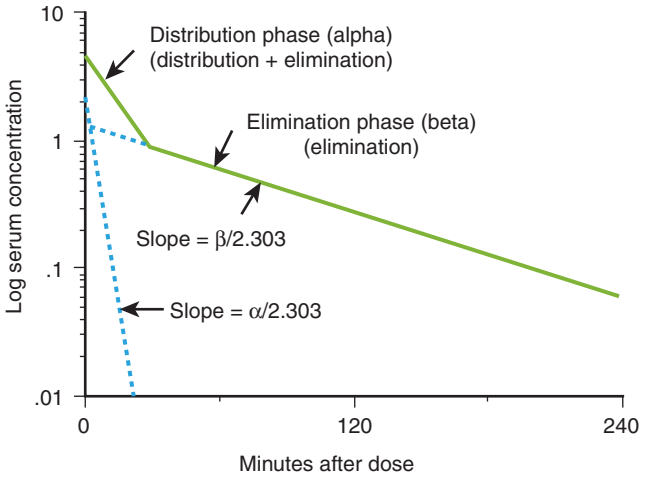
The rate of removal of many drugs from the circulation is often biphasic. An initial rapid decrease in concentration is referred to as the distribution (α) phase, often lasting 15 to 45 minutes, which is followed by a sustained slower rate of removal, the elimination (β) phase. Such biphasic processes are best visualized from semi-logarithmic graphs of drug concentration versus time. When such semi-logarithmic graphs show kinetics that best fit two straight lines, the kinetics are described as *biexponential*, or reflective of a drug that shows *two-compartment first-order pharmacokinetics* (Fig. 21.2). Two exponential terms are needed to describe the change in concentration over time, as:

$$C = Ae^{-\alpha t} + Be^{\beta t}$$

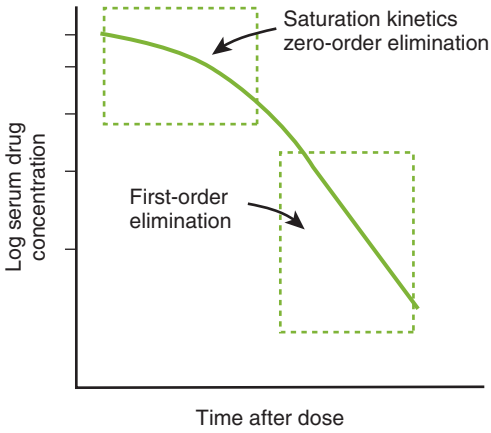
In this equation the rate constant for distribution is designated α to discriminate it from the rate constant for terminal elimination (β), where A and B are the $t = 0$ intercepts for the lines describing distribution and elimination, respectively. Division by 2.303 converts logarithms to natural logarithms.

After an intravenous dose, drug loss from the vascular space during the distribution phase occurs through both distribution and elimination (see Fig. 21.2). The rate constant of distribution (α) can be determined by a plot of the difference between the total amount of drug lost initially and the amount of drug lost through elimination.[27] This produces the line with the steeper slope (equal to $\alpha/2.303$) below the serum concentration graph in Fig. 21.2. The single slope of the distribution phase and of the terminal elimination phase does not imply that distribution or elimination occurs through a single process. The observed rates usually represent the sum of several simultaneous processes, each with differing rates, occurring in various tissues.

When the time course of drug elimination is observed for prolonged periods, a third rate of elimination, or γ phase, may also be observed and is usually attributed to the elimination of a drug that has re-equilibrated from deep tissue compartments back into the plasma. Such kinetics are designated *three-compartment first-order pharmacokinetics*. The kinetics of a drug are expressed with the smallest number of compartments that accurately describes its concentration changes over time.



• **Fig. 21.2** Multi-compartment serum drug disappearance curve. α, Rate constant for distribution; β, rate constant for terminal elimination.



• **Fig. 21.3** Saturation, or zero-order (serum concentration–dependent), and first-order (serum concentration–independent) pharmacokinetics.

Apparent Single-Compartment First-Order Kinetics

When a semi-logarithmic graph of concentration versus time reveals a single slope with no distribution phase, the kinetics are characterized as *apparent single-compartment first-order kinetics* (see Fig. 21.1). This kind of kinetics can occur when a drug remains entirely within the vascular space or central compartment or when a drug passes very rapidly back and forth between the blood and peripheral sites until it is metabolized or eliminated by first-order kinetics. The adjective *apparent* is used because careful study (e.g., very early sampling) often shows that distribution occurs even though the kinetic curve has only a single slope. Single-compartment kinetics implies that the drug rapidly and completely distributes homogeneously throughout the body, which rarely occurs clinically.

In many pharmacokinetic studies in newborns, blood samples are not obtained early enough to allow calculation of the distribution phase, and the kinetics are described as single-compartment kinetics. If sampling begins after the distribution phase, the concentration–time points may fit a single-compartment first-order model, which determines the elimination rate constant (β).

Zero-Order Kinetics

Some drugs demonstrate *zero-order kinetics*, in which a constant *amount* of drug, rather than a constant proportion or percentage, is removed per unit of time. This relationship can be expressed as:

$$\frac{dC}{dt} = -k$$

It is important to understand when zero-order kinetics occurs, how to recognize it, and how it affects drug concentrations. Zero-order kinetics is sometimes referred to as *saturation kinetics* because it may occur when excess amounts of drug completely saturate enzymes or transport systems such that they metabolize or transport only a *constant amount* of drug over time. Zero-order processes produce a curvilinear shape in a semi-logarithmic graph of concentrations versus time (Fig. 21.3). When drug concentrations are high from a drug overdose or the pathway for elimination is impaired as in renal dysfunction, the kinetics may become zero order initially and be followed by first-order kinetics at lower concentrations. For drugs exhibiting zero-order kinetics, small increments in dose may cause disproportionately large increments in serum concentration. Certain drugs or excipients (inactive substances that serve as vehicle or medium for a drug or other active substance, like filler, preservative or coloring agent) administered to newborns exhibit zero-order kinetics at concentrations observed in the clinical setting and must be recognized for potential accumulation (Box 21.2).

Phenytoin
Ethanol and other alcohols (excipients)

Noncompartmental Analysis

Noncompartmental analysis is based on describing drug exposure measured by the area under the concentration–time curve (AUC) without any assumptions about the pattern of elimination or the number of compartments.[28] Central to this analysis is the determination of drug clearance (CL) from the dose and the AUC:

$$CL = Dose/AUC$$

If the dose is administered intravenously, then noncompartmental analysis allows the direct determination of drug clearance with use of this relationship. Estimation of the elimination half-life is generally done with the slope of the log-transformed concentration measurements made during the end of a pharmacokinetic study. With an estimation of clearance and elimination rate, the apparent distribution volume (V) can also be estimated from:

$$CL = V \times k$$

Thus, noncompartmental PK provides a simple means to assess fundamental pharmacokinetic parameters that may be useful for dosing patients when detailed knowledge of the complete pharmacokinetic profile is not available or not needed.[27]

Advanced Mathematical Approaches: Population- and Physiology-Based Pharmacokinetic Models

Pharmacokinetic studies in newborns remain challenging due to sample size, heterogeneity of study population, and patient burden (blood sampling). The optimal PK sampling strategy must consider both the timing and number of samples per patient, and minimize sample volume using innovative bioanalytical methods.[30]

The population approach describes the concentration versus time profile for samples in all patients simultaneously, estimating population parameters that describe the average pharmacokinetic profile of the complete study group and patient-specific parameters that define the individual patients in the study. It can use fewer samples taken from each patient, if the samples are taken at different specified times, time windows or even opportunistic times when other blood samples are taken over the complete time profile of interest for the study analysis.[31] For example, one group of 28 to 32 weeks gestation neonates might have samples drawn at 1, 4, and 12 hours, while another group of 28 to 32 weeks gestation neonates might have blood sampled at 0.5, 2, and 8 hours. The concentrations from these two groups of similar patients are then analyzed in aggregate so as to provide information during both the distribution phase and the elimination phase, thus describing the kinetics with a limited volume of blood sampled from each patient.

Furthermore, the population approach allows the investigation of patient covariates of interest that might explain differences within the population of patients enrolled in the trial. Typical covariates such as postnatal age, GA at birth, weight, sex, organ dysfunction, and disease conditions can also be assessed for their contribution to differences seen between participants in a clinical study. These covariates can be very helpful for gaining a better understanding of factors that may alter the PK of infants that might otherwise be considered similar. Because of both conditions (fewer samples, exploration of covariates), the use of population pharmacokinetic studies in clinical studies is also strongly supported by the relevant regulatory agencies as an important contribution to drug research in this population.[28,29,32]

The PBPK approach is gaining interest as the preferred methodology to reliably predict PK in the neonatal population, especially during drug development studies. In a PBPK approach, drug-specific information (solubility, pH, molecular weight) is combined with anatomical and physiological knowledge—in this case specific to (pre)term neonates, including diseases—into a predictive model. To achieve this, the anatomical structure of the human body is represented by physiologically relevant compartments that are connected via the blood circulation.[33–35]

Target Drug Concentration Strategy

Drug treatment of newborns commonly uses the *target drug concentration strategy* (Table 21.1), in which drug therapy corrects a specific problem by producing an effective concentration of free drug at a specific site of action.[28] The target site of drug action (e.g., central nervous system, subcutaneous tissue) is usually inaccessible for monitoring of concentrations. A specific concentration or range of circulating concentrations is correlated with the effective concentration at the site of action, which provides a "therapeutic" concentration range. However, caregivers should be aware that such target drug concentrations are commonly extrapolated from other patient populations and are only rarely validated in newborns.[24]

The requirements for effective and accurate application of the target drug concentration treatment in adults have been discussed by Spector et al.[36] When applied to newborns, these requirements highlight the special problems of drug therapy in these patients and the special circumstances in which clinical drug concentration monitoring is appropriate. Some of these requirements are as follows:

- Availability of a reliable, valid analytic procedure for accurate measurement of drug concentrations in small blood volumes;
- A wide variation in PK among individuals with the knowledge that population-based kinetics do not accurately predict individual kinetics;
- Drug effects proportional to plasma drug concentrations;
- A narrow concentration range between efficacy and toxicity (narrow therapeutic index);
- Constant pharmacologic effect over time, in which tolerance does not develop;
- Clinical studies that have determined the target and toxic drug concentration ranges.

Therapeutic Drug Monitoring (TDM)

Table 21.1 describes the basic assumptions of TDM: the total plasma drug concentrations correlate with dose but also with the circulating unbound drug concentrations and the unbound drug concentration at the site of action. Measurements of drug concentrations are usually total drug concentrations, while the active portion is the unbound portion (see discussion in the Distribution section). Two broad indications for TDM are to (1) attain effective concentrations and (2) avoid toxic concentrations. However, drug concentration ranges are not absolute reflections but only indirect markers of effective therapy. Patient response, not a specific drug concentration range, is the end point of therapy.[37]

Although the concentrations of aminoglycoside or glycopeptide antibiotics are monitored frequently in newborns, the current perception is that toxicity is much less common in newborns than in adults.[38,39] Because of the limited evidence of toxicity in newborns, it is more important to measure these concentrations to achieve effective concentrations for treatment of culture-proven infections than to avoid toxicity. When the desired concentration

TABLE 21.1 Target Drug Concentration Strategy

Drug dose	↔	Plasma total drug concentration	↔	Plasma unbound drug concentration	↔	Target site unbound drug concentration	↔	Desired pharmacologic effect

range and kinetic parameters are known, dosages may be estimated to reach that concentration with single bolus doses or bolus doses followed by continuous infusions. TDM hereby typically covers a PK assessment based on a drug concentration, with subsequent dose adaptation, or not. We anticipate that in the near future, such dose adaptation will be guided by MIPD tools. MIPD is a new dosing paradigm, combining mathematical models for drugs and diseases with individual patient characteristics (e.g., TDM, weight, age) and disease characteristics (e.g., pathogen susceptibility) to calculate the optimal dose, preferably at the bedside. As computer technology becomes ever more readily available bedside, this is a very realistic, feasible aim with the potential to significantly improve the interpretation of TDM results as integrated with other relevant information of the individual patient.[1]

Pharmacokinetic-Based Dosing

The following equations can be used both to guide dosing and to derive kinetic parameters for individual patients:

$$\text{Dose} = \Delta C \cdot \text{Vd} = \left[C_{\text{desired}} - C_{\text{initial}}\right] \cdot \text{Vd}$$
$$(\text{mg/kg}) = (\text{mg/L})(\text{L/kg}) = (\text{mg/L})(\text{L/kg})$$

where C is the concentration and Vd is the apparent volume of distribution.

This equation may be used to estimate dosage changes needed to increase or decrease concentration. For the first dose, the starting concentration is zero; for doses after the first, the calculation of the volume of distribution should use the change (Δ) in concentration from the preceding trough to the peak associated with that dose. To reach a desired concentration rapidly, a loading dose can be administered, followed by a sustaining infusion. The equation for calculation of infusion doses to maintain a constant concentration is as follows:

$$\text{infusion rate} = k \cdot \text{Vd} \cdot \text{C}$$
$$(\text{mg/kg})\left(\text{min}^{-1}\right) = \left(\text{min}^{-1}\right)(\text{L/kg})\,(\text{mg/L})$$

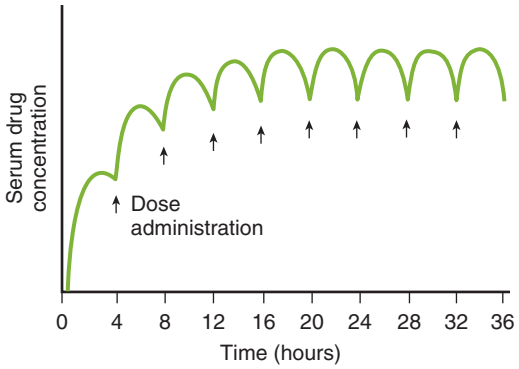
where C is the concentration, Vd is the volume of distribution, and k is the rate constant of elimination.

A steady state is reached when tissue concentrations are in equilibrium and the amount of drug removed equals the amount of drug infused. The time needed to reach a steady state depends on the elimination half-life. While the time needed is *not* shortened by the administration of a loading dose, a loading dose can allow the patient to achieve therapeutic concentrations rapidly, and these can be maintained with an infusion during the steady state.

It is important to consider that if drug clearance decreases, the steady-state concentration during an infusion will increase proportionally. Additionally, the half-life increases and the rate constant decreases. Since concentrations are not measured for most of the drugs administered by continuous infusion in the neonatal intensive care unit (NICU), it is important to consider to adjust dosages for factors that reduce clearance, such as kidney or liver dysfunction or reduced kidney or liver blood flow, to avoid high and potentially toxic concentrations.

Repetitive Dosing and the "Plateau Principle"

During a typical course, drug doses are administered before complete elimination of previous doses, and the drug accumulates in the body. Consequently, during repeated administration, the peak and trough concentrations after each dose will increase until a steady-state situation has been reached. *Steady-state*, or *plateau*, concentrations are reached when the amount of drug eliminated equals the amount of drug administered during each dosing interval. During repetitive dosing, the steady-state concentrations achieved are related to the half-life, dose, and dosing interval relative to the elimination half-life.



• **Fig. 21.4** Multiple dosing with accumulation of serum drug concentrations to the steady-state concentration.

Fig. 21.4 illustrates a hypothetical concentration–time curve for a drug with a half-life of 4 hours administered orally every 4 hours, so the dosing interval corresponds to one half-life. Several important principles of PK are illustrated in Fig. 21.4. Drug concentrations increase and decrease with drug administration (absorption) and elimination. For dosing intervals of one half-life, accumulation is 88% complete after the third dose, 94% complete after the fourth dose, and 97% complete after the fifth dose. At steady state, the peak and trough concentrations between doses are the same after each dose. If a drug is administered with a dosing interval equal to one half-life, the steady-state peak and trough concentrations are two times those reached after the first dose. If the dosing interval is shortened to half of a half-life, the concentration decreases less before the next dose, more total drug is administered per day, and the steady-state peak and trough concentrations are considerably higher (3.4 times the peak and trough concentrations after the first dose). Therefore, the shorter the dosing interval to half-life ratio, the higher the drug accumulation. As noted during infusions, the *length of time* required to reach steady-state concentrations depends primarily on the elimination half-life, not the dosing interval.

Clearance

Clearance of drugs, as for creatinine, describes the *volume of blood* from which all the drug is removed per unit of time. Clearance is proportional to organ blood flow and the intrinsic capacity of organs to metabolize or remove a drug from the circulation. In its simplest form, clearance is proportional to the flow to a single organ (Q) and to the arterial–venous difference in drug concentrations compared with the amount of drug in the circulation, expressed as follows:

$$\text{CL} = \text{Q} \cdot \frac{C_{\text{arterial}} - C_{\text{venous}}}{C_{\text{arterial}}}$$

Total body clearance usually reflects the combined clearance of multiple organs with different enzyme activities and different

rates of blood flow. Clearance can be measured by the rate of appearance of a drug outside the body (such as urinary creatinine clearance) or by the rate of disappearance of a drug from the blood compared with the blood concentration. For calculations, *clearance* is defined as the dose divided by the AUC and by the rate of drug input per steady-state concentration (Css) average, where the rate of input is the dose/dosing interval (τ). For a drug administered by continuous infusion, this is simply the infusion rate (milligrams per kilogram per hour) divided by Css as follows:

$$\mathrm{CL} = \frac{\mathrm{Dose}}{\mathrm{AUC}} = \frac{\mathrm{Dose}/\tau}{\mathrm{Css}} = \frac{\mathrm{Infusion\ Rate}}{\mathrm{Css}}$$

Once clearance is known, this equation can be rearranged to calculate the dose necessary to achieve any desired steady-state concentration:

$$\mathrm{Infusion\ Rate} = \mathrm{Css} \cdot \mathrm{CL}$$
$$(\mathrm{mg/kg})\,\mathrm{hr}^{-1} = (\mathrm{mg/L})(\mathrm{mL/kg})\,\mathrm{hr}^{-1}$$

Total body clearance changes significantly for several drugs during the period of fetal and infant development because renal clearance and/or the activity of drug-metabolizing enzymes increase with advancing gestational and/or postnatal age. If available, values for clearance and the volume of distribution at different stages of development can be used to estimate the dosages needed to achieve and maintain "therapeutic" concentrations associated with desired clinical responses. To illustrate this for renal clearance, a higher dose (mg/kg) and a further extended time interval are applied for aminoglycosides or vancomycin to compensate for the higher distribution volume (peak concentration) and the lower renal clearance (trough concentration).[40,41]

Studies of the analgesic fentanyl illustrate the developmental changes in metabolic clearance and how they may be used to calculate dosages to reach and maintain concentrations associated with effective analgesia. Analgesia has been associated with a serum fentanyl concentration of 1 to 2 ng/mL.[42] If analgesic treatment is initiated with a continuous infusion of fentanyl, five half-lives are needed to reach a steady state. The fentanyl half-life ranges from 3 hours in term newborns to 12.7 hours in preterm newborns.[42–44] Because of this prolonged half-life, the patient may be inadequately treated for a long time unless a loading dose is administered to reach an effective concentration more rapidly. In general, initiation of analgesic treatment and increases in infusion dosages of analgesics should begin with a loading dose based on the estimated volume of distribution in the central compartment (circulation) and the desired concentration. Use of a loading dose shortens the time to reach higher effective analgesic concentrations but also increases the likelihood of toxicity, as has been reported with opioids or milrinone.

The available data on GA-related changes in fentanyl clearance show that there is an increase with advancing GA[42–44] and postnatal age.[42,44,45] The linear graph of clearance versus GA from 38 neonates in whom treatment began within 47 hours after their birth was used to derive mean rates of clearance at different GAs as shown in Table 21.2.[42,45]

Other investigators studied single-dose fentanyl kinetics during anesthesia and found an apparent central volume of distribution of fentanyl in neonates of 1.45 L/kg.[43] This distribution volume is smaller than the steady-state volume of distribution of 5.1 L/kg also calculated after a single dose of fentanyl.[43] In turn, the apparent steady-state volume of distribution after a single bolus dose of a lipophilic drug is usually smaller than that associated with continuous drug infusions, during which tissues throughout the body become saturated with drug. The steady-state distribution volume for fentanyl during continuous infusions was calculated as 17 L/kg.[42] Because fentanyl is a highly lipid-soluble drug, it distributes rapidly from the central compartment into the peripheral tissue compartment. This large distribution volume likely reflects the period during the infusion when drug is leaving the circulation to penetrate peripheral tissues, such as fat and brain. Because it may take 15 to 60 hours to achieve a steady-state concentration (five half-lives) after a fentanyl infusion is begun or the infusion rate is increased, a patient may need repeated bolus doses to maintain effective plasma concentrations in the central compartment. The best approach is to repeat the calculated loading dose until the desired clinical effect is achieved. This also illustrates why, for sedation specifically, dosing should be adjusted to achieve the desired clinical effect. Clearance calculations, however, can guide the starting dosages to achieve effective sedation, as illustrated later.

TABLE 21.2 Developmental Pharmacokinetics of Fentanyl

Gestational Age (Wk)	Clearance at 0–47 h After Birth (mL/min/kg)
29	9.6
33	11.4
37	13.2
41	15.0

Data from Saarenmaa E, Neuvonen PJ, Fellman V. Gestational age and birth weight effects on plasma clearance of fentanyl in newborn infants. *J Pediatr*. 2000;136:767–770.

The kinetic parameters for fentanyl in premature newborns reported by Koehntop et al.[43] can be used to calculate a loading and infusion dose to reach a fentanyl concentration of 2 ng/mL, which is considered an analgesic concentration.[46] This is estimated for a premature newborn at 33 weeks GA (note that nanograms per milliliter is equivalent to micrograms per liter) as:

$$\mathrm{C}(\mu\mathrm{g/L}) = \frac{\mathrm{Loading\ Dose}\ (\mu\mathrm{g/kg})}{\mathrm{Vd}_{\mathrm{central}}\ (\mathrm{L/kg})}$$

$$\mathrm{Loading\ Dose}\ (\mu\mathrm{g/kg}) = 2\left(\frac{\mu\mathrm{g}}{\mathrm{L}}\right) \times 1.45(\mathrm{L/kg}) = 2.9\ \mu\mathrm{g/kg}$$

$$\mathrm{Infusion\ Rate}\left(\frac{\mu\mathrm{g}}{\mathrm{kg}}\cdot\mathrm{h}\right) = \mathrm{C}\left(\frac{\mu}{\mathrm{L}}\right) \times (\mathrm{ml/kg}\times\mathrm{h}) = 2\ \frac{\mu\mathrm{g}}{\mathrm{L}} \times 11.4\ \mathrm{mL/kg/min} \times 1\frac{\mathrm{L}}{1000}\ \mathrm{mL} \times 60\,\mathrm{min/h} = 1.4\ \mu\mathrm{g/kg}\cdot\mathrm{h}$$

Studies have also reported on increased fentanyl clearance with advancing postnatal age.[42,44,45] This postnatal increase in clearance of fentanyl likely relates either to maturation of CYP3A4

(the enzyme responsible for fentanyl metabolism) activity or to increased hepatic blood flow after birth, because fentanyl has a high hepatic extraction rate. For drugs such as fentanyl with a high hepatic extraction rate, the rate-limiting factor in clearance is the flow of blood to the liver.[46] Some researchers have observed that increased intra-abdominal pressure reduces fentanyl clearance, which is likely caused by reduced hepatic blood flow.[43,45] Clinical covariates known to alter fentanyl clearance should be used to adjust starting dosages, but dosing should be adjusted primarily for the desired clinical effect. Such an approach should also consider subsequent development of drug tolerance (i.e., a higher concentration is needed to attain a similar effect).

Modeling and Simulations

Pharmacokinetic modeling and simulations can be used to estimate the impact of important developmental changes and disease processes on pharmacokinetic parameters for distribution volume, elimination rate, and total body clearance. These can identify clinical situations and conditions when dosages are likely to require modification (e.g., drug–drug interactions, genetic polymorphisms, advancing age, renal impairment). Mathematical simulations create theoretical pharmacokinetic profiles for patients after a dose using the range of pharmacokinetic parameters determined from a patient population. These can then be calculated for 100 to 1000 hypothetical patients to define the expected range of concentrations that are likely after a dose. For drugs such as antiinfectives of which serum concentrations have been correlated with effectiveness, this provides estimates of how large a dose is needed to reach effective concentrations. Modeling and simulation methods can also be used for clinical study design to support decisions about the number of participants, optimal times of sampling, covariates, phenotypic analyses, and population analyses.

Clinical Applications of Pharmacokinetics

How to Estimate Dose Adjustments

Gentamicin and phenobarbital will be used to illustrate the clinical application of the principles of PK and TDM discussed earlier. The calculations can be performed with standard arithmetic calculators and provide close enough estimates of the kinetics for drugs with a long half-life to adjust dosages at the bedside.

Gentamicin

Assume that the optimal gentamicin target concentrations are:

$$\text{Peak} = 6-10\,\mu\text{g/mL}$$
$$\text{Trough} = 0.5-2\,\mu\text{/mL}$$

Following the fourth conventional dose (4 mg/kg) of gentamicin to a hydropic premature newborn, the peak concentration was 4.5 µg/mL; 18 hours after the peak was obtained, the trough was 2.25 µg/mL. It appears that the distribution volume is greater than anticipated, because the peak concentration is lower than expected, and the half-life is longer than anticipated, because the trough is higher than expected. The time of drug administration and that of blood sampling was confirmed (an important step), so the half-life is 18 hours, because the concentration decreases by 50% from 4.5 to 2.25 µg/mL in 18 hours (assuming that the kinetics are exponential and first order):

$$\begin{aligned}\text{Vd (mL/kg)} &= \text{Dose (mg/kg)} \times (1000\,\mu\text{g/mg})\ \Delta\text{C}\ (\mu\text{g/mL})\\ &= 4.0\ (\text{mg/kg}) \times 1000/4.5 - 2.25\ (\mu\text{g/mL})\\ &= 4000\ \text{mL}/2.25\ \text{kg} = 1.777\ \text{mL/kg}.\end{aligned}$$

To ensure a trough concentration of 2.0 µg/mL or less, doses are administered every two half-lives, or every 36 hours. When two half-lives have passed after the fourth dose, the gentamicin concentration should be about 1.1 µg/mL (50% of 2.25 µg/mL). Increasing the concentration from the 1.1 µg/mL trough to more than 6 µg/mL requires a concentration difference of 4.9 µg/mL or more. With a distribution volume of 1777 mL/kg, a dose of 8.7 mg/kg should raise the concentration from a trough of 1.1 µg/mL to a peak of 6.00 µg/mL:

$$\text{Vd (mL/kg)} = \text{Dose (mg/kg)} \times (1000\ \mu\text{g/mg})/\Delta\text{C}\ (\mu\text{g/mL})$$

$$1777\ \text{mL/kg} = \text{Dose (mg/kg)} \times (1000\ \mu\text{g/mg})/4.9\ (\mu\text{g/mL})$$

$$\text{Dose (mg/kg)} = (1777/1000)/\text{kg} \times 4.9\ \text{mg} = 8.7\ \text{mg/kg}.$$

In one half-life, this concentration will decrease to 3.0 µg/mL, and in two half-lives, or 36 hours, it will decrease to 1.5 µg/mL. Another 8.7 mg/kg dose will raise the peak concentration by 4.9 µg/mL to 6.4 µg/mL, which will fall to 3.2 µg/mL in one half-life and to 1.6 µg/mL in two half-lives. The variation between the peak and trough concentrations after the last dose is within the desired range for the optimal gentamicin concentrations defined previously.

Phenobarbital

Seizures that were hard to control developed in a 3.6-kg asphyxiated newborn. Seizures continued after two 20 mg/kg phenobarbital doses until an additional 10 mg/kg dose was administered. A maintenance dose of 7 mg/kg/day was started 24 hours after the loading doses were administered. At 10 days, the infant was increasingly somnolent. The phenobarbital level measured in a blood specimen drawn 2 hours after administration of the oral maintenance dose was 50 µg/mL. Additional doses were withheld, and the phenobarbital concentration was checked daily; the results were as follows:

- 24 hours: 40 µg/mL
- 48 hours: 31 µg/mL
- 72 hours: 25 µg/mL
- 96 hours: 21 µg/mL

The maintenance dose (7 mg/kg) was resumed immediately after the 21 µg/mL concentration was measured and produced a peak concentration of 30 µg/mL after administration of the dose. These concentrations and dosages can be used to calculate the volume of distribution and a dose to maintain the phenobarbital concentration between 20 and 30 µg/mL as:

$$\begin{aligned}\text{Vd}\left(\frac{\text{L}}{\text{kg}}\right) &= \frac{\text{Dose}\,(\text{mg/kg})}{\text{C}\,(\mu\text{g/mL} = \text{mg/L})}\\ &= \frac{7.0\,(\text{mg/kg})}{(30-21)(\text{mg/L})}\\ &= \frac{7\,(\text{mg/kg})}{9\,(\text{mg/L})}\\ &= 0.78\,\text{L/kg}\end{aligned}$$

Half-life can be estimated from inspection, because the concentration decreased from 50 to 25 μg/mL in 72 hours. Thus it should take 72 hours for the concentration to decrease by one half-life from 30 to 15 μg/mL. Assuming that the elimination rate does not change, the concentration will decrease approximately 5 μg/mL every 24 hours, or one-third of a half-life. Dividing the half-life into fractions is an approximation because it estimates the change in concentration as linear rather than exponential. To be more accurate, the concentration decreases by 59% in half of one half-life. Although this approximation violates certain principles of PK, it allows estimation of the change in concentration for each one-third of a half-life as one-third of the change during one half-life. Thus the concentration decreases by about 5 μg/mL in 24 hours. The following approach can be used to estimate the daily phenobarbital dose needed to return the concentration to 30 μg/mL, a change in concentration of 5 μg/mL:

$$\Delta C\ (\text{mg/L}) = \frac{\text{Dose (mg/kg)}}{\text{Vd (L/kg)}}$$

$$5\ (\text{mg/L}) = \frac{\text{Dose (mg/kg)}}{(0.78)\ (\text{L/kg})}$$

$$3.6\,\text{mg/kg} = \text{Dose (mg/kg)}$$

Adverse Drug Reactions

Adverse event assessment includes signal *detection*, *causality* assessment, and *severity* assessment. For signal detection and incidence, as well as for causality and severity assessment, disentangling confounders from adverse drug events remains a major challenge. In a prospective study on the epidemiology of adverse drug reactions (ADRs) in 200 consecutively admitted neonates, 136 ADRs occurred in 60 neonates (30%), 20 were life threatening, and 24 were of moderate intensity (prolonged hospital stay); about 50% of the neonates had multiple ADRs. In a more recent study of a mixed population of 313 neonates admitted to the NICU or the intermediate care unit, 116 ADRs occurred in the neonates (17%), and 44% of these ADRs needed specific treatment.[47] The reasons behind drug-related morbidity and mortality are diverse and complex. In addition to a lack of specific labeling for this special patient population, absence of age-appropriate neonate-friendly formulations and a high frequency of (poly)pharmacy, there is also the immature organ function and substantial comorbidities that will further increase the risks of ADRs in neonates. To improve *causality* detection, Du et al. suggested and validated an algorithm to detect ADR in the NICU.[48] However, intra- and interrater assessment of causality of ADRs remained only fair (kappa scores ≤0.3) in a recently reported prospective observational study on neonatal events.[49]

Related to *severity assessment*, the International Neonatal Consortium (INC) Adverse Event Severity Scale has recently been reported. Immediate functional consequences (on age-appropriate behavior and basal physiological functions), together with resulting care changes, were established as the parameters of the generic severity scale. This generic severity scale was subsequently tailored to 35 event-specific severity criteria related to neurological, cardiovascular, respiratory, infectious, gastrointestinal, infectious, or general neonatal care events.[50]

Illustrations of Adverse Drug Reactions in Neonates

Chloramphenicol was released in the 1940s, and the recommended dosages were 50 to 100 mg/kg/day for patients weighing 15 kg or less. Before 1959, the year that Sutherland reported three cases of sudden death in newborns treated with high dosages of chloramphenicol (up to 230 mg/kg/day), the drug was considered "well tolerated and nontoxic."[51] Burns et al. reported the disturbing results of a controlled trial of the following four prophylactic treatment regimens for newborn sepsis: (1) no treatment, (2) chloramphenicol alone, (3) penicillin and streptomycin, and (4) penicillin, streptomycin, and chloramphenicol. The groups that received chloramphenicol (100 to 165 mg/kg/day) had higher mortality rates (60% and 68%), and the deaths of these newborns demonstrated the stereotyped sequence of symptoms and signs caused by chloramphenicol accumulation, coined *grey baby syndrome*.[52] This syndrome consisted of abdominal distention, poor peripheral perfusion and cyanosis, vasomotor collapse, irregular respirations, and death within hours of onset of these symptoms.

The discovery of the mechanism (glucuronidation deficiency) of chloramphenicol toxicity in newborns illustrates several important aspects of neonatal pharmacology. Because chloramphenicol was considered well-tolerated in older children and adults, it was regarded as nontoxic to newborns. Higher doses were administered to newborns despite recognition that its clearance required glucuronide conjugation, which was known to be immature in newborns. The unexpected finding that chloramphenicol in dosages of 100 to 165 mg/kg/day could be lethal to newborns was demonstrated because the study conducted by Burns et al. included appropriate control groups.[52] Similar case observations with the mechanism involved are summarized in Table 21.3 to illustrate that these observations can still be seen.

Reduction and Prevention of Medication Errors in Newborn Care

Medication errors represent a significant and often preventable cause of morbidity and mortality in neonates. While many errors are without consequences, others result in serious adverse effects. Medication errors incur significant costs, ranging from obvious ones such as direct patient injury, prolonged hospital stays, and additional corrective treatments to more subtle ones such as the costs associated with monitoring and regulation of medication use.[53,54] In two studies performed in NICUs, about one-third of the "iatrogenic" events were preventable, and one-quarter were related to drugs.[53,54] For drug errors, ordering and prescription as well as administration-related errors were observed. The top five preventable errors relate to incorrect doses, medications that are inappropriate for the medical condition, failure to monitor newborns for drug-related side effects, failure of communication, and failure to monitor drug concentrations.

The process for ordering, preparing, dispensing, and administering medications is often complicated and may contribute directly to errors. The frequency of those errors, however, may be reduced in almost every unit. A barcode medication administration system (verification of drug and patient), in combination with a double-check when further manipulation (such as dilution) is needed, is required to effectively reduce this burden of

TABLE 21.3 Illustrations of Formulation (Active Compound, Excipient)-Specific Drug-Induced Illnesses in Neonates and the Mechanism Involved

Compound/ Formulation	Clinical Syndrome	Mechanism Involved
Sulfonamides (1956)	Kernicterus	Highly albumin bound antibiotic, competitive with endogenous compounds, including bilirubin. This results in higher free bilirubin concentration and subsequent kernicterus.
Benzyl alcohol (1982)	Gasping syndrome	Benzyl alcohol, coadministered as preservative in parenteral formulations results in accumulation in preterm neonates because of their limited metabolic (alcohol dehydrogenase) clearance capacity. Accumulation results in metabolic acidosis followed by seizures, bradycardia, gasping respirations, hypotension preceding cardiovascular collapse, and ultimately death.
Dexamethasone (2000)	Cerebral palsy	High-dose dexamethasone exposure in neonatal life results in an increased risk for cerebral palsy in later life, likely due to increased neuroapoptosis.
Lopinavir/ ritonavir (2005)	Alcohol accumulation	Lopinavir/ritonavir (Kaletra) is an effective treatment of human immunodeficiency virus (HIV). Its syrup contains both ethanol and propylene glycol. Impaired metabolism results in accumulation and subsequent hyperosmolality, lactic acidosis, renal toxicity, central nervous system impairment, cardiac arrhythmia, hemolysis, and collapse (FDA black box warning).
Ceftriaxone plus calcium (2009)	Cardiovascular collapse	Simultaneous administration of calcium-containing infusions and ceftriaxone results in intravascular precipitation, as observed during autopsy (FDA black box warning).
Caffeine (2015)	Apnea of prematurity	In a pilot study, high versus regular dosing was associated with an increased incidence of cerebellar bleeding in the high-dose group.

targeted, preventable, medication errors in the NICU setting.[55] Although these kinds of complex and expensive computerized systems may help reduce medication errors, caregivers can take steps that are completely within their control to reduce medication errors without waiting for changes in the entire pharmacy process within the hospital. Prescriptions and drug orders are a means of communicating, yet clinicians often devote too little attention to make these documents legible, clear, and unambiguous. Prescribers should keep the following recommendations in mind to ensure that they communicate their medication orders more effectively:

- Write out instructions rather than use abbreviations.
- Avoid vague instructions (e.g., "take as directed").
- Specify exact dosage strengths.
- Avoid abbreviations of drug names (e.g., MS could mean morphine sulfate or magnesium sulfate).
- Avoid "U" as an abbreviation for units as the "U" may be mistaken for a "0."
- Avoid trailing zeroes (e.g., 5.0 mg).
- Use leading zeroes (e.g., 0.5 mg).
- Minimize the use of verbal orders.
- Ensure that prescriptions and signatures are legible, even if it means printing the prescriber's name that corresponds to the signature.

Changes in the pharmacy process can also be effective, as highlighted by Campino et al., who evaluated the impact of a care bundle intervention (protocol standardization, education) on the number of errors and documented significant reductions in both calculation errors (1.35% to 0%) and accuracy error rates (from 54.7% to 23% at the bedside and from 38.3% to 14.6% in the hospital pharmacy).[56] In a systematic review on interventions to reduce medication errors in neonatal care, several effective interventions were identified related to technology (like electronic prescribing), organization (guidelines, procedures), personnel (staff education), pharmacy (clinical pharmacy services), hazard and risk analysis (error detection tools), or a combination of such interventions (care bundle concept).[55]

Drug Elimination in Breast Milk

Breast milk-related drug exposure remains a source of confusion and concern for physicians and families.[57,58] However, knowledge is increasing, and access to information through, for example, LactMed (http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm) has improved. The Pregnancy and Lactation Labeling Final Rule provides a tool to generate and collect more reliable information on maternal drug use during breastfeeding. A common misconception about safety is "*when in doubt, do not provide breastfeeding*," since breastfeeding itself provides benefits to the infant and the mother. On average, the nursing infant receives around 2% to 3% of a maternal dose through milk, but drugs that are organic bases or are lipid soluble may reach higher concentrations in milk than in maternal serum. However, this should not by definition affect the infant. To illustrate this more balanced approach, breastfeeding in infants of women taking antiepileptic drugs was associated with improved neurodevelopmental outcome compared with those who either did not breastfeed or breastfed for less than 6 months.[59] Similarly, breastfeeding by opioid-taking women may help to control neonatal abstinence syndrome, and may even increase signs of withdrawal when reduced or stopped.[60] Likewise, it may also be associated with neonatal oversedation.[61] Overall, the available data regarding drug exposure of the newborn through human milk have been organized, in decreasing levels of concern, from drugs that are associated with adverse effects on the infant during nursing to those that are of concern pharmacologically to those that have not been associated with problems during nursing. The list of drugs that clearly cause problems during nursing is surprisingly short.[62,63]

Neonatal Drug Development Remains an Obvious and Shared Need

Recent legislative initiatives have resulted in a substantial increase in pharmacologic studies in children, and a significant increase in label changes. Unfortunately, only a few have included drug label changes for neonates.[64,65] Neonatologists should realize that almost all compounds currently used in neonates were initially developed for other populations, with subsequent tailoring to neonates. Key to stimulating and facilitating neonatal drug development is basing product development on neonatal physiology and pharmacology, while incorporating already available knowledge from non-neonatal settings. Furthermore, the central role of families in research and the value of the entire neonatal team in the design, implementation and interpretation of studies are crucial.[66] Surfactant hereby serves as a very obvious illustration of the potential impact of neonatal drug discovery.

During drug development, dosing in neonates should be based on integrated knowledge of disease, neonatal physiology, and PK and PD of a given drug.[64] Subsequent PD assessment, covering both efficacy as well as safety, necessitates valid population-tailored tools and methods. Recently, the INC has been developed as part of the Critical Path Initiative to serve as a forum for the neonatal community to develop consensus statements (e.g., standardization of methods, standard-of-care consensus statements, population-specific biomarkers, modeling approaches, trial designs, clinical outcome assessment tools, formulation issues) with the ultimate goal to improve, to accelerate neonatal drug development.[66,67] It is crucial to realize that the INC is an international multi-stakeholder construct, facilitating interaction between regulators, academia, clinical researchers, industry, parents and NICU staff from the United States, Europe, Japan, and Canada. With its focus on neonatal drug development, the INC construct itself is embedded in the Critical Path Initiative, a broader FDA national strategy to drive innovation in the scientific processes through which medical products are developed, evaluated, and manufactured.

Summary

Drug therapy for newborns requires application of the basic principles of PK (drug absorption, distribution, metabolism, and elimination) and PD (both desired efficacy and unwanted side effects) to estimate and individualize dosages. However, owing to a lack of gestational age-appropriate kinetic data in the rapidly maturing fetus and newborn, drug therapy is still commonly based on empiric, off-label prescriptions. Combined with the extensive drug exposure of neonates in the NICU, this is hazardous and likely explains the high frequency of adverse, sometimes fatal, drug reactions. Methods appropriate for the study of therapeutics in newborns present unique difficulties, but recent legislative and methodological progress provides additional assistance for investigators and helps advance this area of pharmacology.[68–72] Recent collaborative initiatives should further stimulate development of both new and already existing drugs for use in neonates.[66,67]

Neonatal Pain and Stress

VILMARIS QUIÑONES CARDONA, DENNIS E. MAYOCK, AND RACHEL FLEISHMAN

KEY POINTS

- Pain and discomfort in infants are common occurrences in intensive care.
- Identification and management of neonatal pain remain challenging.
- Many neonatal pain scoring tools assist in classifying pain, but many were not validated in clinical practice.
- Neonatal pain recognition with near-infrared spectroscopy and amplitude-integrated electroencephalography does not always align with clinical manifestations of pain, raising questions about how best to define, diagnose, and treat pain.
- Untreated neonatal pain can result in long-term adverse outcomes due to alterations in brain structure and hormone imbalance, resulting in abnormal childhood pain responses.
- Pharmacologic treatment of pain is widely used, but nonpharmacologic interventions may be just as effective.

Background

In the 1980s, a public outcry regarding the recognition and management of pain in hospitalized patients prompted the US Department of Health and Human Services, The Joint Commission, and other professional organizations to mandate pain management practices for all patients, including neonates. An initial statement endorsing pain management for neonates undergoing surgical interventions, regardless of age and cortical immaturity, was jointly issued by the American Academy of Pediatrics Committees on Fetus and Newborn, the Committee on Drugs, the Section on Anesthesiology, the Section on Surgery as well as the American Society of Anesthesiologists.[1] The Acute Pain Management Guideline Panel of the US Agency for Health Care Policy and Research[2] also endorsed the need for pain management in neonates.

The subsequent conundrum was that neonatal caregivers were expected to assess and treat perceived neonatal pain and discomfort in the absence of evidence-based methods with which to base their assessment and therapy. The lack of verbal skills, immature behaviors in response to pain, and the nonspecific nature of physiologic indicators of pain in a critically ill patient all combine to make accurately assessing pain in term and preterm neonates challenging. The challenge of pain assessment is further compounded by typical NICU interventions such as mechanical ventilation, physical restraints, and pharmacologic sedation, all of which mask distress behaviors. Because the gold standard of pain assessment (self-reporting using validated scales) is not applicable to neonatal patients, providers must reply on physiologic, behavioral, and biobehavioral indicators as surrogates for self-reporting pain.

Taxonomy

Defining neonatal pain and its myriad presentations may help clinicians to recognize and therefore treat it. The proposed taxonomy includes distinctions between acute episodic pain, acute recurrent pain, prolonged pain, persistent pain, and chronic pain (Table 22.1).[3] The origin and resultant physiologic status for various painful stimuli can be quite different. Tools for assessment of neonatal pain and stress must be based on an understanding of the normal development of behavioral responses to pain and stress—an infant is not a small adult.

An international survey of experts in neonatal pain, including physicians, nurses, researchers, and parents from around the world, used the Delphi method to propose a definition of chronic pain in neonates. They put forth the following:

"Chronic pain can often not be associated with a specific cause. It has no obvious endpoint in sight and is no longer proximate to an event or procedure. Chronic pain may alter perception causing non-noxious events to be perceived as painful, leading to a chronic pain response. It depletes stress hormones, increases energy consumption, and therefore interferes with growth. As a consequence, chronic pain may likely prolong hospitalization and add to existing neonatal morbidities."[4]

The optimal approach to neonatal pain management relies on a concerted, mindful practice that involves:

- Reducing the frequency of painful procedures
- Decreasing environmental stressors
- Facilitating neurologic development
- Determining the best technique to minimize the pain and stress associated with procedures
- Empowering nurses to manage pain assessment and treatment
- Using a balanced multimodal approach to pain control

Parents remain an underutilized resource in managing neonatal pain,[5] in part because of medical paternalism.[6] Parent awareness of their own role, as well as how NICU staff engage with and educate them, impacts how they advocate for pharmacologic and nonpharmacologic analgesia for their children.[7] When providers perceive maternal information regarding premature infant pain as sufficient and necessary, maternal involvement during painful procedures increases.[8] Parents randomized to receive a pain information booklet were better prepared to understand infant pain cues and comforting techniques and took more active roles in their hospitalized infant's pain care.[9,10]

TABLE 22.1 Suggested Starting Point for Defining the Pain Terms Used for Neonatal Pain

Pain Term	Onset	Duration	Character*	Primary Hyperalgesia
Acute episodic	Immediate	0–120† min	Sharp, well-localized	Present, mild, short-lasting
Acute recurrent	Immediate	Variable	Sharp, well-localized	Present, moderate or severe
Prolonged‡	Rapid, may be gradual	1 h–24† h	Sharp, diffusely localized	Present, moderate or severe
Persistent‡	Rapid or gradual, cumulative	1–7 days	Dull/sharp, diffusely localized	Present, moderate or severe
Chronic	Usually gradual	8 days or longer	Dull, diffusely localized	May be present or absent, mild if present

Pain Term	Secondary Hyperalgesia	Allodynia	Behavioral Phenotype	Physiological Phenotype
Acute episodic	Probably absent	Probably absent	Strongly reactive and reflexive	High peak, sympathetic activation
Acute recurrent	Present, mild or moderate	Probably absent	Weakly reactive or reflexive	Prolonged peak, sympathetic activation
Prolonged‡	Mild or absent	Probably absent	Strongly reactive on stimulation	High plateau, sympathetic activation
Persistent‡	Present, mild or moderate	May be present, mild/moderate	Hyperreactive initially, later hyporeactive	Normal or low sympathetic activation
Chronic	Present, moderate, or severe	May be present, moderate/severe	Hyporeactive more often, could also be hyperreactive	Normal or suppressed sympathetic drive

*Based on descriptions in adult patients but may be discerned by a careful physical examination.
†Some infants with increased sensitivity to pain may have a slower decay of the acute pain following an invasive procedure, thus justifying some overlap in the durations of acute episodic pain and prolonged pain.
‡Continuous pain may be characterized as either "prolonged" or "persistent."

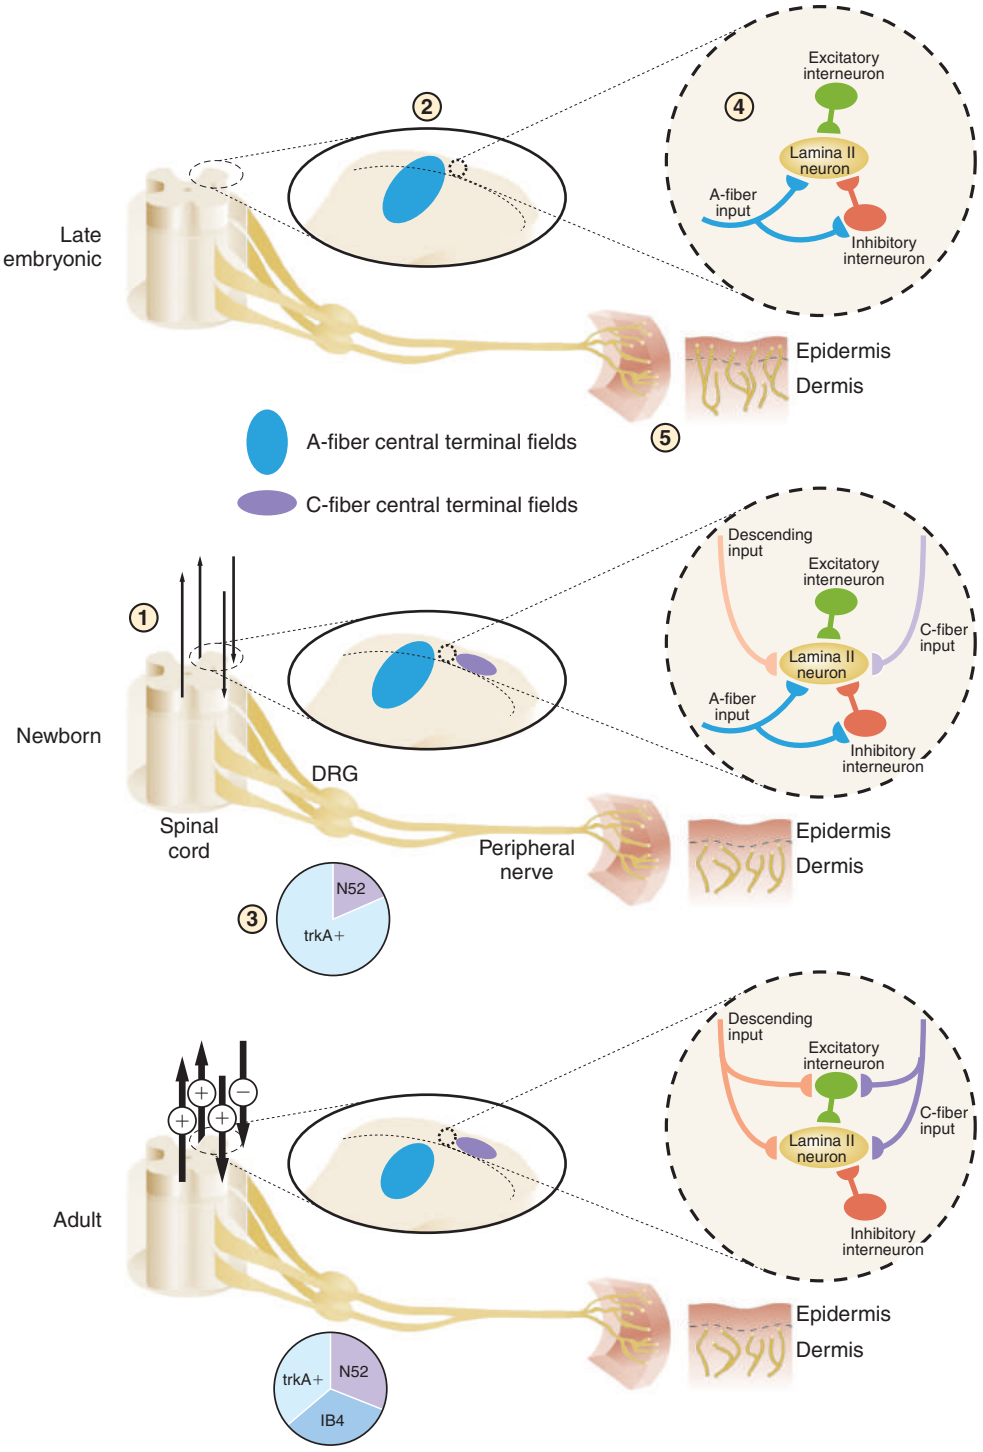
Ontogeny and Development of Pain and Stress Responses

Pain is a progressive, adaptive process that develops gradually throughout fetal life. The human fetus must develop both neurons to sense pain and the cortex to process painful sensations to experience pain.[11] Direct thalamocortical fibers not specific to pain emerge between 23 and 30 weeks' gestational age.[12] These thalamic afferent neurons reach the cortical plate as early as 24 weeks' gestation.[13] Neuronal connections within the cortex appear to form at approximately 22 weeks' gestation.[14] Cortical activity can be captured by electroencephalogram (EEG) as early as 24 weeks as well. However, thalamocortical pathways may not begin functioning until 29 to 30 weeks' gestational age,[12] suggesting that higher cortical level pain processing may be limited despite the presence of a behavioral response.[15] Facial movements consistent with pain response are noted as early as 28 weeks. The possibility of interpreting these facial movements with 4-dimensional ultrasound to assess fetal pain responses is an area of intrigue for those performing fetal surgery.[16]

When infants are born preterm, the sensory system is immature (Fig. 22.1). Afferent input from both noxious and nonnoxious stimuli terminate in the dorsal horn of the spinal cord in a diffuse manner on multiple cells, resulting in the infants' inability to distinguish between noxious and nonnoxious stimuli and limits the care provider's ability to correctly interpret the infants' behavioral response. In the neonatal rat, separation of sensory input is not complete until 3 to 4 weeks after birth (approximately 1 to 2 years in humans);[17] this prevents the newborn from consistently differentiating touch from painful sensory input. The responses of the infant are therefore nonspecific. Local tissue injury resulting from repeated heel sticks and invasive procedures trigger increased proliferation of nerve endings in surrounding tissues, particularly when this damage occurs early in gestation. As a result, scars (e.g., from heel sticks, old intravenous sites) and surrounding tissues can remain hypersensitive well beyond the neonatal period.[18]

Infants may lose any discriminatory ability with repeated painful exposures and develop hypersensitive states for long periods. This hypersensitivity persists even if nonnoxious stimuli are introduced.[18] The responses are less synchronized in the immature central nervous system because of underdeveloped myelination and slower synaptic transmission as manifested in longer and more variable latencies.[18] In addition, the neonate lacks sufficient descending modulatory control, thereby limiting their ability to benefit from endogenous control over noxious stimuli compared with adults.[19,20]

Neurophysiologic investigations have dramatically changed our understanding of nociception in newborns. Using research methods such as near-infrared spectroscopy and EEG techniques such as amplitude-integrated EEG, it is clear that cerebral cortical activation occurs with noxious stimulation, such as needle pokes, as early as 24 weeks' gestation. Moreover, cortical activation has been noted even in infants who manifest no behavioral response to a stimulus.[21] The converse has also been found in studies reporting that oral sucrose administration decreases clinical observational scores with no changes noted in cortical activation from noxious stimulation.[22,23] Such findings raise the question that our patients may be perceiving pain at a cortical level despite our pain-relieving



• **Fig. 22.1** *1*, In early postnatal life, descending fibers are present, but inhibitory and excitatory influences are weak or absent. The connections gradually strengthen, becoming fully functional at the end of the third postnatal week. *2*, A-fibers are the first primary afferents to enter the dorsal horn gray matter and are present during the last few embryonic days. Their distribution is diffuse with exuberant, more superficial projections gradually retracting over the first 3 postnatal weeks. C-fibers are present in the dorsal horn during late embryonic stages but only enter the gray matter 2 to 3 days before birth. Unlike A-fibers, they project to topographically appropriate regions in lamina II of the spinal cord as soon as they enter. C-fiber synaptic connectivity is present, although weak at the time of birth, with connections strengthening over the first 2 postnatal weeks. *3*, At birth, the majority (approximately 80%) of dorsal root ganglion (DRG) neurons express the nerve growth factor (NGF) receptor trkA. Over the first postnatal week, this population reduces, with approximately half of these neurons losing their trkA expression and beginning to express receptors for glial cell line-derived neurotrophic factor (GDNF) (identifiable as the IB4-binding population). *4*, The balance of excitation and inhibition in the superficial dorsal horn develops postnatally through changes in both local interneuron circuitry and descending fibers. A-fiber input is stronger in the neonate and weakens as the influence of C-fiber input increases. *5*, Primary afferent innervations of the skin occur earlier than central projections. By late embryonic stages, primary afferents of all classes have reached the skin and innervate through the dermis into the epidermis. These projections die back during the immediate perinatal period to leave the full adult situation of dermal innervations present soon after birth. (From Beggs S, Fitzgerald M. Development of peripheral and spinal nociceptive systems. In: Anand KJ, Stevens BJ, McGrath PJ, eds. Pain in Neonates and Infants. 3rd ed. Philadelphia: Elsevier; 2007:1124.)

interventions (pharmacologic and nonpharmacologic) and that pain scoring tools may only provide limited information, possibly underestimating pain in neonates.[24]

Noxious stimuli in adults result in the release of inflammatory and trophic factors that activate and sensitize nociceptors in the injured tissue. Such noxious stimuli lead to nociceptive afferent input to the central nervous system, exciting nociceptive circuits in the spinal cord, brainstem, thalamus, somatosensory cortex, cingulate cortex, and amygdala.[25] However, noxious stimuli in infants do not evoke similar patterns of central nervous system activity. The response to noxious stimuli is more diffuse and less spatially focused in infants. Studies in rats demonstrate significant alterations in neuronal circuitry with maturation. These animal data may parallel developmental changes that have been noted in humans.

Behavioral responses to noxious stimuli in infants are not always predictable because of the immaturity of the central nervous system. Typical changes in facial expression related to noxious stimulation are inconsistent before 34 weeks' gestational age.[26] This makes an assessment of pain and response to therapeutic intervention unreliable. Significant structural and functional changes occur in pain pathways during development, and these continue after birth.

In summary, the immature infant's nervous system

- Lacks the ability to discriminate consistently between noxious and nonnoxious stimuli, often reacting with similar behavior to a variety of stimuli
- Lacks the ability to modulate pain responses
- Does not consistently manifest signs or symptoms that allow care providers to accurately assess the infant's level of pain and discomfort

Recognizing and Treating Pain

Neonatal care providers and parents all play front-line roles in recognizing and ameliorating neonatal pain. The factors at play in assessing the depth and breadth of pain and determining its treatment include nationality, level of education of bedside providers, use of clinical pain scales, time of day, and unit acuity. Surveys of neonatal providers from around the world note deficits in recognizing and treating pain. Despite efforts to garner awareness and provide systematic approaches toward ameliorating pain, the provision of analgesia is not consistent.

A prospective cohort of 6680 neonates enrolled in 243 NICUs in 18 European countries, dubbed the EUROPAIN (EUROpean-Pain-Audit-In-Neonates) cohort,[27] cataloged demographics, methods of respiration, use of continuous or intermittent sedation, analgesia, or neuromuscular blockers, pain assessments, and drug withdrawal symptoms over the first 28 days of admission. Wide variations in practice were documented regarding the recording of pain scores, genres of respiratory support and their association with analgesia, and use of analgesia for any neonates receiving any modality of respiratory support. Despite the results of trials such as NEOPAIN,[28] the median use of sedation or analgesia for intubated neonates was 89%, with 74% of these neonates receiving opioids, 25% receiving midazolam, and 25% receiving neuromuscular blockers. The large, prospective nature of this study provides a compelling snapshot of how pain is assessed and how pharmacologic analgesia is prescribed for many neonates in the NICU. Continuous pain assessments occurred in fewer than one third of NICU admissions and daily in only 10% of neonates.[29]

Infant Pain Scores

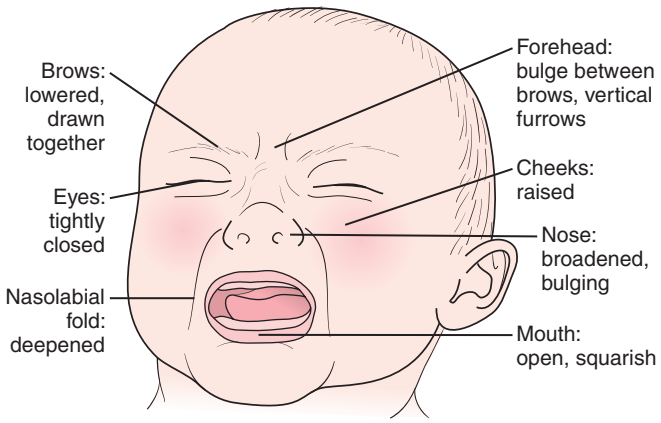
Multiple neonatal pain scoring tools integrate physiologic, behavioral, and biobehavioral indicators into a total score; these tools assess the response to noxious stimuli by categorizing the infant's behavioral or physiologic reactions or a combination of both. The behavioral responses include limb movements, muscle tone, crying, and characteristic facial expressions; crying is the least reliable indicator of neonatal pain. The physiologic measures include heart rate, oxygen saturation, and respiratory rate. Specific facial expression changes are believed to be the most reliable indicators of pain (brow bulge, eye squeeze, nasolabial furrow, taut lips, and open mouth). See Fig. 22.2 for examples of these characteristic facial changes. The use of facial expression changes can be challenging when the infant's face is partially covered with adhesives used to secure tubes and lines, respiratory equipment, or with a phototherapy mask in place.

Many discrete scoring tools exist to assess pain in neonates, but the majority have been validated only for research purposes.[30] Scoring tools that provide a multidimensional assessment of pain are preferred; however, they are still subjective. Some tools lack sensitivity and specificity by relying, for example, only on changes in vital signs.[31] Recent publications list currently available neonatal pain assessment tools.[24,32] Only five of these neonatal pain scales have undergone rigorous psychometric testing with patients serving as their own controls:

- Neonatal Facial Coding System
- Premature Infant Pain Profile (PIPP)
- Neonatal Pain and Sedation Scale (NPASS)
- Behavioral Infant Pain Profile (BIPP)
- Douleur Aiguë du Nouveau-né (DAN).

The PIPP scale is one of the most commonly used and well-validated scales. A review of 62 studies of the PIPP scores over 13 years reinforced this scoring measure as valid, reliable, clinically feasible, and useful at measuring acute, procedural, or postoperative pain[33] with strength lying in a composite (measuring behavioral and physiological indicators) approach. In 2014, researchers refined the scoring tool further, termed the PIPP-Revised score, to better encompass markers of pain and distress across the spectrum of gestational age.[64]

Ideally, a neonatal pain-scoring tool would be matched with the anticipated types of pain that an infant may suffer (such as



• **Fig. 22.2** Facial expressions of physical distress and pain in the infant. (From Hockenberry MJ, Wilson D: *Wong's Clinical Manual of Pediatric Nursing*, ed 8, St Louis: Elsevier; 2011.)

acute, procedural, postoperative, or chronic pain). A common conundrum is that providers find themselves treating chronic pain related to complications of intensive care using tools designed and validated for acute, procedural, and postoperative pain.[4] Several studies have tried to match specific pain scales to specific clinical populations. For example, a prospective comparison of multiple pain scores in neonates after cardiac surgery demonstrated that the COMFORT score was most closely correlated with the infants' pain and analgesic response.[34] COMFORT and N-PASS scales are most effective for pain assessment in mechanically ventilated infants while PIPP and CRIES are recommended for assessment of acute and postoperative pain.[35] Another example is a validated scoring tool called the Echelle Douleur Inconfort Nouveau-Né (EDIN), which was developed specifically to assess prolonged pain in preterm infants.[36]

Practically speaking, it is difficult to train and maintain provider skills in the use of multiple scoring tools in a single NICU. Determining which scoring tool best matches local patient composition allows care providers to become experts in using a single tool or two. The current reliance on routine assessment and documentation of pain scores as a proxy for routine pain assessment for preterm and term neonates throughout their hospital stay may not adequately capture what patients experience, both because of the manner with which they are assigned[37] and the lens through which any given tool was developed.[3]

Bedside Noninvasive Neurophysiologic Measures to Evaluate Pain and Stress

Changes in infant electrophysiological and hemodynamic brain activity occur in response to noxious stimuli.[38] Brain-derived approaches such as near-infrared spectroscopy[39] and amplitude-integrated electroencephalography to capture neonatal and infant pain are promising, as they can assess cortical activation in neonates in response to tactile and painful stimuli.[40] A proposed template of nociceptive brain activity can guide researchers in measuring and interpreting neonatal and infant pain with more precision.[38] The evoked brain activity described by this template is meant to aid researchers but is not yet validated or generalized for direct pain measurement in individual patients.[38]

Clinical pain scores, based on pain-related behavioral changes, do not consistently overlap with noxious-evoked brain activity.[38] Simultaneously measuring physiology, behavior, and cortical response to painful stimuli will help elucidate how best to assess, and then treat, neonatal pain.[41] The *Procedural Pain in Premature Infants (Poppi)* study[42] was one such trial. Because NIRS and EEG do not consistently reflect noxious-evoked brain activity when pain scores and biomarkers such as cortisol suggest a painful response, these tools raise questions about how to define a pain response and what composite measures should be used in research and clinical settings.[43]

Long-Term Consequences of Neonatal Pain and Stress

Untreated pain and stress experienced during the neonatal period are linked to adverse long-term outcomes. The acute physiologic responses to pain—elevations of cortisol, catecholamines, and lactate; hypertension, tachycardia, respiratory instability, glucose instability, and changes in cerebral blood flow—affect developing organs, especially the brain. Exposure to pain and painful procedures is related to the acuity of the hospitalization; studies evaluating a direct relationship between pain and outcomes must account for multiple clinical confounders.

Data suggest that structural changes on MRI at both terms corrected[44] and 7 years of age[45] may be related to increased exposure to pain. Untreated pain in the NICU is also associated with altered pain perception to subsequent immunizations after circumcision without anesthesia, abnormal cortisol responses to stress in later infancy[46] and at school age,[47] and altered pain responses in childhood.[48] Cortisol levels and overall hypothalamic pituitary adrenal axis function at school age for children born preterm are influenced by pain and stress in the neonatal period.[47] Higher cortisol levels at 4 years of age are associated with sensory processing and cortisol reactivity to stress.[49]

Greater neonatal pain exposure is associated with lower body weight percentiles at 32 weeks' corrected gestation.[50] A prospective daily assessment of acute pain and chronic pain/stress concluded that increased pain and stress exposures in the first 4 weeks of life result in altered habituation and stress responses for former preterm infants at 36 weeks' corrected gestational age.[51] There is concern that such hormonal changes might lead to the development of cardiovascular disease and type 2 diabetes in adulthood.[52,53]

Higher numbers of skin-breaking procedures from birth to term-corrected gestation predict lower cognitive and motor development indices of Bayley Scales of Infant Development at 8 and 18 months, after controlling for early illness severity, overall morphine exposure, and days of postnatal dexamethasone.[54] Prolonged placement of indwelling arterial lines to decrease the frequency of skin-breaking painful procedures in the preterm neonates improved thalamic growth and school-age neurodevelopment.[55]

Chronic pain can affect growth, immune function, recovery, and length of hospitalization. In addition, a growing body of evidence has drawn attention to the potentially deleterious effects of repeated handling, stress, and pain on long-term memory, social and cognitive development, and neural plasticity. Greater neonatal invasive procedures are associated with lower thalamic and amygdala volumes, leading to poorer cognitive, visual-motor, and behavioral outcomes.[56]

Clinical Pain and Stress Management Strategies

Fetal Interventions

The fetus has increasingly become a candidate for interventions to repair fetal anomalies and to treat fetal disorders such as severe anemia secondary to hemolytic diseases. The type of anesthesia prescribed to pregnant mothers during fetal surgery falls into one of three categories: anesthesia for minimally invasive fetal surgery, anesthesia for open fetal surgery, and anesthesia for an Ex Utero Intrapartum Treatment (EXIT) procedure.[57] Prescription of maternal anesthesia requires an understanding of placental pharmacology to ensure the fetus is appropriately anesthetized for each procedure. Fetal pain management should aim to attenuate fetal physiologic and hormonal stress responses.[58,59]

Fetal anesthesia is not without risk.[60] Fetal exposure to opioids may result in smaller brain volumes in neonates after birth.[61] There are no human studies examining the effect of anesthesia on the developing fetal brain.[57] Despite this, the US Food and Drug Administration issued a warning in 2016[62] regarding impaired brain development in children, including fetuses during the

third trimester of pregnancy, following exposure to the inhalational anesthetics isoflurane, sevoflurane, and desflurane, and the intravenous agents propofol and midazolam. The impact of these recommendations places the burden of weighing the risks and benefits of anesthesia for fetal surgery on the parents and providers for each fetal and neonatal surgical procedure.[63]

Postoperative Pain Management Strategies

Pain management after surgical intervention, like acute pain management, requires knowledge of the developmental status and function of the end-organ system and the potential adverse and toxic effects of specific analgesic agents. Unfortunately, the current body of neonatal pain literature focuses heavily on procedural pain management and lacks systematic data on acute perioperative pain management in neonates.[64] In the developing world, if infants survive the challenges of diagnosis and surgery for their congenital anomalies, postoperative pain is often not considered or under-managed.[65]

Postoperative pain trajectory in neonates is variable. Ilhan et al. described typical and atypical pain trajectories in infants under 6 months undergoing major thoracic or abdominal surgery, with those in the atypical group having more days and instances of pain. These infants had higher rates of iatrogenic neonatal abstinence syndrome.[66] Taylor et al., surveyed 10 NICUs regarding their postoperative pain assessment and management practices; they found that pain assessment documentation was inconsistent. Nursing documentation was done for most infants, whereas few physicians documented any assessment. Most infants were treated with opioids, benzodiazepines, or both, and some infants (7%) received no analgesia despite recent major surgery.[67] Van der Marel et al.[68] evaluated the use of rectal acetaminophens as an adjuvant treatment to continuous morphine infusion in postoperative neonates and could not demonstrate any additional analgesia effect. However, a quality improvement initiative by Grabski et al. demonstrated that postoperative IV acetaminophen for 48 hours and provider education reduced opioid use, postoperative ventilation time, and use of parenteral nutrition without worsening pain scores.[69] Neonates likely require less morphine to control pain and discomfort than older infants do, based on monitoring of pain scale data. Bouwmeester et al.[70,71] determined that neonates required less morphine for postoperative pain control and that the dose requirement increased with age. Both studies found that morphine was equally effective whether given by bolus or continuous infusion.

Epidurals are effective in treating postoperative pain and alleviating unwanted side effects of systemic opioids in adults and older children. While the literature does support benefits of epidurals for perioperative pain control for term and preterm neonates,[72] there is concern that the risk of placing thoracic epidurals by physicians without sufficient experience exposes neonates to the possibility of catastrophic neurologic outcomes.[73] In a study of infants <6 months of age who required thoracotomy for congenital pulmonary malformations, those randomized to epidural anesthesia had faster time to full feedings and reduced intensity of postoperative care when compared to those randomized to systemic analgesia.[74] Regional anesthesia, when used alone, may also reduce the incidence of postoperative apnea in preterm infants. Studies of parent- and nurse-controlled analgesia (PNCA) as an alternative to continuous opioid infusion for pain management in postsurgical infants in the NICU provides promising data that PNCA may provide more individualized care and potentially reduce opioid consumption.[75,76]

Mechanical Ventilation

Despite an ongoing shift in neonatology toward noninvasive respiratory support for neonates with immature lungs or infants with lung injury, invasive mechanical ventilation is still frequently utilized to save lives. Adults who require mechanical ventilation are routinely sedated. This finding prompted research surrounding opiate sedation in ventilated neonates,[77] despite limited information regarding safety and efficacy in neonates. Preemptive use of pharmacologic sedation during mechanical ventilation in newborns, especially preterm infants, remains controversial.[78]

Mechanical ventilation in neonates is associated with an increase in hormonal stress responses, including increased cortisol and catecholamine levels.[79,80] In the past, infants who appeared uncomfortable while ventilated demonstrated asynchronous respiratory effort (i.e., "fighting" the ventilator), compromised gas exchange, and altered stress responses. Pain and stress in newborns receiving mechanical ventilation was associated with decreased pulmonary compliance, atelectasis, and intrapulmonary shunting. However, with the introduction and use of surfactant replacement therapy, noninvasive ventilatory support, and synchronized ventilation, many of these problems have been minimized or eliminated.[81–83]

A randomized, double-blind, placebo-controlled clinical trial of nearly 900 neonates (NEOPAIN) reported no beneficial effect of preemptive morphine infusions in ventilated preterm infants and an increased incidence of severe intraventricular hemorrhage in preterm infants born at 27 to 29 weeks' gestation receiving preemptive morphine.[28] A parallel study conducted by Simmons in 2003 randomized 150 ventilated neonates to lower dose preemptive analgesia with morphine. This study failed to find any benefit of empiric morphine analgesia and did not recommend this practice.[84] Secondary analysis of the NEOPAIN trial found that morphine infusions were independently associated with increased risk for air leak, a longer requirement for ventilatory support[85], and a longer time to reach full-volume enteral feedings.[86] Neither this trial nor the smaller pilot trials that preceded it[87,88] provided evidence that routine narcotic sedation during mechanical ventilatory support in neonates is beneficial.

A subsequent trial conducted in 2013 randomized premature neonates to continuous infusion of fentanyl or placebo. Similar to prior trials of morphine results demonstrated increased duration of mechanical ventilation and no decrease in prolonged pain in the treatment group. Continuous fentanyl infusion reduced acute pain scores and had fewer side effects than open-label fentanyl boluses. The authors concluded that, just like morphine, "there is no place for the routine use of continuous fentanyl infusion in ventilated preterm newborns because of a lack of continued pain score reduction and increased side effects of continuous infusion compared with the bolus administration of fentanyl."[89]

A Cochrane Review combining outcomes of these and other, smaller trials evaluated the effects of opioid analgesics on pain, duration of mechanical ventilation, mortality, growth, and development in neonates requiring mechanical ventilation.[90] The authors found no differences in mortality, duration of mechanical ventilation, and short- and long-term neurodevelopmental outcomes. As morphine sedation prolongs ventilatory support and time to full enteral feedings, an increase in complications related

to the use of intravenous lines (bloodstream infections) and parenteral nutrition (cholestasis) can occur.[91] Two independent reviews concluded "there is insufficient evidence to recommend routine use of opioids in mechanically ventilated newborns."[91,92]

One comprehensive review of analgesia and sedation for ventilated neonates produced five standard-of-care recommendations[93]:

- Reduce neonatal stress and use nonpharmacological analgesia during invasive ventilation.
- Favor intermittent boluses of opioids, administered after pain scores and before invasive procedures, during short, expected periods of mechanical ventilation.
- Do not use morphine infusion in preterm infants under 27 gestational weeks.
- Always use algometric (pain sensitivity) scores to titrate analgesic drug doses.
- Use premedication before endotracheal intubation.

Additionally, studies of midazolam infusions as an alternative to either morphine or fentanyl infusions for intubated and ventilated infants have raised safety concerns.[94] Midazolam infusions are thus not recommended for neonates.

Procedures

Infants undergoing intensive care endure many painful procedures, often several times each day, with the most immature infants receiving the most significant number of painful stimuli. Pain relief strategies are underused for routine minor yet painful neonatal procedures.[95] Minimizing negative impacts of untreated pain is best achieved with a balance of medications, including opioid-sparing medications and nonpharmacologic agents and behaviors.[96]

Positive correlations between clinical pain scores and malondialdehyde, a marker for oxidative stress, suggest a significant relationship between procedural pain and oxidative stress in preterm neonates.[97] Mode of delivery may alter acute pain response in full-term neonates, with those born vaginally having higher saliva cortisol levels and clinical pain response than those delivered via C-section.[98] Healthy term neonates who are sleeping or drowsy have decreased pain scores and shorter duration of crying compared to awake term neonates when exposed to a painful stimulus.[99]

Both nonpharmacologic and pharmacologic treatment strategies can decrease or completely ameliorate procedural pain and stress.[55] Nonpharmacologic strategies including, but not limited to, sucrose, breastfeeding, nonnutritive sucking, sensorial saturation, and skin-to-skin care can be adapted for many procedures. These strategies are further discussed in "Nonpharmacologic Analgesia."

Blood Sampling and Monitoring

Heel sticks are routinely performed to obtain blood samples from neonates. The heel should be warmed to aid in blood sampling. The most appropriate method for relieving pain from a heel stick has yet to be determined; however, nonpharmacologic therapies are efficacious and without detrimental effects making these the first line of analgesia for heel sticks.[100] A prospective study comparing the ability of fentanyl, facilitated tucking, and sensorial saturation at decreasing both clinical pain scores and cytokine markers of stress concluded that both fentanyl and sensorial saturation were efficacious at decreasing pain and stress from heel lance.[101] Several meta-analyses found skin-to-skin care, termed *kangaroo care*, to be effective at decreasing composite pain indicators for single painful procedures such as heel lance or venipuncture.[102,103] Swaddling,[104] nesting,[105] and sucrose[106] are effective at diminishing acute pain from heel lance. Kangaroo care is efficacious over time at relieving pain from repeated blood draws.[107] Neonates undergoing venipuncture had lower pain scores than those who underwent heel stick for blood sampling. In selected neonates, venipuncture should be used preferentially over heel stick.

A eutectic mixture of local anesthetics (EMLA) cream does not relieve the pain of a heel lance.[108,109] EMLA does not diminish the nociceptive pain response captured from cortical monitoring.[38] Multiple studies have also concluded that acetaminophen alone does not reduce the pain from heel lance.[110] Further, morphine was ineffective at mitigating nociceptive brain activity or diminishing pain scores for heel lance in a prospective, blinded, randomized controlled trial.[42]

Tracheal Intubation

Premedication prior to tracheal intubation facilitates the procedure, controls pain and agitation, and minimizes physiologic disturbances such as bradycardia, tachycardia, and increased intracranial pressure in the newborn. Premedication optimizes conditions for the procedure, increasing success for proceduralists at every skill level. In 2010, the American Academy of Pediatrics issued a policy statement with grade A evidence-based recommendations recommending that all newborn infants receive analgesic premedication for endotracheal intubation except for emergency intubations during resuscitation or infants in whom instrumentation of the airway is likely to be extremely difficult.[111,112] A key component of premedication is analgesia.

Premedication for intubation is inconsistent across NICUs. Concerns about rapid medication availability, the ability to maintain the airway, and the ability to provide ongoing ventilatory support continue to cause controversy. The debate about the best medication regimen is ongoing in the literature, particularly surrounding the INtubate, SURfactant, and Extubate (INSURE) procedure which involves intubation to administer surfactant with subsequent rapid extubation to positive pressure,[113] the concern being that sedation for intubation may make it more challenging to extubate rapidly. One center reported using naloxone to facilitate extubation after INSURE for infants with a poor respiratory drive from sedation for intubation.[114] As the Less Invasive Surfactant Administration (LISA) procedure becomes more common, sedation to facilitate this procedure, with associated analgesia, has been encouraged.[115]

Once the decision has been made to premedicate, the next question is which medications to use. Medication combinations typically include a vagolytic to stabilize patient vital signs, an analgesic to provide pain control, and a muscle relaxant.

Atropine is the preferred vagolytic for intubation. A dose of atropine at 0.02 mg/kg IV or IM, with no minimum dosage, has a grade A evidence-base for its efficacy as a vagolytic.[111,112]

Options for pain control are more varied with studies of opioids such as morphine, fentanyl, and remifentanil. The current best choice is fentanyl, a fast-acting opioid, as morphine has been shown to be no better than a placebo in randomized trials due to its slow onset of action.[111,112] Remifentanil, a short-acting opioid with extremely rapid onset and half-life, is also an acceptable option for analgesia,[116,117] although when given for INSURE in

one study, it predisposed to the rigid chest and provided suboptimal analgesia.[118] Careful administration of fentanyl and remifentanil can prevent rigid chest.[119]

Rapid-onset muscle relaxants also carry grade A evidence-based recommendations for the ability to facilitate the procedure; however, many providers have concerns about depressing spontaneous respiratory drive. Options include depolarizing and nondepolarizing neuromuscular blockers. Nondepolarizing neuromuscular blockers, such as vecuronium or rocuronium, are more common. Vecuronium is given at a dose of 0.1 mg/kg, whereas rocuronium, which has a shorter onset of action and half-life, is given at a dose of 0.5 mg/kg.[119]

Propofol, an anesthetic that provides no analgesia, was thought to be a possible substitute for the combination of atropine and a muscle relaxant because it allows continued spontaneous breathing. Pharmacologic studies failed to identify an optimal propofol dose and patients experienced unpredictable hypotension without achieving adequate sedation.[120] In addition, there is the risk of pain when injected into small veins and extreme pain with extravasation.[111]

Midazolam, a sedative, is contraindicated when intubating preterm neonates, as it has been associated with adverse events in a small prospective, randomized controlled trial.[112]

Circumcision

Neonatal male circumcision is the most common pediatric surgical procedure, performed in 38% to 39% of male infants worldwide.[121] In 2012, the AAP Circumcision Policy Statement[122] not only affirmed the benefits of circumcision but unequivocally stated that analgesia must be provided during neonatal circumcision. Effective, evidence-based options for analgesia include EMLA cream, a topical anesthetic; dorsal penile nerve block, which provides local analgesia; subcutaneous ring block or caudal block, which also provides local analgesia; topical lidocaine; or acetaminophen 10 mg/kg orally.[121] However, anesthesiologists argue that topical EMLA may be insufficient.[123] Subcutaneous ring block has been found to be more effective than EMLA or dorsal penile nerve block. Nonpharmacologic techniques such as breastfeeding, positioning, nonnutritive sucking, sucrose solution, or dextrose solution, when used alone, are not acceptable alternatives for pain control but provide added benefit when used in concert with pharmacologic analgesia.

A randomized clinical trial assessing neonatal circumcision pain with a Gomco versus Mogen clamp, performed in 251 infants, concluded that the Mogen clamp is associated with less physiologic signs of pain but with no difference in CRIES pain scores.[124]

Other Invasive Procedures

Placement of a central venous catheter is facilitated by topical anesthesia with EMLA or infiltration of the skin with lidocaine. In addition, a parenteral opioid, such as morphine or fentanyl, is typically required. Ultrasound-guided central line placement is less painful than standard peripherally inserted catheter (PICC) placement.[125] Intravenous paracetamol is no better than sucrose at mitigating pain with PICC placement.[126]

The pain of lumbar puncture is compounded by both the needle puncture and the distress caused by the body position required for the procedure. EMLA has been shown to decrease the pain of lumbar puncture.[127] Fentanyl does decrease the pain of lumbar puncture with the caveat that it can cause respiratory depression.[128]

Chest tube insertion requires an intravenous opioid, adequate local analgesia (lidocaine), or both.

Laser surgery for retinopathy of prematurity requires pain control. A prospective study concluded that fentanyl infusion was more efficacious than sucrose alone.[129] Fentanyl combined with propofol helped prevent the need for intubation for this procedure while providing adequate analgesia.[130]

Pharmacologic Analgesia

The severity of the pain, its etiology, available administration routes, and potential side effects should all be considered during selection of an analgesic. Once medication administration has begun, careful monitoring for efficacy and side effects can decrease potential adverse events. A key component of effective pain management is continued reassessment after each intervention is introduced, although this is difficult to do with limited pain assessment tools.

Nonopioid Analgesics

Nonsteroidal Antiinflammatory Drugs (Indomethacin, Ibuprofen, Ketorolac)

Prostaglandins are part of the mechanism of local inflammatory response that results in pain. Inhibiting prostaglandin synthesis allows nonsteroidal anti-inflammatory drugs (NSAIDs) to inhibit pain. NSAIDs have many adverse physiologic and developmental effects, including sleep cycle disruption, increased risk of pulmonary hypertension, cerebral blood flow alterations, decreased glomerular filtration rate, alteration in thermoregulatory control, and changes in platelet function. The development of the central nervous, cardiovascular, and renal systems depends on prostaglandins, so these potential adverse effects are particularly worrisome for neonates and infants.

A retrospective analysis by Walsh et al. showed that ibuprofen use was not associated with more side effects in children younger than 6 months compared to those older than 6 months. However, adverse events were increased in the less than 6-month cohort who were prescribed ibuprofen compared to acetaminophen,[131] mainly gastrointestinal bleeding and renal injury. Infants less than 21 days of age and less than 37 weeks' corrected gestational age were more likely to have bleeding events when given ketorolac for postoperative pain than older, more mature infants less than 3 months of age in a retrospective review.[132]

Acetaminophen

Acetaminophen is the most widely administered analgesic in patients of all ages. It inhibits the activity of cyclooxygenase in the central nervous system, decreasing the production of prostaglandins, and peripherally blocking pain impulse generation. Neonates are able to form the metabolite that results in hepatocellular damage; however, it is not necessary to withhold acetaminophen in newborns because of concerns of liver toxicity. In fact, the immaturity of the newborn's cytochrome P-450 system may actually decrease the potential for toxicity by reducing production of toxic metabolites.[133]

Pharmacodynamic and pharmacokinetic studies of acetaminophen in infants recommend less frequent enteral dosing intervals

of acetaminophen (every 8 to 12 hours in preterm and term neonates) because of slow clearance and higher rectal dosing due to decreased absorption. Rectally administered acetaminophen has a longer half-life, but absorption is highly variable because it depends on the individual infant and the placement of the suppository. It should also be noted that the suppository may contain the entire drug in its tip and should be divided lengthwise if a partial dose is desired. Intravenous acetaminophen has become available in recent years with dosing recommendations that lack validated pharmacokinetic or pharmacodynamic correlates.[134] While rectal acetaminophen does not appear to decrease narcotic needs,[68] IV acetaminophen can decrease the need for morphine analgesia in preterm infants[135] and those undergoing major noncardiac surgery.[69,136]

A 2020 Cochrane review emphasized that data are insufficient to establish acetaminophen as an effective analgesic for procedural pain in neonates.[137] Acetaminophen may increase the response to later painful exposures after assisted vaginal birth and may decrease overall opiate needs after major surgery.[137]

Epidemiologic data suggest a link between perinatal acetaminophen exposure and an increased risk of developing asthma,[138] autism spectrum disorder (ASD),[139–141] and attention-deficit hyperactivity disorder.[142] While the association between acetaminophen and autism correlates with maternal use during pregnancy, its risk is mainly seen when ASD is comorbid with a hyperkinetic condition. Meanwhile, the association with asthma is strongest with acetaminophen use in infancy. As with all epidemiologic studies, causation is difficult to ascertain.

Opioid Analgesics

Opioids are believed to provide the most effective treatment for moderate to severe pain in patients of all ages, but there is a wide range of inter-patient pharmacokinetic variability. Opioid dosing depends on the severity of pain as well as the age and clinical condition of the infant.

Morphine

Morphine remains the gold standard opioid for pharmacologic pain treatment in neonates, although not necessarily because it has been shown to be the most effective. It is derived from the opium poppy and metabolized in the liver by uridine diphosphate glucuronyltransferase into two active metabolites: (1) morphine-6-glucuronide (M6G), a potent opiate receptor agonist, and (2) morphine-3-glucuronide (M3G), a potent opiate receptor antagonist. Both metabolites and some unchanged morphine are excreted in the urine. The predominant metabolite in preterm and full-term neonates is M3G. Because of slow renal excretion, both metabolites can accumulate substantially over time, especially M3G.[143] There is thus the potential for late respiratory depression because of a delayed release of morphine from less well-perfused tissues and the sedating properties of the active M6G metabolite.

Using the lowest dose possible to achieve the needed analgesia is advised. Escalating morphine doses will also increase the levels of M3G in the infant, interfering with the goal of adequate analgesia. Doses as low as 1 to 5 µg/kg/h can provide adequate analgesia, minimizing the risk of accumulation of high M3G levels, given that metabolite's prolonged half-life.[70,71]

Clearance or elimination of morphine and other opioids is prolonged in infants because of the immaturity of the cytochrome P-450 system; it approaches that of adults after 6 months of age. Chronologic age is a better indicator than gestational age of infant opioid metabolism.[144]

Infants are at greater risk for opioid-associated respiratory depression because of their immature respiratory control mechanisms. There is an increase in unbound or free morphine and M6G available to reach the brain as a result of the reduced concentration of albumin and α_1 acid glycoproteins.

Hypotension, bradycardia, and flushing constitute the response to the histamine release associated with rapid intravenous administration of morphine. Histamine release may occasionally cause bronchospasm in infants with chronic lung disease. Morphine sedation may result in the extended need for ventilatory support in neonates.[85] The duration of morphine is also a predictor of severe necrotizing enterocolitis.[145]

Dosing recommendations currently reflect the wide range of inter-patient pharmacokinetic variability. In the past, 0.03 mg/kg of morphine IV was suggested as a starting dose in infants not receiving mechanical ventilation, whereas 0.05 to 0.1 mg/kg of morphine IV was recommended as an appropriate starting dose in infants on ventilators. Significantly lower doses are now recommended.[146] Titration to the desired clinical effect is required by adjusting the dose and the frequency of administration while continually assessing needs and responses. As the use of morphine for analgesia and sedation in neonates is explored further, it is becoming clear that some of the risks (as discussed in the Long-Term Effects of Neonatal Opioid Exposure section) without clear improvement in measures of pain should encourage conscientious morphine prescription.[30] With this in mind, efforts to reduce opioid exposure in the hospitalized neonatal and pediatric population are being undertaken with strategies aimed at standardizing analgesia management pathways, including weaning as well as the use of pain and withdrawal scores.[147,148]

Fentanyl

Fentanyl is 80- to 100-fold more potent than morphine and causes less histamine release, making it potentially a better choice for infants with hypovolemia, hemodynamic instability, chronic lung disease, or congenital heart disease. Another clinical advantage of fentanyl is its ability to reduce pulmonary vascular resistance, which can benefit infants who have undergone cardiac surgery, have persistent pulmonary hypertension, or need extracorporeal life support. Bolus doses of fentanyl must be administered over a minimum of 3 to 5 minutes to avoid chest wall rigidity, a serious side effect observed after rapid infusion. This adverse effect is treatable with naloxone or a muscle relaxant. Intranasal fentanyl has been shown to reduce pain scores during retinopathy of prematurity screening examinations without increasing the risk of respiratory depression.[149]

Fentanyl has a quick onset and relatively short duration of action. In infants, 3 to 12 months of age, total body clearance of fentanyl is greater than that of older children, and the elimination half-life is longer because of its increased volume of distribution.

Fentanyl is highly lipophilic. A rebound transient increase in plasma fentanyl levels is a phenomenon known to occur after discontinuation of therapy in neonates. It is a result of the accumulation of fentanyl in fatty tissues, which can prolong its effects after continued use; therefore, caution must be exercised in the use of repeated doses or continuous infusions. Because of tachyphylaxis, continuous infusion rates of fentanyl are often increased to maintain constant levels of sedation and pain control. Infusion dosing can reach substantial levels, which then require a prolonged withdrawal period.

Enterally Dosed Opioids

Methadone is used in infants, primarily in the context of withdrawal from either maternal narcotic use or chronic narcotic use in the NICU. The limited data regarding its efficacy and pharmacokinetics in this population suggest no dosing modifications are needed from those recommended for adults.[150] The respiratory depressant effect of methadone is longer than its analgesic effect; it is metabolized slowly and has a long half-life.

Codeine use in any pediatric patient is not recommended due to safety concerns.[151] No data are available regarding its effectiveness in neonates, and its use in this population is discouraged. Acetaminophen and codeine can be given in a set formula, consisting of acetaminophen (120 mg) and codeine phosphate (12 mg/5 mL) with alcohol (7%). The dose prescribed is limited by the appropriate dose of codeine and the safe dose of acetaminophen. This combination is not recommended in neonates.

Oxycodone dosing at 0.05 to 0.15 mg/kg orally every 4 to 6 hours has been used in neonates. However, no data are available to recommend oxycodone in neonates.

Nalbuphine is a mixed agonist-antagonist opioid receptor drug; therefore its administration in infants of opioid-addicted mothers may precipitate withdrawal. This agent is equianalgesic with morphine and has an analgesic ceiling effect. It is not recommended for neonates, although it may be useful during opioid drug withdrawal treatment.[152]

Long-Term Effects of Neonatal Opioid Exposure

Experimental Animal Studies

Perinatal and neonatal opioid exposure in experimental animals is associated with both short- and long-term adverse neurologic effects that should prompt clinicians to wonder whether use of such medications is warranted. Opioid receptor-mediated signaling likely has a role in several aspects of early brain development.[153] The developing cerebral circulation is extremely vulnerable to physiologic perturbations and the effects of drugs. Cerebrovascular effects of drug exposure early in development can have lifelong consequences, including increased risk for stroke. Perinatal narcotic exposure restricts brain growth, induces neuronal apoptosis, and alters behavioral pain responses later in life.[154]

The acute effects of exogenous narcotics, including morphine, on the developing cerebral circulation, have been described in piglets and include modulation of prostaglandin-induced pial artery dilation during hypoxia, alteration in endothelin production, and increases in endothelin A receptor mRNA expression.[155] Morphine causes dose-mediated responses to mRNA expression in mice that suggest long-term alterations in hippocampal functioning.[156] Endogenous opioids are important regulators of cerebrovascular tone and angiogenesis. Permanent neurobehavioral and neuropathologic changes are demonstrable in a rodent model of neonatal stress and morphine exposure.[157–159] Morphine causes rodent thalamic cell death.[160] Certain alleles of morphine biotransformation gene variants in combination with increased morphine exposure in the neonatal period are linked to anxiety, depression, and externalizing behaviors at 18 months corrected age.[161]

Understanding the clinical relevance of these animal studies regarding the long-term effects of neonatal opioids is difficult because of species differences in the timing of brain development, the development of opiate receptors and major neurotransmitter systems, and the pharmacokinetics of administered opioids.

Clinical Studies

Clinical studies addressing the short- and long-term effects of prolonged opiate use in neonates are limited. The few that exist are contradictory and confounded by illness severity. Possible confounders including illness acuity, concurrent medications such as steroids and benzodiazepines, and morphine given preemptively make these results difficulty to interpret.[162] Cohort studies using regression analysis to control for drug exposure, gestational age, acuity, and other variables, are inconsistent but concerning in their reports.

The EPIPAGE cohort in 2008 noted that preterm infants exposed to more than 7 days of sedation or analgesia were at increased risk of severe or moderate disability at 5 years. However, this association did not remain significant when adjusting for gestational age and infant acuity.[163] Conversely, the EPIPAGE 2 cohort[164] published data in 2014 noting that ventilated preterm infants treated with continuous opioid and/or midazolam infusion in the first 7 days of age were more likely to survive without measurable differences in moderate or severe sensorimotor impairment at 2 years of age.[165]

A 2015 cohort study of preterm infants noted that low-dose morphine analgesia in the NICU was associated with altered cerebral structure and behavioral problems that resolved in childhood.[166] A cohort study published in 2016 noted that premature infants correlated worse cognitive scores on the Bayley III test administered at 20 months of age with high levels of opioid exposure in the neonatal period after controlling for neonatal and social confounders.[167]

Preterm infants evaluated at 36 weeks' post-conceptual age in the prospective, randomized 2004 NEOPAIN study demonstrated neurobehavioral abnormalities if exposed to morphine.[168] A small pilot follow-up of the NEOPAIN trial in 2012 included only 19 patients at age 5 to 7 years and showed an association between those given preemptive morphine infusions and smaller head circumference, lower body weight, and increased social problems, and altered response latencies.[169] Two-year follow-up results of the study randomizing ventilated infants to fentanyl versus placebo for analgesia concluded in 2017 that infants randomized to fentanyl had impaired hand-eye coordination not explained by acuity alone.[170]

A cohort of preterm infants admitted to a single NICU was tracked prospectively for acuity, painful procedures, and morphine exposure. Results published in 2016 noted that MRIs performed at term equivalent gestation demonstrated a strong statistical association of morphine exposure with smaller cerebellar volumes and poor motor and cognitive outcomes despite rigorous control for confounders.[171]

Several follow-up studies tracked some of the 150 neonates included in a 2013 randomized controlled trial of preemptive analgesia for ventilated, preterm neonates.[84] Five-year follow-up controlling for open-label morphine and clinically relevant variables implied a trend toward more negative outcomes in subjects who received morphine concerning intelligence, visual-motor integration, behavior, chronic pain, and health-related quality of life. Morphine use, both preemptive and open-label, was also associated with worse performance on the visual analysis subset of the intelligence quotient testing.[172] When the same investigators conducted follow-ups at 8 to 9 years of age, they obtained different results. IQ testing did not differ between the two groups, and children who were exposed to morphine had fewer problems on the subscales of inhibition, organization of materials, and monitoring as observed by parents and on the subscale

of planning and organization as observed by their teachers.[173] No differences were found in thermal detection and pain thresholds, the incidence of chronic pain, or overall neurologic functioning between those who received continuous morphine infusion in the NICU for preemptive analgesia and those who did not arrive at 8 to 9 years of age.[174]

The Preterm Epo Neuroprotection Trial (PENUT Trial), published in 2020, enrolled 941 extremely low gestational age infants and evaluated survivors at 2 years of corrected age. Prolonged combined use of opioids and benzodiazepines increased the risk of poorer neurodevelopmental outcomes.[175]

The conflicting nature of these studies, multiple clinical confounders, and the fact that few of these studies are adequately powered to address the issue of long-term effects of neonatal morphine exposure make the question of the long-term effects of morphine on the developing brain an area in need of robust research.

Long-term use of narcotics and other drugs leads to drug tolerance and the need to wean slowly to avoid drug withdrawal. The drugs themselves, as well as drug tolerance and drug withdrawal, may all contribute to adverse effects on brain development and neurodevelopmental outcomes.

Topical and Local Anesthetics

Lidocaine reduces the pain and stress of venipuncture and IV catheter placement. ELMA is a cream containing the active ingredients lidocaine and prilocaine. The cream can be placed on the area where anesthesia is desired and then covered with an occlusive dressing for 1 hour before a procedure. Longer application times provide deeper local anesthetic penetration but can lead to toxicity. There is a slight risk of methemoglobinemia with the use of EMLA cream in patients who are G6PD deficient and in infants younger than 12 months who are also receiving methemoglobinemia-inducing drugs such as acetaminophen, sulfonamides, nitrates, phenytoin, and class I antiarrhythmics. A rare occurrence, methemoglobinemia, can happen when hemoglobin is oxidized by exposure to prilocaine. EMLA should not be used in patients with methemoglobinemia. A study of 30 preterm infants found that a single 0.5-g dose of EMLA applied for an hour did not lead to a measurable change in methemoglobin levels. A systematic review concluded that EMLA diminishes the pain during circumcision. Limited efficacy was noted with pain from venipuncture, arterial puncture, and percutaneous venous line placement.[176] EMLA was not found to diminish pain from heel lancing.[109] A Cochrane review concluded that there is insufficient evidence of the effectiveness or safety of EMLA in term or preterm infants to support clinical recommendations.[177] Oral sucrose or glucose may be as effective as EMLA for venipuncture.

Sedatives

Benzodiazepines

Benzodiazepines such as lorazepam and midazolam are sedatives that activate gamma-aminobutyric acid receptors and should not be used in place of appropriate pain medication, as this class of medication has no analgesic effect. For painful procedures, an analgesic must be used in conjunction with the benzodiazepine. Benzodiazepines are administered to decrease irritability and agitation in infants, providing sedation.

In ventilated infants, benzodiazepines can help to avoid hypoxia and hypercarbia from breathing out of synchrony with the ventilator, although the common use of synchronized infant ventilators makes this clinical problem much less likely. When given continuous infusions, dosing often escalates rapidly to maintain apparent sedation creating a need for prolonged weaning. In the 1999 NOPAIN trial, midazolam was associated with a significantly higher incidence of adverse neurologic events such as death, severe intraventricular hemorrhage, and periventricular leukomalacia.[88] Meta-analysis concluded that there are "insufficient data to promote the use of intravenous midazolam infusion as a sedative for neonates undergoing intensive care…[and there are] concerns about the safety of midazolam in neonates."[94]

Use of such benzodiazepines is associated with abnormal neurologic movements in both preterm[178] and term infants.[179] Prolonged midazolam dosing in preterm infants has been correlated with abnormal hippocampal growth and poorer neurodevelopmental outcomes.[180] Despite this, midazolam is commonly prescribed for infants receiving mechanical ventilation.[27] Clinicians are concerned and should use these drugs with caution in the NICU.

Dexmedetomidine and Clonidine

Dexmedetomidine is a potent and relatively selective α_2-adrenergic receptor agonist indicated for the short-term sedation of patients in intensive care settings, especially those receiving mechanical ventilatory support. The drug is given by either IV bolus doses for short procedural sedation (1 to 3 μg/kg) or continuous intravenous infusion (0.25 to 0.6 μg/kg/h). Because dexmedetomidine does not produce significant respiratory depression, it has been used for procedural interventions in spontaneously breathing infants.[181–183] Animal studies have been reassuring, and some have demonstrated that dexmedetomidine may be neuroprotective.[184–186]

As neonatologists become more familiar with dexmedetomidine, its use has increased;[187–191] however, short- and long-term safety and effectiveness information in infants is limited. A trial prescribing dexmedetomidine for infants undergoing therapeutic hypothermia reported no adverse events with decreased opioid usage for those in the treatment arm.[192] Dexmedetomidine successfully reduces benzodiazepine exposure when given as an intranasal sedative for preterm infants undergoing MRI.[193] In contrast, the use of dexmedetomidine in a retrospective study of surgical neonates did not show reduced opioid exposure highlighting the need for effectiveness data.[194]

Clonidine, another α_2-agonist similar to dexmedetomidine, is not deemed efficacious or safe based on available data to recommend its use as a sedative for infants receiving mechanical ventilation, according to a recent Cochrane review.[195]

Gabapentin

Gabapentin is a gamma-aminobutyric acid (GABA) analog that acts by binding the α_2-δ subunit on voltage-gated calcium channels, thereby blocking the release of excitatory neurotransmitters that cause pain.[196] It is predominantly renally excreted, and children under 5 years require approximately 30% higher doses, presumably due to age-related changes in renal function.[197] Gabapentin utilization in NICUs is highly variable, with patients ranging from term infants, ≤28 weeks' gestation preterm infants, and infants with chronic genetic, neurological, and gastrointestinal diagnoses.[198] Its use in neonates has been limited to those with refractory pain or agitation that fails to respond to standard therapy with opiates and benzodiazepines. In a retrospective observational study of 22 infants in a level IV NICU, gabapentin

successfully reduced N-PASS scores and the need for analgesic and sedative medications.[199] Gabapentin has also been used for visceral hyperalgesia due to neurologic or gastrointestinal morbidities. A study by Edwards et al. in this population noted improvement in chronic irritability and feeding intolerance as well as decreased usage of opioids and benzodiazepines.[200] Caution is advised as adverse events occurred with abrupt discontinuation.[200] This limited but growing literature suggests there may be a subset of neonates with refractory pain, agitation, or neurodevelopmentally impaired infants with feeding intolerance, for whom gabapentin may be a useful adjunct.

Nonpharmacologic Analgesia

Nonpharmacologic interventions for prevention or relief of neonatal pain and stress are numerous, can be effective, and have minimal risks or disadvantages for patients, yet are frequently underused.[201] This may be in part to inconsistent findings on effectiveness, small pain relief provided and/or the lack of a clear superior method.[202] Nonetheless, nonpharmacologic strategies to minimize pain should always be undertaken, especially with commonly performed procedures in the NICU.[203] The 2016 American Academy of Pediatrics policy update on prevention and management of pain endorses nonpharmacologic management as a key component to infant analgesia.[32]

Oral sucrose is the most widely studied nonpharmacologic "analgesic"; it safely and effectively reduces the acute behavioral response to procedural pain from one-time painful events.[106] Clinical equipoise suggests further studies of sucrose must enroll controls who have efficacious analgesia.[204] Sucrose does not, however, reduce spinal reflex responses, cortical activity,[22,23] or hyperalgesia, raising philosophical and ethical questions about the use of sucrose for procedural analgesia. "Sugar may be better understood not as an analgesic, removing or relieving pain, but as a compensating pleasure."[205] When combined with other nonpharmacologic analgesic interventions, sucrose continues to effectively decrease neonatal behavioral responses to pain. Sucrose plus nonnutritive sucking, for example, provides improved pain relief (as assessed by behavioral scores) from heel lance compared to placebo or either method alone.[206] However, despite immediate pain relief, glucose used for analgesia does not appear to mitigate the adverse effects of pain on brain development at 18-month neurodevelopmental follow-up.[207] Sucrose use in highly preterm, unstable, and ventilated neonates is not adequately addressed in the literature, nor is the effect of repeated sucrose administration.[23]

Several other nonpharmacologic therapies provide efficacious analgesia, alone and in concert with each other. Nonnutritive sucking with pacifiers reduces pain responses to heel prick, injections, venipuncture, and circumcision procedures.[208–210] Nonnutritive sucking is also efficacious in combination with breast milk and/or facilitated tucking (flexed position) to mitigate acute procedural pain.[211] Infant massage has been demonstrated to decrease plasma cortisol and catecholamine levels in preterm infants.[212,213] Preterm neonates benefit from skin-to-skin contact[214] or facilitated tucking[215] to ameliorate acute procedural pain responses. Among positioning strategies, facilitated tucking by parents for at least 30 minutes duration, starting 15 minutes before, during, and 15 minutes after a painful procedure, was recommended in a systematic review as the first position of choice during painful procedures in the NICU.[216]

Skin-to-skin contact (also termed *kangaroo care*) is associated with greater physiologic stability and reduced responses to and recovery from acute pain.[103] Kangaroo care is also efficacious for repetitive painful procedures in the NICU.[107] Kangaroo care can decrease Neonatal Infant Pain Scale scores after vitamin K injections.[217] When compared to oral sucrose, kangaroo care during heel lancing is more effective for pain relief in preterm infants.[218]

Breastfeeding in combination with kangaroo care reduces the physiologic and behavioral responses to acute pain and stress and is the first line of treatment.[219–221] Breastfeeding[222] and feeding expressed breast milk[223] can decrease acute procedural pain, as can the odor of maternal breast milk.[224] In full-term infants, direct breastfeeding is more effective in reducing pain responses than maternal holding, skin-to-skin, topical anesthetics, and music therapy, and more effective than sucrose solutions.[225]

Another approach is multisensory stimulation (sensorial saturation) of preterm infants undergoing painful procedures. This approach entails simultaneous gentle massage, soothing vocalizations, eye contact, smelling perfume, and sucking on a pacifier. This technique was associated with analgesia and calming the infants in several reports from one unit.[226–229]

Music therapy may reduce the behavioral and physiologic responses to acute procedural pain.[230] Maternal rocking, distinct from kangaroo care, diminishes neonatal distress.[231] Warmth is also an analgesic for acute, procedural pain in healthy term infants.[232,233] Other interventions such as white noise[234] and flaxseed pillows[235] are under investigation for their effects as either an acute analgesic or modulator of chronic pain.

Summary

Recognition and treatment of pain and discomfort in neonates remain challenging. Despite significant progress in the understanding of human neurodevelopment, pharmacology, and more careful attention to the care of sick infants, there is still much to learn. Potentially best practices include avoiding aggressive interventions, prioritizing nonpharmacologic pain management, and grouping interventions and exams with nursing care times. Providers can limit skin-breaking procedures by batching or decreasing blood draws and by maximizing the use of indwelling central lines in lieu of heel lancing for lab draws as able. When pharmacologic analgesia is prescribed, providers should utilize the least amount of drug that controls the pain and discontinue the medication as soon as possible; escalation of drug doses may exacerbate the problem. Bedside providers should feel empowered to prevent pain by making time for appropriate and effective pharmacologic and nonpharmacologic analgesia.[236] Mindful practice to minimize pain and distress mitigates adverse effects on neurodevelopment.

Palliative Care

DONNAMARIA E. CORTEZZO AND BRIAN S. CARTER

KEY POINTS

- Palliative care is the total care of a patient with a life-limiting illness regardless of the disease trajectory or treatment options chosen.
- There is a special focus on pain/symptom management, communication, quality of life, family support, and grief support.
- Up to 3% of pregnancies are complicated by a life-limiting diagnosis. Roughly one-third of deaths in children's hospitals in the United States occur in neonatal intensive care units (NICUs). Many babies and families in the NICU benefit from palliative care.
- There is a special role for palliative care when the likelihood of long-term survival is uncertain or minimal or when there is a low likelihood of survival without severe morbidity. Decisions around the most appropriate treatment plan are often based around views of acceptable quality of life.
- While palliative care is essential to individuals in the NICU, it is often overlooked, and there are many barriers to it being considered or implemented in suitable cases.
- Palliative care can be readily integrated in to the management of neonates with life-limiting illnesses and can be provided concurrently with cure-oriented or life-extending care.

What Is Palliative Care?

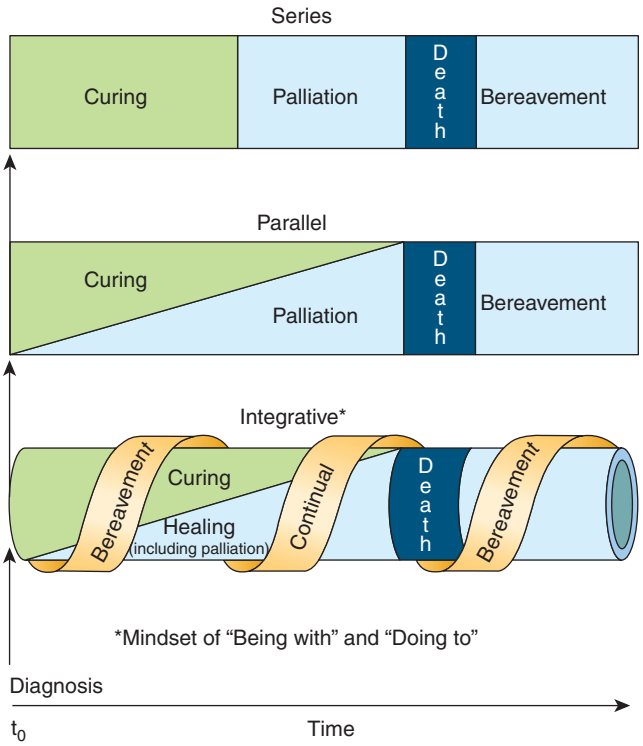
The concept of palliative care has been acknowledged in medicine for centuries. The name is derived from the Latin word *palliare*, meaning "to cloak," and has been more broadly interpreted as "to alleviate without the intent of curing." Over the years the definition and scope of palliative care have evolved.[1] The field gained great momentum with adults during the 1960s with the hospice movement and the realization that modern medicine alone does not address all of the issues patients with serious and life-limiting illnesses experience. More recently, the incorporation of palliative care in pediatrics has become a critical focus for the field.[2–11] The World Health Organization defines pediatric palliative care as the total care of a child with a life-limiting illness. It involves caring for the mind, body, and spirit of the child and supporting the family through the process. It begins with diagnosis and continues regardless of the disease trajectory or treatment options chosen. There is a special focus on pain and symptom management and alleviating distress through a multidisciplinary approach.[12] Palliative care is not limited to end-of-life (EOL) care. It can occur concurrently with other treatments in an attempt to cure a patient or prolong his or her life independently of if or when the transition to EOL care occurs. Hospice care is a small and important part of palliative care. Once it has been determined that there is no chance of meaningful survival, the focus of care shifts to pain and symptom management, grief support, preparing for the dying process, and bereavement support.[13]

In recent years, the American Academy of Pediatrics has acknowledged the importance of this growing field and recognizes that all large healthcare organizations providing care to children with life-limiting illnesses should have a dedicated pediatric palliative care team. They have discussed in detail the principles for palliative care and the importance of educating trainees.[14,15] Governing academies and families alike have come to see the importance of the provision of palliative care in pediatrics and more specifically in taking care of the sickest neonates. US News and World Report's Best Children's Hospitals Rankings in Neonatology now include a section for neonatal intensive care unit (NICU)-specific palliative care programs.

Despite the increasing focus on neonatal palliative care, the concept has existed for decades. In the 1970s the difficulties of withholding therapies in a special care nursery were described for the first time.[16] In this landmark article, the authors describe a collaborative process in which parents and physicians determined through joint decision-making the low likelihood of meaningful survival for 43 babies and opted to redirect care for them. They also acknowledge the difficulty of these decisions for parents and physicians, something that is still experienced today. Several years later, the notion of adapting concepts from an adult hospice model to address issues related to caring for a dying neonate in various settings was described.[17–21] Since this time, the importance of extending these concepts to the perinatal period and providing such care during pregnancy once a potentially life-limiting fetal diagnosis is made has been recognized.[22]

Paradigms of Palliative Care

There are multiple paradigms in which palliative care can be provided. As Fig. 23.1 illustrates, the first model represents the serial approach. This is congruent with the earliest view of palliative care. Once a terminal condition has been diagnosed, curative therapies continue until they are seen as futile. Then palliation and comfort measures are offered until the point of death. After death, bereavement support is offered. As the field of palliative care has evolved, adult palliative care has adapted the parallel model in which palliative care is introduced early in combination with curative therapies, and as the disease trajectory changes with time, the care model changes with it. Again, once death occurs,



• **Fig. 23.1** Various models for providing palliative care. (Modified from Milstein J. A paradigm of integrative care: healing with curing throughout life, "being with" and "doing to." J Perinatol. 2005;25:563–568.)

bereavement support is offered. The final model, the integrated model, is one that has been adopted most often by the growing field of pediatric palliative care and is most conducive to the distinctive environment of the NICU and neonatal-perinatal palliative care. When a life-limiting diagnosis is made, the concepts of palliation are often introduced at times along with curative therapies and the focus and goals change with the disease trajectory. With recognition that the family is experiencing loss on multiple levels at the time of diagnosis, bereavement and grief support are offered in a multidisciplinary fashion from the time of diagnosis, through the entire illness course, and after death.[23]

Because the perinatal-neonatal period is unique, it requires a different approach to palliative care from that in most other fields. The perinatal-neonatal period is usually a time of joy, anticipation of life, and hope for making many memories growing as a family. When a diagnosis of a life-limiting condition that results in a high likelihood of fetal or neonatal death is made, every milestone and stage of the pregnancy, birth, life, and death are very different from what was hoped for and anticipated.[11,24–29] In the NICU environment, clinicians are trained to offer intensive and invasive therapies with the goal of saving lives. It can be challenging to shift goals of care in the face of a life-limiting illness.[25,30–32] With increased recognition of the importance of neonatal-palliative care and the unique challenges clinicians face, the number of programs dedicated to providing this care continue to grow. There are marked differences in the structures of these programs and how care is provided.[33,34] While there is no standard for the components of a neonatal-perinatal palliative care program or how the care is delivered, a consistent and important theme is the focus on and goal of maximizing quality of life and providing support to families as they navigate through goals of care and complex medical decisions. Regardless of the specific make up, having formal programs in place leads to more comprehensive and cohesive care.[35]

Scope of the Problem

While neonatal–perinatal palliative care provides unique challenges for families and healthcare professionals alike, it is something that most individuals who care for neonates will be faced with. Despite the many advances in medical therapies and improvements in neonatal survival and outcomes, newborns will still die. At times, while the timing and cause of death may differ depending on the type of care provided, some babies will die regardless of the treatment options chosen by the family and medical care team. Each year, in the United States, there are more than 1 million fetal deaths, with more than 20,000 occurring after 20 weeks' gestational age.[36] Up to 3% of pregnancies are complicated by a life-limiting fetal diagnosis.[37–39] Expanded testing options and advanced technology have allowed for earlier and more frequent life-limiting diagnoses to be made in utero.[22,40] When such a diagnosis is made, between 20% and 40% of individuals choose to continue the pregnancy.[41] Some fetuses will die in utero. For others a live birth is followed by a death in the immediate neonatal period. Other newborns with a life-limiting diagnosis will survive for a period of time, even beyond the neonatal period, with interventions.[22,42–45] Yet there are more than 15,000 neonatal deaths each year, accounting for nearly 70% of deaths within the first year of life.[36] Roughly one-third of deaths in children's hospitals in the United States occur in the NICU setting.[46] As a result, most clinicians who care for neonates will be faced with the death of a patient and navigating goals of care with a family. Most infants who died within the first year experienced severe and chronic illnesses stemming from the time of birth. When a baby survives, there may be multiple treatment options or approaches to care. Some of the options may alter the disease trajectory but cannot correct the diagnosis or significantly impact the prognosis. It is important that families understand the prognosis, implications of interventions and care plans, and explore goals of care so that there is a focus on value-driven medical care when determining the most appropriate treatment options. With a value-driven approach, some families will seek a comfort measures-only approach to care while others, up to 50%, wish to explore varying degrees of life-sustaining medical interventions.[47]

Given the likelihood that neonatologists will care for patients with life-limiting illnesses throughout their careers, it is pertinent that they incorporate the precepts of palliative care in to daily practices to best care for patients and families. The uncertainty of prognosis, physical constraints of the NICU, time constraints, moral distress, and lack of education are known barriers to providing palliative care in the NICU.[28,31,32,48–50] In an intensive care setting it can be challenging to shift from cure-directed aggressive and invasive interventions to palliation and comfort care. However, early initiation of palliative care has been associated with improved memory making, decreased pain, decreased rates of invasive procedures that are unlikely to change the outcome, and increased parental satisfaction.[4,51–53] Consequently, it is imperative that all healthcare professionals view success for the unique subset of patients with life-limiting illnesses as eliminating unnecessary suffering, supporting families through navigating complex decisions, helping them find meaning in their baby's life, and ensuring that the care provided is in line with the values and goals of the family.[23,54] Failure in these situations is not the

inability to sustain life but rather unnecessary pain and suffering and an undignified death.

Which Patients Benefit From Neonatal-Perinatal Palliative Care?

Many neonates will respond to intensive care therapies, graduate from the NICU, and lead long, meaningful lives. Knowing this, which patients and families benefit from palliative care in the NICU setting? There is a role for palliative care in neonates with serious but possibly reversible or treatable conditions where intensive interventions will be beneficial. Arguably, many aspects of palliative care should be incorporated in to the multidisciplinary approach to care of any baby in the NICU. Any family member of a newborn requiring resuscitation or intensive interventions, regardless of the ultimate outcome, experiences grief and loss. The family has to alter its expectations for a healthy and uneventful pregnancy leading to a healthy baby. The family often requires spiritual, emotional, and psychosocial support to navigate goals and cope with this trauma both in the immediate period and moving forward.[55]

However, there is a special and more pronounced role for palliative care when the likelihood of long-term survival is uncertain or minimal. This is also true when there is a low likelihood of survival without severe morbidity or prolonged technology dependence. Decisions around the most appropriate treatment plan are often based around views of acceptable quality of life. At times it may help both clinicians and families who find it challenging to process this to a consider what the quality of each day is like in the NICU. When death is almost certain or the chance of survival without severe morbidity that would lead to an unacceptable quality of life is minimal, continuing life-sustaining treatments may prolong the suffering of the neonate and give the family false hope of meaningful survival. The care initiated and the treatments that follow may be aggressive and at the expense of the comfort of the neonate. Palliative care focuses on the prevention and relief of physical pain and suffering that can be experienced by periviable or extremely premature infants, actively dying infants, or those severe morbidities and possibly technology dependence, as well as on supporting the needs of the family.[56] Everyone involved in the care of these neonates, as well as the neonates themselves, can strongly benefit from this type of care. In these situations, regardless of whether a neonate dies, lives with a permanent impairment, or goes on to live a normal life, there is a necessary role for palliative care. Beyond addressing symptoms such as pain, this approach offers support to families and addresses short-term and long-term measures to ensure that there is value-driven medical care so the infant has the best quality of life for as long as they may live.[21,57–59]

While every patient and family dynamic is different and goals need to be explored for each patient, there are several categories where it is appropriate to discuss transitioning from life-extending therapies to comfort measures:[21,22,24,25,28,42,54,60,61]

1. Periviable or extremely premature newborns based on gestational age or birth weight, especially when they have significant complications.
2. Neonates with multiple congenital anomalies considered life-limiting or that may threaten vital functions. Under these circumstances, intensive care therapies may alter the time course and the baby's/family's life experience but likely will not change the long-term outcome. Individuals may be expected to have varying degrees of survival and severe morbidity. These conditions may involve any single-organ or multiple-organ systems and at times are the result of genetic abnormalities.
3. Newborns who have received intensive interventions and despite efforts are not responding to therapy, continue to decline, have continued life-threatening events, or interventions are seen as overly burdensome.

When these difficult situations arise, it is important to have a multidisciplinary approach to caring for the patient and family, starting from the time of diagnosis. The NICU provides a unique environment in which intensive life-sustaining therapies are provided with an emphasis on comfort of the patient and involvement of the family in the care process.[24] It is one of the few places in hospitals where a multidisciplinary team (physicians, nurses, social workers, chaplains, etc.) is focusing on multiple aspects of the total care of the baby–family unit. This lends itself nicely to the provision of palliative care because much of the framework already exists and allows for families to explore and share their hopes and goals while focusing on parenting their baby. Yet, while many clinicians in NICU settings feel they are comfortable and competent in providing palliative and EOL care for neonates, there is a wide variety in the care patients receive and in the discussions of goals of care with families.[24,52,62] Similarly, there may be attitudinal barriers to consulting palliative care clinicians. Evidence suggests, however, that once the need for and importance of palliative care in the NICU are realized, palliative care clinicians can be readily integrated into the management of neonates with life-limiting illnesses.[63]

Timing of the News

Families may learn of a life-limiting condition in the early prenatal period, late prenatal period, or early neonatal period.[8] While the job of the healthcare team remains the same in supporting the family members and helping them find meaning in their baby's life, the timing can slightly alter the approach to care.

Early Prenatal Diagnosis

If the news is given in the early prenatal period, parents often have time to begin grieving the loss of a healthy pregnancy and reframe their idea of hope. If palliative care is initiated early on, the family members may benefit from the involvement of palliative care clinicians who learn about the family and support them through the process. They can facilitate bonding and memory making throughout the pregnancy. They also have time to navigate their goals of care and develop a care plan that includes a birth plan and advance care planning known by all clinicians at the time of delivery. This allows the family and care team to explore desires for the pregnancy, labor and delivery, and care of the baby afterward. It can give the family a sense of control and ensures that the care team will know and attempt to honor their wishes. Box 23.1 highlights important components of a perinatal palliative care birth plan. The delivery room resuscitation plan should be discussed ahead of time with the family.[29,53,64–66] Staff need to remain ready to adapt such plans to the reality of the newborn's condition at birth. Families may change their minds, the newborn's condition may be better or worse than anticipated, and decision-making remains rather fluid. Ethics and palliative care support may aid parents and facilitate their navigation through difficult decisions and how they choose to spend whatever amount of time they have with their baby.

• BOX 23.1 Components of a Perinatal Palliative Birth Plan

Important Information for the Care Team
- The baby's name (if known)
- A diagnosis for the baby (if known) and pertinent medical information
- What the family has been told to expect
- Names and numbers for important providers

Clarify Maternal Goals
- Site of delivery
  Community or tertiary
- Fetal heart monitoring
- Mode of delivery
  Burdens, benefits, values
- Analgesia for mother
- Special requests during labor
- Who should be in attendance
- Who should cut the umbilical cord
- Preferences for if the baby is stillborn

Clarify Neonatal Goals
- Invasive interventions vs. comfort measures only
  Any specific interventions they would or would not want
  Specified components of resuscitation and care
    - Intubation, noninvasive respiratory support, medications, access
- Site of care for the baby
  Mother's room, nursery, intensive care unit, home
- Wishes for delaying routine procedures or providing them while the baby is in the parent's arms
- Wishes for feeding the baby
  Breast, tube, cup, finger, none
- Wishes for medications
- Wishes for additional testing
- Wishes for memory-making and support
  Photographs and videos
  Keepsakes: footprints, handprints, locks of hair, crib card, ID bands, blankets, clothing, heartbeat recording
  Wishes for bathing the baby and special outfits
  Family involvement
  Spiritual rituals/wishes

Goals for if the Baby Survives the First Day
- Intensive care versus take their baby home for end-of-life care versus receive end-of-life care in the hospital
- If they wish to be discharged home
  The name of the hospice/home care that will support them
  Anticipated care needs at home
  Information about whom to notify if baby dies at home

Wishes for if the Baby Dies Before Discharge
- Symptom management
- Wishes for organ/tissue donation if eligible
- Wishes for autopsy or further testing
- Funeral home information
- Special wishes about transportation of the body
- Any other additional requests the family may have

Late Prenatal Diagnosis

If the news of a life-limiting illness is discovered late in the pregnancy or just before delivery, it often results in a more chaotic and less formulaic approach. Teams are working rapidly to provide immediate care to the pregnant individual and fetus/neonate. There often is not time to have lengthy discussions or learn the parent's values. In the chaos, communication can be rushed and fragmented. It remains imperative to provide accurate information and support to the parents while making the environment as calm and private as possible, allowing the family members to express their emotions. In the time that follows, discussions can be continued and goals and treatment plans can evolve.

Postnatal Diagnosis

If the news of a life-limited illness is made after delivery, parents are often shocked. Most assume that if a pregnancy and delivery are uncomplicated, their baby will be healthy. For them it is an abrupt loss of the healthy baby they were holding moments before they received the news. It is vital to continue to promote bonding with the baby and ease suffering. The care team should use the medical information along with the knowledge of the family's values to shape the goals of care and aid in decision making. Extra time is often necessary in this situation, with care to provide support for the family and staff in redefining and redirecting hope and the goals for the newborn's care.

Parents note (especially with a postnatal diagnosis) that the delivery of the news and the discussions that follow shape their experience with the care team, their memories of time with their child, and their subsequent bereavement.[67] Some parents report that the manner in which news about a diagnosis, prognosis, or treatment options was given, was insensitive. They wish to be included in the decision-making process and know that their input as parents is what matters most. They also desire privacy, support, and time to come to terms with their loss.[51,68–74] They feel quality care was best provided when providers listened, aided in decision-making, supported their goals, explored the range of outcomes, included the family in care, asked about hopes and fears, and provided ongoing compassionate support.[75]

Components of Neonatal-Perinatal Palliative Care in the Neonatal Intensive Care Unit

The major components of neonatal-perinatal palliative care are a focus on communication, quality of life, family support, and grief support.[64,76] Ideally, clinicians who have become familiar with the family (including neonatologists, nurses, social workers, and chaplains) and have developed a rapport with them should initiate and be present for difficult conversations. Depending on the timing of diagnosis, these conversations may begin before the birth of the baby. Conversations with family members should be clear, direct, and honest.[77] The intent is to provide the necessary medical information and in that context explore goals of care. This is unlikely to be achieved in a single discussion. Rather, the clinician is engaging in a conversation that starts the journey they will be embarking on with the family. When important or new information is being conveyed, it should occur in a quiet environment where the family has the clinician's undivided attention. Parents wish that difficult news be delivered in an honest and compassionate manner that lets them know their child matters.[65,74,77,78] After the diagnosis and the relative certainty of the prognosis have been discussed, the focus of these conversations should shift to exploring the values of the family, wherein the care team can better understand the family, how the family members make decisions, what is important to them, and how in the context of their specific situation and values or goals the medical information is important.

In these conversations it is important to help the family identify—and often redefine or redirect—their hopes. By being open and compassionate, clinicians can give family members a sense of realistic hope during this difficult time without misleading them toward a false sense of the likelihood of survival.[51,65,74] It is often helpful to focus the conversation on what is meaningful to the family members in the context of given prognosis.[54] Their idea, or object, of hope may change over the course of the baby's life. With a better understanding of the family's values, the care team can participate with the family in shared decision-making and ultimately define or redefine the goals of care. These conversations and the decisions made are unique to each family regardless of the diagnosis. It is not uncommon for parents and the care team to have different agendas and priorities during this time.[79] It is critical to attend to the parent's priorities and ensure that they feel valued, listened to, and a member of the care team. It is the care team's job to understand the family's values and goals and to make medical recommendations based on those goals. There are times when the choices of the family may be in opposition to the views of the care team.[80,81] It is the team's obligation to continue conversations with the intent of better understanding the reasoning behind the family member's decisions/goals and support them through the process. The goal should not be to convince the family that an alternative approach is most appropriate. In partnership with the NICU team, palliative care clinicians may be instrumental in facilitating such ongoing conversations, especially as primary neonatal clinicians may change every week or every 2 weeks.

When the end of life (EOL) is approaching, it may also be important to have open conversations about organ or tissue donation, autopsy, and funeral, memorial, or burial services. Many NICUs have a team of social workers, chaplains, and psychologists to help attend to these needs. The addition of palliative care clinicians can bring expertise in providing additional support during these very unique and difficult times. When there is an anticipated compassionate withdrawal of life-sustaining medical treatment, it may be beneficial to contact a liaison with a regional organ procurement organization to engage families in discussions about organ/tissue donation.

Regardless of the family's care goals or treatment options, the baby's quality of life should remain paramount. Care should be taken to ensure that painful procedures are minimized, unnecessary tests stopped, the physical environment is made comfortable and conducive to family bonding, and that pain and symptoms are addressed with nonpharmacologic and pharmacologic management when necessary.

Neonatal End-of-Life Care

Palliative care is extremely important during EOL care, when a neonate is imminently dying. Every effort is made to ensure the family members can shape the death experience in a way that is most meaningful to them and that they are as prepared as they can be for the dying process. For some families, it is important that they understand the physiologic changes that they will likely see ahead of time. If family members wish to stay in the hospital for the death of their baby, every effort should be made to bring them to a private room within the NICU or to a different location within the hospital. The environment should be as peaceful and homelike as possible. Monitors and unnecessary equipment should be removed. Families should determine who they wish to have present and if they would like to hold their baby or perform any rituals. Care should be taken to respect any cultural or spiritual desires of the family. If parents desire to take their baby home for EOL care, clinicians should coordinate with local home hospice programs or home-health services to ensure that the family will have access to the care, support, equipment, and medication needed during this time. Parents should be reassured that regardless of location, they will not be abandoned and that care will be taken to attend to pain and symptom management. The focus should be on what the team can do for the baby and family as opposed to what the team can no longer achieve.[64,82,83] Neonates feel pain and other symptoms of distress, and those symptoms should be addressed accordingly.[84,85] Symptoms that should be anticipated, assessed for, and may require treatment at the EOL include pain, agitation, dyspnea, and secretions.[86–88] Nonpharmacologic interventions to address these issues, such as decreasing stimulation, a soothing environment, massage, kangaroo care, elevating the head, fluid restriction, and gentle suctioning, are important. At times, especially during the EOL, nonpharmacologic interventions will not be enough. It is important to anticipate this and to help alleviate the stress of the family by discussing it ahead of time. It is both clinically and ethically appropriate to provide pharmacologic symptom relief. While there may be a concern of hastening death with certain medications (e.g., opioids), at appropriate doses this generally does not happen. The intent to provide relief of pain and suffering, it can be argued, outweighs the small chance of respiratory depression. Tables 23.1 and 23.2 provide common pharmacologic and nonpharmacological symptom management at the EOL. It is important to note that for pharmacological management, the doses and the medication choices need to be altered based on the patient's previous medication exposure history. The medications used can be tailored based on the symptoms and symptom severity expected from the clinical situation and underlying disease process. Opioids, for example, are most effective for dyspnea and pain while benzodiazepines are effective for agitation. The route of administration will depend on the illness severity and location of end-of-life care.[87] Intravenous administration, especially in the NICU setting, is typically utilized. In the home or hospital setting, most of the medications can be administered via other routes. Most opioids can be administered orally or buccally. Fentanyl, midazolam, and dexmedetomidine can be administered intranasally.

In addition to the care provided to the baby surrounding the time of death, there are other considerations that will need to be addressed either before or after death occurs. If the mother has been providing breast milk, she will need to be educated about options including lactation suppression and milk donations. These are very personal decisions as some women find milk donation therapeutic or a way to have their baby's legacy continue, while others feel it is a painful reminder of their baby who is no longer able to breast feed.[35,47,89] Regardless of the decision around milk donation, she will need to be counseled about the options available as continuing to produce milk or trying to decrease the milk supply without guidance can be painful and lead to medical complications.

Other important topics to discuss are organ and tissue donation and a postmortem exam. Organ donation options for medical purposes and research are variable by area and often connection with a local organ procurement center will allow parents to know what options are available.[35,47] If they wish to pursue organ or tissue donation it is important that they are prepared for the necessary procedures ahead of time and how that might change the EOL experience they have with their baby and the time with the body afterward. Similarly, the discussion of a postmortem exam,

TABLE 23.1 Symptom Management for End-of-Life Care: Pharmacologic

Symptom	Medication	Class	Starting Dose with Route and Frequency
Pain	Acetaminophen	COX2 inhibitor	15 mg/kg PO/PR q6 6–8 mg/kg IV q8
	Dexmedetomidine	Selective alpha 2 agonist	0.5–1 mcg/kg IV/IN q2 0.5–1 mcg/kg/hr IV continuous
	Fentanyl	Opioid	0.5–2 mcg/kg IN/IV q2 1–4 mcg/kg/hr IV continuous

IN, Intranasal; *IM*, intramuscular; *IV*, intravenous; *PO*, per os; *PR*, per rectum; *q2*, every 2 hours; *q2–4*, every 2–4 hours; *q4–6*, every 4–6 hours; *q6*, every 6 hours; *q8*, every 8 hours; *q12–24*, every 12–24 hours.

or autopsy, is a delicate topic that requires care and attention. At times, an autopsy can provide valuable information to the family. It leads to a change in diagnosis or additional findings in 22% to 76% of cases.[90] Depending on the circumstances and what is already known, this can give insight and answers to families both for this baby and possibly future pregnancies. When a diagnosis is not known, given the potential to reveal additional information, it is suggested that clinicians encourage families to consent to an autopsy.[90–94] In order to do so, it is important that providers are knowledgeable about the exam itself and options available as there are stigmas and perceptions about the exam. Concerns with autopsy include the invasive nature, the timing of the autopsy, transporting the body, religious and cultural concerns, and poor communication about the potential value.[95] To address some of these concerns, it is important that clinicians having these discussions be familiar with what happens to the body, the timeframe, and the expectation/limitations.[92] There are options for full, limited, stepwise, or noninvasive post-mortem exams and

TABLE 23.2 Symptom Management for End-of-Life Care: Nonpharmacologic

Symptom	Action	Provider
Pain or agitation	Reduce ambient noise	Clinician
	Reduce procedural touching (handling, suctioning, laboratory tests, and imaging)	Clinician
	Reduce temperature swings	Clinician
	Swaddle; facilitated tuck	Clinician or parent
	Nonnutritive suckling	Clinician or parent
	Skin-to-skin contact	Parent
Dyspnea	Postural positioning (may be lateral, upright, or prone; may include neck, chest, or shoulder roll)	Clinician or parent
	Consider fan or humidified air	Clinician
Secretions	Oral and nasal suctioning	Clinician or parent

more recently genomic autopsies.[90] Over time, the rates of the postmortem exam for neonates has decreased, with over 50% of families declining the exam, prompting the need for other methods of providing information to families. When families decline a full autopsy, there are minimally invasive or noninvasive options such as tissue sampling, MRI, and x-ray that may yield some answers depending on the suspected diagnosis.[94–98] There are certain diagnoses that will not be discovered with these approaches, but oftentimes they can still yield some results.[95] Some may find benefit by contributing to medical knowledge, or altruism, but most who find benefit do so because it gives them answers as to the cause of death. It is important to have open, honest conversations about the exam itself and value of and limitations of such exams because there are times when autopsies can lead to answers and other times when it can contribute to further grief.[99] It is also important to provide a clear plan about how the details of the autopsy will be discussed with the family. It is also important that they know when to expect the information (often, results from a full autopsy take two or more months) and how it will be disclosed to them. In-person meetings at a neutral location where there is time to discuss the details of the exam and any questions the family may have is ideal. It may be important to follow up with them after the initial meeting to provide support as they continue to process the information.

Memory-making, Legacy Building, and Grief and Bereavement Support

Grief support should be initiated shortly after a life-limiting diagnosis. Initially such support may focus on grieving the loss of the healthy newborn and the life the family members anticipated in the context of still celebrating and enjoying their baby. Attention should be given to ensure the parents, siblings, grandparents, and extended family members are able to make memories with the baby. During this stressful time, especially if it is their first child, parents are often unable to think about what memories would be important for them to make. Some families wish to take pictures, have handprints/footprints or molds made, record heartbeats, bathe the child, sing/read to the child, take the child outside, have the child meet a family pet, taste foods, sleep in a bed, or participate in spiritual/religious ceremonies.[100] Legacy-making activities, while new to the neonatal population, can be meaningful for families to explore.[101] Every effort should be made to help these families maximize the experiences they have with their baby during what may be a brief life span. Bereavement support for parents, siblings, grandparents, and other family members should start before the death of the baby and continue for a period afterward.[53,102] Parents appreciate bereavement support and follow-up phone calls from or meetings with physicians who provided care for their child and other forms of acknowledgment such as condolence cards.[53] It is also imperative to recognize that staff members benefit greatly from grief support.[52,103,104] Often the NICU staff has been involved in the care of the baby for much of his or her life and has spent time becoming familiar with the family. News of a poor prognosis can be emotionally trying staff as well. Because the staff are attending to the immediate care needs of the baby, family, and other neonates in the unit, they may be unable to process such difficult news. It is important that we support them as well.[104,105]

Ethical Concerns

With advances in equipment and medicine, and more rigorously studied and implemented care practices, neonates are increasingly benefiting from their NICU stays. The gestational age of viability has dropped with continuously improving clinical capabilities and we are able to offer interventions for diagnoses for which there previously were no treatment options.[106,107] As we become better at saving one group, the limits are pushed for another group of neonates.[108] Yet these advances have come with a variety of uncertainties and outcomes. Difficulty remains around the borderlines of viability and diagnoses such as bilateral renal agenesis. When to offer resuscitation? When to forgo life-sustaining therapies? Whether or not to redirect care toward palliation? At 22 weeks' gestation, for example, some centers universally offer a trial of intensive care whereas others do not, or do so on only an individual basis.[109,110]

It is often difficult to predict a neonate's course or future complications. This uncertainty brings many questions and discussions among professionals and families about the neonate's response to intensive care, complications encountered, and what actions are in the neonate's best interests.[56,106,107,111–115] Families are often faced with decisions that are not seen elsewhere in medicine. These decisions are complicated by the urgency of need for action and the uncertainty of prognosis.[8] Many times both families and care teams feel that once care is initiated, everything possible must be done to save the neonate. However, there may come a point in time when certain life-sustaining interventions are considered acceptable by some families whereas others believe such continued intervention or technology dependence render a quality of life for their baby that they do not find acceptable.

Ethically and legally withholding an intervention or withdrawing one already started are considered equivalent.[116] In other fields of medicine this seems to be more readily accepted. The thought of withdrawing life-sustaining medical therapies (LSMT) from a neonate leads many parents to believe they are actively aiding in their baby's death. When discussions are based on notions or

descriptions of futility or a perceived quality of life, a contest of whose perception of these terms matters most (clinicians or families) often results. Consequently, physicians may have difficulties addressing these issues, discussions may be limited, and if they occur it is late in the treatment course.[48,49]

Withdrawing/withholding LSMT, while a relatively infrequent phenomenon in a given NICU, is the most frequent mode of dying in both neonatal and pediatric ICUs.[117–119] It is understandable that parents want to be sure that there is essentially no chance of survival with an acceptable quality of life before such decisions are made. This warrants open communication, transparency in prognostication, and attention to empathy.[108,120]

Barriers to Palliative Care in the Neonatal Intensive Care Unit

While palliative care is essential to individuals in the NICU, it is often overlooked and there are many barriers. The NICU environment is often noisy and crowded, with little room for privacy.[60] Also, with current advances in technology, death may be viewed as a failure. The technologic imperative is so operant that if a therapy is available, it must be used without full consideration of how burdensome it is or if it will ultimately benefit the neonate.[60,121,122] Often families are overwhelmed by the technology and feel an incredible burden that the decisions are solely on their shoulders. If the outcome is certain and the treatment is a standard of care, then this is often not an issue. However, there is rarely such certainty. Beyond that, the lack of training for clinicians and organizational barriers remain a challenge in establishing programs and providing quality neonatal-perinatal palliative care.[122] Some have suggested that using standard criteria to prompt the involvement of palliative care is effective at overcoming some of the barriers.[123]

Training in Neonatal–Perinatal Palliative Care

Clinicians' discomfort in addressing the limits of medicine and technology and to redirect the prevailing care paradigm from one that is disease based and cure oriented to one that is palliative and comfort oriented is likely contributed to by a relative lack of palliative care training in neonatal-perinatal training programs. One published study addressing the training of neonatal fellows in discussions with families and helping them make decisions regarding critically ill neonates was particularly revealing.[124] Fellows from 83% of the accredited programs participated. For the most part, all fellows felt confident in their medical training. However, more than 40% stated that they had not had any formal communication or clinical communication skills training. More than 90% felt that training in this area—specifically palliative care, spiritual needs, and managing conflicts of opinion—was lacking or nonexistent in their training program. It is imperative that neonatologists learn these skills because families who have lost a child often cite how important physician communication with them is. Parents desire to hear information in a manner they can understand/handle and have the physician address all of their palliative care and spiritual needs so that they can collaboratively develop a clear plan.[32,52,124–127]

Research Opportunities/Future Directions

While in recent years there have been many advances in the field of neonatal palliative care, there are still many exciting opportunities for research. Studies have yet to determine which interventions offer optimal pain and symptom management at the EOL. There are also many opportunities for research addressing communication training and quality improvement investigations looking at the timing and delivery of palliative care, which paradigm of delivery is most effective, and how it will alter the course of living with neonatal loss for these families. The goal of this much-needed research is to advance the evidence base to help develop best practice models and approaches to treatment and care.

Risk Assessment and Neurodevelopmental Outcomes

SARA B. DEMAURO AND SUSAN R. HINTZ

KEY POINTS

- Preterm and critically ill infants are at high risk for cognitive and motor development problems, neurobehavioral and executive function problems, learning and academic problems, neurosensory problems, and poor functional outcomes.
- Neonatal morbidities, socioeconomic factors, and early interventions can influence long-term outcomes for high-risk infants.
- While neurodevelopmental impairment (NDI) at 2 years corrected age is a common outcome in neonatal clinical trials, there is ongoing debate regarding the appropriateness of this outcome as a gold standard and limitations to interpretation of NDI data.
- Early neurodevelopmental outcomes do not consistently predict abilities and challenges in later childhood and beyond. Longitudinal assessments into school age, adolescence, and adulthood are essential to understand the lifetime trajectory of former high-risk infants.
- All high-risk infants and their families must have access to comprehensive, multidisciplinary developmental follow-up programs and early intervention services in order to optimize both short-term and long-term outcomes.

Outcome Assessment in High-Risk Infants

Who Is the "High-Risk" Infant?

The term *high-risk infant* has been defined in many ways and has been burdened with many negative connotations. However, one general goal for attempting to delineate infants who are high risk is to heighten awareness and focus on those children who may benefit from increased surveillance and early intervention across a number of domains. In a policy statement from the American Academy of Pediatrics (AAP),[1] high-risk infants were defined broadly as including[1] the preterm infant;[2] the infant with special healthcare needs or dependence on technology;[3] the infant at risk because of family issues; and[4] the infant with anticipated early death. Others have underscored the importance of critically assessing risk in any infant admitted to the neonatal intensive care unit (NICU) or special care nursery.[2] Many clinical conditions and risk factors seen in term-born infants—including but not limited to congenital heart disease (CHD) (3), need for extracorporeal membrane oxygenation (ECMO) in the neonatal period,[4] and hypoxic–ischemic encephalopathy (HIE) regardless of treatment with therapeutic hypothermia[5,6]—place them at high risk for neurologic, developmental, functional, and health outcome challenges in early childhood and beyond. Unfortunately, although the risks for postdischarge difficulties, in addition to medical morbidities, have been increasingly well-described in the literature for these and other predisposing risk factors, the neurodevelopmental needs of many of these term-born, high-risk infants may be overlooked for referral at hospital discharge, or they may not obtain or have access to follow-up even if referred.[7,8]

Preterm infants are the most recognized and targeted population of high-risk infants. Preterm birth, defined by the World Health Organization (WHO) as delivery before 37 completed weeks of pregnancy, remains a crucial global health challenge.[9] According to the Centers for Disease Control and Prevention National Center for Health Statistics, in the United States in 2019, the proportion of live births <37 weeks' estimated gestational age [EGA] was 10.23%.[10] This represents the fifth consecutive year of an increase in the preterm birth rate from the 2014 rate of 9.57%. The increase in total preterm birth rate from 2018 to 2019 was among infants born late preterm (34 to 36 weeks) (7.28% to 7.46%), while the early preterm birth rate (less than 34 weeks) of 2.77% in 2019 was essentially unchanged. The proportion of infants delivered very preterm in 2019 (VPT, <32 weeks' EGA) stands at 1.59%, which remains relatively unchanged. Similarly, the extremely preterm (EPT, <28 weeks' estimated EGA) birth rate is relatively stable; in 2019 the EPT birth rate was 0.66%, exactly the same as 2018, and minimally changed from 2014 (0.69%). Although the VPT and EPT birth rates seem to be miniscule, the impact in terms of total births is important. With nearly 3.75 million births annually in the United States, more than 380,000 neonates <37 weeks' EGA, 100,000 early preterm neonates, and 25,000 EPT neonates were born in 2019 alone.

What Is Meant by "Outcomes"?

As survival of even the most EPT and complex infants has improved over the decades, short-term mortality and morbidities have moved from being the only outcomes reported for high-risk infants to being only the first of many outcomes of interest. There is increasing recognition of the critical significance of understanding later outcomes in order to evaluate the true impact of interventions and management approaches in the NICU, to inform counseling, and direct early detection and preventive care.

Certainly, for some trials of treatments and management strategies designed to test a hypothesis of improved in-hospital morbidities, the primary outcome may best be short term.[11–13] However, longer-term follow-up or later primary endpoints may provide valuable additional outcomes data, safety assessments, or information about functional elements.[14–20]

What are these post-discharge outcomes of potential importance? How are they measured, and what are the barriers or benefits of focusing on various outcomes? The value placed on one outcome or group of outcomes may differ greatly for families, children, and adults who were born high risk, physicians, and other care providers, investigators, educators, and those involved in developing public policy.[21,22] The importance of various outcomes may also vary substantially among individuals within these groups and across different time points of their lives. Furthermore, later cognitive and behavioral outcomes are complex and influenced by the postdischarge environment, relationships, and biologic factors.[23,24] Functional and adaptive outcomes may be considered the most important in some scenarios as these skills are related to essential daily tasks, abilities, and interactions, and their assessment generally does not require detailed and normative evaluations.[25,26] Therefore the concept that there is one "best" outcome measure among those born preterm or at high risk is ill conceived.

In the following section, we provide an overview of some general later outcome categories that have been frequently reported and proposed for high-risk infants, particularly for those born extremely preterm or at very low birth weight (VLBW). We begin with special attention to early neurodevelopmental outcomes assessments (18 to 36 months) since these are most frequently reported in trials and prospective observational studies. We discuss challenges and strengths reported at this age, using frequently reported definitions of impairment and disability, and describe the usual battery of tests and assessments. Limitations of standard outcomes definitions and challenges to interpretation of early neurodevelopmental outcome studies are considered. We also highlight abilities and difficulties assessed through school age and adulthood.

Early Neurodevelopmental Outcome Assessments

For the vast majority of interventional trials and prospective observational studies involving high-risk infants, neurodevelopmental outcome at approximately 2 years corrected age, and usually death or "neurodevelopmental impairment" (NDI), is reported as a primary outcome. Although the rationale for the combined outcome is clear in the setting of competing outcomes, there is ongoing and substantial debate regarding the appropriateness of this outcome as a gold standard for all trials.[27] Furthermore, the NDI outcome is itself a composite outcome, composed of morbidities from neurodevelopmental and sensory domains with different risk profiles, causal pathways, and predictive validity. There are challenges to interpretation of these data, potential limitations in terms of comparisons across cohorts and across years, and concerns regarding the value of early neurodevelopmental outcomes to predict abilities and challenges in later childhood and beyond.

In this section, we will focus specifically on the neurodevelopmental components generally presented in studies of 2- to 3-year follow-up. The traditional battery of tests and assessments includes motor function, cognitive/developmental capabilities, and neurosensory outcomes including hearing and vision impairments. These general components have been proposed and recommended by expert panels and working groups,[28–30] and within the context of prospective studies and trials although the specific evaluations within each area differ among groups and over time.

Motor Function

Motor impairments including cerebral palsy (CP) are among the most frequently reported neurodevelopmental outcomes for high-risk infants. Motor difficulties may become evident over months or years, yet timely identification of motor difficulties may allow for interventions to improve outcomes, thereby reinforcing the critical importance of vigilant long-term follow-up. CP is defined as a disorder of movement and posture that involves abnormalities in tone, reflexes, coordination, and movement, delays in motor milestone achievement, and aberration in primitive reflexes that is permanent but not unchanging and is caused by a nonprogressive interference, lesion, or abnormality of the developing immature brain.[31,32] CP is also categorized by type (spastic, dyskinetic, or dystonic); topography (limbs involvement); and descriptors of extent and pattern of involvement (monoplegia, diplegia, hemiplegia, and quadriplegia). Previously, it was considered that CP could not be diagnosed prior to approximately 18 to 24 months corrected age. However, it is now clear that a child may receive an accurate diagnosis of CP or high-risk for CP before 6 months of corrected age using evidence-based and standardized clinical assessment tools and imaging appropriate for age.[33] In a systematic review utilizing Grading of Recommendations Assessment, Development, and Evaluation (GRADE) framework, Novak and colleagues presented specific essential and additional criteria, and detection pathway options based on level of risk. In terms of standardized assessment tools, they found that in combination with medical history and depending on age of assessment, magnetic resonance imaging, the Prechtl Qualitative Assessment of General Movements, the Hammersmith Infant Neurological Examination, and the Developmental Assessment of Young Children were most predictive for detecting risk for CP. Of note, successful deployment of these guidelines for early diagnosis and risk stratification has been demonstrated across diverse high-risk infant follow-up clinic populations.[34] The goal of early identification of children with CP or high-risk for CP is to allow for early and targeted intervention, thereby maximizing neuroplasticity in the developing brain, and minimizing adverse impact of CP to muscle and bone growth and development.[35,36] There is evidence that involving and supporting parents as a critical part of this intervention process also leads to improved parent outcomes as well as parent-child interactions.[36–38] International clinical practice guidelines have recently been published to guide early intervention approaches for CP across the domains of motor function, cognitive skills, communication, eating and drinking, vision, sleep, managing muscle tone, musculoskeletal health, and parental support.[38]

The Gross Motor Function Classification System (GMFCS)[39–41] provides a valid and reliable system to classify the extent of activity limitation in CP. It is a five-level system (I to V) used to categorize children up to 18 years of age based on their usual performance, with a focus on functional capabilities, including sitting, mobilizing, walking, and need for assistive devices. Such classification helps clinicians communicate information about severity, choice of interventions, and prognosis in a standardized, easy-to-use, valid, and reliable way. Higher level on the GMFCS is associated with increasing functional difficulty, but, of note, distinctions between levels I and II are not as significant as differences between other levels, particularly for younger children. Children classified

as level I overall are able to walk without restrictions but may have difficulty with the speed, balance, and coordination required for higher-level skills; between 2 and 4 years, they are able to floor sit with both hands free to manipulate objects, move in and out of floor sitting and standing without adult assistance, and they walk as the preferred method of mobility without the need for any assistive mobility device. In contrast, children classified as level V are profoundly impaired with no means for independent mobility; between 2 and 4 years, this is described as physical impairments that restrict voluntary control of movement and the ability to maintain antigravity head and trunk postures and functional limitations in sitting and standing that are not fully compensated with the use of adaptive equipment. GMFCS categorization in children less than 2 years old depends predominantly on the amount of support required for the child to sit and also considers more advanced skills such as crawling and walking. Although some children diagnosed before 2 years of age will require reclassification, most are not reclassified by more than one level. The positive predictive value (PPV) of a classification of GMFCS level I, II, or III (child will walk with or without aids) as compared with level IV or V (child will probably need a wheelchair for mobility) is very high (0.96). Thus the GMFCS provides a sound approximation, rather than a definitive final categorization, in this age group.[42]

Although CP with severe functional limitations is of great concern, it is relatively rare. An Australian CP registry review from the 1970s to 2004 showed increasing prevalence of CP in the 1970s and 1980s attributed to the increasing survival of EPT infants; however, CP rates stabilized or decreased between the early 1990s and 2004.[43,44] Analysis of the Danish nationwide CP registry revealed a significant decline in the rate of CP in birth years 2005–2007 explained primarily by fewer cases of severe bilateral spastic CP among term children between these periods, although the rate of CP among premature infants had been shown to dramatically decline in previous periods.[45] Among infants born < 27 weeks' GA in the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network (NRN) and assessed at 18 to 26 months' corrected age, there was a decrease in the rate of any CP (16% in 2011 compared with 12% in 2014), with a decrease in severe CP (26% to 16% of all CP cases) during the study period.[46]

There are numerous motor and coordination challenges apart from CP that are reported in high-risk children, including those born preterm. Developmental coordination disorder (DCD) is diagnosed when (1) coordinated motor skills are substantially below those expected given the individual's chronological age; (2) the motor skills deficit significantly and persistently interferes with the activities of everyday living appropriate to chronological age and impacts school, play, and leisure activities; (3) the motor skills deficits are not better accounted for by any other medical, neurodevelopmental, psychological, social condition, or cultural background; and (4) the onset of symptoms was during childhood.[47] Current recommendations for diagnosis of DCD include a score less than the 16th percentile on the Movement Assessment Battery for Children[48] or equivalent test such as the Bruininks–Oseretsky Test of Motor Proficiency.[49] A recent longitudinal study of children born <30 weeks' GA demonstrated that at 5 and 7 years of age, nearly 1 in 3 had DCD, with an approximately fourfold increased odds for DCD compared with term-born children.[50] Although the motor difficulties associated with DCD are usually considered "minor" motor impairments, particularly in comparison with disabling CP, nonetheless they can have significant impact on the child. These difficulties may include important functional skills such as fine motor skills, speed and accuracy in motor planning, balance, and coordination. Children with DCD or probable DCD have been shown to be at increased risk for executive function and cognitive challenges, social–emotional and behavior problems, speech and language impairment, and other issues.[51,52]

Cognitive Assessment

A central component of a high-risk infant neurodevelopmental follow-up visit has been administration of a standardized developmental test. These tests are intended to provide a measure of "cognitive" function, although there are widely acknowledged limitations including the evolution of test versions making it difficult to compare across cohorts, preclusion of extrapolation of 2- to 3-year results to intelligent quotient (IQ) at later time points, and challenges to interpretation of results in the preterm population using standardized "cut points" alone and in the absence of a contemporaneous normal birthweight (NBW) term control group (see later section Limitations and Challenges to Interpreting Early Neurodevelopmental Outcomes Studies).

The Bayley Scales of Infant and Toddler Development (BSID), with a test age range of 1 to 42 months, is now the most widely used developmental test for high-risk infants across the United States and Europe. The original version, released in 1969, was revised in 1993.[53] The BSID-II had two developmental scores: the Mental Developmental Index (MDI), a composite of cognitive and language tasks, and the Psychomotor Developmental Index (PDI), a composite of fine and gross motor skills. This perceived drawback, as well as the usual drive to revise editions due to the "Flynn effect,"[54] contributed to the development of BSID-III,[55] which contains three main domains, (1) a cognitive composite score, (2) a language composite score (with receptive and expressive subscores), and (3) a motor composite score (with gross and fine motor subscores), in addition to social–emotional and adaptive behavior domains. The goal of the BSID-III was to allow identification of delays, as well as relative strengths and challenges, in specific developmental domains, and to target interventions to areas of need. However, in part because of a change in approach to norming the BSID-III, and also possibly because of separation of the cognitive and language scales, cognitive scores on the BSID-III are substantially higher than anticipated among both preterm high-risk children and term control groups.[56,57] These findings also led to concern that the BSID-III underestimates developmental delay if utilizing normative test means alone, which has serious implications for both clinical and research endeavors. Previously, commonly used "cut points" for categorization of "moderate" and "severe" developmental delay or disability were 2 to 3 standard deviations (SD) and greater than 3 SD below the normative mean, respectively; thus for BSID-II, MDI 55 to 70 was considered a moderate delay whereas an MDI less than 55 was considered a severe delay.[57] However, in the absence of contemporaneous term control groups, commonly used cut points shifted in the era of the BSID-III. Some have recommended that BSID-III cognitive and language scores less than 85 or "combined BSID-III" scores less than 80 provide the best definition of "moderate-to-severe" delay for equivalence with BSID-II MDI less than 70,[58] whereas others have modified the threshold for cognitive delay categorization to define moderate delay as 70 to 84, severe delay 55 to 69, and profound delay as less than 54.[16,59,60] The Bayley Scales of Infant and Toddler Development, Fourth Edition (Bayley-4) was published in 2019.[61] The Bayley-4 has more contemporary normative data; notably, this sample does not include the 10% of at-risk children that had been included in the BSID-III normative sample.

The Parent Report of Children's Abilities-Revised (PARCA-R) is a parent questionnaire assessing a child's cognitive and language development, but is limited to evaluation at 24 to 27 months of age or corrected for prematurity.[62] The PARCA-R is available for free (https://www2.le.ac.uk/partnership/parca-r), in multiple translations, and has concurrent validity with examiner-administered developmental tests, and excellent test-retest reliability.[63,64] Age- and sex-adjusted standard scores were developed using data from over 6,000 children, with a normative mean of 100 and SD of 15 and allow an assessment of development ranging from < −3SD to > +3 SD.[62] Norms and percentile ranks can therefore now be used to aid in identifying children with either advanced or delayed cognitive and/or language development. The PARCA-R has been used as an outcome measure in observational studies and clinical trials and has been recommended to screen children born preterm in NICE (United Kingdom) developmental follow-up guidelines.[28] Of note, this instrument has also been used widely in telehealth-based assessments.

There are numerous cognitive development tests available to provide full-scale IQ or equivalent that have been used for later childhood assessments, including the Wechsler Preschool and Primary Scale of Intelligence (age range: 2 years 6 months to 7 years 7 months), now in the fourth edition (WPPSI-IV),[65] the Differential Ability Scales (age range: 2 years 6 months to 17 years 11 months), now in the second edition (DAS-II),[66] and the Wechsler Intelligence Scale for Children (age range: 6 years 0 months to 16 years 11 months), now in the fifth edition (WISC-V).[67] The Wechsler Individual Achievement Test (age range: 4 years 0 months to 50 years 11 months), now in the fourth edition (WIAT-4),[68] identifies *academic* strengths and weaknesses, and has been used in clinical, research, and educational settings.

Hearing and Vision Outcomes

Severe neurosensory impairments, including profound hearing and vision impairment, among preterm infants are now low in incidence but have important long-term consequences. Rates of blindness and significant hearing impairment are inversely related to gestational age.[69] Both moderate-to-severe vision and hearing impairment are more common among high-risk infants and with neonatal morbidities including bronchopulmonary dysplasia (BPD), brain injury, and seizures.[70–72]

Early detection of hearing impairment is vital for optimizing speech and language development, and guidelines and recommendations reflect the importance of recognizing potential problems as early as possible. As stated in the AAP Joint Committee on Infant Hearing position statement,[73] infants admitted to the NICU for more than 5 days are to have auditory brainstem response included as part of their predischarge screening so that neural hearing loss will not be missed; for those who fail, referral should be made directly to an audiologist for rescreening and, when indicated, comprehensive evaluation for hearing loss. Reevaluation should occur, regardless of initial evaluation results, based on individual risk factors and readmissions. All infants, including well infants, should have a hearing screening by 1 month of age, with rescreening and referral for audiology evaluation by 3 months of age for those who do not pass the initial screen. In addition, a validated global screening tool is administered to all infants at 9, 18, and 24 to 30 months or sooner when there is concern about hearing or language.

Prematurely born children have an increased risk of various ophthalmic and visual dysfunctions and abnormalities, in particular those children with a history of severe or treatment-requiring retinopathy of prematurity (ROP) and those with severe brain injury. These functional visual challenges include strabismus, problems with acuity, convergence and visual fields, and retinal morphology.[74] It is important to recognize that a short-term outcome of severe ROP in the NICU may not result in the most severe functional vision outcomes in early childhood.[12,17] Even children born preterm without a history of ROP or with only mild ROP also have an increased risk of problems. Among EPT children in the population-based Extremely Preterm Infants in Sweden Study (EXPRESS) at 6.5 years of age, 55% had poor visual-motor integration (VMI) performance.[75] Compared with term-born controls, VMI scores of EPT-born children were lower, and were associated with challenges in everyday school activities. In addition, VMI was most impaired in the children with the lowest. Recommendations from the AAP and the American Association of Pediatric Ophthalmology outlines a detailed construct for the termination of acute retinal examinations based on age and retinal ophthalmoscopic findings; therefore, if hospital discharge is considered before appropriate retinal development, follow-up must be arranged with an ophthalmologist trained in ROP care prior to discharge.[76] Furthermore, regardless of whether infants have required treatment for ROP, ophthalmologic follow-up is indicated within 4 to 6 months after discharge because they are at increased risk for other seemingly unrelated visual disorders, such as strabismus, amblyopia, high refractive errors, cataracts, and glaucoma.[76]

For early neurodevelopmental outcomes studies among preterm infants at 18 to 30 months' corrected age, criteria for "profound" or "severe" disability in the hearing domain have generally included some definition of "no useful hearing" even with aids or "some hearing but loss not corrected by aids," whether accompanied by specific decibel hearing loss (dBHL) audiologic evaluation cut points (profound >90 dBHL; severe 70 to 90 dBHL) or by examination and observation of bilateral hearing loss not correctable by amplification. Similarly, "severe" disability in the visual domain has generally been defined as functional bilateral blindness, including examination consistent with presumed visual acuity less than 20/200, or inability to perceive light, or only able to perceive light or reflecting objects. Definitions of "moderate" hearing and vision impairment differ among studies.

