AVERY'S DISEASES OF THE NEWBORN, ELEVENTH EDITION **ISBN: 978-0-323-82823-9**

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility. With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

The Publisher

Publisher: Sarah Barth
Senior Content Development Manager: Meghan Andress
Content Development Specialist: Erika Ninsin
Publishing Services Manager: Catherine Jackson
Senior Project Manager: John Casey
Design Direction: Brian Salisbury

Printed in India 9 8 7 6 5 4 3 2 1

To the babies—our patients—who humble and inspire us.
To their families, who encourage us to keep moving our field forward.
To neonatal caregivers everywhere, with gratitude for all you do.

Contributors

Steven H. Abman, MD
Professor of Pediatrics
University of Colorado Health Sciences Center
Director, Pediatric Heart Lung Center
Children's Hospital Colorado
Aurora, Colorado

Noorjahan Ali, MD, MSc
Associate Professor of Pediatrics
Division of Neonatal-Perinatal Medicine
Department of Pediatrics
UT Southwestern
Dallas, Texas

Karel Allegaert, MD, PhD
Professor
Department of Development and Regeneration
and Department of Pharmaceutical and
Pharmacological Science
KU Leuven
Leuven, Belgium;
Senior Consultant
Department of Hospital Pharmacy
Erasmus Medical Center
Rotterdam, Netherlands

Jamie E. Anderson, MD, MPH
Assistant Professor
Department of Surgery
Division of Pediatric Surgery
UC Davis Children's Hospital
Sacramento, California

Deidra A. Ansah, MD
Assistant Professor
Section of Pediatric Cardiology
Texas Children's Hospital
Baylor College of Medicine
Houston, Texas

Bhawna Arya, MD
Associate Professor
Director of Fetal Cardiology
Department of Pediatrics
Seattle Children's Hospital
University of Washington School of Medicine
Seattle, Washington

David Askenazi, MD, MSPH
Professor
Department of Pediatrics
Division of Nephrology
University of Alabama at Birmingham
Birmingham, Alabama

Susan W. Aucott, MD
Associate Professor
Department of Pediatrics
Johns Hopkins University School of Medicine
Baltimore, Maryland;
Director, Neonatology
Department of Pediatrics
Greater Baltimore Medical Center
Towson, Maryland

Stephen A. Back, MD, PhD
Clyde and Elda Munson Professor of Pediatric Research
Departments of Pediatrics and Neurology
Director, Neuroscience Section
Papé Family Pediatric Research Institute
Oregon Health & Science University
Portland, Oregon

Gerri R. Baer, MD
Medical Officer
U.S. Food and Drug Administration
Silver Spring, Maryland

H. Scott Baldwin, MD
Professor of Pediatrics
Division of Pediatric Cardiology
Vanderbilt University Medical Center
Nashville, Tennessee

Jerasimos Ballas, MD, MPH
Associate Clinical Professor
Obstetrics, Gynecology and Reproductive Sciences
University of California San Diego
San Diego, California

Maneesh Batra, MD, MPH
Professor
Department of Pediatrics-Neonatology
Adjunct Professor
Department of Global Health
University of Washington School of Medicine
Seattle, Washington

Cheryl Bayart, MD, MPH
Assistant Professor
Department of Pediatrics
University of Cincinnati
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Gary A. Bellus, MD, PhD
Director, Clinical Genetics and Genomic Medicine
Department of Pediatrics
Geisinger Health System
Danville, Pennsylvania

John T. Benjamin, MD, MPH
Assistant Professor
Department of Pediatrics
Division of Neonatology
Vanderbilt University Medical Center
Nashville, Tennessee

Gerard T. Berry, MD
Professor
Department of Genetics
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts

Zeenia C. Billimoria, MD
Associate Professor
Department of Pediatrics
University of Washington School of Medicine
Seattle Children's Hospital
Seattle, Washington

Gil Binenbaum, MD, MSCE
Mabel Leslie Chair and Chief
Department of Ophthalmology
The Children's Hospital of Philadelphia
Associate Professor
Department of Ophthalmology
University of Pennsylvania Perelman School of Medicine
Philadelphia, Pennsylvania

Matthew S. Blessing, MD
Associate Professor
Department of Pediatrics
University of Washington
Craniofacial Center
Seattle Children's Hospital
Seattle, Washington

Markus D. Boos, MD, PhD
Associate Professor
Department of Pediatrics and Dermatology
University of Washington School of Medicine
Seattle, Washington

Brad Bosse, MD
MFM Fellow
Department of Obstetrics and Gynecology
University of Wisconsin–Madison
School of Medicine and Public Health
Madison, Wisconsin

Maryse L. Bouchard, MD, MSc
Pediatric Orthopaedic Surgeon
Division of Orthopaedic Surgery
The Hospital for Sick Children
Assistant Professor of Surgery
University of Toronto
Toronto, Ontario, Canada

Heather A. Brandling-Bennett, MD
Associate Professor
Department of Pediatrics
University of Washington
Seattle Children's Hospital
Seattle, Washington

Colleen Brown, WHNP-BC, MSN
Nurse Practitioner
Obstetrics and Gynecology
Cayaba Care, LLC
Philadelphia, Pennsylvania

Erin G. Brown, MD
Associate Professor
Division of Pediatric General, Thoracic, and Fetal Surgery
UC Davis Medical Center
Sacramento, California

Katherine H. Campbell, MD, MPH
Associate Professor
Department of Obstetrics, Gynecology & Reproductive Sciences
Yale School of Medicine
New Haven, Connecticut

Katie Carlberg, MD
Clinical Assistant Professor
Department of Pediatrics
Department of Cancer and Blood Disorders
Seattle Children's Hospital
Seattle, Washington

Brian S. Carter, MD
Professor of Pediatrics, Medical Humanities & Bioethics
Department of Pediatrics–Neonatology
University of Missouri–Kansas City School of Medicine
Bioethicist, Bioethics Center
Children's Mercy Hospital
Kansas City, Missouri

Shilpi Chabra, MD
Professor of Pediatrics
University of Washington School of Medicine
Seattle Children's Hospital
Seattle, Washington

Irene J. Chang, MD
Assistant Professor
Department of Pediatrics
Division of Genetic Medicine
University of Washington
Seattle, Washington

Edith Y. Cheng, MD, MS
Professor, Department of Obstetrics and Gynecology
Division Chief, Maternal Fetal Medicine
Medical Director, Perinatal Genetics and Fetal Therapy Program
University of Washington
Program Director, Fetal Care and Treatment Center
Seattle Children's Hospital
Seattle, Washington

Kai-wen Chiang
Health Science Assistant Clinical Professor
Department of Urology–Pediatric Urology
UC Irvine
Irvine, California

Robert D. Christensen, MD
Professor of Pediatrics
University of Utah
Salt Lake City, Utah

Terrence Chun, MD
Associate Professor of Pediatrics
University of Washington
Seattle, Washington

Ronald I. Clyman, MD
Professor Emeritus
Department of Pediatrics
UC San Francisco
San Francisco, California

DonnaMaria E. Cortezzo, MD
Associate Professor of Pediatrics and Anesthesia
University of Cincinnati
Divisions of Neonatology and Pulmonary Biology, and
Pediatric Palliative Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

C.M. Cotten, MD, MHS
Professor of Pediatrics
Department of Pediatrics-Neonatology
Duke University School of Medicine
Durham, North Carolina

Sherry E. Courtney, MD, MS
Professor of Pediatrics
University of Arkansas for Medical Sciences
Little Rock, Arkansas

Jonathan M. Davis, MD
Professor of Pediatrics
Tufts University School of Medicine
Vice-Chair of Pediatrics and Chief of Newborn Medicine
Department of Pediatrics
Tufts Medical Center
Boston, Massachusetts

Alejandra G. de Alba Campomanes, MD, MPH
Professor of Clinical Ophthalmology and Pediatrics
Department of Ophthalmology
UC San Francisco
San Francisco, California

Benjamin Dean, MD, PhD
Pediatric Neurology
Mary Bridge Children's Hospital
Tacoma, Washington

Ellen Dees, MD
Assistant Professor of Pediatrics
Division of Pediatric Cardiology
Vanderbilt University Medical Center
Nashville, Tennessee

Sara B. DeMauro, MD, MSCE
Associate Professor of Pediatrics
University of Pennsylvania Perelman School
of Medicine
Program Director, Neonatal Follow-Up
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Scott C. Denne, MD
Professor of Pediatrics
Indiana University
Indianapolis, Indiana

Emöke Deschmann, MD, MMSc, PhD
Senior Attending Neonatologist, Postdoctoral Fellow
Department of Women's and Children's Health
Division of Neonatology
Karolinska Institutet and Karolinska University Hospital
Stockholm, Sweden

Carolina Cecilia Di Blasi, MD
Clinical Associate Professor
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Sara A. DiVall, MD
Associate Professor
Departments of Pediatrics and Pediatric Endocrinology
University of Washington
Seattle, Washington

Dan Doherty, MD, PhD
Interim Chief, Developmental Medicine
Professor of Pediatrics
Divisions of Developmental Medicine and Genetic Medicine
University of Washington
Seattle Children's Hospital
Seattle, Washington

David J. Durand, MD
Division of Neonatology
UCSF Benioff Children's Hospital Oakland
Oakland, California

Nicolle Fernández Dyess, MD, MEd
Assistant Professor
Department of Pediatrics
University of Colorado School of Medicine
Aurora, Colorado

Eric C. Eichenwald, MD
Professor
Department of Pediatrics/Neonatology
University of Pennsylvania Perelman School of Medicine
Chief, Division of Neonatology
Department of Pediatrics
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Kelsey B. Eitel, MD
Fellow
Department of Pediatrics
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Rachel M. Engen, MD, MS
Assistant Professor
Department of Pediatrics
University of Wisconsin, Madison
Madison, Wisconsin

Kelly N. Evans, MD
Associate Professor
Department of Pediatrics
University of Washington
Craniofacial Center
Seattle Children's Hospital
Seattle, Washington

Diana L. Farmer, MD, FACS, FRCS
Distinguished Professor and Pearl Stamps Stewart Endowed Chair
Department of Surgery
UC Davis Medical Center
Surgeon-in-Chief
UC Davis Children's Hospital
Sacramento, California

Emily Fay, MD
Assistant Professor
Department of Obstetrics and Gynecology
Division of Maternal Fetal Medicine
University of Washington
Seattle, Washington

Patricia Y. Fechner, MD
Professor of Pediatric Endocrinology
University of Washington
Director, DSD Program
Director, CAH Center of Excellence
Co-Medical Director
Turner Syndrome Clinic
Seattle Children's Hospital
Seattle, Washington

Rachel Fleishman, MD
Assistant Professor of Pediatrics
Sidney Kimmel Medical College of Thomas Jefferson University
Attending Neonatologist
Department of Pediatrics
Albert Einstein Medical Center
Philadelphia, Pennsylvania

Bobbi Fleiss, PhD
School of Health and Biomedical Sciences
STEM College
Royal Melbourne Institute of Technology University
Bundoora, Victoria, Australia

Joseph Flynn, Jr., MD, MS
Professor of Pediatrics
University of Washington School of Medicine
Chief, Division of Nephrology
Seattle Children's Hospital
Seattle, Washington

Katherine T. Flynn-O'Brien, MD, MPH
Assistant Professor of Surgery
Medical College of Wisconsin
Associate Trauma Medical Director
Division of Pediatric Surgery
Children's Wisconsin
Milwaukee, Wisconsin

G. Kyle Fulton, MD
Assistant Professor
Department of Pediatrics
Louisiana State University Health Sciences Center
Medical Director
Craniofacial Center
Children's Hospital New Orleans
New Orleans, Louisiana

Renata C. Gallagher, MD, PhD
Professor of Clinical Pediatrics
Department of Pediatrics
UC San Francisco
San Francisco, California

Estelle B. Gauda, MD
Professor of Pediatrics
University of Toronto
Head, Division of Neonatology
Women's Auxiliary Chair in Neonatology at SickKids
Senior Associate Scientist, SickKids Research Institute
Director, Toronto Centre for Neonatal Health
The Hospital for Sick Children
Toronto, Ontario, Canada

W. Christopher Golden, MD
Associate Professor of Pediatrics
Johns Hopkins University School of Medicine
Baltimore, Maryland

Michelle M. Gontasz, MD
Clinical Associate/Instructor
Department of Neonatology
Department of Pediatrics
Johns Hopkins University School of Medicine
Associate Medical Director
Neonatal Intensive Care Unit
Johns Hopkins Bayview Medical Center
Baltimore, Maryland

Natasha González Estévez, MD
Assistant Professor
Department of Pediatrics, Pediatric Cardiology Section
University Pediatric Hospital
University of Puerto Rico School of Medicine
San Juan, Puerto Rico

Sidney M. Gospe, Jr., MD, PhD
Herman and Faye Sarkowsky Endowed Chair of Child Neurology Emeritus
Departments of Neurology and Pediatrics
University of Washington
Seattle, Washington;
Adjunct Professor
Department of Pediatrics
Duke University
Durham, North Carolina

Pierre Gressens, MD, PhD
Professor
U1141 Inserm
Paris, France

Deepti Gupta, MD
Associate Professor of Pediatrics
Division of Dermatology
Seattle Children's Hospital
University of Washington
Seattle, Washington

Sangeeta Hingorani, MD, MPH
Professor of Pediatrics
University of Washington
Seattle Children's Hospital
Division of Nephrology
Associate Member
Clinical Research Division
Fred Hutchinson Cancer Research Center
Seattle, Washington

Ashley P. Hinson, MD
Clinical Associate Professor
Wake Forest School of Medicine
Pediatric Hematology Oncology
Levine Children's Hospital, Atrium Health
Charlotte, North Carolina

Susan R. Hintz, MD, MS (Epi)
Professor of Pediatrics
Division of Neonatal and Developmental Medicine
Stanford University School of Medicine
Director, Fetal and Pregnancy Health Program
Lucile Packard Children's Hospital Stanford
Palo Alto, California

W. Alan Hodson, MMSc, MD
Professor Emeritus
Department of Pediatrics
University of Washington
Seattle, Washington

Kara K. Hoppe, DO, MS
Associate Professor
Department of Obstetrics and Gynecology
University of Wisconsin–Madison
School of Medicine and Public Health
Madison, Wisconsin

Alyssa Huang, MD
Acting Assistant Professor
Department of Pediatrics
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Benjamin Huang, MD
Assistant Professor of Pediatrics
UC San Francisco
San Francisco, California

Kathy Huen, MD, MPH
Assistant Clinical Professor
Department of Urology
David Geffen School of Medicine at UCLA
Los Angeles, California

Katie A. Huff, MD, MS
Assistant Professor of Pediatrics
Indiana University School of Medicine
Indianapolis, Indiana

Cristian Ionita, MD
Associate Clinical Professor
Department of Pediatrics and Neurology
Yale School of Medicine
New Haven, Connecticut

J. Craig Jackson, MD, MHA
Professor of Pediatrics
University of Washington
Neonatologist
Fetal Care and Treatment Center
Seattle Children's Hospital
Seattle, Washington

Jordan E. Jackson, MD
Pediatric and Fetal Surgery Research Fellow
Division of Pediatric General, Thoracic, and Fetal Surgery
UC Davis Medical Center
Sacramento, California

Tom Jaksic, MD, PhD
W. Hardy Hendren Professor of Surgery
Harvard Medical School
Vice-Chair Pediatric Surgery
Surgical Director, Center for Advanced Intestinal Rehabilitation (CAIR)
Boston Children's Hospital
Boston, Massachusetts

Patrick J. Javid, MD
Professor of Surgery
University of Washington School of Medicine
Pediatric Surgeon
Seattle Children's Hospital
Seattle, Washington

Julia Johnson, MD, PhD
Assistant Professor of Pediatrics
Division of Neonatology
Johns Hopkins University School of Medicine
Assistant Professor of International Health
Johns Hopkins Bloomberg School of Public Health
Baltimore, Maryland

Cassandra D. Josephson, MD
Department of Oncology
Johns Hopkins University School of Medicine
Director, Cancer and Blood Disorders Institute
Director, Blood Bank and Transfusion Medicine
Johns Hopkins All Children's Hospital
St. Petersburg, Florida

Emily S. Jungheim, MD, MSCI
Edmond Confino MD Professor of Obstetrics and Gynecology
Chief, Division of Reproductive Endocrinology and Infertility
Department of Obstetrics and Gynecology
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Sandra E. Juul, MD, PhD
Professor of Pediatrics
Department of Pediatrics, Division of Neonatology
University of Washington School of Medicine
Seattle Children's Hospital
Seattle, Washington

Mohammad Nasser Kabbany, MD
Pediatric Gastroenterology, Hepatology, and Nutrition
Cleveland Clinic Children's Hospital
Assistant Professor of Pediatrics
Cleveland Clinic Lerner College of Medicine
Case Western Reserve University
Cleveland, Ohio

Heidi Karpen, MD
Associate Professor
Department of Pediatrics
Emory University and Children's Healthcare of Atlanta
Atlanta, Georgia

Gregory Keefe, MD
Research Fellow
Department of Surgery
Boston Children's Hospital
Boston, Massachusetts

Jennifer C. Keene, MD, MS, MBA
Assistant Clinical Professor
Division of Pediatric Neurology
University of Utah Health
Salt Lake City, Utah

Amaris M. Keiser, MD
Assistant Professor
Department of Pediatrics
Johns Hopkins University School of Medicine
Baltimore, Maryland

Roberta L. Keller, MD
Professor of Clinical Pediatrics
Director of Neonatal Services
Fetal Treatment Center
UC San Francisco
UCSF Benioff Children's Hospital
San Francisco, California

Thomas F. Kelly, MD
Clinical Professor and Chief, Division of Perinatal Medicine
Obstetrics, Gynecology and Reproductive Sciences
UC San Diego School of Medicine
Director of Maternity Services
UCSD Medical Center
La Jolla, California

Kate Khorsand, MD
Staff Dermatologist
North Idaho Dermatology
Coeur D'Alene, Idaho

Grace Kim, MD, MS
Associate Professor
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

John P. Kinsella, MD
Professor of Pediatrics
University of Colorado School of Medicine
Children's Hospital Colorado
Aurora, Colorado

Allison S. Komorowski, MD
Fellow Physician
Division of Reproductive Endocrinology and Infertility
Department of Obstetrics & Gynecology
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Ildiko H. Koves, MD, FRACP
Department of Pediatrics
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Joanne M. Lagatta, MD, MS
Professor
Department of Pediatrics
Medical College of Wisconsin
Milwaukee, Wisconsin

Satyan Lakshminrusimha, MBBS, MD, FAAP
Dennis & Nancy Marks Professor and Chair
Department of Pediatrics
UC Davis Medical Center
Pediatrician-in-Chief
UC Davis Children's Hospital
Sacramento, California

Christina Lam, MD
Associate Professor
Department of Pediatrics
University of Washington and Seattle Children's Research Center
Seattle, Washington

John D. Lantos, MD
JDL Consulting
New York, New York

Janessa B. Law, MD
Assistant Professor
Department of Pediatrics – Neonatology
University of Washington
Seattle, Washington

Su Yeon Lee, MD
Pediatric and Fetal Surgery Research Fellow
Division of Pediatric General, Thoracic, and Fetal Surgery
UC Davis Medical Center
Sacramento, California

Ofer Levy, MD, PhD
Director, Precision Vaccines Program
Division of Infectious Diseases
Boston Children's Hospital
Professor of Pediatrics
Harvard Medical School
Boston, Massachusetts;
Associate Member
Broad Institute of MT & Harvard
Cambridge, Massachusetts

David B. Lewis, MD
Professor
Chief, Division of Allergy, Immunology, and Rheumatology
Department of Pediatrics
Stanford University School of Medicine
Stanford, California;
Attending Physician
Lucile Salter Packard Children's Hospital
Palo Alto, California

Philana Ling Lin, MD, MSc
Associate Professor
Department of Pediatrics
Division of Pediatric Infectious Diseases
UPMC Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Scott A. Lorch, MD, MSCE
Kristine Sandberg Knisely Professor
Department of Pediatrics
University of Pennsylvania Perelman School of Medicine
Attending Neonatologist
Department of Pediatrics, Division of Neonatology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Tiffany L. Lucas, MD
Associate Physician
Division of Pediatric Hematology/Oncology
Kaiser Permanente Medical Group
Oakland, California

Akhil Maheshwari, MD
Chair, Department of Neonatology
Global Newborn Society
Clarksville, Maryland