Neurodevelopmental Impairment—Difficulties and Realities of a Composite Outcome

Neurodevelopmental impairment is a composite outcome, combining criteria and cut points from several domains as presented above, including neuromotor, cognitive, hearing, and vision. The relative prevalence of each of these outcomes is not consistent, and rates of each outcome may respond differently to an experimental therapy. This necessarily leads to a number of difficulties in overall interpretation, as well as challenges in generalizability and counseling. Use of composite outcomes during counseling in the prenatal or postnatal setting may not be meaningful to parents and families. The value of each of the components may vary broadly for each individual family, outcomes may be conceived differently, and statistics are probably difficult to grasp.[77,78]

In addition, significant center variation in 18- to 22-month neurodevelopmental outcomes has been demonstrated even after adjustment for demographic variables, prenatal interventions, and neonatal clinical factors, thus presenting challenges to accurate counseling from multicenter datasets.[69,79] Unfortunately, robust data from a single center on outcomes of specific high-risk groups are generally unavailable. Furthermore, the largest contributing

component to the composite outcome is that of "cognitive" delay or impairment. As explored previously and discussed in more detail later in the section School-Age Outcomes After Prematurity, developmental tests at 18 to 30 months are intended to assess cognitive abilities. However, in children born at extremely low birth weight (ELBW) and EPT, scores on these early administered tests predict cognitive scores at school age poorly.[15,80–83]

Death or NDI at 2 to 3 years is a primary or main secondary outcome in many clinical trials and prospective studies in neonatal medicine, particularly for EPT infants.[27] This combination is understandable because death and NDI are competing outcomes; it is assumed in this context that adverse outcomes (death and NDI) will not be influenced in opposite directions by an intervention and ideally that components of the combined outcome will carry similar value; these tenets may not always be true. Because the incidence of the composite outcome is greater than any individual component, death or NDI may also be a logical statistical choice for powering a trial; however, it may not be the most biologically plausible target. Moreover, although neurodevelopmental outcome at 2 to 3 years is critically important for any prospective observational study or clinical trial of high-risk infants, it may not be the most appropriate primary outcome for every trial depending on the intervention under evaluation.

Limitations and Challenges to Interpreting Early Neurodevelopmental Outcomes Studies

As described previously, early childhood follow-up visits for high-risk infants at 18 months to 3 years typically assess outcomes in multiple domains. Although these evaluations are important and informative, interpretation and comparison of studies are difficult. Many studies report outcomes by categories and frequently include *any* adverse finding to yield an "impaired" or "unimpaired" status. The definitions of "adverse" outcomes may not be consistent across studies; indeed, the definitions of the individual components of "impairment" such as CP, blindness, deafness, and developmental delay often differ across studies. A literature review highlighted the impact of varying definitions of NDI, applying definitions from several international neonatal follow-up networks to infants 23 to 28 weeks' GA in the Canadian Neonatal Network from 2009 to 2011 with follow-up at 18 to 22 months' corrected age.[84] A fourfold difference in severe NDI incidence was noted, ranging from 3.5% to 14.9%. In addition, differences in risk factors associated with severe NDI were found depending on the definition applied. Furthermore, not all prospective studies have enrolled contemporaneous term, NBW controls. Comparing test scores from a VPT or EPT study group with standardized norms instead of scores from a peer, term-born control group has been demonstrated to substantively limit the relevance and veracity of the findings and may have important public policy and resource implications.[85–88]

Very early childhood developmental and neurologic outcomes evaluations should only be considered as a first step to comprehensive follow-up; assessments into school age, adolescence, and adulthood are critically important to understand the lifetime trajectory and functional and societal outcomes of former high-risk infants.[89–91] Concerns regarding changes in cognitive abilities over time, and an increasing recognition that physical and environmental effects as well as early intervention approaches may modify recovery, underscore the need for later assessments. Some neurocognitive, executive function, and behavioral challenges may only be detected at school age; even recognizing that such learning and attention problems may occur in preterm infants is a critical step to ensuring adequate support and services for families and teachers to help children achieve their best possible outcomes. Evaluation of neuromotor outcomes throughout childhood is also critical. Although most toddler-age and very early childhood outcome studies focus narrowly on the diagnosis of CP, later neuromotor and coordination problems, such as DCD, are prevalent among school-age children born EPT compared with term and can be associated with other functional challenges and academic difficulties. Furthermore, parental perceptions of DCD are not reliable, yet interventions may be able to remediate the functional limitations of DCD, reinforcing the importance of ongoing clinical assessments throughout childhood.[92]

Similarly, there are substantial concerns regarding the ability of developmental or cognitive tests at toddler age, particularly the BSID, to detect developmental delay when using standardized test norms. In a group of EPT and ELBW infants at 2 years' corrected age, Anderson et al.[56] found mean BSID-III cognitive scores of 96.9 and motor scores of 100.4 but also substantially higher than expected scores among a term-born control group. If normative BSID-III cut-point criteria alone were applied to the scores of this cohort, it would severely underestimate moderate-to-severe cognitive and motor delay relative to the control group. Vohr et al.[57] compared mean BSID-II versus BSID-III scores at 18 to 22 months' corrected age for prematurity among infants less than 27 weeks' EGA born in National Institute of Child Health and Human Development (NICHD) Neonatal Research Network (NRN) hospitals over two adjacent periods and found mean cognitive composite scores on the BSID-III to be 11 points higher than mean BSID-II MDI scores. Even after adjusting for differences between groups, BSID-III was a significant factor in a perceived decrease in neurodevelopmental impairment in the more recent time period. Dilemmas also exist with regard to meaningful utilization of BSID-III motor composite and fine motor scaled score normative data and cut points in the context of other gross motor assessments at 18 to 24 months corrected age and the value of these early evaluations to predict later outcomes and intervene appropriately.[93] In a prospective, longitudinal EPT cohort from the Victoria Infant Collaborative Study Group (VICS Group), the BSID-III motor scale normative cut points for impairment at 2 years seriously underestimated rates of motor impairment at 4 years.[94] In addition, although the BSID-III cognitive and language scales at 2 years were associated with cognitive functioning at 4 years as assessed by DAS-II, developmental delay at 2 years as determined by BSID-III reference data and normative cut points had low sensitivity in predicting future cognitive, verbal, and nonverbal reasoning impairments at 4 years on the DAS-II.[82] All of these findings have important implications for resource availability and public policy. In countries, states, or regions without specific policies advocating for ongoing, longitudinal assessments and services for children born EPT, the 2-year or 3-year evaluation may be the final opportunity to identify challenges before transitioning to the school system. If ongoing needs are determined only by scoring below a normative cut point on the BSID-III, many children at significant risk for future impairments could be left behind.

Despite these many challenges and provisos, a substantial body of literature exists on early neurologic and cognitive outcomes. An understanding of the range of initial neurodevelopmental outcomes, and the factors associated with adverse outcomes, is crucial for both the family and medical care team. In later sections of this chapter, we review early neurodevelopmental outcomes of recent

high-risk cohorts, including those born EPT and selected groups of high-risk late preterm and term infants.

Focus on Functional and Adaptive Outcomes

The WHO has defined "disability" as an umbrella term, covering impairments, activity limitations, and participation restrictions. An impairment is a problem in body function or structure; an activity limitation is a difficulty encountered by an individual in executing a task or action; and a participation restriction is a problem experienced by an individual in involvement in life situations. According to the World Report on Disabilities,[95] approximately 95 million infants, children, and youths 0 to 14 years of age worldwide (5%) live with a disability, of whom 13 million (0.7%) are considered to have severe disabilities. Nearly 800 million (~16%) individuals more than 15 years old live with a disability. The WHO International Classification of Functioning, Disability, and Health (ICF) provides standard language and a framework for the description of health and health-related states that are focused on functioning rather than diagnosis alone.[96] It is a classification of health and health-related domains that describes what a person with a health condition can do in a standard environment, as well as how he or she can perform in his or her usual environment. These domains are classified from body, individual, and societal perspectives organized in two parts, each comprising two components. Part 1—Functioning and Disability—includes Body Functions and Structures and Activities and Participation; Part 2—Contextual Factors—incorporates Environmental Factors and Personal Factors. The ICF is meant to be universally applicable and useful in a range of different sectors, including individual assessments, public policy, and research. The focus of the ICF is on health and functioning, rather than on disability. In most studies and approaches, particularly in early childhood and even through school age, impairments are identified through tests or examinations, and an individual is classified with regard to that finding alone. In contrast, the ICF approach is to measure functioning in society, regardless of underlying impairments. This allows for a broader view than a traditional classification of health and disability. The ICF shifts the focus from diagnosis or label to impact on function, which may be affected by environment, intervention, and other factors.

In 2011, the WHO approved a "derived" classification, the International Classification of Functioning, Disability and Health for Children and Youth, which conforms to the common classifications of the ICF, with a goal of creating a comprehensive, lifespan approach to describing health and functioning. However, attempts to apply these functional outcome classification approaches to very early childhood follow-up studies of high-risk infants have been limited, with some notable exceptions, including Msall and colleagues, who have championed the framework of function, even at early preschool age, as a highly relevant and measurable outcome.[25] Among the several instruments available, the Vineland Adaptive Behavior Scale (VABS) is an interview survey for assessing adaptive behavior (Sparrow et al., 2005).[97] In children less than 6 years old, the domains include communication (receptive, expressive language), daily living skills (self-care/personal), socialization (interpersonal relations and play), and motor skills (gross and fine). There is a classroom edition for children 3 years 0 months to 12 years 11 months. The Pediatric Evaluation of Disability Inventory (PEDI) assesses self-care, mobility, and social functional activities in children 6 months to 7 years[98] and has been used extensively in children with severe perceived or known disabilities including those with CP and other physical impairments. The Warner Initial Developmental Evaluation of Adaptive and Functional Skills (WIDEA-FS) is a measure of multidomain development, including adaptive and functional skills.[25] The WIDEA-FS is a 50-item parent questionnaire designed to assess the adaptive skills of a child in several domains, including mobility, communication, social cognition, and self-care. The WIDEA-FS takes 10 to 15 minutes to administer, can be conducted by phone, and is available in English and Spanish. WIDEA-FS scores were significantly associated with Bayley-III scores in all domains. Studies have demonstrated concurrent validity between the WIDEA-FS and BSID-III[99] as well as with the Capute Scales.[100] Lower scores on the WIDEA-FS were significantly associated with an increased risk of adverse developmental performance on all BSID-III scales, and cut points for WIDEA-FS scores with at least 90% sensitivity have been published.[99] The WIDEA-FS has been used in studies where in-person evaluations are not feasible, including in an international follow-up study of outcomes after Zika exposure.[101]

Outcomes of Preterm Infants Across the Life Spectrum

Early Neurodevelopmental Outcomes of Extremely Preterm Infants

Early neurodevelopmental outcomes of several large cohorts of EPT infants around the world have been reported. These are summarized in Table 24.1 and presented in detail later.

The Victoria Infant Collaborative Study Group

The VICS Group has reported on a series of birth cohorts of EPT neonates born in the state of Victoria (Australia) from 1991 to 1992, in 1997 and 2005, and most recently from April 1, 2016, to March 31, 2017.[86,102,103] Neonates born alive at 22 to 27 completed gestational weeks and surviving to follow-up received neurodevelopmental assessment at 2 years of corrected age (1991–1992, $n = 219$, 97% of survivors; 1997, $n = 149$, 99% of survivors; 2005, $n = 163$, 95% of survivors; 2016–2017, $n = 174$, 81% of survivors).[103] Importantly, contemporaneous term controls were also enrolled and evaluated for each cohort. Children were evaluated for blindness, deafness (hearing loss requiring amplification or worse), and developmental delay. To account for the different versions of the Bayley Scales used, developmental delay was classified relative to the MDI or combined cognitive and language composite scores for the contemporaneous term controls, rather than the normative test scores and cut points alone. Developmental delay was defined as less than −1 SD relative to the mean of the controls and categorized as mild (−2 SDs to < −1 SD), moderate (−3 SDs to < −2 SDs), or severe (< −3 SDs). Neurologic examination for CP was also performed, utilizing the GMFCS, describing "severe" CP as unlikely ever to walk and "moderate" CP as unable to walk at 2 years but likely to walk. Overall disability was considered "severe" for children with severe CP, blindness, or severe developmental delay; "moderate" with moderate CP, deafness, or moderate developmental delay; and "mild" with mild CP or mild developmental delay. "Major" disability comprised either the moderate or severe category.

Neurodevelopmental outcomes of the 2016–2017 VICS cohort at 2 years' corrected age[103] are shown in Table 24.1. The birth cohorts, rates of any disability, and moderate-severe

TABLE 24.1 **Early Neurodevelopmental Outcomes: Selected Extremely Preterm Cohorts**

*For VICS: developmental delay was classified relative to contemporaneous term control group; for EPICure 2: Predicted MDI (Mental Developmental Index) BSID ed 2 from Bayley-III; for EXPRESS: aggregated Bayley-III cognitive and language score information, with mean and SD relative to a contemporaneous 37- to 41-week GA control group; for Japan NRN: formal evaluation by the Kyoto Scale of Psychological Development (KSPD) was available for 472.
†Multiple imputation from perinatal, neonatal, and sociodemographic information estimated outcomes for the entire cohort.
‡Defined as blindness or no functional vision in one or both eyes.

disability at 2 years were not significantly different across eras. However, survival with no major disability increased over time from 42% in the 1991–1992 cohort to 62% in the 2016–2017 cohort (odds ratio [OR] 1.3 per decade, 95% confidence interval [CI] 1.15 to 1.48, p<0.001). Of note, for the 1991–1992, 1997, and 2005 cohorts, rates of any CP were 11%, 12%, and 10% respectively, whereas for the 2016–2017 cohort the rate of any CP had decreased to 6%. Moderate or severe developmental delay were similar overall across cohorts, with a decrease noted between 1997 and 2005 but an increase in 2016. In terms of 2-year outcomes by gestational ages, mortality and survival with no major disability appeared stable across birth cohorts for those born at 22 and 23 weeks. Mortality improved consistently for those born at 24 weeks from 1991–1992 to 2016–2017. A trend toward improving rates of survival with no major disability was observed across cohorts particularly for those in the more advanced gestational age week groups, with approximately 80% of those born at 26 weeks and 27 weeks in the 2016–2017 cohort having survived with no major disability at 2 years' corrected age. Although the follow-up rate was lower for the most recent birth cohort compared with previous cohorts, multiple imputation and sensitivity analysis was performed, which resulted in the same results and conclusions.

EPICure 2

The EPICure 2 Study is a population-based mortality, morbidity, and neurodevelopmental outcomes study.[104] All neonates born at 22 to 26 $\frac{6}{7}$ weeks' gestation in the United Kingdom during 2006 were identified and data about death and morbidities were collected from the delivery room through hospitalization.[105] Comparisons between EPICure 1[106] (1995 birth cohort) and EPICure 2, both on short-term and neurodevelopmental outcomes, were limited to those 22 to 25 $\frac{6}{7}$ weeks' gestation and born in England. For EPICure 2, follow-up was hampered by changes in national research governance procedures in the United Kingdom and increased privacy restrictions by the National Health Service. Therefore, tracking success was substantially limited in comparison with the previous study, and multiple imputation was therefore used to estimate outcomes of patients lost to follow-up. Follow-up assessments in EPICure 2 were with the BSID-III at a target age of 36 months, and at a target age of 30 months with the BSID-II in EPICure 1. In order to directly compare results from the two cohorts, combined BSID-III scores were converted to "predicted MDI."[107] "Severe impairment" was defined as nonambulant CP (GMFCS III to V), blindness, profound hearing loss, or developmental quotient less than 3 SD below the mean for age. "Moderate impairment" was defined as ambulant CP (GMFCS 2), functionally impaired vision, hearing loss improved by aids, or developmental score of 2 and 3 SD below the mean.

Of the 1031 children in EPICure 2 who survived to follow-up (1041 survivors to discharge, 10 died after discharge), study examiners evaluated 576 (55.3%, median 34 months), and information from an additional 191 were available from local records (18.3%, median 25 months) (see Table 24.1). The groups seen in person and not seen in person had similar baseline perinatal and neonatal characteristics, but socioeconomic factors differed; children from families with greater social disadvantage were less likely to have a formal study evaluation.

Among the EPICure 2 group with formal study evaluations, 75% were free from impairment or had mild impairment. Survival without disability for the entire EPICure 2 cohort, including imputed outcomes, among those admitted to the NICU demonstrated increases with each week in gestational age: 22 weeks, 5% (95% CI, 0% to 26%); 23 weeks, 15% (95% CI, 10% to 21%); 24 weeks, 30% (95% CI, 25% to 35%); 25 weeks, 49% (95% CI, 43% to 55%); 26 weeks, 62% (95% CI, 57% to 67%). In addition, 66% had no hearing, vision, or communication disability, but only 36% of children were reported to have no developmental disability (BSID-II scores >85). However, robust comparisons are difficult, given that patient numbers were quite small, particularly for the less than 23 weeks' EGA group. This finding underscores the grave prognosis for survival among the most premature infants in this cohort; only 18% of less than 23 weeks' EGA neonates admitted alive to an NICU survived to discharge, compared with 48% of 25 weeks' EGA neonates.

Extremely Preterm Infants in Sweden Study

The Extremely Preterm Infants in Sweden Study (EXPRESS) cohort (birth year 2004–2007, <27 weeks' gestation) was followed to a median of 30.5 months, at which point BSID-III, neurologic examinations, and parental questionnaires were administered.[108] Of the 707 liveborn infants, 491 survived to follow-up (69%), 415 of 461 who were eligible for inclusion were assessed (90% follow-up rate), and 399 of these completed at least part of the BSID-III. Chart review was available for 41 additional children. The group was skewed to higher gestational age, with only 52 (11%) of the cohort born at 22 or 23 weeks' gestation. Of importance, a control group (37 to 41 weeks' gestation, matched 2:1 with the preterm group) was recruited by random selection from the Swedish Medical Birth Registry. Severe disability was defined as BSID-III composite cognitive, language, or motor score greater than 3 SD below the mean relative to the control group, severe CP, or bilateral blindness or deafness. Moderate disability was defined as scores between 2 and 3 SD from the mean of any of the BSID-III scales, moderate CP, and moderate visual or hearing impairment. Mild disability was defined as scores between 1 and 2 SD from the mean of any of the BSID-III scales or mild CP.

As summarized in Table 24.1, of those children born EPT, 11.3% had moderate or severe cognitive disability by BSID-III, compared with 0.5% of controls. When considering cognitive, language, or motor scores, 15% of EPT and 3% of control had moderate disability, and 8.9% of EPT and 0.3% of controls had severe disability. The proportion of children with mild or no disabilities increased from 40% at 22 weeks to 83% at 26 weeks. There was a significant decrease in severe disabilities with each increase in gestational week, with an OR of 0.58 (99% CI, 0.39 to 0.86), $P < .001$. Overall, 42% of the EPT children in this group had no disability at 30 months, compared with 78% of control children. The majority of the 58% disabled EPT children had mild disability (31%). In further analyses, Serenius et al.[109] explored whether intensity of perinatal care in regions across Sweden was associated with an increased risk of death or NDI at 2.5 years. The investigators found significant variation in obstetric and neonatal intervention practices. In regions with more aggressive perinatal intervention practices, the risk of death or NDI at 2.5 years was reduced, but only for the 22 to 24 weeks group. Furthermore, there was no increase in NDI among survivors associated with more aggressive perinatal practices.

Another national Swedish birth cohort, EXPRESS 2, included all births in Sweden at 22 to 26 weeks' gestational age during a three-year period between January 1, 2014, and December 31, 2016.[110]

Japan Neonatal Research Network

The NRN of Japan reported outcomes of neonates born alive at 22 to 24 $^{6}/_{7}$ weeks' gestation during two periods (period 1, 2003–2007 and period 2, 2008–2012) from 52 tertiary centers with at least 10 infants of that gestational age range inborn during each period.[111] Neurodevelopmental assessments were performed at 36 to 42 months' chronologic age by a trained pediatrician and consisted of a neurologic examination, functional assessment for vision and hearing, and cognitive evaluation by the Kyoto Scale of Psychological Development (KSPD). A developmental quotient (DQ) was derived, with a mean SD score of 100.6 ± 13.4. NDI for this study was defined as any CP with GMFCS II to V, hearing impairment (amplification was required), visual impairment (blindness with no functional vision in at least one eye or bilateral amblyopia), or KSPD DQ score of less than 70. Of note, this group has previously published that KSPD DQ <70 is equivalent to BSID-III cognitive score < 85.[112]

Highlights of outcomes are shown in Table 24.1. Active treatment, defined as receiving any of tracheal intubation, ventilator support including continuous positive airway pressure, surfactant therapy, or parental nutrition at delivery or in the NICU period, was reported for 98.6% of infants in period 1 and 98% of infants in period 2. Infant survival to 3 years increased from 66.5% in period 1 to 74.6% in period 2. At 3 years, of 983 survivors in period 1 and 1372 survivors in period 2, 631 (64.1% of survivors) and 832 (60.7% of survivors) had some neurodevelopmental outcome data. Among infants with actual evaluations, CP with GMFCS ≥II (15.9% vs. 9.5%, p<0.01), visual impairment (13.6% vs. 4.4%, p<0.01), and hearing impairment (2.6% vs. 1%, p<0.05) decreased significantly from period 1 to period 2. The proportion of DQ of KSPD <70 increased from 32.8% to 37.3% although this was not significant. No significant changes were noted in NDI between period 1 and 2 among infants with full evaluations (39.4% vs. 39.1%) or in those with incomplete evaluations (45.7% vs. 38.1%). Multiple imputation was also used to account for missing data with the assumption that data were missing at random, modelled to adjust for potential confounding demographic and perinatal factors between periods. Results after multiple imputation indicated that death or NDI decreased between periods 1 and 2 from 53.7% to 46.9% (aOR 0.83, 95% CI 0.71 to 0.97), but both KSPD DQ <70 (26.7% vs. 27.8%) and NDI (30.3% vs. 28.8%) were not significantly different.

Eunice Kennedy Shriver NICHD Neonatal Research Network Follow-Up Study Group

The NICHD NRN was initiated in 1986 as a multicenter effort in the United States with the main objective of providing a registry of uniformly collected baseline and morbidity and mortality data information to provide the basis for planning and implementing clinical trials. The NICHD NRN Follow-Up Study Group was later added to provide neurodevelopmental follow-up for trials and for those meeting NRN Follow-Up Study criteria, which now includes infants less than 27 weeks' gestation. Highlights of selected works noted below are summarized in Table 24.1.

The NICHD NRN reported on the spectrum of neurodevelopmental outcomes of neonates born < 27 weeks' GA at 18 to 26 months' corrected age with follow-up assessments completed April 2011 to January 2015.[46] The follow-up visit included the BSID-III, as well as standardized neurosensory and motor examinations. Predefined criteria were utilized for neurologic outcomes including normal, suspect (isolated abnormal neurologic findings without functional impairment), abnormal but without CP (neurologic findings and functional impairment), and CP. Severity of CP was defined as mild with GMFCS level I, moderate with GMFCS level II or III, and severe with GMFCS level IV or V. For the primary analyses, NDI was defined by presence of 1 or more of moderate to severe motor impairment (CP or non-CP) with a GMFCS level ≥II, a BSID III cognitive score of <70, severe visual impairment (absence of functional vision in both eyes), or bilateral severe hearing loss (permanent, not allowing for ability to understand spoken words with or without amplification). Analyses defining moderate-severe NDI were also performed using a BSID III cognitive score cutoff of <85. The results of this analysis were important, as they demonstrated the range of neurologic outcomes among extremely preterm infants, with 59% with normal neurologic exams, 19% suspect, 9.8% abnormal but non-CP, and 11.7% with CP. Overall, CP was mild in 41%, moderate in 40%, and severe in 18%; the diagnosis of CP decreased from 2011 (16%) to 2014 (9%), and among those with CP the proportion with severe CP decreased (26% to 16%). For the entire cohort, the rate of NDI with BSID-III cognitive cutoff <70 was 19% (28% among 22 to 24 weeks' GA, 14% among 35 to 36 weeks GA). The rate of NDI with cutoff <85 was 32%. The rate of NDI by either definition did not decrease significantly over the years encompassed in this analysis.

The NICHD NRN also reported on the neurodevelopmental outcomes at 18 to 22 months' corrected age among children born at 22 $^{0}/_{7}$ to 24 $^{6}/_{7}$ weeks across three birth epochs (2000–2003, 2004–2007, 2008–2011).[113] As these epochs spanned BSID editions, moderate-severe NDI was defined as any of BSID-II MDI <70 or BSID-III cognitive composite score <85, GMFCS level II or greater, profound hearing loss bilaterally, or profound visual impairment. A significant decline in mortality across epochs for this population was accompanied by an increase in both the rates of survival without and with NDI. Among survivors to follow-up in epochs 1, 2, and 3, rates of NDI (49%, 46%, 43%) and moderate-severe CP (15%, 11%, 11%) were not found to have decreased significantly. However, profound visual impairment (2%, 2%, <1%) decreased significantly across epochs (p = 0.04).

As with *p*revious analyses from the NICHD NRN,[79] center differences in outcomes were observed in these studies, suggesting that variability beyond what can be explained by perinatal and neonatal risk factors plays an important role in outcomes. Between-hospital variation in survival and NDI at 18 to 22 months was also explored by Rysavy et al.[114] among infants inborn at an NRN site before 27 weeks between 2006 and 2011. Outcomes were evaluated in relation to hospital rates of "active treatment," defined as potentially lifesaving treatments initiated after delivery. For all infants, overall mean rates of survival without severe impairment were 3.4%, 17.9%, 44.7%, 61.1%, and 75.6% for 22, 23, 24, 25, and 26 weeks' gestation, respectively. However, there were significant differences among hospital rates of active treatment for those born at 22 to 24 weeks, which accounted for a substantial proportion of variation in outcomes. In an update to and validation of the NICHD Extremely Preterm Outcomes Tool (https://www.nichd.nih.gov/research/supported/EPBO), Rysavy and colleagues demonstrated that among actively treated infants born <26 weeks' GA, rates of moderate-severe NDI at 18 to 26 months' corrected age were 21% among those with an estimated survival probability greater than 80%, and 78% among those with an estimated survival probability of 11% to 20%.[60] No actively treated infants with a probability of survival ≤10% survived to follow-up.

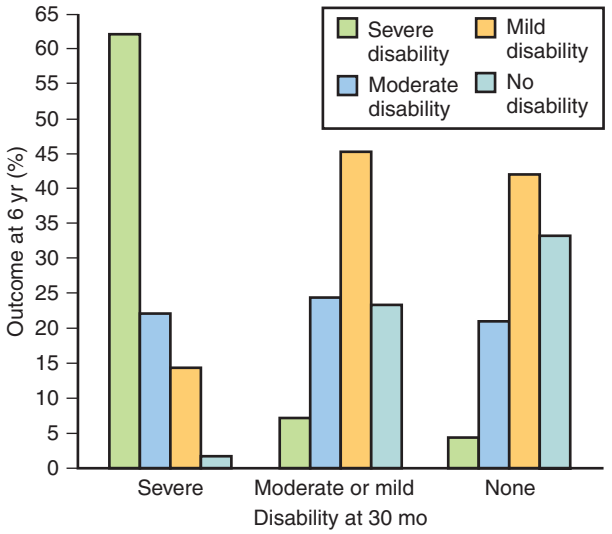
Canadian Neonatal Follow-Up Network (CNFUN)

The Canadian Neonatal Follow-Up Network (CNFUN) is a collaboration between Neonatal and Perinatal Follow-Up Programs in Canada and their multidisciplinary team members, developed in coordination with the Canadian Neonatal Network (CNN) and the Canadian Institutes of Health Research (CIHR) Team in the Maternal-Infant Care (MiCare) study. The CNFUN developed a national standardized assessment and data collection database for infants at 18 to 21 months' GA, with the ability to link data to the CNN database to advance research and knowledge translation to improve care and outcomes.

The CNFUN reported on neurodevelopmental impairment (NDI) and significant NDI (sNDI) and their determinants at 18 to 21 months' corrected age among infants born between 2009 and 2011 at <29 weeks' gestational age, admitted to one of 28 CNN NICUs.[69] Infants were excluded if they were moribund on admission or had life-threatening congenital anomalies. The NDI definition included any of CP with GMFCS I or higher; BSID-III motor, language, or cognitive composite < 85; any sensorineural or mixed hearing loss; or unilateral or bilateral visual impairment. Significant NDI included any of CP with GMFCS III or higher; BSID-III motor, language, or cognitive composite <70; need for hearing aid or cochlear implant; or bilateral visual impairment. Of 3700 eligible infants admitted to NICUs, 592 died prior to discharge, 276 were not linked to CNFUN, and there were 22 post-discharge deaths; 2340/2810 survivors (83.3%) had assessment at 18 to 21 months' corrected age. Among those, 16.5% were categorized with sNDI and 46.0% with NDI. Rates of NDI and sNDI were inversely correlated to GA, with sNDI was present in 37.1% of those both ≤23 weeks' GA but only 8.4% of those 28 weeks' GA, and NDI present in 62.7% of those both ≤23 weeks' GA and 36.2% of those 28 weeks' GA. For the entire cohort, a diagnosis of CP of any severity was made in 6.4%, ranging from 4.8% for those 28 weeks' GA, to 13.1% for those ≤23 weeks' GA. Factors independently associated with sNDI included lower GA, sex, higher SNAP score, ROP, brain injury, and infection. As in other multicenter studies, substantial center variation was also noted in NDI, sNDI, death or sNDI, and the components of NDI.

School-Age Outcomes After Prematurity

School-age survivors of prematurity have high rates of neurodevelopmental impairment, with CP rates 9% to 10% and cognitive disability rates of 4% to 36%, depending on the population evaluated, outcome definitions, and age at assessment.[115] Rates of major neurosensory disability and average IQ at school age among former extremely preterm infants have not improved significantly since the 1990s.[116] Infants who have *severe* cognitive, motor, or neurosensory impairments in early years (2 to 3 years of life) often have moderate or severe impairments at school age.[85,117,118] In the EPICure cohort of infants born ≤25 weeks' gestational age, 86% of children with severe disability at 30 months continued to have moderate or severe disability at 6 years (Fig. 24.1).[85] In the more recent Extremely Low Gestational Age Newborn (ELGAN) cohort of infants born <28 weeks of gestation, 64% of children classified as profoundly impaired at 2 years had moderate, severe, or profound disability at 10 years.[118] Most commonly, though, school-age survivors of ELBW or very preterm birth have more mild impairments that are difficult to identify or predict at earlier ages. These impairments include mild cognitive impairment (IQ 1 to 2 SDs below the mean, or 70 to 84); learning, emotional, behavior, motor coordination, and executive function disorders; and poor academic achievement.



• **Fig. 24.1** Severity of disability at 6 years, based on classification at 30 months corrected age. Data are based on 236 children who were born at 25 or fewer completed weeks of gestation in the United Kingdom and Ireland in 1995. (From Marlow N, Wolke D, Bracewell MA, Samara M, EPICure Study Group. Neurologic and developmental disability at six years of age after extremely preterm birth. *N Engl J Med*. 2005;352:9–19.)

Cognitive delay is the most common impairment in children who were born very preterm. In a 2018 systematic review of 71 studies that included 7752 preterm infants and 5155 controls at 5 to 20 years of age, preterm born children had 0.86 SD lower intelligence quotient (IQ) than controls.[119] The most immature infants have the highest risk for poor cognitive outcome.[85,120] For example, at 6 years 49% of boys and 32% of girls in the EPICure cohort (≤25 weeks' gestation at birth) had cognitive impairment.[85] Yet, even moderate and late preterm infants have an increased risk for poor cognitive functioning compared to full-term peers at school age.[121] Biologic factors such as sex, birth weight, and race are predictive of early cognitive outcomes.[122] As children enter school age, parental education is more predictive of cognitive outcome than biologic or perinatal factors. Furthermore, children with social advantage (two-parent household, educated parents, employed parents) demonstrate more cognitive gains through early childhood than those without social advantage.[123]

Similarly, in 14 studies of school-age academic achievement, very low birth weight or very preterm infants have scores on math, reading, and spelling tests that are one-half to three-quarters of an SD below term peers.[124] Performance on academic assessments is also closely correlated with both birth weight and gestational age.[120,124,125] Thus, the most immature infants born at or before 25 weeks of gestation have eight times higher odds of serious impairment in academic achievement than matched term controls.[85]

Measures of executive function (verbal fluency, working memory, and cognitive flexibility) also demonstrate decreases of about a half SD between very preterm or very-low-birth-weight infants and term controls.[120,124,126] Unlike cognitive performance, executive functions may not be influenced by socioeconomic status and dysfunctions in some domains such as working memory and

organization may be increasing among the children born most recently.[126]

At school age, children who were born preterm are more frequently reported by both their parents and their teachers to have behavior problems. Very preterm and even late preterm infants are more likely to have internalizing or externalizing symptoms on the Child Behavior Checklist than term counterparts.[125,127,128] Internalizing symptoms manifest as shyness, social maladaptation, anxiety, and withdrawn behavior.[129,130] It is critical to note that behavioral problems commonly co-occur in children with cognitive disabilities. In the French regional EPIPAGE cohort of children born <33 weeks, there was a direct correlation between cognitive performance and behavioral problems.[128] Children with IQ more than 2 SDs below the mean had 2.6 times higher odds of behavior problems than those with IQ less than 1 SD below the mean. However, cognitive disabilities did not entirely explain the higher rates of behavior problems in preterm-born children, because preterms remained at higher risk even after adjustment for cognitive performance. Behavioral problems in this cohort were more common in boys and in children with more complex medical histories, socioeconomic risk factors, and poor maternal well-being.

Neurobehavioral or psychiatric problems including autism spectrum disorders (ASDs) and attention deficit-hyperactivity disorder (ADHD) are reported with higher frequency in school-aged former preterm children than in the general population.[125] In the Extremely Low Gestational Age Newborn (ELGAN) study of infants born before 28 weeks, 7% were diagnosed with ASD at school age.[131] Boys were twice as likely as girls to have ASD in this cohort. Moderate and late preterm infants may also be more likely to have ASD: one study reported that these children have 1.55 higher odds of being diagnosed with autism by 10 years than full-term-born children.[132] In preterm-born children, risk of ASD seems to be particularly increased among those who were small for gestational age, those with congenital malformations, low 5-minute Apgar scores, intracranial bleeding, cerebral edema, or seizures in the neonatal period, and those born to mothers with preeclampsia.[132]

In a systematic review, preterm-born children had a relative risk for being diagnosed with ADHD of 2.64 (95% CI 1.85 to 3.78) when compared to term-born children.[125] In a large Swedish cohort, odds of ADHD at school age decreased with increasing gestational age until term-corrected age.[133] Odds of ADHD were 2.1 among the most immature (23 to 28 weeks' gestation) infants and 1.1 among early term (37 to 38 weeks' gestation) infants. In the most preterm children, risk of ADHD does not seem to be significantly impacted by socioeconomic factors. However, sociodemographic risk—particularly low maternal education—may increase risk for ADHD in moderately preterm children born to women with lower education.[133] Across the entire gestational age spectrum, school-age boys are about four times more likely to be diagnosed with ADHD than girls. Children with multiple psychiatric disorders, such as ADHD and ASD, have significantly higher likelihood of repeating a grade, requiring an aide in school, or being placed in a special classroom setting and have lower quality of life.[134]

Because adverse developmental and neurobehavioral outcomes are considerably more common among preterm infants, it is essential for the pediatrician caring for former preterm school-age children to have a high index of suspicion for these problems. Many developmental and behavioral problems are more common among preterm-born male children than female children. Further, while risk is highest in the most extremely preterm infants, moderately preterm and late preterm infants are also at higher risk for adverse outcome at school age than term-born counterparts. School-age problems in the older preterm infant include fine and gross motor coordination problems, academic difficulties, attention problems, and need for special support in school.[135] As moderate and late preterm infants far outnumber very preterm infants, it is critical to be aware of the likelihood of such outcomes and address any concerns or potential problems expeditiously. Early access to services is essential for optimizing outcomes in these children. Cognitive and neurobehavioral problems in all high-risk children significantly increase special education costs and resource utilization at school age and strongly influence outcomes later in life.

Adolescent and Adult Outcomes After Prematurity

The advent of assisted ventilation, surfactant, and antenatal corticosteroids in the late 20th century led to the first substantive generations of extremely low birth weight (ELBW) and extremely preterm-born survivors. These surviving preterms are now adolescents and adults, whose outcomes are of importance not only to pediatricians, but also to the adult physicians who will care for them for the remainder of the life course. The associations between increased risk for all categories of adverse outcomes and decreasing gestational age continues into adolescence and adulthood.[136] Medical sequelae of prematurity include impacts on respiratory, cardiovascular, and renal function. Surviving ELBW infants are more likely to have CP, blindness, and deafness than term-born matched controls.[137] As these are typically fixed impairments, rates in adulthood closely mirror rates at school age. Further, over time, ELBW survivors have higher rates of other visual impairments, including refractive errors and late retinal detachment.[138] In adulthood, preterm survivors are more likely to receive disability pensions than term-born controls.[137]

Very preterm, very-low-birth-weight, and moderately preterm-born adolescents are less likely to complete high school than adolescents born full term.[139–141] However, the majority do not require special education support and are able to complete high school.[136] Very-low-birth-weight or very preterm-born adults are also less likely to seek education beyond high school.[139,141,142] In adulthood, preterm-born cohorts have worse performance on tests of academic achievement than term-born controls.[139] Few studies have closely evaluated cognitive function in preterm survivors. IQ is generally reported to be about a half a SD below term controls, but differences depend on the population studied. Predictors of adolescent and young adult IQ include maternal educational level, birth weight, gestational age, and small for gestational age birth.[139,143,144]

Even in adults without neurosensory or cognitive impairment, impairments in learning or executive function may interfere with educational and vocational achievement. Executive function deficits primarily involve impairments in response inhibition and mental flexibility.[145] As discussed above, autism and attention deficit disorders are more common among both very preterm or low-birth-weight children and even moderate-/late-preterm children; these disorders likely persist into adulthood.[146,147] Reports of increased rates of schizophrenia, anxiety, and depression among

preterm-born adults are inconsistent and conflicting.[147,148] In a large Norwegian study, relative risk of autism spectrum disorder was 9.7 times higher among adults born before 28 weeks as compared to those born at term.[147] Furthermore, relative risk of having a disorder of psychological development, behavior, and emotion resulting in a need to claim disability benefits was 10.5 times higher among those born before 28 weeks.

Adults who were born at 23 to 27 weeks' gestation are 7.5 (95% CI 5.5 to 10.0) times more likely to have a medical disability affecting the ability to work than those who were born full term.[147] Among those who do not have a medical disability, very preterm-born adults have significantly lower educational level, have lower income, and are less likely to get married and become parents.[90,147] Relative risk of having at least one child among men born at 22 to 27 weeks is 0.24, relative risk among women is 0.33.[149] Further, preterm-born women are more likely to have preterm babies. Preterm-born adults are less likely to move outside their parents' home or cohabitate with a partner.[141,149] Net income is significantly lower among very preterm-born adults.[90,147] On the positive side, preterm- and very-low-birth-weight-born adults are consistently reported to have lower rates of risk-taking including smoking, alcohol, and drug use, and delinquent behavior.[90,148] This is likely related to persistent tendencies toward internalizing behaviors and fewer externalizing behaviors throughout life.[150]

Health-related quality of life is an important consideration as our most fragile and vulnerable patients age into adulthood.[151,152] Only a few small studies have evaluated the long-term impact of prematurity on self-reported quality of life. Saigal and colleagues assessed health-related quality of life in a population of ELBW infants born in 1977–1982 when the participants were 24 years old. Despite more functional limitations (cognition, sensation, mobility, and self-care), the ELBW participants did not report significantly different health-related quality of life from term-born controls. Later, in their 30 s, the same cohort indicated lower self-esteem along with lower measures of multiple functional and health-related outcomes.[90] Similarly, in a small Danish cohort of young adults, objective quality of life (based on societal standards) was lower in those born very preterm or with a chronic health problem.[152] However, subjective quality of life (based on individual life preferences and experiences) was not significantly different.

In summary, the impact of prematurity on medical, developmental, psychological, and functional domains persists throughout the life course. It is critical to note that the most extremely preterm (22 to 23 weeks' gestation) infants are only now surviving into adulthood. Adolescent and adult impact of survival at the limits of viability remains to be fully described in the current era of neonatal medicine.

Risk Factors for Adverse Outcomes in Preterm Infants

As described above, preterm infants as a group are at risk for multiple adverse outcomes throughout childhood and into adulthood. These risks are modified by patient characteristics, morbidities, and complications that occur during the neonatal period. Important neonatal morbidities that directly impact outcomes of preterm infants include brain injury, bronchopulmonary dysplasia (BPD), ROP, infection, necrotizing enterocolitis (NEC), and poor growth and nutrition. We end this section by addressing the relationships between socioeconomic factors and childhood outcomes.

Brain Injury

Cranial Ultrasound

Cranial ultrasound (CUS) has been used to image preterm infant brain injury since the late 1970s.[153,154] With the development of a standardized grading system for intracranial hemorrhage (ICH),[155] CUS quickly became and remains the neuroimaging standard of care for preterm infants.[156] Although many still seem to rely heavily on simply the presence of grade 3 ICH, intraparenchymal hemorrhage (IPH), or cystic periventricular leukomalacia (PVL) to counsel families about the neurodevelopmental outcomes of their preterm infants, the complexity of interpretation of CUS findings, and limitations of prediction of outcomes with any single neuroimaging or other finding, should give clinicians cause for prudence and careful consideration.

Virtually every major study of early neurodevelopmental outcomes among preterm and ELBW infants has confirmed a strong association between major CUS abnormalities and adverse neurologic and developmental outcomes. Definitions of CUS abnormalities as well as specific outcomes differ among studies. Traditionally, adverse neuroimaging findings have included Papile ICH grade 3 or 4, regardless of laterality. Other studies consider intraparenchymal hemorrhage (IPH), ventriculomegaly (VM), or cystic changes, also often without respect to laterality or extent of the findings, to be severe abnormalities. In some, persistence of periventricular echodensity or "flaring" is included.[157–159] The diagnosis reported in studies is frequently based on the results from a single CUS, either the "worst" or the "final" imaging study, but some prospective cohorts include serial imaging.

The focus of many studies has been on exploring the association of major CUS findings with CP. The ELGAN study followed infants of less than 28 weeks' gestation from 14 institutions across five states in the United States from 2002 to 2004.[160,161] Three study CUS were performed during hospitalization and by multiple radiologists. BSID-II and standardized neurologic examinations for CP were performed at 2 years. There were strong independent associations between CUS findings and CP with about half of the children with CUS echolucency or VM going on to develop CP. Late occurrence of VM, bilateral echolucency, and IPH or PVL were strongly predictive of quadriparesis. However, almost half of the children with CP at 2 years had completely normal CUS, and the PPV of VM or echolucency for moderate or severe CP was poor. Isolated intraventricular hemorrhage (IVH) was not strongly predictive of CP. In three birth cohorts (1991–1992, 1997, 2005) born in Victoria, Australia, grade 3 or 4 ICH on neonatal CUS was independently associated with ninefold increased odds for CP and more than fourfold increased odds for any motor dysfunction at 8 years.[162] Of note, the rate of any motor dysfunction among those with no IVH was 24%, compared with 43% among those with grade 3 IVH and 92% among those with grade 4 IVH. Grade 1 and 2 IVH were associated with a twofold increased odds for CP.

However, CUS findings alone are poorly predictive of early developmental outcomes or later childhood cognitive and learning outcomes,[163] and 30% to 40% of those with "normal" CUS have neurodevelopmental challenges at 18 to 30 months.[164] The ELGAN study group showed that IVH was associated with increased risk for motor or developmental impairment at 2 years *only* when accompanied or followed by white matter lesions,[165] highlighting the limited predictive value of both early CUS findings and IVH alone. Children in the ELGAN cohort were also evaluated for neurological and cognitive outcomes at 10 years.[166] The presence of white matter lesions without IVH was found to

be associated with a more than threefold increased odds of cognitive impairment and sevenfold odds of epilepsy; similar association were found for white matter lesions accompanied by IVH. However, isolated IVH was not significantly associated with cognitive impairment or epilepsy. In later childhood follow-up studies of the EPIPAGE cohort, including infants born at 22 to 32 weeks in nine regions in France in 1997, approximately 40% of those with major neonatal CUS abnormalities had no significant cognitive or learning challenges identified at 8 years, whereas 30% to 40% of those with no neonatal CUS abnormalities had moderate-to-severe challenges.[167,168] In the Victoria, Australia birth cohorts followed to 8 years of age, neonatal CUS with grades 3 and 4 IVH were each independently associated with higher risk for poorer intellectual and academic outcomes at 8 years.[162] Of note, among those with grade 3 IVH, 22% and 24% had scores <2 SD below the term comparison mean for IQ and for any academic skill, respectively; this compared with 12% and 16% among those with no IVH. Lower IVH grades were generally benign with respect to cognitive outcomes. These findings taken together underscore the need for truly long-term surveillance through childhood for all born EPT, allowing for consideration for interventions to improve outcomes.

Nevertheless, in skilled hands, with meticulous technical attention and serial CUS imaging, much can be seen beyond ICH by CUS. In a single center, deVries et al.[157] reported 76% sensitivity and 95% specificity of CUS abnormalities for CP at 2 years for patients of less than 32 weeks' EGA. Of importance, among those with major CUS abnormalities who developed CP, approximately 30% were noted only after 28 days. Major CUS abnormalities were also not strongly associated with cognitive delay at 2 years. More recent findings from this group, using magnetic resonance imaging (MRI) at term-equivalent age (TEA) to refine specific CUS findings, have resulted in PPV and negative predictive value of 96% and 69%, respectively, for CP at 2 years among preterm infants.[158]

CUS is an operator-dependent modality, imaging procedures and views differ among institutions and studies, and there is no uniform approach to serial imaging protocols. Although interrater reliability and accuracy are very good to excellent for severe ICH, agreement is only fair or poor for subtler findings and PVL alone.[169] Cerebellar hemorrhage, a finding that may be missed without appropriate CUS views, is associated with neurodevelopmental disabilities in children born preterm,[170–172] and more detailed understanding of size of cerebellar hemorrhage is increasingly recognized as important for prognosis.[173,174] Transient lesions may be missed, including echodense periventricular lesions or collapsing small cystic lesions.[175] Isolated IPHs and of course large IVHs can be seen by CUS; however, not all "severe" hemorrhages can be considered equivalent in terms of association with early neurodevelopmental outcomes. Characteristics of the hemorrhage including laterality, midline shift, and extent of hemorrhage,[176,177] as well as the presence or absence of other adverse clinical factors,[178,179] impact prediction of neurodevelopmental outcomes.

Magnetic Resonance Imaging

Brain MRI has been used more extensively in recent years among very and extremely preterm infants, both for research and for clinical indications. MRI provides a more comprehensive and detailed picture of the brain, with better delineation of deep structure and cortical injury. Potentially most importantly, MRI provides improved detection of white matter injury (WMI), which is common among preterm infants at term-corrected age. Identification of WMI is critically important to understanding the structure–function relationship of the developing preterm brain, influences on later neuromotor and cognitive outcomes, and developing future neuroprotective strategies.[180] Subtle WMI on MRI is associated with reduced total brain and gray matter volumes, reduced cerebellar volume, and reduced basal ganglia and thalamic volume, which in turn are associated with childhood developmental impairments among preterm infants. These findings and others provide evidence that WMI in the preterm is associated with brain maturational disturbances, suggesting an overall link to impaired neural connectivity.[181]

A number of single and multicenter efforts have investigated whether MRI may provide enhanced information by which to predict outcomes for very and extremely preterm, particularly in comparison with CUS. Scoring systems were developed,[182,183] and larger cohort studies have been published, initially implementing primarily qualitative brain MRI at near term. Among the first of the larger multicenter studies compared CUS with near-term MRI findings and their association with 2-year outcomes in 167 infants of less than 30 weeks' EGA in Australia and New Zealand.[184] This study demonstrated that moderate-to-severe WMI on term-equivalent age (TEA) MRI was significantly associated with neuromotor delay and CP, independent of CUS findings and other risk factors. Increasing WMI severity was also related to lower BSID-II MDI scores, but an independent association of moderate-to-severe WMI with severe cognitive delay was not detected. However, CUS was assessed only with respect to early findings including grade of ICH and periventricular cystic changes, and a substantial proportion of infants with moderate-to-severe WMI by MRI did not have adverse 2-year outcomes. The NICHD Neuroimaging and Neurodevelopmental Outcomes study was a prospective study of early and late CUS and near-term MRI, which included 480 infants of less than 28 weeks' gestation, with outcomes including BSID-III assessed at 18 to 22 months.[185] In multivariable models, both late CUS findings reflective of WMI and MRI findings of significant cerebellar injury remained independently associated with adverse neurodevelopmental outcomes. In models that did not include late CUS, MRI findings of both moderate-to-severe WMI and significant cerebellar lesions were independently associated with adverse outcomes. Early CUS findings were not associated with adverse outcomes when any late neuroimaging was taken into account. In 6- to 7-year follow-up of that cohort, severe but rare adverse late CUS findings were most strongly associated with IQ <70 and the composite outcome of disability, which included moderate-severe CP. Significant cerebellar lesions seen on MRI were associated with disability.[18] Similarly, in a prospective study of serial CUS and near-term MRI among neonates of less than 27 weeks' gestation in Sweden, associations between MRI findings and 30-month outcomes were demonstrated, but the investigators determined that any substantial abnormalities on MRI were detected by the late CUS done on the same day.[186] Diffuse excessive high signal intensity on TEA MRI has been shown not to be associated with adverse early childhood outcomes in several studies[187,188] nor in later childhood or early adolescence.[189] In contrast, longitudinal brain MRI studies of very PT infants using a more comprehensive scoring system,[190] taking into account WMI and also measures of cortical gray matter, deep gray matter, and cerebellum, demonstrated that moderate-severe global abnormality on TEA MRI was associated with a reduction in IQ, math, and motor scores at 7 years independent of the other perinatal and neonatal confounders including severe abnormalities on neonatal CUS.[191] However, in a Dutch cohort of infants born extremely preterm, the prognostic value of that

MRI scoring system for 2-year outcomes was limited.[192] Other studies have pointed to associations of TEA MRI findings and growth of specific brain regions and outcomes, including that WMI, deep gray matter nuclear injury, and earlier gestational age are associated with smaller TEA cerebellar volume and growth trajectory through childhood, which in turn is associated with poorer IQ, language, and motor function.[193] A recent systematic review compared CUS and MRI to detect brain injury and predict outcomes,[194] which concluded that MRI provided more detailed information on the severity and the extent of preterm brain injury, particularly for white matter injury and cerebellar hemorrhage. The authors suggested that prediction of outcomes may be enhanced with MRI, citing improved negative predictive value compared with CUS, but acknowledging both lower PPV and wide heterogeneity among studies.

Despite what appears to be substantial experience with CUS and conventional brain MRI in preterm infants, controversies and questions remain as to which studies to perform, when to perform them and under what circumstances, and relative values in prognosis. These are not simple questions, as the value of additional information may vary by clinical circumstances and for individual parents and physicians.[195] Guidelines published in 2002, prior to the vast majority of large studies related to CUS and MRI comparisons, did not recommend TEA MRI for routine PT infant neuroimaging.[156] In 2015, the "Choosing Wisely Top Five for newborn medicine" suggested avoidance of routine term-equivalent conventional brain MRI for screening purposes because there was "insufficient evidence that the practice improves long-term outcomes."[196] In 2020, the AAP Committee on Fetus and Newborn, Section on Neurology, and Section on Radiology published a joint clinical report as guidance for routine neuroimaging for the PT infant.[197] The document included recommendation for routine CUS with anterior and mastoid fontanelle views by 7 to 10 days for all infants ≤30 weeks' EGA, with repeat CUS at 4 to 6 weeks and at TEA or before hospital discharge. The guidelines indicated that TEA MRI for infants ≤30 weeks is "not indicated as a routine procedure" although may be offered for the "high-risk infant" after counseling with the family regarding prognostic limitations of MRI. Of note, what is considered "high-risk" was not described, and certainly may be interpreted variably across institutions, among neonatologists, and by individual parents and families. Furthermore, careful counseling and discussion with a family about prognostic limitations of a test should not be limited to TEA MRI. The same careful review and acknowledgements should accompany discussion of CUS findings, or for that matter any other test.

Scientific conversations will certainly continue on the topic of appropriate and "best" neuroimaging for PT infants in specific circumstances, particularly as the evolution and advances in quantitative MRI continues. Future studies may focus on identifying high-risk groups of preterm infants to allow for neuroprotective or interventional trial risk stratification, and approaches to improve positive prediction of outcomes of importance both to parents and investigators. Investigations with advanced magnetic resonance techniques, including diffusion tensor imaging, functional connectivity MRI, surface morphometry, and volumetric methods, hold enormous promise to help to explore these questions.[198]

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is the most common morbidity of prematurity. BPD occurs in nearly half of infants born ≤28 weeks' gestation, and rates may be increasing over time.[199] Historically, BPD was most commonly defined as oxygen dependence at 36 weeks postmenstrual age (PMA). However, it is now increasingly recognized that grading of BPD according to level of respiratory support at 36 weeks PMA is more closely associated with risk for respiratory and neurodevelopmental sequelae through 2 years' corrected age.[200] BPD is associated with adverse respiratory, developmental, educational, and health economic outcomes. Extremely preterm infants with BPD have increased coughing, respiratory medication use, hospitalizations, and impact of respiratory disease on the family at 18 to 22 months corrected age, compared to those without BPD.[201] A meta-analysis of pulmonary function testing in children born preterm with BPD, those born preterm without BPD, and children born at term demonstrated significantly decreased $\%FEV_1$ in those born preterm, with a further decrease in those with BPD.[202]

MRI studies have shown changes in brain structure and function that may underpin the differences in development that are observed in children with BPD.[203–205] Several investigators have reported adverse neurodevelopmental outcomes in toddlers with a history of BPD, when compared to preterm-born toddlers without BPD.[179,206–211] BPD is a consistent independent predictor of risk for developmental impairment at 2 and 5 years.[179] Adjusted odds of adverse outcomes at 5 years are 2.3 (95% CI 1.8 to 3.0) times higher among very preterm-born children with BPD than among those without BPD.[179] Reports of cognitive outcomes at 8 years suggest that preterm-born children with BPD have lower IQs than those without.[212,213] In a large meta-analysis, BPD explained about 65% of the observed variance in cognition among children who were born prematurely.[119] BPD was associated with about a 1 SD decrease in childhood intelligence. A second meta-analysis reported that BPD is also associated with CP at school age, and infants receiving mechanical ventilation at 36 weeks' PMA (Jensen grade 3) have the highest risk for CP.[214]

Multiple large, randomized trials have evaluated strategies to decrease BPD in extremely preterm infants by applying interventions or drugs either in the delivery room or during the neonatal hospitalization. While some interventions or medications successfully improve rates of BPD, few have demonstrated improved developmental outcomes. Vitamin A reduces BPD or death in extremely-low-birth-weight infants (relative risk 0.89) but does not improve developmental outcomes at 18 to 22 months.[215] Postnatal corticosteroids reduce BPD, but significantly increase risk for CP if given in the first 4 days of life. Use of systemic corticosteroids after 7 days of life reduces BPD without increasing risk for CP.[216,217] Use of inhaled steroids after 7 days of life does not reduce BPD and developmental impacts are unknown.[218] Neither is recommended for use before 7 days.[219,220] Caffeine reduces BPD at 36 weeks, CP at 2 years, and severity of motor impairment at 5 and 11 years.[11,15,221,222] In multiple randomized trials, surfactant therapy for respiratory distress syndrome reduces both air leak syndromes and mortality.[223] It may reduce mild disability at 1 year but does not reduce moderate or severe disability at 1 year or any adverse outcomes at 2 years.[224]

Lastly, although antenatal corticosteroids reduce many complications of prematurity including mortality and respiratory distress syndrome, it is unclear whether they improve rates of chronic lung disease.[225,226] In the most immature (≤25 weeks) infants, antenatal steroids may increase rates of BPD, perhaps by leading to increased survival of high-risk infants.[226] Yet, antenatal steroid treatment is associated with a reduction in developmental disability or developmental impairment in childhood survivors.[225,226]

This includes decreased rates of cognitive impairment and CP among infants ≤25 weeks gestation who are exposed to antenatal steroids.[226]

Numerous neonatal trials have evaluated various methods of respiratory support in the delivery room and during the hospitalization. Early extubation to or complete reliance on noninvasive support such as continuous positive airway pressure (CPAP) has become standard of care.[227] However, none of these respiratory interventions has clearly led to measurable improvements in developmental outcomes.[17]

Retinopathy of Prematurity

ROP occurs in about 60% of neonates born at less than 28 weeks' gestation in the United States, and stage 3 or higher ROP disease occurs in about 15% of those neonates.[199] Incidence of both ROP and high-grade ROP possibly requiring treatment increase significantly with decreasing gestational age.[199] With the evolution of cryotherapy, laser therapy, and antivascular endothelial growth factor (VEGF) pharmacologic treatment, blindness caused by ROP in the developed world is now rare. Nevertheless, on a global level, as many as 20,000 children annually are blind from ROP.[228] Prematurely born children who are treated for ROP are at clear risk for long-term visual morbidities. However, infants with ROP that do not require therapy or lead to blindness are also at risk for long-term visual problems. At a 6.5-year follow-up of the Swedish EXPRESS cohort of neonates born at less than 27 weeks' gestation, 38% had at least some ophthalmologic abnormality, including blindness, strabismus, and refractive errors.[229] Visual problems were strongly associated with ROP treatment and lower gestational age.

Like BPD, ROP is associated with abnormal brain development in very preterm infants.[209,230] This may explain why severe ROP is associated with both visual and non-visual disabilities.[230] For example, at 5 years, stage 4 or 5 ROP or treated ROP is an independent predictor of poor neurodevelopmental outcome.[179] This effect is similar in magnitude to and additive to the risks associated with severe brain injury or bronchopulmonary dysplasia (see above). These infants have more than four times higher odds of motor and cognitive disability than infants without severe ROP.[231] In addition, they are more likely to have impairment in multiple domains.

The primary strategy utilized by neonatologists to reduce ROP has been restriction of supplemental oxygen. In a meta-analysis of five oxygen saturation targeting trials in EPT infants, targeting lower oxygen saturations (85% to 89%) as compared with higher oxygen saturations (91% to 95%) was associated with a somewhat lower risk of ROP (risk ratio 0.72, 95% CI 0.50 to 1.04).[232] Offsetting this potential benefit, the low saturation targeting strategy was also associated with an increase in risk of death before discharge (risk ratio 1.18, 95% CI 1.03 to 1.36) though not a significant difference in death by 18 to 24 months. Thus careful targeting of oxygen saturations alone is insufficient to eliminate risk of ROP in EPT infants, and low oxygen saturation targeting is unlikely to prevent enough ROP to justify potential risks.

The effect of ROP treatment itself may also have important implications for both visual and developmental outcomes. Laser therapy is the current standard treatment, but injection of antivascular endothelial growth factor (VEGF) agents is increasingly used to treat acute ROP. In one small randomized trial, an anti-VEGF agent appeared to be superior to laser therapy for treatment of Zone 1 ROP.[233] However, due to concerns about systemic absorption of the drug, late proliferative vascular changes that lead to retinal detachment, and only minimal differences in refractive outcomes at 2.5 years, many neonatologists and ophthalmologists remain apprehensive about use of these drugs.[234] Such concerns are augmented by inconsistent reports about neurodevelopmental outcomes of infants treated with anti-VEGF drugs as compared to laser therapy.[235,236] Recent meta-analysis suggests that anti-VEGF treatment does not increase risk for poor outcomes, though existing studies are small and generally rated as low quality of evidence.[237] Further research is needed to identify both novel strategies for prevention of ROP as well as treatments that are safe and lead to improved visual outcomes without adverse developmental impacts.

Infection

Preterm infants are at high risk for both perinatally acquired and postnatally acquired infections. Due in large part to the introduction of peripartum prophylaxis against group B streptococcal infections coupled with intense efforts to reduce iatrogenic late-onset sepsis, rates of neonatal infection have fallen in recent years. Nevertheless, about a quarter of extremely preterm infants (born ≤28 weeks) have culture-positive bacterial sepsis while in the intensive care unit.[199,238] Like other neonatal morbidities, risk for late-onset sepsis increases significantly as gestational age decreases. Infection is associated with poor growth, and poor head growth in particular, which is an independent predictor of adverse outcome in preterm infants (see below).[239] Furthermore, neonatal bacterial infection is associated with increased risk for low cognitive performance, CP, and vision impairment at 2 years' corrected age.[238,240–242] Yet, the overall risk for neurodevelopmental impairment (any one of cognitive impairment, CP, or vision or hearing impairment) associated with neonatal bacterial sepsis is slightly less significant than risks associated with severe IVH, ROP, or BPD.[238,243] By 5 years of age, both early- and late-onset sepsis in very preterm infants remain associated with significantly increased odds of CP; associations with cognition are less certain.[244]

In addition to bacterial infections, infections with other types of pathogens can also have significant adverse effects on neurodevelopment, particularly in preterm-born children. Infants with candida sepsis and/or meningitis and infants with bacterial meningitis experience a more significant increase in risk for poor developmental outcomes in early childhood than those with bacterial sepsis alone.[243,245] Additionally, many viral infections acquired in utero or during the perinatal period are associated with significant brain injury and developmental aberrations, both in term infants and preterm-born infants.[246]

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is diagnosed in about 7% to 13% of infants born ≤28 weeks.[199] As with other morbidities of prematurity, risk for NEC increases with decreasing gestational age and birth weight. The bowel injury and necrosis pathognomonic of necrotizing enterocolitis trigger a systemic inflammatory response which is thought to be injurious to the premature brain.[247] Infants with NEC are at increased risk for death, cognitive delay, CP, severe vision or hearing impairment, and the composite outcome of developmental impairment at 18 months.[243,248] In one large observational study, nearly all of this increase in risk for adverse outcome was associated with NEC requiring surgical

intervention.[249] Surgical NEC and spontaneous intestinal perforation are associated with more than doubled odds of neurodevelopmental impairment among survivors.[250] However, similar to infection, the overall risk for adverse outcome associated with NEC is less significant than risks associated with severe IVH, ROP, or BPD.[243]

Antenatal corticosteroid treatment leads to a significant reduction in necrotizing enterocolitis.[225,226] Despite this reduction in NEC, as noted above, the impact of antenatal steroids on developmental outcomes remains uncertain. Exclusive maternal milk feeding reduces risk for NEC and improves developmental outcomes, though it is unclear that these two benefits are causally related to one another. When compared to preterm formula, donor human milk leads to decreased incidence of NEC but no change in cognitive, language, or motor development at 2 years corrected age.[251] Additional interventions such as lactoferrin and probiotics show promise for further decreasing rates of NEC, but there is currently insufficient data about long-term impact on developmental outcomes.[252,253]

Growth and Nutrition

A focus on growth and nutrition both in the NICU and after discharge is increasingly recognized as essential for optimization of longer-term developmental outcomes. In a large cohort study, infants born 501 to 1000 g were divided into quartiles of in-hospital growth velocity.[239] Quartile of in-hospital growth velocity was associated with risk for CP and developmental outcomes more than two SDs below the mean at 18 to 22 months' corrected age, even after adjustment for other factors predictive of poor growth and development. Preterm infants who fail to thrive in the first 8 months after discharge have poor developmental outcomes compared with those who demonstrate catch-up growth or maintain an appropriate growth trajectory.[254] Greater head growth over the first 2 years is associated with higher school-age IQ and lower risk for poor executive function or motor function at school age.[255]

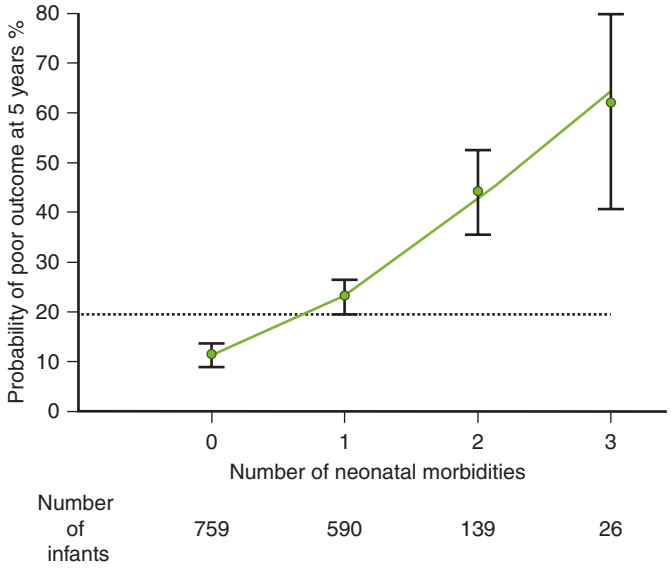
Because of the strong associations between nutrition and growth during the first year of life and developmental outcomes, multiple strategies to improve growth have been evaluated. Early aggressive nutrition in the NICU currently includes early administration of parenteral nutrition, early enteral nutrition with maternal or donor human milk, and fortification of enteral milk feedings. While many of these strategies successfully improve in-hospital growth, there is little evidence to date that any of these interventions improve long-term growth or developmental outcomes.[251,255–258]

Socioeconomic Status

The critical importance of socioeconomic factors in the long-term development of high-risk infants cannot be over-emphasized.[259] Socioeconomic factors that influence cognitive outcomes include parent education, having two parents in the household, neighborhood, and social and racial backgrounds.[123,129] Furthermore, these factors influence the chance that a child's cognitive status will improve over the first years of life.[123] Similarly, adverse socioeconomic factors such as younger maternal age and poor maternal well-being are strongly associated with increased behavior problems in preterm-born children.[128]

As high-risk children get older, perinatal factors have progressively less influence on outcome, while parental education remains highly important.[122] Older children with functional limitations are more likely to live in families with limited resources, have less access to health care, and be exposed to less healthy home environments.[260] This is associated with decreased access to necessary health care due to cost. Therefore, as with biologic risk factors, social risk factors including poor parental education, single-parent household, low social class, and maternal well-being must be taken into consideration when assessing an individual child's risk for adverse developmental and behavioral outcomes.

In summary, multiple adverse events during the neonatal course can impact longer-term developmental risk. Each of these events is associated with a unique level of risk and may impact development in somewhat different ways. These morbidities interact with one another to additionally increase risk. After gestational age and birth weight, the most significant risk factors for poor developmental outcomes in very preterm infants are IVH, ROP, or BPD (Fig. 24.2).[179] Each of these morbidities is associated with a linear, additive increase in risk for adverse developmental outcome. Neonatal infection—particularly fungal infection and meningitis—and necrotizing enterocolitis—particularly surgical NEC—add to the prediction of poor outcome. Poor growth is independently predictive of adverse outcome. Additional neonatal factors that increase risk for poor outcome include surgical ligation of the patent ductus arteriosus, general anesthesia, seizures, serious pulmonary hemorrhage, small size for gestational age, and congenital abnormalities. Lastly, the family's socioeconomic status is of increasing importance as children grow. Assessment of the number and severity of neonatal risk factors will aid in counseling



• **Fig. 24.2** The probability of neurodevelopmental impairment (NDI) in the Caffeine for Apnea of Prematurity Trial participants (n = 1514) at 5 years corrected age, based on the number of neonatal morbidities. Morbidities included were severe brain injury, bronchopulmonary dysplasia, and severe retinopathy of prematurity. The error bars represent 95% confidence intervals, the sloping green solid line indicates predictions based on a fitted morbidity count model, and the horizontal black dotted line indicates overall probability of NDI in the entire cohort. (From Schmidt B, Roberts RS, Davis PG, et al. Prediction of late death or disability at age 5 years using a count of 3 neonatal morbidities in very low birth weight infants. *J Pediatr*. 2015;167:982–986.)

of families about likely developmental outcomes and determination of possible need for services during early childhood.

Other Infants at High Risk for Adverse Outcomes

Though the primary focus of the current chapter is risk assessment and outcomes of preterm and low-birth-weight infants, select groups of late preterm and full-term infants also have significantly increased risk for poor outcomes and are addressed below.

Hypoxic–Ischemic Encephalopathy

Infants with perinatal depression or HIE are at risk for poor outcomes due to a peripartum or immediate postnatal neurologic insult. Diagnosis of HIE is made by a standardized neurologic examination consistent with encephalopathy, history of an acute perinatal event, low Apgar scores, and evidence of acidosis from either the umbilical cord or an infant blood sample obtained soon after birth.

More than 1000 full-term and near-term infants with moderate or severe HIE have been enrolled in randomized trials of therapeutic hypothermia or "cooling" for HIE. These trials have demonstrated that cooling significantly reduces mortality (RR 0.75, 95% CI 0.63 to 0.88) and decreases rates of survival with major disability at 18 months of age (RR 0.68, 95% CI 0.56 to 0.83).[261] Benefits of cooling persist at least until school age. Follow-up of two randomized trials of therapeutic hypothermia for HIE reveals lower rates of death or severe disability, CP, and moderate or severe disability, in addition to improved motor function scores, at 6 to 7 years.[6,262] Despite the success of this intervention, about half of children with moderate or severe HIE still die or suffer long-term neurologic impairment. CP is diagnosed in nearly 20% and developmental delay in more than 22% of surviving cooled infants.[261]

The relationships between several clinical factors and outcomes of infants with HIE have been studied. Certainly, the degree of encephalopathy based on the original clinical assessment is closely correlated with risk for both mortality and developmental impairment. Other early clinical signs predictive of poor longer-term outcome are administration of chest compressions for greater than 1 minute at birth, onset of spontaneous breathing greater than 30 minutes after birth, and base deficit of greater than 16 at any time.[263] Serial clinical examinations are more predictive of outcome than any single examination. Improvement in the clinical examination during cooling or by 72 hours of life and normal examination at discharge are associated with decreased rates of death or disability by 18 months.[264,265]

Children undergoing cooling are often monitored with either electroencephalography (EEG) or amplitude-integrated electroencephalography (aEEG). Prolonged discontinuity on EEG is associated with brain injury on MRI and poor developmental outcomes.[266] Burst suppression, low voltage, and flat trace predict developmental outcomes at greater than 12 months.[267] However, it is uncertain whether aEEG or EEG data add significantly to the initial clinical assessment based on severity of encephalopathy in the era of therapeutic hypothermia.[268,269] Particularly in cooled infants, *serial* evaluation of aEEG background may improve prediction of poor outcome just as *serial* clinical examinations improve prediction.[270] About half of newborns with HIE have seizures on EEG.[271] When managed with cooling, infants with HIE have lower overall seizure burden and shorter duration of seizures. The AAP recommends that centers offering therapeutic hypothermia have monitoring with aEEG or EEG available.[272]

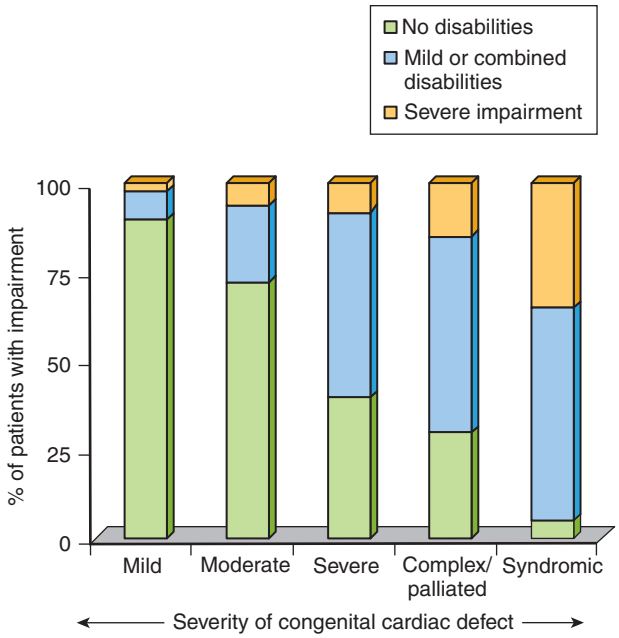
MRI-detected patterns and extent of brain injury are predictive of developmental outcome both at 2 years and at school age in HIE.[273] In particular, injury to the basal ganglia and/or thalami is highly predictive of poor outcome.[274] Interpretation of MRI findings depends on timing of the examination after birth, because sequelae of the initial insult may evolve over the first days to weeks of life. Infants treated with cooling are more likely to have normal MRI than those who are not cooled, but an MRI without abnormal findings does not guarantee "normal" developmental outcome after HIE.[275] Therefore all hospitals that provide cooling should also be capable of providing longitudinal neurodevelopmental monitoring and care.[272]

With therapeutic hypothermia established as standard of care and adjunctive agents under study, attention is turning to evaluation of whether these strategies are also safe and effective for more immature infants with HIE.[276] In addition, infants with mild HIE have not been evaluated in prior therapeutic trials; however, data suggest that these children may also be at risk for poor neurodevelopmental outcomes.[277] Thus, identification and optimal treatment of infants of any gestational age with mild HIE are critical areas for future investigation.

Congenital Heart Disease

Over the past several decades, improved surgical techniques and medical management have resulted in significantly improved survival rates for the 0.6% to 0.9% of infants who are born with CHD.[3,278] This has led to increasing interest in the longer-term developmental and quality-of-life outcomes of children and young adult survivors of CHD. A 2012 position statement from the American Heart Association and the AAP stratifies children based on risk for poor outcome, and suggests age-based approaches to surveillance, screening, and evaluation of children with CHD.[3] Noncardiac complications of CHD include cognitive, academic, financial, and psychological problems. Prevalence of poor outcome increases with severity of the heart lesion.[279] Furthermore, children who have genetic abnormalities or prematurity in addition to CHD have increased risk for developmental delays compared with those without these confounding conditions (Fig. 24.3).

Infants with CHD are often born with brains that are both small and immature for their gestational age,[280] which is thought to lead to increased vulnerability during the perioperative period. On MRI imaging, brain injury is detected both preoperatively and postoperatively, and predominantly consists of white matter injury. However, degree of white matter injury has not yet been correlated with developmental outcomes in the CHD population.[278] In children with CHD, gross motor problems are often evident in early infancy and during the toddler period. However, rates of CP are low, especially in comparison to other high-risk groups such as extremely preterm infants or full-term infants with HIE. Intelligence in children with a history of CHD is decreased from expected values by 5 to 10 points and is <70 in about 10% to 20% of these children. This is associated with increased rates of language and learning problems at school age, emotional and behavioral problems in up to 40%, visuomotor and fine motor coordination problems, and a significant impact on executive function. Behavioral problems, ADHD, depression, and anxiety



• **Fig. 24.3** Relationship between severity of congenital heart lesion in children with and without syndromes and severity of neurodevelopmental impairment. (Modified from Wernovsky G. Current insights regarding neurological and developmental abnormalities in children and young adults with complex congenital cardiac disease. *Cardiol Young*. 2006;16:92–104.)

are also common in children with CHD and quality of life is lower than among children without CHD.[281,282]

Adverse neurologic or developmental outcome in congenital heart disease is associated with multiple factors that are known in the neonatal and perioperative period.[281] Just as clinical examination in HIE is predictive of longer-term outcome, so too is a careful neurologic examination of the infant with congenital heart disease.[283] Neurobehavioral problems are often evident even before surgical palliation of the CHD. Seizures occur in more than 10% of infants who undergo bypass surgery and are associated with poor outcomes including mortality.[284,285] Duration of intensive care stay is a strong risk factor for adverse cognitive outcome up to 8 years, likely because it is a surrogate measure of overall severity of illness in this population.[286] Similarly, need for repeat hospitalizations and surgical procedures are associated with risk for adverse outcomes.[281]

Survivors of CHD often require habilitative services including therapies and special education. As in adults who were born preterm, persistence of these problems over time is likely to impact academic achievement, employment, and quality of life. Because the first generations of survivors of CHD are now entering adulthood, more work to describe the developmental, functional, and quality-of-life outcomes of CHD across the lifespan will continue to be essential.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is a lifesaving therapy for patients with severe cardiac or respiratory failure that cannot be managed with conventional medical therapies. Almost half of all patients treated with ECMO are neonates, and about three-quarters survive to discharge.[287] Both survival and longer-term developmental outcome after ECMO depend on the original indication for ECMO, pre-ECMO course, and complications while on ECMO. Infants with medical indications for ECMO such as meconium aspiration syndrome have higher survival rates than those with surgical indications such as congenital diaphragmatic hernia. Lower gestational age and birth weight are associated with higher risk of both complications and mortality. The primary neurologic complication of concern while on ECMO is intracranial bleeding.

Children who were treated with ECMO during the neonatal period are at higher risk for later respiratory morbidity; hearing loss; poor motor, cognitive, and visuomotor performance; and behavior problems. Developmental delays are observed in multiple domains at least through 2 years.[288] Infants with CHD who are supported with ECMO have a higher risk for poor neurodevelopmental outcomes than those not treated with ECMO.[289] A randomized trial of therapeutic hypothermia during ECMO failed to demonstrate any neuroprotective effects at 2 years.[290] However, even without ECMO these children are likely to remain at high risk for many of these outcomes and are likely to have higher rates of mortality. For example, infants with congenital diaphragmatic hernias who do not undergo ECMO have lower developmental outcomes at one year than expected norms, and 13% have severe cognitive, motor, or language delays.[291]

In summary, infants in each of these high-risk categories are at high risk for problems in multiple neurodevelopmental domains throughout childhood. They should all be followed throughout the early childhood years by a multidisciplinary neurodevelopmental follow-up clinic that is capable of comprehensive surveillance, screening, diagnosis, and management. Monitoring should include traditional cognitive and motor assessments, behavioral evaluations, and surveillance for neurosensory deficits. This proactive approach will ensure that these high-risk infants achieve their greatest potential as they mature through childhood and adolescence.

Postdischarge Management of the High-Risk Infant

Discharge Planning for the High-Risk Infant

Proper discharge planning will ensure a smooth transition home from the hospital both for the high-risk infant and for the family. A pre-discharge conference to review the infant's hospital course and plans for discharge will provide an opportunity to discuss the infant's progress and goals for discharge, identify risk factors for developmental challenges, assess the parents' understanding, and make clear plans for post-discharge care. In review of the infant's various risk factors, an honest but sensitive discussion about the range of possible outcomes will help put risk for neurodevelopmental disabilities into perspective. Parents should be reassured wherever possible and given opportunity to hope.

Discharge teaching includes routine well-baby care, cardiopulmonary resuscitation, use of any special equipment or medication, and anticipatory guidance about car seats, safe sleep, and other common topics. When infants are discharged on medication or equipment, parents must demonstrate safe administration of the medication and use of the equipment. A pediatrician must be identified before discharge, and the inpatient team must personally communicate all relevant data about the child's hospital

• BOX 24.1 Considerations for the Primary Care Physician Caring for the High-Risk Infant After Discharge

1. *Growth*—Monitor weight, length, and head circumference in all children and especially in children with BPD. Follow feeding skills closely.
2. *Neurosensory*—Diagnostic audiology assessment by 24 to 30 months (Harlor and Bower, 2009). Continued ophthalmology screenings and evaluation postdischarge for children with or at risk for ROP (Fierson, 2013).
3. *Immunizations*—Routine immunizations according to birth date, rather than corrected age. Influenza immunization yearly for child and caregivers. Palivizumab for all high-risk infants and young children per AAP recommendations (AAP, 2014).
4. *Neurodevelopmental*—Screen for neurodevelopmental problems, including ADHD and ASD, behavioral problems, and developmental delays.
5. *Motor*—Perform careful neuromotor examination and refer to physical or occupational therapy if not meeting milestones or abnormal examination.
6. *Learning*—Refer for evaluation for learning and executive function disorders if children struggle in school.
7. *Sociodemographic*—Assess for sociodemographic factors that may adversely impact outcomes, including parental anxiety and depression. Provide access to social supports as indicated.

course and postdischarge plans with the pediatrician. The AAP has established a policy for the screening and surveillance of developmental concerns in the primary care setting.[292] General recommendations for primary care givers who care for high-risk infants after discharge are shown in Box 24.1. Most premature infants will require ongoing ophthalmologic surveillance for progression and/or sequelae of ROP. Infants who have had complications during the hospital course may require ongoing care from various subspecialists. Lastly, all high-risk infants should be evaluated on an intermittent basis by a comprehensive developmental follow-up clinic and early intervention program. These services are an essential part of the continuum of care provided to high-risk infants and their families.

Referral for Early Intervention Services

All preterm children and high-risk children with abilities in any domain that are consistently below expectations based on their age should be referred for early intervention. Eligibility for surveillance or services for high-risk infants or children differs by geography. In the United States, the Individuals with Disabilities Education Act requires states to provide early intervention services for infants and toddlers up to 3 years of age with developmental delays and with conditions that lead to developmental delays. However, states differ in definitions of delay, standards regarding correction for prematurity, and services offered.[293]

Infants may be referred to early intervention by the NICU, follow-up clinic, pediatrician, or family. Each child who is referred is entitled to a multidisciplinary assessment and a service coordinator to facilitate the assessment and services. Early intervention programs recognize the importance of (1) viewing each child as a unique individual, (2) evaluating not only needs but also strengths, (3) including the family in the planning process, and (4) coordinating all intervention services. The choice of interventions is determined by the individual child's developmental profile and health, the needs of the family, and available resources.

Early intervention helps ensure that children reach their maximum potential but does not necessarily prevent disability.[35] Research about the efficacy of early intervention includes many different interventions, applied with different intensity, in different populations, and for different lengths of time. Hearing and visual impairments are responsive to early intervention, and early therapies can significantly improve long-term functioning and quality of life. In general, early intervention programs have been shown to have positive effects on developmental and neurologic outcomes for preterm infants during infancy and early childhood.[35] Specifically, early intervention is associated with improved behavioral outcomes, reduced anxiety and depression for primary caregivers, and cognitive benefits through preschool age. Importantly, early intervention programs focused on the parent–child relationship are more effective than programs focused on the child or the parent alone.

Early intervention has less of an impact on motor outcomes and no impact on rates of CP. However, a few recent small studies of focused, intensive, goal-oriented therapy for infants at high risk for CP have demonstrated improved motor outcomes.[294,295] No long-term studies of such interventions for infants at risk for CP have been completed to date. Thus, it remains uncertain whether any specific forms of early intervention or disability-focused therapies have significant long-term impact on functional motor outcomes at school or at home. However, once a child has a diagnosis of CP or DCD, targeted interventions are then aimed at prevention of further delay and compensating for deficits, to optimize the child's function and independence.[209] The most effective therapeutic approach to teaching motor skills to children with DCD is the task-oriented approach, which includes cognitive approaches with a focus on specific aspects of a motor skill.[296] Continued research is essential to identify the best therapies, including timing, intensity, and duration, to optimize outcomes for preterm and high-risk infants and children.

What Is Multidisciplinary Follow-Up Care for the High-Risk Infant?

Challenges of the Current State

In 2008, the AAP Committee on Fetus and Newborn released a policy statement to guide hospital discharge planning and postdischarge care for infants deemed "high-risk."[1] However, the definition of high-risk infant and the criteria for referral to comprehensive developmental follow-up vary widely, based on state and regional requirements often linked with NICU certifications or approvals, available resources in the community, and funding. Furthermore, the nature of care provided in "NICU follow-up" settings vary widely. In 2006, an expert panel from the AAP, NICHD, Vermont Oxford Network (VON), and the California Children's Services (CCS) published quality-of-care indicators for

high-risk infant follow-up, developed through a modified Delphi process, resulting in 70 indicators including general care; physical, neurosensory, behavioral and developmental, and psychosocial assessments, and many interventions.[30] Although comprehensive, the metrics and indicators are extensive, and implementation across numerous post-discharge care settings would be required in most areas, thus would be difficult to enforce. Some NICU follow-up clinics focus on neurodevelopmental and behavioral evaluation only, while others may provide truly comprehensive care encompassing primary care, complex medical follow-up and coordination as well as neurodevelopmental assessment and interventions. In reality, care for the NICU graduate is usually very fragmented, with numerous subspecialties involved due to medical morbidities, technology, and therapies; nutrition and laboratory follow-up; coordination of appointments; as well as neurodevelopmental and behavioral care, depending on the needs of the child.[297] The substantial bulk of the complex coordination, surveillance, and communication will fall to the primary care provider and parents or primary caregivers, ideally in close collaboration in the setting of a family-centered approach. The AAP has recognized and endorsed the medical home model for primary care of all children and youth, and particularly for those with special health care needs,[298,299] and certainly a medical home would serve as an outstanding family-centered location from which to optimize the patient's medical and neurodevelopmental outcomes. However, access to and engagement with a true medical home is not consistent, with disparities reported based on special health care needs and sociodemographic factors.[300–302] Clinics and teams focused more narrowly on neurodevelopmental follow-up for NICU graduates very often attempt to fill the gap around coordination at least in part. However, NICU follow-up clinics are not uniform, and themselves struggle with numerous personnel, funding, and other barriers. In a survey of NICU follow-up directors of academic (55% response rate) and private institutions (45% response rate), less than 20% reported providing primary care, many reported significant challenges in supporting needs of the most complex medical conditions, and very few reported availability of services to support financial or legal challenges for the family.[303] Others challenges reported by follow-up clinics suggest a large burden on administrative assistants to improve workflow in the setting of a lack of adequate administrative resources and frequent cancellations, limited clinic time and space to serve their patients and families, limited availability of various personnel in clinic, and substantial funding challenges.[304,305] There is also a clear recognition by follow-up clinics of the significant parent and family challenges in getting to what are often many appointments requiring time off work, and particularly for those who live at a distance from the clinic.[304] Sociodemographic, program-level, and rural residence disparities in follow-up for both very preterm and high-risk term infants have also been demonstrated.[8,306–308] Taken together, the current challenges and confusion for families, providers, and clinic systems present make consistent and comprehensive follow-up care difficult in many instances, and highlight gaps in efforts to achieve ideal support for high-risk infants and their families.

Goals for the Future State

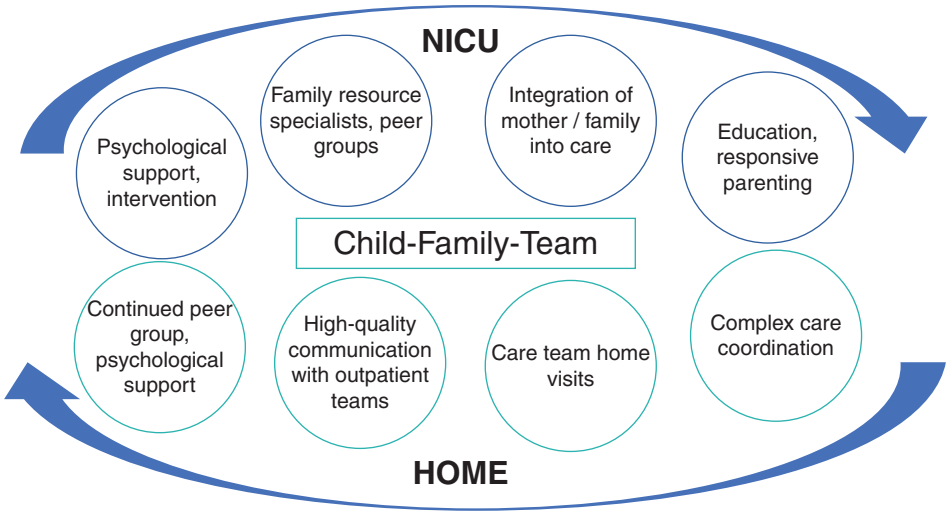
A recent perspective authored by Vermont Oxford Network (VON) leadership takes a more encompassing stance to the concept of "NICU follow-up" by proposing the construct of "follow-through" for high-risk children and their families.[309] This framework highlights the responsibility of all care providers to participate in care for the high-risk infant and their family from prenatal care through NICU to childhood and beyond. The perspective presents multiple potentially better practices (PBPs) in six categories (Table 24.2). Although implementation of the dozens of PBPs within these categories cannot be achieved for all programs in the short term, the perspective presents a clear view of the life-course challenges and barriers that high-risk infants and their families face, and the imperatives to build toward a cohesive, consistent, and equitable construct for high-risk infant follow-up care.

These broad concepts may be considered as opportunities for quality improvement efforts for high-risk infants and their families.[310] Certainly, NICU follow-up structures must continue to include serial neurodevelopmental and behavioral assessments, and the personnel and expertise to provide recommendations and interventions. However, multiple interdisciplinary connections between families, providers, and communities beginning in the NICU and continuing through childhood are needed (Fig. 24.4). Attaining this broad goal may include increasing alignment toward a comprehensive complex care outpatient model for children with special health care needs, including high-risk infants after NICU discharge. Although this type of "enhanced medical home" may

TABLE 24.2 Potential Better Practices for NICU Follow-Through

Promote a culture of equity	Establish cultural sensitivity; acknowledge and manage implicit and explicit personal biases; facilitate nurse-led rounds
Identify social risks of families and provide interventions to prevent and mitigate those risks	Screen for social determinants of health; provide support when necessary such as assistance with housing, meals, and transportation and counseling for mental health, drug or alcohol problems, or smoking cessation; include social workers and legal specialists on teams
Take action to assist families after discharge	Provide carefully tailored discharge teaching; use home visiting and social media; establish meaningful clinical-community partnerships
Maintain support for families through infancy	Use parent coaches and innovative medical visit structures; provide contraception, family planning, and high-quality obstetric care; provide evidence-based early intervention programs
Develop robust QI efforts to ensure equitable, high-quality NICU and follow through care to all newborns by eliminating modifiable disparities	Establish measurable aims; engage all disciplines, parents, and primary care providers; obtain support from organizational leaders through a formal charter
Advocate for social justice at the local, state, and national levels	Ensure that social justice is part of every organization's mission; advocate that health care organizations accept and act on their responsibility for the populations and neighborhoods that they serve; speak out!

From Horbar JD, Edwards EM, Ogbolu Y. Our responsibility to follow through for NICU infants and their families. *Pediatrics*. 2020 December;146(6):e20200360.



• **Fig. 24.4** Conceptualizing transition from NICU to home and community. (From Litt JS, Hintz SR. Quality improvement for NICU graduates: feasible, relevant, impactful. *Semin Fetal Neonatal Med*. 2021;26[1]:101205.)

be considered costly and challenging to create, and potentially not feasible in some settings, it has been shown to reduce emergency room visits, total hospital admissions, ICU admissions, number of days in the hospital, and costs.[311,312] However, even in the absence of this structure, the goal toward a connected, family-focused, continuum of care approach must be the driving goal for the future state of NICU follow-up. Achieving the best possible outcomes for high-risk infants necessarily means enveloping parents, families, physicians and providers, and community in the "follow-up" process, from early in the NICU course to discharge and well beyond. NICU follow-up programs have expanded to fill this role, engaging closely and often daily with parents and families, NICU teams, primary medical care providers, and community resources in creating parent-integrated "transition to home" programs.[313,314] Team personnel may vary depending on the approach, but involve physicians, APPs or clinical nurse specialists and educators, coordinators, clinical social workers, and peer parent, and family specialists, and include home visits as well as phone availability for some period after discharge. Programs may have differing bundles of interventions including parent education in complex and general medical care issues, nutrition, developmental progress, as well as training in community resources, positive parenting, and enhancing self-efficacy. But they have demonstrated positive results including reduced ER visits and hospitalizations, reduced Medicaid costs,[315,316] and better cognitive, motor, and symbolic communication skills at 2 years of corrected age.[317] As parents of NICU babies are at substantially increased risk for anxiety, depression, and trauma with potentially significant later impacts on child and family function, integration of parental mental health support and appropriate interventions during NICU stay and beyond is crucial.[318–321] The previous models of preventative early intervention are fortunately beginning to change, as research has demonstrated that programs with individually family-centered and home-based components, enhancing parent responsiveness and resilience, and combining child health and service support have the most comprehensive effect on outcomes.[35,322]

Challenges to and Importance of Follow-Up

In the research setting, there is a growing reliance on complete evaluation and reporting of neurodevelopmental outcomes in prospective studies and trials and an increasing and appropriate recognition that it is crucial to fully understand outcomes beyond the initial hospitalization and even beyond early childhood. Yet, the challenges of following a cohort for years or decades and the potential barriers to achieving reliable results are numerous. Long-term follow-up requires time, dedication, and persistence from both follow-up staff and from families. Achieving a high follow-up rate is essential to limit bias. Social and demographic disparities and population differences have long been shown to be associated with increased attrition,[7,305,323,324] which is of concern not only because of the potential bias introduced but also because those children and families lost to follow-up could potentially benefit most from supports and services. Questions related to generalizability of findings may be inherent, regardless of outstanding follow-up rates. Thus population-based or large regional-based cohorts may be considered the ideal model of prospective observational studies of high-risk infants. Caution is advised when comparing outcomes of different cohorts over time, because of differences in the enrolled populations and attrition rates, changes in versions of or use of different instruments, and varying approaches to use of term control groups. However, it is also important to broaden the scope of outcomes considered for study and trial endpoints beyond the traditional 2-year neurodevelopmental outcomes.[325] Inviting parents to meaningfully participate in research, from evaluating consents, questionnaires, and information documents to identifying research targets and planning studies, may also contribute to increasing the value of research to families and to the children and adults who were high-risk infants.[326]

Outside the scientific framework of follow-up for research purposes, there is a substantial *clinical* need for high-risk infant follow-up. The purpose and potential value of this difficult undertaking are manyfold. As survival of even the most extremely preterm and complex infants has improved, there is increasing recognition of the importance of neurodevelopmental outcomes, rather than short-term endpoints alone, as a measure of the impact of interventions and management strategies in the NICU. Much has been invested in assuring the survival of these high-risk infants and must be invested similarly to assure that all of these children reach their best potential. In addition to traditional quality improvement measures to decrease in-hospital morbidities that

are associated with adverse neurodevelopmental outcomes, early detection, preventive care, and intervention programs inclusive of both infants and families hold the best promise for changing the trajectory of outcomes.

Within an ecologic framework, the home environment and relationships are the most immediate and proximal influences on child development.[327] More distal factors, such as family income and broader community factors, influence children's development both directly and indirectly through interaction with other proximal environmental factors. In understanding the developmental systems approach and recognizing the profound potential to influence brain development, positive outcomes can be understood in terms of improvements in developmental pathways associated with parental sensitive–responsiveness and child participation in intensive intervention-oriented child care.[328–330]

Without a doubt, implementing a comprehensive system of NICU-to-community early and preventive interventions for high-risk infants is a time-intensive and resource-intensive undertaking. But we are unlikely to truly transform long-term care and improve the lifetime outcomes of high-risk infants without such an investment in their future.

25 The Human Genome and Neonatal Care

C.M. COTTEN

KEY POINTS

- Twenty percent of infant deaths in the United States and a larger portion of infant deaths in the NICU have been attributed to chromosomal and congenital anomalies, with the prevalence increasing with the expanded use of genetic diagnostic tools.
- Thousands of individuals have had their entire genomes or exomes sequenced and shared, along with corresponding phenotype information. This comprehensive, linked information enhances our ability to identify genetic links with previously unexplained structural and functional disorders among newborns.
- Linking genetic variations to disease is a key step to advancing understanding of pathophysiology and development which will lead to better treatment and management strategies.
- Studies evaluating use of rapid next-generation gene sequencing in diagnosis of infants with diseases of unknown etiology have begun in NICUs, and early results reveal increasingly higher rates of diagnosis with time to result now in days to weeks rather than months to years.
- Ethical issues related to incidental findings arising from sequencing must be addressed as these approaches are applied in the NICU.
- Identifying genes and variants associated with the more common complex disorders of prematurity (ROP, IVH, NEC, BPD) remains a challenge.
- Application of genomics and genetics to clinical neonatology is evolving rapidly as the prices drop and the speed of sequencing, identifying, and analyzing variants for their association with a growing number of gene-disease databases accelerates.

Within 50 years of the discovery of the double helix structure of DNA, the Human Genome Project achieved the major milestone of identifying an almost complete sequence of the approximately 3 billion nucleotides in the human haploid genome.[1,2] Advances in sequencing technology have enabled the reporting of over 100,000 complete genomes and the characterization of millions of genetic variants in millions of individuals since the publication of these single, consensus genomes. Linking genetic variations to disease is a key step to advancing understanding of pathophysiology and development which will lead to better treatment and management strategies.[3] Clinicians in neonatal intensive care units (NICUs) are partnering with experts in genetics, gaining expertise and utilizing tools such as variant panels and next-generation sequencing to diagnose causes of birth defects and other systemic disorders that become apparent in infancy. This chapter will review concepts about the human genome relevant to neonatal care providers, including (1) the approach and evolving genome-focused tools that clinicians are using to diagnose neonates with genetic disorders; and (2) a summary of work seeking to identify associations between relatively common genetic variations and complex disorders associated with preterm birth. To facilitate reading, Table 25.1 lists and defines common terms applicable to genetics and genomics in the NICU.

The Human Genome Project and the Big Picture of Genomic Medicine

The Human Genome Project was an international effort that included a focus on identifying the chromosomal location of normal and disease-causing genetic variants.[4] The international effort continues with some countries' population-based studies applying whole genome or exome sequencing to tens of thousands of individuals, mostly in relatively high-resource countries with overrepresentation of communities with European ancestry.[5] The Global Genomic Medicine Collaborative (G2MC) was formed in 2015 to facilitate implementation of genomic medicine worldwide to improve individual and population health, with the imperative for inclusion of geographic and population diversity.[6] More global efforts in accumulating cohorts with extensive genomic information have begun,[7] and the G2MC has prioritized the need for provider education programs, as this is likely to be a rate-limiting step in appropriate allocation and utilization of genomic testing.[8]

By participating in collaborative efforts, clinicians and researchers have published studies of comprehensive views of genetic variation for thousands of individuals with type 2 diabetes, breast cancer, or traits such as height or birth weight. These collaborative international efforts have created the framework for one of the greatest successes of the Human Genome Project—that is, information generated relevant to the human DNA sequence and its variation, held in public trust with open access to the scientific community through dozens of accessible databases and analytic platforms.[9]

One major hub for clinicians that contains both clinical and scientific descriptors of genetic findings on a disease basis is located on the website Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim/)—a comprehensive catalogue, updated daily, of more than 16,000 described genes, including the ever-growing total of over 7000 genes with phenotyping associations with a known molecular basis, and over 4500 genes with phenotype-causing mutation.[10] The online version, a compendium of human genes and genetic phenotypes, also provides links to online resources that provide information about genetic variants, their

TABLE 25.1 Glossary of Terms Used in Genetics and Genomics

Allele: variant form of a gene at a certain locus

Autosomal: gene is located on one of the numbered (nonsex) chromosomes

CNV: copy number variant)– INDELS (insertions/deletions)

Curation: a term used to describe the analysis of the existing data and evidence about a specific gene or gene variant and its relation to a specific phenotype

Exome: the sum of all exons (coding sequence, splice sites, 5′ and 3′ UTRs, miRNAs) in the genome ~ 50 Mb or 2% of genome)

FISH: fluorescence in situ hybridization (FISH), which determines the presence or absence of discrete segments of DNA

Genome-wide association: in studies testing thousands or millions of variants for association with a phenotype, the statistical standard for likelihood a variant contributes to risk of the condition in question. In genome wide association studies (GWAS) is often set at $p < 10^{-8}$

Heritability: a quantitative measure of the extent to which genetic factors account for phenotypic variance

Human Genome: 3 billion nucleotides, with approximately 25,000 genes (+ 2× more highly conserved regions)

Linkage: cotraveling of alleles usually near one another—when you find one, you usually find the other; multiple alleles traveling together would be haplotype

Locus: position on a chromosome

NGS: next-generation sequencing, which includes whole exome sequencing (WES), and whole genome sequencing (WGS)

SNP: single nucleotide polymorphism, a variation in gene sequence that is the most common type of genetic variation among people. On average, each person has 4–5 million SNPs in their genome; about one occurs every 1000 nucleotides

VUS: variants of unknown significance

associations with disease, and multiple other aspects of these genes such as their commonality across species and the differences in variant prevalence between populations of different ancestry, proteins and variations in protein structures, and which genes are in which biological pathways (http://omim.org/help/external; www.ncbi.nlm.nih.gov/omim/).

The Clinical Sequencing Exploratory Research (CSER) Consortium, funded by the National Human Genome Research Institute (NHGRI) and the National Cancer Institute (NCI), is exploring analytic and clinical validity and utility, as well as the ethical, legal, and social implications of sequencing via multidisciplinary approaches.[11] OMIM also includes a link to ClinVar, a freely accessible, public archive of reports of the relationships among human variations and phenotypes, with supporting evidence (https://www.ncbi.nlm.nih.gov/clinvar/intro/). These and some of the other online tools that provide information about genetic variations and links to phenotypes are listed in Table 25.2.

TABLE 25.2 Online Genomics Resources

ACMG Recommendations for Reporting of Incidental Findings in Clinical Exome and Genome Sequencing https://www.ncbi.nlm.nih.gov/clinvar/docs/acmg/. Annually updated minimum list of genes that should be evaluated in individuals undergoing clinical ES/GS based on the medical actionability of the associated condition

ClinGen: a National Institutes of Health (NIH)-funded resource dedicated to building a central resource that defines the clinical relevance of genes and variants for use in precision medicine and research: https://clinicalgenome.org/

ClinVar: freely accessible, public archive of reports of the relationships among human variations and phenotypes, with supporting evidence: https://www.ncbi.nlm.nih.gov/clinvar/

Database of Genotype and Phenotype (dbGaP): an archive of data from genome-wide association studies on a variety of diseases and conditions accessible through this NCBI: https://www.ncbi.nlm.nih.gov/gap/

DECIPHER: a database of reported copy number variants and linked phenotypes: https://decipher.sanger.ac.uk/

Ensembl: a genome browser for vertebrate genomes that supports research in comparative genomics, evolution, sequence variation, and transcriptional regulation. Ensembl annotates genes, computes multiple alignments, predicts regulatory function, and collects disease data: https://www.ensembl.org/index.html

GeneMatcher: web site that enables connections between clinicians who have a patient with a candidate or ultra-rare gene and researchers who have an interest in that gene: https://genematcher.org/

GeneReviews: a clinical resource for many genetic conditions that provides clinically actionable information including diagnosis, inheritance, and management as well as a differential diagnosis of related conditions: https://www.ncbi.nlm.nih.gov/books/NBK1116/

GenomeConnect: GenomeConnect is an online registry designed by the Clinical Genome Resource (ClinGen) for people who are interested in sharing de-identified genetic and health information to improve understanding of genetics and health: https://www.genomeconnect.org/

Human Phenotype Ontology (HPO): a standardized set of phenotypic terms; a widely used resource for capturing human disease phenotypes for computational analysis to support differential diagnostics: https://hpo.jax.org/app/116

Online Mendelian Inheritance in Man (OMIM): a searchable database of clinical features, phenotypes, and genes: https://omim.org/

Unique: a website with patient-/family-facing resources regarding chromosome and gene disorders: https://www.rarechromo.org/

University of California Santa Cruz Genome Browser: a website created initially to ensure public access to the initial human genome assembly, has now evolved to include a broad collection of vertebrate and model organism assemblies and annotations, along with a large suite of tools for viewing, analyzing, and downloading data: https://genome.ucsc.edu/

VVP (VAAST Variant Prioritizer) rapidly prioritizes genetic variants: https://github.com/Yandell-Lab/VVP-pub

The Genome and Genomics

Genetics focuses on the study of single genes and their effects. Genomics is defined as the comprehensive study of the functions and interactions of all the genes in the genome. The Human Genome Project provided key information about the genome. It quantified the total number of base pairs (approximately 3 billion), defined genes, and provided more information about how genomic DNA might be classified.[1,2] The genomic DNA of

eukaryotic organisms includes exons (regions of DNA that are "expressed," or translated into protein) and introns (intervening regions not translated into protein). Despite their apparent importance, exons account for less than 2% of the DNA in the entire genome. The regions outside of the exons are increasingly recognized to play critical roles in how and when the genes are expressed. The definition of what a "gene" is changes regularly as we learn more about distant regulatory elements, DNA modifications, chromatin structure, gene/gene interactions, exon skipping, post translational modification, and a host of other factors that determine what a "gene" does.

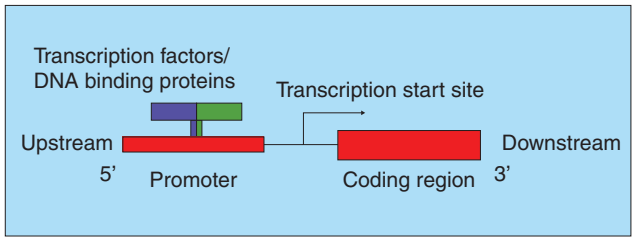
Understanding how conserved "noncoding" sequences influence human health and disease continues to be an important area of study. Even before the sequencing of the complete human genome, we knew that there were regulatory regions of the genome close to exons, sometimes called promotor regions. These are sites where transcription factors can bind to "turn on" or "turn off" a gene's expression. The regulatory region is usually a different set of base pairs than the actual transcription start site where transcription of mRNA is initiated. We also know that certain combinations of mRNA result in "stop codons," marking the point in the sequence where transcription stops (Fig. 25.1).

https://www.ncbi.nlm.nih.gov/Class/MLACourse/Modules/MolBioReview/alternative_splicing.html[12]

In addition to describing functional aspects of the genome, the origins of the human genome are also intriguing. Almost half of the genome is derived from foreign DNA.[1] These entered the genome via germ cells as transposable element DNA, first described in maize by Barbara McClintock.[13] Interestingly, we have learned that approximately 8% of the intronic base sequences are the products of human endogenous retroviruses (HERVs). The segments are DNA-based copies of their own viral RNA genetic material inserted into the human genome over millennia.[14] Evidence is accumulating to suggest a potential functional role of these HERVs in numerous pathologies including neurodegenerative diseases, autoimmune disorders, and multiple cancers.[15]

As our understanding of the genome has expanded, we know that many more RNAs and proteins can be made from the DNA in the genome. While approximately 20,000 protein-coding genes are known, the principle of alternative splicing (i.e., mRNA comprised of different exons from the same gene coding different proteins) increases the estimate of the number of proteins from the 20,000 one would imagine to well over 100,000. This is particularly important in the developing neuronal system, in which over 90% of multiexon genes are alternatively spliced throughout development (Fig. 25.2).[16–20]

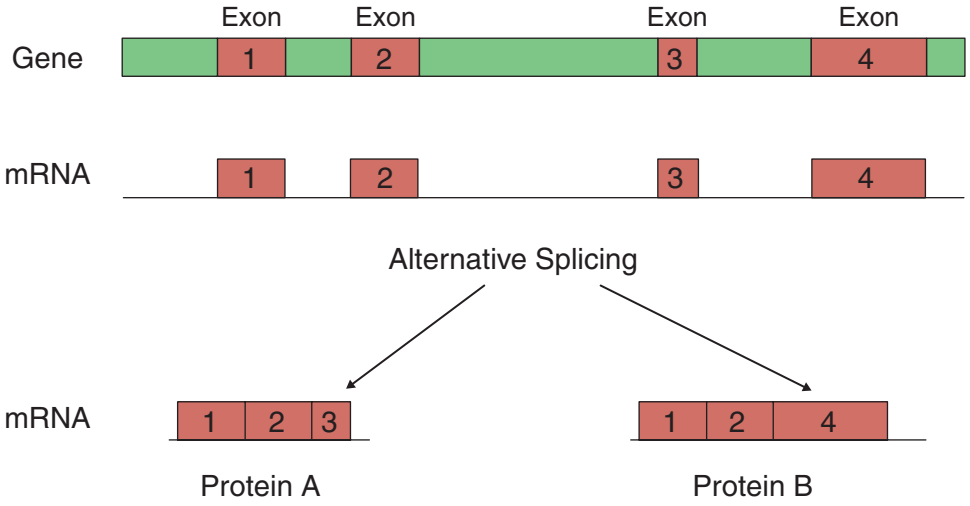
https://www.ncbi.nlm.nih.gov/Class/MLACourse/Modules/MolBioReview/alternative_splicing.html[12]



• **Fig. 25.1** Gene Control: Regulatory Regions. A diagrammatic depiction of gene structure, incorporating the exon, or coding region, as well as the promoter region, which is intronic, but key to a gene's function.[117] (https://www.ncbi.nlm.nih.gov/Class/MLACourse/Modules/MolBioReview/gene_control.html.)

Mitochondrial Deoxyribonucleic Acid

Mitochondria are the energy-processing organelles within each cell. Each mitochondrion has its own genome, distinct from the nuclear genome and thought to arise from incorporation of bacterial DNA. The mitochondrial genome is approximately 16,500 base pairs in length and encodes 37 genes. A wide range of disorders have been associated with variation in mitochondrial sequence. In addition, because mitochondria reside in the cytoplasm and are not found in sperm, they have a unique pattern of maternal-only inheritance, in which mothers pass their mitochondria on to all their offspring, with the daughters then passing their mothers' mitochondrial DNA on to subsequent generations. The knowledge that variants in mitochondrial DNA can cause disease plus the progress made in techniques for molecular and cellular manipulation have led to embryonic mitochondrial transplantation, where "healthy" mitochondria are transplanted into



• **Fig. 25.2** Alternative Splicing. A single gene can produce multiple related proteins, or isoforms, by means of alternative splicing of different exons from the same gene.[117,118] (https://www.ncbi.nlm.nih.gov/Class/MLACourse/Modules/MolBioReview/alternative_splicing.html.)

the cytoplasm of an early-stage embryo identified to have a lethal mitochondrial variant.[21,22]

Variations in the Human Genome

Genetic variations are differences in the DNA sequence and structure among individuals. Variant types include single nucleotide polymorphisms (SNPs), copy number variants (CNV), insertions and deletions (indels), polymorphic repeats, and microsatellite variants. Additionally, there are differences in the amount of chromosomal material, termed aneuploidies.

Single Nucleotide Polymorphisms

Single nucleotide polymorphisms (SNPs) were the first commonly characterized contributors to human genetic variation. SNPs are specific nucleotide sites in the human genome, where it is possible to have two (or even three or four) different nucleotides at a specific position on a chromosome. For example, there might be either a T or a G at a specific point in an individual's genomic sequence, with differences in populations in which 40% of the individuals have a T at the specific locus, and 60% have a G. These variant sites are common, with up to 1% of the 3 billion base pairs of human DNA sequence varying between any two individuals, resulting in millions of SNPs across the genome. Most variation is found across all human populations, although some variants appear to be highly population or ancestry specific. Chip-based DNA sequence detection allows assays of greater than 1 million SNPs simultaneously on one individual at a cost approximating $100. Since 1999 over 500 million SNPs have been catalogued in the online public-domain resource, the Single Nucleotide Polymorphism database (dbSNP: http://www.ncbi.nlm.nih.gov/snp). The vast majority of SNPs do not appear to be disease-causing, although they may lie adjacent to DNA changes that do contribute to disease predisposition and can be detected using the phenomena of linkage disequilibrium, in which the genotype of one SNP correlates highly with the genotype of nearby SNPs.[23]

Copy Number Variants

Copy number variants (CNVs) are another form of genetic variation that can contribute to inherited disorders. Although both small and large deletion and duplication events in human DNA sequence have been known since the 1970s, only recently has the widespread role that these play in disease been recognized. CNVs can range in size from a few nucleotides to thousands of base pairs in length, resulting in the possibility that two healthy people have genomes with total numbers of base pairs that differ by millions.[24] These variations may contain one or multiple genes that can exist in two, three, or more copies arrayed in tandem at particular chromosomal positions. When these tandem arrays of largely identical sequences align themselves during meiosis, there is occasionally a misalignment that can result in deletion or duplication of one or more of the copies. This event in turn can create a range of the number of copies present from zero to many.[25] When functional genes are contained within the copied or deleted element, the amount of gene product made may be higher or lower than a reference level.

Examples in which CNVs contribute to disease include the Di George syndrome 22q-deletion and deletions associated with spinal muscular atrophy (SMA) and Charcot-Marie-Tooth disease. Microdeletion syndromes are now characterized with great precision using array-based DNA analysis. The recognizable syndromes with an identifiable phenotype such as 22q- and 15q11–q13 associated with Prader-Willi and Angelman syndrome, are complemented by rare deletion or duplication events that result in congenital anomalies, developmental delay, or both, and where their etiologic nature can be inferred from the normal structure of the parental chromosomes. Microdeletion duplication events are also a likely explanation for the sometimes sporadic, as well as familiar, nature of disorders such as autism.

CNVs are estimated to cause approximately 10% of all known variant-contributed disease. Chromosomal microarrays have become the most commonly used clinical test to identify CNVs.[26] Despite their importance, technical and clinical issues related to their identification and meaning must be resolved given their prevalence among healthy individuals and uncertainty regarding disease causation when a CNV in a genomic region is found in a patient with a specific phenotype with no clear link between genes involved and the patient's presentation.[27–29]

Variant Counts in Individuals

In the years since completion of the human genome map, the number of identified variants in the map has exploded. In 2015, results of the 1000 Genomes project were published. The report provided information from whole genome sequencing of over 2500 individuals of varying ancestry and identified over 88 million variants. Almost 85 million of the identified variants were SNPs, 3.6 million were insertion/deletions, and 60,000 were structural variants. Approximately 64% of the autosomal variants identified across all individuals had population frequencies of less than 0.5%. Many of these were observed to be much more common in at least one specific geographically defined ancestry group. A "typical" single individual was likely to have 4 to 5 million variants, with most being SNPs and short insertion/deletions, with only 1 to 5% of these (40,000 to 200,000) being "rare variants" with a frequency less than 0.5% in the population. Most of the identified variants do not appear to be linked with disease, either by being predicted as protein-truncating variants or peptide-sequence altering variants, or variants overlapping known promotor regions or other functional genomic regions.[30]

Linking Genes and Diseases

One hundred and one years prior to the sequencing of the human genome, Archibald Garrod hypothesized that alkaptonuria, which he noted to occur at high prevalence among children born to parents who were first cousins, was likely a disorder of metabolism inherited according to Mendel's laws of heredity. It was the first disorder in humans attributed to what would become genetics. He also noted that the chemical basis for darkening the urine could be a sign of human biological diversity, one which could be harmless, but for other traits, might be manifest in lethal disease. He coined the term "inborn errors of metabolism" to describe diseases caused by errors and variations in chemical pathways.[31,32]

Over the next hundred plus years, facts about DNA and its impact on human development and disease have come to light, including the identification of the double helix as the structure that allows for transcription and translation.[33] Since then, we know that the estimated gene number located on the 23 human chromosomes has been clarified to be approximately 20,000, with only 2% to 3% of the base pair composition of DNA comprising

specific protein-encoding sequences, or exons, while the vast majority of base pairs are considered "introns."[12] From this basic material, normal and abnormal development occurs.

We estimate that 5% to 10% of newborns have suspected disease-causing chromosomal disorders. For decades, 20% of infant deaths in the United States, and a larger portion of infant deaths in the NICU, have been attributed to chromosomal and congenital anomalies. With the expanded application of genetic sequencing linked with powerful informatics tools, prevalence of genetic variant-linked disease is increasing.[34–38] In addition to mortality risk, infants with complex congenital anomalies and chromosomal disorders who survive beyond the first days are vastly overrepresented among hospitalizations in pediatric wards and intensive care units. Affected children are hospitalized more often, and have hospitalizations that are longer and more expensive than children without underlying chromosomal anomalies or congenital defects.[39–42] As more genetic variants are linked with disease, our hope is that our ability to provide care based on better understanding of the pathophysiology of the disease, and susceptibility to complications that arises from awareness of the genetic variations at the heart of the problem will guide preventive and treatment strategies that will improve outcomes.[43]

Making a Diagnosis in the Post Human Genome Era

In infants suspected of having a genetic disease, knowing the etiology can inform subsequent care, both for treatment and prevention of problems associated or anticipated.[44] The broadening availability and reductions in cost of sequencing since completion of the Human Genome Project have increased the availability of extensive sequencing and has led to questions of when such sequencing should be done relative to more familiar testing including karyotypes and chromosomal microarray.[45] Of note, this will continue to be examined and change, as we are likely less than a decade away from a cost of only $20 to sequence the entire genome.[46]

Tools most commonly used for genetic testing include approaches that assess the amount, structure, and sequence of an individual's genome (Table 25.3). Traditionally, genetic testing began with a karyotype, providing information on chromosomal quantity and structure, and at times, a very targeted sequencing of specific regions and genes that the clinician had rounded up as the usual suspect gene(s) for a given phenotype. These first-line tests included a karyotype, and/or fluorescence in situ hybridization (FISH) testing for aneuploidy, or other chromosomal anomalies such as chromosomal rearrangements and large gains and losses in chromosomal material.

Currently, clinicians often order a karyotype and chromosomal microarray (CMA), with CMA able to identify specific variants as well as CNVs and much higher resolution gains and losses in genetic material such as insertions and deletions (indels).[47] CMA are used to assess infants with multiple anomalies (including verifying suspected aneuploidies). Much progress has come as the CMA has evolved to include oligonucleotide and single nucleotide probes that identify both single nucleotide variants as well as CNVs (including microduplication and microdeletion syndromes with high sensitivity and specificity). Today, CMAs may identify up to 20% of potentially causative genetic variations which have previously been associated with disease phenotypes.[47] This traditional, step-by-step approach is in transition as the cost and time to complete whole exome and whole genome sequencing are both rapidly decreasing, but not so drastically as to eliminate the utility of karyotype, microarray, and use of specific gene and variant panels.[48]

TABLE 25.3 Testing for Chromosomal and Molecular Syndromes

Test	Discoverable Aberrations	Clinical Indications
Karyotype	Large structural changes, aneuploidies, translocations, large insertions and deletions	Suspicion of chromosome syndrome Infertility or recurrent miscarriage Rule out structural variant after microarray finding
FISH (fluorescent in situ hybridization)	Specific probes used to identify aneuploidies, copy number variants, translocations, inversions, insertions	Prenatal or postnatal tests for suspected aneuploidies or deletions/insertions
SNP Array (single nucleotide polymorphism array)	Copy number changes associated with unbalanced structural changes Regions of homozygosity	Congenital anomalies, intellectual disabilities
NGS Panel (next-generation sequencing panel)	Single nucleotide variants, indels, copy number changes	Phenotype specific gene panels (hypotonia, seizures, etc.)
WES (whole exome sequence)	Variation in exon sequence, to individual variant level, may miss indels	Suspected genetic-related disease phenotype
WGS (whole genome sequence)	Tests the order of all the nucleotides in an individual's deoxyribonucleic acid and can determine variations in any part of the genome. Captures most indels	Suspected genetic-related disease phenotype

Adapted from Lalonde E, Rentas S, Lin F, Dulik MC, Skraban CM, Spinner NB. Genomic diagnosis for pediatric disorders: revolution and evolution. *Front Pediatr*. 2020;8:373. doi:10.3389/fped.2020.00373.

Clinical Application of Next-Generation Sequencing

Whole exome sequencing (WES) and whole genome sequencing (WGS) are now being applied clinically. Initially, approximately 10 years ago, due to cost and time to return results, WES and WGS were used only in cases where a genetics cause was suspected but where karyotyping, FISH, or chromosomal microarray with CNV analysis did not provide a specific answer for the clinical phenotype. The potential for NGS to reduce the time to diagnosis and meaningfully redirect care was clearly demonstrated in one of the first case reports of use of extensive exome sequencing to

identify a specific disease-causing variant leading to a change in treatment, dramatically altering a child's course. The 15-month-old male patient first presented at 15 months of age with failure to thrive and a perianal abscess. The child was treated for months with presumptive diagnosis of Crohn disease. His fistulae persisted, and he underwent a colostomy. The child was treated with multiple medical regimens for several years, including with cyclophosphamide. Simultaneously, he underwent extensive immunologic function testing, specific genetic testing for known defects, and CNV assessments suggested by experts, but all were negative. Ultimately, given the complexity of his course, the lack of an identified diagnosis after multiple tests, and his poor prognosis, the care team decided to take the relatively newly available agnostic approach to try to identify a causative mutation, and used 5 micrograms of the patient's DNA to sequence exons from approximately 180,000 protein coding exons and 700 miRNA exons. Exome sequencing identified 16,124 variants. Further analysis identified a novel, hemizygous missense mutation, a G to A substitution at a highly conserved position, in the X-linked inhibitor of apoptosis gene (XIAP), resulting in a hemizygous cysteine to tyrosine amino acid substitution. The team reporting the case did not find this variant at this position in a search of over 2000 human control sequences or in orthologous genes from other species, a key step in the analysis to identify potentially pathogenic variants. Functional assays demonstrated pathology consistent with disease phenotype, and maternal testing confirmed her as a carrier. Based on the findings, an allogeneic hematopoietic progenitor cell transplant was performed to prevent the development of life-threatening hemophagocytic lymphohistiocytosis, in concordance with the recommended treatment for X-linked inhibitor of apoptosis deficiency. Six weeks post transplant, the child was able to eat and drink, and had no recurrence of gastrointestinal disease.[49]

Since this landmark report, multiple groups have tested the utility of NGS in children. These NGS studies rely on rapidly evolving genetic sequencing methodologies and advanced automated analysis of rapidly accumulating genotype and linked phenotype data. These groups use either selected panels of genes, or the entire genome (WGS), or selectively sequence the exons that make up the vast majority of the genes in the genome (WES). Sequencing is followed by in silico analysis, or analysis by a computer, comparing the generated sequence against a reference human genome to identify variants. Variants are further analyzed with tools that predict protein structure and function that would result from the sequence change, and assess their frequency in populations of varying ancestry. With this information, plus the growing information about genes identified to be disease causing, variants can be labeled using standard nomenclature on a 5-point scale as pathogenic, likely pathogenic, a variant of unknown significance (VUS) or likely benign, or benign. This is usually followed by review by experts in the disease phenotype and by genetic epidemiologists to affirm the classification for the variant in particular infants. The overall process, inclusive of the in silico analysis and expert review of the sequence variants relative to the phenotype, is sometimes called "curation."[48]

Because there are multiple software tools to do this type of analysis, there can be discrepancies in how different reporting laboratories classify variants.[50] The effort to build consistency into up-to-date classification of the gene-disease and variant-disease relationship is through the efforts of the NHGRI-funded Clinical Genome Resource (ClinGen).[51] ClinGen has developed tools to evaluate clinical validity of gene-disease associations and pathogenicity of genetic variants for use in clinical care. ClinGen's work is made publicly available via another resource, ClinVar, the NCBI archival database that aggregates information about genomic variation and relationships to health that are provided by researchers, clinical sequencing laboratories, expert groups, clinics, and patient registries. While single investigators may submit a variant suspected of association with specific disease, ClinVar submissions are scored based on the number and types of sources submitting the same data, and validation by working groups and expert panels that examine the genetic epidemiologic evidence as well as supportive evidence from experimental model systems. These curations, as well as user interfaces, are constantly evolving, as data from multiple sources becomes available for consideration by expert panels.[52,53] The ClinGen website (https://clinicalgenome.org/) includes lists and links to the over 20 working groups and over 30 variant curation panels, links to multiple educational modules, and publicly available browser tools. Data continues to accumulate, and the number of expert panels that have been trained using ClinGen programs is also growing, with the aim to decrease heterogeneity of interpretation about significance of gene/variant/disease associations.[54,55] Clinicians should be aware that although data does continue to accumulate, recent reports indicate that some discordance among the experts can exist. In one study, 17 of 158 variants tested for consistency of classification had a discordance that could affect clinical recommendations (pathogenic or likely pathogenic vs. VUS, likely benign or benign).[56] In addition to these variations in classifications, sequencing and curation may not identify a variant, but the test may be negative because of technical limitations of testing, or because the affected gene–disease relationship has not been described. Also, some disorders, like those from epigenetic alterations like Prader–Willi or Beckwith–Wiedemann syndrome, or repeat disorders like congenital myotonic dystrophy, may not be diagnosed.[48]

Despite its limitations, NGS testing in infants and children with suspected but previously undiagnosed genetic disease suggests that utilization of deeper sequencing is likely to lead to diagnoses more often, and more rapidly, than previous incremental approaches.[57–59] In a report on 307 infants from three tertiary centers in Shanghai, China, WES or sequence panels identified pathogenic genetic etiologies in over 40% of the patients, including genetic etiologies in over 60% of the infants who died during the study's 180-day follow-up period. Of note and indicative of the importance of selection criteria for which babies to test with NGS, infants in the study cohort who exhibited integument, complex immune-related conditions, metabolism, and nervous system signs had higher chances of carrying variants in known disease-causing genes.[60]

The next step for clinical application of NGS is using either full WES or WGS with a rapid (days rather than weeks) turnaround time for results linking phenotype to identified sequence variation. A recent meta-analysis of 37 studies compared diagnostic rates of WES and WGS with chromosomal microarray in children and concluded that WGS/WES should be considered as a first-line genetic test, based on the greater diagnostic and clinical utility of both, when compared to CMA (<20% diagnostic yield). Interestingly, this analysis found that the diagnostic utility of WGS (41%) was similar to WES (36%). Additionally, the meta-analysis of studies, inclusive of over 20,000 children and published between 2011 and 2017, found that availability of parental samples for "trio" analysis of WES and WGS and hospital-based interpretation enhanced diagnostic utility.[58]

Initial studies in the NICU patient population have thus far reported successful outcomes, quoting WGS diagnostic

percentages of 42% to 57%, clinical management alterations (as a result of the diagnosis) in 30% to 72%, and change in outcomes experienced by 24% to 34% of patients in the studies who receive rapid WGS.[57,59,61,62]

The NIH-funded "Newborn Sequencing In Genomic medicine and public HealTh" NSIGHT1-randomized controlled trial (NCT02225522) aimed to enroll 1000 critically ill infants less than 4 months old with illnesses of unknown etiology to determine if rapid (26 hours) whole-genome sequencing (rWGS), followed by variant interpretation utilizing American College of Medical Genetics guidelines for pathogenic and likely pathogenic classifications, increased the proportion of infants who received a genetic diagnosis within 28 days compared to standard genetic tests including newborn screening (included in analysis for both groups), chromosomal testing (karyotyping, FISH), CMA, tests of methylation and CNVs, metabolic testing, and nonexpedited targeted genotyping or sequencing.[63] In this study, the next-generation (nextgen) sequencing approach utilized did not detect CNVs and structural variants. The study was terminated early, after 65 infants (64 in the NICU) were enrolled, because approximately 80% of the control infants received sequencing as a standard test as nonexpedited WGS became available as a standard diagnostic test during the study, and 5 of the control infants received "compassionate cross-over" to rWGS. For the primary outcome, 10 of 32 infants randomized to rWGS, and 3 of 33 infants randomized to standard testing were diagnosed within 28 days. Among infants enrolled in the first 25 postnatal days, 7 of 22 infants randomized to rWGS were diagnosed within their first 28 postnatal days while none of the infants randomized to standard testing had a diagnosis by postnatal day 28. Overall, 41% of the rWGS infants were diagnosed with a genetic disease, and 24% of the infants limited to standard testing ended the study with a genetic diagnosis. It is important to note that 5 (33%) of 15 diagnoses by standard tests would not have been detected by rWGS due to copy number or structural variants ($n = 4$) or a change in DNA methylation ($n = 1$). Also of note, the study protocol required confirmation of rWGS genotyping results by another method prior to clinical reporting except in cases where life-threatening progression was imminent. De novo rather than inherited variants accounted for more than half of the causative or likely pathogenic variants. Importantly, management changed for 10 of the 21 infants with diagnoses.[64]

The increasing availability of sequencing panels (Table 25.4) for certain phenotypes, and WES and even WGS during the study period changed the definition of "standard tests," which contributed to the early termination of the study. These factors, along with the growing list of validated genes and variants identified to be associated with or causative of disease which increases the potential clinical impact of utilizing sequencing in the NICU, led the study group to implement the second Newborn Sequencing in Genomic Medicine and Public Health study (NSIGHT2; NCT03211039), a randomized trial comparing rWGS to rapid whole-exome sequencing (rWES) in infants at a single tertiary center with diseases of unknown etiology admitted to pediatric or neonatal intensive care units.[64]

The NSIGHT2 study aimed to compare diagnosis of genetic disease obtained by rWGS or rWES, and to compare analysis of only the proband's sample with analysis using familial trios. The study team did not randomize enrolled infants who were identified as "gravely ill" but provided them with ultra-rapid whole-genome sequencing (urWGS). Genetic diseases were diagnosed by identification of pathogenic or likely pathogenic variants in genes known to cause diseases with similar presentations to those observed in study infants. For NSIGHT2, infants <4 months of age, with time from admission or time from development of a feature suggestive of a genetic condition of <96 hours were eligible. Exclusion criteria included infection or sepsis with normal response to therapy, prematurity alone, isolated unconjugated hyperbilirubinemia, hypoxic-ischemic encephalopathy with a precipitating event, a previously confirmed genetic diagnosis that explained the condition, isolated transient neonatal tachypnea, and nonviable neonates with modified code status. In this study, different from NSIGHT1, initial genomic interpretation was done on the proband alone. If no diagnosis was made in singleton analysis, the infant was reanalyzed as a trio. In this study reflecting technology advances since NSIGHT1, molecular methodologies for WGS and WES could detect CNVs and indels. Analysis, interpretation, and reporting required an average of 6 hours of expert effort. If rWGS or rWES established a provisional diagnosis for which a specific treatment was available to prevent morbidity or mortality, this was immediately conveyed to the clinical team. Of note, and always an issue when considering WGS or WES in the clinical realm, secondary findings such as variants linked with adult-onset disease risk were not reported, but medically actionable incidental findings were reported if families provided consent to receiving this information.[65]

Consistent with the goal of studying WGS and WES as a first-tier test in infants in the first 4 postnatal months—a group estimated to have a relatively low population pretest probability for a genetic diagnosis—almost half of the infants admitted to ICUs during the study period were identified as eligible. Two hundred thirteen were ultimately enrolled (37%). Ninety-four infants were randomized to receive rWGS and 95 infants to receive rWES. Overall, 24% of these infants received a genetic diagnosis. Diagnostic performance (19% vs. 20%) and time to result (11.0 vs. 11.2 days) were quite similar for rWGS and rWES. Among the 24 critically ill infants who had urWGS, 11 (46%) received a diagnosis and median time to result was 4.6 days. No infant received a false positive result. One rWGS infant's diagnosis would have been missed had he been randomized to the rWES group. More than half of the identified variants were sequence variants, and the others were CNVs or structural variants, or small insertions or deletions. More than half of the variants were de novo. Diagnostic yield was improved for only 1 of 147 infants by analyzing the trio in addition to the proband; however, for infants in the urWGS group, trios were genotyped to eliminate the time needed for confirmatory sequencing of the identified variants in the proband plus parents which was done for infants in the rWES and rWGS groups.[65] In addition to the diagnostic endpoints, participating clinicians perceived high clinical utility and low likelihood of harm with first-tier rapid genomic sequencing of infants in ICUs with diseases of unknown etiology. The rapid sequencing and delivery of results was perceived as beneficial irrespective of whether results were positive or negative.[66]

In addition to the groundbreaking single center NSIGHT studies, two multicenter studies of the application of NGS have been focused in the NICU: (1) the NICU-Seq study (NCT03290469) and (2) the GEMINI study (NCT03890679).

NICU-Seq (*NICUSeq: A Trial to Evaluate the Clinical Utility of Human Whole Genome Sequencing [WGS] Compared to Standard of Care [SOC] in Acute Care Neonates and Infants)* completed enrollment in 2020. Investigators at five centers enrolled infants to receive either SOC testing as determined by the site clinical team, or clinical whole genome sequencing (cWGS). Upon enrollment, each proband was randomly assigned to the 15-day cWGS group or the SOC group. A time-delayed study design was used to ensure that all participants received access to WGS. The experimental cWGS group received results of the cWGS at 15 days while undergoing standard care, and the SOC group received cWGS results at 60 days while undergoing SOC. Eligible patients were up to 120 days of age, with a suspected genetic disease based on objective clinical findings. At least one biological parent was required for participation. Exclusion criteria included an established genetic diagnosis, high clinical suspicion for aneuploidy, or full explanation of the patient's phenotype by complications of prematurity. Three hundred and fifty-four subjects, 176 infants in the early arm and 178 in the delayed arm, were enrolled over 19 months. The mean participant age at enrollment was 15 days. More than 80% of patients were in the NICU at time of enrollment. The rate of infants with molecular diagnosis by 60 days was higher among those in the 15-day cWGS group compared with SOC testing (31% vs. 15 %). At 60 days, twice as many infants in the early group versus the delayed group received a change of management (COM, the study's primary outcome), 21.1% versus 10.3%. By 90 days, after the SOC group's cWGS results were known, 28% of the SOC infants had COM. No differences in hospital length of stay or survival were observed. Usual-care testing during the observation period varied substantially by site, ranging from karyotyping to WGS, with negative microarray testing making up the majority of test results. Overall, approximately two thirds of the infants with a genetic diagnosis had a COM, approximately one-fourth of the entire study cohort. One infant in the early group was diagnosed by WGS with Wiskott-Aldrich syndrome (OMIM 301000) and received a corrective bone marrow transplant. Another infant, enrolled in the delayed group at 11 postnatal days with epilepsy, was ultimately diagnosed by WGS with an unsuspected *KCNQ2* (OMIM 602235) variation. Her ongoing metabolic work-up was stopped, and ineffective administration of pyridoxine was discontinued. WGS revealed a wide range of causal variant types, including terminal and interstitial chromosomal copy number variants, complex compound heterozygous variants, mitochondrial variants, and SMN1 copy loss leading to spinal muscular atrophy. The study team concluded that their findings demonstrate that WGS leads to focused, and therefore improved, patient care and should be considered as a primary tool in the assessment of critically ill infants with a suspected genetic disease.[67]

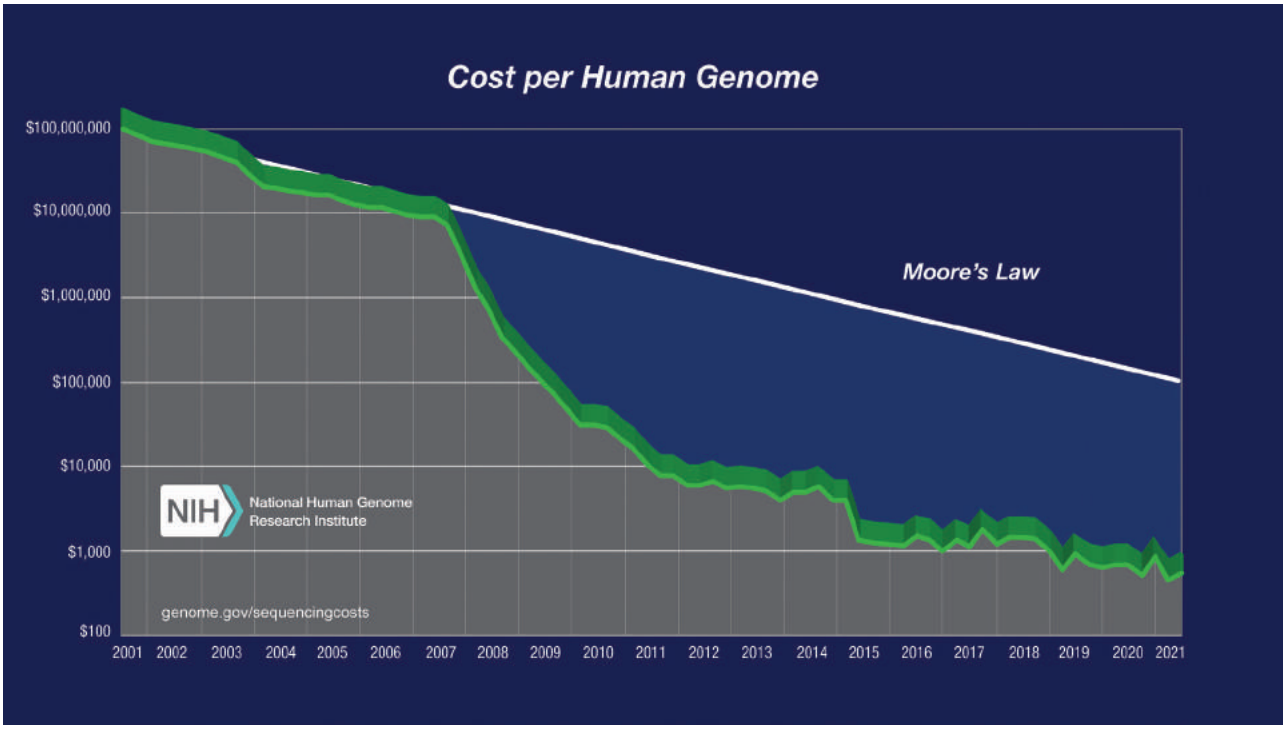
The GEMINI study *(Genomic Medicine for Ill Neonates and Infants*) aims to compare the clinical and economic utility of performing rapid whole genomic sequencing versus a targeted genomic sequencing panel (NewbornDx, which sequences 1722 actionable genes targeting disorders presenting in infancy) on 400 high-risk neonates and infants at 6 hospitals who are suspected of having a genetic disorder. The infants will be up to 1 year of age, with signs and symptoms of a genetic disorder. Exclusion criteria include already having a known genetic diagnosis, having a major congenital anomaly associated with a chromosomal anomaly

detected on prenatal testing, presence of a congenital infection or being nonviable because of extreme prematurity. Infants will undergo NewbornDx and rWGS (proband) testing. The biological parent(s), when available, will undergo NewbornDx gene panel testing at the same time as the infant. For rWGS, the infant will undergo testing first. If a specific diagnosis consistent with the phenotype is not made with rWGS proband analysis alone, the parent(s) will undergo rWGS. Both tests are designed to have sequence and analysis of results to identify variants that could contribute to disease in 14 or fewer days. Infants are classified as urgent if they (1) require mechanical ventilation, (2) exhibit severe neurological complications, (3) are hemodynamically unstable, or (4) are categorized as such at the request of the site's principal investigator. Urgent cases undergo ultra-rapid sequencing and analysis with a preliminary report generated within 72 hours of specimen arrival. Sequencing results undergo *in silico* analysis in comparing individual infants' results against known normals, and then the hundreds of variants are screened against known disease gene databases for likelihood of contribution to disease by panels of experts. Analysis includes assessment of inheritance pattern, frequency of variant, variant consequence, and reports in public databases. Variants are classified as pathogenic (P), likely pathogenic (LP), or VUS.

In the recently published interim report of the first 113 enrolled patients, diagnostic and/or VUSs were returned for 51 patients (45%). Results were concordant between WGS and the selected high-risk panel in 83 patients (73%). Significant alterations to care were made for 29 infants after results were obtained. Lessons learned included the limitations of the targeted sequencing to identify aneuploidy and other structural variants, and identification of variants in 8 genes identified by WGS but not assessed on the targeted sequencing panel. Three parents and other family members were newly diagnosed with a genetic condition based on the infant's diagnosis. Notably, while the rate of identifying likely causative genetic variants approaches 50%, even with WGS, more than 50% of the infants did not have a genetic diagnosis. One possible reason is that the rapid sequencing and analytics used are limited to identifying variation in genes and regions already known to be related to disease. As databases and analytic techniques become more robust or as an infant develops additional signs and symptoms to add to the information, genetic disorders may still be identified. Lastly, some infants may not have a genetic cause. Teratogens, environmental exposures, and potential epigenetic modifications could contribute to disease. While sequencing technology has advanced, the ability to understand and interpret these results and how they relate to or influence complex processes in newborns is limited and continues to evolve.[68]

Incidental Findings

While evidence supporting next-generation sequencing approaches is growing and costs of sequencing and time to result drop, cost alone will not be the only consideration in this application of sequencing (https://www.genome.gov/about-genomics/fact-sheets/DNA-Sequencing-Costs-Data) (Fig. 25.3). The ethical issues of incidental findings arising from sequencing must be addressed as these approaches are applied in the NICU. WES and WGS can disclose a range of risks applicable much later in life. Guidelines for these incidental findings in the context of neonatal testing are evolving and debate around the issue continues, as evidenced by the use of consent for incidental findings in NSIGHT2. The American College of Medical Genetics has



• **Fig. 25.3** Cost per Human Genome Sequence, Changes Over Time. To illustrate the nature of the reductions in deoxyribonucleic acid sequencing costs, the graph also shows hypothetical data reflecting Moore's law, which describes a long-term trend in the computer hardware industry that involves the doubling of "compute power" every 2 years (see: Moore's law [wikipedia.org]). Technology improvements that "keep up" with Moore's Law are widely regarded to be doing exceedingly well, making it useful for comparison. The drop-off in 2008 occurs with sequencing labs switching to nextgen rapid sequencing techniques. (https://www.genome.gov/about-genomics/fact-sheets/DNA-Sequencing-Costs-Data.)

addressed this issue and now provides guidance, updated annually, on the recommended genes (now 73) for reporting results when extensive sequencing is done.[69,70]

Genomics of Common Complex Diseases Associated With Prematurity

While NGS-based testing continues to inform clinicians and families about the genes and variants that contribute to complex, severe phenotypes in NICU patients, identifying genes and variants associated with the more common complex disorders of prematurity such as retinopathy of prematurity (ROP), intraventricular hemorrhage (IVH), necrotizing enterocolitis (NEC), and bronchopulmonary dysplasia (BPD) remains a challenge.

Morbidities of prematurity are strongly associated with mortality and long-term neurodevelopmental disabilities.[71–73] Identifying genetic variations related to these diseases would inform development of prevention and treatment approaches based on the individual patient's genotype. Dosing and treatment strategies based on genotype exist in several diseases usually associated with adult onset, including cancer, with various tumor genotypes guiding therapeutic decisions.[74] In addition, when management trials targeting these morbidities are undertaken, considering genetic variation as a potential confounder on the effect of specific management strategies may be important, as in the interactions of *CYP2C19* genotypes in combination with clopidogrel and aspirin in adults.[75,76]

Before going to the trouble of testing genetic variants for associations with disease, heritability, a quantitative measure of the extent to which genetic factors account for the phenotypic variance, must be assessed in the target population. For newborns, the process has relied heavily on testing disease prevalence among monozygotic versus dizygotic twins, as outlined by Bhandari and Gruen.[77] In studies with mono- and dizygotic twins, significant heritability has been identified for ROP, NEC, sepsis, IVH, and BPD.[78–83]

With the establishment of an inherited basis for these common complex neonatal diseases, researchers began to test associations between "single nucleotide polymorphisms" (SNPs) and disease. Having the minor (less common) allele can sometimes increase or decrease the functionality of the gene product. Early work on neonatal diseases focused on assessing associations between SNPs in genes for TNF alpha or IL-6, proteins associated with immune response or inflammation, and diseases such as BPD or late-onset sepsis, often with disparate results for the same SNP.[83,84] Tests for associations with a handful of SNPs in relatively small cohorts have dominated early reports, and some have identified associations with p values <0.05; however, with 3 billion nucleotides comprising the genome, over 30 million known SNPs, and thousands of variants in the genome of any one individual, and relatively small sample sizes, replication has proven difficult, and the concept of the candidate gene analysis, or, more specifically, candidate SNP analysis, approach was called into question unless study cohorts included thousands of cases and controls.[85,86]

With early evidence encouraging a more agnostic approach, broader arrays of genes and variants have been developed to test common variations in multiple candidate genes across the genome, short of whole exome or whole genome sequencing. When an allele for a SNP has a known genotype, the SNPs in linkage disequilibrium can have specific genotypes that frequently occur together. With expanding knowledge of the genome, many SNPs that are in linkage disequilibrium have been identified. This allows for "imputation" of multiple "tagSNPs," in which actual genotyping of one SNP allows prediction of the genotypes of 5 to 10 neighboring SNPs.[87]

In a genome-wide association study (GWAS) hundreds of thousands, even millions, of SNPs are genotyped and tagSNPs imputed, and then each SNP can be individually tested for association in well-phenotyped cohorts. Statistical approaches have been adapted to the millions of tested associations using GWAS. The standard has been to determine "genome wide significance" when the P values identified with the comparison are less than 5×10^{-8}.[87,88] In order to realistically test hypotheses using GWAS, large cohorts with thousands of subjects with the disease phenotype are ideal. As an example, in a case control study testing APOE gene variants in Alzheimer disease patients, variants were found to be associated with Alzheimer with a P value of 2.52×10^{-53}.[89] NICU patients included in GWAS studies have numbered in the hundreds and rarely thousands, far fewer than in the adult cohorts.[90–95]

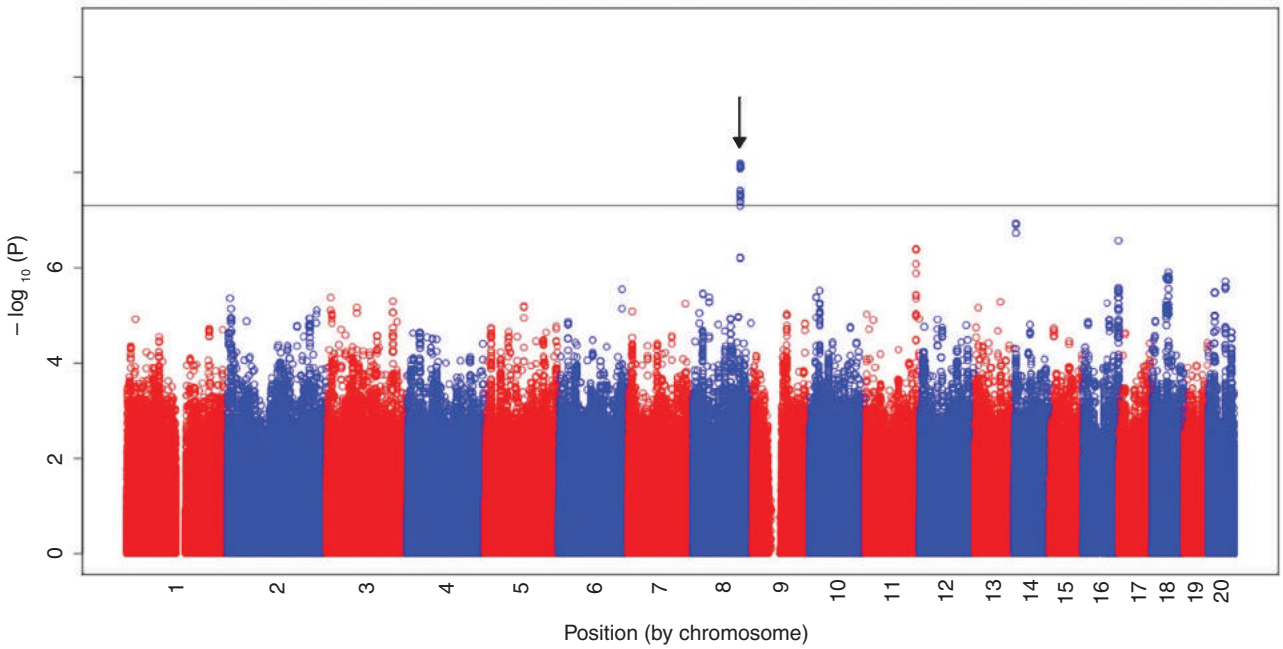
An additional challenge for genomic analysis among extremely preterm cohorts are the differences in minor allele frequency among study cohorts of differing ancestry. While studies using samples from relatively homogenous nations, such as Iceland, may produce fairly homogenous, replicable results, results from cohorts of mixed ancestry, which is more common in the United States, present challenges to analyzing associations between variants that differ in prevalence in cohorts of different ancestry.[96,97]

Retinopathy of Prematurity

Multiple attempts have been made to identify associations that are plausibly associated with the pathophysiologic mechanisms of ROP, including VEGF and VEGF receptors, but the candidate gene/SNP studies have not identified variants with genome wide significance. One report, which tested a panel of over 1000 variants in over 100 genes related to inflammation and organ development, identified two intronic variants in the brain-derived neurotrophic factor (BDNF) gene in patients with severe ROP (versus nonsevere or no ROP) with a P value of less than 5×10^{-7}.[98] Lower serum levels of BDNF have been associated with a higher likelihood of ROP in premature infants. This adds some plausibility to an ROP association with BDNF variants, or an association with another gene product/component of a pathway important for neurovascular development that includes BDNF.[99–101] While promising, impact of variants on BDNF levels has not been described. More recently, epigenetic analysis has identified placental CpG methylation of 12 different genes associated with development of prethreshold ROP. Interestingly, the genes with methylation changes associated with ROP included BDNF.[102] No GWAS has been done to examine ROP to date.

Necrotizing Enterocolitis

In a cohort study using a GWAS approach, minor allele(s) in a cluster of SNPs spanning a 43-kb region of chromosome 8 (8q23.3) conferred an odds ratio of 4.72 (95% confidence interval [CI]: 2.51 to 8.88) for elevated risk of NEC, with multiple SNPs associated with P values $<10^{-8}$ (Fig. 25.4). Like many candidate gene association studies done in the extremely preterm population, this analysis was limited by a small sample size ($n = 751$, only 30 with surgical NEC), from multiple sites in the United States, with significant ancestry admixture. Interestingly, the increased risk was similar for all three genetic ancestries represented in this population.[103] The investigators were not able to validate the associations



• **Fig. 25.4** Manhattan Plot of Single Nucleotide Polymorphisms (SNPs) That Exhibited Association With Surgical Necrotizing Enterocolitis (NEC) Versus Controls. Manhattan Plot of SNPs that exhibited association with surgical NEC versus controls. Data shown are –log P values on the Y axis along versus chromosome locations on the X axis. Arrow points to the NECRISK region on chromosome 8.104.

of the SNPs in the chromosome 8 region with NEC in a separate cohort ($n = 1018$, 26 with surgical NEC) of premature infants enrolled in a study using GWAS to identify variants associated with severe IVH.[93] In in silico analysis, the NEC-associated region of chromosome 8 appears to be evolutionarily conserved, but without any previously identified genes. Pathway analysis, testing variants in multiple pathway-linked genes for associations with NEC, identified associations with over 50 pathways, including pathways involved with immune response, growth regulation, and G-protein signaling. Interestingly, the *LTB4R* gene close to the chromosome 14 region with strong association with surgical NEC encodes an eicosanoid receptor. Pathway analysis revealed eicosanoid receptor signaling as the second most prominent pathway affected by NEC-associated SNPs. LTB4 plays a significant role in a toll-like receptor 4 and cyclooxygenase-2 mediated mechanism of intestinal ischemia/reperfusion injury.[103]

Intraventricular Hemorrhage

Several candidate gene studies have been conducted in relatively small cohorts testing associations between SNPs in inflammation, complement, and coagulation pathways.[104,105] The Gene Targets for Intraventricular Hemorrhage study group conducted a candidate gene study of SNPs in 7 genes, in 224 preterm infants with grade III-IV IVH, and 389 matched controls. Only SNPs in the Methylenetetrahydrofolate Reductase (MTHFR) gene gave even equivocal results of an association with severe IVH.[106] In the GWAS analysis, the group tested over 600,000 SNPs in 458 neonates with severe IVH and 866 infants without IVH, from U.S. and Scandinavian cohorts. No individual SNP reached genome-wide significance. A 10-SNP haplotype ranging from the intergenic region of *GM140* and *CACNA1E* to the intron region of *CACNA1E* had a P value of 7.16×10^{-10}. CACNA1E (calcium channel, voltage-dependent, R type, alpha 1E subunit) is mutated in a Mendelian form of hemiplegic migraine, a known vascular phenotype, as well as various epilepsies (Online Mendelian Inheritance in Man, OMIM. Johns Hopkins University, Baltimore, MD. MIM Number: 618285: last edited: 11/18/2020). None of the prior candidate individual SNPs reached genome-wide significance. Like many similar endeavors, the summary of this GWAS for severe IVH concluded, "Because common variants have small-to-moderate effects, a large-scale neonatal genomic medicine network must be developed with the infrastructural capacity to host an accessible database of sequence variants, their phenotypic associations and environmental risk factors."[93]

Bronchopulmonary Dysplasia

Severe ROP, NEC, and IVH each have phenotypes that are defined by imaging or direct visualization. However, BPD is usually defined by some level of respiratory support, making the anatomic and physiologic details of the phenotype that might be influenced by genetic variations challenging.[107,108] Five groups have used an agnostic GWAS approach to try to identify variants or groups of variants in genes and pathways associated with epidemiologically defined BPD and met with limited success.[90–92,94,95] Hadchouel identified SNPs in the *SPOCK2* gene associated with BPD in their discovery cohorts (of African and Caucasian ancestry) and a replication cohort.[90] Wang et al. studied over 2000 very low birthweight infants born in California, and did not identify genomic loci or pathways associated with moderate to severe BPD with genome-wide significance.[91] Ambalavanan et al. studied 751 infants with birthweights ranging between 401 and 1000 g (428 diagnosed with BPD or who died) and found no SNPs that achieved genome-wide significance. Pathways of lung development and repair and novel molecules and pathways (adenosine deaminase, targets of microRNA or miR-219) were associated with BPD. Pathways associated with mild BPD were different from the pathways associated with severe BPD. In addition, the variants/pathways associated with BPD varied by ancestry.[92,109]

In a Finnish case control study ($n = 60$ infants with moderate-to-severe BPD; $n = 114$ control infants), an SNP flanking the C-reactive protein gene had the strongest association with BPD ($P = 3.4 \times 10^{-6}$), and in multivariable logistic regression this SNP was associated with BPD in two replication cohorts (one Finnish and one comprised of European and African individuals).[94,95] In the most recent GWAS study, which tested 9 million genotyped and imputed variants from 387 preterm infants who participated in the Trial of Late Surfactant (TolSURF) study for associations with BPD, no individual SNPs were associated with BPD with genome wide significance. Similar to the study by Ambalavanan, this group reported that genetic ancestry was associated with survival without BPD. The associations between genetic ancestry and BPD suggest that patterns of genetic variation in infants with or without BPD are likely to differ by continental origin.[95] Ultimately, the five GWAS studies failed to identify a specific gene or gene variant to be specifically and convincingly associated with BPD; however, the studies, individually and collectively, are limited by small sample sizes and high levels of phenotype variation.

Investigators have also applied WES to BPD, with hopes that much more extensive sequencing in patients with extreme phenotypes could identify rare variants associated with disease.[110–112] Carrera et al. studied 26 infants with severe BPD. Identified variants were classified as likely to have high, moderate, or low impact based on predicted protein effects, and whether or not they were novel variants in genes with occurrence in more than one subject. As expected, each subject had approximately 200,000 identified variants, with about 10% of all variants identified from all subjects as possibly having moderate or high impact. In each sample, approximately 100 variants were identified that were hypothesized by structural predictive analysis to have an impact on protein structure. Two subjects had novel missense mutations in *ABCA3*, a gene whose product is responsible for transporting phospholipids to lamellar bodies in type II alveolar cells. Rare and novel variants in *NOS2* and toll-receptor genes and C-reactive protein were also identified.[110] Li et al. used newborn screening samples for exome sequencing of 50 twin pairs, including 51 infants with BPD. The accumulated variants in 258 genes in the subjects with BPD had a significantly higher haploinsufficiency score (haploinsufficiency can be defined as the situation when one copy of a gene is either deleted or has a loss-of-function variant, and dosage of the gene product is reduced enough to affect function).[111,113] Variants clustered in genes in pathways involved in embryonic epithelial development, collagen organization, and Wnt-signaling were increased among the infants with BPD compared with non-BPD infants. This group also looked at tissue expression in human tissue from patients with BPD, and in lung tissue from the hyperoxic mouse model of BPD, and detected increased expression in the exome-identified BPD candidate genes in hyperoxia exposed animals.[111] Most recently, Hamvas et al. reported WES results from 146 subjects (85 with BPD and 61 unaffected) enrolled in the Prematurity and Respiratory Outcomes Program (PROP). Three hundred forty-five genes with extremely rare, nonsynonymous variants (variants that would lead to a change in the amino acid sequence of the gene product) were identified only in the BPD-affected subjects. This study, the largest to date, replicated 28 genes with extremely rare variants in patients with BPD that were previously associated with BPD in the California cohort reported by Li et al.[111,112]

The GWAS and WES studies to date are also limited by their small sample size and challenges to phenotyping, as well as their ability to identify rare variants in noncoding regions that may be of importance to the pathogenesis of BPD, or other important morbidities of prematurity; however, the WES approach has identified associations with genes containing rare variants and candidate pathways, and the WGS approach has yet to be tested. As described in the NGS studies in the NICU, wider application of these extensive sequencing methodologies to more infants are likely to uncover genetic contributors to disease in individual infants.[114]

Conclusion

The application of genomics and genetics to clinical neonatology is evolving rapidly as prices drop and the speed of sequencing, identifying, and analyzing variants for their association with a growing number of gene-disease databases accelerates.[46] Diagnoses are being made at a much more rapid pace, and clinical care must adapt quickly to the new knowledge. That said, we have the "good problem" of how best to apply this growing knowledge. As an example, a NICU clinician seeking to understand why a premature infant has worse than expected respiratory disease could consider a number of approaches to test for variants in a number of genes that contribute to respiratory disease.[114,115] One choice would be to order a gene panel to avoid the current cost of WGS or WES. But which panel to choose? A quick Google search using the search terms "respiratory disease neonate genetic panel" identifies four different products, from four companies. One additional panel, a well-known test for respiratory-related problems, by the group at Johns Hopkins DNA Diagnostic lab is also included as an option. The testing panels cover a range of 5 to 125 genes. All utilize sequencing of the exons of the panel's genes and areas close to the exons that are likely regulatory regions. Three genes, ABCA3, SFTPB, and SFTPC, are included in all five panels. Two genes, FOXF1 and NKX2-1, are included in four panels, and two genes, CSF2RA and CSF2RB, are included in two panels.

Clearly, we are in an extremely rapid learning phase of how best to apply genomics in the NICU! Clinicians should be aware of the details and the range of the genetic tests that can be ordered, their strengths and weaknesses, and should strongly consider partnering with colleagues in medical genetics to best interpret results and to discuss their ramifications with families.

Prenatal Diagnosis and Counseling

EDITH Y. CHENG AND J. CRAIG JACKSON

KEY POINTS

- All pregnant women should have the option to undergo prenatal screening/diagnosis for genetic conditions and/or birth defects.
- Specific indications for genetic counseling and prenatal diagnosis testing include a history of chromosome abnormality, Mendelian genetic disorder, or metabolic disorder; increased risk for neural tube defect; abnormal maternal serum screening test; abnormal cell free DNA result; or a fetal anomaly suspected/diagnosed on ultrasound.
- Successful prenatal diagnosis requires a known condition associated with a structural abnormality visible in the fetus, a biochemical abnormality in amniotic fluid/amniocytes, or a known molecular mutation.
- Preimplantation genetic screening/diagnosis selects out embryos with a genetic condition or aneuploidy and transfers either chromosomally normal embryos or embryos without the at-risk genetic condition.
- Prenatal counseling is especially challenging because decisions with lifelong impact are often required on behalf of the unborn patient, and when the interests of the fetus and parents are in conflict.
- It is essential to respond empathetically to the inevitable strong emotion resulting from the unwanted news of a fetal abnormality and to align with the parents' goals and values before proposing a treatment plan.

Background

In the late 1970s, only two testing programs comprised the paradigms in prenatal screening/diagnosis: (1) elevated maternal serum alpha fetoprotein (MSAFP) to screen for open neural tube defects (NTDs) and (2) maternal age over 35 years at delivery to screen for Down syndrome (DS). Neither program used imaging routinely and only second trimester amniocentesis for fetal karyotyping was available. Today, more than 50 years later, genomic discoveries and advances in fetal imaging technology present women with many prenatal screening and/or diagnostic options for the evaluation of their fetus for birth defects and/or genomic abnormalities and, in some cases, provide an opportunity for in utero treatment. Early diagnosis of birth defects broadens the scope of management options and allows preparation for delivery and postnatal support, all of which have improved viability and outcome of serious birth defects that in previous decades would be termed prenatally as "lethal anomalies." The care of the mother–fetus dyad is now multidisciplinary through partnerships between maternal–fetal medicine, neonatology, pediatric surgery, and pediatric subspecialists. The goal of this chapter is to discuss the breadth of prenatal diagnosis to illustrate the complexity of the technology and choices; recognize their benefits, accuracy, and limitations; and understand their impact in the care of pregnancies with genetic disorders or fetal anomalies.

Principles of Prenatal Screening and Diagnosis

Screening is the systematic application of a test to identify individuals at high risk for an asymptomatic, well-defined serious medical condition with an established incidence, for which identification would lead to prevention and/or treatment. The screening test should be cost effective, simple and safe, readily available and accessible, and should have a well-defined performance. An accurate diagnostic test should be available to confirm or refute the screen positive result. In prenatal screening programs, there should be timely transfer of test results, counseling, respect for the ethical and cultural values and decisions of patients, and full discussion of all options if the suspected condition is confirmed.

Diagnosis of a suspected condition in an at-risk fetus requires a known diagnosis for which the condition is associated with a detectable abnormality either within the fetus and/or the fetal tissues. This could be in the form of a structural abnormality readily seen on ultrasound (that appears at the appropriate developmental stage of the system affected), a cytogenetic abnormality, a biochemical abnormality in the amniotic fluid or in cultured amniocytes, a genomic duplication or deficiency identified on microarray analysis, or a known genetic mutation associated with the condition. For example, a mother with autosomal dominant achondroplasia has a 50% chance of having an affected child. Knowing that in an affected fetus the long bones do not demonstrate growth deceleration until after 24 weeks' gestation, a normal growth ultrasound at 20 weeks' gestation would not be reassuring, but a normal growth ultrasound at 30 weeks' gestation would essentially exclude the diagnosis in her fetus. Conversely, if she had a known mutation for achondroplasia, genetic testing of chorionic villi retrieved at 13 weeks' gestation or amniocytes retrieved by amniocentesis at 16 weeks would inform the status of the fetus before the condition is visible on prenatal imaging; or, preimplantation testing for the mutation in embryos with transfer of an unaffected embryo would eliminate the risk of an affected fetus.

Invasive Prenatal Diagnostic Procedures

Midtrimester Genetic Amniocentesis

The term *amniocentesis* refers to the procedure of removing amniotic fluid under ultrasound guidance from the uterus and is performed for many reasons. For prenatal diagnosis, it is usually performed between 15 and 20 weeks' gestation. The amniotic fluid contains desquamated cells from fetal skin, bladder, and the gastrointestinal tract, which serve as sources for cytogenetic and enzymatic/biochemical studies. DNA can also be extracted from these cultured amniocytes for genomic studies. Proteins such as alpha fetoprotein (AFP) and acetylcholinesterase are measured to confirm an open NTD suspected on ultrasound.

The benefits of second trimester amniocentesis include its large international clinical experience of over 40 years; the standardization of culture and cytogenomic techniques which decrease the culture failure rate to 0.1%; and its diagnostic accuracy, broad availability, and relative safety.[1] Based predominantly on data obtained in the 1980s and 1990s when second trimester amniocentesis was widely performed, the incidence for minor complications such as cramping and leakage of fluid immediately after the procedure was collectively about 1%, while the incidence of significant complications such as chorioamnionitis and/or miscarriage was 0.25% to 0.5%.[2]

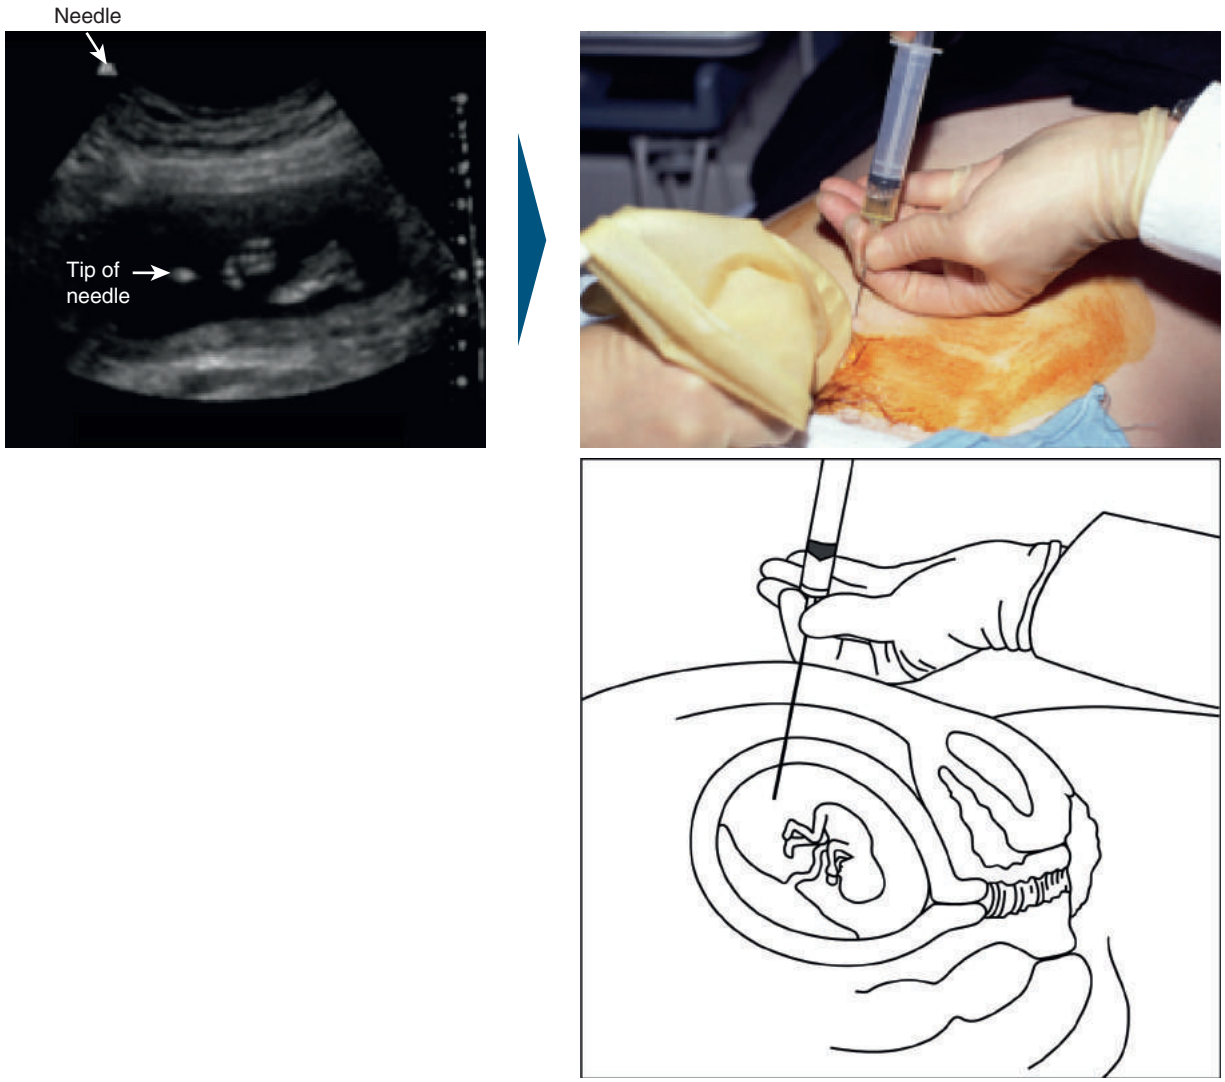
The relative safety of midtrimester amniocentesis when completed by experienced providers has been confirmed by many studies. The multicenter First Trimester and Second Trimester Evaluation Risk (FASTER) trial in 2004 observed a procedural loss rate after second trimester amniocentesis (and before 24 weeks' gestation) of 0.06% or 1/1600.[3] Prior studies reporting high pregnancy loss rate likely reflect the nuances that contribute to the safety of any procedure that requires technical expertise. Ultrasound guidance, use of a smaller 22-gauge needle, and a large volume of patients at a referral institution allowed practitioners to maintain their technical skills. Each institution should calculate its own complication rate. In 2008, Odibo and colleagues reported on a single center's 16-year experience and identified a fetal loss rate of 0.13% or 1/769. A 2015 meta-analysis of miscarriage after amniocentesis in more than 42,000 women who had the procedure—compared with 138,000 who did not—estimated the procedural loss rate to be approximately 0.11% or 1/900.[4,5] These data support that midtrimester amniocentesis is safe when the procedure is performed by experienced providers in large volume referral centers. Thus the current estimated procedural risk discussed with patients is approximately 0.1% to 0.3%. To date, even with maternal serum screening and cfDNA as options for screening, midtrimester amniocentesis remains the procedure indicated for prenatal diagnosis of fetuses with ultrasound anomalies and/or screening results suspicious for fetal cytogenomic abnormalities.

Early amniocentesis, performed between 11 and 14 weeks' gestation, was briefly explored in the late 1990s. The only large prospective study, the Canadian Early and Mid-Trimester Amniocentesis Trial, randomized 4334 women to early amniocentesis versus midtrimester amniocentesis and observed a higher pregnancy loss rate, more rupture of membranes, more culture failures, and greater procedural difficulty in the early amniocentesis group.[6,7] An unanticipated observation was a 1.3% incidence of club feet when early amniocentesis was performed between 11 and 13 weeks' gestation, compared with 0.1% after midtrimester amniocentesis.

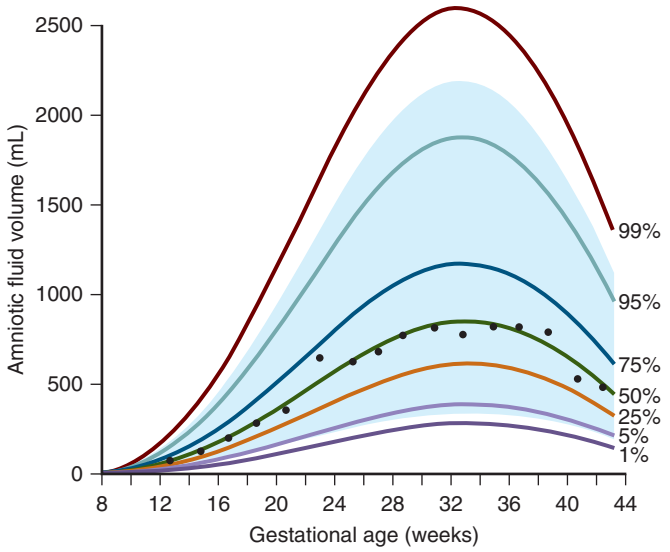
The timing of second trimester amniocentesis is based on a number of factors. Midtrimester amniocentesis is usually performed after 15 to 16 weeks of pregnancy because the uterus prior to this gestational age is still within the maternal pelvis and not easily accessible (Fig. 26.1). At midtrimester, the volume of amniotic fluid is about 150 to 300 mL, with the fetal kidneys beginning to produce urine (Fig. 26.2). There is uncertainty about the rate of fetal urine production in early pregnancy, but at 25 weeks' gestation, the fetal urine output is estimated to be about 110 mL/kg/24 h. For fetal karyotyping and genomic studies, approximately 20 to 40 ml of amniotic fluid is necessary to obtain an adequate number of amniocytes for culture in order to provide results with appropriate accuracy and confidence. While midtrimester amniocentesis has not been associated with permanent structural or functional consequences to the exposed fetuses, the association of early amniocentesis with a 10-fold increase in club feet demonstrates the importance of an adequate amount of amniotic fluid at this developmental stage for normal orthopedic development of the fetus. Midtrimester amniocentesis performed later, at 18 to 22 weeks' gestation, is technically easier, and there is less concern for removing 40 ml of amniotic fluid. However, cases requiring complex molecular testing may involve weeks of analysis, thus extending completion of testing late in pregnancy and potentially limiting management options.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) involves the aspiration of the chorion frondosum either transabdominally or transcervically between 10 and 13 weeks' gestation (Fig. 26.3). Trophoblasts and mesenchymal core cells of the chorionic villi provide actively growing cells for karyotype and genomic analyses and biochemical/enzymatic studies. In contrast to second trimester amniocentesis, mosaicism (the finding of two or more cell lines with a different chromosome constitution—usually trisomy) occurs in about 1% to 2% of cases.[8] Because the cell types represent both extraembryonic and embryonic tissue, resolution of a mosaic CVS result requires identification of the source of the cytogenomic abnormality by completing an amniocentesis and, in some cases, fetal blood sampling for further clarification. As a result of CVS, the developmental processes of *confined placental mosaicism, trisomic rescue*, and *uniparental disomy* were discovered.[9] Depending on the placental cell lineage from which the chromosome abnormality was derived, confined placental mosaicism could result in (1) generalized mosaicism affecting both the placenta and fetus; (2) mosaicism in the placenta only and a diploid/chromosomally normal fetus; (3) chromosome abnormality confined to the placenta with a chromosomally normal fetus; or (4) chromosomally normal placenta and a mosaic fetus. Trisomic rescue refers to the process by which the zygote began as a trisomic conceptus and, through postzygotic loss of the extra chromosome, became diploid while the placenta remained mosaic or completely abnormal. The clinical consequence of trisomic rescue is chromosome dependent because some genes require the presence of both maternal and paternal copies to express a normal phenotype. In the case of chromosome 15, for example, if CVS demonstrated mosaicism for



• **Fig. 26.1** Midtrimester genetic amniocentesis under ultrasound guidance.

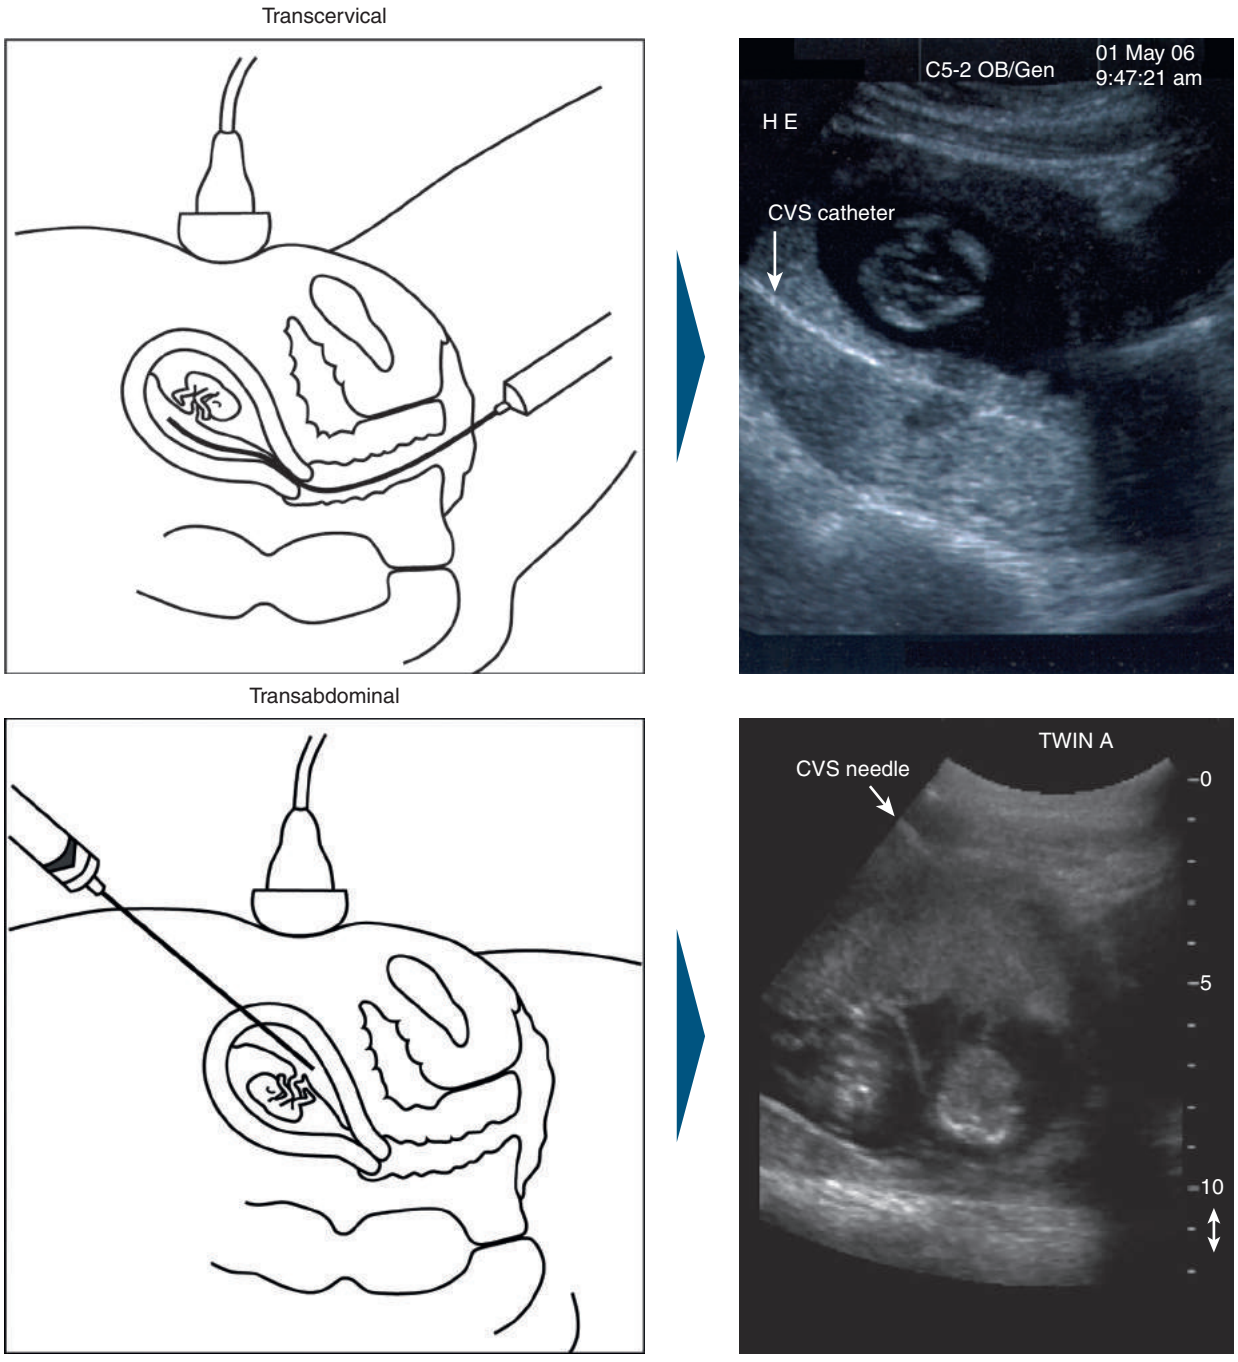


• **Fig. 26.2** Volume of amniotic fluid across fetal gestation. (Adapted from Bruce RA, Wolf EF. Normal amniotic fluid volume changes throughout pregnancy. *Am J Obstet Gynecol.* 1989;161:382–388.)

trisomy 15 and genetic amniocentesis demonstrated that the fetus was diploid for chromosome 15, studies to confirm that biparental inheritance must be completed to predict a normal fetal phenotype. However, if the fetus contained two maternal copies of chromosome 15, it would be predicted to have Prader–Willi syndrome, or Angelman syndrome if it had two paternal copies of chromosome 15.

CVS is associated with a pregnancy loss rate of about 1/500.[5] It requires operator expertise and continuous ultrasound guidance. Maternal cell contamination studies are completed to discriminate between female fetal results and contamination from maternal cells. CVS allows for early diagnosis at a time when the privacy of the pregnancy can still be maintained and should be considered if complex diagnostic strategies (requiring time) are anticipated. Because CVS is dependent on operator expertise within a small gestational age window, it is not readily accessible to all patients.

Characteristics of midtrimester amniocentesis and CVS are compared in Table 26.1.



• **Fig. 26.3** Transcervical and transabdominal chorionic villus sampling under ultrasound guidance. *CVS*, Chorionic villus sampling.

Percutaneous Umbilical Cord Blood Sampling

Fetal cordocentesis or percutaneous umbilical cord blood sampling (PUBS) was introduced in 1985.[10] The ease of DNA-based testing for genetic conditions has essentially replaced PUBS as a diagnostic tool in prenatal diagnosis. Today, the sampling of fetal blood is most commonly used for the diagnosis of fetal anemia or thrombocytopenia. However, there remains rare chromosomal abnormalities identified from CVS or midtrimester amniocentesis in which PUBS is necessary to clarify the true fetal chromosome abnormality. As a therapeutic tool, it is used for *in utero* transfusion of blood or platelets and, rarely, for administration of antiarrhythmic medications for the treatment of fetal tachyarrhythmias. The procedure is completed under continuous ultrasound guidance with a 22-gauge spinal needle placed into the umbilical vein and can be performed beginning as early as 18 weeks' gestation and subsequently throughout the remainder of the pregnancy. Before 18 weeks' gestation, the fetal umbilical vein may be too small, although our group has completed a successful transfusion of a 16-week hydropic fetus due to Kell isoimmunization; in this type of urgent situation, direct transfusion into the fetal heart is also possible. Exsanguination (if the cord is lacerated), periumbilical vein hematoma in Wharton jelly, preterm rupture of membranes, preterm labor, or placental abruption

TABLE 26.1 Characteristics of Midtrimester Amniocentesis and Chorionic Villus Sampling for Prenatal Diagnosis

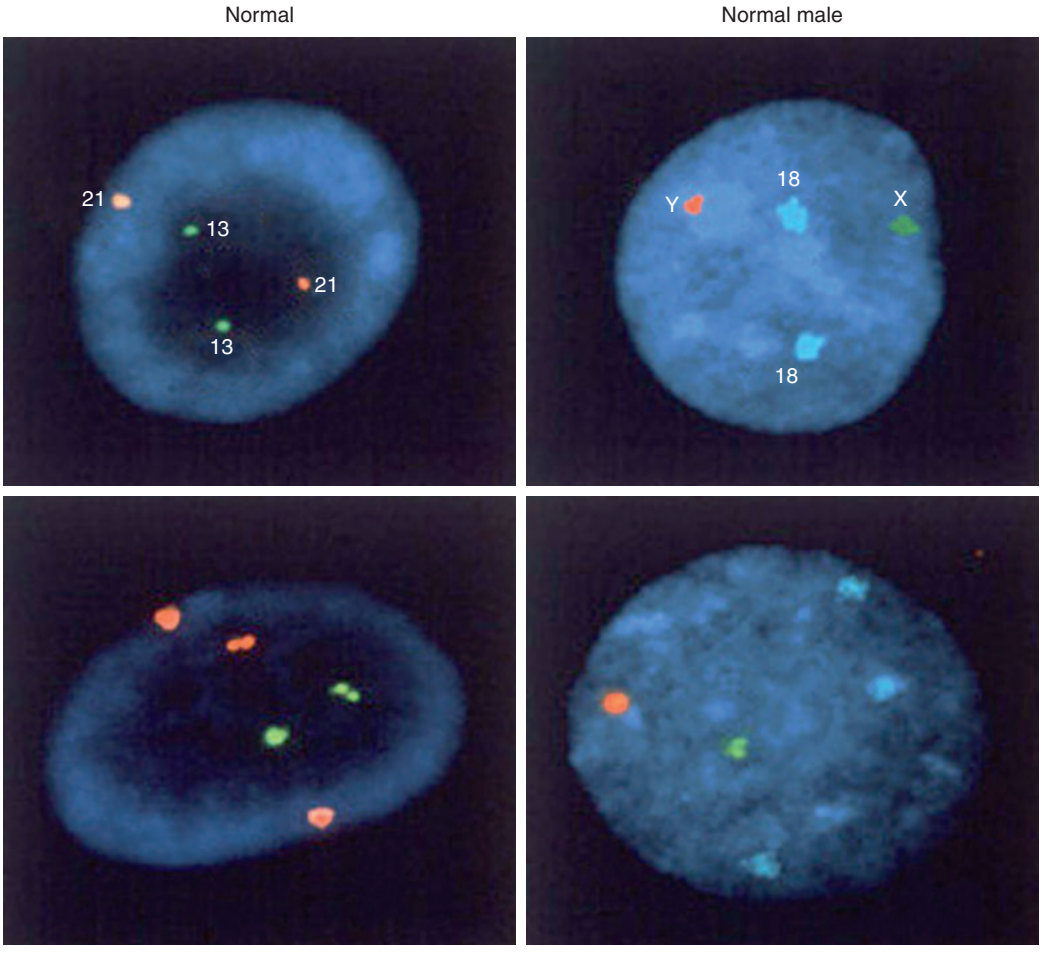
	CVS	Amniocentesis
Gestational age at procedure	10–13 weeks	15–20 weeks
Miscarriage rate	1/500	1/500–1/800
Culture mosaicism	1%–2%	0.1%
Turnaround time	7–10 days	7–14 days
Diagnostic accuracy	>99%	>99%
IFISH	+	+
Karyotype	+	+
Microarray	+	+
Neural tube defect screening*	–	+

*Women who undergo CVS will need to have midtrimester maternal serum screening for maternal serum alpha fetoprotein.
CVS, Chorionic villus sampling; *IFISH*, interphase fluorescent in situ hybridization.

are some of the complications of PUBS. The procedure requires operator expertise and the risk of the procedure is about 1%.

Genetic Testing of the Fetus

Fetal karyotyping still has a role in prenatal diagnosis and can be completed on chorionic villi, amniocytes, and fetal blood. Interphase fluorescent in situ hybridization (IFISH) with small chromosome-specific DNA probes (10 to 300 kb) is used for rapid confirmation of suspected aneuploidy in uncultured amniocytes (Fig. 26.4). Historically, IFISH has been used for identification of extra chromosome material and specific submicroscopic gene deletions associated with genetic disorders. Today, this cytogenetic tool has been largely replaced by microarray analyses that expose genomic deficiencies and duplications that are smaller than those previously identified by IFISH. IFISH to exclude trisomy 21, 18, or 13 on cord blood at delivery may be helpful when rapid (24-hour) turnaround may be used to assist in decision making, such as whether to offer life-sustaining neonatal surgery. In cases in which a genetic condition is not associated with a known mutation, biochemical and enzymatic/functional studies of cultured amniocytes may be the only means for prenatal diagnosis for the condition in question.



• **Fig. 26.4** Interphase fluorescent in situ hybridization on uncultured amniocytes. The hybridization process takes approximately 24 hours after which the signals are counted for diagnosis.

Microarray Technology

Chromosomal microarray (CMA) technologies are bridges between cytogenetics and molecular genetics. They have greater resolution than traditional cytogenetics and are platforms designed to measure DNA regions for gains or losses across the entire genome simultaneously. The utility of microarray technology has been thoroughly evaluated in the postnatal and adult population, and now replaces the standard banded karyotype that geneticists relied on since the 1970s. CMA is now the first-line diagnostic test for individuals with autism spectrum disorder and unexplained birth defects and/or cognitive delay.[11] Compared with standard karyotyping, CMA detects a causative genomic imbalance in an additional 10% to 15% of these patients. In 2013, The American College of Obstetricians and Gynecologists and the American College of Medical Genetics independently supported the use of CMA analysis in prenatal diagnosis which is reaffirmed in the most recent ACOG/SMFM practice bulletin.[12–14] In a large multicentered trial supported by the Eunice Kennedy Shriver National Institute of Child Health and Human Development, CMA was found to perform just as well as standard karyotyping in the diagnosis of common aneuploidies in fetal samples (from CVS or amniocentesis) from women undergoing prenatal diagnosis.[15] In pregnancies with normal ultrasounds that had been referred for standard indications, such as advanced maternal age or positive screening for DS, CMA yielded clinically relevant information in an additional 1.7% of pregnancies. However, in pregnancies with abnormal ultrasounds and a normal karyotype, CMA identified clinically significant genomic changes in an additional 6% of pregnancies. The value of microarray analysis is also seen in the genetic evaluation of stillbirths. Reddy and colleagues found that microarray analysis yielded more relevant genetic information than karyotyping in term stillbirths with or without anomalies, even after correcting for aneuploidy.[16]

Although there is no consensus regarding the type of array platforms used in prenatal diagnosis, *high-density single nucleotide polymorphism (SNP) array* is now the platform of choice, as they allow for greater in-depth coverage of the genome to reveal smaller duplications and deficiencies. In addition, SNP arrays have the advantage of detecting long continuous stretches of DNA homozygosity (identical DNA sequences between a pair of chromosomes). These findings could reveal uniparental disomy, as seen in rare genetic conditions such as Angelman syndrome, as part of the work-up for confined placental mosaicism or could uncover consanguinity.

Because the mechanisms causing genetic conditions are diverse and complex, no microarray platform will be completely diagnostic. Genetic conditions not associated with a relative change in DNA sequences will not be identified. Depending on the platform used, low level mosaicism and genomic regions not represented by the platform may not be detected. Other mechanisms of genetic disease such as point mutations, methylation disorders, and mitochondrial disorders cannot be uncovered using microarray technology. In addition, as the resolution of the technology improves, secondary and incidental findings, both with and without known clinical implications, will arise as the genome is searched. Copy number variants not previously reported in established databases are referred to as *variations of unknown significance*. For these reasons, women should have pretest and posttest genetic counseling to discuss expectations and limitations of microarray testing in their pregnancy.

Whole Exome Sequencing

Whole exome sequencing (WES) focuses on targeted sequencing of the protein coding regions of the genomic DNA and shows promise as a new tool in gene discovery for complex diseases and for facilitating the accurate diagnosis of individuals with unsolved Mendelian conditions. Reports of increased diagnostic yield in children with unexplained but presumed underlying genetic syndrome after normal karyotype and CMA suggest that WES could be applied to the prenatal population of fetuses with unexplained complex malformations or stillbirths with anomalies.[17–21] One recent prospective cohort study of 234 pregnancies demonstrated an additional 10% yield for pathogenic variants in fetuses with abnormal ultrasounds and normal CMA.[22] A second study of 127 cases of unexplained Non-Immune Hydrops Fetalis identified a diagnostic genetic variant in 29% of cases.[23] More recent attention has been directed to rapid exome sequencing (rES) with turnaround times of 24 to 36 hours, which could provide valuable information for providers in the postnatal management of neonates with serious and/or life-threating conditions.[24] In spite of these exciting developments and increasing utilization of WES, this technology (at the time of this writing) remains a second-tier diagnostic test.

Noninvasive Prenatal Screening

Maternal Serum Screening

Second trimester maternal serum screening for abnormal fetal conditions in the 1970s preceded ultrasound and focused on identifying fetal open NTD through elevated MSAFP. An elevated MSAFP level of 2.5 multiples of the median (MoM) or greater generally signals a pregnancy that should undergo further evaluation. Because AFP is a circulating protein in the fetus, any disruption in the integrity of the fetal body, such as an open NTD, gastroschisis, or omphalocele and some dermatologic disorders, will be associated with elevations of AFP in maternal serum and amniotic fluid. Other considerations for elevated MSAFP are incorrect dating of the pregnancy, multiple gestation, impending fetal demise, and history of vaginal bleeding.

In 1984, screening for DS and trisomy 18, because of low MSAFP, was added.[25] Other analytes—human chorionic gonadotropin (hCG), unconjugated estriol (UE3), and inhibin-A (INH)—were subsequently added to improve the detection rate for DS. Analyte levels are reported in MoM to standardize the gestational age dependency of the interpretation of the levels.

In the first trimester, three markers—fetal nuchal thickness (NT) measured by ultrasound, maternal serum pregnancy-associated plasma protein-A (PAPP-A), and hCG—can be used to calculate a patient's risk for DS. The combination of all the components of the first and second trimester screening elements, known as the Integrated Screen, provides the highest detection rate for DS when a 5% screen positive rate is used.[26] However, many options for screening are available depending on the gestational age at entry to prenatal care, access to first trimester ultrasound for NT evaluation, and patient desire for information at different stages of her pregnancy.[14] The benefit of second trimester maternal serum screening is that it provides risks for three fetal conditions: DS, trisomy 18, and open NTD.

Cell-Free DNA (Noninvasive Prenatal Screening—NIPS)

cfDNA analysis in maternal plasma is used in noninvasive prenatal screening (NIPS) with greatest focus on prenatal detection of aneuploidy for chromosomes 13, 18, 21, and X. In pregnancy, approximately 3% to 20% of the total cfDNA in maternal plasma is derived from the pregnancy.[27,28] Although many refer to this as "free fetal DNA," the DNA is in fact derived *primarily from the placenta*, which serves as a surrogate for the fetus and is cleared from the maternal circulation within hours after delivery.[28,29] The molecular principle behind NIPS is the measurement of relative amounts of circulating free placental DNA compared with the amount of circulating free maternal DNA. In other words, a pregnancy at 14 weeks affected with DS will show an excess of DNA fragments for chromosome 21, assuming that the mother does not herself have DS or is not mosaic for DS. *cfDNA* is present throughout pregnancy, and unlike maternal serum screening, which is gestational age dependent, *cfDNA* can be used for aneuploidy screening into later gestational ages.

As in any screening program, the positive predictive value (PPV) of a test is dependent on the population prevalence of the disease. The performance of NIPS is highest in women age 40 and older, with a PPV of 91% to 99% for DS and lowest at 38% to 80% in women age 20.[15] The test performance for sex chromosome aneuploidy is low, with a PPV of only 39%, because the sex chromosome aneuploidy may reflect the mother rather than the fetus.[29] Sex determination of the fetus can be misleading if the mother is a transplant organ recipient.[30] False-positive and false-negative results may be related to fetal mosaicism, vanishing twin, confined placental mosaicism, unsuspected maternal chromosome abnormality, or unsuspected maternal malignancy.[31] For these reasons, the American College of Obstetricians and Gynecologists and the Society for Maternal–Fetal Medicine strongly recommend that NIPS should "be an informed patient choice after pretest counseling and should not be part of routine prenatal laboratory assessment." They further recommend that "a patient with a positive test result should be referred for genetic counseling and should be offered invasive prenatal diagnosis for confirmation of test results."[20]

Other considerations in the performance of cfDNA screening include its dependency on gestational age and "fetal fraction." Low fetal fraction (defined as less than 4% fetal DNA in maternal serum) is inversely associated with maternal body mass index. Early gestational age (less than 9–10 weeks) and concurrent maternal treatment with low molecular weight heparin have been associated with inadequate DNA, leading to "test failures" or "no call report."[32] The clinical significance of "test failure" cases is now becoming evident and continues to evolve. Low-risk women with no reportable results on cfDNA testing were found to have an aneuploidy rate of 2.7% (1/38) compared to low-risk women with adequate cfDNA fraction (1/236, 0.4%).[32] Another important consideration about current NIPS is that it offers reliable information about the three most common aneuploidies. In a recent review of 220 chromosome abnormalities identified prenatally through amniocentesis between 2009 and 2014, cfDNA testing did not detect about half of the clinically significant chromosome abnormalities that were found either by karyotyping or microarray when amniocentesis was performed.[33] More importantly, 79% of the abnormalities were from pregnancies with abnormal serum screening and/or abnormal ultrasound findings. These findings underscore the fact that current cfDNA technology is still a screening tool and does not yet have the breadth and depth to offer the scope of genomic information about the fetus with multiple complex anomalies that could be obtained through CVS or genetic amniocentesis. Although some companies are offering expanded testing for selected microdeletion syndromes, these tests have not been validated clinically and should not be chosen for diagnosis of a fetus with multiple anomalies; direct testing by CVS or amniocentesis remains the gold standard at this time.

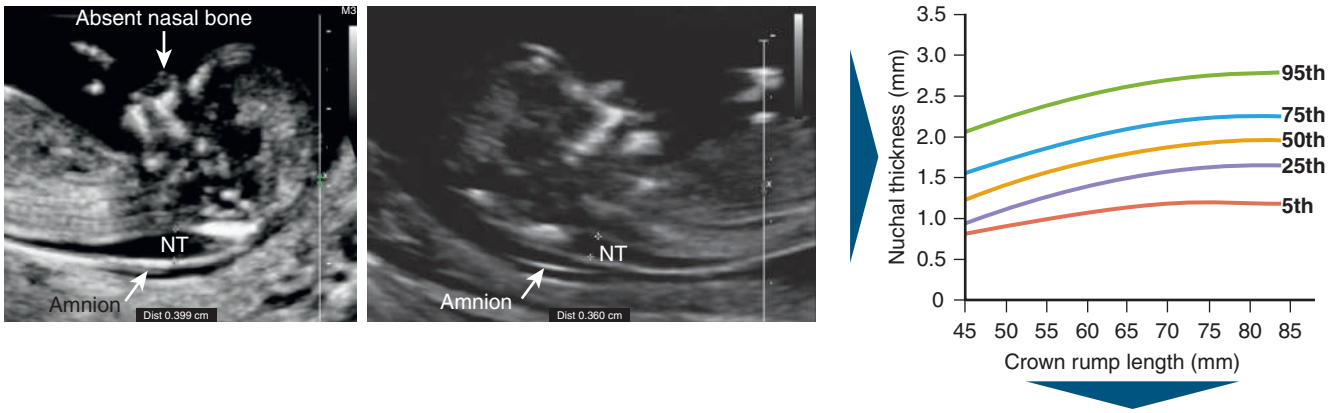
NIPS for twin gestations for aneuploidy screening is currently available.[34] However, the test does not identify the at-risk twin (unless there are ultrasound markers) or confirm the concordance of the fetal sexes, that is, the finding of Y chromosome material can indicate that both twins are male, or, at least one of the twins is male, unless there is ultrasound diagnosis of the fetal sexes. A positive result, even if there are ultrasound markers, should be confirmed by CVS or amniocentesis. Fetal demise and vanishing twin can produce inaccurate results. Therefore pregnancies that have undergone early fetal reduction should not use cfDNA as a screening tool for the remaining fetus(es).

Prenatal Fetal Imaging

First trimester nuchal translucency (NT) or *thickness* refers to the measurement of the normal subcutaneous fluid-filled space at the back of the fetal neck between 10 and 14 weeks' gestation. In normal fetuses, the maximal thickness increases with increasing gestational age as defined by the crown rump length (CRL). An increased NT is associated with DS, and is used in conjunction with maternal age and first and second trimester maternal serum analytes to provide the highest detection rate for DS.[14] Other chromosome abnormalities, fetal anomalies, and poor pregnancy outcomes are also observed with increasing NT (Fig. 26.5).

NT measurement is obtained by transabdominal imaging of the pregnancy, and its success as a screening tool depends on the accurate procurement of images for measurement, which is dependent on the size and position of the fetus, maternal habitus, and operator performance. Operator performance is audited for quality following formal training and certification of competency. The highest success rates in obtaining NT measurements are when the CRL is between 45 and 84 mm, corresponding to 11 weeks 3 days and 14 weeks 2 days of gestation, respectively.[35] The additional benefit of completing the ultrasound in this gestational age window is the opportunity to confirm pregnancy viability and identify other fetal anomalies such as anencephaly, abdominal wall defects, and possibly congenital heart defects.

Other ultrasound findings in the first trimester fetus that may be associated with DS include *absent* or *hypoplastic nasal bone, abnormal ductus venosus blood flow*, and *tricuspid regurgitation*. Initially thought promising, their performance may not be applicable to a general low risk population since their performance was judged on high-risk fetuses and the ultrasound acquisition required experienced sonographers. The scope of information regarding *second trimester ultrasonography for aneuploidy screening and diagnosis of fetal anomalies* is too broad and complex to cover in this chapter. In the United States, prenatal diagnosis units follow the practice guidelines developed in conjunction with the American College of Radiology, the American College of Obstetricians and Gynecologists, and the Society of Radiologists in Ultrasound.[36] The following discussion summarizes some key concepts in prenatal diagnosis and second trimester imaging of the fetus.



Nuchal thickness	Chromosomal defects	Normal karyotype		
		Fetal death	Major fetal abnormalities	Alive and well
<95th %ile	0.2%	1.3%	1.0%	97%
95th–99th %iles	3.7%	1.3%	2.5%	93%
3.5–4.4 mm	21.1%	2.7%	10.0%	70%
4.5–5.4 mm	33.3%	3.4%	18.5%	50%
5.5–6.4 mm	50.5%	10.1%	24.2%	30%
>6.5 mm	64.5%	19.0%	46.2%	15%

• **Fig. 26.5** Interpretation of nuchal thickness and relationship to gestational age and risk for fetal outcomes. *NT, Nuchal thickness*. (Adapted from Souka AP, Von Kaisenberg CS, Hyett JA, Sonek JD, Nicolaides KH. Increased nuchal thickness with normal karyotype. *Am J Obstet Gynecol.* 2005;192:1005–1021.)

In addition to an increased first trimester NT, DS fetuses can exhibit other abnormalities in the second trimester that would adjust the patient's *a priori* risk. Table 26.2 provides an overview of the common ultrasound markers and their likelihood ratios. Note that some of these markers signal other pathologic processes. Therefore it is important to consider the entire breadth of diagnoses for some of these markers. Calculation of DS adjusted risk, based on markers, can be performed at http://perinatology.com/calculators2.htm (Age-Adjusted Ultrasound Risk Assessment).

Accurate identification of *fetal NTD* can be readily accomplished in the second trimester ultrasound. This is especially important for maximizing management options for the pregnancy in light of the availability of in utero fetal surgery for repair of the defect.[37] The "lemon" sign representing scalloping of the frontal bones and the "banana" sign representing obliteration of the cisterna magna with distortion of the cerebellum due to herniation of the hindbrain (Chiari malformation) are the two most sensitive and specific findings for an open NTD. Observation of these cranial defects should initiate a detailed survey of the fetal spine. Mild ventriculomegaly in the second trimester is observed in only 70% of cases. The location and extent of the defect are important for anticipation of postnatal bowel and bladder function, ambulation, neurocognitive development, and consideration for *in utero* fetal surgery. Amniocentesis is recommended to confirm an open defect by demonstrating elevated amniotic fluid AFP levels and presence of acetylcholinesterase and to exclude fetal genomic abnormalities, which are found in 10% of fetuses with an open NTD.[38]

TABLE 26.2 Ultrasound Markers Associated With Aneuploidy and Down Syndrome

Marker	Likelihood Ratio
Cystic hygroma (first trimester)	>50% aneuploid, Turner syndrome
Isolated echogenic intracardiac focus (second trimester)	1.4–1.8 for DS
Renal pelviectasis ≥4 mm (20 weeks' gestation)	1.5–1.6 for DS
Echogenic bowel*	5.5–6.7 for DS
Ventriculomegaly (10–15 mm)	25 for DS
Isolated choroid plexus cyst(s) (≤20 weeks' gestation)	No association
Short femur length (<2.5%ile for gestational age)	1.1–2.2 for DS

*Grade 3 = density same as bone.
DS, Down syndrome.

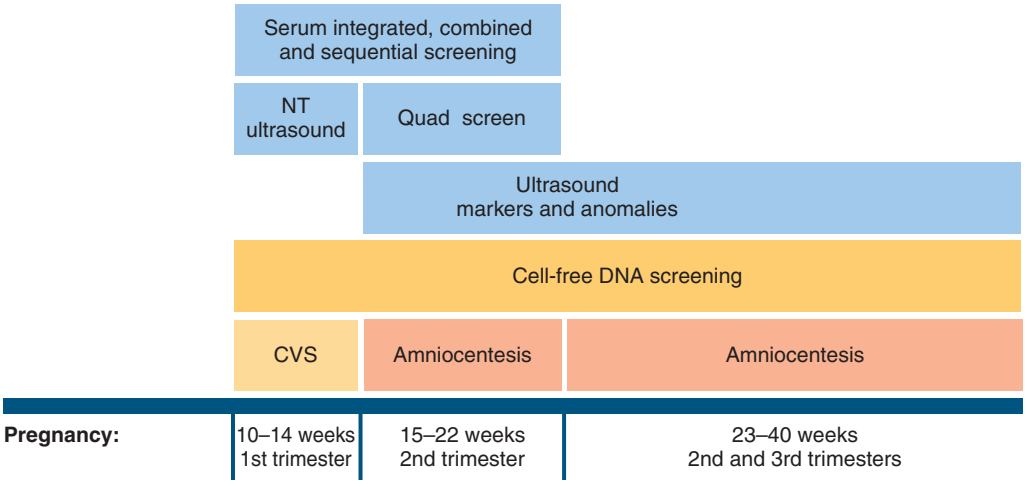
Eligibility for fetal surgery includes a chromosomally normal fetus diagnosed between 19 weeks 0 days and 25 weeks 6 days with an isolated myelomeningocele between T1 and S1, with evidence of hindbrain herniation in a nonobese (body mass index <35) healthy woman with no history or risk factor for preterm delivery. Among children who underwent in utero surgery for repair of spina bifida between 19 and 25 weeks'

gestation under the Management of Myelomeningocele Study (MOMs trial), there was a 50% reduction in the need for a ventricular shunt, less Chiari malformation, and improved motor skills, with twice as many children walking independently at 30 months compared with the postnatal surgery group.[39] First and second trimester ultrasounds readily diagnose *anencephaly, fetal gastroschisis*, and *fetal omphalocele*. The gestational age at which nuchal thickness (NT) screening is performed is especially efficient in identifying these conditions. Early diagnosis of fetal anencephaly maximizes management options and decreases maternal complications. Large gastroschisis is readily identified during the evaluation of the NT. Fetal omphaloceles may be ambiguous in the first trimester because of the physiologic herniation of the midgut into the base of the umbilical cord before 12 weeks' gestation. After 12 weeks, the gut returns to the abdominal cavity; persistence of a midline abdominal wall saccular defect with the umbilical cord arising from the apex of the sac and abdominal contents in the sac is diagnostic of an omphalocele. In contrast, gastroschisis is typically paraumbilical to the right of the cord insertion with free floating eviscerated bowel in the amniotic fluid. It is important to differentiate between these two anatomic defects; gastroschisis is rarely associated with structural or chromosome abnormalities. However, this condition is associated with a high rate of intrauterine growth restriction, oligohydramnios, and intrauterine fetal demise; prenatal care pathways for surveillance may be helpful in optimizing the fetus for postnatal interventions. In contrast, omphalocele is strongly associated with other pathologic processes, including other structural anomalies and genomic or syndromic conditions. Amniocentesis is recommended to exclude an underlying genomic imbalance that could impact postnatal interventions and prognosis. Fetuses with gastroschisis tolerate labor and vaginal delivery well, while fetuses with large omphaloceles are delivered by cesarean section because of the risk of rupture during vaginal delivery.

Prenatal skeletal dysplasia should be suspected when the long bone measurements are at or less than the 5th percentile or more than three standard deviations below the mean for gestational age.[40] Concurrent abnormalities such as fractures (osteogenesis imperfecta types II–IV), shape of the skull (thanatophoric dwarf), or decreased mineralization (hypophosphatasia) may direct the diagnosis. However, the diagnosis of most nonlethal congenital skeletal dysplasias will not be made until after birth or even into adulthood. Thus prenatal diagnosis of skeletal dysplasia raises the possibility of lethal pulmonary hypoplasia, which directs the prenatal and postnatal management of the pregnancy.

To date, two-dimensional ultrasound remains the standard imaging modality for prenatal screening and diagnosis. Three-dimensional ultrasound is helpful in visualizing any external structural abnormalities such as cleft lip/palate and spina bifida. The use of fetal magnetic resonance imaging (MRI) is increasing and is most helpful in evaluating fetal intracranial abnormalities suspected on ultrasound. Fetal MRI is noninvasive, does not involve ionizing radiation, and has no known short- or long-term effects on fetus or mother. The main drawback is fetal motion, but the development of fast MRI sequences has significantly reduced motion artifact. A recent review[41] provides a practical approach to fetal brain MRI performance and interpretation. Both fetal and postnatal brain MRI may play important roles in the diagnosis and management of patients with CNS anomalies, and together can be complementary in treatment planning.[42] Fetal MRI may be valuable in the prenatal diagnosis of fetal neck, chest, and abdominal malformations.[43] It is useful in estimating the degree of pulmonary hypoplasia in fetuses with congenital diaphragmatic hernia and predicting their need for ECMO and likelihood of survival.[44]

In summary, noninvasive prenatal screening has expanded to cover the entire course of pregnancy, allowing directed diagnosis of several common chromosomal conditions without invasive testing (Fig. 26.6). In the United States, ACOG recommends that all women, regardless of maternal age or history, should be offered prenatal screening (serum screening with or without NT screening, cfDNA, 2nd trimester ultrasound, 2nd trimester serum screening, CVS, or amniocentesis).[14] The next frontier in genomic medicine and prenatal diagnosis is clinical application of noninvasive sequencing of the entire prenatal genome for prenatal diagnosis which is beyond the scope of this chapter. This is a rapidly expanding area of development in diagnostic platforms, improving precision, and turn around time with the intent for early diagnosis to optimize choices and possible prenatal treatment; these advances will undoubtedly add to our understanding of genomic regulation of normal and abnormal developmental processes, but like cfDNA, will uncover information for which we may not yet have experience for interpretation.[45–49]



• **Fig. 26.6** Prenatal screening and testing options during pregnancy. *CVS*, Chorionic villus sampling; *NT*, nuchal thickness.

Preimplantation Genetic Diagnosis/ Screening

Preimplantation Genetics

Preimplantation genetic testing (PGT) provides genetic and/or aneuploidy information about the embryo, requires in vitro fertilization (IVF) technology, and can be considered a form of prenatal diagnosis. PGT-A refers to preimplantation testing for aneuploidy to identify euploid embryos for transfer. PGT-M refers to preimplantation genetic testing of embryos for single gene mendelian disorders, and PGT-SR refers to testing of embryos at risk for chromosomal structural rearrangements. Knowledge of the genetic mechanisms and risks for fetal anomalies as a function of the IVF and PGT processes is important as these women undergo prenatal screening with ultrasound, maternal serum screening, or NIPS. For the neonatologist, this background information may influence, for example, the suspicion that a newborn may have Beckwith–Wiedemann syndrome, since this syndrome is associated with pregnancies achieved through IVF technologies. Women of advanced maternal age who achieve pregnancies using their own eggs often undergo PGT-A of the embryos for aneuploidy. Confirmatory testing by CVS or amniocentesis is recommended, but few women elect to undergo an invasive procedure that risks a much-desired pregnancy. NIPS offers these women an intermediate solution for "confirmation" of a euploid fetus. However, knowledge of the number of embryos transferred and concordance with the number of viable fetuses seen on ultrasound are important if NIPS is used; an embryonic demise of a transferred twin could result in discordant NIPS results. Unique to IVF pregnancies, regardless of whether or not embryos have undergone PGT, is the concern for genetic conditions and/or birth defects as a result of imprinting errors or other mechanisms that may disrupt the normal developmental processes of the early embryo. Maternal serum screening for aneuploidy is not as robust in twin gestations as it is in singleton pregnancies. NIPS for twin gestation has now been accepted. ACOG recommends appropriate choice of patients and counseling before proceeding.[14] Definitive prenatal diagnosis of twins discordant for birth defects still requires CVS or amniocentesis.

Building a Prenatal Diagnosis Center

Whatever its size and scope, a prenatal diagnosis program can provide pregnant people and their partners with accurate information about fetal diagnosis and prognosis within the limits of their center's capacities and their team's expertise. The care team can be transparent about those limits and refer to other centers as appropriate. Only large prenatal centers should attempt fetal intervention, given the extraordinary resources of people and capital required[50] and the complexity of counseling and consent.[51]

The People

1. **Maternal Fetal Medicine:** Experienced and skilled MFM physicians determine whether an affected fetus may benefit from fetal intervention, extra fetal monitoring, or special services at or soon after delivery. They work closely with pediatric specialists who are experts in caring for patients with congenital defects. They are skilled in communicating difficult or serious news (see section on Prenatal Counseling) and provide information tailored to what the parents want and need to hear. They and their teammates can sensitively explore whether the parents wish to end the pregnancy if a life-threatening birth defect is detected, and then help arrange or refer as appropriate. In partnership with the referring provider, they ensure high-quality obstetrical care through the end of the pregnancy.
2. **Nursing:** One or more nurses or nurse practitioners assist and empower prenatal patients during the often long and complex journey until delivery. They are knowledgeable about the typical timing and urgency of visits, and which tests and specialists need to be involved and when. Ideally, they serve as a navigator throughout each clinic visit, participating in the preclinic huddle, the counseling, and the wrap-up for next steps. They can also make available teaching materials and videos of parents sharing their experiences with their children with similar fetal diagnosis. For an example of a video for parents, see https://www.seattlechildrens.org/conditions/gastroschisis/.
3. **Support staff:** One or more staff members can assist with the many nonclinical tasks such as scheduling complex clinic visits with multiple procedures and specialists, communicating with referring providers, maintaining a database, etc.
4. **Genetic counselor:** Given the ever-changing field of genetic testing and the complexity of prenatal counseling, it is very helpful to have a genetic counselor embedded in the prenatal clinic.
5. **Social worker:** Given the diverse life experiences and resources of prenatal clinic patients, and the complex housing and transportation needs of those who live remotely from the clinic, a social worker or other mental health professional, knowledgeable about the physical and psychological needs of pregnant women and their families, is essential. When appropriate, they can connect the patient with a parent who has gone through a similar experience or to an online support group.
6. **Neonatologists:** It is essential that the MFM have a close working relationship with neonatologists or neonatal advanced practice providers who can help develop postnatal plans for the baby and sometimes assist the family in making difficult choices (see section The Role of a Neonatologist in Prenatal Diagnosis Clinic).
7. **Pediatric and surgical specialists:** Based on volume, the pediatric specialists most likely to be needed, either in person or virtually, include fetal cardiologists, general surgeons, neurodevelopmental experts, nephrologists, urologists, skeletal dysplasia experts, cardiac surgeons, cardiac intensivists, otolaryngologists, and members of the single-ventricle cardiology team. Radiologists with experience in prenatal diagnosis by ultrasound and MRI are invaluable in many situations.
8. **Sonographers:** Fetal ultrasound and echocardiography require advanced training and skills. They work closely with MFM and prenatal cardiologists, respectively.
9. **Palliative care:** Whenever the postnatal journey will likely be difficult or long, prenatal consultation with palliative care provides an extra layer of support. This is true regardless of the newborn's prognosis for survival but is especially important if the parents are considering immediate comfort care after delivery for a life-threatening fetal condition.

The Infrastructure

The basic facilities required for a prenatal diagnosis center include rooms for ultrasound, echocardiography, and counseling. Ideally there will also be equipment for virtual interdisciplinary visits with

multiple specialists simultaneously. Procedures like amniocentesis, termination of pregnancy, and fetal intervention require a hospital partner with labor and delivery as well as NICU capabilities, and advanced genetic testing requires partnerships with hospital and private laboratories. A description of the requirements of a fetal intervention program is beyond the scope of this chapter.

In addition to close connection with a high-risk delivery hospital, prenatal diagnosis programs benefit from having one or more of the following:

1. Database for quality improvement and for reporting to outside agencies
2. Quality improvement programs that are connected to their home departments of obstetrics, neonatology, cardiology, surgery, and neurodevelopment, and their long-term follow-up programs
3. Research programs related to prenatal care and fetal outcomes
4. Telemedicine support for virtual counseling
5. Training and continuing education programs
6. Regular interdisciplinary conferences for management of challenging prenatal cases; perinatal genetics, imaging, and pathology conferences; mortality and morbidity review, and neonatal outcomes of recent deliveries.

A Practical Guide to Prenatal Counseling

Prepare for the encounter: Ideally each member of the prenatal clinic team will have advanced communication skills due to the challenges of delivering difficult or serious news to prenatal patients.[52] Many of these patients and their partners will be grieving over the loss of their dreams for a healthy baby and the normal life experiences of pregnancy and childbirth. For many, this grief will be compounded by guilt, anxiety over diagnostic and prognostic uncertainty, and/or ambivalence about the outcome. The requirement for a personalized antenatal counseling approach is well described by Haward et al.[53] and is highly recommended for those doing this challenging work.

Because of the complex and multidisciplinary nature of the issues, more than one provider will often be involved in counseling. For these reasons, a precounseling team meeting to discuss obstetrical and maternal issues, delivery planning, neonatal support, and psychosocial readiness of the patient and partner is critical to everyone's understanding of different perspectives. The team should review the most up-to-date information about the fetus and the parents' psychosocial readiness to hear the information, discuss the goals for the encounter, and agree on the headline—a one- or two-sentence summary of the problem that includes both information and meaning, such as *"we've discovered that your baby has small, underdeveloped lungs and we're worried that she may not live to go home from the hospital."* The team should also coordinate their counseling so that the encounter is seamless, with each specialty provider adding content that collectively will give the patient the whole picture of the pregnancy, labor and delivery, and postnatal care of the baby. See Box 26.1 for summary of the key steps.

Connection: Practices that foster connecting to patients include (1) preparing with intention, (2) listening intently and completely, (3) agreeing on what matters most, (4) connecting with the patient's story, and (5) exploring emotional cues.[54–56] Creating an inviting neutral environment is important in relationship development. Because clinic staff and nurses often have had preconsultation encounters with the patient, for example, scheduling appointments, instructions, and anticipatory explanations about the nature of the consults, they play a critical role in introducing and connecting the subspecialty team members to the patient. In our program, the nurse assigned to the patient will escort the patient into different rooms for ultrasound and echocardiography, and then participate in the counseling session with specialists. When beginning the session, each participant should introduce themselves and their role, and then ask the patient and partner *"What do you like to be called? What would you like us to know about you? How can we be most helpful to you today?"* This sends the message that the team is engaged in the entirety of their situation and not just the medical issues; it is important that the patient and partner understand that the prenatal team is respectful of the impact of the diagnosis on the baby, parents, and extended family.

The VitalTalk REMAP acronym, widely used by palliative care providers and communication experts,[57,58] is useful for structuring the counseling, especially if unwelcome and unexpected news will be shared and a life-altering decision must be made.

Reframe: Most patients referred to a prenatal diagnosis center have already been given news from their obstetrical provider that there is something seriously wrong with the pregnancy or baby. Many have already searched the internet and talked to family and friends which may lead to misunderstanding or incorrect assumptions. Thus, it is important to begin by assessing what the patient and partner know or think they know about their situation, and then reframe the discussion around what is known and what it means. Ask *"So that I know where to begin, could you tell me what you know so far about your situation?"* If they already understand the key information, skip to the Emotion step below. If not, ask permission with *"Would it be okay if we talk about what we've discovered so far and what is concerning to us?"* If yes, ask *"Is there anyone else you'd like to be here with you, or on the phone or videocall?"* Provide the headline as developed in the huddle, and then wait for a response which is usually one of emotion. If there is no visible emotional reaction, ask *"we just gave you some hard news—how are you doing with it?"*

Emotion: Effective headlines almost always lead to intense emotions like disappointment, sadness, anger, and fear. It is counterproductive to give more information without first allowing the patient and partner to process their emotional reaction to the headline. The VitalTalk NURSE acronym (www.vitaltalk.org) provides ways to respond empathetically, depending on the situation: Naming, Understanding, Respecting, Supporting, and Exploring statements. Examples of NURSE statements include, respectively, *"I can see that you're disappointed," "This news must be*

• BOX 26.1 Key Steps in Counseling

Prepare for the encounter: huddle, create headline with information and meaning.

Connect

REMAP

Reframe	Assess their understanding of the problem. Provide the headline and wait for emotional response.
Emotion	Respond empathetically with NURSE statements: Naming, Understanding, Respecting, Supporting, and Exploring.
Map out values	Determine what is important, concerns, tradeoffs.
Align	Show your work and confirm accuracy.
Plan	Ask permission to make a recommendation. Propose a plan. Check-in. Reassure.

*such a shock," "You've done everything you could do for your baby," "We'll be here for you," and "Could you tell me more about what you mean when you say***?"* Until emotions have been acknowledged and validated as normal with one or more of these statements, defer answering questions that appear to be requests for information but are actually emotional cues that need to be addressed before proceeding. When the fetal defects are complicated, the cumulative information from each subspecialist can be overwhelming. Pause after each NURSE statement to gauge its impact and check in periodically: *"We just said a lot about the heart defect—how are you doing with this information? Let us know when you are ready to talk about***."*

Map out values: Before reviewing options, it is critical to gather information about the parents' values and goals. Determine what is important by asking *"Knowing this news, what is important to you?" and "What do you think might be important to your baby?"* Ask *"what worries or concerns do you have*?" When appropriate, ask about tradeoffs: *"What abilities are so critical to your baby's life that you can't imagine him or her living without them?"* If they respond that they are hoping for a miracle, respond with "*we are hoping for a miracle with you."* After pausing, ask *"Would it be okay to talk about what would be important to you if the miracle we're hoping for doesn't happen?"* When they are ready for information, let the parents take the lead in asking questions, and then respond specifically, concisely, and compassionately—pausing as they absorb the news. Ask whether they are the kind of person who wants to hear all the details and statistics, or someone who wants just the big picture. Avoid cognitive overload. Stop to listen. Respond empathetically when new emotions arise. Allow room for silence—it is often followed by important reflections or insightful questions.

Align values with treatment options: Show your work and confirm its accuracy: "It sounds like*** is important to you, and that you're worried about***. Did I get that right? Is there anything that I missed?"

Plan: Ask permission: "Would it be okay if I made a recommendation based on the things you just told me?" If yes, propose a plan: "From what you've shared with me, and given where things are medically, I recommend***." Check-in: "How does that sound?" Reassure: "No matter what happens, we will be here to support you through each step of this journey." And then follow through on your commitment.

The Role of a Neonatologist in Prenatal Diagnosis Clinic

Depending on the size and complexity of the prenatal diagnosis program and the availability of other pediatric specialists, the role of the neonatologist[59] or neonatal advanced practice provider may include one or more of the following:

1. **What to expect at delivery:** Prospective parents who are expected to have anything other than a normal delivery and a neonatal course should meet with someone who can accurately describe the most likely events after birth and the spectrum of other possible outcomes. This may be provided by the prenatal clinic nurse or nurse practitioner if they have recent delivery room and NICU experience, or by the prenatal medical specialists like cardiologists and general surgeons. However, most prenatal clinic patients appreciate the opportunity to meet during the final weeks before delivery with a NICU provider who can represent the NICU team, review in detail the plans for their baby immediately after birth, answer questions, and when appropriate offer continuity of care of their baby after delivery. The parents may benefit from reassurance that the NICU team present at delivery will be knowledgeable about the birth plan, prepared to address every contingency after birth, and flexible in modifying the plan if required based on the parents' values and goals. Here are some suggestions for beginning this conversation:
   - "Hi, I'm***. I'm a neonatologist who works with the newborn intensive care team who will care for your baby after birth. I'm here today to review the plans for your baby and answer your questions—is that okay? Is there anything else you'd like to cover? So that I know where to begin, could you tell me what you already know about the plans for your baby after birth?"
   - After listening carefully without any interruption or corrections, ask "Would you like me to describe the most likely events for your baby after delivery? If so, do you want details, or the big picture?"
   - To help the NICU team understand the parents' preferences, especially since there may be unexpected problems after delivery, ask "What is most important to you after delivery of your baby?", "What else is important?", "What are you worried will happen after your baby is born?", and "What else are you worried about?".
2. **Interdisciplinary counseling with pediatric specialists:** When the NICU stay is likely to be complicated and prolonged, parents may find it helpful to meet early in pregnancy with the relevant specialists and a neonatologist at the same time because of their different areas of expertise and experience. It will be reassuring to the parents to see that the members of their team are all on the same page and that they communicate well with one another.
3. **Refine the details of the birth plan:** Although the general outline of the plan is often developed by the MFM and pediatric specialists, the neonatologist is especially qualified to give advice on location of delivery due to knowledge of the services the newborn may need and the abilities of NICUs in the region to provide them safely and effectively. Also, in collaboration with the other pediatric specialists, the neonatologist should have input into proposing the timing of transfer of the baby from delivery room to NICU or to another hospital for definitive treatment. This is because the specialists may underestimate the importance of keeping the mother and baby together during the first hour after birth for bonding and successful breast feeding if that can be done safely, or understand the level of monitoring available in different NICUs. When fetal imaging suggests that the baby's survival may depend on immediate surgical or catheter-directed intervention (e.g., obstructed total anomalous pulmonary venous return) and the delivery hospital does not provide those services, the neonatologist can help arrange for the transport team to be present at the delivery. Patients with surgical problems like congenital diaphragmatic hernia without severe pulmonary hypoplasia on prenatal imaging should generally be admitted to the delivery hospital's NICU for confirmation of good endotracheal tube placement if placed, insertion of umbilical catheters, and adjustment of respiratory support before transfer when stable to a surgical NICU. Newborns with known ductal-dependent heart defects can often have their transfer from the delivery hospital to a cardiac ICU deferred for several hours if started on alprostadil in the first 1 to 2 hours after birth and then carefully monitored

in the NICU while facilitating maternal bonding and breast feeding. Babies too premature or small for cardiac intervention may benefit from staying days or weeks in the delivery hospital's NICU, on alprostadil if ductal dependent, until larger and mature enough for intervention.

4. **Develop birth plan when survival is uncertain:** When survival without severe impairment is unlikely and yet the parents say that they want full intervention for their unborn baby, the neonatologist can represent the NICU team and its treatment philosophy during prenatal counseling. The critical elements of this counseling are described in the Practical Guide to Prenatal Counseling section of this chapter. Among the prenatal team members, the neonatologist may be best positioned to explain the degree of diagnostic and prognostic uncertainty, review the options of immediate comfort care versus transferring the baby elsewhere for intervention, and compassionately discussing the tradeoffs between efforts to prolong life and to prevent suffering. Input from experts in perinatal palliative care can be of great benefit before and after delivery in these situations.
5. **Undecided about whether to continue the pregnancy:** The MFM who has knowledge of methods of ending pregnancy and local legal restrictions is essential to these difficult conversations, but the parents' decision may hinge on the likelihood of survival and quality of life. When the fetus has a condition like hypoplastic left heart syndrome, the cardiologist is best equipped to answer the parents' questions. However, for conditions at risk for life-threatening respiratory problems (e.g., extreme prematurity, prolonged oligohydramnios, diaphragmatic hernia, skeletal dysplasia), the neonatologist can provide valuable information to the parents regarding the degree of uncertainty from prenatal testing and the range of possible outcomes.

Summary

This exciting period of discoveries and advancements in prenatal diagnosis offers women a broad choice of studies to investigate the health of the fetus. For couples at high risk for a known condition, the option of PGT or DNA-based prenatal diagnosis offers them hope and a chance for a healthy baby. For fetuses with life-threatening structural anomalies, such as hypoplastic left heart syndrome, prenatal diagnosis offers preparation for delivery at a high-risk center where neonatal support and subspecialty intervention offer the neonate a good chance for survival. In these efforts, we have educated our patients and ourselves, for in the last 40 years we have had a window to peek into the developmental processes of the human embryo through imaging and genomics. Now, we have the potential to understand the action of developmental genes over time in both normal and abnormal conditions, along the fetal–pediatric–adult continuum. And in these opportunities to improve survival of serious and complex conditions, parents are faced with difficult decisions. Centers that have the capabilities to offer intervention will need to be prepared to provide the complex counseling needed to support families through their journey.

The Dysmorphic Infant

K. TAYLOR WILD, SARAH E. SHEPPARD, AND ELAINE H. ZACKAI

KEY POINTS

- A genetic diagnosis can direct medical care (treatment, screening for other anomalies or issues that will arise in the future), provide information about prognosis, and give a recurrence risk to families.
- A genetics evaluation should be considered for a patient in the setting of multiple anatomic anomalies, known maternal exposure to a teratogen, a history of familial disorders, increased carrier frequency or ethnic risk, consanguinity, or multiple pregnancy losses.
- The essential components of a genetic evaluation include the medical history, family history, dysmorphology examination, literature review, and diagnostic testing.
- Exome sequencing (ES) allows for a genetic diagnosis in about one-third of patients.[1]
- In cases in which there is no clear diagnosis, prognosis and treatment should be determined according to the organ systems involved and the extent of their impairment.

TABLE 27.1 Genetic Disorders in Pediatric Hospital Admissions

Genetic Disorders	Montreal (1973)	Seattle (1978)	Cleveland (2004)
Chromosome, single gene (%)	7.3	4.5	11
Polygenic (%)	29	49	60
Nongenetic disorders (%)	64	47	29
Total number of admissions	12,801	4115	5747

Genetic disorders have a major impact on public health, as indicated by several large epidemiologic studies (Table 27.1).[2–5] Genetic factors may also contribute to more than two-thirds of the conditions prompting admission to a children's hospital.[4] Early identification of the genetic nature of a given condition may then help to appropriately focus resources for providing better care to these individuals. It is therefore critical to implement a systematic approach to evaluating a newborn with dysmorphic features or congenital anomalies. This chapter outlines a general approach.

When and Why to Consider a Genetic Evaluation

A genetic evaluation can provide many benefits besides providing an underlying diagnosis. Management changes may occur in over half of patients.[1] Management changes may include screening for additional congenital anomalies, screening for hypertrophic cardiomyopathy or cancer, or changes to an inhibitor (in vascular anomalies). Importantly, genetic diagnosis can also give families a recurrence risk and give them the option for preimplantation genetic testing or other prenatal diagnostic options.

When should a genetics evaluation be considered? The following clinical situations prompt a further genetic evaluation and counseling by a specialist:

- Multiple anatomic anomalies
- History of maternal exposure to teratogens
- Familial disorders
- Increased carrier frequency or ethnic risk
- Consanguinity
- Multiple pregnancy losses

If a congenital anomaly is identified in the presenting patient or proband, especially if the defect is associated with other anatomic anomalies, short stature, or developmental delays, the features of a specific genetic syndrome may be present. A known history of maternal exposure to a potential teratogen would also be an indication for consultation. Conditions appearing to be familial, a family history of hereditary disorders involving malformation of a major organ, or major physical differences such as unusual body proportions, short stature, or irregular skin pigmentation would warrant genetic investigation. Intellectual disability, blindness, hearing loss, or neurologic deterioration in multiple family members suggests a genetic etiology. Likewise, a genetics evaluation is indicated for strong family history of cancer or a defined ethnic risk for specific disorders, such as the higher carrier frequency for Tay–Sachs disease in individuals with Ashkenazi Jewish heritage. The occurrence of multiple pregnancy losses would also raise the suspicion of a genetically influenced cause and indicate the need for further investigation and counseling.

Patterns of Anomalies

When performing the evaluation, it is important for the physician to consider if the anomaly is primary or secondary and how the multiple congenital anomalies may be associated with each other. The occurrence of malformations can fit into one of several

• BOX 27.1 Underlying Mechanisms of Malformation

Syndrome: Pathogenetically related pattern of anomalies
Sequence: Pattern of anomalies derived from a presumed or known previous anomaly or mechanical disturbance
Association: Nonrandom occurrence of multiple anomalies
Field Defect: Disturbance of a developmental field leading to a pattern of anomalies

• BOX 27.2 Processes Leading to Altered Form or Structure

Deformation: Abnormal form resulting from mechanical forces
Disruption: Morphologic defect caused by interference with a previously normal developmental process
Dysplasia: Altered morphology because of abnormal organization of cells into a given tissue

categories (Box 27.1). A *syndrome* is a "collection of anomalies involving more than one developmental region or organ system."[6] The word itself means a "running together" or "pattern of multiple anomalies thought to be pathogenically related." Therefore, a given congenital anomaly may be an isolated defect in an otherwise normal individual or part of a multiple malformation syndrome. In some individuals, a *sequence* may occur when the primary malformation itself can determine additional defects through an interrelated cascade of physical and functional processes. A classic example is the Pierre Robin sequence (PRS), consisting of a small, recessed jaw, midline U-shaped cleft palate, and relatively large and protruding tongue. The primary anomaly is the small jaw, which does not allow adequate room for the tongue and displaces it superiorly. The displaced tongue prevents closure of the palatine shelves, causing the cleft palate.

In addition, a cluster of several malformations that are not developmentally related can occur in a nonrandom fashion called an *association* that may appear without characteristic dysmorphic features. One such statistically nonrandom association of defects consists of *v*ertebral defects, *a*nal atresia, *c*ardiac defects, *t*racheoesophageal fistula, *e*sophageal atresia, *r*enal dysplasia, and *l*imb anomalies (VACTERL). It should be noted that not all features need to be present and that the extent of involvement of each system is widely variable. Although there have been various candidate genes and chromosomal regions described in some patients with VACTERL association, there is no common genetic etiology known at this time,[7] likely due to the heterogenous presentation of these patients. However, there are many overlapping genetic syndromes that need to be excluded before concluding that a patient has VACTERL association. Associations often manifest as sporadic rather than familial occurrences. Because they are not clearly related by a common etiology or pathogenesis, associations are not considered syndromes and do not technically constitute a diagnosis. Instead, they are a recognition of a statistically significant association of features. It is important to remember that many of these same anomalies can occur as features of chromosomal aneuploidy or other syndromes. Chromosomal aneuploidy refers to the presence of an abnormal number of chromosomes in a cell.

Syndromic malformations tend to occur in more than one developmental field. A *field defect* or complex is a set of primary malformations in a developmental field that originates from a single or primary abnormality in embryonic development (see Box 27.1).

When generating a differential diagnosis of malformations that might occur together, the evaluator must also consider structures that may appear abnormally formed but in fact are structures that underwent normal development and then received some insult that distorted their true form (Box 27.2). For example, a *deformation* describes the abnormal form, shape, or position of a part of the body that was caused by mechanical forces. Examples are clubfoot, hip dislocation, and craniofacial asymmetry; they can result from intrinsic (embryonic) or extrinsic (intrauterine) mechanical forces that alter the shape or position of an organ or part that had already undergone normal differentiation. Deformations are estimated to occur in 2% of births, and such factors as fetal crowding from the presence of multiple fetuses and uterine malformations, as well as oligohydramnios, and a face presentation during delivery can cause them.

TABLE 27.2 Examples of Morphologic Differences

Malformation	Cardiac septal defects Cleft lip
Deformation	Clubfoot
Disruption	Amniotic bands
Dysplasia	*Localized*: hemangioma *Generalized* (skeletal): achondroplasia

Along similar lines, a *disruption* describes a "morphologic defect of an organ, part of an organ, or larger region of the body resulting from the extrinsic breakdown of, or an interference with, an originally normal developmental process."[6] The classic example of a disruption is entanglement of the fetus in amniotic bands. Amniotic bands are ribbons of amnion that have ruptured *in utero* and cause disruptions of normal developmental processes in the fetus, either through physical blockage or interruption of the blood supply or by entangling and tearing of developing structures. This effect is seen most often with digits and limbs, and remnants of the bands, or constriction marks, can frequently be seen at birth. If the fetus should swallow a band, a cleft palate might result; this etiology is a very different etiology from that of cleft palate occurring as a primary malformation. Recurrence risk counseling of the parent would be very different in these two scenarios.

Dysplasias occur when there is "an abnormal organization of cells into tissue(s) and its morphologic results."[6] Dysplasia tends to be tissue-specific rather than organ-specific (e.g., skeletal dysplasia) and can be localized or generalized.

In summary, structural or morphologic changes identified at birth can occur during intrauterine development as a result of malformations, deformations, disruptions, or dysplasias. However, approximately 90% of deformations undergo spontaneous correction. Malformations and disruptions often require surgical intervention when possible. Dysplasias are typically not correctable, and the affected individual experiences the clinical effects of the underlying cell or tissue abnormality for life (Table 27.2).

Genetics Evaluation

The clinical geneticist incorporates the following five essential tools in the evaluation of a child suspected of having a primary genetic disorder:

- History: prenatal, birth, and medical
- Pedigree analysis and family history
- Specialized clinical evaluations: Physical examination and adjunct studies
- Literature review
- Specialized laboratory tests (e.g., karyotype, chromosomal microarray, sequencing)

History

Prenatal

A complete gestational history should be generated, including details of conception, prenatal testing, exposures, and pregnancy course. The maternal age at conception should be documented as the risk of chromosomal anomalies due to nondisjunction rises with maternal age. Paternal age should also be documented as there is increasing evidence that the risk of autism, certain types of developmental disorders, and forms of craniosynostosis, including Apert syndrome and Muenke syndrome, increases with paternal age.[8–10] Any use of assisted reproductive technology to aid in conception should also be noted as there is an increased risk of imprinting disorders such as Beckwith–Wiedemann syndrome (BWS), Prader–Willi syndrome, and Angelman syndrome in children born with the assistance of in vitro fertilization and intracytoplasmic sperm injection.[11] Results of prenatal testing may include carrier testing, maternal serum and/or noninvasive prenatal screening, ultrasonography and other imaging techniques such as fetal echocardiogram or magnetic resonance imaging (MRI) if applicable, and diagnostic genetic testing through chorionic villus sampling or amniocentesis (Box 27.3).

Noninvasive prenatal screening (NIPS) is a screening test for chromosomal aneuploidies that is obtained from cell-free DNA from the fetus that circulates in the maternal serum. It can be drawn from a peripheral blood draw as early as 10 to 11 weeks of gestation. NIPS was initially developed to screen for trisomy 13, 18, and 21 and has very high sensitivity, specificity, and positive predictive values for these disorders.[12–14] For trisomy 21, NIPS has a higher sensitivity, a lower false-positive rate, and a higher positive predictive value than standard screening with nuchal translucency measurement and biochemical analytes.[14] NIPS was subsequently expanded to screen for sex chromosome aneuploidy, but has a poorer detection rate and a higher false-positive rate for the sex chromosome aneuploidies, particularly for monosomy X.[15] Some companies have even expanded NIPS further to include five common microdeletion syndromes including 1p36, 4p (Wolf–Hirschhorn syndrome), 5p (cri-du-chat syndrome), 15q11-13 (Prader–Willi or Angelman syndrome), or 22q11.2 deletion syndrome. However, while NIPS will screen for these microdeletion disorders, the positive predictive value is low at 9.2%.[16] Furthermore, ACOG does not recommend NIPS screening for microdeletion syndromes and this is not performed at most centers.[17] It is important to note that NIPS is only a screening test and should be confirmed with diagnostic testing.

It is important to identify prenatal exposures. Prenatal exposures may include infection, medications, maternal habits such as alcohol and drug use, maternal chronic illnesses such as maternal diabetes or obesity, travel, and other *teratogens*. Teratogens are environmental agents that may cause structural and functional diseases in an exposed fetus. Each teratogen may have a characteristic expression pattern, with a specific range of associated structural anomalies and dysmorphic features. Specific effects and the extent of those effects depend on the time of exposure, duration, and dosage, as well as interactions with maternal and genetic susceptibility factors. In general, more severe effects are typically correlated with exposure early in the pregnancy and with more extensive (i.e., higher dose) exposure. The list of well-documented human teratogens is short and includes such substances as alcohol, thalidomide, warfarin, trimethadione, valproate, isotretinoin, angiotensin converting enzyme inhibitors, chemotherapeutics, lithium, amiodarone, azole fungicides, high-dose methotrexate, and hydantoin.[18] If history of an exposure is documented, an effort should be made to identify the developmental time and level of exposure. This information is critical, because the counseling and calculation of recurrence risk for a given malformation are vastly different if environmental exposures are involved.

Another important component of the gestational history is obtaining information on fetal activity, size, position, and amniotic fluid. Often, the mother's subjective impressions can be further confirmed by examining obstetric records of the prenatal period. A history of hypotonia may be further supplemented by reports of poor fetal movements and breech presentation and a history of seizures may be supplemented by frequent fetal hiccups. Oligohydramnios (decreased amniotic fluid volume) can be associated with either a fluid leak or a genitourinary abnormality, whereas polyhydramnios (excess amniotic fluid volume) can be seen in fetuses with neuromuscular disease or gastrointestinal malformations.

• BOX 27.3 Elements of Prenatal History for the Dysmorphic Newborn

Maternal Health
Age
Disease: diabetes, hypertension, obesity, seizure disorder

Mode of Conception
Natural
Assisted reproductive technologies

Prenatal Testing
Ultrasonography (gestational age performed)
Advanced fetal imaging (fetal echocardiogram or MRI)
Maternal serum screening
Noninvasive prenatal screening (NIPS)
Chorionic villus sampling or amniocentesis

Birth

Perinatal information including gestational age, fetal position at delivery, the length of labor, type of delivery, and any evidence of fetal distress, such as passage of meconium, are all relevant data (Box 27.4). Apgar scores, the need for resuscitation, birth parameters (weight, length, and head circumference), any malformations seen at birth, and all abnormal test results should be noted.

Medical

A full review of the medical issues of the child should include the baby's general health, newborn screen results, any laboratory or imaging results, identification of any chronic medical issues, detailed feeding history, and need for hospitalization or surgeries. Evaluation of growth, review of systems, detailed developmental assessment, and notation of unusual behaviors can also provide important clues to a diagnosis.

Pedigree Analysis and Family History

A critical part of any genetic evaluation is the family history (Box 27.5); this is best accomplished by creating a three-generation pedigree, which is a schematic diagram depicting familial relationships using standard accepted symbols (Fig. 27.1). This formal record can also be used to summarize positive responses elicited during the interview. Special attention should be paid to ethnic origins of both sides of the family, consanguinity, and any first-degree relatives with similar malformations to those of the patient being evaluated, also known as the *index case, proband*, or *propositus*. An extended family history should be used to identify relatives with congenital anomalies, developmental abnormalities, physical differences, or sudden death. Often photographs can provide clear objective evidence of a descriptive history. If any family members have had genetic testing, it is important to obtain the reports.

Reproductive histories, especially of the parents, should be elicited. Specifically, questions should be asked about infertility, miscarriages, and stillbirths. The occurrence of more than two first-trimester miscarriages increases the probability of finding a balanced translocation in one parent.[19,20] A balanced translocation is a rearrangement of genetic material such that two chromosomes have an equal exchange without loss or gain of material. There are typically no associated clinical features with such a rearrangement. However, when chromosomes align to recombine for meiosis in the sperm or egg, this exchange produces a risk of unequal distribution and an unbalanced translocation in the resulting fetus. In this case, there would be aneuploidy for part of a chromosome. It has been estimated that 25% of stillbirths exhibit single or multiple malformations, and in at least half of these cases there is a genetic etiology for the malformations. Couples with two or more pregnancy losses should undergo routine chromosome analysis or karyotyping to evaluate for a balanced translocation. A chromosomal microarray should be performed on fetal tissue (i.e., amniotic fluid, placenta, or products of conception) in the evaluation of intrauterine fetal death or stillbirth.[21] Compared to a karyotype, a chromosomal microarray yields a higher rate of results, and it can identify maternal cell contamination, which is important in reducing false-negative results; however a microarray will not detect a balanced translocation. In summary, in a patient with multiple congenital anomalies and parents with history of infertility or multiple pregnancy losses, the clinician should be suspicious for a balanced translocation in one of the parents manifesting as an unbalanced translocation in the proband.

Obtaining a formal family history is helpful in discovering information that is often critical to making a diagnosis. Positive responses may help to discern a Mendelian pattern of inheritance for a given genetic disorder. For example, a disease affecting every

generation, with both males and females involved, such as Marfan syndrome, displays an autosomal dominant pattern of inheritance. A pattern of X-linked recessive disease, such as hemophilia, instead shows affected males related through unaffected or minimally affected females; transmission in this pattern should not occur from father to son.

Specialized Clinical Evaluations

Physical Examination for Dysmorphology

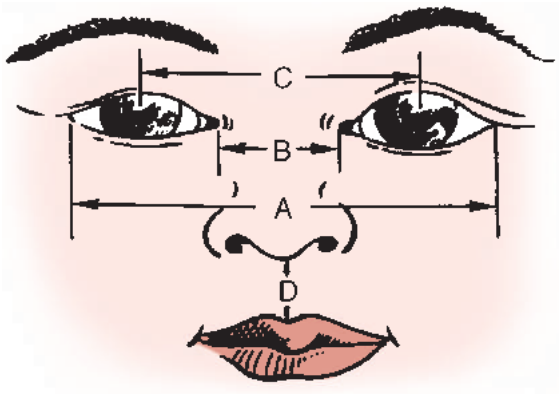
A congenital malformation can be described as a "morphologic defect of an organ, part of an organ, or larger region of the body resulting from an intrinsically abnormal developmental process."[22] The term *dysmorphology* was introduced by Dr. David Smith in the 1960s to describe the study of human congenital malformations.[6,23] This study of "abnormal form" emphasizes a focus on structural errors in development with an attempt to identify the underlying genetic etiology and pathogenesis of the disorder.

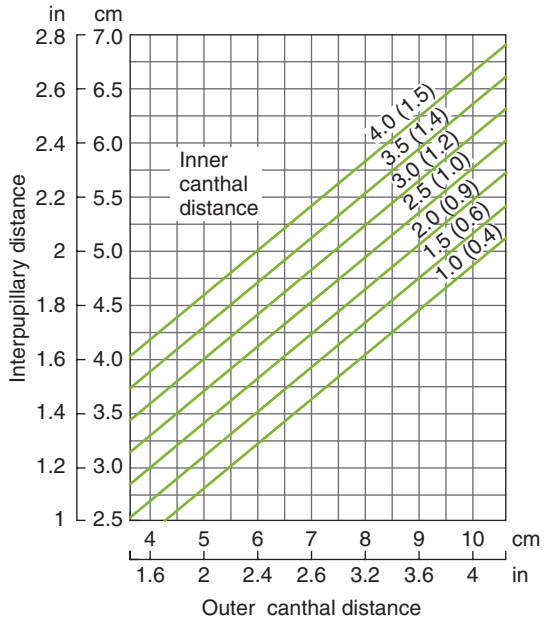
In a landmark study, Feingold and Bossert examined more than 2000 children to define normal values for a number of physical features.[24] These standards were devised as screening tools to objectively identify children with differences possibly attributable to a genetic disorder. Important measurements include head circumference, inner and outer canthal distances, interpupillary distances (IPDs), ear length, ear placement, internipple distances, chest circumference, and hand and foot lengths. In some instances, limb length and limb girth are needed. Other graphs and measurements using age-appropriate standards can be found in compendia such as the *Handbook of Physical Measurements*.[25]

The assessment should begin with newborn growth parameters that can reflect the degree of any prenatal insult. Measurements such as length, weight (usually reflecting nutrition), and head circumference should be plotted on newborn graphs. Gestational age-appropriate graphs should be used for premature neonates. It is often helpful to express values that are outside the normal range as 50th percentile for a different gestational age or in the number of standard deviations above or below the mean. For example, a full-term baby with microcephaly may have a head circumference of less than the fifth percentile for 38 weeks. This degree of microcephaly could be stated more clearly if described as $Z = -2.5$ or 50th percentile for 32 weeks' gestational age.

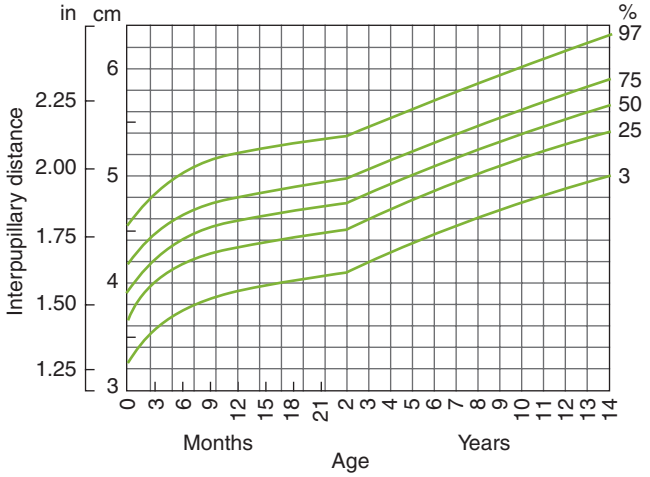
A complete physical examination should include assessment of patient anatomy for features varying from usual or normal standards. This assessment can often provide clues to embryologic mechanisms. The data obtained should then be interpreted using comprehensive standard tables that are available for these purposes. Special attention to familial or ethnic variation should be considered. There is a lack of phenotypic images available in globally diverse populations. As clinical findings in individuals with genetic syndromes can differ across different population groups, atlases will need to be created that are more representative of the global population.[26–28] The Atlas of Human Malformation Syndromes is one such resource.[27]

The shape and size of the head and fontanelles should be noted as well as the cranial sutures, with assessment for evidence of craniosynostosis or an underlying brain malformation. Any scalp defects should also be documented. The shape of the forehead, appearance of the eyebrows (such as synophrys), and the texture and distribution of hair should be noted. The spacing of the eyes, or canthal measurements (Fig. 27.2), the IPD (Fig. 27.3; see also Fig. 27.2), palpebral fissure lengths (Fig. 27.4), presence or absence of colobomata and epicanthal folds, and determination





• **Fig. 27.2** Canthal Measurements. Various eye measurements are depicted *(top)*. *A*, outer canthal distance; *B*, inner canthal distance; *C*, interpupillary distance (*IPD*), which is difficult to measure directly. The IPD can be determined using the graph at the *bottom* or with the Pryor formula: IPD = (A – B) 2 + B. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser*. 1974;10:1–16.)[24]



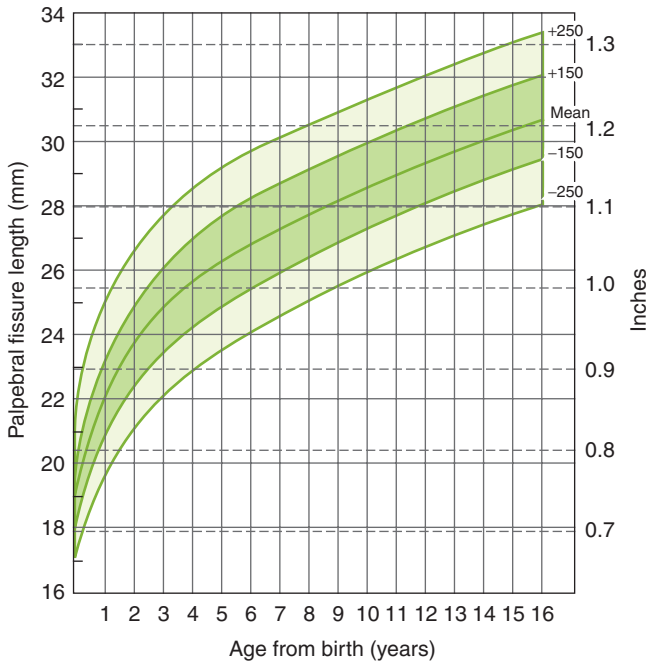
• **Fig. 27.3** A nomogram for interpupillary distance at different ages for both sexes. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser*. 1974;10:1–16.)[24]

of whether the palpebral fissures are turned upward or downward are components of the morphological examination of the eyes. Examination of the ears should include a search for preauricular and postauricular pits and tags, and assessment of the placement (Fig. 27.5), length (Fig. 27.6), and folding of the ear is important. Ear development occurs in a temporal frame similar to that of the kidneys during embryogenesis, and external ear anomalies can be associated with renal anomalies. Evaluation of the nose should cover the shape of the nasal bridge, nasal tip, the alae nasi, presence of anteverted nares, the length of the columella, and patency of the choanae. The mouth and throat are examined for the philtrum, presence of a cleft lip or palate; the shape of the palate and uvula is noted, and the presence of unusual features, such as tongue deformities, lip pits, multiple frenula, and natal teeth, is recorded. A small retrognathic or receding chin, which can be a part of several syndromes or an isolated finding, should be noted. The neck is inspected for excess nuchal folds or skin, evidence of webbing, and pits or branchial clefts. Any bony abnormalities in the neck should prompt an evaluation of the cervical vertebrae to confirm cervical and airway stability.

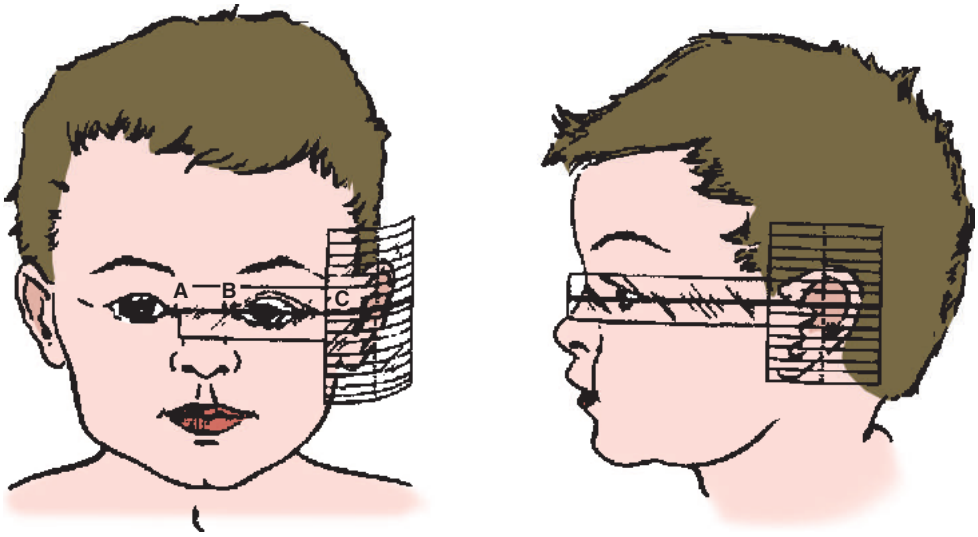
Evaluation of the chest and thorax involves lung auscultation and cardiac examination. Abnormal findings should prompt a consultation with a pediatric cardiologist and appropriate echocardiographic or invasive studies as needed. External measurements include determining the internipple distance and its ratio with respect to the chest circumference (Fig. 27.7). The presence of inverted or supernumerary nipples should be noted. The abdominal examination is focused on determining whether organomegaly is present, a finding that may be associated with an inborn error of metabolism. The umbilicus should also be examined, with any hernias and the number of vessels present in the newborn cord being noted. A two-vessel cord, in which only a single artery is present, can be associated with cardiac, renal, and other anomalies.[29] The genitourinary examination concentrates on determining whether anomalies such as hypospadias, chordee, cryptorchidism, other abnormalities of the scrotum, microphallus, and ambiguous genitalia are present. These external anomalies may be associated with internal anomalies involving the upper urinary tract as well. The anus is examined for evidence of tags, its placement, and its patency.

The back should be assessed, especially for the shape of the spine and any associated defects, such as myelomeningocele. These defects prompt further radiologic evaluation to assess for potential functional limitations. In addition, a sacral dimple or hair tuft at the base of the spine should be noted, because either could signify developmental abnormalities in the underlying neural tissue.

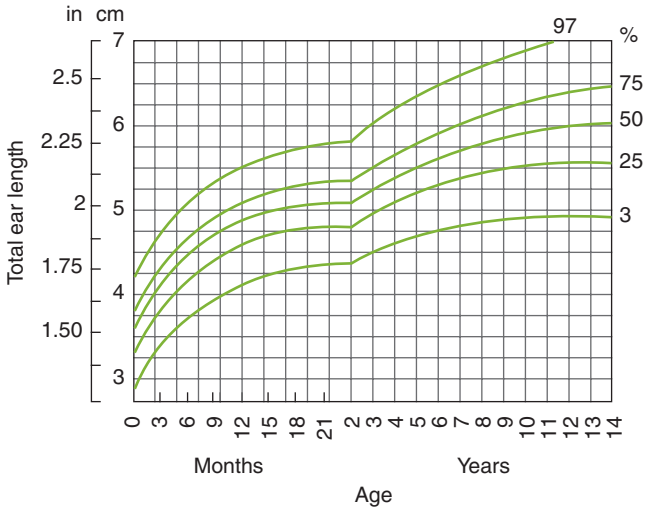
Minor anomalies are often manifested in the extremities. Gross differences in the hands and feet include polydactyly (more than five digits), syndactyly (fusion of the digits), and clinodactyly (incurving of the digits). It should be noted whether the extra



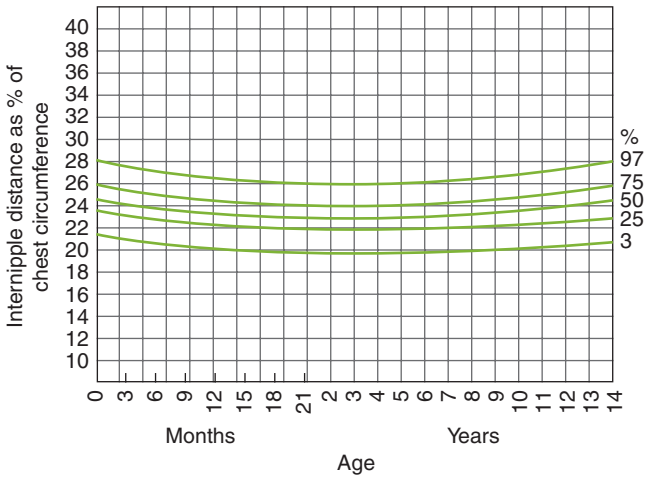
• **Fig. 27.4** A graph of palpebral fissure length from birth to age 16 years for both sexes. (From Gripp KW, Slavotinek AM, Hall JG, Allanson JE. *Handbook of Physical Measurements*. 3rd ed. Oxford UK: Oxford University Press; 2013.)[25]



• **Fig. 27.5** Ear Placement. Using the medial canthi *A* and *B* as landmarks, one draws a central horizontal line and extends it to a point *C* on the side of the face. Ears attached below this line are considered low set. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser*. 1974;10:1–16.)[24]



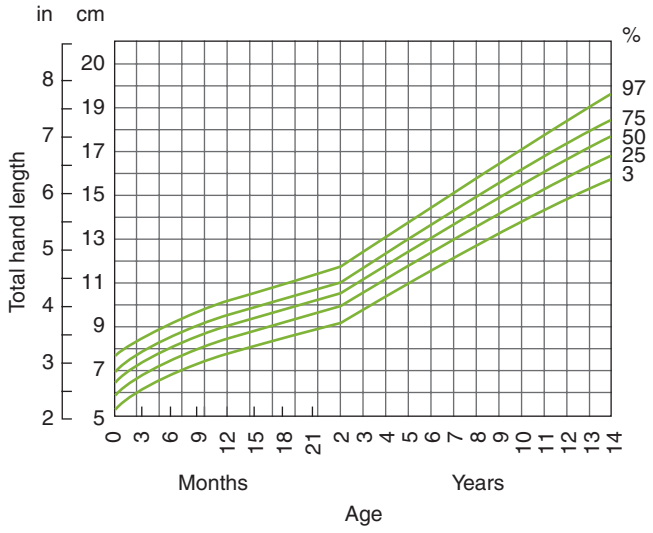
• **Fig. 27.6** Graph showing various percentiles for ear length plotted against age. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser.* 1974;10:1–16.)[24]



• **Fig. 27.7** The internipple distance as a percentage of the chest circumference plotted against age for both sexes. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser*. 1974;10:1–16.)[24]

digits are located in a preaxial (first digit) or postaxial (fifth digit) position. Hand and foot lengths, which should be expressed as a percentile measured on age-appropriate graphs (Figs. 27.8 and 27.9), are important to document. Often these data can provide important clues to a unifying syndrome.

Dermal ridge patterns, or dermatoglyphics, are formed on the palms and soles early in embryonic life, and they vary considerably among individuals. This variation can be inherited and can be influenced by disturbances to the development of the peripheral limb buds. Environmental exposures and chromosomal aberrations can greatly affect the formation of these structures and are reflected by the dermatoglyphic pattern of an individual. Each of the distal phalanges has one of three basic dermal ridge patterns: arches, whorls, or loops (Fig. 27.10). The predominance of a single pattern can be an associated feature of a genetic disorder. For example, the occurrence of arches on eight or more digits is a rare event but is frequently encountered in children with trisomy 18 (Table 27.3).



• **Fig. 27.8** The total hand length plotted against age for both sexes. (From Feingold M, Bossert WH. Normal values for selected physical parameters: an aid to syndrome delineation. *Birth Defects Orig Artic Ser.* 1974;10:1–16.)[24]

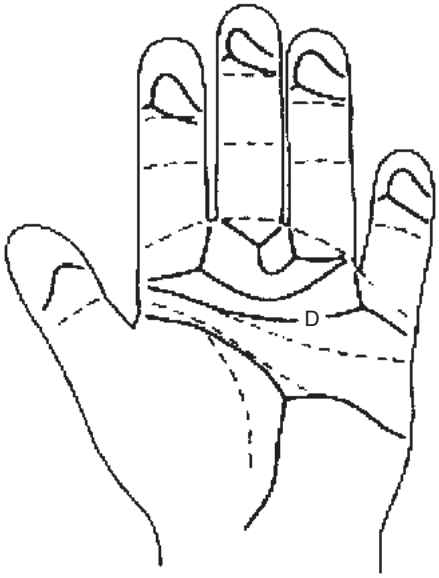
• **Fig. 27.10** Basic fingerprint patterns (dermatoglyphics). (From Holt SB. *The Genetics of Dermal Ridges*. Springfield, IL: Charles C. Thomas; 1968.)[30]

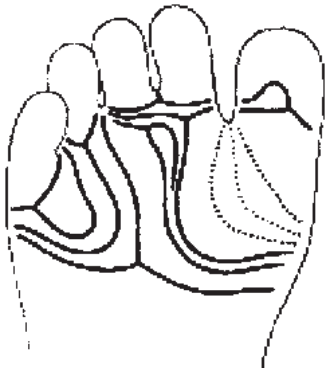
TABLE 27.3 Dermatoglyphic Patterns Associated With Specific Dysmorphic Disorders

Dermatoglyphic Pattern	Associated Disorders
Excess arches	Trisomy 13, trisomy 18, Klinefelter syndrome (47, XXY), deletion 5p (cri-du-chat syndrome), fetal phenytoin exposure
Excess ulnar loops	Trisomy 21, 22q11.2 deletion syndrome[37]
Excess whorls	Smith–Lemli–Opitz syndrome, Turner syndrome (45, X), 18q deletion

Deltas, or triradii, form at the convergence of three sets of ridges on the palm. This junction is where the hypothenar, thenar, and distal palmar patterns converge. There are typically no triradii in the hypothenar area of the palm, but when patterning is present or is large, a distal triradius arises, which is found in only 4% of normal Caucasian individuals, but in 85% of patients with trisomy 21 (Down syndrome).[30,31] A single transverse palmar crease is found in 4% of controls, but in more than half of patients with trisomy 21 (Fig. 27.11), and in even greater proportions in patients



• **Fig. 27.11** The patterns on the hand of a patient with Down syndrome depicting the palmar crease (*D*). (From Holt SB. *The Genetics of Dermal Ridges*. Springfield, IL: Charles C. Thomas; 1968.)[30]



• **Fig. 27.12** The distal sole of the foot of a patient with Down syndrome, depicting the characteristic "open field" hallucal pattern. (From Holt SB. *The Genetics of Dermal Ridges*. Springfield, IL: Charles C Thomas; 1968.)[30]

with other trisomies. The hallucal area of the foot, located at the base of the big toe, also has a dermal ridge pattern, usually a loop or whorl. A simple pattern or open field in this region is found in less than 1% of controls, but in more than 50% of patients with Down syndrome (Fig. 27.12).[30,31] This unusual dermal pattern is also associated with hypoplasia of the hallucal pad and a wide space, sometimes called a "sandal gap deformity," between the great and second toes in these patients.

An examination of the skin is also important, since phakomatoses or skin manifestations can herald the presence of an underlying disorder.[32] Examples are café-au-lait spots (associated with neurofibromatosis type I) and ash leaf spots (associated with tuberous sclerosis and detected with the use of a Wood lamp). Irregular pigmentation can be suggestive of chromosomal mosaicism, in which the different skin pigmentation patterns represent a different, mixed chromosomal composition.[33] Capillary malformations and other skin diseases are also noteworthy.

Finally, a careful neurologic examination with input from a specialist is often warranted in the child with multiple anomalies, because the neurologic status is often the most reliable prognostic indicator. Evaluation of tone, feeding, unusual movements, and

- Electroencephalography as indicated
- Electromyography as indicated
- Subspecialty consultation

the presence of seizure activity are critical pieces of diagnostic information.

Adjunct Studies

An exhaustive physical examination often reveals differences that require further evaluation for diagnostic, prognostic, and treatment purposes (Box 27.6). For instance, poor feeding or cyanosis may prompt an echocardiogram or recurrent emesis may lead to an abdominal ultrasound that may lead to detection of internal organ malformations. Differences in head shape suggest the need for skull radiographs, three-dimensional computed tomography, or MRI of the brain. A disproportionality of the limbs prompts a skeletal survey and bone age measurement.

It is prudent in children with anomalies involving multiple systems to obtain the input of relevant specialists. This step is often essential to medical decision making and for planning interventions. Abnormal neurologic findings should prompt a consultation with a trained specialist and interpretation of studies such as head ultrasonography, brain MRI, brainstem auditory evoked responses, and electroencephalogram for seizure activity. Muscle dysfunction might result in the ordering of electromyography, muscle ultrasound, or nerve conduction studies. Visual involvement requires a fundoscopic examination by an experienced pediatric ophthalmologist, and sometimes studies of visual evoked responses or electroretinograms are needed to predict visual prognosis. Often, there are well-characterized genetic disorders that have a specific pattern of abnormal findings in these highly specialized studies. Even when a unifying diagnosis is reached, there is often variation in the clinical phenotype, and determining the patient's prognosis on a system-by-system basis is typically the most appropriate and accurate way to proceed.

Literature Review

After the history and physical evaluation are complete, a cross-reference of two or more anomalies is useful to generate a differential diagnosis. When the rest of the neonate's physical and history findings are added, the possibilities can often be narrowed down to a few entities that may be amenable to diagnostic testing. If multiple anomalies are present, it is usually best to start with the least common. As Aase has stated, "The best clues are the rarest. The physical features that will be the most helpful on differential diagnosis are those infrequently seen either in isolation or as part of syndromes. Quite often, these are not the most obvious anomalies or even the ones that have the greatest significance for the patient's health."[6] Cross-referencing is usually best accomplished by using published compendia of malformation syndromes. These compendia have been supplemented by databases that are accessible online (i.e., GeneReviews, Online Mendelian Inheritance in Man, Ovid MEDLINE, PubMed, SimulConsult, Phenomizer, etc.). The availability of such tools allows the cross-referenced features to be compared easily with those of other described syndromes that may include similar malformations. This systematic review produces a differential diagnosis for the constellation of features described and identifies references to pertinent literature.

The recognition of patterns of genetic entities involves the comparison of the proband with the examiner's personal experience of known cases and a search of the literature. Multiple anomalies may be causally related, occur together in a statistically associated basis, or occur together merely by chance. Diagnosis of a genetic disorder relies heavily on the ability of the clinician to suspect, detect, and correctly interpret physical and developmental findings and to recognize specific patterns. Accurate diagnosis of a syndrome in a child is important to the identification of major complications and their treatment if possible. It is also crucial for long-term management of patients and for parental counseling about recurrence in future offspring.

Specialized Laboratory Tests

In sorting through the multiple possibilities listed, the geneticist uses another important tool—the availability of highly specialized cytogenetic and molecular genetic testing, including:

- Karyotype
- Fluorescence in situ hybridization
- Chromosomal microarray (see Chapter 28)
- Molecular analysis, such as sequencing (single gene, panel, exome, genome), methylation testing (e.g., for Beckwith–Wiedemann, Prader–Willi, or Angelman syndromes), or polymerase chain reaction-based techniques (e.g., for congenital myotonic dystrophy or fragile X syndrome).

The most common methods of genetic testing are summarized in Table 27.4. The standard karyotype, or analysis of stretched and stained chromosome preparations usually taken from a peripheral blood sample, can often confirm a suggested diagnosis or explain a set of major malformations not classically encountered together. Further description of specific chromosomal abnormalities is addressed in Chapter 28; it is sufficient to note that multiple malformation syndromes can result from large visible chromosome rearrangements that lead to deletion or addition of genetic material (aneuploidy). These rearrangements can involve an entire arm of a chromosome or can be submicroscopic, requiring further special testing. While a karyotype is still the only test to detect chromosomal rearrangements, more specialized molecular testing methods, such as a chromosomal microarray, have since become the standard of care, as an adjunct to or instead of karyotype analysis. In general, microarray-based methods are currently focused on detecting copy number changes (smaller deletions or duplications not detectable by a karyotype) and can be performed in a targeted or genome-wide fashion.[34] For individuals with features suggestive of a particular syndrome or with an anomaly that has known associated gene(s), individual gene sequencing or next-generation sequencing (NGS) of a panel of genes can be performed. For instance, in an individual with pleural effusions and pulmonic stenosis, a Noonan syndrome gene panel may be helpful, whereas in an individual with craniosynostosis, a craniosynostosis gene panel may be helpful. For individuals with multiple

TABLE 27.4 Common Methods of Genetic Testing

Test	Methodology	Clinical Indication
Karyotype	• Involves analysis of the entire chromosome complement under a microscope. • A solution of colchicine is used to arrest cells during cell division. A Giemsa dye is then applied to cells to make them visible under the microscope.	• Used to identify aneuploidy involving whole chromosomes, or large (>5–7 Mb) rearrangements such as duplications and deletions within chromosomes (i.e., trisomy 13, 18, or 21 or disorders of the sex chromosomes). • Still the only clinical diagnostic technique that can detect balanced translocations where chromosomal material from one chromosome is rearranged onto another.
Fluorescence in situ hybridization (FISH)	• Specific fluorescent-tagged DNA probes representing a single locus or part of a particular chromosomal region hybridize to that region of the genome.	• Clinicians must know and specifically order the proper FISH test for a given chromosomal locus. • Can be used to identify deletions such as 22q11.2 deletions (although FISH can miss small deletions).
Chromosomal microarray	• Uses synthesized oligonucleotide probes or single nucleotide polymorphism (SNP)-based probes densely arranged on a microarray chip to assess for submicroscopic chromosome rearrangements. • Automated processing. • Copy number variation is compared against a large panel of standards.	• Often the first-line study for cases of multiple congenital malformations. • Can detect copy number changes (deletions or duplications) in the 50–100 kb range. • Disadvantages: 1. Changes of unknown significance can be detected and require further investigation and often examination of parental samples to help interpret the proband's results. 2. Structural changes that do not result in copy number variation, such as a balanced translocation or inversion of part of a chromosome, will not be detected by this technique.
Direct gene sequencing or single gene or gene panels	• Alterations of a single base pair, or insertions or deletions of even a small number of nucleotides, can disrupt the gene and subsequently, its protein product. • Because these mutations can be as small as a single base pair, they cannot be detected by a karyotype or chromosomal microarray. • Direct sequencing of a target gene can detect a single base pair mutation or a small insertion or deletion. Larger deletions or duplications that involve either part or all of the gene are often more difficult to detect, being too small to detect on a chromosomal microarray, but too large to detect with standard sequencing. These genetic lesions often require PCR-based deletion/duplication testing targeted to a specific gene locus.	• With well-characterized phenotypes, a clinician can sequence a specific gene or genes associated with that phenotype. • Over the past decade or so, next-generation sequencing (NGS) has allowed multiple genes associated with a phenotype to be tested simultaneously in a gene panel.
Exome sequencing (ES)	• Sequences the protein-coding regions or exons of the human genome. This includes approximately 20,000 genes and accounts for about 2% of the total genome. • Following massively parallel sequencing, the individual's sequence is compared to reference DNA sequences, published control individuals, and the patient's family members. • Clinical analysis is required to reduce thousands of variants to those that may be related to the individual's phenotype. • Limited to the protein-coding regions of the genome.	• Useful for individuals with multiple congenital anomalies without a unifying diagnosis, or with a suspected, but unclear genetic diagnosis.
Genome sequencing (GS)	• Sequences the entire genome, including the noncoding regions (introns) and the coding regions (exons). • Like ES, GS requires significant clinical analysis to reduce thousands of variants to those that may be related to the individual's phenotype.	• Primarily done on a research basis. • Like ES, GS may be useful for individuals with multiple congenital anomalies without a unifying diagnosis, or with a suspected, but unclear genetic diagnosis. • May also be useful if a genetic diagnosis is strongly suspected, but ES was negative.
RNA sequencing (RNA-Seq)	• NGS is performed to detect and quantify RNA in a sample at a particular time. • RNA-Seq can evaluate the continuously changing cellular transcriptome.	• Can evaluate alternative gene spliced transcripts, posttranscriptional modifications, gene fusion, mutations/SNPs, and changes in gene expression over time.

TABLE 27.4 Common Methods of Genetic Testing—cont'd

Test	Methodology	Clinical Indication
Noninvasive prenatal screening (NIPS)	• Obtained from cell-free DNA in the maternal circulation that comes from the fetus. • Isolated cell-free DNA is then sequenced to assess for common aneuploidies. • Obtained from a peripheral blood draw as early as 10–11 weeks of gestation. • Is only a screening test.	• Developed to screen for trisomy 13, 18, and 21 during the first trimester of pregnancy. • Has high sensitivity, specificity, and positive predictive values for these disorders. • Now expanded to screen for sex chromosome aneuploidy, but has a poorer detection rate and a higher false-positive rate for the sex chromosome aneuploidies, particularly for monosomy X.

congenital anomalies without a unifying diagnosis, or with a suspected, but unclear genetic diagnosis, exome sequencing (ES) may be indicated. ES sequences all of the protein-coding regions or exons of the human genome. This includes approximately 20,000 genes, but accounts for only 2% of the genome. The advantages to ES are that it is a very comprehensive test and clinicians do not have to predetermine which genes to sequence. Disadvantages include that significant clinical analysis and expertise are required to reduce thousands of variants to those that may be related to an individual's phenotype, which makes the test expensive and time-intensive to complete. Finally, ES is limited to only the protein-coding regions of the genome. Thus, genome sequencing (GS), which sequences the entire genome, including the noncoding regions (introns) and the coding regions (exons), is now being performed, primarily on a research basis, as the most comprehensive genetic testing available. Like ES, GS requires significant clinical analysis and is both expensive and time-intensive to perform. RNA sequencing (RNA-Seq) is also emerging, primarily on a research basis, to evaluate the continuously changing cellular transcriptome. RNA-Seq allows for the evaluation of alternative gene spliced transcripts, posttranscriptional modifications, gene fusion, mutations/single nucleotide polymorphism (SNPs), and changes in gene expression over time.

For some disorders, other types of specialized testing methods may be indicated. For instance, if there is suspicion for a methylation disorder such as Beckwith–Wiedemann, Prader–Willi, Angelman, or Russell Silver syndromes, methylation testing is required; for trinucleotide repeat disorders like congenital myotonic dystrophy or Fragile X syndrome, polymerase chain reaction–based techniques may be required. It can be useful to inquire with a geneticist or genetic counselor for the availability of specific gene mutation testing that may be clinically available or performed on a research basis. GeneTests and the Genetic Testing Registry are Internet databases of laboratories worldwide that provide such services (https://www.genetests.org; https://www.ncbi.nlm.nih.gov/gtr/).

There is also an increasing awareness about the importance of the sample type used for genetic testing. Classically, genetic testing has been performed on either peripheral blood samples or on chorionic villi or amniotic fluid when testing is performed prenatally. However, with disorders that may have mosaicism, it is essential to sequence the affected tissue itself to obtain a diagnosis. This is because somatic mutations, which may occur in a single body cell, may not be detected in a peripheral blood sample, in contrast to germline mutations which occur in gametes and are thus present in every cell.

Diagnosis

There are cases in which, after a detailed examination, exhaustive literature search, and genetic testing, no unifying diagnosis is evident. Aase, a dysmorphologist, advises, "Don't panic! The absence of a diagnosis may be distressing to the diagnostician and the family, but it is much less dangerous than the possibility of assigning the wrong diagnosis with the risk of erroneous genetic and prognostic counseling and possibly hazardous treatment."[6] Therefore, in cases in which there is no clear diagnosis, prognosis and treatment should be determined according to the organ systems involved and the extent of their impairment. In addition, when the newborn has a severe, untreatable impairment or the patient's condition is critical, it may be prudent to offer and obtain consent for a full postmortem examination by an experienced pediatric pathologist. A skin sample, and sometimes blood, can be taken from the expired fetus (or newborn prior to death) for establishing a cell line or for extracting DNA for future testing. Information gained from such investigations may often become relevant for family members, including the parents, allowing one to provide accurate recurrence risk counseling and perhaps offer prenatal testing of a new pregnancy. Such information can often help to provide closure for the family as well.

Example Evaluations for Common Neonatal Anomalies

There are many common neonatal anomalies that should prompt an immediate genetics consultation. These include choanal atresia, cleft palate, congenital diaphragmatic hernia (CDH), congenital heart defects, craniosynostosis, micrognathia, omphalocele, any limb anomalies concerning for a skeletal dysplasia, and tracheoesophageal fistula, to name just a few. Many of these common neonatal anomalies have a broad genetic differential. For instance, in the evaluation of a cleft palate, it is important to determine whether the cleft palate is isolated or associated with other anomalies. A cleft palate may also occur as part of PRS, where the primary anomaly of micrognathia sets off a cascade of additional defects including glossoptosis, tongue-based airway obstruction, and in some cases, a secondary cleft palate. Among patients with PRS, about 30% are found to have Stickler syndrome.[35] Stickler syndrome is a clinical triad of PRS, hearing loss, and ocular abnormalities (high myopia, vitreoretinal degeneration, retinal detachment, cataracts). An eye exam is often very helpful in the diagnosis of Stickler syndrome, as myopia is a very unusual finding in infancy and in this context, if found, is strongly suggestive

of Stickler syndrome. A careful physical examination should be performed with close attention to the eyes, ears, and chin. If there is any hooding of the eyes, micrognathia, or ear anomalies, testing should be sent for 22q11.2 deletion syndrome. A chest x-ray should be obtained to evaluate for any rib gaps, which would be concerning for cerebrocostomandibular syndrome. Finally, the lips should be closely evaluated for any lip pits, which would be consistent with Van der Woude syndrome.

Similarly, in the case of an omphalocele, it is also important to look closely for other anomalies as 50% to 80% of babies will have an additional anomaly, including 50% of whom will have a congenital heart defect.[36] The syndromic differential for an omphalocele includes BWS, Carpenter, CHARGE (coloboma, heart defect, choanal atresia, retarded growth and development, ear anomalies), Goltz, Marshall–Smith, Meckel–Gruber, otopalato-digital type II, trisomy 13, and trisomy 18 syndromes. BWS occurs in ~25% of babies with small omphaloceles and includes an omphalocele (typically small), macroglossia, ear creases and/or pits, hemihypertrophy, and hypoglycemia. The presence of multiple associated anomalies should raise concern for trisomy 13 or 18. Omphalocele is also found as a component of the **O**mphalocele, **E**xstrophy of the bladder, **I**mperforate anus, **S**pinal defects complex. This complex has no known genetic etiology. Unlike omphalocele, gastroschisis is not commonly associated with other anomalies. It is typically secondary to a vascular accident and not an underlying genetic etiology.

As a final example, in the case of a CDH, a genetic etiology is currently identified in 30% of babies, although this number is growing. The genetic differential diagnosis for CDH can be divided into syndromic causes (meaning CDH in the context of other anomalies) and nonsyndromic causes. The most common syndromic causes of CDH are 22q11.2 deletion, Craniofrontal nasal, Cornelia de Lange, Donnai–Barrow, Fryns, Pallister–Killian, Simpson–Golabi–Behmel, Wolf–Hirschhorn, and trisomy 18 syndromes, as well as a growing list of other single gene disorders. There are also several nonsyndromic causes, including microdeletions at 15q26, 8p23.1, 8q23, or 1q41-42 that are important in terms of recurrence counseling. A careful physical exam should pay close attention to the growth parameters, chest circumference and nipples, hairline, genitalia, hands and feet, and fingernails. Large growth parameters raise suspicion for Simpson–Golabi–Behmel syndrome, a temporal sparing pattern of the hairline is concerning for Pallister–Killian syndrome, and widely spaced nipples and hypoplasia of the fingernails are concerning for Fryns syndrome. Multiple congenital anomalies including congenital heart disease, limb anomalies, or cleft palate, in addition to CDH, should raise suspicion for Cornelia de Lange syndrome or trisomy 18 syndrome.

Summary

Diseases with underlying genetic bases have significant effects on health care and its delivery. An appreciation of these entities, coupled with an organized, systematic evaluation, can help to define the nature of a given disorder and aid in the development of the optimal plan of treatment and care for the patient.

Chromosome Disorders

T. NIROSHI SENARATNE, ELAINE H. ZACKAI, AND SULAGNA C. SAITTA

KEY POINTS

- Early identification of an underlying genetic condition in a patient can aid in defining a treatment plan and help to identify resources for better care for patients and their families.
- In counseling the family of a newborn with a newly diagnosed chromosomal disorder, it is important to include the organ systems affected in the baby and the severity of each malformation when discussing prognosis. The variability of most phenotypes should be emphasized, with a care plan tailored to the needs of the individual patient.
- Although the prognosis in trisomy 13 and trisomy 18 is extremely poor, there is emerging evidence that in some cases, interventions can improve the survival and quality of life for the child and the family, and they should be discussed with the parents during a prenatal or postnatal visit.
- The use of chromosomal microarray testing allows the identification of smaller genomic deletions and duplications that are largely undetectable by standard karyotyping techniques, and it is recommended as a first-tier test in the genetic evaluation of a newborn with multiple congenital anomalies (excluding cases with high clinical suspicion for well-recognized whole chromosome disorders such as trisomies 13, 18, and 21 and Turner syndrome).
- Noninvasive prenatal screening (NIPS) is a relatively new technology that analyzes the cell-free fetal DNA fraction circulating in maternal peripheral blood. The fetal DNA is derived from cells forming the developing placenta and is accepted as an initial screen for select aneuploidy conditions. In cases where a high risk for an abnormality is identified, then diagnostic testing such as karyotyping or chromosomal microarray analysis of amniotic fluid or chorionic villus samples is recommended.

According to estimates from the Centers for Disease Control and Prevention (CDC), congenital malformations occur in approximately 3% of newborns in the United States. Congenital anomalies affecting major organ systems can result from chromosomal imbalances that affect the dosage or copy number of developmental genes that are located in the affected region. This chapter will focus on genetic disorders and syndromes with underlying chromosomal abnormalities that typically manifest themselves in the newborn period. In addition, it will discuss the shift in genetic evaluation and diagnosis in both prenatal and postnatal cases, to the use of microarray and next generation sequencing-based diagnostic techniques.

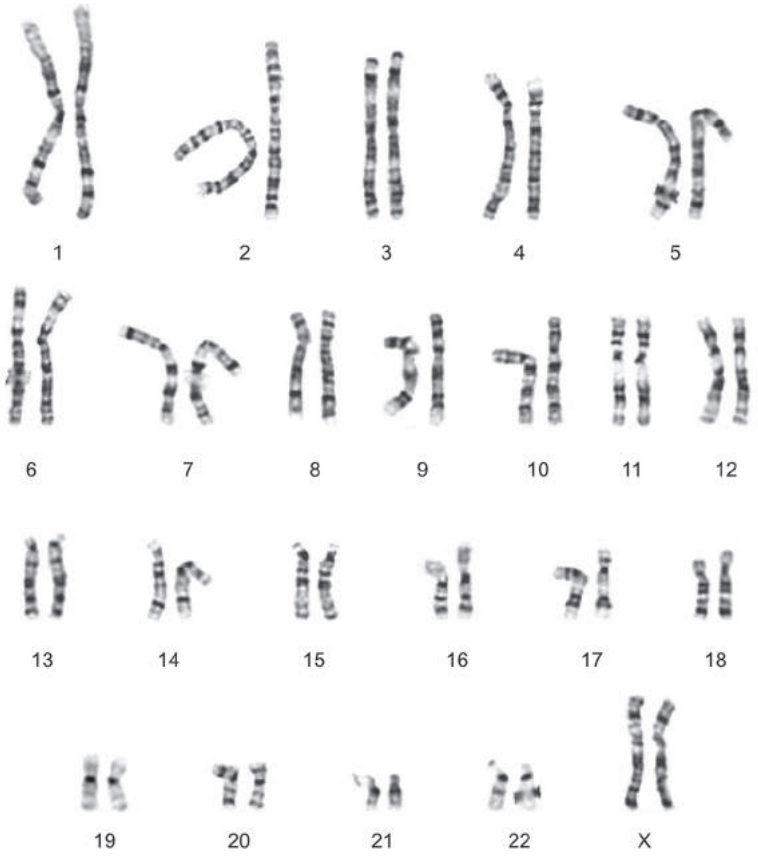
Human Karyotype

Chromosomes consist of single molecules of DNA whose structure is maintained by association with histones and other proteins. Chromosomes from dividing cells can be visualized under the light microscope as linear structures with two arms joined by a *centromere*. The short arm is designated the *p arm* and the long arm is designated the *q arm*. The ends or tips of the p and q arms are known as *telomeres*. The chromosome complement, or karyotype, in human cells normally consists of 46 chromosomes, with 22 pairs of autosomes (numbered in general from largest to smallest) and one set of sex chromosomes–two X chromosomes in genetic females (46,XX) and an X chromosome and a Y chromosome in genetic males (46,XY) (Fig. 28.1). After treatment with special dyes, each pair shows a distinctive size, centromeric position, and staining or banding pattern allowing it to be identified and classified. Human cells were first determined to have 46 chromosomes in 1956,[1,2] and the presence of recurrent numerical abnormalities in syndromes including Down, Turner, and Klinefelter syndrome were identified soon after.[3]

Karyotype analysis is performed in cells undergoing mitosis, or cell division, in which the chromosomes condense and can be stained and visualized. At this stage, each chromosome consists of two sister chromatids, which are the products of DNA replication. Karyotype analysis can be successfully performed on cell types that can be stimulated to divide and grow in culture, such as peripheral blood lymphocytes, skin fibroblasts, and amniocytes, or cell types that are normally undergoing rapid cell division, such as bone marrow or chorionic villi. Historically, several different staining methods have been described. However, G-banding (Giemsa staining) is most commonly used. At the highest resolution, G-banding can allow the detection of structural rearrangements as small as 5 to 10 million base pairs or 5 to 10 megabase (Mb) pairs, though the maximum attainable resolution varies by preparation and by specimen type.

Prior to fertilization, gamete formation, either spermatogenesis or oogenesis, is accomplished by a process known as *meiosis*. In the first part of meiosis (meiosis I), homologous chromosomes align as pairs and cross over, exchanging genetic material, also known as *recombination*. In this stage, named reduction division, the recombined pairs separate and the typical diploid content (46 chromosomes) of the cell is reduced by half to a haploid complement of 23 chromosomes. In the next stage, meiosis II, the sister chromatids of each chromosome separate, similar to mitosis.[4] The full diploid state of the cell (46 chromosomes) will be restored at the time of fertilization.

An imbalance of genetic material, or aneuploidy, occurs from a *net loss or gain* of genetic material during sperm or egg formation or less commonly, after fertilization during the initial divisions of the



• **Fig. 28.1** G-banded human female karyotype. The 46 chromosomes are arranged in 23 pairs, each with a specific banding pattern. (Courtesy UCLA Cytogenetics Laboratory.)

embryo. This missing or extra genetic material can be small pieces or parts of chromosomes (partial or segmental aneuploidy) or an entire chromosome itself. The classic recognizable aneuploidy syndromes involve trisomy (three copies of a full chromosome) such as those of chromosomes 13, 18, and 21, or monosomy (only a single copy) of a complete chromosome, such as the X chromosome. Aneuploidy can result from nondisjunction, a failure of normal chromosome separation. In such cases, a pair of homologs or sister chromatids does not separate in meiosis, and one daughter cell receives both copies of that pair, while the other cell receives none. This event can occur in either stage of gamete division, meiosis I or meiosis II. Most human meiotic nondisjunction arises during oocyte formation, specifically in maternal meiosis I. The occurrence of meiotic nondisjunction increases significantly with maternal age. Therefore, prenatal karyotyping from amniocentesis or chorionic villus sampling (CVS) is offered to women aged 35 years or older.[4]

Noninvasive prenatal screening (NIPS), also known as noninvasive prenatal testing (NIPT) or cell-free DNA (cfDNA) screening, is a relatively new technology that analyzes the cell-free fetal DNA fraction (derived from placental trophoblasts) circulating in maternal peripheral blood and can be offered starting at 9 to 10 weeks of gestation.[5,6] While NIPS was initially recommended for women at high risk for carrying a fetus with a chromosome abnormality, recent guidelines recommend that it should be offered to all pregnant women regardless of age or other risk factors.[7] The technical approaches and analyses vary by platform, but in general NIPS uses next-generation sequencing to assess the copy number of different chromosome regions in cfDNA. It is performed as an initial screen for common aneuploidy conditions, with some laboratories screening for rarer aneuploidies, as well as microdeletion/microduplication syndromes (see additional details below) and other segmental aneuploidies. An important metric to consider when counseling patients with abnormal NIPS results is the positive predictive value (PPV), which is the probability that a positive test result represents a *true positive*. While NIPS has high PPV for common aneuploidies such as trisomy 21, the PPV is significantly lower for rarer conditions such as microdeletions, and appropriate follow-up testing and genetic counseling are critical.[7–10] In addition, since the risk of trisomy increases with maternal age, the PPV of NIPS is age-dependent. For patients where NIPS shows a high risk of a chromosomal abnormality in the fetus, or with atypical/inconclusive results, diagnostic testing such as karyotyping or chromosomal microarray analysis of amniotic fluid or chorionic villus specimens is recommended.[7]

Nondisjunction can also occur later, in mitosis, with uneven division of genetic material during an early embryonic cell division. This can result in two cell lines: one trisomic lineage that is potentially viable and one monosomic line. If this event occurs after the first postzygotic division, cells with a normal chromosome complement may also coexist with cells containing an aneuploid complement, as a *mosaic* chromosome constitution. This is considered a possible mechanism for the occurrence of mosaic Down syndrome, where a percentage of the cells in the patient have three copies of chromosome 21, and the remainder of the cells have the expected two copies. Mosaicism is also seen with sex chromosome

aneuploidies, most notably mosaic Turner syndrome, where a subset of the cells examined show a 45,X complement and another population of cells from the patient may have a normal 46,XX or XY complement.

Partial aneuploidy may result from several mechanisms and may be inherited or can occur *de novo* seen only in the patient. For carriers of a balanced translocation, who have a rearrangement or exchange of material between chromosomes, the carrier parent has no net loss or gain of genetic material (balanced) and is usually phenotypically normal. However, segregation of these abnormal derivative chromosomes during meiosis can lead to offspring having an *unbalanced* rearrangement and its phenotypic consequences. Unbalanced rearrangements or translocations can also arise sporadically. This is often seen in recurrent deletion syndromes caused by the loss of genetic material from specific chromosomes (e.g., 1p–, 4p–, 5p–), with a resulting, often recognizable, phenotype.

Other chromosome microdeletions resulting in partial aneuploidy, have been mechanistically tied to aberrant recombination due to the presence of segmental duplications, or large "blocks" or segments of DNA that contain chromosome-specific repetitive sequences.[11] In these cases, the highly homologous repeats can mediate misalignment and nonallelic homologous recombination between two homologs. Segmental duplications are present in regions of the genome prone to rearrangements, such as the pericentromeric regions of 7q11, 15q11, 17q12, and 22q11, leading to the phenotypes seen in Williams–Beuren syndrome, Prader–Willi or Angelman syndrome, Charcot–Marie–Tooth disease or hereditary neuropathy with liability to pressure palsies, and the recurrent 22q11.2 deletion syndromes, respectively.[12]

Fluorescence *in situ* hybridization (FISH)

While deletions and duplications larger than 5 Mb may be observed by standard chromosome analysis, smaller rearrangements are generally not visible. These submicroscopic deletions and duplications are often referred to as copy number variants (CNVs). CNVs may be detected by fluorescence *in situ* hybridization or FISH, which utilizes fluorescently labeled DNA molecules ("probes") that bind to a specific region of interest in the genome, followed by visualization of the hybridization patterns using fluorescence microscopy.[13–15] FISH has many advantages including rapid turnaround time (same-day or overnight for certain specimen types), improved resolution compared to karyotype (can detect changes as small as 100 to 200 kb, depending on probe design), high sensitivity for mosaicism, and the ability to interrogate non-dividing tissues, which means FISH may be performed on a wide variety of specimen types. However, a limitation of FISH is that it is only informative for the specific regions being targeted and therefore requires prior knowledge of specific conditions to test for; even then, it may miss atypical rearrangements of these regions that are outside the region targeted by the FISH probes.

Chromosomal Microarray Analysis (CMA)

Another technology which has facilitated the identification of CNVs is chromosomal microarray analysis, which can identify submicroscopic losses and gains of chromosomal material (typically less than 5 Mb) that cannot be seen by standard karyotyping.[16–18] Chromosomal microarrays use DNA probes which are arrayed on a glass slide or other solid support, and patient DNA is fragmented and fluorescently labeled before being hybridized to the array (Fig. 28.2).[14,19] Microarray testing can be performed for either a targeted region, or more commonly, in a genome-wide fashion. One approach known as array comparative genomic hybridization (array CGH or aCGH) involves hybridizing both patient and control DNA, each labeled with different colored dyes, followed by comparison of the relative fluorescence intensities, identifying regions where the patient DNA shows a copy number loss or gain relative to the control. Another commonly used technique is single nucleotide polymorphism (SNP) chromosomal microarray, which includes probes targeting polymorphic regions in the human genome and involves an *in silico* comparison of fluorescence intensities to a set of control data. The resolution of an array depends on the density of probes; most genome-wide array platforms can detect copy number variants as small as 50 to 100 kb (kilobases). Targeted arrays with a high density of probes surrounding genes of interests may be able to detect smaller variants, such as those involving a single exon of a gene.

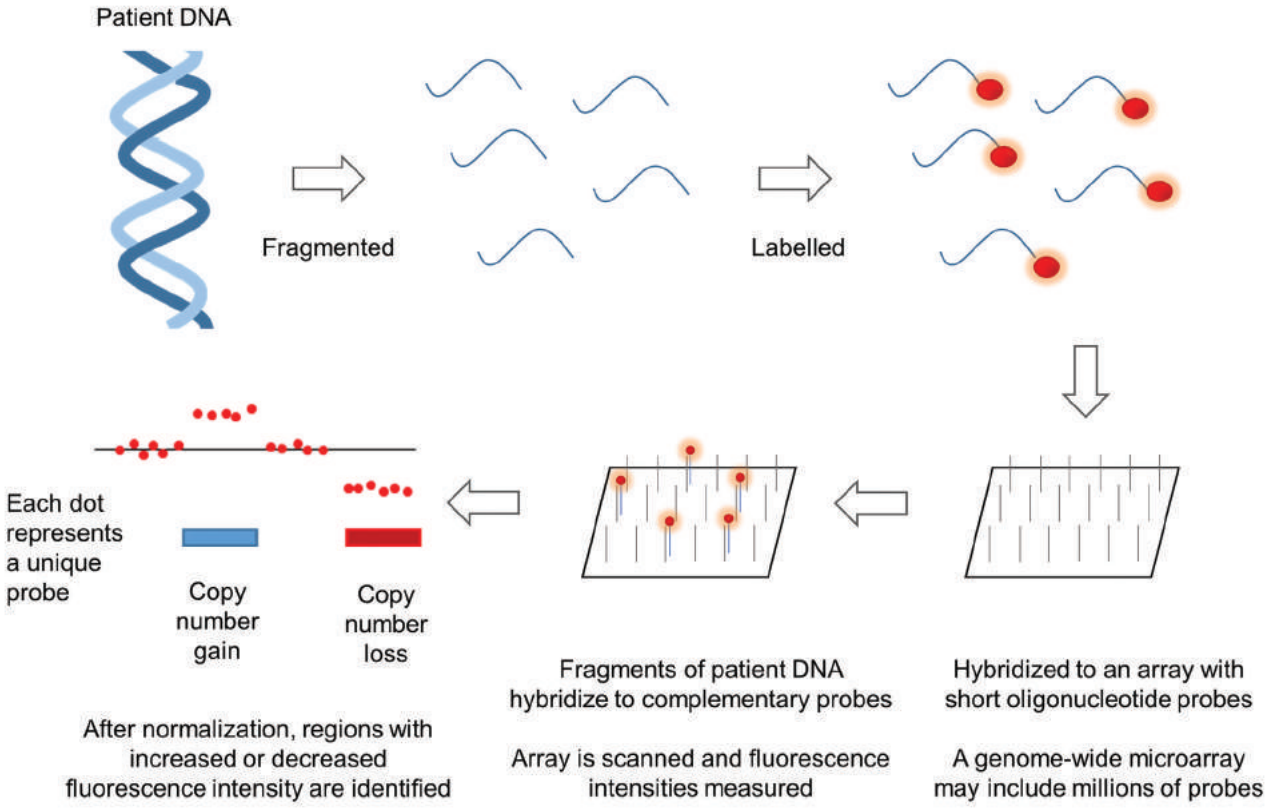
Microarray-based methods are focused on detecting copy number changes, while structural rearrangements that do not affect copy number such as balanced translocations or inversions are not detectable by this method. With a single test, microarrays can detect copy number variants in a genome-wide approach, revealing disorders usually identified by cytogenetic analysis and multiple individual FISH studies. The use of high-resolution microarrays in infants with multiple congenital anomalies has, in many cases, led to the identification of a specific genotype, with clinical evaluation then further defining the associated phenotype. In addition, SNP arrays include probes that can detect known polymorphisms present in the human genome, which may help identify regions of homozygosity, uniparental disomy (UPD), identity-by-descent, triploidy, mosaicism, chimerism, or maternal cell contamination.

In the postnatal setting, for patients with developmental delays/intellectual disability, autism spectrum disorder, or multiple congenital anomalies, CMA allows an increased diagnostic yield (approximately 15% to 20%) compared to G-banded karyotypes.[17] In the prenatal setting, in cases with ultrasound abnormalities and a normal karyotype, CMA provides additional information in 6% to 7% of cases.[20] Whereas microarray analysis can afford a robust and exceptional level of resolution from a diagnostic perspective, one major difficulty with interpretation of the results lies in assigning causality and clinical significance to the multiple alterations that are detected in each individual. Toward this end, the use of online databases (e.g., Database of Genomic Variants, http://dgv.tcag.ca/dgv/app/home) with information on normal variation in multiple ethnic populations and testing the infant's unaffected parents can help in discerning whether a copy number change is likely the cause of the patient's clinical features.

Trisomies

Down Syndrome (Trisomy 21)

Lejeune, Gautier, and Turpin (1959) demonstrated that trisomy of human chromosome 21 caused the constellation of findings recognized as Down syndrome (Fig. 28.3). This chromosome disorder was the first to be described and is the most common viable autosomal trisomy, occurring in approximately 1 in 700 live births in the United States.[21] The vast majority (>90%) occur secondary to meiotic nondisjunction, and a pronounced maternal age effect is encountered. Approximately 4% of cases are caused by a translocation that could be either *de novo* or inherited from a balanced translocation-carrier parent that subsequently becomes



• **Fig. 28.2** Example of a typical workflow for chromosomal microarray analysis. Patient DNA is fragmented and labeled, before being hybridized to an "array" of oligonucleotide probes on a solid support such as a glass slide. Following a period of hybridization and further processing, the arrays are scanned and the relative fluorescence intensity is measured. Normalization may be performed by concurrent hybridization of a control sample labeled with a different color (array CGH) or by a computational, *in silico* comparison to a set of controls (e.g., SNP microarray). *CGH*, comparative genomic hybridization; *SNP*, single nucleotide polymorphism.

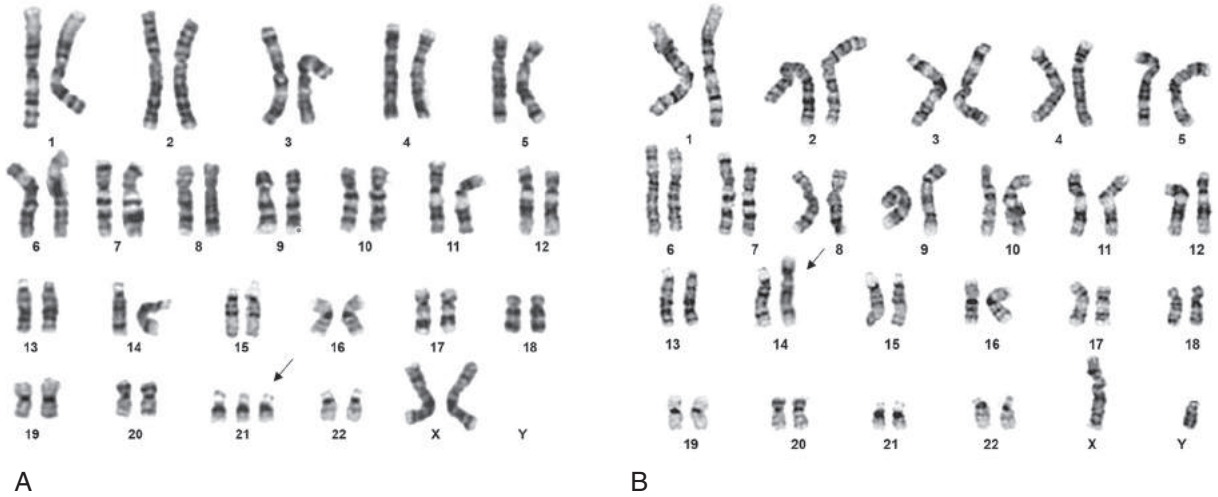
• **Fig. 28.3** Child with Down syndrome (trisomy 21). Some of the typical features such as epicanthal folds, flattened nasal bridge, posterior rotated ears, and fifth finger clinodactyly are demonstrated.

unbalanced causing trisomy in the fetus. Typically, the translocated chromosome 21 rearranges with another acrocentric chromosome, often chromosome 14, resulting in a Robertsonian translocation (Fig. 28.4). Mitotic nondisjunction, or mosaic Down syndrome, has been demonstrated in approximately 3% to 5% of cases as well, with variable features ranging from normal to a typical Down syndrome phenotype.

Clinical Features

It is the more common occurrence of Down syndrome in babies of older mothers that led to the recommendation for prenatal karyotyping for advanced maternal age (>35 years at the time of conception). Diagnostic samples are usually obtained by amniocentesis after 15 weeks' gestation or CVS at 10 to 12 weeks' gestation. Maternal serum analyte testing is recommended for prenatal screening purposes for all pregnant women, with results showing low alpha fetoprotein, low unconjugated estriol, and elevated total human chorionic gonadotropin levels. Noninvasive prenatal screening is also accepted as an initial study for fetal aneuploidy and is particularly robust for detecting trisomy 21.[7] Associated ultrasonographic findings for Down syndrome, including a cardiac defect, shortened long bones, underdeveloped fetal nasal bone, nuchal translucency or thickening, echogenic small bowel, and duodenal atresia ("double-bubble" sign), may be seen in 50% to 60% of fetuses.

Most patients with Down syndrome, if it is not diagnosed prenatally, are usually recognized at birth because of the



• **Fig. 28.4** Karyotypes that may be found in patients with Down syndrome or DS. (A) This case shows an extra copy of chromosome 21 (arrow), with 47 chromosomes total [47,XX,+21]. Standard trisomy is seen in ~95% of DS cases. (B) This case still shows three copies of chromosome 21, but the extra copy of 21 is present on chromosome 14 (arrow) in a (14;21) Robertsonian translocation, and there are 46 chromosomes total [46,XY,der(14;21)(q10;q10),+21]. Robertsonian translocations are observed in approximately 4% of DS. *(Courtesy UCLA Cytogenetics Laboratory.)*

well-established phenotypic features. The constellation of associated physical findings includes brachycephaly, the presence of a third or confluent fontanelle, upward-slanted palpebral fissures, epicanthal folds, Brushfield spots in the irises, flattened nasal root, small posteriorly rotated ears with overfolded superior helices, prominent tongue, short neck with excess nuchal skin, single palmar creases, brachydactyly, fifth-finger clinodactyly, exaggerated gap between the first and second toes, open field hallucal pattern, and hypotonia (see Fig. 28.3). Often the physical features conform to an easily distinguishable phenotype, but in some cases prematurity or ethnic variation can make a clinical diagnosis less straightforward. An immediate karyotype is indicated to confirm the diagnosis and its mechanism (e.g. trisomy or translocation) and to provide accurate recurrence risk counseling for the family. Malformations involving many organ systems have been described in Down syndrome, and whether the diagnosis is known prenatally or determined in the newborn period, several clinical investigations are warranted when this diagnosis is suggested.[22] The most common malformation is congenital heart disease (seen in over 50% of cases), which may require surgical intervention. Atrioventricular canal defects are often encountered (~40%), although ventricular septal defects (VSDs), atrial septal defects (ASDs), tetralogy of Fallot, and patent ductus arteriosus (PDA) are all described in the disorder. An echocardiogram is indicated in all cases, and medical and surgical interventions for cardiac lesions are routine. Gastrointestinal malformations, especially duodenal atresia (2% to 5%), in addition to Hirschsprung disease and less frequently encountered conditions, such as esophageal atresias, fistulas, and webs throughout the tract have been described. It is critical to carefully monitor the baby's feeding and bowel function before considering discharge from the nursery.

Although growth parameters can be within the normal range at birth, significantly decreased postnatal growth velocity is encountered in these patients. Separate growth curves have been devised for patients with Down syndrome because growth retardation involving height, weight, and head circumference has been well documented. However, the most recent health supervision guidelines for patients with Down syndrome recommend that patients be assessed on the basis of the World Health Organization or Centers for Disease Control and Prevention growth curves. An initial ophthalmologic evaluation is also indicated in the first few months of life and then annually, because strabismus, cataracts, myopia, and glaucoma have been shown to be more common in children with Down syndrome. In addition, hearing loss of heterogenous origin is present in approximately half of patients, with middle ear disease contributing to this problem.

Spinal cord compression caused by atlantoaxial subluxation from ligamentous laxity and subsequent neurologic sequelae can be a complication of the disorder. Radiographs are obtained in the early childhood years when there is concern for myopathic symptoms related to spinal cord compression (weakness, abnormal reflexes, incontinence, etc.). Physicians should be vigilant in evaluating the cervical spine, especially before procedures requiring positioning for anesthesia. Other associated disorders that merit screening are hypothyroidism in approximately 5% of patients, seen with the presence of thyroid autoantibodies. Initial evaluation occurs with newborn screening programs, followed by additional measurement of thyroid-stimulating hormone and free thyroxine levels at 6 months, 12 months, and then yearly thereafter. Hematopoietic abnormalities are common, and a complete blood count with differential should be performed at birth and later in infancy in accordance with published guidelines. Approximately 5% to 10% of newborns develop transient myeloproliferative disorder (TMD), which usually resolves spontaneously, but in 20% to 30% of cases these children will go on to develop myeloid leukemia of Down syndrome (ML-DS) by age 2 to 4 years.[23,24] Overall, the relative risk of leukemia is elevated in children with Down syndrome, who have a greater than 100-fold increased risk for myeloid leukemia (in particular, acute megakaryoblastic leukemia) and a 27-fold increased risk for acute lymphoblastic leukemia or ALL, in particular B-ALL.[24] Children with ML-DS show significantly better outcomes than non-DS children with AML, while children with DS-ALL have worse outcomes compared to non-DS cases, due to higher relapse rates, increased risk of infection, treatment-related

mortality, and induction failure.[24] Survival of patients with Down syndrome is shorter after a diagnosis of acute lymphoblastic leukemia than in diploid patients.[25] There is also an increased risk of iron-deficiency anemia, with recommended screening to include annual hemoglobin level measurement starting at 12 months of age then annually thereafter. If the hemoglobin level is low, then a complete blood count with iron studies should be performed.

Patients with Down syndrome demonstrate a wide range of developmental abilities, with highly variable personalities and behavioral phenotypes as well.[26] Central hypotonia with concomitant motor delay is most pronounced in the first 3 years of life, as are language delays. Therefore, immediate and intensive early intervention and developmental therapy are critical for maximizing the developmental outcome. A range of intellectual ability has been described, with conflicting data on genetic and environmental modifiers of outcome.[25] Seizure disorders occur in 5% to 10% of patients, often manifesting themselves in infancy.

The most common causes of death in patients with Down syndrome are related to congenital heart disease, infection (e.g., pneumonia) that is thought to be associated with defects in T-cell maturation and function, and malignancy.[27] Once medical and surgical interventions for the correction of associated congenital malformations are complete and successful, the long-term survival rate is good. However, less than half of patients survive to 60 years, and less than 15% survive past 68 years—and neurodegenerative disease with features of Alzheimer disease is encountered in many patients older than 40 years. Men with Down syndrome are almost always infertile, whereas small numbers of affected women have reproduced.[25]

In counseling the family of a newborn in whom Down syndrome has been diagnosed, it is important to include the organ systems affected in the baby and the severity of each malformation when one is defining a prognosis. Above all, the wide variability of the phenotype should be emphasized, with a care plan tailored to the needs of the individual patient.

Genetic Counseling

In cases with non-translocation Down syndrome (including mosaic cases) parental karyotypes are generally not analyzed, because the karyotypes are normal in virtually all cases. After having one child with Down syndrome, a mother's recurrence risk for another affected child is approximately 1% higher than her age-specific risk.[28,29] This fact is especially significant in younger mothers, whose age-specific risks are low. If a *de novo* translocation resulting in Down syndrome is found, the recurrence risk is less than 1%. If the mother is found to carry a constitutional balanced Robertsonian translocation, the risk of another translocation Down syndrome fetus is approximately 15% at the gestational age when amniocentesis is offered and 10% at birth. However, if the father is the translocation carrier, the recurrence risk is significantly smaller, approximately 1% to 2%.[30] While array-based diagnostic techniques will identify the copy number change associated with the trisomy, structural rearrangements such as Robertsonian translocations are not detected. In this situation, a karyotype will provide information regarding the mechanism of the trisomy, which is needed for accurate recurrence risk counseling.

Trisomy 18 (Edwards Syndrome)

Trisomy 18 is encountered in 1.07 cases per 10,000 live births and 4.08 cases per 10,000 births overall, and it is associated with a high rate of intrauterine demise.[31] It is estimated that only 5% of conceptuses with trisomy 18 survive to birth. The rates of pregnancy loss have been estimated between 70% and 72% in cases with a viable fetus at 12 weeks, and 59% between 24 weeks and term.[32,33] Findings on prenatal ultrasonography can raise suspicion for the disorder—growth retardation, oligohydramnios or polyhydramnios, heart defects, myelomeningocele, clenched fists, and limb anomalies. Diagnostic testing is recommended when prenatal ultrasonography findings are suggestive of this condition. Maternal serum screening can show low values for alpha fetoprotein, unconjugated estradiol, and total human chorionic gonadotropin. The PPV of NIPS for trisomy 18 is currently 45% for a 36 year-old woman at 16 weeks' gestation (https://www.perinatalquality.org/Vendors/NSGC/NIPT/), thus high resolution anatomy ultrasounds and diagnostic testing by amniocentesis are currently recommended for follow up.[7]

Clinical Features

The classical phenotypic features reported at birth include intrauterine growth restriction (1500 to 2500 g at term), small narrow cranium with prominent occiput, open metopic suture, low-set posteriorly rotated ears, and micrognathia with small mouth. Characteristic clenched hands with overlapping digits, an excess of arches on dermatoglyphic examination, hypoplastic nails, and "rocker-bottom" feet or prominent heels with convex soles (Fig. 28.5) are described. Additional malformations encountered in this syndrome include congenital heart disease (ASD, VSD, PDA, pulmonic stenosis, aortic coarctation) in over 70% of patients,[34] cleft palate, clubfoot deformity, renal malformations, brain anomalies, choanal atresia, eye malformations, vertebral anomalies, hypospadias, cryptorchidism, and limb defects, especially radial ray defects.

Historically, the prognosis in this disorder is extremely poor with survival estimates of 37.2% at 28 days and 13.4% at one year.[35] Death is related to central apnea, infection, and congestive heart failure. The newborn period is characterized by poor feeding and growth, typically requiring tube feedings. Universal poor growth and profound intellectual disability have been documented, with developmental progress typically leveling at that of a 6 to 8-month-old infant.[34] Malignant tumors such as

• **Fig. 28.5** Newborn with trisomy 18, showing prominent occiput, characteristic facial appearance, and clenched hands.

hepatoblastoma and Wilms tumor have been described in some survivors.[36] There is emerging evidence that various interventions can improve the survival and quality of life for the child and the family, and this should be discussed with the parents during a prenatal or postnatal visit.

Families have indicated a desire to be able to take the infant home and spend time as a family, understanding the dismal prognosis. Many institutions have determined specific protocols typically based on each infant's clinical findings such as their ability to breathe without mechanical ventilation, for example, when considering surgical interventions such as cardiac repair. In general, those who do not require mechanical ventilation have less complex cardiac defects and do not show other major malformations, (e.g. omphalocele) benefit the most from intervention.[37] However, it is important to evaluate each infant on an individual basis during such considerations and have a team-based plan involving neonatology, cardiology, cardiac surgery, genetics, and other appropriate specialists when considering intervention.

Genetic Counseling

The estimate of the recurrence risk for trisomy 18 in a future pregnancy is a 1% risk over the maternal age-specific risk for any viable autosomal trisomy. Trisomy occurring from a structural rearrangement, such as a translocation, warrants parental karyotype analysis before the recurrence risk can be assessed.

Trisomy 13 (Patau Syndrome)

The frequency of trisomy 13 is estimated to be 0.55 per 10,000 live births and 1.68 per 10,000 births overall.[31] It has been estimated that approximately 2% to 3% of conceptions with trisomy 13 survive to birth, with rates of pregnancy loss estimated at 49% to 50% for cases with a viable fetus at 12 weeks and 35% between 24 weeks and term.[32,33] As with other trisomies, abnormal NIPS findings or the presence of fetal ultrasonographic findings should prompt diagnostic testing by CVS or amniocentesis that can result in a prenatal diagnosis of trisomy 13. Currently, the calculated PPV of NIPS for trisomy 13 is 26% for a 36-year-old woman at 16 weeks' gestation, underscoring the need for appropriate genetic counseling and formal diagnostic testing.

Clinical Features

Trisomy 13 is associated with midline anatomic malformations including congenital heart disease, cleft palate, holoprosencephaly, renal anomalies, and postaxial polydactyly (Fig. 28.6). In addition, microcephaly, eye anomalies, and scalp defects can suggest the diagnosis. Brain malformations including holoprosencephaly are found in more than half of patients and can feature concomitant seizure disorders. Microcephaly, split sutures, and splayed fontanelles are encountered. A scalp defect (cutis aplasia) is relatively specific to the disorder, found in 50% of cases. Eye malformations, including iris colobomas and hamartomatous cartilage "islands," can be seen on fundoscopic examination.

Congenital heart disease is present in approximately 80% of patients, commonly VSD, ASD, PDA, or dextrocardia are seen. Minor anomalies of the extremities, such as postaxial polydactyly, single palmar creases, and hyperconvex narrow fingernails, are also seen. The fingers can be flexed or overlapped with camptodactyly noted. An increased frequency of nuclear projections in neutrophils, giving a drumstick appearance similar to that of Barr bodies, has been described. This finding would be especially striking in males, in whom Barr bodies would not be expected.

• **Fig. 28.6** Stillborn with trisomy 13. The facial appearance is that of cebocephaly, which is associated with holoprosencephaly. There is an extra digit on the ulnar border of the right hand.

As with trisomy 18, prognosis for the fetus with trisomy 13 is extremely poor, with survival estimates of 25.5% at 28 days and 11.5% at one year.[35] Intellectual disability is profound, and many patients have blindness and deafness as well. Feeding difficulties are typical. Similar to trisomy 18, specific interventions can increase the survival of some trisomy 13 infants and may improve their overall quality of life. A discussion with the parents should be considered regarding these possibilities but tailored to the specific defects seen in each individual infant. An institutional assessment protocol can be a helpful approach to determining when intervention may be offered.[37–39] For cases of trisomy 13 and trisomy 18 that are recognized for their exceptionally poor outcomes, early involvement of providers with experience in palliative care approaches can be beneficial for both the infant's family as well as the primary neonatal care team.

Genetic Counseling

Recurrence risk data suggest that, as with trisomy 18, the chances of having a child with *any* trisomy after a pregnancy affected by trisomy 13 is rare. The estimated risk is 1% higher than the maternal age–related risk for the recurrence of any viable autosomal trisomy in a subsequent pregnancy. Parental karyotypes are recommended in cases where a translocation has been identified in the affected infant in order to provide accurate recurrence risk counseling.

45,X (Turner Syndrome)

In early female embryogenesis, two X chromosomes are required for normal development. Turner syndrome, a phenotype associated with loss of all or part of one copy of the X chromosome in

a female conceptus, occurs in approximately 1 in 2500 female newborns. The 45,X karyotype or loss of one entire X chromosome accounts for approximately half of the cases. A variety of X chromosome anomalies—including deletions, isochromosomes, ring chromosomes, and translocations—account for the remainder. It is important to note that approximately 0.1% of fetuses with a 45,X complement survive to term; the vast majority (>99%) are spontaneously aborted underscoring the requirement for two normal X chromosomes during early embryonic development. Additional studies have shown that in approximately 80% of cases, it is the paternally derived X chromosome that is lost.[40]

Clinical Features

There is wide phenotypic variability in patients with Turner syndrome. Features present at birth include short stature, webbed neck, craniofacial differences (epicanthal folds and high arched palate), hearing loss, shield chest, renal anomalies, lymphedema of the hands and feet with nail hypoplasia, and congenital heart disease. Typical cardiac defects include bicuspid aortic valve, coarctation of the aorta, valvular aortic stenosis, and mitral valve prolapse.

Growth issues, especially short stature, are the predominant concern in childhood and adolescence; the mean adult height of patients with Turner syndrome is 135 to 150 cm without treatment. In cases with evidence of growth failure, growth hormone therapy is recommended with initiation of treatment around 4 to 6 years of age and preferably before 12 to 13 years.[41] Primary ovarian failure caused by gonadal dysplasia can result in delay of secondary sexual characteristics and primary amenorrhea. Cyclic hormonal therapy can be used to reflect the process of normal puberty[42] to aid the development of secondary sex characteristics and menses as well as to support bone mass. Infertility, related to gonadal dysplasia, is well described and has been successfully treated with assisted reproduction techniques and donor oocytes. It is important to evaluate the patient for structural cardiovascular defects before pregnancy.

In terms of intellectual development, specific difficulties with spatial and perceptual thinking can lead to a lower performance scores on neuropsychological testing; however, this syndrome is not characterized by intellectual disability.

Triploidy (69,XXX or 69,XXY)

As its name implies, triploidy is a karyotype containing three copies of *each* chromosome. The mechanisms that lead to this state include fertilization of the egg by two different sperm (dispermy) and complete failure of normal chromosome separation in maternal meiosis. The vast majority of triploid fetuses are spontaneously aborted, accounting for up to 15% of chromosomally abnormal pregnancy losses. Live births of affected fetuses are rare, and reports of survival beyond infancy are rarer still. Mosaicism with combinations of diploid and triploid cells (mixoploid) has also been documented. Malformations, including hydrocephalus, neural tube defects, ocular and auricular malformations, cardiac defects, and 3 to 4 syndactyly of the fingers are known findings. In cases where the extra set of chromosomes is paternal in origin (diandry), the placenta is often abnormal, typically large and cystic (partial hydatidiform moles). In cases where the extra set of chromosomes is maternal in origin (digyny), the placenta is small and non-cystic, with a severely growth-restricted fetus and relative macrocephaly.

Deletion Syndromes

In addition to the aneuploid conditions described above, partial monosomy of a chromosome can lead to recurrent recognizable patterns of malformation. Three well-described syndromes that are associated with the deletion or loss of genetic material from the short, or *p* arms of chromosomes 1, 4, and 5 are discussed below. All of these syndromes are associated with heterozygous deletions that involve the loss of many genes located in a specific region, resulting in their haploinsufficiency. While the three disorders below are recurrent, the deletion sizes vary, contributing to clinical variability since the gene content of the deleted region can be quite different from patient to patient. In general, larger deletions with more genes showing copy number loss tend to have more severe clinical consequences.

Chromosome 1p Deletion Syndrome (1p–)

Monosomy for the distal short arm of chromosome 1, or deletion 1p36, has been associated with a constellation of clinical findings. A characteristic facies consisting of frontal bossing, large anterior fontanel, flattened midface with deep-set eyes, and developmental delay has been described (Fig. 28.7). Orofacial clefting, hypotonia, seizures, deafness, and cardiomyopathy are also noted.

This deletion syndrome is estimated to occur in approximately 1 in 5000 live births and is the most frequently occurring subtelomeric deletion.[43] Greater recognition of the phenotype and widespread use of chromosomal microarrays has led to improved diagnosis of this condition. Most deletions arise *de novo* in the patient with approximately 3% attributable to malsegregation of a balanced parental translocation. The size of the deletion differs amongst patients, from submicroscopic (<5 Mb) to large, cytogenetically visible deletions larger than 30 Mb. A genotype-phenotype correlation has been described with certain genes within the deleted region being associated with different aspects of the phenotype.[44]

Wolf–Hirschhorn Syndrome (4p–)

Distal deletions in the short arm of chromosome 4 are associated with a recognizable pattern of malformation. This syndrome is estimated to occur in 1 in 50,000 to 1 in 20,000 births[45] and has features including intrauterine growth restriction, microcephaly, midline structural defects such as cleft lip and cleft palate, cardiac septal defects, and hypospadias. The characteristic facial features are described as resembling a *Greek helmet*, as evidenced by hypertelorism with epicanthi, a high forehead with a prominent glabella, and a beaked nose. Prominent, low-set ears are also seen. Hypotonia, failure to thrive, and developmental delay are common, with approximately 30% mortality in the first year of life. Many patients have lived well into childhood and even into adulthood, although profound growth impairment and intellectual disability are usually described and are often accompanied by seizures.