Emin Maltepe, MD, PhD
Professor
Department of Pediatrics, Biomedical Sciences, Developmental and Stem Cell Biology
UC San Francisco
San Francisco, California

Erica Mandell, DO
Associate Professor of Pediatrics
University of Colorado Health Science Center
Children's Hospital Colorado
Aurora, Colorado

Winston M. Manimtim, MD
Professor of Pediatrics
University of Missouri–Kansas City
Neonatologist
Department of Pediatrics
Children's Mercy Kansas City
Kansas City, Missouri

Richard J. Martin, MBBS
Professor
Departments of Pediatrics, Reproductive Biology, and Physiology & Biophysics
Case Western Reserve University School of Medicine
Drusinsky/Fanaroff Professor
Director, Neonatal Research
Department of Pediatrics
Rainbow Babies & Children's Hospital
Cleveland, Ohio

Dennis E. Mayock, MD
Professor of Pediatrics
University of Washington
Seattle, Washington

Irene McAleer, MD, JD, MBA
Health Sciences Clinical Professor (Ret)
Department of Urology–Pediatric Urology
UC Irvine
Irvine, California

Patrick McQuillen, MD
Professor of Pediatrics and Neurology
Department of Pediatrics
UC San Francisco
UCSF Benioff Children's Hospital
San Francisco, California

Ann J. Melvin, MD, MPH
Professor
Department of Pediatrics
University of Washington
Pediatric Infectious Disease
Seattle Children's Hospital
Seattle, Washington

Paul A. Merguerian, MD, MS
Division Chief Urology
Seattle Children's Hospital
Professor of Urology
Michael Mitchell Chair Pediatric Urology
University of Washington
Seattle, Washington

Lina Merjaneh, MD
Associate Professor
Departments of Pediatrics and Pediatric Endocrinology
University of Washington
Seattle, Washington

J. Lawrence Merritt, II, MD
Clinical Professor
Department of Pediatrics
University of Washington
Seattle, Washington

Valerie Mezger, PhD
Director of Research CNRS
Université Paris Cité
CNRS,Epigenetics and Cell Fate
Paris, France

Marian G. Michaels, MD, MPH
Professor of Pediatrics and Surgery
UPMC Children's Hospital of Pittsburgh
Division of Pediatric Infectious Diseases
Pittsburgh, Pennsylvania

Ulrike Mietzsch, MD
Clinical Associate Professor of Pediatrics
Department of Pediatrics, Division of Neonatology
University of Washington School of Medicine
Seattle Children's Hospital
Seattle, Washington

Steven P. Miller, MDCM, MAS
Professor and Head
Department of Pediatrics
University of British Columbia
Chief, Pediatric Medicine
Department of Pediatrics
BC Children's Hospital
Vancouver, British Columbia, Canada;
Adjunct Senior Scientist
Neuroscience & Mental Health
SickKids Research Institute
Chair in Pediatric Neuroscience
Bloorview Children's Hospital
Toronto, Ontario, Canada

Thomas R. Moore, MD
Professor Emeritus of Maternal Fetal Medicine
Department of Obstetrics, Gynecology and Reproductive Sciences
UC San Diego
San Diego, California

Karen F. Murray, MD
Chair, Pediatrics Institute
Cleveland Clinic
DeBartolo Family Endowed Chair in Pediatrics
Physician-in-Chief, Cleveland Clinic Children's Hospital
President, Cleveland Clinic Children's Hospital for Rehabilitation
Professor and Chair, Department of Pediatrics
Cleveland Clinic Lerner College of Medicine
Case Western Reserve University
Cleveland, Ohio

Debika Nandi-Munshi, MD
Clinical Associate Professor
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Niranjana Natarajan, MD
Associate Professor
Department of Neurology
Division of Child Neurology
University of Washington
Seattle, Washington

Kathryn D. Ness, MD, MSCI
Clinical Professor
Department of Pediatrics
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Josef Neu, MD
Professor of Pediatrics
University of Florida
Gainesville, Florida

Shahab Noori, MD, MS, CBTI
Professor of Pediatrics
Fetal and Neonatal Institute
Division of Neonatology
Children's Hospital Los Angeles
Department of Pediatrics
Keck School of Medicine
University of Southern California
Los Angeles, California

Thomas Michael O'Shea, Jr., MD, MPH
Professor of Pediatrics
University of North Carolina
Chapel Hill, North Carolina

Julius T. Oatts, MD, MHS
Assistant Professor
Department of Ophthalmology
UC San Francisco
San Francisco, California

Nigel Paneth, MD, MPH
University Distinguished Professor Emeritus
Department of Epidemiology and Biostatistics
Michigan State University
East Lansing, Michigan

Thomas A. Parker, MD
Professor of Pediatrics
University of Colorado School of Medicine
Aurora, Colorado

Ravi Mangal Patel, MD, MSc
Associate Professor
Department of Pediatrics
Emory University School of Medicine
Children's Healthcare of Atlanta
Atlanta, Georgia

Simran Patel, BS
Eugene Applebaum College of Pharmacy and Health Sciences
Wayne State University
Detroit, Michigan

Anna A. Penn, MD, PhD
L. Stanley James Associate Professor of Pediatrics
Director, Neonatology
Department of Pediatrics
Columbia University/ NYP Morgan Stanley Children's Hospital
New York, New York

Christian M. Pettker, MD
Professor
Department of Obstetrics, Gynecology, & Reproductive Sciences
Yale School of Medicine
New Haven, Connecticut

Shabnam Peyvandi, MD, MAS
Associate Professor of Clinical Pediatrics
Department of Pediatric Cardiology
UC San Francisco
UCSF Benioff Children's Hospital
San Francisco, California

Catherine Pihoker, MD
Professor
Department of Pediatrics
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Erin Plosa, MD
Assistant Professor
Department of Pediatrics
Mildred Stahlman Division of Neonatology
Vanderbilt University School of Medicine
Nashville, Tennessee

Brenda Poindexter, MD, MS
Chief, Division of Neonatology
Department of Pediatrics
Emory University and Children's Healthcare of Atlanta
Atlanta, Georgia

Michael A. Posencheg, MD
Associate Professor of Clinical Pediatrics
Department of Pediatrics
University of Pennsylvania Perelman School of Medicine
Medical Director, Intensive Care Nursery
Neonatology and Newborn Services
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Mihai Puia-Dumitrescu, MD, MPH
Assistant Professor of Pediatrics
University of Washington
Seattle, Washington

Vilmaris Quiñones Cardona, MD
Assistant Professor of Pediatrics
Drexel University College of Medicine
Neonatologist, Department of Pediatrics
St. Christopher's Hospital for Children
Philadelphia, Pennsylvania

Samuel E. Rice-Townsend, MD
Assistant Professor
Pediatric General and Thoracic Surgery
Department of Surgery
University of Washington
Seattle, Washington

Art Riddle, MD, PhD
Assistant Professor
Department of Pediatrics
Division of Pediatric Neurology
Oregon Health & Science University
Portland, Oregon

Elizabeth Robbins, MD
Clinical Professor of Pediatrics
UC San Francisco
San Francisco, California

Mark D. Rollins, MD, PhD
Professor
Anesthesiology and Perioperative Medicine
Mayo Clinic
Rochester, Minnesota

Mark A. Rosen, MD
Professor Emeritus
Department of Anesthesia and Perioperative Care
Obstetrics, Gynecology, and Reproductive Sciences
UC San Francisco
San Francisco, California

Courtney K. Rowe, MD
Pediatric Urologist
Department of Urology
Connecticut Children's
Hartford, Connecticut;
Assistant Professor of Pediatrics
University of Connecticut Medical School
Farmington, Connecticut

Inderneel Sahai, MD
Chief Medical Officer
New England Newborn Screening Program
UMass Chan Medical School
Worcester, Massachusetts;
Attending Physician
Department of Genetics and Metabolism
Massachusetts General Hospital
Boston, Massachusetts

Sulagna C. Saitta, MD, PhD
Health Sciences Professor
Division of Clinical Genetics
Department of Pediatrics
Director, Division of Reproductive Genetics
Department of Obstetrics and Gynecology
David Geffen School of Medicine at UCLA
Los Angeles, California

Parisa Salehi, MD
Associate Professor
Department of Pediatrics
Division of Endocrinology and Diabetes
University of Washington
Seattle Children's Hospital
Seattle, Washington

Pablo J. Sanchez, MD
Professor of Pediatrics
Divisions of Neonatology and Pediatric Infectious Diseases
Center for Perinatal Research
Abigail Wexner Research Institute at Nationwide Children's Hospital
Ohio State University College of Medicine
Columbus, Ohio

Taylor Sawyer, DO, MBA, MEd
Professor of Pediatrics
Division of Neonatology
University of Washington School of Medicine
Seattle Children's Hospital
Seattle, Washington

Matthew A. Saxonhouse, MD
Clinical Associate Professor
Wake Forest School of Medicine
Levine Children's Hospital, Atrium Health
Division of Neonatology
Charlotte, North Carolina

Katherine M. Schroeder, MD, MS
Assistant Professor
Orthopaedic Surgery
Seattle Children's Hospital
Seattle, Washington

David T. Selewski, MD, MSCR
Associate Professor
Department of Pediatrics
Division of Nephrology
Medical University of South Carolina
Charleston, South Carolina

T. Niroshi Senaratne, PhD, FACMG
Assistant Clinical Professor
Department of Pathology and Laboratory Medicine
David Geffen School of Medicine at UCLA
Los Angeles, California

Istvan Seri, MD, PhD, HonD, HonP
Professor
First Department of Pediatrics
Semmelweis University
Budapest, Hungary;
Adjunct Professor of Pediatrics
Department of Pediatrics and Neonatology
Children's Hospital Los Angeles
USC Keck School of Medicine
Los Angeles, California

Emily E. Sharpe, MD
Assistant Professor
Department of Anesthesiology and Perioperative Medicine
Mayo Clinic
Rochester, Minnesota

Sarah E. Sheppard, MD, PhD
Tenure-Track Investigator
Unit on Vascular Malformations, Division of Translational Medicine
Division of Intramural Research
Eunice Kennedy Shriver National Institute of Child Health and Human Development
National Institutes of Health
Bethesda, Maryland

Margarett Shnorhavorian, MD, MPH, FAAP, FACS
Professor
Department of Urology
University of Washington School of Medicine
Pediatric Urologist
Seattle Children's Hospital
Seattle, Washington

Robert Sidbury, MD, MPH
Professor of Pediatrics
Chief, Division of Dermatology
Seattle Children's Hospital
University of Washington School of Medicine
Seattle, Washington

LaVone Simmons, MD
Clinical Assistant Professor
Department of Obstetrics and Gynecology
Division of Maternal Fetal Medicine
University of Washington
Seattle, Washington

Rebecca A. Simmons, MD
Hallam Hurt Professor of Pediatrics
Department of Pediatrics
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Rachana Singh, MD, MS
Professor of Pediatrics
Tufts University School of Medicine
Associate Chief, Newborn Medicine
Department of Pediatrics
Tufts Medical Center
Boston, Massachusetts

Martha C. Sola-Visner, MD
Associate Professor
Department of Pediatrics
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts

Lakshmi Srinivasan, MBBS, MTR
Assistant Professor of Pediatrics
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Heidi J. Steflik, MD, MSCR
Assistant Professor
Department of Pediatrics
Division of Neonatal-Perinatal Medicine
Medical University of South Carolina
Charleston, South Carolina

Robin H. Steinhorn, MD
Professor and Vice Dean
Department of Pediatrics
Rady Children's Hospital and UC San Diego
San Diego, California

Caleb Stokes, MD, PhD
Acting Assistant Professor
Department of Pediatrics
University of Washington
Pediatric Infectious Disease
Seattle Children's Hospital
Seattle, Washington

Helen Stolp, BSc(Hons), PhD
Perinatal Imaging and Health
King's College London
London, United Kingdom

Jennifer Sucre, MD
Assistant Professor
Department of Pediatrics
Mildred Stahlman Division of Neonatology
Vanderbilt University School of Medicine
Nashville, Tennessee

Angela Sun, MD
Physician
Department of Pediatrics
University of Washington
Seattle, Washington

Dalal K. Taha, DO
Associate Professor of Clinical Pediatrics

Preface

"The neonatal period therefore represents the last frontier of medicine, territory which has just begun to be cleared of its forests and underbrush in preparation for its eagerly anticipated crops of saved lives."

From the Introduction to the 1st edition of *Diseases of the Newborn*

The History of *Diseases of the Newborn*

Diseases of the Newborn was one of the first books dedicated to the diagnosis and treatment of problems of the neonate. The 1st edition was published in 1960 by Dr. Alexander Schaffer, a well-known Baltimore pediatrician who first coined the terms *neonatology* and *neonatologist*. He described neonatology as an emerging pediatric subspecialty concentrating on the "art and science of diagnosis and treatment of disorders of the newborn infant," and a neonatologist as a "physician whose primary concern lay in that specialty." Dr. Schaffer served as sole author for both the 1st and 2nd editions (1966) of the book. Dr. Mary Ellen Avery joined Dr. Schaffer as a co-author for the 3rd edition in 1971. Drs. Avery and Schaffer recognized that their book needed multiple contributors with subspecialty expertise as they developed the 4th edition in 1977, and they became co-editors, rather than co-authors. Dr. Schaffer died in 1981 and Dr. H. William Taeusch joined Dr. Avery in 1984 as co-editor for the 5th edition. Dr. Roberta Ballard joined Drs. Taeusch and Avery for the 6th edition in 1991, then titled, *Schaffer & Avery's Diseases of the Newborn*. The 7th edition, edited by Drs. Taeusch and Ballard, was published in 1998, and was entitled *Avery's Diseases of the Newborn*, in recognition of Dr. Avery's diligent work on the book through four editions over 20 years. Dr. Christine Gleason joined Drs. Taeusch and Ballard in 2005 as editors for the 8th edition. In 2009, Drs. Avery, Taeusch, and Ballard retired from editing *Avery's*, and became "editors emeriti." Sadly, Dr. Avery passed away in 2011. Her legacy lives on, however, in the title of this book. Dr. Sherin Devaskar joined Dr. Gleason in 2012 as co-editor for the 9th edition—the first edition with accompanying online content. For the 10th edition, Dr. Sandra "Sunny" Juul teamed with Dr. Gleason as co-editor, marking the first time since the 5th edition that all editors were faculty at the same institution. For this new, 11th edition, Dr. Taylor Sawyer, also on the faculty at Dr. Gleason's institution, joins as co-editor. This edition marks the fourth that Dr. Gleason has co-edited, making her the longest serving editor since Dr. Avery.

The 1st edition of *Diseases of the Newborn* was used mainly for diagnosis, but also included descriptions of early neonatal therapies that had led to a remarkable decrease in the infant mortality rate in the United States: from 47 deaths per 1000 live births in 1940 to 26 per 1000 in 1960. However, a pivotal year for the fledgling subspecialty of neonatology came in 1963, 3 years after the first publication of *Diseases of the Newborn*, with the birth of President John F. Kennedy's son, Patrick Bouvier Kennedy. Patrick was a preterm infant, born at 34-35 weeks' gestation, and his death at 3 days of age from complications of respiratory distress syndrome accelerated the development of infant ventilators, which, coupled with micro-blood gas analysis and the use of umbilical artery catheterization, led to the development of newborn intensive care in the late 1960s.

Advances in neonatal surgery and cardiology, along with ongoing technological innovations, stimulated the development of neonatal intensive care units and regionalization of care for sick newborn infants over the next several decades. These developments were accompanied by an explosion of research that improved our understanding of the pathophysiology and genetic basis of diseases of the newborn. This in turn led to spectacular advances in neonatal diagnosis and therapeutics—particularly in the care of preterm infants. Combined, these advances have resulted in significant reductions in infant mortality worldwide: from 6.45% in 1990 to 2.82% in 2019. Current research efforts are focused on decreasing the unacceptable regional, ethnic, and global disparities in infant mortality, improving neonatal long-term outcomes, advancing neonatal therapeutics, preventing newborn diseases, and finally—teaming with our obstetrical colleagues—preventing prematurity. This edition tries—as all prior editions have—to translate the findings of ongoing research into practical advice for use at the bedside by neonatal caregivers.

What's New and Improved About This Edition?

Perhaps the most significant change to this edition is what was removed rather than what was added. We carefully reviewed the 10th edition's table of contents, examining each chapter with a keen eye on keeping the book targeted on diseases of the newborn, bringing the content more in line with the original editions. Thus, several chapters that were not specifically disease-focused were archived, while chapters in some sections were subdivided into new chapters focused on disease-specific content.

This book continues to be thoroughly (and sometimes painfully) revised and updated by some of the best clinicians and investigators in their fields—several of whom are new contributors. Some chapters required more extensive updates than others. For all chapters, however, we challenged authors to decrease the word count, use boxes, tables, and figures to break up dense text, and to do their best to make the content as disease-focused as appropriate. This resulted in a more concise, readable, and hopefully, clinically helpful text. We are so grateful to our authors for their contributions and hope readers appreciate their work.

Do We Still Need Textbooks?

With the incredible amount of information immediately available on the internet, what's the value of a textbook? We believe that textbooks, such as *Avery's Diseases of the Newborn*, will always be needed by clinicians striving to provide state-of-the-art neonatal care, by educators working to train the next generation of caregivers, and by investigators diligently advancing neonatal research and scholarship. A textbook's content is only as good as its contributors. This book, like in previous editions, has awesome contributors.

The authors were chosen for their expertise and ability to integrate their knowledge into a comprehensive, readable, and useful chapter. They did this in the hope that their syntheses could, as Ethel Dunham wrote in the foreword to the 1st edition, "spread more widely what is already known … and make it possible to apply these facts."

We are grateful that the online content of this textbook enjoys increasing popularity. However, we still find printed copies of this and other books lying dog-eared, coffee-stained, annotated, and broken-spined in places where neonatal caregivers congregate.

With each subsequent edition, the authors of *Diseases of the Newborn* help fulfill Dr. Schaffer's vision of clearing the underbrush from the last frontier of medicine in preparation for its eagerly anticipated crops of saved neonatal lives. Textbooks connect us to the past, bring us up to date on the present, and prepare and excite us for the future. We will always need them, in one form or another. To that end, we have challenged ourselves to meet, and hopefully exceed, that need—for our field, for our colleagues, and for the babies entrusted to our care.

Acknowledgments and Gratitude

We wish to thank some key staff at Elsevier— our Content Development Specialist, Erika Ninsin; our Senior Content Development Manager, Meghan Andress; our Publishing Services Manager, Catherine Jackson; our Senior Project Manager, John Casey; our Design Director, Brian Salisbury; and our Publisher, Sarah Barth. They demonstrated patience, guidance, and persistence; without them, we would still be hard at work, trying to make this book a reality! We also wish to thank our colleagues at our academic institution, the University of Washington, especially our Division Chief, Sunny Juul, and our Department Chair, Leslie Walker-Harding, whose leadership and unwavering support have meant so much to us both. We are deeply indebted to our chapter authors, who wrote the book and did so willingly, enthusiastically, and (for the most part) in a timely fashion—despite myriad other responsibilities in their lives, and a worldwide COVID-19 pandemic! Finally, we are extremely grateful for the support of our families throughout the long, and often challenging, editorial process.

Christine Gleason and **Taylor Sawyer**

1 Neonatal and Perinatal Epidemiology

NIGEL PANETH, SIMRAN PATEL, AND THOMAS MICHAEL O'SHEA JR.

KEY POINTS

- Maternal and child health in the population have traditionally been assessed by monitoring two key statistics—the maternal mortality ratio and the infant mortality rate. The infant mortality rate is the sum of the neonatal mortality and post-neonatal mortality rates.
- Due to improvements in income, housing, birth spacing, and nutrition, along with public health interventions to produce cleaner food and water, improve maternal and infant nutrition, and immunize mothers and infants against infectious diseases, maternal mortality and infant mortality declined steadily through the 20th century. By 2000, neonatal mortality had declined by 90% from its 1915 value, postneonatal mortality by 93%, and maternal mortality by 98%.
- In high-income countries, the leading causes of neonatal mortality are preterm birth and congenital anomalies. The leading cause of postneonatal mortality is sudden infant death syndrome.
- Health disparities are especially prominent in the perinatal period. Even as rates of infant mortality decline in both Black and White babies, infant mortality among Black babies remains about twice that of White infant mortality in the United States.
- Despite comparable, or lower, birthweight-specific infant mortality rates, the United States has one of the highest infant mortality rates among high-income countries. This surprising phenomenon is due to the striking excess of preterm births in the United States, as compared with other high-income countries.
- Notable improvements in health outcomes resulting from epidemiologic research include reductions in neural tube defects (reduced by prenatal folate), sudden infant death syndrome (reduced by supine infant sleeping), and cerebral palsy among preterm infants (reduced by maternal magnesium sulfate).