The 4p deletions can be cytogenetically visible on karyotype analysis, although small submicroscopic deletions have also been described and range from 2 Mb to 30 Mb.[46] In cases where the clinical features are suggestive of the syndrome but the karyotype is not revealing, further cytogenetic analysis has been performed using specific 4p FISH probes or more commonly, chromosomal microarray. Microarray analysis also provides information about the relative size and gene content of the deleted region.

• **Fig. 28.7** Child with deletion in chromosome 1p36.

Genotype-phenotype correlations and critical regions for different aspects of the phenotype have been described.[47] Approximately 55% of patients have a 4p deletion as the only cytogenetic abnormality, while others have more complex abnormalities including ring chromosome 4, mosaicism for 4p loss, or an unbalanced translocation involving chromosome 4.[45] More than 80% of 4p deletions arise *de novo* in the patient with minimal risk of recurrence. In the 10% to 15% of cases resulting from a translocation, analysis of parental samples is indicated for appropriate recurrence risk counseling.

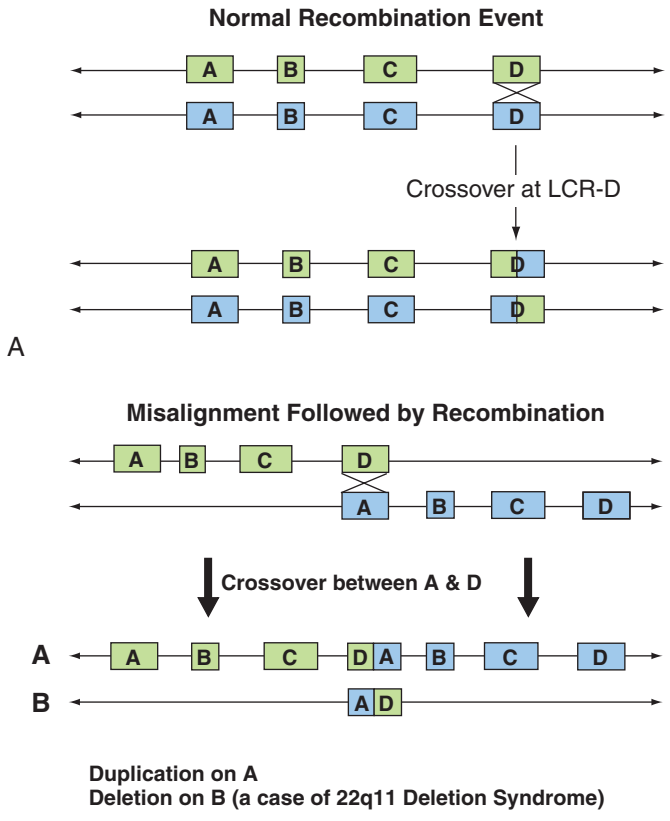
Cri du Chat Syndrome (5p–)

Partial monosomy of chromosome 5p is seen in approximately 1 in 15,000 to 1 in 50,000 live births[48] and is associated with a multiple congenital anomaly syndrome named for the unusual cry of the affected babies, described as similar to that of a cat or *cri du chat*. The constellation of features associated with this disorder includes low birth weight, microcephaly, round face, hypertelorism or telecanthus, downward-slanting palpebral fissures, epicanthi, and broad nasal bridge. Hypotonia, laryngomalacia, and cardiac defects are also seen, including ASD, VSD, and tetralogy of Fallot. Early issues include failure to thrive and pronounced developmental delay. The unusual cry resolves during infancy, and survival into adulthood is possible but is often marked by severe intellectual disability. Intensive therapy appears to provide benefit, and more sensitive measures of cognition demonstrate clearly better receptive language skills than expressive language ability. Therefore, affected children may understand more complex verbal language than their expressive skills can demonstrate.[49]

It is estimated that almost 100 genes are lost when the putative critical region from 5p15.2 to p15.33 is deleted,[50,51] and different regions associated with different aspects of the phenotype have been described.[48] Close to 90% of 5p deletions arise *de novo* in the affected child, incurring a minimal risk of recurrence (<1%). The remainder arise from malsegregation of a balanced rearrangement in a carrier parent, which would be associated with a risk of recurrence of an unbalanced karyotype in a future liveborn infant (risk varies depending on the specific translocation). Parental chromosome analysis is indicated for proper recurrence risk counseling.

Segmental Duplications and Microdeletion/Microduplication Syndromes

A greater appreciation for the complexity of the human genome and its structure was afforded with the completion of the human genome sequence. This work focused attention on regions of the genome susceptible to rearrangement. The presence of such regions appears to have a significant role in the origin of several genetic disorders.[11,12] These disorders result from inappropriate dosage of crucial genes in a given genomic segment via structural mechanisms (deletion or duplication) and in some cases, functional mechanisms (e.g. imprinting). Many of the regions prone to recurrent rearrangements have a common element: the presence of large, chromosome-specific segmental duplications. These repeat structures appear to mediate misalignment and aberrant crossover during recombination, resulting in inversions, deletions, and duplications within chromosomes (Fig. 28.8). Segmental duplications are large, low copy repeat structures mostly unique to humans and are localized to single chromosomes or within a single chromosomal band. Examples of the genomic disorders they cause include hemophilia A (inversion of Xq28), Sotos syndrome (where a number of patients have a deletion in 5q35), Smith–Magenis syndrome (deletion of 17p11.2), Charcot–Marie–Tooth disease (interstitial duplication in 17p12), and the reciprocal deletion of this same region in 17p12, leading to hereditary neuropathy with liability to pressure palsies, and a small percentage of patients with neurofibromatosis type I (deletion involving 17q11.2).



• **Fig. 28.8** (A) Alignment of low copy repeats before exchange. (B) Misalignment of low copy repeats before exchange can result in rearrangement. *LCR*, Low copy repeats.

In this section, we highlight several deletion syndromes that occur on chromosomes whose underlying genomic structure contains segmental duplications. Since the deletion endpoints coincide with the locations of the segmental duplications, these deletions tend to have recurrent deletion sizes and gene content. These include Williams–Beuren syndrome (involving 7q11.2), Prader–Willi syndrome (PWS) or Angelman syndrome (involving an imprinted region of 15q11 through 15q13), and 22q11.2 microdeletion syndrome (also known as DiGeorge or velocardiofacial syndrome). The latter is the most commonly occurring microdeletion syndrome in humans. It is important to note that in several of these microdeletion syndromes, reciprocal duplications of the exact same region may also occur (see Fig. 28.8) and can show a different phenotype than the deletion of the same region. In general, duplication syndromes cause fewer anatomic defects and show a wider phenotypic variability, but they are often characterized by developmental delays with or without behavioral abnormalities.

More recently recognized recurrent microdeletion syndromes (e.g., 1q21.1, 3q29, 15q13.3, 16p11.2, and 17q21) were identified because of the increased use of chromosomal microarrays in the clinical and research settings. These regions are similarly flanked by segmental duplications, likely predisposing to their rearrangements. Many of the patients with these particular rearrangements do not receive a clinical diagnosis in the newborn period, since they may not present with significant anatomic malformations or dysmorphic features that prompt a genetic evaluation in the NICU; however, they can present in early childhood with variable clinical findings. Typically there is developmental delay, behavioral abnormalities (such as autism spectrum disorder), or intellectual disability. Many of these syndromes are complicated by incomplete penetrance, meaning that unaffected family members may also carry the genomic imbalance, which can be challenging for genetic counseling.

When an abnormality is identified by microarray analysis, the genes located in the affected region can be identified. It is then possible to decide what role, if any, the affected genes have in the observed phenotype. For example, deleted genes could be identified that may predispose a patient to cancer because of a germline loss of one copy of a tumor suppressor gene,[52] prompting careful surveillance for tumor formation. This underscores the utility of early identification of underlying chromosomal disorders for anticipatory guidance in clinical care.

Williams–Beuren Syndrome (7q11.2 Deletion)

The estimated incidence of Williams–Beuren syndrome (also known as Williams syndrome) is 1 in 10,000 live births. The phenotype has a variable spectrum but usually consists of distinctive facies, growth and developmental delay, cardiovascular anomalies, and occasionally infantile hypercalcemia (Fig. 28.9). Babies with Williams–Beuren syndrome usually show some degree of intrauterine growth restriction with mild microcephaly. Facial features include epicanthal folds with periorbital fullness of subcutaneous tissues, flat midface, anteverted nostrils, long philtrum, thick lips, large open mouth, and stellate irises that may not be discernible at birth. Many infants have cardiovascular anomalies; supravalvular aortic stenosis (SVAS) is the most commonly described defect, seen in more than 50% of cases. Pulmonary artery stenosis is also often encountered. It is interesting to note that isolated SVAS can also exist as a separate autosomal dominant trait and has been shown to occur from mutations within the elastin gene (*ELN*), which is located in the Williams syndrome region in chromosome 7q11.2. Patients with Williams–Beuren syndrome, have a deletion of 7q11.2 and are typically missing one entire copy of the elastin gene as well as other genes.

Hypercalcemia, which is manifested in approximately 10% of patients with this disorder is severe and persists through infancy. Umbilical and inguinal hernias are also associated features. Issues in infancy include feeding and growth problems, with pronounced irritability and colicky behavior. Hoarse voice, strabismus, hypertension, and joint mobility restrictions may develop later in childhood. In terms of development, the typical mild to moderate intellectual disability can be masked by relatively advanced language skills, although gross motor and visual–motor integration skills are typically affected. Attention-deficit disorders are common, and a characteristic outgoing personality is often described in affected children.

Many of the classic features of Williams–Beuren syndrome are not clearly discernible in the newborn period, but the diagnosis should be suggested in any child with SVAS, hypercalcemia, and facial features consistent with the disorder. The diagnosis can be confirmed quickly by chromosomal microarray analysis or FISH using probes specific for the deleted region of 7q11.2. Because the condition is typically sporadic and most deletions arise *de novo*, the risk of recurrence in subsequent pregnancies is minimal. An affected adult, however, would pass on the condition in an autosomal dominant manner, with a 50% risk of the disorder in his or her child.

• **Fig. 28.9** Williams–Beuren syndrome. (A) Neonate with a coarse face, periorbital fullness, wide mouth, and thick lips with decreased Cupid's bow. (B) Neonate profile showing periorbital fullness, flat nasal bridge with full tip, and prominent cheeks. (C) Infant with periorbital fullness, flat nasal bridge, thick lips with decreased Cupid's bow, pouty lower lip, and low-set, full cheeks. (D) Infant profile showing dolichocephaly (increased anteroposterior diameter of head), a higher nasal bridge than in the neonate, full nasal tip, pouty lower lip, long neck, sloping shoulders, and part of pectus excavatum.

22q11.2 Deletion Syndrome

A deletion of 22q11.2 has been identified in most patients with the classically termed conditions DiGeorge, velocardiofacial, and conotruncal anomaly face syndromes, leading to the realization that these clinical entities all reflect features of the same genomic disorder.[53] The list of findings associated with 22q11.2 deletion syndrome is extensive and differs among patients even when the deletion sizes appear identical. Estimates indicate that 22q11.2 microdeletion syndrome occurs in approximately 1 in 1000 fetuses.[54] This disorder is the most common microdeletion syndrome occurring in humans, seen in 1:3000 live births and is a significant health concern in the general population.

The phenotype is characterized by a conotruncal cardiac anomaly and often aplasia or hypoplasia of the thymus and parathyroid glands. Most patients with a deletion can receive a diagnosis as newborns or infants with significant cardiovascular malformations, including interrupted aortic arch type B, truncus arteriosus, or tetralogy of Fallot, along with functional T-cell abnormalities, and hypocalcemia. In addition, facial dysmorphia may be present (Fig. 28.10), including hooded eyelids, hypertelorism, overfolded ears, bulbous nasal tip, a small mouth, and micrognathia. Since the initial report by DiGeorge in 1968,[55] the spectrum of associated clinical features has been expanded to include anomalies such as palate defects (overt or submucous clefts, velopharyngeal incompetence), vascular rings, feeding and

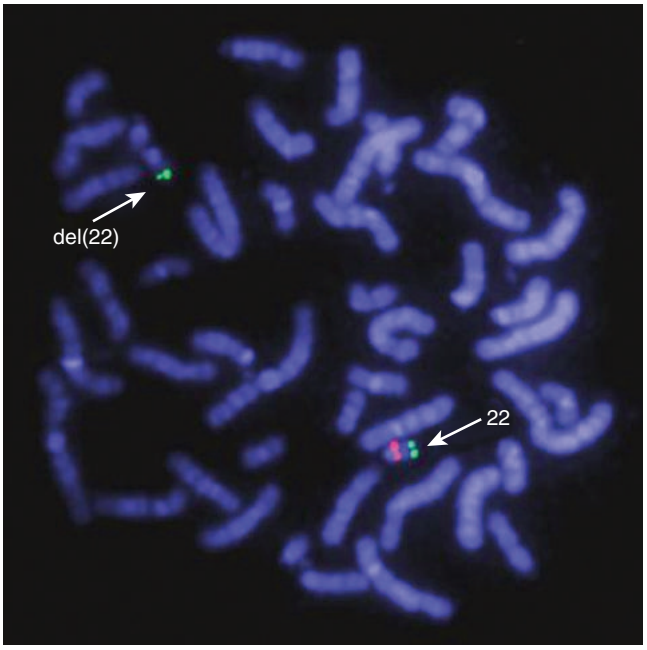
• **Fig. 28.10** Facial differences associated with 22q deletion syndrome. (A) Frontal view showing upslanting palpebral fissures, bulbous nose, and small chin. (B) Profile view showing deep set eyes and overfolded superior helices.

swallowing problems, gastroesophageal reflux, renal agenesis, and hypospadias.

Developmental delays or learning disabilities have been reported in most patients with 22q11.2 deletion syndrome, and a wide range of developmental and behavioral findings have been observed in young children.[56] In the preschool years, affected children were most commonly found to be hypotonic and developmentally delayed with language and speech difficulties. Severe or profound retardation was not seen, and one-third of patients functioned within the low average range.[56]

The majority of patients (80% to 90%) have the same large deletion, approximately 2.4 to 3 Mb that was historically detected by FISH (Fig. 28.11), but more commonly now by chromosomal microarray. This "typical" deletion includes approximately 50 genes and 7 micro ribonucleic acids.[53] The size of the deletion remains unchanged when it is inherited from an affected parent. However, the phenotype can be widely variable, even among affected members of the same family. Although smaller recurrent deletions that are half the size of the common deletion occur (1.5 Mb), a smaller size does not necessarily correspond to milder symptoms, making genotype–phenotype correlations difficult.

Most 22q11 deletions occur as *de novo* events, with less than 10% of them inherited from an affected parent. The prevalence of these de novo 22q11.2 deletions indicates a high rearrangement rate within this genomic region that is related to the presence of recombination-permissive segmental duplications in 22q11.[11,12,57]



• **Fig. 28.11** Fluorescence in situ hybridization study of a 22q deletion. The arrows point to both copies of the 22nd chromosome. One chromosome 22 shows a hybridization pattern involving a control probe *(green)* and the 22q11.2 region probe *(red)*. The other chromosome 22 shows a hybridization pattern of a control probe *(green)* and absent 22q11.2 region probe (*red*), suggesting this region is deleted. (Courtesy of Beverly S. Emanuel.)

Additional Microdeletion and Microduplication Syndromes

As mentioned previously, many genetic syndromes have been described with the increased use of chromosomal microarrays.[58,59] Several of the regions are also flanked by segmental duplications, which is the likely reason for their prevalence in diverse patient populations, and the occurrence of reciprocal rearrangements (deletion or duplication) of the same chromosomal region. Almost all of the patients with these more recently recognized deletions or duplications were not initially identified on the basis of their clinical features but were instead ascertained by microarray analysis.

Deletions of chromosome 1q21.1 with a size of approximately 1.35 Mb have been seen in patients with variable presentations, including developmental and behavioral abnormalities, mild facial dysmorphia, and microcephaly.[60,61] In the 3q29 microdeletion

syndrome, an approximately 1.6 Mb deletion was initially discovered[62] in patients with mild to moderate intellectual disability, microcephaly, and nonspecific facial dysmorphia. Duplications of this region have also been described in patients with developmental delays, intellectual disability, and microcephaly.[63] Reciprocal *duplications* of the region deleted in Williams–Beuren syndrome (7q11.23) are characterized by distinctive facial features, congenital anomalies, and intellectual and developmental disabilities including *poor* expressive speech in contrast to the deletion of the same region.[64]

The chromosome 15q13.3 region is distal to the more commonly known 15q11-q13 locus associated with Prader–Willi and Angelman syndromes and is prone to several recurrent deletions/duplications, with different breakpoints corresponding to the locations of segmental duplications in the region.[65] The most extensively documented is a 1.5 to 2 Mb deletion of 15q13.3, which is associated with variable phenotypes but typically includes seizures or abnormal electroencephalograms.[66] Interestingly, this deletion is often maternally inherited, suggesting that there might be an imprinting mechanism involved. A smaller 680-kilobase (kb) deletion within this region has also been described in patients with a range of neurobehavioral phenotypes.[67] Deletions of 16p12.2 can manifest as developmental and intellectual disability, cardiac malformations, epilepsy, hearing loss, renal and genital anomalies (the latter in males), and cleft lip/palate.[68] A recurrent 550-kb deletion of 16p11.2 has been described in approximately 1% of patients with autism[69] and its reciprocal duplication is associated with attention deficit–hyperactivity disorder and schizophrenia.[70,71] Chromosome deletions of 17q21.31 of approximately 500 to 650 kb were also found in patients with developmental delays, learning disabilities, and variable facial dysmorphia. Mutations of *KANSL1*, located within the 17q21.31 interval, can also be associated with the same phenotype.[72]

Disorders of Imprinted Chromosomes

A growing recognition of mechanisms regulating gene expression has emerged in the last few decades. Two of the most exciting concepts with important clinical correlates are imprinting and *UPD or uniparental disomy*. The term *genomic imprinting* implies that a whole region of a chromosome or a group of genes in a given region is subject to a difference in their expression that depends on whether they reside on the maternally inherited or the paternally inherited chromosome. In these cases, a genetic disorder might manifest itself on the basis of whether the genomic region was inherited maternally or paternally. The genes in an imprinted region are not necessarily mutated, but they are epigenetically marked such that the cell can distinguish between the maternal and paternal copies and coordinate expression on the basis of that distinction. At the molecular level, it appears that differences in the methylation of the DNA, and its replication and regulation at the transcriptional level, appear to be involved in this mechanism. The process of imprinting has become an area of important research initiatives, and there are now more than 270 known or predicted genes and chromosomal regions thought to be important in human disease (http://www.geneimprint.com/site/genes-by-species).

Prader–Willi Syndrome

It has been demonstrated that occasionally, instead of one copy of each chromosome being inherited from each parent, both copies of a given chromosome or chromosomal region can come from the same parent. This phenomenon, known as *uniparental disomy* or *UPD*, is associated with advanced maternal age. It becomes a significant issue when the chromosome involved is imprinted or has regions in it that are imprinted. UPD can occur as isodisomy, when two identical copies of a chromosome are inherited from the same parent (meiosis II error) or heterodisomy, when two different copies of a chromosome are inherited from the same parent (meiosis I error).

PWS involves the loss of activity from the paternally derived proximal long arm of chromosome 15 (15q11 to 15q13). This loss can occur through deletion or disruption of this region or through maternal UPD such that no paternal chromosome 15 is present.[73] Newborns with PWS have pronounced central hypotonia, hyporeflexia, and a weak cry. The poor tone manifests itself as sucking and swallowing difficulties that can lead to failure to thrive and the need for feeding tubes in infancy. Facial differences that have been described include bifrontal narrowing, almond-shaped eyes, and a small, downturned mouth. Genitalia are often hypoplastic, with cryptorchidism common in boys with this syndrome. The commonly reported small hands and feet are not always demonstrated in the newborn. Strabismus and hypopigmentation relative to the family are also common.

For infants with PWS, a history of poor fetal activity during the pregnancy can often be elicited, especially if the mother has had prior pregnancies as a comparison. Consistent with the hypotonia, breech presentation and perinatal insults are found more frequently than usual. The extreme hypotonia begins to abate in the first year of life and motor development improves, although developmental delay is the rule, especially for gross motor skills and speech. The feeding improves in the first few years of life and gives way to often uncontrollable hyperphagia and obesity. This issue and other behavioral problems, including severe temper tantrums, obsessive–compulsive disorder, and autism spectrum disorders, are encountered throughout life. Most patients manifest mild to moderate intellectual disability. Early diagnosis and recognition of the various medical issues along with preemptive implementation of behavioral therapy are essential components of the optimal management of these issues.

Deletions of the region critical in PWS have been demonstrated in up to 70% of patients. The deletion can be detected by a chromosomal microarray which has largely replaced FISH analysis using a probe specific for this region of chromosome 15. As these tests cannot determine whether the deletion involves the paternal or the maternal allele, further testing such as methylation analysis is required to distinguish it from Angelman syndrome (see below). A small number of patients have a disruption of this area as the result of a chromosomal translocation. To date, no single gene in this region has been implicated as the cause, but five genes are known to have paternal-only expression of protein-encoding genes (*MKRN3, MAGEL2, NECDIN, SNURF*, and *SNRPN*), as well as several paternally expressed noncoding RNA genes. It has been noted, however, that patients who have PWS as a result of a deletion of the region are more likely to be hypopigmented relative to their family. This feature has been attributed to deletion of a gene involved in pigmentation, *OCA2*.[74] Recurrence risks are negligible in cases in which de novo deletions are found and sporadic occurrence is usually encountered. In addition to hypopigmentation, patients with a deletion have a higher risk of sleep disturbance, speech defects, and need for feeding support.[75]

While large chromosome-specific segmental duplications are found in 15q11 and have been implicated in mediating the recurrent deletion of this genomic region (reviewed in[11,12]), approximately 20% to 25% of patients with PWS show maternal UPD that can be detected by means of a molecular assay designed to

assess specific methylation differences between maternal and paternal alleles. SNP microarray may detect UPD in cases of isodisomy, but not heterodisomy (which is relatively common in PWS), and microarray cannot distinguish paternal from maternal UPD without further testing including parental samples. Methylation analysis findings are abnormal in more than 99% of affected individuals but will not determine whether the cause is a deletion or maternal UPD. Further study is required if an abnormal methylation result is obtained. A maternal age effect has been demonstrated in UPD cases, and recurrence risks in families without deletions are estimated at 1 in 1000.

Angelman Syndrome

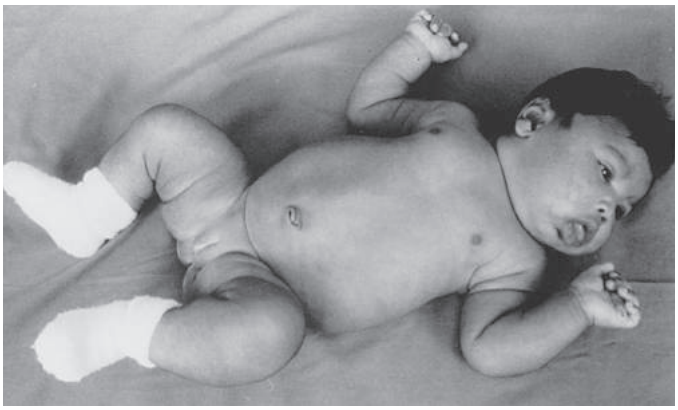
Loss of genetic material from the 15q11 to 15q13 region from the maternal copy of chromosome 15 is associated with Angelman syndrome. Clinical features are not evident in the newborn period and infancy but include significant intellectual disability, seizures, ataxic gait, tongue thrusting, inappropriate bursts of laughter, and facial differences, including protruding jaw, wide mouth, thin upper lip, and widely spaced teeth. The intellectual disability and hypopigmentation overlap with the features of PWS, but Angelman syndrome is a distinct entity.

Seventy percent to 75% of patients have a deletion of 15q that is detectable by chromosomal microarray (or specific FISH). A small percentage (3% to 5%) have evidence of paternal isodisomy (two paternal copies) of this region of chromosome 15, with no apparent maternal chromosome contribution. Unlike PWS, Angelman syndrome has been associated with mutations in a single gene, *UBE3A* (which encodes an enzyme involved in the ubiquitin pathway of protein degradation) that has been detected in up to 10% of patients. In addition, mutations of an imprinting center locus on chromosome 15 are associated with 1% to 2% of Angelman phenotypes.[76] Methylation analysis can be performed and will detect abnormalities in approximately 75% to 80% of patients because of a deletion or UPD. If methylation analysis findings are normal but Angelman syndrome is still suspected, *UBE3A* sequence analysis should be considered. The vast majority of cases result from a sporadic event, and the risk of recurrence can be best evaluated once the genetic mechanism has been determined for a given patient.

Beckwith–Wiedemann Syndrome

Beckwith–Wiedemann syndrome affects approximately 1 in 14,000 newborns and manifests itself as an overgrowth syndrome in the neonatal period. The characteristic findings are macrosomia, abdominal wall defect, and macroglossia (Fig. 28.12). Affected babies are large for their gestational age with proportionate length and weight. Infants of mothers with diabetes also manifest macrosomia but are more likely to have a weight disproportionately greater than length. Advanced bone age is also noted in Beckwith–Wiedemann syndrome. Hemihypertrophy caused by asymmetric growth is common, as is visceromegaly of various organs, including the spleen, kidneys, liver, pancreas, and adrenal glands.

Other characteristic features of the syndrome are macroglossia, linear creases of the earlobe with indentations on the posterior helix, and severe hypoglycemia. Although the hypoglycemia responds quickly to therapy, it can be present for several months; therefore recognition of the condition and immediate therapeutic intervention are critical in these cases. The hypoglycemia resolves spontaneously with age, and the physical diagnostic features also become less prominent with age, making the diagnosis more difficult to ascertain.



• **Fig. 28.12** Macrosomic infant with macroglossia and lax abdominal musculature. These findings are typical of Beckwith–Wiedemann syndrome. (From Viljoen DL, Jaquire Z, Woods DL. Prenatal diagnosis in autosomal dominant Beckwith-Wiedemann syndrome. Prenat Diagn. 1991;11:167–175.)

Equally important is the establishment of routine ultrasonographic surveillance at regular intervals, because children with Beckwith–Wiedemann syndrome are at increased risk of malignant tumors, especially Wilms tumor. The estimated risk is as high as 8% for patients with hemihypertrophy. Recommended screening for children with BWS includes full abdominal ultrasound and monitoring of serum alpha fetoprotein every three months until age 4 (screening for both Wilms tumor and hepatoblastoma) followed by renal ultrasound including the adrenal glands every three months until age 7 years.[77]

Although most cases of Beckwith–Wiedemann syndrome appear to arise de novo, up to 15% may be familial. In familial cases, the transmission is autosomal dominant, because of mutations in the maternally inherited *CDKN1C* gene in 40% of familial cases but only in 5%–10% of *de novo* cases. In addition, this region of the genome (11p15.5) is differentially imprinted such that certain genes are expressed only from the maternal allele, and others only from the paternal allele. The insulin-like growth factor type 2 gene (*IGF2*) is located in this region and encodes an important factor involved in fetal growth which is paternally expressed. Overexpression of the paternal allele results in an imbalance of expression leading to the overgrowth and tumor formation encountered in these patients. Paternal UPD has proved to be a mechanism involved in 10% to 20% of sporadic cases of Beckwith–Wiedemann syndrome. Methylation abnormalities at two distinct genetic loci within 11p15 account for approximately 60% of patients and is related to the overexpression of the *IGF2* gene. Therefore, all the available testing methods combined can detect the cause in approximately 85% of patients with Beckwith–Weidemann syndrome. The recurrence risk for future affected siblings or offspring of the proband depends on the specific genetic abnormality causing the disorder and can range from low (UPD, methylation abnormality) to as high as 50% (*CDKN1C* mutation).

Russell–Silver Syndrome

Russell–Silver syndrome presents in neonates with intrauterine growth retardation followed by postnatal growth deficiency. The head size is usually normal, causing a relative macrocephaly that

may have the appearance of hydrocephalus. Facial features can include a broad and prominent forehead, triangular-shaped face with a small chin, and downturned corners of the mouth. The fingers can show brachydactyly, camptodactyly, or more commonly fifth-finger clinodactyly. Other concerns involve limb-length discrepancy, delayed bone age, café au lait macules, hypospadias in males, developmental delays, diaphoresis, and hypoglycemia during the first 3 years of life. These patients are often examined by a geneticist as a toddler with growth retardation, proportionate short stature, and normal head circumference. When one is evaluating patients with growth retardation, it becomes important to know the prenatal and postnatal growth parameters, because they might provide a clue to the diagnosis of Russell–Silver syndrome.

The molecular mechanisms underlying the pathogenesis show that Russell–Silver syndrome is likely caused by abnormalities of imprinted genes. Maternal UPD of chromosome 7 is present in 7% to 10% of patients, and the symptoms are likely caused by overexpression of the maternal *GRB10* gene, which suppresses the activity of various growth factor receptors. In approximately 35% of patients, imprinting abnormalities of 11p15.5 occur because of a loss of the paternally expressed *IGF2* gene, leading to decreased prenatal and postnatal growth. This finding contrasts with that for some patients with Beckwith–Wiedemann syndrome, in whom *IGF2* is overexpressed, causing increased growth. For that reason, patients with Russell–Silver syndrome do not have a significantly increased risk of neoplasia compared with patients with Beckwith–Wiedemann syndrome, and routine cancer surveillance protocols are typically not recommended.

Future Directions: Characterization of Structural Variation by Genome Sequencing

Microarray-based testing has played a significant role in closing the gap between what is visible by karyotype/FISH and changes occurring at the single-nucleotide level that are routinely assayed by sequencing. However, there are still limitations to array-based testing in terms of the size of the events that can be detected and the precision of the breakpoints that can be identified. Currently, a growing number of technological developments is allowing for the detection of copy number variants using sequencing, which offers higher resolution and precision than arrays and provides the added benefit of being able to detect balanced chromosome rearrangements.[78] Exome sequencing, which is a widely-used technology for detection of single nucleotide variants and small insertions/deletions, is limited to the interrogation of the coding regions of the genome ("exons"). In contrast, whole genome sequencing provides more uniform coverage that includes inter- and intra-genic regions. Genome sequencing has shown the ability to accurately detect CNVs for clinical diagnosis and may ultimately replace array-based testing.[79,80] Other developments facilitating the detection of structural variation include long-read sequencing, which allows for sequencing of longer DNA molecules[81] and alternatives to sequencing such as optical genome mapping, in which DNA is labeled at specific sequence motifs and then linearized and passed through nanochannels, which allows large molecules of DNA to be imaged.[82–84] Whatever the method by which CNVs are detected, similar challenges will be faced in interpreting and assigning clinical significance to these variants, in particular CNVs involving intronic or non-coding regions of the genome.

Summary

This chapter has summarized the rapidly expanding field of chromosomal and genomic disorders, concentrating on those that commonly manifest themselves in the newborn period. The widespread development and clinical implementation of molecular cytogenetic techniques have allowed the identification of subtle rearrangements that were previously undetectable. These advances now enable the discernment of new syndromes in which the chromosomal anomaly may be defined before a characteristic phenotype is recognized. In addition, a greater understanding of the role of segmental duplications and their effects on human genetic disorders as well as of the influence of mechanisms that regulate gene expression, such as imprinting, is emerging. The tremendous advances in genomics led by the completion of the Human Genome Project and the development of new molecular diagnostic tools present new challenges for clinicians to better diagnose, understand, and care for patients with genetic disorders and their families.

29 Inborn Errors of Carbohydrate, Ammonia, Amino Acid, and Organic Acid Metabolism

J. LAWRENCE MERRITT II AND RENATA C. GALLAGHER

Acute, life-threatening disease during the newborn period is a feature of many inborn errors of metabolism, including those of ammonia, carbohydrate, amino acid, fatty acid, ketone, and mitochondrial energy metabolism. Therefore, it is critical that neonatologists are familiar with the clinical symptoms, laboratory findings, methods of diagnosis, and empiric—as well as specific—management of each of these classes of disease (Table 29.1). Importantly, newborn screening (NBS) is only available for some disorders within each class. The use of NBS has resulted in presymptomatic identification, allowing early institution of therapy and improved outcome for many affected individuals. However, clinical presentation before the development of symptoms may still occur because of environmental and biologic factors, as well as local NBS and follow-up protocols. Factors that prevent or delay identification by NBS include when the disease is not detected by NBS or is incompletely ascertained, when the newborn develops symptoms before the NBS result being reported, and when follow-up testing has not been completed. Familiarity with these diseases and their characteristic signs and symptoms is critical for early clinical recognition and the initiation of potentially life-saving empiric management (Table 29.2). First-tier testing, including biochemical and analyte testing, is indicated although broad DNA sequencing, either exome or genome, has demonstrated utility in diagnosis of genetic and metabolic disease in critically ill children in the neonatal intensive care unit, and is increasingly being adopted as first- or second-tier testing.[1] Inborn errors of metabolism should also be considered in infants who develop symptoms outside of the immediate newborn period, as each of these disorders can have a later-onset presentation.

Carbohydrate Metabolism Disorders

Galactosemia

Elevated blood galactose, or *galactosemia*, is a result of a defect in one of three enzymes of the galactose metabolic pathway that converts galactose to glucose (Fig. 29.1). The disorder most clinically relevant in the newborn period is severe *galactose-1-phosphate uridyltransferase* (GALT) *deficiency*. It is a cause of neonatal jaundice and coagulopathy and is life threatening. It is commonly referred to as "classic galactosemia." This condition is the primary target of NBS for galactosemia. The other two enzyme defects that cause elevated blood galactose are *galactokinase* and *uridine diphosphate galactose-4-epimerase* deficiencies. Clinical features associated with each disorder are described. In classic galactosemia, with the ingestion of lactose, a disaccharide of glucose and galactose, the substrate of the enzyme galactose-1-phosphate accumulates, as does galactose and the secondary metabolites galactitol and/or galactonate. Elevations of galactitol may cause characteristic "oil drop" cataracts that may be present at birth. The roles of the other metabolites in pathogenesis of the liver, kidney, brain, and ovarian dysfunction of severe GALT deficiency are not understood. They likely include the deficiency of galactose-1-phosphate conjugated to uridine, as well as toxicity of accumulating metabolites.

The frequency of classic galactosemia is estimated to be 1 in 60,000 to 1 in 75,000 births in the United States and Europe.[2] There are also milder forms of unclear clinical significance, such as Duarte variant galactosemia, with enzyme activity of roughly 25% of wild type, which are frequently identified by abnormal NBS but are currently believed not to require treatment.[3]

NBS methods for identification of classic galactosemia vary by state and include measurement of "total galactose" (galactose plus galactose-1-phosphate) and GALT enzyme activity. Testing after an abnormal NBS may include DNA analysis to identify common mutations in the *GALT* gene. In states that measure analytes, children with galactokinase or epimerase deficiencies may be identified. These disorders will not be detected through screening for classic galactosemia through deficient GALT enzyme activity alone. The accuracy of NBS is dependent on information provided by the ordering nursery, as transfused red blood cells may cause a false-negative NBS for galactosemia. Transfusion of red blood cells will also impact detection of hemoglobinopathies. Thus, infants transfused before NBS require follow-up testing for galactosemia and hemoglobinopathies at least 4 weeks after transfusion. Also, infants who have not received a lactose-containing feeding (i.e., breast milk or non-soy-based formulas) before screening may not have elevated galactose levels and may have false-negative NBS if

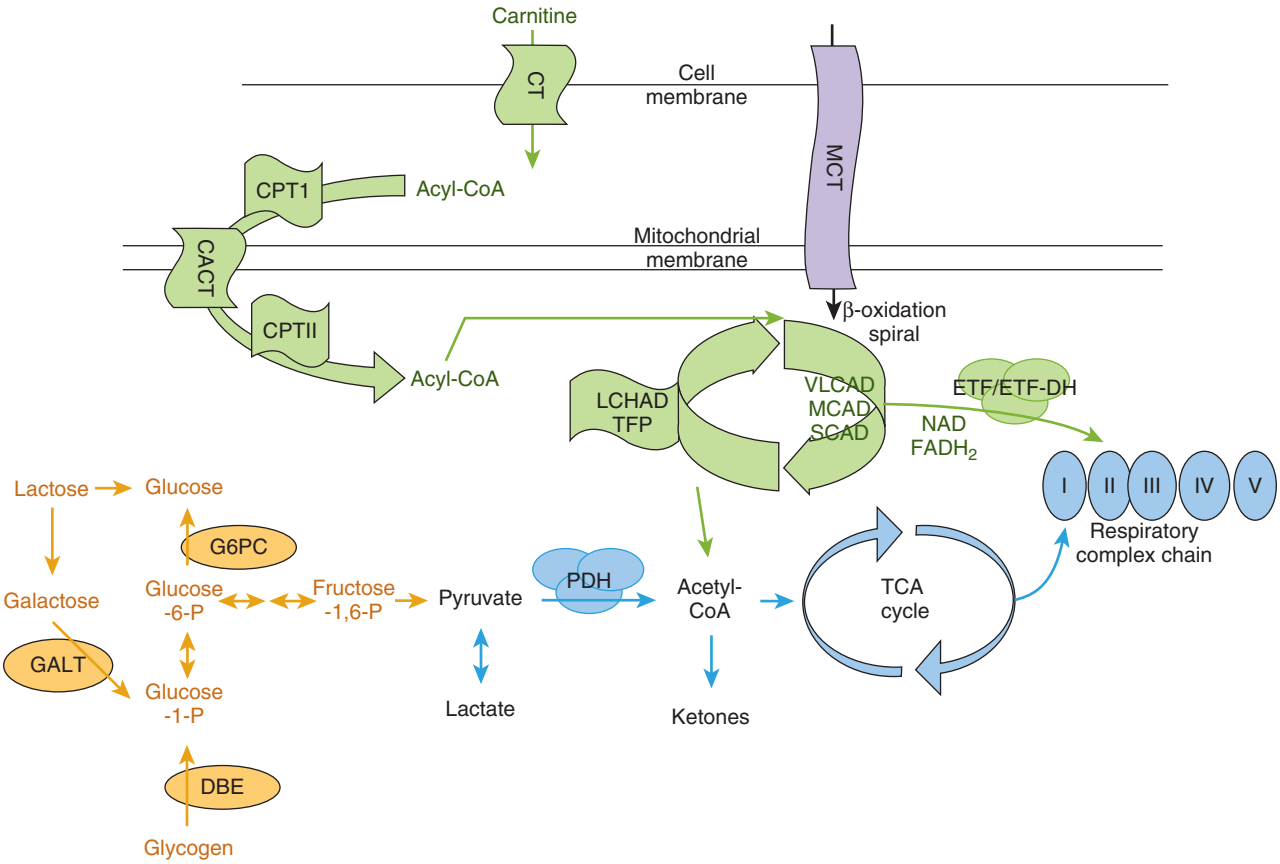
the screening method is analyte rather than enzyme-based. False-positive NBS results can occur in hot weather if the screening method is enzyme activity, as the enzyme is denatured in heat. Mutation analysis and enzyme activity help identify neonates with classic galactosemia (<1% control GALT activity), who have a poorer prognosis than those with variant (nonclassic) galactosemia (1% to 10% control GALT activity).[4]

At presentation, total blood galactose levels may be elevated with elevated red blood cell galactose-1-phosphate (Gal-1-P) and urine galactitol levels. During this phase of severe hypergalactosemia, positive reducing substances will be present in urine, but these resolve within hours with dietary restriction of galactose. There may be factitious elevation of glucose in affected individuals, as measured by bedside glucometers.[5] Following the initiation



• **Fig. 29.1** Overview of metabolism of carnitine transport, fatty acid oxidation, glucose, TCA cycle, and mitochondrial respiratory chain. *CACT*, Carnitine acylcarnitine translocase; *CT*, carnitine transporter; *CPTI*, carnitine palmitoyltransferase I; *CPTII*, carnitine palmitoyltransferase II; *$FADH_2$*, flavin adenine dinucleotide; *DBE*, debranching enzyme; *GALT*, galactose-1-phosphate uridyltransferase; *Acyl-CoA*, long-chain fatty acid attached to Coenzyme A; *LCHAD*, long-chain 3-hydroxy acyl-CoA dehydrogenase; *ETF/ETF-DH*, electron transfer flavoprotein/electron transfer flavoprotein dehydrogenase; these are deficient in MADD; *MADD*, multiple acyl-CoA dehydrogenase deficiency; *MCAD*, medium-chain acyl-CoA dehydrogenase; *MCT*, medium-chain triglyceride; *NAD*, nicotinamide adenine dinucleotide; *PDH*, pyruvate dehydrogenase; *SCAD*, short-chain acyl-CoA dehydrogenase; *TCA*, tricarboxylic acid; *TFP*, trifunctional protein; *VLCAD*, very long chain acyl-CoA dehydrogenase.

of treatment with a lactose-free diet, Gal-1-P levels decrease but rarely normalize, remaining elevated for the lifetime of the patient. There is a target range for treatment, and maintenance of Gal-1-P levels in treatment range through dietary restriction of galactose is the current goal of short- and long-term dietary therapy.[6]

Untreated classic galactosemia may present with severe multiorgan (liver and kidney) disease in the first days to weeks of life. The most common clinical symptoms are vomiting, poor feeding, failure to thrive, and lethargy, with jaundice and hepatomegaly on physical examination. About 10% of affected neonates develop sepsis, often due to *Escherichia coli*; other causative organisms include *Klebsiella* and *Enterobacter*.[4] Characteristic laboratory findings are indirect hyperbilirubinemia and apparent liver failure with markedly elevated coagulation parameters out of proportion to the transaminase elevations. With continued lactose/galactose ingestion, liver disease can progress to cirrhosis with portal hypertension and splenomegaly. Renal Fanconi syndrome may also develop. Cataracts may develop in the first few weeks of life in untreated individuals, while some neonates are born with cataracts.

Management of the liver disease entails dietary restriction of galactose and supportive care. The coagulopathy resolves over several days. A lactose-free formula should be initiated as soon as classic galactosemia is suspected as this can be life-saving. An early change to soy formula may mask the symptoms of the disease. With early dietary restriction, improvement has been seen in severe clinical presentations and in neonatal mortality.[2] While growth and feeding return to normal, treated individuals may develop long-term complications including speech and language disorders, below average intelligence and cognitive functioning, cataracts, primary ovarian insufficiency (in most females), decreased bone mineral density, tremor, dystonia, coordination problems, or severe ataxia.[2,7,8] The cause of these complications is unknown, and they may not be improved by dietary restriction.[9,10]

Patients with classic galactosemia are advised to continue a lactose-restricted diet for their entire lives, but this diet does have significant risk of calcium and vitamin D deficiencies, and these must be supplemented. Dairy and high galactose nondairy foods including fruits, legumes, and vegetables are restricted. Not all

galactose is exogenous; there is some endogenous galactose production. Treatment compliance is monitored through frequent assessment of Gal-1-P levels. The restriction of galactose-containing fruits and vegetables may not be necessary lifelong.[11]

NBS has changed the clinical outcome of classic galactosemia and when results are provided as early as 3 to 4 days of life—before significant clinical symptoms—hospitalization is often avoided. A systematic review of NBS for galactosemia in Europe identified significant variability in galactosemia screening methods, cutoff values, and screening ages. Mortality ranged from 0% to 100% with no agreement regarding treatment of variant forms, or timing of clinical follow-up, and evidence in favor of NBS was considered insufficient. The greatest confounder of the cost-benefit assessment of NBS was the false-positive testing rate and the effects of these test results on families.[2]

Epimerase Deficiency Galactosemia

Uridine diphosphate-galactose 4-epimerase (GALE) *deficiency* has several forms. Generalized GALE deficiency may present similarly to GALT deficiency when the enzyme is deficient in all tissues. Peripheral or intermediate forms of GALE deficiency are associated with deficient enzyme activity in red blood cells, with normal or only partially decreased enzyme activity in other tissues (i.e., white blood cells or fibroblasts). For the peripheral or intermediate forms, children receiving a normal, lactose-containing diet will not become symptomatic. GALE deficiency may be detected on newborn screen in states that test for classic galactosemia by analyte. These children have elevated Gal-1-P levels with normal GALT enzyme testing. Individuals with generalized disease can develop severe liver and renal disease if untreated, and they can be diagnosed with GALE deficiency through assessment of activity in red blood cells. GALE deficiency is treated identically to GALT deficiency, when symptomatic.[12]

Galactokinase Deficiency

Galactokinase (GALK) *deficiency* causes elevated galactose with a normal Gal-1-P level. Affected individuals also have elevated galactitol and may develop dense cataracts if untreated. GALK deficiency is also associated with pseudotumor cerebri, but the disease does not cause systemic effects.[13] As for GALE deficiency, GALK deficiency may be detected on newborn screen in states that test for classic galactosemia by analyte. GALT enzyme testing is normal. Cataracts may develop in the neonatal period, and early treatment may improve or resolve cataracts if infants are treated with galactose restriction before 4 to 8 weeks of life.[14] A recent evaluation of the GalNet registry has identified additional complications in neonates of elevated transaminases, bleeding diathesis, and encephalopathy.[10] Dietary galactose restriction may be necessary but is milder than that required for GALT deficiency.

Glycogen Storage Diseases

Glycogen storage diseases (GSDs) are due to abnormalities in glycogen synthesis or utilization for energy production. They are divided into types primarily affecting the liver (types I, IIIb, IV, VI, and IX), the muscles (types II, V, and VII), or mixed (type IIIa and forms of IX). Hypoglycemia is often a presenting symptom of the liver-based GSDs. Most GSDs are inherited in an autosomal recessive manner, except GSD IXa and IXd (hepatic and muscle phosphorylase kinase deficiencies, respectively), which are X-linked. Severe GSD II is associated with an infantile cardiomyopathy and is the GSD that is most likely to be encountered in the neonatal intensive care unit. Treatments for GSDs are of variable efficacy given the spectrum of these diseases. Currently, there are multiple clinical trials underway including gene therapy technologies for many types of GSDs, including GSD 1a and GSD II.

Hepatic Glycogen Storage Diseases

GSD I is due to glucose-6-phosphatase deficiency (von Gierke disease, Ia) or to deficient glucose-6-phosphate transport (Ib). Glucose-6-phosphatase plays a critical role in both glycogenolysis and gluconeogenesis (see Fig. 29.1). The frequency of GSD type I is estimated to be 1 in 100,000 births, with 80% of cases being type Ia. The frequency is 1 in 20,000 in Ashkenazi Jews due to a founder mutation.[15]

GSD I may not manifest in the neonatal period, as frequent newborn feeding may prevent symptomatic hypoglycemia and the development of hepatomegaly. Major clinical findings include failure to thrive, with an enlarged abdominal girth from hepatomegaly and hypoglycemia. Major laboratory findings are a rapid fasting hypoglycemia (typically within a few hours) with ketosis and lactic acidosis. Because of the high lactate level, individuals may appear relatively asymptomatic from the hypoglycemia. Hypercholesterolemia, hypertriglyceridemia, and hyperuricemia may be seen in older individuals. The disease also affects the kidneys and causes focal segmental glomerulosclerosis and progressive renal insufficiency. Patients with GSD Ib develop recurrent infections because of neutropenia and defective neutrophil function along with inflammatory bowel disease that may develop in the first year of life. Diagnosis is now often confirmed through DNA sequencing of the *G6PC* (GSD Ia) and *SLC37A4* (GSD Ib) genes, although liver biopsy for enzyme activity may also be performed.

Therapy focuses on the prevention of hypoglycemia and resultant brain damage and growth failure through frequent feedings and restriction of lactose and sucrose, as galactose and fructose derived from these feed into the blocked pathway.[15] Continuous nasogastric feedings or boluses of uncooked cornstarch are essential at night and often during the day and do improve glucose control and growth but do not completely correct other biochemical abnormalities. A comprehensive plan for treatment of intercurrent illnesses and emergencies is required. Neutropenia in type Ib may be treated with granulocyte colony-stimulating factor. Liver transplantation has been shown to improve metabolic control, fasting hypoglycemia, and growth.[16]

Muscular Glycogen Storage Diseases

The most common and significant form of muscular GSD is type II, commonly called *Pompe disease* (*acid alpha-glucosidase deficiency* [abbreviated as GAA], also known as *acid maltase deficiency* or *lysosomal α-1,4-glucosidase deficiency*). This GSD was the first identified lysosomal storage disease (LSD), as glycogen accumulates within the lysosome because of a defect in lysosomal-mediated glycogen degradation. Muscle pathology will demonstrate vacuolar myopathy with glycogen storage within lysosomes and free glycogen in the cytoplasm demonstrated by electron microscopy. The vacuoles are periodic acid-Schiff positive, digestible by diastase, and positive for acid phosphatase. As for some other LSDs, enzyme replacement therapy has been developed for Pompe disease and is the only currently effective therapy.

Pompe disease has an estimated incidence of 1 in 40,000 in the Netherlands, based on the country's screening for three common mutations in newborn blood spots. The incidence ranges from 1 in 57,000 for late-onset disease to 1 in 138,000 for classic infantile disease.[17,18] The classic infantile presentation of Pompe disease

is hypotonia and hypertrophic cardiomyopathy. Creatine kinase, lactate dehydrogenase, and aspartate aminotransferase are elevated. The electrocardiogram is abnormal with a short PR interval and giant QRS complex in all leads, suggesting biventricular hypertrophy (Fig. 29.2). Late-onset presentations are of myopathy and have been diagnosed as early as the second year of life. Diagnosis is made through the identification of decreased GAA activity in dried blood spots—from newborn screening or diagnostic testing—or in fibroblasts or muscle biopsy. Confirmation via sequencing of the *GAA* gene is recommended following any GAA enzyme testing due to the presence of pseudodeficiency alleles in which the in vitro enzyme activity is abnormal, but in vivo activity is normal, and to avoid muscle biopsy.[19]

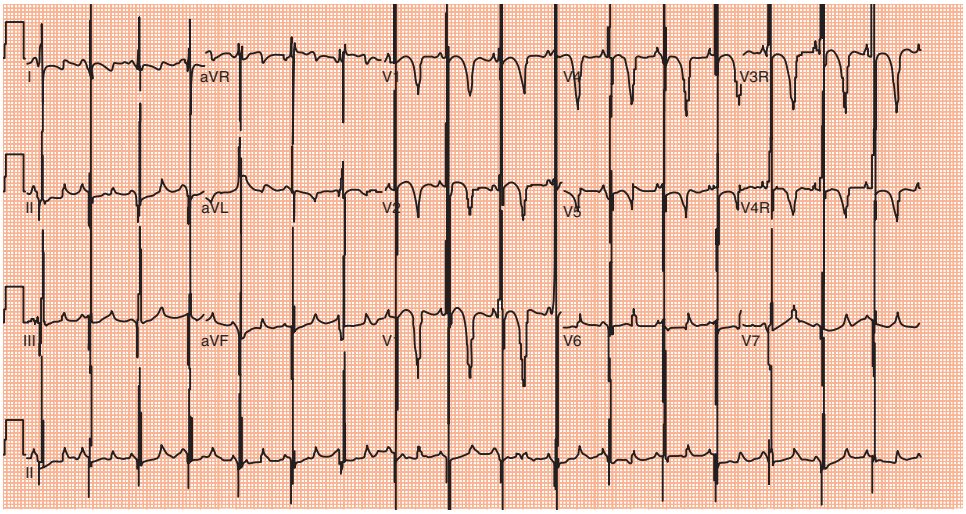
Decisions regarding which disorders are included on a state's NBS panel are made by each state, and many states now include Pompe disease due to the markedly improved outcome of infantile-onset Pompe disease (IOPD) with early treatment. NBS and early initiation of enzyme replacement therapy has demonstrated improvement in cardiac size, muscle pathology, growth, and gross motor function in affected individuals but not in arrhythmias such as Wolff-Parkinson-White or in dysphagia or osteopenia.[20–22] Long-term follow-up of early-treated individuals has demonstrated increased life span and increased ambulation with individuals not requiring mechanical ventilation and increased muscle strength and function.[23,24] Gene therapy is being investigated with promising results in a mouse model and with initial clinical trials being implemented.[25]

Andersen disease, or GSD IV, is due to deficiency of glycogen branching enzyme, expressed in multiple tissues, and may manifest primarily as hepatic or muscular disease, with involvement of the heart and/or the nervous system in up to five different clinical presentations. Two rare neuromuscular subtypes may present in the newborn period. The fatal perinatal neuromuscular subtype presents with fetal akinesia sequence with polyhydramnios, decreased fetal movement, fetal hydrops, and neonatal death or with hypotonia, muscular atrophy, arthrogryposis, and death in the neonatal period from cardiopulmonary failure.[26] The second congenital neuromuscular subtype presents with profound hypotonia, respiratory distress requiring mechanical ventilation, dilated cardiomyopathy, and death in early infancy. The classic GSD IV subtype is the progressive hepatic subtype. Children are often normal at birth but develop failure to thrive, hypotonia, and potentially progressive liver dysfunction leading to cirrhosis and cardiomyopathy requiring liver and heart transplantation, respectively.[27] Death may result from progressive cardiomyopathy despite liver transplantation. There is also a non-progressive hepatic subtype and a childhood neuromuscular subtype. GSD IV is a rare autosomal recessive disorder, and diagnosis is confirmed through DNA sequencing of the *GBE1* gene or by detection of abnormal enzyme activity in muscle, liver, or skin fibroblasts.

Fructose Metabolism

The primary disorder of fructose metabolism is *hereditary fructose intolerance* (HFI). This is a rare autosomal recessive disorder triggered by ingestion of fructose, sucrose, or sorbitol, which may present clinically when infants are weaned from breast milk or formula and juice or fruit are added to the diet or when they receive a formula that contains fructose.[28] Affected infants or neonates who are given sucrose solutions for pain relief during minor procedures may develop hypoglycemia, and a diagnosis of HFI should be considered in these cases. Clinical findings include pallor, lethargy, poor feeding, vomiting, loose stools, poor growth, hepatomegaly, and hypoglycemia, lactic acidemia, hyperuricemia, transaminase elevations, and positive urine reducing substances with ingestion of fructose. There are reports of neonates who developed life-threatening acute liver failure after receiving fructose-containing formulas.[29] Renal tubular dysfunction may be present. Diagnostic testing consists of measuring enzyme activity in liver tissue and/or sequencing of *ALDOB*. Treatment includes elimination of fructose, sucrose, and sorbitol from the diet and medications. In practice, complete elimination of these can be quite difficult but is necessary for optimal outcome. There is no current newborn screening for HFI.

Fructose-1,6-bisphosphatase deficiency is not a disorder of fructose metabolism. It is a disorder of gluconeogenesis, although as with other disorders of gluconeogenesis, therapy may include some limitation of dietary fructose. Patients may present in the newborn period with lactic acidosis and hypoglycemia when glycogen reserves are limited and then be clinically silent and present later (typically before 2 years of age) during times of fasting or following a fructose load. Acute crisis presents similarly to HFI and GSD Ia, and these are in the differential diagnosis for symptoms of acidosis and hypoglycemia. This is a very rare autosomal



• **Fig. 29.2** Pompe disease electrocardiogram.

recessive disorder resulting from mutations in the *FBP1* gene, with an estimated incidence between 1 in 350,000 and 1 in 900,000.[30]

Urea Cycle Disorders

Removal of excess nitrogen is the function of the urea cycle. Urea cycle disorders (UCD) result from inhibition of the synthesis of urea from ammonia and classically manifest in the newborn period, although these may manifest at any age. Symptoms of hyperammonemia are provoked during episodes of protein catabolism (e.g., because of illness and poor oral intake) or dietary protein excess. Hyperammonemia is treated by controlling protein catabolism through dietary limitation of protein and removing offending toxic products (chiefly ammonia) with ammonia-scavenging medications or dialysis. UCDs are frequently classified as proximal (mitochondrial) and distal (cytoplasmic). The three proximal UCDs are N-*acetylglutamate synthase deficiency* (NAGS), *carbamyl phosphate synthetase I* (CPSI) *deficiency*, and *ornithine transcarbamylase deficiency* (OTCD). The distal UCDs are *argininosuccinate synthetase deficiency* (known as *ASS deficiency* or *citrullinemia type I*, *CIT1*), *argininosuccinate lyase (ASL) deficiency* (also known as *argininosuccinic aciduria*, ASA), and *arginase 1 deficiency*. Additionally, disorders of the urea cycle include two of mitochondrial membrane transport. Deficiency of the mitochondrial ornithine transporter 1 is a cause of hyperammonemia, hyperornithinemia, and homocitrullinuria syndrome, and deficiency of the mitochondrial aspartate–glutamate transporter is a cause of citrullinemia type II or citrin deficiency. A defect of a plasma membrane transporter affects the renal tubular transport of cationic amino acids, including lysine, arginine, and the amino acids required for urea cycle function, and results in *lysinuric protein intolerance*, a multisystem disorder that only rarely manifests with neonatal hyperammonemia. Incidence estimates of all UCDs are 1 in 35,000 births, with OTCD, the most common UCD, estimated at 1 in 56,500 births.[31] All UCDs are autosomal recessive except for OTCD, which is X-linked. Roughly 20% of heterozygote females manifest symptoms at some time in their life, and some of these present in the newborn period.

One complete turn of the urea cycle will produce a molecule of urea from two molecules of ammonia and one of bicarbonate. The nitrogen in ammonia is generated from the hepatic nitrogen pool of amino acids including glutamine, glutamate, and glycine. *N*-acetylglutamate is the product of the first enzyme in the cycle and is an essential activator of carbamyl phosphate synthetase I, which converts ammonia and bicarbonate into carbamyl phosphate. Ornithine and carbamyl phosphate are condensed by ornithine transcarbamylase to generate citrulline. Citrulline is combined with aspartate by argininosuccinate synthetase to create argininosuccinic acid. Fumarate is released from this by argininosuccinate lyase to create arginine. Urea is generated from arginine by arginase 1 and is excreted while ornithine reenters the urea cycle (Fig. 29.3).

Clinical symptoms in the newborn period are similar for all UCDs and are due to hyperammonemia. Severely affected

newborns exhibit progressive alteration of level of consciousness with drowsiness and lethargy progressing to unresponsiveness, beginning after 24 hours of life. Typical symptoms include poor feeding, vomiting, hyperventilation (caused by ammonia elevation and resulting in a primary respiratory alkalosis), and temperature instability. There may be peripheral circulatory failure that progresses to multiorgan failure. Marked hyperammonemia causes acute encephalopathy, leading to seizures, coma, and death if untreated. Ammonia levels should be checked in any infant with these symptoms, which may mimic sepsis or intestinal obstruction, and, if elevated, should be treated rapidly. Later-onset presentations include recurrent emesis, ataxia, liver dysfunction or apparent failure with coagulopathy, postpartum psychosis, and other psychiatric symptoms such as aggression, agitation, mania, and personality changes.[32]

Without rapid treatment severe UCDs are almost always fatal or result in severe and irreversible brain damage. The primary goal of treatment is to remove excess ammonia, which is neurotoxic. The effects of ammonia include alterations in amino acid pathways, neurotransmitters, energy production, nitric oxide synthesis, axonal and dendritic growth, and signal transduction in the developing brain. Additionally, excess glutamine may cause cerebral swelling and edema in the mature brain.[33] Acute hyperammonemic episodes may be associated with transaminase elevation and synthetic liver dysfunction or apparent liver failure, and it is important to assess transaminases and coagulation parameters.

Individuals affected by proximal UCDs have been reported to present earlier in life, to have a higher peak ammonia level, and to have a longer average length of stay compared with patients with distal UCDs. Reports identify the age at first admission for hyperammonemia as less than or equal to 2 days in 55% of OTCD and CPSI patients and at less than 7 days in 84% of these patients.[34] For OTCD patients, nearly half of the males but only 4% of females will present between 0 and 30 days of age.[35]

The critical laboratory abnormality in a UCD is elevated plasma ammonia. While artifactual elevations may occur due to problems with sample collection and processing, hyperammonemia in a newborn is a medical emergency, and, if elevated, the test should be repeated, and additional evaluation and management initiated immediately. Normal plasma ammonia levels in newborns are as high as 110 µmol/L (although care should be taken to confirm units as some laboratories report mg/dL). A level of greater than 150 µmol/L (255 mg/dL) should prompt suspicion of, and evaluation for, an inborn error of metabolism in neonates. In older infants, children, and adults the reference range for ammonia is less than 35 µmol/L (60 mg/dL). In primary or secondary disorders of the urea cycle that present in the newborn period, ammonia levels may be in the thousands. The differential diagnosis of hyperammonemia in the newborn period includes urea cycle defects, organic acidemias, fatty acid oxidation disorders (FAODs), CA-VA (carbonic anhydrase VA) deficiency, and transient hyperammonemia of the newborn (THAN). In UCDs the hyperammonemia is often associated with a respiratory alkalosis caused by the effect of ammonia on the respiratory control centers in the brainstem. A primary respiratory alkalosis in a newborn should prompt a physician to order an ammonia level. Early involvement of a geneticist with experience in the evaluation and management of inborn errors of metabolism is critical. Specialized biochemical laboratory testing should include plasma amino acids, total and free plasma carnitine, plasma acylcarnitine profile, total plasma homocysteine, plasma B12 level, urine organic acids, urine amino acids, and a quantitative urine orotic acid to assess for UCDs, as well as fatty acid oxidation disorders and organic acidemias, which can also present with marked hyperammonemia in the newborn period.

In proximal UCDs, there is decreased citrulline on plasma amino acid analysis, while patients with distal UCDs have either elevated citrulline (in CIT1 and ASA deficiency), elevated argininosuccinic acid (in ASA deficiency), or elevated arginine (in arginase deficiency). In OTCD, increased urinary orotic acid is present and may be identified on urine organic acid analysis, but a quantitative value is recommended because of variability in detection. NBS for CIT1, ASA, and arginase deficiency is performed through measurements of citrulline (CIT1, ASA) and arginine (arginase deficiency) in blood spots as these are elevated in these conditions. Proximal UCDs are not well identified on NBS because of the poor sensitivity of low citrulline levels, and only a few states have started screening for proximal UCDs.[36] When a UCD is suspected, further evaluation through blood and urine metabolite testing and confirmation of a diagnosis is necessary through DNA testing. For OTCD this should include analysis for gene copy number and intronic variants through deep sequencing, but still may only detect mutations in about 90% of patients.[37] In some cases, liver biopsy and enzyme analysis of liver tissue are required.

Treatments with medications, dialysis, or liver transplantations will control ammonia levels, though neurologic outcomes are poorer when presenting blood ammonia levels are greater than 360 µmol/L.[38] Hemodialysis is the primary method for rapid removal of ammonia. Recent consensus guidelines have been published for hyperammonemia management through medical management and renal replacement therapy. Renal replacement therapy was recommended in cases of a rapidly increasing ammonia level greater than 150 µmol/L with a rapidly deteriorating neurological status, rapidly increasing levels greater than 300 µmol/L that are uncontrolled, or an ammonia level of greater than 400 µmol/L when medical measures are ineffective.[39] Continuous arteriovenous hemofiltration (CAVH) provides a lower clearance rate but has the added benefit of continuous use and a lesser likelihood of major swings in intravascular volume that can exacerbate an already fragile state and cerebral edema. Ammonia clearance with peritoneal dialysis is approximately one-tenth that of CAVH and is not recommended unless other methods of kidney replacement therapy are not available.[39,40] Ammonia is not cleared effectively by exchange transfusion.

Medical treatment of hyperammonemia through alternative pathway or nitrogen-scavenging therapies are effective and are critical in acute and chronic management (see Fig. 29.3). When hyperammonemia is recognized and a UCD suspected, alternative pathway therapy can be rapidly implemented before hemodialysis, continued throughout, and maintained afterward and transitioned from intravenous (IV) to oral therapy for chronic management. The only approved IV therapy for treatment of hyperammonemia is sodium benzoate plus sodium phenylacetate (Ammonul). Arginine becomes an essential amino acid in severe early urea cycle defects; it stimulates the CPSI enzyme and is required for urea cycle function as it is one of the amino acids that comprises the urea cycle. Thus, arginine should be provided IV for suspected neonatal OTCD or CPSI and is especially effective in patients with CIT1 and ASA. It should not be given in known or suspected arginase 1 deficiency. Ammonul is rarely stocked except in pharmacies of tertiary care metabolic centers, and 10% arginine HCl is commonly available.

Nitrogen-scavenging therapies can effectively help control hyperammonemia and should be considered when the ammonia level is greater than 150 µmol/L. When combined with other therapies, nitrogen-scavenging therapies are critical to the acute management of marked hyperammonemia. In acute management of hyperammonemia, Ammonul is given as a loading dose of 250 mg/kg (of sodium benzoate and of sodium phenylacetate) over 90 minutes followed by a 250 mg/kg dose over 24 hours by continuous IV infusion. Arginine hydrochloride should be provided in known or suspected cases of NAGS, CPSI, or OTCD and is given as a 250 mg/kg loading dose over 90 minutes followed by a 250 mg/kg 24-hour maintenance dose. The dose is 600 mg/kg for known or suspected CIT1 or ASA.[39,40] Also critical is reversal of catabolism, and at least age appropriate and even higher calories must be provided by IV glucose at high concentration and IV intralipid (once a disorder of fat metabolism has been excluded). Parenteral nutrition, including provision of catabolism-sparing essential amino acids, should be initiated when ammonia has been controlled, ideally within 24 to 36 hours of the initiation of treatment. This treatment should be performed in collaboration with a clinical biochemical geneticist with experience in the treatment of UCDs. An enzyme replacement therapy is now being investigated for arginase deficiency has shown improvements in baseline lower-limb spasticity, developmental delay, and previous hyperammonemic events.[41]

Chronic management of infants with UCDs consists of providing adequate dietary protein, which will require a combination of natural (whole) protein from a regular infant formula as well as a special metabolic formula consisting of only essential amino acids to decrease the nitrogen burden, oral/enteral ammonia-scavenging medications, and arginine or citrulline, depending on the defect and severity. Also critical is the prevention of protein catabolism during times of illness or other physiologic stress, and an emergency sick-day diet and emergency letter should be provided at hospital discharge. Children must be monitored frequently, and medications and diet adjusted to prevent hyperammonemia and to allow adequate growth without over-restriction of protein resulting in poor growth and provoking catabolism. Long-term management requires a multidisciplinary team of a clinical biochemical geneticist, biochemical nutritionist, and genetic counselors and, in some cases nurses, a neurodevelopmental pediatrician, a neurologist, and rehabilitative medicine specialist, depending on the presence and severity of early brain injury.

The height of the initial ammonia concentration is associated with cognitive impairment in the proximal UCDs, hyperornithinemia–hyperammonemia–homocitrullinuria syndrome, and citrin deficiency, as compared with the distal UCDs.[42] A 2005 review estimated a poor outcome with a mortality of 84% in neonatal-onset cases and 28% in late-onset cases, before the use of nitrogen-scavenging therapies in Europe.[43] When reviewing survival according to age, diagnosis, and first or recurrent episodes, the lowest survival is seen in male OTCD neonates at first episode. In an open label trial, newborns less than 30 days old had survival rates of 73% compared with 94% in infants greater than 30 days of age.[44] In a 2009 study, intellectual disability in neonatal-onset cases was reported at almost 50%, compared with historical estimates of 60% to 80%.[45] Currently, early liver transplantation in the first year of life, especially if initial rescue therapy has limited the peak and duration of hyperammonemia, is recommended.[46] Early recognition of hyperammonemia and rapid lowering of ammonia is critical to decreasing the extent and severity of early brain injury.[47]

Rare cases of carbonic anhydrase VA (CA-VA) deficiency are being more frequently confirmed through whole exome sequencing with mutations in the *CA5A* gene following neonatal presentations of hyperammonemia with elevated orotic acid and glutamine levels (similar on initial interpretation to a proximal UCD) with lactic acidosis and ketosis. Following treatment this disorder may have a good prognosis.[48]

Transient Hyperammonemia of the Newborn

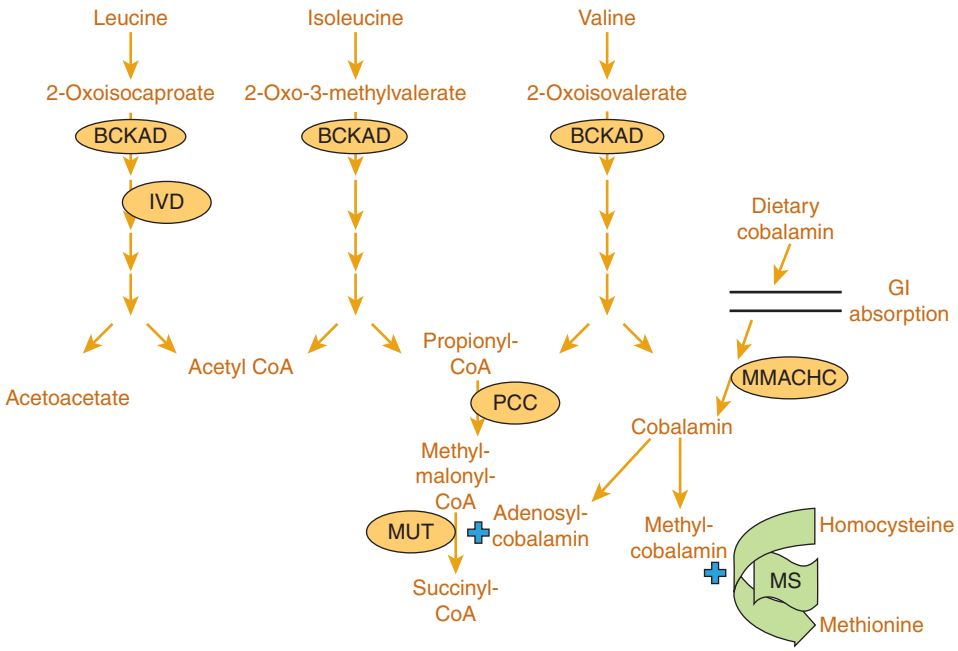
THAN is most common in preterm newborns less than 36 weeks gestational age that have a birth weight of less than 2.5 kg. Typically, it occurs following respiratory distress syndrome in the first 24 hours of life, and coma develops within the first 48 hours of life.[49] Serum ammonia levels can surpass 1500 µmol/L, and infants may require hemodialysis and protein restriction.[50]

The cause of this disease is unknown. When suspected, a Doppler ultrasound of the portal vein should be performed to evaluate for a clot in the portal vein. Plasma amino acid levels may have elevations of citrulline and arginine. The glutamine-to-ammonia ratio may distinguish this from a urea cycle defect (glutamine to ammonia ratio <1.6 in THAN, ensuring units are the same). There may be no respiratory alkalosis.[50] The mortality rate in THAN appears to be linked to the duration of coma; outcome can be good in surviving infants, and long-term treatment and protein restriction may not be necessary.

Amino Acid Metabolism Disorders

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is a rare autosomal recessive inborn error of amino acid metabolism caused by branched-chain α-ketoacid dehydrogenase (BCKAD) complex deficiency. This enzyme is involved in the metabolism of the three branched-chain amino acids (BCAAs), leucine, isoleucine, and valine, at the step of conversion of each of their respective α-ketoacid derivatives into their decarboxylated coenzyme A (CoA) metabolites in the mitochondria (Fig. 29.4). The enzyme complex is composed of three components, E1, E2, and E3. E1 has two subunits, E1α and E1β, encoded by the *BCKDHA* and *BCKDHB* genes, respectively. E2 is dihydrolipoamide branched-chain transacylase (*DBT* gene). Mutations in the gene encoding the E3 subunit (*DLD*) cause a related but more severe disorder with lactic acidosis and elevations of pyruvate, alanine, and the α-ketoacids, as the E3 subunit is also a component of the pyruvate dehydrogenase (PDH) and α-ketoglutarate dehydrogenase complexes. MSUD occurs in 1 in 185,000 newborns, but in the old-order Mennonite communities of the United States in areas of eastern Pennsylvania, Kentucky, New York, Indiana, Wisconsin, Michigan, Iowa, and Missouri, the frequency is 1 in 358 due to a founder effect for a missense mutation (c.1312T>A in *BCKDA*, $E_1\alpha$).[51] The classic—and most frequent—presentation of MSUD is seen as early as 48 hours of life with poor feeding, irritability, lethargy, and a shrill and high-pitched cry. Symptoms rapidly progress to intermittent apnea, opisthotonus, and stereotyped movements described as "bicycling" or "fencing" alternating with hypotonia, as cerebral edema progresses. A bulging fontanelle may be present. As the illness progresses, coma, apnea, bradycardia, and respiratory failure will develop and usually result in death in the absence of specific



• **Fig. 29.4** Overview of branched-chain amino acid metabolism. *Plus sign* indicates allosteric cobalamin activator. *BCKAD*, Branched-chain α-ketoacid dehydrogenase; *MMACHC*, cobalamin C defect; *MS*, methionine synthase; *GI*; gastrointestinal; *IVD*, isovaleryl-CoA dehydrogenase; *MUT*; methylmalonyl-CoA mutase; *PCC*; propionyl-CoA carboxylase.

medical intervention. The odor of maple syrup in the cerumen may be detected after the first days of life and then in the saliva, breath, urine, and feces.

Neurologic progression is accompanied by, and due to, increasing elevations of the BCAA leucine, which is most readily assessed in plasma. Leucine and the related metabolite α-ketoisocaproic acid (α-KIC) may cause depletion of glutamine, glutamate, aspartate, and pyruvate. The mitochondrial respiratory chain may be inhibited by α-KIC and cause accumulation of lactic acid in the central nervous system (CNS).[52,53]

Neonates with MSUD present with lethargy and metabolic acidosis may develop or may be present initially. Untreated infants may develop ketonuria, which is separate from the ketoacidosis, and an elevated anion gap. Urine ketones may be negative in the presence of high levels of ketoacids. Quantitative plasma amino acid analysis and urine organic acid analysis should be diagnostic in the severe form of the disorder. The former demonstrates marked elevations of BCAAs and the presence of high levels of allo-isoleucine, a compound considered pathognomonic for MSUD. Analysis of urine organic acids will identify high levels of the relevant α-ketoacids in an ill child with the severe form of the disorder. Leucine may be in the thousands and elevated and rising levels require immediate treatment. This is a medical emergency due to the high risk of death and permanent neurologic damage. NBS results report "leucine," but this is the sum of leucine + isoleucine + hydroxyproline as these cannot be separated by tandem mass spectrometry without column chromatography. Ratios of leucine:alanine, leucine:phenylalanine, and valine:phenylalanine have improved the sensitivity and specificity of NBS as has implementation of a second-tier test of quantitation of allo-isoleucine after a high leucine value has been identified.[54]

An aggressive nutritional approach appears to work to lower leucine effectively in MSUD.[55] BCAA-free modified parenteral nutrition solution can be used in infants and older children with acute leucinosis but is rarely immediately available locally. This should be given in combination with IV glucose at high concentrations with IV intralipids. An insulin drip may also be necessary to curtail the effects of the catabolic stimulus and prevent hyperglycemia but must be carefully performed to avoid hypoglycemia. CAVH or hemodialysis may achieve more rapid normalization of the plasma BCAAs and their corresponding branched-chain ketoacids.

Neurologic outcomes in classic MSUD have improved with NBS, although the risk for subsequent brain injury or death remains, and long-term follow-up and continued vigilance are necessary to prevent injury.[52,56] Long-term neuropsychiatric assessments are showing that those who remain asymptomatic in the neonatal time period and in whom strict metabolic control is maintained can optimize their long-term mental health.[52] Liver transplantation appears to result in similar outcomes when compared with those who have not had transplantation, but liver transplant may prevent further neurocognitive impairment from prevention of injury during recurrent acute events.[57,58]

Long-term MSUD treatment focuses on a BCAA-free formula balanced with the provision of sufficient BCAAs to maintain normal growth and development. The goal is that plasma leucine, isoleucine, and valine levels are in the near-normal range, though this may be difficult to achieve outside of infancy. Affected individuals must be closely monitored, and careful management by a biochemical genetic nutritionist is critical. Care must be given to ensure adequate supplementation with isoleucine and valine as BCAA-free formulas may lead to over-restriction of these. Over-restriction of isoleucine can result in anemia and a severe exfoliative rash similar to acrodermatitis enteropathica. A rare thiamine-responsive variant of MSUD may show improved BCAA levels and a decreased need for protein restriction with thiamine supplementation.

Tyrosinemia Type 1

Tyrosinemia type 1 (TYR1), or *hepatorenal tyrosinemia*, is an autosomal recessive disorder caused by a deficiency of the enzyme fumarylacetoacetate hydrolase as a result of mutations in the *FAH* gene. This enzymatic reaction is the last in the catabolism of phenylalanine and tyrosine to fumaric acid and acetoacetate, and the accumulation of tyrosine is due to other accumulating metabolites. The primary metabolites that accumulate are maleylacetoacetic acid and fumarylacetoacetic acid, and these both result in the elevation of succinylacetone. This compound is pathognomonic for this disease and is the primary confirmatory metabolite identified on urine organic acid analysis. It is a more sensitive and specific marker than tyrosine in NBS but is not available in all NBS programs. The estimated incidence is 1 in 100,000 to 1 in 120,000 in the general population. The incidence is higher in specific populations with estimates of 1 in 60,000 to 1 in 74,000 in Norway and Finland, 1 in 16,000 in Quebec, and 1 in 1846 in the Saguenay-Lac Saint-Jean region of Quebec because of common founder mutations in these areas.[59]

The phenotype of TYR1 is variable. One presentation is of an acute, early-onset, severe liver disease at less than 2 months of age; there is also an infantile-onset presentation and a chronic presentation after 1 year of age. The acute, early-infantile presentation may be fatal with hepatomegaly, jaundice, elevated transaminases, and profound prolongations of prothrombin time and partial thromboplastin time. Affected individuals develop a renal Fanconi syndrome with generalized aminoaciduria, glycosuria, hypophosphatemia, hypouricemia, proteinuria, and an unusual urine odor of "boiled cabbage." Children with the chronic phenotype exhibit liver disease, hypophosphatemic rickets as a result of the renal Fanconi syndrome, cardiomyopathy (in 20% to 30%), and porphyria-like neurologic crises with abdominal pain, peripheral neuropathy, and respiratory failure.[59]

Plasma amino acid analysis will demonstrate elevated tyrosine levels, but this is not diagnostic as elevations of tyrosine and methionine are nonspecific and may be found in any disease causing liver dysfunction. Serum alpha fetoprotein levels are abnormally high. The identification of succinylacetone on urine organic acid analysis is diagnostic, and this may be detected within the first 12 hours of life.[60] As for most metabolic disorders, the characteristic metabolite abnormalities may not be present or detectable at all times.

NBS has allowed early treatment with 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC), and this has improved clinical outcome.[61,62] Treatment for TYR1 includes NTBC, which inhibits *p*-hydroxyphenylpyruvate dioxygenase, a proximal enzyme in the pathway, reducing the accumulation of succinylacetone but resulting in increased tyrosine levels. NTBC improves liver and renal disease but requires the implementation of a low-tyrosine, low-phenylalanine diet for improved neurologic outcome.[63] Early treatment, ideally within the first month of life, results in a significant reduction in the development of acute liver disease, hepatomegaly, cirrhosis, hepatocellular carcinoma, renal dysfunction, rickets, and the need for liver transplantation.[61] Before the use of NTBC, most infants with the early-onset form of TYR1 died in early to late infancy. Unfortunately, patients treated with NTBC have shown impaired cognitive outcomes including a lower intelligence quotient, suboptimal executive functioning (working memory and cognitive flexibility), and social cognition (face recognition and the identification of facial emotion) when treated with a natural protein-restricted diet.[63,64] Dietary over-restriction leading to hypophenylalaninemia may be the cause of these neurocognitive deficits, poor growth, cortical myoclonus, and eczema, although these have been seen to improve or resolve following phenylalanine supplementation.[65]

One complication of TYR1 is the development of hepatocellular carcinoma, typically occurring in later presentations in older children. Monitoring through serial liver ultrasounds and alpha fetoprotein levels is necessary. Treatment with NTBC will improve the biochemical markers and liver dysfunction, but liver transplantation may still be necessary in those who are NTBC-resistant or who have chronic liver disease or poor quality of life.[61]

Other forms of tyrosinemia may be detected with elevated tyrosine levels on NBS or plasma amino acid analysis. Tyrosinemia type 2, or oculocutaneous tyrosinemia, presents with corneal tyrosine crystals, causing photophobia and hyperkeratotic plaques on the hands and soles of the feet. Tyrosinemia type 3 is extremely rare and has a variable phenotype including ataxia and mild mental retardation.[66] These are due to enzyme defects in tyrosine aminotransferase and *p*-hydroxyphenylpyruvate dioxygenase, respectively.

Transient tyrosinemia of the newborn is common in premature infants and is probably the most common disturbance of amino acid metabolism identified on NBS. It is due to delayed maturation of *p*-hydroxyphenylpyruvate dioxygenase or liver immaturity.

Nonketotic Hyperglycinemia

Glycine encephalopathy, also termed *nonketotic hyperglycinemia* (NKH), is an autosomal recessive disorder of the catabolism of glycine to carbon dioxide and ammonia.[67] The incidence is about 1 in 60,000. The glycine cleavage system is composed of four proteins, glycine decarboxylase (GLDC), amino-methyltransferase (AMT), the glycine cleavage H protein, and lipoamide dehydrogenase. These are also called the *P (pyridoxal-phosphate)*, *T (tetrahydrofolate)*, *H (hydrogen)*, and *L (lipoamide) proteins*, respectively, for the cofactor each utilizes. GLDC removes carbon dioxide, the AMT protein removes ammonia, the H protein removes the hydrogen, and the L protein regenerates the reduced form of the protein.[67] The majority of affected individuals have mutations in the *GLDC* or *AMT* genes.[68] The pathophysiology is likely related to glycine's role in the CNS as both an inhibitory and an excitatory neurotransmitter. The most common form of the disorder manifests in the first week of life as apnea and treatment refractory seizures associated with a burst-suppression pattern on electroencephalogram (EEG). This neonatal-onset form is associated with a very poor prognosis, even with early diagnosis and treatment.[68,69] There are milder forms of the disorder that manifest in the first months of life or later.

The diagnosis of NKH is based on both the absolute value of glycine in cerebrospinal fluid (CSF) and on the ratio of CSF glycine to plasma glycine. CSF and plasma amino acids must be obtained concurrently. However, the presence of blood in the CSF invalidates the results as CSF amino acid values will not be accurate.[70] CSF glycine is generally greater than 40 µmol/L in affected individuals, and a CSF-to-plasma glycine ratio of 0.08 or greater is considered diagnostic of NKH.[68] This disorder is not identified through NBS because of high false-positive rates of blood spot glycine levels.

One goal of treatment is to lower CSF glycine through high-dose sodium benzoate therapy. Benzoate is conjugated with glycine to form hippuric acid, which is excreted. In addition,

dextromethorphan, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, is prescribed to counteract the activation of the NMDA receptor by glycine. Restriction of dietary protein to restrict the amino acid glycine is not an effective therapy. Other care is supportive as the majority of affected individuals have profound intellectual disability and develop spastic quadriplegic cerebral palsy. Mildly affected individuals with a later-onset presentation with autism have been described. Withdrawal of support in the newborn period has been performed because of the poor prognosis, but the existence of a "mimic" of the disorder associated with identical, but transient, biochemical and clinical features—and with a good outcome—may complicate this decision.[71]

Two classes of disorders that have a secondary effect on the glycine cleavage system have been described. One class was identified through candidate gene sequencing of individuals with defects in the glycine cleavage system that lacked mutations in the known causative genes.[72] The two classes are defects in lipoate synthesis, as lipoate is a cofactor of the L protein, and defects in iron–sulfur cluster biogenesis, as lipoate synthase is an iron–sulfur-containing protein. The disorders have unique clinical and biochemical features, and all have deficient glycine cleavage.[73] It is important to consider these variant disorders in a neonate with apparent NKH. DNA testing should be performed to confirm the correct diagnosis, as the results are necessary for accurate treatment, prognosis, and genetic counseling.

Hyperhomocysteinemias: Cystathionine β-Synthase Deficiency and Remethylation Disorders

In humans, through conversion of the essential amino acid methionine to homocysteine, a methyl donor is made available for multiple methylation reactions. Homocysteine may then either be metabolized to cysteine (the transsulfuration pathway) via cystathionine β-synthase or be remethylated back to methionine; defects in the relevant enzymes may lead to homocystinemia (or homocystinuria).

Classic homocystinuria is caused by an autosomal recessive deficiency of the cystathionine β-synthase enzyme as a result of mutations in the *CBS* gene and rarely presents in early infancy. The population frequency is estimated to be between 1 in 1800 and 1 in 900,000. NBS detects elevated methionine levels, but this will not detect all affected infants, particularly those with the pyridoxine-responsive form of the disease. Early treatment, which may include pyridoxine, dietary therapy and betaine, improves clinical outcomes, including ectopia lentis, myopia, mental impairment, a marfanoid body habitus, osteoporosis, thromboembolic events, and behavioral problems.[74] Infants may present with thrombosis, and homocysteine should be assayed for any thrombotic event, regardless of the NBS result.

Defective methionine remethylation may be due to methionine synthetase deficiency, methionine synthetase reductase deficiency, 5-methylenetetrahydrofolate reductase (MTHFR) deficiency, and other defects in cobalamin (a cofactor for methionine synthase) metabolism or transport. Newborns may come to clinical attention with encephalopathy with lethargy, feeding difficulties, hypotonia, seizures, pancytopenia with megaloblastic anemia, cardiomyopathy, and optic atrophy and retinopathy.[75,76] Previously thought to be rare, these disorders are now identified more frequently as a result of NBS, and false positives for these may be due to maternal nutritional cobalamin deficiency. The disorders of cobalamin intracellular processing or transport are identified by decreased methionine, elevated homocysteine, and/or elevated methylmalonic acid and C3-(propionyl)-acylcarnitine levels (see Methylmalonic Acidemia). Infants may quickly develop postnatal failure to thrive, and appropriate treatment, which may include hydroxocobalamin, betaine, folinic acid, carnitine, and methionine supplementation, is now resulting in improvements in clinical outcome.[75,76]

Patients with MTHFR deficiency may present as neonates with decreased consciousness, hydrocephalus, hypotonia, and feeding difficulties. There may be severe cortical atrophy and brain lesions caused by thromboses of the arteries or veins. This may present as an acute disorder of intoxication in the newborn period. Treatment with high-dose betaine, which enhances the remethylation of homocysteine to methionine through an alternate betaine–homocysteine methyltransferase pathway, is reported to improve or normalize development.[75,76]

Early detection of disorders of remethylation and of classic homocystinuria is possible through NBS, which utilizes a high methionine level to detect classic homocystinuria and a low methionine level to detect remethylation disorders. NBS is not fully sensitive or specific for these disorders. One cause of false positives is heterozygous mutations in the *MAT1A* gene causing hypermethioninemia, which may be benign. The sensitivity of NBS for cystathionine β-synthase deficiency is improved by using elevated methionine levels together with methionine:phenylalanine and methionine:total homocysteine ratios, although measurement of total homocysteine is not available universally. NBS for some remethylation disorders is possible by detection of low methionine levels with elevated C3-acylcarnitine levels, depending on the individual state programs.[76] Confirmatory DNA testing is available for all of the disorders.

Phenylketonuria

Phenylketonuria (PKU) is an autosomal recessive disorder resulting from deficiency of phenylalanine hydroxylase (PAH). The most severe form causes intellectual disability if untreated. It is the most common inborn error of amino acid metabolism, affecting about 1 in 10,000 northern European or east Asians, 1 in 2600 individuals in Turkey, and 1 in 4500 in Ireland, but only 1 in 143,000 in Japan and 1 in 200,000 both in Finland and among those of Ashkenazi Jewish ancestry.[77] The enzyme defect results in elevated levels of phenylalanine, which is the cause of the CNS injury, and decreased levels of tyrosine, which is of unclear clinical significance, but low levels may lead to supplementation. PAH requires the cofactor tetrahydrobiopterin (BH_4), and PAH enzyme deficiency may also result from a deficiency in the synthesis or recycling of BH_4. Disorders of BH_4 metabolism may result in elevated phenylalanine levels and should be ruled out when performing follow-up NBS testing, as treatment and outcomes differ.[78] BH_4 is also a cofactor for tyrosine hydroxylase, tryptophan hydroxylase, and nitric oxide synthase, and BH_4 deficiency also leads to impaired levels of L-dopa, dopamine, norepinephrine, melanin, serotonin, citrulline, and nitric oxide. PKU does not present with symptoms in the newborn period. It is a cause of intellectual disability, and there are no systemic manifestations. Treatment, however, should be instituted in the first several weeks of life for optimal outcome, and it is important that physicians caring for newborns are familiar with the evaluation and management of newborns with an abnormal NBS for PKU.

PKU was the first disorder for which NBS was implemented in the 1960s. NBS for PKU is a model for preventative and personalized medicine, as well as for public health screening and intervention. The blood spot phenylalanine level and the phenylalanine:tyrosine ratio will be elevated and detected by NBS. The blood spot should be collected after 24 hours of age following breastfeeding or formula feeding. Elevated urine phenyl ketones and phenylacetic acid result in a "mousey" urine odor. Diagnosis should be confirmed through plasma amino acid analysis and testing for BH_4 metabolism disorders in blood and urine. DNA sequencing of the *PAH* gene may provide helpful information for genetic counseling and treatment.

Untreated PKU patients will develop developmental and intellectual disabilities, eczema, hypopigmented skin and hair, and epilepsy in infancy and at older ages. Dietary phenylalanine restriction with strict compliance in order to maintain plasma phenylalanine levels in treatment range is necessary to prevent intellectual disability and other features. Dietary compliance may be difficult for teenagers and adults, but lifelong dietary treatment is necessary to avoid neuropsychiatric symptoms such as inattention, hyperactivity, depression, and anxiety.[79] Mothers who are poorly compliant during pregnancy and have phenylalanine levels above the recommended treatment range may have children with microcephaly, fetal growth restriction, congenital heart defects, and other malformations, known as *maternal PKU syndrome*. Attaining plasma phenylalanine levels within treatment range before the 8th week of pregnancy is essential and ideally should be achieved before pregnancy. Phenylalanine levels should be maintained between 120 and 360 µmol/L (or 2 to 6 mg/dL), the typical treatment range in the United States, throughout the pregnancy.[78] Plasma phenylalanine levels in untreated individuals with classic PKU are greater than 1200 µmol/L (20 mg/dL).

Dietary therapy for PKU is effective and is a low natural-protein diet supplemented with phenylalanine-free medical formula to ensure adequate total protein and micronutrients. An adequate amount of phenylalanine from whole protein in formulas and/or food is necessary for normal growth and protein synthesis, with a goal of maintaining plasma phenylalanine levels less than 360 µmol/L.[78] In patients with classic PKU, protein tolerance may be as low as 5 g of protein per day, requiring metabolic formula lacking phenylalanine to provide the majority of needed daily protein (0.9 to 1 g/kg/day for an adult, i.e., about 70 g for a 70 kg adult). This diet is difficult to maintain lifelong and other therapies have been developed. Sapropterin (a synthetic form of the BH_4 cofactor) may be beneficial in lowering phenylalanine levels in the 25% to 50% of patients who are sapropterin responsive. Other therapies include large neutral amino acids that compete for the same gut and brain transporter as phenylalanine in older children and adults, and lower brain phenylalanine levels, and use of an alternate enzyme, polyethylene glycol-conjugated phenylalanine ammonia lyase, that converts phenylalanine to transcinnamic acid, which is nontoxic and is excreted. The enzyme is given subcutaneously to reduce plasma phenylalanine levels and may result in patients being able to tolerate an unrestricted diet.[78]

Organic Acidemias

The classical organic acidemias (or acidurias, the terms are interchangeable) are characterized by systemic illness and presentation in the newborn period in the severe forms and include methylmalonic acidemia (MMA), propionic acidemia, and isovaleric acidemia. These are due to defects in pathways that affect the catabolism of one or more of the BCAAs (leucine, isoleucine, and valine) as well as other amino acids (see Fig. 29.4). An organic acid is any organic compound that contains a carboxy functional group but no α-amino group. They are intermediates in multiple pathways, including those of amino acid, fatty acid, cholesterol, and neurotransmitter metabolism. Disorders of fatty acid oxidation, ketone body metabolism, and lactic acid metabolism may also be detected through organic acid analysis.

Before NBS, these disorders were diagnosed only after patients became symptomatic, unless there was a known affected family member. While early presentation does occur before NBS results are available, with widespread NBS it is more common to be confronted with an asymptomatic or early symptomatic patient and a differential diagnosis that is based on the NBS results. Presenting symptoms of the classic organic acidemias in the neonate result from the progressive hyperammonemia, keto lactic acidosis, and hypoglycemia.

Methylmalonic Acidemia

Multiple genetic defects can lead to the elevation of methylmalonic acid. Isolated methylmalonic acidemia (MMA) is caused by methylmalonyl-CoA mutase enzyme deficiency because of mutations in the *MUT* gene. Adenosylcobalamin is a required cofactor for the mutase enzyme, and cobalamin (vitamin B_{12}) disorders of processing or transport may present with elevations of methylmalonic acid alone or in combination with elevated homocysteine, as homocysteine is also metabolized by a cobalamin-dependent enzyme, cystathionine β-synthase (see Hyperhomocysteinemias and Remethylation Disorders). Cobalamin is acquired through dietary sources and must be appropriately transported and then undergoes a series of intracellular modifications. Thus, impaired cellular cobalamin metabolism and other inherited defects in cobalamin transport or modification result in MMA. Inherited defects of cobalamin transport or modification may cause isolated MMA, or a combined defect with homocystinuria.[80,81] Methylmalonic acid is detected in the blood, CSF, and urine of affected individuals. The disorder is typically identified through urine organic acid analysis after an abnormal NBS or in a clinically presenting neonate. The precursors of methylmalonyl-CoA are primarily isoleucine and valine but additionally include methionine, threonine, thymine, and odd-chain fatty acids.[82]

There is a spectrum of severity of isolated MMA that ranges from severe, catastrophic newborn-onset disease to benign forms.[81] Patients presenting in the newborn period have a severe phenotype but may have a vitamin responsive form of the disorder (e.g., cobalamin A deficiency). Levels of homocysteine and vitamin B_{12} should always be assessed when elevated methylmalonic acid has been identified, and cobalamin should be provided empirically. The neonate appears well at birth but may rapidly progress as early as the second or third day of life to having problems with feeding and then develop vomiting, lethargy, and perhaps seizures. There may be tachypnea to compensate for metabolic acidosis. Crucial laboratory findings include metabolic acidosis with an increased anion gap, elevated lactate, elevated ketones, and elevated ammonia. The elevation of ammonia may be as high as that found in neonates presenting with early-onset UCDs, and specialized biochemical genetic laboratory testing is required for diagnosis and should include a urine organic acid analysis and a plasma amino acid analysis, a plasma acylcarnitine profile, and a quantitative orotic acid level. Ketonuria is uncommon in newborns, and the physician must always consider an organic acidemia in an acutely

ill newborn with ketosis. Other laboratory findings are thrombocytopenia, leukopenia, and anemia caused by effects of the metabolite on hematopoietic elements in bone marrow. Plasma amino acid analysis may reveal elevations of glycine and alanine. Elevations of C3-(propionyl)-acylcarnitines may result in a secondary free carnitine deficiency caused by conjugation of accumulating metabolites, and so carnitine supplementation should be initiated. Methylmalonic acid and other metabolites are detected in urine by organic acid analysis. The specific genetic diagnosis should be identified by DNA testing. Next-generation DNA sequencing panels are available, although results often take weeks to return. Most are inherited as autosomal recessive conditions, except for cobalamin X deficiency caused by a defect in *HCFC1*, a transcription factor that regulates the cobalamin C gene.[83]

Rapid institution of empiric therapy may improve outcome. Acute management protocols are available and should be administered in conjunction with a biochemical geneticist.[82] The treatment of acute metabolic decompensation includes cessation (for no more than 12 to 24 hours) of protein intake, empiric therapy with cobalamin, provision of high calories through protein-free enteral formula, and/or IV glucose at high concentration with IV intralipids, insulin, and carnitine. Some patients are responsive to pharmacologic doses of cobalamin, and 1 mg/day intramuscular hydroxocobalamin (preferred formulation) should be given as empiric therapy to a newborn presenting with hyperammonemia and acidosis.[82] Sodium bicarbonate should be used if indicated to correct acidosis. Dialysis is indicated for refractory hyperammonemia or acidosis. Additional therapies may include ammonia scavenger medications and carglumic acid, a stable analogue of the coactivator of the urea cycle that is depleted in MMA, causing the secondary hyperammonemia.[82] Chronic treatment includes a low natural-protein diet, an amino acid supplement lacking the MMA precursors, carnitine, and appropriate calories and fluid. Cobalamin is used chronically only when a specific and reproducible response is noted.

Most patients are now identified by NBS, although there are missed cases, and infants may become ill before the NBS result has been returned. False-positive NBS may result from maternal cobalamin deficiency. If the NBS and follow-up results are rapidly available, the outlook for the neonatal period may be improved. Episodes of decompensation will still occur after the newborn period associated typically with infection or other stressors. Patients who are particularly brittle or who develop renal failure receive either liver, kidney, or combined liver–kidney transplants. Long-term complications include basal ganglia stroke (which may occur in the newborn period), renal disease and failure, and pancreatitis.[82]

Propionic Acidemia

Propionic acidemia (PA) is due to a deficiency of propionyl-CoA carboxylase and is an autosomal recessive disorder. It was originally referred to as "ketotic hyperglycinemia," because patients may have elevations of glycine as well as ketosis. Propionyl-CoA carboxylase is the enzymatic reaction just upstream of methylmalonyl-CoA mutase, and the precursors are identical (see Fig. 29.4). The clinical presentation and therapy of PA in the newborn period are similar to that of MMA. A biochemical geneticist with experience in the management of inborn errors should guide care and help guide diagnosis and the differentiation of MMA and PA from other possible disorders. Empiric therapy should be administered as described for MMA, with the provision of calories, IV glucose at high concentration with IV intralipid (once a disorder of fat metabolism has been ruled out), insulin (if needed), carnitine, cobalamin (for possible cobalamin-responsive MMA), and temporary cessation (no more than 12 to 24 hours from last intake) of protein. Hyperammonemia may be marked, and dialysis may be indicated. Ammonia-scavenging medications and carglumic acid may also be used, as for MMA.[82]

Elevated ammonia levels may be associated with CNS injury. Metabolic stroke, because of cell death in the absence of thrombosis or ischemia, may be seen in both MMA and PA and may result in damage to the basal ganglia. In MMA the globus pallidus is classically affected, while in PA the caudate and putamen are typically affected, resulting in severe choreoathetosis.[82,84] Chronic therapy consists of a low natural-protein diet, supplementation with metabolic formula lacking the MMA/PA precursors, carnitine, and adequate calories and micronutrients.[82] Biotin is a cofactor for the enzyme, but no case of biotin-responsive PA has been described; an empiric trial can be considered. Intestinal bacteria (*Propionibacterium* species) contribute to propionate production. Antimicrobial therapy with metronidazole has been used to lower propionate metabolites in acute illness and may be given as intermittent therapy to lower metabolites as part of chronic therapy. While not curative of the disorder, liver transplantation is being performed in individuals with early-onset PA with the goal of ameliorating long-term complications and enhancing quality of life.[82] The efficacy of liver transplant is unclear.

Outside of the newborn period, or in late-presenting individuals, episodes of metabolic decompensation are characterized by hyperammonemia, acidosis, and ketosis precipitated by excessive protein intake or more commonly by infection resulting in poor oral intake and protein catabolism. Families may use home urine ketone strips for monitoring so that early decompensation can be recognized and aggressive measures instituted to avoid further decompensation, as episodes can result in permanent neurologic damage. Affected individuals may exhibit neurological symptoms including developmental delay, seizures, cerebral atrophy, and EEG abnormalities; other complications such as optic atrophy, cardiomyopathy, and pancreatitis; and late-onset presentations with only neurologic features.[84]

Diagnosis is made through urine organic acid analysis and confirmed by enzymatic and/or DNA testing. The acylcarnitine profile, on NBS or in plasma, will have elevated C3-(propionyl)-acylcarnitine, and urine organic acid analysis is required to distinguish between MMA and PA. In PA the urine has elevated 3-hydroxypropionic, propionyl glycine, and methylcitric acid but not methylmalonic acid. Both chronically and during acute decompensation, plasma ammonia may be mild to moderately elevated. The enzyme activity of propionyl-CoA carboxylase can be assayed in white blood cells or cultured skin fibroblasts. DNA testing may identify the numerous mutations that have been described in the two genes (*PCCA* and *PCCB*) that encode the subunits of this multimeric enzyme. Most patients are now identified by NBS, and the severe neonatal decompensation may be ameliorated if the results are rapidly available.

Isovaleric Acidemia

Isovaleric acidemia (IVA) is an autosomal recessive disorder caused by deficiency of the enzyme isovaleryl-CoA dehydrogenase. This is a defect in catabolism of the amino acid leucine. There are two major phenotypes, distinguished by the degree of enzyme deficiency and differing mutations. The acute form manifests as

catastrophic disease in the newborn period. The late-onset type is characterized by chronic, intermittent episodes of metabolic decompensation.[85] In the acute form the infants become ill in the first week of life, similar to MMA and PA. Marked acidosis and ketosis suggest an organic acidemia, and urine organic acid analysis is required for diagnosis and shows elevations of isovalerylglycine and 3-hydroxyisovaleric acid. An elevated C5-(isovaleryl)-acylcarnitine value on plasma acylcarnitine analysis or on NBS is strongly suggestive of this diagnosis, although urine organic acid analysis is still required. DNA mutation analysis of the *IVD* gene is available. Another diagnostic clue is the characteristic "sweaty-feet, rancid cheese, or dirty socks" odor caused by isovaleric acid, which is detectable in blood and urine, especially during acidosis. Dialysis may be necessary if there is marked hyperammonemia. As for other organic acid disorders, acute treatment consists of protein restriction (for 12 to 24 hours) with the provision of calories, IV glucose at high concentration with IV intralipids, insulin (if necessary), carnitine, and sodium bicarbonate if indicated, followed by a protein-free formula to provide additional calories via nasogastric tube if enteral nutrition is tolerated and oral glycine (150 to 250 mg/kg/day) for known or suspected IVA and oral or IV carnitine supplementation.[85] The excretion of isovaleric acid as the glycine conjugate is highly efficient, and improvement can occur rapidly with provision of glycine and other therapy.

In the chronic, intermittent form of IVA, patients have repeated episodes of metabolic decompensation precipitated by infection, other catabolic stress such as surgery, or excessive protein intake. These episodes may mimic Reye syndrome. The same therapeutic principles are applied as for the acute treatment of the neonatal disorder. Chronic therapy consists of a diet with low natural protein (limiting leucine to the amount required for growth), a leucine-free amino acid supplement to provide sufficient protein for growth, and glycine, which enhances isovalerylglycine production and reduces free isovaleric acid levels in body fluids while carnitine administration can augment the excretion of isovalerylcarnitine.[85] Some patients who remain largely asymptomatic are ascertained through NBS. This form of IVA is associated with a specific mutation (p.A282V) in the *IVD* gene.[86] NBS and early institution of treatment can alter the prognosis of affected individuals.[87]

Multiple Carboxylase Deficiency

Two enzymatic defects, holocarboxylase synthetase deficiency and biotinidase deficiency, lead to deficiency of the four carboxylase enzymes, propionyl-CoA carboxylase, pyruvate carboxylase (PC), 3-methylcrotonyl-CoA carboxylase, and acetyl-CoA carboxylase; these require covalent linkage of the cofactor biotin to a lysine residue of the enzyme for normal activity.[88] Holocarboxylase synthase is the enzyme that catalyzes this covalent linkage, and a severe defect of this enzyme causes early-onset multiple carboxylase deficiency. The biotinidase enzyme regenerates biotin from the amide biocytin, formed by biotin and lysine. Biotinidase deficiency causes late-onset multiple carboxylase deficiency because of the failure to regenerate biotin. This condition typically does not manifest in the newborn period. High-dose biotin therapy is extremely efficacious in both conditions.

Infants with severe deficiency of holocarboxylase synthase become ill in the newborn period. They develop a marked metabolic acidosis with severe lactic acidosis and become encephalopathic. Administration of enteral biotin is life-saving, and empiric therapy should be administered if there is a concern for this disorder. In an affected neonate, administration of this vitamin results in a dramatic improvement in clinical and laboratory findings. As described for MMA, PA, and IVA, empiric management should include initial protein restriction, provision of high calories, correction of acidosis, and empiric administration of cofactors and carnitine. After an initial period of empiric management, specific management should be based on the results of specialized biochemical testing. The goal is to have these results within 24 hours in order to provide the correct therapy. Evaluation and management should be guided by a biochemical geneticist familiar with the management of inborn errors.

The characteristic plasma acylcarnitine profile exhibits elevations of C3-(propionyl)-acylcarnitine and C5-OH-(3-hydroxyisovaleryl)-acylcarnitine and may be detected on NBS. Urine organic acid analysis identifies marked elevations of metabolites because of the deficiencies of pyruvate, propionyl-CoA, and 3-methylcrotonyl carboxylases. These include lactate, 3-hydroxypropionic acid and propionylglycine, and 3-methylcrotonylglycine, respectively. In most patients the defect is associated with decreased affinity of the holocarboxylase synthetase enzyme for biotin, and effective treatment requires between 10 mg and 100 mg of oral biotin per day. Long-term treatment may include dietary protein restriction and carnitine supplementation. The enzyme defect can be confirmed in cultured skin fibroblasts, or the diagnosis can be confirmed by DNA mutation analysis of the *BTD* or *HCLS* gene. Assay of individual carboxylases in white blood cells will show deficiency of all three carboxylases assayed, but this is not specific. The disorder is inherited as an autosomal recessive trait.

NBS also detects individuals with partial biotinidase deficiency (30% enzyme activity) who do not develop the severe symptoms of the profound deficiency. Enzyme analysis and mutation analysis distinguish these.[89,90]

Late-onset multiple carboxylase deficiency caused by profound biotinidase deficiency may present as seizures and lactic acidosis and episodic decompensation. Long-term sequelae include hearing loss and optic atrophy. This disorder is effectively treated with biotin (10 to 20 mg/day), which prevents these long-term complications.[88] Effective NBS requires a specific biotinidase enzyme assay as it is not reliably detected by tandem mass spectrometry.

Glutaric Aciduria Type 1

Glutaric aciduria type 1 (GA1) is due to a deficiency of glutaryl-CoA dehydrogenase, an enzyme in the catabolic pathway of the amino acids lysine, hydroxylysine, and tryptophan.[91] Unlike the organic acid disorders described previously that have systemic manifestations including hyperammonemia, lactic acidosis, ketosis, and bone marrow suppression, GA1 is termed a "cerebral" organic aciduria. In most instances the systemic manifestations of decompensation are not present, and GA1 does not have a catastrophic presentation in the newborn period. The classic presentation of GA1 is that of a child with normal growth and development in the first 6 to 18 months of life who experiences a metabolic stroke of the basal ganglia during illness, surgery, or another event that provokes catabolism.[92] Clinically affected children sustain irreversible bilateral damage to the caudate and putamen and, more rarely, the globus pallidus, structures of the basal ganglia that influence the control of voluntary movement, resulting in incapacitating dystonia and decreased life expectancy. Other affected individuals appear to have a slowly progressive course with hypotonia, dystonia, and dyskinesia in the first several years of life; these may have sustained early injury without a

recognized encephalopathic illness. Remarkably, there is a vulnerable period for neurologic injury, and affected individuals who do not have injury in the first 6 years of life may have normal growth and development. This disorder is identified on NBS with elevations of C5-DC-(glutaryl)-acylcarnitine, though some individuals termed "low excretors" may be missed.[91] Chronic therapy includes a low natural-protein diet balanced with supplementation of a lysine-free, tryptophan-reduced, and arginine-containing formula, carnitine, and riboflavin (the enzyme cofactor that may result in biochemical improvements in some cases). Acute emergency therapy includes protein restriction (for 12 to 24 hours) with the provision of calories as IV glucose at high concentrations with IV intralipids, insulin (if necessary), and carnitine, with supportive care from neurology or neurosurgery. These are critical to decreasing the incidence of devastating neurologic injury in affected individuals.[91,93]

GA1 may mimic nonaccidental trauma, as some individuals have subdural hematomata and retinal hemorrhages, independent of basal ganglia injury. Subdural hematomas may be identified in the investigation of crossing of percentiles for head circumference, a finding in GA1. Another finding that may prompt investigation for GA1 is increased fluid in the perisylvian fissures observed on brain computerized tomography or magnetic resonance imaging (MRI).[91] Manifestations in the newborn period include nonfamilial macrocephaly, increased fluid in the perisylvian fissures, and an abnormal NBS. Initial testing after an abnormal newborn screen, or if there is a clinical concern, should include a plasma acylcarnitine profile, measurement of total and free carnitine, and a urine organic acid analysis.

Urine organic acid analysis will identify elevated glutaric acid and 3-hydroxyglutaric acid, though the latter compound, considered diagnostic of GA1, may be normal or near normal in a non-decompensated state in some individuals. Critically, these individuals, termed low excretors, are at no less risk of severe neurologic injury. The diagnosis may be confirmed by enzyme assay in fibroblasts or by DNA mutation analysis of the *GCDH* gene. NBS has resulted in a decrease in the incidence of neurologic injury in affected individuals.[91,93]

Fatty Acid Oxidation Disorders

Fatty acid oxidation disorders (FAODs) are inborn errors of metabolism resulting in failure of β-oxidation within, or transport of fatty acids into, the mitochondria. There are at least 31 enzymes described. While short- and medium-chain fatty acids enter the mitochondria directly, carnitine is required for transport of long-chain fatty acids. Within the mitochondria the β-oxidation cycle will form acetyl-CoA and generate nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$), enabling electron transfer to the respiratory chain for adenosine triphosphate (ATP) generation. Acetyl-CoA is used as a substrate in the Krebs cycle to produce reducing equivalents for the electron transport chain (ETC) and ketone synthesis. FAODs lead to a deficit of energy production and produce a wide range of clinical presentations from mild hypotonia in adults to sudden death.[94]

FAODs present at all ages and spare the CNS when in good metabolic control. Life-threatening phenotypes present in the first few days of life (typically after 24 to 48 hours of life) because of the severe catabolic state and enhanced breakdown of free fatty acids from adipose stores, often before NBS results have been received.[95] Signs include hypoglycemia, liver disease and liver failure, cardiac and skeletal myopathy, rhabdomyolysis, and retinal degeneration.[94] The accumulation of long-chain acylcarnitine species has been suggested to be dysrhythmogenic and may be associated with cardiac dysfunction.[94]

Overall, the incidence of all FAODs ranges from about 0.9 to 15.2 per 100,000, with significant variability due to regional and genetic population differences, with founder populations having much higher incidences as would be expected, and the incidence on NBS has been higher than that from clinically identified symptoms.[95] Medium-chain acyl-CoA dehydrogenase deficiency (MCADD) is the most common FAOD, while very long chain acyl-CoA dehydrogenase deficiency (VLCADD) is the most common long-chain FAOD with an estimated incidence of 0.07 to 1.19 per 100,000, the other disorders being commonly less than 1 in 100,000.[95] There is significant variability in which FAODS are included in NBS panels around the world. The diagnosis is confirmed with a plasma acylcarnitine profile, total and free carnitine levels, and DNA testing. Urine organic acid analysis and measurement of urine acylglycines should also be performed. If variants of uncertain significance are identified on DNA sequencing, leukocyte, fibroblast, or liver enzyme assays may be implemented to determine whether an individual is affected. All FAODS are autosomal recessive and false-positive NBSs are commonly found due to carrier status. Many infants are now being identified with milder, and perhaps persistent, elevations of specific acylcarnitines but are not thought to be at significant risk for clinical disease, although long-term follow-up studies are needed to determine what, if any, risk is present for later-onset forms of these disorders, such as VLCADD. There is accumulating evidence from retrospective analyses that supports NBS identification in the neonatal period has improved outcomes compared with patients diagnosed clinically after development of symptoms.[95]

Treatment of FAOD shares many common features. Treatment primarily is targeted at prolonged fasting avoidance to maintain a constant energy supply and prevent the use of fat for energy, together with a higher-carbohydrate, low-fat diet. Safe fasting periods for different age groups have been proposed: neonates until about 3 months of age should fast no longer than 3 to 4 hours, with this time gradually increasing through infancy.[96,97] IV fluids with 10% dextrose at 150% maintenance rate should be given when the patient is fasting for surgery.

For long-chain FAOD, supplementation with medium-chain triglyceride (MCT) oil is used to provide a substrate for β-oxidation and should be prescribed to provide 20% to 25% of total calories.[97] Avoiding essential fatty acid deficiency may require supplementation with additional oils, depending on the degree of long-chain fat restriction. MCT supplementation and the recently approved anaplerotic treatment with triheptanoin (Dojolvi) has been associated with a reversal of cardiomyopathy in carnitine acylcarnitine translocase deficiency (CACT) and VLCADD, although compliant VLCADD patients still had significant muscle weakness, muscle pain, or myoglobinuria.[98–100] Carnitine supplementation is controversial although is supported if there is free carnitine deficiency.[97]

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase deficiency (MCADD) is the most common FAOD with a frequency reaching approximately 1 in 20,000 births in northern European populations with the common mutation, c.985A>G. Classic presentations occur in

older infants during an infection, with poor oral intake, vomiting, dehydration, lethargy, hypoglycemia, seizures, and a presentation similar to Reye syndrome, leading to death from brain edema and hyperammonemia. Severe lethal presentations will develop during the first days of life before NBS, and MCADD is a recognized cause of sudden infant death syndrome.

The initial presenting episode historically has a high mortality rate, but this has improved with NBS.[101,102] Plasma acylcarnitine profiles demonstrate increased levels of C6, C8, C10, and C10:1 values. Urine acylglycine analysis shows elevations of suberylglycine and hexanoylglycine. Sequence analysis of *ACADM* confirms the diagnosis. Treatment focuses on avoiding prolonged fasting, especially during intercurrent illness, avoidance of MCT supplementation, and carnitine supplementation if necessary.[96]

Very Long-Chain Acyl-CoA Dehydrogenase Deficiency

VLCADD presents with variable phenotypes ranging from severe cardiomyopathy that may result in death in the first few days of life to recurrent hypoketotic hypoglycemia or to later-onset presentations with myopathy and/or rhabdomyolysis in adolescence or adulthood.[96,103] Cardiomyopathy and arrhythmias have been reported in a high proportion of cases presenting at less than 6 years in a country without newborn screening.[104]

Most patients with VLCADD are detected through NBS but present a significant challenge in that a large number of individuals appear to have mild or perhaps benign DNA variants and normal follow-up plasma acylcarnitine profiles. Many of these cases will have a single heterozygous mutation and so appear to be unaffected carriers. Others may have two compound heterozygous mutations but may have a reduced clinical risk of symptoms. Plasma acylcarnitines show a pattern of elevations of C14:1-, C14-, C16:1-, and C16-acylcarnitines levels with low secondary free carnitine levels in some infants. With an acute metabolic decompensation, urine organic acid analysis may demonstrate dicarboxylic aciduria. Confirmation by sequencing and deletion/duplication analysis of *ACADVL* is recommended. Functional enzyme assay or fibroblast acylcarnitine probe analysis may be helpful to determine treatment when a single heterozygous mutation is found, novel uncharacterized variants are found, and/or there are persistent elevations of acylcarnitines inconsistent with the genotype.[105]

Treatment follows the general principles for long-chain FAOD treatment, consisting of prolonged fasting avoidance, long-chain dietary fat restriction, medium-chain fat supplementation, and carnitine supplementation if necessary. Medium chain fat may be provided by MCT oil, powder, or as a component of formula (e.g., Enfaport) or as triheptanoin.[97] Triheptanoin (Dojolvi), which contains an odd-chain fat that is a source of additional anaplerotic energy to the TCA cycle was recently approved for infants with long-chain fat metabolism defects. Its use is associated with improved cardiac phenotype and decreased frequency of hospitalizations for rhabdomyolysis when compared to conventional MCT.[106] Severely affected infants should discontinue breastfeeding because of the high fat content in breast milk, with implementation of an MCT-containing formula or with formula and triheptanoin. Treatment of milder forms of VLCADD may include supplementation of breastfeeding with an MCT-containing formula.[97]

Short-Chain Acyl-CoA Dehydrogenase Deficiency

Short-chain acyl-CoA dehydrogenase deficiency (SCADD) is diagnosed through the detection of elevations of C4-acylcarnitine, urinary ethylmalonic acid, and butyrylglycine. Prior reports found decreased SCAD enzyme activity to be associated with failure to thrive, poor feeding, hypotonia, and seizures. Subsequently, up to 14% of the normal population has been found compound heterozygous or homozygous for two common polymorphisms (c.511 C>T and c.625 G>A) with the biochemical abnormalities of SCADD.[107] Currently, most infants with SCADD are detected on NBS and remain clinically asymptomatic, leading many to consider this a benign condition.[108,109] The need for treatment, carnitine or riboflavin supplementation, or management during illness is unclear.

Long-Chain 3-Hydroxy Acyl-CoA Dehydrogenase Deficiency and Trifunctional Protein Deficiency

The mitochondrial trifunctional protein complex of four alpha and four beta subunits comprises three enzymes: long-chain enoyl-CoA hydratase, long-chain 3-hydroxy acyl-CoA dehydrogenase, and 3-ketoacyl-CoA thiolase. Long-chain 3-hydroxy acyl-CoA dehydrogenase deficiency (LCHADD) occurs when there is only reduced dehydrogenase activity because of mutations in the *HADHA* gene, while trifunctional protein deficiency (TFP) results from mutations in either the *HADHA* or *HADHB* gene and in deficient activity of all three enzymes. The most severe forms of LCHADD or TFP present with a rapidly progressive neonatal cardiomyopathy.[110,111] Infants may later develop recurrent hypoketotic hypoglycemia with acute catabolic illness resulting in liver dysfunction (a Reye-like syndrome), cardiomyopathy, myopathy, and rhabdomyolysis. Sixty-five percent of surviving individuals with LCHADD or TFP experience skeletal myopathy, 21% develop a slowly progressing peripheral neuropathy, and 43% have pigmentary retinopathy.[111] Some patients may have severe liver disease with fibrosis in addition to necrosis and steatosis. Older children, adolescents, and adults may develop recurrent rhabdomyolysis during illness.

Heterozygous mothers may rarely develop either acute fatty liver of pregnancy or hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome) when carrying a child with LCHADD.[112]

Diagnosis is made through the demonstration of elevations of C16:1-OH-, C16-OH-, C18:1-OH-, and C18-OH-acylcarnitines levels and the demonstration of longer-chain 3-hydroxydicarboxylic acids on urine organic acid analysis. Enzymatic diagnosis can be made in lymphocytes or in skin fibroblasts, but a combination of clinical biochemical abnormalities and *HADHA* or *HADHB* mutation analysis is often sufficient. The majority of moderate-to-severe cases are diagnosed by NBS. Follow-up of cases diagnosed on NBS demonstrates improved growth and development, but NBS does not completely prevent morbidity and mortality, especially in TFP, which has poorer survival.[110,111,113]

Treatment of LCHADD and TFP involves avoidance of prolonged fasting, dietary long-chain fat restriction, and MCT supplementation. A low long-chain fat diet and MCT or triheptanoin supplementation will decrease plasma hydroxyl acylcarnitine levels, and some LCHADD patients remain healthy without metabolic decompensation; many patients will have symptoms that

are refractory to therapy including pigmentary retinopathy and peripheral neuropathy.[114]

Primary Carnitine Transporter Deficiency

Carnitine is essential for long-chain fatty acid transport across the mitochondrial inner membrane. This is dependent upon a sodium-dependent plasma membrane carnitine transporter, two transferases that covalently link and then remove carnitine to the long-chain fatty acid, and a mitochondrial membrane translocase.

Carnitine transporter deficiency (CTD, primary carnitine deficiency, carnitine uptake defect) is characterized by hypoketotic hypoglycemia, hyperammonemia, liver dysfunction, cardiomyopathy, and skeletal hypotonia. Neonatal presentations are not common. In some older patients, cardiomyopathy may be the presenting sign. Profoundly low plasma total and free carnitine levels (typically <10 μmol/L in plasma) are found. False-positive NBS for low free carnitine levels may be due to neonatal nutritional deficiency or secondary to low maternal plasma carnitine levels from either a dietary restriction (e.g., vegan diet) or previously unrecognized maternal primary carnitine deficiency or organic acidemia. Measurement of maternal total and free carnitine levels is often necessary when performing follow-up testing of an abnormal NBS. Women with true maternal primary carnitine deficiency may be apparently asymptomatic at diagnosis. Diagnostic confirmation is through DNA sequencing of *SLC22A5* or analysis of fibroblast carnitine uptake.[115]

Treatment of primary carnitine deficiency involves supplementation of carnitine at 100 to 200 mg/kg/day to maintain normal or near-normal plasma carnitine levels. Treatment is successful in preventing or reversing symptoms but is dependent upon compliance.

Carnitine Palmitoyltransferase Type I Deficiency

Carnitine palmitoyltransferase type I (CPTI) covalently links long-chain fatty acids to carnitine prior to mitochondrial transport. CPTI deficiency will present in early childhood with hypoketotic hypoglycemia and liver dysfunction, less commonly as an adult-onset skeletal myopathy, and only with rare presentations of neonatal hypoglycemia.[116] Cardiomyopathy is typically not seen. Renal tubular acidosis has been reported.[117] Diagnostic laboratory findings include elevated total and free plasma carnitine levels, while NBS additionally uses a C0/(C16+C18) ratio to improve specificity. Confirmatory testing will demonstrate mutations in the *CPT1A* gene or through enzyme activity in skin fibroblasts. A common *CPTIA* variant, c.1436C>T (p.P479L), has been identified in the Arctic populations of the Inuit, Alaskan Native, Canadian First Nation, and Hutterite and has been associated with higher infant mortality and impaired fasting intolerance in these populations.[95,118,119] Treatment involves fasting avoidance, a low-fat diet, and MCT supplementation in some cases, and results in a normal outcome, although some suffer neurologic impairment from repeated episodes of metabolic decompensation.[117,120]

Carnitine Acylcarnitine Translocase Deficiency

Carnitine acylcarnitine translocase (CACT) transports fatty acids conjugated to carnitine across the mitochondrial membrane; CACT deficiency is one of the more severe FAODs, and the most common presentation is ventricular dysrhythmia and sudden neonatal death. Symptoms include hypoglycemia, vomiting, gastroesophageal reflux, and mild chronic hyperammonemia, as well as severe skeletal myopathy and mild hypertrophic cardiomyopathy. Early diagnosis and treatment can be beneficial, although significant morbidity includes profound developmental delay, seizures, and other complications despite NBS.[103,113,121,122] Milder disease is associated with higher residual enzyme activity.[123]

Individuals will have elevated C16-, C16:1-, C18-, and C18:1-acyclarnitine levels with low free carnitine levels on diagnostic testing and NBS. DNA sequencing of *SLC25A20* will confirm disease. Treatment includes prolonged fasting avoidance, a low long-chain fat, high-carbohydrate formula, MCT or triheptanoin supplementation, and carnitine.

Carnitine Palmitoyltransferase Type II Deficiency

Carnitine palmitoyltransferase type II deficiency (CPTII) results in identical elevations of C16- and C18:1-acylcarnitines in NBS as found with CACT deficiency; DNA testing of the gene *CPT2* is required for diagnosis; treatment depends on severity and is similar to that for CACT deficiency. Children with the severe form of CPTII deficiency may have congenital anomalies including renal cysts, dysmorphic facies, and brain malformations and may present with hypotonia, cardiomyopathy, arrhythmias, and seizures within the newborn period.[103,122] The later-onset form of CPTII deficiency is much more common and presents in the second or third decade of life with exercise intolerance or rhabdomyolysis.[122]

Multiple Acyl-CoA Dehydrogenase Deficiency

Multiple acyl-CoA dehydrogenase deficiency (MADD; also called *glutaric acidemia type 2*) is the result of a defect of electron transfer from multiple acyl-CoA dehydrogenases to the mitochondrial ETC. Each acyl-CoA dehydrogenase enzyme binds electron transfer flavoprotein (ETF); ETF accepts electrons from the $FADH_2$ cofactor in the oxidative dehydrogenation reactions and is made up of three subunits. Mutations in the genes for the three subunits, *ETFA, ETFB*, and *ETFDH*, will interfere with electron transfer from ETF to coenzyme Q10 within the mitochondria. Riboflavin (an $FADH_2$ component) deficiency or deficient riboflavin transport may show a similar presentation—a riboflavin-responsive form of MADD has been described. Because of the multiple dehydrogenase enzymes involved there will be elevations of metabolites from short-, medium-, and long-chain fatty acids and amino acid metabolism.[94,124]

There are three major ways MADD may present. Neonatal MADD presents with metabolic acidosis, hypoketotic hypoglycemia, and often hypertrophic cardiomyopathy. Neonatal presentations with congenital malformations may include enlarged polycystic kidneys, rocker-bottom feet, defects of the inferior abdominal musculature, and hypospadias and chordee. Hypotonia, cerebral cortical dysplasia, and gliosis have been reported, and dysmorphic facies may include telecanthus, malformed ears, macrocephaly, large anterior fontanel, high forehead, and a flat nasal bridge.[96] Later-onset MADD have a lifelong risk of acute intermittent episodes with vomiting, dehydration, hypoketotic hypoglycemia, acidosis and some with hepatomegaly and muscle disease including myopathy and rhabdomyolysis.

Many infants do not survive beyond the first few weeks or months of life because of rapidly progressing cardiomyopathy. In individuals identified through NBS and in whom treatment is initiated early, acute, life-threatening events or sudden death may still occur.[125,126]

Diagnosis of MADD is suspected due to the combination of increased anion gap lactic acidosis, hypoketotic hypoglycemia, and hyperammonemia. Patients may have an odor of isovaleric acid. Increased serum transaminases and prolongations of prothrombin time and partial thromboplastin time suggest liver dysfunction. Diagnostic testing should include plasma acylcarnitines and elevations of C4 and C5 acylcarnitines may be seen (which are the primary analytes on NBS), and elevated medium- and long-chain acylcarnitines may also be present (i.e., C8-, C10:1-, C12-, C14-, C14:1-, C16-, C16:1-, C18-, C18:1-, C16-OH-, C16:1-OH-, C18-OH-, and C18:1-OH-acylcarnitines). Urine organic acid analysis will show elevations of ethylmalonic acid, glutaric acid, 2-hydroxyglutaric acid, and 3-hydroxyisovalerate in addition to lactic acid, medium- and long-chain dicarboxylic acids, the glycine conjugates isovalerylglycine, isobutyrylglycine, and 2-methylbutyrylglycine. Ketone bodies, including acetoacetic acid and 3-hydroxybutyric acids, are minimal or undetectable. Generalized aminoaciduria will reflect impaired renal tubular function; DNA sequencing of *ETFA, ETFB*, and *ETFDH* will confirm the diagnosis.

Treatment of MADD includes a low-protein and low-fat diet, fasting avoidance, and supplementation with carnitine, riboflavin, and glycine. Individualized metabolic formulas often have to be designed to meet nutritional goals. Individuals at least heterozygous for common *ETFDH* mutations confer a milder riboflavin-responsive phenotype with some cases of complete correction of clinical and biochemical parameters after riboflavin treatment.[96,127] Acute decompensation should be treated with IV glucose and carnitine to restore anabolism with close monitoring of cardiac, hepatic, and renal function. Research is demonstrating that supplementation with D,L-3-HB treatment can be effective and safe in MADD patients.[128]

Ketone Metabolism Disorders

Disorders of ketone metabolism result from the inability to use ketone bodies, 3-hydroxybutyric acid and acetoacetic acid, for energy generation. Each cycle of fatty acid β-oxidation generates a single acetyl-CoA. This acetyl-CoA has to be converted to acetoacetic acid by mitochondrial acetoacetyl-CoA thiolase, 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) synthase, and then HMG-CoA lyase. Acetoacetic acid and 3-hydroxybutyric acid are transported out of liver mitochondria and hepatocytes into blood to be used by other tissues, especially the brain and heart.

Patients with mitochondrial acetoacetyl-CoA thiolase deficiency (β-ketothiolase or 3-oxothiolase deficiency) have a metabolic acidosis associated with excess ketosis and most commonly presents in children around 15 months of age, but cases have been reported as early as 3 and 4 days of age.[129,130] The clinical presentation varies from severe, acute metabolic decompensation in infants to asymptomatic adults. The episodes are intermittent, are typically associated with a catabolic stressor or a high dietary protein intake, and have been associated with mild hyperketotic hypoglycemia and liver dysfunction, without hyperammonemia. Cardiomyopathy is rare. Plasma acylcarnitines and NBS will demonstrate elevations of C5-OH- and C5:1-acylcarnitines. Urine organic acid analysis demonstrates significant elevations of lactate and ketone bodies and a specific pattern of elevations of 2-methylacetoacetate, 2-methyl-3-hydroxybutyrate, and tiglylglycine. Diagnosis is confirmed by DNA sequence analysis of the *ACAT1* gene in this autosomal recessive disorder. Acute treatment involves IV glucose and bicarbonate to correct metabolic acidosis, which is often severe, while long-term therapy includes mild protein restriction, avoidance of prolonged fasting, and prompt attention to any intercurrent illness or catabolic stressor, as treatment and avoidance of severe ketoacidosis may lead to normal development.

HMG-CoA lyase deficiency is the most severe disorder of ketone metabolism and has been identified in only 211 patients.[131] It is the last step in synthesis of acetoacetate from HMG-CoA via the HMG-CoA lyase enzyme. Neonates present as early as 3 days of life with an often-catastrophic illness characterized by vomiting, lethargy, hypoketotic hypoglycemia, metabolic acidosis, hyperammonemia, elevated transaminases, hepatomegaly, seizures, and coma. Urine organic acid analysis reveals 3-hydroxy-3-methylglutaric acid, 3-methylglutaconic acid, and 3-hydroxyisovaleric acid in a specific diagnostic pattern with elevations of C5-OH- and C6-DC-acylcarnitines on plasma acylcarnitine analysis and NBS. Levels of acetoacetic acid and 3-hydroxybutyric acid may be unexpectedly low. Lactate values may be elevated during the acute metabolic decompensation. While nearly all patients are symptomatic, over 60% have normal development.[131] An autosomal recessive disorder, HMG-CoA lyase deficiency is confirmed by mutation analysis of the *HMGCL* gene. Acute treatment of an episode of decompensation consists of administration of IV rehydration with provision of glucose and bicarbonate to correct metabolic acidosis. Long-term treatment consists of avoiding prolonged fasting, a low-protein and high-carbohydrate diet, and carnitine supplementation.

Succinyl-CoA 3-ketoacid-CoA transferase deficiency results from the failure of extrahepatic tissues to convert acetoacetate back to acetoacetyl-CoA. This is required for hydrolysis to acetyl-CoA for final metabolism in the TCA cycle. Affected patients have a persistent ketosis with intermittent ketoacidosis that does not resolve, even postprandially. Affected newborns often present in the first week of life with severe ketosis, lactic acidosis, hypoglycemia, and coma, and many do not survive.[132] Elevated acetoacetate and 3-hydroxybutyrate levels are almost always present in blood and urine. Therapy focuses on fasting avoidance, which can cause profound acidosis and ketosis, and IV fluids, glucose, and sodium bicarbonate during crisis. Enzyme analysis in fibroblasts is available, but DNA sequencing of the *OXCT1* gene will likely confirm the diagnosis in this autosomal recessive disorder. Milder forms do exist, and patients may have nonketotic periods. In addition, there have been reports of heterozygotes with severe presentations.[133]

Mitochondrial Disorders

Primary Lactic Acidosis

Congenital lactic acidosis (CLA) is due to a severe disorder of energy metabolism. This can be caused by one of multiple diseases, including those in which lactate and pyruvate metabolism are impaired because of a primary defect in the mitochondrial electron transport chain (ETC) or the tricarboxylic acid (TCA) cycle. These disorders affect pyruvate metabolism, which, in turn, affects lactate. The majority of neonates presenting with CLA have defects of the mitochondrial ETC, of the pyruvate dehydrogenase (PDH) complex, or of the pyruvate carboxylase (PC) enzyme. Inborn errors of the TCA cycle are much rarer but should be considered in the differential diagnosis. An autosomal recessive

disorder of metabolism of the amino acid valine, short-chain enoyl-CoA hydratase deficiency due to mutations in the *ECHS1* gene, appears to cause a secondary inhibition of PDH and can present with refractory CLA with a Leigh disease-like presentation, neurodegeneration, and neonatal death.[134]

Some patients with CLA present with overwhelming lactic acidosis in the neonatal period. In others, lactate may be elevated only in CSF. This "cerebral" lactic acidosis may present more indolently. When blood lactate is elevated, the ratio of blood lactate to pyruvate can help narrow the differential diagnosis. The ratio is low to normal (10 to 20) in PDH deficiency, may be modestly elevated in PC type B deficiency (see later), but may be greatly elevated (>25) in an ETC defect. This ratio reflects the oxidation-reduction state of the mitochondria. When calculating this it is important to ensure the units of the two analytes are the same. These conditions are not identified through NBS, and patients will not be identified pre-symptomatically unless there has been a prior affected family member such as an older affected sibling.

Pyruvate Dehydrogenase Complex Deficiency

The PDH complex converts pyruvate, which is derived from the catabolism of glucose, to acetyl-CoA, which enters the TCA cycle at citrate synthase. Severe PDH deficiency may manifest in the neonatal period with profound lactic acidosis and a low to normal lactate-to-pyruvate ratio (<20). Patients may have moderately elevated plasma ammonia and congenital brain anomalies including an absent or underdeveloped corpus callosum and heterotopias. Patients are hypotonic and may require mechanical ventilation. Prognosis is poor, even with early recognition and intervention. Importantly, the high concentration dextrose-containing IV and enteral empiric therapy that may be life-saving for a child with a possible organic aciduria or urea cycle defect exacerbates the lactic acidosis in the neonate with PDH deficiency or other mitochondrial energy metabolism disorders. This worsening may suggest a primary energy metabolism disorder in the neonate. A possible diagnosis of PDH deficiency is inferred from the patient presentation, the clinical course, and the results of routine and specialized biochemical laboratory testing. Alanine will be elevated on plasma amino acid analysis, and TCA cycle intermediates may be elevated in the urine organic acid analysis. There is no specific diagnostic compound that identifies this disorder. The diagnosis is made through abnormal enzyme analysis in skin fibroblasts or white blood cells and/or by DNA testing. PDH is a large, multisubunit complex. It contains three enzymatic subunits and several regulatory subunits, including a phosphatase and a kinase. The first enzymatic step is a decarboxylation reaction catalyzed by a heterodimeric system consisting of the E1-α subunit and E1-β. The majority of individuals have a mutation in the *PDHA1* gene, which encodes the E1-α subunit of the PDH enzyme complex. This is an X-linked gene and this causes an X-linked dominant condition. Disorders associated with defects in all other subunits are autosomal recessive. Mutations in *PDHA1* account for 80% of cases of PDH deficiency.[135]

The majority of patients are indolent on clinical presentation with developmental delay and an MRI indicative of Leigh disease. This group of patients often responds well biochemically to a high-fat and low-carbohydrate, or ketogenic, diet. Fat, as acetyl-CoA, enters the energy pathway after the block, whereas glucose must traverse the defective PDH enzymatic reaction to provide energy.

Defects of the PDH complex due to defects in the two other enzyme subunits, the activating and deactivating enzymes and a structural protein that binds one subunit (E3 binding protein), are rarer. These usually result in chronic psychomotor retardation syndrome in late infancy and childhood. Deficiency of the E3 subunit of the PDH complex has pleiotropic biochemical effects because the subunit is a component of two other dehydrogenase complexes: the BCKAD complex and the α-ketoglutarate dehydrogenase complex of the TCA cycle. Therefore, these patients may have elevated BCAAs as in MSUD, which is due to BCKAD deficiency, as well as elevated TCA cycle metabolites because of α-ketoglutarate dehydrogenase complex deficiency. Most patients with E3 deficiency present after the newborn period and have progressive neurodegenerative disease. The key laboratory findings are the elevation of lactic acid in blood with elevated pyruvate and a low lactate-to-pyruvate ratio, elevated BCAAs on plasma amino acid analysis, and detection of α-ketoglutarate and BCAA metabolites in urine organic acid analysis. PDH phosphatase deficiency is a rare cause of CLA. Apart from E3 deficiency, defects in the PDH complex are responsive to the ketogenic diet.

In addition to E3 deficiency there is another class of defects that affects PDH and other enzyme complexes, including BCKAD and α-ketoglutarate dehydrogenase complex, because of the requirement for lipoate in these and the complex synthesis of lipoate. Defects in eight genes encoding proteins required for lipoate synthesis have been reported, and these may present as CLA. Symptoms are variable and may be characteristic of the specific genetic defect. In an early-onset presentation, symptoms can include seizures, encephalopathy, and cardiomyopathy.[136]

Pyruvate Carboxylase Deficiency

Pyruvate carboxylase (PC) is involved in gluconeogenesis. The enzyme adds bicarbonate to pyruvate to form oxaloacetate, a compound also involved in replenishing intermediates of the TCA cycle. PC is one of the four biotin requiring carboxylases. There are three main types of PC deficiency. Type A is characterized by lactic acidosis in the newborn period and delayed development, and the disease has a chronic course. Type B is the catastrophic form of the disorder. In type B, the neonate is acutely ill in the first week of life, is encephalopathic, and develops severe metabolic acidosis with lactic acidosis and hyperammonemia. The mortality rate from the type B form of PC deficiency is high. Type C is considered intermittent and benign.[137]

Most patients with the type B form of PC deficiency have been of French or English background. The blood lactate-to-pyruvate ratio is normal in type A as both lactate and pyruvate are comparably elevated, while patients with type B often have an elevated lactate-to-pyruvate ratio. Because oxaloacetate produces aspartate, which then combines with citrulline to create argininosuccinate through the urea cycle, PC deficiency leads to elevations of plasma citrulline and plasma ammonia. Although PC is an important enzyme in gluconeogenesis, hypoglycemia is not common. The liver may be enlarged. Prognosis is poor. Enzyme testing may be performed in white blood cells or fibroblasts. DNA mutational analysis may also be performed for diagnosis.

Electron Transport Chain Defects

Oxidative phosphorylation results in the generation of ATP and is the central process performed by mitochondria. Genetic defects

affecting the tightly coupled and regulated process of ATP generation may have profound effects on one or more organ systems. Derivatives of nutrients such as pyruvate and fatty acids are converted to carbon dioxide in mitochondria. The energy derived from this is harnessed by allowing the reducing equivalents (as NADH or $FADH_2$, which are derived from such metabolism) to combine with oxygen to form water and, in the process the synthesis of ATP is coupled to the flow of electrons down the ETC.

The important components in the mitochondrial respiratory chain are complex I (NADH dehydrogenase), complex II (succinate dehydrogenase), complex III (cytochromes *b*, c_1), and the terminal complex in this chain, complex IV (cytochrome *c* oxidase). In addition, there is a complex V (ATP synthetase), and an adenine nucleotide translocase that permit transport of adenosine diphosphate into, and ATP out of, the mitochondria. Complex II is involved primarily in fatty acid oxidation and oxidation of succinate derived from the TCA cycle, because the reducing equivalents extracted from fatty acids, glutaric acid, and succinate flow from ETF into complex II. Early understanding of the molecular mechanisms that produce ETC disturbances concerned those attributed to mutations of mitochondrial DNA (mtDNA—a small circular DNA molecule located within the mitochondria) genes, although multiple disorders that effect the ETC caused by nuclear (chromosomal) encoded genes have been identified through DNA sequencing. The mtDNA encodes at least one protein subunit of each respiratory chain complex—except for complex II. It also encodes components of the mitochondrial translational machinery required for mitochondrial protein synthesis (rRNA and tRNA). CLA caused by defects in ETC components can be due to either nuclear or mtDNA encoded subunits. This is important for genetic counseling of families of affected children, as mitochondrial DNA is maternally inherited. In addition to defects of the structural components of a respiratory chain complex, ETC deficiency can be due to defects in genes encoding proteins responsible for the assembly of the protein subunits into functional complexes. Nuclear DNA encodes these assembly proteins, and, taken together, defects in more than 1000 nuclear and mitochondrially encoded genes can result in ETC deficiency.[138]

The relationship between phenotype and a specific mtDNA mutation is not straightforward, due, at least in part, to heteroplasmy (the proportion of mutant and nonmutant mtDNA molecules within each cell, each of which contain many mitochondria that also each contain multiple copies of mtDNA). Mitochondria and the mtDNA are inherited solely from the mother. Random segregation of mitochondria—having greater or fewer mutant mtDNA molecules as oocytes are formed—can lead to a "bottleneck effect" in which the fetus has a higher concentration of cells with mutant mtDNA than the mother, who may have little or no mutant mtDNA detectable in blood. Often there is a different proportion of defective mitochondria in different cells and different tissues, and, crucially, there is a tissue-specific "threshold effect"; that is, a certain proportion of mutant mtDNA molecules must be present to have clinical consequences in a given tissue.[138,139]

The disorders caused by nuclear DNA gene mutations are most often autosomal recessive, and they comprise the majority of ETC disease presenting in neonates and infants, with a minority resulting from mtDNA gene mutations with a maternal inheritance pattern in this age group. With the exception of *n*eurogenic muscle weakness, *a*taxia, and *r*etinitis *p*igmentosa (NARP, caused by a mutation at position 8993 of the mtDNA), only a minority of diseases caused by mtDNA mutations manifest in the newborn period.[140] Other examples of syndromes caused by mtDNA mutations are MELAS (*m*itochondrial *e*ncephalopathy, *l*actic *a*cidosis, and *s*troke-like episodes, mtDNA position 3243) and MERRF (*m*yoclonic *e*pilepsy with *r*agged-*r*ed *f*ibers, position 8344) syndromes, Leber hereditary optic neuropathy,[139] and sporadic deletion–duplication syndromes such as Pearson marrow–pancreas syndrome.[141] Important mitochondrial energy metabolism disorders that affect infants include CLA, the most dramatic form, with presentation often in the first few days of life during which there is marked lactic acidosis[142,143]; subacute necrotizing encephalomyopathy or Leigh disease that classically presents at later than 3 months of age but can present earlier; Alpers disease presenting with seizures and liver disease; benign infantile mitochondrial myopathy, cardiomyopathy, or both; lethal infantile mitochondrial disease; lethal infantile cardiomyopathy; and Pearson syndrome. The hallmarks of mitochondrial disease are often multisystem involvement and lactic acidosis, but involvement of only one organ system and the absence of lactic acidosis do not exclude mitochondrial disease.

Important classes of mitochondrial disorders include nuclear encoded mtDNA depletion syndromes resulting from defects in mtDNA replication component proteins or in the availability of nucleotides for DNA replication, which may include fatal hepatopathy.[144,145] Another class is the defects in lipoate synthesis, including those of iron–sulfur protein synthesis.[136] A potentially treatable class is that of coenzyme Q10 biosynthesis diagnosed by DNA testing of nuclear genes or by coenzyme Q10 levels in muscle. This includes a severe infantile multisystem disease, and it is important to identify these defects as they are one of the few classes of mitochondrial disorders in which administration of coenzyme Q10 may be effective.[146]

The diagnostic tests for electron transport chain defects include standard measurements of plasma lactate and pyruvate and analysis of urine organic and plasma amino acids. CSF lactate may be measured by lumbar puncture and by magnetic resonance spectroscopy during MRI. The current availability of mtDNA sequencing panels and whole exome sequencing with full sequencing of the mitochondrial genome has decreased the use of muscle biopsy. However, histologic analysis of muscle tissue by light and electron microscopy and mitochondrial respiratory chain complex assay on either fresh (preferred, but infrequently available) or flash-frozen tissue may be of aid in diagnosis. In many cases however, DNA sequencing has replaced muscle biopsy as a first-line test for suspected mitochondrial disease.[138] In fatal cases, rapid (metabolic) autopsy and proper preservation of tissue specimens are essential if functional assays are to be performed. DNA testing can also be performed on tissues.

Leigh Disease: Subacute Necrotizing Encephalomyelopathy

Leigh disease is a progressive neurodegenerative disorder with severe hypotonia, seizures, extrapyramidal movement disorder, optic atrophy, and defects in automatic ventilation or respiratory control.[147] Generally, disease onset is outside of the neonatal period, but symptoms may be evident in the first months of life. There are more than 75 genetic defects associated with Leigh disease.[148] These include defects in the PDH complex, ETC structural proteins, assembly factors of individual ETC complexes, coenzyme Q10 biosynthesis, biotinidase, and others. MRI

characteristically shows bilateral symmetrical T2-weighted hyperintense lesions in the basal ganglia. One disorder with features of Leigh disease is biotin–thiamine-responsive basal ganglia disease caused by *SLC19A3* deficiency, and empiric biotin and thiamine should be trialed.[147]

Clinical findings in infants with Leigh disease include optic atrophy, ophthalmoplegia, nystagmus, respiratory abnormalities, ataxia, hypotonia, spasticity, seizures, developmental delay, psychomotor retardation, myopathy, and renal tubular dysfunction. Some patients may manifest hypertrophic cardiomyopathy, liver dysfunction, and microcephaly. The neuropathologic lesions include demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain lesions.

Pearson Syndrome

One class of mitochondrial disorders that is genetic but not familial is caused by a spontaneous mtDNA deletion or duplication. The disorders include Kearns–Sayre syndrome and chronic progressive external ophthalmoplegia, which manifest in older individuals. The manifestation in early infancy is Pearson syndrome. This disorder manifests with anemia, ringed sideroblasts, and exocrine pancreatic dysfunction. This disease of the bone marrow can lead to death in infancy. However, patients able to recover or who benefit from aggressive therapy may demonstrate other signs of this systemic disorder in late infancy or childhood, such as poor growth, pancreas dysfunction, mitochondrial myopathy, lactic acidosis, and progressive neurologic damage, and develop Kearns–Sayre syndrome.[149]

Barth Syndrome

Barth syndrome is an X-linked disorder associated with cardiomyopathy, skeletal muscle disease, and neutropenia.[150] Skeletal muscle shows abnormal mitochondrial morphology and deficiencies of respiratory chain complexes III and IV. The *TAZ* gene encodes tafazzin, a cardiolipin acyltransferase. Deficiency of this leads to disruption of the inner mitochondrial membrane and disruption of ETC function. The accumulation of NADH and $FADH_2$ inhibit the TCA cycle, causing lactic acidosis, the development of muscle weakness, and cardiomyopathy. Urine organic acid analysis demonstrates increased urinary excretion of 3-methylglutaconic acid. Barth syndrome is also known as *3-methylglutaconic aciduria type II* and is genetically distinct from primary 3-methylglutaconic aciduria type I, caused by mutations in *AUH* involved in leucine metabolism, and other forms of 3-methylglutaconic aciduria.[151] Patients must be supported from birth to early infancy as acute neonatal presentations may have lactic acidosis, hypoglycemia, hyperammonemia, and liver dysfunction. Fetal loss and stillbirth have also been reported. Treatment includes standard support for heart failure and neutropenia as well as nutrition support and physical therapy.[150]

Early Lethal Lactic Acidosis

In some patients with primary disturbances of mitochondrial ETC, massive lactic acidosis develops within 24 to 72 hours of birth. Commonly the condition is untreatable, because it is relentless and unresponsive to buffer therapy.[152] Dialysis may be helpful but is not a cure and is not feasible in all patients. Often, affected infants have no obvious organ damage early in the course or evidence of malformations. In addition, acidemia per se can easily cause the coma or impaired cardiac contractility that may be encountered. Some infants have survived with aggressive therapy, and specific treatments can include thiamine, biotin, riboflavin, coenzyme Q10, or carnitine.[152] Overall prognosis is likely poor, and the care of neonates with severe lactic acidosis is difficult as the prognosis is unclear. Decisions regarding management must be individualized, because the mitochondrial dysfunction and resultant pathophysiology can vary among infants, and expedited nuclear and mitochondrial DNA testing, to facilitate diagnosis and therefore guide prognosis, should be considered.

Lysosomal Storage Disorders Presenting in the Neonate

IRENE J. CHANG, ANGELA SUN, AND GERARD T. BERRY

KEY POINTS

- Lysosomal storage diseases are a genetically and phenotypically heterogeneous group of metabolic disorders caused by multisystemic accumulation of complex substrates.
- Clinical manifestations of lysosomal storage diseases in the neonatal period are myriad, including nonimmune hydrops fetalis, respiratory distress, sepsis, macular cherry-red spot, dysmorphic facial features, dysostosis multiplex, and hepatosplenomegaly.
- Newborn screening for certain lysosomal storage diseases such as mucopolysaccharidosis type I and Pompe disease is included on the Recommended Uniform Screening Panel and has been implemented in most states.
- Growing recognition of neonatal symptoms and improved analytic methods has led to early diagnosis and treatment of lysosomal storage diseases in the newborn period.
- Treatment options for lysosomal storage diseases are advancing rapidly, including enzyme replacement therapy, substrate reduction therapy, and hematopoietic stem cell transplantation. Gene therapy trials are ongoing.

Introduction

Lysosomes are single membrane–bound intracellular organelles that contain enzymes called hydrolases. These lysosomal enzymes are responsible for splitting large molecules into simple, low-molecular-weight compounds, which can be recycled. The endogenous materials digested by lysosomes are derived from endocytosis and phagocytosis, and separated from other intracellular materials and delivered to lysosomes through the process of autophagy.

Lysosomal storage diseases (LSDs) are a genetically and phenotypically diverse group of metabolic disorders caused by enzyme deficiencies that result in the pathologic accumulation of complex substrates within lysosomes throughout various tissues in the body.[1] LSDs are classified according to the stored compound. The common element of all compounds digested by lysosomal enzymes is a carbohydrate portion attached to a protein or lipid. These glycoconjugates include glycolipids, glycoproteins, and glycosaminoglycans (GAGs).

Glycolipids are large molecules with carbohydrates attached to a lipid moiety. Sphingolipids, globosides, gangliosides, cerebrosides, and lipid sulfates all are glycolipids. The different classes of glycolipids are distinguished from one another primarily by different polar groups at C-1. Sphingolipids are complex membrane lipids composed of one molecule of each of the amino alcohol sphingosine, a long-chain fatty acid, and various polar head groups attached by a β-glycosidic linkage. Sphingolipids occur in the blood and nearly all tissues of the body, the highest concentration being found in white matter of the central nervous system (CNS). In addition, various sphingolipids are components of the plasma membrane of practically all cells. The core structure of natural sphingolipids is ceramide, a long-chain fatty acid amide derivative of sphingosine. Free ceramide, an intermediate in the biosynthesis and catabolism of glycosphingolipids and sphingomyelin, composes 16% to 20% of normal lipid content of stratum corneum of the skin. Sphingomyelin, a ceramide phosphocholine, is one of the principal structural lipids of membranes of nervous tissue.

Cerebrosides are a group of ceramide monohexosides with a single sugar, either glucose or galactose, and an additional sulfate group on galactose. The two most common cerebrosides are galactocerebroside and glucocerebroside. The largest concentration of galactocerebroside is found in the brain. Glucocerebroside is an intermediate in the synthesis and degradation of more complex glycosphingolipids. Gangliosides, the most complex class of glycolipids, contain several sugar units and one or more sialic acid residues. Gangliosides are normal components of cell membranes and are found in high concentrations in ganglion cells of the CNS, particularly in nerve endings and dendrites. GM1 is the major ganglioside in the brain of vertebrates.

GAGs, also called mucopolysaccharides, are complex heterosaccharides consisting of long sugar chains rich in sulfate groups. The polymeric chains are bound to specific proteins (core proteins). Glycoproteins contain oligosaccharide chains (long sugar molecules) attached covalently to a peptide core. Glycosylation occurs in the endoplasmic reticulum and Golgi apparatus. Most glycoproteins are secreted from cells and include transport proteins, glycoprotein hormones, complement factors, enzymes, and enzyme inhibitors. There is extensive diversity in the composition and structure of oligosaccharides.

The degradation of glycolipids, GAGs, and glycoproteins occurs within lysosomes of phagocytic cells, related to histiocytes and macrophages, in any tissue or organ. A series of hydrolytic enzymes cleaves specific bonds, resulting in stepwise removal of constituents such as sugars and sulfate as well as degrading

complex glycoconjugates to their basic building blocks. LSDs most commonly result when an inherited defect causes significantly decreased activity in one of these hydrolases.

Our understanding of the pathogenesis of LSDs continues to evolve. In addition to catabolic enzyme deficiencies, abnormal autophagy, aberrant vesicular trafficking, cellular signaling, and homeostasis have also been implicated in the multifaceted pathomechanism of LSDs.[2–4] Regardless of etiology, incompletely metabolized molecules accumulate, especially within the tissue responsible for catabolism of the glycoconjugate. Excess storage material may be excreted in urine.

While individually rare, there are over 70 different LSDs, with a collective incidence of approximately 1 in 5000 live births. Approximately 20 of these LSDs may present in the newborn period, of which 14 are reviewed in this chapter.[5]

The neonatal clinical presentation of LSDs includes nonimmune hydrops fetalis, respiratory distress, seizures, cherry-red spot in the macula, dysmorphic facial features, sepsis, dysostosis multiplex, and/or hepatosplenomegaly. However, symptoms may be nonspecific and physical findings such as skeletal abnormalities may not be apparent in the neonatal period. Diagnosis is typically confirmed with enzyme assay in conjunction with molecular testing.

Clinical Presentations

Table 30.1 summarizes the clinical characteristics of the neonatal presentations of LSDs.

Acid Sphingomyelinase Deficiency (Niemann–Pick Disease Types A and B)

Etiology

Acid sphingomyelinase deficiency (ASMD; also known as Niemann-Pick disease types A and B [NPD-A and NPD-B]) is caused by deficiency of the enzyme sphingomyelinase. Historically, ASMD was grouped with Niemann-Pick disease type C (NPC) due to similar pathology findings of accumulated foamy sea-blue histiocytes,[6] but they are now understood to be genetically distinct disorders. Sphingomyelinase normally catalyzes the breakdown of sphingomyelin to form ceramide and phosphocholine. Sphingomyelinase deficiency results in the pathologic accumulation of sphingomyelin within lysosomes particularly in the nervous system, spleen, liver, and lungs. Cholesterol is also stored, suggesting that its metabolism is tied to that of sphingomyelin. Sphingomyelin normally composes 5% to 20% of phospholipids in the liver, spleen, and brain, but in ASMD it can compose up to 70% of phospholipids. Patients with severe ASMD usually have less than 5% of normal enzyme activity.

Clinical Features

ASMD was historically classified into NPD-A and NPD-B based on severity, clinical manifestations, and age of onset. NPD-A presents as severe, infantile-onset neurovisceral disease, whereas NPD-B presents later in childhood. Patients with NPD-A typically present with massive hepatosplenomegaly by 3 months of age.[7,8] Other clinical features include constipation, feeding difficulties, and vomiting, with consequent failure to thrive, and respiratory failure. Patients eventually appear strikingly emaciated with a protuberant abdomen and thin extremities. Neurologic disease is evident by 6 months of age, with hypotonia, decrease or absence of deep tendon reflexes, and weakness. Loss of motor skills, spasticity, rigidity, irritability, and loss of vision and hearing occur later. Seizures are rare. A macular cherry-red spot is present in about half of cases, and the electroretinographic findings are abnormal. Respiratory infections are common. The skin may have an ochre or brownish-yellow color, and xanthomas have been observed. Radiographic findings consist of widening of medullary cavities, cortical thinning of long bones, and osteoporosis. In the brain and spinal cord, neuronal accumulation of sphingomyelin is widespread, leading to cytoplasmic swelling together with atrophy of cerebellum. Bone marrow and tissue biopsy samples may show foam cells or sea-blue histiocytes, which represent lipid-laden cells of the monocyte–macrophage system. Similarly, vacuolated lymphocytes or monocytes may be present in peripheral blood. Tissue cholesterol levels may be threefold to tenfold that of normal, and patients may have a microcytic anemia and thrombocytopenia. Death occurs by 2 to 3 years of age after a rapid neurodegenerative course.

Niemann-Pick Disease Type C

Etiology

NPC is caused by a defect in the intracellular transport of exogenous low-density lipoprotein (LDL)-derived cholesterol, which leads to impaired esterification of cholesterol and trapping of unesterified cholesterol in lysosomes.[9,10] The incidence is roughly 1 in 100,000 births.[11] NPC is caused by a defect of either the NPC1 or NPC2 protein. The latter binds cholesterol liberated by acid lipase and shuttles it to NPC1, which facilitates egress of cholesterol from late endosomes/lysosomes to the endoplasmic reticulum. There is secondary storage of sphingomyelin. Sphingomyelinase activity appears normal or elevated in most tissues but is partially deficient in fibroblasts from most patients with this disorder. Storage of sphingomyelin in tissues is much less than in ASMD and is accompanied by additional storage of unesterified cholesterol, phospholipids, and glycolipids in the liver and spleen. Only glycolipids levels are increased in the brain.

Clinical Features

The age of onset, clinical features, and natural history of NPC are highly variable. Onset can occur from birth to adulthood. Findings on prenatal ultrasound include fetal ascites or hydrops, hepatosplenomegaly, intrauterine growth restriction, and oligohydramnios or polyhydramnios.[12] In the neonatal period, 50% of infants have conjugated hyperbilirubinemia, which usually resolves spontaneously. Liver failure, sometimes misdiagnosed as fetal hepatitis, and respiratory failure can occur, with neurologic symptoms appearing later in childhood in those who survive. In the severe infantile form, hepatosplenomegaly is common and often present at birth, accompanied by hypotonia and delayed motor development. Further neurologic regression is usually evident by the age of 1 to 1.5 years, in association with vertical supranuclear ophthalmoplegia, progressive ataxia, dystonia, spasticity, drooling, dysphagia, and dysarthria. Seizures are rare. Foam cells and sea-blue histiocytes may be found in many tissues. Neuronal accumulation of glycolipids with cytoplasmic ballooning, inclusions, meganeurites, and axonal spheroids is also seen. The average survival is 5 years or less. Patients with mutations in the *NPC2* gene have pronounced pulmonary involvement as accumulation of cholesterol in alveolar macrophages leads to abnormal surfactant composition, resulting in early death due to respiratory failure.[13]

TABLE 30.1 Lysosomal Storage Disorders in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation

Disorder	Onset	Facies	Neurologic Findings	Distinctive Features	Eye Findings	Cardiovascular Findings	Dysostosis Multiplex	Hepatomegaly/ Splenomegaly	Defect	Gene Location/ Molecular Findings	Ethnic Predilection
Acid sphingomyelinase deficiency (Niemann–Pick disease type A)	Early infancy	Frontal bossing	Difficulty feeding, apathy, deafness, blindness, hypotonia	Brownish-yellow skin, xanthomas	Cherry-red spot (50%)	—	—	++/+	Sphingomyelinase deficiency	*SMPD1* gene at 11p15.4; three of 18 mutations account for approximately 92% of mutant alleles in the Ashkenazi population	1:40,000 in Ashkenazi Jews with carrier frequency of 1:60
Niemann–Pick C disease	Birth–3 months	Normal	Developmental delay, vertical gaze paralysis, hypotonia, later spasticity	—	—	—	—	+/++	Abnormal cholesterol esterification	*NPC1* gene at 18q11 accounts for >95% of cases; *HE1* gene mutations may account for remaining cases	Increased in French Canadians of Nova Scotia and Spanish Americans in the southwest United States
Gaucher disease type 2	In utero–6 months	Normal	Poor suck and swallow, weak cry, squint, trismus, strabismus, opsoclonus, hypertonic, later flaccidity	Congenital ichthyosis, collodion skin	—	—	—	+/++	Glucocerebrosidase deficiency	1q21; large number of mutations known; five mutations account for approximately 97% of mutant alleles in the Ashkenazi population but approximately 75% in the non-Jewish population	Panethnic
Krabbe disease	3–6 months	Normal	Irritability, tonic spasms with light or noise stimulation, seizures, hypertonia, later flaccidity	Increased CSF protein level	Optic atrophy	—	—	–/–	Galactocerebrosidase deficiency	14q 24.3–q32.1; >60 mutations with some common mutations in specific populations	Increased in Scandinavian countries and in a large Druze kindred in Israel

GM1 gangliosidosis	Birth	Coarse	Poor suck, weak cry, lethargy, exaggerated startle, blindness, hypotonia, later spasticity	Gingival hypertrophy, edema, rashes	Cherry-red spot (50%)	—	+	+/+	β-Galactosidase deficiency	3pter–3p21; heterogeneous mutations; common mutations in specific populations	Panethnic
Mucopolysaccharidosis type I	Childhood	Variable coarseness	Mild to severe mental retardation	Gibbus deformity	Variable corneal clouding	Variable	++	Variable	α-L-iduronidase deficiency	*IDUA* gene at 4p16.3; heterogeneous mutations	Panethnic
Mucopolysaccharidosis type VII	In utero–childhood	Variable coarseness	Mild to severe mental retardation	Nonimmune fetal hydrops	Variable corneal clouding	Variable	++	Variable	β-Glucuronidase deficiency	*GUSB* gene at 7q21.2–q22; heterogeneous mutations	Panethnic
Wolman disease	First weeks of life	Normal	Mental deterioration	Vomiting, diarrhea, steatorrhea, abdominal distention, failure to thrive, anemia, adrenal calcifications	—	—	—	+/+	Lysosomal acid lipase deficiency	10q23.2–q23.3; variety of mutations identified	Increased in Iranian Jews and in non-Jewish and Arab populations of Galilee
Farber disease	Birth-infancy	Normal		Joint swelling with nodules, hoarseness	Normal macula, corneal opacities	—	—	++/++	Acid ceramidase deficiency	*ASAH1* gene at 8p21.3–p22	Panethnic
Congenital sialidosis	In utero–birth	Coarse, edema	Mental retardation, hypotonia	Neonatal ascites, inguinal hernias, renal disease	Corneal clouding	—	+	+/+	Neuraminidase (sialidase) deficiency	*NEU1* gene at 6p21	Panethnic

TABLE 30.1 Lysosomal Storage Disorders in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation—cont'd

Disorder	Onset	Facies	Neurologic Findings	Distinctive Features	Eye Findings	Cardiovascular Findings	Dysostosis Multiplex	Hepatomegaly/ Splenomegaly	Defect	Gene Location/ Molecular Findings	Ethnic Predilection
Galactosialidosis	In utero–birth	Coarse	Mental retardation, occasional deafness, hypotonia	Ascites, edema, inguinal hernias, renal disease, telangiectasias	Cherry-red spot, corneal clouding	Cardiomegaly progressing to failure	+	+/+	Absence of a protective protein that safeguards neuraminidase and β-galactosidase from premature degradation	*CTSA* gene at 20q13.12	Panethnic
Infantile sialic acid storage disease	In utero–birth	Coarse, dysmorphic	Mental retardation, hypotonia	Ascites, anemia, diarrhea, failure to thrive	—	Congestive heart failure	+	+/+	Defective transport of sialic acid out of the lysosome	*SLC17A5* gene at 6q13	Panethnic
I-cell disease	In utero–birth	Coarse	Mental retardation, deafness	Gingival hyperplasia, restricted joint mobility, hernias	Corneal clouding	Valvular disease, congestive heart failure, cor pulmonale	++	+++/+++	Lysosomal enzymes lack mannose 6-phosphate recognition marker and fail to enter the lysosome (phosphotransferase deficiency, 3-subunit complex [α2 β2 γ2])	Enzyme encoded by two genes; α and β subunits encoded by *GNPTAB* gene at 12p23.2; γ subunit encoded by *GNPTAG* gene at 16p13.3	Panethnic
Mucolipidosis type IV	Birth–3 months	Normal	Mental retardation, hypotonia	—	Severe corneal clouding, retinal degeneration, blindness	—	—	—/—	Unknown; some patients with partial deficiency of ganglioside sialidase	*MCOLN1* gene at 19p13.2–13.3 encoding mucolipin 1; two founder mutations accounting for 95% of mutant alleles in the Ashkenazi population	Increased in Ashkenazi Jews

—, Not seen; +, typically present, usually not severe; ++, usually present and moderately severe; +++, always present, usually severe; *CSF*, cerebrospinal fluid; *HSM*, hepatosplenomegaly.

Gaucher Disease Type 2 (Acute Neuronopathic)

Etiology

Gaucher disease is caused by deficiency of lysosomal glucocerebrosidase and results in storage of glucocerebroside in mononuclear phagocytes. Glucocerebrosidase splits glucose from cerebroside, yielding ceramide and glucose. Three types of Gaucher disease have been defined. Type 1, the non-neuronopathic form, is the most common and is distinguished from types 2 and 3 by the lack of CNS involvement. Type 1 disease most commonly manifests itself in early childhood but may do so in adulthood. Type 2 disease, the acute neuronopathic form, is the rarest form and is characterized by infantile onset of severe CNS involvement. Type 3 disease, the subacute neuronopathic form, presents in childhood with slower neurologic progression. Although there is significant variability in clinical presentation among individuals with the same mutations in *GBA*, there are some correlations between certain mutations and clinical symptoms involving the CNS.[14] A few patients with Gaucher disease type 2 have a deficiency of saposin C, a cohydrolase required by glucocerebrosidase.

Clinical Features

The age of onset of Gaucher disease type 2 is approximately 3 months. Clinical features include early hepatosplenomegaly (splenomegaly predominates) with later neurologic deterioration including bulbar signs, hyperextension of the neck, spasticity, and horizontal gaze palsy. Hydrops fetalis, congenital ichthyosis, and collodion skin are well-described presentations.[5] In a review of 18 cases of Gaucher disease manifesting in the newborn period, Sidransky et al. found that eight patients had associated dermatologic findings, and six patients had hydrops.[15] The cause of the association of such findings in Gaucher disease is unclear, although the enzyme deficiency appears to be directly responsible. Ceramides have been shown to be major components of intracellular bilayers in epidermal stratum corneum, and they have an important role in skin homeostasis.[16] Therefore Gaucher disease should be considered in the differential diagnosis for infants with hydrops fetalis and congenital ichthyosis. For the subset of patients who present in the prenatal period or at birth, death commonly occurs within 2 to 3 months. In other infants, splenomegaly, cachexia, and chronic pulmonary disease are progressive, and death follows within 2 years.

Krabbe Disease (Globoid Cell Leukodystrophy)

Etiology

The synonym for Krabbe disease, globoid cell leukodystrophy, is derived from the finding of large numbers of multinuclear macrophages in cerebral white matter that contain undigested galactocerebroside. Krabbe disease is caused by a deficiency of lysosomal galactocerebroside β-galactosidase, which degrades galactocerebroside to ceramide and galactose, resulting in storage of galactocerebroside. Galactocerebroside is present almost exclusively in myelin sheaths. Accumulation of the toxic metabolite psychosine, another substrate for the enzyme, leads to early destruction of oligodendroglia. Impaired catabolism of galactosylceramide is also important in the pathogenesis of the disease. Saposin A is an activator protein that aids the galactocerebroside β-galactosidase enzyme. Saposin A deficiency presents with a Krabbe-like phenotype.

Clinical Features

The age of onset ranges from the first weeks of life to adulthood. The typical age of onset of infantile Krabbe disease is between 3 and 6 months, but there are cases in which neurologic symptoms are evident within weeks after birth. Signs and symptoms are confined to the nervous system; no visceral involvement is present. The clinical course has been divided into three stages. In stage I, patients who appeared relatively normal after birth begin to exhibit hyperirritability, vomiting, episodic fevers, hyperesthesia, tonic spasms with light or noise stimulation, stiffness, and seizures. Peripheral neuropathy is present, but reflexes are increased. Stage II is marked by CNS deterioration and hypertonia that progresses to hypotonia and flaccidity. Deep tendon reflexes are eventually lost. Patients with stage III disease are decerebrate, deaf, and blind with hyperpyrexia, hypersalivation, and frequent seizures. Routine laboratory findings are unremarkable except for an elevation of the level of cerebrospinal fluid protein. Cerebral atrophy and demyelination become evident in the CNS, and segmental demyelination, axonal degeneration, fibrosis, and macrophage infiltration are common in the peripheral nervous system. The segmental demyelination of peripheral nerves is demonstrated by the finding of decreased motor nerve conduction. The white matter is severely depleted of all lipids, especially glycolipids, and nerve and brain biopsies show globoid cells. Death from hyperpyrexia, respiratory complications, or aspiration occurs at a median age of 13 months.

GM1 Gangliosidosis

Etiology

Infantile GM1 gangliosidosis is caused by a deficiency of lysosomal β-galactosidase. The enzyme cleaves the terminal galactose in a β linkage from oligosaccharides, keratan sulfate, and GM1 ganglioside. Deficiency of the enzyme results in storage of GM1 ganglioside and oligosaccharides. Clinical severity correlates with the extent of residual enzyme activity and substrate storage. The same enzyme is deficient in mucopolysaccharidosis (MPS) type IVB, but in MPS-type IVB the breakdown of keratan sulfate is primarily affected.

Clinical Features

The age of onset ranges from prenatal to adult. Infantile or type 1 GM1 gangliosidosis may be evident at birth as coarse and thick skin, hirsutism on the forehead and neck, and coarse facial features consisting of a puffy face, frontal bossing, depressed nasal bridge, maxillary hyperplasia, large and low-set ears, macroglossia, and gingival hypertrophy. These dysmorphic features, however, are not always obvious in the neonate. A retinal cherry-red spot is seen in 50% of patients, and corneal clouding is often observed. Shortly after birth, or by 3 to 6 months of age, failure to thrive and hepatosplenomegaly become evident, as does neurologic involvement with developmental delay, hyperreflexia, hypotonia, and seizures. Cardiomyopathy can develop in the first few months of life. Cranial imaging shows diffuse atrophy of the brain, enlargement of the ventricular system, and evidence of myelin loss in white matter. The neurologic deterioration is progressive, resulting in generalized spasticity, vision impairment, hypersensitive startle response, and psychomotor regression. By 6 months of age, skeletal features are present, including kyphoscoliosis, stiff joints with generalized contractures, and striking bone changes including vertebral beaking in the thoracolumbar region, broadening of

shafts of the long bones with distal and proximal tapering, and widening of the metacarpal shafts with proximal pinching of four lateral metacarpals. Tissue biopsy samples demonstrate neurons filled with membranous cytoplasmic bodies and various types of inclusions as well as foam cells in the bone marrow. Death generally occurs before 2 years of age.

Mucopolysaccharidosis Type I

Etiology

Mucopolysaccharidosis (MPS) type I, also known as Hurler syndrome, is caused by deficiency of the enzyme alpha-L-iduronidase, which results in accumulation of dermatan and heparan sulfate in various organs including the brain, eye, heart, liver, spleen, and bone. The alpha-L-iduronidase enzyme is encoded by the *IDUA* gene. Pathogenic variants that critically disrupt the protein result in severe clinical disease, whereas milder variants give rise to an attenuated phenotype.[17] The incidence is 1 in 100,000 births.[18]

Clinical Features

Infants with MPS type I appear normal at birth. However, this condition was added to the Recommended Uniform Screening Panel for newborn screening in 2016, so the diagnosis is now made shortly after birth when the infant is presymptomatic. Therefore, the neonatologist must be prepared to counsel families appropriately and work with a metabolic specialist to manage the newborn's care. As with other LSDs, a spectrum of clinical severity exists in MPS type I. In infants with severe disease, developmental delay is evident in the first 6 to 12 months of life. Respiratory tract infections are common. A gibbus deformity (kyphosis in the mid-back region) may be an early sign of severe disease. With time, signs of storage emerge including coarse facial features, hepatosplenomegaly, upper airway obstruction, short stature, and specific skeletal changes termed dysostosis multiplex. Ultimately, neurologic regression occurs, leading to early death, although treatment can extend lifespan. In the mildest form of MPS type I, cognition and lifespan can be normal, although somatic manifestations can lead to significant morbidity.

Mucopolysaccharidosis Type VII (Sly Disease)

Etiology

Sly disease is a member of a group of LSDs called MPSs that are caused by deficiencies of enzymes catalyzing the stepwise degradation of complex sugar molecules called GAGs. There is a wide spectrum of clinical severity and variable skeletal and neurologic involvement among the MPSs, even within a single enzyme deficiency. Most of these disorders manifest in childhood, but type VII is included in this chapter because of its well-recognized neonatal and infantile presentations. Sly disease is caused by β-glucuronidase deficiency and results in lysosomal accumulation of GAGs, including dermatan sulfate, heparan sulfate, and chondroitin sulfate, causing cell, tissue, and organ dysfunction.

Clinical Features

Sly disease has a wide spectrum of severity. One unique and distinguishing symptom in up to 41% of patients with the neonatal form of disease is nonimmune fetal hydrops.[19] Other clinical features in infantile-onset disease may include coarse facies, hepatosplenomegaly, moderate dysostosis multiplex, hernias, cardiac valvular disease and cardiomyopathy, pulmonary insufficiency, and cognitive impairment. Corneal clouding is variably present. Frequent episodes of pneumonia during the first year of life are common. Short stature becomes evident. Causes of death include cardiopulmonary and renal failure. There are also milder forms of the disease with later onset.

Wolman Disease

Etiology

Wolman disease is caused by deficiency of lysosomal acid lipase, which is an enzyme involved in cellular cholesterol homeostasis and responsible for hydrolysis of cholesterol esters and triglycerides. Lysosomal acid lipase deficiency causes defective release of free cholesterol from lysosomes, leading to upregulation of endogenous LDL and cholesterol synthesis and further deposition of lipids in lysosomes. As a result, nonhydrolyzed cholesterol esters and triglycerides accumulate in most tissues of the body, including the liver, spleen, lymph nodes, heart, blood vessels, and brain. An extreme level of lipid accumulation occurs in cells of the small intestine, particularly in the mucosa. In addition, neurons of the myenteric plexus demonstrate a high level of lipid accumulation, with evidence of neuronal cell death, which may account for the prominence of gastrointestinal (GI) symptoms.[20]

Clinical Features

Clinical presentation of Wolman disease is within weeks of birth, with evidence of malnutrition and malabsorption, including symptoms of vomiting, diarrhea, steatorrhea, faltering growth, abdominal distention, and hepatosplenomegaly. Adrenal calcifications may be seen on radiographs, and adrenal insufficiency occurs. The presence of adrenal calcifications in association with hepatosplenomegaly and GI symptoms is strongly suggestive of Wolman disease. Later, mental deterioration becomes apparent. Laboratory findings include anemia secondary to foam cell infiltration of the bone marrow and evidence of adrenal insufficiency. The serum cholesterol level is normal. Death usually occurs before 1 year of age.

Farber Lipogranulomatosis

Etiology

Farber lipogranulomatosis results from a deficiency of lysosomal acid ceramidase. Ceramidase catalyzes the degradation of ceramide into its long-chain base, sphingosine, and a fatty acid. Clinical disease is a consequence of storage of ceramide and other glycolipids, particularly gangliosides, in various organs and body fluids. In severely affected cases, ceramide content of subcutaneous nodules, liver, kidney, and brain can be quite high. Mildly affected cases may have normal levels. In all types of Farber lipogranulomatosis, tissue biopsy samples show granulomatous infiltration, foam cells, and lysosomes with comma-shaped, curvilinear tubular structures called *Farber bodies*.

Clinical Features

Farber lipogranulomatosis is classified into five types based on age of onset, severity, and systems affected, but the disease is now understood to lie along a phenotypic continuum.[21,22] Types 1 and 4 present in the neonatal period. Type 1, classic disease, presents in the first weeks of life with the clinical triad of painful, progressive joint swelling and deformity, palpable subcutaneous nodules at pressure points and over joints, and hoarse cry developing into aphonia from granulomas of the larynx and epiglottis.

Patients also exhibit feeding and respiratory difficulties, poor weight gain, and intermittent fever caused by granuloma formation and swelling.[21,23] Later, joint contractures and pulmonary disease appear. Liver and cardiac involvement can occur, and patients can have a subtle macular cherry-red spot. Severe and progressive psychomotor impairment can occur, as can seizures, decreased deep tendon reflexes, hypotonia, and muscle atrophy. Affected patients die in early infancy prior to 2 years of age, usually of infiltrative pulmonary disease. Cerebrospinal fluid protein level may be elevated in patients with type 1 disease. Type 4, neonatal visceral disease, manifests at birth as hepatosplenomegaly caused by massive histiocyte infiltration of the liver and spleen, and also in the lungs, thymus, and lymphocytes.[23] Subcutaneous nodules and laryngeal involvement may be subtle. Death occurs by 6 months of age.

Sialidosis

Etiology

Sialidosis is caused by a deficiency of neuraminidase, which is responsible for the cleavage of terminal sialyl linkages of several oligosaccharides and glycopeptides. The defect results in multisystem lysosomal accumulation of sugars rich in sialic acid. In sialidosis, vacuolated cells can be seen in almost all tissues, and in bone marrow foam cells are present. The activities of the sialidase 1 and β-galactosidase enzymes are reduced, respectively, to less than 1% and ~15% of normal values in fibroblasts. The activity of cathepsin A, which is the lysosomal protective protein (PPCA), is markedly reduced in leukocytes and fibroblasts. Urine-bound sialic acid may be elevated, while the free sialic acid is normal.

Clinical Features

Sialidosis is divided into two types: type I and type II. Type I sialidosis is characterized by retinal cherry-red spots and generalized myoclonus with onset generally in the second decade of life. Type II is distinguished from type I by the early onset of a progressive, severe phenotype with somatic features. Type II is often subdivided into juvenile, infantile, and congenital forms. Congenital sialidosis begins in utero and manifests at birth as coarse features, facial edema, hepatosplenomegaly, ascites, hernias, and hypotonia and occasionally frank hydrops fetalis. Radiographs demonstrate dysostosis multiplex and epiphyseal stippling. Individuals with sialidosis type II may have a brain MRI with cerebellar atrophy and spinal cord lesions. They may have anemia. A bull's eye maculopathy has been noted. Delayed mental development is often apparent. The patient may have recurrent infections. Severely dilated coronary arteries, excessive retinal vascular tortuosity, and an erythematous macular rash may also be features of this disease.[24] Most patients with congenital type II sialidosis are stillborn or die before 1 year of age.

Galactosialidosis

Etiology

Galactosialidosis results from a deficiency of two lysosomal enzymes: neuraminidase and β-galactosidase. The primary defect in galactosialidosis is a defect in the protective protein cathepsin A, an intralysosomal protein that protects the two enzymes from premature proteolytic processing. The protective protein has catalytic and protective functions, and the two functions appear to be distinct. Deficiency of the enzymes results in the accumulation of sialyloligosaccharides in tissue lysosomes and in excreted body fluids.

Clinical Features

Galactosialidosis has been divided into three phenotypic subtypes based on age of onset and severity of clinical manifestations. Most cases occur in adolescence and adulthood, but early infantile and late infantile presentations occur. Galactosialidosis is one of the most important causes of nonimmune hydrops fetalis. Patients develop early infantile galactosialidosis between birth and 3 months of age, with ascites, edema, coarse facial features, inguinal hernias, proteinuria, hypotonia, and telangiectasias. Patients subsequently demonstrate organomegaly, including cardiomegaly progressing to cardiac failure, psychomotor delay, and skeletal changes, particularly in the spine. Ocular abnormalities can occur, including corneal clouding and retinal cherry-red spots. Death occurs at an average age of 8 months, usually from cardiac and renal failure. Galactosialidosis can be a cause of recurrent fetal loss or recurrent hydrops fetalis.

Late infantile galactosialidosis manifests itself in the first months of life as coarse facial features, hepatosplenomegaly, and skeletal changes consistent with dysostosis multiplex. Cherry-red spots and corneal clouding may also be present. Neurologic involvement may be absent or mild. Valvular heart disease is a common feature, as is growth retardation, partially because of spinal involvement and often in association with muscular atrophy. Early death is not a feature of the late infantile form. Vacuolated cells in blood smears and foam cells in bone marrow are present in all forms of galactosialidosis.

Infantile Sialic Acid Storage Disease

Etiology

Infantile sialic acid storage disease is caused by a defective lysosomal sialic acid transporter that is responsible for efflux of sialic acid and other acidic monosaccharides from the lysosomal compartment. The defective transporter results in greater storage of free sialic acid and glucuronic acid within lysosomes and increased sialic acid excretion.

Clinical Features

Infantile sialic acid storage disease often manifests at birth as mildly coarse features, hepatosplenomegaly, ascites, hypopigmentation, and generalized hypotonia. Mild dysostosis multiplex may be seen on radiographs. Failure to thrive and severe mental and motor retardation soon appear. Cardiomegaly may be present. Corneas are clear, but albinoid fundi have been reported.[25] Vacuolated cells are seen in a tissue biopsy sample, and electron microscopy demonstrates swollen lysosomes filled with finely granular material. CNS changes include myelin loss, axonal spheroids, gliosis, and neuronal storage. Death occurs in early childhood. Infantile sialic acid storage disease can also manifest itself as fetal ascites, nonimmune fetal hydrops, or infantile nephrotic syndrome.[25]

I-Cell Disease

Etiology

In normal cells, targeting of enzymes to lysosomes is mediated by receptors that bind a mannose 6-phosphate recognition marker on the enzyme. The recognition marker is synthesized in a two-step reaction in the Golgi complex. It is the enzyme that catalyzes the first step of this process, uridine diphosphate–N-acetylglucosamine:lysosomal enzyme N-acetylglucosaminyl-1-phosphotransferase, that is defective in I-cell disease. As a

result, the enzymes lack the mannose 6-phosphate recognition signal, and the newly synthesized lysosomal enzymes are secreted into the extracellular matrix instead of being targeted to the lysosome. Consequently, multiple lysosomal enzymes are found in plasma at 10 to 20 times their normal concentrations. Affected cells, especially fibroblasts, show dense inclusions of storage material that probably consists of oligosaccharides, GAGs, and lipids; these are the inclusion bodies from which the disease name is derived. This disorder is found more frequently in Ashkenazi Jews, because of a putative founder effect.

Clinical Features

I-cell disease can manifest itself at birth as coarse features, corneal clouding, organomegaly, hypotonia, and gingival hyperplasia. Birthweight and length are often below normal. Kyphoscoliosis, lumbar gibbus, and restricted joint movement are often present, and there may be hip dislocation, fractures, hernias, or bilateral talipes equinovarus. Dysostosis multiplex may be seen on radiographs. Severe psychomotor retardation, evident by 6 months of age, and progressive failure to thrive occur. The facial features become progressively coarser, with a high forehead, puffy eyelids, epicanthal folds, flat nasal bridge, anteverted nares, and macroglossia. Linear growth slows during the first year of life and halts completely thereafter. The skeletal involvement is also progressive, with development of increasing joint immobility and claw-hand deformities. Respiratory infections, otitis media, and cardiac involvement are common complications. Death usually occurs in the first decade of life because of cardiorespiratory complications.

Mucolipidosis Type IV

Etiology

Although mucolipidosis type IV (ML4) is associated with a partial deficiency of the lysosomal enzyme ganglioside sialidase, a deficiency of mucolipin 1, a member of the transient receptor potential mucolipin subfamily of channel proteins, is the cause of the disorder.[26,27] Mutations in the *MCOLN1* gene result in lysosomal storage of lipids such as gangliosides, plus water-soluble materials such as GAGs and glycoproteins in cells from almost all tissues.

Clinical Features

The age of onset for ML4 ranges from infancy to 5 years. Presenting features include corneal clouding (may be congenital), retinal degeneration, blindness, hypotonia, and mental retardation. An usual feature of ML4 is the presence of achlorhydria. Cytoplasmic inclusions are noted in many cells, including those in conjunctiva, liver, and spleen, as well as fibroblasts. Survival of affected patients into the fourth decade of life has been reported.[28]

Diagnosis, Management, and Prognosis of Lysosomal Storage Diseases

Growing recognition of LSDs in the neonate has led to expansion of the spectrum of possible clinical presentations in the newborn period. Diagnostic tools and options for treatment also continue to advance. Newborn screening for LSDs has been implemented in almost every state, with the goal to offer treatment with enzyme replacement therapy (ERT) or hematopoietic stem cell transplantation (HSCT) for affected babies. Currently, a federal advisory committee actively reviews and makes recommendations to the US Secretary of Health and Human Services for the introduction of new newborn screening tests in the United States, with the aim of vetting proposed tests for need, cost-effectiveness, and availability of effective and timely therapy. The Recommended Uniform Screening Panel now includes MPS type I and Pompe disease. Larger panels of multiplex testing in some states include Gaucher disease, Fabry disease, and Krabbe disease. Depending on the screening assay, false-positive results can be an issue. For example, Krabbe disease, MPS type I, and Pompe disease are associated with well-known pseudodeficiency alleles, which result in enzyme deficiency in vitro but do not cause clinical disease. In some cases, molecular testing identifies variants of uncertain significance, which may require time to establish pathogenicity. The neonatologist must work closely with appropriate experts to determine which infant with a positive newborn screen may be truly affected and require treatment.

Recognizing LSDs in the newborn period can be difficult because they often mimic more common causes of illness in newborns, such as respiratory distress, nonimmune hydrops fetalis, liver disease, and sepsis. The initial step in the diagnosis of these disorders is to consider them in the differential diagnosis of a sick or unusual-appearing newborn. At times, the phenotype may suggest a specific diagnosis, such as respiratory distress and painful, swollen joints in Farber lipogranulomatosis; neonatal cholestasis in NPC; or GI symptoms, hepatosplenomegaly, and adrenal calcifications in Wolman disease. Subtle dysmorphic features, coarse facies, and radiographic evidence of dysostosis multiplex are also strong indications that a patient may have an LSD. Routine laboratory findings are often normal or nonspecific. Affected infants do not have episodes of acute metabolic decompensation. Anemia and thrombocytopenia may be seen because of bone marrow involvement. Vacuolated cells may be found in peripheral blood, but the absence of this finding does not exclude LSDs. Elevated cerebrospinal fluid protein level is seen in Krabbe disease and Farber lipogranulomatosis type I.

Nonimmune hydrops fetalis deserves special mention. The physician must consider LSDs as the cause of nonimmune hydrops fetalis or unexplained ascites in the affected newborn. The following LSDs are potential causes: sialidosis type II, MPS types IV and VII, infantile sialic acid storage disease, Salla disease, galactosialidosis, Gaucher disease type 2, GM1 gangliosidosis, I-cell disease, NPC, ASMD, Wolman disease, and Farber disease.[5] The mechanisms of fetal edema in these diseases are unclear. Furthermore, not all of the above LSDs routinely appear in the neonatal period.

Various clinical samples can be used to diagnose LSD, including blood, urine, amniotic fluid, skin fibroblasts, and tissue biopsies. Directed analysis of urine is helpful for conditions in which characteristic metabolites are excreted in urine. One- or two-dimensional electrophoresis or thin-layer chromatography can detect excess excretion of urine GAGs, oligosaccharides, or free sialic acid, but all urinary tests for the diagnosis of LSDs can have false-negative results. Examination of bone marrow or other tissues may demonstrate storage macrophages in Gaucher disease, ASMD, and NPC. Small skin or conjunctival biopsy specimens may demonstrate storage within lysosomes in most of these disorders.

Definitive diagnosis for almost all LSDs is confirmed by genetic testing and enzymatic assays in serum, leukocytes, or fibroblasts. Biochemical testing for ASMD and NPC is based on measurement of plasma oxysterol concentrations. In addition, prenatal diagnosis is available for most LSDs using enzyme assays

performed on amniocytes or chorionic villus cells or measurements stored at substrate levels in cultured cells or amniotic fluid. If the responsible gene mutations are known, genetic testing can be performed prenatally. Identifying the specific genetic variants can be helpful as there are well-established genotype-phenotype correlations for some LSDs.

LSDs must also be considered in the dying infant. The neonatologist must be prepared to obtain appropriate samples for diagnosis at the time of death. Samples may include urine, blood for DNA banking, fibroblasts, liver tissue, and others. In surviving patients, treatment and management must be considered. All LSDs are chronic and progressive conditions for which treatments slow disease progression and symptoms but are not curative. Patients must be continually reassessed for evidence of disease progression and associated complications.

ERT is available for Gaucher disease, most of the mucopolysaccharidoses, Pompe disease, Wolman disease, and other disorders which are not covered in this chapter. ERT slows disease progression, and the clinical benefits are greater if treatment is started at a younger age, hence, the importance of newborn screening despite the diagnostic challenges. ERT has minimal impact on CNS disease since little protein crosses the blood-brain barrier. Thus, in some instances (e.g., Gaucher disease type 2), ERT is not indicated.[29]

Substrate reduction therapy is another treatment modality for LSDs. As the name implies, these agents reduce the production of storage material by inhibiting an upstream enzyme. In the case of Gaucher disease, the drugs miglustat and eliglustat inhibit glucosylceramide synthase, the first step in glycosphingolipid synthesis, thereby decreasing glucocerebroside production. These medications are approved for adults only, but off-label use in infants and children has been tried in some cases. Miglustat is approved in Europe for children with NPC.

HSCT is indicated for a small number of LSDs. The rationale for the procedure is that circulating blood cells derived from the transplanted marrow become a source of the lacking enzyme. Results of HSCT in MPS type I show that after successful engraftment, leukocyte and liver tissue enzyme activity normalizes and organomegaly decreases, although significant morbidity remains, including skeletal disease, cardiac valve disease, and corneal clouding.[30] Because early HSCT, ideally in the first few months of life, can stabilize neurocognitive function in MPS type I, it is currently the standard of care for patients with severe disease.[18] HSCT appears to be beneficial for MPS type II,[31,32] but fewer outcome data are available.

HSCT is used for patients with infantile Krabbe disease, but outcomes are not as encouraging as for MPS type I. Because infants become symptomatic much earlier in life, and treatment must be initiated before neurologic deterioration occurs, the window of opportunity for treatment is narrower. In a cohort of 18 children with early infantile Krabbe disease who received HSCT in the first 7 weeks of life, 5 (28%) died (3 from peritransplant complications, 1 from surgical complications, and 1 from disease progression).[33] Of the surviving children, all but one (92%) had cognitive impairment, and most could not walk independently.

Gene therapy holds promise, and clinical trials for many LSDs are under way. Gene therapy employs viral vectors to incorporate a correct copy of the gene into cells and may be administered by various routes including intravenous, intrathecal, and intracerebroventricular. It is thought that gene therapy may provide more a durable therapeutic effect compared to ERT which must be administered weekly or biweekly.

Other therapies for LSDs are not discussed in this chapter as they are only approved in the adult population or are still under investigation. In the future, it is likely that the use of combination therapies will become more prevalent. Regardless of the treatment modality, early initiation of treatment results in better clinical outcomes. Thus, the neonatologist plays an important role in the early diagnosis and treatment of neonates with LSDs.

Congenital Disorders of Glycosylation, Peroxisomal Disorders, and Smith-Lemli-Opitz Syndrome

JANET A. THOMAS AND CHRISTINA LAM

KEY POINTS

- The phenotypic spectrum of glycosylation disorders is broad and ranges from mild to severe and from single-organ system to multisystem disease; glycosylation defects should be considered in any unexplained clinical condition, but especially in multiorgan disease with neurologic involvement.
- Diagnosis of congenital disorders of glycosylation mainly relies on next-generation sequencing techniques. Treatment is largely supportive except for rare exceptions where nutritional supplements are effective.
- Peroxisomal disorders are a broad and heterogeneous group of inherited diseases with most often multisystem features, including craniofacial dysmorphism, neurologic dysfunction, including hearing and vision dysfunction, hepatodigestive dysfunction, renal cysts, and skeletal abnormalities seen in the newborn period.
- Diagnosis of peroxisomal disorders is best made by next-generation sequencing techniques following abnormal biochemical screening test findings. Treatment is supportive.
- Smith-Lemli-Opitz syndrome (SLOS) is a multisystemic, developmental, and dysmorphic disorder with a wide clinical spectrum caused by a defect in cholesterol biosynthesis.
- Diagnosis of SLOS is based on elevated 7-dehydrocholesterol and 8-dehydrocholesterol levels in the blood and treatment is largely supportive.

Congenital Disorders of Glycosylation

Epidemiology of Congenital Disorders of Glycosylation

Congenital disorders of glycosylation (CDGs) are a group of more than 140 genetic diseases which involve various defects in the process of modifying proteins, lipids, or other biomolecules with glycans (sugar molecules or chains).[1,2] Glycosylation, the addition of glycans to biomolecules, is essential to many biologic processes, such as aiding with correct folding, protecting against premature destruction, directing intracellular localization and transport, and modifying the biologic function of these biomolecules.

The first discovered CDG (PMM2-CDG) was described by Professor Jaak Jaeken in 1980 and was initially termed "carbohydrate-deficient glycoprotein syndrome" due to abnormalities seen in multiple serum glycoproteins in the affected individuals.[3,4] When several more human glycosylation disorders were identified, this group of disorders was renamed "congenital disorders of glycosylation." The decision was made to designate types of CDG into either a group I or II disorder based on the transferrin pattern obtained by isoelectro-focusing with specific diagnoses alphabetized consecutively as they were identified (i.e., CDG Ia, Ib, Ic, IIa, IIb, etc.).[5] Improved molecular diagnostics expanded the definition of CDGs to include genetic diseases that primarily disrupt the process of formation of any glycoconjugate (i.e., glycoproteins, glycolipids, glycosaminoglycan [GAG], etc.), resulting in an exponential growth of the number of pathways and individual disorders.[6] In 2009, the nomenclature was updated, and currently specific CDG types are named starting with the affected gene symbol (not in italics) followed by -CDG (e.g., CDG-Ia is now PMM2-CDG).[7]

It is estimated that approximately 3% to 4% (~700) of our genes encode for proteins involved with the glycosylation process. The glycosylation process takes place in a variety of locations within the cell including the cytosol, endoplasmic reticulum (ER), and Golgi apparatus.[8] The underlying mechanism for the clinical manifestations of most of CDGs is still unclear. Given the complexity of glycosylation, there are multiple methods to group these disorders. One classification schema groups CDGs into protein N-linked glycosylation defects, protein O-linked glycosylation defects, glycosylphosphatidylinositol (GPI) anchor glycosylation defects, lipid glycosylation defects, and defects in multiple glycosylation and other pathways.[9] In this chapter, we use this classification method to help organize our discussion of CDGs that manifest in the neonatal period.

Clinical Presentation of Congenital Disorders of Glycosylation

Because so many biologic functions are dependent on the correct glycosylation, the phenotypic spectrum of CDG defects is extremely broad and ranges from mild to severe disease and from a single-organ system to multisystem disease. Clinical features alone are insufficient to define the CDG type. A CDG should be considered in any unexplained clinical condition, but especially in multiorgan disease with neurologic involvement (Table 31.1).

TABLE 31.1 Common Clinical Features of Congenital Disorders of Glycosylation by Pathway

		KEY FEATURES BY SYSTEM									
Pathway	Example Disorders	Neurologic	Ophthalmologic	Cardiologic	Gastroenterological	Hematologic	Renal	Endocrine	Dermatologic	Musculoskeletal/ Other	Diagnostic Screen
N-linked glycosylation	PMM2-CDG, MPI-CDG, ALGx-CDG, MOGS-CDG	ID (except MPI), DD, seizures (50%), hypotonia, ataxia, dysmetria, dysarthria, peripheral neuropathy, cerebral and cerebellar atrophy, myasthenic syndrome	Strabismus, nystagmus, optic hypoplasia, retinal pigmentary changes, alacrima, congenital cataracts	Pericardial effusion, cardiomyopathy, fetal hydrops	Protein-losing enteropathy, diarrhea, failure to thrive, gastroesophageal reflux, hepatopathy with elevated AST & ALT, edema and hypoalbuminemia, low cholesterol	Factors II, V, VII, VIII, IX, X, XI, Antithrombin III, Protein C, Protein S deficiency, increased bleeding tendency, thrombotic events, hypogammopathy, coagulopathy and thrombosis	Hyperechoic kidneys, microcystic changes, proteinuria	Abnormal thyroid function test, short stature, IGF1 deficiency, hypogonadotropic hypogonadism, hyperinsulemic hypoglycemia	Lipodystrophy, hypohidrosis	Osteopenia, kyphoscoliosis, dysmorphic features, skeletal dysplasia	Transferrin profiling, N-glycan profiling, urine oligosaccharide analysis (MOGS-CDG only)
O-linked glycosylation	GALNT3-CDG, B3GLCT-CDG, POMK-CDG, EXT1-CDG, CHST-CDG	ID (not universal), DD, congenital and later onset muscular dystrophy, hypotonia, polymicrogyria lissencephaly	Peters-plus syndrome, other structural eye abnormalities, glaucoma, isolated macular corneal dystrophy, corneal opacity, cataracts		Failure to thrive			Tumoral calcinosis with phosphatemia	Loose skin, Dowling Degos disease	Skeletal dysplasia, short stature, Ehlers-Danlos syndrome, hypermobility, exostoses, elevated creatine kinase, dysmorphic facies	
Mixed glycosylation	COGx-CDG, TMEMx-CDG,	Seizures, ID (not universal), DD, microcephaly, hypotonia, cortical and cerebellar atrophy	All findings seen in N-linked pathway possible	Cardiomyopathy, congenital structural heart defects	All findings seen in N-linked pathway possible, isolated polycystic liver disease, high cholesterol, cholestatic liver disease, prenatal growth retardation	Isolated leukocyte adhesion deficiency, isolated congenital dyserythropoietic anemia type II, immunodeficiency	Obstructive uropathy, micropenis, hypospadias		Ichthyosis, cutis laxa, hypohidrosis, hyperkeratosis	Skeletal dysplasia, dysmorphic features, elevated creatine kinase	Transferrin profiling, N-glycan profiling, O-glycan profiling, APO-CIII profiling

TABLE 31.1 Common Clinical Features of Congenital Disorders of Glycosylation by Pathway—cont'd

		KEY FEATURES BY SYSTEM									
Pathway	Example Disorders	Neurologic	Ophthalmologic	Cardiologic	Gastroenterological	Hematologic	Renal	Endocrine	Dermatologic	Musculoskeletal/ Other	Diagnostic Screen
GPI Anchor disorder	PIGx-CDG, PGAPx-CDG	Seizures, ID, DD, macrocephaly, hypotonia		Congenital heart defects, cardiomyopathy				Accelerated linear growth, advanced bone age, +/− hyperphosphatasia, hypophosphatasia		Dysmorphic features, multiple congenital anomalies	Flow cytometry studies using cell surface markers like FLAER and CD59 on granulocytes, lymphocytes, etc.
Lipid glycosylation	ST3GAL5-CDG (Amish Infantile Epilepsy syndrome)	Seizures, ID, DD, hypotonia, diffuse brain atrophy, irritability, microcephaly	Optic atrophy, cortical visual impairment		Failure to thrive				Dyspigmentation, "salt and pepper" pattern on skin macules		

ALT, Alanine transaminase; *AST*, aspartate transaminase; *DD*, developmental disability; *GPI*, glycosylphosphatidylinositol; *ID*, intellectual disability; *IGF1*, insulin-like growth factor 1.

N-Linked Protein Glycosylation Defects

Etiology

N-linked protein glycosylation, the process involved with attaching glycans to the asparagine residue of target proteins, was the first discovered and is the best understood glycosylation pathway in humans. Classically, these disorders were divided into two categories: type I which results in defects in N-glycan assembly, and type II which results from defects in N-glycan processing.

The initial assembly steps of N-glycosylation take place on the ER membrane, where sugars are attached in a stepwise manner to Dolichol-P to form a lipid-linked oligosaccharide (LLO). Sugars are donated by an activated nucleotide-sugar (UDP-GlcNAc and GDP-Man), with the attached nucleotide providing the necessary energy for the transfer of the sugar to the LLO. This oligosaccharide is then transferred to the nascent protein cotranslationally. Once the oligosaccharide chain has been transferred to the protein, further processing takes place. The oligosaccharide is then transported to the Golgi apparatus, where further processing occurs. Different types of CDGs have been found in affected individuals who have defective enzymes in individual steps of this complex pathway including the enzymes that form the dolichol backbone, transfer single sugars to the growing chain, interconvert activated monosaccharides, and transfer the oligosaccharide from dolichol to protein.[10,11]

Clinical Features

N-linked glycosylation defects encompass many disorders. Taken together these several dozen disorders are typically multisystemic with significant neurologic involvement with the notable exception of MPI-CDG, in which development can be normal.[12] The most common perinatal findings include hypotonia, nonspecific dysmorphic features (inverted nipples or abnormal fat pads occasionally present), feeding problems with growth delay, hepatopathy with elevated transaminases, and abnormal coagulation profiles. Discriminating findings include neonatal hemorrhages (including cerebral hemorrhage) and thrombotic events, pericardial effusion, strabismus, nystagmus, and other ophthalmologic findings, neonatal seizures, abnormal thyroid function screening results, and nonimmune hydrops.[13,14] Transferrin glycosylation analysis previously performed using isoelectric-profiling and now performed using mass spectrometry methods show an abnormal glycosylation pattern in many, but not all, of these disorders.[15]

Two disorders warrant special mention: PMM2-CDG (CDG-Ia) and MPI-CDG (CDG-Ib). PMM2-CDG (CDG-Ia) is the classic and most common presentation, and many other N-linked CDGs mirror its presentation. Most affected infants appear normal at birth, although a subset of individuals present with nonimmune hydrops with and without hypertrophic cardiomyopathy. In infancy, patients with PMM2-CDG can exhibit dysmorphic features, strabismus, nystagmus, hypoglycemia, and feeding difficulties; subsequently patients may exhibit growth failure, hypotonia, lipocutaneous abnormalities (including prominent fat pads on the buttocks), coagulopathy with thrombosis and bleeding, pericardial effusion, and mild to moderate hepatomegaly and hepatopathy.[16] Approximately 20% of patients with PMM2-CDG die during the first year of life after a course of severe fluid imbalance and sometimes anasarca in response to infection or their underlying glycosylation disorder.[17] Having survived infancy, patients with PMM2-CDG can live into their seventh and eighth decades. Later manifestations include intellectual disability, retinitis pigmentosa or retinal degeneration, renal cysts, coagulopathy, stroke-like episodes, thrombotic disease, cerebral and olivopontocerebellar hypoplasia, ataxia, dysarthria, peripheral neuropathy, followed by lower extremity atrophy, kyphoscoliosis, and hypogonadism.[16]

MPI-CDG (CDG-Ib) stands out in this group of disorders because patients with MPI-CDG can have normal development and mannose is a known targeted therapy. Mortality rate during infancy is 23.5%, and the causes of death, when known, included hepatic failure and sepsis. The major manifestations of MPI-CDG are liver fibrosis, hepatomegaly, hypoglycemia, growth restriction, hypoalbuminemia, diarrhea, protein-losing enteropathy, edema, faltering growth, and coagulopathy. Mannose supplementation is not associated with improvement hepatopathy but improves most of the other manifestations. Thus, early diagnosis and treatment of MPI-CDG are imperative.[18]

O-Linked Protein Glycosylation Defects

Etiology

O-glycosylation consists of attachment of a monosaccharide (mannose, fructose, or xylose), or the assembly of a glycan and its attachment to a serine or threonine residue of a target protein. O-glycosylation differs from N-glycosylation in that it does not take place at the same time as the protein is being translated, but occurs posttranslationally, exclusively in the Golgi apparatus, without further processing.[19] O-glycosylation can be classified according to which type of sugar is attached to the serine or threonine. Examples of O-glycosylation include O-mannosylation, O-xylosylation, and O-fucosylation.[8]

Clinical Features

Clinical features vary significantly depending on which type of O-glycosylation is defective. Deficiency of O-N-acetylgalatosamine linkage can lead to familial tumoral calcinosis with phosphatemia and massive calcium deposits in the skin and subcutaneous tissues.[20] A defect in O-fucosylation has been shown to lead to Peters-plus syndrome characterized by anterior eye chamber defects, disproportionate short stature, developmental delay, and cleft lip and/or palate.[21] O-fucosylation defects also lead to Dowling-Degos disease 2 characterized by abnormal skin pigmentation,[22] and spondylocostal dysostosis type 3 characterized by short stature and vertebral abnormalities.[23] Defects in O-xylosylation will lead to defective anchoring of GAGs to proteins and thus impaired proteoglycan formation. Defective O-xylosylation can lead to progeroid-type Ehlers-Danlos syndrome characterized by failure to thrive, loose skin, skeletal abnormalities, hypotonia, and hypermobile joints. Defects in forming heparin sulfate, also attached to proteins via O-xylosylation, cause congenital exostosis, an autosomal dominant disorder where patients have bony outgrowths usually at the growth plate of the long bones. Defective cartilage proteoglycan sulfation leads to achondrogenesis, diastrophic dystrophy, atelosteogenesis that manifest symptoms in cartilage and bone like cleft palate, club feet, and in the most severe cases lead to perinatal death from respiratory insufficiency.[20]

Additionally, there are close to 20 different genetic disorders that lead to a defect in O-mannosylation.[24] O-mannosylation defects lead to hypoglycosylation of α-dystroglycan, an important glycoprotein needed to link the intracellular cytoskeleton of

muscle to the extracellular matrix. These disorders, collectively referred to as α-dystroglycanopathies, have a wide spectrum of clinical severity and encompass previously described disorders, ranging from Walker-Warburg syndrome, muscle-eye-brain disease, Fukuyama congenital muscular dystrophy, to limb-girdle muscular dystrophy.[25,26]

In the neonate, clinical features of O-linked protein glycosylation defects involve the triad of muscle, eye, and brain and may include hypotonia; muscle weakness; microcornea; microphthalmia; pale, hypoplastic or absent optic nerves; colobomas; cataracts; iris hypoplasia; glaucoma; retinal dysplasia or detachment; and brain structural abnormalities including hydrocephalus, brainstem hypoplasia, cerebellar cysts, cobblestone lissencephaly, polymicrogyria, cerebellar vermis and hemisphere atrophy, hypoplasia of the pyramidal tracts, and absence of the corpus callosum. There is no specific blood or urine biochemical marker available for this group of disorders. Elevated creatine kinase is frequently noted. Muscle biopsy with specialized immunohistochemical staining may show deficient glycosylated alpha-dystroglycan and normal beta-dystroglycan. Molecular testing is needed to confirm the specific type.[27]

Combined Glycosylation Defects

Etiology

Combined N- and O- and other glycosylation defects are important because they appear to affect trafficking in the glycosylation machinery.[28] Several of these disorders involve defects in channels involved in activated sugar-nucleotide transport (SLCx-CDG). Some affect vesicular transport (COGx-CDG) in general. Others affect the process of sugar activation (attaching nucleotides to monosaccharides so that they can be used for glycosylation). And yet others cause abnormalities in the Golgi apparatus structure (TMEMx-CDG) that is needed to be intact for glycosylation to proceed.[29]

Clinical Features

In the neonate, the most frequent presenting symptoms of combined glycosylation defects include neonatal microcephaly; neonatal seizures; strabismus; hypotonia; dysmorphic features, especially cutis laxa; feeding problems with growth delay; and hepatic involvement.[13] Neonatal cholestatic hepatic failure can be the presenting or predominant symptom of a neonate with a combined defect.[30] Encompassing a very large group of disorders, presentations are heterogeneous and include not only multisystemic diseases, but also single-system disorders such as congenital dyserythropoietic anemia type II due to SEC23B-CDG.

Glycosylphosphatidylinositol Anchor Glycosylation Defects

Etiology

The biosynthesis and attachment of GPI anchors to proteins occur in the ER and Golgi and involve 11 steps and at least 27 genes.[31] To date, inherited loss of function mutations in over a dozen of these genes have been implicated in human disease. GPI anchors are attached during posttranslational modification and allow these proteins to attach to the outer leaflet of the cell membrane and face the extracellular environment. This permits these proteins to participate in processes such as signal transduction and immune response.[32,33]

Clinical Features

Typically, individuals affected with GPI anchor disorders have a severe phenotype and present in infancy with epilepsy; intellectual disability; and multiple congenital anomalies including heart, skeletal (especially abnormalities in phalanges), endocrine, ophthalmologic, and facial anomalies (dysmorphic features), with possible abnormalities in alkaline phosphatase levels depending on the specific diagnosis.[34,35] Although there is no standard blood or urine biomarker, flow cytometry markers show promise to be effective biomarkers in many of these disorders.[36]

Lipid Glycosylation Defects

To date, three disorders of lipid glycosylation have been described: SIAT9-CDG, ST3GAL-CDG, and B4GALNT1-CDG. SIAT9-CDG, also known as Amish infantile epilepsy was the first identified and is caused by a defect of lactosylceramide α-2,3 sialyltransferase (GM3 synthase).[37] This enzyme catalyzes the initial step in the biosynthesis of most complex gangliosides from lactosylceramide.[19] The defect causes accumulation of lactosylceramide associated with decreased gangliosides.[37] Individuals with this disorder present with infantile-onset epilepsy with developmental stagnation, blindness, poor feeding, vomiting, failure to thrive, later onset "salt and pepper" macules, and variable survival.[38] ST3GAL-CDG is a cause of West syndrome.[39] B4GALNT1-CDG, also known as spastic paraplegia-26, is also a defect in ganglioside biosynthesis. However, onset of symptoms including gait abnormalities, as well as central and peripheral nervous system involvement typically occurs after the neonatal period, in the first two decades of life.[40]

Diagnosis of Congenital Disorders of Glycosylation

CDG should be considered in young infants with a combination of clinical features as shown in Table 31.1. Serum transferrin isoform analysis is the most available screening method for CDGs, but it is only able to detect N-glycosylation and some mixed glycosylation defects. Until about 2000, transferrin screening was achieved by isoelectric focusing of transferrin; failure to correctly synthesize the N-linked glycans alters the charge on serum transferrin and consequently its migration in an electrophoretic field. In recent years, however, mass spectrometric methods, capable of identifying individual oligosaccharides and complete glycans by mass and charge, have replaced transferrin isoelectric focusing as the standard method for screening for CDGs.[15] Transferrin and glycan analysis may yield false-positive results in galactosemia, inborn errors of fructose metabolism, alcohol consumption, certain bacterial (neuraminidase-producing) infections, and in cases of mutations in transferrin itself. False-negatives can occur in the first 3 weeks of life.[36] There are reported cases where initially abnormal transferrin glycosylation normalizes without improvement in symptoms. There are also N-linked defects known to not show transferrin isoform abnormalities (i.e., MOGS-CDG, TUSC3-CDG, SLC35A1-CDG, SLC35C1-CDG).[41]

Apo CIII glycan analysis has been used in the screening of some mixed and O-glycosylation disorders. Urine oligosaccharide screening is useful in detecting a MOGS-CDG. Many defects in GPI synthesis can be identified using flow cytometry of GPI-anchored proteins, such as FLAER or CD59 on leukocytes. Not all subtypes of CDGs have convenient biochemical markers; for example, screening for congenital muscular dystrophies caused by

defective O-mannosylation requires a muscle biopsy with the use of monoclonal antibodies directed against the glycan.[41] There are also no available markers for defects in GAG biosynthesis.

Since the advent of next-generation genome sequencing and exome analysis, the majority of CDGs have been diagnosed molecularly.[42] Once variants are identified in the specific gene, if novel, the functional consequence of the mutation can be confirmed using enzymatic assays in peripheral blood leukocytes or cultured fibroblasts for PMM2-CDG and MPI-CDG as well as on a research basis for other types. Prenatal diagnosis is possible in all types of CDG for which the molecular defect is known.[28] The vast majority of CDGs are autosomal recessive disorders; POGLUT1-CDG and POFUT1-CDG (Dowling-Degos disease), EXT1&2-CDG (hereditary multiple exostoses syndrome), GANAB-CDG (polycystic kidney disease 3), and SEC63-CDG and PRKCSH-CDG (polycystic liver disease), GNE-CDG (sialuria form), DHDDS-CDG (Retinitis pigmentosa 59), NUS1-CDG, COG4-CDG (Saul-Wilson syndrome), COPA-CDG (autoimmune interstitial disease), ARCN1-CDG (Rhizomelic short stature with microcephaly, micrognathia, and developmental delay), SEC23B-CDG (Cowden syndrome), and HS6ST1-CDG, can be autosomal dominant; PIGA-CDG, HS6ST2-CDG, OGT-CDG, SSR4-CDG, SLC35A2-CDG, SLC9A7-CDG, TRAPPC2-CDG, ATP6APT1-CDG, ATP6AP2-CDG, VMA21-CDG, ALG13-CDG, and MAGT1-CDG are X-linked; C1GALT1C1-CDG is somatic.

Management of Congenital Disorders of Glycosylation

Only a minority of CDGs have a specific treatment available. MPI-CDG can be treated with oral mannose,[43] which ameliorates protein losing enteropathy, coagulopathy, and hyperinsulinism, but does not necessarily halt the progression of the liver disease. Heparin has also been used for protein-losing enteropathy in MPI-CDG.[44] In PGM1-CDG, D-galactose supplementation improves hypoglycemia, coagulopathy, rhabdomyolysis, and endocrinopathy, but not muscle weakness and cardiomyopathy.[45,46] Similarly, D-galactose supplementation shows promise in improving similar symptoms in TMEM165-CDG, as well as seizures in SLC39A8-CDG and SLC35A2-CDG. Manganese has also been used in SLC39A8-CDG.[46] In SLC35C1-CDG, some patients respond to oral fucose supplementation; this treatment is only effective with regard to the typical recurrent infections with hyperleukocytosis, and does not correct the neurodevelopmental aspects.[47] In PIGM-CDG, butyrate has been shown to control the seizures in some cases,[48] and in PIGO-CDG, vitamin B6 supplementation has also aided in seizure control.[49,50] Uridine and uridine triacetate have been reported to improve seizures and anemia in CAD-CDG.[51] Sialic acid and ManNAc are also promising therapies for GNE myopathy.[52] Organ transplantation has also been beneficial in several CDGs including liver for MPI-CDG, CCDC115-CDG, ATP6AP1-CDG; heart for DOLK-CDG; and stem cell for PGM3-CDG.[46]

The treatment and management for other types of CDGs are primarily supportive and palliative. In infancy, evidence of multisystem involvement and the resulting complications must be treated promptly. There is substantial mortality in the first years of life because of severe infection or vital organ failure.[28,37] Fresh frozen plasma and/or protein C concentrate has been used to prevent bleeding episodes in multiple CDGs, as well as improving capillary leakage and edema, especially during times of infections.[53]

The future is promising with multiple targeted therapies on the horizon currently being studied and developed including acetazolamide, aldose reductase inhibitors, chaperone therapy, and liposomal mannose-1-phosphate for PMM2-CDG; and gene therapy preclinically in several CDGs.[46]

Peroxisomal Disorders

Epidemiology of Peroxisomal Disorders

Peroxisomes are small, evolutionarily conserved, single membrane–bound cellular organelles that contain no internal structure or DNA. Peroxisomes are characterized by an electron-dense core and a homogeneous matrix. Peroxisomes are found in all cells and tissues except mature erythrocytes and are in highest concentration in the liver and kidneys. They are formed predominantly by growth and division of preexisting peroxisomes, but they can also arise de novo from peroxisomal vesicles that originate from specialized compartments of the ER.[54–56] Their half-life is 1.5 to 2 days before they are randomly destroyed by autophagy. All peroxisomal proteins are encoded by nuclear genes, synthesized in cytosol, and imported posttranslationally into the peroxisome.[54] The import of proteins into the peroxisome is mediated by specific targeting sequences known as peroxisomal targeting sequences (PTS1 and PTS2).[56,57] Peroxisomes have significant interaction with other subcellular organelles, including mitochondria, ER, lysosomes, and lipid bodies, mediated by "tethering proteins".[57,58] Defects related to disturbed contact between two subcellular organelles are increasingly described (e.g., acyl-CoA binding protein 5 [ACBD5] deficiency).[57]

Peroxisomes contain enzymes that use oxygen to oxidize a variety of substrates, thereby forming peroxide. The peroxide is decomposed within the organelle by the enzyme catalase to water. This process protects the cell against peroxide damage through compartmentalization of peroxide metabolism within the organelle. Peroxisomes can also function to dispose of excess reducing equivalents and may contribute to thermogenesis, producing heat from cellular respiration.[59] Peroxisomes also fulfill crucial nonmetabolic roles including participation in the cellular stress response, defense of pathogens and viruses, as signaling platforms, and in healthy aging.[58]

More than 70 enzymes have been found within peroxisomes.[55] The proteins have multiple functions, both synthetic and degradative.[55,56] The primary synthetic functions are plasmalogen synthesis, bile acid, and docosahexanoic acid formation. Plasmalogens constitute 5% to 20% of phospholipids in cell membranes and 80% to 90% of phospholipids in myelin. They are involved in platelet activation and may also protect cells against oxidative stress. Degradative functions include (1) β-oxidation of very-long-chain fatty acids (VLCFAs) ($\geq C_{23}$), fatty acids (down to C_8 to C_6), long-chain dicarboxylic acids, pristanic acid, prostaglandins, and polyunsaturated fatty acids; (2) alpha-oxidation of bile acid intermediates, pipecolic acid and glutaric acid (intermediates in lysine metabolism), and phytanic acid; (3) deamination of D-amino acids and L-amino acids; (4) metabolism of glycolate to glyoxylate; (5) polyamine degradation (spermine and spermidine); and (6) ethanol clearance. At least 16 conditions caused by peroxisomal enzyme deficiencies have been confirmed.[55,56,60]

Peroxisomal disorders constitute a clinically and biochemically heterogeneous group of inherited diseases that result from the absence or dysfunction of one or more peroxisomal enzymes.

Disorders in which more than one enzyme is affected are collectively termed *peroxisomal biogenesis disorders* (PBDs). Disorders in which only one enzyme is affected encompass the remaining known disorders. All but one are inherited in an autosomal recessive manner.

Clinical Presentation of Peroxisomal Disorders

The pathophysiologic features apparently involve either deficiency of necessary products of peroxisomal metabolism or excess of unmetabolized substrates. Disorders with similar biochemical defects may have markedly different clinical features, and disorders with similar clinical features may be associated with different biochemical findings. General features of peroxisomal disorders evident in the newborn period are shown in Table 31.2.

Disorders of Peroxisomal Biogenesis

Conditions in which multiple peroxisomal enzymes are affected can result from a disturbance of biogenesis of the organelle. Peroxisomal assembly includes matrix protein import, synthesis of new organelles, and fusion of existing organelles. The coordinated activity of 16 PEX proteins, or peroxins, encoded by their corresponding genes is required for this process.[61] Peroxins are classified into three groups: (1) those essential for peroxisomal membrane assembly (PEX3, PEX 16, PEX19); (2) those required for matrix protein import (10 different peroxins); and (3) different forms of PEX11 (α, β, γ) involved in peroxisomal division.[62] The PEX genes responsible for disease in most human patients are known, with more than 60% of patients with PBD having mutations in *PEX1*; the second most commonly involved gene is *PEX6*.[54,55,61] The overall incidence of PBD is estimated to be approximately 1 in 50,000 newborns.[55,60]

Zellweger syndrome is the prototype of neonatal peroxisomal disease. It is a disorder of peroxisome biogenesis caused by failure to import newly synthesized peroxisomal proteins into the peroxisome. The proteins remain in the cytosol, where they are rapidly degraded. In this condition, peroxisomes are absent from liver hepatocytes or exist as "ghosts." Neonatal adrenoleukodystrophy and infantile Refsum disease are also disorders of peroxisome biogenesis in which, as in Zellweger syndrome, disruption of function of more than one peroxisomal enzyme is demonstrable. A few residual peroxisomes, however, may be seen in the liver. These disorders represent a continuum of clinical severity, and the term *Zellweger spectrum disorders* (ZSDs) is now preferred.[55,61]

Features common across the spectrum of ZSDs include liver disease, variable neurologic dysfunction, developmental delay, retinopathy, neurosensory hearing loss, and adrenocortical dysfunction.[60,63] Rhizomelic chondrodysplasia punctata (RCDP), types 1 and 5, are caused by a defect in a subset of peroxisomal enzymes resulting from mutations in the *PEX7* gene and the *PEX5L* isoform, respectively. PEX5L is required for PEX7-mediated protein import.[57] In these disorders, impaired alpha-oxidation of phytanic acid and impaired synthesis of plasmalogens result in the accumulation of phytanic acid and deficiency of plasmalogens. Liver peroxisomes are demonstrable and normal in number, but their distribution and structure are abnormal.

A relatively new category of disorders, referred to as *peroxisomal fission defects*, has also been recognized. Peroxisomal fission defects are disorders caused by defects in proteins known to be involved with membrane dynamics and the proliferation and division of peroxisomes rather than by loss of metabolic function.[54,56,64–66] Peroxisomal growth and division involves the coordinated interplay of key membrane-shaping and fission proteins such as PEX11β, FIS1 (mitochondrial fission protein 1), MFF (mitochondrial fission factor), and DRP1 (dynamin-like protein 1 encoded by the *DNML1* gene).[66] With the exception of PEX11β, these proteins are also key mitochondrial division factors.[66] Finally, Heimler syndrome, a rare recessive disorder, typically presenting in young childhood with sensorineural hearing loss, amelogenesis imperfecta, nail abnormalities, and retinal pigmentation, was recognized as a mild PBD involving mutations in *PEX1* and *PEX6*.[67,68] With the advent of next-generation sequencing, broader, often atypical, phenotypes are being increasingly recognized, often presenting in later childhood with nonclassical signs and symptoms and longer survival.[57,62,69,70]

TABLE 31.2 Common Clinical Features of Peroxisomal Disorders Evident in the Newborn Period

- Dysmorphic craniofacial features
- Neurologic dysfunction, including severe hypotonia, possibly associated with hypertonia of extremities, seizures, vision difficulties, hearing loss, and abnormalities in neuronal migration
- Hepato-digestive dysfunction, including hepatomegaly, cholestasis, prolonged hyperbilirubinemia, coagulopathy secondary to vitamin K malabsorption, and feeding difficulties
- Rhizomelic shortening of the limbs, stippled calcifications of epiphyses
- Renal cysts

Zellweger Syndrome

Zellweger syndrome is most often evident at birth, with affected newborns having dysmorphic facial features including large fontanels, high forehead, flat occiput, epicanthus, hypertelorism, upward-slanting palpebral fissures, hypoplastic supraorbital ridges, abnormal ears, severe weakness and hypotonia, hepatomegaly, multicystic kidneys, and congenital heart disease. Seizures, feeding difficulties, and postnatal growth failure soon manifest themselves. Ophthalmologic examination may detect cataracts, corneal clouding, glaucoma, optic atrophy, retinitis pigmentosa, and Brushfield spots. Somatosensory evoked responses and electroretinograms are abnormal. Hearing assessment often shows an abnormal brainstem auditory evoked response consistent with sensorineural hearing loss. Skeletal radiographs demonstrate epiphyseal stippling, and cranial imaging may show brain atrophy, germinolytic cysts, corpus callosum dysgenesis, disorders of myelination, leukodystrophy, and/or neuronal migration abnormalities (typically perisylvian polymicrogyria).[71] Progressive hepatic fibrosis, cirrhosis, and liver failure, and severe psychomotor retardation occur later. Laboratory analysis often demonstrates abnormal liver function values, hyperbilirubinemia, hypoprothrombinemia, coagulopathy, and/or adrenal insufficiency. Death usually occurs within the first year of life with the average life span being 12.5 weeks.

Neonatal Adrenoleukodystrophy

Clinically, neonatal adrenoleukodystrophy is similar to, but less severe than, Zellweger syndrome. Differences include less dysmorphology and absence of chondrodysplasia punctata and renal cysts. Patients with neonatal adrenoleukodystrophy may have striking white matter signal abnormalities with early-onset progressive

leukoencephalopathy with or without perisylvian polymicrogyria.[71] They often show degenerative changes in the adrenal glands. They have slow psychomotor development followed by neurodegeneration that usually begins before the end of the first year of life. Disease progression is slower than that observed in Zellweger syndrome, and longer survival is usual, to an average of approximately 15 months of age or into the teen years.[56]

Infantile Refsum Disease

Patients with infantile Refsum disease also have relatively mild dysmorphic features, such as epicanthic folds, midface hypoplasia with low-set ears, and mild hypotonia. Early neurodevelopment is normal, possibly up to 6 months of age, but then slow deterioration begins. Later, sensorineural hearing loss (100%), anosmia, retinitis pigmentosa, hepatomegaly with impaired function, and severe cognitive impairment are evident. Patients learn to walk, although their gait may be ataxic and broad-based. Diarrhea and failure to thrive may also be seen. Chondrodysplasia punctata and renal cysts are absent. Neuroimaging findings range from normal to progressive leukodystrophy.[71] Adrenal hypoplasia occurs. The life span of patients with infantile Refsum disease ranges from 3 to 11 years or into adulthood.

Rhizomelic Chondrodysplasia Punctata

Patients with defects in the biosynthesis of ether phospholipids present with RCDP. Five genetically distinct, but clinically indistinguishable, groups exist, three of which are single-enzyme defects (types 2, 3, and 4) and the other two of which are peroxisomal biogenesis defects (types 1 and 5).[56] RCDP, type 1 accounts for greater than 90% of all reported cases with an incidence of 1 per 10,000 live births.[72] At birth, patients with RCDP have facial dysmorphia, microcephaly, cataracts, hearing loss, rhizomelic shortening of extremities with prominent stippling, and coronal clefting of vertebral bodies. The chondrodysplasia punctata is more widespread than in Zellweger syndrome and may involve extraskeletal tissues. Neuroimaging may show delayed myelination, white matter signal abnormalities, generalized cerebral atrophy, or progressive cerebellar atrophy.[71] Infants with this disorder have severe psychomotor retardation from birth onward and severe failure to thrive. In addition, patients may have joint contractures, and 25% experience ichthyosis. The life span is usually less than 1 year.

Peroxisomal Fission Defects

The first described patient with a peroxisomal fission defect was a severely affected female patient with mitochondrial encephalopathy who died at 1 month of age.[64] She was noted to have microcephaly, mild dysmorphic features, truncal hypotonia, absent deep tendon reflexes, optic atrophy, failure to thrive, abnormal brain development, and severe developmental delay. She had elevated peripheral and central lactic acid and alanine levels, mildly elevated VLCFA levels, and abnormal-appearing peroxisomes and mitochondria in fibroblasts but normal oxidative phosphorylation values in fibroblasts and skeletal muscle specimens.[64] Evaluation revealed a peroxisomal and mitochondrial fission defect with a heterozygous, dominant-negative mutation in the dynamin-like protein 1 gene (*DLP1*).[64] Additional patients with *DLP1* mutations have now been described with variable clinical phenotypes ranging from severe neonatal presentations to later, more mild presentations.[73–78] In addition, multiple patients with MFF deficiency have been described.[58,79–82] These individuals present with Leigh-like encephalopathy associated with global developmental delay and/or developmental regression, acquired microcephaly, early-onset seizures, optic atrophy, and peripheral neuropathy typically within the first year of life.[58,79,80,82] Patients may not show significant peroxisomal or biochemical abnormalities.

Single Peroxisomal Enzyme Defects

Of patients with suspected ZSD and elevated VLCFA levels, approximately 10% to 15% will have a single enzyme defect.[55,61] To date, three childhood disorders of peroxisomal fatty acid β-oxidation have been defined: D-bifunctional protein deficiency (DBPD), acyl-CoA oxidase deficiency, and 2-methylacyl-CoA racemase deficiency.[56] The clinical presentation resembles that of biogenesis disorders. Previously, an isolated case of a fourth disorder, peroxisomal thiolase deficiency, was described.[83] On reinvestigation, however, this case was identified as DBPD.[84]

D-Bifunctional Protein Deficiency

DBPD is a rare single peroxisomal enzyme defect that results in a phenotype similar to Zellweger syndrome. It is caused by mutations in the *HSD17B4* gene encoding 17β-estradiol dehydrogenase, an enzyme involved in β-oxidation of VLCFAs and branched-chain fatty acids, including pristanic acid and bile acid intermediates, resulting in accumulation of VLCFAs, pristanic acid, dihydroxycholestanoic acid, and trihydroxycholestanoic acid.[56,85] DBPD can be divided into three subtypes according to the functional subunit involved. Deficiency of both the 2-enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase functional subunits represent the type 1 subgroup and individuals have the most severe phenotype with early onset of symptoms and early death (<2 years of age).[71] Isolated deficiency of either subunit results in type II and III disease (hydratase and dehydrogenase, respectively) typically with less severe phenotype and longer survival (>10 years).[71] In general, children have severe neurologic involvement consisting of profound hypotonia, uncontrolled seizures, and failure to acquire any significant developmental milestones. Children are usually born at term without evidence of intrauterine growth restriction. Dysmorphic features, similar to those seen in Zellweger syndrome, are notable in most children. In most cases, neuronal migration is disturbed, with areas of polymicrogyria and heterotopic neurons in the cerebrum and cerebellum. Periventricular white matter signal abnormalities and thinning of the corpus callosum can also been seen.[71] Death generally occurs before 1 year of age, but survival to at least 3 years of age is possible.

Acyl-Coenzyme A Oxidase Deficiency

Acyl-CoA oxidase deficiency, also called *pseudoneonatal adrenoleukodystrophy*, is a rare, neuroinflammatory, neurodegenerative disorder.[86,87] It is caused by mutations in *ACOX1* exclusively involved in the β-oxidation of straight-chain fatty acids resulting in only the accumulation of VLCFAs.[56,86] Patients exhibit global hypotonia, early onset seizures, deafness, failure to thrive, hepatomegaly, areflexia, and delayed developmental milestones with or without facial dysmorphic features as well as retinopathy with extinguished electroretinograms, nystagmus, and optic atrophy.[86,88,89] Patients often demonstrate early developmental skills and have a normal brain MRI, but then show regression of skills typically

between 24 and 48 months of age.[71,87] Eventually, brain MRI shows diffuse and progressive leukodystrophy and white matter demyelination.[71]

2-Methylacyl-Coenzyme A Racemase Deficiency

2-Methylacyl-CoA racemase (AMACR) deficiency is a rare disorder caused by mutations in the *AMACR* gene encoding the enzyme 2-methylacyl-CoA racemase. The enzyme catalyzes the isomerization of fatty acids with a methyl group in the *R* configuration to the corresponding *S* configuration, an obligatory reaction in the steps leading to peroxisomal β-oxidation. This results in impaired bile acid synthesis and pristanic acid metabolism and subsequent accumulation of pristanic acid, (25 *R*)-trihydroxycholestanoic acid, and (25 *R*)-dihydroxycholestanoic acid.[90] Most patients present with an adult-onset ataxia and sensory neuropathy; however, an infantile presentation with cholestatic liver disease, coagulopathy, and fat-soluble vitamin deficiency has been reported.[56,90]

X-Linked Adrenoleukodystrophy

X-linked adrenoleukodystrophy (X-ALD) is the most common peroxisomal disorder, with an estimated incidence of ~1 in 15,000.[56,91,92] It is caused by the altered function of the peroxisomal transmembrane protein ABCD1, which predominantly catalyzes the import of straight-chain VLCFAs into peroxisomes.[56] Defects in ABCD1 lead to an inability to transport VLCFAs across the peroxisomal membrane resulting in accumulation of VLCFA in plasma and tissues, preferentially in the central nervous system, adrenal cortex, and Leydig cells of the testes. X-ALD does not usually present in the newborn period; however, contiguous *ABCD1 DXS1357E* deletion syndrome, caused by a contiguous gene deletion of *ABCD1* and its upstream gene *DXS1357E*, may. Four male patients have been reported with profound neonatal hypotonia, severe growth and developmental retardation, cholestatic liver disease, accumulation of VLCFAs, and death within the first year of life.[85,93,94] Increasingly, as more and more states adopt newborn screening (NBS) for X-ALD, this diagnosis will be made in the newborn period. Notably, adrenal insufficiency, a common feature of this disorder, has been found in infants as young as 4.5 months of age with biochemical evidence of adrenal insufficiency as young as 5 weeks of age.[92,95] Early screening for adrenal insufficiency is, thus, recommended.[92]

Diagnosis of Peroxisomal Disorders

The key to diagnosing peroxisomal disorders is a high index of suspicion. Peroxisomal disorders should be considered in newborns with dysmorphic facial features, skeletal abnormalities, shortened proximal limbs, neurologic abnormalities (including hypotonia or hypertonia), ocular abnormalities, and hepatic and renal abnormalities. Babies with abnormal vision, hearing, or somatosensory evoked potentials should also be considered for these diagnoses.

Peroxisomal disorders are not associated with acute metabolic derangements or abnormal routine laboratory test findings. Measurements of the levels of VLCFAs, phytanic acid, pristanic acid, pipecolic acid, bile acid intermediates, and plasmalogens are required for diagnosis and remain the screening studies of choice. Zellweger syndrome is associated with elevations of the levels of VLCFAs, phytanic acid, pipecolic acid, and bile acid intermediates as well as a decrease in plasmalogen synthesis. Neonatal adrenoleukodystrophy and infantile Refsum disease have similar biochemical findings; however, the defect in plasmalogen synthesis and the degree of VLCFA accumulation are less severe. Laboratory findings in RCDP include elevations of the levels of phytanic and pipecolic acids, a decrease in the levels of plasmalogens, and normal levels of VLCFAs and bile acid intermediates. Hence, biochemical screening using only levels of VLCFAs will fail to detect RCDP. Also, a small number of patients with mutations in PEX genes have been identified with mild or absent elevations in VLCFA levels.[55,57] DBPD is associated with deficient oxidation of C23:0 and pristanic acid, leading to elevations of the levels of pristanic acid and, to a lesser extent, phytanic acid. This deficiency results in an elevated pristanic acid to phytanic acid ratio, which is generally not elevated in PBD. Abnormal VLCFA levels and elevations of the levels of varanic acid, an intermediate metabolite in β-oxidation, are also seen. Accumulation of bile acid intermediates is a variable finding. Recently, C26:0-lysophosphatidylcholine (C26:0 lyso PC) measurement in dried blood spots using liquid chromatography tandem mass spectrometry (LC-MS/MS) has been introduced as a screening method, but may be of limited practical use due to its limited clinical availability.[57,96] Another possible biomarker for VLCFA accumulation is C26-carnitine. This, too, can be measured in dried blood spots, but also has limited clinical availability.[57,96]

Abnormalities in the levels of phytanic acid and plasmalogens are age-dependent. The elevation of the levels of phytanic and pristanic acids might not be demonstrable in newborns not consuming dairy products or other dietary sources of these fatty acids, and reduction in red blood cell plasmalogen levels may not be evident in children older than 20 weeks.[55,59,97] Pipecolic acid levels are more likely to be abnormal in the urine of newborns and more abnormal in plasma at later ages.[55] A ketogenic diet may elevate VLCFA levels as will excess dietary intake of peanuts.[55,96,97] A liver biopsy may be a useful adjunct diagnostic tool to assess the presence or absence and structure of peroxisomes. Definitive diagnosis for all types may require cultured skin fibroblasts for measurement of the levels of VLCFAs and their β-oxidation and, as needed, assay of the peroxisomal steps of plasmalogen synthesis, phytanic acid oxidation, subcellular localization of catalase, enzyme assays, and immunocytochemistry studies. Increasingly, next-generation sequencing panels for the PEX genes and whole exome/genome sequencing are being used for both diagnostic and confirmatory testing.[55,96] DNA study for deletions also has a role in diagnostic evaluation in some cases as demonstrated by the neonatal presentation of cases with deletion of the *ABCD1* gene on the X chromosome.[85,93,94] Diagnostic flow diagrams have been published by Shimozawa et al. and Klouwer et al.[60,85]

Prenatal diagnosis with a variety of methods is available. It can be accomplished in the first or second trimester by biochemical or genetic testing in chorionic villi cells or cultured amniocytes.[54,55,60] Preimplantation genetic diagnosis can be performed when the PEX mutations are known. Carriers cannot be identified by biochemical testing.[54]

One of the more interesting recent developments in peroxisomal diseases is consideration of NBS. The combination of liquid chromatography and tandem mass spectrometry to detect elevated levels of VLCFAs (C26:0-lysophosphatidylcholine) in newborn dried blood spots has been validated as a diagnostic approach for X-ALD.[55] Screening for X-ALD was approved for addition to the Recommended Uniform Screening Panel in 2016 and an increasing number of states are implementing NBS for X-ALD. NBS for X-ALD should also detect the majority of ZSDs, permitting early diagnosis and intervention.[55,57,60]

Management of Peroxisomal Disorders

Treatment for all peroxisomal disorders in the newborn period remains symptomatic and supportive. These disorders are chronic, progressive diseases with no currently available curative therapy. In patients with severe disease, seizure control, feeding, and respiratory support are the main focus of management.[55] Feeding difficulties, including malabsorption, are prominent and may require the use of elemental formulas and/or gastrostomy tube placement. Dietary reduction in VLCFAs has not been shown to reduce plasma VLCFA levels as most VLCFAs are produced endogenously.[55] In patients with X-ALD, dietary reduction of VLCFAs in combination with supplementation with Lorenzo's oil (a 4:1 mixture of glyceryl trioleate and glyceryl trierucate) can reduce plasma VLCFA levels but does not affect progression of already present leukodystrophy.[55,98] Use of Lorenzo's oil has not been studied in ZSDs but may be contraindicated because of the presence of increased levels of dietary monounsaturated fatty acids in patients who already accumulate large amounts of C26:1.[55,60] Because of impaired synthesis of docosahexanoic acid, supplementation with docosahexanoic acid was previously recommended. A placebo-controlled study, however, showed no clinical benefit with supplementation.[99] Also, because of defective bile acid synthesis, supplementation with the fat-soluble vitamins, A, D, E, and K, is recommended.[55] Studies evaluating the effectiveness of bile acid supplementation (cholic acid and chenodeoxycholic acid) are limited, but bile acid supplementation may improve liver function, urine bile acids, and growth, but does not appear to impact extra-hepatic disease manifestations or disease progression.[55,57,90,100] Caution is warranted in individuals with preexisting advanced liver disease due to possible hepatoxic effects.[57] Bezafibrate has been suggested as a possible therapeutic option in DNML1 deficiency.[81] Betaine and arginine have been recognized to be molecular chaperones that can improve peroxisomal assembly and may have a future therapeutic role.[54]

Further supportive care includes use of antiepileptic medications for seizure control, oxygen supplementation as needed for respiratory difficulties, use of hearing aids or cochlear implants for hearing loss, use of glasses for vision difficulties, routine dental care, and routine immunizations. Screening for adrenal insufficiency should occur regularly, and replacement therapy should be started as indicated with stress doses when necessary. Citrate therapy may help prevent renal oxalate stones. Bone density and vitamin D status should be monitored. Comprehensive developmental services should be provided. Treatment guidelines have been proposed and published by Braverman et al.[55]

Hematopoietic stem cell transplantation (HSCT) is the established therapy for the cerebral childhood form of X-ALD, but there are no reports describing HSCT in ZSDs.[60] Use of HSCT was reported in a young child with acyl-CoA oxidase deficiency. It was considered as a possible disease-arresting therapeutic intervention following recognition that the neuropathologic features of acyl-CoA oxidase deficiency resemble those of X-ALD.[87] Despite full engraftment, the child experienced neurodegeneration and died in childhood.[87] Hepatocyte transplantation and orthotopic and living donor liver transplantation have been described in patients with infantile Refsum disease with improvement in biochemical parameters and clinical course.[101–104] Gene therapy may provide future hope.[105,106]

Outcomes of Peroxisomal Disorders

The prognosis for patients with a neonatal-onset peroxisomal disease remains poor, and patients frequently die within the first year of life. Patients with later presentation have a better prognosis but still have progressive disease. Plasma levels of metabolites do not correlate well with disease severity.[60] There is, however, a generally good correlation between the defective PEX gene, the type of mutation, and the impact on peroxisomal assembly and function and the clinical severity.[54]

Smith-Lemli-Opitz Syndrome

Etiology of Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome (SLOS) is a well-recognized autosomal recessive malformation syndrome, with an estimated incidence ranging from 1 in 10,000 to 1 in 70,000 in various populations.[107–109] In 1993, it was discovered that SLOS is caused by a defect in cholesterol biosynthesis that results in low levels of cholesterol and elevated levels of 7-dehydrocholesterol (7DHC) and its isomer 8-dehydrocholesterol (8DHC).[110,111] Patients with SLOS have markedly reduced activity of 7DHC reductase,[112] the enzyme responsible for conversion of 7DHC to cholesterol encoded by the gene *DHCR7*.[113] The cause of the clinical phenotype of SLOS may be related to deficient cholesterol, deficient total sterols, and toxic effects of either 7DHC or compounds derived from it, or a combination of these factors.[114]

Cholesterol is a major lipid component of cellular membranes such as myelin, and it is an important structural component of lipid rafts, which play a major role in intracellular signaling. In animal and in vitro models of SLOS, altered ratios of cholesterol, its dehydrocholesterol precursors, and its derivatives have been noted to alter membrane rigidity, alter electrostatic properties of biologic membranes that can change the activity of ion-dependent adenosine triphosphatases and channels, decrease the stability of lipid rafts leading to increases in degranulation of mast cells, and reduce ligand binding to receptors such as the serotonin 1 A receptor. In addition, bile acids, steroid hormones, neuroactive steroids, and oxysterols are all synthesized from cholesterol, and dehydrocholesterols can also serve as precursors of related steroids, bile acids, and oxysterols that may be antagonists or agonists of the ones derived from cholesterol.[114] Cholesterol is also involved in hedgehog signaling by acting as a cofactor and covalent adduct to hedgehog members.[115] Hedgehog is a family of signaling proteins that are critical to pattern formation through interactions with the homeobox genes during embryonic development, and altered hedgehog signaling could explain some malformations seen in SLOS, such as holoprosencephaly and postaxial polydactyly.[115–117] In addition, 7DHC is highly sensitive to oxidation, and thus increased free radical generation may be a possible contributor to certain aspects of the disease, such as retinal degeneration.[118,119]

Clinical Features of Smith-Lemli-Opitz Syndrome

Classic SLOS is often evident at or before birth; affected patients have prenatal and postnatal growth retardation, microcephaly, and facial dysmorphism, including bitemporal narrowing,

ptosis, epicanthic folds, anteverted nares, broad nasal tip, prominent lateral palatine ridges, retromicrognathia, and low-set ears. Other features include two-three toe syndactyly (found in 95% of patients), small proximally placed thumbs, equinovarus foot deformity, postaxial polydactyly, and cataracts. Males usually have hypospadias, cryptorchidism, and a hypoplastic scrotum but may have ambiguous or female genitalia. Females may have a bicornuate uterus and/or septate vagina. Pyloric stenosis, cleft palate, bifid uvula, pancreatic anomalies, constipation, Hirschsprung disease, renal anomalies, renal calculi, congenital heart defects, lung segmentation defects, anomalies of thymus development, hypothyroidism, and hypoparathyroidism have also been reported. Hypotonia progressing to hypertonia is also present. Feeding difficulties and vomiting are common problems in infancy. Irritable behavior and shrill screaming may also pose problems during infancy. Additional features reported in infancy include pulmonary vein stenosis, adrenal insufficiency with hyperkalemia and hyponatremia, hypocalcemia and hypercalcemia, necrotizing enterocolitis, sepsis-like episodes, and cholestasis with frequent early death.[120–122] Hydrops fetalis has also been reported.[121] Older children frequently have hyperactivity, self-injurious behavior, sleep difficulties, and autistic characteristics. Acute adrenal crisis has been reported as a rare initial presentation of SLOS.[123] Neuroimaging studies and autopsies show defects in brain morphogenesis, including holoprosencephaly, frontal lobes, cerebellum, and brainstem hypoplasia, irregular gyral patterns, and irregular neuronal organization.[114,124]

Historically, approximately 20% of patients die within the first year of life, although others may survive for more than 30 years. The clinical severity in SLOS correlates best with either reduction in absolute cholesterol levels or the sum of 7DHC and 8DHC levels expressed as a fraction of total sterol levels.[125] In one report, a plasma cholesterol level of less than 0.35 mmol/L was associated with early death, but a direct correlation between cholesterol levels and severity of symptoms could not be firmly established.[121] Life expectancy appears to correlate inversely with the number and severity of organ defects and with the kinds and numbers of limb, facial, and genital abnormalities.[126] Developmental outcomes are also highly variable, ranging from severe mental retardation to normal intelligence.[127] Intelligence quotient does not, however, correlate with genotype.[127] Growth is typically lower than in unaffected individuals, and specific growth charts have been developed.[128] In adults, depression and anxiety may manifest themselves, and there has at least been one mildly affected female who has undergone a pregnancy with a good outcome.[129] Testing for SLOS has been suggested for all patients with idiopathic intellectual impairment, behavioral anomalies, or both when associated with nonfamilial two-three toe syndactyly and failure to thrive.[130]

Diagnosis of Smith-Lemli-Opitz Syndrome

Recognition of the biochemical defect in SLOS provided the diagnostic test required to recognize the mildest and severest cases, substantially expanding the clinical spectrum of the condition. Biochemical testing is thus the first-tier choice for the diagnosis of SLOS. The diagnosis is based on findings of elevated levels of 7DHC and 8DHC. False-positive elevations of 7DHC levels occur in patients taking psychoactive medications such as aripiprazole, trazodone, and haloperidol as well as in patients with increased cholesterol synthesis because of bile acid loss after ileal resection.[114] Plasma cholesterol levels are usually low, but cholesterol is a poor diagnostic marker since, and as many as 10% of patients with SLOS have normal cholesterol levels. Also, in many laboratories, measured cholesterol levels include cholesterol as well as 7DHC and 8DHC.[117]

Confirmation of diagnosis through molecular analysis of *DHCR7* is possible and recommended in cases where the serum concentration of 7DHC is difficult to interpret or prenatal or preimplantation genetic diagnosis is desired. Rapid whole genome sequencing is quickly becoming the test of choice for an ill neonate. Phenotype-genotype correlation is poor and patients with the same genotype can have markedly different severity.[131] Modifier genes are likely present, and maternal *APOE* and *ABCA1* genotypes that alter maternoplacental cholesterol transfer appear to modify disease severity.[132,133] If the genotype is unknown but prenatal testing is desired, abnormal levels of 7DHC from amniotic fluid or tissue from chorionic villus samples can be used for prenatal diagnosis, although false-negatives can occur in mild cases. Prenatal sonographic findings of intrauterine growth retardation, increased nuchal translucency, nonimmune hydrops, unusual facial features, cystic hygroma, or major malformations in brain, heart, kidneys, limbs, genitalia, and palate are consistent with SLOS but have low sensitivity and specificity. Maternal serum screening showing low levels of unconjugated estriol, human chorionic gonadotropin, and alpha-fetoprotein is also consistent with SLOS.[124]

Management of Smith-Lemli-Opitz Syndrome

Because of the underlying biochemical defect in SLOS, targeted treatment strategies to date have mainly focused on supplying exogenous cholesterol with the goal of raising cholesterol levels and secondarily lowering 7DHC and 8DHC levels by downregulating the patient's endogenous cholesterol synthesis. Cholesterol is typically given as a dietary modification (egg yolk, breast milk in infants), as a crystalline cholesterol suspension, or as a microencapsulated cholesterol powder with dosing dependent on the formulation ranging from 20 to 300 mg/kg.[117,134,135] Unfortunately, dietary studies on cholesterol supplementation have not been conducted in a randomized fashion except for one short-term study that found no difference in short-term behavior in patients treated with cholesterol supplementation.[136] Case series have reported that cholesterol supplementation in SLOS has improved growth, development, and behavior, increased nerve conduction velocity, and decreased skin photosensitivity, susceptibility to infection, and cholestatic liver disease of infancy when used with and without bile acid replacement. Cholesterol supplementation in SLOS has minimal side effects.[114,124] However, given that dietary cholesterol does not cross the blood–brain barrier and that SLOS cells have impaired intracellular cholesterol transport, the efficacy of cholesterol supplementation is likely limited.[137,138]

Other targeted therapies have also been attempted, but none have been validated by controlled studies. Bile acid replacement has been used with cholestatic liver disease in infancy. Fresh frozen plasma, which contains high levels of cholesterol-rich lipoproteins such as low density lipoprotein (LDL), has been used in acutely ill or severely stressed patients and in the setting of fetal intravenous and intraperitoneal transfusion. Stress steroid dosing has been used when there is evidence of adrenal insufficiency. A 3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitor (simvastatin) has been used to improve cholesterol profiles, but its use had to be stopped in one individual who experienced liver dysfunction.[114] A more recent randomized, double-blind, placebo controlled, crossover

trial of simvastatin in 23 individuals with SLOS was well tolerated and appeared to improve serum DHC/total sterol ratio and significantly improve irritability symptoms.[139] Additionally, there may be a role for antioxidants in SLOS since 7DHC is highly reactive and gives rise to biologically active oxysterols.[140] Direct delivery of cholesterol to the CNS by low-pressure catheter infusions has been proposed but not tested.[141] Gene therapy, the use of neuroactive steroids, and inhibition of glycosphingolipids are also being investigated as possible therapeutic options in SLOS.[142]

Even without proven targeted treatments, appropriate supportive management is important. Following the initial diagnosis, to establish the extent of disease and the needs of the individual, recommended evaluations include the following lengthy list: developmental assessment, ophthalmologic evaluation, cardiac evaluation including ECG and echocardiogram, musculoskeletal evaluation especially for the need for orthotics, genital urinary examination, nutritional assessment, renal ultrasonography, brain magnetic resonance imaging, hearing evaluation, GI evaluation with special effort to evaluate the patient for pyloric stenosis, gastroesophageal reflux, and Hirschsprung disease if indicated, evaluation of immune status, medical genetics consultation, and laboratory studies to evaluate the patient for adrenal insufficiency, thyroid dysfunction, electrolytes abnormalities, and cholestatic liver disease. Referral to early intervention and physical, occupational, and speech therapies is needed in the majority of cases. Surgical interventions, such as gastrectomy tube insertion, surgical repair of cataracts, ptosis, or strabismus, pyloromyotomy, surgical repair of syndactyly or polydactyly, tendon release surgery in cases with significant hypertonia, and tympanostomy may be required in individuals with SLOS. Anesthetic complications of malignant hyperthermia have been reported. Treatment with medications with high affinity for the 7DHC reductase substrate may worsen the biochemical abnormalities so when medications such as haloperidol, trazodone, or aripiprazole are being used, potential benefits need to be weighed against the theoretical risk of worsening the underlying disease. Some infants with severe feeding problems benefit from use of hypoallergenic, elemental formulas. Patients also need to avoid extended periods of sun exposure and use appropriate sun protection measures given the issue with photosensitivity.[124]

32 Immunology of the Fetus and Newborn

JOERN-HENDRIK WEITKAMP, DAVID B. LEWIS, AND OFER LEVY

KEY POINTS

- The fetus and newborn express a distinct and evolving immune system that mediates transition from intrauterine life to the microbe- and antigen-rich world.
- Multiple mechanisms including regulatory T cells help ensure maternofetal immune compatibility.
- Newborns are highly reliant on soluble and cellular innate immune mechanisms whose ontogeny depends on gestational and postnatal age.
- Adaptive immunity in newborns features distinct ontogeny and functionality of T and B cells.
- Primary immunodeficiencies that present in early life include genetic defects in innate and adaptive immunity.

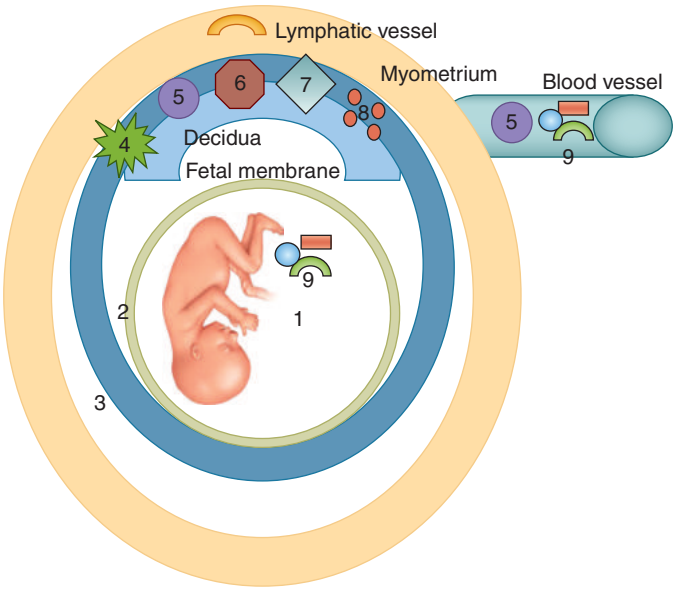
Newborns are at high risk of infection-induced morbidity and death. Understanding the contribution of the newborn's distinct immune response to age-dependent susceptibility to infectious diseases has important implications for efforts to protect newborns from infection and entails review of the immunologic environment of pregnancy and the ontogeny of fetal and neonatal immunity.[1] The distinct functions of fetal, neonatal, and maternal immunity reflect adaptation to developmental challenges such as preservation of fetal well-being as an allogeneic graft versus adequate immunologic protection in the extrauterine environment. These immunologic transitions are regulated by a number of incompletely understood developmental and genetic mechanisms. The diversity and importance of these mechanisms are suggested by the heterogeneity and frequency of neonatal infections. Differences in immunologic responsiveness between newborns and adults are not defects or abnormalities but rather highly regulated ontogenic differences that facilitate transitions between distinct age-specific challenges. Just as the ductus arteriosus, a cardiopulmonary necessity in the intrauterine environment, closes at different rates in different infants, there is variability in the pace at which developmentally and genetically programmed human fetal and newborn immunity changes from graft preservation to identification and destruction of invading pathogens.

Maternal and Placental Immunology

Immunologic tolerance to the growing fetus is a prerequisite for a successful pregnancy. The maternal–fetal interface is a dynamic site that encompasses multiple cellular interactions in an environment rich in cytokines and hormones. While immune mechanisms need to be in place to defend against microbial invasion,[2,3] the placenta is typically programmed to protect the fetus from rejection by the maternal immune system.[3,4]

Several distinct but complementary innate and adaptive immune mechanisms contribute to the commensal immunologic relationship between the mother and the fetus throughout pregnancy (Fig. 32.1 and Table 32.1). Local (placental) and systemic (circulatory) factors mediate maternal tolerance to the fetus.[4] For example, human trophoblasts do not express conventional major histocompatibility complex (MHC) class I human leukocyte antigen (HLA)-A or HLA-B molecules, likely contributing to reduced alloantigenic recognition at the fetal–maternal interface. Human trophoblasts express HLA-C, principally during the first trimester of pregnancy,[5] and two nonclassical HLA molecules, HLA-E and HLA-G. HLA-G class Ib is expressed on extravillous cytotrophoblast and endothelial cells of fetal vessels in the chorionic villi as well as in amnion cells and amniotic fluid.[6,7] Unlike classical MHC molecules, HLA-G does not have a significant role in stimulating $CD8^+$ T cells via the T-cell receptor (TCR) complex. Rather, the principal function of HLA-G molecules expressed by the trophoblast appears to be modulation of the activity of natural killer (NK) cells. HLA-G has additional immunomodulatory properties, including inhibition of activity of cytotoxic T cells, inhibition of alloproliferative responses by $CD4^+$ T cells, and modulation of dendritic cell (DC) maturation and function.[8] These data reveal that the unique MHC class I molecule expression pattern on fetal trophoblast constitutes an intricate mechanism for orchestrating the activity of immune cells.

Other local factors contributing to maternal–fetal tolerance include selective degradation of tryptophan by the inducible enzyme indoleamine 2,3-dioxygenase inhibiting T-cell proliferation[9] and engagement of the proapoptotic molecule Fas on maternal lymphocytes by its ligand (FasL) on interstitial trophoblast cells.[10] FasL is expressed in both maternal and fetal components of the uteroplacental unit throughout gestation. Activated T cells express the Fas receptor, which delivers an apoptotic (death) signal when bound by FasL. Therefore, expression of FasL limits the reciprocal migration of activated fetal and maternal T cells. Mice with a nonfunctional FasL demonstrate leukocyte infiltration and necrosis at the decidual–placental border, with many resorption sites and small litters.[11] Progesterone-induced blocking factor is an immunomodulatory molecule released in response to progesterone by trophoblasts.[12] Its properties include indirect suppression of NK-cell function and inducement of bias of $CD4^+$ T cells toward T_h2-type cytokine secretion.[13]



• **Fig. 32.1** Immunology of the Fetomaternal Interphase. While competent immune cells and bacteria can enter the fetomaternal interphase, multiple complex immune interactions are in place during healthy pregnancy to balance immune defense with immune tolerance between the mother and the allogeneic fetus. Several distinct but complementary innate and adaptive immune mechanisms contribute to the commensal immunologic relationship that exists between the mother and the fetus throughout pregnancy. In humans the decidua represents the uterine implantation site, where maternal blood flows into the intervillous space, "bathing" fetus-derived villous trees composed primarily of cytotrophoblasts. The surface of these villi consists of multinucleate syncytiotrophoblasts mediating nutrient and gas exchange between maternal and fetal tissues. The villi are directly exposed to circulating maternal immune cells. However, these cells do not recognize fetal tissue as "foreign" mainly because human trophoblasts lack classical class I and class II antigens and instead express human leukocyte antigen G (HLA-G). HLA-G and pregnancy hormones suppress natural killer (*NK*) cell and macrophage function and induce a bias of $CD4^+$ T cells toward T_h2-type cytokine secretion. DCs are present in small numbers during pregnancy in decidual tissue but show impaired migration to draining uterine lymph nodes (entrapment). Regulatory T (*Treg*) cells specific to the fetus increase in number in the mother during gestation, and cells maintaining tolerance to fetal antigen can rapidly expand during a subsequent pregnancy. The role of exposure to microbial antigens in fetal immune priming seems important, but the exact mechanism is still being explored.

TABLE 32.1 Local and Systemic Factors Mediating Maternal Tolerance to the Fetus

Factor	Function
Expression of nonclassical HLA molecules (e.g., HLA-G)	Inhibition of NK cells, $CD4^+$ T cells, and cytotoxic T cells, and modulation of dendritic cell maturation and function
Indoleamine 2,3-dioxygenase	Depletes tryptophan and prevents T-cell proliferation
Fas ligand	Apoptosis of activated fetal and maternal T cells
Programmed death 1 and its ligand	Negative regulator of T-cell responses
Galectins	Apoptosis of activated fetal and maternal T cells
Decay-accelerating factor	Control of complement activation
Cytokines	T_h2 bias prevents immune activation
Decidual macrophages	Suppressing immune activation
Decidual NK cells	Suppressing immune activation
$FoxP3^+$ regulatory T cells	Suppressing immune effector cells (e.g., in response to paternal antigens)
Microbiome	Balanced immune response

FoxP3, Forkhead box P3; *HLA*, human leukocyte antigen, *NK*, natural killer.

Galectins are expressed in human placenta primarily by the syncytiotrophoblast early in pregnancy.[14] On cell surface contact, galectins downregulate the cellular immune response, in part by inducing programmed cell death (apoptosis) of T lymphocytes.[15]

On a cellular level, DCs, an important type of antigen-presenting cell (APC) critical for cellular and humoral immune responses, play a prominent role in organ transplant rejection. The potential deleterious actions of DCs against the fetus may be curtailed by at least two factors: the progressive decline of decidual DC tissue densities shortly after implantation and impaired migration from decidual tissue to draining uterine lymph nodes. This entrapment of DCs during pregnancy may reflect both disappearance of lymphatic vessels during decidualization[16] and stromal cell-based processes limiting chemokine-directed cell migration.[17] Other important cellular factors that may limit potential anti-fetal immune responses include the immunosuppressive phenotype of decidual macrophages[18] and decidual NK cells.

Complement inhibition is essential for normal pregnancy in a murine model of antiphospholipid syndrome, an autoimmune condition characterized by thrombosis, thrombocytopenia, and recurrent fetal loss. In this model, fetal injury results from placental inflammation initiated by local dysregulation of complement proteins. Both complement activation and fetal loss can be prevented by administration of anticoagulants with complement-inhibitory properties such as heparin but not by anticoagulants lacking complement-binding properties.[19,20] Some but not all human clinical interventional studies using anticoagulants with complement-binding properties to prevent fetal loss in antiphospholipid syndrome have suggested benefit.[21] Control of complement activation during human pregnancy is achieved by expression of decay-accelerating factor, membrane cofactor protein, and CD59 (protectin) on the trophoblast membrane,[22] as well as high reproductive tract and systemic prostaglandin E_2 levels contributing to maternal immune tolerance to the fetus.[23]

In addition to local components, systemic elements are in place to maintain immune tolerance at the maternal–fetal interface. Abatement of certain autoimmune diseases during pregnancy[24] and an increased risk of infections[25] provide evidence for a broadly immunosuppressive state during pregnancy.[26] Although the precise mechanisms underlying this phenomenon are incompletely characterized, several reproductive hormones may play critical roles. For example, a relatively large study demonstrated that 48% of

patients with at least moderate rheumatoid arthritis showed signs of remission in the first trimester of pregnancy, while ~40% had a disease flare-up in the postpartum period.[24] The rate of relapse in multiple sclerosis declines during pregnancy,[27] and treatment with pregnancy levels of estriol significantly reduced enhancing lesions on brain imaging.[28] In addition, estrogen (17β-estradiol) in concentrations typically expressed during normal pregnancy augments forkhead box P3 (FoxP3) expression and expansion of T regulatory (Treg) cells in vitro and in vivo.[29,30]

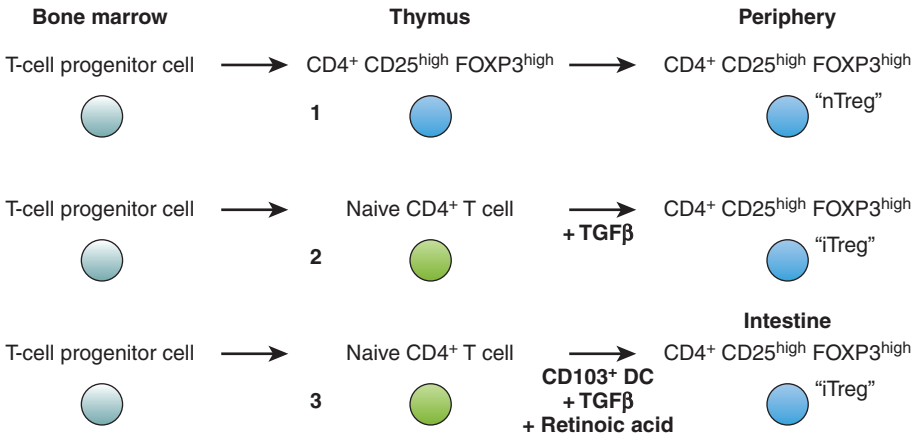
T cells and T-cell–derived cytokines play a central role in immune regulation and inflammation. T_h1 cells are involved in cellular immunity and transplant rejection and are characterized by production of interleukin (IL)-2, interferon gamma (IFN-γ), and tumor necrosis factor alpha (TNF-α). In contrast, T_h2 cells are mediators of humoral immunity and produce IL-4, IL-5, and IL-13. Traditional dogma holds that a bias in T-cell cytokine secretion toward T_h2-type cytokines and away from T_h1-type cytokines is an immunologic condition necessary for maintaining healthy pregnancy.[31] For example, IL-10 is a pregnancy-compatible cytokine that plays a vital role in maintaining immune tolerance.[32] For example, IL-10 induces expression of HLA-G on trophoblasts, which has direct and indirect immune suppressive effects as described above.[33] In vitro, IL-10 suppresses macrophage activity and $CD4^+$ T-cell proliferation and can convert DCs and conventional T cells into a tolerogenic state.[34] In human pregnancy, lower levels of serum IL-10 are associated with pregnancy complications such as spontaneous miscarriage, preeclampsia, and fetal growth restriction.[35]

Significant shifts in the T_h1/T_h2 balance have been associated with various immune-mediated pregnancy complications. However, the emerging role of NK cells and cytokines such as IL-12, IL-15, IL-18, IL-19, and IL-20 suggest that the T_h1/T_h2 paradigm may be oversimplified.[36,37] For example, a subset of CD4 T cells that produce IL-17A and IL-17F, called *T_h17 cells*, may be involved in rejection of the fetus.[38,39] Another molecule with an immunomodulatory effect on multiple cell types present in the decidua is TGF-β. TGF-β suppresses APCs and decidual NK cells, while promoting the development of regulatory T cells.[34] Serum concentrations of TGF-β are elevated in pregnant women and may protect them from spontaneous abortion.[40]

Role of Regulatory T Cells in Pregnancy

The discovery of a distinct lineage of T lymphocytes with dominant immunosuppressive properties[41] provided a significant breakthrough in understanding the mechanisms whereby adaptive allogeneic responses against paternal antigens are actively suppressed during pregnancy. This type of Treg cell is characterized by expression of a lineage-specific transcription factor, FoxP3 (Fig. 32.2). Upon activation via their antigen-specific TCR, Treg cells suppress immune effector cells, including DCs and effector T cells via a variety of mechanisms,[42] thereby preventing a fatal form of autoimmune disease throughout life.[43] Treg cells and T_h17 cells are two distinct lymphocyte subsets with opposing actions and share a complex relationship. Treg cells have a role in suppressing autoimmune responses and preventing the rejection of the fetus, and a decrease in Treg cell number is associated with miscarriage. In contrast, T_h17 cells promote inflammation, transplant rejection, and autoimmunity, and increases in T_h17 cell numbers and decreases in Treg cell numbers are associated with recurrent miscarriage.[38,39,44] The numbers of Treg cells specific to the fetus increase in the mother during gestation, and cells maintaining tolerance to fetal antigen can rapidly expand during subsequent pregnancy.[45] Paternal antigens may induce expansion of Treg cells, likely contributing to maternal tolerance to the allogeneic fetus.[46] Maternal and fetal Treg cells are essential in promoting fetal survival by avoiding the recognition of paternal semi-allogeneic tissues by the maternal immune system.[44,47]

In addition to $FOXP3^+$ Treg cells, $FoxP3^-$ $HLA\text{-}G^+$, Tr1, and T_h3 Tregs, $CD8^+$ Treg cells, nitric oxide (NO) induced FoxP3– Tregs, $TIGIT^+$ Tregs, $FoxP3^{dim}$ Tregs, and gamma/delta T cells have been reviewed.[34] Similar to $FOXP3^+$ Tregs, these cells via



• **Fig. 32.2** Forkhead Box P3–Positive Regulatory T-Cell Subpopulations and Their Development. Most human regulatory T (*Treg*) cells in peripheral blood originate from the thymus and are typically called *natural Treg* (*nTreg*) or *thymus-derived Treg cells* (*1*). Treg cells can originate from naive T cells in the periphery and are induced to express the identifying transcription factor forkhead box P3 (*FOXP3*) under the influence of transforming growth factor beta (*TGFβ*), at least in vitro (*2*). The Treg cells are often called *induced Treg* (*iTreg*) *cells*. Most Treg cells in the intestinal mucosa are thought to be iTreg cells originating from naive T cells in the mucosal immune system under the influence of specific antiinflammatory dendritic cells ($CD103^+$ dendritic cells), TGFβ, and retinoic acid (*3*). The iTreg cells play an important role in pregnancy maintenance. *DC*, Dendritic cell.

production of soluble factors such as soluble HLA-G, IL-10, or TGF-β or costimulatory molecules, such as programmed death 1 (PD1). The interaction between PD1 and its ligand (PDL1) plays important roles in maintaining tolerance at the fetomaternal interface. PDL1 is expressed on the trophoblasts of the placenta, and PD1 is expressed on the maternal effector T cells and Treg cells. PDL1 expression maintains Treg cell/effector T-cell ratios and suppresses increases in the number of T_h17 cells.[48] Blockade of PDL1 signaling in animal models results in fetal rejection.[49] The role and ontogeny of fetal Treg cells is discussed more fully in the section entitled Adaptive Immunity.

Role of the Microbiome

The paradigm of a sterile uterus postulates that the fetus develops free of bacteria and antigenic agents.[50] However, bacteria can be cultured from amniotic fluid and fetal tissues in pregnancies complicated by preterm labor even without rupture of membranes.[51] Bacterial DNA was detected in the intestines and placentas of fetal mice at late gestation (day 17).[52] Analysis of human fetal tissues in the second trimester detected microbial signals in fetal gut, skin, placenta, and lungs as well as live bacteria that were able to induce the activation of memory T cells in the fetal mesenteric lymph node.[53] Of note, no microbial signatures were detected in fetal meconium, in contrast to postnatal first-pass meconium, suggesting that microbial colonization of the intestine occurs predominantly during and/or immediately after birth.[54] While fetal intestinal samples did not contain detectable bacterial DNA, a metabolomic intestinal profile was noted with an abundance of bacterial metabolites and aryl hydrocarbon receptor (AHR) ligands implicated in mucosal immune regulation.[55] While not yet widely accepted in humans, maternal microbial transmission to the fetus is a universal phenomenon in animals and even plants, likely constituting an essential evolutionary act of symbiosis.[56,57] The exact mechanisms by which bacterial antigens may pass from the mother to the fetus are being investigated. Placental bacteria resemble most closely the human oral microbiome,[2] suggesting hematogenous bacterial transfer. In mice, the majority of fetal gut genera overlapped with placental, maternal oral, and vaginal taxa but not with maternal or newborn feces.[52]

Globally, these studies imply a possibly critical role of maternal bacteria to inform normal immune development of the developing fetus. The importance of fetal programming has been well described for cardiovascular and metabolic diseases and is now also considered in the context of environmentally influenced immune-mediated diseases. Initial exposure of bacterial molecular patterns to the fetus in utero may prime the immune system and/or the epithelium to respond appropriately to pathogens and commensals after birth.[58,59] For example, maternal exposure to farm animals during pregnancy was associated with greater Toll-like receptor (TLR) gene expression and lower risk of atopic sensitization in children.[60] Similar protective effects against atopic sensitization were observed after dietary interventions during pregnancy, such as maternal supplementation with fish oil[61] or probiotics.[62] In contrast, antibiotic use in pregnancy was associated with asthma during the fifth year of life.[63]

The mechanism underlying prenatal immune priming is unknown. In an experimental asthma model, microbial exposure to pregnant mice resulted in epigenetic changes in promoter regions of cytokines associated with an allergic phenotype-increased expression of IFN-γ and reduced expression of IL-4, IL-5, and IL-13.[64] This concept has been confirmed in human studies where exposure to farms during pregnancy has been associated with increased DNA demethylation of the FoxP3 locus and increased number and function of Treg cells in UCB cells.[65]

Maternal dietary factors may play an important role in microbiome-associated fetal immune education. For example, short chain fatty acids derived from fermentation of dietary fiber by intestinal microbes of the pregnant mother increased fetal Treg cells and protected offspring from inflammatory diseases, including asthma and metabolic syndrome.[66–68] Maternal gut colonization during pregnancy programs transcriptional profiles of the offspring that not only decrease susceptibility to inflammation but can also strengthen innate immune defenses, such as the integrity of the intestinal epithelial barrier. Some of these effects seem dependent on maternal antibodies that potentially retain microbial molecules and transmit them to the offspring during pregnancy.[69]

Despite growing evidence of the importance of the maternal microbiome on fetal immune regulation, much remains to be learned regarding the molecular mechanisms strengthening fetal immunity while at the same time promoting tolerance and anti-inflammatory acceptance of the antigen-rich postnatal environment.

Effect of Chorioamnionitis on the Developing Fetal Immune System

To enable initiation and maintenance of pregnancy, the intrauterine environment significantly shapes the developing immune system as is evident from the anti-inflammatory cytokine profile and protection from atopic sensitization in offspring after maternal exposure to farming activities and farm dairy products during pregnancy.[70,71] This effect is at least in part mediated through an increase in the number of fetal Treg cells.[65]

In contrast, fetal exposure to inflammation during critical developmental windows can influence immune programming to augment inflammatory neonatal responses. Histologic chorioamnionitis (HCA) is a common complication of pregnancy, typically caused by intrauterine bacterial infection and defined by inflammation of the fetal membranes. Fetal exposure to HCA induces immune activation, resulting in fetal inflammatory response syndrome (FIRS), and shapes the neonatal transcriptomic immune response.[72] The clinical characteristics of FIRS consist of systemic inflammation and elevation of fetal plasma IL-6 and other proinflammatory cytokine levels.[73] Long-term sequelae of the sustained systemic inflammation precipitated by fetal exposure to HCA include blindness,[74] cerebral palsy,[75] impaired cardiac function,[76] lung disease,[77] and disruption of normal fetal immune development.[78–82] In humans, placental infection, chorioamnionitis, or villitis together with a fetal inflammatory response appear to increase the risk of surgical necrotizing enterocolitis (NEC).[83]

Studies of fetal sheep and human UCB have demonstrated activation of the adaptive immune system following exposure to HCA. In a model of chorioamnionitis and FIRS caused by administration of intra-amniotic lipopolysaccharide (LPS) in rhesus monkeys at approximately 80% of gestation, fetal Treg cell generation in the thymus was inhibited, while the concentration of proinflammatory cells in the spleen increased.[84] The immunologic changes associated with endotoxin-induced systemic and organ-specific immune priming in the fetus can be mimicked by administration of IL-1α or IL-1β, suggesting a possibly important role of IL-1 receptor signaling in FIRS. In a similar model using intra-amniotic injection of LPS 7 or 14 days before preterm delivery in fetal sheep, involution and activation

of the fetal thymus with structural organ changes was observed.[85] Furthermore, UCB derived from human neonates with clinical evidence of perinatal infection exhibited a higher proportion of T_h1 cells than UCB from uninfected neonates.[86] There is evidence that fetal immune activation persists at least for weeks after birth. $CD4^+$ T cells isolated from preterm blood 10 days post-partum showed altered metabolomic activity and a strong T_h1-biased immune profile.[87]

Overall, epidemiologic and experimental data point to the central role of maternal immune activation and/or FIRS in the pathogenesis of many immune-mediated complications of prematurity such as chronic lung disease, brain damage, retinopathy of prematurity, gut injury, and behavior abnormalities. On the other hand, prenatal immune activation may improve vaccine responses and render the newborn more resistant to infectious challenges later in life.[88]

Developmental Fetal–Neonatal Immunology

Newborn and young infants, especially those born preterm, are at increased risk of developing a range of bacterial and viral opportunistic infections. This age-dependent susceptibility is in part based on immune ontogeny.[1,89] In the past few decades research has focused on the molecular, cellular, and functional bases for immunologic differences between newborns and older individuals, which we discuss as they relate to innate and adaptive immunity.

Innate Immunity

During fetal/newborn adaptation from the intrauterine environment to the colonization of skin and mucosal surfaces following birth, the innate immune system shields the newborn from infection while orchestrating the acquisition of protective adaptive immune responses.[90] These innate mechanisms evolve across gestation and postnatal age (Fig. 32.3) and include protective barriers such as the vernix caseosa, which contains antimicrobial proteins and peptides (APPs) and microbicidal fatty acids,[91] developmentally controlled functional regulation of TLR signaling,[92] expression of acute-phase reactants (Fig. 32.4)[90] and complement proteins, and alterations in neutrophil and monocyte function.[93,94] Importantly, functional maturation of innate immunity enables colonization with commensal organisms while limiting potentially dangerous inflammatory responses.[1] Herein we discuss key features of innate immunity in early life beginning with soluble-based defense systems that progress to leukocyte-based defense systems.

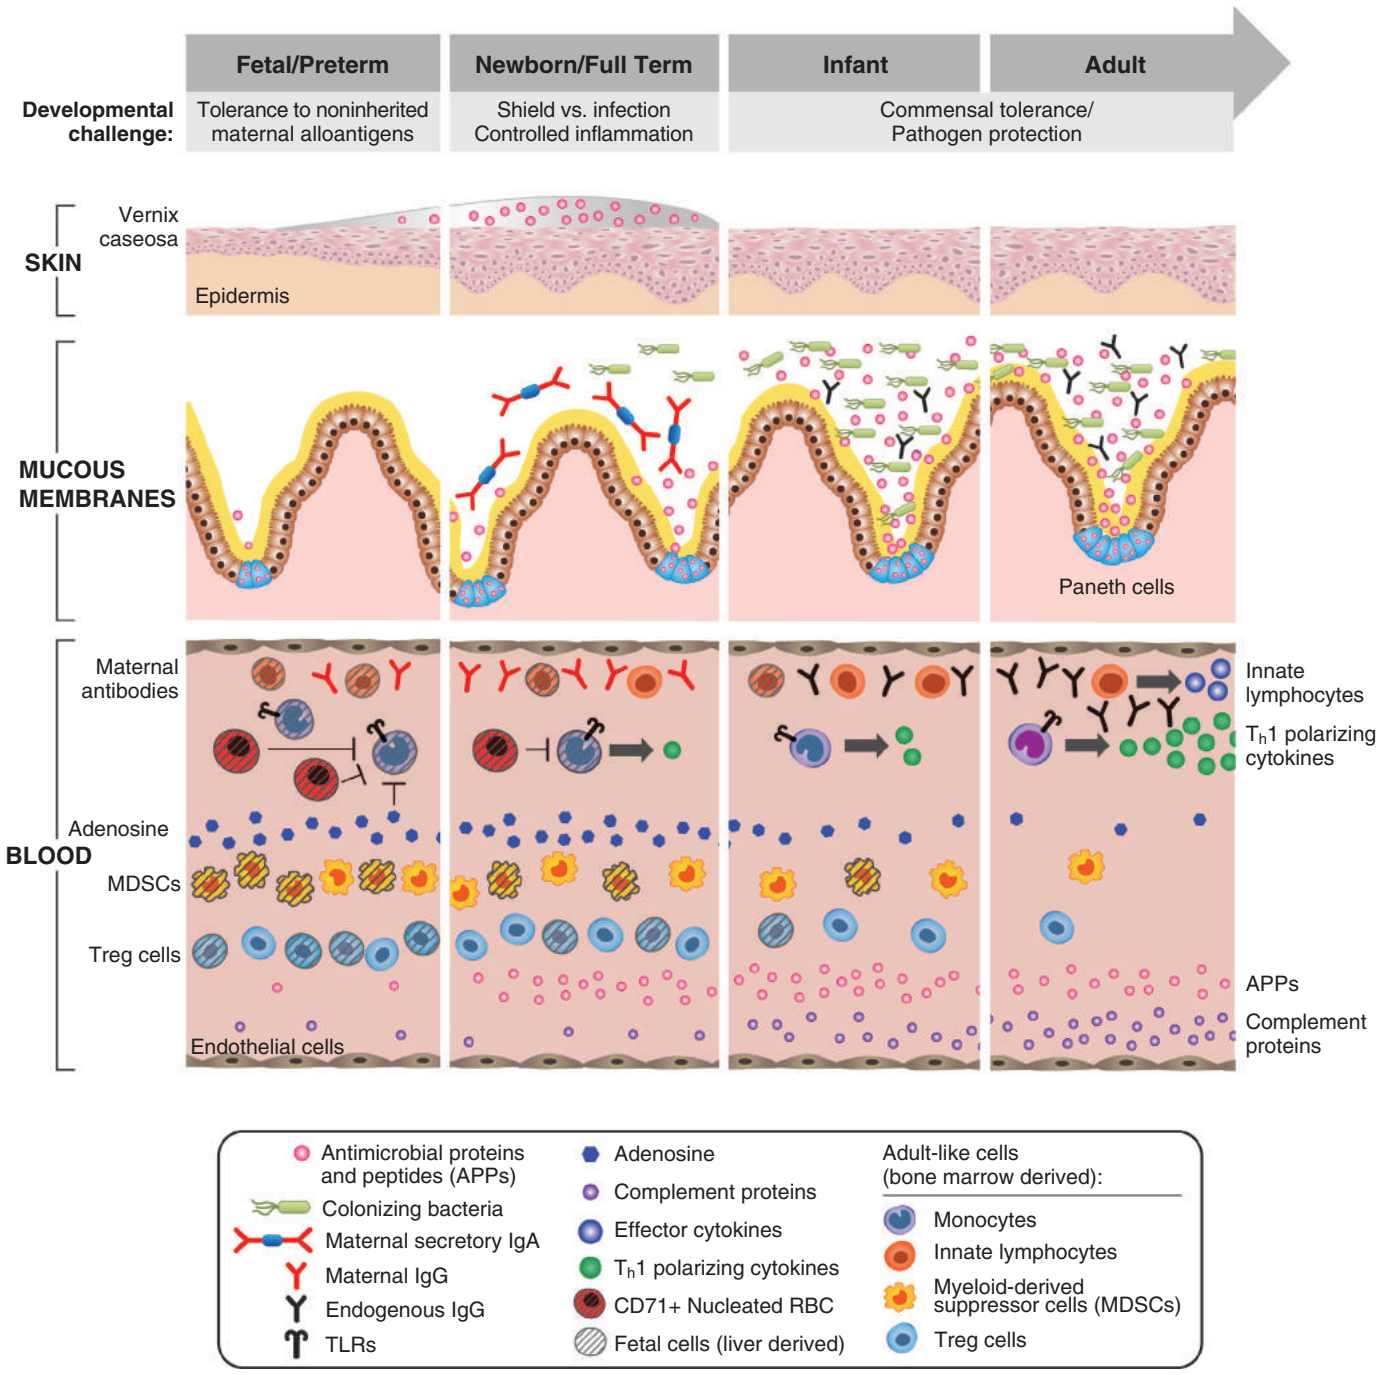
Complement

Central to the innate immune response is the complement system that consists of >40 plasma, cell surface, and regulatory proteins that interact to regulate multiple physiologic functions, including resistance to pyogenic infections, interaction between innate and adaptive immunity, and elimination of immune complexes, products of inflammatory injury, and apoptotic self cells.[95] Components of the complement system recognize and lyse bacteria, opsonize microorganisms, release anaphylatoxins, solubilize immune complexes, and induce B-cell proliferation and differentiation.

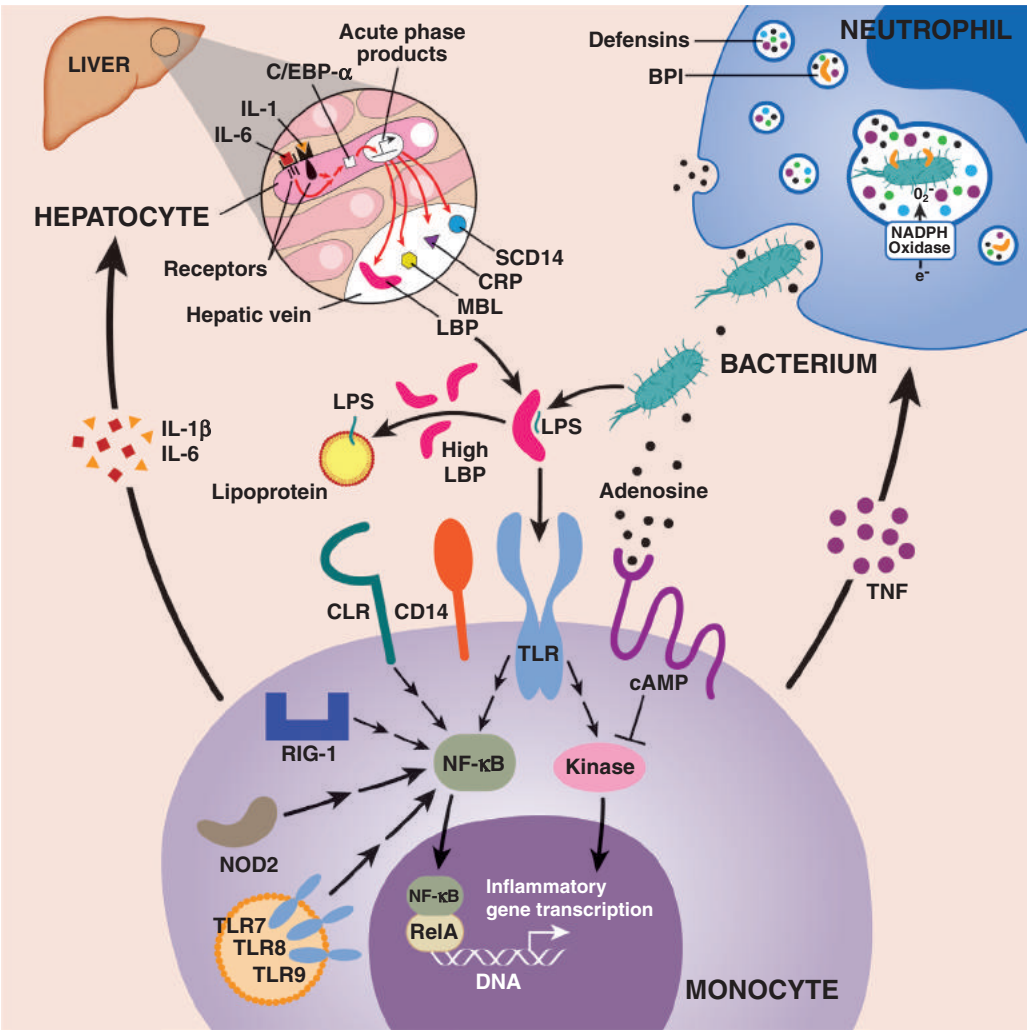
Activation of the complement cascade occurs via three pathways—classical, lectin, or alternative.[95,96] Several characteristics of the complement cascade are important for fetal–neonatal immunity. First, the complement system features both antibody-dependent specificity via the classical pathway activation triggered by interaction of antigens with antibodies, and antibody-independent activation of the alternative and lectin pathways initiated by pathogen-associated structures such as endotoxin and polysaccharides. Thus for the fetus or infant who has not received from the mother or has not yet produced antigen-specific immunoglobulin (Ig) G for immunologic recognition, the alternative and lectin pathways may be critical for triggering the effector functions of the complement cascade.[97,98] Second, the enzymatic activation of the complement cascade enables rapid functional amplification: deposition of a single Ig molecule or C3b fragment can generate enzymatic cleavage of thousands of later-acting components and thus multiple complement activities.[95,99] In addition, the alternative pathway can be amplified via a positive feedback activation mechanism, because C3b, an activation product of the alternative pathway C3 convertase, is a component of this convertase.[100] As the fetus and newborn are particularly dependent on antibody-independent pathogen recognition for immunologic responsiveness, the positive amplification loop of the alternative pathway may be particularly critical for rapid generation of complement effector functions in early life in the absence of antibody-based recognition. Third, the continuous activation of the alternative pathway requires rigorous regulation in the fetus to avoid tissue damage during organ remodeling.[101] Finally, the contributions of the lectin pathway to fetal–neonatal complement activation and fetal well-being are still under investigation.

Studies of fetal and neonatal complement have focused on quantification of serum concentrations of individual components, examining maternal–fetal transport of these proteins, assessing specific effector functions of the classical and alternative pathways, and investigating contributions of complement activation to common neonatal diseases. Detectable concentrations of C3 (1% of adult levels) and C1 inhibitor (20% of adult levels) can be measured as early as 5 to 6 weeks' gestation.[102] By 26 to 28 weeks' gestation, both C3 and C1 inhibitor concentrations increased to 66% of adult levels. Functionally and immunochemically measured classical and alternative pathway protein concentrations in UCB increase with advancing gestational age, such that impairment in CH50 is particularly evident in the preterm,[103] and at full-term gestation the concentrations are only approximately 50% to 75% of adult concentrations.[104,105] Although neonatal UCB lectin pathway component concentrations are lower than those in older children and adults, the correlation between mannose-binding lectin (MBL) and gestational age has not been consistently observed.[106,107] Of note, on the basis of studies of genetically determined, structurally distinct complement variants in maternal and umbilical cord serum, no transplacental passage from the mother to the fetus of C3, C4, factor B, or C6 has been observed.[108]

Much remains to be learned regarding regulation of complement effector functions in the fetus and newborn. Activation of the alternative pathway or the lectin pathway enables opsonization of invading microorganisms without specific Ig recognition. Accordingly, for preterm infants or those without organism-specific maternal IgG, alternative or lectin pathway activation provides a critical mechanism for engaging complement effector functions.[107,109,110] The functional contribution of the classical pathway to effector functions has been assessed through the use of blood-mediated opsonophagocytosis by polymorphonuclear leukocytes of group B streptococci (GBS) type Ia.[111] This GBS serotype may be opsonized by classical pathway components in the absence of specific antibodies and thus enables characterization of classical pathway function. In 8 of 20 neonatal



• **Fig. 32.3** Ontogeny of Skin, Soluble, and Cellular Innate Defense Systems. Host-protective barrier functions include physical, chemical, and functional components of the skin and mucous membrane epithelia of the fetus, neonate (birth to 28 days of age), and infant (1 month to 1 year of age). Skin: while physical and chemical barriers are impaired in early life, especially in the preterm newborn, the vernix caseosa and skin epithelia of full-term newborns robustly express antimicrobial proteins and peptides (*APPs*). Mucous membranes: in parallel with and induced by an increasingly complex microbiota, the newborn intestinal mucosal epithelium rapidly changes structurally, with an increase in the population of crypts and crypt-based Paneth cells, as well as functionally with increasing APP expression. Blood: the composition of neonatal blood is distinct, with relatively low concentrations of complement components and APPs and high concentrations of the immunosuppressive purine metabolite adenosine. Plasma also contains maternal antibodies that are transferred beginning midgestation and supplemented by postnatal factors derived from breast milk. Innate immunity is detectable from the end of the first month of gestation, with changes driven largely by the increasing exposure to environmental microbes. Neonatal antigen-presenting cells such as blood monocytes express pattern recognition receptors (e.g., Toll-like receptors, *TLRs*) with distinct functional responses, including limited T_h1-polarizing cytokine production, to most stimuli. Adaptive immunity develops from 4 weeks of gestation onward, with changes driven by an evolving chimerism reflecting fetal (liver-derived, *shaded cells*) regulatory T (*Treg*)-cell–rich lymphocytes, and more adultlike (bone marrow derived, *unshaded cells*) lymphocytes with distinct epigenetically encoded functional programs. *Ig*, Immunoglobulin; *RBC*, red blood cell. (Modified from Kollmann TR, Kampmann B, Mazmanian SK, et al. *Protecting the newborn and young infant from infectious diseases: lessons from immune ontogeny*. Immunity. 2007;46:350–363.)



• **Fig. 32.4** Innate Detection, Signaling, and Effector Functions of Blood Phagocytic Leukocytes and Hepatocytes. Innate immune signals are detected via signaling loops. Monocytes express pattern recognition receptors, including C-type lectin receptors (*CLR*s), CD14, and Toll-like receptors (*TLR*s). TLR-mediated monocyte activation engages signaling pathways resulting in kinase and nuclear factor κB (*NF-κB*) pathway activation, culminating in inflammatory gene transcription, including generation of cytokines that amplify an antiinfective response. For example, interleukin (*IL*)-1β and IL-6 engage cognate cytokine receptors on hepatocytes, inducing acute-phase response, including production and secretion of lipopolysaccharide (*LPS*)-binding protein (*LBP*), mannose-binding lectin (*MBL*), the pentraxin C–reactive protein (*CRP*), and soluble CD14 (*SCD14*). These molecules recognize and modulate inflammatory activity of microbial products. For example, LBP at low concentrations delivers LPS to TLR4, thereby enhancing signaling but at higher LBP concentrations detoxifies LPS by delivering it to plasma lipoproteins. Monocyte production of tumor necrosis factor (*TNF*) activates neutrophils that deploy antimicrobial systems that are oxygen dependent, such as nicotinamide adenine dinucleotide phosphate (*NADPH*) oxidase, as well as those that are oxygen independent, such as membrane-active antimicrobial proteins and peptides, including defensins and bactericidal/permeability-increasing protein (*BPI*), an LBP homologue that binds to and neutralizes endotoxin. Soluble mediators, such as the antiinflammatory purine metabolite adenosine, can limit proinflammatory responses. *cAMP*, Cyclic adenosine monophosphate; *C/EBP-α*, CCAAT/enhancer binding protein; *NOD2*, nucleotide-binding oligomerization domain-containing protein 2; *RelA*, NF-κB subfamily protein; *RIG-1*, retinoic acid-inducible gene 1.

serum samples examined, decreased bactericidal activity was detected and correlated with significantly lower functional activity of C1q and C4. These studies did not determine whether this decrease was mediated by an inhibitor of function or by an intrinsic change in functional activity of these components in neonatal sera. Studies of MBL concentrations and pathway activity suggest a contribution of the lectin pathway to neonatal susceptibility to infection.[97,107,112–114] Complement regulatory proteins (e.g., C4b-binding protein and factor H) also contribute to neonatal susceptibility as suggested by the failure of neonatal serum to reduce invasion by GBS and *Escherichia coli* into human brain microvascular endothelial cells.[109] In vitro experiments in which killing of *E. coli* by neonatal serum samples was limited by C9, but not by other classical pathway components, suggest that this terminal complement component is apparently important for cytolysis of this pathogen.[115,116] Although relatively

lower concentrations of complement components likely contribute to poor control of bacterial replication, these complement concentrations are nevertheless sufficient, via C3- and factor B-dependent activity in the alternative pathway, to enhance GBS-induced production of TNF-α by monocytes in human newborn UCB tested in vitro.[117]

In addition to relatively low serum concentrations of classical, alternative, and lectin pathway complement proteins, additional complement functions important for fetal and neonatal well-being can contribute to reduced capacity to activate the classical and alternative pathways. For example, fetal and neonatal serum demonstrates reduced concentration of C4b-binding protein, a critical regulator of classical pathway C3 convertase activity.[118–121] Lower C4b-binding protein concentration increases the functional anticoagulant activity of protein S, with which it complexes and thereby contributes to decreased coagulation function of the fetus and newborn. Consideration of complement components that also express nonimmunologic functions will likely be important in characterizing developmental regulation of complement component production.

Complement activation contributes to tissue injury in several common neonatal diseases, including neonatal hypoxic–ischemic encephalopathy, NEC, meconium aspiration syndrome, and intrauterine growth restriction and fetal loss.[122–127] Unregulated complement activation may occur in selected infants undergoing extracorporeal membrane oxygenation therapy, raising concern for inflammatory injury on that basis.[128,129] C5a is present in the cerebrospinal fluid of human newborns, at especially high concentrations in those born preterm,[130] raising the possibility that complement activation in the neonatal brain may contribute to preterm brain injury.

Overall, study of the complement system in early life, including characterization of the developmental and genetic regulation of this important group of plasma and cell surface proteins, promises to shed further light on immune ontogeny in relation to health and disease.

Antimicrobial Proteins and Peptides

The human body expresses natural antibiotics, including APPs that act alone and in combination with endogenous (e.g., complement) and exogenous (e.g., conventional antibiotic) systems to prevent infection and/or eliminate invading microorganisms.[131] APPs are expressed by a range of cells, including epithelial cells and leukocytes, especially neutrophils (see Fig. 32.4), and are found associated both with cells and in plasma. Plasma levels of APPs vary with gestational age such that preterm plasma is relatively deficient in multiple APPs, likely contributing to reduced microbicidal capacity (see Fig. 32.3).[132] Examples of APPs include (1) lactoferrin, an 80-kDa protein with iron-binding and direct membrane perturbing properties found in tear fluid, saliva, and neutrophil secondary granules, (2) the 5-kDa bactericidal/permeability-increasing protein (BPI), expressed on certain mucosal epithelia as well as neutrophil primary granules, with high affinity for LPS that enables it to neutralize the inflammatory activity of endotoxin and targets its microbicidal activity toward Gram-negative bacteria, (3) 14-kDa phospholipase A_2, an acute-phase reactant expressed in liver with ability to enzymatically kill a range of gram-positive pathogens, and (4) 4-kDa disulfide-rich defensin peptides of neutrophil primary (azurophilic) granules with broad microbicidal activity.[131] Ongoing efforts are aimed at developing congeners of APPs as novel antiinfective agents for individuals who are relatively APP deficient, including preterm infants and those undergoing chemoradiotherapy.[133] For example, oral administration of lactoferrin to human preterm newborns has shown promise in reducing the incidence of sepsis and NEC.[134]

Innate Lymphoid Cells, Including Natural Killer Cells

Innate lymphoid cells (ILCs) are derived from a common lymphoid progenitor, are defined by the absence of antigen-specific B-cell receptors (BCRs) or TCRs, and do not express myeloid or DC markers.[135] ILCs are divided into subgroups based in part on the cytokine profile they produce: (1) group 1 ILCs produce IFN-γ and are functionally dependent on the transcription factor T-bet; (2) group 2 ILCs produce type 2 cytokines (e.g., IL-4, IL-5, IL-9, and IL-13) in response to helminth infection and are dependent on RORα and GATA3; and (3) group 3 ILCs produce IL-17A and/or IL-22 and are dependent on the transcription factor RORγt.

NK cells are the most studied of the ILCs. These group 1 ILCs constitute approximately 10% to 15% of all peripheral blood lymphocytes. They are present in the spleen, lungs, and liver and are also rarely found in lymph nodes and thoracic duct lymph.[136] NK cells represent up to 70% of all lymphocytes in the maternal decidual tissue.[137] They demonstrate distinct morphology, function, and surface molecule expression, including expression of CD16 (Fc gamma receptor FγRγIII) and CD56 (nerve cell adhesion molecule 1). Mature NK cells appear larger and more granular than T or B cells[138] and express both activating and inhibitory receptors that are used to selectively identify and kill virally infected cells and tumors.[139] The presence of MHC class I molecules on potential target cells induces signals that suppress NK-cell function. MHC class I–deficient target cells activate NK-cell function, triggering release of lysosomal granules containing serine proteases, perforin, and transforming growth factor beta (TGF-β), thereby disrupting the target cell membrane and inducing an inflammatory response. Fetuses and neonates demonstrate reduced NK-cell activity compared with adults.[140,141]

NK cells are derived from a common hematopoietic progenitor that retains T-cell and B-cell developmental potential.[142] NK cells first make their appearance in fetal liver as early as 6 weeks' gestation. Committed $CD34^+CD56^-$ NK cell progenitors have been identified in the fetal thymus, bone marrow, and liver. In the human neonate, the NK-cell population is immature: only half of all NK cells express CD56, and the NK-cell cytolytic activity is lower.[143] This functional reduction in NK-cell activity may contribute to the severity of neonatal herpes simplex virus (HSV) infections. Profound defects in NK-cell activity result in familial hemophagocytic lymphohistiocytosis (HLH), a disease characterized by fever, hepatosplenomegaly, cytopenia, hyperferritinemia, and hemophagocytosis. Familial HLH arises from mutations in genes that encode proteins involved in the granule-exocytosis pathway and can be fatal without bone marrow transplant.[144,145]

NK-cell receptors are fundamentally different from TCRs and BCRs. NK-cell receptor gene expression does not require gene segment rearrangement, and the receptors are not clonally distributed. Instead, NK cells use an array of stimulatory and inhibitory receptors to regulate their cytolytic functions.[146] A cluster of 10 or more genes encoding killer-cell Ig-like receptors (KIRs) is located on human chromosome band 19q13.4.[139] Each of these type I glycoproteins recognizes a different allelic group of HLA-A–, HLA-B–, HLA-C–, or HLA-G–encoded proteins, and each KIR is expressed by only a subset of NK cells. Another family of

Ig-like receptor genes termed *ILT* is present near the KIR locus at 19q13.3. These receptors are not as restricted as the KIRs and bind multiple HLA class I molecules. A third inhibitory receptor gene locus is on chromosome band 12p12-p13, encoding a C-type lectin inhibitory heterodimeric receptor called *CD94/NKG2* that binds HLA-E. Those KIRs, ILT receptors, and CD94/NGK2 molecules with long cytoplasmic tails and two immunoreceptor tyrosine-based inhibitory motifs (ITIMs) function as inhibitory receptors. On phosphorylation, the two ITIMs recruit and activate the Src homology domain 2 (SH2)-containing phosphatases, which turn off the kinase-driven activation cascade.[147] The KIR family member KIR2DL4 is distinct from other KIRs in structure and distribution. KIR2DL4 binds HLA-G and has a single ITIM in the cytoplasmic tail and a lysine in the transmembrane region, enabling association with adaptor proteins. This inhibitory receptor was found on all decidual NK cells in the placenta at term but not on circulating maternal NK cells, suggesting that expression of KIR2DL4 is induced during pregnancy.[148]

Other KIRs or members of the C-type lectin receptor superfamily are activating receptors.[149] These receptors lack the long cytoplasmic tail of the inhibitory receptors and therefore do not contain ITIMs. Instead, they have a charged amino acid in the transmembrane region that enables receptor association with the adaptor molecule DAP12.[150] This adaptor contains an immunoreceptor tyrosine-based activation motif (ITAM) that allows these receptors to activate NK cells. The physiologic role of these HLA class I–specific activating receptors remains unknown. NK cell–activating receptors also include *natural cytotoxicity receptors* (NKp46, NKp30, NKp44), proteins that are Ig superfamily members with little similarity to one another or to other NK-cell receptors.[149] These receptors are highly specific for NK cells and apparently interact with non-HLA molecules.

CD244 (2B4) is a member of the signaling lymphocyte activation molecule (SLAM) family of receptors expressed on all human NK cells.[151] On interaction with the ligand CD48 on target cells, NK-cell signaling proceeds via interactions between the immunoreceptor tyrosine-based switch motif (ITSM) (switch motif) in the cytoplasmic tail of CD244 and one of two SH2 domain-containing adaptor proteins, SLAM-associated protein (SAP) and Ewing sarcoma–associated transcript 2 (EAT-2). SAP interactions trigger activation, as evidenced in humans with X-linked lymphoproliferative disease, caused by loss-of-function mutations in the SAP linker. In the absence of SAP, interactions with EAT-2 may be inhibitory.[146]

Recent studies have explored the potential contribution of ILCs beyond NK cells. A role for lung group 2 ILCs in mediating respiratory syncytial virus (RSV)-induced IL-33–driven T_h2-biased immunopathology has been demonstrated in neonatal mice.[152] IL-23–responsive group 3 ILCs played a role in the pathogenesis of neonatal intestinal inflammation in a murine model.[153] Much remains to be learned regarding the ontogeny of ILC function with respect to both the quantity and the quality of these cells in the very young.

Polymorphonuclear Neutrophils

Neonatal polymorphonuclear neutrophils (PMNs) are present at early stages of gestation, but their functional capacities are different from those of adult PMNs. Progenitor cells that are committed to maturation along granulocyte or macrophage cell lineages (granulocyte–macrophage colony-forming units) are detectable in the human fetal liver between 6 and 12 weeks' gestation in similar proportions as in adult bone marrow.[154] Human fetal blood has detectable granulocyte–macrophage colony-forming units from 12 weeks' gestation to term.[154] Although these progenitor cells are detectable in the fetus and newborn, developmental differences between adult and mature neonatal PMNs have been demonstrated—in signal transduction, cell surface protein expression, cytoskeletal rigidity, rolling adhesion, microfilament contraction, transmigration oxygen metabolism, intracellular antioxidant mechanisms, and neutrophil extracellular trap formation.[90,155–158] The magnitude of PMN functional differences correlates with the maturity of the infant and begins to decrease within the first few weeks after birth.[157]

In addition to intrinsic age-dependent differences in PMN function, age-dependent cell extrinsic soluble factors may developmentally regulate induction of specific functions and maturation of these cells.[154,159] For example, low concentrations of the chemoattractant complement component C5a in neonatal sera might impair establishment of chemoattractant gradients at sites of inflammation. In addition, elevated concentrations in human neonatal blood plasma of adenosine,[160] an endogenous purine metabolite that acts via seven-transmembrane adenosine receptors to inhibit inflammatory leukocyte responses, could contribute to inhibition of newborn neutrophil function.

Systemic bacterial infection in newborns is frequently accompanied by profound neutropenia, prompting investigation of neutrophil kinetics in infected infants.[161,162] These studies have suggested diverse, developmentally specific regulatory mechanisms required for mobilization of the neutrophil response to infection. The absence of detectable neutrophil precursors in bone marrow aspirates of infected infants and systemic neutropenia motivated studies of neutrophil replacement therapy in neutropenic, infected infants.[163] Although this approach has been successful in some cases, the results have not been uniformly beneficial, and a Cochrane review suggests a need for adequately powered multicenter trials of granulocyte transfusions in neutropenic septic neonates.[164] Metaanalysis suggesting that granulocyte colony-stimulating factor or granulocyte–macrophage colony-stimulating factor may reduce mortality in newborns when systemic infection is accompanied by severe neutropenia requires confirmation in adequately powered trials.[165] Heterogeneity in the impact of neutrophil modulation may reflect the importance of individualizing immunologic interventions for the genetic background, developmental stage, and pathogenic microorganism being treated.

Monocytes, Macrophages, and Dendritic Cells

Cells committed to phagocyte maturation, including granulocyte or monocyte–macrophages, are detectable in the human fetal liver by 6 weeks' gestation and in peripheral fetal blood by 15 weeks' gestation. Unlike granulocytes, whose tissue half-life is hours to days, macrophages migrate into tissues and reside for weeks to months. In a tissue-specific fashion, these cells regulate availability of multiple factors, including proteases, antiproteases, prostaglandins, growth factors, reactive oxygen intermediates, and a range of cytokines and chemokines. Importantly, monocytes can migrate from the bloodstream to tissue sites, becoming tissue-based DCs. Monocytes, macrophages, and DCs share the ability to present antigens to T lymphocytes, thereby triggering the classic adaptive immune responses.

Compared with their adult counterparts, newborn monocytes, macrophages, and DCs demonstrate reduced chemotaxis and

phagocytosis as well as distinct TLR signaling that is polarized toward T_h2 and antiinflammatory cytokine production.[92] The distinct function of newborn APCs reflects both intrinsic characteristics, including reduced nucleosome remodeling for IL-12 p70 production[166] as well as the modulatory effects of age-specific extrinsic factors such as the antiinflammatory purine metabolite adenosine, the level of which is relatively elevated in human newborn UCB plasma.[159,160]

Stimulation of monocytes results in a change in innate "set-point" such that responses to subsequent stimuli are altered.[167] This phenomenon, reflecting adaptive features of the innate immune system that are mediated by epigenetic changes, has been termed *trained immunity*[168] and may contribute to the heterologous beneficial ("nonspecific") effects of live attenuated vaccines (Goodridge et al., 2016). Recent studies indicate that trained immunity varies by age, with human neonatal monocytes demonstrating distinct immunometabolic BCG-induced training resulting in tolerogenic cytokine responses to subsequent LPS stimulation in vitro.[169] Much remains to be learned regarding the scope, ontogeny, and mechanisms underlying innate training/innate memory.

Adaptive Immunity

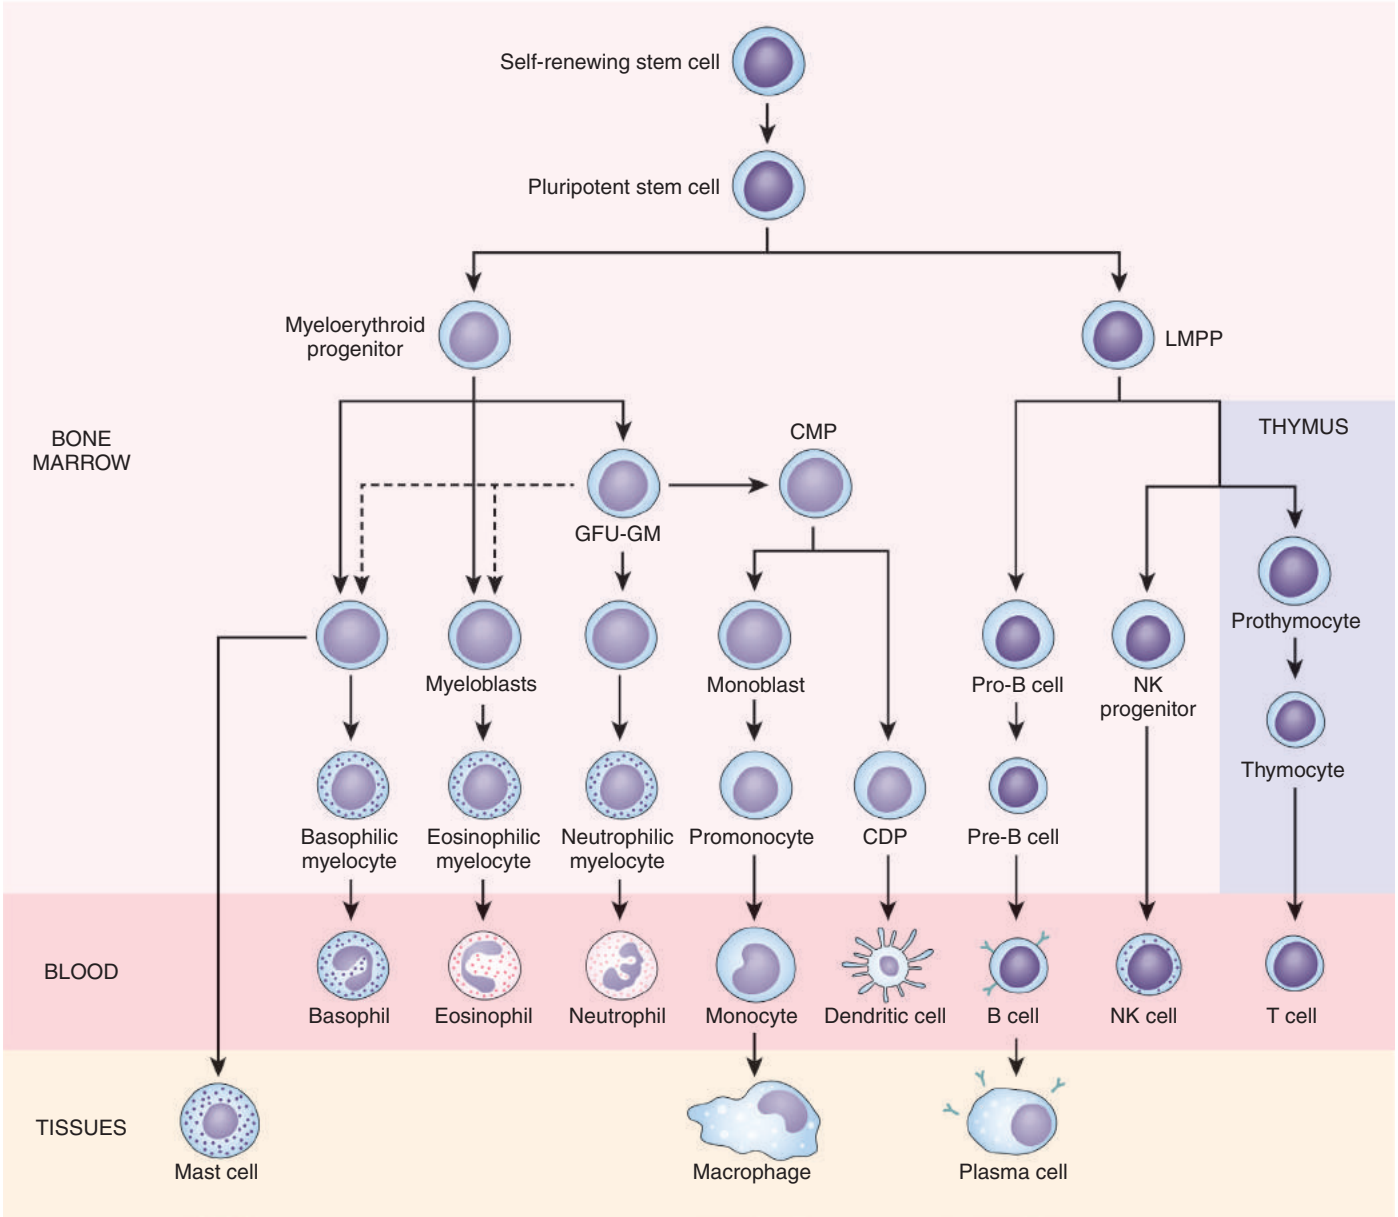
Antigen-specific T and B lymphocytes bearing TCRs and BCRs, respectively, play multiple critical roles in adaptive immunity. T cells responding to a specific antigen secrete cytokines and kill infected target cells and tumor cells by cell-mediated cytotoxicity. These functions of CD4 and CD8 T cells depend on their TCRs specifically recognizing antigenic peptides bound to MHC molecules. Several T-cell populations have a more restricted expression of TCRs that recognize ligands other than peptide/MHC ligands and have an innate-like role early in the immune response; these include NK T (NKT) cells, mucosal-associated invariant T (MAIT) cells, and T cells expressing γδ TCRs (γδ T cells). As discussed in the section entitled Role of Regulatory T cells in Pregnancy, $CD4^+$ Treg cells serve as negative regulators of effector responses. Analogously, antigen-specific B cells can be divided into populations that are involved in the conventional immune response and that depend on CD4 T-cell help for their differentiation into antibody-secreting cells; those that have an innate immunity-like function and act early in immune responses, such as marginal zone B cells; and those with regulatory-like suppressive function ("Breg cells").

All major lymphocyte lineages, which include T cells, B cells, and ILCs, which lack antigen-specific receptors and include NK cells,[170] develop from $CD34^+CD38^{dim}$ pluripotent hematopoietic stem cells (HSCs) found in the fetal liver and bone marrow in a perivascular niche (Fig. 32.5).[171] The process of lymphocyte differentiation and hematopoiesis has traditionally been viewed as a linear progressive narrowing of differentiation potential based on the sequential expression of specific transcriptional regulators. However, the pathways of development of the human myeloid, erythroid, and megakaryocyte lineages may undergo major shifts during ontogeny. For example, in fetal liver, the HSCs and their $CD34^+CD38^+$ progenitor cell derivatives have a similar ratio of cells with multipotent versus unilineage potential, whereas in bone marrow, which is the definitive site of hematopoiesis starting in the second trimester of gestation, $CD34^+CD38^+$ progenitor cells predominantly have unilineage potential.[172] Another example is that the HSCs of UCB have a greater potential to differentiate into the T lineage than HSCs of adult bone marrow.[173]

T Lymphocytes

Most T cells develop in the thymus, which includes cell types of nonhematopoietic origin, such as epithelial cells, as well as multiple cell types of hematopoietic origin, including the developing immature T cells or thymocytes, DCs, mononuclear phagocytes, and small numbers of B cells. The thymic epithelial cells are derived from the third branchial cleft and the third or fourth branchial pouch, a process that is perturbed in DiGeorge syndrome, resulting in thymic epithelial hypoplasia. Thymic lobes can be divided into four regions, which, proceeding from outward to inward, are the subcapsular region, cortex, corticomedullary junction, and medulla. Prothymocytes, which are bone marrow–derived $CD34^+CD38^+CD62L^+$ lymphoid cells, have the capacity to commit to the T-cell or other lymphocyte lineages depending on their receipt of instructive signals.[174] Circulating prothymocytes enter the thymus via vessels at the cortical–medullary junction. The prothymocyte becomes committed to the T-cell lineage by the engagement of its surface notch 1 receptor by ligands displayed on the thymic epithelium, such as delta-like ligand 4. This engagement results in an early T-cell progenitor that acquires expression of CD1a, CD2, CD7, and progressively loses its initial capacity for B-cell, myeloid, or NK-cell differentiation and becomes a fully T-lineage committed pro-T cell.[175] The pro-T cell migrates to the subcapsular region just below the outer capsule.

The subcapsular pro-T cell expresses all of the internal proteins required for V(D)J recombination, including the recombinase activating gene (RAG) 1 and RAG2 endonucleases that make double-stranded breaks in DNA; the proteins involved in nonhomologous end joining repair (e.g., Artemis, XLF [Cernunnos], and DNA ligase IV); and those that are essential for generating junctional diversity at complementarity determining region (CDR) 3 (e.g., terminal deoxynucleotidyl transferase [TdT]). CDR3, which is the most variable in amino acid sequence, is located at the center of the antigen-specific binding site of both TCRs and BCRs. The pro-T cell lacks most cell surface proteins characteristic of mature peripheral T cells, including CD3, CD4, and CD8, and is therefore also referred to as a *triple-negative thymocyte* (Fig. 32.6). The pro-T cell is the first stage in which there is VDJ rearrangement of TCR gene loci, with the TCRγ gene rearrangement occurring most frequently.[176] If this rearrangement is productive (i.e., capable of expressing a full-length TCRγ chain protein) and the thymocyte subsequently undergoes a productive TCRδ gene arrangement, a γδ TCR heterodimer is expressed on the cell surface, allowing the thymocyte to differentiate into a mature γδ T cell that emigrates from the thymus into the periphery. More frequently (>95% of the time) these TCRγ and/or TCRδ gene rearrangements are nonproductive, and the pro-T cell attempts TCRβ chain gene rearrangement. If this arrangement is productive, the TCRβ chain is expressed on the cell surface in association with an invariant pre-T alpha chain forming the pre-TCR complex, which defines the pre-T-cell stage of development. Like the mature TCR, the pre-TCR is associated with the CD3 complex of proteins, which includes CD3γ, CD3δ, CD3ε, and CD3ζ (also known as CD247) chains, all of which have cytoplasmic tails containing specific amino acid sequences called ITAMs. These ITAMs serve as molecular targets for tyrosine phosphorylation and binding by tyrosine kinases, such as Lck and zeta chain-associated protein of 70 kDa (ZAP-70), which generate intracellular signals leading to the induction of target genes.[177] These signals direct the pre-T cell

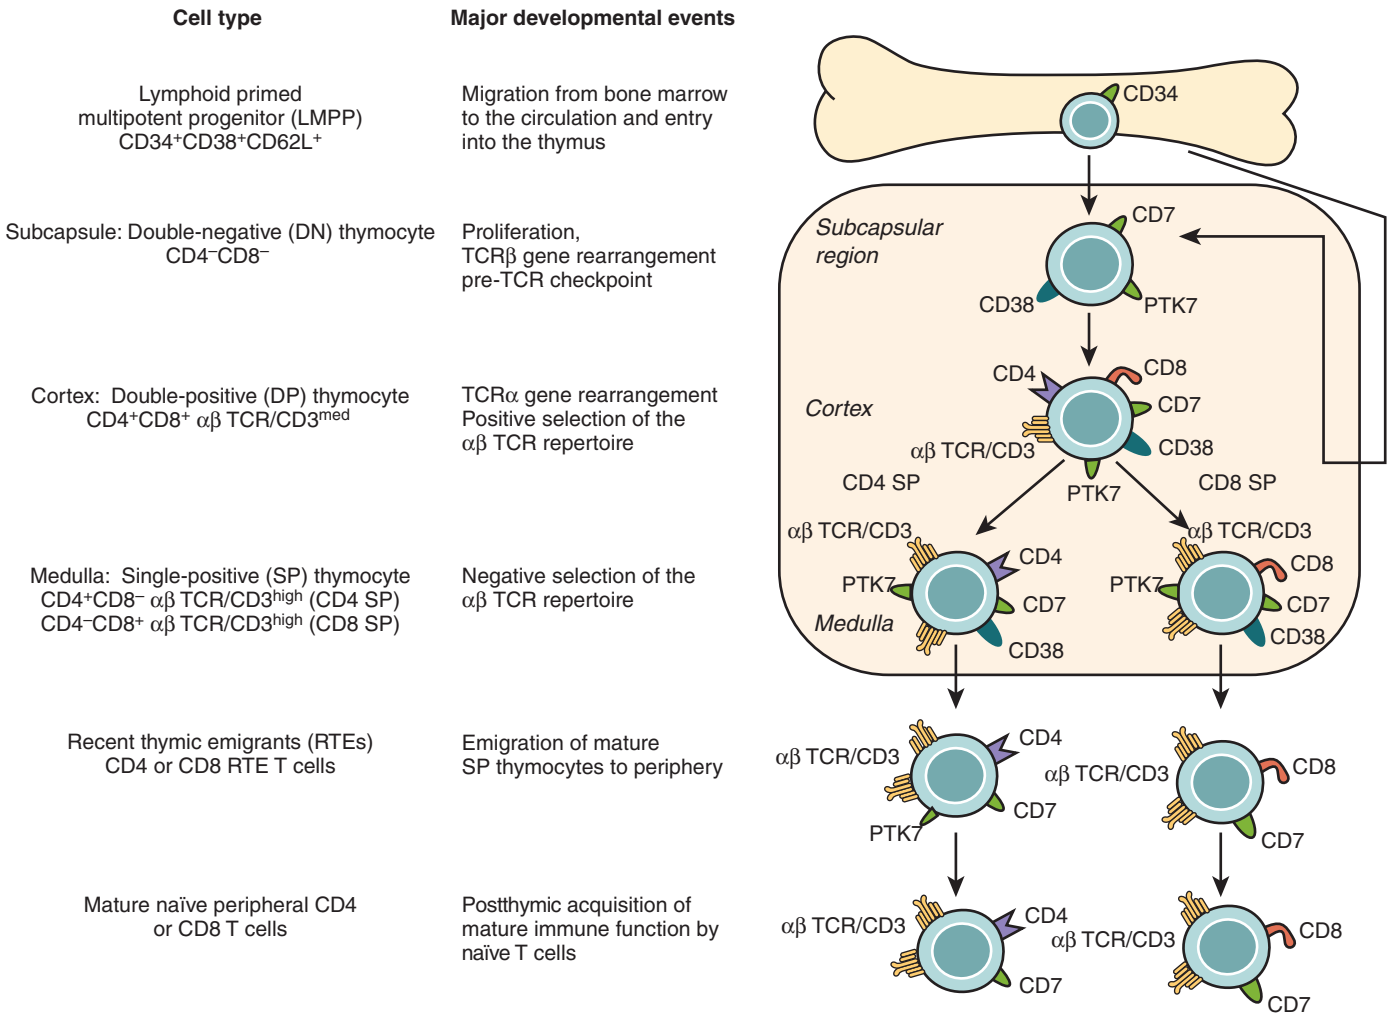


• **Fig. 32.5** Myeloid and Lymphoid Differentiation in the Bone Marrow, Blood, and Tissues. *CDP*, Committed dendritic cell progenitor; *CFU-GM*, colony-forming unit granulocyte–macrophage; *CMP*, common myeloid progenitor; *LMPP*, lymphoid primed multipotent progenitor; *NK*, natural killer.

to (1) proliferate, (2) upregulate expression of CD4 and CD8 and become a double-positive ($CD4^+CD8^+$) thymocyte, (3) migrate from the subcapsular area to the thymic cortex, and (4) start rearrangement of the TCRα chain gene locus (see Fig. 32.6).