Introduction—Epidemiologic Approaches to the Perinatal and Neonatal Period

The period surrounding the time of birth, the *perinatal* period, is a critical window in human development, as the infant makes the transition from its dependence upon maternal and placental support—oxidative, nutritional, and endocrinologic—to establishing independent life. That this transition is not always successful is signaled by an annualized mortality rate in the neonatal period that is not exceeded until age 85 and older,[1] and risks for damage to organ systems, most notably the brain, that can be lifelong. However, years must pass before the effects on higher cortical functions of insults and injuries occurring during the perinatal period can reliably be detected. Epidemiologic approaches to the perinatal period must therefore be bidirectional—looking backward to examine the causes of adverse health conditions that arise during the perinatal period and looking forward to seeing how these conditions shape disorders of health found later in life.

Traditionally the perinatal period was described as extending from 28 weeks of gestation until 1 week of life, but in 2004 the World Health Organization (WHO) antedated the onset of the perinatal period to 22 weeks.[2] For the purposes of this discussion we will define perinatal more expansively, as including the second half of gestation (by which time most organogenesis has occurred, but growth and maturation of many systems has yet to occur) and the first month of life. The *neonatal* period, usually considered as the first month of life, is thus included in the term perinatal, reflecting the view that addressing the problems of the neonate requires an understanding of intrauterine phenomena.

Health Disorders of Pregnancy and the Perinatal Period

Key Population Mortality Statistics

Maternal and child health in the population have traditionally been assessed by monitoring two key statistics—the maternal mortality ratio and the infant mortality rate. A maternal death is defined by the WHO as the death of a woman during pregnancy or within 42 days of pregnancy.[3] Because maternal deaths are not part of the denominator of births, the resulting fraction is referred to as the **maternal mortality ratio**. When the cause of death is attributed to a pregnancy-related cause, it is described as *direct*. When pregnancy has aggravated an underlying health disorder present before pregnancy, the death is termed an *indirect* maternal death. The WHO recommends that both direct and total (direct plus indirect) maternal mortality rates be monitored. Typically, the ratio is indexed to 100,000 births.

Because pregnancy can contribute to deaths beyond 42 days, the term "late maternal death" has been used to describe the death of a woman from direct or indirect obstetric causes more than 42 days but less than 1 year after termination of pregnancy.

These later deaths are not usually included in tabulations of maternal mortality in vital data,[4,5] although they are included in "pregnancy-associated mortality" as defined by the Centers for Disease Control and Prevention (CDC).[6]

Deaths unrelated to pregnancy, but occurring within 42 days of pregnancy, are termed *incidental* maternal deaths and are not included in maternal mortality.[7] However, even incidental deaths may bear a relation to pregnancy; for example, homicide and suicide are more common in pregnancy and shortly thereafter and might not be entirely incidental to it.[8,9]

In most geographic entities, infant mortality is defined as all deaths occurring from birth to 365 days of age. The infant mortality rate is the number of infant deaths in a calendar year divided by the number of births occurring in the same year. This approach makes for imprecision because some deaths in the examined year occurred to the previous year's birth cohort, and some births in the examined year will die as infants in the following year. In recent years, birth-death linkage has permitted vital registration areas in the United States to provide infant mortality rates that avoid this imprecision. The standard infant mortality rate reported by the National Center for Health Statistics (NCHS) links *deaths* for the index year to all births to whom the death occurred, including births that took place the *previous* year. This form of infant mortality is termed *period* infant mortality. An alternative procedure is to take births for the index year and link them to infant deaths, including those taking place the *following* year. This is referred to as *birth cohort* infant mortality and is not used for regular annual comparisons because it cannot be completed in as timely a fashion as can period infant mortality.[10] The denominator for all forms of infant mortality is 1000 live births.

Infant deaths are conventionally divided into deaths in the first 28 days of life (*neonatal* deaths) and deaths later in the first year *(postneonatal* deaths). Neonatal deaths, which are largely related to preterm birth and birth defects, tend to reflect the circumstances of pregnancy and birth; postneonatal deaths, when high, are largely from infection, often in the setting of poor nutrition. In high-income countries (HICs), neonatal deaths have for many years made up a larger proportion of infant mortality than postneonatal deaths. This has been true of the United States since 1921, and in recent years the ratio of neonatal to postneonatal deaths in the United States has consistently been approximately 2 to 1. Until quite recently, postnatal deaths outnumbered neonatal deaths in low- and middle-income countries (LMICs), but in 2019, infant mortality was 28.2/1000 live births in LMICs while neonatal mortality was 17.9/1000 live births, indicating that infant mortality in LMICs is beginning to resemble patterns seen in HICs.[11]

Perinatal mortality is a term used for a rate that combines stillbirths and neonatal deaths in some fashion.[2] Stillbirth reporting prior to 28 weeks is probably incomplete, even in the United States, where such births are required to be reported in every state.[12] Nonetheless, stillbirths continue to be reported at a level not much lower than that of neonatal deaths, and our understanding of the causes of stillbirth remains very uncertain.[13]

Sources of Information on Mortality—Vital Data

All US mortality data depend upon the collection of information about all births and deaths. Routinely collected vital data are the nation's key resource for monitoring progress in caring for mothers and children. Annual counts of births and deaths collected by the 52 vital registration areas of the United States (50 states, District of Columbia [DC], and NYC) are assembled into national data sets by the NCHS and described under the heading of National Vital Statistics Reports (NVSRs).[14] Unlike data collected in hospitals or clinics, or even from nationally representative surveys, birth and death certificates are required by law to be completed for each birth and death. Birth and death registration have been virtually 100% complete for all parts of the United States since the 1950s. The universality of this process renders many findings from vital data analyses stable and generalizable, although formatting changes recommended in 2003, affecting both the birth and death certificates, have created some difficulties in interpretation because the NCHS can only *recommend* format revisions in vital data certificates; each state is free to adopt them or not.

The 2003 revision of the birth certificate emphasized recording of data from medical records rather than maternal interview and recommended the reformatting of some elements, such as date of first prenatal visit, in ways that produced differences in findings compared to an earlier revision made in 1989. To complicate matters further, states adopted the 2003 revision at different times, and for much of the next decade, both versions of the birth certificate—1989 and 2003 revisions—were in use, leading to the NCHS deciding not to issue national data for several years for the prevalence of gestational diabetes, gestational hypertension, and gestational age at initiation of prenatal care. This problem has now been resolved because, as of 2016, all 50 states, the DC, Puerto Rico, Guam, Commonwealth of the Northern Marianas, and US Virgin Islands reported data based on the 2003 US Certificate of Live Birth. American Samoa continues to report based on the earlier 1989 birth certificate revision.[15]

In 2003, the NCHS also recommended revisions to the US Standard Certificate of Death,[16] including a special checkbox for identifying whether the decedent, if female, was pregnant or had been pregnant in the previous 42 days. As with the birth certificate, this revision was variably followed by states, and it has been found that the number of deaths recognized as maternal in states that adopted the checkbox is higher than in those that did not (Fig. 1.1).[17]

The limitations of vital data are well known. Causes of death are subject to certifier variability and, perhaps more importantly, to professional trends in diagnostic categorization. The accuracy of recording of conditions and measures on birth certificates is often uncertain and variable from state to state and hospital to hospital. Yet the frequencies of births and deaths in subgroups defined objectively and recorded consistently, such as birthweight and mode of delivery, are likely to be valid.

Time Trends in Mortality Rates of the Perinatal Period in the United States

Maternal mortality and infant mortality declined steadily through the 20th century; by 2000, neonatal mortality had declined by 90% from its 1915 value, postneonatal mortality by 93%, and maternal mortality by 98%. These extraordinary and unprecedented changes are the product of a variety of complex social factors including improvements in income, housing, birth spacing, and nutrition, as well as ecological-level public health interventions that produced cleaner food and water.[18] Public health action at the individual level, including targeted maternal and infant nutrition programs and immunization programs have made a lesser, but still notable contribution. Medical care per se was, until recently, less critically involved in these declines, with the exception of the decline in maternal mortality, which was very sensitive to the developments in blood banking and antibiotics that began in the 1930s.

MOTHER

29a. DATE OF FIRST PRENATAL CARE VISIT
_____/_____/_____ No Prenatal Care
M M D D YYYY

29b. DATE OF LAST PRENATAL CARE VISIT
_____/_____/_____
M M D D YYYY

40. MOTHER'S MEDICAL RECORD NUMBER

MEDICAL AND HEALTH INFORMATION

41. RISK FACTORS IN THIS PREGNANCY (Check all that apply)
Diabetes
Prepregnancy (Diagnosis prior to this pregnancy)
Gestational (Diagnosis in this pregnancy)

Hypertension
Prepregnancy (Chronic)
Gestational (PIH, preeclampsia)
Eclampsia

Previous preterm birth

Other previous poor pregnancy outcome (Includes perinatal death, small-for-gestational age/intrauterine growth restricted birth)

Pregnancy resulted from infertility treatment-If yes, check all that apply:
Fertility-enhancing drugs, Artificial insemination or Intrauterine insemination
Assisted reproductive technology (e.g., in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT))

Mother had a previous cesarean delivery
If yes, how many _____

None of the above

42. INFECTIONS PRESENT AND/OR TREATED DURING THIS PREGNANCY (Check all that apply)
Gonorrhea
Syphilis
Chlamydia
Hepatitis B
Hepatitis C
None of the above

43. OBSTETRIC PROCEDURES (Check all that apply)
Cervical cerclage
Tocolysis

External cephalic version:
Successful
Failed

None of the above

44. ONSET OF LABOR (Check all that apply)
Premature Rupture of the Membranes (prolonged, ∃12 hrs.)
Precipitous Labor (<3 hrs.)
Prolonged Labor (∃ 20 hrs.)
None of the above

45. CHARACTERISTICS OF LABOR AND DELIVERY (Check all that apply)
Induction of labor
Augmentation of labor
Non-vertex presentation
Steroids (glucocorticoids) for fetal lung maturation received by the mother prior to delivery
Antibiotics received by the mother during labor
Clinical chorioamnionitis diagnosed during labor or maternal temperature ≥38°C (100.4°F)
Moderate/heavy meconium staining of the amniotic fluid
Fetal intolerance of labor such that one or more of the following actions was taken: in-utero resuscitative measures, further fetal assessment, or operative delivery
Epidural or spinal anesthesia during labor
None of the above

46. METHOD OF DELIVERY
A. Was delivery with forceps attempted but unsuccessful?
Yes No
B. Was delivery with vacuum extraction attempted but unsuccessful?
Yes No
C. Fetal presentation at birth
Cephalic
Breech
Other
D. Final route and method of delivery (Check one)
Vaginal/Spontaneous
Vaginal/Forceps
Vaginal/Vacuum
Cesarean
If cesarean, was a trial of labor attempted?
Yes
No

47. MATERNAL MORBIDITY (Check all that apply) (Complications associated with labor and delivery)
Maternal transfusion
Third or fourth degree perineal laceration
Ruptured uterus
Unplanned hysterectomy
Admission to intensive care unit
Unplanned operating room procedure following delivery
None of the above

NEWBORN

NEWBORN INFORMATION

48. NEWBORN MEDICAL RECORD NUMBER

49. BIRTHWEIGHT (grams preferred, specify unit)
_____
9 grams 9 lb/oz

50. OBSTETRIC ESTIMATE OF GESTATION:
_____ (completed weeks)

51. APGAR SCORE:
Score at 5 minutes:_____
If 5 minute score is less than 6,
Score at 10 minutes: _____

52. PLURALITY - Single, Twin, Triplet, etc.
(Specify)_____

53. IF NOT SINGLE BIRTH - Born First, Second, Third, etc. (Specify) _____

54. ABNORMAL CONDITIONS OF THE NEWBORN (Check all that apply)
Assisted ventilation required immediately following delivery
Assisted ventilation required for more than six hours
NICU admission
Newborn given surfactant replacement therapy
Antibiotics received by the newborn for suspected neonatal sepsis
Seizure or serious neurologic dysfunction
Significant birth injury (skeletal fracture(s), peripheral nerve injury, and/or soft tissue/solid organ hemorrhage which requires intervention)
9 None of the above

55. CONGENITAL ANOMALIES OF THE NEWBORN (Check all that apply)
Anencephaly
Meningomyelocele/Spina bifida
Cyanotic congenital heart disease
Congenital diaphragmatic hernia
Omphalocele
Gastroschisis
Limb reduction defect (excluding congenital amputation and dwarfing syndromes)
Cleft Lip with or without Cleft Palate
Cleft Palate alone
Down Syndrome
Karyotype confirmed
Karyotype pending
Suspected chromosomal disorder
Karyotype confirmed
Karyotype pending
Hypospadias
None of the anomalies listed above

56. WAS INFANT TRANSFERRED WITHIN 24 HOURS OF DELIVERY? 9 Yes 9 No
IF YES, NAME OF FACILITY INFANT TRANSFERRED
TO:_____

57. IS INFANT LIVING AT TIME OF REPORT?
Yes No Infant transferred, status unknown

58. IS THE INFANT BEING BREASTFED AT DISCHARGE?
Yes No

Mother's Name _____ Mother's Medical Record No. _____

42. LOCATION OF INJURY: State: City or Town: Street & Number: Apartment No.: Zip Code:

43. DESCRIBE HOW INJURY OCCURRED: | 44. IF TRANSPORTATION INJURY, SPECIFY: ☐ Driver/Operator ☐ Passenger ☐ Pedestrian ☐ Other (Specify)

45. CERTIFIER (Check only one):
☐ Certifying physician-To the best of my knowledge, death occurred due to the cause(s) and manner stated.
☐ Pronouncing & Certifying physician-To the best of my knowledge, death occurred at the time, date, and place, and due to the cause(s) and manner stated.
☐ Medical Examiner/Coroner-On the basis of examination, and/or investigation, in my opinion, death occurred at the time, date, and place, and due to the cause(s) and manner stated.

Signature of certifier:_____

46. NAME, ADDRESS, AND ZIP CODE OF PERSON COMPLETING CAUSE OF DEATH (Item 32)

47. TITLE OF CERTIFIER | 48. LICENSE NUMBER | 49. DATE CERTIFIED (Mo/Day/Yr) | 50. **FOR REGISTRAR ONLY**- DATE FILED (Mo/Day/Yr)

To Be Completed By: FUNERAL DIRECTOR

51. DECEDENT'S EDUCATION-Check the box that best describes the highest degree or level of school completed at the time of death.
☐ 8th grade or less
☐ 9th - 12th grade; no diploma
☐ High school graduate or GED completed
☐ Some college credit, but no degree
☐ Associate degree (e.g., AA, AS)
☐ Bachelor's degree (e.g., BA, AB, BS)
☐ Master's degree (e.g., MA, MS, MEng, MEd, MSW, MBA)
☐ Doctorate (e.g., PhD, EdD) or Professional degree (e.g., MD, DDS, DVM, LLB, JD)

52. DECEDENT OF HISPANIC ORIGIN? Check the box that best describes whether the decedent is Spanish/Hispanic/Latino. Check the "No" box if decedent is not Spanish/Hispanic/Latino.
☐ No, not Spanish/Hispanic/Latino
☐ Yes, Mexican, Mexican American, Chicano
☐ Yes, Puerto Rican
☐ Yes, Cuban
☐ Yes, other Spanish/Hispanic/Latino (Specify) _____

53. DECEDENT'S RACE (Check one or more races to indicate what the decedent considered himself or herself to be)
☐ White
☐ Black or African American
☐ American Indian or Alaska Native (Name of the enrolled or principal tribe) _____
☐ Asian Indian
☐ Chinese
☐ Filipino
☐ Japanese
☐ Korean
☐ Vietnamese
☐ Other Asian (Specify)_____
☐ Native Hawaiian
☐ Guamanian or Chamorro
☐ Samoan
☐ Other Pacific Islander (Specify)_____
☐ Other (Specify)_____

Cause-of-death – Background, Examples, and Common Problems

Accurate cause of death information is important
•to the public health community in evaluating and improving the health of all citizens, and
•often to the family, now and in the future, and to the person settling the decedent's estate.

The cause-of-death section consists of two parts. **Part I** is for reporting a chain of events leading directly to death, with the **immediate cause** of death (the final disease, injury, or complication directly causing death) on line a and the **underlying cause** of death (the disease or injury that initiated the chain of events that led directly and inevitably to death) on the lowest used line. **Part II** is for reporting all other significant diseases, conditions, or injuries that contributed to death but which did not result in the underlying cause of death given in **Part I. The cause-of-death information should be YOUR best medical OPINION.** A condition can be listed as "probable" even if it has not been definitively diagnosed.

Examples of properly completed medical certifications

CAUSE OF DEATH (See instructions and examples)

32. **PART I.** Enter the chain of events--diseases, injuries, or complications--that directly caused the death. DO NOT enter terminal events such as cardiac arrest, respiratory arrest, or ventricular fibrillation without showing the etiology. DO NOT ABBREVIATE. Enter only one cause on a line. Add additional lines if necessary.

		Approximate interval: Onset to death
IMMEDIATE CAUSE (Final disease or condition ---------> resulting in death)	a. Rupture of myocardium	Minutes
	Due to (or as a consequence of):	
Sequentially list conditions, if any, leading to the cause listed on line a. Enter the **UNDERLYING CAUSE** (disease or injury that initiated the events resulting in death) **LAST**	b. Acute myocardial infarction	6 days
	Due to (or as a consequence of):	
	c. Coronary artery thrombosis	5 years
	Due to (or as a consequence of):	
	d. Atherosclerotic coronary artery disease	7 years

PART II. Enter other significant conditions contributing to death but not resulting in the underlying cause given in PART I

Diabetes, Chronic obstructive pulmonary disease, smoking

33. WAS AN AUTOPSY PERFORMED? ■ Yes □ No

34. WERE AUTOPSY FINDINGS AVAILABLE TO COMPLETE THE CAUSE OF DEATH? ■ Yes □ No

35. DID TOBACCO USE CONTRIBUTE TO DEATH? ■ Yes □ Probably □ No □ Unknown

36. IF FEMALE: ■ Not pregnant within past year □ Pregnant at time of death □ Not pregnant, but pregnant within 42 days of death □ Not pregnant, but pregnant 43 days to 1 year before death □ Unknown if pregnant within the past year

37. MANNER OF DEATH ■ Natural □ Homicide □ Accident □ Pending Investigation □ Suicide □ Could not be determined

CAUSE OF DEATH (See instructions and examples)

32. **PART I.** Enter the chain of events--diseases, injuries, or complications--that directly caused the death. DO NOT enter terminal events such as cardiac arrest, respiratory arrest, or ventricular fibrillation without showing the etiology. DO NOT ABBREVIATE. Enter only one cause on a line. Add additional lines if necessary.

		Approximate interval: Onset to death

38. DATE OF INJURY (Mo/Day/Yr) (Spell Month): August 15, 2003

39. TIME OF INJURY: Approx. 2320

40. PLACE OF INJURY (e.g., Decedent's home; construction site; restaurant; wooded area): road side near state highway

41. INJURY AT WORK? □ Yes ■ No

42. LOCATION OF INJURY: State: Missouri City or Town: near Alexandria Street & Number: mile marker 17 on state route 46a Apartment No.: Zip Code:

43. DESCRIBE HOW INJURY OCCURRED: Decedent driver of van, ran off road into tree

44. IF TRANSPORTATION INJURY, SPECIFY: ■ Driver/Operator □ Passenger □ Pedestrian □ Other (Specify)

Common problems in death certification

The **elderly decedent** should have a clear and distinct etiological sequence for cause of death, if possible. Terms such as senescence, infirmity, old age, and advanced age have little value for public health or medical research. Age is recorded elsewhere on the certificate. When a number of conditions resulted in death, the physician should choose the single sequence that, in his or her opinion, best describes the process leading to death, and place any other pertinent conditions in Part II. If after careful consideration the physician cannot determine a sequence that ends in death, then the medical examiner or coroner should be consulted about conducting an investigation or providing assistance in completing the cause of death.