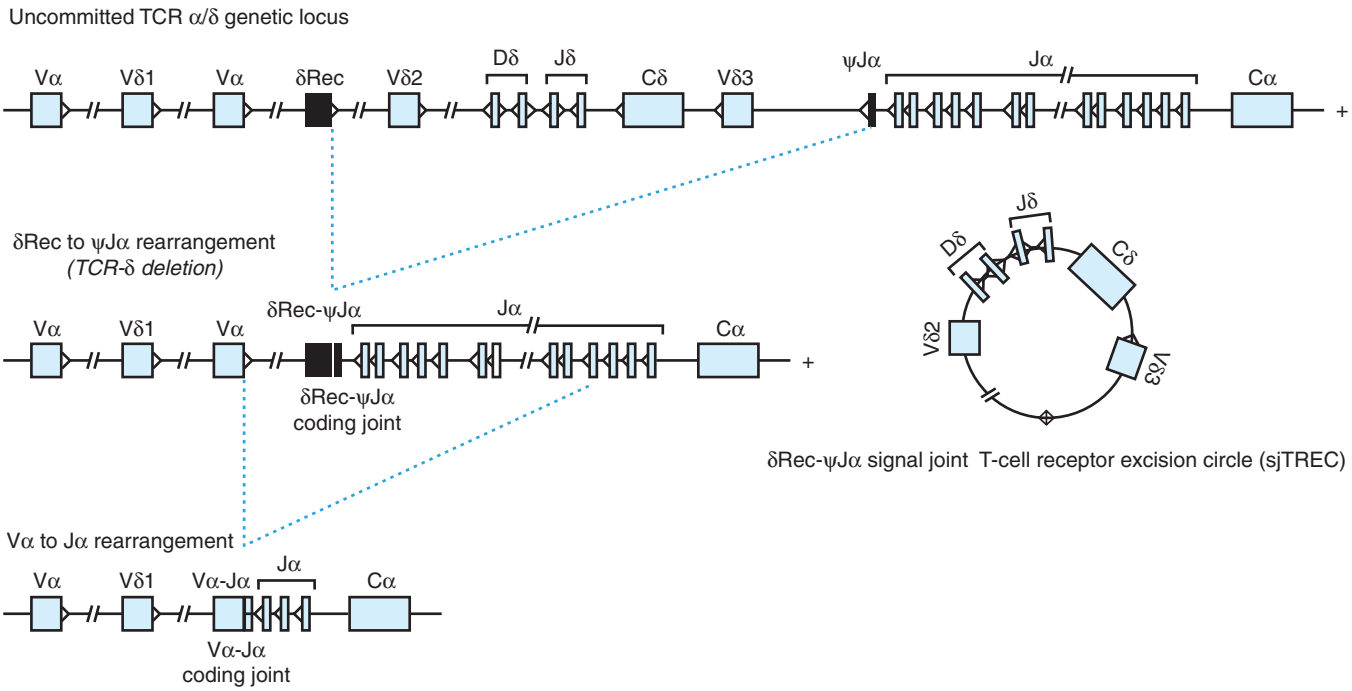
Rearrangement of the TCRα chain gene by $CD4^+CD8^+$ thymocytes is a two-step process in which there first is an internal deletion of a ψδ rec segment that brings the unrearranged Vα segments in close proximity with J_α segments and the C_α constant region.[178] The intervening DNA, which is excised as a circular product with fused signal joint sequences, referred to as a *signal joint TCR excision circle* (sjTREC), is highly stable within the cell (Fig. 32.7). The sjTREC content of the T-lineage cell subsequently decreases mainly as a result of cell proliferation, which under normal conditions is minimal until the mature T cell undergoes antigen activation-induced clonal proliferation. Thus, the measurement of the sjTREC content by peripheral blood T cells is an indirect but useful assessment of the adequacy of production of new T cells by the thymus. The measurement of sjTRECs in neonatal blood spots is routinely used for newborn screening in all 50 United States for identifying infants with impaired production of T cells by the thymus as occurs in most forms of severe combined immunodeficiency (SCID) (see Specific Immunologic Deficiencies of the Newborn and Their Diagnosis).

Double-positive thymocytes that have productive TCRα chain gene rearrangements replace their pre-TCR with a TCR consisting of an αβ TCR heterodimer in association with the CD3 proteins (see Fig. 32.6). The next major checkpoint of thymocyte development is positive selection, in which the αβ TCR of the $CD4^+CD8^+$ thymocyte is tested for whether it has significant affinity for either the MHC class I alleles (HLA-A, HLA-B, and HLA-C in humans) or the MHC class II alleles (HLA-DR, HLA-DP, and HLA-DQ in humans) expressed by thymic cortical epithelial (TCE) cells.



• **Fig. 32.6** Stages of Human αβ T-Cell Receptor–Positive Thymocyte Development. Prothymocytes from the bone marrow or, before the third trimester, fetal liver, which express CD34, CD38, and CD62 ligand (*CD62L*), but lack CD4, CD8, or CD3/T-cell receptor (*TCR*), enter the thymus via vessels at the junction between the thymic cortex and medulla. They differentiate to progressively more mature αβ TCR+ thymocytes, defined by their pattern of expression of the αβ TCR-CD3, CD4, CD8, and CD38. Protein tyrosine kinase 7 (*PTK7*) is expressed throughout thymocyte development. The TCRβ chain gene and then the TCRα chain gene are rearranged in the outer cortex. Positive selection occurs mainly in the central thymic cortex by interaction with thymic epithelial cells that express major histocompatibility complex (MHC) class I and class II proteins, and negative selection occurs mainly in the medulla by the interaction with thymic DCs that display MHC associated with self-peptides that are derived from medullary thymic epithelial cells. Following these selection processes, medullary thymocytes emigrate into the circulation and colonize the peripheral lymphoid organs as CD4 and CD8 T cells with high levels of αβ TCR/CD3. These recent thymic emigrants (RTEs) also have a high content of signal joint TCR excision circles (sjTRECs), which are a circular product of TCR gene rearrangement (see Fig. 32.7). In adults, most RTEs have modest levels of surface expression of PTK7 but probably lack CD38. In contrast, in neonates, most peripheral T cells have high levels of surface expression of PTK7 and CD38 and have relatively high amounts of sjTRECs compared with adult peripheral T cells.

All MHC class I and class II molecules during their biosynthesis have peptides loaded into their peptide-binding grooves. In the absence of infection or vaccination with foreign proteins, these peptides are derived from self-proteins, as is the case for the MHC of TCE cells. A specialized set of MHC class I-binding peptides may be generated by a special type of proteasome expressed by TCE cells (the thymoproteasome) and that these play an important role in increasing the antigen responsiveness of mature peripheral T cells.[179] In positive selection, thymocytes with TCRs that are unable to bind to MHC/peptide complexes on TCE cells with sufficient affinity to generate intracellular signals die by apoptosis, the default pathway. In cases where the TCR binding to MHC generates a relatively weak to moderate signal, the thymocyte is positively selected for survival. A large range of "analog" signals—from relatively weak to medium strength—are converted by the intracellular signaling protein Themis into a single "digital" outcome of thymocyte survival and maturation.[180] In cases where the TCRs of CD4+CD8= thymocytes receive very high levels of signaling, double-positive cortical thymocytes undergo apoptosis.[181] CD4+CD8+ thymocytes with TCRs that receive



• **Fig. 32.7** Sequential rearrangements in the T-cell receptor (*TCR*) α/δ genetic loci generate signal joint TCR excision circles (sjTRECs) and Vα–Jα rearrangements. Rearrangement of the δRec segment to the J_α segment commits the thymocyte to the αβ TCR lineage as this deletes the C and J segments that are necessary to encode a productive TCRδ chain. The δRec–ψJ_α rearrangement also generates an sjTREC, which is commonly used for monitoring peripheral T-cell populations for their recent thymic origin. The δRec–ψJ_α rearrangement and excision of an sjTREC are followed by TCRα (V_α–J_α) rearrangements, which if productive result in expression of an αβ TCR/CD3 complex on the thymocyte cell surface. Most thymocytes that express αβ TCRs have molecular evidence of nonproductive rearrangements of portions of the TCRδ gene locus (not shown).

MHC class II/peptide survival signals lose CD8 expression and upregulate CD3 expression, thereby becoming $CD4^+CD8^-$ thymocytes that are $CD3^{high}$. $CD4^+CD8^-$ thymocytes also begin to acquire a gene expression pattern that is characteristic of mature peripheral CD4 T cells that is required for their capacity to carry antigen-induced effector functions, such as IL-2 secretion and CD40-ligand (CD40L) expression. $CD4^+CD8^+$ thymocytes with TCRs that receive MHC class I/peptide survival signals lose CD4 expression and upregulate CD3 expression, thereby becoming $CD4^-CD8^-$ thymocytes; they also begin to express genes that are characteristic of peripheral CD8 T cells and that are required for their antigen-induced capacity to become cytotoxic cells. These $CD4^+CD8^-$ thymocyte-specific versus $CD4^-CD8^+$ thymocyte-specific outcomes of positive selection are directed by the master transcription factors ThPOK (encoded by the Zbtb7b gene) and Runx3, respectively.[182]

A small subset of thymocytes bearing TCRα chains containing the $V_\alpha24J_\alpha18$ segments in association with TCRβ chains containing $V_\beta11$ segments interact with relatively high affinity with CD1d, an MHC class I-like protein that is expressed on double-positive thymocytes.[183] This TCR interaction leads to the thymocyte-positive selection for NKT-lineage cells, which are distinct in function from conventional T cells in having the ability to secrete rapidly large amounts of cytokines, such as IFN-γ and IL-4, during the early phase of innate immune responses to pathogens.[184]

Another subset of thymocytes bearing TCRα chains with $V_\alpha7.2$-$J_\alpha33$ segments paired with TCRβ chains using either $V_\beta2$ or $V_\beta13$ interact with high affinity with an MHC class I-like protein, MR1, on non-hematopoietic cells, resulting in the positive selection of mucosal-associated invariant T (MAIT) cells.[185] MAIT cells, which are predominantly CD8 single positive, are found in greatest amounts in mucosal tissues, such as the intestine, lung, and liver.[186]

Positively selected single-positive $CD4^+CD8^-$ or $CD4^-CD8^+$ thymocytes move into the medulla, where they undergo a final selection process before emigrating from the thymus as CD4 and CD8 T cells called *negative selection*. This selection process, which is an important mechanism for maintaining tolerance of T cells to peptides derived from self-proteins, involves the exposure of the mature thymocytes to medullary APCs expressing a highly diverse repertoire of peptides derived from self-proteins. These self-proteins include those that are normally expressed in a tissue-restricted manner (e.g., peptides derived from insulin, which is produced by pancreatic beta islet cells or parathyroid hormone) or that are characteristic of only certain stages of early development.[187] This unusual pattern of protein expression by medullary DCs and B cells is the result, at in part, of a nuclear protein encoded by the autoimmune regulator (AIRE) gene.[188,189] AIRE stochastically relieves the transcriptional repression of these tissue-specific and developmentally regulated genes and the proteins they encode are transferred to thymic $CD11c^+$ dendritic cells, which play a major role in presenting these self-peptide/MHC complexes to medullary thymocytes (Breed et al., 2018). Thymocytes that have high levels of signaling for peptides derived from self-proteins are induced to undergo apoptosis, whereas intermediate levels of signaling by $CD4^+CD8^-$ thymocytes result in their differentiation

into Treg cells.[190] Thus, thymically derived Treg cells have TCRs that have substantial affinity for self-proteins expressed in a tissue-specific or developmental-specific manner.

Recent Thymic Emigrants and the Naïve T-Cell Compartment

Following negative selection, single-positive mature thymocytes undergo additional maturation before exiting the thymus as recent thymic emigrant (RTE) naïve T cells, including upregulation of CC-chemokine receptor 7 (CCR7), IL-7 receptor alpha chain (CD127), L-selectin (CD62L), and Smad interacting protein 1.[191] In humans, this maturation also includes downregulation of the CD45R0 isoform and upregulation of the CD45RA isoform of the CD45 protein tyrosine phosphatase. The fully mature thymocyte then enters the circulation as an RTE naïve T cell that is $CD45RA^+CD45R0^-CCR7^+CD62L^+$ and that retains surface expression of protein tyrosine kinase 7 (PTK7), a protein that is highly expressed during intrathymic development.[192] The RTE naïve T cell recirculates between the peripheral lymphoid tissue and the blood. The entry of the circulating naïve T cells involves the interaction of T-cell surface adhesion molecules, such as L-selectin (CD62L) with sialomucins expressed on high endothelial venules and the T-cell CCR7 chemokine receptor with its chemokine ligands, which are expressed within peripheral lymphoid tissues. RTE naïve T cells also undergo postthymic antigen-independent maturation over a period of several months with the loss of PTK7, a decrease in the capacity for activation-induced chemokine (C-X-C motif) ligand 1 (CXCL)8 (IL-8) production,[193] and an increase in the capacity for IFN-γ production.[192] $PTK7^+$ RTE naïve T cells also undergo one to two homeostatic cell divisions as part of this maturation.[192]

In the human embryo the first naïve, mature T cells appear in the circulation and lymphoid organs at approximately 11 to 12 weeks' embryonic development and have been found in the fetal intestine at 11 weeks' gestation.[194,195] Thymopoiesis normally continues at least through age 40 years as indicated by the presence of circulating $PTK7^+$ RTEs[192] and by the results of in vivo metabolic labeling studies with deuterium.[196] Thymectomy early in life (e.g., as part of open heart surgery for congenital heart disease or for the treatment of certain autoimmune diseases, such as myasthenia gravis) results in a substantial loss of naïve T cells, including $PTK7^+$ RTEs[192] and CXCL8-expressing RTEs.[193] Thymectomy also results in an oligoclonal memory T-cell compartment.[197,198] Some children who have undergone neonatal thymectomy appear to regenerate thymic tissue, which is associated with the reacquisition of naïve T cells with RTE features.[193] In individuals who do not recover thymic function, the decay process is accelerated by chronic cytomegalovirus (CMV) infection, resulting in an immunosenescent T-cell phenotype similar to that seen in elderly individuals and associated with increased morbidity and mortality.[199] Naïve T cells of the peripheral lymphoid compartment can undergo homeostatic expansion in response to cytokines, such as IL-7, and this proliferation may be particularly important in disease states that impair the production of RTEs and result in profound peripheral lymphopenia, such as treatment with chemotherapy or human immunodeficiency virus (HIV) infection.

Naïve CD4 T-Cell Activation into Effector T_h1, T_h2, T_h17, and Follicular Helper T cells

Naïve T-cell activation requires a complex molecular signaling cascade that involves the reorganization of signaling molecules of the T-cell membrane into an "immunologic synapse" with the APCs bearing MHC/peptide.[200] For naïve T-cell activation, $CD11c^+$ DCs are particularly effective as APCs. TCR engagement by a high-affinity MHC/peptide ligand results in phosphorylation of components of the CD3 complex associated with the αβ TCR. The CD3 proteins contain cytoplasmic tails with specific amino acid sequences called ITAMs, which serve as molecular targets for the tyrosine kinase Lck, which is associated with the cytoplasmic domains of CD4 and CD8. The CD3ζ chain is thought to be the most critical component and is found as a homodimer. The tyrosine phosphorylated CD3ζ chain binds the tyrosine kinase ZAP-70, which, in turn, phosphorylates linker for activation of T cells (LAT), a large protein that serves as a docking site for multiple signaling molecules. Full naïve T-cell activation also requires costimulation by engagement of CD28 on the T-cell surface by CD80 or CD86 on the APC. Together, signaling generated by the TCR and CD28 results in the activation of several parallel signaling pathways, including those of the increased free calcium/calcineurin/NFAT, Ras/ErkAP-1 (fos/jun), and protein kinase C-theta/nuclear factor κB (NF-κB) pathways. This results in entry of the transcription factors nuclear factor of activated T-cells (NFAT), activator protein-1 (AP-1), and NF-κB into the nucleus, where they bind to the *cis*-regulatory elements of hundreds of genes and alter their transcription.[200]

In response to signals generated through binding to the TCR/CD3 complex and CD28, cord blood naïve CD4 T cells have both enhanced calcium fluxes and activation of the Ras-Erk-AP-1 pathway.[201] However, both AP-1-dependent transcription[201] and nuclear translocation of NFAT[202] are impaired in comparison to adult naïve CD4 T cells. Later in infancy, calcium fluxes by activated naïve CD4 T cells are reduced compared to adult. Together, these results suggest that the outcome of neonatal and young infant naïve CD4 T-cell activation is suboptimal and may contribute to impaired development of effector function and memory formation. On the other hand, neonatal naïve CD4 T cells appear to be in cell cycle at baseline and undergo more robust expansion in response to IL-7 than their adult counterparts.[203]

After their activation, naïve CD4 T cells differentiate into effector T_h1, T_h2, T_h17, or follicular helper T (T_{fh}) cells.[204–206] Differentiation into peripheral Treg cells can also occur, and these cells are discussed in the section entitled Regulatory T cells. Each of these CD4 T cell types is defined by prototypical master transcription factors and by secretion of a characteristic profile of cytokines in response to antigenic stimulation and preferential expression of particular chemokine receptors. The cytokine milieu produced by non-T cells in the local environment during antigen presentation is a primary factor influencing the developmental fate of a naïve T cell following activation.[207] The outcome of differentiation may also be influenced by the strength of TCR-mediated signaling, at least in some contexts, such as during naïve CD4 T-cell interactions with CD11c+ dendritic cells.[208]

Activated T_h1 cells produce IFN-γ, which is the signature T_h1 cytokine, IL-2, lymphotoxin α, and TNF-α, and also express surface CD40L (CD154). IL-12 produced by DCs and IFN-γ produced by NK cells promote T_h1 cell development by a signal transducer and activator of transcription (STAT) 4-dependent mechanism, and this results in expression of the master transcription factor T-bet. T_h1 responses are generally proinflammatory, and IFN-γ secretion is particularly important in activating mononuclear phagocytes for the control of intracellular bacterial pathogens, such as *Mycobacteria*, *Salmonella*, and *Listeria*. IFN-γ also increases MHC expression, which may be particularly important

in counteracting the attempt by herpesviruses to avoid antigen detection by their production of a number of proteins that decrease MHC class I and class II antigen presentation. Human neonatal CD4 T cells are biased against T_h1 polarization relative to adult T cells,[209] and this bias may continue into infancy and contribute to the increased vulnerability of infants to severe and disseminated tuberculosis.[210] Both CD4 T cell-intrinsic mechanisms[211] and APC-intrinsic mechanisms, such as decreased expression of IL-12 p70 by neonatal and infant DCs,[166,212] appear to contribute to blunted T_h1 immunity. However, T_h1 immunity is not depressed in all immunologic contexts in the fetus and neonate: The fetal intestine includes an innate-like CD4 T-cell population that express CD161, a marker for T cells with innate-like functional properties and that include the capacity to produce IFN-γ, which may normally play a role in tissue development/homeostasis rather than in host defense against microbes[213]; however, this cell type may contribute to immunopathology post-natally in intestinal inflammatory contexts, such as gastroschisis. In addition, as previously noted, premature infants may have increased T_h1 responses following in utero exposure to chorioamnionitis.[87]

Activated T_h2 cells produce IL-4, IL-5, and IL-13 and are important in the response to infections with multicellular parasites, such as helminths, and classic allergic diseases in which the level of IgE is elevated. Their development is facilitated by a number of non–T-cell–derived cytokines, particularly from epithelial sources, including thymic stromal lymphopoietin (TSLP), IL-25, and IL-33, as well as IL-4 produced by basophils. This non-T-cell-derived IL-4 activates STAT6, which, in turn, induces GATA3, the master transcription factor for T_h2 differentiation from naïve CD4 T cells. The T_h2 cytokines IL-4 and IL-13 induce Ig heavy chain class switching to the IgE isotype (the T_h2 phenotype). IL-5 is an eosinophil growth factor and promotes eosinophil survival in inflamed tissues. IL-13 promotes goblet cell hyperplasia and mucous secretion. Thus, T_h2 cells coordinate many of the characteristic responses of the skin and mucosal tissues to parasitic infection and allergens. Murine neonatal CD4 T cells appear to be intrinsically biased toward T_h2 polarization,[214] but in vitro studies using human UCB CD4 T cells and adult allogeneic DCs as an APC source have not observed this bias.[211]

Activated T_h17 CD4 T cells secrete the closely related cytokines, IL-17A and IL-17F, which act upstream to induce increased epithelial barrier function and to promote local production of antimicrobial peptides, inflammatory cytokines, and chemokine production by neutrophils and mononuclear phagocytes.[215] These collective effects lead to increased tissue resistance of the mucosa and skin to fungal and bacterial infection. In addition to T_h17 cells, IL-17 is produced by the ILC3 innate lymphocytes and by subsets γδ T cells, NK T cells, and MAIT cells and all of these IL-17-producing cell types are CD161 positive.

In humans, IL-17 is important for the control of mucocutaneous fungal infection, particularly with *Candida* spp. (Okada et al.[216]) and in limiting nasopharyngeal carriage with *Streptococcus pneumoniae* (Basha et al., 2017). Memory/effector CD4 T cells producing IL-22, which is often co-expressed with IL-17, also provides substantial protection from *C. albicans* infection (Sheri et al., 2016). There is also growing evidence for the importance of IL-17 produced by either T_h17 cells or $T_h1/17$ cells that express both cytokines[217] and recognize MHC class II/peptide complexes in limiting pulmonary infection with *Mycobacterium tuberculosis*[218,219] and, in young children, nontuberculous mycobacterial lymphadenitis.[220]

The differentiation of activated naïve CD4 T cells into T_h17 cells is promoted by IL-1β and TGF-β and cytokines that activate STAT3, including IL-6 and IL-23. Activated STAT3 induces the expression of RORγt, which is the master transcription factor for T_h17 cell differentiation.[221] In addition to their role in host defense, T_h17 cells are also prominently involved in the pathogenesis of inflammatory bowel disease, psoriasis, multiple sclerosis, rheumatoid arthritis, and other autoimmune diseases. Umbilical cord blood naïve CD4 T cells also include a small but detectable percentage of CD161+IL-23 receptor+CCR6+ RORγt+ cells that are capable of rapidly differentiating into T_h17 cells using an appropriate cytokine milieu.[222,223] However, it remains unclear to what extent this naïve T_h17 precursor cell is involved in the post-natal acquisition of memory/effector T_h17 cells in response to infections. Circulating T_h17 memory cell numbers are at a similar or lower frequency than T_h1 memory cells in young infants (Sheri et al., 2016), and it is plausible that limitations in T_h17 immunity early after birth contribute to the increased susceptibility of the neonate and young infant to infections with Candida, Mycobacteria, and extracellular bacteria. Activated T_{fh} cells secrete IL-21 and express surface CD40L, both of which provide essential signals for the activation and differentiation of B cells to produce antibody against protein antigens.[206] Human naïve CD4 T-cell differentiation into T_{fh} cells appears to be promoted by the combination of IL-12, IL-21, IL-23, and TGF-β and engagement of inducible T-cell costimulator (ICOS) on the T cell by ICOS ligand. The master transcription factor for T_{fh} differentiation is Bcl6, which is induced by ThPOK.[224] Whether the differentiation of human neonatal naïve CD4 T cells into T_{fh} cells is as robust as that of older children and adults is unclear. However, the observation that young infants, compared with older children, have reduced primary antibody responses to protein antigens, such as the hepatitis B vaccine,[225] could be a reflection of less robust T_{fh} cell generation following immunization.

Circulating Cord Blood CD4 T Cells with T_h1, T_h2, and T_h17 Memory Phenotypes

CD4 T cells with a naïve (CD45RA+CD45R0-CCR7+) phenotype predominate in the fetal circulation. However, approximately 1% to 6% of CD4 T cells in cord blood of healthy term infants have a CD25lowCD127highCD45R0 surface phenotype, a polyclonal αβ-TCR repertoire, and a capacity to produce cytokines and/or express chemokine receptors that are characteristic of T_h1 cells, T_h2 cells, and T_h17 cells.[226] Whether these memory CD4 T cells are the result of activation by microbial products, a possibility supported by a recent report of low levels of bacteria in the second trimester fetus,[53] or are tissue resident memory T cells that have re-entered from a non-lymphoid tissue site (see section entitled Tissue Resident Memory CD4 and CD8 T Cells) remains unclear.

Naïve CD8 T-Cell Activation into Cytolytic Effector Cells

Naïve CD8 T cells have a similar $CD45RA^+CD45R0^-CD62L^+CCR7^+$ surface phenotype as those of the CD4 T-cell subset and recirculate between the blood and secondary lymphoid tissue by the same mechanisms. As for naïve CD4 T cells, antigen presentation by $CD11c^+$ DCs is particularly efficient for CD8 T-cell activation, which results in the acquisition of cytolytic effector function mediated by perforin and granzymes and the expression of FasL. Many activated CD8 T cells also secrete T_h1 cytokines, such as IFN-γ and TNF-α.

Human naïve neonatal (cord blood) CD8 T cells have a transcriptome and chromatin landscape distinct from those of adults that is functionally biased toward acting in innate immune responses.[227] Compared to adult cells, neonatal naïve CD8 T cells express lower basal levels of transcripts for proteins involved in cytotoxicity, for example, FasL, granzymes B and H, perforin, and had lower basal and activation-induced levels of effector cytokines, for example, IFN-γ and IL-2. Moreover, neonatal naïve CD8 T cells induced less apoptotic cell death of allogeneic targets than their adult counterparts. In contrast to adult cells, neonatal CD8 T cells had a markedly greater increased rate of spontaneous (homeostatic) proliferation and markedly greater expansion to polyclonal stimulation, and the transcription of multiple genes involved in innate immunity, such as antimicrobial peptides, and more typical of innate cells, such as neutrophils. These enhanced innate-like responses may be due both to alterations in transcription factors and chromatin configuration[227] as well as enhanced basal signaling for a number of pathways.[228] Interestingly, the exposure of neonatal naïve CD8 T cells to IL-12 results in the rapid downregulation of the neutrophil-like gene expression pattern,[227] suggesting the possibility that there could be rapid reprogramming of CD8 T cells for more effective adaptive immunity following "tuning" of the immune system by exposure to the microbiome.

Compared to infants born at term, cord blood CD8 T cells from preterm infants are reduced in number and appear to have undergone substantial homeostatic expansion in utero based on the loss of CD27 and CD31 surface expression.[229] This homeostatic expansion in a relatively lymphopenic environment appeared to result in antigen-independent T-cell maturation as indicated by an exaggerated production of pro-inflammatory cytokines in response to TCR/CD3 complex stimulation.[229] Based on murine studies, such maturation, coupled, in some cases, with exposure to inflammatory stimuli, for example, premature rupture of membranes, would compromise the adequacy of the antigen-specific response and CD8 T-cell memory formation.

Congenital CMV infection induces robust CMV-specific fetal CD8 T-cell responses,[230] suggesting that this pathway for differentiation is intact with a strong source of antigenic stimulation although a lag in the development of these responses may still occur. There is limited information on the neonatal and young infant CD8 T-cell responses to acute viral infection. Studies of older infants and young children indicate a relatively robust CMV-specific CD8 T-cell response to primary infection.[231]

Antigen-Specific Memory T-Cell Responses

Memory T cells, which are generated as part of the primary antigen-specific T-cell response, are defined by function (i.e., more rapid effector response) and by expression of a $CD45RA^{-}CD45R0^{+}$ surface phenotype. A recently identified T memory stem cell (Tmsc) subset, which differentiates from naïve T cells early in the immune response, appears to play an important role in the long-term generation of antigen-specific CD4 and CD8 memory T cells.[232] This generation does not appear to require continued exposure of the Tmsc to antigen, accounting for the persistence of T-cell memory for decades following a single acute infection with pathogens that are completely cleared from the body. Tmsc give rise to central memory T cells, which have a $CD45R0^{+}CD62L^{+}CCR7^{+}$ surface phenotype and survey the peripheral lymphoid tissues for specific antigen. A second population of cells, called *effector memory T cells*, have a $CD45R0^{+}$ $CD62L^{-}$ surface phenotype, express a variety of chemokine receptors other than CCR7, and survey the nonlymphoid tissues for specific antigen. The extent to which effector memory cells are derived from central memory cells or directly differentiate from Tmsc cells remains unclear. Both central and effector memory T cells recirculate, with substantial numbers of both cell subsets found in the blood. A fourth memory cell population, T resident memory (Trm) cells, is found in nonlymphoid tissues, such as the skin and lung, and does not recirculate in the blood (see section entitled T Resident Memory CD4 and CD8 T cells). Studies comparing the memory CD4 T-cell responses of infants and young children with those of adults following primary CMV infection suggest that the infant/child responses are skewed toward central memory rather than effector memory responses, with an overall reduced production of T_h1 cytokines.[233] Similarly, the pertussis antigen-specific CD4 T-cell response of infants following the receipt of either a diphtheria, tetanus, acellular pertussis (DTaP) or a tetanus toxoid, reduced diphtheria toxoid, acellular pertussis [TdaP] (DTaP) vaccination series appears to be skewed toward central memory cells and limited IFN-γ production compared with that of TdaP-vaccinated adults.[234] Relative blunting of T_h1 memory cell responses in older infants and children likely also applies to the young infant and may contribute to the vulnerability of human infants to severe and disseminated primary tuberculosis.[210]

Regulatory T Cells

Treg cells have a $CD25^{high}CD127^{low}$ surface phenotype and are a distinct subset of CD4 T helper cells critical for maintenance of immune self-tolerance and homeostasis by suppressing aberrant or excessive immune responses harmful to the host.[235] Treg cells are defined by having an immune-suppressive phenotype with high, sustained expression of the transcription factor FOXP3 and a number of other Treg cell signature genes.[236] Mutations in the *FOXP3* gene can result in an inherited multisystem autoimmune disease characterized clinically by diarrhea, insulin-dependent diabetes mellitus, thyroid disorders, and eczema, called *X-linked neonatal diabetes mellitus, enteropathy, and endocrinopathy syndrome*.[237]

Natural (thymic) Treg cells develop as a distinct lineage in the thymus, while induced (peripheral) Treg cells arise in the periphery from conventional CD4 T cells in the presence of TGF-β, retinoic acid, and microbial antigens and metabolites, such as short chain fatty acids.[238] Naïve CD4 T cells of the second-trimester fetus are skewed toward differentiation into peripheral Treg cells rather than effector cells compared with adult naïve CD4 T cells by a Helios-dependent transcriptional mechanism.[239] Murine SCID/human chimera experiments suggest that this skewing is a feature of naïve CD4 T cells that arise from fetal HSCs rather than adult HSCs.[240] It is not known when in ontogeny hematopoiesis switches from the fetal-type HSC to the adult type, raising the possibility that at least some neonatal and infant T cells could be fetal HSC derivatives and, as a result, have distinct immune function. Defects in Treg cell function and number have been described in a series of different autoimmune diseases, including type 1 diabetes, systemic lupus erythematosus, rheumatoid arthritis, multiple sclerosis, and inflammatory bowel disease. Relevant to the interpretation of animal models for neonatal immunology, ontogeny of FoxP3-expressing Treg cells is much more advanced in humans than in mice.[241] $FoxP3^{+}$ Treg cells are almost completely lacking in neonatal mice, while they are abundant in the thymus and mesenteric lymph nodes in the human fetus as early as 20 weeks' gestation.[242] It appears that maternal cells cross the

placenta to reside in fetal lymph nodes, inducing the development of fetal Treg cells suppressing immunity against maternal antigens and probably also playing a role in immune homeostasis after birth.[47] Therefore, it does not seem surprising that Treg cells can be detected in neonatal tissues as early as 23 weeks' gestation.[243] Consistent with the increased concentration of Treg cells in fetal tissues between 12 and 20 weeks' gestation, UCB from preterm infants born between 24 and 31 weeks' gestation contains a higher percentage of Treg cells compared with that of term infants.[244] This imbalance persists until later childhood and may play a role in the immune challenges former preterm infants face. In general, the critical maturation events in the developing immune system that underlie the high vulnerability to both infection and inflammation in the (preterm) neonate remain largely understudied.[245]

γδ T Cells

About 2% to 5% of T-lineage cells of the thymus and peripheral blood express γδ TCR. Despite the potential for a highly diverse γδ TCR repertoire, γδ TCR use is highly restricted in terms of variable (V) segment use, with $V_\gamma 9V_\delta 2$ T cells being the predominant γδ T-cell subset in adult peripheral blood. Gamma–delta T cells, which can be more innate-like or more adaptive-like in their immune function depending on the context,[246] can produce T_h1- and T_h17-type cytokines, kill virally infected or tumor target cells by cell-mediated cytotoxicity, and functionally interact with other cell types of the immune system, such as B cells and NK cells. $V_\gamma 9V_\delta 2^+$ T cells are innate-like in their immune function in that they are not activated by their TCR-recognizing MHC/peptides but rather utilize other receptors, such as the butyrophilin subfamily 3 member A1 (BTN3A1) and butyrophilin 2A1, to recognize microbe- and host-derived phosphorylated prenyl metabolites (collectively referred to as *phosphoantigens*).[246,247] Older work suggested that this Vγ9Vδ2 T-cell predominance was due to postnatal expansion in response to exposure to bacterial-derived phosphoantigens. However, studies of the human fetus suggest otherwise in that $V_\gamma 9V_\delta 2$ T cells are also the predominant γδ T-cell subset in fetal blood and, like their adult counterparts, are programmed to rapidly respond to phosphoantigens with IFN-γ and cytotoxin release.[248] These fetal $V_\gamma 9V_\delta 2$ T cells expand after birth and acquire potent cytotoxic function by 10 weeks of age, most likely in response to environmental phosphoantigen exposure.[249] An example of a γδ T-cell response that is dependent on TCR recognition of antigen is illustrated by $V_\gamma 8V_\delta 1^+$ T cells, which were first identified in fetuses with congenital CMV infection.[250] These $V_\gamma 8V_\delta 1^+$ T cells have the ability to lyse CMV-infected target cells in a TCR-dependent manner and have the potential to serve as non-MHC-restricted antiviral adoptive immunotherapy (e.g., in the post-HSC transplant setting).[251] These CMV-reactive $V_\gamma 8V_\delta 1^+$ T cells have innate T-cell like features including invariant TCRs and low levels of TdT so that there are minimal CDR3 insertions. Moreover, they acquire stereotypical effector function (IFN-γ and granzyme expression) during intrathymic development.[252]

Natural Killer T Cells

NKT cells are so named because they express αβ TCRs in conjunction with CD161 (NKR-P1A), the human orthologue of the mouse NK1.1 protein, and other NK-cell markers, including CD56, CD57, and NKG2D. Unlike conventional αβ T cells, NKT cells that emigrate from the thymus into the periphery have a uniformly $CD45R0^+$ surface phenotype and the ability to rapidly secrete high levels of T_h1 and T_h2 cytokines and to carry out cell-mediated cytotoxicity. Human NKT cells have a highly restricted repertoire of αβ TCR (TCRα chains containing the Vα24Jα18 segments in association with TCRβ chains containing Vβ11 segments) and are positively selected during thymocyte development by the nonclassical MHC molecule CD1d rather than by MHC class I or class II molecules. The invariant TCR of NKT cells can recognize lipids bound to CD1 that are either endogenously produced glycolipids for example, α-glycosylceramide and α-galactosylceramide secreted by thymocytes and CD11c+ dendritic cells,[253] or human gut microbiota derived glycolipids, for example, α-galactosylceramide produced by *Bacteroides*.[254] The role of the invariant αβ TCR in NKT-cell immunity remains controversial, and it has been proposed that activation of these cells by cytokines, such as IL-12, may be more important for their mediating an innate-like immune response.[184] NKG2D-dependent but TCR-independent activation of NKT cells (e.g., for cytotoxic activity) can also occur. NKT cells with invariant TCR can be divided into a $CD4^+(CD8^-)$ subset that expresses CD62L and may be involved in recirculation in secondary lymphoid tissues and a $CD4^-CD8^-$ cell subset that may mainly serve as effector cells at sites of extralymphoid tissue inflammation. In addition to their potential role in antimicrobial host defense, NKT cells have also been implicated as negative regulators of certain T-cell-mediated immunopathologic responses, as relative deficiency of their numbers has been associated with certain autoimmune diseases, graft-versus-host disease following hematopoietic cell transplant, and asthma.

NKT-lineage cells are present in the human fetal thymus by the beginning of the second trimester of gestation, and their relative frequencies compared with those of the other thymocyte subsets decline with increasing gestational age because of the rapid expansion of thymocytes differentiating by the conventional positive selection. Fetal and postnatal thymic NKT cells, which are largely $CD4^+CD45R0^+$, express high levels of IL-7 receptors, and their development appears to be largely IL-7 dependent. Extrathymic fetal NKT-cell populations are found in the small intestine, where they may constitute up to 5% of all T cells in this tissue, and in the lung, spleen, and mesenteric lymph nodes.[255] Those NKT cells found in the fetal small intestine are distinct from those of fetal peripheral lymphoid tissue in having greater capacity to produce IFN-γ and lower levels of expression of CD62L. Murine studies suggest that commensal bacteria may be an important source for NKT-cell expansion and maturation, but the finding of a human NKT-cell population with mature features in the fetal intestine before most bacterial colonization of the gut occurs suggests a different mechanism, such as the presentation of endogenous glycolipids by CD1d, which is abundantly expressed in the fetal intestine. Circulating NKT cells in the neonate, infant, and young child constitute approximately 0.06% of circulating lymphocytes, a frequency that is only modestly lower than the mean of 0.2% for adult peripheral blood.[256] At all ages there is striking individual variation in values, with frequencies ranging from less than 0.001% to greater than 0.5% of circulating lymphocytes.

Mucosal-Associated Invariant T Cells

MAIT cells are a population of $CD8^+$ or $CD8^-CD4^-$ αβ T cells that predominantly express an invariant $V_\alpha 7.2$ and $J_\alpha 33$ TCRα chain. They are positively selected during thymic development by MR1, an MHC class I-like protein that is widely expressed on

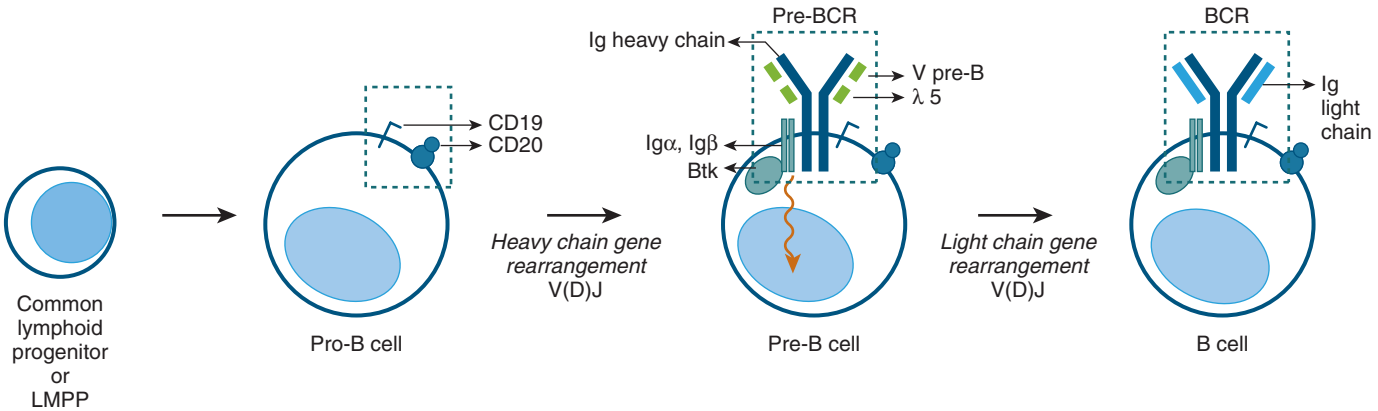
hematopoietic and epithelial cells.[257] There is growing evidence that MAIT cells serve a homeostatic role in tissue repair at epithelia where they are particularly abundant. Antigen for the MAIT cell αβ TCR consists of bacterial- or fungal-derived metabolites of the riboflavin biosynthetic pathway that bind to MR1 at a site analogous to the peptide-binding groove used by conventional MHC class I heavy chains.[258] These metabolites derived from the microbiota rapidly travel from mucosal surfaces to the thymus where they are captured by MR1 and serve in intrathymic MAIT cell selection.[259] MAIT cells produce T_h1 and T_h17 cytokines in response to polyclonal stimuli, including treatment with IL-12 or IL-18, and can kill bacterially infected epithelial cells by cell-mediated cytotoxicity. MAIT cells constitute up to 10% of circulating αβ T cells of healthy adults and uniformly have a memory ($CD45RA^-CD45R0^+$) cell surface phenotype. MAIT cells are the predominant αβ T-cell type in the liver and the lamina propria of the healthy intestine[260] and are also found in lung tissue. Murine studies have shown that MAIT cells can mediate protection against a variety of bacterial pathogens, including mycobacteria. Putative intrathymic MAIT cell precursors, which are $CD161^{high}V_\alpha7.2^+$ but $IL\text{-}18R^{low}$, are detectable at 18 weeks' gestation. MAIT cells with an activated and proliferative phenotype (i.e., $IL\text{-}18R^{high}CD45R0^+Ki67^+$) are easily detected in the small intestine, liver, and lung between 18 and 23 weeks' gestation.[261] These fetal intestinal $CD161^{high}V_\alpha7.2^+$ cells secrete IFN-γ and IL-22 in response to *E. coli* and anti-CD28 monoclonal antibody, but it is unclear if these cells are activated for these effector functions by MR1 antigen recognition. These cells may serve a TCR-dependent developmental/tissue repair homeostatic function as has been described for other MAIT cell populations associated with epithelia.[262] Studies using MR1 tetramers for analysis of circulating human T-cell populations suggest that the use of surrogate markers, such as expression of TCRs with $V_\alpha7.2$, may underestimate the phenotypic and functional diversity of MAIT cells.[263] MAIT cells in the UCB of neonates, which constitute approximately 0.7% of circulating αβ T cells, have a surface phenotype (e.g., $CD45RA^+$) that suggests that they may be RTEs that are in transit to the extralymphoid tissues, where they may mature and acquire a memory phenotype, as apparently occurs in the fetus.[261]

Tissue Resident Memory (TRM) CD4 and CD8 T Cells

Many non-lymphoid tissues of the body, including the lung, skin, and intestine, have substantial numbers of T cells that are mainly sessile and do not recirculate.[264] These resident T-cell populations include γδ T cells, NK T cells, MAIT cells, as well as αβ-TCR+ CD4 and CD8 T cells. In some tissues, such as the lung, substantial accumulation of CD4 and CD8 TRM cells occur only after birth in response to infection and the lack of these cells may contribute to the greater severity of viral infections in the neonate and young infant, for example, RSV infection of the lung.[265] CD4 TRM cells in the human lung may also be important for the control of pulmonary tuberculosis.[266] TRM cells are distinguished from other memory CD4 and CD8 T cell populations, such as effector memory cells, by their uniformly high surface levels of CD69 and CD103. At other sites, such as the intestine and skin, there may be relatively large populations of fetal CD4 and CD8 TRM cells with diverse TCR repertoires as early as the second trimester.[58,267,268] Fetal TRM populations mainly serve a homeostatic/tissue regulatory role and may have an activated phenotype in response to endogenous self-tissue-derived signals rather than due to microbial derived products.[269]

B Lymphocytes

B cells are lymphocytes that express BCRs, which consist of surface Ig in association with Igα and Igβ signaling molecules and the cytoplasmic Bruton tyrosine kinase (Btk) (Fig. 32.8). The engagement of the BCR by high-affinity antigen results in B-cell activation and clonal expansion and, in some instances, terminal B-cell differentiation into antibody-secreting plasma cells. Secreted antibodies form the humoral arm of the immune system and provide the main form of immune protection against many pathogens, particularly during the extracellular phases of their life cycle. Although the B-cell compartment is well formed before birth,



• **Fig. 32.8** Human B-Cell Development. A common lymphoid progenitor or lymphoid-primed multipotent progenitor (*LMPP*) cell gives rise to a pro-B cell that expresses surface CD19 and CD20 and that is committed to B-lineage–cell differentiation. The immunoglobulin (*Ig*) heavy chain gene locus undergoes V(D)J rearrangement, and, if productive, the B-lineage cell proceeds to the pre-B-cell stage, expressing a pre-B-cell receptor (*pre-BCR*). The pre-BCR consists of the Ig heavy chain in association with a surrogate light chain that consists of two polypeptides—V pre-B and λ5—and the proteins Igα and Igβ that are required for receptor complex surface expression and signaling. The Ig light chains undergo rearrangement in the pre-B cell, and, if productive, the pre-B cell differentiates into a B cell that expresses a B-cell receptor (*BCR*) that contains a mature surface Ig molecule. *Btk*, Bruton tyrosine kinase.

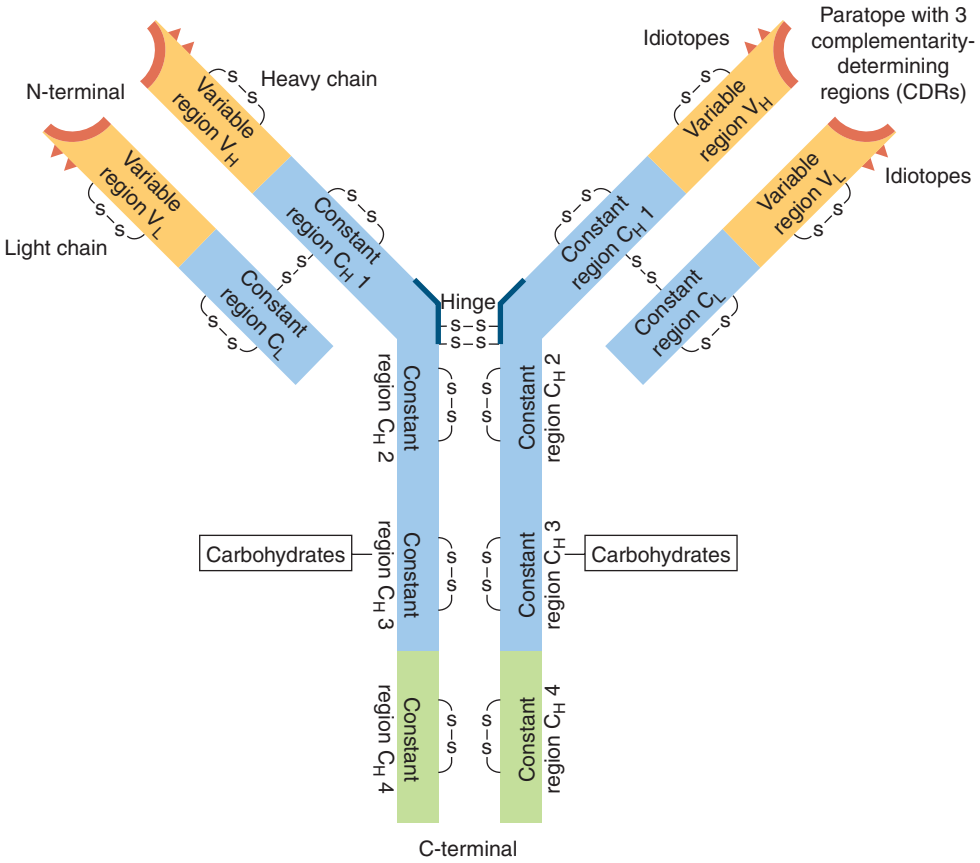
full diversification of the antibody repertoire and the efficiency of somatic hypermutation, which generates higher affinity antibodies, is not achieved until late in infancy.

B-Cell Development

The early phase of B-cell development, like T-cell development, is antigen-independent. In the human fetal bone marrow, a $CD10^-$ $CD19^+$ B-progenitor cell that is B-lineage committed undergoes dramatic expansion during the early second trimester.[270] This precursor gives rise to $CD19^+$ pro-B cells that have not undergone V(D)J recombination of the Ig genes and express CD34, TdT, RAG1, and RAG2. These cells undergo heavy chain D to J gene segment rearrangements followed by V to DJ rearrangement. As in TCR gene rearrangement, TdT inserts nucleotides between the segments to create additional junctional diversity at CDR3, which is encoded by the 3′ end of the V segment and the D and J segments. CDR3 is an important determinant of antibody specificity as it forms the central portion of the antigen-binding site. If the Ig heavy chain gene rearrangement is productive, it is expressed on the cell surface in association with a surrogate light chain consisting of the V-preB and λ5 polypeptides. Cells with a nonfunctional Ig heavy chain gene rearrangement or that express Ig heavy chain protein that assembles poorly with the surrogate light chain die by apoptosis. The pre-BCR signals use Btk (Fig. 32.9), which accounts genetic deficiency of Btk (X-linked agammaglobulinemia) resulting in a maturational arrest at the pre-B-cell stage. The next stage involves V_L to J_L light chain gene rearrangement, and, if productive, the newly expressed Ig light chain replaces the surrogate light chain. The light chain can be derived from either the kappa chain (60% of B cells) or the lambda chain (40% of B cells) gene clusters. The completed BCR is antigen specific and contains a surface IgM molecule. B-lineage cells also express surface IgD with the same antigen specificity as IgM, which is generated by alternative exon usage in the constant region of the Ig heavy chain gene. B-cell development initially occurs in the fetal liver, with a switch to the bone marrow beginning in the second trimester of gestation.

B-Cell Preimmune Selection and Maturation

Immature B cells of the bone marrow that have successfully produced productive heavy and light chains express these as IgM on the cell surface. A large proportion of these BCRs are autoreactive (i.e., they bind with relatively high affinity to molecules on other cell types within the bone marrow microenvironment or peripheral lymphoid organs). An important immune tolerance mechanism is the testing of immature B-lineage cells of the bone marrow for self-reactivity. At this stage of B-cell development, BCR signaling as part of self-reactivity maintains RAG activity, allowing the B cell to undergo a secondary V-to-J light chain rearrangement, a process known as *receptor editing*. If this eliminates BCR autoreactivity and cell signaling, RAG activity ceases, and the B cell enters the circulation as a peripheral transitional B cell to complete its maturation. Otherwise, additional light chain rearrangement can occur. Most initially autoreactive immature B cells can be converted to nonautoreactivity by receptor editing, allowing most B cells with productive Ig heavy chain rearrangements to contribute to the final repertoire.



• **Fig. 32.9** Structure of Monomeric Immunoglobulin. (Modified from Mix E, Goertsches R, Zett UKL. Immunoglobulins: basic considerations. *J Neurol*. 2006;253:V9–V17.)

Persistently autoreactive B cells are probably eliminated either by a process of clonal deletion, which involves apoptosis induced by strong BCR signaling,[271] or by anergy, in which the B cells are functionally inactivated. Anergic B cells have been identified as having an $IgD^{+}IgM^{-}CD27^{-}$ surface phenotype and constitute ~3% of peripheral blood B cells in adults. These anergic B cells have BCRs with autoreactive antigen specificity that mediate a decreased calcium flux and tyrosine phosphorylation after their engagement.[272]

These tolerance mechanisms appear to be incomplete in the human fetus such that antigenically naïve B cells that mature in the fetal liver and bone marrow have the capacity to produce antibodies that are polyreactive and that bind both to apoptotic cells and to commensal bacteria from healthy adults.[273] This restricted polyreactive antibody repertoire may be beneficial for the removal of apoptotic cells during development and for influencing the assembly of the gut microbiota after birth.

$IgM^{high}IgD^{high}$ transitional B cells can be identified in the bone marrow and circulation by their high levels of expression of CD5, CD10, CD24, and CD38 and low levels of adenosine triphosphate-binding cassette subfamily B member 1 (ABCB1).[274] Analogous to RTEs, these circulating transitional B cells undergo a post-bone marrow phase of peripheral maturation into fully mature naïve B cells that involves an increase in CD21 and ABCB1 expression and a decrease in CD5, CD10, CD24, and CD38 expression. The maturation of transitional B cells into fully mature antigenically naïve B cells includes negative selection of B cells with autoreactive BCRs that have entered the periphery and that have somehow escaped central tolerance mechanisms in the bone marrow.[275,276] Although the mechanisms involved in this secondary checkpoint for B-cell tolerance remain poorly understood, they may involve, at least in part, the death of autoreactive B cells because of their greater dependence for survival on B-cell activating factor (BAFF), a member of the TNF ligand superfamily, than nonautoreactive B cells.

The transitional B-cell subset is also enriched in regulatory B cells (Bregs), which have the capacity to express IL-10 after strong stimulation and, like Treg cells, may negatively regulate adaptive immune responses. Neonates and infants also have a circulating Breg population with a $CD5^{hi}CD10^{-}CD24^{lo}CD38^{lo}IgM^{lo}IgD^{lo}$ surface phenotype that is distinct from most transitional B cells and adult Bregs. These neonatal Bregs have a high capacity to produce IL-10 after their infection by RSV via viral interactions with the BCR and the CX3CR1 chemokine receptor, with the secreted IL-10 inhibiting the in vitro generation of T_h1 immunity.[277] Studies of young infants with RSV bronchiolitis found an inverse correlation with the frequency of neonatal Bregs in the circulation and nasopharyngeal aspirates with the circulating levels of CXCR3+ T_h1 cells and a direct correlation with disease severity.[277] Together, these findings indicate that Bregs, like Tregs, may inhibit effector T-cell function and immune control of infection and that this effect may be particularly prominent in RSV infection of neonates and young infants. Most transitional B cells that escape negative selection become fully mature naïve $IgM^{high}IgD^{high}CD27^{-}$ $ABCB1^{+}$ follicular B cells and enter follicle areas of the secondary lymphoid tissue by the interaction of their CXCR5 chemokine receptors with chemokines in the follicle (CXCL13). These cells can recirculate between the follicles of the peripheral lymphoid organs, including the spleen, lymph nodes, and Peyer patches, and the blood and lymph.[278] Follicular B cells include most of those that are involved in adaptive immune responses to T-dependent antigens, such as proteins and protein–carbohydrate conjugates.

Fetal and Neonatal B-Cell Development and Surface Phenotype

B cells expressing surface IgM are present by 10 weeks' gestation. The frequency of B cells in the tissues rapidly increases, such that by 22 weeks' gestation the proportion of B cells in the spleen, blood, and bone marrow is similar to that of adults. The concentration of B cells in the circulation is higher during the second and third trimesters than at birth.[279] After birth, the concentration of B cells increases to peak levels between 6 and 12 months of age, which is followed by a gradual decrease until stable adult values are reached.

Approximately 70% to 75% of UCB B cells are of the transitional subset, whereas transitional B cells usually constitute 10% or less of adult peripheral blood B cells, and 25% to 30% are fully naïve B cells.[274,280] $CD27^{+}$ B cells, which include most memory B cells in adults, are at low levels or undetectable in UCB, consistent with the antigenic naïveté of the healthy newborn. Neonatal naïve B cells are functionally distinct from their adult counterparts, having significantly lower expression of the IL-4 receptor alpha chain and responsiveness to IL-4 as assessed by tyrosine phosphorylation of STAT6.[281] Circulating newborn B cells are deficient in the purine ectoenzyme CD73, impairing their capacity for extracellular purine salvage.[282] Newborn naïve B cells demonstrate adult-level expression of TLRs and CD40, but responses to stimulation of these receptors are distinct, including (1) impaired neonatal TLR2- and TLR7-mediated as well as (CD40+ TLR)-mediated but enhanced TLR9-mediated cytokine production and (2) impaired CD40-mediated Ig secretion.[283] With respect to the quantity of B cells, absolute B-cell numbers double in the first 6 months of life from those at birth, mainly due to expansion of fully mature naïve B cells and, to a lesser extent, transitional B cells.

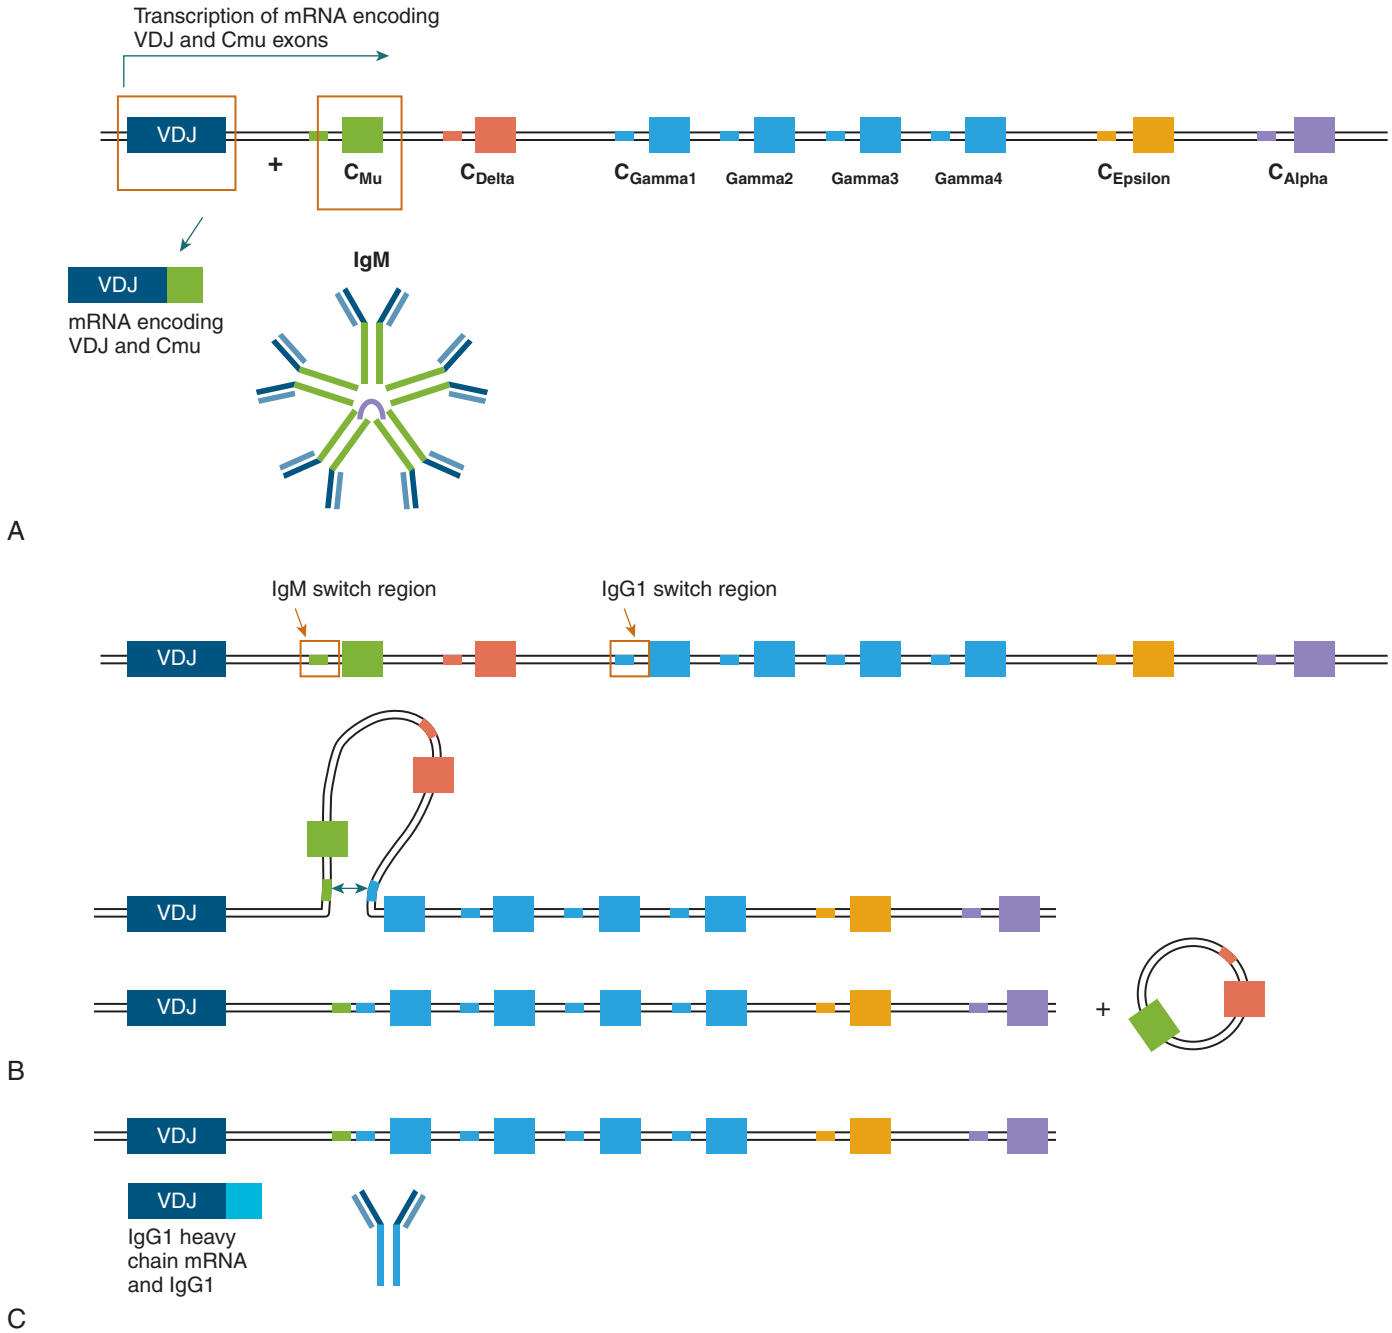
B-Cell Activation, Somatic Hypermutation, and Isotype Switching

When mature naïve B cells contact antigen through the BCR, a signal is transduced that promotes further growth and differentiation into memory B cells and plasma cells. BCR signaling involves activation of the tyrosine kinases spleen tyrosine kinase (Syk) and Btk, which are also involved in pre-BCR signal transduction, which results in transcriptional regulation by Elk-1, c-Myc, NF-κB, and NFAT.[284] The T-dependent B-cell response to protein antigens involves the internalization of protein bound to the BCR and its processing into peptides that are loaded onto MHC class II molecules. These peptide/MHC class II complexes that are expressed on the B-cell surface activate CD4 T cells via their TCR, resulting in a series of CD4 T cell/B-cell interactions, including between CD40L and CD40 receptor, between IL-21 and IL-21 receptor, between ICOS and ICOS ligand.

Both the B cells activated by protein antigen and the peptide antigen-specific CD4 T cells they activate and interact with enter the follicles of secondary lymphoid tissue, where these interactions continue. The activated B cells undergo massive clonal expansion and differentiation giving rise to histologically evident germinal centers.[285] Most B cells in the light zone of the germinal center undergo somatic hypermutation of the antigen combining site regions encoded by productively rearranged V, D, and J segments of the Ig heavy chain gene and the V and J segments of the light chain gene. Somatic hypermutation, which requires activation-induced cytidine deaminase and error-prone DNA polymerases expression by germinal center B cells, results in random point mutations that may lead to amino acid substitutions, premature

stop codons, or, less commonly insertions or deletions that result in frameshift mutations. B cells that have damaged immunoglobulin receptors as a result of somatic hypermutation are eliminated by apoptosis in the light zone.[286] B cells then enter the dark zone of the germinal center where B cells with BCRs with amino acid substitutions that have the highest affinity for antigen survive and those with lower affinity receptors die by apoptosis.[286] This affinity maturation process dramatically increases the ability of antibody to perform effector function, such as neutralization or opsonization. The peak of somatic mutation is approximately 10 to 12 days after immunization with a protein antigen.

Human B cells produce five isotypes of antibody (i.e., IgM, IgD, IgG, IgA, and IgE). The IgG and IgA isotypes can be, respectively, divided into the IgA1 and IgA2 subclasses and the IgG1, IgG2, IgG3, and IgG4 subclasses. During their process of differentiation from naïve B cells into memory B cells or plasma cells, B cells are able to change from expressing IgM to expressing other antibody isotypes without changing antigen specificity. This switching involves isotype recombination, the genetic replacement of the IgM-specific portion of the constant region (C_μ) of the heavy chain with a new isotype-specific gene segment (Fig. 32.10). As in V(D)J recombination, the intervening DNA



• **Fig. 32.10** Variable (V), Diversity (D), and Joining (J) Gene Segment Recombination. (A) Transcription of messenger RNA (mRNA) encoding VDJ and constant C_μ exons. (B) Recombination highlighting the immunoglobulin M (*IgM*) and the immunoglobulin G1 (*IgG1*) switch regions. (C) IgG1 heavy chain mRNA and protein.

is excised as a circle. Isotype recombination is mediated by switch regions that are positioned immediately upstream of each of the isotype-specific C regions. Successive multiple isotype switching by a single B cell can also occur—for example, IgM to IgG and then, on reactivation by antigen, IgG to IgE. Cytokines secreted by T cells or other cell types play an important role in promoting or inhibiting switching to a specific isotype. For example, IL-4 or IL-13 is required for isotype switching to IgE, a process that can be inhibited by the presence of IFN-γ.

IgA, which is the predominant Ig isotype secreted into mucosal secretions, has a distinct CD4 T-cell-independent and CD40L-independent pathway for its generation by isotype switching that utilizes the TNF ligand superfamily—a proliferation-inducing ligand (APRIL) and BAFF. These cell surface proteins, which are expressed by a variety of cell types, including intestinal epithelium, may play an important role in the development of IgA-secreting plasma cells in the gut in response to commensal bacteria.

Immunoglobulins

Igs, or antibodies, are a heterogeneous group of proteins that are detectable in plasma and body fluids and on the surfaces of mucosal barriers and B cells that bind specifically to antigens. The functions of Igs relevant to fetal and neonatal immunity are summarized in Table 32.2. There are five known classes of Igs: IgG, IgM, IgA, IgE, and IgD. Human IgM circulates as a pentamer or hexamer, and IgA circulates as a dimer. Multimers are formed in association with an additional J chain. The functions of individual Ig classes are different but overlapping (see Table 32.2). The prototype Ig molecule consists of a pair of identical heavy chains that determine the Ig class in combination with a pair of identical light chains, which are linked by disulfide bonds (see Fig. 32.9). Each Ig molecule contains two N-terminal, identical domains with antigen-binding activity that are formed by the variable regions of a heavy chain and a light chain. The antigen-binding site is formed by three complementarity-determining regions: CDR1, CDR2, and CDR3, which are hypervariable in their amino acid sequences as a result of V(D)J recombination of the heavy and light chain genes and, in some instances, somatic hypermutation. The C-terminal region of the two heavy chains forms the Fc (fraction crystallizable) region, which is not involved in antigen binding but mediates Ig effector functions. The principal functions of the Fc region include receptor-mediated phagocytosis (IgG), antibody-dependent cellular cytotoxicity (IgG), release of inflammatory mediators from mast cells and basophils (IgE), receptor-mediated transport through mucosa (IgA and IgM) and placenta (IgG), and complement activation (IgG1, IgG2, IgG3, and IgM). The five different isotype classes of human Igs (IgG, IgM, IgA, IgD, and IgE) are defined structurally by differences in the heavy chain constant regions (CH)1 and CH2 domains of the Fc fragments. Within isotypes, there are four IgG subclasses (IgG1, IgG2, IgG3, and IgG4) and two IgA subclasses (IgA1 and IgA2).

Immunoglobulin G

IgG is the predominant Ig isotype at all ages.[287] In adults, IgG1 is the predominant subclass, accounting for approximately 70% of total IgG, and IgG2, IgG3, and IgG4 account for ~20%, 7%, and 3% of the total, respectively. Passively derived maternal IgG is the source of virtually all of the IgG subclasses detected in the fetus and neonate. Because the IgG plasma half-life is about 21 days, these maternally derived IgG levels fall rapidly after birth. The levels of IgG synthesized by the neonate and that are derived from the mother are approximately equal at 2 months of age, and by 10 to 12 months of age nearly all of the IgG is infant derived. IgG values typically reach a nadir of approximately 400 mg/dL in term infants at 3 to 4 months of age and rise thereafter. Premature infants have lower IgG concentrations at birth that typically reach a nadir at 3 months of age; mean IgG values of 82 and 104 mg/dL are observed in infants born at 25 to 28 weeks' gestation and 29 to 32 weeks' gestation, respectively.

Murine studies suggest that commensal microbiota-specific serum IgG responses are frequent in adults and appear to arise by T-independent type 1 response involving engagement of B-cell TLRs. In pregnant mothers, these IgG antibodies can be transferred to the fetus via the FcRN and after birth appear to play an important role in limiting commensal bacterial translocation and potentially harmful anti-commensal T-cell responses.[288] This role for maternally-derived IgG may be particularly important early after birth prior to the full establishment of IgA-specific responses after 4 weeks of age.[289] Maternally derived anti-commensal IgG and IgA antibodies in breast milk may also play an important role in limiting undesirable anti-commensal immune responses.[290]

Other murine studies suggest that maternal IgG antibodies can inhibit neonatal and infant responses to vaccination in a titer-dependent manner by acting on germinal centers to reduce the output of memory B cells and plasma cells and altering the BCRs that emerge from somatic hypermutation.[291] These mechanisms may be relevant to vaccination in humans, as the titer of maternal antibodies in young infants is associated with impaired antibody responses for a variety of different childhood vaccines, including those that are inactivated or live-attenuated.[292]

Immunoglobulin M

IgM is the only isotype besides IgG that binds and activates complement. IgM has a half-life in the blood of 5 days and exists in either a pentameric or hexameric form, which confers a high avidity for antigen and highly efficient complement activation. The concentration of IgM in the blood increases from a mean of 6 mg/dL in infants born at less than 28 weeks' gestation to 11 mg/dL for those born at term.[293] This IgM is likely to be preimmune and not the result of a B-cell response to foreign antigens. Rather, it is likely enriched for polyreactive natural antibodies that may play an important role in innate defense against infection. Postnatal IgM concentrations rise rapidly for the first month and then more gradually, presumably in response to antigenic stimulation in both premature infants and term infants. By 1 year of age, the values are ~60% of those in adults. Because maternal–fetal transport of IgM does not occur, elevated (>20 mg/dL) IgM concentrations in UCB suggest possible intrauterine infections, although many infants with congenital infections have normal values.

Immunoglobulin A

IgA does not cross the placenta, and its concentration in UCB is usually 0.1 to 5.0 mg/dL, approximately 0.5% of the levels in maternal sera.[293] The concentrations are similar in term and premature neonates,[294] and both IgA1 and IgA2 are present. IgA has a half-life of 6 days in blood. Secretory IgA can be detected in the saliva of neonates as early as 3 days after birth.

The concentrations of IgA in serum increase to 20% of adult levels by 1 year of age and rise progressively through adolescence. Increased UCB IgA concentrations are observed in some infants with congenital infection, such as toxoplasmosis, and are common in those infected with HIV by vertical transmission. The amount of IgA produced daily is estimated to exceed that of all Ig isotypes combined. The overall importance of IgA in host defenses is only

TABLE 32.2 Characteristics and Functions of Immunoglobulins

	Molecular Mass (kDa)	Serum Concentration (g/L)	Serum Half-Life (Days)	Neutralization	Opsonization	Complement Activation	Epithelial Transport	Placental Transport	Sensitization for Killing by Natural Killer Cells	Sensitization of Mast Cells and Basophils

partially understood, as individuals with complete IgA deficiency are typically asymptomatic. Recent studies suggest that mucosally secreted IgA may play an important role in regulating the composition of the human gut microbiome by a number of potential mechanisms, including suppressing or enhancing bacterial growth.[289,295] In cases of IgA deficiency, this role in regulating gut microbiota may be compensated for by mucosally secreted IgM.

Immunoglobulin E

Although IgE synthesis by the fetus is detectable as early as 11 weeks, the concentrations of IgE in UCB are typically low, with a mean of ~0.5% of maternal levels.[293] IgE concentrations are higher in infants born at 40 to 42 weeks' gestation than in those born at 37 to 39 weeks. The rate of postnatal increase differs and is greater in infants predisposed to allergic disease or greater environmental exposure to allergens.[296] The concentration of IgE at birth appears to have limited predictive value for later development of atopic disease for most individuals. Maternofetal transfer of IgE appears to be a common cause of elevated IgE concentration at birth.[297] Based on murine experiments, one potential mechanism for such transfer may be IgG anti-IgE complexes being transported via FcRN, which has substantial affinity only for IgG.

Immunoglobulin D

IgD is mainly produced by plasma cell derivatives of B cells from the aerodigestive mucosa that have undergone isotype switching from the Cμ to Cδ constant switch region and have an IgM–IgD+ surface phenotype.[273] IgD is detectable in serum from the UCB of term and premature infants, with mean levels of approximately 0.05 mg/dL.[293] These levels increase during the first year of life. Along with the IgA, IgM, and IgG isotypes, secreted IgD is enriched at mucosal sites of chronic infection and inflammation, such as the lung and tonsils, and can play a role in host defense by binding to pathogens as well as in microbial homeostasis by binding to some commensal microbes.[298] IgD binds to basophils via CD44 and galectin 9, and its engagement by antigen results in basophil activation and tissue infiltration. Elevated levels of IgD are also associated with certain monogenic autoinflammatory disorders, such as mevalonate kinase deficiency and familial Mediterranean fever.

Specific Immunologic Deficiencies of the Newborn

The most common reason for increased immunologic susceptibility to infection in newborns, besides prematurity, is iatrogenic immunosuppression caused by administration of corticosteroids for treatment or prevention of bronchopulmonary dysplasia. Such therapy is particularly associated with an increased risk of fungal infection, such as candidemia, particularly in the setting of indwelling intravascular catheters used for total parenteral nutrition.

Although less common than therapeutically induced immunodeficiency, genetically inherited primary immunodeficiencies (PIDs) can present in the neonatal period and may require prompt intervention for optimal outcome. There are approximately 450 recognized PIDs,[299] most of which are monogenic disorders.[300] The physician should attempt to differentiate infants with specific genetically regulated immunologic deficiencies from those with developmentally regulated, environmentally induced, or infection-related susceptibility to microbial invasion.[301] Documenting a full family history during a prenatal visit, including whether there is consanguinity or the family is of an ethnicity that is known to have a high incidence of a particular PID (e.g., those of Athabascan Indian heritage and SCID caused by Artemis deficiency), can be helpful in identifying families who may have a PID. However, the lack of such history does not exclude PID, as a patient can have de novo mutations causing PID. These de novo mutations are not present in either the biological mother or father or siblings and are the result of a mutation in the egg of the mother or sperm of the father, or in rare instances in the fertilized egg itself. Such de novo mutations are increasingly recognized as result of whole-exome sequencing of the biological mother, biological father, and affected child trios.[302] What follows is a discussion of specific PIDs that may present in the newborn period and are important to recognize promptly.

Severe Combined Immunodeficiency Syndrome

Epidemiology

SCID, which occurs in ~1 in 58,000 live births in the United States, is mainly an inherited severe immunodeficiency with marked deficiency of the de novo production by the thymus of antigenically naïve (CD45RA+CD45RO−) T cells with profound T-cell lymphopenia as a result. For a few etiologies, naïve peripheral T cells may be present in normal or near normal numbers that are unable to carry out immune function. The frequency of SCID in live births may be substantially higher in regions with high consanguinity, for example, parts of North Africa, the Middle East, and Southern India.

Pathophysiology

In SCID with profound T-cell lymphopenia there is either a reduced intrathymic production (most etiologies) or, rarely, a block in their egress from the thymus to the periphery [coronin 1A (CORO1A) deficiency.[303] The "combined" term in SCID reflects the fact that severe T-cell deficiency invariably compromises B-cell function, even if B cells are present in normal numbers. This is because CD4 T-cell help provided by T follicular helper cells in the form of surface CD40 ligand and secreted cytokines, such as IL-21, is required for B cells to produce antibodies to proteins. In addition, some forms of SCID result in the development of peripheral B cells that are functionally defective. In SCID, there is variable loss of NK cell numbers and other ILCs, depending on the specific gene defect involved. Thus, phenotyping by flow cytometry for T-cell, B-cell, and NK-cell subsets is useful in assessing the genetic etiologies and disease mechanisms that are likely to be involved.

SCID can be due to single X-linked or biallelic autosomal recessive (AR) gene defects (hereafter the specific genes involved in disease are capitalized and italicized).[303–306] Much less commonly, SCID can result from heterozygosity for gain-of-function mutations that inhibit hematopoietic cell function (e.g., certain Rac2 deficiency cases).[307] Most types of SCID due to monogenic defects are hematopoietic cells autonomous with the disease potentially curable by hematopoietic stem cell (HSC) transplantation or HSC-based gene therapy. There are a few rare genetic etiologies of SCID gene in which thymic hypoplasia and peripheral T-cell lymphopenia are due to defective thymic epithelial cell development, and these cases are important to identify as their definitive treatment requires a thymus transplant (see DiGeorge Syndrome section, below).

X-linked SCID, which comprises ~40% to 50% of cases of SCID in most series, is a form of T-B+NK- SCID in which T cells and NK cells are very low/absent in the peripheral blood but B cells are present in normal to increased numbers. X-linked SCID is due to deficiency of the IL-2 receptor gamma chain gene (*IL2RG*), which encodes for CD132, the common gamma chain protein. CD132 is an obligatory component of receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. The IL-7 receptor, which consists of the IL-7R alpha chain (CD127) and CD132, is critical for thymocytes to grow in response to IL-7 such that *IL2RG* deficiency results in arrested T-cell development.[303,306] Although B cells develop normally and are present in normal or increased numbers, their lack of functional receptors for IL-21 results in their inability to respond to IL-21-mediated help for immunoglobulin production.[308] Deficiency of CD132 also results in the loss of functional surface receptors for IL-15, which results in NK-cell developmental arrest in the bone marrow.[303,306] T-B+NK- SCID can also result from AR inheritance of biallelic defects of the JAK3 gene, which encodes Janus kinase-3 that is associated with the cytoplasmic domain of CD132.[303,306]

Patients with $T^-B^-NK^+$ SCID have biallelic mutations of genes that encode proteins that are required for TCR and Ig gene rearrangement by V(D)J recombination, including RAG1, RAG2, Artemis (*DCLRE1C*), DNA-dependent protein kinase catalytic subunit (*PRKDC*), Cernunnos (*NHEJ1*), and DNA ligase IV (*LIG4*).[309] These mutations prevent the formation of pre-TCRs on thymocytes and pre-BCRs on immature B cells, resulting in early T-cell and B-cell maturational arrest and an absence of peripheral T cells and B cells. Except for RAG1 and RAG2, these proteins are also involved in non-homologous end-joining (NHEJ) gene repair for all cell types and these patients are highly susceptible to toxicity from irradiation that is sometimes used for HSC transplantation conditioning.

$T^-B^+NK^+$ SCID with severe T-cell lymphopenia and an AR inheritance pattern can be due to defects in the ability of the thymocyte TCRs to transmit intracellular survival or activation signals (e.g., biallelic genetic deficiencies encoding CD3-δ, CD3-ε, TCR-zeta [CD147], and CD45) or thymic epithelium differentiation is impaired (e.g., biallelic *PAX1* or *FOXN1* gene defects). A SCID-like clinical presentation with severe T-cell lymphopenia may occur for some causes of AR T-cell immunodeficiencies that more often present with a less severe phenotype and retention of greater numbers of T cells, such as cartilage hair hypoplasia syndrome (*RMRP*), zeta-associated protein of 70-kilodaltons kinase (*ZAP70*) deficiency, purine nucleoside phosphorylase (*PNP*) deficiency, sarcoma homology 2 domain-containing leukocyte protein of 76 kilodaltons (*SLP76*) deficiency, Coloboma, Heart defects, choanal Atresia, growth Retardation, Genital abnormalities, and Ear abnormalities (CHARGE) syndrome (*CHD7*), or tetratricopeptide repeat domain 7 deficiency (*TTCA7*) with intestinal atresias.[305] This T-B+NK+ SCID phenotype also occurs in coronin 1A deficiency, in which there is a block in emigration of mature thymocytes into the periphery but otherwise normal intrathymic T-cell development.

The $T^-B^-NK^-$ SCID phenotype is due to biallelic mutations in genes encoding the enzymes adenosine deaminase (*ADA*) and adenylate kinase 2 (*AK2*). Patients who lack ADA, an enzyme in the purine salvage pathway, accumulate deoxyadenosine triphosphate in red blood cells and lymphocytes, and the concentration correlates with disease severity. The ADA substrates, adenosine and deoxyadenosine, are found at increased levels in the serum. Developing thymocytes are particularly sensitive to these metabolic effects. ADA deficiency may also result in neonatal hepatitis, renal dysfunction, bone abnormalities (including flaring of the costochondral junction as seen on the lateral chest radiograph [termed *rachitic rosary*] and pelvic dysplasia), sensorineural hearing impairment, and cognitive impairment. Patients with AK2 deficiency, which is also known as *reticular dysgenesis*, have severe neutropenia and also sensorineural hearing impairment.

An AR T^+ SCID-like phenotype with severe immunodeficiency and opportunistic infections can also result in cases in which the production of T cells by the thymus is normal or modestly impaired but the peripheral T cells have severe functional defects. These defects can either be T-cell intrinsic, such as biallelic mutations of the genes encoding caspase recruitment domain family member 11 (CARD11), CD3γ, or the calcium channel proteins Stim1 and Orai1 that are involved in T-cell signaling, or that are T-cell extrinsic and are due to a lack of MHC class II–restricted antigen presentation. MHC class II deficiency is due to biallelic mutations of the regulatory factor X family member genes *RFXANK*, *RFXAP*, and *RFX5*, or of *CIITA*, which all encode proteins that positively regulate the transcription of the MHC class II genetic loci.[310]

T^+ SCID in which B cells are markedly decreased and NK cell numbers are normal can also occur in Omenn syndrome, which often presents in the neonatal period with diarrhea, intense erythroderma, alopecia, hepatosplenomegaly, and lymphadenopathy. Omenn syndrome was first described in cases of biallelic hypomorphic missense mutations of the *RAG1* gene or the *RAG2* gene but has also been reported in cases of SCID caused by *IL2RG*, *LIG4*, *IL7R*, *ADA*, *DCLREIC*, *AK2*, *RMRP*, *ZAP70*, *CHD7*, or *CARD11* mutations. Regardless of the genetic cause, the hematologic and immune phenotype is characteristic, with markedly increased eosinophilia, highly elevated serum levels of IgE, increased numbers of CD4 T cells, and markedly reduced numbers of CD8 T cells. Unlike CD4 T cells in healthy newborns, the CD4 T cells of Omenn syndrome are uniformly $CD45R0^+$ and lack CD45RA expression.

Mutations of genes that cause SCID that are hypomorphic (i.e., preserve some degree of normal protein function) can result in atypical forms in which the T-cell numbers may range from being only moderately depressed to normal values (e.g., certain missense mutations of the *IL2RG* gene in X-linked SCID).

T^+ SCID can also be the result of the engraftment of maternal T cells into the fetus. The clinical consequences of maternal engraftment can range from asymptomatic to a mild erythematous rash to full-blown symptoms of graft-versus-host disease (e.g., severe dermatitis, gastroenteritis, hepatitis, and lung disease). Maternal T-cell engraftment can also result in hemophagocytic syndrome, which can lead to secondary changes in the numbers of other cell types, such as B cells, NK cells, and neutrophils, which can obscure the SCID diagnosis.

Clinical Presentation

Most infants with SCID appear healthy at birth. In the neonatal period, a morbilliform rash, probably the result of attenuated graft-versus-host disease from transplacental passage of maternal lymphocytes may be the only symptom of SCID. Maternal T-cell engraftment may also result in hemophagocytic lymphohistiocytosis syndrome, with secondary cytopenias, such as neutropenia, predisposing to bacterial sepsis. Cases of SCID complicated by Omenn syndrome typically present as with severe erythroderma

and marked lymphadenopathy and hepatosplenomegaly. During the first several months of life, as acquired maternal antibody levels drop, failure to thrive and undue susceptibility to infection become universal features. Intractable diarrhea, pneumonia, and persistent thrush, especially oral thrush, constitute the triad of findings most frequently seen in infants with this disease. A diffuse pneumonia with severe hypoxemia due to *Pneumocystis jirovecii* is a classic presentation of SCID and usually occurs between 3 and 6 months of age although it rarely may occur in the neonatal period. CMV either acquired by passage through the birth canal or by breast-feeding can result in a severe/fatal disease that includes severe pneumonia or CNS involvement. Severe adenovirus pneumonia and/or hepatitis may also be a SCID presentation. Patients with SCID who receive live rotavirus vaccine, which is routinely first administered at 2 months of age, often develop persistent shedding and disease,[311] and such symptoms should raise the suspicion of SCID or other severe T-cell immunodeficiency. Similarly, BCGosis (disseminated infection with BCG) following neonatal vaccination should raise the possibility of SCID or other T-cell immunodeficiency disorders.[312]

Other manifestations that are characteristic of specific SCID etiologies include boney abnormalities (rachitic rosary) and noncholestatic hepatitis found in some cases of *ADA* deficiency, sensorineural hearing loss in *ADA* and *AK2* deficiency, intestinal atresias in *TTC7A* deficiency, skeletal dysmorphic features in cartilage hair hypoplasia and PAX1 deficiency, the absence of hair in cartilage hair hypoplasia syndrome and *FOXN1* deficiency.

Evaluation

The diagnosis of SCID is often suggested by an opportunistic or unusually severe infection in the setting of profound lymphopenia (<1000 lymphocytes per microliter). Only 10% of patients with SCID have lymphocyte counts in the normal range. Flow-cytometric analysis of T-cell, B-cell, and NK-cell populations, including the enumeration of CD4 and CD8 T cells and their naïve (CD45RA) and memory (CD45R0) subsets, is an essential part of the early workup. Based on the results of flow cytometry, the patient can often be assigned to one of four characteristic groups (T-B+NK-; T-B-NK+, T-B+NK+, and T-B-NK-) that point toward potential genetic etiologies. However, patients with high levels of maternal T-cell engraftment, hypomorphic mutations, for example, for *IL2RG*, Omenn syndrome, for forms of T+B+NK+ SCID may present a challenge in such an assignment. Clues to maternal engraftment include the finding of uniform expression of CD45R0 by the circulating T cells, and unusual CD4 T cell to CD8 T cell ratios. Omenn syndrome is suggested by normal or increased numbers of CD4 T cells that are uniformly CD45R0, decreased or absent CD8 T cells and B cells, and marked elevation of total serum IgE. The involvement of a clinical immunologist with expertise in primary immunodeficiency is strongly recommended early on in the diagnostic and treatment process given the potential complexity of interpretation and the importance of decisions on early therapy.

Other useful tests include measurements of ADA and purine nucleoside phosphorylase activity in red blood cells. Quantitative Ig levels are not particularly helpful in the diagnosis of neonatal SCID, because most IgG is maternal in origin, and IgA and IgM levels are often low in the neonatal period. Omenn syndrome may be suggested by elevation of IgE in conjunction with characteristic flow cytometry phenotypic features. A determination of T-cell mitogen responses, including to PHA, is helpful as a baseline for patients who will undergo HSC transplantation, as the PHA response is frequently used clinically to measure post-transplant T-cell immune reconstitution.

Routine neonatal screening for SCID using Guthrie card blood spots is carried out in all states of the United States, Puerto Rico, and the Navajo Nation.[313,314] The test is based on the real-time PCR detection of sjTRECs, generated during V(D)J recombination of the TCR α/δ gene locus (see Fig. 32.7) in total DNA isolated from the blood spots. sjTREC screening is effective at identifying most causes of SCID in which levels are markedly low in most instances. However, there are a few disorders in which sjTREC levels are normal, such as MHC class II deficiency and CARD11 deficiency, whereas sjTREC levels may be low in some otherwise healthy premature born infants. The turnaround time of the test is usually about 1 to 3 weeks. Abnormally low values of sjTRECs should lead to prompt flow-cytometric evaluation of lymphocyte populations as described above.

The importance of making a specific genetic diagnosis of SCID cannot be overemphasized, as this may have an important influence on expediting appropriate definitive therapy, for example, HSC transplantation versus thymic transplantation or HSC transplantation versus lentiviral gene therapy. Next generation sequencing panels for monogenic inborn errors of immunity include almost all of the known genetic etiologies of SCID disorder and can be very useful in helping target later confirmative Sanger sequencing.

Early consultation with an expert clinical HSC transplantation team is also highly recommended. In preparation for potential HSC transplantation, HLA typing of the patient and their parents is recommended as is an evaluation for maternal chimerism. Maternal engraftment can be readily diagnosed by means of T-cell chimerism assays, such as the polymerase chain reaction (PCR)-based short tandem repeats/variable number tandem repeats (STR/VNTR) system.[315]

The thymus gland is not seen on chest radiographs except in some cases of T^+ SCID or T-B+NK+ SCID because of defects in thymocyte egress, such as coronin 1A deficiency. The lack of thymus tissue by chest radiograph or computed tomography is not specific for a SCID disorder, and may occur in patients who appear well and who have relatively subtle abnormalities based on flow cytometry, for example, ataxia telangiectasia. Most of these monogenic non-SCID disorders can be readily diagnosed as part of the commercially available next generation sequencing (NGS) panels.

The possibility of complete DiGeorge syndrome (see section below) should be considered in SCID patients who have a $T^-B^+NK^+$ phenotype and/or who have features such as facial dysmorphism, congenital heart disease, velocardial insufficiency, or hypocalcemia/hypoparathyroidism. Since patients also have been identified having both DiGeorge syndrome from a hemizygous 22q11.2 deletion and SCID from a genetic deficiency, we routinely send the 22q11.2 deletion fluorescent *in situ* hybridization (FISH) chromosomal analysis on all patients being evaluated for SCID.

Management

After SCID is diagnosed and appropriate blood samples for total and antigen-specific immunoglobulin levels have been obtained, intravenous immune globulin (IVIG) usually is administered pending a definitive treatment plan. Only irradiated CMV-negative blood products should be administered. All live vaccines, including oral poliovirus vaccine, rotavirus vaccine, measles, mumps rubella (MMR) vaccine, varicella vaccine, vaccinia, BCG, attenuated influenza vaccine, and oral *Salmonella*

Typhi vaccine, are contraindicated. IVIG therapy obviates the benefit of vaccination with "killed" vaccines (e.g., inactivated poliovirus vaccine) by providing passive antibody. Therefore, inactivated or protein/polysaccharide component vaccines, although safe in SCID and other immunodeficiencies, typically are not administered after IVIG therapy is begun. CMV infection can be transmitted to the infant by breast milk or during passage through the birth canal and cause severe complications. For all infants with suspected or diagnostically confirmed SCID, the mother's CMV serostatus should be determined and the infant's CMV infection status should be determined by blood PCR. If the mother is seropositive, any breast feeding should be discontinued. Confirmed or suspected SCID patients should be put into an appropriate level of high-grade protective isolation, Detailed approaches used by expert clinicians for prophylaxis of herpesviruses, RSV, pneumocystis, and fungal infections of infants with SCID are available.[316]

SCID treatment usually requires allogeneic HSC transplant, ideally from an HLA-matched sibling.[317] In one approach, conditioning regimens, such as busulfan, are not used and recipients usually become chimeric, with only T and NK cells of donor origin. B-cell function is frequently deficient, and many patients continue to require Ig replacement therapy. As there is not replacement of totipotent HSCs of the recipient with those of the donor, there is eventually a drop-off in T-cell numbers, requiring that the patients receive a "boost" transplant from the original donor.[318] An alternative approach is to use standard conditioning regimens that result in the replacement of all hematopoietic cell types of the recipient with those of the donor, including HSCs. This approach has an increased risk of complications in the early posttransplant period but avoids the need for later transplants and often leads to normal B-cell function, obviating the need for potentially lifetime Ig replacement therapy. ADA deficiency can be treated with enzyme replacement. This treatment involves weekly injections of ADA coupled to polyethylene glycol. Response, consisting of decreasing deoxyadenosine triphosphate levels and increasing T-cell numbers, is seen in most patients within weeks. Finally, retroviral lentiviral gene therapy based on vector-mediated transfer of a therapeutic gene into autologous HSCs is a therapeutic option for the treatment of ADA SCID and is in late-phase clinical trials for X-linked SCID.[319] The correction of the T-cell immunodeficiency treatment for $T^-B^+NK^+$ SCID that is due to thymic epithelial abnormalities, for example, PAX1 or FOXN1 deficiency, CHARGE syndrome, and that requires thymic transplantation is discussed in the DiGeorge Syndrome section.

Outcome

SCID is a pediatric emergency and is invariably fatal if untreated. Most untreated patients die in the first year of life. HSC transplantation, which is the definitive therapy for most types of SCID has had excellent results in cases where an early genetic diagnosis is made. Nevertheless, there is still an appreciable mortality of ~5% with the HSC transplantation approach and further refinements with safe conditioning regimens and treatments for graft-versus-host disease may further improve this already excellent outcome. Recently published results for eight infants with X-linked SCID treated with lentiviral gene therapy suggest that this approach is safe, with a low risk to cause dysregulation of endogenous genes near the lentiviral insertion sites that could lead to oncogenesis, and is effective (based on immune reconstitution and the clearing of opportunistic infections).[320] The treatment of ADA SCID by lentiviral gene therapy has not encountered any major safety issues and has had a long-term outcome that appears to be equivalent or superior to that obtained with HSC transplantation.[321]

DiGeorge Syndrome (22q11.2 Deletion Syndrome)

Epidemiology

DiGeorge Syndrome, 22q11.2 deletion syndrome (22q11.2DS), is the most common human chromosomal microdeletion syndrome, occurring in approximately 1 in every 1000 fetuses and 1 in every 3000 live births. The syndrome affects both sexes equally and occurs in all major racial and ethnic groups. About 85% of cases are due to hemizygosity for a de novo stereotypical deletion of 3.0 mB between the low copy repeat (LCR) regions LCR22A and LCR22D. This 3.0 mB segment contains 90 known or predicted genes, including 46 protein-encoding genes, 7 genes encoding microRNAs, and 10 non-coding RNAs.[322] A quantitative T-cell immunodeficiency due to thymic hypoplasia occurs in up to 75% of patients that ranges from mild to moderate in severity more than 99% of the time. However, for unclear reasons, approximately 0.1% of patients with the 22q11.2DS and 3.0 mB deletion have a severe T-cell immunodeficiency with circulating naïve ($CD45RA^+CD62L^+$) T-cell numbers less than 50 per microliter.

Pathophysiology

The embryologic anlage of the thymus, parathyroid, and a portion of the great vessels is the endodermal epithelium of the third and fourth pharyngeal pouches.[322] When normal development of these structures is disturbed, thymic and parathyroid hypoplasia and congenital heart disease involving the great vessels can occur resulting in DGS. The molecular mechanisms by which 22q11.2 region haploinsufficiency perturbs thymic and parathyroid, great vessel, and cardiac development as well as that of other organs remains poorly understood. Haploinsufficiency of the TBX1 gene, which encodes the T-box1 transcription factor, appears to make a major contribution to pathogenesis, particularly for the effects on the thymus, parathyroids, and cardiac system, but there are many unanswered questions for why there is such variable penetrance of the DGS phenotype. Although the 22q11.2Del syndrome is the most likely cause of DGS, other etiologies include maternal gestational diabetes, maternal prenatal retinoic acid exposure, single gene disorders that include mutations in PAX1, TBX1 (which encodes the T-box1 transcription factor), or CHD7 (which results in CHARGE syndrome), or other chromosomal deletions, such as those involving the 10p13-14 region.[322] Like the 22q11.2Del syndrome, most of these etiologies usually result in a mild to moderate immune deficiency but can result in complete DGS with severe T-cell immunodeficiency; biallelic disease with PAX1 usually has a severe T-cell phenotype and less commonly presents with hypocalcemia/hypoparathyroidism.

Clinical Presentation

Infants with 22q11.2DS can exhibit abnormalities of calcium homeostasis during the neonatal period (hypocalcemia and tetany) and variable T-cell deficits, which are usually subclinical and only severe in less than 1% of cases. Often, the syndrome is suspected because of congenital conotruncal cardiac defects (about 60% of cases), low-set ears, midline facial clefts, hypomandibular abnormalities, and hypertelorism. The cardiac anomalies

associated with 22q11.2DS are variable but usually involve the outflow tract and the derivatives of the branchial arch arteries. These defects include interrupted aortic arch type B, truncus arteriosus, and tetralogy of Fallot. Children with 22q11.2DSalso exhibit a higher incidence of receptive-expressive language difficulties, cognitive impairment, and behavioral problems, including psychotic illness.[323,324]

Evaluation

About 95% of neonates and young infants presenting with clinical DGS will have the 22q11.2DS due to the 3.0 mB deletion and will be readily diagnosed by fluorescence in situ hybridization using standard probes.[322] Cases of DiGeorge syndrome lacking the 22q11.2 deletion should be evaluated for *TBX1* loss-of-function mutations, which can result in most of the features of DiGeorge syndrome, including T-cell immunodeficiency, hypoparathyroidism, and/or conotruncal cardiac lesions.[325] Other assays such as comparative genomic hybridization may reveal nested deletions that are distal to the clinically used FISH probes between LCR22B to LCR22D or between LCR22C to LCR22D or other chromosomal deletions that have been associated with DGS, for example, involving 10p13-14 and 11q23-ter. Clinical features suggestive of DiGeorge syndrome can also be observed in some cases of PAX1 deficiency and with *CHD7* mutations that cause CHARGE syndrome. CHARGE syndrome usually has additional phenotypic abnormalities, such as colobomas and choanal atresia that point to this as the etiology of DGS.

In the nursery, identification of infants with congenital conotruncal abnormalities or unexplained persistent hypocalcemia should prompt consideration of CHARGE. In most cases, the T-cell deficiency is not severe, with decreases in circulating CD4 T-cell and CD8 T-cell numbers to levels that are 25% to 50% of those normal for age. However, in about 1 in 400,000 deliveries, infants with features of DiGeorge syndrome may have severe T-cell lymphopenia—that is, circulating naïve ($CD45RA^+CD62L^+$) T-cell numbers less than 50 per microliter. Severe T-cell lymphopenia in association with hypoparathyroidism and conotruncal congenital heart disease is called *complete DiGeorge syndrome* and is due to the 22q11.2 deletion in about 50% of cases, CHARGE syndrome in about 25% of cases, and gestational diabetes in about 15% of cases.[326]

Management

Like SCID, complete DiGeorge syndrome is a medical emergency that prompts antibiotic prophylaxis for *P. jirovecii* and nontuberculous mycobacteria (azithromycin), Ig replacement therapy, and protective isolation. All patients should also be evaluated for their CMV infection status, and, if positive, antiviral therapy should be started. Patients who are not infected with CMV should not be breastfed if their mother is CMV IgG antibody positive and in cases of potential exposure to CMV from breastmilk, prophylaxis may include valganciclovir. About 30% of complete DiGeorge syndrome patients develop an extensive erythematous rash sometimes accompanied by gastrointestinal symptoms and hepatitis, which is referred to as *atypical complete DGS*. These patients often have increased levels of circulating T cells in their blood that express memory markers, such as CD45R0, with similar T cells found in skin biopsy. These T cells, which are produced by the patient and are not the result of maternal engraftment, are oligoclonal in their TCR usage and do not provide useful immune function. Patients harboring these autoreactive T cells should be treated with immunosuppressive drugs, such as calcineurin inhibitors and glucocorticoids, particularly if the T-cell lymphocytosis is marked and the patient has moderate to severe skin disease and extra-cutaneous sites are involved with T-cell mediated inflammation.

The only definitive therapy for complete DGS due to the 22q11.2 is transplant of thymic epithelial tissue. The transplant is derived from thymus tissue removed from otherwise healthy children as part of surgery for congenital heart disease and that is cultured for deplete thymocytes and enriched for the thymic epithelial cells.[327] Small pieces of thymic epithelia are placed within the quadriceps muscle, and the de novo production of CD4 and CD8 T cells begins approximately 4 to 6 months after transplant.

Outcome

The thymic transplant is successful in ~80% of cases, so that antibiotic prophylaxis, Ig replacement therapy, and protective isolation can be discontinued. Patients that have good engraftment with normalization of CD4 and CD8 T cell numbers for age can receive MMR vaccination. There is a relatively high risk of complete DGS patients developing autoimmune diseases, such as thyroiditis, following transplant, suggesting that the intrathymic mechanisms of tolerance, such as negative selection and/or Treg production, may not be as effective as the native thymus. In the absence of thymic transplant most patients with complete DGS often die by 3 years of age.

Combined Immune Disorders Involving T Cells and B Cells

Many monogenic immune disorders have complex phenotypes that involve both T and B cells in which the residual T-cell function is sufficient to result in a delayed presentation after the neonatal period. For example, Wiskott–Aldrich syndrome (WAS) is a combined immune disorder involving T cells, B cells, and APCs.[328] WAS affects males and is due to mutations of a gene located on the X chromosome that encodes WAS protein (WASp), an intracellular protein. WASp is expressed in all hematopoietic cells that interact with actin cytoskeleton and can also participate in transcriptional regulation. WAS is characterized by eczema (usually severe), thrombocytopenia, increased risk of malignancy, and susceptibility to recurrent sinopulmonary infections, severe herpesvirus infection, and, less commonly, classic opportunistic infections, such as infection with *P. jirovecii*. Other manifestations that may be present in the newborn period include petechiae and bruises, bloody diarrhea, and hemorrhage after procedures. In infants with any of these clinical findings, thrombocytopenia in a complete blood count report is an important clue to possible WAS. In contrast to immune thrombocytopenia purpura, WAS platelets have a low mean platelet volume, and this finding is pathognomonic of the disorder. Characteristic immunologic findings include moderately decreased numbers of T cells, particularly those of the CD8 subset, with relatively subtle defects in T-cell proliferation, decreased IgM levels, and increased IgA and IgE levels. Many of these immunologic findings may not be evident in the neonatal period. Flow cytometry can be used to evaluate leukocyte WASp expression to make a provisional diagnosis of WAS. As for children with SCID, all blood products given to children with WAS should be CMV negative and irradiated before administration to avoid T-cell engraftment and graft-versus-host disease. WAS can be cured by HSC transplant, with the best results obtained with transplant before 3 years of age. Lentiviral gene therapy is a promising alternative for treatment.[319]

B-Cell Immunodeficiencies

Most genetic defects that target B-cell immunity but leave T-cell immunity intact, such as X-linked agammaglobulinemia (XLA), are not detected in the neonatal period without special screening tests, such as flow cytometry to evaluate circulating B-cell numbers, intracellular expression of Btk by monocytes.[329] Because of maternal transfer of IgG during the last trimester of pregnancy, infants with selective immunodeficiencies of B cells typically do not develop clinically significant hypogammaglobulinemia and recurrent or severe sinopulmonary infections with encapsulated organisms until after 3 to 6 months of age. Moreover, the absence of B cells from the circulation does not usually result in clinically detectable lymphopenia on the complete blood count. Analogous to screening for severe T-cell deficiency, neonatal screening for quantitative B-cell immunodeficiency is possible by assaying by PCR for kappa receptor excision circles (KRECs), which are stable circular DNA byproducts of V(D)J rearrangement of the kappa light chain Ig gene in B-lineage cells.[330] Currently, KREC evaluation is not part of routine newborn screening in the United States.

Innate Immune Deficiency Disorders

Immune deficiencies that include neutropenia as part of a syndrome, such as SCID due to AK2 deficiency (reticular dysgenesis), or that result in isolated quantitative or qualitative defects of neutrophils often present in the neonatal period. This reflects the essential role of neutrophils in phagocytosing pathogenic bacteria and fungi and eliminating them by oxidative and nonoxidative mechanisms within the phagosome.[331] Bacterial infections, such as bacteremia with gram-negative organisms such as *Escherichia coli* or *Pseudomonas aeruginosa* or gram-positive organisms such as *Staphylococcus aureus*, are frequent with neutrophil disorders. Delayed umbilical cord separation and omphalitis are important clinical signs that should lead to evaluation for neutrophil deficiency, such as leukocyte adhesion defect, which is most commonly due to biallelic mutations of the *CD18* gene. An important clue to leukocyte adhesion defect is that the neutrophil count is always elevated above normal values, even in the absence of infection or other inflammatory stimuli. Chronic granulomatous disease (CGD) is due to mutations of genes encoding the phagocyte oxidase system, which is required for oxidative killing within the phagosome. The clinical infections characteristic of CGD, such as deep tissue infections with bacteria or fungi, can present during the neonatal period, although in most cases this occurs later in infancy.

Although relatively rare, monogenic immune deficiencies of innate immune cell signaling may present in the neonatal period with severe gram-positive or gram-negative bacterial infections or fungal infections. Among the best characterized are biallelic mutations of the genes encoding MyD88 or IL-1 receptor–associated kinase 4 (IRAK-4), which are cytoplasmic proteins that are required for both TLR and IL-1 receptor family (IL-1R) signaling.[332] The lack of IL-1R signaling results in an impaired febrile response, and the absence of any fever in a neonatal patient with a severe invasive bacterial or fungal infection should lead to an evaluation for these disorders. A useful screening test for MyD88 or IRAK-4 deficiency is to evaluate peripheral blood mononuclear cells for their production of TNF-α in response to incubation with TLR ligands, such as endotoxin, flagellin, or oligodeoxynucleotides containing unmethylated CpG residues. Such production is markedly impaired or absent in these patients.

Implications of Studies of Immune Ontogeny for Enhancing Neonatal Immunization

Hepatitis B vaccine, polio vaccines, and bacille Calmette–Guérin (BCG) vaccine are the only childhood vaccines routinely given at birth. Immunization shortly after birth offers important logistic advantages for providing protection against infectious diseases, as birth is the most reliable point of healthcare contact worldwide, especially in less developed countries.[333] However, the response of the neonate to vaccination with T-independent polysaccharide vaccines, such as unconjugated pneumococcal vaccine, is negligible and the humoral response to T-dependent antigens, such as proteins and protein–polysaccharide conjugate vaccines, is less robust and durable than that of the adult.[334] Thus, extending neonatal immunization to involve other routine childhood vaccines may require the development of formulations that are more immunogenic when administered in the first few days after birth.

A growing appreciation of distinct immunity with age has prompted efforts to develop vaccines that may induce robust protection in the newborn and the young infant.[335] One approach for improving the response to neonatal vaccination has been to combine vaccine antigens with adjuvants to enhance immune responses, focusing on adjuvants for which human neonatal APCs have robust adult-like responsiveness in vitro.[89,335,336] A promising example of this approach is to combine TLR agonists that are particularly active in early life such as imidazoquinoline TLR7/8 agonists with the 13-valent pneumococcal polysaccharide protein conjugate vaccine (Prevnar 13). Immunization of 1-day-old nonhuman primates with the combination of TLR7/8 agonist and Prevnar 13 resulted in a 10-fold to 100-fold increase in specific antibody titer that was associated with robust increases in the CD4 T-cell responses to the vaccine protein conjugate.[337] A similar approach could be potentially used for other inactivated vaccines that currently are routinely administered at 2 months of age. Together, these observations indicate compelling rationale to characterize early-life immune ontogeny to provide fresh perspectives on neonatal health and disease and inform novel approaches to protect the fetus and young infant.[1]

Neonatal Bacterial Sepsis and Meningitis

GREGORY C. VALENTINE AND LINDA D. WALLEN

KEY POINTS

- Group B streptococcus and *Escherichia coli* account for most of the cases of neonatal early-onset bacterial sepsis.
- Prevention of infection by maternal treatment is the main factor accounting for the decreased incidence of early-onset group B streptococcus sepsis but does not affect rates of late-onset group B streptococcus sepsis.
- Microbiologic blood cultures of adequate volume (at least 1.0 mL) represent the mainstay for the diagnosis of infection.
- Management of the asymptomatic newborn at risk of infection due to maternal risk factors is evolving, with evidence supporting evaluation and treatment of only a small proportion of asymptomatic infants.
- Ampicillin and gentamicin are recommended as initial therapy in neonates with suspected bacterial sepsis. Treatment can then be narrowed appropriately after the results of antibiotic susceptibility studies.

Neonatal sepsis is one of the leading causes of morbidity and mortality of newborns worldwide.[1] It is estimated that nearly 430,000 neonatal deaths occurred in 2013 due to neonatal sepsis, approximately 15% of all neonatal deaths. Thus, neonatal sepsis is a common and deadly disease process that requires an understanding of the pathogenesis and timely treatment to prevent severe morbidity or mortality.

Bacterial sepsis in newborns is commonly divided into two categories: early-onset sepsis (EOS) and late-onset sepsis (LOS) based upon time since birth. Traditionally, EOS is classified as either occurring in the first 72 hours or, in some cases, within the first 7 days after birth. In this chapter, we will define EOS as occurring within the first 72 hours after birth and LOS as occurring after 72 hours. Here, we will discuss early-onset neonatal bacterial infections, including the pathogenesis, epidemiology, clinical signs and symptoms, common bacterial pathogens, evaluation methodology, and prevention strategies. We will then explore late-onset neonatal bacterial infections and conclude with an evaluation of the medical literature surrounding neonatal bacterial meningitis.

Early-Onset Neonatal Bacterial Infections

Early-onset bacterial sepsis remains a major cause of neonatal morbidity and death, although the sepsis-associated death rates per 100,000 live births has declined significantly from 2000 to 2015. The introduction of intrapartum antibiotic prophylaxis (IAP) in pregnant women during labor and delivery contributed to much of this decline in mortality.[2–5] Mortality rates in infected premature and very immature neonates are significantly higher than those in term neonates. Significant improvements in neonatal intensive care and early identification of infected neonates have contributed to reduced mortality rates in the newborn period.

Pathogenesis of Early-Onset Neonatal Bacterial Infections

Vertical transmission is the main route through which EOS occurs and involves the passage of pathogenic bacteria from the mother to the neonate before or during delivery. Maternal chorioamnionitis and acute inflammation from presumed infection of the membranes surrounding the fetus in utero is a well-known risk factor for EOS.[6–9] Other potential routes for group B streptococcus (GBS) acquisition and EOS include ascending spread from the vaginal environment to the uterus following membrane rupture or fetal contact with pathogenic bacteria during passage through the birth canal at delivery. Less commonly, bacteria reach the fetus through the in utero transplacental passage, as suggested by the presence of high-grade bacteremia and severe sepsis that are clinically apparent at the time of birth in the presence of an intact membrane in neonates born via cesarean delivery.[10–12] Although organisms recovered from the amniotic sac in the mother are usually polymicrobial and include organisms such as GBS, group D enterococcus, aerobic gram-negative bacteria, and anaerobes such as *Bacteroides* spp., a single organism causing bacterial sepsis is the rule in sepsis of the newborn.[1,6,13]

Pathogenesis of neonatal sepsis is due to several key factors, including but not limited to timing and duration of exposure, inoculum size, the virulence of the pathogenic bacteria, and the immune status of the neonate. Although many microorganisms recovered from the amniotic cavity are thought to induce spontaneous preterm labor and possibly premature rupture of membranes, the exact mechanisms by which this may occur are debatable. Clinical or subclinical chorioamnionitis can incite a marked inflammatory response with the release of cytokines that can contribute to the onset of preterm labor and premature rupture of membranes. Other risk factors for clinical intra-amniotic infection include young maternal age, prolonged labor, prolonged rupture of membranes (≥18 hours), internal scalp fetal monitoring, the presence of urinary tract infections (UTIs), and a history of bacterial vaginosis.[14,15]

Epidemiology of Early-Onset Bacterial Infections

The incidence of early-onset bacterial infection is variable and ranges from 1 to 5 per 1000 live births.[16] Rates of neonatal sepsis are inversely related to gestational age. Notably, there has been a reduction in the rate of EOS in the United States since the implementation of IAP against GBS. Early-onset GBS infection rates in the United States have declined from 0.37 per 1000 live births in 2006 to 0.23 per 1000 live births in 2015.[17] However, despite IAP, late-onset rates have remained relatively stable at approximately 0.31 per 1000 live births.[17]

Infants with EOS frequently have one or more identifiable risk factors.[18,19] Prematurity is the single greatest risk factor for EOS. Because extremely low birth weight infants have impaired host defenses and since preterm birth may be associated with low-grade chorioamnionitis, it is not surprising that premature neonates have nearly 30 times higher rates of mortality from EOS compared to term neonates (1.6% in term neonates vs. 30% mortality in those at 25 to 28 weeks of gestation).[20–22] Neonatal susceptibility to GBS infection is increased with deficiencies in circulating levels of GBS type-specific antibody and complement, and is further heightened by neutrophil dysfunction seen in infants who are more premature.[23–26] Other risk factors for EOS are maternal age, health and nutrition, colonization with well-known pathogens (e.g., GBS), maternal fever, and longer duration of rupture of membranes.[19,27]

Bacterial Pathogens in Early-Onset Infections

The most common bacterial pathogens associated with EOS are GBS and *Escherichia coli*. Here we review these two primary pathogens in depth before briefly exploring other less common bacterial etiologies of EOS, such as *Listeria monocytogenes* and other gram-negative enteric bacilli.

Group B Streptococcal Infections

Transmission of GBS to Infants and the Role of Intrapartum Antibiotic Prophylaxis

GBS accounts for nearly 45% of culture-confirmed cases of EOS in term neonates and 25% among very low birth weight (VLBW) infants (weighing <1500 g at birth).[20,28] Approximately 20% to 30% of pregnant women in the United States are colonized with GBS.[29–33] Treatment of GBS-colonized women during pregnancy only temporarily eradicates the organism. Most women are recolonized within several weeks. Before the introduction of IAP, approximately 50% of neonates born to mothers known to be GBS carriers became colonized, and approximately 1% to 2% of colonized neonates developed GBS infection.[34–37] Since the widespread use of IAP, approximately 60% to 80% of GBS cases occur in infants born to mothers who screened negative for GBS.[38,39]

Detection of maternal GBS colonization has been emphasized since 1996, approximately. Early studies determined that the optimal sampling sites for GBS were the genitourinary and gastrointestinal tracts. The optimal time for performing prenatal cultures is between 36 0/7 and 37 6/7 weeks' gestation, and the highest culture yield is obtained when both the lower vaginal area and anal or rectal sites are sampled.[40,41] Furthermore, GBS testing should be performed on pregnant women who present in preterm labor or with the rupture of membranes (PROM) before 37 0/7 weeks' gestation. If GBS has previously been detected through urine culture during pregnancy, no further confirmation by vaginal-rectal culture is necessary.[40,41] By identifying the pregnant woman who is colonized with GBS, IAP can be provided in a timely manner. Since the introduction of IAP recommendations, the national incidence of GBS EOS has decreased from 1.8 cases (1990) to 0.23 cases (2015) per 1000 live births.[17] However, late-onset GBS incidence has not changed.

To prevent GBS EOS, IAP is recommended for all women with GBS colonization identified by antenatal recto-vaginal culture, with a history of GBS bacteriuria during the same pregnancy, with a history of a former infant with GBS disease, or for women who present in preterm labor or have PROM <37 0/7 weeks' gestation.[40,41] For women who present in labor ≥37 0/7 weeks' gestation with unknown GBS status should have IAP if maternal temperature ≥38°C or duration of rupture of membranes ≥18 hours.[40,41]

GBS is sensitive to penicillin, which is the drug of choice because of its narrow spectrum; the alternative is ampicillin. If a mother is allergic to penicillin but considered low-risk for anaphylaxis, the use of cefazolin is recommended. When patients are at a high risk of anaphylaxis, tests for antimicrobial susceptibility of prenatal GBS to clindamycin should be performed. In 2016, 42% of GBS isolates were found to be resistant to clindamycin.[40,41] Therefore if the prenatal GBS is sensitive to clindamycin, patients can receive clindamycin intravenously (IV) until delivery. Of note, erythromycin is no longer recommended as an IAP due to high resistance patterns.[40,41] When GBS is resistant to clindamycin, IV vancomycin every 12 hours until delivery is recommended. The high levels of resistance highlight the importance of antibiotic susceptibility testing on the group B streptococcal isolates from pregnant women. Only penicillin G, ampicillin, or cefazolin are considered adequate IAP.[40,41] If clindamycin or vancomycin are used, while likely capable of providing some protection against invasive early-onset GBS disease in the newborn, it is considered inadequate IAP coverage due to limited data on their clinical efficacy.

Group B Streptococcal Virulence Factors

There are 10 known serotypes of GBS (I, Ia, II-IX) that are distinguished by a specific polysaccharide capsule. The polysaccharide capsule helps the GBS evade complement deposition, opsonization, and phagocytosis by the infant's immune system and is considered the most important virulence factor.[42–45] Other virulence factors include proteases (such as C5a peptidase), which cleave complement and surface proteins (such as alpha and beta C-proteins) and promote evasion of human host defenses.[46] Serotype III is associated with an estimated 62% of invasive infant strains and 25% of colonizing strains and is also a common cause of GBS meningitis.[17,47] Globally, serotypes I to V are responsible for the vast majority, 98% of colonization and 97% of invasive infant strains.[31,48] Multivalent vaccines against specific capsular polysaccharides have been investigated through phase I and II clinical trials and demonstrated their safety and immunogenicity.[49–51] Further clinical trials are planned.

GBS Sepsis

While most EOS is classified as sepsis in the first 72 hours after birth, for GBS infection, early-onset disease (EOD) is classified in the first 7 days after birth. Subsequently, late-onset disease occurs from 1 week to 3 months of age, and very-late-onset disease occurs more than 3 months after birth (Table 33.1).[1] Although IAP has led to a significant decrease in the incidence of GBS EOD, there is no evidence that chemoprophylaxis prevents late-onset or very-late-onset disease.[52–54] GBS EOD is generally believed to be caused

TABLE 33.1 Manifestations of Early-Onset and Late-Onset Group B Streptococcal (GBS) Disease

Characteristic	Early Onset	Late Onset
Age at onset	Birth to 7 days of life	7 days to 3 months of life
Symptoms	Respiratory distress, apnea	Irritability, fever, poor feeding
Findings	Pneumonia, sepsis	Sepsis, meningitis, osteoarthritis
Maternal obstetric complications	Frequent	Uncommon
Mode of transmission	Vertical, in utero, or intrapartum	Nosocomial, horizontal
Predominant GBS serotypes	Ia, III, V*	III, Ia, V*
Effect of intrapartum antibiotic prophylaxis recommended by the Centers for Disease Control and Prevention	Reduces incidence by 85%–90%	No effect

*In decreasing order of frequency.

by ascending infection from the maternal birth canal to the uterine compartment, with subsequent fetal infection through colonization of the skin or aspiration of infected amniotic fluid.[41] The strongest risk factor for GBS EOD is maternal GBS colonization. However, even if a mother has screened negative for GBS, GBS EOD can still occur due to maternal colonization status during the time from screening to delivery. Evaluation of neonates at risk for GBS EOD is discussed separately below.

Escherichia Coli Infections

Historically, *E. coli* is the second most common pathogen causing sepsis and meningitis in newborns. The antigenic structure of *E. coli* is complex and is composed of approximately 150 somatic or cell wall O antigens, 50 flagellar H antigens, and approximately 80 capsular K antigens. However, a limited number of specific K antigen *E. coli* strains cause meningitis. Approximately 80% of the strains causing meningitis and 40% of the strains causing bacteremia or sepsis express the K1 antigen.[55] The capsular K1 polysaccharide antigen is highly homologous to the capsular antigen of group B *Neisseria meningitidis*. Because a high percentage of women have bacteriuria with strains of *E. coli* that express the K1 antigen or are colonized with it at the time of delivery, it is surprising that *E. coli* sepsis or meningitis is not more common.

Surveillance data from the National Institute of Child Health and Human Development Neonatal Research Network, a consortium of 16 US academic neonatal centers, revealed that in the era of widespread implementation of antibiotic prophylaxis, the rate of *E. coli* sepsis increased from 3.2 to 6.8 cases per 1000 live births.[56] This increase was observed in the 1998–2000 era and persisted from 2002 to 2003. Approximately 85% of *E. coli* infections in VLBW infants were ampicillin-resistant.[56] Yet, while most evidence suggests that IAP has not been associated with a concomitant increase in the incidence of *E. coli* or other non-GBS bacterial causes, other evidence demonstrates that the incidence of *E. coli* and ampicillin-resistant *E. coli* infections increased significantly among preterm infants.[57] Furthermore, neonates who developed *E. coli* infections with ampicillin-resistant strains are more likely to be born from mothers with IAP with ampicillin.[56,58,59] In VLBW neonates, the incidence of EOS with *E. coli* has increased, with nearly 85% of cases having resistance to ampicillin.[56,58] Thus, while the benefits of IAP on reducing EOS attributable to GBS are well-documented, the balance of preventing resistance by other bacterial pathogens is still under investigation.

Listeria Monocytogenes Infections

L. monocytogenes is a small, facultative anaerobic, gram-positive, motile bacillus that produces a narrow zone of beta hemolysis on blood agar plates. It can be confused with GBS unless a careful Gram stain, a catalase reaction, and other tests are performed. Most *L. monocytogenes* infections are due to three serotypes: 1a, 1b, and 4b. The last serotype has been described in most outbreaks of listeriosis.[60]

Most cases of listeriosis appear to be food-borne. Foods commonly contaminated by *L. monocytogenes* include raw vegetables such as cabbage, raw milk products, fish, poultry, processed chicken, beef, and hot dogs.[61] Transmission to the fetus occurs through either a hematogenous (transplacental) route or via an ascending infection through the birth canal. Frequently, infections with *Listeria* spp. early in gestation result in abortion; later in pregnancy, infection with *Listeria* spp. can result in the premature delivery of a stillborn or infected newborn. Approximately 70% of *Listeria*-infected women deliver before 35 weeks' gestation.

L. monocytogenes illness in the mother may be undetected as it can be a vague influenza-like illnesses that may not come to medical attention. In approximately half of the perinatal cases, illness in the mother has preceded delivery by 2 days to 2 weeks. An autopsy of stillborn neonates or those who die in the perinatal period from *L. monocytogenes*, granulomas are found throughout organs such as the liver and lungs, and infection is widely disseminated, including involvement of the meninges and even a skin rash due to microabscesses and granulomas called granulomatosis infantisepticum.[62] Treatment of *Listeria* spp. infection or bacteremia during pregnancy can prevent infection in the fetus.[63]

Like GBS infection, *Listeria* spp. infection may have either an early-onset or a late-onset presentation. Epidemics of neonatal *Listeria* spp. infection has been described after the ingestion of contaminated foods such as cheese or coleslaw. The first clearly documented food-borne (coleslaw) outbreak of listeriosis was in 1981 from the Maritimes in Canada; it was associated with a fatality rate of 27%.[61] There are reports of repeated abortions in women with colonization of *Listeria* spp. in the gastrointestinal tract, and cultures can be performed to detect fecal carriage in such women; selective media for *Listeria* spp. is recommended to isolate the organism from various foods or stool specimens. Rapid antigen tests based on nucleic acid amplification are available but not commonly used in clinical diagnostic laboratories. There is no vaccine for *Listeria* spp. infection, but preventive measures have included the surveillance programs from the US Department of Agriculture, prohibiting the sale of contaminated meats. Between 1996 and 2006, the incidence of *Listeria* spp. infections declined by 36%; however, an outbreak of the disease in 2002 related to contaminated turkey meat led to 54 illnesses, 8 deaths, and 3 fetal deaths in 9 states within the US.[60]

Miscellaneous Bacterial Pathogens

The bacteria responsible for early-onset neonatal sepsis have changed over time, and there are regional differences in the organisms commonly responsible for early-onset sepsis. In addition to the organisms mentioned previously, other bacterial pathogens associated with early-onset bacteremia or sepsis in newborns include *Enterococcus* spp., viridans group *Streptococcus* spp., *Klebsiella* spp., *Enterobacter* spp., *Haemophilus influenzae* (typeable and nontypeable), *Staphylococcus aureus, Streptococcus pneumoniae*, group A streptococcus and other beta-hemolytic streptococci, and coagulase-negative staphylococci (CONS).

Clinical Signs of Early-Onset Bacterial Infections

There is great variability in the clinical presentations of neonates with early-onset bacterial sepsis (Box 33.1). Most neonates exhibit respiratory distress in the first 12 hours of life, frequently immediately after birth. In these neonates, the progression may be rapid, with cardiovascular instability, shock, and death. Presentation within the first 12 hours of life suggests that the infection occurred at or near the time of birth or during the immediate postnatal period. Neonates with in utero hypoxia may gasp, inhaling contaminated amniotic fluid and setting the stage for early-onset pneumonia, bacteremia, and sepsis.

The signs of early-onset infection may be subtle, such as tachypnea, or may be more overt, with respiratory distress and hypotension. Because the signs of sepsis can be relatively nonspecific, such as poor feeding and increased sleepiness, they can be overlooked. The clinical signs of neonatal sepsis include, but are not limited to, temperature instability (hyperthermia or hypothermia); respiratory distress; cyanosis; jaundice; hepatomegaly; abdominal distention; feeding abnormalities; and neurologic abnormalities (including lethargy, apnea, and seizures).

Evaluation of Early-Onset Bacterial Infections

Laboratory Testing

Many laboratory tests have been evaluated for infants with possible sepsis, and the results must be interpreted with caution, assessing the sensitivity and specificity of a particular test as well as its positive and negative predictive accuracy.

BOX 33.1 Common Clinical Signs of Neonatal Sepsis

- Abnormal neurologic status: irritability, lethargy, poor feeding.
- Abnormal temperature: hyperthermia or hypothermia.
- Apnea.
- Bleeding problems: petechiae, purpura, oozing.
- Cardiovascular compromise: tachycardia, hypotension, poor perfusion.
- Cyanosis.
- Gastrointestinal symptoms: abdominal distention, emesis, diarrhea.
- Jaundice.
- Respiratory distress: tachypnea, increased work of breathing, hypoxemia.
- Seizures.

Blood Culture

The gold standard for the detection of bacteremia in newborns with suspected sepsis is a positive blood culture result. The sensitivity of detecting positive blood culture results has increased with the introduction of semi-automated blood culture detection instruments that determine the presence of growth from bacterial carbon dioxide production detected by the internal computer of the instrument every minute. An important variable that influences the sensitivity of detecting bacteremia is the volume of blood placed in the culture bottles. It was previously considered standard practice to obtain 0.5 mL of blood for neonatal blood cultures. However, studies reported that approximately 25% of neonates with bacteremia may have low levels of bacterial load in their blood (≤4 colony forming units/mL).[64–66] Further evidence suggests that 0.5 mL of blood for culture is insufficient as the sensitivity decreases by 10% to 40% when 0.5 mL is used rather than 1.0 mL.[64,67] Therefore 1 mL of blood is now considered the standard volume for neonatal blood cultures to prevent false-negative results.[68] With the use of new technology, most positive blood culture results are detected within 24 to 48 hours.[69,70] In a term infant who remains asymptomatic after initiating antibiotic therapy, stopping antibiotic administration if the blood culture results remain negative after 36 hours is recommended.[71–73] However, the decision to discontinue treatment with antibiotics should not rely solely on a negative blood culture.

Blood cultures can be falsely negative due to inadequate blood volume in the blood culture, use of antibiotics in the mother or neonate before culture sampling, or other factors. Thus, when the suspicion of sepsis based on clinical signs and symptoms is high and other causes are unlikely, clinicians may consider continuing antibiotic therapy for a complete course despite negative blood culture results.[74] As a caveat, studies have demonstrated that healthcare providers cannot reliably differentiate sepsis from other conditions that occur in ill newborns, especially premature neonates where hemodynamic instability, respiratory distress, and temperature instability are common.[75] Recent literature suggests that antibiotics in the neonatal period may have a deleterious effect on long-term outcomes. Therefore careful consideration of discontinuing antibiotics when possible is an important component of antibiotic stewardship.[76–79]

Urine Culture

The frequency of positive urine culture results in infants with early-onset sepsis is low (<2%), and it is rare to find bacteriuria in infants with negative blood culture results.[80] Therefore it is generally not recommended to obtain urine specimens in the first 72 hours after birth as part of the EOS evaluation.[81]

Cerebrospinal Fluid

In any neonate with signs of sepsis, a lumbar puncture should be considered. Because meningitis is less common in EOS than in late-onset sepsis, lumbar punctures are not always routinely performed during sepsis evaluations occurring within the first 72 hours after birth. However, if a bacterial culture returns positive, a lumbar puncture should be performed as bacteremia can lead to hematogenous seeding of the meninges. Lumbar punctures are deferred in infants with clinical instability or uncorrected bleeding disorders. The details of the examination of cerebrospinal fluid (CSF) and the diagnostic approach for examining CSF is discussed below.

White Blood Cell Count and Neutrophil Indices

White blood cell (WBC) counts, differential, immature; total neutrophil ratio (I/T ratio); and absolute neutrophil count (ANC) vary based upon time since birth and gestational age. None has proven singularly useful for predicting the majority of cases of neonatal sepsis.[82,83] For instance, in a study evaluating over 30,000 complete blood counts of premature neonates, neonates born <28 weeks had peak neutrophil concentrations at approximately 24 hours of age, and those born at ≥28 weeks gestation peaked at 4 to 6 hours of age.[84] Furthermore, maternal and neonatal factors can impact the WBC count and ANC; the presence of labor or being of female sex at birth is associated with higher values. Total WBC counts have a poor positive predictive value for neonatal sepsis, while neutropenia has greater specificity.[85] A number of clinical conditions affect the total neutrophil count. Prolonged crying, meconium aspiration syndrome, maternal fever, and asphyxia are all associated with an increase in the total neutrophil count, and there may be an increase in the total immature neutrophil forms, as well as an increased I/T ratio. Maternal hypertension is associated with a decrease in the total neutrophil count.[86–88]

A large study that evaluated 166,092 neonates found 60% of neonates with positive blood cultures had normal WBC counts (between 5000 and 19,000/mm^3), 87% did not have neutropenia (ANC ≥1500/mm^3), and 31% had an I/T ratio considered normal (<0.2).[89] The sensitivity was quite low for all measures of the complete blood cell (CBC) count (0.3% to 54.5%). Thus, the utility of a CBC, including evaluation of WBC count, differential, ANC, or I/T ratio, to evaluate for EOS is extremely limited. Using CBC results to define an infant as high risk for sepsis poses both a significant risk of missing cases of neonatal sepsis and a risk of unnecessarily prolonging antibiotic administration.

Platelet Counts

Platelet counts are not sensitive for predicting or diagnosing EOS. One study demonstrated that 82% of neonates with positive blood cultures had a normal platelet count of between 150,000 and 400,000/mm^3.[89] The same study demonstrated a sensitivity of predicting EOS with a platelet count of <100,000/mm^3 of 4.0%.[89] While it is presumed that accelerated platelet destruction and possibly depressed production caused by bacterial products on the bone marrow are the underlying mechanisms for thrombocytopenia in some infected infants, it does not occur in all neonates with sepsis. Platelet counts are neither helpful for predicting neonatal sepsis nor evaluating response to effective antimicrobial treatment.[90,91]

Acute-Phase Reactants

No single biomarker has demonstrated superiority in predicting or diagnosing EOS. Moreover, variations in the timing that biomarkers naturally peak, their duration of elevation, and their half-lives make choosing the optimal timing of testing difficult. Here, we will evaluate several biomarkers that have been studied in the quest to improve diagnostic assessment and identification of EOS. Most of these biomarkers are derived from components of the complex inflammatory response to an invading pathogen and are considered acute phase reactants.

Procalcitonin (PCT) and C-reactive protein (CRP) are the most studied acute-phase reactants in neonatal sepsis.[92–94] PCT is the precursor of calcitonin, normally synthesized in the C cells of the thyroid gland. PCT is induced by systemic inflammation resulting from bacterial sepsis and is produced by cells such as hepatocytes, nephrons, and monocytes. The physiologic function of PCT is unknown. In bacterial infections, plasma PCT concentrations increase from 0.001 to 0.01 ng/mL at the baseline to values ranging from 1 to 1000 ng/mL. PCT concentrations rise much faster than CRP concentrations (6 to 8 hours vs. 48 hours for maximum levels). In healthy newborns, plasma PCT concentrations increase gradually after birth, reaching peak levels at approximately 24 hours of age (range 0.1 to 20 ng/mL) and then decreasing to normal values of less than 0.5 ng/mL by 48 to 72 hours of age.[95] This natural increase soon after birth makes PCT a less sensitive method of detecting EOS as compared to LOS. Studies on the use of PCT as a marker of neonatal sepsis have yielded contradictory results regarding its utility for clinical decision-making in both diagnosis and length of antibiotic therapy. In a study of 121 newborns with suspected early-onset sepsis, serial PCT concentration determinations could be used to shorten the duration of antibiotic therapy.[95] However, noninfectious conditions that commonly affect neonates, such as respiratory distress syndrome, infants of diabetic mothers, or hemodynamic instability, can also lead to elevations of PCT levels. Larger studies are needed to determine the value of PCT in diagnosis and therapy.

Monitoring CRP levels has been widely promulgated as an aid to diagnosing neonatal infection and adjusting the duration of antibiotic therapy in infants with suspected versus proven sepsis.[96,97] CRP is produced by the liver in response to stimulation by the pro-inflammatory cytokine IL-6, which is produced by both T and B cells.[92,93] CRP concentration increases within 6 to 8 hours and peaks around 24 hours after infection.[98,99] However, the use of CRP in diagnosing EOS is limited by its natural rise over the first 3 days after birth.[92,94] Specifically, one study evaluated 176 neonates >1500 g at birth and demonstrated a negative predictive value of CRP to be 99% in EOS.[100] Another study demonstrated two CRP measurements <1 mg/dL obtained 24 hours apart between 8 and 48 hours after presentation had a 99.7% negative predictive value for EOS and a 98.8% negative predictive value for late-onset sepsis.[100,101] However, obtaining a CRP at the time of initial infectious evaluation did not prove sensitive for predicting sepsis, and the negative predictive value did not improve when combined with later CRP measurements done at least 8 hours after the initial value. Therefore some suggest using serial CRP measurements that are normal (<1 mg/dL) to help determine early discontinuation of antibiotics rather than as a guide to starting antibiotics.[101]

Because exposure of the host to bacterial products results in a substantial and rapid increase in IL-6 concentrations, IL-6 may be a more useful marker than CRP during the early phase of infection. In one study, the IL-6 concentration had a sensitivity of 89% versus 60% for CRP at the onset of clinical suspicion of neonatal infection.[93] Other studies have demonstrated a sensitivity of 78% and a specificity of 79% for detecting neonatal sepsis.[102] With IL-6 levels and kinetics differing based upon gestational age, further investigations are needed to determine the utility of IL-6 in EOS testing and prediction strategies.[103] IL-6 use is not currently widely recommended outside of experimental testing.

High-sensitivity CRP (hsCRP) measurement has been shown to provide increased sensitivity for detecting neonatal infection.[104] Not all diagnostic laboratories can provide hsCRP values in a timely fashion. In addition, the optimum diagnostic cutoff levels for CRP and hsCRP are debatable. Serum soluble intercel-

lular adhesion molecule 1 (slSAM-1), hsCRP, soluble E-selectin (sE-selectin), and serum amyloid A, individually and in combination, have been studied for the diagnosis of sepsis in a neonatal intensive care unit.[104] In one study, all four measurements had some diagnostic value for neonatal infection; however, slSAM-1, hsCRP, and sE-selectin demonstrated the highest negative predictive value individually (slSAM-1, 84%; hsCRP, 79%; and sE-selectin, 74%).[104] Use of a combination of these measurements enhanced the diagnostic value, with sensitivities of 90.3% and a negative predictive value of 91.3%.[104] However, the application of this set of diagnostic markers is not available for most facilities, and more investigative work is needed to confirm their role in excluding early-onset infection.

To date, similar to the CBC, various cytokine determinations lack clear efficacy and sensitivity in detecting or predicting EOS and therefore have not been recommended for widespread use in EOS evaluation.

Bacterial Polymerase Chain Reaction (PCR)

Other molecular technologies to diagnose neonatal sepsis by the rapid identification and differentiation of gram-negative and gram-positive bacterial bloodstream infections are also being studied. Polymerase chain reaction (PCR), using universal bacterial primers, targets conserved regions of the 16 S ribosomal RNA gene common to all bacteria but not found in other organisms.[105] In one study, universal primer PCR was performed in newborns with clinically suspected sepsis. PCR was performed before antibiotic therapy was started and was repeated at 12, 24, and 48 hours after drug therapy had started.[105] The sensitivity, specificity, and positive and negative predictive values of universal primer PCR were 96.2%, 96.3%, 87.7%, and 98.8%, respectively. Two patients were blood culture positive but 0-hour PCR negative and seven patients were 0-hour PCR positive, but the blood culture result was negative. Of the patients with a 0-hour PCR-positive result, seven remained positive at 12 hours, but none remained positive at 24 and 48 hours after starting antibiotic therapy. Although universal bacterial primer PCR may be a useful test for diagnosing an early episode of culture-proven sepsis, it cannot be used for diagnosis if the patient has been exposed to antibiotic therapy for 12 hours or more.[105] Larger studies are required before this assay can be recommended for routine clinical use in newborns suspected of having sepsis.

Diagnostic Approach to Neonates with Suspected Sepsis

All symptomatic newborns must be carefully evaluated for the possibility of bacterial sepsis and treated with antibiotics, if necessary. Although the presence of various risk factors should increase the suspicion of sepsis, the absence of risk factors in the symptomatic infant does not indicate that sepsis risk can be dismissed. In adjusting to postnatal life, some newborns exhibit abnormal signs transiently, such as tachypnea, before becoming asymptomatic. However, in any newborn who has other findings or is still symptomatic 4 to 6 hours after birth, consideration of including a sepsis evaluation is imperative; a diagnostic evaluation with a blood culture and, as appropriate, a chest radiograph should be strongly considered. Antibiotic therapy can be stopped when the clinical suspicion of sepsis is low, the physical findings are normal, and the screening results for sepsis, including the blood culture results, remain negative. If the blood culture is positive or there are persistent clinical signs of sepsis, the newborn should be treated with an appropriate course of antibiotics. Furthermore, if a lumbar puncture was not done initially and the blood culture was positive, a lumbar puncture should be performed due to potential hematogenous seeding of the brain from bacteremia.

Deciding to evaluate and/or treat asymptomatic neonates for EOS is a difficult task. Combining the objective risk factors found to be most highly associated with neonatal sepsis with the newborn physical examination over the first 12 hours led to the development of a Neonatal Early-Onset Sepsis Calculator to guide evaluation and therapy of the late preterm (≥34 weeks' gestation at birth) and term infant who has maternal risk factors for sepsis.[19,106] The current version of the neonatal EOS calculator (found at https://neonatalsepsiscalculator.kaiserpermanente.org/) includes definitions of clinical status, including three specific categories: clinical illness, equivocal symptoms, and well-appearing. Combining clinical status with maternal risk factors, the calculator provides a numerical estimate of the risk of sepsis and a clinical recommendation for management and monitoring. Several studies have demonstrated the benefit of using this EOS calculator in reducing unnecessary antibiotic exposures.[107,108] A systematic review reported a 44% decrease in empiric antibiotic utilization with the implementation of the EOS calculator.[109]

For preterm neonates born at ≤34 weeks' gestation, the decision to evaluate and treat empirically for EOS is even more challenging. Notably, the EOS calculator does not include neonates born below 34 weeks' gestation, and with decreasing gestational age, there is an increased association with sepsis. Furthermore, very preterm neonates often have temperature instability, respiratory distress, and hypotension that are independent of infection, making the determination of whether symptoms are due to clinical infection or simply prematurity difficult. Preterm neonates who are born to a mother with cervical incompetence, pre-labor rupture of membranes (PROM), chorioamnionitis, intraamniotic infection, preterm labor, or otherwise unexplained etiology for a nonreassuring fetal status are considered high-risk for EOS and should have a blood culture and empiric antibiotics initiated immediately after birth. Preterm infants considered to be at lower risk for EOS include neonates born to mothers who had preterm delivery via (1) cesarean delivery, (2) due to an obstetric indication such as pre-eclampsia or noninfectious medical illness, and (3) no labor, rupture of membranes, or induction of labor occurred prior to delivery, and they may be monitored clinically without evaluation or treatment for EOS.[110] If the neonate is born via vaginal delivery or cesarean, but the mother had induction of labor or rupture of membranes prior to birth, and the delivery was due to noninfectious maternal etiologies, the neonate can still be monitored clinically, or a blood culture can be obtained. In these latter two low-risk situations, antibiotics can be initiated promptly if the neonate develops signs and symptoms of sepsis after birth.[110]

Diagnostic Approach for Neonates at Risk for GBS Early-Onset Disease (GBS-EOD)

The AAP has specific recommendations for the prevention of early-onset neonatal GBS sepsis that overlap with the AAP EOS clinical guidelines. Per the AAP recommendations, evaluation for GBS-EOD is based upon gestational age categories: those born ≥35 weeks' gestation versus those born <35 weeks' gestation. The Neonatal Early-Onset Sepsis Calculator (previously discussed) is a multivariate risk assessment that includes all causes of

EOS, including GBS, and can be used for those infants born ≥35 weeks' gestation. Another option for determining proper evaluation methods for GBS-EOD in those born ≥35 weeks' gestation is through a risk assessment based on the newborn's clinical condition. Of neonates with GBS-EOD, nearly 95% develop symptoms within the first 48 hours after birth.[17] Using this data, for those who develop signs of illness within the first 48 hours after birth, empiric antibiotics are initiated.[111–113]

For those born <35 weeks' gestation, the decision to empirically treat neonates from birth depends on the risk factors discussed above and the indication for delivery. For neonates born by cesarean section to mothers who had preterm birth due to noninfectious medical illness of the mother (e.g., pre-eclampsia, gestational hypertension, placental insufficiency, severe intrauterine growth restriction, multiples), or birth that occurred with no labor, it is reasonable to consider whether to perform laboratory evaluation due to the low-risk status for GBS EOD or other causes of EOS and to defer use of empiric antibiotics. However, if the neonate demonstrates signs of hemodynamic instability after birth, empiric antibiotics may be initiated. Preterm infants may be considered low risk for sepsis if they are born due to noninfectious maternal or fetal indications but had an induction of labor. For these infants, close observation is recommended as long as the mother received adequate IAP for GBS, if indicated. If not, the infant should be considered high-risk. High-risk infants born <35 weeks' gestation are those born preterm due to cervical insufficiency, preterm labor, chorioamnionitis, PROM, or other unexplained onset of non-reassuring fetal heart rate tracings. In these high-risk infants for both GBS-EOD and EOS, obtaining a blood culture and starting empiric antibiotics is recommended.

Treatment of Early-Onset Bacterial Infections

Antimicrobial Therapy

The choice of antibiotic for an infant with suspected early-onset sepsis depends on the predominant bacterial pathogens and the antibiotic susceptibility profiles for the microorganisms causing early-onset disease in a particular geographic region. Any decision to discontinue antimicrobial therapy should be based on the level of suspicion for sepsis when treatment was begun, the culture results, laboratory test results, and the clinical behavior and course of the infant. If sepsis is highly suspected in an infant, antibiotics should be considered for a full course even if the culture results are negative.

Empiric therapy for early-onset sepsis generally consists of combinations of antibiotics effective against the most common gram-positive pathogens (e.g., GBS, *L. monocytogenes*) and gram-negative pathogens (e.g., *E. coli*) associated with EOS. The two combinations most commonly used are (1) ampicillin with an aminoglycoside, usually gentamicin, or (2) ampicillin with a third-generation cephalosporin, usually cefotaxime. Cefotaxime has minimal toxicity and is well tolerated by newborns. However, the third-generation cephalosporins are associated with the induction of various β-lactamase–producing gram-negative bacteria, including extended-spectrum β-lactamase–producing organisms that are resistant to all β-lactam antibiotics and frequently to other antibiotics.[114] Cephalosporins and vancomycin, a glycopeptide antibiotic, are also associated with the development of vancomycin-resistant enterococci.[115] Another disadvantage of cephalosporin antibiotics is the lack of effectiveness against enterococci or *L. monocytogenes*. Moreover, studies have demonstrated an association between empiric third-generation cephalosporin use and invasive candidiasis in preterm neonates.[116] Therefore ampicillin and an aminoglycoside are the primary antibiotics recommended for empiric EOS treatment, depending upon local antibiotic resistance patterns. A third-generation cephalosporin is warranted in empiric treatment if there is suspicion of underlying meningitis. In infants with bacteremia and sepsis caused by GBS or *L. monocytogenes*, the combination of gentamicin with ampicillin or penicillin is used during the first few days, and the remainder of the course of therapy is completed with ampicillin or penicillin monotherapy once sterility of blood, CSF, and/or urine is achieved.

When the likelihood of infection is very low, antibiotic therapy should be stopped as soon as possible. In most hospitals using modern blood culture instrumentation, 36 hours is sufficient to determine whether a blood culture result is negative, assuming that no antibiotics were given before the culture was obtained.[117] One recent study reported that all pathogenic blood cultures collected before antibiotic implementation in EOS were positive within 24 hours, and other studies have demonstrated 92% to 100% culture positivity by 24 hours after collection.[70,118–121] Therefore the duration of empiric antibiotics may become shorter pending future clinical studies.

Experimental Immunologic Adjuvant Therapies

Various adjunctive therapies have been proposed to improve the immune status of the newborn to reduce neonatal sepsis mortality. Some of these therapies, such as intravenous immunoglobulin (IVIG), have been conclusively ruled out as potential preventative or therapeutic options for neonatal sepsis. A Cochrane review and a large clinical trial that enrolled 3493 infants reported that IVIG administration did not reduce mortality, the severity of illness, or major disability during hospital stay or by 2 years of age.[122]

Other immunomodulating factors such as granulocyte colony-stimulating factor (G-CSF) have been studied to both prevent and treat neonatal sepsis. A Cochrane meta-analysis concluded that prophylaxis with G-CSF does not significantly reduce mortality in all infants, although in premature infants with neutropenia (ANC <1750), mortality may be reduced.[123] Another meta-analysis reported G-CSF as an adjunct treatment for neonatal sepsis significantly decreased mortality with the most benefit for preterm neonates, those with baseline neutropenia, and those with low birthweight.[124] Further studies, such as a large randomized clinical trial, are warranted to investigate G-CSF's adjuvant effects in the treatment of neonatal sepsis.

Late-Onset Neonatal Bacterial Infections

LOS occurring after the first 72 hours of birth is a significant cause of morbidity and mortality among neonates worldwide. LOS attributed to nosocomial, or healthcare-acquired, infections is discussed in Chapter 37. Here, we examine the literature surrounding non-nosocomial LOS.

Pathogenesis and Epidemiology of Late-Onset Neonatal Bacterial Infections

While vertical transmission from mother-to-neonate before or during delivery is the cause of most cases of EOS, LOS occurs predominantly through horizontal transmission. Horizontal infection refers to contact with environmental sources or care providers after birth rather than directly related to the birthing

process. The neonate becomes colonized by potentially pathogenic bacteria within their environments, including skin and gut microbiomes. The causative pathogen associated with LOS is commonly found in abundance in the affected neonate's gut microbiome, which has implications for other aspects of neonatal management.[125] Processes that disrupt the skin barrier, such as the use of intravenous catheters, scalp electrodes, or even forceps delivery, predispose infants to develop LOS.[125] Other risk factors associated with LOS are delayed early enteral feeding with breast milk or underlying cardiac or pulmonary disease.[126–130] However, the most important risk factor for LOS is the same as for EOS—extreme prematurity, with the incidence of LOS inversely related to gestational age. One study reported approximately 36% of neonates born <28 weeks of gestational age had at least one episode of LOS, which decreased to 30% between 29 and 32 weeks, 18% between 33 and 36 weeks, and 17% for term neonates.[128]

Late-Onset Bacterial Pathogens

Coagulase-Negative Staphylococci

CONS can create biofilms, especially on central lines, and is a predominant etiology for nosocomial infections; therefore it is primarily discussed in Chapter 37.

Gram-Negative Bacteria

Gram-negative bacilli are also commonly associated with LOS and include *E. coli*, *Enterobacter* spp. *Klebsiella* spp, and *Pseudomonas* spp. When *E. coli* infection occurs after 6 days of age, an evaluation for galactosemia should be considered. Fungi such as *Candida* spp. are also a significant contributor to LOS and vary based upon geography, and are discussed in Chapter 36.[127,131]

Bacterial Pathogens Causing Both EOS and LOS: GBS and *L. monocytogenes*

While most bacterial pathogens can cause both early- and late-onset sepsis, GBS and *L. monocytogenes* are common etiologies for both time periods. Within this chapter, we have already discussed in detail GBS and *L. monocytogenes*.

Prevention Strategies for Late-Onset Neonatal Bacterial Infections

Several strategies can be implemented to reduce the risk of LOS. Early introduction of enteral feeds, specifically with breast milk, is an evidence-based strategy to prevent LOS. Breast milk contains antibodies, lactoferrin, human milk oligosaccharides, nutrients, and other beneficial factors that promote nutrition, growth, passive immune protection, and the promotion of the neonate's own immune functions.[132–134] Starting human milk feeding within the first 72 hours after birth is associated with a significant 3-fold reduction in the risk of LOS.[135]

Lactoferrin, a protein in human milk that is a part of the innate immune system in preventing infection, has been found to decrease the risk of LOS compared to placebo.[136–138] A Cochrane review reported that low-quality evidence exists demonstrating enteral lactoferrin supplementation decreases LOS but not NEC, all-cause mortality, or neurodevelopmental outcomes at 24 months of age in preterm infants. Therefore, the routine use of lactoferrin is not recommended.

Probiotics are another strategy to potentially reduce LOS. The gut microbiome of neonates undergoes profound change immediately after birth. It is thought that an abnormal gut microbiome can lead to alterations in the intestinal barrier and bacterial translocation from the gastrointestinal tract to the bloodstream, leading to sepsis. Probiotics containing potentially "beneficial" strains of bacteria such as *Bifidobacterium* or *Lactobacillus* spp. are believed to facilitate colonization of the gut microbiome with these "healthy" commensal bacteria as opposed to pathogenic bacteria such as CONS. A systematic review and meta-analysis reported that probiotics significantly reduce the incidence of LOS in exclusively human milk-fed preterm infants.[139] However, some studies have demonstrated probiotic-associated neonatal sepsis as well as recalls of certain probiotics due to contamination with *Salmonella*, *Rhizopus*, or *Penicillium* species. Thus, the American Academy of Pediatrics cautions against the routine use of probiotics at this time.[140] Further studies are needed to clarify the specific strains, dosing, and frequency of probiotics to potentially optimize their effectiveness in the prevention of LOS.

Evaluation of a Neonate with Potential Late-Onset Bacterial Sepsis

Neonates with late-onset sepsis admitted from the community are at lower risk for multidrug-resistant bacteria than neonates who have been admitted to the hospital since birth. UTIs and meningitis are more likely to occur in LOS than in EOS, and therefore, blood, urine, and CSF cultures should be performed in neonates presenting with signs of sepsis after 72 hours from birth, especially those presenting after 7 days from birth.

In contrast to older pediatric patients and adults, male neonates are more likely than female neonates to have a UTI until approximately 1 year of age. After 1 year of age, females become more likely than males to have a UTI. UTIs rarely occur as part of EOS but are more common after 72 hours of age. Therefore, urine culture by sterile techniques is a routine part of a sepsis evaluation for LOS. The most common pathogen associated with UTIs in neonates is *E. coli*.[141,142] A urine culture should be obtained by sterile catheterization or suprapubic bladder tap. A renal ultrasound should be performed if the neonate has a UTI due to the association with renal abnormalities in 20% to 50% of neonates with a UTI.[141,142] A renal ultrasound can detect hydronephrosis or structural abnormalities, but it cannot detect vesicoureteral reflux, a potential cause of neonatal and infant UTIs. If indicated, a voiding cystourethrogram (VCUG) can be performed approximately 1 to 2 months after the completion of antibiotic therapy.

A lumbar puncture should be performed in any neonate with signs of sepsis, a positive blood culture, or worsening clinical status while on antimicrobial treatment. A lumbar puncture can be deferred to a later time in neonates with life-threatening cardiopulmonary compromise or coagulopathy with a severe risk of bleeding. In clinically unstable neonates and those with coagulopathy, the lumbar puncture should be performed once the infant has stabilized.

Treatment of Late-Onset Neonatal Bacterial Infections

Neonates with LOS admitted from home are at lower risk for multidrug-resistant bacteria than neonates who have been in the hospital since birth. Therefore treatment strategies will be different for a neonate with a community-acquired infection versus those with a high risk of nosocomial infection. This latter group

will be discussed in a separate chapter on nosocomial infections. In general, treatment with ampicillin and an aminoglycoside (generally gentamicin) is an appropriate empiric treatment for LOS. The addition of an extended-spectrum cephalosporin (cefotaxime, ceftazidime, or cefepime) is warranted if there is a concern about underlying meningitis. Dosing of ampicillin and gentamicin depends upon gestational age and days since birth. If the site of infection is skin, bone, or joints, then nafcillin or vancomycin (if high rates of methicillin-resistant *S. aureus* are common in the community) rather than ampicillin should be substituted to treat for potential pathogens commonly associated with neonatal osteomyelitis and septic arthritis—*S. aureus*, GBS, *E. coli*.[143,144] Finally, if the infection is suspected to be from the gastrointestinal tract, such as with necrotizing enterocolitis, an antibiotic with more robust anaerobic bacterial coverage—such as clindamycin or metronidazole—can be added to the empiric treatment regimen.

Neonatal Bacterial Meningitis

Neonatal bacterial meningitis is associated with higher mortality and morbidity. Meningitis is associated with the same pathogens that cause bacterial sepsis, with GBS and *E. coli* accounting for approximately 70% of all cases, and *L. monocytogenes* accounting for an additional 5% in the first week of life. On occasion, it is possible to isolate *S. pneumoniae* and *H. influenzae*. In newborns older than 1 week and residing in neonatal intensive care units, coagulase-negative staphylococci are common isolates. The underlying pathogenesis of bacterial meningitis is a seeding of the meninges during bacteremia, and bacterial meningitis occurs in approximately 15% to 25% of neonates with bacteremia. This high occurrence rate highlights the importance of a lumbar puncture if a blood culture is positive and a lumbar puncture has not been performed.[145]

GBS meningitis usually presents as a late-onset disease. The most common GBS serotype identified is III.[146] Ansong et al. reported that GBS meningitis complicated 22 of 145 episodes (15%) of early-onset GBS sepsis and 13 of 23 episodes (57%) of late-onset GBS sepsis.[147] GBS meningitis has a mortality approaching 30% and morbidity of 50% and can occur in the presence of negative blood culture results. In one study, 20% of infants with GBS meningitis had negative blood culture results.[147]

Approximately 80% of all serotypes of *E. coli* that cause meningitis in newborns possess the K1 capsular antigen. The K1 capsular polysaccharide antigen is considered one of the primary virulence factors of this capsular type of *E. coli* because antibody against K1 antigen has been shown to be protective in neonatal rat models of infection. Mortality rates for neonatal *E. coli* meningitis range from 20% to 60%.[148]

Pathology and Clinical Manifestations of Neonatal Bacterial Meningitis

At autopsy, infants who die of meningitis often have purulent exudates on the meninges and the surfaces of the ventricles associated with inflammation. Historically, hydrocephalus and nonspecific encephalopathy were demonstrated in approximately 50% of infants who died of bacterial meningitis.[149]

The signs and symptoms of neonatal meningitis are not easy to distinguish from those of sepsis. Temperature instability, including hypo- or hyperthermia, is considered one of the most common findings and is seen in nearly 60% of newborns with bacterial meningitis.[150,151] Neurologic signs such as irritability, tremors, twitching, lethargy, and seizures are also quite common. Irritability has been reported to occur in approximately 60% of cases, and seizures in 20% to 50%.[150] Notably, seizures are more common in gram-negative bacterial meningitis than gram-positive pathogens. Seizures occur due to direct central nervous system inflammation or by metabolic abnormalities such as hypoglycemia or hyponatremia.[152] Other common findings include feeding intolerance, including emesis (50%), respiratory distress (50%), and apnea (10% to 30%).[150] A bulging fontanel may occur, but this is usually a late manifestation.

Diagnosis of Neonatal Bacterial Meningitis

The gold standard for the diagnosis of meningitis is the analysis of the CSF, including the WBC count, glucose and protein levels, Gram stain, and culture. The interpretation of CSF cell counts in newborns may be difficult.[153,154] There can be significant overlap in the WBC count, glucose, and protein levels between neonates with bacterial meningitis and those without meningitis. The CSF WBC count slowly decreases in term newborns during the first week after birth but may remain high or even increase in premature newborns. There is no change in CSF WBC counts or protein content with gestational age, but there is a significant decrease with postnatal age.[155] The 95th percentile for CSF WBC count for neonates is reported to be 19/μL, but individual infants with no proven infection had higher WBC counts ranging from 75 to 100/μL.[156,157] CSF WBC counts of >21 cells/μL have both a sensitivity and specificity of approximately 80% in predicting culture-positive bacterial meningitis.[153] However, it is important to note that culture-proven bacterial meningitis with normal CSF parameters occurs in 1% to 10% of infants with proven meningitis.[153,154,158] Finally, CSF glucose and protein values are highly variable and have significant overlap between those with meningitis and those without meningitis.[153,159–161]

A Gram stain of CSF must be carefully examined in every infant with suspected meningitis. Approximately 20% of newborns with proven meningitis are reported as showing "no bacteria seen." Although an increase is expected in the number of neutrophils with bacterial meningitis, one may see a predominance of lymphocytes before a conversion to polymorphonuclear leukocytes. With *L. monocytogenes*, examination of the CSF shows a mononuclear cellular response. In clinical care units, repeating the CSF examination and culture 2 to 3 days after the initiation of antibiotic therapy can be helpful to demonstrate the effectiveness of the antimicrobial regimen and associated sterility of the CSF. This examination is especially important if the patient has not responded clinically and is experiencing seizures or continued fever. At times, it is difficult to eradicate the organism from the CSF, and consideration can be given to examining the inhibitory and bactericidal concentrations in CSF. It is especially important to repeat the CSF examination before antibiotic therapy is stopped in patients with more complicated courses and in cases of enteric gram-negative bacterial meningitis.

Treatment of Neonatal Bacterial Meningitis

Infants with bacterial meningitis are frequently ill and should be monitored in the intensive care unit. These patients may require mechanical ventilation, complex fluid management to attenuate the effects of cerebral edema and of secretion of inappropriate antidiuretic hormone, seizure control, vasopressor support, and

cardiopulmonary monitoring. The choice of appropriate antibiotic therapy is based on several factors, including the achievable CSF levels of drugs that have in vitro efficacy against the microorganism. In gram-positive bacteria, the use of penicillin and ampicillin will achieve 10- to 100-fold higher concentrations than the minimal inhibitory concentrations needed to inhibit the bacteria, and there will be rapid sterilization of the CSF. In contrast, aminoglycosides, such as gentamicin and tobramycin, achieve only 40% of peak serum levels in the CSF and may not achieve minimal inhibitory concentrations more than those equal to or slightly greater than those found in vitro for gram-negative bacteria.

Generally, initial empiric antimicrobial therapy selection for presumed early-onset or community-acquired bacterial meningitis includes ampicillin and an aminoglycoside (typically gentamicin) along with a third- or fourth-generation cephalosporin (e.g., cefotaxime, ceftazidime, cefepime). This regimen is effective against common bacterial pathogens associated with early-onset and late-onset sepsis and meningitis (GBS, *E. coli, L. monocytogene*). The addition of an expanded-spectrum cephalosporin increases coverage against *S. pneumococci* and ampicillin-resistant strains of *E. coli*. Ampicillin-resistant bacteria are known to be a common cause of neonatal meningitis, and one study found nearly 80% of infants with meningitis had ampicillin-resistant strains of bacteria as the underlying etiology.[162] Thus, ampicillin and gentamicin are effective therapy against GBS and Listeria, and the addition of a higher generation cephalosporin treats ampicillin-resistant gram-negative bacterial pathogens that are of increasing prevalence. Of note, ceftriaxone should not be used in neonates as it is known to displace bilirubin from albumin and increase the risk for kernicterus and bilirubin-induced neurologic dysfunction (BIND). Furthermore, ceftriaxone is contraindicated when calcium infusing intravenous fluids are also being administered due to the risk of calcium precipitation.