The **infant decedent** should have a clear and distinct etiological sequence for cause of death, if possible. "Prematurity" should not be entered without explaining the etiology of prematurity. Maternal conditions may have initiated or affected the sequence that resulted in infant death, and such maternal causes should be reported in addition to the infant causes on the infant's death certificate (e.g., Hyaline membrane disease **due to** prematurity, 28 weeks **due to** placental abruption **due to** blunt trauma to mother's abdomen).

When **SIDS** is suspected, a complete investigation should be conducted, typically by a medical examiner or coroner. If the infant is under 1 year of age, no cause of death is determined after scene investigation, clinical history is reviewed, and a complete autopsy is performed, then the death can be reported as Sudden Infant Death Syndrome.

When processes such as the following are reported, additional information about the etiology should be reported:

Abscess
Abdominal hemorrhage
Adhesions
Adult respiratory distress syndrome
Acute myocardial infarction
Altered mental status
Anemia
Anoxia
Anoxic encephalopathy
Arrhythmia
Ascites
Aspiration
Atrial fibrillation
Bacteremia
Bedridden
Biliary obstruction
Bowel obstruction
Brain injury
Brain stem herniation
Carcinogenesis
Carcinomatosis
Cardiac arrest
Cardiac dysrhythmia
Cardiomyopathy
Cardiopulmonary arrest
Cellulitis
Cerebral edema
Cerebrovascular accident
Cerebellar tonsillar herniation
Chronic bedridden state
Cirrhosis
Coagulopathy
Compression fracture
Congestive heart failure
Convulsions
Decubiti
Dehydration
Dementia (when not otherwise specified)
Diarrhea
Disseminated intra vascular coagulopathy
Dysrhythmia
End-stage liver disease
End-stage renal disease
Epidural hematoma
Exsanguination
Failure to thrive
Fracture
Gangrene
Gastrointestinal hemorrhage
Heart failure
Hemothorax
Hepatic failure
Hepatitis
Hepatorenal syndrome
Hyperglycemia
Hyperkalemia
Hypovolemic shock
Hyponatremia
Hypotension
Immunosuppression
Increased intra cranial pressure
Intra cranial hemorrhage
Malnutrition
Metabolic encephalopathy
Multi-organ failure
Multi-system organ failure
Myocardial infarction
Necrotizing soft-tissue infection
Old age
Open (or closed) head injury
Paralysis
Pancytopenia
Perforated gallbladder
Peritonitis
Pleural effusions
Pneumonia
Pulmonary arrest
Pulmonary edema
Pulmonary embolism
Pulmonary insufficiency
Renal failure
Respiratory arrest
Seizures
Sepsis
Septic shock
Shock
Starvation
Subdural hematoma
Subarachnoid hemorrhage
Sudden death
Thrombocytopenia
Uncal herniation
Urinary tract infection
Ventricular fibrillation
Ventricular tachycardia
Volume depletion

If the certifier is unable to determine the etiology of a process such as those shown above, the process must be qualified as being of an unknown, undetermined, probable, presumed, or unspecified etiology so it is clear that a distinct etiology was not inadvertently or carelessly omitted.

The following conditions and types of death might seem to be specific or natural but when the medical history is examined further may be found to be complications of an injury or poisoning (possibly occurring long ago). Such cases should be reported to the medical examiner/coroner.

Asphyxia
Bolus
Choking
Drug or alcohol overdose/drug or alcohol abuse
Epidural hematoma
Exsanguination
Fall
Fracture
Hip fracture
Hyperthermia
Hypothermia
Open reduction of fracture
Pulmonary emboli
Seizure disorder
Sepsis
Subarachnoid hemorrhage
Subdural hematoma
Surgery
Thermal burns/chemical burns

REV. 11/2003

• Fig. 1.1, cont'd

Maternal mortality remains a major public health problem in much of the world, and such manageable complications as hemorrhage and infection continue to account for a large fraction of the world's maternal deaths.[19]

A notable feature of the last half of the 20th century was the sharp decline in all three mortality rates beginning in the 1960s, following a period of stagnation in the 1950s. The decline began with maternal mortality, followed by postneonatal and then neonatal. The contribution of medical care of the neonate was most clearly seen in national statistics in the 1970s, a decade that witnessed a larger proportional decline in neonatal mortality than in any previous decade of the century. All of the change in neonatal mortality between 1950 and 1975 was in mortality for a given birthweight; no improvement was seen in the birthweight distribution.[20] This finding suggested the effectiveness of newborn intensive care, whose impact on mortality in very small babies has been striking. In 1960, shortly before the development of newborn intensive care, survival of an infant with birthweight of 1000 g was no more than 5%. Forty years later, survival at that birthweight was 95%.[21] In retrospect, several factors seem to have played critical roles in the rapid development of the newborn intensive care programs that largely accounted for this rapid decline in birthweight-specific neonatal mortality. Perhaps the most important was the provision of more than nursing care to marginal populations such as the premature infant. Although the death of the mildly premature son of President Kennedy in 1963 provided a stimulus to the development of newborn intensive care,[22] it should be noted that the decline in infant mortality that began in the 1970s was paralleled by a similar decline in mortality for the extremely old,[23] perhaps an indicator that the availability of federal funding through Medicare and Medicaid enabled previously underserved populations at the extremes of age to receive greater medical attention than before. The Medicaid program, adopted in 1965, may have made it feasible for the first time to pay for the intensive care of premature newborns, among whom the medically indigent are overrepresented. While financial support for newborn intensive care may have been a necessary ingredient in its development, finances would not have been sufficient to improve neonatal mortality had not new medical technologies, especially those supporting ventilation of the immature newborn lung, been developed at about the same time.[24]

Advances in newborn care have ameliorated the impact of premature birth and birth defects on mortality. Progress has come from improved medical care of the high-risk pregnancy and the sick infant, rather than through understanding and prevention of the disorders themselves. Unfortunately, the frequencies of underlying disorders that drive perinatal mortality have shown less improvement.

With the very important exception of neural tube defects, the prevalence of which has declined with folate fortification of flour in the United States and programs to encourage intake of folate in women of child-bearing age,[25] prevalence rates of the major causes of death—preterm birth and birth defects—have not declined. The incidence of cerebral palsy, the major neurodevelopmental disorder that can be of perinatal origin, was remarkably stable for decades,[26] notwithstanding advances in obstetric and neonatal care. However, there are now suggestions from some parts of the world that the birth prevalence of this disorder is on the decline.[27]

The pace of decline in infant, neonatal, and postneonatal mortality in the United States began to slow in 1995 and changed little in the following decade. However, a decline of nearly 20% in both neonatal and postneonatal mortality has been seen since 2005 (Table 1.1). For infants weighing 501 to 1500 g at birth, data from the Vermont Oxford Neonatal Network encompassing more than a quarter of a million newborns from hundreds of largely North American neonatal units showed a decline in mortality of 12.2% in the final decade of the 20th century[28] and a further decline of 13.3% from 2000 to 2009.[29] For infants at the threshold of viability (born at 22 to 24 weeks), the large multicenter National Institute of Child Health and Human Development (NICHD) neonatal network has reported that mortality declined by 12.6% between 2000 and 2011.[30]

These declines are more modest than in the early days of newborn intensive care. From 1960 to 1985, a greater than 50% decline in mortality for infants weighing 501 to 1500 g at birth was recorded in national data,[31,32] even though much of the first decade of that interval preceded the use of newborn intensive care technology in all but a few pioneering centers. The pace of advances in newborn medicine and the expansion of newborn intensive care to populations previously underserved, factors that have exerted a constant downward pressure on infant mortality since the 1960 s, have lessened in the past two decades or so.

Reported maternal mortality has actually climbed substantially in recent years, but this almost certainly reflects the effect of improved reporting. The CDC has a special unit dedicated to the problem of maternal mortality, the Pregnancy Mortality Surveillance System (PMSS).[33] Established in 1987, its counts of "pregnancy-related" deaths, based on more in-depth exploration than is possible from a vital registration system alone, have provided consistently higher estimates of maternal mortality than data reported by the HCHS, as shown in Fig. 1.2, in part because the CDC count includes deaths occurring up to 1 year after delivery.

The major reason for the increase in reported maternal mortality was the recommendation by the NCHS in 2003 that all death certificates to females include a checkbox indicating whether the decedent had been pregnant in the prior year. This recommendation was initially adopted by some states and not others, producing considerable variability across states' reported maternal mortality ratios. The inconsistency led the NCHS to not report on maternal mortality ratios in the United States from 2008 to 2017, as seen in Fig. 1.2.[34]

Inasmuch as use of the checkbox has now been adopted by all states, the NCHS resumed reporting maternal mortality ratios in 2018 and has provided a detailed overview of issues in defining this important health parameter in vital data.[35] The checkbox on the death certificate has proven to be a mixed blessing. While it uncovers many otherwise unknown maternal deaths, it also produces a small number of false positives. For example, in 2013, seven births were reported to women in their 60s, yet 53 death certificates for women of that age had indicated a recent pregnancy. The careful assessments by NCHS of the procedures for recording maternal deaths may account for a welcome convergence of estimates of maternal mortality from the two systems. PMSS estimated the maternal mortality ratio at 17.3/100,000 in 2017, and the NCHS estimated it at 17.4 in 2018. However, the NCHS reported an increase in the maternal mortality ratio to 20.1/100,000 in 2019, although with continued cautions about data quality.[36]

The risk of preterm birth (<37 weeks' gestation) increased steadily in the first years of the present century, peaked in 2007, and has declined since. These changes occurred largely in moderately preterm babies and likely reflected a period in which obstetricians became more comfortable with earlier inductions of labor as well as the increased prevalence of twins and triplets, who are

TABLE 1.1 US Perinatal Mortality, Morbidity, Interventions, and Pregnancy Health Conditions and Behaviors, 2000–2019

	2000	2005	2010	2019	Net Change (2000–2019) (%)
Mortality					
Maternal mortality per 100,000 live births	13.2	15.2	17.8	20.1	+52.3
Infant mortality per 1000 live births	6.9	6.9	6.1	5.7	−17.7
Neonatal mortality per 1000 live births	4.6	4.5	4.0	3.8	−18.0
Postneonatal mortality per 1000 live births	2.3	2.3	2.1	1.9	−17.4
Morbidity (percentage of live births)					
Preterm birth (<37 weeks)	11.6%	12.7%	12.0%	10.2%	−11.8
Very preterm birth (<32 weeks)	1.9%	2.0%	2.0%	1.6%	−16.3
Extremely preterm birth (<28 weeks)	0.7%	0.8%	0.7%	0.7%	−5.7
Moderately low birthweight	7.1%	7.3%	6.7%	6.9%	−2.4
Low birthweight	7.6%	8.2%	8.2%	8.3%	+9.3
Very low birthweight	1.4%	1.5%	1.5%	1.4%	−1.4
Pregnancy-associated hypertension[1,2]	3.9%	4.0%	–	8.1%	+106.9
Diabetes in pregnancy[1]	2.9%	3.8%	5.1%	6.9%	+138.3
Interventions (percentage of live births)					
Cesarean section	22.9%	30.3%	32.8%	31.7%	+38.4
Induction of labor	19.9%	22.3%	23.4%	29.4%	+47.7
Health Behaviors (percentage of live births)					
Smoking	12.2%	10.7%	–	6.0%	−50.8
Late or no prenatal care	3.9%	3.5%	–	6.4%	+64.1
Unmarried	33.2%	36.9%	40.8%	40.0%	+20.5
Multiple births	3.1%	3.4%	3.4%	3.3%	+6.4
Fertility rate (women 15–44)	6.8%	6.7%	6.4%	5.8%	−13.6

[1]Birth certificate data underreports medical complications of pregnancy.
[2]Data includes preeclampsia, pregnancy-induced hypertension, and eclampsia values combined.
All rates denominatored to 1000 unless specified.

generally born preterm, resulting from in vitro fertilization. The newer data suggest some modifications of these earlier practices.

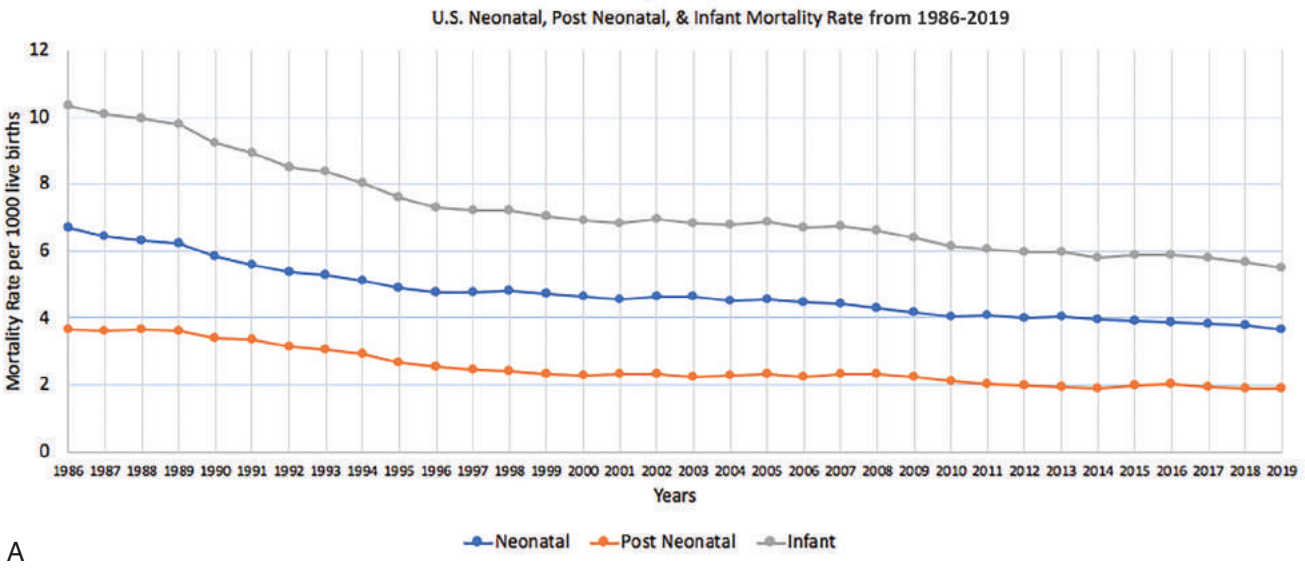
The recording of diabetes in pregnancy on birth certificates has increased substantially in the 21st century, with the 2019 prevalence 2.5 times higher than in 2000 (Table 1.2).[37] It is possible that some of this increase might reflect more complete reporting on the 2003 birth certificate revision, but the obesity epidemic has likely contributed to increased prevalence of both prenatal and gestational diabetes.[38]

The cesarean section rate continues its long-term increase, from 5% in 1970 to 23% in 1990, peaking at nearly 33% in 2010, with a faint decline to 31.7% in 2019. The reasons for this long-term increase are multifactorial and include pressures from patients, physicians, and the medical malpractice system. The steady reduction in smoking in pregnancy, which is now reported to be just 6%, is encouraging and parallels the decline in smoking in the general population but may unfortunately also reflect the uncertainty of medical records from which this information is obtained since the 2003 birth certificate revision. The proportion of mothers unmarried when they gave birth peaked at more than 50% in 2007 to 2008 but declined to 40% in 2019.

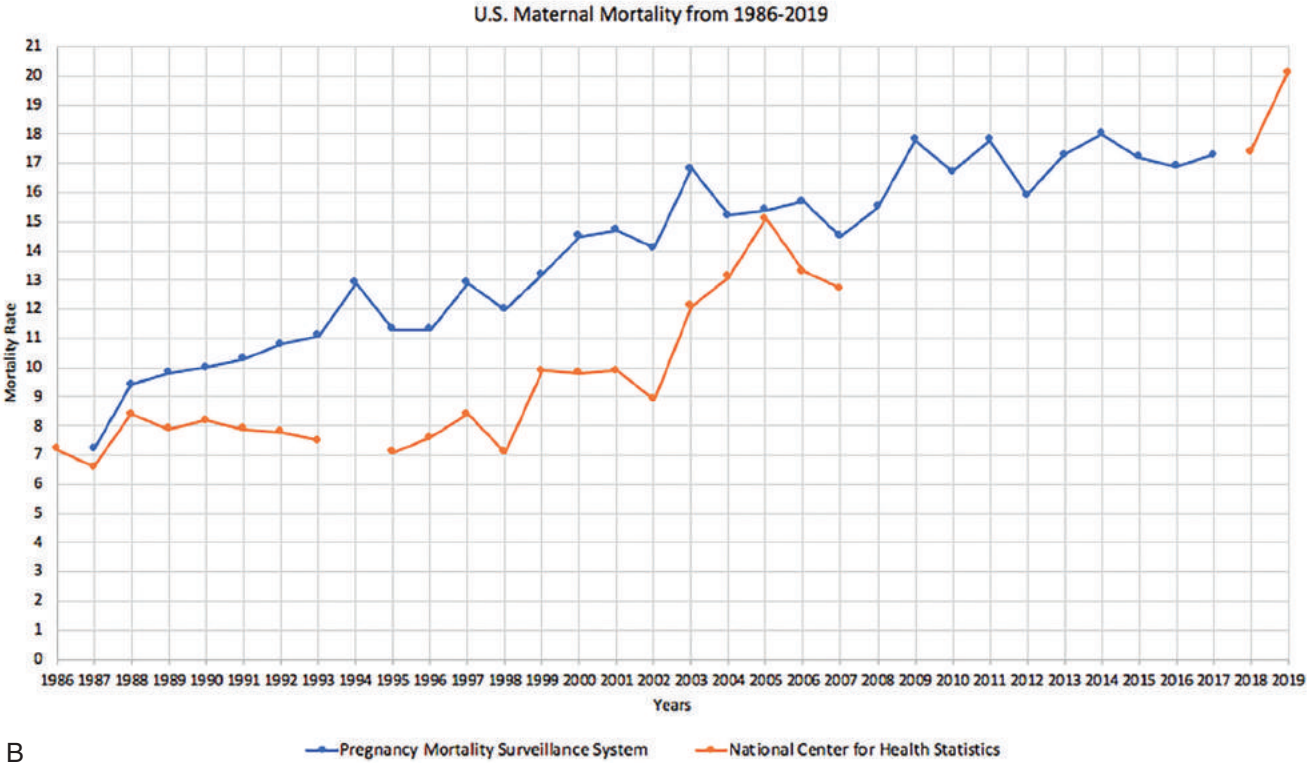
The long-term decline in the US fertility rate was accentuated in 2020, the year of the COVID-19 pandemic, when it was lower than at any time since the Depression. The number of US births declined by 4% in 2020.[39] The preterm birth rate declined as well, by slightly more than 1%, with a suggestion that the decline in births before 34 weeks was slightly greater.

International Comparisons

The relatively high rate in the United States, in comparison with other HICs, is well known. The United States ranked 33rd of



A



B

• **Fig. 1.2** Maternal, Neonatal, and Postneonatal Mortality Rates. (A) Neonatal, post-neonatal and infant mortality rates, 1986–2019. (B) Maternal mortality rates, 1986–2019.

36 countries in the Organisation for Economic Co-operation and Development (OECD) countries in the 2019 annual report.[40] Only Chile, Turkey, and Mexico had higher infant mortality rates among OECD countries. This surprising phenomenon, in light of more favorable socioeconomic and medical care circumstances in the United States than in many nations with lower infant mortality, cannot be attributed to inferior neonatal care because mortality rates for low birthweight infants are generally lower in the United States than in European and Asian nations.

A likely contributor is the more complete reporting of marginally viable small newborns as live births in the United States.[41] It is likely that the recording of such infants as live births rather than stillbirths is more pronounced in the United States than in Europe.[42] While this practice makes a contribution to our higher prematurity and infant mortality rates, it cannot fully explain them.

The key driver of the relatively high US infant mortality rate is that our nation suffers from a striking excess of premature births. While the US Black population is especially vulnerable to prematurity and especially severe prematurity, prematurity rates are also considerably higher in White Americans than in most European populations.

TABLE 1.2 Ethnic Disparities in Key Perinatal Outcomes and Exposures in 2019

	Non-Hispanic White	African - American	RR Compared With White	Hispanic	RR Compared With White
Mortality					
Maternal mortality per 100,000 live births	17.9	44.0	2.5	12.6	0.70
Infant mortality per 1000 live births	4.6	10.8	2.3	4.9	1.1
Neonatal mortality per 1000 live births	3.0	7.1	2.4	3.4	1.1
Postneonatal mortality per 1000 live births	1.6	4.1	2.6	1.4	0.88
Morbidity (percentage of live births)					
Preterm birth (<37 weeks)	9.3%	14.4%	1.6	10.0%	1.1
Very preterm birth (<32 weeks)	1.2%	3.2%	2.6	1.5%	1.2
Extremely preterm birth (<28 weeks)	0.4%	1.5%	3.5	0.6%	1.4
Moderately low birthweight	5.9%	11.2%	1.9	6.3%	1.1
Low birthweight	6.9%	14.2%	2.1	7.6%	1.1
Very low birthweight	1.0%	2.9%	2.9	1.3%	1.2
Pregnancy-associated hypertension[1,2]	8.6%	9.8%	1.1	6.7%	0.78
Diabetes in pregnancy[1]	6.3%	5.4%	0.86	7.4%	1.2
Overweight or obese (BMI of 25.0 or greater)	52.2%	65.9%	1.3	63.2%	1.2
Interventions (percentage of live births)					
Cesarean section	30.7%	35.9%	1.2	31.3%	1.0
Induction of labor	32.7%	27.7%	0.85	24.9%	0.76
Health Behaviors (percentage of live births)					
Late or no prenatal care	4.5%	9.6%	2.1	8.2%	1.8
Unmarried	28.2%	70.0%	2.5	52.1%	1.8
Fertility rate (women 15–44)	5.5%	6.1%	1.1	6.5%	1.2
Multiple births	3.4%	4.2%	1.2	2.5%	0.74

[1]Birth certificate data underreports medical complications of pregnancy.
[2]Data includes preeclampsia, pregnancy-induced hypertension, and eclampsia values combined.
All rates denominatored to 1000 unless specified.

Premature birth, fetal growth restriction, and infant mortality are tightly linked, in every setting in which they have been studied, to most measures of social class, especially to maternal education. However, uncovering precisely what it is about lower social class that drives these important differences in pregnancy outcomes has been elusive. Factors such as smoking have at times been implicated but can explain only a small fraction of the social class effect. It is unlikely that this situation will change until a better understanding of the complex social, environmental, and biologic roots of preterm birth is achieved.

Health Disparities in the Perinatal Period

In 2019, 51.1% of all US births were to non-Hispanic White mothers, 23.7% were to Hispanic mothers, 14.6% were to African-American (AA) mothers, 6.4% were to Asian mothers, and the remainder were to mothers of other ethnic groups or of multiple ethnicities or of unknown ethnicity.[43] Health disparities are especially prominent in the perinatal period, with AA infant mortality stubbornly remaining about double that of White infant mortality in the United States, even as rates decline in both populations. Preterm birth is the central contributor to this racial disparity in infant mortality, and the more severe the degree of prematurity, the higher the excess risk for AA infants. In 2019, the risk of birth before 32 weeks of gestation was 1.6 times higher in AA infants than in non-Hispanic Whites, the risk of birth before 34 weeks was 2.6 times higher, and for births before 28 weeks, the risk for AA mothers was 3.5 times higher. Reduction in infant mortality disparities in the United States thus requires better understanding of the etiology and mechanisms of preterm birth. Birth defect mortality shows a less pronounced gradient by ethnic group and does not contribute in a major way to overall infant mortality disparities.[44]

The "Hispanic paradox" is a term often used to describe the observation that infant mortality is the same or lower in US citizens classified as Hispanic than in non-Hispanic Whites, in spite of the generally lower income and education levels of US Hispanics.[45] The infant mortality experience of Hispanics in the United States reflects the principle that premature birth and low birthweight are key determinants of infant mortality, because the rates of these outcomes are also lower among Hispanics. Smoking is much less common among Hispanics in the United States, but this factor alone does not fully explain the paradox.

Major Causes of Death

Cause-of-death analysis, a staple of epidemiologic investigation, has limitations when applied to the perinatal period. Birth defect mortality is relatively accurate, but causes of deaths among preterm infants are divided among categories such as respiratory distress syndrome, immaturity, and a variety of complications of prematurity. The choice of which particular epiphenomenon of preterm birth should be listed as the primary cause of death is to some extent arbitrary. Some maternal complications, such as preeclampsia, that can lead to preterm birth are also occasionally listed as causes of newborn death.

Postmortem pathologic examination (autopsy) of the deceased fetus or infant can provide valuable information about cause of death. However, the rate at which parents provide consent for autopsy has declined over the past several decades so that alternative methods have been proposed, such as ultrasound, magnetic resonance imaging, and needle biopsy.[46]

In the period before prenatal ultrasound permitted reasonably accurate gestational age estimation, a high fraction of neonatal deaths was attributed to low birthweight, but most of these deaths occurred in premature infants, because premature birth is much more important as a cause of death than is fetal growth restriction. Extreme prematurity makes a contribution to infant mortality well beyond its frequency in the population. The 1.6% of births born prior to 32 weeks in 2018 accounted for 51% of all infant deaths.[10]

After premature birth, the next most important group of causes of death is congenital anomalies. With the signal exception of the folate-neural tube association, we have no clearly effective primary prevention program for any birth defect. For very severe defects, pregnancy screening and termination is an option, and noninvasive prenatal screening may have increased the reach of this therapeutic option.[47]

The major postneonatal cause of death since approximately the 1970s in the United States is the sudden infant death syndrome (SIDS). Although this cause of death has declined substantially in the United States in parallel with successful public health efforts to discourage prone sleeping in infancy,[48] sudden unexpected death in infancy (which includes suffocation and unknown causes along with SIDS) has been stable for the past two decades.[49]

Factors Affecting Perinatal Health

Health States in Pregnancy

The major causes of neonatal morbidity—prematurity and birth defects—generally occur in pregnancies free of antecedent complications. Having a previous birth with an anomaly or a previous preterm birth raises the maternal risk for recurrence of the condition. Indeed, for preterm birth, no other known risk factor carries as much risk as having previously delivered preterm.[50]

More than a quarter of preterm births are iatrogenic, the result of induced labor in pregnancies in which the mother's and/or fetus' health is severely compromised. In general, the reason is preeclampsia with attendant impairments in uterine blood flow and poor fetal growth, but poor uterine blood flow and impaired fetal growth can also occur independently of diagnosed preeclampsia. The other major complication of pregnancy is diabetes, most often gestational, but at times preexisting. Hyperglycemia in the mother promotes the same elevation in the fetus, and typically the infant of the diabetic mother is large for gestational age. However, severe diabetes can be accompanied by fetal growth restriction.

Health Behaviors

The most carefully studied and well-established health behavior affecting newborns is maternal cigarette smoking, which more than doubles the likelihood of intrauterine growth restriction and increases the risk of premature birth by 20% to 50%.[51] Infants with growth restriction from smoking paradoxically survive slightly more often than do infants of the same weight whose mothers did not smoke, but the net effect of smoking is to increase perinatal mortality. The risk of SIDS is also increased in the babies of smoking mothers.[52] Although the subject is much debated, it has not been conclusively shown that prenatal smoking has independent long-term effects on child cognitive capacity.[53]

Mothers who drink alcohol heavily in pregnancy are at risk of having infants with the cluster of defects known as the fetal alcohol syndrome.[54] Cocaine use in pregnancy is a restrictor of fetal growth[55] and may affect neonatal behavior, but the long-term effects of this exposure on infant cognition and behavior are not as great as initially feared.[56]

The frequency of marijuana use during pregnancy has increased substantially in recent years, in parallel with legalization in several states. Between 2002 and 2017, self-reported cannabis use more than doubled, from 3.4% to 7.0%, among pregnant participants in the National Survey on Drug Use and Health (NSDUH),[57] and pregnant women in states with legalized recreational cannabis are twice as likely to use cannabis than their counterparts in states where cannabis remains illegal.[58] In addition, the potency of recreational and medicinal cannabis, measured by the concentration of tetrahydrocannabinol (THC), the main psychoactive constituent of cannabis, appears to have tripled in recent decades.[59] THC crosses the human placenta, with greater transfer during the early stages of pregnancy when the fetus is most susceptible to the adverse effects of drug use.[60] Although the evidence that marijuana use during pregnancy adversely affects neurodevelopment of the offspring is inconclusive,[61] the American College of Obstetricians and Gynecologists recommends against use by women who are considering pregnancy or who become pregnant.[62]

Perinatal Medical Care

In light of the potent effects of medical care on the neonate, it has been important to develop systems of care that ensure, or at least facilitate, provision of care to neonates in need. This concept was first promoted by the March of Dimes Foundation, which in its committee report of 1976 recommended that all hospitals caring for babies be classified as either Level 1 (care for healthy and mildly ill newborns), Level 2 (care for most sick in-born newborns but not accepting transfers), and Level 3 (regional centers caring for complex surgical disease and receiving transfers).[63] This concept of a regional approach to neonatal care, with different

hospitals playing distinct roles in providing care, was endorsed by organizations such as American College of Obstetricians and Gynecologists and the American Academy of Pediatrics and by many state health departments. While it is important to transfer sick babies to Level 3 centers when needed, it is preferable, if at all possible, to transfer mothers at risk of delivering prematurely or of having a sick neonate, because transport of the fetus in utero is far superior to any form of postnatal transport. Birth at a level 3 center has consistently been shown to produce lower mortality rates for small or premature infants than birth in other levels of care,[64] although this reduction in mortality is not clearly seen for infants born at term of normal weight.[65]

Epidemiologic Study Designs in the Perinatal Period

Epidemiologic studies have contributed substantially to better understanding of patterns of risk and prognosis in the perinatal period, to tracking patterns of mortality and morbidity, to assessing regional medical care, to identifying pre- and perinatal hazards, and to evaluating the efficacy of treatments. The use of vital data to provide *descriptive* epidemiology of the health of mothers and infants and to monitor time trends has already been mentioned, but *analytic* epidemiology, drawing on cohort, case-control and randomized trial designs, has been essential to advances in neonatology.

Cohort Studies Beginning in Pregnancy or at Birth

Studies that follow populations of infants over time, beginning at birth or even before birth, continuing to hospital discharge, to early childhood or even into adult life, are the leading sources of information about perinatal risk factors for disease and adverse outcomes. As with all observational studies, cohort studies produce associations of exposures and outcomes whose strength and consistency must be carefully judged in the light of other biologic evidence and with attention to confounding and bias. Collaborations across centers in assembling such data are very valuable. One such notable collaboration is the Vermont-Oxford Network, which provides continuous information on the frequency of conditions observed and diagnoses made in hundreds of US and overseas hospitals, with a particular emphasis on using these data for improving care.[66] Another is the NICHD-supported Neonatal Research Network, which has not only been a rich source of randomized clinical trials but also has produced observations about prognosis based on very large samples of low birthweight babies.[67]

Multicenter cohort studies focusing on diagnosis and follow-up of brain injury in preterm infants have contributed much to our understanding of the prognostic value of brain injury imaged by ultrasound in the neonatal period because they include follow-up to age 2 or later. Of particular value have been regional or population-wide studies of low birthweight infants with follow-up to at least school age, among which are included the NBH study from the United States and also important studies from France,[68] Germany,[69] Holland,[70] Great Britain,[71] and Canada.[72]

Newborn intensive care has been in place long enough that the first reports of adult outcomes in very small infants have been published,[73] and they paint a picture that is perhaps less dire than many had anticipated. The Adults Born Preterm International Collaboration is an expanding resource for epidemiologic studies on adult outcomes after preterm birth.[74]

From 1959 to 1966, the National Collaborative Perinatal Project assembled data on approximately 50,000 pregnancies in 12 major medical centers and followed them to age 7.[75] This highly productive exercise, one of whose major contributions was to show that birth asphyxia is a rare cause of cerebral palsy, has now been followed by the development of even larger pregnancy cohort studies. These studies, all of which archive biologic material such as blood and/or urine in pregnancy, should, in principle, permit us to learn a great deal about the unrecognized pregnancy factors that lead to adverse perinatal and child health outcomes. For reasons not entirely clear, a sample size of 100,000 has been universally adopted in studies in Norway,[76] Denmark,[77] and, most recently, Japan.[78] Efforts to mount a similar study in the United States have not been successful, but the recently launched National Institutes of Health (NIH)-sponsored Environmental Influences on Child Health Outcomes Program holds is beginning to create a useful database of prenatal, perinatal, and postnatal data, with assessments of neurodevelopmental outcomes, obesity, and asthma in childhood.[79]

Case-Control Studies

A notable contribution using the case-control approach was the 1971 discovery that diethylstilbestrol (DES) is a prenatal carcinogen. Notably, this study was based on only 8 cases of vaginal clear cell adenocarcinoma in adolescents and young women, but the linkage to exposure to DES in utero was unmistakable (7 of 8 cases, none of 32 controls).[80] The US Food and Drug Administration (FDA) banned the use of DES in pregnancy 5 months after the publication of the study, and a very large decline in the incidence of vaginal clear cell adenocarcinoma has since been documented.[81]

As noted previously, the United States has witnessed a large decline in the incidence of SIDS. This decline is almost certainly owed to the discovery, in two well-done case-control studies, one in Holland the other in New Zealand, that prone sleeping is a strong risk factor for SIDS.[82,83] The decline in SIDS incidence closely paralleled remarkably rapid changes in maternal behavior, with the placing of babies in the prone position for sleep declining steeply in just a few short years.[84]

Randomized Controlled Trials

Few areas of medicine have adopted the randomized trial as wholeheartedly as newborn medicine. The number of trials mounted has been large and their influence on practice strong. A notable influence on this field has been the National Perinatal Epidemiology Unit (NPEU) at Oxford University, established in 1978, which prioritized randomized trials among their several investigations of perinatal care practices and other circumstances affecting maternal and newborn outcomes. The NICHD neonatal research network was established in 1986, principally to support trials in newborns. Hundreds of trials have been mounted by just these two organizations alone, but many other centers have contributed to the trial literature.

Trials in pregnancy or in labor have also been supported by the NPEU and by a network of obstetric centers supported by NICHD, the maternal-fetal research network, established, like the neonatal network, in 1986 but by and large involving different medical centers. These trials have often had important implications for newborns and for mothers, most notably, the one trial

that has thus far successfully reduced the risk of preterm birth, the administration of 17-OH hydroxyprogesterone caproate in midgestation to high-risk women.[85] Vaginal progesterone may also be effective.[86]

Most newborn trials have focused on outcomes evident in the newborn period, such as mortality, chronic lung disease, brain damage visualized on ultrasound, duration of mechanical ventilation, and/or hospital stay. Recently, however, trials extending into infancy or even to early childhood that incorporate measures of cognition or neurologic function have been a welcome addition to the trial arena. In the past two decades, we have learned from such trials that induced hypothermia can reduce mortality and brain damage in asphyxiated term infants[87] and that both caffeine for apnea treatment[88] and magnesium sulfate administered in labor may reduce the risk of cerebral palsy.[89]

Trials in which both mortality and later outcome are combined raise complex methodologic issues. Imbalance in the frequency of the two outcomes being combined can result in random variation in the commoner outcome overwhelming a significant finding in the other. Precisely how best to conduct such dual or multioutcome trials is the subject of discussion and debate in the neonatal and epidemiologic communities.

As trials multiply, not all of them sufficiently powered, the methodology for summarizing them and drawing effective conclusions has become increasingly important to neonatologists. The terms "systematic review" and "meta analysis" have firmly entered the research lexicon, especially the randomized trial literature. The Cochrane collaboration is an international organization that uses an army of volunteers to systematically review trial results in all fields of medicine. The collaboration, established in 1993, began in the field of perinatal medical trials. Systematic reviews of neonatal trials reviewed by the Cochrane Collaboration are hosted on the website of the NICHD.[90]

In a particularly valuable experiment, women at high risk of having a child with a neural tube defect were randomized to receive 4 mg folate or placebo, showing conclusively that folate administration in the preconceptional period prevented neural tube defects.[91] A trial in unselected women also showed a beneficial effect but was underpowered.[92] Major efforts to promote folate intake in women of childbearing age have been followed by reductions in the birth prevalence of neural tube defects, especially in countries, which, like the United States, have also mandated fortification of flour with folic acid.[93]

Summary and Conclusions

The patterns of disease, mortality, and later outcome in the perinatal period are complex. Some factors, such as the long-term trends in preterm birth and birthweight, are reasonably stable, whereas others, such as the rates of cesarean section and twinning, can undergo rapid change. The success of newborn intensive care is well established. No other organized medical care program, targeted at a broad patient population, has had such remarkable success in lowering mortality rates in such a short period of time. Much of that success is owed to the evidence-based nature of neonatal practice.

Nonetheless, this success has opened the door to new problems as survivors of intensive care face the challenges of the information age. Resource allocations similar to those that permitted the development of newborn intensive care are now needed to address the educational and rehabilitative needs of survivors. A hopeful sign is the success of some recently studied interventions in reducing the burden of brain damage.

On the nontechnologic front, targeted epidemiologic efforts to address perinatal disorders have yielded progress as well. Careful study of the circumstances surrounding infant sleep patterns led to active discouragement of prone sleeping, which has produced a halving of mortality from SIDS.[47] Observational research, followed by two important randomized trials in Europe, led to interventions that increased folate intake in women of child-bearing age and a substantial reduction in the birth prevalence of neural tube defects.

The population-level study of health events occurring in pregnancy and infancy, their antecedents, and long-term consequences has been an important component of the success of newborn care. Careful self-evaluation through monitoring of vital data and of collaborative clinical data, rigorous assessment of new treatments through randomized trials, and alertness to opportunities to implement prevention activities following discovery of important risk factors should continue to guide care of the newborn.

Ethics, Data, and Policy in Newborn Intensive Care

JOANNE M. LAGATTA AND JOHN D. LANTOS

KEY POINTS

- Increasingly available data in neonatal intensive care may help guide ethical decision-making about sick infants.
- Despite better ability to predict outcomes for sick infants, prognostic efforts are imperfect.
- When using data to guide decision-making in the neonatal intensive care unit, it is important to choose appropriate outcomes that match families' values.
- There are policy implications to both limited data, as in predicting outcomes for preterm infants, and to increasingly available data, as in newer advances in genetic screening.

Background

Ethics in the neonatal intensive care unit (NICU), as in all clinical contexts, starts with the traditional triangular framework of principles. Autonomy means to do what the patient, or in this case the parent, thinks is right; paternalism means to do what the doctor thinks is best; beneficence and nonmaleficence mean to do what is most beneficial and least harmful. These principles are widely accepted as the basis of ethical medical practice. Their applications occur daily. The problem with using these widely accepted principles to guide practice is they sometimes conflict with one another. Then one must decide quickly which compromises are best. What is the right thing? What facts should be brought to bear in the decision? What weight should be given to each fact? Whose opinion should count?

Many decisions in the NICU evoke and reflect these principles. Sometimes, neonatologists make relatively straightforward decisions not to resuscitate babies born at 21 weeks, or to provide obligatory support to babies born at 28 weeks, or to not perform cardiopulmonary resuscitation on infants with lethal anomalies. In more difficult cases, when ethical principles are in conflict, their application to a particular case is not straightforward. Faced with a difficult case, it is rare that simply applying principles will help to devise a solution.

Applying ethical principles requires attention to the specific details of each case. We must ground our concerns in context, take data into account, and be sympathetic to patient preferences when the balance of benefits and burdens is not clear. In the NICU, health professionals are constantly and anxiously aware that the burdens of treatment are real, immediate, and significant, whereas the benefits of NICU interventions are distant, statistical, and unpredictable. Babies must undergo months of painful procedures such as intubation, ventilation, and intravenous catheterization in the hope that everything will turn out well in the end. However, sometimes outcomes are ambiguous. Babies are left with lifelong sequelae. How should we decide whether we did the right thing? How should we decide whether, in similar circumstances, we should again do the same thing?

To make good decisions, we need good data. We need to know (1) where to get data; (2) how to decide which data matters; (3) the implications of limited data; and (4) the implications of increasingly available data. These questions are the focus of this chapter.