In neonates who have been in the hospital since birth and may have had central lines or other risk factors for coagulase-negative staphylococcus or methicillin-resistant *Staphylococcus aureus* (MRSA), there should be a consideration for vancomycin as part of the empiric treatment regimen for suspected late-onset bacterial meningitis. Importantly, ampicillin should be added if there is a concern for GBS or *L. monocytogenes* such as a Gram stain, culture, or history suggesting a high risk for these pathogens. Although used in the past, neither intrathecal nor intraventricular administration of antibiotics has been found to reduce the morbidity or mortality associated with gram-negative bacterial meningitis.[163]

Once the microorganism has been identified and the antibiotic susceptibility results are available, either a single drug or a combination of drugs found to be effective should be prescribed. GBS is uniformly susceptible to ampicillin and penicillin; therefore, after an initial course of dual therapy, monotherapy with Penicillin G is generally the definitive course of treatment. GBS meningitis is treated for 14 to 21 days. Due to evidence that a dual therapy regimen is more efficacious than ampicillin monotherapy, Listeria is traditionally treated with dual therapy of ampicillin and gentamicin until CSF sterility is documented. Once CSF sterility is achieved, monotherapy with ampicillin can be prescribed to complete a treatment duration of 14 to 21 days. For *E. coli* infections, ampicillin is the preferred treatment for strains that are ampicillin susceptible. For ampicillin-resistant strains, including other gram-negative enteric bacteria with ampicillin resistance, an extended-spectrum cephalosporin (i.e., cefotaxime, cefepime, or ceftazidime) plus an aminoglycoside (generally gentamicin) is the initial therapy until CSF sterility is achieved. At this point, the aminoglycoside can be discontinued, and monotherapy with the cephalosporin can be continued to complete a minimum of 21 days of treatment duration. In settings where multi-drug-resistant pathogens are the etiology of bacterial meningitis, consultation with the hospital microbiology laboratory and the infectious disease team is necessary to determine the best treatment strategy and duration. For gram-positive organisms, a 14-day treatment course is generally sufficient. For gram-negative organisms, a 21-day course is the minimum.

A Cochrane review of two trials of adjuvant corticosteroids in neonatal bacterial meningitis suggested a reduction in death and hearing loss with steroid therapy, but there was no reduction in neurologic sequelae at 10 weeks.[164] However, a clinical trial evaluating the outcomes of neonates exposed to dexamethasone plus antibiotic therapy versus only antibiotic therapy demonstrated no differences in rates of neurologic deficit, mortality, or hearing loss at 2 years of age.[165] Therefore adjunctive steroid use is not currently recommended for the treatment of neonatal bacterial meningitis.

It may be prudent to repeat a CSF examination and culture after the initiation of therapy, especially if the clinical response is less than satisfactory. If organisms are seen on Gram-stained smears of the fluid, modification of the therapeutic regimen should be considered. In general, approximately 3 days or more are required for an antibiotic regimen to sterilize the CSF in infants with gram-negative meningitis. In infants with gram-positive meningitis, sterilization is usually seen within 36 to 48 hours. Neuroimaging should be considered for all neonates with meningitis to exclude parameningeal foci and abscess formation and to assist in assessing the infant's prognosis. Neuroimaging is required in infants with signs of neurologic complications or failure to improve clinically after 24 to 48 hours of appropriate antibiotic treatment.

Outcomes of Neonatal Bacterial Meningitis

Mortality from neonatal meningitis occurs in approximately 10% of cases.[166–172] Meningitis survivors are at high risk for neurodevelopmental impairment. Approximately 35% of survivors go on to have mild disability, and 20% develop moderate or severe disability.[169,171,172] Complications from neonatal meningitis include brain abscess, communicating or non-communicating hydrocephalus, subdural effusions, ventriculitis, deafness, and blindness. An infant who had meningitis may appear relatively healthy at the time of discharge, and only after careful follow-up do perceptual difficulties, reading problems, or signs of brain damage become apparent. Infants who survive neonatal meningitis should have regular audiology, language, and neurologic evaluations until they enter school.[173,174]

Viral Infections of the Fetus and Newborn

CALEB STOKES AND ANN J. MELVIN

KEY POINTS

- Viral infections of the fetus and newborn are common problems in neonatology practice.
- Fetal (congenital) viral infections should be considered in the differential diagnosis of newborns with intrauterine growth retardation, physical examination and laboratory abnormalities, and illness in the newborn period.
- Perinatal viral infections involve transmission during the birth process and can result in severe neonatal disease both due to high inoculum and relative lack of protective maternal immunity.
- Postnatal viral infections are common and can cause a diverse range of clinical illness from isolated fever to severe pneumonia to viral sepsis with shock.
- The diversity of virus-caused disease is vast. Laboratory studies focused on virologic detection, driven in most cases by molecular assays such as polymerase chain reaction (PCR), are much more precise and reliable than serologic diagnosis.
- Antiviral therapies are now available for many viral pathogens, underscoring the importance of making a specific and timely diagnosis.

Introduction

Viral infections of the fetus and newborn are common and underrecognized (Box 34.1). Given the life-threatening nature of invasive bacterial infection in the neonate, the identification of viral infections is often assumed to be a matter of secondary importance. However, identifying viral infections is a matter of great urgency because an increasing number of antiviral therapeutic agents are available. Thus, a high index of clinical suspicion in identifying neonatal viral infections can be lifesaving. Moreover, identification of viral disease in the neonate may provide important prognostic information, particularly for viruses associated with a high risk of neurodevelopmental issues. Accordingly, making a diagnosis of a viral infection can help to direct and focus long-term management by the child's pediatrician. This chapter reviews the epidemiology, pathogenesis, diagnosis, and clinical management of many common congenital and perinatal viral infections encountered in neonates.

Of central importance in the evaluation, treatment, and prevention of viral disease in the newborn is identifying the time the infection was acquired. In this chapter, congenital infection is defined as any infection acquired by the fetus *in utero*. Perinatal infections are defined as those acquired during the labor and delivery process, also known as intrapartum. Postnatal infections are defined as infections acquired after delivery (postpartum) through the first month of life. Correctly identifying the timing of acquisition of infection can have substantial implications, not only for the care of the infant but for predicting the long-term prognosis. Fig. 34.1 outlines the most common neonatal viral infections with an emphasis on the relative importance of the risk interval for timing of acquisition. However, as some viral infections can be transmitted at any of these time points, specific disease outcomes based on the timing of infection will be considered on a pathogen-by-pathogen basis.

Several features of maternal and fetal immunity influence susceptibility to viral infection in important ways. Pregnancy is an altered immune state in which there is both immune suppression to promote tolerance of a "foreign" fetus, and heightened immune function, particularly at the maternal-fetal interface via Th2 polarization. While the consequences of this balance are somewhat pathogen specific, pregnant women have been found to be at risk of increased severity of infection with the following viruses: influenza, HSV, hepatitis E, Ebola, SARS-CoV-2, varicella, and measles.[1] While there are clear deleterious consequences of systemic infection regardless of pathogen in pregnancy, ranging from altered neurodevelopmental outcomes[2] to preterm birth,[3] these are generally beyond the scope of this chapter (in part because the risks are generally higher with bacterial as compared to viral infection). In the setting of maternal infection, viral tropism for the maternal-fetal interface is an important determinant of congenital infection; viral replication in maternal decidua or placental trophoblasts has been demonstrated to be important in the following fetal pathogens: cytomegalovirus (CMV), herpes simplex virus (HSV), and Zika virus. Finally, transfer of maternal antibody to the fetus (almost exclusively IgG) occurs via active transplacental transport which begins around 17 weeks of gestation and peaks around 37 weeks.[4,5] Additionally there is uptake from colostrum in the intestine (predominantly IgG) in the first week of life.[6,7] These antibodies typically remain detectable for 6 to 12 months and confer protective immunity in the newborn. Maternal antibody is an important determinant of disease severity particularly in neonatal HSV, VZV, respiratory syncytial virus (RSV), and influenza infections.

BOX 34.1 Viral Pathogens Reported to Cause Congenital/Neonatal Infections

Adenoviridae
- Adenovirus serogroup 3

Arenaviridae
- Lymphocytic choriomeningitis virus
- Lassa fever virus

Bunyaviridae
- Bunyamwera serogroup (Cache Valley virus)
- La Crosse encephalitis virus

Flaviviridae
- Zika virus
- Hepatitis C virus
- Japanese encephalitis virus
- West Nile virus
- St. Louis encephalitis virus
- Yellow fever virus
- Dengue virus

Hepadnaviridae
- Hepatitis B virus

Herpesviridae
- Herpes simplex viruses 1 and 2
- Varicella zoster virus
- Cytomegalovirus
- Epstein–Barr virus
- Human herpesviruses 6 and 7

Orthomyxoviridae and Paramyxoviridae
- Influenza viruses
- Measles virus

Parvoviridae
- Human parvovirus B19

Picornaviridae
- Poliovirus
- Coxsackievirus
- Enteric cytopathic human orphan virus
- Parechovirus
- Hepatitis A virus

Retroviridae
- Human T-lymphotropic viruses 1 and 2
- Human immunodeficiency virus

Togaviridae
- Chikungunya virus
- Rubella virus
- Western equine encephalitis virus
- Venezuelan equine encephalitis virus

General Diagnostic Concepts

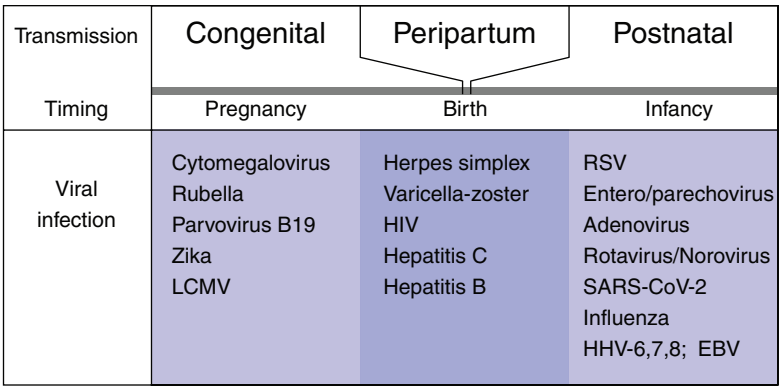
Clinicians caring for newborns have long recognized that there are some common clinical manifestations that suggest the presence of a congenital or perinatal viral infection. These manifestations include intrauterine growth restriction (IUGR), microcephaly, hydrops fetalis, hepatomegaly, splenomegaly, pneumonitis, bone lesions, rashes, and hematologic abnormalities. Because congenital viral infections are commonly encountered in neonatology practice, it is appropriate for clinicians to have a high index of suspicion in any newborn with suggestive signs or symptoms.[8] However, caution should be taken to thoughtfully consider diagnostic possibilities suggested by the history and physical examination, recognizing the specific etiologic diagnoses compatible with an infant's presentation (Table 34.1).

The acronym *TORCH*, first coined by Nahmias et al. in 1971, stands for toxoplasmosis, "other" infections, rubella, CMV, and herpes simplex virus HSV.[9] Numerous variants of this acronym have been suggested in the past 5 decades.[10–14] The use of '*TORCH titers*' in the diagnostic approach to a symptomatic neonate oversimplifies and seriously underestimates the diversity of neonatal viral infections encountered in practice.[15] This acronym has outlived its usefulness and should be discarded from clinical parlance. Unfortunately, numerous clinical laboratories continue to offer the "TORCH panel," typically consisting of serologic tests for toxoplasmosis, syphilis, HSV, CMV, and rubella.

Molecular tools based on polymerase chain reaction (PCR) amplification of viral nucleic acid are now available to identify virtually all pathogenic viruses. PCR tests are more sensitive and specific than serologic tests. Furthermore, measurements of neonatal immunoglobulin G (IgG) antibody titers virtually always reflect transplacentally transferred maternal antibody and provide little information of relevance to the infant's infection status. Also, congenital and perinatal infection can occur with HSV and CMV, even in the face of preconception maternal immunity. Thus, the finding of IgG antibody against these viruses in a TORCH titer is neither diagnostic of infection nor reassuring regarding protection against that infection.

Rather than relying on a large battery of serologic tests, the astute clinician can typically formulate a focused differential diagnosis of a suspected neonatal or congenital viral infection with the history and physical examination, followed by the use of specific diagnostic studies emphasizing virologic methods. Important questions include:
- What is the health and infection history of the mother?
- Did she have any symptomatic infectious illnesses during pregnancy?
- What is her immunization history?
- Has she had chickenpox or other childhood infections?
- What part of the world is she from?
- Is there a recent travel history?
- Are there potential animal exposures (e.g., exposure to cat litter or consumption of undercooked meat might suggest toxoplasmosis; exposure to rodents might suggest lymphocytic choriomeningitis virus [LCMV])?
- Does she have other children, and, if so, what are their ages, overall health status, and histories of group day care attendance?
- Have there been recent illnesses in the household? What time of year is it (e.g., RSV and enterovirus infections have characteristic seasonality in temperate zones)?
- What are her occupational exposures?

The answers to these types of questions, considered in the context of the infant's physical examination, can direct the next steps in establishing a definitive etiologic diagnosis. Some of the classic presentations of the more common perinatal viral infections are provided in Table 34.1. There can be considerable overlap of these clinical features across the different infectious categories listed; for example, the "blueberry muffin" rash of congenital rubella syndrome (CRS) may be indistinguishable from that



• **Fig. 34.1** Overview of viral infections of the fetus and newborn highlighted in this chapter. Individual viruses are listed beneath the timing of transmission that leads to the most significant pathology in the neonate. Some neonatal virus infections (e.g., cytomegalovirus) can be substantial causes of disease whether acquired during gestation or acquired postpartum, whereas others (e.g., RSV) are typically acquired in the postnatal period. *EBV*, Epstein-Barr virus; *HHV*, human herpesvirus; *HIV*, human immunodeficiency virus; *LCMV*, lymphocytic choriomeningitis virus; *RSV*, respiratory syncytial virus; *SARS-CoV*, severe acute respiratory syndrome coronavirus.

TABLE 34.1 Early Clinical Findings Associated With Congenital Viral Infections

Clinical Finding	Congenital Viral Causes (Ranked by Likelihood of Finding in Given Viral Infection)	Nonviral Causes (Including Nonviral Congenital Infections)
Abnormal prenatal ultrasound	CMV (echogenic bowel, brain abnormalities, intrahepatic calcifications), parvovirus B19 (fetal anemia, hydrops), Zika (microcephaly), VZV (limb hypoplasia)	Anatomic (neural tube defects, abdominal wall defects, congenital heart defects), genetic (aneuploidy)
Placental pathology	CMV (chronic villitis), HSV (placental infarcts), Zika (villitis), parvovirus B19, enterovirus, SARS-CoV-2 (acute villitis)	Idiopathic (villitis of unknown etiology), infection (granulomatous villitis: toxoplasma, acute villitis: group B streptococcus, *Escherichia coli*)
Intrauterine growth restriction	CMV, rubella, VZV (limb hypoplasia), HSV	Infection (toxoplasma, malaria, syphilis), genetic (aneuploidy, IGF pathway mutations), placental abnormalities, maternal chronic illness
Congenital contractures/ arthrogryposis	Rubella, varicella, Zika, Coxsackie B	Idiopathic (clubfoot), genetic mutations (distal arthrogryposis), neuromuscular disorders
Skeletal defects	Rubella ("celery stalking" with longitudinal demineralization)	Genetic (osteogenesis imperfecta, achondroplasia), toxin, infection (syphilis)
Microcephaly	CMV, Zika, rubella, LCMV	Genetic (Aicardi-Goutières syndrome, JAM3, NDE1, ANKLE2 mutations), toxins, placental insufficiency, malnutrition
Intracranial calcifications	CMV (periventricular), Zika (parenchymal), LCMV, rubella (basal ganglia)	Infection (toxoplasma), genetic (Aicardi-Goutières syndrome, RNASET2 mutations)
Sensorineural hearing loss	CMV, rubella, LCMV, HSV, VZV, mumps, measles, Zika	Genetic (GJB2, STRC mutations, syndromic), infection (toxoplasma, syphilis), toxins (alcohol, quinine, retinoic acid), maternal thyroid peroxidase antibodies
Congenital cataracts	Rubella, VZV, HSV	Genetic (crystallin, connexin mutations, aneuploidy, galactosemia), infection (toxoplasma, syphilis), medications (long-term glucocorticoids)
Chorioretinitis	Rubella (pigmented retina, cloudy cornea), CMV, VZV LCMV, Zika	Infection (toxoplasma), retinoblastoma
Keratoconjunctivitis	HSV	Postnatal infection (chlamydia, gonorrhea), anatomic (nasolacrimal duct obstruction)
Skin lesions	CMV (purpuric macules of extramedullary hematopoiesis), rubella (purpuric macules of extramedullary hematopoiesis), VZV (cicatricial regions, vesicles), HSV (vesicles)	Erythema toxicum, transient pustular melanosis, milia, acne neonatorum, seborrheic dermatitis, infection (toxoplasma, syphilis, bacterial sepsis, candida)

Continued

TABLE 34.1 Early Clinical Findings Associated With Congenital Viral Infections—cont'd

Clinical Finding	Congenital Viral Causes (Ranked by Likelihood of Finding in Given Viral Infection)	Nonviral Causes (Including Nonviral Congenital Infections)
Thrombocytopenia	CMV, rubella, HSV, HIV	Alloimmune, genetic (Wiskott-Aldrich, thrombocytopenia with absent radius, Bernard-Soulier syndromes, MYH-9 mutations)
Nonimmune hydrops fetalis	Parvovirus B19, CMV, rubella	Infection (toxoplasma, syphilis), genetic (aneuploidy, inborn errors of metabolism, congenital nephrotic syndrome)
Hemolytic anemia	Parvovirus B19, CMV	Alloimmune, genetic (hemoglobinopathies, erythrocyte membrane defects, G6PD deficiency)
Jaundice (conjugated hyperbilirubinemia)	CMV, rubella, HSV, LCMV	Anatomic (biliary atresia), genetic (Alagille syndrome, inborn errors of metabolism), infection (toxoplasma, syphilis)
Hepatosplenomegaly	CMV, rubella, parvovirus B19, LCMV	Genetic (inborn errors of metabolism), tumor, alloimmune hemolytic disease, infection (toxoplasma)
Pneumonitis	CMV, HSV, rubella	Infection (toxoplasma, syphilis)
Cardiac abnormalities	Rubella (PDA, pulmonary artery hypoplasia), parvovirus B19 (hypertrophic cardiopathy)	Idiopathic, genetic (aneuploidy) infection (syphilis)
Myocarditis	Coxsackie B virus, parvovirus B19, enterovirus	Genetic (inborn errors of metabolism, Noonan syndrome), alloimmune, vascular (infarct)

CMV, Cytomegalovirus; *G6PD*, glucose-6-phosphate dehydrogenase; *HSV*, herpes simplex virus; *HIV*, human immunodeficiency virus; *IGF*, insulin-like growth factor; *LCMV*, lymphocytic choriomeningitis virus; *PDA*, patent ductus arteriosus; *SARS-CoV*, severe acute respiratory syndrome coronavirus; *VZV*, varicella zoster virus.

of congenital CMV infection, and both syndromes can include sensorineural hearing loss. The presence of brain calcifications and/or microcephaly, although nonspecific, should always suggest a differential diagnosis that includes CMV, toxoplasmosis, and Zika virus. Because neuroradiology studies cannot reliably distinguish these entities, definitive diagnostic virology is necessary. In this chapter we review specific viral pathogens, their basic virology, the clinical manifestations of diseases they cause in the newborn, management strategies, and prospects for prevention on a pathogen-specific basis.

Cytomegalovirus

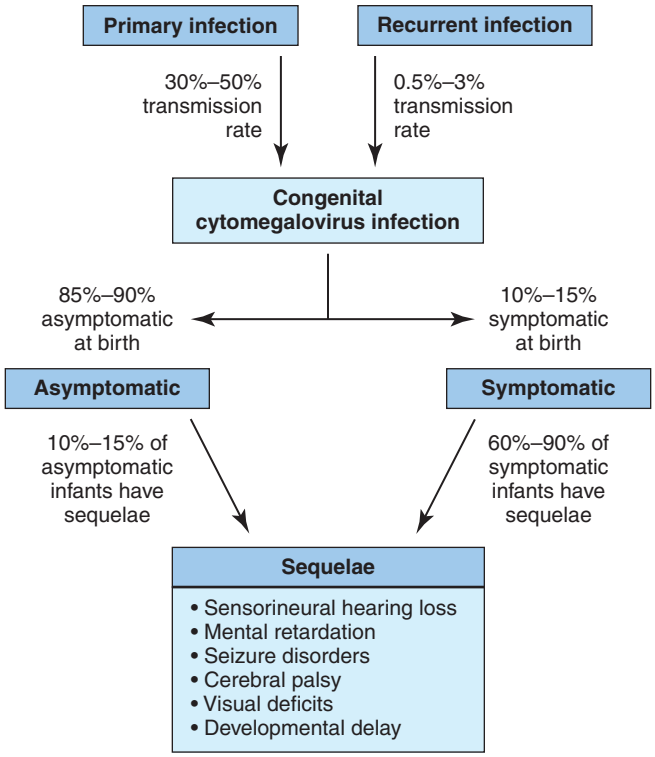
CMV infection is ubiquitous in the general population and usually produces few if any symptoms in the immunocompetent infant, child, or adult. However, CMV-induced illness can be severe in those with impaired, suppressed, or immature immune systems, including newborns. Among the congenitally acquired viral infections in the developed world, CMV infection imposes the largest economic burden and produces the greatest long-term neurodevelopmental morbidity.

Epidemiology

The first description of congenital CMV disease was in 1904,[16] when Ribbert observed the large inclusion-bearing cells that represent the typical histopathologic finding of CMV end-organ disease in a stillborn infant. In 1920 a viral cause was proposed for the "cytomegaly" seen in tissue sections of these inclusion-bearing cells,[17] but it would be several more decades before the ubiquitous nature of this virus and the depth and breadth of the disease it produces would be elucidated. In the developed world, CMV transmission occurs in 0.5% to 1% of all successful pregnancies, making CMV infection the most common congenital viral infection.[18–23] Seroprevalence rates for CMV differ significantly globally, but in general increase with age and are inversely correlated with socioeconomic status.[19] Although the lifetime risk of acquiring CMV infection is high, approaching 90% by the eighth decade of life,[24] seroprevalence is substantially lower among women of childbearing age. Seronegative women are therefore at risk of acquiring primary infections during pregnancy. Among pregnant women, the overall estimated annual seroconversion rate in the United States is 2.3%.[25] Acquisition of CMV occurs via contact with infectious secretions, including blood, saliva, urine, semen, vaginal fluid, and breast milk.[26,27] Primary sources for maternal CMV acquisition are through sexual activity and exposure to young children.[28]

Young children in group day care settings have particularly high rates of salivary CMV shedding,[29–31] thus day care providers and parents of young children in day care are at elevated risk of acquisition of primary CMV infections.[25,32–35] Health care providers in contrast are not at increased risk of acquisition of a primary CMV infection.[25,36]

The risk of intrauterine transmission after primary infection is estimated to be 30% to 50%, [37,38] with increasing rates of fetal infection at later stages in pregnancy.[38,39] However, the risk of symptomatic congenital CMV is highest for women with primary CMV infection during periconception and the first trimester, with acquisition during the second or third trimester rarely leading to adverse fetal outcomes.[38,40,41] In women with preexisting immunity, the risk of congenital infection is significantly lower (1% to 3%). However, reinfection with a different CMV strain, or reactivation, can lead to symptomatic infant disease and sequelae (Fig. 34.2).[42–45] Paradoxically, therefore the highest rates of congenital CMV are seen in populations with higher CMV seroprevalence.[46–49]



• **Fig. 34.2** Profiles of congenital cytomegalovirus (CMV) epidemiology, infection, and outcome. The rates of transmission to the fetus are highest in the setting of primary maternal infection (up to 50%), although 0.5% to 3% of women with preconception immunity may nonetheless transmit CMV because of reinfection or reactivation of latent infection. Among all infants with congenital CMV infection, regardless of maternal immune status during pregnancy, approximately 10% to 15% have symptoms or signs at birth (e.g., microcephaly, chorioretinitis, hepatosplenomegaly, petechiae, purpura, thrombocytopenia, hepatitis, seizures, pneumonitis). Symptomatic infants have the highest risk of neurodevelopmental sequelae, although any infant with congenital CMV infection is potentially at risk of sequelae. Among asymptomatic congenitally infected infants with sequelae, the most common manifestation is sensorineural hearing loss, which may not be present at birth.

Postnatal Acquisition of Cytomegalovirus: Implications for the Premature Infant

In addition to congenital infection, CMV can be acquired in the postnatal period. Postnatal CMV infection in healthy term infants is typically asymptomatic, with no convincing evidence of any adverse neurodevelopmental sequelae.[50,51] In contrast, primary CMV infection in preterm infants can lead to significant morbidity. Potential routes of neonatal infection include exposure to infectious cervicovaginal secretions during delivery,[27,52] ingestion of breast milk, contact with saliva, and via blood transfusion. Of these, the most common is via breast milk.[50,53–55] Detection of CMV by PCR or culture in breastmilk samples of CMV positive women is reported between 63% and 97%[27,50,56] and approximately 20% (range 6% to 59%) of premature infants fed breastmilk from CMV-infected mothers will become infected.[50] Risk for severe illness is greatest in very low birth weight (VLBW) infants, in whom rates of symptomatic illness or death are as high as 17% to 18%.[57,58] Symptoms in these infants include hepatopathy, neutropenia, thrombocytopenia, pneumonitis, and sepsis-like deterioration. The Centers for Disease Control and Prevention (CDC) has estimated that annually up to 4.5% of VLBW and premature infants, or an estimated 2000 infants, in the United States may develop CMV sepsis syndrome because of breast milk-acquired CMV infections.[21] Acquisition of CMV infection in the premature infant may contribute to the development of chronic lung disease.[59,60] The neurodevelopmental consequences of postnatal CMV infection in preterm infants are unclear, with some studies finding a detrimental effect[61] and others not.[51,62]

Proposed efforts to reduce the infectivity of breast milk from seropositive mothers have included freezing breast milk at −20°C, Holder pasteurization, and short-term pasteurization.[54] Of these methods, freezing is the most studied and most likely to maintain the salutary immunologic properties of breast milk. Although freezing of breast milk may lower the incidence of postnatally acquired CMV infection, it does not eliminate the risk.[63,64] Further evidence is necessary to make recommendations regarding what, if any, interventions are appropriate in low birth weight, preterm infants receiving breast milk from CMV-seropositive mothers.

Transfusion-associated CMV infections were at one time a major problem in the neonatal intensive care setting.[65–67] Two approaches are currently used to decrease the risks of transfusion-associated CMV infection: leukocyte reduction and directed transfusion of CMV-negative blood products.[68] A prospective, multicenter birth-cohort study conducted at three neonatal intensive care units (NICUs) in the United States found no evidence of transfusion-associated CMV infection when leukocyte-reduced blood was used for transfusion of VLBW infants.[58] These data support the practice of transfusing leukocyte-reduced blood products to premature infants, including blood from CMV-seropositive donors, to prevent transfusion-associated CMV infection in the NICU.

Pathophysiology

The mechanisms by which CMV injures the fetus involve a complex interplay of viral gene products, maternal immune response, and placental biology. The pathogenesis of disease associated with acute CMV infection has been attributed to lytic virus replication, with end-organ damage occurring either secondary to virus-mediated cell death or from pathologic host immune responses targeting virus-infected cells.[69,70] The factors that contribute to fetal injury include the timing of infection relative to the gestational age of the fetus,[71] the maternal immune status,[72] the extent of associated placental injury,[73] the magnitude of the viral load in the amniotic fluid,[74] the induction of host genes occurring in response to infection,[75] and possibly the genotype of the particular strain of CMV infecting the fetus.[76,77] Much of the injury that CMV produces in the newborn may be caused by placental insufficiency.[78] CMV infection of the placenta might also contribute to IUGR and fetal injury via induction of proinflammatory cytokines and modulation of normal trophoblast gene expression.[79–82] The developing fetal brain is also highly susceptible to CMV-induced injury.[83–85] The pathogenesis of CMV infection in the central nervous system (CNS) seems to be strongly related to perturbations in neural migration, neural death, cellular compositions, and the immune system of the brain.[86,87] In infants with symptomatic congenital CMV infection, histopathologic evidence of viral dissemination can be found in the brain, ear structures, retina, liver, lung, kidney, and endocrine glands.[88–90] The pathogenesis of sensorineural hearing loss (SNHL) is related to an inflammatory labyrinthitis.[91–93] CMV-infected cells can be seen in the semicircular canals, vestibular membrane, cochlea, and other structures of the ear.[89,93]

Clinical Presentation

Signs and symptoms are apparent at birth in 10% to 15% of all children with congenital CMV infection. Infection in the symptomatic infant can involve any organ and manifests itself along a spectrum from mild illness to severe disseminated multi-organ system disease (see Table 34.1). A wide spectrum of disease can be observed, including hemolysis, bone marrow suppression, hepatitis, pneumonitis, enteritis, and nephritis. Infants with symptomatic disease are often premature and small for their gestational age. Clinical features include jaundice, hepatosplenomegaly, lethargy, respiratory distress, seizures, and petechial rash. Common laboratory abnormalities include thrombocytopenia, anemia, and elevated transaminase and conjugated bilirubin levels.

CNS disease is common in symptomatic infants: signs and symptoms may include hypotonia, lethargy, seizures, and microcephaly.[94] Imaging by cranial ultrasound may reveal intracranial calcifications, periventricular cysts, ventriculomegaly, cerebellar hypoplasia, or lenticulostriate vasculopathy.[90,95,96] Additional findings such as white matter abnormalities and neuronal migration disorders may be identified by MRI.[90,96–98]

Ophthalmologic abnormalities are seen in 20% to 40% of symptomatic infants, but rarely in asymptomatic infants.[99,100] Common findings include retinal scars, optic atrophy, and chorioretinitis. SNHL is either present at birth or develops in 40% to 70% of symptomatic infants[94,101,102] and 10% to 15% of infants who are otherwise asymptomatic.[101,103–105] SNHL can be progressive and fluctuating in both asymptomatic and symptomatically congenitally infected infants.[106] It ranges in severity from a unilateral, mild hearing deficit to severe, bilateral, profound deafness. CMV-induced SNHL may be present at birth or can appear later in childhood. Delayed-onset hearing loss usually presents in the first few years of life[101,107–110] but has been reported to evolve and progress through 5 years of age and beyond.

Mortality due to symptomatic congenital CMV disease in the neonatal period is uncommon, likely less than 5%.[111,112] However, long-term neurodevelopmental disabilities are observed in 50% to 75% of children who are symptomatic at birth[102,113] and can include motor deficits (paresis or paralysis), cerebral palsy, intellectual disability, seizures, vision impairment, hearing loss, and learning disabilities.[86,114] In contrast, several studies have suggested that the intellectual development of asymptomatic congenitally infected infants appears to be normal.[115,116]

Diagnosis

Prenatal Diagnosis

Primary infection during pregnancy can be identified by serologic testing, although testing for CMV immunity is not currently standard practice during pregnancy. Recommended testing includes CMV IgG and IgM antibody levels with IgG avidity testing for women in whom CMV IgM is detected. While the presence of CMV IgM is a sensitive marker for primary infection, the specificity for recent primary infection is lower as IgM can persist for months after infection. The additional IgG avidity testing can improve the specificity; a low IgG avidity index is consistent with recent primary infection.[117]

Prenatal ultrasonography provides clues to the possible diagnosis of fetal CMV infection; however, ultrasound has low sensitivity.[118] Findings suggesting possible congenital CMV include echogenic bowel, IUGR, brain abnormalities (microcephaly, ventriculomegaly, periventricular calcifications, periventricular hyperechogenicity), polyhydramnios, pericardial effusion, fetal hydrops, hepatosplenomegaly, intrahepatic calcifications, and placental enlargement.[118–122] Abnormal prenatal findings on ultrasound examination are associated with increased risk of sequelae,[123] while normal cranial imaging by ultrasound or MRI is reassuring for low risk of adverse postnatal outcome.[124–127] When in utero CMV acquisition is suspected due to detection of maternal primary infection in early pregnancy and abnormalities identified by fetal ultrasound, amniotic fluid can be tested by PCR to determine fetal infection. Testing is recommended to be done at least 6 weeks after maternal infection and after 20 weeks' gestation for the highest sensitivity.[117,122,128] This allows sufficient time for transplacental passage, replication in the kidneys, and excretion into amniotic fluid.[129]

Postnatal Diagnosis

Congenital CMV infection is best diagnosed by detection of virus in samples collected from the neonate in the first 2 to 3 weeks of life. The timing of collection of these samples is important because viral isolation beyond 3 weeks of age may represent infection acquired in the birth canal or more likely after exposure to breast milk[130] and not congenital infection. Urine and saliva are the clinical samples of choice for virus detection. Although the "gold standard" for CMV diagnosis has traditionally been viral shell vial culture, PCR has better sensitivity,[131–134] and fewer laboratories are offering viral culture. Thus, CMV culture has largely been replaced by PCR.

Serologic tests are of limited utility in the diagnosis of congenital CMV. Unlike IgG which can reflect maternal antibodies, the presence of IgM antibodies to CMV in cord or neonatal blood represents fetal antibody response. However, IgM serologic tests lack sensitivity and cannot be relied on for diagnosis of congenital CMV infection.[135]

A retrospective diagnosis of congenital CMV in an infant determined to be CMV infected after the first 3 weeks of life can be done by CMV DNA PCR testing of the dried blood spot (DBS) samples collected for newborn screening. The sensitivity of DBS testing depends on the characteristics of the PCR assay performed and is reported to be between 70% and 95%.[23,136,137] Because DBSs are stable in storage for several years, retrospective diagnosis of congenital CMV infection can be made in older infants with identified SNHL.[138,139]

Infants diagnosed with congenital CMV should receive a comprehensive evaluation to identify unapparent signs of symptomatic disease as these may affect treatment recommendations and prognosis. This would include a complete blood count, liver function tests, hearing evaluation, eye examination, and cranial imaging.[140] CMV DNA PCR from blood should be considered at baseline as viral levels in the congenitally infected infant may be associated with long-term outcome.[141–144] Because the finding of CNS disease is a potential harbinger of permanent sequelae, diagnostic CNS imaging is warranted in all suspected cases of congenital infection.[83,84,90,95,145–147] Ultrasonography is an appropriate initial study and is particularly sensitive in detecting periventricular calcifications and lenticulostriate vasculopathy. For symptomatic infants and those with abnormal findings on cranial ultrasound, MRI may provide important additional information. Therefore, the staged sequential use of an initial cranial ultrasound followed by MRI is probably the preferred approach to CNS imaging in this setting. Ophthalmologic evaluations are particularly important for symptomatic infants. Asymptomatic

infants with normal eye exams are unlikely to develop later abnormalities.[99,100]

All congenitally infected infants, regardless of the results of functional hearing assessment at birth, should be monitored prospectively for SNHL.[101,140,148] Children with congenital CMV, whether symptomatic or not, should have neurodevelopmental assessment and follow-up with early intervention if indicated.[140,148]

Mothers of infants with congenital CMV infection should be counseled regarding future pregnancies. For infants with symptomatic congenital CMV infection born to women with low CMV IgG avidity antibodies,[149] some authorities recommend monitoring for the emergence of high-avidity antibody before future pregnancies are contemplated.

Management

The benefits of ganciclovir in neonates with symptomatically congenital CMV have been demonstrated in controlled trials. Neonates with virologically confirmed symptomatic congenital CMV disease involving the CNS who received a 6-week course of IV ganciclovir therapy had a statistically higher likelihood of normal or improved hearing at 6 months of age compared with untreated neonates.[150] Infants in this trial who received IV ganciclovir therapy also had fewer developmental delays at 6 and 12 months, as assessed by the Denver Developmental Screening Test, compared with untreated infants.[151] A subsequent study compared 6 weeks versus 6 months of oral valganciclovir in neonates with symptomatic congenital CMV disease. In this study, all participants received valganciclovir for 6 weeks. Participants were then randomized to receive either continued valganciclovir therapy or placebo for 4.5 months. Hearing was more likely to be improved or to remain normal at 12 and 24 months in the 6-month treatment group than in the 6-week treatment group, and this group also had better neurodevelopmental scores on the Bayley Scales of Infant and Toddler Development at 24 months.[152] Six months of oral valganciclovir therapy (Table 34.2) should thus be considered for all neonates with symptomatic congenital CMV infection with any evidence of CNS involvement (microcephaly, abnormal CNS imaging, CSF positive for CMV DNA, chorioretinitis, or evidence of SNHL). Careful monitoring for neutropenia, the major side effect of valganciclovir therapy, is essential.

Ganciclovir therapy should also be used in any infant with severe or life-threatening end-organ CMV disease (see Table 34.2), whether acquired via congenital infection or by a postnatal route, such as via breastfeeding in a low birth weight premature infant.[153] CMV chorioretinitis, if present, should be managed in consultation with an ophthalmologist and infectious diseases expert and may require prolonged ganciclovir treatment.[154]

TABLE 34.2 Antiviral Agents Commonly Used in Neonatology Practice

Antiviral Agent	Indication	Dose, Route of Administration, Duration of Therapy	Comments
Acyclovir	Neonatal HSV infection	20 mg/kg/dose every 8 h intravenously; 21 days for disseminated or CNS disease; 14 days for SEM disease	Monitor CBC twice weekly; adjust dosage for renal insufficiency.
	Oral suppression following neonatal HSV infection	300 mg/m²/dose, three times a day; duration of therapy, 6 months	Neutropenia observed in half to two-thirds of infants
	VZV infection	10 mg/kg/dose every 8 h for a minimum of 5–7 days	Longer courses may be needed for severe end-organ disease (pneumonia, hepatitis)
Trifluridine, 1%	HSV ophthalmic disease	Apply as eye drops; one drop every 2 h to the affected cornea while awake; maximum nine drops per day	Treat in consultation with an ophthalmologist.
Ganciclovir	Symptomatic congenital CMV infection unable to take oral therapy; acquired symptomatic CMV infection	6 mg/kg/dose every 12 h intravenously; duration of 14–21 days for serious end-organ disease—6 weeks for prevention of hearing loss in infants with congenital disease or until able to take oral valganciclovir	Efficacy against CMV-associated hearing loss in controlled trial; benefits of shorter courses of therapy unknown; neutropenia observed in 63% of patients in controlled trial; adjust dose for renal insufficiency; consider use of G-CSF if continued therapy desired in the setting of neutropenia
Valganciclovir	Symptomatic congenital CMV infection	16 mg/kg/dose, twice daily for 6 months	Valine ester (prodrug) of ganciclovir; toxicity profile similar to that of ganciclovir; theoretical concerns of carcinogenesis, gonadal toxicity
Oseltamivir	Influenza A virus infection, influenza B virus infection	Treatment: Infants <9 months: 3 mg/kg/dose oral twice daily for 5 days (maximum 30 mg) Infants 9–12 months: 3.5 mg/kg/dose oral twice daily for 5 days (maximum 30 mg) Prophylaxis: same doses as above given once daily for 10 days	Dose adjustments required for premature infants

CBC, Complete blood cell count; *CMV*, cytomegalovirus; *CNS*, central nervous system; *G-CSF*, granulocyte colony-stimulating factor; *HSV*, herpes simplex virus, *SEM*, skin, eye, or mucous membranes; *VZV*, varicella–zoster virus.

Although ganciclovir/valganciclovir improves hearing and neurodevelopmental outcomes for symptomatic infants when initiated within the first month of life, it is not yet clear whether valganciclovir holds the promise of improving outcomes in infants with asymptomatic congenital CMV infection, or for infants presenting outside the neonatal period with isolated SNHL. A clinical trial is ongoing to determine whether valganciclovir therapy could prevent progression of hearing loss in older infants with isolated SNHL.[155]

Ganciclovir has been demonstrated to cross the placenta, and therefore could theoretically be used to treat CMV infection in utero,[156] however there are concerns for potential teratogenicity.[157] There have been case reports of treatment of congenital CMV infection in utero with valganciclovir,[158,159] but no systematic trials. High-dosage oral valacyclovir therapy (8 g/day) in recent studies has been found to be safe and to decrease the risk of fetal CMV infection and symptomatic congenital disease.[160,161]

Passive immunization with CMV human immunoglobulin (HIG), a pooled, high-titer immunoglobulin preparation, has been studied for in utero treatment and prevention of congenital CMV infection. Reduction in congenital infection and symptomatic neonatal disease has been seen in CMV HIG-treated pregnant women in several uncontrolled unblinded studies.[162–164] However, other observational studies[165] and a randomized, blinded placebo-controlled trial of CMV HIG for the treatment and prevention of congenital CMV infection failed to demonstrate a benefit.[166] A National Institutes of Health-funded multicenter randomized, placebo-controlled trial of CMV HIG during pregnancy in the setting of primary maternal infection was recently stopped early due to futility with no significant difference in transmission between the treatment and placebo arms of the study.[167] Therefore, it remains unclear if CMV HIG is useful in prevention of viral transmission or sequelae.

Prevention

One important strategy for addressing the problem of congenital CMV infection is the education of women of childbearing age about the risks of CMV transmission and strategies for prevention. Because most maternal CMV infections are asymptomatic, a major goal is education of all women of childbearing age on hygienic practices.[168–170] Hygienic strategies are important because the saliva and urine of infected children are significant sources of CMV infection among pregnant women. Strategies include washing hands whenever there is contact with a child's saliva or urine, not sharing food, utensils, or cups, and not kissing a child on the mouth or cheek.[171–173] In several surveys, only 14% to 30% of women had previously heard of CMV.[174,175] Therefore, educating women on methods to prevent CMV transmission may be effective to decrease seroconversion during pregnancy.[173,176–178]

Prenatal maternal screening for CMV antibodies is controversial. Women who are CMV immune can be infected with new strains with subsequent fetal infection and developmental sequelae.[42,43,45,179] A positive preconception titer result for CMV IgG antibody may provide a false sense of reassurance and decrease a pregnant woman's motivation to engage in careful hygienic practices.

Ultimately the control of congenital CMV infection could be realized by the development of an effective vaccine. No CMV vaccines are currently licensed; however, multiple candidate vaccines are in various stages of development including in active clinical trials.[180]

Rubella

Rubella virus is an enveloped, single-stranded, positive-sense RNA virus belonging to the family *Togaviridae*. Humans are the only known natural host for rubella virus. Rubella usually results in a mild illness with an accompanying exanthem in adults and children; however, rubella infection during pregnancy can produce serious fetal anomalies. An ophthalmologist, Norman Gregg, offered the first description of congenital rubella syndrome (CRS) in 1941 while investigating an epidemic of neonatal cataracts.[181,182] Not until the global pandemic of 1964 to 1965, however, were the multiple teratogenic manifestations of CRS, including permanent neurodevelopmental consequences, fully appreciated. The introduction of rubella vaccine in 1969 led to an immediate reduction in the incidence of CRS in the United States and other developed countries[183] and now most cases occur in women who contracted rubella in countries without widespread vaccine coverage.[184–187]

Epidemiology

The annual incidence of rubella cases has decreased dramatically from 58 per 100,000 population in 1969 to only 10 cases reported in the US in 2012.[188,189] CRS cases in the United States have demonstrated a similar dramatic decline, and in 2004 the CDC concluded that endemic rubella had been eliminated from the United States.[190–192] Rubella is still an important and potentially preventable cause of birth defects globally, with more than 100,000 cases of CRS occurring annually in developing countries in the last decade (Table 34.3).[193] This number is likely lower now as significant progress toward elimination of rubella has been made worldwide, although there are still countries with suboptimal national vaccination programs.[194–198]

The frequency of congenital infection after maternal rubella is 70% to 85% if infection occurs during the first 12 weeks of gestation, 30% to 54% during the first 13 to 16 weeks of gestation, and 10% to 25% at the end of the second trimester.[199,200] The classic findings of congenital rubella are most typically associated with the onset of maternal infection during the first 11 weeks of gestation,[199] and the risk of any teratogenic effect is extremely low after 17 weeks' gestation.[201]

Pathogenesis

Rubella virus is transmitted via respiratory droplets. Viral replication begins in the upper respiratory tract and nasopharyngeal lymphoid tissue, followed by contiguous spread to regional lymph nodes and hematogenous dissemination to distant sites. Fetal infection is believed to occur as a consequence of maternal viremia. The mechanism by which fetal rubella infection leads to teratogenesis has not been fully determined, but the cytopathology in infected fetal tissues suggests necrosis, apoptosis, or both, as well as inhibition of cell division of precursor cells involved in organogenesis.[201,202] Macrovascular fetal endothelial cells have been found to be highly permissive for rubella virus replication, suggesting that the vascular diseases in CRS are triggered by persistent rubella virus infection of endothelial cells.[203,204]

Clinical Presentation

The typical illness in adults and children with acquired rubella consists of an acute generalized maculopapular rash, fever, and arthralgias, arthritis, or lymphadenopathy. Conjunctivitis

TABLE 34.3 Clinically Important but Uncommon Causes of Congenital Infection

Virus	Epidemiology	Pathology	Clinical Presentation (Neonates)	Diagnosis of Fetal/Infant Infection	Management	Prevention	Outcome
Coxsackie B	Congenital infection quite rare	Direct viral myocardial injury	Newborns often asymptomatic, develop heart failure in first week	PCR	Supportive care	None available	Persistent myocardial dysfunction in 33%–66%
HHV-6	Generally acquired prior to age 2, but *in utero* transmission very rare	Can be chromosomally integrated	Asymptomatic in newborns; roseola infantum, febrile seizures	PCR	Supportive care	None available	Possible neurodevelopmental concerns with germline transmission
LCMV	Very rare	Viral- and immune-mediated brain injury	Chorioretinitis, microcephaly, hydrocephalus, neural migration defects	Infant serum, CSF PCR; maternal serology	Supportive care	Avoid rodent exposures in pregnancy	Mortality 35%, neurologic sequelae in 63% of survivors
Parvovirus B19	~1% seroconversion during pregnancy; 25%–50% fetal infection with 3%–12% adverse fetal outcome	Cytotoxic to fetal red blood cells	Risk for fetal hydrops	Amniotic fluid, cord blood PCR	Serial prenatal ultrasounds and IUT for fetal anemia/hydrops	None available	Mortality 15%–25% for severe fetal hydrops even with IUT, slight risk for neurodevelopmental abnormalities in infants requiring IUT
Rubella	Rare in the United States; CRS remains an important cause of birth defects in countries without adequate maternal immunization	Infection of fetal tissues	See Table 34.4	Serology, PCR	Supportive care	Vaccine	Neurologic/neurodevelopmental abnormalities, SNHL, autoimmune disorders
Varicella	CVS—very rare	Destruction of neural tissue	Cicatricial skin lesions, limb hypoplasia, eye abnormalities	Amniotic fluid PCR	Supportive care	Maternal vaccine pre-conception; VariZIG for maternal exposure during pregnancy	Mortality CVS 30%, developmental delay common
Zika	6%–17% of affected pregnancies develop congenital anomalies; 14% have fetal loss	Viral perturbation of neural development	Microcephaly, intracranial calcifications, retinal abnormalities	Infant PCR and IgM	Supportive care	Avoid travel to endemic countries, insect repellent	Visual and/or hearing impairment frequent; developmental delay common even if asymptomatic at birth

CVS, Congenital varicella syndrome; *HHV*, human herpesvirus; *IUT*, intrauterine transfusion; *LCMV*, lymphocytic choriomeningitis virus; *PCR*, polymerase chain reaction.

is also common. Viremia can be detected as early as 9 days prior to the onset of rash. Up to 50% of primary infections are asymptomatic.

Infants with congenital rubella are usually born at term but are often small for their gestational age. Transient manifestations may include skin lesions described as resembling a blueberry muffin which represent extramedullary dermal hematopoiesis,[205–208] thrombocytopenia, hyperbilirubinemia, and leukopenia, hepatosplenomegaly, jaundice, pneumonia, and meningoencephalitis. Radiographic findings include a large anterior fontanel, linear areas of radiolucency in the long bones (i.e., celery stalking), increased densities in the metaphysis, and irregular provisional zones of calcification.[209,210] Permanent findings include SNHL, heart defects, eye abnormalities, neurologic defects, and developmental delay (Table 34.4).[196,208] The most common isolated finding of congenital rubella is SNHL.[199,211] Cardiac lesions are noted in 45% to 70% of infants with the most common abnormalities being patent ductus arteriosus, peripheral pulmonic stenosis, and valve abnormalities.[212–214] Ocular findings include cataracts, pigmentary retinopathy, microphthalmia, glaucoma, and strabismus. The triad of deafness, cataracts, and congenital heart disease constitutes the classic CRS.[215]

The clinical manifestations of CRS differ to some extent depending on the timing of fetal infection. In a prospective study following up pregnant women with confirmed rubella by trimester, a full range of rubella-associated defects (including congenital heart disease and deafness) were observed in nine infants infected before the 11th week. Thirty-five percent of infants (9 of 26) infected between 13 and 16 weeks' gestation had deafness alone.[199]

Evaluation

Diagnosis of congenital rubella syndrome is based on both clinical and laboratory findings. In the first year of life, laboratory evidence of congenital rubella infection can be demonstrated by a positive rubella IgM titer; infant rubella IgG level that persists at a higher level and for a longer period than expected from passive transfer of maternal antibody; isolation of rubella virus from nasal, blood, throat, urine, or CSF samples; or detection of viral nucleic acid by PCR from the throat, CSF, or lens (obtained during cataract surgery). An infected infant can shed the virus for many months after birth despite the presence of neutralizing antibody and thus may pose a hazard to susceptible individuals.[216]

Women who are exposed to rubella during pregnancy should be screened for evidence of previous immunity. If rubella IgG is detectable at the time of exposure, the fetus is probably protected. If no antibody is detectable, additional samples for rubella IgG and IgM should be obtained at 2 to 3 weeks after exposure and again at 4 to 6 weeks after exposure. These samples can be run concurrently with the first serum sample to ascertain whether infection has occurred (i.e., seroconversion).[48]

TABLE 34.4 Manifestations of Congenital Rubella

Transient	Permanent	Delayed Onset

• Low birth weight
• Extramedullary dermal hematopoiesis
• Thrombocytopenia
• Hyperbilirubinemia
• Leukopenia
• Hepatosplenomegaly
• Pneumonia
• Meningoencephalitis
• Linear radiolucent areas in the long bones
• Metaphyseal densities
	• Sensorineural hearing loss
	• Heart defects
	  • Patent ductus arteriosus
	  • Peripheral pulmonic stenosis
	  • Valve abnormalities
	• Eye defects
	  • Cataracts
	  • Pigmentary retinopathy
	  • Microphthalmia
	• Microcephaly
	• Developmental delay
		• Abnormal dental development
		• Autoimmune diseases
		  • Diabetes
		  • Thyroid disease
		• Immunologic abnormalities
		• Progressive panencephalitis
		• Ophthalmologic
		  • Glaucoma
		  • Uveitis

Management

There is no specific antiviral therapy for congenital rubella. Initially the infant may need general supportive care, such as administration of blood transfusion for anemia or active bleeding, seizure control, and phototherapy for hyperbilirubinemia.

Outcomes

Long-term care requires a multidisciplinary approach consisting of occupational and physical therapy, close neurologic and audiologic monitoring, and surgical interventions as needed for cardiac malformations and cataracts.[217] Over half of surviving infants have neurologic and/or developmental abnormalities,[208,218] which may not be diagnosed until the infants are older. Other delayed manifestations include late-onset glaucoma and other ophthalmologic abnormalities,[218,219] progressive SNHL, autism spectrum disorders,[208,220] progressive rubella panencephalitis, abnormal dental development,[221] and immunologic and autoimmune endocrine disorders (see Table 34.3). A higher-than-expected incidence of autoimmune diseases, such as thyroid disorders and diabetes mellitus, has also been reported years after the diagnosis of congenital rubella.[181,213,222,223] Delayed onset immunologic abnormalities include abnormalities in immunoglobulin levels[224–227] and cellular immune responses.[228–230]

Prevention

The critical intervention in prevention of CRS is to ensure that women who are considering pregnancy get appropriately vaccinated. The Advisory Committee on Immunization Practices recommends screening of all pregnant women for rubella immunity and postpartum vaccination of those who are susceptible.[231] Immunity to rubella appears to confer almost complete protection against CRS. Rare cases of documented subclinical maternal reinfection with rubella virus leading to CRS have been reported.[232–235]

Live attenuated rubella virus vaccine is safe and effective, although the duration of immunity is uncertain. Rubella vaccine is currently administered in the United States in a trivalent formulation in combination as measles–mumps–rubella (MMR) vaccine. The vaccine is recommended for children at 12 to 15 months of age and at 4 to 5 years of age. It is also recommended for women of childbearing age in whom the results of both a hemagglutination inhibition antibody test and a pregnancy test are negative. Although no cases of symptomatic congenital rubella have been reported after vaccination during pregnancy in the more than 500 cases monitored, vaccination is not recommended during pregnancy because of the theoretical hazard to the fetus.[236–238]

If a pregnant woman is found to be nonimmune, vaccine should be administered during the immediate postpartum period before discharge. Breastfeeding is not a contraindication to postpartum immunization. Immunization in the postpartum period has rarely produced polyarticular arthritis, neurologic symptoms, or chronic rubella viremia.[239] Immune globulin does not prevent rubella infection after exposure and is not recommended for routine postexposure prophylaxis in pregnancy.[240,241]

Human Parvovirus B19

Parvovirus B19, a small, single-stranded DNA virus, is the only member of the parvovirus family that causes human disease. Primary infection with parvovirus B19 is commonly known as *fifth disease* or *erythema infectiosum* and is classically described as a childhood exanthem with a "slapped cheek" appearance.[242] The spectrum of parvovirus B19-associated disease continues to expand and includes neurologic disease, arthritis, autoimmune disease, hematologic disease, and other dermatologic manifestations.[243–247]

Epidemiology

Parvovirus B19 infection is common in childhood and continues at a low rate throughout adult life. The virus is spread primarily by respiratory droplets[248] but can also be transmitted by blood products[249] and transplacentally.[250,251] Seroprevalence in the population varies by age and geographic location, but averages about 40% to 60% in women of childbearing age.[251–254] Seroconversion during pregnancy is reported to be about 1% with increased rates noted during periodic epidemics.[253]

It is estimated that one-fourth to half of maternal parvovirus B19 infections result in transmission of infection to the fetus.[255–257] The spectrum of diseases associated with parvovirus B19 infection remains incompletely defined, as there is no routine surveillance during pregnancy; however, most pregnancies are unaffected. The overall risk of adverse fetal outcome is between 3% and 12%.[250,257,258] The risk of adverse fetal outcome is increased if maternal infection occurs before 20 weeks' gestation.[255,257–261]

Pathophysiology

Fetal infection most likely occurs transplacentally during maternal viremia. Parvovirus B19 binds to a glycolipid receptor (P-antigen or globoside) present on erythroid progenitor cells[262,263] and placental trophoblasts.[264] P-antigen expression by villous trophoblasts is gestation dependent and is highest in the first trimester.[264] It has been postulated that parvovirus B19 infection leads to cytotoxicity and subsequent anemia by inducing apoptosis of infected red blood cells.[265,266] The virus targets the erythroid lineage cells in the fetal liver, the primary site of erythrocyte production in the fetus.[267] The fetus is especially susceptible to adverse consequences of red blood cell infection secondary to the intrinsic short fetal erythrocyte life span and rapidly expanding blood volume, especially during the second trimester. The P-antigen is also expressed on fetal cardiac myocytes, enabling parvovirus B19 to infect myocardial cells,[268] leading to myocarditis.[269,270] Myocarditis induced by parvovirus B19 can contribute to high-output cardiac failure, and the myocardial inflammation and subendocardial fibroelastosis may also contribute to fetal hydrops.[271,272]

Clinical Presentation

Parvovirus B19 infection causes *erythema infectiosum* in normal hosts, aplastic crisis in patients with hemolytic disorders, and chronic anemia in immunocompromised hosts. A substantial proportion of infected adult women may also have arthropathy in association with parvovirus B19 infection.[273] Once the virus establishes infection, viremia occurs, accompanied by mild systemic symptoms such as fever and malaise. Viremia is short-lived, lasting only 1 to 3 days, and the characteristic immune-mediated rash develops 1 to 2 weeks later. Once the rash appears, an individual is no longer infectious. Infection with parvovirus B19 infection during pregnancy may be asymptomatic more than half of the time.[255,256]

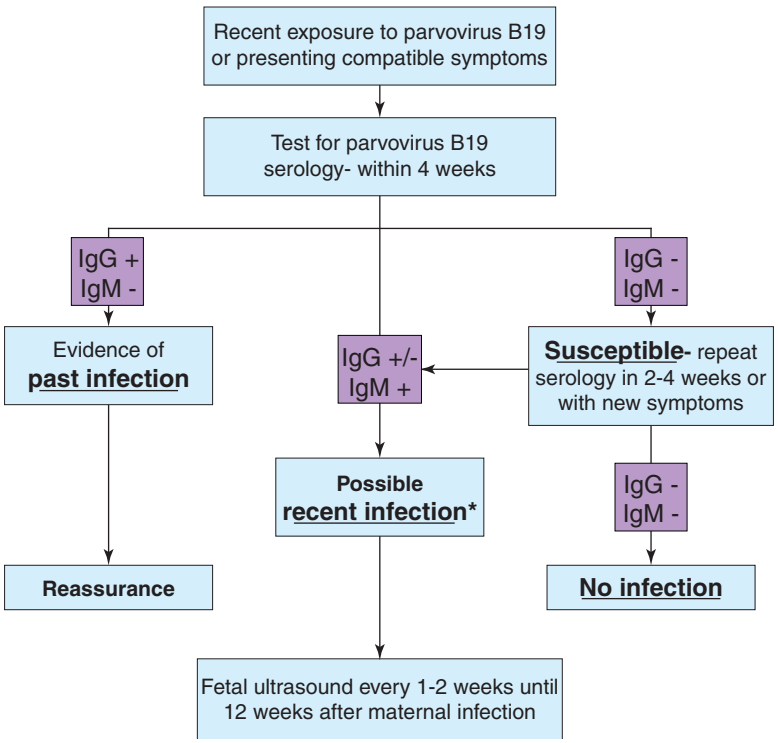
The major clinical presentation of parvovirus B19 infection in the fetus is nonimmune hydrops fetalis (NIHF). Various estimates suggest that human parvovirus B19 infection contributes from 10% to 27% of cases of NIHF.[274–276] The risk of NIHF secondary to maternal parvovirus B19 infection is between 4% and 12% in most reports and is highest for women who acquire parvovirus B19 infection between 13 and 20 weeks' gestation.[250,251] NIHF usually develops 2 to 8 weeks after maternal parvovirus B19 infection.[257] The role that parvovirus B19 plays in intrauterine fetal demise in the absence of hydrops fetalis is incompletely defined. Some studies show increased risk of fetal loss, spontaneous abortion, and stillbirth,[277–279] while others do not.[280,281] The estimated risk of fetal loss in infants infected with parvovirus B19 prior to 20 weeks gestation is 13% and decreases to 0.5% after 20 weeks' gestation.[282]

Parvovirus B19 has been implicated in some cases of congenital anemia.[283–286] Investigation for parvovirus B19 infection should be included in the evaluation for congenital anemias. Thrombocytopenia is common in parvovirus B19-infected fetuses with NIHF. In one series, 46% of fetuses with parvovirus B19-associated NIHF had severe thrombocytopenia.[287]

Evaluation

In children and adults, the diagnosis of human parvovirus B19 infection is most commonly made clinically through recognition of the characteristic rash. Women exposed to parvovirus B19 during pregnancy should be tested for virus-specific IgG and IgM antibodies. Those who are IgG positive and IgM negative are immune and therefore not at risk for infection. Women who are IgM and IgG negative should be monitored for seroconversion by repeat serologic testing in 4 weeks. Women who develop anti-parvovirus B19 antibodies or who demonstrate parvovirus B19 IgM at initial testing should be monitored for potential fetal infection (Fig. 34.3).[288] Parvovirus B19 DNA can be detected in plasma of infected women early in the course of infection and is more sensitive than serology for diagnosis of acute infection. A combination of serology and PCR can be used to improve the accuracy of diagnosis.[251,255,289]

Pregnant mothers with evidence of acute infection should be counseled regarding risks of fetal transmission, fetal loss, and hydrops, and serial ultrasound examinations should be performed every 1 to 2 weeks, up to 12 weeks after acute infection, to detect development of anemia and hydrops.[251,282,288] Monitoring should include assessment for ascites, placentomegaly, cardiomegaly, hydrops fetalis, and impaired fetal growth. Middle cerebral artery Doppler imaging for peak systolic velocity should



• **Fig. 34.3** Management algorithm for parvovirus B19 exposure during pregnancy. *If IgG–, IgM+ can confirm with repeat serology in 1 to 2 weeks or maternal plasma polymerase chain reaction. (Adapted from Crane J, Mundle W, Boucoiran I, et al. Parvovirus B19 infection in pregnancy. J Obstet Gynaecol Can. 2014;36[12]:1107–1116.)

be performed as this is an accurate predictor of fetal anemia which can be detected with this technique before fetal hydrops is evident.[290] Maternal parvovirus B19 infection should also be considered when prenatal ultrasounds show evidence of fetal anemia, cardiomegaly, or hydrops fetalis. As fetal manifestations of parvovirus B19 infection occur weeks after maternal infection, absence of maternal parvovirus B19 IgM or plasma B19 DNA does not exclude infection. In one study,[289] women tested due to suspicion of fetal infection were IgM positive 62.5% and DNA PCR positive 87.5%. Detectable parvovirus B19 DNA by PCR in amniotic fluid or fetal blood establishes the diagnosis in the fetus.[288,289]

Management

Spontaneous resolution of fetal anemia without hydrops has been reported in about 50% of fetal infections, however, spontaneous resolution of hydrops is less common (5% to 30%).[291,292] Because most fetuses do not recover without intervention, fetal transfusion is usually recommended.[288,293,294] The earlier intrauterine transfusion (IUT) is attempted, the more likely it is to be successful. Cordocentesis allows precise assessment of the magnitude of fetal anemia, which can then be corrected by blood transfusion, typically using packed red blood cells. With this approach, outcomes have been favorable in most reported series, even among severely anemic fetuses. Because of the frequency of concurrent thrombocytopenia, platelet transfusion is also frequently required at the time of IUT.[251,295,296] Small studies suggest a survival rate of 76-85% for fetuses with severe hydrops fetalis who receive IUT, compared to 100% mortality for non-transfused fetuses.[259,297] Although high-dose IVIG has been used in the setting of acute infection to attempt to prevent hydrops fetalis during pregnancy,[298] treatment with this modality in the pregnant woman has not been shown to improve fetal outcomes.

Outcomes

Results from several long-term prospective studies of infants born to mothers with documented primary parvovirus B19 infection during pregnancy found no evidence of increased risk of long-term morbidity, development delay, or death in childhood.[299–301] Increasingly, however, there have been reports of neurologic morbidity in infants surviving severe anemia or NIHF due to parvovirus B19. Structural brain abnormalities have been seen in infants with severe anemia or NIHF,[292,302] including small cerebellum,[302] polymicrogyria,[303,304] and heterotopia.[303] Neurologic abnormalities have been noted on follow-up in approximately 10% of infants surviving IUT for B19-associated NIHF.[292,305]

Prevention

There has been limited progress in the development of a candidate parvovirus B19 vaccine. At the current time, routine screening of pregnant women for parvovirus B19 is not recommended.[288] If a pregnant woman has a significant exposure to an infectious case of parvovirus B19, counseling should be provided regarding the potential risk of infection and testing and follow-up as described above should be recommended.

Pregnant healthcare providers should be counseled about the potential risks to their fetus from parvovirus B19 infections. They should consider not caring for immunocompromised patients

with chronic parvovirus B19 infection or patients with parvovirus B19-induced aplastic crises, or should, at a minimum, follow strict infection control procedures including standard droplet precautions.[306]

Zika Virus

Zika virus is a single-stranded RNA virus of the Flavivirus family that was first isolated in 1947 from the Zika forest of Uganda.[307,308] For many years Zika remained endemic in central Africa and was known to cause a mild febrile illness. In the early 2000s another lineage of the virus in Asia and the South Pacific caused several outbreaks, and this Asian lineage Zika virus has been associated with Guillain-Barré syndrome.[309] It was during a global outbreak centered in Brazil and the Americas in 2015–2016 that Zika was identified as a fetal pathogen.[310] Infection by Zika virus of either lineage in infants, children, and adults is generally mild. In contrast, maternal infection with the Asian lineage can cause severe fetal anomalies including intracranial calcifications, microcephaly, and intrauterine demise (see Table 34.3).

Epidemiology

Like many flaviviruses, Zika is spread through mosquito vectors, in this case primarily *Aedes aegypti*. The virus is therefore limited to the equatorial range of this mosquito, although climate change is predicted to enlarge this range.[311] The primary reservoirs are thought to be humans and non-human primates. In addition to blood, Zika virus can be isolated from seminal fluid (as long as 69 days after initial infection) and, to a lesser extent, from saliva, vaginal fluid, and breast milk. Sexual transmission has been well documented. Although it likely only contributes to a small percentage of overall cases, sexual transmission can contribute to new cases in non-endemic areas.[312] Transmission via breast milk has been proposed but documented evidence is quite rare.[313,314] Zika transmission is seasonal. Although cases can occur any time during the year, the majority occur during summer months. Serological studies have demonstrated a relatively high prevalence in endemic areas: 10% in Southeast Asia[315] and 13% in West Africa.[316] At the peak of the outbreak in the Americas in the first half of 2016 seroprevalence reached levels as high as 63%.[317] While new cases in the Americas have decreased sharply since 2016, local spread continues in endemic areas including West Africa, the Caribbean, and Southeast Asia. Fetal anomalies have only been associated with the Asian lineage of Zika and have been documented in the Americas, Southeast Asia,[318,319] and Africa.[320] Up-to-date epidemiologic data is available through the World Health Organization (WHO).[321]

Pathophysiology

Initial inoculation with Zika virus is followed by an incubation period estimated to last 6 days (range: 3 to 14), followed by a symptomatic phase that corresponds to viremia and typically lasts for 5 to 6 days.[322,323] In a pregnant mother, the virus can gain access to the fetus via transplacental spread. Zika has a high degree of tropism for placental trophoblasts and the fetal central nervous system, establishing infection in these tissues that may persist for months.[324–326] For Zika infection, as for most congenital infections that cause fetal anomalies, the consequences for fetal development are worst when infection occurs late in the first or early in the second trimester.[327,328] Congenital Zika syndrome (CZS) includes a heterogeneous set of anomalies that reflect the virus' tropism for neural tissue and harmful consequences on brain development: microcephaly, thin cerebral cortex with subcortical calcifications, retinal abnormalities, congenital contractures, and early hypotonia.[329] The mechanism underlying these findings remains the subject of active investigation, but the pattern of injury mimics fetal brain disruption sequence, a syndrome in which loss of cells in the brain parenchyma results in collapse of the fetal skull during development.[330] Viral infection of neural progenitor cells is thought to be central to CZS, leading to disruption of the fetal brain either by directly causing cell death, altering developmental programs, or inducing a type I interferon response.[331–336] Epidemiological studies have only linked CZS to Asian lineage Zika virus. There is speculation that this is because congenital infection with African lineage viruses results in severe pathology and ultimately loss of pregnancy, whereas pathology resulting from Asian lineage virus infection is less severe resulting in a viable pregnancy, albeit with abnormal development.[337,338]

Clinical Presentation

It is important to recognize that severe microcephaly frequently depicted in the media is at one end of the CZS spectrum, which ranges from asymptomatic to intrauterine demise. Among pregnancies affected by maternal Zika infection, an estimated 6% to 17% develop congenital anomalies, while fetal loss may occur in as many as 14%.[339–342] Neonatal mortality in the first week of life may be as high as 4% to 7%.[341,342] Identified risk factors associated with death in CZS include low birth weight, prematurity, and 5-minute APGAR less than 7.[343] Microcephaly is by far the most common clinical finding described in CZS, occurring in as many as 91% of affected infants.[344] Additionally, the spectrum of structural neurologic abnormalities includes (in order of decreasing frequency): intracranial calcifications, increased ventricular and extra-axial fluid spaces, cortical thinning with abnormal gyral patterns, hypoplasia of the corpus callosum, decreased myelination, and cerebellar hypoplasia.[329] Notably, intracranial calcifications in CZS are typically subcortical and not periventricular as in CMV (Fig. 34.4). Even in infants with normal neuroimaging, as many as 10% may have functional neurologic impairment (see outcomes, below).[345] Eye abnormalities are also frequently seen (24% to 55% of cases). Microphthalmia, focal pigmentary mottling, and chorioretinal atrophy are the most common, but cataracts, intraocular calcifications, and optic nerve findings have been described.[346–348] Sensorineural hearing loss appears to be less common, affecting approximately 6% of infants with microcephaly.[349] Congenital contractures have been reported in approximately 10% of microcephalic CZS cases and may be related to loss of upper motor neurons or pathology within spinal cord and nerve roots.[350,351]

In children and adults, acute Zika virus infection is symptomatic in only 20% to 50% of cases.[352] Symptoms are generally mild and include headache, arthralgia, myalgia, non-purulent conjunctivitis, erythematous (and often pruritic) rash, and lower back pain.[341] Perinatal and postnatal acquisition of acute Zika virus infection in infants has only rarely been described, but case reports and animal data suggest very young children may be at higher risk for neurologic complications.[353]

Evaluation

Laboratory diagnosis of acute Zika virus infection relies on PCR of serum or urine, which should be obtained within 7 days of

symptom onset. Serologic testing (particularly IgM) is unreliable due to cross-reactivity of Zika and dengue antibodies, and persistence of Zika IgM beyond the initial infectious period. Laboratory abnormalities in the setting of acute Zika virus infection are often nonspecific and may include leukopenia, thrombocytopenia, and elevated hepatic function tests.[354] Interestingly, hematologic, hepatic, or renal abnormalities have not been documented in infants born with congenital Zika infection.[329]

The CDC has issued guidance on testing for pregnant women who may have had Zika virus exposure, including a screening tool for providers to help evaluate the risk level for infants who may have been exposed to Zika virus in utero.[355] In general, risk of exposure is defined as travel to Zika-endemic areas or sex with a partner with travel or residence in these areas. Testing of asymptomatic patients (including pregnant women) is not recommended even with Zika virus exposure. For pregnant women who do have symptoms, testing for Zika virus and dengue virus by PCR can be considered. For women who have Zika exposure and a fetus with ultrasound findings consistent with CZS, PCR from maternal serum and urine and IgM are recommended; testing of amniotic fluid or placental and fetal tissues may be considered depending on level of concern.

For infants with findings suggestive of CZS, or documented maternal infection with Zika virus during pregnancy, a comprehensive physical examination (including growth parameters) and additional laboratory evaluation of the newborn is recommended.[356] As of 2017, CDC guidance recommends the following screening evaluation for all infants with in utero Zika exposure: Zika PCR (from serum and urine) and IgM (serum) obtained perinatally, head ultrasound, comprehensive ophthalmologic examination, and automated auditory brainstem response testing performed before one month of age. In addition, for infants with any findings concerning for CZS, PCR and IgM testing from CSF can be considered. In an infant with findings consistent with CZS, the differential diagnosis should include infectious etiologies including CMV, rubella, toxoplasmosis, syphilis, and HIV. Congenital abnormalities due to infections with related flaviviruses, such as West Nile virus, have been described[357] but appear to be far rarer than CZS.[358,359] Genetic etiologies should also be considered including Aicardi-Goutières Syndrome, and mutations in JAM3, NDE1, and ANKLE2 genes.[329] There has been description of familial fetal brain disruption sequence, although a genetic diagnosis has not been defined. Additional specificity may be obtained by considering the differential for individual findings, as in Table 34.1. For infants with Zika exposure, close follow up is warranted with attention to neurodevelopmental, vision, hearing, and growth parameters. For infants where there is concern for CZS, referral to a neurodevelopmental specialist, early intervention services, and provision of additional family support is recommended.

Management

As of 2021, no specific medication has been developed for the treatment of infection due to Zika virus or any other flaviviruses, despite active research in this area.[360,361] The success of nucleotide analog drugs that are highly effective in treating the closely related hepatitis C virus offers promise, and many of these drugs are being investigated for repurposing to treat Zika infection.[362] Vaccine development is also an active field of Zika research, and several vaccines have entered Phase I and II trials.[363]

Avoidance of travel to high-risk areas currently is the most reliable prevention strategy for men and women of reproductive age. If Zika-endemic areas are unavoidable, the WHO recommends use of an FDA-approved insect repellant (e.g. DEET, IR3535, or Icaridin) as well as the use of personal nets when sleeping or resting.[364] The WHO also has extensive guidelines for limiting transmission and avoiding CZS, which include the following: women should not engage in sex that could lead to conception for 2 months after known or presumptive infection with Zika virus, while men should abstain from sex or use condoms to prevent transmission for 3 months after known or presumptive infection.[365] Mosquito vector control is also a widely discussed aspect of limiting the human consequences of disease. As Zika virus can be transmitted via blood transfusion (even from asymptomatic donors),[366] screening of blood products is an important tool for preventing spread—particularly if the donor pool is impacted by an ongoing outbreak.

Outcomes

Because of the relatively recent appreciation of the role of Zika virus in fetal developmental anomalies, neurodevelopmental surveillance data regarding the long-term outcomes of CZS are somewhat limited. As with other etiologies of microcephaly, the severity of structural abnormality is a strong predictor of the severity of neurologic impairment.[367–369] Microcephaly can progress after birth[370] (perhaps due to persistent viral replication[324]), but resolution of microcephaly and normal neurodevelopment have also been described.[371] Outcomes in normocephalic infants with Zika exposure in utero vary. Some studies have found that infants without overt CZS findings have normal neurodevelopment,[372] while most studies find some abnormalities (albeit less severe than those with overt CZS).[368,373,374] Across neurodevelopmental domains, motor function appears to be the most consistently impaired, with receptive language ability relatively spared in many infants.[368,373] Long-term sequelae suffered by infants who experience CZS may include neurodevelopmental delay, hypertonia and contractures, seizures, ophthalmic abnormalities and visual impairment, hearing loss, cryptorchidism, and endocrine dysfunction.[371,374–376]

Lymphocytic Choriomeningitis Virus

LCMV is a negative-strand RNA virus in the family *Arenaviridae* that is associated with congenital anomalies. Rodents are the primary reservoir, particularly mice and hamsters. Sequelae of human infection range from asymptomatic to flu-like illness to encephalitis, while congenital infection can result in severe developmental anomalies. LCMV was first described as a cause of congenital infection in 1955 in a 12-day-old infant.[377] Because primary infection may be mild or asymptomatic and testing not commonly available, LCMV is likely underdiagnosed as a cause of congenital infections.[378]

Epidemiology

Human seroprevalence ranges between less than 1% and 10% worldwide and differs extensively with geographic region, primarily related to the degree of contact with rodent reservoirs.[379–382] Studies conducted in the 1940s–1970s found as many as 11% of cases of aseptic meningitis and encephalitis were associated with LCMV infection,[383] but this incidence has decreased significantly in more recent studies.[384,385] In temperate climates, human exposure is more common during the fall and winter, when rodents move indoors. Outbreaks have been detected in individuals with contact with hamsters and mice as laboratory animals[386,387] or as pets.[388–390] Awareness of LCMV as a congenital pathogen increased in the 1990s–2000s with several case series published,[378,390–392] however the true frequency of congenital LCMV infection is unknown because there is no active surveillance. Maternal exposure to rodents during pregnancy is only identified in approximately one-fourth to one-half of congenital cases.[392] The diagnosis of LCMV infection should be considered in all cases of infant hydrocephalus.

Pathophysiology

Humans acquire LCMV infection from aerosolized particles, bites, or fomite contact with virus excreted from rodents.[393] Human-to-human horizontal transmission by organ transplant has been documented.[394] LCMV is well-studied in rodents but its pathophysiology in humans is relatively poorly understood. Like other arenaviruses, LCMV replicates either at the site of infection or in draining lymph nodes; this localized replication is followed by viremia which leads to viral spread to parenchymal organs and the CNS.[395] Pathologic findings include lymphocytic infiltration and extramedullary hematopoiesis. The pathogenesis of LCMV-mediated brain injury is likely a combination of virus-mediated lysis and immune-mediated secondary damage due to infiltrating $CD8^+$ T-cells and pathogenic cytokine release.[395–397] In some settings LCMV appears to establish persistent infection, which may be facilitated by viral inactivation of the host innate type 1 IFN response,[398] or by a high rate of spontaneous mutation.[399]

Clinical Presentation

The typical presentation of LCMV infection is a nonspecific flu-like illness. Symptoms include fever, malaise, nausea, vomiting, myalgias, headache, pharyngitis, cough, and adenopathy; it is estimated that asymptomatic or mild LCMV infections occur in approximately one-third of patients infected. CNS disease typically develops as a second phase after resolution of constitutional symptoms. Neurologic manifestations occur in approximately one-fourth of infectious episodes and range from simple meningitis to fulminant meningoencephalitis; transverse myelitis, Guillain–Barré syndrome, and deafness have also been reported. Severe non-neurologic complications may also include pneumonitis, arthritis, myocarditis, parotitis, and dermatitis. Recovery may take months but usually occurs without lasting sequelae.[400]

Congenital anomalies are most severe when maternal infection occurs in the first or second trimester, but only 50% to 60% of mothers of infants with a diagnosis of congenital LCMV infection recall having symptoms.[401] Neurologic findings dominate the developmental anomalies caused by fetal LCMV infection, and chorioretinitis, hydrocephalus, and intracranial calcifications are the most common findings (see Table 34.3).[401,402] Chorioretinitis is nearly universal, present in more than 90% of cases. Other ocular findings include chorioretinal scars, optic atrophy (usually bilateral), nystagmus, esotropia, exotropia, leukocoria, cataracts, and microphthalmia.[392,403,404] Microcephaly and macrocephaly are both common (30% to 40% each) and neuropathology may be severe, including porencephalic cysts, periventricular infection, and cerebellar hypoplasia.[400] Flattened gyri, lissencephaly, and schizencephaly have been reported,[392] suggesting LCMV infection results in fetal neuronal migration defects.[395]

Most affected infants are born at term, and birthweights are generally appropriate or large for gestational age. Systemic symptoms are rare, although hepatosplenomegaly and jaundice have been noted. Other individual case report findings include pes valgus, dermatologic findings resembling staphylococcal scalded-skin syndrome,[401] spontaneous abortion,[388] and intrauterine demise secondary to hydrops fetalis.[403,405,406] It is important to note that because systemic symptoms are typically minimal at birth, the diagnosis of congenital LCMV infection may not be considered until an affected infant is a few months old, when microcephaly, macrocephaly, visual loss, or developmental delay are noted.

Evaluation

While the virus can be detected by PCR in serum or CSF during acute infection,[407] maternal and/or infant serology is often the more feasible method to diagnose LCMV disease, particularly when congenital infection is suspected.[392] Because of the low

baseline population seroprevalence, a positive LCMV antibody test is much more useful for diagnosis than is detection of antibodies to other potential congenital infections such as CMV. There is a commercially available immunofluorescent antibody test that detects both IgM and IgG for LCMV, although enzyme-linked immunosorbent assay antibody testing (performed by the CDC) is more sensitive.[408–410] Some studies have found antibody as late as 30 years after suspected exposure.[411]

Information about routine laboratory data in patients with a diagnosis of congenital LCMV infection is minimal, but thrombocytopenia and hyperbilirubinemia have been reported. CSF findings are variable. Up to half of cases demonstrate a mild increase in white blood cell count (up to 64 cells per microliter in one case series of 18 infants), the serum protein concentration may be normal or mildly elevated, and the serum glucose concentration may be normal or mildly decreased.[401]

Management

No approved treatments exist for LCMV infection. Ribavirin has been used for management of other arenavirus infections and inhibits LCMV growth in vitro.[412] Although novel approaches are being used to develop antivirals against LCMV and other pathogenic arenaviruses, which include Ebola, there are currently no recommendations for the use of antiviral agents against these viruses.[413,414] In an outbreak associated with solid organ transplant, one affected recipient received ribavirin and reduced levels of immunosuppressive therapy and survived.[394]

Prevention

Public health officials and clinicians should be aware that (1) wild, laboratory, and pet rodent exposure can lead to intrauterine infection with LCMV and (2) congenital infection has been associated with potentially devastating ophthalmologic and neurologic sequelae. Pregnant women should be educated about the risks of exposure to infected rodent excreta and instructed to avoid rodents and rodent droppings. Obstetricians and neonatologists should seek a history of pet or wild rodent exposure for counseling purposes and to aid in the evaluation of infants with unexplained CNS diseases. There are currently no vaccines approved by the FDA for the prevention of arenavirus disease, although candidate multivalent arenavirus vaccines capable of providing T cell-mediated protection against a variety of pathogenic arenaviruses are currently in development.[415] Attenuated LCMV is itself being used as a vector for vaccine development for heterologous pathogens.[416]

Outcomes

The proportion of asymptomatic infected infants is unknown. Chorioretinitis is the most common clinical finding, and the incidence of LCMV-caused retinal disease may be markedly underestimated.[404,417] In a review of 26 serologically confirmed infant cases, 9 infants (35%) died and 10 (63%) of the 16 survivors had severe neurologic injury.[401] Neurologic sequelae reported in the setting of congenital LCMV infection include spastic quadriparesis, mental retardation, developmental delay, seizures, sensorineural hearing loss, and visual impairment.[392,400,418,419] The combination of microcephaly and periventricular calcifications are associated with poor long-term prognosis.[402]

Herpes Simplex Viruses

HSV-1 and HSV-2 are highly related viruses. Although classically HSV-1 has been identified as a cause of oral infections (gingivostomatitis and pharyngitis), and HSV-2 has been implicated as the most common virus associated with genital herpes, in recent years these distinctions have become blurred. The greatest risk for the newborn is in the context of a first-time episode of maternal genital HSV infection occurring during pregnancy.

Epidemiology

In the United States, the reported incidence of neonatal herpes ranges from 1 in 2000 births to 1 in 10,000 births,[420–424] likely depending on the local prevalence of genital HSV and specificity of reporting. The incidence of neonatal HSV infection in the US has increased over the past decade.[424] The greatest risk of transmission to the fetus and the newborn occurs when an initial maternal infection is contracted in the second half of pregnancy.[425] Primary genital herpes infection in a pregnant mother results in an estimated attack rate of 33% to 60% for her infant, whereas recurrent maternal infection results in a 1% to 3% attack rate.[426–429] Approximately 85% of infants with neonatal HSV infection acquire the infection from the maternal genital tract at the time of delivery, but only 15% to 30% of mothers who give birth to neonates with neonatal HSV infection have a known history of genital HSV infection.[430] It is estimated that 22% of pregnant women are infected genitally with HSV, but most of these women are unaware of their infection.[429,431] Approximately 2% of women acquire primary HSV infections during pregnancy.[428] The majority of neonatal herpes simplex infections were caused by HSV-2 in early reports,[432,433] however, genital HSV infections in the US are increasingly caused by HSV-1, leading to an increased risk for neonatal infections due to HSV-1.[434,435]

Most HSV infections in newborns are acquired peripartum due to exposure to infected genital secretions.[427,436] Other modes of infection from maternal transmission include maternal viremia near the time of delivery[437] and post-natal acquisition during breast feeding from HSV lesions on the breast.[438–440] Intrapartum interventions that risk penetrating fetal skin, such as scalp electrode monitoring, increase the risk of transmission to the infant.[441,442] Post-natal acquisition of HSV from an individual other than the mother, such as from a recurrent oropharyngeal lesion[443–445] or a complication of ritual circumcision[446–448] has been reported.

Pathophysiology

The degree of genetic relatedness of HSV-1 and HSV-2 is approximately 45%, and the genome structures and morphology of the virion (virus particle) are virtually identical.[449] Both are acquired predominantly at mucosal surfaces and require intimate contact for transmission. After primary infection in epithelial cells, intraaxonal trafficking of viral DNA to the dorsal route ganglia results in the establishment of latency.[450–452] A variety of triggers, including ultraviolet radiation, stress, and immunosuppression, can cause the virus to reactivate at the level of the dorsal route ganglia and lead to the production of infectious virus, which can traffic via the axon to the cutaneous surface or ocular surface, producing lesions.[453] The recrudescence of HSV lesions, usually manifested as vesicular or ulcerative lesions at the site of primary infection,

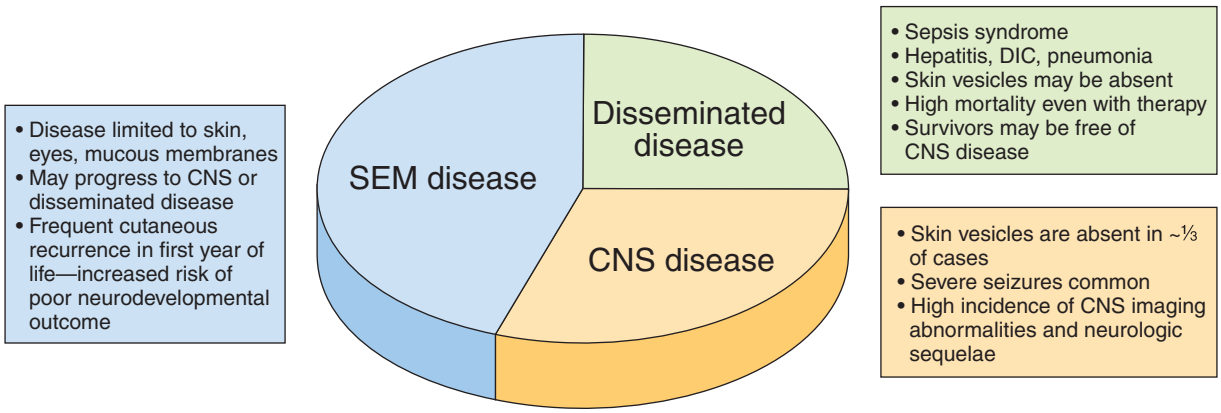
can in turn lead to person-to-person transmission, including maternal–fetal and maternal–infant transmission.

A wide variety of disease syndromes are associated with primary and recurrent HSV infection. HSV-1 is the primary causal agent of herpetic gingivostomatitis, herpes labialis, and keratoconjunctivitis. HSV-2 is almost always a genital pathogen, although genital herpes is associated with both HSV-1 and HSV-2. Exposure to an individual (including a healthcare provider) with any of these cutaneous manifestations of HSV infection could put a newborn at risk of acquisition of infection if care is not taken to protect the newborn. Typically, symptomatic disease manifests itself with a mixture of vesicles, ruptured vesicles with resulting ulcers, and crusted lesions on the genital area, buttocks, or both. Systemic flulike symptoms such as headache, fever, and swollen glands can accompany an outbreak of genital herpes, particularly during primary infection. Other symptoms include dysuria, urinary retention, vaginal or penile discharge, genital itching, burning, tingling, and groin sensitivity. Primary genital herpes during pregnancy can be associated with disseminated maternal disease, including severe hepatitis, disseminated intravascular coagulation (DIC), and CNS infection.[454–458] It has been recognized in recent years that many individuals with genital herpes are asymptomatic and unaware of their status.[459,460] Therefore, a negative maternal history of HSV *should not* dissuade the clinician from considering the possibility of neonatal herpes in an infant with compatible signs and symptoms. Although a history of maternal cervical, vaginal, or labial lesions should be sought when neonatal HSV infection is being considered in the differential diagnosis, overt herpetic disease in the maternal genital tract is evident in only approximately one-third of patients.[461] In the remaining two-thirds of cases, infection occurs in the context of asymptomatic maternal genital tract shedding of HSV.

Clinical Presentation

Neonatal herpes can have devastating long-term consequences, making early recognition of paramount importance. Most newborns with perinatal or postnatal HSV infection are normal at birth. Illness typically develops after 3 days of age; therefore, the presence of skin lesions, oral ulcers, and other signs and symptoms in the first 72 hours of life can suggest diagnoses other than HSV. Premature infants appear to be at greater risk, possibly because of reduced transplacental transfer of protective antibody. Approximately one-third of affected infants are of less than 36 weeks' gestational age.[432,462]

Infection can manifest itself in newborns in one of three forms: disease limited to the skin, eye, or mucous membrane (SEM disease); disease involving the CNS; or disseminated HSV infection, frequently manifesting itself as a sepsis-like syndrome, with pneumonia, hepatitis, and viremia (Fig. 34.5).[463,464] There can be overlap in these syndromes; for example, an infant with disseminated disease may initially have only skin lesions. The relative proportion of infants with disseminated disease has been declining in recent years, probably because earlier recognition and treatment of SEM disease have resulted in more timely intervention with antiviral therapy. Disseminated disease usually begins toward the end of the first week of life. Skin vesicles may be an early sign, but they are entirely absent in almost half of patients. The scalp should be inspected carefully, particularly near the site of insertion of fetal scalp electrodes, because such lesions are easy to overlook. Systemic symptoms, although initially insidious in onset, progress rapidly. Poor feeding, lethargy, and fever may be accompanied by irritability or seizures if the CNS is involved. These symptoms are followed rapidly by jaundice, hypotension, DIC, apnea, and shock. This form of disease is indistinguishable at its onset from both neonatal enterovirus infection and bacterial sepsis. HSV infection should be considered in the differential diagnosis of infants who have fever during the first 2 weeks of life, because fever can herald the onset of systemic disease. Localized disease may begin somewhat later, with most cases appearing in the second to third weeks of life. When the CNS is the primary site of infection, the skin or eyes may or may not be involved: importantly, up to one-third of infants with documented neonatal HSV CNS disease will never have skin lesions during their clinical course.[465] These infants are lethargic, irritable, and tremulous, and seizures are common and often difficult to control.



• **Fig. 34.5** Characteristic presentations of neonatal herpes simplex virus (HSV) infection. Approximately 45% of neonatal HSV infections manifest themselves as skin, eye, or mucous membrane disease (SEM disease), 25% as disseminated disease, and 30% as central nervous system (CNS) disease. Characteristic features of each subtype of neonatal HSV are listed. Disease may span categories; for example, infants with SEM disease may progress to disseminated or CNS disease, and infants with CNS disease may develop skin vesicles later in the hospital course, although up to one-third of infants with CNS disease never have cutaneous manifestations. Overall, approximately half of all infants with neonatal HSV disease will have CNS involvement (CNS disease or disseminated disease with CNS involvement). *DIC*, Disseminated intravascular coagulation.

Other less common but potentially localized findings are keratoconjunctivitis, chorioretinitis, and pneumonitis. Pneumonitis can manifest itself as a focal infiltrate or as diffuse bilateral disease. Secondary dissemination from a localized infection is common in the neonate. Acute retinal necrosis has been described in a series of infants with neonatal HSV infection[466] and can also be a late finding associated with recurrence.[467,468] Intracranial hemorrhage, aseptic meningitis, and fulminant liver failure have been described.[469–473] Some of the less common presentations of neonatal HSV infection can include hydrops fetalis,[474,475] laryngitis,[476] and supraglottitis.[477] Intrauterine infection is uncommon but can present with neurologic, ophthalmologic, and cutaneous manifestations.[478,479]

Evaluation

The cornerstone of the diagnosis of neonatal HSV infection is virologic detection; serology is of limited use in the management of suspected infection in the infant, although type-specific serology is useful in evaluation of maternal HSV status in the setting of infants born to women with active genital HSV lesions.[480] HSV-1 and HSV-2 are both easily recovered by culture of clinical samples and culture has been the primary diagnostic modality. However, use of HSV DNA PCR for all sample types is increasing. Although there are no large studies comparing the two modalities, HSV DNA PCR has been shown to be more sensitive than culture for surface swabs in neonates[481,482] and viral culture is becoming less available.[483] Diagnostic evaluation for neonatal HSV infection should include specimens from the mouth, nasopharynx, conjunctiva, anus, and any skin vesicles for culture (if available) and/or HSV PCR; whole blood or plasma for HSV PCR; and CSF for cell count, protein, glucose, and HSV PCR.[241] In addition, blood should be sent for a complete blood count including differential and platelets and transaminases. No single test is sufficiently sensitive to identify all the variable presentations of neonatal HSV. Therefore, is it important to obtain all of the recommended specimens to guide diagnosis and treatment.[482,484] HSV DNA is detectable in plasma/blood in all infants with disseminated disease and many infants with CNS and SEM disease.[481,484,485] Plasma HSV PCR levels correlate with outcome in infants with DIS disease.[484,486] In the absence of other signs of disseminated infection, a positive blood PCR does not define disseminated disease as many infants with SEM disease will be viremic.[481,484–486]

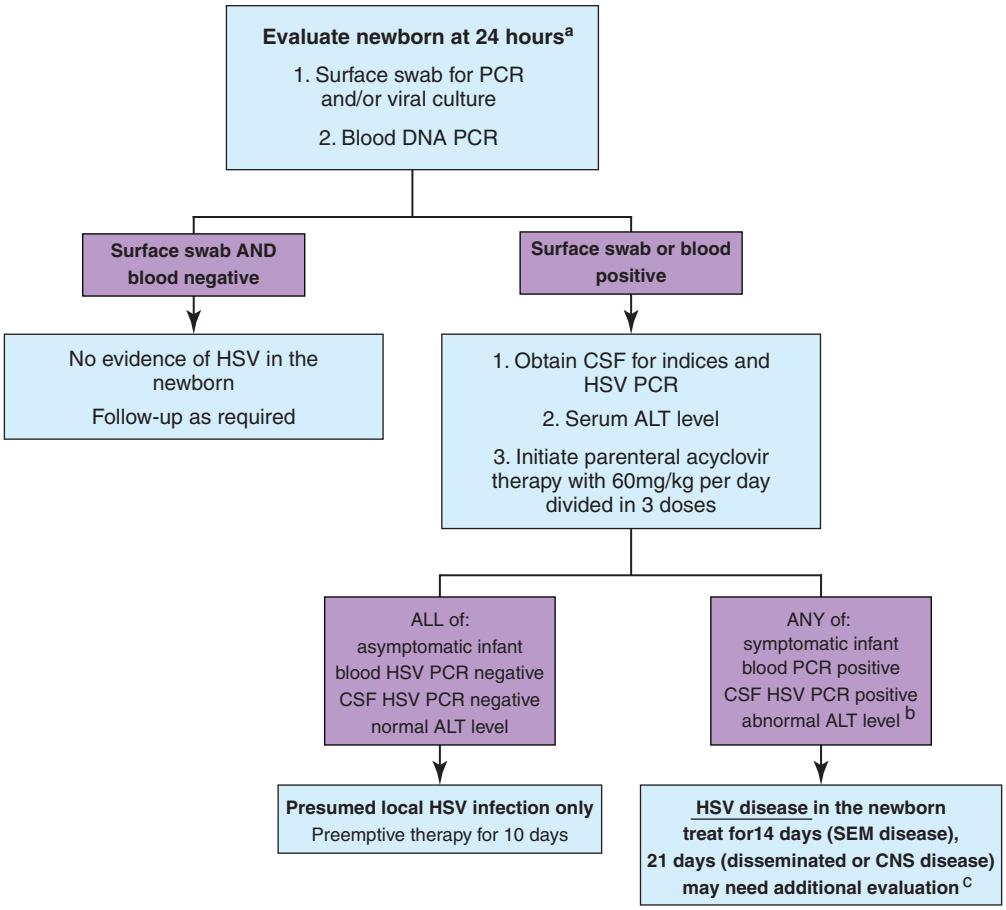
If the CNS is involved, evaluation of the CSF usually reveals a lymphocytosis, red blood cells, normal or high protein level, and low or normal glucose level. HSV DNA is detected only about 70% of the time in infants with clinical CNS disease, therefore absence of HSV by PCR does not rule out CNS disease.[484,486] Some experts recommend a second CSF specimen be obtained for evaluation at the end of antiviral therapy, as persistence of HSV DNA may be a poor prognostic factor and an indication for continuing antiviral therapy.[429,487–489]

Infants with CNS disease should undergo neuroradiographic imaging with computed tomography (CT) or magnetic resonance imaging (MRI). Neurodevelopmental sequelae in infants have been correlated with MRI abnormalities, particularly with diffusion-weighted imaging, which appears to be a valuable prognostic adjunct in neonatal HSV disease.[490] Electroencephalography (EEG) to evaluate for seizures should also be considered in infants with CNS involvement or with disseminated disease. EEG findings will be abnormal in approximately 80% of such patients.[432] Ophthalmologic evaluations are indicated, particularly in any infant with evidence of conjunctivitis.[241]

Management

Intravenous acyclovir at a dosage of 60 mg/kg per day, divided into three doses given every 8 hours is the standard of care for neonatal HSV (see Table 34.2). Treatment should be for 14 days for infants with SEM disease or 21 days for infants with disseminated or CNS disease. Infants with CNS disease should have a repeat lumbar puncture prior to stopping treatment. Those with HSV DNA detected by PCR in the CSF at the end of 21 days of therapy should receive acyclovir for an additional 7 days.[480] There is no role for orally administered acyclovir in the initial management of neonatal HSV, and no role for topically administered acyclovir in neonatal SEM disease. Herpetic keratoconjunctivitis should receive topical ophthalmic antiviral therapy along with parenteral treatment. In addition to antiviral therapy, appropriate supportive care is essential, with anticipatory management targeting complications of neonatal HSV disease such as seizures, pneumonitis, and hepatic insufficiency.

Treatment of asymptomatic neonates born to women noted to have genital lesions at the time of delivery is controversial. Guidelines endorsed by the AAP, as summarized in Fig. 34.6, provide evidence-based guidance on the treatment of neonates born to women with active genital herpetic lesions.[480,491] Implementation of these guidelines requires coordination between the pediatric and obstetric teams and availability of maternal PCR and/or culture of suspect lesions coupled with serologic assessment, along with virologic testing of the newborn at 24 hours of age. The key determination of risk for the infant is the serostatus of the mother. Infants born to women with primary, first-episode genital HSV infection have up to a 60% risk of neonatal HSV infection.[436] On the other hand, term infants born to women with a history of recurrent genital herpes are at low risk (<1%) of infection. For infants born in settings where PCR and type-specific serology may not be readily available, the most important variable informing clinical management is the maternal history. If the maternal HSV history is unclear, the infant is premature, or other obstetric complications or risk factors are present (e.g., prolonged rupture of membranes, maternal fever, signs or symptoms of chorioamnionitis, fetal scalp electrode monitoring), then empiric antiviral therapy is warranted. In settings where PCR and type-specific serology may not be readily available, after the appropriate specimens have been collected and sent for virologic analysis, the infant should receive parenteral acyclovir therapy (60 mg/kg per day) pending the results of diagnostic virology studies. In all cases, the family should be educated on signs and symptoms of neonatal HSV disease, and the infant should be followed closely. For post-natal exposure, which is an uncommon but documented cause of neonatal HSV, a similar decision algorithm for assessment and treatment of the exposed infant has been proposed.[492] There is no established standard of care for HSV testing among neonates evaluated for concerns of neonatal sepsis.[493] Some experts recommend the use of empiric acyclovir therapy in this setting,[494] and others recommend a more selective approach, based on analysis of history, risk factors, and laboratory analyses, such as liver function tests and CSF parameters.[495–497] A retrospective analysis of an empiric acyclovir strategy restricted to newborns with onset of febrile illness at 21 days of age or earlier, who would typically receive empiric parenteral antibiotic therapy, captured 90% of HSV cases.[497,498] Estimated rates of HSV infection among neonates evaluated for serious bacterial



• **Fig. 34.6** Treatment of a newborn born to a woman with presumed active genital herpes simplex virus (HSV) lesions at delivery in the setting of recurrent genital HSV infection. [a]Awaiting period of 24 hours is currently recommended in this setting before HSV surface cultures and/or PCRs are obtained for HSV genome detection from the neonate. This approach aids in differentiation of contamination of neonatal skin from maternal secretions from true infection of the newborn. [b]ALT level greater than 2 times the upper limit of normal. [c]Additional evaluation may be required based on symptoms and response to therapy. *ALT*, Alanine aminotransferase; *CSF*, cerebrospinal fluid; *PCR*, polymerase chain reaction. Guidance on management of asymptomatic neonates born to women with active genital herpes lesions. Pediatrics. 2013;131:e635–e646.)

infection is 0.7% to 2%.[497–499] Regardless of the strategy chosen, it is important to be aware that while most infants present with signs and symptoms that suggest HSV infection, a significant minority present with non-specific symptoms.[500,501]

The observation that recurrent skin lesions within the first 6 months of life predicted an adverse neurologic prognosis, possibly because recurrent skin lesions are a surrogate marker for subclinical reactivation events in the CNS,[502] led to the evaluation of the use of oral acyclovir for HSV suppression following the initial IV treatment. A phase III, placebo-controlled trial performed by the Combined Antiviral Study Group (CASG) confirmed that acyclovir suppressive therapy for 6 months after completion of IV therapy for neonatal HSV disease resulted in improved neurodevelopmental outcomes.[503] Infants with CNS disease randomized to receive oral acyclovir therapy had improved neurodevelopmental outcome and fewer frequent recurrences of skin lesions while receiving therapy. The results of this study have led to a recommendation that infants with neonatal HSV infection of any disease classification should receive oral acyclovir therapy for 6 months (see Table 34.2). Absolute neutrophil counts should be monitored at 2 and 4 weeks, and monthly thereafter, after commencement of suppressive therapy.[491]

Prevention

Neither routine HSV screening of pregnant women nor antepartum genital HSV cultures in asymptomatic women with recurrent disease is currently recommended.[504] However, women with recurrent HSV outbreaks during pregnancy or with a first episode of HSV during pregnancy should be offered suppressive acyclovir therapy beginning at 36 weeks of pregnancy. Although there is no evidence that suppressive acyclovir therapy reduces disease in newborns[505] and there are documented cases of neonatal infection in women on suppressive therapy,[506] it has been shown to reduce maternal asymptomatic shedding, risk of clinical recurrence of HSV at the time of delivery, and need for cesarean birth for recurrent HSV.[507] Cesarean delivery of women with active genital lesions at the time of delivery has been shown to reduce,

although not completely prevent, vertical transmission of HSV to the infants. Therefore, cesarean delivery is indicated in women with active genital lesions or prodromal symptoms, such as vulvar pain or burning, at delivery, because these symptoms may indicate viral shedding.[504]

Even with careful histories and meticulous physical examination during labor and delivery, many at-risk deliveries cannot be predicted or identified, because so many HSV-seropositive women are asymptomatic, do not know that they have genital herpes, and may unknowingly shed virus at the time of delivery. Infants in whom HSV infection is known or highly suspected should be isolated with contact precautions, and skin lesions should be covered. Finally, any healthcare provider with active herpetic whitlow or other skin lesions should not have direct patient care responsibilities for neonates.

While there have been multiple clinical trials of HSV vaccines for the prevention of genital HSV, to date none have shown significant success.[508]

Outcomes

Even with timely institution of antiviral therapy, the prognosis following neonatal HSV infection is guarded for infants with disseminated and CNS infections. Mortality rates for infants with disseminated disease have improved with the use of high-dose acyclovir treatment but are still 30% to 40%.[432] Antiviral therapy has decreased neonatal CNS infection mortality from approximately 50% to 6%, but 50% to 70% of survivors have sequelae.[420,432,484,509] Risk factors for increased morbidity and mortality associated with CNS infection include prematurity, seizures on initiation of therapy, and infection with HSV-2.[432,486,502,510] Lethargy at initiation of therapy has been associated with a higher mortality rate in neonates with disseminated HSV infection.[432] Infants with skin involvement often have recurrent crops of skin vesicles for several years, particularly those infected with HSV-2. Recurrences in the first 6 months of life have decreased with the use of oral suppressive acyclovir. In an infant younger than 6 months, readmission to the hospital for evaluation and IV acyclovir is appropriate when cutaneous recurrences are observed. Ongoing diligence in infants with CNS infections is warranted as late recurrences can result in additional CNS morbidity.[511,512]

Varicella-Zoster Virus

VZV is a member of the α-herpesvirus subfamily of the *Herpesviridae*. Like the related HSV-1 and HSV-2, VZV can infect neurons, where it establishes latent infection. Primary varicella infection, commonly known as *chickenpox*, usually results in a fever and a characteristic vesicular exanthem. Reactivation from latency, which can occur years or decades after the primary VZV infection, is referred to as *zoster* or *shingles*. Zoster is characterized by a painful vesicular rash in a dermatomal distribution.

The neonatologist may encounter consequences of maternal VZV infection in two different clinical presentations. In *congenital* varicella, VZV is transmitted to the fetus in the first or second trimester of pregnancy, where it can produce a number of teratogenic consequences.[513–516] In contrast, *neonatal* varicella occurs in the setting of primary maternal varicella acquired late in the third trimester, and the affected infant can exhibit symptoms and signs in the neonatal period. This section reviews both presentations of VZV-related disease in infants.

Epidemiology

Primary VZV infection during pregnancy occurred with a frequency of about 1 per 10,000 pregnancies in a population-based study from 2003 to 2010 in the United States.[517] The major concern in the setting of primary maternal VZV infection early in pregnancy is the risk of congenital varicella syndrome (CVS). Approximately 130 cases of CVS were reported in the literature between 1947 and 2013.[518,519] The risk of symptomatic intrauterine VZV infection after maternal varicella occurring during the first 20 weeks of pregnancy is approximately 1% to 2%.[519–522] Symptomatic disease appears to be more common in female infants.[518] Although rare,[520] CVS following maternal zoster has been reported.[519]

Maternal infection in the third trimester is not associated with CVS, presumably because this falls outside the time frame when VZV is teratogenic to the developing fetus. However, maternal infection just before or after delivery poses a high risk of neonatal varicella. For neonates born to a mother whose illness begins 5 days or less before delivery or up to 2 days after delivery, the neonatal infection rate is 17% to 31%.[523–525]

Pathophysiology

Congenital varicella syndrome results from maternal primary varicella infection occurring during the first or second trimester, and results from transplacental passage of virus during maternal viremia. It has been proposed that some of the congenital malformations associated with CVS may be a consequence of zoster-like virus reactivation in the infected fetus rather than the direct effects of the primary viral infection. The common finding of unusual cicatricial rashes in dermatomal distributions in newborns with CVS is more compatible with zosteriform reactivation events than primary skin infection.[526,527] Immature cell-mediated immune response in the fetus may underlie episodes of reactivation in utero.[526,528] Pathology reports have noted destruction of neural tissue with residual dystrophic calcifications, chronic active inflammation in non-neural tissues surrounding viral inclusions, and evidence of chronic placental villitis.[529–531]

Neonatal varicella is usually caused by maternal chickenpox acquired near term or immediately postpartum. Infection is primarily transmitted by transplacental viremia; it can also be contracted postnatally by the aerosol route or by direct contact with infectious lesions. Neonatal acquisition due to maternal zoster is very rare. Serious postnatal infection acquired from maternal varicella via breastfeeding has not been reported. Transplacentally transmitted infections manifest in the first 10 to 12 days of life, whereas chickenpox after that time is most likely acquired by postnatal infection.

Clinical Presentation

Congenital

Cicatricial skin lesions occur in most infants with CVS. These may appear initially as areas of skin loss which become cicatricial with time.[532] Other common findings include neurologic abnormalities (cortical or spinal cord atrophy, seizures, microcephaly, encephalitis, Horner syndrome), ophthalmologic abnormalities (chorioretinitis, microphthalmia, atrophy, and cataracts), and asymmetric muscular atrophy with limb hypoplasia.[518,524,525]

Intrauterine growth retardation, gastrointestinal, and genitourinary abnormalities have also been reported.[532,533]

Neonatal

When maternal varicella occurs more than 5 days before delivery, neonatal disease usually begins within the first 4 days of life and is typically mild. In contrast, varicella in a newborn whose mother develops varicella from 5 days before until 2 days after delivery is associated with a high risk of morbidity and mortality.[534,535] In this second group, neonatal disease typically begins between 5 and 10 days after delivery, and fatal outcomes have been reported in 23% to 30% of cases.[536,537] When the disease appears in this setting, it closely resembles varicella in the immunodeficient or immunosuppressed host. Recurrent crops of skin vesicles develop over a prolonged period. Typical presenting signs are fever, hemorrhagic rash, and visceral dissemination with involvement of the liver, lung, and brain. Secondary bacterial infection may occur.

Evaluation

Congenital

CVS should be suspected in a newborn with compatible abnormalities whose mother had a history of varicella in the first or second trimester. Confirmation requires evidence of intrauterine varicella infection, which could be done via direct viral detection from newborn samples,[538] or serologically by documenting persistence of VZV IgG beyond 6 or 7 months (the presumed duration of passive transfer of maternal antibodies) or detection of VZV IgM in infant blood. The latter is less useful as only one-fourth of infants reported with classic CVS have positive VZV IgM titer test results.[518,520] VZV can also be detected from skin lesions,[539] blood, or CSF by PCR, although there is no data on the sensitivity of VZV PCR for diagnosis in congenital disease. Development of clinical zoster in early infancy also suggests previous *in utero* infection.[518,520] Similar congenital skin lesions have rarely been associated with congenital herpes simplex virus[540] and coxsackievirus infections.[518] Diagnosis of CVS prenatally requires both documentation of varicella infection and consistent clinical findings by ultrasound.[541] Infection is determined by detection of VZV DNA by PCR in amniotic fluid.[528,542] Reported prenatal ultrasonography findings include polyhydramnios, hydrops, progressive IUGR, microcephaly, limb hypoplasia, and liver hyperechogenicities.[531,543] Abnormal ultrasonography findings may not develop in the fetus for at least 5 weeks after maternal infection.[544–546] Repeat ultrasound is indicated if the VZV DNA PCR is positive but the initial ultrasound is normal.

Neonatal

Neonatal varicella can be diagnosed based on presence of a clinically consistent rash following exposure to varicella and confirmed by VZV DNA PCR of the lesions.[539] Direct fluorescent antibody testing of a vesicle scraping provides a more rapid result, but is less sensitive than PCR.

Management

Although there are no controlled studies of acyclovir in pregnancy, treatment with oral acyclovir or valacyclovir is recommended by some experts especially during the second and third trimesters.[288] IV acyclovir is recommended for pregnant women with serious complications of varicella, particularly pneumonia. There are no recommendations for the use of acyclovir or IVIG for treatment or prevention of CVS. For neonatal varicella, treatment with IV acyclovir, 30 mg/kg per day divided into doses every 8 hours, is recommended, particularly for infants at the highest risk of adverse outcomes (i.e., the infant born to a woman who develops varicella from 5 days before until 2 days after delivery; Table 34.2).

Prevention

Pregnant women who lack a history of VZV infection or immunity should receive varicella zoster immune globulin (VariZIG) as soon as possible following VZV exposure. VariZIG should ideally be given within 96 hours of exposure but can be given up to 10 days after exposure.[288] The incidence of varicella following VariZIG is between 7% and 30%.[547,548] Newborns of mothers in whom varicella develops from 5 days before to 2 days after delivery should receive VariZIG as soon as possible (Box 34.2). VariZIG is given intramuscularly at a recommended dose of 125 units per 10-kg bodyweight (62.5 units for infants ≤2 kg, 125 units for infants >2 kg to ≤10 kg), up to a maximum of 625 units. If VariZIG is unavailable, IVIG (400 mg/kg) can be a substitute. A recent review of the VariZIG expanded access program found the incidence of varicella in exposed neonates after receiving VariZIG was 23.7% with only one infant having disseminated disease.[547] For healthy term newborns exposed postnatally to varicella, including newborns whose mother's rash began more than 48 hours after delivery, VariZIG is not generally indicated. However, some experts would consider administering VariZIG to infants exposed within the first 2 weeks of life whose mothers do not have evidence of immunity to varicella as they may also be at increased risk for severe disease due to their immature T-cell immunity.[241] VariZIG is not indicated for an infant whose mother has zoster. Infants receiving VariZIG should be placed in respiratory isolation for 28 days or until discharge, because administration of VariZIG can prolong the incubation period.

In the event of a significant varicella exposure in a newborn nursery, exposed infants born at less than 28 weeks' gestation or with birth weights less than 1000 g, regardless of maternal history, should receive VariZIG. Premature infants older than 28 weeks' gestation at birth should receive VariZIG if their mothers do not have documentation of immunization, serologic immunity, or a prior history of varicella (see Box 34.2).[241]

The best means of preventing VZV infection in the fetus and neonate is to follow current recommendations for universal varicella immunization of all children at 12 to 15 months of age, as well as vaccination of all susceptible adolescents and adults. There

• BOX 34.2 Candidates for Varicella–Zoster Immunoglobulin After Significant Exposure to Varicella–Zoster Virus Infection in Perinatology and Neonatology Practice

- Pregnant women without evidence of immunity
- Newborn whose mother develops chickenpox within 5 days before delivery or within 48 h after delivery
- Hospitalized premature infant (≥28 weeks' gestational age) whose mother lacks evidence of immunity to varicella
- Hospitalized preterm infants (<28 weeks' gestational age or birthweight ≤1000 g) regardless of maternal immunity

is no evidence that CVS occurs after exposure to varicella vaccine during pregnancy. From March 17, 1995, through March 16, 2005, 981 women were enrolled in a pregnancy registry for women exposed to varicella vaccine.[549–551] Pregnancy outcomes were available for 629 prospectively enrolled women. Among the 131 live births to previously VZV-seronegative women who received vaccine, there was no evidence of CVS. Nonetheless it is recommended that adolescents and women of childbearing age should avoid pregnancy for at least 1 month after immunization.

Outcomes

Overall mortality rates for CVS are estimated at 30%. Deaths occur in the first few months of life, usually secondary to severe pulmonary disease.[518,521] Zoster during early infancy is common[518] and is considered by some experts to be a criterion for diagnosis of CVS. Between 1% and 2% of infants without clinical evidence of CVS, but whose mothers had chickenpox in the second and third trimesters, develop zoster in the first few weeks of life. If zoster occurs, consideration should be given to ophthalmologic evaluations to rule out the possibility of CVS.[518,520]

Prior to the availability of varicella immune globulin and acyclovir, the mortality from neonatal varicella acquired from a mother with varicella contracted around the time of delivery (–5 days to +2 days) was reported as 23% to 30% of cases.[536,537] Approximately 25% to 50% of exposed infants treated with varicella zoster immune globulin may still develop varicella, but the disease is often attenuated, with no reports of mortality.[547,552]

Human Immunodeficiency Virus

Epidemiology

The HIV epidemic has seen dramatic shifts since the first cases were identified in the early 1980s. HIV-2 is endemic in West Africa and is significantly less prevalent than HIV-1. More than 99% of infections in the US are due to HIV-1.[553] In this section HIV will be used to denote HIV-1 unless otherwise indicated. Great strides have been made in diagnosis and treatment which have converted HIV from an almost universally fatal infection to a chronic but manageable disease. Mother-to-child transmission can occur in utero, peripartum, or post-partum via breastfeeding. However, the majority of transmission occurs peripartum. Without treatment the risk of transmission from an infected woman to her infant is around 25%, however, with universal prenatal HIV counseling and testing,[554] maternal antiretroviral (ARV) therapy, scheduled cesarean deliveries for higher-risk women, infant ARV prophylaxis, and avoidance of breastfeeding, the rate of mother-to-child transmission has dropped to 1% to 2% in the United States and Europe.[555,556] Of an estimated 5000 women with HIV giving birth annually in the US,[557] the number of new cases of perinatally-acquired HIV has been less than 100 in recent years.

Through efforts such as the UNAIDS Global Plan,[558] there has also been significant progress toward the global elimination of mother-to-child transmission of HIV, however, there remains much work to be done. In 2021, 81% of pregnant women living with HIV had access to ARVs to prevent maternal to child transmission. One result of increased maternal access to ARVs is the decline in infections among children (52% decline between 2010 and 2019), however, worldwide there were still 160,000 new infections in children in 2021.[559]

Prevention

Antepartum

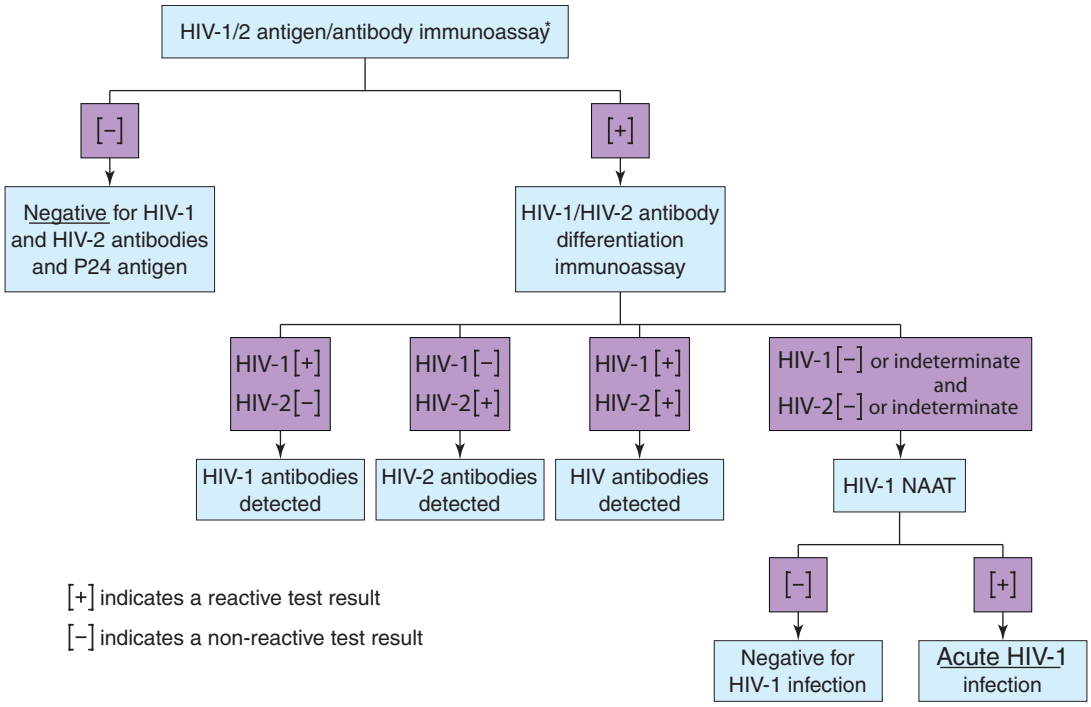
All pregnant women with an unknown HIV status should be tested for HIV with their first routine prenatal screening.[554] The best screening test is an FDA-approved HIV antigen/antibody combination immunoassay. This test detects both HIV-1 and HIV-2 antibodies as well as the HIV-1 p24 antigen. The addition of antigen testing shortens the window to detect infection to about 2 weeks after initial infection compared with the 4-week window of other assays. A reactive antigen/antibody immunoassay should be followed with a supplemental HIV-1/HIV-2 antibody differentiation test. Discordant results should be then tested with an FDA-approved plasma HIV RNA PCR assay (Fig. 34.7) to establish a diagnosis of acute infection vs a false-positive antigen/antibody screen.[560]

Women with an initial negative HIV test who are considered to be high risk should be tested again with an HIV antibody–antigen combination test in the third trimester, ideally before their 36th week of gestation. This includes women with a new sexually transmitted infection diagnosed in pregnancy, with high-risk HIV-associated behaviors, who have signs and symptoms concerning for acute HIV, who are incarcerated or who live in areas or receive care in facilities with an HIV incidence of at least 1 case per 1000 pregnant women per year.[561]

Acute HIV infection during pregnancy or breastfeeding poses an increased risk of mother-to-child transmission of HIV because of the high levels of HIV. Providers must be diligent and quick to test or retest pregnant women who are high risk or who present with a constellation of symptoms suggestive of acute retroviral syndrome such as pharyngitis, lymphadenopathy, myalgia, arthralgia, rash, or fever. A plasma HIV RNA PCR test should be sent in addition to an antigen/antibody combination immunoassay when acute HIV infection is suspected as the virologic assay will detect HIV about 5 days earlier.[562]

Once a pregnant woman has been identified as infected with HIV, antiretroviral therapy (ART) should be started as soon as possible. All pregnant women with HIV-1 infection should receive combination ART regardless of the absolute CD4 count or viral load. ARV drug resistance testing should be performed for women who are ARV-naive or ARV-experienced with a viral load of more than 500 copies/mL (usual threshold for genotypic resistance testing), but ART should be started while the results are pending and adjusted accordingly later because of the importance of viral load suppression.[563–565] Maternal ARVs decrease the risk of infant transmission by decreasing levels of virus in maternal blood and genital secretions as well as by providing ARV prophylaxis to the infant through placental transfer.

The choice of ARV drug combination is based on many factors, but in general ARV-naive pregnant women should receive at least three active ARVs. Preferred ARV regimens change frequently, and a thorough discussion of risks and benefits of potential ARV regimens is beyond the scope of this chapter. Currently recommended preferred regimens can be found online in the regularly updated Department of Health and Human Services Guideline, "Recommendations for the Use of Antiretroviral Drugs in Pregnant Women with HIV Infection and Interventions to Reduce Perinatal HIV Transmission in the United States,"[562] referred to in this chapter as the "DHHS Perinatal ARV guidelines" or by calling the National Perinatal HIV Hotline (1-888-448-8765).



• **Fig. 34.7** Human immunodeficiency virus (HIV) testing diagnostic algorithm. *For serum or plasma. *PCR*, Polymerase chain reaction. (Adapted from Centers for Disease Control and Prevention and Association of Public Health Laboratories. *Laboratory Testing for the Diagnosis of HIV Infection: Updated Recommendations. 2014.*)

The goal of ART is to maintain a viral load below the limit of detection throughout pregnancy. To that end, viral load should be tested several times during the pregnancy with a plasma HIV RNA PCR. Testing should be performed at the initial visit, 2 to 4 weeks after initiation or change of ART, monthly until viral load is undetectable, and at least every 3 months after suppression is achieved. An additional test must be done in all cases at 34 to 36 weeks' gestation to ensure viral suppression at delivery and to plan for the mode of delivery.

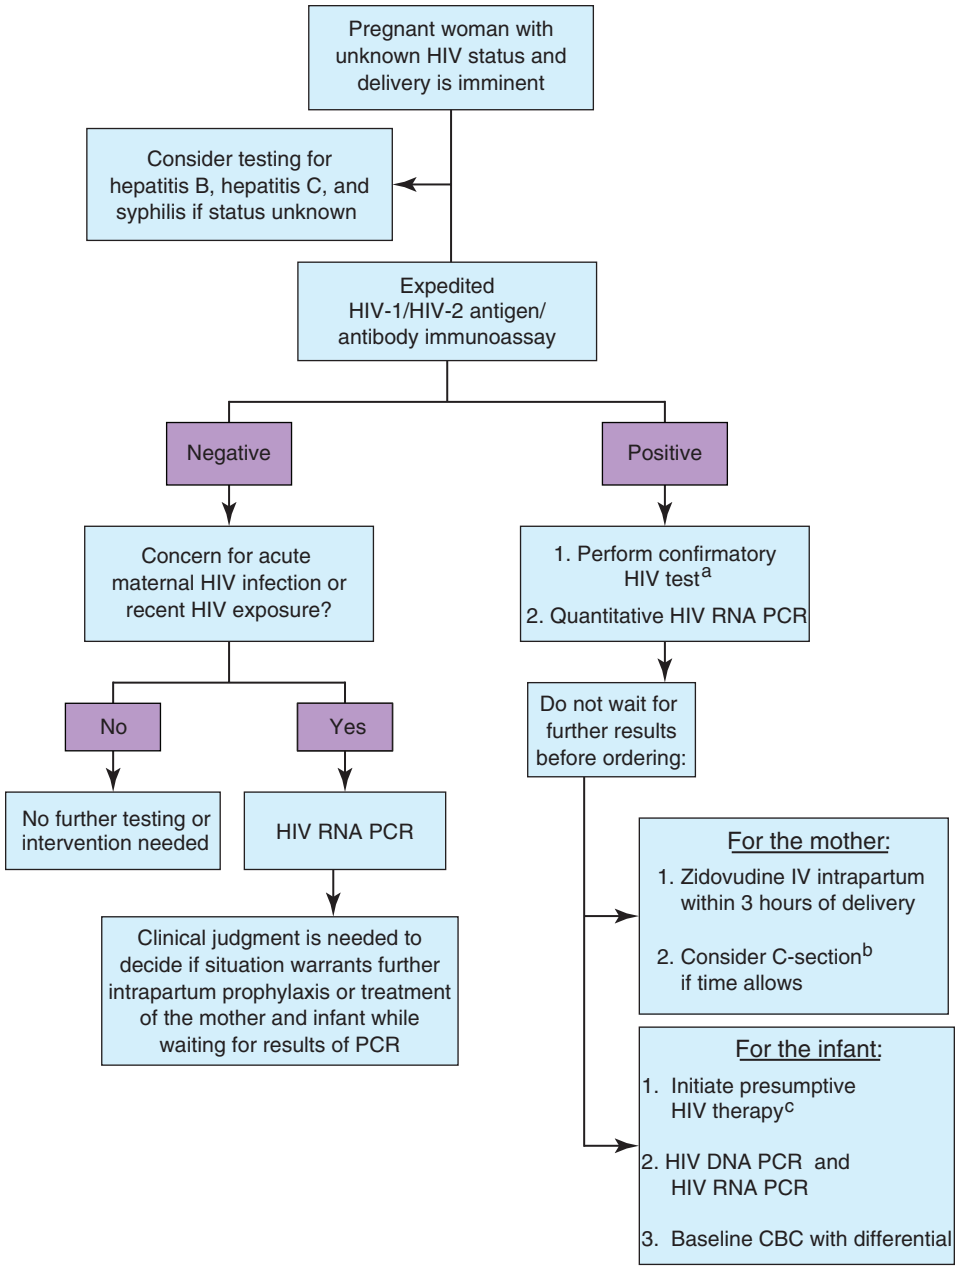
Antiretroviral therapy initiated prior to pregnancy or within the first trimester may be associated with an increased risk of preterm birth and low birth weight. However, this risk is outweighed by the benefits of ARV treatment during pregnancy to prevent infant HIV infection.[562]

Guidelines on the prevention of HIV-2 (in contrast to HIV-1) transmission during pregnancy are based largely on expert opinion. Data suggest that the rates of perinatal transmission of HIV-2 are low regardless of intervention (0% to 4% reported). There are no randomized clinical trials investigating optimal ARV prophylaxis during pregnancy for women infected with HIV-2. Treatment with ARVs known to be active against HIV-2 should be initiated for women who are pregnant or trying to conceive.[562] Breastfeeding should also be avoided by women living with HIV-2.

Intrapartum

The first study to demonstrate the effectiveness of ARVs in preventing maternal-to-child HIV transmission was Pediatric AIDS Clinical Trials Group (PACTG) protocol 076 which provided oral zidovudine (ZDV) to women during pregnancy, IV ZDV during labor, and oral ZDV to the infants.[566] Following these results, IV ZDV during labor for women with HIV became standard. However, now with more effective combination ART which achieves viral suppression, IV ZDV during labor is no longer universal. The French Perinatal Cohort group demonstrated that the difference in transmission for women with HIV RNA levels below 1000 copies/mL at delivery was not significantly different between those who received IV ZDV and those who did not.[567] IV zidovudine therapy should be given to HIV-infected women in labor with HIV RNA loads greater than 1000 copies/mL or with unknown viral loads. It is not required for HIV-infected women receiving ART who have documented viral loads of less than 50 copies/mL near delivery and for whom there are no concerns about adherence to their ARV regimen.[562] IV ZDV can be considered for women with HIV RNA levels between 50 and 1000 copies/mL as the transmission rate is slightly higher in this situation than it is for women with HIV levels less than 50 copies/mL at delivery.[568,569]

Women presenting in labor without a documented HIV result available or who are at increased risk of HIV acquisition and were not retested in the third trimester should be tested as soon as possible, ideally with an HIV 1/2 antigen/antibody combination immunoassay. If these results would not be available in less than 1 hour, then testing should be done with the most sensitive expedited test available.[562,570] If the initial screening test is positive, confirmatory testing should be done and intravenous ZDV should be initiated pending these results. See Fig. 34.8 for a suggested approach for a pregnant woman with unknown HIV status with delivery imminent. IV zidovudine should be started at least 3 hours prior to delivery and is given as a 2 mg/kg continuous infusion during the first hour and then 1 mg/kg IV continuous infusion each hour thereafter until the cord is clamped.



• **Fig. 34.8** Proposed algorithm for management of a woman presenting for delivery with unknown HIV status. A rapid turnaround time (<1 hour) HIV 1/2 antigen/antibody combination immunoassay should be performed. If an expedited HIV 1/2 antigen/antibody combination immunoassay is not available, initial testing should be performed by the most sensitive expedited test available. If the result is positive, confirmatory testing should be sent and maternal IV zidovudine therapy should be started immediately. The recommended dosing is 2 mg/kg IV continuous infusion during the first hour followed by 1 mg/kg IV continuous infusion each hour thereafter until the cord is clamped. This should begin at least 3 hours before delivery. Presumptive HIV therapy should be started in the newborn. This can be discontinued if the follow-up maternal testing does not confirm HIV positivity. [a]See fig. 34.7 for HIV diagnostic testing algorithm. [b]C-section should be considered if labor has not started. [c]Recommendations for presumptive therapy (which also serves as infant prophylaxis) are available in the Pediatric Antiretroviral Guidelines: Antiretroviral Management of Newborns with Perinatal HIV Exposure or HIV Infection available at Antiretroviral Management of Newborns with Perinatal HIV Exposure or HIV Infection | NIH. *CBC*, complete blood count; *C-section*, cesarean section; *HIV*, human immunodeficiency virus; *IV*, intravenous; *RNA*, ribonucleic acid; *PCR*, polymerase chain reaction.

Women on stable ART with viral loads less than 1000 copies/mL near the time of delivery should continue their oral ARVs during labor and delivery and be offered standard vaginal delivery. There is a potential increased risk of transmission with some obstetric procedures, including artificial rupture of membranes, invasive fetal monitoring such as with fetal scalp electrodes, and use of forceps or vacuum-assisted delivery. Hence, these should be avoided if possible, particularly for women with viral loads ≥50 copies/mL.

HIV-1-infected pregnant women who have plasma viral loads with more than 1000 copies/mL or unknown viral loads near the time of delivery should have a scheduled cesarean delivery at 38 weeks. This timing is recommended to decrease the possibility of the onset of labor or rupture of membranes before delivery can occur. Studies in 1999 (both a multicenter randomized controlled trial[571] and a metaanalysis[572]) showed a decreased risk of transmission by 50% to 80% when cesarean deliveries were performed at this juncture. However, cesarean section is not recommended for the sole purpose of prevention of perinatal HIV transmission in women on ART with viral loads less than 1000 copies/mL near the time of delivery as there is minimal additional benefit in this situation[568,573] and there is increased risk for complications from cesarean section in women with HIV.[574]

Postpartum

Mothers with HIV-1 infection should continue their ARV regimen after delivery, as ART is now recommended for all HIV-1-infected individuals. The unique challenges of labor, delivery, and motherhood may increase the barriers to adherence, and so the mother should receive additional support to continue therapy. Contraception options should be discussed early. As the mother will no longer receive obstetric care after her postpartum visit, careful attention should be made to ensure that she is following up with an HIV care provider.

Breastfeeding by HIV-infected mothers is not recommended in the United States and other developed countries where replacement feeding (formula) is affordable, the water supply is safe, and the risk of infant death due to diarrheal and respiratory infections is low.[575] Risk of transmission from breastfeeding is 15% to 20% over the first 2 years when neither maternal nor infant ARV prophylaxis is used.[576] Maternal ART continued during breastfeeding significantly decreases the risk of transmission,[577–579] however, infant prophylaxis with ART and maternal postpartum ART cannot completely eliminate the risk of infection. Maternal ARVs decrease the amount of cell-free HIV in breastmilk but have less effect on cell-associated HIV.[580]

There may be times when an HIV-infected mother chooses to breastfeed despite being counseled otherwise due to cultural or other psychosocial issues. In this situation, maternal viral suppression should be documented prior to delivery and throughout breastfeeding. Adherence support should be provided, and maternal viral load monitored regularly during breastfeeding. Exclusive breastfeeding is recommended for the first 6 months. For women on combination ARVs with suppressed virus, infant ARVs beyond the initial 6 weeks are not required, however, some experts recommend continuing infant prophylaxis until 1 to 4 weeks after cessation of breastfeeding (DHHS Perinatal ARV guidelines).[562] Infants should be tested for HIV every 3 months during breastfeeding and then at 4 to 6 weeks, 3 months, and 6 months after weaning.

Another potential mode for mother-to-child transmission is via premasticated food.[581,582] Healthcare providers should be aware of this risk and counsel mothers and other HIV-infected caregivers to avoid this practice.

Management

Management of the HIV-Exposed Infant

Antiretroviral prophylaxis should be started as soon as possible and ideally within 6 to 12 hours of birth in all HIV-exposed newborns. Recommendations for infant ARV prophylaxis vary depending on the risk of transmission to the newborn. Infants born to women who have been on effective ART with viral loads less than 50 copies/mL near the time of delivery are at low risk of transmission and should receive oral zidovudine for 4 weeks. See Table 34.5 for recommended zidovudine dosing based on gestational age. A complete blood count with differential should be performed before zidovudine therapy is started. Anemia, and less commonly neutropenia, are the primary complications seen in infants on a prophylactic zidovudine regimen. If the infant also had in utero exposure to maternal combination ART, there may be more anemia and/or neutropenia than found in infants only treated postnatally with zidovudine.[583] Many experts will check a complete blood count with differential again when they are also drawing blood for a nucleic acid amplification test or if the infant has symptoms of anemia.

TABLE 34.5 Zidovudine Prophylaxis Dosing for Human Immunodeficiency Virus-Exposed Infants

	Dosing	Duration
Zidovudine	≥35 weeks' gestation at birth: 4 mg/kg per dose orally* twice daily ≥30–<35 weeks' gestation at birth: 2 mg/kg per dose orally advanced to 3 mg/kg per dose orally at age 15 days <30 weeks' gestation at birth: 2 mg/kg body weight per dose orally advanced to 3 mg/kg per dose every 12 h after age 4 weeks	Start as soon as possible after birth, preferably within 6–12 h of delivery—continue for 4–6 weeks†

Modified from Panel on Treatment of Pregnant Women with HIV Infection and Prevention of Perinatal Transmission. *Recommendations for Use of Antiretroviral Drugs in Transmission in the United States*. Available at https://clinicalinfo.hiv.gov/sites/default/files/guidelines/documents/Perinatal_GL.pdf

*If unable to tolerate oral medicines the IV dose is 75% of the oral dose provided at the same interval

†Duration of 4 weeks recommended for infants at low risk of perinatal transmission (see text). 6 weeks is recommended for infants at high risk of perinatal HIV transmission along with additional antiretroviral agents (see guidelines).

Newborns considered to be at higher risk of HIV transmission include those born to mothers who did not receive any antepartum or intrapartum ART, received only intrapartum ARVs, received ARVs during pregnancy but did not achieve viral suppression to below 50 copies/mL near delivery, or had primary or acute HIV during pregnancy. These infants have a higher risk for both in utero and peripartum transmission and should begin *presumptive* HIV therapy as soon as possible after delivery, which also serves as prophylaxis against HIV acquisition.[562] Infants born to women with unknown HIV status during pregnancy but with a positive expedited HIV test at the time of delivery should also begin presumptive therapy which can be discontinued if the maternal infection is not confirmed (see Fig. 34.8). Current recommendations for presumptive HIV therapy include a three-drug regimen—zidovudine, lamivudine, plus nevirapine or raltegravir. Dosing recommendations are based on gestational age and birth weight. Information on and availability of new antiretroviral agents for neonates change frequently, and recommendations for

preferred regimens and doses are updated regularly in the DHHS pediatric ARV guidelines.[584] Length of therapy depends on level of risk and results of infant HIV testing but is usually 4 to 6 weeks in the absence of any positive HIV test results.

Nucleic acid amplification tests should be used to determine HIV status in exposed newborns, as antibody testing will reflect the mother's serologic status until the infant is older than 18 months. Testing can be done with either HIV RNA PCR or HIV DNA PCR assays. Testing should generally be done at birth, 14 to 21 days, 1 to 2 months, and 4 to 6 months. Birth testing can be omitted for low-risk infants for whom there are no concerns regarding access to follow-up. Additional testing should be done 2 to 6 weeks after discontinuing presumptive HIV therapy in high-risk infants who discontinue therapy.

Infants are considered presumptively HIV uninfected if they have had two negative nucleic acid amplification test results at age ≥14 days and at age ≥4 weeks or one negative result at ≥8 weeks. HIV infection can definitively be excluded with negative testing at ≥1 month and ≥4 months of age in exposed infants who are not breastfed. If the HIV status is unknown or not at least presumptively excluded by the time the prophylaxis course is complete at 4 to 6 weeks, infants should start prophylaxis for *Pneumocystis jirovecii* pneumonia.

HIV-infected mothers may have an increased incidence of coinfection with other pathogens that can be transmitted from mother to child. Pathogens to consider include HBV, HCV, *Treponema pallidum, Mycobacterium tuberculosis*, HSV, CMV, and *Toxoplasma gondii*. Infants may need additional testing depending on any known coinfections in the mother and the clinical history of the mother, including evidence of any of these diseases during the perinatal period.

Management of the HIV-Infected Infant

Early diagnosis and treatment initiation are important due to the benefits of early therapy in infants and young children. Infants with asymptomatic HIV aged 6 to 12 weeks were randomized to early versus delayed ART in a clinical trial in South Africa.[585] There was a 75% reduction in mortality in the infants randomized to early therapy. Infants treated early also had improved growth and neurodevelopmental outcomes.[586] Early initiation of treatment for infants diagnosed at birth also results in more rapid viral suppression and reduces the size of the viral reservoirs, which may have implications for future control of viral replication.[587–589] Managing antiretroviral therapy in neonates is challenging and recommendations for dosing of specific antiretrovirals in young infants are updated regularly as new data are available.[584] Infants infected with HIV should be referred to a pediatric HIV expert.

If the result of a nucleic acid amplification test is positive, the test should be repeated for confirmation. Viral genotypic resistance testing should be performed, and the ART regimen adjusted as needed. Genotype testing reflects the actual genetic mutations that may or may not confer clinically important resistance. With the more rapid turnaround of nucleic acid amplification tests, diagnoses are made earlier than previously experienced and increasingly there is more information available on dosing and safety of ARVs in the early newborn period. ARVs used during pregnancy, labor, and breastfeeding and for infant prophylaxis have dramatically reduced mother-to-child transmission of HIV. In addition, improvements in HIV diagnosis and treatment have resulted in decreased morbidity and mortality in infants and children infected with HIV. To capitalize on these advances, vigilance is necessary to ensure that all women are tested and treated appropriately during pregnancy.

Guidelines for the treatment of women during pregnancy, ART, infant prophylaxis, and pediatric ART change rapidly. We recommend readers access the US Department of Health and Human Services HIV management website at clinicalinfo.hiv/gov for the most up to date guidelines and information.[590]

Hepatitis Viruses

There are six distinct viruses known to cause viral hepatitis—hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (delta agent) (HDV), hepatitis E virus (HEV), and hepatitis G virus (HGV). The main features of each virus type are listed in Table 34.6.[591–593] HAV is passed by fecal–oral transmission and is a rare cause of neonatal disease, although nosocomial transmission in the NICU setting has been reported. HEV is similar to HAV in its mode of transmission and clinical manifestations, except for an increased mortality in pregnant women infected with HEV.[594,595] There are no data regarding perinatal transmission of HEV. HDV may cause only coinfection or superinfection with HBV. The only clinical significance of HDV is that HBV infection may become more severe when HDV is present. Perinatal transmission has been described[596] but is uncommon. HGV, also known as *GB virus type C*, has been associated with acute and chronic hepatitis, and HGV infection is usually noted as a coinfection with HBV or HCV. Perinatal transmission can occur in 60% to 80% of infants born to HGV-viremic mothers, but there has been no report of clinical hepatitis attributed to HGV infection in this setting[597–599] and the clinical significance of HGV infection is still poorly understood. HBV and HCV are both transmitted vertically and are of the greatest importance to the care of newborns. In this section we focus on HBV and HBC.

Hepatitis B Virus

Epidemiology

The incidence of acute HBV infection decreased in the United States by 90% after the introduction of HBV vaccine, from 9.6 cases per 100,000 population in 1982 to 1 case per 100,000 in 2018.[600] Estimates of the number of people with chronic HBV in the United States vary from 850,000 to over 2 million, with the majority coming from countries where HBV is endemic.[600] In the United States, approximately 20,000 infants are born annually to mothers who are chronic HBV carriers,[601] with about 20 perinatally infected children identified each year.[602] Globally about 1% of children are chronically infected with HBV.[603] There were an estimated 257 million people infected with hepatitis B worldwide in 2015 with 900,000 deaths. Most deaths are a result of cirrhosis or hepatocellular carcinoma (HCC) in adults as a result of infection acquired in childhood.[603]

Most maternal to child transmission of HBV occurs during labor and delivery, however, in utero infections can occur which accounts in part for infant infection despite immunoprophylaxis.[604–607] In the absence of prophylaxis, infants born to women who are hepatitis B surface antigen (HBsAg)- and hepatitis B e antigen (HBeAg)-positive have a 70% to 90% chance of acquiring infection. In contrast, the risk of an infant acquiring HBV infection if born to an HBsAg-positive but HBeAg-negative mother is significantly lower (0% to 30%).[606,608–611]

TABLE 34.6 Viral Hepatitis Types A, B, C, D, E, and G: Comparison of Clinical, Epidemiologic, Immunologic, and Therapeutic Features

Feature	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E	Hepatitis G
Virus	Hepatitis A virus	Hepatitis B virus	Hepatitis C virus	Hepatitis D virus (hepatitis delta virus)	Hepatitis E virus	Hepatitis G virus (GB virus type C)

From Krugman S. Viral hepatitis: A, B, C, D and E—infection. *Pediatr Rev.* June 1992;13(6):203–212; DOI: 10.1542/pir.13-6-203

Pathophysiology

HBV is a DNA virus that localizes primarily in hepatic parenchymal cells but circulates in the bloodstream, along with several viral proteins or subviral antigens. Several distinct genotypes have been identified, and these subtypes show biologic variability in transmission and disease progression.[612–615] Innate immune responses in the trophoblast appear to play a key role in defense against transplacental transmission, particularly Toll-like receptors 7 and 8.[616] Immunoglobulin against HBV also plays a role in prevention of transmission at the placental level: antibody deposition in Hofbauer cells that serves as an immune barrier to transmission between the mother and the fetus.[617] HBeAg plays a role in immune tolerance to infection in the newborn. HBeAg is the only HBV antigen to cross the placenta, and its presence leads to tolerance of the viral capsid protein by helper T cells in the newborn.[614] Transplacental leakage of HBeAg-positive maternal blood is a potential source of intrauterine infection[618] as is infection of the ovarian follicles and placenta.[605,619–621] Most infants born to mothers infected with HBV have a negative test result for HBsAg at birth but in the absence of prophylaxis are at risk of becoming HBsAg-positive during the first 3 months of life, suggesting that transmission is primarily peripartum and not transplacental.[591,622–624] High maternal HBV DNA levels are the most important risk factor for perinatal transmission and failure of post-natal immunoprophylaxis.[625–629]

Clinical Presentation

Infants with HBV infection do not show clinical or chemical signs of disease at birth. In some infants the infection becomes clinically manifest, with jaundice, fever, hepatomegaly, and anorexia in the first few months of life, followed by either recovery or chronic active hepatitis. Fulminant hepatitis in infancy occurs more commonly in infants who acquire infection from mothers who are HBeAg negative and HBeAb positive.[630–633]

Perinatally infected children typically initially experience an immune-tolerant phase with high levels of virus, but minimal or no hepatic inflammation. This phase can last for years, eventually transitioning into an immune active phase with increases in liver enzyme levels and evidence of hepatic inflammation. The immune active phase can be prolonged, leading to hepatic fibrosis. With time the majority will develop into an inactive carrier state with normalization of their liver enzymes, decreased inflammation, and HBeAg seroconversion.[634–637] Chronic HBV infection develops in up to 90% of perinatally infected infants.[638]

Evaluation

Diagnosis of HBV infection is by detection of subviral antigens in serum. HBsAg appears early, usually before liver disease is evident and persists in those who become long-term carriers. HBeAg, HBeAb, aminotransferases, and HBV DNA PCR are important in confirming diagnosis and monitoring disease activity.

Prevention

In the United States, in the past three decades a comprehensive immunization strategy[639] has been implemented consisting of four components:

1. Universal immunization of all infants beginning at birth.
2. Prevention of perinatal infection through routine screening of all pregnant women and appropriate immunoprophylaxis of infants born to HBsAg-positive women (or women whose HBsAg status is unknown) (Table 34.7).
3. Routine immunization of children and adolescents who have not been immunized previously.
4. Immunization of nonimmunized adults at increased risk of infection.

The doses and recommended options for administration of HBV vaccines currently licensed in the United States are provided in Table 34.8.[639] Infants who received hepatitis B immunoglobulin and HBV vaccine at birth, followed by two or three additional

TABLE 34.7 Hepatitis B Virus Immunoprophylaxis by Maternal HBsAg Status

Maternal HBsAg Status	Infant Birthweight (g)	Birth		Follow-up*
HBsAg positive	≥2000	HBV vaccine†HBIG	≤12 h	Complete a 3 dose HBV vaccine series
	<2000	HBV vaccine†HBIG	≤12 h	Complete a 4 dose HBV vaccine series
HBsAg negative	≥2000	HBV vaccine†	≤24 h	Complete a 3 dose HBV vaccine series
	<2000	HBV vaccine†	Hospital discharge or age 1 month	Complete a 3 dose HBV vaccine series

Adults aged >20 years	10 µg (1.0 mL)	20 µg (1.0 mL)	20 µg (1.0 mL)	NA	NA

Adapted and updated from Schillie S, Vellozzi C, Reingold A, et al. Prevention of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep*. 2018;67(No. RR-1):1–31. DOI: http://doi.org/10.15585/mmwr.rr6701a1

NA, not applicable.

*Twinrix is a combination of Engerix-B (20 µg) and hepatitis A vaccine, licensed for use in people aged 18 years or older in a three-dose series in a 0-, 1-, and 6-month schedule.

†Vaxelis is a combination of diphtheria and tetanus toxoids and acellular pertussis (DTaP), inactivated poliovirus (IPV), *Haemophilus influenzae* type b conjugate, and hepatitis B recombinant vaccines approved for use at 2, 4, and 6 months of age to be used from 6 weeks of age through age 4. Not to be used for the birth dose or for children 5 years and older.

‡Pediarix is a combination of hepatitis B (Engerix-B, 10 µg) with diphtheria and tetanus toxoids and acellular pertussis (i.e., DTaP), and inactivated poliovirus. It is recommended for use at 2, 4, and 6 months of age but should not be administered at birth, before 6 weeks of age, or after 7 years of age.

§Recombivax and Engerix are monovalent recombinant hepatitis B vaccines that can be administered starting at birth. Each vaccine has a pediatric and adult dose formulation. For both vaccines, pediatric and adult doses are administered on a 0-, 1-, and 6-month schedule, although Recombivax can also be administered to adolescents 11–15 years of age as two adult doses on a 0- and 4- to 6-month schedule.

immunizations (see Table 34.7), should be tested for HBsAb and HBsAg at 9 to 12 months of age or 1 to 2 months after the last vaccine. Infants who did not receive postnatal prophylaxis should be tested as soon as they are identified.

Approximately 5% to 10% of exposed infants are infected despite receiving HBIG and HBV vaccine at birth, with infants born to women with high viral loads being the most at risk.[625–627,636] Provision of oral antiviral therapy to highly viremic women in addition to immunoprophylaxis for the infant can almost eliminate the risk of transmission of HBV to their newborns.[640–643] Therefore, the American Association for the Study of Liver Diseases (AASLD) and World Health Organization (WHO) guidelines recommend that pregnant women who do not require HBV treatment for their own infection have HBV DNA levels obtained at 26 to 28 weeks of pregnancy and if greater than 200,000 IU/mL should be started on tenofovir at 28 to 32 weeks of gestation.[603,644] While tenofovir disoproxil fumarate is the recommended antiviral in the AASLD guidelines due to the lack of significant data on tenofovir alafenamide (TAF), subsequent studies have found TAF to be equally efficacious.[641,642] Although HBsAg has been found in breast milk, breastfeeding does not appear to have any influence on the rate of transmission[645] and maternal HBV infection is not a contraindication to breastfeeding.

Management

Treatment is not recommended for children who have normal transaminase levels and are immune tolerant or inactive carriers regardless of HBV DNA levels.[644,646] For children with immune active disease, ALT elevation and measurable HBV DNA, treatment should be considered. Currently preferred agents for treatment of children with chronic HBV and evidence of active disease include interferons (IFN alfa-2b and PEGylated IFN alfa-2a) and the nucleoside/nucleotide analogues entecavir and tenofovir. Choice of agents depends on stage of disease and age.[644,646,647] Infants and children with chronic HBV infection should be referred to a pediatric hepatologist for management.

Outcomes

Infants who become infected with HBV have a 90% risk of chronic infection. Without treatment there is a 15% to 40% risk of developing cirrhosis and/or hepatocellular carcinoma.[634,636,648–651]

Hepatitis C Virus

In 1989, HCV was identified to be the main cause of non-HAV, non-HBV, parenterally transmitted hepatitis. HCV is now a major cause of chronic hepatitis, cirrhosis, and hepatocellular carcinoma in the United States and globally.[652,653] HCV is a small, single-stranded RNA virus that is a member of the family *Flaviviridae;* this family consists primarily of vector-borne viruses including Zika virus and West Nile virus. HCV is an exception in this family because it is not transmitted by insect vectors. Seven genotypes are described, with significant biologic differences in regard to disease progression and responsiveness to therapy.[654]

Epidemiology

In the United States, the number of reported cases of hepatitis C infection has increased every year since 2009, with the highest incidence in people aged 20 to 39 years.[653,655] It is estimated that over 2 million people or ~1% of all adults in the United States are living with HCV.[653] HCV is primarily transmitted through exposure to infected blood with IV drug use being the greatest risk factor in the United States.[655] Transmission in the health care setting can occur through improper infection prevention practices. The risk of HCV infection from transfused blood after the advent of HCV screening is estimated to be less than 1 in 1 million units transfused. Sexual transmission is less efficient, although high-risk sexual behaviors contribute to HCV transmission.[656]

Perinatal transmission is the most common route of infection in children and the leading cause of childhood HCV infection.[657] Although data in pregnancy is incomplete due to lack of universal testing, the prevalence of HCV in pregnant women in the US is reported as approximately 0.4% to 0.7% in recent years,[658] with significant geographic variability.[655] The vertical transmission rate of HCV is approximately 5% in HIV-negative mothers and 10% from mothers co-infected with HIV.[657] An estimated 1700 children are infected with perinatally acquired HCV each year in the United States.[659]

Pathophysiology

Transmission of HCV from mother to child occurs either in utero or more frequently peri-partum.[660] HCV has been shown to productively infect placental trophoblasts in cell culture,[661] although a direct transplacental route of infection remains unproven. Placental innate immunity mediated by natural killer cell responses may prevent direct transplacental transmission of virus in most cases.[662] Infection of and replication in maternal peripheral blood monocytes can also affect the ability of the virus to infect the fetus or newborn.[663] HCV mother-to-infant transmission is highest in women with detectable blood levels of HCV RNA during pregnancy. Although there is no clear level of viremia associated with transmission.[657,664] Transmission by women with undetectable HCV RNA levels is uncommon. Maternal coinfection with HCV and HIV and history of IV drug use are risk factors for transmission because of increased maternal HCV viral load.[665,666]

Although mode of delivery is not demonstrably associated with transmission risk,[664] procedures which increase exposure to maternal blood during delivery such as scalp electrode monitoring and episiotomy, are associated with an increased risk of transmission[667–669] and should be avoided if possible.[670] Rupture of membranes greater than 6 hours is also associated with increased risk of transmission.[664]

Although HCV can be found in breast milk and colostrum,[671,672] studies comparing breastfed and bottle-fed infants born to HCV-infected mothers have not shown a statistically significant difference in rates of transmission.[664,673,674] Maternal HCV infection, therefore, is not a contraindication to breastfeeding;[670] however, it may be prudent for mothers who are infected with HCV and who choose to breastfeed to consider abstaining from breastfeeding if their nipples are cracked and bleeding.[675]

Clinical Presentation

Several studies have found that infants born to HCV-infected women are at higher risk for prematurity and low birth weight.[670] Most neonates perinatally infected with HCV demonstrate little in the way of clinical symptoms; they may have elevated liver ALT

levels either transiently, intermittently, or persistently,[676] most commonly noted between 3 and 6 months of age and peaking in the first 2 years of life. The most common clinical finding is hepatomegaly which develops in approximately 10% of children.[676]

Evaluation

Diagnosis of perinatally acquired HCV can be through detection of anti-HCV IgG after 18 months of age by which time at least 99% will have cleared maternal antibody.[677] Earlier identification of infected infants can be done by obtaining serum or plasma HCV RNA PCR after 1 to 2 months of age as the highest sensitivity of PCR is reported after 1 month of age.[678] Exposed infants whose initial RNA PCR is negative should still have anti-HCV IgG tested at 18 months of age.[241]

Management

Infants confirmed as HCV-infected should be monitored yearly for clinical and laboratory evidence of liver disease[679] and should be referred to a pediatric gastroenterologist for evaluation and treatment. Until recently, only IFN and ribavirin were approved by the FDA to treat adults and children with chronic HCV infection. The development of novel and highly effective direct-acting antivirals (DAAs) such as protease inhibitors, non-structural protein 5a inhibitors, and nucleotide and non-nucleotide polymerase inhibitors for HCV infection has revolutionized the care of infected patients[680,681] and PEG-IFN/ribavirin regimens are no longer recommended.[679,682] Choice of specific combinations of the DAA agents and length of treatment is based on the HCV genotype, previous treatment, age, and disease severity.[683,684] There are now several DAA agents labeled for use in children down to age 3 years, with more under study.[684–688] Efficacy and tolerability of these agents is excellent with sustained virologic response achieved in 90% to 100% of treated children.[684]

Prevention

Although development of an HCV vaccine is a major public health priority,[689] currently no vaccine is available. Like all other infants, infants with HCV should receive routine HBV immunization. In addition, they should receive HAV vaccination at 2 years of age. Parents should be advised to avoid unnecessary administration of medicines known to be hepatotoxic. Standard precautions are recommended for the hospitalized infant.

Outcomes

Chronic hepatitis develops in 60% to 80% of HCV-infected adults, which leads to cirrhosis or liver failure within 20 to 30 years after infection in one third of infected adults.[690] In patients with cirrhosis, the incidence of hepatocellular carcinoma is 2% to 5% per year. In children, 20% to 25% will experience spontaneous viral clearance.[676,679,691] Polymorphisms in the *IL28B* gene, and infection with HCV genotype 3, have been associated with greater chances of spontaneous viral clearance.[692] About 50% of infected children will develop chronic asymptomatic infection with the remaining 25% to 30% developing chronic, active infection.[676] In general, HCV progression is mild or moderate in children with chronic infection, however approximately one-third will develop cirrhosis by the third decade of life.[693] Early treatment with DAAs should prevent progression of HCV-related liver disease.

Enteroviruses and Parechoviruses

Enteroviruses are non-enveloped, single-stranded positive-sense RNA viruses in the family *Picornaviridae* (*pico* means very small in Spanish). Human enteroviruses include polioviruses 1, 2, and 3, coxsackieviruses A and B, and the echoviruses. Parechoviruses will be included here as they are closely related to enteroviruses and cause a similar spectrum of disease. Historically, poliovirus infection has been responsible for the greatest morbidity in infants, causing severe or fatal disease as well as residual paralysis in a high proportion of survivors. Global efforts to extend vaccination coverage have resulted in a significant decrease in polio cases and have effectively eradicated the disease in the developed world. Neonatal diseases associated with non-polio enteroviruses, for which there are no vaccines, remain common and can be associated with serious morbidity and occasional death. Typically acquired postnatally, these agents are associated with a wide range of clinical syndromes in the NICU, including CNS infection, myocarditis, and viral sepsis. Enteroviruses are the most frequently identified etiology in infants undergoing workup for neonatal fever.

Epidemiology

Enterovirus and parechovirus infections are seasonal, occurring most commonly during summer and autumn in temperate climates. The incidence varies from year to year, with outbreaks frequently caused by a single serotype and sometimes by multiple serotypes.[694–696] An estimated one fourth of all symptomatic enterovirus infections occur in children less than 1 year of age.[697] Although mild or asymptomatic disease is the rule even in infants, the incidence and severity of infections are inversely correlated with age.[698] In infants, as in older children and adults, transmission is typically via the fecal–oral route; as non-enveloped viruses, enteroviruses are stable in the environment for days to weeks.[699] Asymptomatic transmission is common; in one study of families of infants with fever and enterovirus or parechovirus infection, approximately 90% of siblings were simultaneously infected, while approximately one-third of these were asymptomatic. The adults in these households had lower rates of simultaneous infection but higher rates (around 85%) of asymptomatic infection.[31] Nosocomial outbreaks can be a significant source of infections: nursery and obstetric clinic outbreaks of both coxsackievirus B[700–702] and echovirus[703–705] infections have been reported with severe, and sometimes fatal, illness.

Enterovirus infections account for at least one-third of admissions of febrile neonates for suspected sepsis and, during the peak enterovirus season, between half and two-thirds of all neonatal admissions.[706,707] A comprehensive study prospectively enrolled over 600 healthy mother-infant pairs in Rochester, NY from June through October and tested for enterovirus from throat or stool cultures.[708] Remarkably, 12.8% of all newborns tested positive within the first month of life, although 79% of these infections were asymptomatic. In the remaining (21%) of infections, lethargy and fever were the most common symptoms. All symptomatic infants were admitted to a hospital for an evaluation to rule out sepsis per established guidelines, leading to a hospitalization rate of 7 per 1000 live births and making enterovirus infection a more common reason for hospitalization than group B streptococcus, HSV, and CMV infections combined. Parechoviruses appear to be similarly common in both febrile and well infants.[709,710]

Pathophysiology

Neonates can acquire enterovirus infections *in utero*, during labor and delivery, or postnatally. The dominant mode of transmission of serious neonatal infection is through contact with maternal blood, fecal material, or vaginal or cervical secretions, most likely during or shortly after delivery.[708,711] Having an older sibling in the household is an independent risk factor for acquisition of neonatal disease.[712] Intrauterine transmission appears to occur via transplacental spread in late pregnancy, secondary to maternal viremia, and has been described in up to 22% of cases of neonatal enterovirus infection when symptoms are present in the first day of life.[713,714] Except for transplacental infections, the portal of entry for enteroviruses is via the oral or respiratory route. Enteroviruses are resistant to the acidity of the stomach and replicate easily in the upper GI tract. After local replication, virus seeds the draining lymphoid tissue and then the blood. Severe enterovirus disease results from viral dissemination to distal tissues, which can include the heart, CNS, liver, pancreas, adrenal glands, skin, mucous membranes, and respiratory tract. Viral infection can cause direct cellular dysfunction, as in polio virus infection of lower motor neurons[715] or coxsackievirus B3 infection of cardiac myocytes.[716] However, in severe or persistent infections an aggressive local inflammatory response, including extensive infiltration by lymphocytes, mononuclear cells, histiocytes, and polymorphonuclear leukocytes, is a prominent feature.[717]

The presence of transplacental maternally derived antibody significantly mitigates the severity of disease,[718] and breastfeeding appears to provide a relative degree of protection against acquisition of infection.[719] Development of antibody is associated with recovery, although virus may continue to be shed in the stool for several weeks. Failure to clear enterovirus infection, particularly from the CNS, should suggest an underlying humoral immunodeficiency such as aggamaglobulinemia.[720,721] Infected individuals shed virus via the gut primarily, but secretion of virus in saliva and respiratory secretions has been shown.