Getting Data

Neonatologists have a number of repositories through which data are collected and analyzed. The Vermont Oxford Network (VON) and the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network Generic Database use prespecified data elements to describe outcomes of preterm infants.[1,2] Similar databases exist to describe outcomes of other neonatal populations. These include the Extracorporeal Life Support Organization database and the Congenital Diaphragmatic Hernia Study Group.[3,4] For all these biorepositories, data are gathered using trained abstractors and ongoing quality assurance regarding data collection. Each has discrete variables related to the population of interest. Secondary analysis of electronic health record (EHR) data is a more feasible option than previous manual chart review, following meaningful use incentives for implementation of EHRs.[5] Administrative data from billing claims are another commonly used source of outcomes information; examples include the Pediatric Health Information System from children's hospitals, the National Inpatient Sample and its associated Kids Inpatient Database from the Agency for Healthcare Research and Quality, or the Kaiser Permanente Neonatal Minimum Data Set.[6–8] From the standpoint of understanding outcomes to inform decision-making for sick infants, each type of data has benefits and drawbacks. Benefits of abstracted data include ongoing quality assurance for variables related to the disease of interest. Limitations include differences in definitions between data sources, and the way that individual data are aggregated into discrete variables. EHR data have the benefit of extreme

detail and potential flexibility in defining measures of interest, but they are limited by the accuracy of the recording clinician. Claims data have the benefit of understanding costs of care but are limited by the accuracy of coding and discrepancies between clinical diagnosis and coding terminology for common diseases.

These multiple potential sources of information offer opportunities for those who want to better understand the determinants of outcomes, but the plethora of information is a mixed blessing. Databases can be local, regional, national, or international. They can gather data on all babies or only on specific subpopulations of babies. These variations lead to different outputs. Caregivers must then decide which database to use and how to interpret and apply the results.

Getting Data That Matters

What kind of information would parents, physicians, or judges need to decide when treatment should be obligatory and when it should be optional?

One essential truth at the intersection of NICU epidemiology and ethics is that gestational age—particularly at the margins of viability—is a powerful predictor of survival. In the United States, as in virtually all the industrialized world, infants born after 24 weeks' gestation have survival rates greater than 80%. This is high enough so that treatment is generally considered obligatory. For these infants, the ethical principle of best interest requires their resuscitation, in the same way that sick children born at term deserve resuscitation. Conversely, for infants born before 22 weeks' gestation, survival is essentially zero. Consequently, these infants and their parents deserve our compassion but not necessarily our interventions, on the ethical grounds of strict futility.

In between, spanning approximately 3 weeks of gestational age, from 22 to 24 weeks, we require not only data but also its interpretation. Tyson et al., using the NICHD Neonatal Research Network, attempted to quantify additional risk factors for both mortality and neurologic morbidity among infants born on the cusp of viability.[9] Their analysis revealed that, for babies at the same gestational age, singleton status, birth weight, antenatal steroids, and female gender all improve the likelihood of survival and intact neurodevelopmental outcome. By considering these factors—which are available at the time of birth—caregivers can more accurately estimate the chances that a baby will survive or that those survivors will have neurodevelopmental impairment. This predictive model has been turned into a publicly available and widely used calculator, which is used in many locations to counsel families at risk of delivering a baby in this gestational age range. The model has been updated recently to include more modern neonatal and obstetric outcomes and to provide a range to account for the wide center variability in outcomes.[10,11]

However, two problems remain. First, for many infants, the algorithm's predictive value is still not very good—some lower-risk patients will die, and some of the highest-risk patients will survive. Second, by only using data available at the time of birth, the algorithm ignores a potentially important feature of NICU care—time. It does not account for prognostic features that might become available as the infant's course unfolds in the NICU. This is an important limitation that has ethical implications.

There are distinct advantages to making decisions over the first few days of an infant's NICU stay rather than in the delivery room at the time of birth. The first is emotional. Parents often appreciate the opportunity to get to know their baby as an individual, as opposed to making decisions based only on anonymous population-based prognostications that are available at the time of birth. Second, there is valuable information to learn while the baby is in the NICU. Several time-sensitive prognostic features have been evaluated for infants born at the border of viability. These include illness severity scores such as the Score for Neonatal Acute Physiology (SNAP), cranial ultrasound results in the first week or two of life, and caregiver intuitions that the patient would "die before NICU discharge."[12,13] Unfortunately, although illness severity scores on the first day of life have good prognostic power for death or survival, their power diminishes over time. Intriguingly, serial intuitions that an individual baby will die before discharge—offered by medical caregivers for infants who require mechanical ventilation and for whom there is an ethical alternative to continued ventilation, namely extubation and palliative care—are remarkably accurate in predicting a combined outcome of either death or survival with neurodevelopmental impairment (mental developmental index [MDI] or psychomotor developmental index [PDI] <70). Babies with abnormal results from a cranial ultrasound examination whose doctors agree with one another that the babies are likely to die have a less than 5% chance of surviving with both MDI and PDI greater than 70 at 2 years, independent of their gestational age. The predictive power of these data, acquired over time during an individual infant's NICU course, although not perfect, is greater than any algorithm available at the time of birth.

What do prospective parents consider when asked to decide whether to resuscitate their micropreemie? They may not want the precise prognostic estimates that we try to offer. For many parents, the death of their baby in the NICU is not necessarily the worst outcome. Instead, for many parents, it may be emotionally more difficult to not try to save their baby than it is to try and fail. The decision not to try may leave parents with a lifetime of self-doubt about whether, had they only tried, their baby might have survived. The old adage, "It is better to try and fail than not to try at all" seems to summarize these attitudes.

If trying and failing is seen as a more acceptable option than not trying at all, that could help us figure out which outcome statistic is most relevant to parents. Many studies based on database information, including that of the NICHD, try to predict how many babies either die or survive with severe neurodevelopmental impairment. This approach implicitly considers both severe disability and death to be equivalent and equally bad outcomes. The implicit assumption is that, if there is a high likelihood of death, then we should not attempt resuscitation or provide life-sustaining interventions. By contrast, if trying and failing is better than not trying at all, then perhaps we should combine different variables—reporting the percentage of survivors who are neurologically intact while leaving the babies who die out of the denominator. Understanding outcomes as a fraction of infants who survive to discharge is often obscured in research reports of preterm infant outcomes, due to epidemiologic concerns about "competing outcomes."[14] Because an infant who does not survive to NICU discharge cannot have developmental delays at age 2, these two very different outcomes—death or severe disability—are reported together. This is problematic for two reasons. First, while combining competing outcomes makes sense from a statistical perspective, from a family or clinician's perspective, death in the NICU and delays at age 2 are very different scenarios. For the parent who prefers that the NICU team attempt resuscitation, these combined outcomes do not offer a sense of what happens if the baby does survive. Second, presenting NICU outcomes data as combined outcomes obscures

an important fact of neurologic morbidity in extremely preterm infants: the incidence of neurologic morbidity in NICU survivors is not very different when comparing infants at 23, 24, 25, and 26 weeks' gestation. The essential epidemiologic difference for infants born in this gestational range appears to be whether the baby will survive at all. Once the baby leaves the NICU, the risk of severe morbidity is largely the same. This is true in single-center and multicenter studies, in the United Kingdom, Canada, Europe, and the United States.[9,15]

It has been traditionally, and inaccurately, perceived that mortality follows morbidity, meaning that because infants born at 22 to 24 weeks' gestation have the highest rate of mortality, survivors have the highest rates of neurologic morbidity. This belief is supported by the lack of parsing out outcomes of mortality versus morbidity among survivors. It could contribute to an inaccurately pessimistic view of outcomes. A fascinating insight has been offered by Janvier et al., who have done extensive surveys comparing responses to requests for resuscitation of sick micro-preemies with resuscitation of comparably sick patients at other ages (from term infants to 80-year-olds).[16] Consistently, it appears that micro-preemies are devalued. For comparable likelihood of survival and comparable likelihood of neurologic morbidity in survivors, more respondents would not offer resuscitation or would allow a micro-preemie to die.

Finally, there is difficulty in assigning value to morbidity in surviving infants in the NICU. Traditional outcomes studies for survivors of NICU care are generally limited to Bayley scores at 18 to 26 months of age. This is problematic for multiple reasons. First, NICU success is often viewed as "all or none." In most neonatal follow-up literature, a Bayley Mental Developmental Index (MDI) or Psychomotor Developmental Index (PDI) greater than 70 is classified as *normal*, whereas an MDI or PDI less than 70 is classified as an *adverse outcome*. A continuum of scores may be better interpreted as a range of strengths and areas that require additional attention, rather than as a single measure of success or failure. Whether individual clinicians think of developmental delays along a continuum or not, presenting outcomes data as pass/fail in the literature may contribute to the overpessimistic attitudes toward survivors of preterm birth prevalent in the medical community.

Furthermore, studies of former preterm infants have shown limited correlation between Bayley scores at 2 years of age and school readiness by 5 years of age.[17] This has been interpreted in the neonatal community as a poor reflection on the Bayley assessment itself, yet in studies of infants with congenital heart disease there is a much tighter correlation between 2-year and later outcomes.[18] It seems more likely that the problem with assigning value to morbidity is not the Bayley assessment itself but that former preterm infants have significant capacity to continue improving their developmental progress after 2 years of age. It also may be that Bayley scores at age 2 do not yet reflect the higher-order organizational and executive functioning issues that can become problematic by school age in survivors of prematurity. Verrips et al. have attempted to assess the effects of permanent residual disability for NICU survivors and their immediate families; they have demonstrated consistently that children with disabilities and their parents place a much higher value on their lives, and the quality of those lives, than do either physicians or NICU nurses.[19] The vast majority of infants who survive the NICU, even those with significant permanent neurologic compromise, have "lives worth living," as judged by the people most affected by those lives.

Policy Implications of Limited Data

Despite the wealth of available data on outcomes of sick infants after the NICU, we are still unable to predict future neurologic morbidity with the amount of detail needed for many clinicians and parents to make decisions regarding intervention. This, along with changes in the recognition of disability as a social construct as well as a medical one, has led to legal challenges with important implications for clinical care.

Public Policy: The Baby Doe Case

In the 1980s, the federal government attempted to change the rules for neonatal decisions about babies with congenital anomalies.

In 1982, a baby with Down syndrome and esophageal atresia was born in Bloomington, Indiana (USA). Baby Doe's parents refused to consent to surgery and chose palliative care instead. The court sided with the parents. The doctor and hospital appealed. The Indiana Supreme Court refused to hear the appeal, and the baby died after 8 days.[20]

This led to a national controversy that eventually resulted in amendments to the federal Child Abuse and Treatment Act.[21,22] While this law has limited authority in regulating clinical decisions, it symbolically endorses the idea that life-sustaining treatment should not be withheld only on the basis of anticipated disability.

There is still controversy when treatments enable survival but have a high likelihood, or certainty, that survival will be accompanied by severe neurologic impairment. As a result, two questions must be asked: How severe will the neurologic impairment be? What is the likelihood that the child will have the most severe possible impairment?

The shift in moral standards regarding babies with Down syndrome was not related to technology but rather sociology.[23] The capacity to repair Arnold-Chiari malformation and duodenal atresia existed long before it was applied to children with myelomeningocele and Down syndrome. What has changed is a growing recognition that disability is as much a social construct as a medical construct, although it is always both and not one or the other.

Malpractice Cases Against Neonatologists

There are also malpractice cases against neonatologists that have shaped the decision-making climate in the NICU. In *Miller versus Hospital Corporation of America Inc.*, the doctors were sued for resuscitating a tiny premature infant over the objections of the parents. The case focused on events that had occurred in 1990, when Mrs. Miller came to a Hospital Corporation of America hospital in Texas in labor at 23 weeks' gestation. The fetus was estimated to weigh 500 to 600 g. No baby born that size had ever survived at that hospital. Mrs. Miller, her husband, and the attending physicians agreed that the baby was previable and that no intervention was indicated. The baby was born, but a different physician performed resuscitation, and the infant survived with brain damage. As a result, the Millers sued the hospital for a breach of informed consent and were awarded $50 million by a trial jury. The case wound its way to the Texas Supreme Court, which dismissed the verdict and articulated an "emergency exception" for physicians—that is, if a Texas physician finds himself or herself in the emergency position of needing to resuscitate a patient to prevent immediate death, the physician can try to perform resuscitation without being obligated to obtain consent from anyone.

Whether it would be acceptable for a physician not to perform resuscitation in an emergency was left unarticulated by the Texas court.[24]

In Wisconsin, the case of *Montalvo versus Borkovec* took the legal obligations of neonatologists and parents to a different place. The case derived from the resuscitation of a male infant born between 23 and 24 weeks' gestation, weighing 679 g. The parents claimed a violation of informed consent, arguing that the decision to use "extraordinary measures" should have been relegated to the parents. The Wisconsin Appellate Court disagreed, holding that "in the absence of a persistent vegetative state, the right of a parent to withhold life-sustaining treatment from a child does not exist." Because virtually no infant is born in a persistent vegetative state, this decision would apparently eliminate the ethical possibility in Wisconsin of a "gray zone" of parental discretion. No other jurisdiction in the United States has adopted this position. The Wisconsin Appellate Court, like the Texas Supreme Court, was silent on whether physicians have discretion not to resuscitate. However, in Texas and Wisconsin, physicians are apparently not liable if they choose to do so.[25]

A number of other state courts have addressed issues of treatment or nontreatment. In general, the courts are permissive of physicians who resuscitate infants. If courts are asked to sanction decisions to allow infants to die, most will do so only if there is consensus among physicians and parents and occasionally ethics committees. Courts are not eager to punish physicians who treat infants over parental objections or to empower physicians to stop treatment when parents want it to continue.

In 2020, President Trump issued an Executive Order entitled "Protecting Vulnerable Infant and Newborn Children." After alleging that "some hospitals refuse the required medical screening examination and stabilizing treatment or otherwise do not provide potentially lifesaving medical treatment to extremely premature or disabled infants, even when parents plead for such treatment," the Executive Order went on to summarize the legal requirements that are already in place as a result of the Baby Doe controversy, the Emergency Medical Treatment and Labor Act, and the Born-Alive Infant Protection Act. Most experts believe that the Executive Order did not add any legal requirements for treatment beyond those that were already in place.

Relationship Between Policy, Practice, and Outcomes

Many countries' professional societies have policies about resuscitation for babies born at the borderline of viability. In 2015, Guillén et al. reported results of an international study of such policies.[26] They found that, among guidelines in 31 countries, 21 (68%) supported comfort care at 22 weeks' gestation and 20 (65%) supported active care at 25 weeks' gestation. Between 23 and 24 weeks' gestation, there was wide variation from country to country. Wilkinson and colleagues also reviewed international differences in resuscitation policies and the effect of those policies on clinical practices.[27] They found differences in the thresholds for resuscitation in three European countries—Sweden, the United Kingdom, and the Netherlands. In Sweden, most neonatologists set the threshold for resuscitation at 22 weeks. In the United Kingdom, it was 23 weeks. In the Netherlands, it was 24 weeks. These practices mirrored national guidelines that endorse shifts in management on the basis of gestational age. These authors also noted some differences within countries, writing "Among Dutch respondents, 29% would withhold resuscitation at a maximum of 25 + 6/7 weeks' gestation, whereas 33% would withhold resuscitation at up to 26 + 0/7 weeks' gestation; a similar division was evident in Swedish respondents (21% indicating a maximum of up to 22 + 6/7 weeks' gestation and 29% indicating a maximum of up to 23 + 0/7 weeks' gestation) and UK respondents (29% indicating a maximum of up to 23 + 6/7 weeks' gestation and 29% indicating a maximum of up to 24 + 0/7 weeks' gestation)."

Resuscitation policies clearly shape outcome statistics. Myrhaug and colleagues showed how powerful this effect can be.[28] They conducted a meta analysis of outcomes studies of babies born between 22 and 25 weeks of gestation in 19 different countries over the past 20 years. They showed that overall survival rates for infants born at 22 weeks were near zero percent because in most studies such infants were not offered intensive care. For babies who were admitted to a NICU, by contrast, the survival rate was 24.1%.

Both national policies and practices appear to be in flux. Recent reports in some national databases (but not yet in peer-reviewed publications) suggest that resuscitation is more common than it used to be for babies born at 22 weeks of gestation (see, e.g., https://www.npeu.ox.ac.uk/assets/downloads/mbrrace-uk/reports/perinatal-surveillance-report-2018/MBRRACE-UK_Perinatal_Surveillance_Report_2018_-_Tables_and_Figures_v3.pdf; http://www.canadianneonatalnetwork.org/portal/Portals/0/Annual%20Reports/2019%20CNN%20report%20final_links.pdf).

Neonatal Resuscitation and Generational Conflict

Finally, the concept of generational conflict must be considered. Many doctors appear to be quite comfortable calling delivery-room resuscitation of 24-weekers "optional," based on gestational age alone.[29] Given what we know about the factors other than gestational age that influence outcomes, this seems to be a curiously oversimplified approach to clinical decisions. It is not an approach that is used in other areas of medicine. For example, professional societies do not recommend the allocation of intensive care unit resources based on age alone. Such a practice might be called "discriminatory ageism." However, with regard to premature babies, it ought, perhaps, to be considered equally discriminatory and labeled as "gestational ageism."[30] Some suggest that the reason to limit such treatment is because it is too expensive, but studies show that it is remarkably cost-effective compared with the use of intensive care resources for elderly patients with respiratory failure.[31,32] The relative cost-effectiveness of NICUs compared with medical intensive care units is based on the natural history of illnesses that lead to intensive care unit admissions. Most babies who are admitted to the NICU either die relatively quickly or survive. Thus most of the resources in NICUs are expended on patients who survive to leave the hospital. For adults, the opposite is true. With each passing day in the intensive care unit, the chances that an elderly patient will survive to leave the hospital go down. Thus a much higher percentage of the resources expended in adult intensive care units are used by patients who will not leave the hospital alive.

Implications of Increasingly Available Data

Recent developments in perinatal care have led to new types of data available for decision-making. These developments may change the way we think about ethical issues in the newborn period. Examples include the rise of fetal medicine and expanded genomic screening of newborns.

Fetal Medicine Centers

Many children's hospitals have fetal medicine centers. The goal of these centers is to identify fetuses at risk—particularly those with congenital anomalies—and to care for those fetuses and their mothers in centers with expertise in fetal diagnosis, therapy, and neonatal care. The hope is that such centers will allow timely, effective intervention for babies with congenital heart disease, congenital diaphragmatic hernia, or other anomalies.

The effectiveness of fetal medicine centers depends on two factors. First, they depend on effective fetal screening and diagnosis. That can only happen if all pregnant women have access to high-quality prenatal care. The existence of these centers should create an expectation and a demand for better prenatal care and fetal screening. Such screening is likely to include better imaging and screening tests; both will lead to earlier diagnosis of fetal anomalies. These diagnoses will create more complex dilemmas for perinatologists and parents who will need to decide whether to terminate the pregnancy, offer fetal therapy, or offer either palliative care or interventions after birth. Ironically, better fetal diagnosis may increase the likelihood of pregnancy termination, even when postnatal treatment is possible, because better fetal diagnosis allows more time to consider all available options.

Second, the effectiveness of fetal centers will depend on the effectiveness of fetal interventions. To date, fetal interventions have been effective in relatively few conditions. Vascular ablation for twin-to-twin transfusion syndromes clearly improves outcomes in these conditions. In utero surgery for myelomeningocele also leads to better outcomes for babies born with this condition. However, the vast majority of prenatally diagnosed conditions cannot be effectively treated in utero. The real hope of fetal medicine centers today is that they will improve outcomes by allowing better planning for interventions at the time of delivery and immediately after. In some cases, that may lead to changing the timing, mode, or location of delivery. In other cases, it may mean that a team of pediatric subspecialists will be prepared and immediately available to treat the baby in the minutes after birth. These efforts may improve outcomes.

Expanded Newborn Screening

In recent years, the number of diseases and conditions that can be diagnosed through newborn screening has expanded dramatically. Decisions about which conditions to include on the newborn screening panel are complex for at least three reasons. First, even the most accurate test has false-positives. The rarer the condition, the more likely that a positive test will be a false-positive. As more rare conditions are added to a newborn screening panel, there will be more false-positives. False-positives are not harmless. They are associated with considerable parental anxiety and can lead to potentially dangerous and unnecessary diagnostic procedures or treatments.

A second concern about expanded newborn screening is cost. Most of the cost is not for testing itself. Instead, it is for the follow-up counseling and testing after positive screening tests. Such follow-up is essential or the screening programs will not work. The Centers for Disease Control and Prevention (CDC) (2008) has expressed concern about these costs.

Finally, there is the potential for discrimination against patients for whom documented heterozygous carrier status conveys no recognized medical infirmity, but social or psychological stigma may be real. There is little funding available to assist or counsel these patients.