Clinical Presentation

There is little evidence that enterovirus infections in pregnant mothers have adverse developmental consequences of infection on the fetus. While case reports and correlative epidemiological studies have proposed enteroviruses as teratogenic agents,[722–724] these reports are rare and the relatively high incidence of maternal enterovirus infections in normal pregnancies argues against a causal link. Similarly, enteroviruses have been implicated as a cause of fetal demise, but only in isolated cases.[725–727]

When neonatal infection is acquired in utero or perinatally from the mother, infants are typically asymptomatic at birth.[708,713] The mother may have a history of recent high temperatures and GI symptoms. Symptoms develop in the baby after an incubation period of 1 to 5 days, with most affected infants developing symptoms within their first week of life.[698] The most common complaints on initial presentation are fever and poor feeding; one-fourth of infected infants develop diarrhea or vomiting. Many have an erythematous maculopapular rash. Population-based studies find that most enterovirus infections are relatively mild, and overall survival is excellent.[728,729] One large study in Salt Lake City enrolled 1779 febrile infants younger than 90 days who were undergoing sepsis evaluation; 1061 were tested for enterovirus, and 214 (20%) were positive (57% from blood and 74% from CSF). The mean age of infants with enterovirus infection was 33 days; 91% were admitted but only 2% required intensive care.[730] The duration of illness ranges from less than 24 hours to longer than 7 days but generally is 3 to 4 days.

These observations underscore the generally benign and self-limited nature of neonatal enterovirus disease. However, morbidity can be substantial in severe disseminated infection. In infants admitted to the ICU, CNS findings are the most common, followed by respiratory tract disease, with cardiac involvement being less common.[706,731] Many severely affected infants have a viral sepsis syndrome—characterized by DIC, refractory hypotension, and multisystem organ dysfunction. Severe infections are typically acquired in the immediate perinatal period. The mother is commonly symptomatic and may have been empirically treated with broad-spectrum antibiotics for possible chorioamnionitis (a maternal history of suspected chorioamnionitis with negative bacterial cultures should suggest this association, particularly during the typical enterovirus season). If myocarditis is present, congestive heart failure is often severe. Some neonates exhibit primarily pulmonary disease or GI involvement, including diarrhea and necrotizing enterocolitis.[732] In a review of neonatal meningitis seen over a 15-year period in Galveston, Texas, enterovirus was the most common cause of meningitis in newborns older than 7 days.[733] The severity of CNS infection is quite variable, from mild meningitis to severe encephalopathy and periventricular leukomalacia.[734,735] Intracranial bleeding ranging from small to massive, severe hemorrhage has also been reported as a complication of neonatal enterovirus infection.[472,736,737] Other rarely associated findings include disseminated vesicular rash, dermal hematopoiesis, and hemophagocytic syndrome.[518,738,739]

It appears that any species of human enterovirus or parechovirus can cause disease in the newborn, with individual species occasionally associated with specific clinical syndromes. Coxsackie B viruses are frequently associated myocarditis and, less commonly, aseptic meningitis.[740–742] Enterovirus A71 is notable for its etiologic role in epidemics of severe neurologic diseases including brainstem encephalitis, as well as severe pneumonia.[743–745] A 2014 outbreak in the United States highlighted enterovirus D68 as an etiology of severe pneumonia and identified a possible association between this species and acute flaccid myelitis in children.[746–748] Echoviruses are associated with severe nonspecific febrile illnesses including DIC, aseptic meningitis, but can cause fulminant hepatitis.[703,749–751] Parechovirus genotype A3 is the most commonly identified viral etiology of meningitis in infants less than 90 days in some studies.[709,752] Enteroviruses, along with other viruses, have been posited as a potential etiology in sudden infant death syndrome (SIDS), possibly from myocarditis or pulmonary infection,[753,754] but this association has been controversial. In one study of SIDS victims, a comprehensive assessment was undertaken to attempt to identify potential viral infection of the myocardium. Overall, 62 SIDS victims and 11 controls were studied. Enteroviruses were detected in 14 cases (22.5%), adenoviruses in 2 cases (3.2%), EBV in 3 cases (4.8%), and parvovirus B19 in 7 cases (11.2%), whereas control group samples were completely negative for viral nucleic acid.[755] However, another evaluation of histopathologic features and PCR analysis from 24 SIDS cases failed to demonstrate any association with viral infection,[756] leaving this putative linkage unclear.

Evaluation

PCR assays have replaced viral culture as the gold standard diagnostic modality for enterovirus infections.[757] Pan-enterovirus PCR assays, which can be performed on blood, CSF, stool, respiratory, and throat swabs, typically detect all enterovirus species with similar sensitivity, and species identification can be performed by sequencing. In infants, it appears blood PCR has the highest sensitivity for diagnosing enterovirus and parechovirus sepsis,[758,759] although it is also common for non-sterile sites such as the pharynx or GI tract to be the only location where virus is detected despite symptoms involving multiple organ systems.[760] For neonatal enterovirus disease, the dried umbilical cord has been used for PCR-based retrospective diagnosis of in utero infection.[761] Rapid multiplex PCR platforms in widespread use often include a "rhinovirus/enterovirus" target and parechovirus target. Because of genetic similarity within a genus these tests generally cannot provide genotype-level detail but appear to have good sensitivity, including for the detection of enterovirus D68[762] and A71.[763] Serologic tests for enteroviruses exist but are less useful than PCR or culture for initial diagnosis.[764]

Laboratory evaluation is predicated on the clinical syndrome and the end organs involved. In severe systemic enteroviral disease, associated findings may include thrombocytopenia, elevated transaminase levels, hyperbilirubinemia, hyperammonemia, hematologic abnormalities consistent with DIC, anemia, peripheral leukocytosis, and abnormal chest radiographs. Infants with enterovirus meningitis typically have moderate CSF pleocytosis, which can be either lymphocytic or polymorphonuclear but may lack pleocytosis even in the setting of documented CNS infection.[765,766] Accordingly, during periods of active enterovirus infection in the community, CSF should be sent for enterovirus PCR in patients where CNS disease is suspected, even if pleocytosis is absent. When myocarditis is a diagnostic possibility, echocardiogram and electrocardiogram are indicated and may reveal diminished left ventricular function or dysrhythmias. Liver biopsy and histopathologic examination may be warranted in cases of fulminant hepatic failure.[717,737]

Management

The cornerstone of treatment of neonatal enterovirus disease is supportive care. Myocarditis and heart failure can be treated with inotropic support, diuretics, aggressive fluid management, and other supportive measures. DIC should be treated with blood products and other supportive measures as indicated.

The antiviral drug pleconaril was developed specifically to treat picornavirus infections but has failed to obtain FDA approval largely due to an unfavorable side-effect profile and is not available for use in the US. Other small-molecular inhibitors of picornavirus infection are in preclinical development,[767,768] and of these pocapavir has been used on an emergency investigational basis in several cases of neonatal enteroviral infection.[769–771]

IVIG has been reported anecdotally to treat neonatal enterovirus infections with various degrees of success.[772,773] Only one randomized trial has systematically studied its use in infants with enterovirus sepsis. In that 1995 study of 16 infants, which included 9 who were randomized to receive IVIG at a dose of 750 mg/kg, patients given IVIG containing high titers of neutralizing enteroviral-specific antibodies had more rapid resolution of viremia. However, there were no significant differences in other major clinical outcomes, such as the duration of hospitalization, fever, and symptoms of acute illness between treatment and control groups.[774] While IVIG is a relatively common therapy for viral myocarditis in adults and children, individual studies have yielded conflicting results[775] and an ongoing Cochrane Review has not demonstrated evidence of benefit.[776] Similarly, there is no evidence demonstrating corticosteroid or other immunomodulatory therapies are of benefit in treating enterovirus infections.

Prevention

The core tenets of infection prevention—particularly hand washing—are the primary tools of defense against enterovirus infection and spread. Standard contact precautions are typically used for hospitalized infants with known or suspected enterovirus infections, although strict cohorting strategies have been reported to limit nursery outbreaks.[777] Anecdotal reports of the prophylactic use of IVIG in nursery outbreaks to prevent further horizontal transmission of enterovirus infection have produced conflicting results.[778–781] Polio virus vaccine studies have demonstrated the efficacy of vaccination in eliminating enteroviral disease at the population level. In areas of the world where polio infections are still endemic, oral polio vaccination at birth is recommended by the WHO due to evidence supporting the efficacy of this vaccine even in newborn populations. Because there are multiple nonpolio enteroviral serotypes that cause clinical disease, broad immunization against multiple enterovirus species is conceptually difficult. Vaccines against enterovirus A71 have been developed and licensed in China and tested in children as young as two months old.[768,782]

Outcomes

Factors associated with severe neonatal disease include peripartum maternal illness, younger age of neonate, absence of serotype-specific antibody, and absence of fever and irritability.[728] These risk factors, all associated with peripartum infection, support the notion that intrauterine transmission causes particularly severe disease. The highest mortality rates are associated with the combination of severe hepatitis, coagulopathy, and myocarditis. Severe hepatitis caused by enterovirus infection is associated with mortality rates ranging from 30% to 80%.[714,737] By the time DIC has developed, the prognosis is grave; a prothrombin time longer than 30 seconds was an independent predictor of death in one retrospective case review.[737]

Relatively few long-term follow-up studies have been published, but the available information suggests that infants who survive severe enteroviral neonatal sepsis with hepatitis have a complete recovery in most instances.[783] Outcomes of 6 of 11 survivors with follow-up ranging from 9 to 48 months included normal growth and no residual medical problems or liver dysfunction.[737] In contrast, persistent myocardial dysfunction appears to be common (33% to 66%) in survivors of neonatal viral myocarditis.[783,784] Common sequelae include chronic heart failure (ventricular dysfunction), aneurysms within the left ventricle, and mitral regurgitation.

The long-term prognosis following CNS infection is also mixed and appears to depend on virus species. Among picornavirus species, enterovirus A71 and D68 and parechovirus A3 species are associated with severe CNS disease and with lasting neurologic sequelae.[785–788] The presence of seizures or other signs of encephalitis (abnormal CSF, clinical exam, or imaging) are associated with a higher likelihood of long-term neurologic sequelae.[783,789,790] On a

population level, studies in the 1970s found some impairment of intellectual development in 13% to 42% of infants with enterovirus meningitis compared to carefully selected control groups.[791,792] In contrast, several subsequent studies (in the 1980s and 1990s) found no significant differences in neurodevelopmental outcomes compared to controls.[793,794] Larger and more recent studies provide an overall reassuring picture of normal or near-normal developmental outcomes in most neonates with enterovirus and parechovirus infections involving the CNS.[789,795–797] One plausible explanation is that increased availability of PCR-based diagnostic testing, which is now commonly used in blood and CSF evaluation of febrile infants, has led to the inclusion of more patients with mild disease.

Respiratory Viruses

Most newborns with respiratory viral infections are asymptomatic or only mildly symptomatic. However, any respiratory virus can cause symptomatic disease. Respiratory viral infections in the neonatal intensive care unit (NICU) population are likely more common than generally recognized (Box 34.3) and can result in prolonged hospitalization and adverse outcomes.[798–803]

Respiratory syncytial virus (RSV) is the leading cause of viral pneumonia and bronchiolitis in young infants and has been associated with nosocomial outbreaks in NICUs.[804–809] Pregnant women and young infants are at increased risk of complications from influenza virus infection. Therefore, RSV and influenza are reviewed in the following sections.

Respiratory Syncytial Virus

Epidemiology

In temperate climates RSV causes annual epidemics during the winter and early spring months (typically November to April). During these months, RSV can be responsible for up to 20% of all pediatric hospital admissions.[810] Nosocomial infections are frequent during these times, and illness among hospital staff members is a major factor in its spread from infant to infant. Several nursery outbreaks have been described, and hospital acquired RSV infections in the NICU have been shown to result in increased length of hospitalization, increased use of antibiotics, mechanical ventilation, and mortality.[806,809] In one recent outbreak whole genome sequencing was used to determine the pattern of transmission within the NICU.[808] Two community introductions were identified with seven infected infants. Rapid implementation of enhanced infection control measures limited the spread within the NICU. All infected infants were symptomatic: two with lower respiratory disease and three required increased respiratory support. Compared to infections with other respiratory viruses, RSV-infected infants are more likely to require hospitalization and supplemental oxygen.[811] Risk factors for RSV-associated hospitalization include young age, prematurity, siblings in day care or school, and chronic lung disease.[810,812–817]

Clinical Presentation

RSV infection has been associated with apnea, primarily in infants of younger age and a history of prematurity.[818–820] RSV infection in the first few weeks of life may present with apnea, poor feeding, irritability with minimal respiratory symptoms.

Evaluation

Direct fluorescent antibody and immunoassay rapid diagnostics are available for detection of viral antigen in nasopharyngeal or tracheal aspirate, nasopharyngeal swab, or other respiratory secretions. Recently, rapid antigen assays have largely been replaced by PCR, which is preferred because of its higher sensitivity. PCR is commonly performed as a component of a "multiplex" assay that simultaneously tests for multiple viral pathogens.[821]

Treatment of RSV infection is largely supportive. Ribavirin, a nucleoside analog with in vitro activity against RSV, has been trialed for treatment of RSV bronchiolitis, however, while some studies have shown benefit,[822] most have not.[823–825] Aerosolized ribavirin is not recommended for routine use for RSV respiratory infection in infants due to the lack of clear benefit along with concerns about cost and safety.[241] Corticosteroids are not effective in the treatment of RSV infection.

Prevention

Prevention efforts have focused on passive and active immunization. When given as monthly infusions, RSV-specific immunoglobulin was shown to be effective in preventing lower respiratory tract infections, hospitalizations, days in hospital, and days in the intensive care unit in infants with cardiac disease, bronchopulmonary dysplasia, and prematurity.[826,827] Subsequently, palivizumab, a humanized mouse monoclonal antibody was developed which showed similar protection against severe RSV disease. In a randomized, placebo-controlled trial of 1502 infants with prematurity or bronchopulmonary dysplasia, infants receiving monthly injections of palivizumab had a 55% reduction in hospitalizations due to RSV.[828] Palivizumab is given as an intramuscular injection and it does not interfere with live virus vaccines. Current recommendations by the American Academy of Pediatrics (AAP) for the use of palivizumab are summarized in Box 34.4.[306] Additional preventive measures for high-risk infants include minimizing exposure to tobacco smoke, avoidance of crowds and situations in which exposure to infected individuals cannot be controlled, careful hand hygiene by caregivers, vaccination against influenza beginning at 6 months of age, and restriction of participation in childcare during the RSV season whenever feasible. RSV vaccines for both infant and maternal immunization are under active investigation.[829–832]

• BOX 34.4 Guidelines for Prophylaxis in Preterm Infants at the Start of the Respiratory Syncytial Virus Season

- Infants born at ≤29 weeks' gestation who are younger than 12 months at the start of the respiratory syncytial virus (RSV) season. (Monthly prophylaxis should be discontinued if an infant is hospitalized with documented RSV disease.)
- In the first year of life, palivizumab is recommended for premature infants with chronic lung disease of prematurity, defined as birth at <32 weeks' gestation and a requirement for more than 21% oxygen for at least 28 days after birth.
- Clinicians may administer palivizumab prophylaxis in the first year of life to certain infants with hemodynamically significant heart disease (consultation with a pediatric cardiologist is recommended).
- Clinicians may administer up to a maximum of five monthly doses of palivizumab (15 mg/kg per dose) during the RSV season to infants who qualify for prophylaxis in the first year of life (monthly prophylaxis should be discontinued if an infant is hospitalized with documented RSV disease).
- Palivizumab is not recommended in the second year of life except for children with chronic lung disease of prematurity who continue to require medical interventions such as supplemental oxygen, diuretics, and/or corticosteroids.
- Palivizumab may be considered in infants with pulmonary abnormalities, neuromuscular diseases, or profoundly immunocompromised states (including heart transplant in children younger than 2 years) or in Alaskan Native or other remote Native American populations in which costs associated with medical transport are high. Palivizumab therapy is not recommended for children with Down syndrome.

Nosocomial spread of RSV and other respiratory viruses can be minimized by emphasis on hand washing by care providers between contacts with patients. Without additional special precautions, an attack rate of approximately 26% has been observed.[833] Use of standard contact precautions, such as cohort nursing and the use of gowns and gloves for all contacts with RSV-infected children, can reduce the risk of nosocomial RSV infection to 9.5%.[833] Palivizumab has been reported to be a useful adjunct in the control of nursery-associated outbreaks of RSV infection.[809,834,835]

Influenza

Pregnant women are at increased risk for requiring hospitalization due to complications from influenza infection, particularly during the third trimester and if they have comorbid conditions such as diabetes and chronic pulmonary disease.[836] In the 2009 H1N1 pandemic, pregnant women accounted for 5% of the influenza-related deaths even though they were only 1% of the population.[837] Infants born to women with influenza disease during pregnancy are more likely to be premature and be admitted to the intensive care unit.[838,839] Among children who acquire influenza, the highest rates of hospitalization and mortality are in infants less than 6 months of age.[836] Oseltamivir, a neuraminidase inhibitor, is approved for infants down to 2 weeks of age and should be administered within 48 hours of symptom onset for the greatest benefit (Table 34.2).[241,840] Maternal influenza immunization during pregnancy is effective for preventing influenza disease and hospitalization in infants in the first 6 months of life.[841,842]

SARS-CoV-2

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is a positive-sense RNA virus that was first identified in late 2019 and spread rapidly to cause a global pandemic. Like its close phylogenetic relatives, the SARS-CoV-1 and Middle Eastern respiratory syndrome (MERS) viruses, SARS-CoV-2 is thought to have arisen in humans via zoonotic transmission.[843,844] Infection may lead to a spectrum of disease, but the classic clinical syndrome known as coronavirus disease-19 (COVID-19) consists of severe viral pneumonia that is often associated with an exaggerated inflammatory response, organ dysfunction, and coagulopathy. While infants and children on average experience milder disease than adults, infants have a slightly higher risk of severe disease and mortality than do older children.[845]

For the developing fetus, risk is primarily related to the sequelae of severe maternal illness. Perhaps because viremia in SARS-CoV2 infection is unusual, congenital infection due to transmission in utero appears to be exceedingly rare and has not been demonstrated to cause developmental abnormalities.[846] Women who are pregnant and develop COVID-19 have higher rates of ICU admission and mortality compared to non-pregnant women.[847] Fetal loss in the setting of acute COVID-19 has been reported,[848] although cohort studies are conflicted, suggesting only a small increased risk of fetal demise, if any.[849, 849a,849b] Infection later in pregnancy is, however, associated with approximately 1.5 times higher risk of preterm birth.[850–852] There do not appear to be deleterious consequences of maternal steroids for COVID-19 on the fetus, nor are steroids to hasten fetal lung development contraindicated in acute maternal COVID-19.[853]

Intrapartum transmission is rare with appropriate isolation measures (such as maternal masking) and occurs in an estimated 2% of deliveries to SARS-CoV-2 infected mothers.[854] The mechanism of transmission in this setting may be via respiratory droplets or fecal shedding[855] as virus is very rarely found in placenta or vaginal swabs.[856] For babies born to mothers with acute COVID-19, current CDC guidelines recommend SARS-CoV-2 testing at 24 and 48 hours of life via RT-PCR from nasal, nasopharyngeal, or oropharyngeal swab.[857] Testing of placental tissue or amniotic fluid for SARS-CoV-2 by PCR does not appear to be useful for predicting infection of the newborn.[858] In 70% of infected infants, transmission appears to occur after hospital discharge and primarily via respiratory secretions and droplets, as in older children and adults.[859,860] There is no evidence that breast milk is a significant source of SARS-CoV-2 infection.[861,862]

While asymptomatic or mild COVID-19 is more likely in infants than adults, severe disease and mortality do occur. Age less than 1 month is associated with a threefold higher risk of critical care admission, although it is unclear if this represents more severe disease or higher caution among providers.[863] The most common symptoms in infants with symptomatic acute COVID-19 include respiratory distress (53%), fever (44%), gastrointestinal (36%), neurologic (19%), and hemodynamic (10%).[860] Laboratory abnormalities include leukocytosis, thrombocytopenia, elevated lactate (55%) and C-reactive protein (29%).[859,864] While older children are at risk of a post-COVID-19 inflammatory disease known as multisystem inflammatory syndrome in children (MIS-C), there have been only case reports of older infants[865] and no descriptions in neonates. Treatment of acute COVID-19 is largely supportive as the mainstays of therapy in older patients, including remdesivir, dexamethasone, and monoclonal antibody therapy, have not been evaluated in infants.[860]

Prevention of transmission of SARS-CoV-2 to newborns is therefore critical. The AAP has established interim guidelines for the care of infants born to mothers with acute COVID-19.[866] These allow for rooming-in between infected mothers and their infants with maternal mask use and hand hygiene prior to contact. Early data indicate that vaccination using mRNA vaccines against SARS-CoV-2 is safe and effective in pregnant women, with protective antibodies transferred to the fetus.[867,868] Infants born to mothers who developed COVID-19 more than 14 days before delivery have lower infection rates compared to those born to mothers who developed COVID-19 closer to delivery, arguing for a protective role of maternal antibodies.[850] Vaccination of pregnant mothers is an important tool for limiting COVID-19 in infants.

Adenoviruses

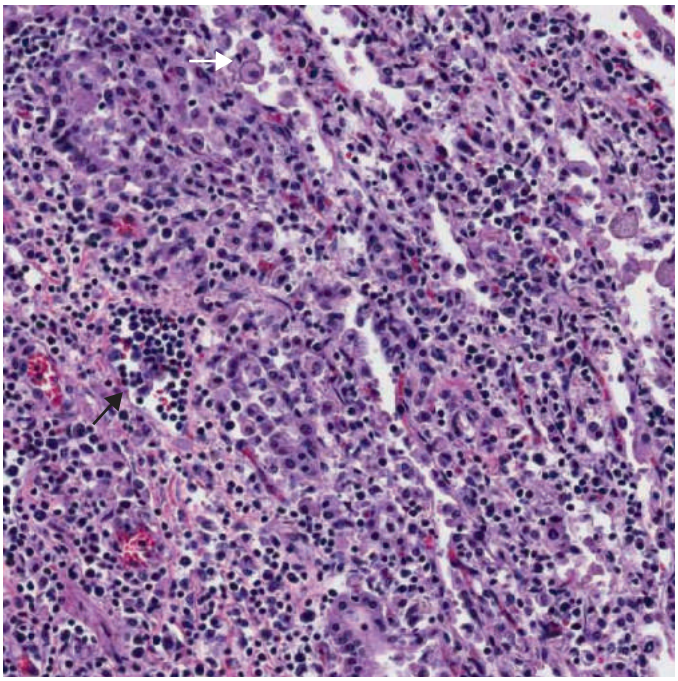
Epidemiology

Adenoviruses are medium-sized, nonenveloped viruses composed of a nucleocapsid and a double-stranded linear DNA genome. There are seven species (A to G) of adenovirus described in humans, comprising over 80 serotypes, and individual serotypes are commonly associated with specific human clinical syndromes as well as outbreaks. The most common clinical syndromes (and associated serotypes) include respiratory tract disease (Ad 1, 2, and 3), gastroenteritis (Ad 40 and 41), and keratoconjunctivitis (Ad 8).[869] Adenoviruses cause 5% to 10% of upper respiratory tract infections in febrile children and many infections in adults as well.[870] Whereas in most infants they cause primary infection, adenoviruses achieve latency and reactivation is a common problem in immunocompromised patients—particularly hematopoietic stem cell and solid organ transplant recipients. Adenovirus infections occur year-round, but they are slightly more frequent in late winter and spring.

Although a few case reports document adenovirus detection in the placenta or fetal tissue after intrauterine demise, the paucity of such cases argues against a significant role in congenital anomalies or fetal disease.[871–873] In contrast, neonatal disease is a well-described phenomenon and is often quite severe, carrying a mortality of nearly 50%.[874,875] Antenatal steroids and the presence of bronchopulmonary dysplasia increased risk of adenoviral pneumonia in one study of NICU babies.[876] Another study identified prolonged rupture of membranes, history of maternal illness, vaginal mode of delivery, and onset of illness within the first 10 days of life as risk factors for severe disease.[877] Maternal antibody appears to confer significant protection against serotype-specific infection for up to 6 to 12 months.[878,879]

Clinical Presentation

Adenovirus infection in newborns most commonly involves pulmonary (Fig. 34.9) or gastrointestinal symptoms and disseminated disease is common.[877,880] Clinical findings in various case reports and case series have included lethargy, fever or hypothermia, anorexia, apnea, hepatomegaly, bleeding, and hemophagocytic lymphohistiocytosis.[881–886] Laboratory abnormalities include thrombocytopenia, coagulopathy, and hepatitis. Acquisition of infection from the mother via vaginal delivery is the presumed mode of transmission in most cases, although transplacental spread has also been implicated. Adenovirus has been identified as a potential cause of chorioamnionitis and premature birth.[887,888] Congenital adenovirus infection (species C) has been associated with childhood leukemia in some studies,[889–891] but other studies have failed to confirm this association.[892] Adenoviruses can cause outbreaks particularly in the nursery setting, with well-documented outbreaks of keratoconjunctivitis transmitted during ophthalmologic exams.[893,894] In older infants, intussusception has a significant association with adenoviral infection of the GI tract.[895]



• **Fig. 34.9** Postmortem histologic analysis from a newborn who died of disseminated adenovirus infection at 2 weeks of age. Hematoxylin and eosin stain of lung demonstrating inflammatory infiltrates *(black arrow)* and intranuclear inclusions *(white arrow)*. This infant had a viral sepsis syndrome characterized by hepatic failure, disseminated intravascular coagulation, and pneumonitis from adenovirus infection presumed to have been acquired intrapartum.

Management

There are no FDA-approved medications for the treatment of adenovirus infection in infants. Cidofovir has become the standard treatment for severe and disseminated adenovirus infections in adults and is becoming widespread as an off-label treatment in pediatrics.[896–898] However, experience with this medication in newborns remains very limited. Intravenous ribavirin use has been described in a few cases,[899,900] but in vitro data argue against significant efficacy for adenovirus infections.[901]

Prevention

Adenoviruses are hardy and resistant to inactivation by physical and chemical methods that kill most viruses, adding to the challenge of hospital infection control during outbreaks. Nosocomial outbreaks have highlighted the importance of careful isolation measures to prevent spread, including sterilization of instruments used in retinopathy of prematurity examinations.[893,902] Adenovirus vaccines are available for use in military personnel but are not offered to the general public.[903]

Gastroenteritis Viruses

Rotavirus

Rotaviruses are historically the most important of the viruses that cause diarrhea from the perspective of the neonatal nursery. This group, with at least four serotypes, is responsible for a large proportion of diarrheal illness in infants aged 6 to 24 months.[904–907] Although the overall burden of rotavirus disease has been reduced substantially by the licensure of several rotavirus vaccines for use in the routine childhood immunization series,[908,909] rotavirus continues to produce disease in infants, particularly in parts of the world where vaccine is not available. While nursery-acquired outbreaks do occur, epidemiologic studies show that rotavirus causes mild or asymptomatic infection in infants younger than 2 months, perhaps due to less virulent strains.[910] Two studies performed in nurseries in Sydney, Australia, and London before widespread vaccination found that 30% to 50% of 5-day-old babies shed the virus, although 90% of the infants were asymptomatic.[911,912] Treatment is supportive and systemic illness is extremely rare. Many NICUs delay rotavirus vaccination for preterm infants until they are discharged due to fears of nosocomial spread of vaccine-strain virus.[913] However, available evidence argues that immunization of preterm infants with live rotavirus vaccines while in the NICU is safe and effective.[914,915]

Norovirus

Noroviruses are a genetically diverse group of single-stranded, positive-sense RNA, non-enveloped viruses. Noroviruses are the most common cause of gastrointestinal disease worldwide.[916,917] Similar to rotavirus, norovirus appears to cause less severe disease in infants less than 6 months of age, perhaps due to protective maternal antibodies.[918,919] Outbreaks of norovirus infection have been described in the NICU setting.[920,921] IUGR infants have been observed to be more likely to shed norovirus and other enteric viruses than infants who are appropriate for gestational age.[922] In addition, infection may have a variety of presentations including apnea and a sepsis-like picture.[921] Therapy is supportive.

Human Herpesviruses 6, 7, and 8

Human Herpesvirus 6 and 7

HHV-6 and HHV-7 are closely related β-herpesviruses that are ubiquitous in humans and typically cause infection in the first 2 years of life. HHV-6 was isolated in tissue culture in 1986 from peripheral blood leukocytes of patients with both lymphoproliferative disorders and HIV infection.[923,924] For several years after its discovery, its role in disease was unclear, but it is now known to be the major etiologic agent of roseola infantum (exanthem subitum) and has been associated with febrile seizures. HHV-6 is sub classified as either variant A or variant B, with HHV-6B typically associated with roseola infantum.[925] A study in Ugandan infants demonstrated that more than 75% of infants acquire HHV-6 infection in the first year of life.[926]

HHV-7 is highly related to HHV-6 and, like HHV-6, is responsible for roseola infantum.[927] As with HHV-6, infection with HHV-7 appears to be ubiquitous, although infection appears to be acquired somewhat later in life than HHV-6 infection.[928,929] Approximately 40% to 45% of children have antibodies to HHV-7 by 2 years of age, and 70% of children are seropositive by 6 years of age.

Saliva is assumed to be the main vehicle for transmission among children and adults.[930] Intrauterine infection can be the result of primary HHV-6 acquisition or maternal reactivation of latent virus. In addition, the HHV-6 genome is capable of integrating into human chromosomes, resulting in a high amount of detectable viral DNA by PCR that may not in fact represent replicating virus. Congenital HHV-6 transmission was first reported in a study of 5638 umbilical cord blood samples in which 57 samples (1%) had HHV-6 DNA by PCR, but none had HHV-7.[931] Another study including 305 umbilical cord blood samples identified HHV-6 DNA by PCR in 1.6% of samples.[932] Of note, all newborns were asymptomatic, and it is not clear if vertically transmitted DNA reactivates to produce bona fide virus particles. Indeed, vertical transmission of HHV-6 most often (90% of cases) occurs not from actively replicating virus but because of the germline passage of maternal HHV-6 through chromosomally integrated viral DNA.[933,934] The clinical consequences of such transmission and the differences between germline transmission and the more common postnatal acquisition of HHV-6 in early childhood remain unknown. Recent evidence suggests that there may be long-term neurodevelopmental concerns in infants who have germline transmission of viral DNA.[935] The HHV-6 genome appears to integrate into the telomere—a chromosomal component important in cellular aging and in cancer—suggesting there may be long-term consequences associated with vertical germline transmission.[936,937]

Peripartum and postnatal vertical transmission of HHV-6 and HHV-7 have been postulated[938] but not confirmed. In addition to saliva, both viruses can be found by PCR in cervical secretions[939–941] and breast milk,[942,943] but serological analysis in these studies suggest these are rare sources of peripartum transmission. With the advent of rapid molecular diagnostic platforms, it is increasingly common to detect HHV-6 nucleic acid in samples—particularly CSF—and identifying pathologic infection can be difficult. As many as 10% of infants with germline transmission of chromosomally integrated HHV-6 show early reactivation without symptoms.[931] Infants who acquire HHV-6 (as compared to older children) appear to have a higher incidence of symptomatic infection, including seizures and persistent viremia.[944,945] There are no approved antiviral medications to treat HHV-6. Although ganciclovir, foscarnet, and cidofovir have showed in vitro efficacy, small trials have not shown clinical benefit.[946]

Human Herpesvirus 8

In 1994 a novel herpesvirus, Kaposi sarcoma–associated herpesvirus (KSHV, also known as HHV-8) was identified in patients with AIDS-associated Kaposi sarcoma (KS).[947] This virus was assigned to the γ-herpesvirus subfamily of the *Herpesviridae*, due to its molecular and sequence similarity to the other prototypical γ-herpesvirus, EBV. Subsequent studies have linked KSHV to both AIDS-associated KS and the endemic forms of KS that are prevalent in elderly Mediterranean men. Cross-sectional studies of the seroprevalence of KSHV in children and adolescents in the United States reveal prevalence estimates ranging from 1% to 26%.[948,949] In sub-Saharan Africa, prevalence in children is even higher, approaching 60% in some studies[950] and are associated, in some cases, with single-gene inborn errors of immunity.[951] Postnatal transmission is thought to be primarily

via saliva.[952,953] There are reports of infections in infants that suggest possible vertical transmission, but congenital infection has not been confirmed by PCR techniques.[954] KSHV can also be transmitted by blood transfusion;[955] this observation suggests that transplacental transmission is at least theoretically feasible. In a study of 89 KSHV-seropositive women, KSHV DNA was detected in the peripheral blood mononuclear cells of 13 mothers (14.6%), and in the peripheral blood mononuclear cells of 2 of 89 samples drawn at birth from neonates born to these mothers. KSHV has also been demonstrated to infect placental cells, suggesting that a transplacental route of infection is feasible.[956] These findings suggest that KSHV can be transmitted perinatally, but infrequently.[957] Primary KSHV infection in immunocompetent children typically consists of mild illness with fever and rash as predominant symptoms.[958] Additional information on the epidemiology and modes of transmission of this pathogen, particularly in the prenatal and intrapartum period, is needed.

Epstein-Barr Virus

Epstein-Barr virus (EBV) is the causative agent of infectious mononucleosis and is associated with nasopharyngeal carcinoma, Burkitt lymphoma, and lymphoproliferative disease in immunocompromised patients.[959] Diagnosis based on classic evolution of early and late antibodies may be unreliable in young infants, therefore PCR is optimal to detect active infection.[960,961] Primary EBV infection during pregnancy appears to be rare,[962] and it is not clear whether transplacental passage of EBV occurs. It has been postulated that high-titer antibodies cross the placenta and protect the fetus from hematogenous transmission of virus in women who reactivate EBV during pregnancy.[963] While small case series have reported evidence of EBV infection associated with intrauterine fetal demise or developmental abnormalities,[964–968] large studies have not demonstrated a significant association of either primary or reactivated EBV with these outcomes.[969,970] Late congenital transmission appears to occur in 2% to 3% of pregnancies. In a study of 67 seropositive postpartum women and their neonates, 3% (2/67) of neonates were positive for EBV DNA by nested PCP.[971] Similarly, a 2% congenital EBV transmission rate has been described in HIV-infected newborns.[972] Early postnatal acquisition is uncommon based on serologic studies. Seropositivity increases sharply around 8 months of age, although the protective effect of maternal antibodies is a subject of debate.[960,973,974] Primary infection in newborns is almost always asymptomatic, although there are case reports of severe disease in premature infants.[968] High viral load in childhood is associated with increased likelihood of development of Burkitt lymphoma.[975]

Congenital Toxoplasmosis, Syphilis, Malaria, and Tuberculosis

MARIAN G. MICHAELS, PABLO J. SÁNCHEZ, AND PHILANA LING LIN

KEY POINTS

- Maternal transmission of *Toxoplasma gondii* in the first trimester causes the greatest damage to the fetus, while infections later in pregnancy are more readily transmissible to the fetus.
- No neonate should be discharged from a birth hospital without documentation of maternal syphilis testing. If maternal syphilis testing is positive, adequacy and timing of maternal treatment, comparison of infant and maternal serology, and infant's examination must be taken into consideration.
- Symptoms of congenital tuberculosis are protean but should be considered in any ill neonate whose mother is from a TB-endemic area.
- Symptoms of congenital malaria are nonspecific, though fever is universal. Parasitemia with *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae* has been reported with congenital malaria and should be considered in any infant whose mother is from a malaria-endemic region.

Congenital Toxoplasmosis

Epidemiology

Toxoplasmosis in the fetus and newborn is due to maternal infection with the parasite *Toxoplasma gondii*. This obligate protozoan parasite is ubiquitous in nature. While the cat is the definitive host, *T. gondii* can infect most warm-blooded animals. Human seroprevalence varies both geographically and by socioeconomic status. In the United States, seroprevalence studies obtained from National Health and Nutrition Examination Survey (NHANES) in 2009–2010 show a continuous decrease in seroprevalence, being around 9% for women of childbearing age compared to prior surveys conducted in 1988–1994 and 1999–2004.[1] Accordingly, over 90% of women of childbearing age in the U.S. are susceptible to primary infection with *T. gondii* during pregnancy, with risk of transmission to the fetus. Seroprevalence is increased for those born outside the United States, living below the poverty level, and with a lower level of education. Global data on seroprevalence show the highest rates in Latin America, parts of Eastern/Central Europe, the Middle East, parts of Southeast Asia, and Africa.[2]

However, seroprevalence rates differ considerably from one country to another, from one region of a country to another, and even from one ethnic group to another in the same region. These widely disparate seroprevalence rates among different adult populations throughout the world have been explained by differences in eating and sanitation practices that contribute to acquisition of infection. Eating goods that are undercooked, raw, cured, dried, as well as meat, raw oysters, clams/mussels, or unwashed raw fruits and vegetables, and drinking unpasteurized goat's milk, working with meat, having three or more kittens, and even certain climactic conditions have been associated with higher risks of infection.[3] Waterborne transmission, particularly from untreated well water, has been noted.[3,4]

Older studies through immunoglobulin (Ig) M screening of newborn blood specimens collected on filter paper showed the prevalence of congenital infection in Massachusetts and New Hampshire to be 0.08 per 1000 births.[5] Higher rates are found in other countries, ranging from 1 to 20 per 10,000 births, but are difficult to compare due to different methodology. Few countries have routine screening of pregnant women.[6] In Massachusetts, a case-control study involving 14 years of newborn screening for congenital toxoplasmosis found that the mother's birth outside the United States, particularly in Cambodia and Laos, as well as the mother's educational level and higher gravidity, were strongly predictive of congenital infection.[7] With approximately 4 million live births annually in the United States, there are an estimated minimum 400 babies born each year with congenital toxoplasmosis,[8] although the true incidence is likely much higher as the majority of infected newborns are asymptomatic at birth and therefore not diagnosed with maternal newborn screening.

Pathogenesis

T. gondii exists in three forms:

1. Sporozoite contained within oocysts that are in the cat's intestinal tract and are shed in cat feces
2. A tachyzoite or endozoite that is the proliferative form and was formerly referred to as a *trophozoite*
3. A tissue cyst that has an intracystic form termed *cystozoite* or *bradyzoite*

Nonfeline mammals or birds ingest infective oocysts from contaminated soil. Tissue cysts then accumulate in the organs and skeletal muscle of these animals. The possible routes of transmission from animal to human are direct contact with infected cat feces, ingestion of undercooked meat containing infective cysts, raw shellfish, and ingestion of fruits, vegetables, or water that

have been in contaminated soil. Rarer methods of transmission can be from infected blood transfusions or organ transplantation.[9] Congenital infection results from placental infection and subsequent hematogenous spread to the fetus.

Infection of the fetus occurs because of maternal primary infection during pregnancy or, rarely, just before conception.[10] Reactivation of latent *T. gondii* infection during pregnancy does not lead to fetal infection, except among immunocompromised women such as those infected with human immunodeficiency virus (HIV) or those receiving chemotherapy or other immunosuppressive therapy as with systemic lupus erythematosis.[11–16] Even under those circumstances, the risk is low. In addition, maternal reinfection with a new, more virulent strain can result in congenital toxoplasmosis.[17] Severity of disease is related to both host and parasite factors as well as stage of pregnancy.[18,19]

Infection of the fetus occurs transplacentally during maternal parasitemia. Placental infection is an important intermediary step, and up to 16 weeks may elapse between placental infection and subsequent infection of the fetus. This time delay has been termed the *prenatal incubation period*[20] and explains the success of therapeutic intervention during pregnancy. Infections in twins show similar clinical manifestations in monozygotic twins, whereas discrepancies in clinical findings are common in dizygotic twins.[21–23]

Overall, approximately 40% of infants born to mothers who acquired toxoplasmosis during pregnancy are congenitally infected with *T. gondii*. The rate of vertical transmission varies according to the trimester in which the mother became infected, with fetal infection rates increasing as pregnancy advances.[20,24,25] Only 15% of infants are infected with maternal infection occurring in the first trimester, whereas transmission rates are 30% and 60% with maternal infection in the second and third trimesters, respectively. The severity of clinical manifestations is greatest, however, when maternal infection is acquired early in pregnancy. Maternal infection in the first trimester results in severe disease in as many as 40% of infected fetuses, and in stillbirth or perinatal death in an additional 35% of infants.[24] Conversely, maternal infection in the third trimester is rarely if ever associated with severe fetal disease or stillbirth, and approximately 90% of infants in such situations have subclinical infection.[24]

Postnatally, transmission of *T. gondii* can occur from transfusion of blood or blood products or from transplantation of organ or bone marrow from a seropositive donor with latent infection. Although the organism has been detected in human milk, transmission by breastfeeding has not been documented.

Clinical Presentation

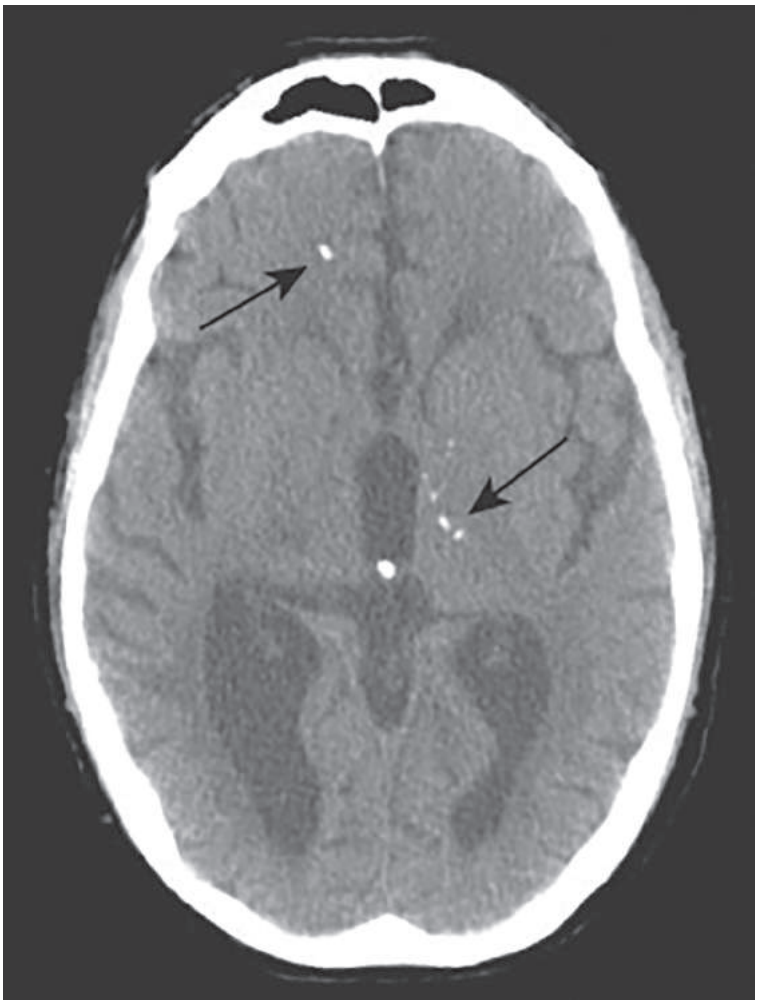
Most newborns with congenital toxoplasmosis are asymptomatic with clinically apparent disease only present in approximately 10% to 25% of infected infants,[5,26,27] although thorough evaluation may demonstrate eye or neurologic abnormalities in approximately 20% of cases. The clinical manifestations of toxoplasmosis are often indistinguishable from those seen with other congenital infections, such as cytomegalovirus or congenital syphilis. Approximately one-third of infants have a generalized form of toxoplasmosis that principally involves organs of the reticuloendothelial system. The abnormalities include temperature instability, hepatosplenomegaly, jaundice, pneumonitis, generalized lymphadenopathy, rash, chorioretinitis, anemia, thrombocytopenia, eosinophilia, and abnormal cerebrospinal fluid (CSF) indices (Table 35.1).[28] The other two-thirds of infected infants principally manifest neurologic disease.

TABLE 35.1 Clinical Findings Among Infants With Congenital Toxoplasmosis

Finding	Infants with findings (%): Neurologic Disease* (108 Cases)	Infants with findings (%): Generalized Disease† (44 Cases)
Chorioretinitis	94	66
Abnormal cerebrospinal fluid	55	84
Anemia	51	77
Convulsions	50	18
Intracranial calcification	50	4
Jaundice	29	80
Hydrocephalus	28	0
Fever	25	77
Splenomegaly	21	90
Lymphadenopathy	17	68
Hepatomegaly	17	77
Vomiting	16	48
Microcephaly	13	0
Diarrhea	6	25
Cataracts	5	0
Eosinophilia	4	18
Abnormal bleeding	3	18
Hypothermia	2	20
Glaucoma	2	0
Optic atrophy	2	0
Microphthalmia	2	0
Rash	1	25
Pneumonitis	0	41

*Infants with otherwise undiagnosed central nervous system diseases in the first year of life.
†Infants with otherwise undiagnosed nonneurologic diseases during the first 2 months of life.
Adapted from Remington JS, McLeod R, Thulliez P, Desmonts G. Toxoplasmosis. In: Remington JS, Klein JO, Wilson CV, Nizet V, eds. *Infectious Diseases of the Fetus and Newborn Infant.* 7th ed. Philadelphia: Elsevier; 2011.

Central nervous system involvement is the hallmark of congenital *T. gondii* infection.[20,29,30] Chorioretinitis, intracranial calcifications (Fig. 35.1), and hydrocephalus are the most characteristic findings, occurring in approximately 86%, 37%, and 20% of symptomatic infants, respectively.[20,28] This constellation of findings has been referred to as the *classic triad of congenital toxoplasmosis;* its presence should alert the clinician to the diagnosis. Intracranial calcifications may be single or multiple, but typically are generalized and located in the caudate nucleus, choroid plexus, meninges, and subependyma;[31] they also may occur periventricularly, as in cytomegalovirus infection. Calcifications are visualized best by computed tomography (CT) but are often detected on ultrasonography as well. Intracranial calcifications may resolve



• **Fig. 35.1** Scattered intracranial calcifications in the right frontal cortex and left thalamic area with ventriculomegaly observed in congenital toxoplasmosis.

with appropriate antimicrobial therapy.[29] Hydrocephalus may be the only manifestation of disease; it results from the extensive periaqueductal and periventricular vasculitis with necrosis that causes obstruction of the ventricular system. Ventriculoperitoneal shunting is often required.[29,32] Abnormalities of the CSF are common; characteristically, they consist of lymphocytic pleocytosis and a markedly elevated protein content. Microcephaly, when present, indicates severe brain injury. Hypothermia and hyperthermia may occur secondary to hypothalamic involvement. *T. gondii* has been detected in the inner ear and mastoid, with the associated inflammation resulting in deafness. An ascending flaccid paralysis with myelitis has also been reported.[33]

Chorioretinitis secondary to congenital toxoplasmosis can manifest at any age, and is often delayed into the second and third decades of life. It usually manifests as strabismus in infants. Defects in visual acuity are more common in older children who had never received treatment. Typically, the eye lesion consists of a focal necrotizing retinitis that is often bilateral with involvement of the macula and even the optic nerve. Complications include blindness, iridocyclitis, and cataracts.[34,35]

Other less common manifestations of congenital toxoplasmosis are nonimmune hydrops fetalis, myocarditis, nephrotic syndrome, and immunoglobulin abnormalities with both hypergammaglobulinemia and hypogammaglobulinemia described. Bony abnormalities consisting of metaphyseal lucencies similar to those seen in congenital syphilis have also been reported.[36] A variety of endocrine abnormalities may occur, including hypothyroidism, diabetes insipidus,[37,38] precocious puberty, and growth hormone deficiency.

Evaluation

Attempts to diagnose congenital toxoplasmosis occur either during pregnancy as part of a surveillance protocol, due to maternal disease or abnormal fetal findings, or, after birth, due to concern for infection. The testing methods vary depending upon the scenario and can be complicated. While commercial laboratories are able to perform some assays, reference laboratories are needed for more intensive evaluation and can be very useful with the availability of their consultative services such as the Palo Alto Medical Foundation *Toxoplasma* Serology Laboratory (PAMF-TSL; Email: toxolab@pamf.org, telephone: 650-853-4828, http:www.pamf.org/serology/).

Serologic assays for measurement of antibodies to *T. gondii* in serum and body fluids are the most widely used methods of diagnosing toxoplasmosis in a pregnant woman and the fetus or newborn, but can be difficult to interpret.[24,39–46] Most commercial laboratories can test for *Toxoplasma* IgG and IgM,

although *Toxoplasma* IgM assays performed in these laboratories are fraught with low sensitivity and, importantly, false positive results. The more commonly used tests that detect *T. gondii*-specific IgG antibodies are IgG enzyme-linked immunosorbent assay (ELISA), indirect immunofluorescent antibody test, and direct agglutination. The Sabin-Feldman dye test is considered the gold standard but requires live organisms, and, accordingly, is performed at reference laboratories.[47] If a pregnant woman is known to be seronegative prior to pregnancy and followed serially, then these IgG assays are useful to document seroconversion during pregnancy and risk of the fetus. However, most countries, including the United States, do not have routine prenatal screening, in which case it is important to decipher whether a positive test represents recent infection or chronic infection without a risk to the fetus. Reference laboratories can perform a differential agglutination test to differentiate acute from chronic maternal infection. This test compares the IgG serologic titer obtained with the use of formalin-fixed tachyzoites (HS antigen) with those obtained with acetone- or methanol-fixed tachyzoites (AC antigen). The latter preparation contains stage-specific *T. gondii* antigens that are recognized by IgG antibodies only during early infection. An additional assay to assist in ruling out maternal infection acquired in the first 3 months of pregnancy is the IgG avidity test performed by the ELISA technique.[44] This test is based on the principle that, although the antibody-binding avidity or affinity for an antigen is initially low after primary antigenic stimulation, IgG antibodies that are present from previous antigenic stimulation are usually of high avidity. Therefore, a high-avidity result in the first trimester would exclude an infection acquired in the previous 12 weeks. Finally, an enzyme-linked immunofiltration assay has been developed that allows some discrimination between IgG antibodies of maternal origin and IgG synthesized by the fetus, as well as identification of antibody subtypes in infected neonates.[48]

Tests that detect *T. gondii*-specific IgM are (1) the double-sandwich IgM ELISA, which has a sensitivity of 75% to 80% and a specificity of 100%;[5] (2) the IgM immunosorbent agglutination assay (ISAGA), which is the most sensitive test but should not be performed on umbilical cord blood because even small quantities of maternal IgM antibodies contaminating the specimen will yield a false-positive result; and (3) the IgM immunofluorescent antibody test. The last test is not recommended because it has a much lower sensitivity than either the IgM ELISA or IgM and it has poor specificity secondary to rheumatoid factors and antinuclear antibodies, contributing to false-positive results. Other tests used in reference laboratories include a *T. gondii*-specific IgA ELISA and IgA immunofiltration assay; a *T. gondii*-specific IgE immunofiltration assay; and IgG, IgM, and IgA immunoblotting tests, which are generally used in comparing samples from the infant and the mother to help determine true infection. Interferon gamma release assays on infants have been used to diagnose congenital infection, but are not available commercially.[47]

Polymerase chain reaction (PCR) analysis has been used successfully to detect *T. gondii* DNA in amniotic fluid, placenta, CSF, brain, urine, and fetal and infant blood.[49–55] PCR performed on amniotic fluid obtained by amniocentesis is the preferred method of confirming in utero infection.[56] False-negative results have been reported, however, and interlaboratory variability in performance of PCR assays has been documented.[52,55] PCR performed on neonatal CSF is recommended for the evaluation of possible central nervous system involvement.

Isolation of *T. gondii* from body fluids and tissues provides definitive evidence of infection. The organism can be isolated from placenta, amniotic fluid, fetal blood obtained by cordocentesis, umbilical cord blood, infant peripheral blood, and CSF by means of intraperitoneal and subcutaneous inoculation into laboratory mice.[20,24,57] Mouse inoculation may require as long as 4 to 6 weeks for demonstration of the parasite. Although it is not a practical method, isolation of the organism should be attempted to confirm a diagnosis and is available at the PAMF-TSL reference laboratory. In addition, tissue culture has been used to isolate *T. gondii* from amniotic fluid.

Histopathologic examination of the placenta and tissues, obtained at postmortem examination or by biopsy from stillborns or infants, should be performed because the specimens may demonstrate the presence of tachyzoites. In addition, tachyzoites have been demonstrated in CSF, ventricular fluid, and aqueous humor by specialized staining techniques.

Because most adults with acquired *T. gondii* infection are asymptomatic, evaluation of the pregnant woman and fetus is usually prompted by either seroconversion or an elevated maternal *Toxoplasma* spp. IgG titer.[58–60] The latter may reflect chronic past infection; therefore, the acuity of the maternal infection is determined serologically with the HS-AC differential agglutination test where agglutination titers to formalin-fixed tachyzoites (HS antigen) are compared with titers against acetone- or methanol-fixed tachyzoites (AC antigen). In general, an acute pattern demonstrates high AC and HS titers, while a nonacute pattern demonstrates high AC titers and low HS titers. This method can differentiate an acute from a remote infection in pregnant women, whereas IgM and IgA antibodies detectable by ELISA or ISAGA are elevated for prolonged periods. If recent maternal infection is documented by an acute pattern on the HS-AC test, seroconversion, or rising IgG antibody titers, the fetus should be evaluated by ultrasonography, and amniotic fluid should be tested for specific *Toxoplasma* spp. DNA with PCR. PCR has supplanted the need for cordocentesis, and a positive result confirms fetal infection.[53] Postnatally, serologic testing of paired maternal and infant sera should be performed at a reliable laboratory that will include assays for *Toxoplasma* spp. IgG, IgM ISAGA and IgA antibodies.[61] Waiting until the newborn is 10 days of age avoids contamination with maternal blood and false positive IgM and IgA results. Subinoculation of placental tissue, amniotic fluid, and umbilical cord blood into mice should be considered. If results of these tests suggest possible infection, the newborn should be evaluated fully with complete blood cell count and platelet determination, liver function tests, CSF evaluation (including tests for IgG and IgM antibodies and PCR),[62] cranial ultrasound or CT imaging of the head, ophthalmologic examination, and hearing evaluation. The presence of neonatal IgM antibody in serum or CSF, or a positive PCR in blood or CSF, indicates congenital infection. In addition, at-risk infants should undergo serologic follow-up to detect rising serum IgG titers during the first year of age, or persistence of IgG antibody beyond 12 to 15 months of age, when most maternal IgG antibody has disappeared.[45,47,63] Uninfected infants show a continuous decline in *T. gondii* IgG titer which usually is gone by 7 months of age with no detectable IgM or IgA antibodies.

Low IgG titers and an HS-AC differential agglutination test that indicate remote maternal infection do not require further evaluation of the mother or infant unless the mother is severely immunosuppressed. Because fetal infection has occurred during chronic *T. gondii* infection in very immunosuppressed women

such as those with poorly controlled HIV infection, their infants should be evaluated serologically at birth for evidence of congenital infection. It has been suggested that HIV-infected pregnant women who have low $CD4^+$ T lymphocyte counts-and who are seropositive for *T. gondii* antibody-receive prophylaxis to prevent fetal infection.[24,64] However, insufficient data currently are available to recommend that such therapy be given routinely for this indication. Nevertheless, if such women previously have had toxoplasma encephalitis, prophylaxis with pyrimethamine, sulfadiazine, and leucovorin (folinic acid) should be considered.[65]

Management

Fetuses and infants younger than 1 year who are infected with *T. gondii* should receive specific therapy effective against this congenital pathogen, even if they have no clinical signs of disease.[24,29,49,58,59,66–75] Compared with untreated historical controls, the outcome is improved substantially by neonatal treatment. The effectiveness of maternal and fetal treatment is less clear. Spiramycin has been used in pregnant women with acute toxoplasmosis to reduce transplacental transmission of *T. gondii*. If fetal infection is confirmed after the 17th week of pregnancy, however, treatment with pyrimethamine, sulfadiazine, and folinic acid is recommended. Prenatal treatment of congenital toxoplasmosis is believed to reduce the clinical severity of infection in the newborn while shifting the disease to a more subclinical form. This may ameliorate the long-term neurologic complications that are commonly seen among infants who have clinical manifestations in the neonatal period. A meta analysis of the effectiveness of prenatal treatment of toxoplasmosis infection found no evidence that such treatment significantly decreased clinical manifestations of disease in infected infants.[76] However, other studies in Brazil, Germany, and France suggest efficacy.[77,78]

Neonatal treatment has resulted in reductions in sensorineural hearing loss, as well as neurodevelopmental and visual handicaps. Table 35.2 shows the recommended guidelines for the treatment of congenital toxoplasmosis. In infants with congenital toxoplasmosis, the treatment consists of pyrimethamine, sulfadiazine, and folinic acid (leucovorin).[20,29,79] The optimal duration of therapy is not known, although prolonged courses of at least 1 year are preferred. Currently most experts recommend combined treatment until the patient is 1 year old.[20,74,80] Accessing pyrimethamine in the United States has recently become difficult due to extreme cost escalation. Assistance with access is available through http://www.daraprimdirect.com (phone number: 1-877-258-2033).

Complete blood cell and platelet counts must be monitored closely while the patient is receiving therapy because granulocytopenia, thrombocytopenia, and megaloblastic anemia can occur. These parameters usually improve once a higher dose of folinic acid (leucovorin) is administered or pyrimethamine and sulfadiazine are discontinued temporarily. The indications for adjunctive therapy with corticosteroids such as prednisone (0.5 mg/kg twice per day) are CSF protein concentration 1 g/dL or higher and chorioretinitis that threatens vision; corticosteroid

TABLE 35.2 Treatment Guidelines for Toxoplasmosis

Condition	Therapy	Dose (Oral Unless Specified)	Duration
Pregnant woman with acute toxoplasmosis	Spiramycin for first 21 weeks of gestation or until term if fetus not infected	3 g/day, divided twice a day without food	Until fetal infection documented or excluded at 21 weeks; if fetal infection documented, replaced with pyrimethamine, leucovorin, and sulfadiazine (see below)
Pregnant women-fetal infection confirmed (amniotic fluid PCR+)	Pyrimethamine (if fetal infection confirmed after 18th week of gestation or if infection acquired in last few weeks of gestation) *and*	Loading dose: 100 mg/day in two divided doses for 2 days followed by 50 mg/day	Until delivery
	Sulfadiazine *and*	3 g/day divided in	Until delivery
	Folinic acid	5–20 mg/day	Until delivery
Congenital *Toxoplasma gondii* infection in infant	Pyrimethamine *and*	Loading dose: 2 mg/kg/day for 2 days; then 1 mg/kg/day for 6 months; then 1 mg/kg/day on Monday, Wednesday, and Friday each week	1 year
	Sulfadiazine *and*	100 mg/kg/day in 2 daily divided doses	1 year
	Leucovorin (folinic acid)†	5–10 mg 3 times weekly	1 year
	Corticosteroids (prednisone)‡	1 mg/kg/daily in 2 daily divided doses	Until resolution of elevated (≥1 g/dL) CSF protein or active chorioretinitis that threatens vision

†Monitor blood and platelet counts weekly; adjust dosage for megaloblastic anemia, granulocytopenia, or thrombocytopenia.
‡When signs of inflammation or active chorioretinitis have subsided, dose can be tapered and eventually discontinued; use only in conjunction with pyrimethamine, sulfadiazine, and leucovorin.
Data from Boyer KM and Nadipuram SM. Toxoplasmosis. In: Cherry JD, Harrison GJ, Kaplan SL, Steinbach WJ, Hotez PJ, eds. *Feigin and Cherry's Textbook of Pediatric Infectious Diseases*. 8th ed. Philadelphia: Elsevier; 2019.

treatment is continued until either condition resolves. Current therapies are not effective against encysted bradyzoites and, therefore, may not prevent reactivation of chorioretinitis and neurologic disease.

Outcomes

Maternal toxoplasmosis acquired during the first and second trimesters has been associated with stillbirth and perinatal death secondary to severe fetal infection in approximately 35% and 7% of cases, respectively. Among infants born with congenital toxoplasmosis, the mortality rate has been reported to be as high as 12%. In addition, infants with congenital toxoplasmosis are at high risk for ophthalmologic, neurodevelopmental, and audiologic impairments, including mental retardation (87%), seizures (82%), spasticity and palsies (71%), and deafness (15%).[28,29,68,69] Of neonates with subclinical infection, long-term follow-up reveals eye or neurologic disease in as many as 80% to 90% by the time they reach adulthood.[81–85] While data from the United States National Collaborative Treatment Trial show that severity is influenced by host and parasite factors, treatment of neonates with congenital toxoplasmosis early and for 1 year resulted in more favorable outcomes than were reported for untreated infants or infants who were treated for only 1 month.[86]

Prevention

Pregnant women whose serologic status for *T. gondii* is negative or unknown, as well as women who are attempting to conceive, should be educated on the prevention of congenital toxoplasmosis through avoidance of at-risk behaviors that may expose them to cat feces or encysted bradyzoites in raw meat.[87–90] Instructions to wear gloves when changing cat litter boxes or gardening and to wash hands after such activities should be given. Daily changing of cat litter will also decrease the chance of infection, because oocysts are not infective during the first 1 to 2 days after passage. In addition, keeping domestic cats inside, and feeding them commercially prepared foods rather than undercooked meats or wild rodents, reduces the likelihood of their becoming infected and capable of transmitting the infection to a pregnant woman. Oral ingestion of *T. gondii* can be prevented by either cooking meat to well done, smoking it, or curing it in brine, and by washing kitchen surfaces and utensils that come into contact with raw meat. Vegetables and fruits should be washed, and hands and kitchen surfaces should be cleaned after handling fruits, vegetables, and raw meat. Flies and cockroaches may serve as transport hosts for *T. gondii*, so their access to food must be prevented.

Routine serologic screening of women during pregnancy has been an effective means of prevention in such countries as France and Austria, where the incidence of congenital toxoplasmosis is high. No such screening is currently in existence in the United States.[91] However, high-risk women, including those who are immunocompromised, should be screened early in pregnancy. Neonatal screening for IgM antibody has also been advocated so that asymptomatic infants can be detected and treated before neurologic symptoms develop.[92] This strategy, however, has been hampered by the lack of readily available and reliable IgM test kits. Moreover, such screening will not detect the approximately 25% of infected neonates who lack anti-*Toxoplasma* spp. IgM antibody. Further study involving cost analyses is needed to define the best preventive strategy for congenital toxoplasmosis in specific populations, regions, and countries.

Congenital Syphilis

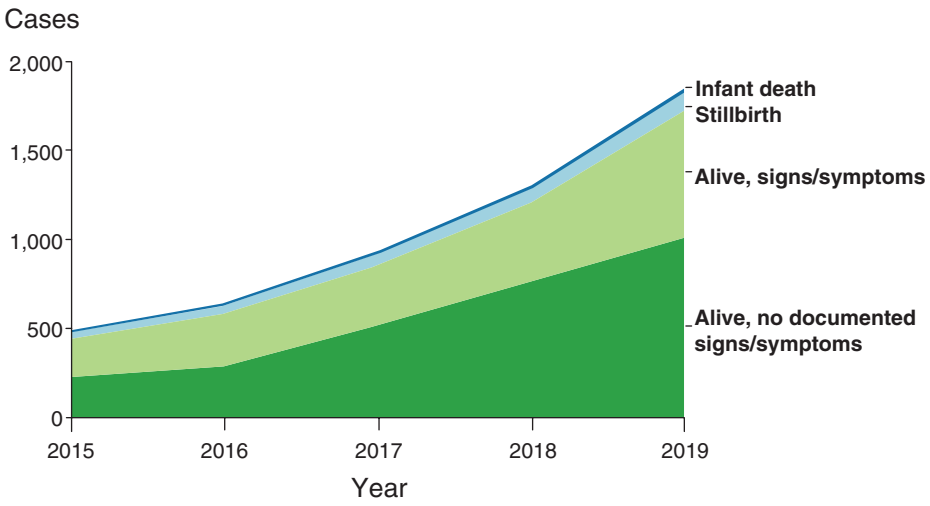
Epidemiology

Congenital syphilis, a result of fetal infection with the spirochete *Treponema pallidum*, remains a major public health problem worldwide. While adults acquire the infection sexually, infants are infected mostly in utero by a transplacental route or possibly during delivery by contact with a genital lesion of an infected mother. When maternal infection is detected during pregnancy, congenital syphilis is both preventable and treatable. However, if infected infants are not identified in a timely fashion, they may experience lifetime consequences. Accordingly, the Centers for Disease Control and Prevention (CDC) recommend that no mother or newborn be discharged from the hospital without the maternal serologic status for syphilis having been documented at least once during the pregnancy, and preferably again at delivery if the mother is at increased risk or lives in a community with high prevalence of syphilis infection.

The incidence of congenital syphilis mirrors the rates of primary and secondary syphilis in women. Overall, congenital syphilis disproportionately affects infants of black women whose prenatal care was inadequate or lacking. Less prenatal care has been associated with increased risk of fetal death that most often occurs by 31 weeks' gestation. From 1999 to 2013 in the United States, neonatal mortality secondary to congenital syphilis was 12/1000 live births, with a case fatality rate of 6.5%. Of the 418 reported deaths, 82% were stillbirths and 89% of the mothers had untreated or inadequately treated syphilis.[93]

During the pre-penicillin era of the 1930s and 1940s in the congenital syphilis clinic of the Harriet Lane Home (Baltimore, MD), 60 to 80 infants and children attended each week for arsenic therapy. Many more were lost to follow-up before completing their 2- to 3-year course of treatment. It was unusual if fewer than three or four new cases were discovered in the general outpatient department each week. Subsequently, the frequency of congenital syphilis declined for several decades, only to increase dramatically in the late 1980s and early 1990s. This increase was fueled by the crack cocaine epidemic with women exchanging drugs for sex with multiple and anonymous partners. At the same time in 1988, the CDC surveillance case definition for reporting cases of congenital syphilis was broadened to include all liveborn and stillborn infants who had reactive serologic tests for syphilis, irrespective of clinical findings, and those delivered to women with untreated or inadequately treated syphilis. This change resulted in a fourfold increase in reported cases of congenital syphilis when compared to the previously used Kaufman criteria that included only symptomatic infants (reviewed in).[94] For unclear reasons, maternal syphilis subsequently declined, and the rate of congenital syphilis decreased from 1991 to 2005 but increased slightly during 2005 to 2008. From 2008 to 2012, the overall rate of congenital syphilis again decreased from 10.5 to 8.4 cases per 100,000 live births, reflecting decreasing trends in primary and secondary syphilis among women in the United States. Since 2012, rates of congenital syphilis increased significantly (8.4 cases per 100,000 live births in 2012 to 48.5 cases per 100,000 live births in 2019). In 2019, there were 1870 cases of congenital syphilis that included 94 stillbirths and 34 infant deaths (Fig. 35.2).[95] The recent increase in syphilis has been attributed to the ongoing opioid epidemic in the United States.

Worldwide, congenital syphilis remains a major cause of fetal and neonatal mortality with more newborns affected by congenital syphilis than by any other neonatal infection.[96] The World Health



• **Fig. 35.2** Reported congenital syphilis cases between 2015 and 2019 and their manifestations. Signs and symptoms include long bone changes, snuffles, condyloma lata, jaundice, hepatitis, syphilitic rash, etc. Sexually Transmitted Disease Surveillance 2019. (Data from Centers for Disease Control and Prevention. *Sexually Transmitted Disease Surveillance 2019*. Atlanta: US Department of Health and Human Services; 2021.)

Organization estimated that, globally, nearly 1 million pregnant women were actively infected with syphilis in 2016,[97] resulting in an estimated 660,000 cases of congenital syphilis, and half of them have infants with adverse outcomes such as stillbirth or prematurity, nonimmune hydrops, and death.[98] The global burden of congenital syphilis is confounded further by the high prevalence of infection with the human immunodeficiency virus (HIV), as syphilis is a known risk factor for acquisition of HIV.

Pathogenesis

The causative agent for syphilis is *T. pallidum*, a thin, corkscrew-shaped, flagellated, highly motile spirochete. *T. pallidum* is able to invade the fetal compartment at any time during gestation, although the risk of fetal infection increases as the stage of pregnancy advances. Spirochetes have been detected in fetal tissue from spontaneous abortion as early as 9 and 10 weeks' gestation and recovered from amniotic fluid at 14 weeks of pregnancy. Vertical transmission is related directly to the maternal stage of syphilis, with early syphilis resulting in significantly higher transmission rates than late latent infection. Ingraham reported in 1950 that among 251 women with syphilis of less than 4 years' duration, 41% of their infants were born alive and had congenital syphilis, 25% were stillborn, 14% died in the neonatal period, 21% had low birth weight but no evidence of syphilis, and 18% were normal full-term infants.[99] In contrast, only 2% of infants born to mothers with late latent disease had congenital syphilis. In 1952, Fiumara and colleagues reported that untreated maternal primary or secondary syphilis resulted in 50% of infants having congenital syphilis while the other 50% were stillborn, premature, or died in the neonatal period. With early and late latent infection, 40% and 10% of infants, respectively, had congenital syphilis.[100] These data are supported by a more recent study of Sheffield and colleagues in which mothers with primary, secondary, early latent, and late latent infection had transmission rates of 29%, 59%, 50%, and 13%, respectively.[101]

Because *T. pallidum* enters the fetal bloodstream directly, the primary stage of infection is completely bypassed. There is no chancre and no local lymphadenopathy. Instead, there is widespread hematogenous spread to all organs and tissues, including the liver, spleen, pancreas, intestine, kidney, skin, mucous membranes of the lips, nose and anus, bones and cartilage, and the central nervous system. Invasion of the lung results in a characteristic "pneumonia alba" that is seen more frequently in developing countries.

Microscopically, the tissue alterations consist of interstitial fibrosis and perivascular inflammation with plasma and round cell infiltration, with visualization of spirochetes by silver or fluorescent staining. Gumma formation is infrequent in neonates, while extramedullary hematopoiesis involving the liver, spleen, dermis, kidneys, and other organs is common.

The placenta of infants with congenital syphilis often is large, thick, and pale. Histopathologic features include villous enlargement, acute villitis, and erythroblastosis. Intense inflammation of the umbilical cord results in a "barber's pole" appearance where the edematous portions have a spiral striped zone of red and pale blue discoloration, interspersed with streaks of chalky white. Histologically, the umbilical cord exhibits abscess-like foci of necrosis within Wharton's jelly and umbilical vessels. Placental and umbilical cord histopathology should be performed on every case of suspected syphilis.

Clinical Presentation

Two characteristic syndromes of congenital syphilis have been described. *Early congenital syphilis* refers to those clinical manifestations that appear in the first 2 years of age, while those features that occur after 2 years and usually at puberty are designated as *late congenital syphilis*. The clinical, laboratory, and radiographic abnormalities of early congenital syphilis are a consequence of active infection with *T. pallidum* and the resultant inflammatory response induced in various body organs and tissues. The severity of these manifestations is highly variable and can range from overwhelming involvement of multiple organs and body systems as occurs in nonimmune fetal hydrops to only laboratory or radiographic abnormalities. Most infants born to mothers with untreated syphilis appear normal and have no clinical or laboratory evidence of infection at birth but may develop manifestations of disease several months to years later if left untreated.

The signs and symptoms of early congenital syphilis are summarized in Table 35.3. Prematurity and low birth weight is seen in

TABLE 35.3 Clinical Features of Congenital Syphilis in the Neonatal Period

Feature	Prevalence (%)
Hepatomegaly with or without splenomegaly*	60–100
Radiographic bone changes (periostitis; osteochondritis);* pseudoparalysis of Parrot	75–100 12
Lymphadenopathy	20–50
Jaundice	50–70
Skin rash*	40
Hepatitis (elevated transaminase concentrations)	40
Anemia and/or thrombocytopenia	20–50
Respiratory distress (pneumonia)	34
Fever	10†
Small for gestational age	10
Nonimmune hydrops	5
Rhinitis, mucous patch, condyloma lata, nephrotic syndrome, myocarditis, diarrhea (malabsorption), pancreatitis, chorioretinitis, cataract	Rare (<5)
Central nervous system (leptomeningitis, cranial nerve palsies, cerebral infarction, seizures, hypopituitarism)	Rare (<5)

*Prominent feature.
†More common when infant presents at >3 weeks of age.

10% to 40% of infants.[102] Hepatosplenomegaly is frequent, with extramedullary hematopoiesis a prominent finding in both the liver and spleen. Approximately one-third of infants have direct and indirect hyperbilirubinemia and elevated transaminase levels that may worsen transiently after initiation of penicillin therapy. Liver abnormalities may require months to resolve, but they rarely lead to cirrhosis. Generalized lymphadenopathy occurs in about 20% of infants, with characteristic enlargement of epitrochlear nodes. Anemia secondary to hemolysis or infection of the bone marrow with hematopoietic suppression may be severe.[103] Thrombocytopenia with petechiae and purpura occurs frequently and may be the sole manifestation of congenital infection. Other less common manifestations include ocular findings (chorioretinitis, cataract, glaucoma, and uveitis), pneumonitis, pneumonia alba, nephrotic syndrome, myocarditis, pancreatitis, and inflammation and fibrosis of the gastrointestinal tract leading to malabsorption and diarrhea.

Mucocutaneous lesions occur in 40% to 60% of affected infants. The rash of congenital syphilis usually is oval and maculopapular but becomes copper-colored with desquamation (Fig. 35.3) mostly in the palms and soles. A characteristic vesicular bullous eruption known as *pemphigus syphiliticus* may develop with erythema, blisters, and eventual crusting and skin wrinkling. Mucocutaneous junctions also may be involved, with the lips becoming weepy, thickened, and rough. Radial cracks may traverse the vermillion zone surrounding the margins of the lips and are the beginning of the radiating scars called rhagades that is seen with late congenital syphilis. Rarely, mucous patches of the lips, tongue, and palate, as well as white, flat, moist, raised plaques known as *condylomata lata* in the perioral and perianal areas, may occur. Rhinitis ("snuffles"), a watery nasal discharge that may become thick, purulent, and blood-tinged, occurred in almost two-thirds of patients in the early literature but is now less prevalent.[104] Both the nasal discharge and vesicular fluid contain large concentrations of spirochetes, and are highly infectious.

Bone radiographs demonstrate characteristic osteochondritis and periostitis in 60% to 80% of infants with clinical signs of congenital syphilis and 20% of well-appearing, congenitally infected infants (Fig. 35.4). These abnormalities tend to involve the long bones (tibia, humerus, femur), ribs, and cranium, and are usually symmetric, with the lower extremities involved more often than the upper extremities. Rarely, the bone lesions may be painful and result in subepiphyseal fracture and epiphyseal dislocation with

pseudoparalysis of the affected limb (pseudoparalysis of Parrot). Osteochondritis involves the metaphysis and is visualized on the long bone radiographs approximately 5 weeks after fetal infection. There is metaphyseal demineralization with a radiolucent band representing a zone of osteoporosis below a radiodense band below the epiphyseal plate that is a widened and enhanced zone of provisional calcification. Roentgenographically, this results in the classic transverse saw-toothed appearance of the metaphysis whose margins become serrated, jagged, and irregular. Bilateral demineralization and osseous destruction of the proximal medial tibial metaphysis is referred to as *Wimberger sign*. Periostitis requires 16 weeks for roentgenographic demonstration and consists of multiple layers of periosteal new bone formation in response to diaphyseal inflammation. After several months, complete healing of the affected bones occurs, even without antibiotic therapy.

Central nervous system invasion by *T. pallidum* occurs in about 50% of infants with clinical, laboratory, or radiographic signs of congenital syphilis. Clinical signs of central nervous system involvement, however, are rare in the neonatal period but can occur later if infected infants are not identified and treated.[103] Such manifestations include bulging fontanelle, seizures, leptomeningitis, cranial nerve palsies, hydrocephalus, cerebral infarction, and pituitary gland dysfunction with hypoglycemia and diabetes insipidus.

The clinical manifestations or stigmata of late congenital syphilis result from persistent inflammation or scarring following early congenital syphilis infection and is prevented by treatment during gestation or within the first 3 months of age. Infants with late congenital syphilis are not infectious. Late manifestations include dental stigmata such as Hutchinson's teeth, where the permanent upper central incisors are small, widely spaced, barrel shaped, and notched, and mulberry molars where the first lower molar has many small cusps instead of the usual four. Osteochondritis affecting the otic capsule may lead to cochlear degeneration and fibrous adhesions resulting in eighth nerve deafness, for which corticosteroid treatment may be beneficial. Late ocular manifestations include uveitis and interstitial keratitis. The constellation of interstitial keratitis, eight cranial nerve deafness, and Hutchinson's teeth is known as Hutchinson's triad.

The sequela of periostitis of the skull is frontal bossing, of the tibia is saber shins, and of the clavicle is Higouménakis sign with sternoclavicular thickening. Clutton joints, or painless synovitis and hydrarthrosis, are rare. The sequelae of syphilitic rhinitis include rhagades and short maxilla with a high palatal arch. If the inflammation of the nasal mucosa extends to the underlying cartilage and bone, perforation of the palate and nasal septum occurs, resulting in a "saddle nose" deformity. Sequelae of central nervous system infection include mental retardation, hydrocephalus, seizure disorder, cranial nerve palsies, paralysis, and optic nerve atrophy.[105,106]

Evaluation

The diagnosis of congenital syphilis is established by the observation of spirochetes in body fluids or tissue and suggested by serologic test results. *T. pallidum* may be identified by dark field microscopy, polymerase chain reaction (PCR) testing, and fluorescent antibody or silver staining of mucocutaneous lesions, nasal discharge, vesicular fluid, amniotic fluid, placenta, umbilical cord, or tissue obtained at autopsy. Its diagnosis, however, remains challenging since *T. pallidum* cannot be cultivated in artificial media and many infected infants lack clinical, laboratory, and radiographic signs of disease. In addition, the diagnosis often can only be inferred since maternal nontreponemal and treponemal IgG antibodies are transferred transplacentally to the fetus, complicating the interpretation of reactive serologic tests for syphilis in neonates. A diagnosis of congenital syphilis is supported by an infant's serum quantitative nontreponemal antibody titer that is at least fourfold higher than the mother's titer. The absence of such a finding, however, does not exclude a diagnosis of congenital syphilis.

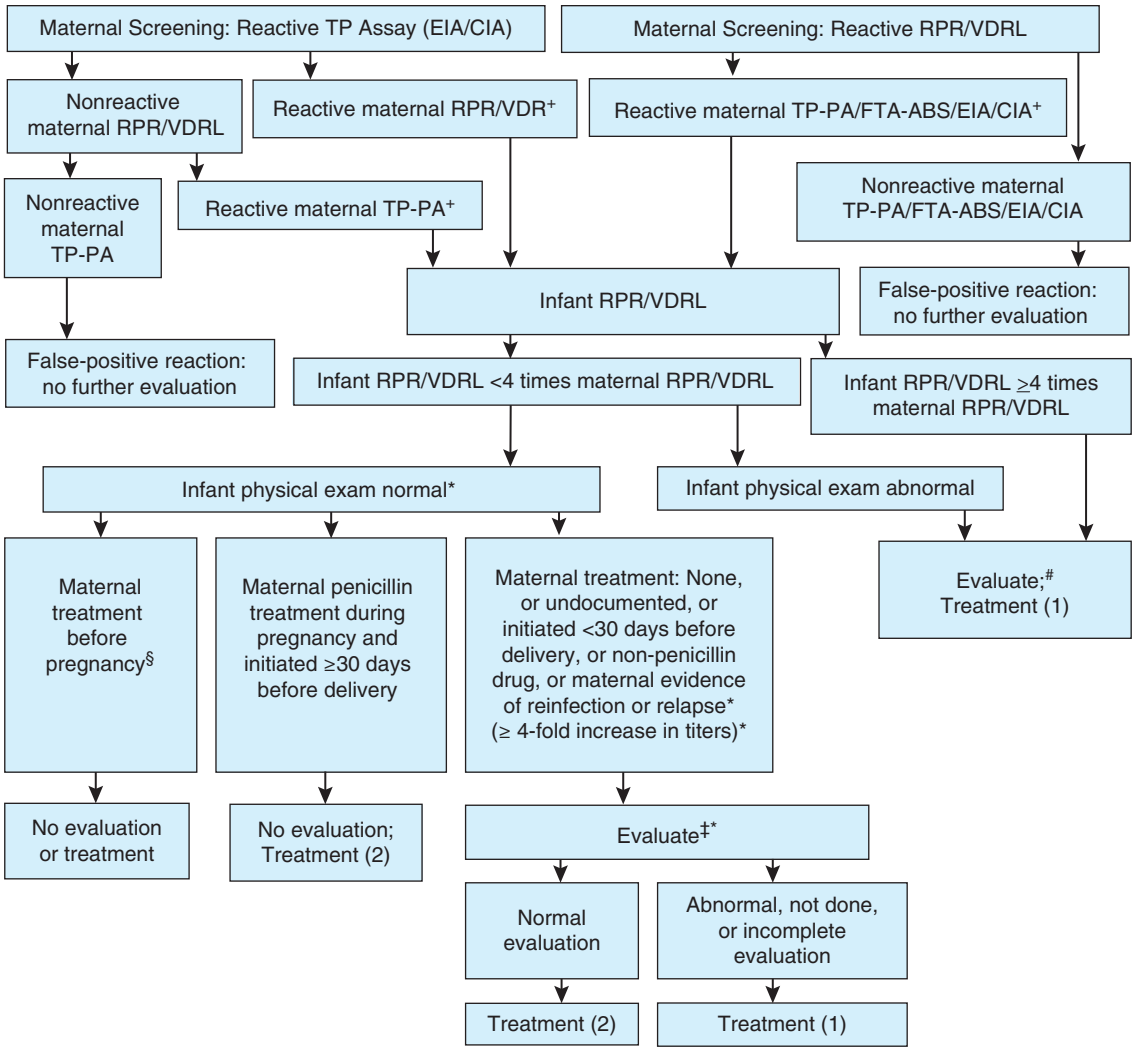
Serologic tests for syphilis are classified into nontreponemal and treponemal tests. Nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin (RPR) test. The same nontreponemal test should be performed on the mother and infant so that accurate comparisons can be made. Serologic testing of the infant should be performed on serum and not umbilical cord blood since false positive test results have been reported secondary to contamination of the specimen with maternal blood or Wharton's jelly. False-negative test results also may occur when the maternal nontreponemal titer is of low dilution.[107] Measurement of total cord IgM levels, as well as use of treponemal IgM enzyme-linked immunosorbent assays (ELISA) and the fluorescent treponemal antibody absorption (FTA-ABS)-IgM test, have not proved useful in the diagnosis of congenital syphilis, and are not recommended.[108]

Treponemal tests include the *T. pallidum* particle agglutination (TP-PA) test, the fluorescent treponemal antibody-absorption (FTA-ABS) test, and treponemal immunoassay (i.e., enzyme immunoassay (EIA), chemiluminescence immunoassay (CIA), and multiplex flow immunoassay). These treponemal tests are used to confirm the diagnosis of syphilis.

The diagnosis of congenital neurosyphilis is difficult to establish, with treponemal infection of the central nervous system only inferred from abnormalities of the cerebrospinal fluid (CSF) such as a reactive VDRL test, pleocytosis (greater than 18 to 25 white blood cells per microliter), and elevated protein content (>150 mg/dL; >170 mg/dL if infant is premature). However, a reactive CSF VDRL test in neonates may be caused by passive transfer of nontreponemal IgG antibodies from serum into the CSF. By inoculation of CSF into rabbit testes with resultant syphilitic infection of the rabbit, Michelow and coworkers found that invasion of the central nervous system with *T. pallidum* occurs in 41% of infants who have clinical, laboratory, or radiographic abnormalities of congenital syphilis and in 60% of those who have an abnormal physical examination consistent with a diagnosis of congenital syphilis.[109] The sensitivity and specificity of a reactive CSF VDRL test, pleocytosis, and elevated protein content were 53% and 90%, 38% and 88%, and 56% and 78%, respectively.[110] Therefore, if clinical, laboratory or radiographic evaluation supports a diagnosis of congenital syphilis, then therapy effective against central nervous system disease is warranted.

A practical approach to the evaluation and treatment of infants born to mothers with reactive serologic tests for syphilis is presented in Fig. 35.5.[104,111]

All pregnant women and their sexual partner(s) who have syphilis should be tested for coinfection with HIV, although infants born to mothers coinfected with syphilis and HIV do not require different evaluation, therapy, or follow-up. Infants born to mothers with reactive serologic test results for syphilis should have a serum quantitative nontreponemal test (VDRL or RPR) performed and be carefully examined for physical signs



\+ Test for HIV-antibody. Infants of HIV-infected mothers do not require different evaluation or treatment.

* If the infant's RPR/VDRL is nonreactive AND the mother has had no treatment, undocumented treatment, treatment initiation <30 days before delivery, or evidence of reinfection or relapse (≥ 4-fold increase in titers), THEN treat infant with a single IM injection of benzathine penicillin (50,000 U/kg). No additional evaluation needed.

§ Women who maintain a VDRL titer ≤1:2 (RPR ≤1:4) beyond 1 year following successful treatment are considered serofast.

\# Evaluation consists of CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL. Other tests as clinically indicated: long-bone x-rays, neuroimaging, auditory brainstem response, eye exam, chest x-ray, liver function tests.

‡ CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL; long-bone x-rays

TREATMENT:

(1) Aqueous penicillin G 50,000 U/kg IV q 12 hr (≤1 wk of age), q 8 hr (>1 wk), or procaine penicillin G 50,000 U/kg IM single daily dose, x 10 days

(2) Benzathine penicillin G 50,000 U/kg IM x 1 dose

• **Fig. 35.5** Algorithm for evaluation and treatment of infants born to mothers with reactive serologic tests for syphilis.

of congenital syphilis. Neonates who have an abnormal physical examination that is consistent with congenital syphilis, a serum quantitative nontreponemal serologic titer that is fourfold or greater than the mother's titer, or a positive dark-field or fluorescent antibody test or PCR result of lesions or body fluid(s) should have a complete blood cell count (CBC) and platelet count performed as well as CSF examination for cell count, protein content, and CSF VDRL test. Other tests, such as bone and chest radiographs, liver function tests, cranial ultrasound, ophthalmologic examination, and auditory brainstem response, should be performed as clinically indicated. These infants are considered to have proven or highly probable disease. Since spirochetemia with invasion of the central nervous system is likely, it is beneficial for follow-up purposes to establish central nervous system abnormalities at presentation by performance of a lumbar puncture for CSF analysis.

For well-appearing neonates who have a normal physical examination and a serum quantitative nontreponemal serologic titer that is equal to or less than fourfold the maternal titer, further evaluation and treatment depends on the maternal treatment history (see Fig. 35.5). If the mother has untreated syphilis or the treatment is undocumented or inadequate (syphilis treatment initiated <4 weeks before delivery or with any non-penicillin G regimen), a complete evaluation consisting of CSF analysis, long bone radiographs, and complete blood cell (CBC) and platelet counts should be performed to guide optimal therapy. The evaluation must be completely normal if the infant is to be treated with a single intramuscular dose of benzathine penicillin G. Almost none of these infants will have central nervous system invasion by *T. pallidum* if their complete evaluation is normal. Alternatively, a complete evaluation is not necessary if 10 days of parenteral penicillin therapy is provided. A complete evaluation also is not indicated in newborns with normal physical examination and nonreactive nontreponemal test results as they are unlikely to have abnormalities detected on conventional laboratory and radiographic testing.[112]

However, treatment of the infant for possible incubating or asymptomatic syphilis is dependent on maternal syphilis treatment history.

Management

Penicillin G is the only known effective antimicrobial agent for prevention of vertical transmission of syphilis and treatment of fetal infection and congenital syphilis. Pregnant women with syphilis should receive the penicillin regimen appropriate for the stage of infection, and if any dose of therapy is missed for latent syphilis, the full course of therapy must be repeated (Table 35.4). Pregnant women who have a history of penicillin allergy should be desensitized and treated with penicillin.[95]

The decision to treat an infant for congenital syphilis is based on the clinical presentation, previous serologic test results and treatment of the mother, and the results of serologic testing of the infant and mother at the time of delivery (Table 35.5; see Fig. 35.5). Infants with proven or highly probable disease, or who have a normal physical examination but their evaluation is abnormal or incomplete, should be treated with either aqueous crystalline penicillin G (50,000 U/kg intravenously every 12 hours for the first week of age, followed by every 8 hours beyond 7 days of age) or aqueous procaine penicillin G (50,000 U/kg intramuscularly once daily) for 10 days. If more than 1 day of therapy is missed, the entire course should be restarted. Data are insufficient regarding the use of other antimicrobial agents (e.g., ampicillin). When possible, a full 10-day course of penicillin is preferred, even if ampicillin was initially provided for possible sepsis.

Infants who have a normal physical examination, CSF studies, CBC and platelet counts, and long bone radiographs can be treated with a single intramuscular injection of benzathine penicillin G at a dose of 50,000 U/kg. If the risk of infection in these infants is substantial and adequate follow-up cannot be ensured, the 10-day course of aqueous or procaine penicillin is recommended by the CDC and American Academy of Pediatrics, regardless of results of the CSF and laboratory examination. Failure of a single injection of benzathine penicillin in the treatment of congenital syphilis has been reported among high-risk seropositive neonates who did not have a complete evaluation. Treatment failures also have been attributed to the inability of penicillin to adequately penetrate and achieve treponemicidal concentrations in certain sites such as the aqueous humor and central nervous system.

TABLE 35.4 Recommended Treatment for Syphilis during Pregnancy

Stage of Syphilis*	Drug (Penicillin)†	Route	Dose (Units)
Primary and secondary	Benzathine penicillin G‡	IM	2.4 million units in a single dose
Early latent (≤1 year duration)	Benzathine penicillin G‡	IM	2.4 million units in a single dose
Late latent (>1 year duration) or latent syphilis of unknown duration	Benzathine penicillin G	IM	2.4 million units weekly × 3
Neurosyphilis and ocular syphilis	Aqueous penicillin G or Procaine penicillin G PLUS Probenecid	IV IM	3–4 million units every 4 h or continuous infusion for 10–14 days§ 2.4 million units IM once daily PLUS 500 mg orally four times a day, both for 10–14 days§

*Persons with HIV infection who have syphilis should be treated as those without HIV infection.
†Pregnant women who have a history of penicillin allergy should be desensitized and treated with penicillin.
‡For women who have primary, secondary, or early latent syphilis, a second dose of benzathine penicillin 2.4 million units IM can be administered 1 week after the initial dose.
§Benzathine penicillin, 2.4 million units IM once per week for up to 3 weeks, can be considered after completion of 10–14 days of intravenous treatment
From Workowski KA, Bachmann LH, Chan PA, et al. Sexually Transmitted Infections Treatment Guidelines, 2021. *MMWR Recomm Rep.* 2021;70(4):1–187. doi:10.15585/mmwr.rr7004a1

Normal neonates born to mothers adequately treated during pregnancy and initiated treatment greater than 4 weeks before delivery should be considered as a "close contact" and receive a single intramuscular injection of benzathine penicillin G (50,000 U/kg), although no evaluation is required or recommended. Similarly, normal infants who have a nonreactive serum nontreponemal test result but are born to mothers with untreated or inadequately treated syphilis can receive a single dose of intramuscular benzathine penicillin G without evaluation—an increasingly common scenario with the use of treponemal tests such as EIAs or CIAs for syphilis screening ("reverse sequence" screening).

During times of penicillin shortage when preparations of penicillin are unavailable, a 10-day course of ceftriaxone can be considered with careful clinical and serologic follow-up, including repeat CSF evaluation.[113] Research efforts are needed to evaluate whether other antibiotics such as ampicillin can effectively treat central nervous system disease.

Within 24 hours of initiation of penicillin therapy, a small percentage of infants who are treated for congenital syphilis may develop a Jarisch-Herxheimer reaction, an acute inflammatory

TABLE 35.5 Recommended Treatment of the Neonate (<30 Days Old) with Syphilis

Neonate	Maternal Stage/Treatment	Evaluation	Antimicrobial Regimen
Confirmed or highly probable disease: (a) Abnormal physical examination consistent with congenital syphilis (b) Abnormal evaluation* (c) Serum nontreponemal titer ≥4 times maternal titer (d) Visualization of spirochetes or detection of *T. pallidum* DNA by PCR of placenta, cord, lesions, or body fluid	Any or none	(1) CSF analysis: VDRL, cell count, and protein (2) CBC and platelet count (3) Other tests as clinically indicated (e.g., long bone radiographs, liver function tests, ophthalmologic examination, hearing evaluation, neuroimaging)	Aqueous crystalline penicillin G 100,000-150,000 units/kg/day IV every 12 h during first 7 days of age and every 8 h when >7 days of age for total 10 days *or* Procaine penicillin G 50,000 units/kg/dose once daily IM × 10 days
Possible congenital syphilis: (1) Normal physical examination; and (2) Serum nontreponemal titer ≤4 times the maternal titer	Any stage of infection *and* Mother was (a) not treated, inadequately treated, or has no documented treatment; (b) treated nonpenicillin regimen; or (c) received appropriate treatment but initiation of treatment <30 days before delivery	(1) CSF analysis for VDRL, cell count, and protein; *and* (2) CBC and platelet count; *and* (3) Long bone radiographs	If complete evaluation normal:† (a) Benzathine penicillin G 50,000 units/kg IM × 1 *or* (b) Aqueous crystalline penicillin G 100,000–150,000 units/kg/day IV every 12 h during first 7 days of age and every 8 h when >7 days of age for total 10 days *or* (c) Procaine penicillin G 50,000 units/kg/dose IM × 10 days
Congenital syphilis less likely: (1) Normal physical exam; and (2) Serum nontreponemal titer ≤4 times maternal titer at delivery	Mother treated appropriately for infection stage and initiation of treatment ≥30 days before delivery; and mother has no evidence of reinfection or relapse.	None	Benzathine penicillin G 50,000 units/kg once daily IM × 1
Congenital syphilis unlikely: (1) Normal physical examination; and (2) Serum nontreponemal titer ≤4 times the maternal titer; and (3) No evidence of re-infection	Mother was adequately treated before pregnancy, and mother's non-treponemal serologic titer remains low and stable before and during pregnancy and delivery (e.g., RPR ≤1:4)	None	None, but benzathine penicillin G 50,000 units/kg IM × 1 may be considered if neonate has reactive nontreponemal test and follow-up is uncertain

*CBC, platelet count, CSF examination, bone radiographs.
†If complete evaluation not done, infant must receive 10 days of penicillin therapy unless infant's RPR/VDRL is nonreactive in which case no evaluation needed but infant should receive benzathine penicillin G (50,000 U/kg IM).
CSF, Cerebrospinal fluid; *VDRL*, Venereal Disease Research Laboratory; *CBC*, complete blood cell count, *RPR*, rapid plasma regain.
From Workowski KA, Bachmann LH, Chan PA, et al. Sexually Transmitted Infections Treatment Guidelines, 2021. *MMWR Recomm Rep.* 2021;70(4):1–187. doi:10.15585/mmwr.rr7004a1

response likely due to the rapid killing of spirochetes. It is characterized by fever, tachypnea, tachycardia, hypotension, accentuation of cutaneous lesions, or even death due to cardiovascular collapse. Treatment is supportive care.

Infants with reactive serologic test results should have serial quantitative nontreponemal tests performed every 2 to 3 months until the test becomes nonreactive. In infants with congenital syphilis, nontreponemal serologic tests should decline fourfold and become nonreactive within 6 to 12 months after appropriate treatment. Uninfected infants usually become seronegative by 6 months of age. Infants with persistently low, stable titers of nontreponemal tests beyond 1 year of age may require retreatment. A reactive treponemal test beyond 18 months of age when the infant has lost all maternal IgG antibodies confirms the diagnosis of congenital syphilis. Infants with abnormal CSF findings at diagnosis no longer need a repeat lumbar puncture performed 6 months after therapy if they are clinically normal and serologic titers have decreased appropriately.[95]

If a lumbar puncture is performed, a reactive CSF VDRL test result or an abnormal protein content or cell count at that time is an indication for retreatment.

Prevention

Congenital syphilis is effectively prevented by prenatal serologic screening of mothers and penicillin treatment of infected women, their sexual partners, and their newborn infants.[114] All pregnant women should have a serologic test for syphilis performed at the first prenatal visit in the first trimester, with the test being repeated at 28 to 32 weeks' gestation and at delivery in areas with a high incidence of syphilis. Serologic screening tests should be performed on mothers and not on infants, because the infant may

have a nonreactive serologic test result, but the mother's test is reactive at a low titer.

Although nontreponemal antibody testing has been recommended for antepartum syphilis screening, treponemal antibody testing (i.e., EIA or CIA) is being used increasingly by many laboratories as a cost-cutting measure for screening pregnant women ("reverse sequence syphilis screening").[115] If a treponemal EIA or CIA test is used for antepartum syphilis screening and is positive, a quantitative nontreponemal test (RPR or VDRL) should then be performed. If the nontreponemal test is reactive, then a diagnosis of past or present syphilis is made and the management of the mother and infant should be handled as discussed previously. However, if the nontreponemal test is negative, then the results are considered discrepant and a second treponemal test (TP-PA preferred) should be performed, preferably on the same specimen. If the second treponemal test is reactive, then current or past syphilis infection is confirmed. For women with a history of adequately treated syphilis, no further treatment is necessary. Women without a history of treatment should be staged and treated accordingly with a recommended penicillin regimen. If the second treponemal test is nonreactive, then the majority of these mothers (65%) are likely to have a false-positive EIA/CIA test result.[116] The need for reflexive testing with a TP-PA is imperative to diagnose syphilis and inform newborn management (see Fig. 35.5). Infants with suspected or proven congenital syphilis can be managed with standard precautions only. If there is cutaneous lesions or mucous membrane involvement, then gloves should be worn as well until 24 hours of treatment has been completed.

All cases of syphilis must be reported to the local public health department, which performs contact investigation and identifies core environments and populations. The public health impact of syphilis in pregnancy and infancy remains substantial, and only through optimal prenatal healthcare services will elimination of maternal-to-child transmission of syphilis become a reality.

Congenital Malaria

Epidemiology

Malaria is a parasitic disease of epidemic proportion. An estimated 214 million new cases of malaria with 409,000 deaths were reported in 2019 alone.[117] The greatest burden of disease occurs in the African regions (94%) and Southeast Asia (3%). In areas of high transmission, mortality is concentrated largely among young children and pregnant women. Children below 5 years of age account for 67% of all malarial deaths[117] with a disproportionate amount occurring in African regions. Malaria is caused by four *Plasmodium* species: *P. falciparum, P. vivax, P. ovale*, and *P. malariae*. Of these, *P. falciparum* is the major cause of morbidity and mortality. Humans typically acquire infection through the bite of the *Anopheles* spp. mosquito. Transmission may also occur through blood transfusion or vertically from the mother to fetus, resulting in congenital malaria.

Congenital malaria occurs with all *Plasmodium* species. Among the 107 cases of congenital malaria reported in 1950 (mostly from Africa), 64% were infected with *P. falciparum*, 32% by *P. vivax*, and 2% by *P. malariae*.[118] Although *P. falciparum* remains the predominant pathogen in sub-Saharan Africa, *P. vivax* may account for a larger proportion of cases in Asia. Among 27 cases reported in Thailand between 1981 and 2005, 82% were caused by *P. vivax*.[119] *P. malariae* is less frequently a causative agent, with fewer than 10 cases reported worldwide since 1950.[120] In China, *P. vivax* accounted for the majority (92.5%) of the 107 cases of congenital malaria cases reported.[121] Concurrent infection with *P. malariae* and *P. vivax* has been documented.[122] In the United States, the predominant *Plasmodium* species causing congenital malaria reflects the countries of origin of the mothers. In Hulbert's (1992) review of 49 cases from 1950 to 1991, 82% of infections were caused by *P. vivax*. In the updated review in the U.S. reflecting 1966–2005, the predominant infecting species remained *P. vivax* (81%), although all four species were represented.[123]

The true rates of congenital malaria reported in the literature vary significantly based on the time span reported, method of reporting, and clinical definition. Congenital malaria is commonly defined as the presence of *Plasmodium* spp. parasites in the peripheral blood during the first 7 days of life where the transmission occurs from the mother via placental transfer.[118,124–127] In contrast, neonatal malaria is defined as the presence of *Plasmodium* spp. parasites in the peripheral blood from 8 to 30 days of life where mosquito transmission is the most likely etiology. These definitions are most applicable in areas of high malaria transmission where, among older infants, it would be difficult to distinguish congenitally acquired from mosquito-acquired disease. This has been suggested by findings from Malawi, where approximately 50% of newborns with cord blood parasitemia were infected with parasites of a different genotype than their mothers at the time of delivery.[128] Outside endemic areas, where postnatal transmission can be reasonably excluded, clinical onset of disease often does not occur until after the first week of life, and age-specific criteria are not useful for the diagnosis of congenital malaria. It is likely that because of the delay in clinical presentation, many cases of congenital malaria in endemic areas were misclassified as being acquired from mosquitoes. Covell found the prevalence of congenital malaria among nonimmune populations (i.e., Europeans residing in or visiting endemic areas) to be approximately 7%.[118] In other estimates prior to the 1970s, the prevalence of congenital malaria—defined as parasitemia detected in the first 7 days of life—was estimated to be 0.3% (16 of 5324 births) among immune mothers. Subsequent reports supported the observed low frequency of congenital malaria—defined as umbilical cord parasitemia or parasitemia in the first 24 hours of life—among indigenous populations.[129–132] These observations have been cited repeatedly in the literature to support the notion that congenital malaria is an uncommon occurrence in endemic areas despite the high prevalence of maternal and placental malaria.

Over the last several decades, however, more in-depth studies of congenital malaria have suggested that it is far more common than initially reported, as rates from endemic and nonendemic areas ranged from 0.2% to 47%.[124,133–135] Many have suggested that low prevalence previously reported for congenital malaria was likely due to inadequate recognition and underreporting.[124,134–140] In Zambia, during a season of heavy malaria transmission, incidence rates for congenital malaria ranged from 4% to 15%.[141] Congenital malaria, defined as neonatal parasitemia, was detected in 15.3% and 17.4% of neonates born in two sites in Nigeria.[142,143] The apparent increase in the frequency of congenital malaria has been attributed to increasing resistance of *P. falciparum* to antimalarial drugs, resulting in increased maternal parasitemia, increased virulence of the parasite, and reduced transmission of antibody from mother to newborn because of malaria chemoprophylaxis administered to pregnant women. Meanwhile a multicentered trial in Nigeria showed an overall prevalence rate of 5% (range of 1.1% to 11.5%).[137] In a recent meta analysis from 2000 to 2019, the overall prevalence rate was estimated at 6.9% and was

significantly higher in unstable malaria transmission areas compared to stable areas.[144] The inconsistency may also represent true environmental differences with differences in levels of maternal immunity. It is clear that congenital malaria can exist in asymptomatic infants which can make reporting in the literature even more variable.[126,127,142]

Congenital malaria in nonendemic areas is rare. As of 1995, only 300 cases of congenital malaria had been reported in the literature,[145] largely from outside of malaria endemic areas. In the United States, the occurrence of congenital malaria is well documented because the country has been free of indigenous disease since the 1950s. From 1950 to 1991, 49 cases of congenital malaria were reported in the literature,[146] and additional cases were reported during the next 15 years.[145,147–151] From 1966 to 2005, 81 cases of congenital malaria were reported to the National Malaria Surveillance system of the CDC.[123] Almost all the cases were among infants whose mothers were foreign born, suggesting that congenital malaria is primarily a health problem of recent immigrants rather than of U.S.-born travelers to malaria-endemic countries. Forty-four women (54%) had emigrated from Asia, 27 (33%) from South or Central America, and 7 (9%) from Africa. Until 1979, one to two cases were reported annually.[152] An abrupt rise to 16 cases around 1981 correlated with an increase in the total number cases of malaria that occurred as a result of a large influx of refugees and immigrants from Southeast Asia, with 15 of the 16 infants being born to mothers from that region.[153] In 2017, the CDC reported two cases of congenital malaria among the 2161 reported cases in the United States.[154,155] The lack of familiarity with this disease in the United States renders it a diagnostic and therapeutic challenge for clinicians, with delays in diagnosis potentially leading to significant morbidity and mortality.[156]

Pathogenesis

Two key features play a critical role in the pathogenesis and natural history of congenital malaria:

1. Maternal and placental parasitemia; and
2. A correlation between umbilical cord parasitemia and neonatal parasitemia.

Pregnancy itself increases the risk of severe malaria. Malaria also increases the risk for adverse pregnancy outcomes, including prematurity, abortion, and stillbirth. Despite major global health efforts, there were 12 million pregnant women at risk for malaria in 2019 in the African region.[157,158] It is well established that both the frequency of disease and density of parasitemia are higher in pregnant women compared with nonpregnant women.[133,159,160] Among 20 studies conducted between 1985 and 2000, the median prevalence of maternal malaria infection (defined as peripheral or placental infection) in all was 28%.[161] More recent studies of endemic areas within the last decade have reported significant geographic variation ranging between 8.1% and 52% prevalence of malaria among pregnant women.[162–164] For this reason, it is widely contended that one in four pregnant women in areas of stable transmission in Africa have evidence of malaria infection at the time of delivery.

The clinical features of *P. falciparum* malaria in a pregnant woman depend to a large degree on her immune status, which in turn is determined by her prior exposure to malaria. Pregnancy itself suppresses both the humoral and cell-mediated portions of the immune system, increasing the susceptibility to severe malaria. Impaired T cell responses reduce systemic control of the infection and the ability to control liver stage infections, resulting in relapse among some forms of *Plasmodium* spp.[165] Primigravidae women have a twofold to fourfold increased risk of placental malaria compared with multigravidae women.[132,133,166] This may be due to levels of antigen specific *Plasmodium* spp. antibodies that appear to be boosted with successive pregnancies.[165] In pregnant women with little or no preexisting malaria immunity, such as women from nonendemic countries or travelers to malaria-endemic areas, infection is associated with high risks of severe disease with significant maternal and perinatal mortality. In contrast, women residing in areas of stable malaria transmission usually have a high level of immunity to malaria. Infection may be frequently asymptomatic and therefore unsuspected or undetected, but it is associated with placental parasitization, with consequent effects on maternal and fetal outcomes.

The most significant consequence of pregnancy-associated malaria is maternal anemia. It is estimated that in sub-Saharan Africa between 200,000 and 500,000 pregnant women develop anemia as a result of malaria, and that up to 10,000 maternal anemia-related deaths are a consequence of *P. falciparum* parasitemia.[166] Malaria in pregnancy also has potentially devastating effects on the fetus and newborn, including spontaneous abortion, still birth, premature delivery, congenital infection, and neonatal death.[128,159] In areas of high transmission in Africa, the risk of LBW approximately doubles if women have placental malaria, with the greatest effect in primigravidae.[133] Pregnancy-associated malaria is believed to be responsible for 30% to 35% of LBW infants and for 75,000 to 200,000 infant deaths each year.[159] In 2019, an estimated 822,000 low birthweight infants were attributed to malaria infection during pregnancy alone.[117]

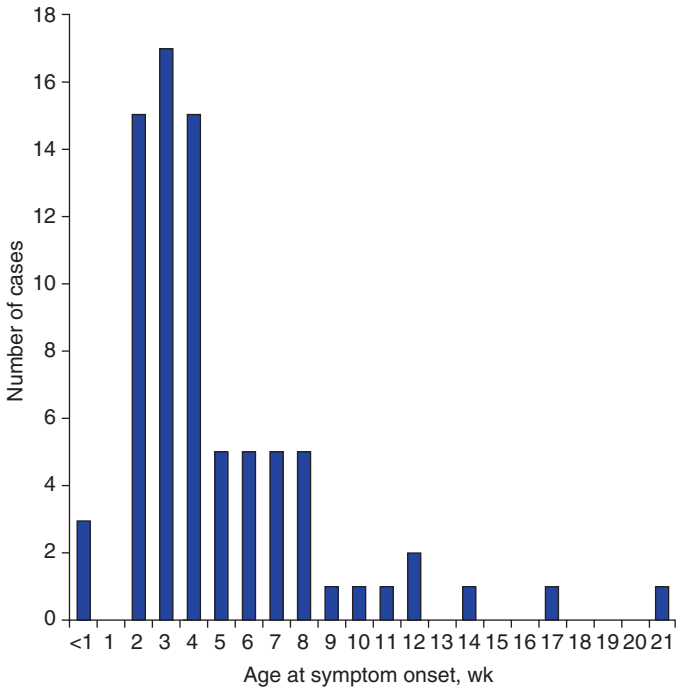
The timing and mechanism of transmission of *Plasmodium* spp. parasites from the mother to the fetus is not well understood. Postulated mechanisms include maternal transfusion into fetal circulation either during pregnancy or at delivery, or direct penetration of parasitized red blood cells through the chorionic villi or through premature separation of the placenta. Plasmodium infected erythrocytes have the unique ability to sequester in the placenta which may facilitate transmission to the fetus.[160,167] In utero transmission is supported by the finding of malarial parasites in fetal tissues at autopsy,[168] by umbilical cord blood parasitemia[132,138,169] and the onset of clinical signs of malaria within hours of birth.[118,149,170] Vertical transmission of malaria probably does not occur as a result of transplacental passage of exoerythrocytic parasites. More likely, transmission occurs by transfusion of parasitized maternal erythrocytes through a breach in the placental barrier that may occur either prematurely during pregnancy or during labor. Transmission of malaria by breastfeeding is not known to occur.

The fate of the *Plasmodium* spp. parasite is unclear after it is transmitted to the fetus. Reinhardt found parasites in thick smears of umbilical cord blood in 22% of 19 infants born to women in the Ivory Coast, but the peripheral blood smears were negative for all of the infants.[171] Similarly, 4% of 1009 infants born to Tanzanian women had parasites in cord blood, but parasitemia was detected on peripheral smear in only 2 of 11 infants.[132] Parasitemia detected shortly after birth may also resolve without evolving into clinically symptomatic disease. The correlation between maternal, placental, umbilical cord, and peripheral parasitemia was evaluated in 1875 mother-baby pairs in Nigeria. Thick and thin blood smears were obtained within 4 hours of birth, and smear-positive (cord or peripheral) neonates were retested on days

2, 3, and 7 of life. Treatment was provided for those with symptoms or persistent parasitemia. The overall prevalence of congenital malaria was 5.1%, with parasitemia detected in 19% of infants born to mothers with peripheral parasitemia, 21% of those born to mothers with placental malaria, and 45% of those with positive cord smears. Spontaneous clearance of parasitemia occurred in 62% of infants before day 2, whereas 33% were symptomatic within 3 days of birth.[137] Depending on the region, spontaneous clearance of peripheral parasitemia has been documented in 87% to 100% of neonates.[123,142] Larkin and Thuma[169] found peripheral parasitemia within 24 hours of age in 19 of 51 newborns (65%), but only 7 had clinical signs of disease. Because all 19 newborns received antimalarial therapy, it is unknown how many would have manifested disease if untreated. The spontaneous clearance of *Plasmodium* spp. has been attributed to the protective effects of passive maternal antibody and weakened adherence to fetal hemoglobin.[172]

Clinical Presentation

Infants with congenital malaria may be asymptomatic or can develop symptoms several weeks after birth. The clinical picture of overt congenital malaria is detailed in cases reported outside of endemic areas.[123,146,173,174] The manifestation of disease, although occasionally noted within hours of birth,[149,170] is typically delayed until the infant is several weeks old. In the classic review of 49 infants with congenital malaria reported in the United States between 1950 and 1992, the mean age at onset of symptoms was 5.5 weeks, with 96% of infants presenting between 2 and 8 weeks of age.[146] Among cases reported to the CDC from 1966 to 2005,[123] the median age of symptom onset for 81 infants was 21.5 days for all species combined (Fig. 35.6). Infants infected with *P. malariae* were significantly older at symptom onset (mean, 53 days) compared with those infected with *P. vivax* or *P. falciparum*.



• **Fig. 35.6** Age in weeks at symptom onset of infants with reported congenital malaria, United States, 1966–2005. (From Lesko CR, Arguin PM, Newman RD. Congenital malaria in the United States: a review of cases from 1966 to 2005. *Arch Pediatr Adolesc Med*. 2007;161:1062–1067.)

The prolonged interval between birth and onset of clinical manifestations may be explained by transmission late in pregnancy or at delivery, such that multiple erythrocytic life cycles are required to produce clinically evident disease. Alternatively, the delay may be attributed to the presence of transplacentally acquired maternal antimalarial antibodies. When such antibodies are present in sufficient concentrations, as in infants born to immune mothers, parasitic replication can be prevented or attenuated, and clinical signs can be mild, delayed, or even absent. The presence of a high concentration of fetal hemoglobin in newborns may also promote resistance to a multiplication of parasites. Among infants born to mothers with low or nonexistent immunity, parasitic replication is more likely uninhibited, and clinical signs of malaria may supervene. Preterm infants, who do not benefit from passive immunity, can manifest clinical signs earlier than full-term infants. In a review of premature neonates with congenital malaria, four of five infants received a diagnosis in the first week of life,[175] although the prompt medical evaluation afforded these infants may have facilitated earlier detection.

The clinical features of congenital malaria are nonspecific and often resemble those of bacterial or viral sepsis and other congenital infections. Fever is almost uniformly present, although without the classic paroxysmal pattern described for malaria beyond the neonatal period. Hulbert[146] noted fever in all 44 infants for whom clinical information was available. In the cases reported from 1966 to 2005, fever was reported in 70 of 81 cases (86%).[123] Hepatomegaly and splenomegaly suggestive of a transplacentally acquired infection are found in a substantial portion of infants (Table 35.6). Anemia (often hemolytic), thrombocytopenia, and hyperbilirubinemia are the most commonly reported laboratory findings. Additional signs, symptoms, and laboratory findings are listed in Table 35-6.

In endemic areas, the traditional belief has been that congenital malaria is rare and that when it occurs the infant is typically asymptomatic and develops no clinical features. The lack of symptoms has been attributed to transplacentally acquired antibodies from the mother as well as the protective effects of high levels of fetal hemoglobin. Falade et al.[137] noted spontaneous clearance of parasitemia in 62% of 95 neonates before day 2 of life. Of the remaining infants, 34% were symptomatic within 3 days of birth, with fever and refusal to eat being the most common signs of disease. When active surveillance for malaria was conducted in newborns being evaluated for possible bacterial sepsis in Nigeria, 16 of 203 (8%) neonates had parasitemia, and 10 (5%) met the definition of congenital malaria.[139] Predominant features of disease included fever, respiratory distress, anemia, and hepatomegaly. In another area in Nigeria, of 202 neonates younger than 1 week who were admitted for evaluation of sepsis, 71 (35%) were diagnosed with congenital malaria.[176] Fever was the most common symptom and was present in 93% of infants. Refusal to feed and jaundice were reported in approximately 33%. These observations suggest that, as in infants diagnosed outside endemic areas, the clinical presentation of congenital malaria in endemic areas does not differ significantly from bacterial sepsis. Because the clinical symptoms of congenital malaria may be indistinguishable from that of neonatal sepsis, it is suggested that screening for malaria be included as part of routine investigation of newborns with fever in areas of high malaria transmission.[143,176]

TABLE 35.6 Frequency of Symptoms, Signs, and Laboratory Findings Among 81 Infants With a Diagnosis of Congenital Malaria (United States, 1966–2005)

Symptoms, Signs, and Laboratory Findings	Infants, No. (%)*
Fever	70 (86)
Anemia	28 (36)
Splenomegaly	25 (31)
Hepatomegaly	16 (20)
Thrombocytopenia	12 (15)
Jaundice	11 (14)
Irritability	8 (10)
Anorexia	8 (10)
Vomiting	8 (10)
Cough	6 (7)
Diarrhea	3 (4)
Lethargy	3 (4)
Hemolysis	3 (4)
Pallor	3 (4)
Hyperbilirubinemia	2 (3)
Failure to thrive	2 (3)
Seizures	2 (3)
Dyspnea	1 (1)
Purpura	1 (1)
Tachycardia	1 (1)
Monocytosis	1 (1)

*Percentages do not total 100% because each case can have more than one symptom, sign, or laboratory finding.
From Lesko CR, Arguin PM, Newman RD. Congenital malaria in the United States: a review of cases from 1966 to 2005. *Arch Pediatr Adolesc Med.* 2007;161:1062–1067.

Evaluation

Diagnostic tests for malaria include blood smears, rapid antigen detection tests (RDTs) and PCR. Definitive diagnosis of congenital malaria is based on the microscopic demonstration of parasites on stained thick and thin blood films. Thick blood smears test for the presence of parasites by concentration of red blood cells, whereas thin blood smears allow species identification and quantification of parasitemia. In cases of suggested congenital malaria, specimens for smears should be obtained from both the infant and the mother. If test results from the initial set of smears are negative, additional sets should be obtained every 12 to 24 hours; three sets are generally considered sufficient for diagnostic evaluation. Response to therapy may also be measured by clearance of parasitemia on blood films.

RDTs are based on the immunochromatographic detection of parasite-specific antigens circulating in the bloodstream. Many RDTs are commercially available outside the United States, and, depending on the antigens targeted, the tests may detect only *P. falciparum* or all *Plasmodium* species. RDTs are simple to use, do not require specialized training or facilities, and offer a useful alternative to microscopy in situations where reliable microscopic diagnostics are not readily available. However, the tests have demonstrated mixed results in multiple trials, and sensitivity remains a problem, especially at low parasite densities. To assure standard high-quality control among RDTs used worldwide, the World Health Organization has provided a laboratory-based evaluation to compare the performance of numerous RDT used amongst malaria programs. (The minimum performance criteria is >90% sensitive, detection of at least 75% of low-density samples, false positive rate of <10% and invalid rate of <5%.) In the most recent round of testing in 2014–2015, all products tested could detect high levels of parasitemia; however, low parasite density (200 parasites/μL) detection varied significantly.[177] Information regarding the sensitivity of these tests is limited for neonatal or congenital malaria. Currently the World Health Organization recommends microscopy or malaria RDT in all patients with suspected malaria before treatment is initiated.

The major advantage of PCR for the diagnosis of malaria is its ability to detect low level parasitemia with species specification. Currently, PCR is used mainly to confirm positive blood smears, particularly when the results of the smear are not definitive or there is a mixed species infection. PCR may detect DNA from circulating nonviable parasites after treatment, resulting in difficulty differentiating an active infection from a recently cleared infection. Currently, PCR is only used for epidemiologic research or survey mapping in endemic areas. Although PCR is a highly sensitive alternative to microscopy, the infrastructure and expertise required preclude its use in malaria-endemic areas and in many health care settings in the United States.[178]

As with malaria in general, the diagnosis of congenital malaria outside of endemic areas is often delayed because of nonspecific features and lack of clinical suspicion. Among the 81 cases reviewed by Lesko et al.[123] a median length of delay of 8.5 days was noted for 15% of the infants. Occasionally, the diagnosis is made incidentally. In all four cases of congenital malaria reported by Quinn et al.[153] *Plasmodium* spp. parasites were noted by hematology technicians on routine smears performed for blood cell counts. Maternal history of recent travel to or emigration from an endemic area may suggest the diagnosis but is often obscured by the lack of clinical or laboratory findings in the mother. Lesko et al.[123] found that, of the mothers for whom a history was available, 67% reported having fever during pregnancy, and 26% reported a diagnosis of malaria during pregnancy. Maternal blood films were performed after either symptomatic illness or malaria diagnosis in the infant. Overall, only 42% of women had parasitemia detected, although it is not clear whether an adequate number of smears was conducted for each patient. As a result, lack of peripheral parasitemia in the mother of an infant with suspected congenital malaria does not exclude the diagnosis.

Further confounding the early recognition of disease in the infant is the potentially prolonged lapse between malaria exposure in the mother and transmission of infection to the infant. *P. vivax* and *P. ovale* may remain dormant in the liver, especially if the infected individual did not receive therapy for the exoerythrocytic stage, which can cause a delayed relapse of malaria in travelers or immigrants. *P. malariae* can persist for 20 to 40 years before clinical symptoms or demonstrable parasitemia appear.[148] Congenital malaria has been reported in an infant whose mother lived in the United States for 5 years before delivery and had

no signs or symptoms or malaria for more than 20 years.[174] In North Carolina, congenital *P. malariae* infection was reported in a 10-week-old infant who was born to a mother who had emigrated from the Democratic Republic of Congo 4 years before delivery.[148] In a review by Lesko et al.[123] the median duration from the mother's last exposure to delivery was 9.5 months. The time elapsed since exposure was longest for those with *P. malariae* infection, ranging from 2 to 12 years.

Recognizing that congenital malaria is an exceptional occurrence in the United States, it is still important to include malaria in the differential diagnosis of fever in infants born to mothers who have been exposed to malaria, even if the exposure is remote and even if the woman is asymptomatic. Of 11 infants with congenital malaria in the United States born to women known to have parasitemia at or shortly after delivery, only five underwent testing by blood smears, and all five had negative test results at the time of delivery.[123] Data are insufficient to determine the overall risk of an infant developing congenital malaria when born to a woman at risk for parasitemia or identified with parasitemia at birth. Consequently, the evaluation of infants born outside endemic areas to women with epidemiologic risk factors for parasitemia should be individualized. In malaria endemic areas, and as a public health measure, it has been recommended that blood smears should be checked as part of the evaluation of neonates with fever born to mothers who have had fever within a few weeks of delivery.[127]

Management

The management of malaria consists of supportive care and antimalarial therapy. Information regarding treatment of congenital malaria is limited, and recommended chemotherapy is similar to that of noncongenital infections. The treatment regimen is based on the infecting species, the possibility of drug resistance, and the severity of disease. For mild infections caused by *P. vivax, P. ovale*, and *P. malariae* or chloroquine-sensitive *P. falciparum*, chloroquine orally (10 mg base/kg initially followed by 5 mg base/kg 6, 24, and 48 hours later) is recommended. Treatment with primaquine is not necessary for congenitally acquired *P. vivax* or *P. ovale* infection because, like transfusion-associated malaria, congenital infection does not involve the exoerythrocytic phase.[179]

The treatment of congenital malaria due to chloroquine-resistant *P. falciparum* is poorly defined. In older children, the three treatment options currently recommended are: (1) oral quinine plus either tetracycline, doxycycline, or clindamycin; (2) atovaquone-proguanil; or (3) mefloquine. For the treatment of congenital malaria, oral quinine sulfate and trimethoprim-sulfamethoxazole for 5 days was recommended by Quinn et al. (1982), who used the regimen to treat a 1-month-old infant.[153] Ahmed et al.[175] used a similar regimen for the treatment of an infant born at 28 weeks' gestation to a mother from Zaire. Quinine and clindamycin have been used for *P. falciparum* congenital malaria.[180] Artemisinin-based combination treatments, such as dihydroartemisinin-piperaquine, can also be used in infants for drug resistant *Plasmodium* spp.[134,181] Other regimens used successfully in neonates include oral quinine sulfate and pyrimethamine-sulfadoxine[149] and intravenous quinine hydrochloride followed by oral quinine.[182] Intravenous quinine is no longer available in the United States. Because of the rarity of congenital malaria in the United States, the changing pattern of resistance, and the potential toxicity associated with drugs used for therapy, current treatment recommendations should be sought from the Malaria Branch of the CDC (www.cdc.gov/malaria). For health care professionals, assistance with management of malaria is also available 24 hours a day through the CDC Malaria Hotline (855-856-4713).

Severe malaria occurs most commonly with *P. falciparum* infection and is characterized by one or more of the following: (1) parasitemia greater than 5% of red blood cells, (2) central nervous system or other end-organ involvement, (3) shock, (4) acidosis, (5) severe anemia, or (6) hypoglycemia. Management of severe malaria involves parenteral treatment in an intensive care setting. Until recently, the only parenteral therapy available in the United States was quinidine gluconate. Quinidine is more cardiotoxic than quinine and should be administered with continuous cardiac monitoring. Artesunates can be given either intravenously or intramuscularly for 24 hours until oral medication can be tolerated, at which time combination therapy should be instituted.[181] Exchange transfusion may be warranted when parasitemia exceeds 10% or if there are complications at lower parasite densities.

The efficacy of treatment should be monitored by examining blood smears (i.e., malaria smears) every 12 hours until negative for malaria parasites. Response to therapy with chloroquine for non-*P. falciparum* malaria is usually favorable.[170,173,183] It has been suggested that infants born to mothers with parasitemia at delivery should be treated presumptively for congenital malaria.[123] Data are insufficient to determine the risk of an infant developing congenital malaria when born to a mother with parasitemia. Although there is evidence from endemic areas that parasitemia detected at or shortly after delivery may clear spontaneously, the clinical relevance of this observation in nonendemic areas is unclear. It is recommended that physicians judge each case individually, considering factors such as access to medical care and reliability of follow up in deciding whether to treat infants presumptively.

Outcomes

Malaria during pregnancy is likely an underappreciated risk factor for increased infant morbidity and mortality in endemic areas. In a review of studies published between 1985 and 2000, a 3% to 8% infant mortality rate was calculated based on population-attributable risks for maternal malaria.[161] It was estimated that 75,000 to 200,000 infant deaths annually are associated with malaria during pregnancy, although what proportion of these are related to congenital malaria is unknown. Outside endemic areas, the short-term outcome of congenital malaria has been favorable. Most infants respond rapidly to therapy, with clearance of parasitemia. There were no reports of death or adverse outcomes in the 49 cases reported from 1950 to 1992 or in the 81 cases reported to the CDC from 1966 to 2005.[123,146] It is unclear, however, whether the outcomes are due to an overall favorable prognosis or to a reporting bias.

Prevention

The prevention of congenital malaria is based on a pregnant woman's avoidance of exposure and use of chemoprophylaxis. The burden of malaria among pregnant women in endemic areas is well recognized, and prevention and control strategies for areas of high *P. falciparum* transmission are aimed at reducing maternal and infant mortality. The World Health Organization has proposed a three-pronged approach: (1) long-lasting insecticidal nets, (2) intermittent preventive treatment with an effective antimalarial agent in pregnancy, and (3) prompt diagnosis and

effective treatment of malaria infection. In areas of moderate to high transmission of *P. falciparum*, this three-pronged intervention is strongly recommended along with intermittent preventive treatment with sulfadoxine/pyrimethamine. This drug regimen is administered during antenatal care starting in the second trimester, at least 1 month apart, until the time of delivery.[184] A meta-analysis of more recent intervention trials suggests that successful prevention of these infections reduces the risk of severe maternal anemia by 38%, LBW by 43%, and perinatal mortality by 27%, among women in their first and second pregnancies.[133] Unfortunately, the full implementation of antenatal malaria prevention efforts is burdened by the challenges associated with health care delivery in the developing world. In 2015, 15 million of the 28 million pregnant women at risk for malaria did not receive a dose of preventive medication.[185] About 80% of pregnant mothers in the African countries at highest risk used antenatal services, of which only 62% received intermittent preventive treatment and only 50% received a second dose.[117]

Pregnant women originally from areas where malaria is endemic, but who are now living in nonendemic areas, may be only partially immune. When traveling to their countries of origin, they should be considered nonimmune and, thus, should receive the same recommendations as nonimmune women. For women in the United States who are pregnant or likely to become pregnant, the CDC advises they avoid travel to areas with malaria transmission. If such travel is unavoidable, consultation with an infectious disease or malaria expert is advised. The use of mosquito netting, mesh screens on windows, insecticides, and mosquito repellents can decrease potential exposure to malaria parasites. For pregnant women traveling to areas where there is no chloroquine-resistant *P. falciparum* malaria, prophylaxis with chloroquine is recommended. The safety of chloroquine for the fetus when used at the recommended doses for malaria prophylaxis is well established.[122] For travel to areas where chloroquine resistance has been reported, mefloquine can be used prophylaxis during pregnancy. Use of atovaquone-proguanil during pregnancy was not associated with increased risk of birth defects[186] and can be used for treatment of malaria in the second and third trimester.[187] Doxycycline is contraindicated because of potential adverse effects on the fetus caused by a related drug, tetracycline, which include enamel hypoplasia and discoloration of teeth and inhibition of bone growth. Health care professionals caring for women who cannot take the recommended antimalarial agent should contact the CDC Malaria Hotline (855-856-4713).

Congenital Tuberculosis

Epidemiology

Tuberculosis (TB) remains one of the leading causes of infectious disease deaths worldwide[188,189] and it remains one of the deadliest communicable diseases. One quarter of the world's population is infected with *Mycobacterium tuberculosis*. In 2019, 10 million new TB cases were identified, and 1.2 million people died from the disease.[188] The greatest burden of disease is in developing countries, where TB remains a major public health threat. While case rates have decreased in the United States and Europe, the corresponding numbers have increased dramatically in the former Soviet Union, where public health efforts are impeded by political unrest, and in sub-Saharan Africa, where TB has been fueled by the epidemic of human immunodeficiency virus (HIV).

In the United States, the incidence of TB declined steadily from 1953 through 1984, reaching a nadir of 9.4 cases per 100,000 people. The resurgence of disease was attributed to multiple factors, including the HIV epidemic, increased immigration, and a decline in public health funding for tuberculosis control. With the availability of antiretroviral therapy for HIV and fortification of public health measures, the epidemiologic trend was reversed. The overall incidence of TB in the United States has decreased dramatically since 1992 from 26,673 per 100,000 to only 9421 per 100,000 in 2014.[190] Despite the decrease in the total burden of disease, tuberculosis continues to disproportionately affect the foreign-born and racial and ethnic minorities. Among the 47,718 people with reported TB in the United States, 67% occurred in foreign-born persons between 2012 and 2016.[191]

The current epidemiology of tuberculosis in pregnancy is not well defined. Historical studies prior to the 1900s indicated that the severity of disease was greater during pregnancy though later reports appeared to contradict these early reports.[192] With the resurgence of tuberculosis in the 1980s, the largest increase in the incidence of disease occurred in the 25- to 44-year age group, and the number of cases among women of childbearing age rose by 40%.[193] In 2014, nearly 40% of TB cases among women were in those of child bearing age between 15 to 45 years of age.[194] Thus women of childbearing age, especially those who are foreign born, and their newborns are at continued risk. An estimated 1.04 million children were treated for TB in 2018 and 2019 worldwide.[188]

The prevalence of congenital TB is likely rare as fewer than 400 case reports have been published in the English-language literature. Most published cases were those in the pre-chemotherapy era.[195] Hageman et al.[196] reported two cases of congenital TB and reviewed another 24 reported in the English-language literature since the introduction of isoniazid (INH) in 1952. In the subsequent 30 years, more than 34 additional cases of neonates with congenital tuberculosis have been described (Table 35.7).[193,195,197–209] The majority of reports describe infants born in low-burden countries to mothers who have emigrated from high-burden countries. Although some reports originate from countries where TB is endemic, it is likely that congenital tuberculosis is underrecognized and underreported in these areas, largely due to the nonspecific clinical features of disease and the limited diagnostic capability. In a recent review of Chinese medical literature, 92 cases of congenital TB were reviewed that included 21 cases between 2011 and 2018.[210] With increased global mobility and the epidemiologic trends of tuberculosis, it is likely that tuberculosis and congenital tuberculosis will continue to be observed in developed countries. The nonspecific features of congenital tuberculosis and the mortality associated with untreated disease underscore the importance of maintaining a high index of suspicion for tuberculosis in pregnant women and young infants.

Pathogenesis

Transmission of *M. tuberculosis* from the mother to the neonate can occur in utero, intrapartum, or postpartum. Although congenital infection is classically considered the result of in utero infection of the fetus, the term *congenital tuberculosis* has historically referred to infection acquired either in utero or intrapartum. The infection can be transmitted by direct spread to the fetus from the placenta via the umbilical vein or by aspiration/ingestion of infected amniotic fluid, either in utero or intrapartum.

TABLE 35.7 Reviews of Cases of Congenital Tuberculosis Cases Reported in the English-Language Literature in the Era of Chemotherapy

Reference	Years Cases Reported	No. of Cases	Age at Clinical Presentation (d)	No. of Infants With Reactive TST	Common Symptoms	Mortality (%) (With Treatment)
Hageman et al. (1980)	1952–1980	26	NR	2 of 14	Respiratory distress, fever, hepatomegaly	46 (12)
Cantwell et al. (1994)	1980–1994	31	Median 24 (range 1–84)	0 of 9	Hepatosplenomegaly, respiratory distress, fever	38 (22)
Abughali et al. (1994)	1952–1994	58	NR	1 of 19	Respiratory distress, hepatomegaly, fever	45 (14)
Laartz et al. (2002)	1994–2002	16	Mean 17.4 (range, 1–60)	1 of 4	Respiratory distress, hepatomegaly, fever	20

TST, Tuberculin skin test.

Historically, congenital tuberculosis criteria were described by Beitzke in 1935 to distinguish congenital tuberculosis from postnatally acquired tuberculosis. The criteria required that the infant have proven tuberculosis lesions and one of the following: (1) a primary hepatic complex as evidence of dissemination of the tubercle bacilli via the umbilical vein or (2) in the absence of a primary complex, the presence of tuberculous lesions in the first few days of life or the exclusion of postnatal infection by separation of the infant at birth from the mother and other potential sources of infection. These criteria were developed before the introduction of chemotherapy, when infant mortality with congenital tuberculosis was high and diagnosis was largely based on autopsy findings. The demonstration of a primary hepatic complex with liver and regional node involvement requires an open surgical procedure; a percutaneous liver biopsy may demonstrate caseating granulomas, but the primary complex will seldom be identified. Given the impractical nature of such criteria, Cantwell et al.[193] proposed a revised set of diagnostic criteria that became more applicable to current practice with improved diagnostic sensitivity. The infant must have proven tuberculous lesions and at least one of the following: (1) lesions in the first week of age, (2) a primary hepatic complex or caseating hepatic granulomas, (3) tuberculous infection of the placenta or maternal genital tract, or (4) exclusion or postnatal transmission by thorough investigation of contacts.

The risk of congenital tuberculosis in infants born to women with tuberculosis is unknown but likely low. Blackall[211] reported only three cases among infants born to 100 mothers with tuberculosis. Ratner et al.[212] identified no cases among infants born to 260 mothers with the disease. In a study of 1369 infants separated at birth from their tuberculous mothers and placed in foster care, only 12 became tuberculin-positive during 4 years of observation, and in all 12 cases there was a source of infection in the postnatal environment.[193] The low incidence of congenital TB is in part attributable to the high likelihood of infertility in women who have endometrial TB.[213] However, in areas with high rates of tuberculosis transmission, neonates may be undiagnosed or underreported, and the incidence of congenital infection or vertical transmission remains unknown.

Congenital TB is transmitted in one of three ways: (1) hematogenous spread from the infected placenta via the umbilical vein, (2) in utero aspiration or ingestion of amniotic fluid infected from the placenta or endometrium, or (3) ingestion of infected amniotic fluid or secretions from maternal genital lesions during delivery. In pregnant women, tuberculous bacillemia can result in dissemination of infection to the placenta, the endometrium, or the genital tract. Hematogenous seeding and in utero aspiration likely account for many congenital TB cases though actual documented sources are not well documented.[209,214–216] Several anecdotal cases of congenital TB have been reported in the literature associated with in vitro fertilization, for which, in retrospect, TB salpingitis was the likely cause of sterility.[217–219] While such events are likely to be associated with a very low frequency of congenital infection, they occur in more medically sophisticated areas that are likely to report them in the medical literature.

Tuberculous bacilli have been demonstrated in the decidua, amnion, and chorionic villi of the placenta.[214] It is unlikely that the fetus can be infected directly from the mother without the presence of a caseous lesion in the placenta, although massive involvement of the placenta does not always result in congenital tuberculosis. When a tubercle ruptures into the fetal circulation, bacilli in the umbilical vein can infect the liver, forming a primary focus with involvement of periportal lymph nodes. The bacilli also may pass through the liver and right ventricle and into the lungs, or they can enter the left ventricle via the foramen ovale and pass into the systemic circulation. The organisms in the lung remain dormant until after birth, when oxygenation and circulation result in their multiplication and the subsequent development of a primary pulmonary focus. Alternatively, if the caseous lesion in the placenta ruptures directly into the uterine cavity and infects the amniotic fluid, the fetus can inhale or ingest the bacilli, leading to primary foci in the lung, intestine, or middle ear. Pathologic examination of tuberculosis in the fetus and newborn usually demonstrates disseminated disease, with the liver and lungs being principally involved. Among 38 postmortem cases,[220] the lungs were involved in 97%, the liver in 82%, and the spleen in 76% of the infants. Other sites described are the gastrointestinal tract, kidneys, adrenal glands, and skin.[196,221,222] It is not always possible to determine whether sites represent multiple primary foci or are secondary to primary lesions in the lung or liver. The only lesion in the neonate that is unquestionably associated with congenital infection is a primary complex in the liver; all others may be acquired congenitally or postnatally.

M. tuberculosis infection acquired in utero or perinatally may be indistinguishable from postpartum infection. Postnatal acquisition of *M. tuberculosis* acquired by airborne inoculation, either from the mother or another contagious adult in the infant's environment, is the most common route of infection of the neonate. In addition, postnatal infection can occur from ingestion of infected breast milk from a mother with a tuberculous breast abscess. In the absence of a breast abscess, transmission of tuberculosis via breast milk has not been documented.[223] The distinction between congenital tuberculosis and postnatally acquired disease may be important for academic or epidemiologic purposes, but the management, treatment, and prognosis of the disease processes are the same.

Clinical Presentation

The clinical manifestations of congenital tuberculosis are protean. Complications from tuberculosis during pregnancy include stillbirth, recurrent abortion, and infertility.[224] A retrospective cohort study from Mexico of infants born to 35 mothers whose pregnancies were complicated by TB demonstrated an approximately two fold risk of prematurity compared with newborns of mothers without tuberculosis.[225] Manifestations of disease resemble those of neonatal sepsis or other congenital infections. The affected infant is commonly born prematurely.[226–231] Clinical signs may be evident shortly after birth, but typically do not appear until 2 to 4 weeks of age (see Table 35.8). Among the 29 cases reviewed by Cantwell et al.[193] the median age of presentation was 24 days. In an updated review of 16 cases reported since 1994, the mean age at presentation was slightly younger, at 17.4 days.[195]

Before the availability of INH, congenital tuberculosis was almost uniformly fatal. Notable signs included failure to thrive, jaundice, and central nervous system involvement. In the post-INH era, the most commonly described features of disease are respiratory distress, hepatomegaly with or without splenomegaly, and fever.[193,196,197,232] Additional findings are listed in Table 35.8. Although it is important to evaluate for meningitis in an infant with suspected congenital tuberculosis, central nervous involvement occurs in fewer than 50% of cases.[196,233] Otitis media with aural discharge has been described as the presenting sign of congenital tuberculosis,[234,235] accompanied by regional lymphadenopathy[201,236] or facial palsy.[205] It is presumed that the infection is due to the accumulation of infected amniotic fluid in the eustachian tube, either in utero or at birth. Cutaneous manifestations of congenital tuberculosis include papular, pustular, or vesicular lesions often surrounded by erythema.[222,237,238] Biopsy of the lesions is often confirmatory, demonstrating granulomatous inflammation and the presence of acid-fast bacilli (AFB) on tissue stain.[196,237] A unique case of congenital tuberculosis involving the spine was recently reported in India.[200]

Laboratory abnormalities among infants with congenital TB are also nonspecific, but include leukocytosis (63.8%), thrombocytopenia (80%), elevated inflammatory markers such as CRP (94.7%) or erythrocyte sedimentation rate (60.8%), and elevated liver function tests (76.4%).[232]

Evaluation

The timely diagnosis of congenital tuberculosis requires a high index of suspicion. Clinical signs of disease in the neonate are nonspecific, and disease in the mother may be unsuspected (as many cases are not diagnosed until the infant has been diagnosed), contributing to further delay in diagnosis. The diagnosis of congenital tuberculosis should be considered in any neonate with suspected infection who is unresponsive to conventional antimicrobial therapy, especially when the mother is from TB endemic regions. Evaluation for suspected disease should include a tuberculin skin test (TST), chest radiography, lumbar puncture, and mycobacterial culture of appropriate specimens. Biopsy specimens of affected tissue, either from the infant or the mother, and the placenta have been confirmatory in several case reports.[193,195–197,237,239]

The TST is the most commonly used diagnostic test for tuberculosis. The test uses five tuberculin units of purified protein derivative injected intradermally on the volar surface of the forearm. The reaction is measured 48 to 72 hours later as millimeters of induration. An estimated 10% to 40% of immune competent children with culture-proven tuberculosis do not initially react to a TST. Host factors such as young age and immunocompromised state can also decrease the sensitivity of the TST. Thus, the TST cannot be used to exclude the diagnosis and must be interpreted in the context of each patient. Specificity of the TST may be compromised by cross-reactivity with Bacille-Calmette-Guérin (BCG) vaccine or with environmental nontuberculous mycobacteria. The TST result is usually negative in neonates with congenital or perinatal tuberculosis, either secondary to immature cell-mediated immunity or because of overwhelming disease. Hageman et al.[196] found that only 2 of 14 infants who underwent skin testing had positive test results; on repeated testing, seven infants subsequently demonstrated positive tuberculin skin tests, the earliest being at 6 weeks of age, almost 4 weeks after presentation with clinical signs. Similarly, results of TSTs performed in 9 of 29 patients described by Cantwell et al.[193] were all negative, with results of subsequent testing being positive in two of the nine infants. Among the 16 infants with congenital tuberculosis

TABLE 35.8 Clinical Signs and Symptoms of Congenital Tuberculosis in 170 Infants

Sign	No. of Patients	% of Patients
Fever	107	64.4
Respiratory distress	106	63.8
Hepatomegaly with or without splenomegaly	108	65.6
Lethargy or irritability	66	39.7
Poor feeding	65	39.1
Failure to thrive	42	25.3
Cough	59	35.5
Cyanosis	39	23.4
Lymphadenopathy	34	20.4
Jaundice	23	13.8
Abdominal distention	37	22.2
Ear discharge	9	15
Skin lesions	17	10.2
Vomiting	14	8.4
Seizure	6	3.6

Adapted from Peng W, Yang J, Liu E. Analysis of 170 cases of congenital TB reported in the literature between 1946 and 2009. *Pediatr Pulmonol.* 2011;46:1215–1224.

recently reviewed by Laartz et al.[195] three of four infants tested had nonreactive TST results.

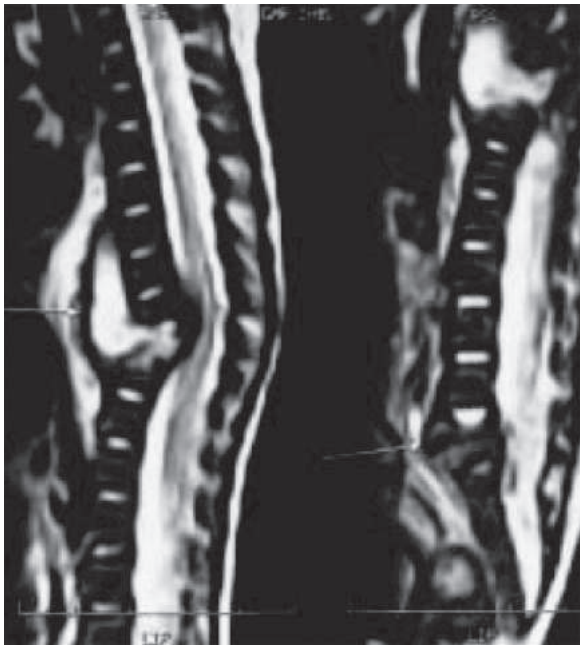
Recent advances in diagnostic tools for tuberculosis include whole-blood interferon γ release assays (IGRAs), which are immunologically based tests that measure interferon γ production from lymphocytes in response to antigens that are specific to *M. tuberculosis*. The two types of assays currently available include the Quantiferon Gold (Cellestis, Valencia, California) and the enzyme-linked immunosorbent spot assay commercially known as the T-Spot.TB (Oxford Immunotec, Abington, Oxfordshire). Advantages of these tests include lack of cross-reactivity with the BCG vaccine and most nontuberculous mycobacteria. However, the correlation between IGRAs and TSTs is variable, and negative results do not definitively exclude tuberculosis. Moreover, published experience with the use of IGRAs in children is limited, and the negative predictive value of these tests in this population is unclear. Although IGRAs are endorsed by the CDC for use in circumstances in which a TST is indicated,[240] the tests are not FDA-approved for use in children younger than 5 years of age.[241] However, many experts in the pediatric infectious disease field have used the IGRAs in children between 2 and 4 years of age.[241] The sensitivity of IGRAs in children less than a year of age is reduced compared to adults,[242] and data on the use of IGRAs in newborns is limited to case reports.[219,243,244] For children 2 years of age or older, TST or IGRA can be used unless they have been BCG vaccinated, in which case the IGRA is preferred.[245]

Given the frequency of respiratory distress in infants with congenital TB, it is not surprising that chest radiograph findings are frequently abnormal at first examination. In a meta-analysis of 170 infants with congenital tuberculosis between 1946 and 2009, 93.1% of all infants had an abnormality on chest radiograph. Among the 29 cases reviewed by Cantwell et al.[193] 23 infants (79%) had chest radiographic abnormalities, the majority being nonspecific infiltrates. Miliary disease was the most common specific radiographic characteristic (46.8%) (Fig. 35.7) followed by multiple pulmonary nodules (11.1%), lobar pneumonia (11.8%), bronchopneumonia (9.7%), and interstitial pneumonia (9%). Cavitation secondary to progressive pulmonary involvement has been reported.[246] Mediastinal adenopathy was also reported in 9.7% of infants. CT imaging of the chest may demonstrate adenopathy suggestive of TB or confirm miliary disease.[247,248] An ultrasound or CT image of the abdomen may reveal enlargement of the liver, spleen, or both, possibly with areas of abscesses,[200,226,235,249] necrotic retroperitoneal of intra-abdominal lymphadenopathy, or ascites.[232] Spinal disease associated with congenital tuberculosis identified by radiograph and confirmed by magnetic resonance imaging has been reported (Fig. 35.8).[200]

Microbiologic confirmation of disease in the neonate should be sought using specimens from multiple sites. For infants and children unable to expectorate sputum, gastric aspirates are considered the specimens of choice. Additional sources for culture include endotracheal aspirate, bronchial washing, middle-ear discharge, bone marrow, lymph node tissue, peritoneal fluid, or other suspected sites of disease. CSF should be analyzed and cultured, although isolation of *M. tuberculosis* from CSF is uncommon.[196,197] Traditionally, the detection of mycobacterial organisms by smear or culture has been considered difficult because children have paucibacillary disease relative to adults. With three morning gastric aspirates collected appropriately in hospitalized children with a clinical diagnosis of tuberculosis, only 40% of children had positive cultures.[250] Only 5% to 12% of samples are actually acid-fast smear positive[251] though fluorescent staining methods are more sensitive than AFB smear.[252] In comparison, cultures of aspirates from infants (younger than the childhood studies discussed before) evaluated at the same institution had a 75% yield.[250,253]

The improved diagnostic yield in infants likely reflects more widely disseminated and progressive disease, with higher bacillary

• **Fig. 35.7** Miliary tuberculosis in a neonate with congenital tuberculosis. (From Singh M, Kothur K, Dayal D, et al: Perinatal tuberculosis a case series, *J Trop Pediatr* 53:135-138, 2006.)



• **Fig. 35.8** Sagittal MRI on the *left* demonstrates destruction of T9 to T11 vertebral bodies with the collapse of T10, leading to a kyphotic deformity causing cord compression. A large prevertebral collection is also seen. The image on the *right* demonstrates destruction with collapse of L5 and S1 vertebral bodies. (From Grover SB, Pati NK, Mehta R, et al. Congenital spine tuberculosis: early diagnosis by imaging studies. *Am J Perinatol*. 2003;20:150.)

loads. Hageman et al. found positive cultures of *M. tuberculosis* in 10 of 12 gastric aspirates, 3 of 3 liver biopsy specimens, 3 of 3 lymph node specimens, and 2 of 4 bone marrow biopsy specimens.[196] Among the 31 cases reviewed by Cantwell et al.[193] noninvasive procedures and biopsy were useful for the diagnosis of congenital tuberculosis in the majority infants (Table 35.9). More recent reports confirm the high yield of cultures from a variety of specimens in neonates.[203,230,231,239,249] Histologic examination of tissue may suggest the diagnosis before culture results are available. For example, histopathological evidence of granulomas or acid fast bacilli on stained tissue samples of skin lesions, lymph nodes, and the liver have suggested the diagnosis before culture results were available.[196,227,249]

Whereas *M. tuberculosis* can require 7 to 42 days for growth by standard culture technique, results from techniques such as PCR may be available within 48 hours. A comparison of PCR, AFB smear, and culture with clinical diagnosis in children found a sensitivity of 60% and a specificity of 97%.[254] Although PCR has been useful for diagnosing congenital tuberculosis in a few case reports, it is not sensitive enough to preclude obtaining specimens for culture. Moreover, isolation of *M. tuberculosis* by culture is still important to determine susceptibilities and to optimize treatment.

The mother of a newborn in whom congenital tuberculosis is suspected is often asymptomatic or has subclinical disease. In the series of congenitally infected infants reported by Hageman et al. the majority of mothers (16 of 26) did not have a diagnosis until after the disease became apparent in their infants.[196] Cantwell et al. found that 50% of the mothers of infected infants were not ill at the time their newborns exhibited clinical signs of disease.[193] Evaluation of the mother should include a TST, a chest radiograph, and, if the radiograph is consistent with TB disease, collection of sputum for microbiological confirmation. Extrapulmonary disease such as meningitis or peritonitis occurs with some regularity among mothers with children born with congenital tuberculosis,[195,255] and evaluation may need to be extended to identify such sites if pulmonary disease is not discovered. In mothers with no clinical evidence of disease, endometritis should be considered.[256] Pathologic examination and culture of the placenta (if available) or endometrial biopsy can confirm the diagnosis of genital transmission.[193,213,257–260] In several case reports, the diagnosis of maternal tuberculosis was ultimately made by endometrial biopsy and culture.[205] Culture of amniotic fluid should be performed when genital involvement is suspected. All mothers with tuberculosis should be tested for HIV infection and, if the mother is seropositive, the infant should be evaluated for perinatally acquired HIV infection.

TABLE 35.9 Results of Diagnostic Procedures Performed on 29 Infants With Congenital Tuberculosis Reported from 1980 to 1994

Type of Specimen	Acid-Fast Smear*	Mycobacterial Culture	Smear or Culture
Gastric aspirate	8/9	8/9	9/11
Endotracheal aspirate	7/7	7/7	7/7
Ear discharge	2/2	1/1	2/2
Cerebrospinal fluid	1/2	1/2	1/2
Urine	0/2	0/2	0/2
Peritoneal fluid	1/1	1/1	1/1
Bronchoscopic specimen	1/1	1/1	1/1
Biopsy specimen	14/19	11/12	16/21
Lymph node	7/8	6/6	7/8†
Liver	4/6	1/2	4/6†
Skin	1/3	1/1	1/3
Lung	1/1	1/1	2/2
Bone marrow	—	1/1	1/1
Ear	1/1	1/1	1/1

*Results expressed as number of positive results per number of patients tested.
†All biopsy specimens of lymph node and liver that tested negative on smear and culture showed histopathologic changes consistent with tuberculosis (i.e., giant cell transformation of granulomas, with or without caseation).
Adapted from Cantwell MF, Shehab ZM, Costello AM, et al. Brief report: congenital tuberculosis. *N Engl J Med.* 1994;330:1051.

Management

The successful management of congenital tuberculosis depends on early recognition and treatment of disease. In suspected cases, treatment should not be delayed while awaiting culture results or other diagnostic tests. Multiple drug therapy for an extended duration has long been recognized as the standard of care for tuberculosis. Because of the rarity of the condition, clinical trials have not been conducted to establish the optimal treatment regimen for congenital tuberculosis. It is assumed that the regimens used for older infants and children are safe and effective for the treatment of neonates with congenital tuberculosis. Consultation with a pediatric infectious disease specialist or tuberculosis expert is advised.

Until susceptibility results are known, infants with proven or suspected tuberculosis should be treated with a four-drug regimen consisting of INH, rifampin (RIF), pyrazinamide (PZA), and ethambutol or an aminoglycoside (Table 35.10). Some experts would recommend administration of three drugs (INH, RIF, PZA) if antimicrobial resistance is not suspected in the mother (e.g., known susceptible strain in either mother or the source case or mother has no risk factors for resistant *M. tuberculosis*). Supplementation with pyridoxine, although not routinely recommended for otherwise healthy older children, should be provided to breastfeeding infants receiving INH. If the *M. tuberculosis* isolate is determined to be susceptible, the regimen can be narrowed to three drugs (INH, RIF, PZA) for the first 2 months of initial treatment, and subsequently to two drugs (INH, RIF) to complete the continuation phase of treatment. The adjunctive use of corticosteroids is recommended for the treatment of tuberculosis meningitis based on decreased mortality and morbidity demonstrated in adults and children[261] and has been used (though controversial) in cases of endobronchial obstruction, pericardial/pleural disease. Once the infant is discharged to home, directly observed therapy is recommended to ensure adherence and to prevent relapse.

The optimal duration of treatment for infants with congenital tuberculosis is unknown. The typical duration of treatment for susceptible *M. tuberculosis* is 6 months for pulmonary disease, pulmonary disease with hilar adenopathy, or hilar adenopathy

TABLE 35.10 Commonly Used Drugs for Treatment of Tuberculosis in Infants, Children, and Adolescents

Drugs	Dose Forms	Daily Dose (mg/kg)	Twice per week Dose (mg/kg)	Maximum Dose	Adverse Reactions
Ethambutol	Tablets (100, 400 mg)	20 (15–25)	50	2.5 g twice a week, 1 g daily	Optic neuritis (usually reversible), decreased red-green color discrimination, gastrointestinal tract disturbances, hypersensitivity
Isoniazid	Scored tablets (100, 300 mg) Syrup 10 mg/mL	10 (10–15)*	20–30	300 mg daily	Mild hepatic enzyme elevation, hepatitis,* peripheral neuritis, hypersensitivity Diarrhea, and gastric irritation caused by vehicle in the syrup
Pyrazinamide	Scored tablets (500 mg)	30–40	50	2 g	Hepatotoxic effects, hyperuricemia, arthralgia, pruritus, rash, gastrointestinal tract upset
Rifampin	Capsules (150, 300 mg) Syrup formulated capsules	15–20	15–20	600 mg	Orange discoloration of secretions or urine, staining of contact lenses, vomiting, hepatitis, influenza-like reaction, thrombocytopenia, pruritus; oral contraceptives may be ineffective

*When isoniazid in a dose exceeding 10 mg/kg/day is used in combination with rifampin, the incidence of hepatotoxic effects may be increased.

alone.[245,262] Except for meningitis, extrapulmonary disease can be treated for the same duration as pulmonary disease. For meningitis, the duration is extended to 9 to 12 months. The duration of treatment for drug-resistant disease can be prolonged up to 24 months or longer depending on the clinical course.[262] Most experts would treat infants with congenital tuberculosis for 9 to 12 months because of the decreased immunocompetence of neonates.[233]

Although there is a substantial amount of data to support the safety of INH, data on the safety and pharmacokinetics of other agents are limited. While INH toxicity is rare in otherwise healthy infants and children for which monitoring is not required, routine determination of serum transaminases and careful monitoring of hepatitis symptoms is indicated in children with severe tuberculosis (e.g., miliary or meningitis), those with concurrent liver or biliary disease, or for those receiving other potentially hepatotoxic drugs. Routine monitoring of liver function should also be considered for neonates with congenital tuberculosis given the paucity of data on adverse effects of antituberculosis agents in this age group.[263] The risks of optic neuritis with ethambutol should be considered when this agent is used, and vision should be monitored periodically.

Outcomes

The prognosis for congenital tuberculosis was dismal in the pre-chemotherapy era, the diagnosis often being only made at autopsy. Although the survival rate subsequently improved, mortality remained approximately 50% due to delayed diagnosis. In a review of 26 cases reported between 1952 and 1980, 12 (46%) patients died, 9 of whom were untreated but with a diagnosis made at autopsy. Similarly, in a review of 92 cases from China between 1976 and 2018, the mortality rate was 44%.[210] The subsequent reviews demonstrate a decrease in case fatality (see Table 35.8), with earlier diagnosis and treatment. Timely diagnosis and initiation of antituberculosis therapy are critical for a favorable outcome.

Prevention

Early diagnosis and treatment of *M. tuberculosis* infection in women of childbearing age is the optimal method of preventing congenital tuberculosis. Risk factors for acquiring tuberculosis infection or progressing to disease should be assessed at prenatal visits, and women with high risk for *M. tuberculosis* infection should undergo tuberculin skin testing or IGRA as recommended by the CDC.[264] More recent studies indicate that IGRA performance is not altered during pregnancy with better compliance in test completion rates compared to TST.[265,266] Previous studies have shown the greatest discordance with IGRA and TST, especially among those with prior BCG vacation.[267] Women who test positive for *M. tuberculosis* infection either by TST or IGRA should undergo evaluation for active disease. The treatment of active tuberculosis during pregnancy is considered standard, and early treatment has been shown to improve maternal and neonatal outcome.[268] The benefit of treating tuberculosis during pregnancy far outweighs the potential risk to the pregnant woman and her fetus. The treatment of latent Mtb infection (LTBI) during pregnancy is somewhat more controversial. In a multicenter, double-blind, placebo-controlled, non-inferiority trial, HIV-infected pregnant women living in TB endemic areas were randomized to either receive INH during pregnancy or 3 months post partum. While the earlier INH treatment was noninferior to postpartum treatment with respect to the incidence of TB and maternal adverse events, there were more adverse pregnancy outcomes (e.g., stillbirth, low birth weight) among the early treatment group.[269] For this reason, the CDC recommends that LTBI treatment in pregnancy be deferred until 2 to 3 months postpartum unless there is significant increased risk of progression to active TB, such as recent infection. This recommendation contrasts with the WHO in which the results of several other studies showed no evidence of adverse outcomes. Accordingly, the WHO recommends that treatment for LTBI should be given to pregnant women at risk for TB regardless of degree of immune

suppression and LTBI testing.[270] In short, benefits and risk of treatment should be considered for each pregnant patient as the postpartum period may be associated with an increased risk of more severe forms of active disease.[245,271]

The management of infants born to mothers with LTBI or tuberculosis disease are based on the categorization of infection in the mother and the potential risk of transmission of tuberculosis to the infant.[245,262] Infants born to mothers with potentially contagious tuberculosis should be evaluated for congenital tuberculosis that includes a TST and IGRA (though its sensitivity is unknown), chest radiograph, lumbar puncture, and appropriate cultures (e.g., gastric aspirate, CSF).[245] Separation of the infant and mother is necessary only in cases in which the mother is considered to be infectious at the time of delivery, nonadherent to medication, has drug-resistant disease, or who has not been on at least 2 weeks of treatment.[224] A mother with latent tuberculosis infection is not contagious. To prevent reactivation disease in the mother and subsequent exposure of the infant, the mother should receive treatment with INH for LTBI if she was not treated during pregnancy. In addition, latent tuberculosis infection in the mother may be a marker for contagious tuberculosis within the household, and it is recommended that all household members and close contacts of the mother be evaluated for tuberculosis.

Breastfeeding is not contraindicated in women with LTBI. The breast milk of a woman with tuberculosis does not contain tubercle bacilli. For women with tuberculosis who are potentially infectious and separated from the newborn, breast milk may be manually expressed and fed to the infant. Once the mother is noninfectious or the infant is receiving therapy, breastfeeding can be resumed. The exception, however, is the mother with an active tuberculous breast lesion. In this situation, the breast milk may be pumped and discarded until resolution of the lesion.[272]

With regard to isolations practices, airborne precautions are recommended for the following pediatric patients: (1) children with and adolescents with adult-type cavitary disease, (2) extensive pulmonary involvement, (3) laryngeal involvement, (4) those with smears positive for AFB, and (5) congenitally infected neonates undergoing oropharyngeal procedures (e.g., endotracheal intubation).[262] In general, children below the age of 10 years are not considered contagious given the lack of tussive force they are able to generate and the paucibacillary load. However, the adult contacts of that child may be the source case and potentially contagious. Thus, visitation of the hospitalized pediatric patient should be restricted to adults in whom contagious tuberculosis has been excluded. Hospitalized children with negative sputum AFB smears (if obtained) require standard precautions, assuming that contagious tuberculosis has been excluded in the visitors.

Compared with older children, neonates likely have a higher concentration of bacilli in their sputum. As noted previously, AFB smears on tracheal aspirates and other specimens are frequently positive in this population compared with older children. Transmission of tuberculosis from congenitally infected neonates to health care workers and other hospitalized infants has been reported and is likely related to aerosolization of bacilli during respiratory manipulation.[195,273–275] Neonates suspected of having congenital tuberculosis should be cared for with airborne infection isolation precautions if intubated or if undergoing any procedure with the potential for aerosolization of infected sputum. Exposed infants, visitors, and health care workers should undergo evaluation for tuberculosis infection or disease.