Many centers have started to offer whole-genome sequencing (WGS) for particular groups of newborns. Like newborn screening, such testing offers the tantalizing prospect of better diagnosis leading to better treatment for some newborns whose conditions have been difficult to diagnose using more conventional methods. However, of concern is the fact that WGS generates not one result but tens of thousands of results. Those results are more difficult to interpret than traditional newborn screening because every baby—and every adult—has many genetic variations. Some are diagnostic of rare diseases, some are known to be benign, and many are of unknown significance.

Variants can only be interpreted after a good clinical history, family history, and physical examination have been performed. Data from these preliminary steps allow physicians to assess whether there are similar or related phenotypes in other family members; if so, the inheritance pattern can then be evaluated and assessed. Physical examination findings allow physicians to begin a search for potentially relevant genes. Mode of inheritance and a comprehensive phenotype can then be used to classify the patient's genomic variants. WGS may lead to the discovery of a known pathogenic variant, a novel pathogenic variant that is likely to be disease-causing, or a variant of unknown clinical significance in a gene known to cause human disease. The issue of fetal WGS testing has emerged as an added controversial aspect of screening. Fetal centers looking to offer improved diagnostics and planning can benefit from this added information prior to delivery, because it may alter the interventions offered; however, even with excellent fetal imaging, the inability to perform a physical exam limits the interpretability of the testing.

Clinical validity is a complicated and challenging aspect of WGS. Evidence is required to prove that a specific rare variant in a particular gene, detected by WGS, is indeed pathogenic and responsible for a particular clinical phenotype.[33]

Summary

In modern neonatal care, we are fortunate to have data to inform many of our decisions. An ethical approach to using data to inform the care of sick babies means we need to understand both the opportunities and limitations of increasingly available data.

3 Development, Function, and Pathology of the Placenta

EMIN MALTEPE AND ANNA A. PENN

KEY POINTS

- The placenta is the first organ to form in mammals and is required for establishment of a maternal–fetal vascular interface capable of supplying the bioenergetic needs of the developing conceptus.
- Multiple placental cell types engage in highly varied functions, from attachment, invasion, and vascular remodeling to cell fusion, hormone production, and nutrient transport.
- Multiple mechanisms allow transport of waste and nutrients across the placenta, including diffusion, transporter protein-mediated (facilitated diffusion and active transporters), and receptor-mediated mechanisms.
- The placenta is not an inert transport interface. It consumes 40% to 60% of the oxygen and glucose delivered to the uterus at term. Thus conditions that alter placental metabolism can indirectly affect nutrient transport to the fetus.
- In the United States, iatrogenic delivery is responsible for almost half the births that occur between 28 and 37 weeks of gestation, primarily caused by placental pathologies such as preeclampsia or intrauterine growth restriction.
- Efforts to standardize placental examination after delivery are in progress so that connections between specific placental problems and poor outcomes can be better defined. In parallel, new advanced imaging techniques and biomarkers for placental function are being developed.

The placenta is a remarkable organ. Its brief existence enables the mammalian fetus to survive and thrive within the otherwise inhospitable confines of the intrauterine environment. To accomplish this, the placenta plays a range of roles, from anchoring the conceptus and preventing its rejection by the maternal immune system to enabling the transport of nutrients and wastes between the mother and the embryo/fetus. As with all organs, multiple specialized cell types derived from lineage-committed precursors are responsible for these functions. Genetic, epigenetic, and physiologic cues direct placental development across gestational stages.[1] Impairments in these processes due to intrinsic or extrinsic insults can lead to placental dysfunction and result in long-lasting increases in disease susceptibility, a process known as fetal programming.[2,3] Both preterm and term infants are at risk from poor placental function, particularly those that have extremely low birth weight (<1 kg). Preterm infants in particular may suffer from placental dysfunction in utero followed by early loss of placental support, including nutrition, hormones, and immune protection. Preterm delivery rates continue to rise while the survival of preterm infants has increased due to numerous advances in medical management and technology.[4] This convergence has generated an expanded population of patients admitted to and graduating from intensive care nurseries. Not only are these infants more likely to develop complications ssuch as bronchopulmonary dysplasia, failure to thrive, pulmonary hypertension, cerebral palsy, and blindness, but they are also more likely to develop chronic adult ailments such as diabetes and heart disease. Although further improvements in neonatal care are critical for diminishing the long-term consequences of prematurity, prevention or delay of preterm delivery will have the greatest healthcare impact for this at-risk population. A better understanding of the most common placental pathologies is therefore critically important for advancing maternal, fetal, and adult medicine.

Development of the Placenta

Trophoblast Lineage Allocation

The placenta is the first organ to form in mammals. This is because it is required for establishment of a functional maternal–fetal vascular interface capable of supplying the bioenergetic needs of the developing conceptus.[1] The fertilized embryo undergoes a series of cell divisions before implantation to produce up to eight seemingly identical cells called blastomeres. Three further sets of divisions generate the blastocyst, consisting of two distinct cell populations. Surrounding the blastocyst is the trophectoderm (TE), which gives rise to the placenta. The inner cell mass (ICM), located inside the blastocyst, gives rise to the embryo and visceral endoderm.[5,6] In mice, each blastomere is able to generate either ICM or TE derivatives and is thus totipotent. This also occurs in humans.[7] Once TE or ICM commitment occurs, however, it is considered largely irreversible. Importantly, however, individual blastomeres are found to harbor intrinsic biases regarding which lineage they adopt as early as the four-cell stage[8,9] and which appear to depend on positional cues.[5]

Multiple factors govern lineage allocation. One major determinant includes differences in polarity and adhesion between inner and outer cells of the blastocyst that are associated with differential activation of the Hippo signaling cascade.[5,10] Hippo helps restrict expression of key lineage regulatory genes such as *Cdx2* that are stochastically expressed as early as the eight-cell stage in

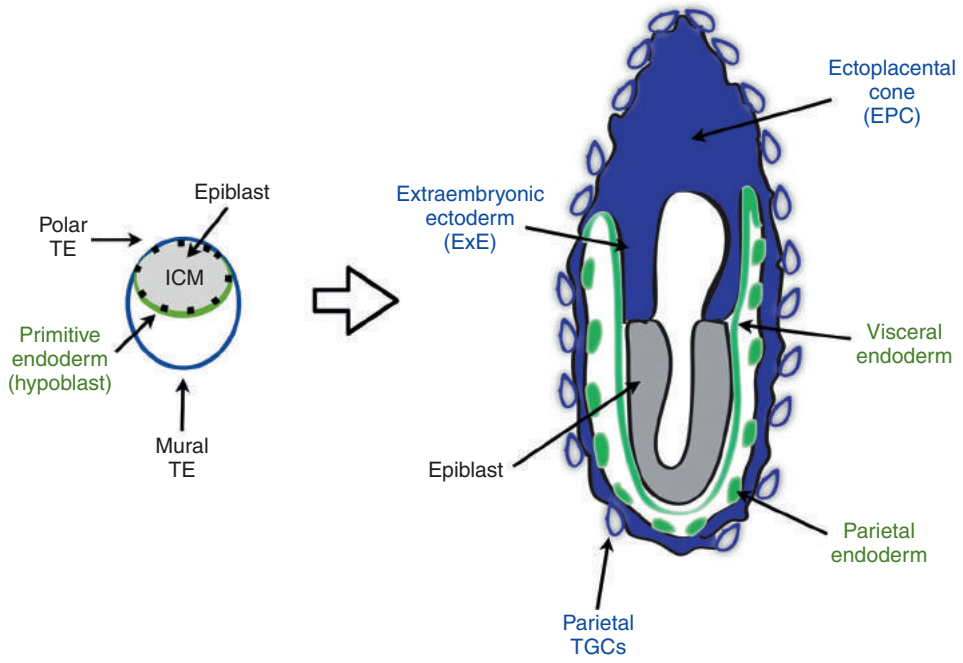
mice but restricted thereafter to the TE.[11] Notch signaling also acts in parallel with Hippo to promote *Cdx2* expression in this process.[12] Positional cues governed by E-cadherin expression help regulate Hippo signaling. Cell–cell contact within inside cells of the ICM activates Hippo and suppresses nuclear YAP activity. In mice, CDX2 helps repress genes critical for ICM identity, such as *Oct4* and *Nanog*. Its absence in mouse embryos results in the lack of TE differentiation, and all cells of the blastocyst stage embryo express the typically ICM-restricted OCT4 protein.[13] Amazingly, in mice its expression is sufficient to convert embryonic stem cells (ESCs) into trophoblast stem cells (TSCs) that can contribute to all lineages found within the placenta.[13,14] *Cdx2* expression is further maintained in mice via a positive feedback loop driven by the combinatorial activities of the transcription factors Eomesodermin (EOMES), ETS-related transcription factor 5 (ELF5), ETS proto-oncogene 2 (ETS2), and transcription factor AP-2, gamma (TCFAP2c) that help maintain the TE lineage.[15–22] Interestingly, ELF5, CDX2, and EOMES can collaborate to regulate hundreds of TSC genes by binding to enhancer elements that harbor endogenous retrovirus-derived sequences, indicating that these serve as trophoblast-specific enhancer elements in mice.[23] This opens the exciting possibility that differences in the incorporation of these foreign viral elements across different placental mammals may have contributed to the diversity of placental structures seen across the animal kingdom.

Uterine evolution paralleled placental evolution in eutherian mammals. This was recently found to involve large-scale and rapid changes in endometrial gene regulatory networks mediated by ancient transposable elements. These modulate responses to pregnancy hormones as well as other pathways to ensure pregnancy success.[24,25] Thus, a set of genetic tricks coupled with host–virus interactions enabled the rapid evolution of the placenta–uterus axis in mammals and helped contribute to the diversity of mammalian life forms and modes of procreation observed today.

Trophoblast Differentiation

The placenta is comprised of multiple different cell types that engage in highly varied functions, ranging from attachment, invasion, and vascular remodeling to cell fusion, hormone production, and nutrient transport.[1] Thus trophoblast-specific progenitors need to enact a complex set of lineage restriction decisions to help form a functioning placenta.

In the mouse, the extraembryonic ectoderm differentiates into cells that comprise the chorion and labyrinth, which perform the transport functions of the placenta; whereas the ectoplacental cone, located nearer to the uterine implantation site, differentiates into the spongiotrophoblast layer as well as glycogen trophoblasts and trophoblast giant cells (TGCs) (Fig. 3.1). To function as a transport organ, the placenta must establish an extensive vascular interface between the maternal and fetal circulatory systems. Humans and rodents have a hemochorial placenta, which means that the maternal vascular space comes in direct contact with differentiated trophoblasts, not endothelial cells.[26] In humans, trophoblasts



• **Fig. 3.1** Embryonic Development in the Mouse Conceptus. At the blastocyst stage, the conceptus is comprised of an inner cell mass (*ICM*) that gives rise to the embryo proper (*epiblast*), overlaid by a layer of primitive endoderm (*hypoblast*) that gives rise to the visceral and parietal endoderm. The outer cells comprise the trophectoderm (*TE*) that gives rise to the placenta. TE cells near the ICM are referred to as polar TE, while TE cells not in contact with the ICM are referred to as mural TE. The mural TE gives rise directly to parietal trophoblast giant cells in the initial wave of trophoblast differentiation. These cells aid the initial attachment and invasion process. The polar TE differentiates into the ectoplacental cone and extraembryonic ectoderm. The ectoplacental cone resides closest to the implantation site and also gives rise to lineages that further help incorporate the conceptus into the receptive uterus. The extraembryonic ectoderm resides closest to the developing epiblast and gives rise to lineages comprising the placental transport interface, such as the syncytiotrophoblast. *TGCs*, Trophoblast giant cells.

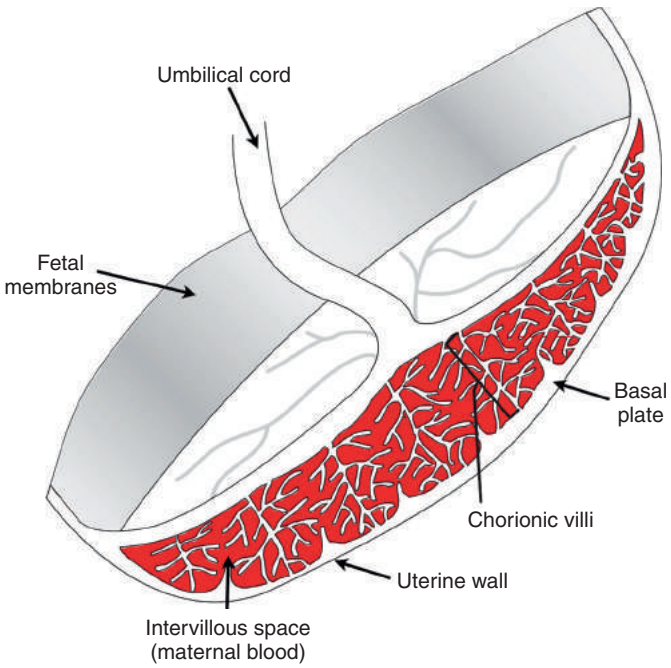
lining maternal arteriolar spaces are relatively well characterized,[27] but very little is known about the cells associated with the draining vascular bed, for example. In mice, there appear to be at least five distinct populations of TGCs that lie at various positions within these maternal vascular spaces and are defined by their location and lineage-specific gene expression.[28] These arise from various sources (Fig. 3.1). Their "giant" size is, in part, a reflection of their DNA content, which continuously replicates without engaging in cell division via a process called endoreplication.[29] Endocycles are thought to be used by cell types that need to be very large or that are highly metabolically active. Consistent with this, TGCs in the mouse placenta are responsible for the bulk of placental hormone production.[30] In humans, placental hormones are produced by the syncytiotrophoblast (SynT) layer, potentially accounting for the reduced ploidy of invasive trophoblast subtypes in this species compared with rodents, although they still appear to exhibit a significant amount of aneuploidy.[31]

Trophoblast Invasion

Primary TGCs differentiate from the mural TE, and this represents the first terminally differentiated cell type in mice to aid in implantation. In humans, the initial wave of invasion following implantation is thought to occur via formation of a primitive syncytium, through which invasive CTBs push following approximately day 13 or 14 of gestation.[32] This early wave of syncytialization does not occur in rodents. In mice, the remaining secondary TGCs differentiate either from trophoblast-specific protein alpha (Tpbpa)/4311+ outer ectoplacental cone cells or from Tpbpa/4311−chorionic progenitors.[28] Secondary TGCs come in various forms that have differing locations as well as characteristics. As the name implies, spiral artery (SpA) TGCs invade the spiral arteries and displace the smooth muscle and endothelial cells to remodel them, canal TGCs line the large vascular spaces delivering maternal blood to the base of the labyrinth, sinusoidal TGCs sit within the small vascular spaces of the labyrinth, and parietal TGCs surround large pools of deoxygenated blood that ultimately drain into the maternal uterine veins.

Trophoblasts that invade and line blood vessels appear to do so via two different mechanisms: (1) vascular invasion with endothelial mimicry and (2) vasculogenic mimicry.[33] In the former, trophoblasts invade and displace maternal endothelial cells from within maternal arterioles and include SpA-TGCs in mice or endovascular trophoblasts (EVTs, also known as extravillous trophoblasts) in humans. During vasculogenic mimicry, however, trophoblasts undergo morphogenesis to create vascular tubes de novo. Sinusoidal TGCs perform this function in mice. Whether this also occurs in human placentation is not clear. Transplanting trophoblasts subcutaneously in mice or culturing them as 3-dimensional trophospheres in vitro allows one to visualize them from de novo vascular spaces, where they generate tumors harboring large blood sinuses surrounded by trophoblasts, as opposed to host endothelium.[33,34] Many pathways known to regulate endothelial development also drive trophoblast differentiation and formation of the maternal–fetal vascular interface.[33] Furthermore, the endothelium and trophoblast are primary regulators of hemostasis in the adult and fetal circulation. Trophoblasts can regulate the coagulation cascade like endothelial cells and produce such molecules as thrombomodulin, tissue factor, tissue factor pathway inhibitor, annexin V, and endothelial protein C receptor.[35–37] These factors are critical for preventing thrombotic or hemorrhagic events from occurring in the developing placenta. Thus, mammalian placentas have solved the problem of hemochorial placentation by having trophoblasts take over functions typically performed by endothelial cells.

Remodeling of uterine vasculature is critical for successful pregnancy in humans and mice.[1,33,38,39] The equivalents of TGCs in humans, invasive EVTs, are derived from column CTB progenitors located at the tips of anchoring villi (Fig. 3.2). They migrate through the uterine parenchyma via interstitial invasion, in search of maternal spiral arterioles and veins. This invasion peaks early in pregnancy, around 9 to 12 weeks of gestation.[40] EVTs then breach the spiral arterioles via a process termed endovascular invasion and replace resident endothelial and smooth muscle cells.[41] This results in these high-resistance vessels being remodeled into low-resistance/high-capacitance conduits necessary for proper fetal perfusion as well as modulation of maternal hemodynamics.[27] While EVT interactions with veins are largely confined to the inner surface of the uterus, they migrate along much of the intrauterine course of maternal arterioles. Although endovascular invasion begins quite early and typically begins within the center of the placental bed, uterine arterial blood only begins to flow into the intervillous space by the end of the first trimester. Before this point, EVTs paradoxically plug these vessels, preventing blood flow to the placenta. As a result, all of first trimester placental development occurs in a highly hypoxic environment with the bulk of placental nutrients being provided by endometrial secretions (i.e., histiotrophic nutrition).[42] Only about one-third of the



• **Fig. 3.2** Human Placenta at Midgestation. The human (and mouse) placenta is disc-shaped (discoid) and hemochorial (i.e., fetal trophoblasts are in direct contact with maternal blood). In contrast to the labyrinthine placenta in mice, the human placenta is comprised of chorionic villi that project into the intervillous space bathed by maternal blood. Fetal blood vessels coursing through the umbilical cord branch when they reach the placenta and dive into the chorionic villi where gas, nutrient, and waste exchange occurs. Tips of anchoring villi attach to the uterine wall (basal plate) and send out waves of invasive cytotrophoblasts (also known as extravillous trophoblasts) to both anchor the placenta and establish blood flow to it. (Adapted from Hunkapiller NM, Fisher SJ. Placental remodeling of the uterine vasculature. *Methods Enzymol*. 2008;445:281–302.)

uterine SpAs are actually invaded by 18 weeks' gestational age,[43] indicating that the more lateral arteries are only invaded throughout the second and third trimesters in a progressive manner[44,45] because most are completely remodeled when examined following delivery at term.

Following unplugging of these vessels, maternal blood begins to bathe floating chorionic villi that are covered by a layer of multinucleated SynTs. SynTs form as a result of the fusion of lineage-committed progenitors. The need for multinucleated syncytium formation is not clear but may have been driven evolutionarily by a response to viral infections that may help minimize pathogen transmission to the fetus.[46] A combination of fusogenic protein expression, particularly syncytins,[47–54] and dramatic cytoskeletal rearrangement appears to be essential for this trophoblast fusion. Additionally, caspase 8 activity—frequently implicated in apoptosis—aids this process during human SynT formation.[55] These cytoskeletal changes are frequently accompanied by another apoptosis-associated process—externalization of phosphatidylserine to the outer leaflet of the plasma membrane. Typically acting as an "eat me" signal for the clearance of apoptotic cells, phosphatidylserine externalization is associated with SynT fusion.[56,57] Apoptosis is not completed during SynT formation, however, and the syncytium is maintained in this "preapoptotic" state until being sloughed off into the maternal circulation. As a result of the dramatic cytoskeletal changes required for cell fusion, in addition to changes in the composition of the membrane lipid bilayer, the biophysical properties of the SynTs change to become much more rigid, possibly aiding the infection barrier properties of the placenta.[58]

Placental Functions

Transport

The transport functions of the placenta are performed by the multinucleated SynTs that sit at the maternal–fetal interface. Multiple mechanisms allow transport of waste and nutrients across the placenta.[59] The simplest is diffusion. The high surface area of the placental transport interface, along with the hemochorial nature of the rodent and human placentas, enables efficient diffusion across the placenta. The rate of diffusion depends on the molecular properties and concentrations of the solute, however, in addition to the composition of the exchange barrier.[60] In the human placenta at term, a single SynT layer separates maternal blood from fetal capillary endothelium, whereas in the mouse, two SynT layers as well as an sinusoidal (S)-TGC layer, surprisingly, separate the vascular spaces.[61] These layers are progressively thinned out to minimize their barrier properties and increase the surface area for exchange.[50] Oxygen is transported across the placenta via passive diffusion, aided by the high affinity of fetal hemoglobin and the concentration differential across the maternal–fetal vascular beds. The orientation of the maternal and fetal vascular blood spaces produces a countercurrent exchange mechanism in mice. This maximizes transport efficiency in rodents, whereas the human placenta has a less efficient multivillous arrangement that necessitates a larger placental size relative to the mouse.[26]

Hydrophilic molecules do not readily cross plasma membranes. Transporter protein-mediated mechanisms are typically required for transporting hydrophilic molecules. Classic transporter proteins include facilitated diffusion transporters (i.e., the glucose transporter [GLUT] family[62]) as well as active transporters (i.e., transporters associated with calcium transport[63] and the amino acid transporters[64]). Transport can occur down a concentration gradient, as is the case with GLUT1-mediated glucose transport,[64] or against a concentration gradient, as is the case with calcium[65] and amino acid transport.[66] Interestingly, nearly all amino acids in the fetal circulation are found at higher levels than in the maternal circulation, indicating active uptake and/or synthesis of these nutrients via the placenta or fetus.

The fetal–placental unit is both physically and metabolically interconnected with each other and the maternal circulation. Ultimately, all fetal–placental metabolism is constrained by the nutrients delivered from the maternal circulation. However, the placenta and fetal liver are both capable of producing and metabolizing various nutrients that impact their levels in the fetal–placental circulation largely independent of placental transport mechanisms.[67] This has been well described in ovine species, wherein the fetal liver of sheep in utero actively produces large quantities of serine and glutamate that are consumed by its placenta.[68,69] In the placenta, serine is converted to glycine via a process that contributes to one-carbon metabolism-dependent DNA methylation pathways that play important roles in cell fate regulation and growth mechanisms.[70] Additionally, nonglucose carbohydrates such as fructose, mannose, inositol, and sorbitol are also either transported by or synthesized in the placenta[66,71] and play important roles in regulating fetal growth as well as in redox regulation.

Finally, antibody-mediated immunity is transferred from mother to fetus across the placenta via receptor-mediated mechanisms.[72,73] Immunoglobulin G (IgG) transport across the human placenta, for example, begins at approximately 16 weeks' gestation, and fetal serum IgG levels reach maternal levels by 26 weeks' gestational age. This process is highly efficient, enabling fetal concentrations to exceed maternal values at term.

Metabolism

The placenta is not an inert transport interface. It consumes 40% to 60% of the oxygen and glucose delivered to the uterus at term, despite only comprising approximately 10% to 20% of the total mass of the uterus at that time.[74,75] Changes in this metabolism can regulate placental biology. Mitochondrial fusion, a process that enables greater mitochondrial bioenergetic capacity, is critical for invasive TGC formation in mice, triggering placental failure when compromised.[76,77] Interestingly, mitochondrial fusion can promote cardiomyocyte differentiation as well, highlighting conserved mechanisms between cellular metabolism and cell fate determination.[78] Thus, alterations of placental metabolic function can impact oxygen and nutrient delivery to the fetus, both by altering placental metabolic demand intrinsically as well as by impacting cell fate regulatory pathways. Primary culture of human CTBs indicates that they exhibit high rates of aerobic glycolysis when compared with other terminally differentiated adult cells,[79] much like rapidly proliferating cancer cells that rely on high glycolytic flux rates to augment biosynthetic precursor production. Aerobic lactate production (i.e., the Warburg effect), also allows the placenta to produce and transfer large amounts of lactate to the fetus, which can readily oxidize it. Interestingly, the placenta also appears able to metabolize lactate during midgestation but loses this ability by term.[80] These studies additionally suggest that glycogen breakdown (glycogenolysis) helps supply the high rates of glucose consumption in proliferating trophoblasts before differentiation into terminally differentiated SynTs. Interestingly, excess glycogen accumulation has been noted within the SynT layer of

some human preeclampsia (PE) placentas,[81] consistent with their altered turnover and suggesting a potential link to altered glucose metabolism in the setting of this pregnancy complication. Importantly, epidemiologic studies confirm that derangements in glucose and fatty acid metabolism may drive pregnancy complications. For example, maternal gestational diabetes mellitus (GDM) and obesity are independently and additively associated with elevated rates of PE[82] as well as spontaneous preterm birth.[83] There may be shared mechanisms involving impaired trophoblast invasion contributing to PE and preterm labor (PTL) pathogenesis. For example, up to 30% of patients with spontaneous PTL have placental lesions consistent with impaired SpA remodeling typically observed during PE.[84–86] Thus, improving our understanding of the links between placental metabolism and placental development may shed light on the growing epidemic of preterm birth.

Metabolic stressors such as hypoxia at high altitude or placental underperfusion associated with intrauterine growth restriction (IUGR) alter placental metabolism in particular ways. During isolated hypoxia induced at high altitude, for example, the human placenta appears to decrease its consumption of oxygen in favor of glycolysis to maintain its bioenergetic needs,[87] which preserves placental growth. While preserving fetal oxygen (O_2) delivery, this comes at the expense of glucose, however.[88] Given that fetal hypoglycemia is strongly associated with fetal growth restriction, this limits fetal growth. With maternal undernutrition, however, where uterine O_2 delivery is relatively spared, glucose delivery to the fetus is compromised[89,90] in a manner associated with restricted placental growth. Given that the placenta is a complex organ with multiple different cell types,[28,50] it is likely that changes in placental cellular composition due to alterations in cell fate regulatory pathways play important roles in the reallocation of placental metabolic flux patterns. Consistent with this, maternal calorie restriction leads to a loss of glycogen trophoblasts in the mouse.[90] Importantly, isolated hypoxia results in increased hypoxia-inducible factor-1 (HIF-1) levels and target gene expression in the human placenta,[91–93] and HIF activity regulates trophoblast cell fate decisions, suggesting a potential contribution to these pathologic changes.[94–97] HIF activity can mediate metabolic adaptation to hypoxia via numerous ways,[98] including repressing mitochondrial O_2 consumption while increasing glycolysis and modulating glucose transport as well as amino acid metabolism.

Endocrine Function

In addition to performing the essential transport functions of the placenta in humans, SynTs secrete numerous pregnancy-related hormones.[1] Mammalian placenta produces a greater diversity of hormones in greater quantity than any other single endocrine tissue. Near term, steroid hormones (primarily estrogens and progestins) are being made at the rate of 0.5 g/day, and protein hormones (lactogens, growth factors, and other hormones similar to those of the hypothalamic–pituitary–adrenal [HPA] axis) are being made at more than twice this rate. Many of these hormones are species specific, but the categories of hormones (i.e., steroids, pituitary-like, hypothalamic-like etc.) and their endocrine, paracrine, and autocrine functions in pregnancy are frequently conserved (Table 3.1).

Steroid Hormones

The placenta is an "incomplete" steroidogenic organ and does not express a complete set of enzymes for de novo production of estrogens and progestins. Steroid hormone synthesis in the placenta is dependent on precursors from mother and fetus, leading to the concept of an integrated *maternal–fetal–placental unit*.[99]

TABLE 3.1 Placental Classification (Incorporating the 2014 Amsterdam Placental Workshop Group Criteria)

1. Placental Vascular Processes
   a. Maternal stromal-vascular lesions
      Developmental
         Superficial implantation/decidual arteriopathy
         Increased immature extravillous trophoblast
      Malperfusion
         Global/partial
         Early: distal villous hypoplasia
         Late: accelerated villous maturation
         Segmental/complete
         Villous infarct(s)
      Loss of integrity
         Abruptio placenta (atrial)
         Marginal abruption (venous)
         Acute
         Chronic
   b. Fetal stromal-vascular lesion
      Developmental
         Villous capillary lesions
         Delayed villous maturation (maturation defect)
         Dysmorphic villi
      Malperfusion
         Global/partial
         Obstructive lesions of umbilical cord
         Recent intramural fibrin in large fetoplacental vessels
         Small foci of avascular or karyorrhectic villi
      Segmental/complete
         Chorionic plate or stem villous thrombi
         Large foci of avascular or karyorrhectic villi
      Loss of integrity
         Large vessel rupture (fetal hemorrhage)
         Small vessel rupture (fetomaternal hemorrhage)
         Villous edema

2. Placental Inflammatory Immune Processes
   a. Infectious inflammatory lesions
      Acute
         Maternal inflammatory response: chorioamnionitis, subchorionitis
         Fetal inflammatory response: chorionic/umbilical vasculitis
      Chronic
         Villitis (CMV, others)
         Intervillositis (malaria, others)
   b. Immune/idiopathic inflammatory lesions
      Villitis of unknown etiology and related/associated lesions
         Chronic villitis
         Chronic chorioamnionitis
         Lymphoplasmacytic deciduitis
         Eosinophil T-cell fetal vasculitis
         Chronic histiocytic intervillositis

3. Other Placental Processes
   Massive perivillous fibrin(oid) deposition (maternal floor infarction)
   Abnormal placental shape or umbilical insertion site
   Morbidly adherent placentas (accreta)
   Meconium-associated changes
   Increased circulating nucleated red blood cells

CMV, Cytomegalovirus.

• **Fig. 3.3** Basal Plate of the Human Placenta at Midgestation. A multinucleated layer of syncytiotrophoblasts (SynTs) covers the finger-like projections of chorionic villi. SynTs perform all of the transport functions of the placenta. A single cell layer of cytotrophoblasts (CTBs) sits just below the SynT layer and is referred to as villous CTB. These cells fuse with each other as they differentiate into SynTs. At the tips of anchoring villi sits a column of CTBs that are proliferative and put out waves of invasive CTBs (extravillous trophoblasts) that help anchor the placenta to the uterus. Importantly, these also invade maternal spiral arterioles where they replace the endothelial lining, induce the apoptotic death of surrounding smooth muscle cells, and transdifferentiate into an endothelialized cell type. This invasion typically courses through the extent of the uterine myometrium. CTBs can also invade veins but do not appear to remodel them. Additionally, maternal uterine immune cells, such as natural killer cells, appear to play an important role in enabling CTBs to invade the uterus and its vasculature. Finally, establishment of a receptive deciduum is also of critical importance for proper placental development and pregnancy success. (Adapted from Genbacev O, Krtolica A, Kaelin W, et al. Human cytotrophoblast expression of the von Hippel-Lindau protein is downregulated during uterine invasion in situ and upregulated by hypoxia in vitro. *Dev Biol*. 2001;233(2):526–536.)

Fig. 3.3 diagrams the tissues and enzymes that participate in the biosynthesis of progestins and estrogens.[100] The concentration of steroid hormones in the maternal circulation increases dramatically throughout gestation.[101]

Progesterone

Maternal cholesterol, derived from low-density lipoprotein, is transported to the placenta and bound to low-density lipoprotein receptors on SynTs, where it is incorporated by endocytosis and hydrolyzed to free cholesterol in lysosomes.[102] There is no significant 3-hydroxy-3-methylglutaryl coenzyme A activity in human placenta, and thus maternal cholesterol must be used for production of pregnenolone—the first step in steroid synthesis. Cholesterol is converted to pregnenolone in the mitochondria by cytochrome P450 cholesterol side-chain cleavage enzyme. After transfer to the cytosol, progesterone is produced from pregnenolone by type-1 3β-hydroxysteroid dehydrogenase.[103,104] Before the ovarian–placental shift, the corpus luteum of pregnancy is the primary source of progesterone, but by 35 to 47 days postovulation the placenta produces enough progesterone to maintain pregnancy.[105] The majority (>90%) of progesterone goes to the mother and the rest to the fetus. A limited amount of pregnenolone is also released into the circulation. The fetus has the enzyme activity needed for pregnenolone synthesis but has minimal ability to produce progesterone. High levels of circulating fetal progesterone are of placental origin so that circulating progesterone levels thus reflect placental function, not fetal well-being.

Progesterone can be metabolized to 17-hydroxyprogesterone (17-OHP), but relative efficiency of the enzymes favors progesterone production. 17-OHP levels do rise in the third trimester as progesterone levels peak. Additional progesterone metabolites, particularly 5-dihydroprogesterone (5-DHP) and its metabolite allopregnanolone, are also produced in the SynT at increased levels during gestation.[106] These steroids have been hypothesized to play an endocrine role in fetal brain development and provide neuroprotection in the face of hypoxia.[107,108]

Progesterone[109] or a synthetic form of 17-OHP[110] is used therapeutically in gestation as an adjunct for pregnancy maintenance after in vitro fertilization or in the second half of gestation for prevention of preterm delivery in women with a prior history of preterm birth.[111] Progesterone is required for the maintenance of pregnancy in part by means of its suppressant effect on uterine contractions.[100,105,112] Progesterone inhibits genes that promote contractility[113] and has immunosuppressive activity that may promote uterine quiescence.[112,114] Progesterone also counteracts uterine estrogen effects. Unlike the drop in progesterone levels prior to labor seen in most mammals, there is no progesterone withdrawal per se that occurs before labor in women; however, modulation of progesterone receptor expression in combination with a shift in the progesterone to estrogen balance is presumed to play the same

biological role. The relationship of therapeutic response to normal physiologic mechanisms at work in the maternal–fetal–placental unit is not yet understood.

Estrogens

Unlike the requirement for maternal precursors for progesterone production, estrogen production relies on fetal precursors. In pregnancy, estrogens are synthesized from C19 steroids,[115] primarily from dehydroepiandrosterone sulfate (DHEA-S) made in the fetal adrenals. The fetal adrenals rapidly inactivate steroids through sulfatization. Pregnenolone is sulfated and converted to DHEA-S,[116] which then may be hydroxylated in the fetal liver. These biologically inactive androgens are then transferred back to the placenta. Placental sulfatases rapidly cleave the sulfate, and placental 3β-hydroxysteroid dehydrogenase converts DHEA or hydroxylated DHEA to androstenedione or hydroxylated androstenediones, respectively. These androgens are then aromatized to estrone (E1), 16α-OH estrone, or 15α-OH estrone and then converted to estradiol (E2), estriol (E3), or estetrol (E4) respectively by placental 17β-hydroxylation.[117–119] E3 is the major estrogen of pregnancy with the majority secreted into the maternal compartment; E1 is the only estrogen preferentially secreted into the fetal compartment. Although maternal DHEA-S serves as 40% of the precursor for E2 synthesis, E3 and E4 are formed predominantly from fetal precursors because the maternal liver has limited 5α-hydroxylation or 16α-hydroxylation capabilities.[120] E3 and E4 are thus indicators of fetal function,[101] although neither is a clinically useful marker because of rapid shifts in circulating levels. The primary function of high E3 levels remains unclear, but it does increase uteroplacental blood flow.[121]

Estrogens influence uterine growth, blood flow, contractility, metabolism, and breast development.[122] However, high estrogen levels are not apparently needed for pregnancy. Parturition can proceed in the absence of fetal and placental sulfatase[123] or aromatase,[124] although in the latter case both fetus and mother are virilized. In such pregnancies, there is still circulating estradiol. There are no reports of pregnancy without detectable estrogen levels, suggesting that a basal level of estrogen is likely required. Before parturition, an increase in the estrogen to progesterone ratio occurs within the intrauterine tissues and may increase prostaglandin (PG) and oxytocin (OT) activity. Steroid hormone production is altered by trophic hormones and other factors, including hypothalamic-like releasing or inhibiting hormones. In turn, estrogens affect other endocrine systems (i.e., renin–angiotensin system)[125] and support organ maturation, such as surfactant production in the lung.[126]

Glucocorticoids

In addition to the sex steroids, circulating levels of glucocorticoids and mineralocorticoids are increased in pregnancy.[127] The placenta has the ability to produce cortisol and to convert it to inactive cortisone via 11β-hydroxysteroid dehydrogenase type 2. This enzyme also converts maternal cortisol to cortisone at the placental interface. The primary role of this system appears to be to protect the fetus from elevated cortisol exposure, which may play a role in long-term reprogramming of the fetal HPA axis.[128] Dual oxidative and reductive enzymatic activity regulates the balance between cortisol and cortisone.[129] In the placenta, oxidation of cortisol to cortisone predominates, whereas in the decidua the reverse reaction dominates, potentially providing localized hormone exposure.

Pituitary-Like Hormones

A combination of pituitary-like growth hormones is required to support fetal growth while maintaining maternal metabolic homeostasis.

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is one of the first hormones of pregnancy, produced by trophoblasts even before placenta formation,[130] and is unique to human pregnancy.[131] After placentation, hCG is synthesized primarily by the SynT[132] and passes into the maternal circulation via secretion into the intravillous space. hCG is a glycoprotein heterodimer (36 to 40 kDa) composed of α and β subunits encoded by genes on chromosome 6 and 19, respectively.[102,133] The α subunit is homologous to pituitary thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH), while the β subunit is homologous to LH. Intact hCG (i.e., having both α and β subunits) is required for hCG endocrine activities. Since it shares a receptor with LH, the LH chorionic gonadotrophin receptor (LHCGR), hCG mimics the function of LH, but the functions of LH and hCG are quantitatively different due to the longer half-life of hCG and its relative stability compared with the pulsatile release of pituitary LH.[134]

hCG maintains corpus luteal progesterone production until this function shifts to the maturing placenta. hCG peaks approximately 2 weeks after the shift of progesterone production from ovary to placenta, potentially minimizing the chance of loss of the progestational environment. hCG can be detected in human serum or urine within a week of conception and is the most frequently used biochemical marker for pregnancy. hCG doubling time may be used in early gestation to predict general pregnancy outcome. After hCG can first be detected, it increases with a doubling time averaging 2.11 days. It reaches peak levels of approximately 50 international units (IU)/mL at 9 to 10 weeks from the date of the last menstrual period, declining to 1 IU/mL by midgestation.[104] An abnormally slow doubling time of hCG is considered to be a sign of a poor prognosis for pregnancy outcome, while rising hCG without detection of an intrauterine embryo suggests an ectopic pregnancy.[135]

In addition to corpus luteum maintenance, hCG has multiple additional activities that regulate placental structure and function. hCG acts as an autocrine signal in trophoblasts expressing LHCGR promoting the differentiation of SynTs, thus amplifying its own production since it is made primarily by these cells.[119] Phosphorylation of the receptors via this pathway also decreases LHCGR expression in differentiating SynTs, thus completing a feedback loop.[136] hCG may also have roles in endometrial angiogenesis, uterine quiescence, and immunotolerance to the fetus.[104,133,135] In addition, hCG can alter maternal TSH levels, elevating free thyroxine (T4), although this increase does not appear to cause maternal hyperthyroidism.[137]

Glycosylation state and subunit availability regulate hCG activity. A hyperglycosylated form (hCG-H) has been detected in early pregnancy as well as in choriocarcinoma cells. hCG-H appears to enhance trophoblast invasion[133] and thus may be a very early biomarker of placental invasion of the endometrium. A decreased level of hCG glycosylation in very early pregnancy has been correlated with early pregnancy loss.[103,133,138] Isoform production may also regulate activity. β-Subunit production exceeds α-subunit production in early pregnancy, but this ratio rapidly shifts to

α-subunit excess, increasing as gestation progresses; circulating hCG is mostly intact hCG or free α-hCG. It has been proposed that ratios of hCG isoforms (intact hCG, independent subunits, and nicked breakdown products) present in maternal blood and urine might be useful for detection of pregnancy-related disorders since only intact hCG is fully active.[139]

Local and systemic factors influence hCG production. Locally, its expression is regulated by a releasing factor—gonadotropin-releasing hormone (GnRH) 1 and 2.[140–142] Neurotransmitters,[119] cyclic adenosine monophosphate,[117] epidermal growth factor (EGF),[118] activing,[143] cytokine,[144] and PGs[145] regulate hCG production, as does hCG itself as noted previously. Each of these factors is produced by the placenta as well as by other extraembryonic tissues. hCG alters placental steroidogenesis by stimulating both progesterone and estrogen formation. Estrogens inhibit GnRH stimulation of hCG,[122] thereby completing a feedback axis in the placenta.

Human Chorionic Somatomammotropin

Human chorionic somatomammotropin (hCS), originally known as human placental lactogen,[146,147] has both growth hormone-like and lactogenic activity. hCS is detectable in extraembryonic tissues within 10 days of conception and in maternal serum by the third to fourth week of gestation. It is a single 191 amino acid nonglycosylated peptide chain with considerable homology to growth hormone (GH) (96%) and PRL (67%); it is transcribed from a gene cluster on chromosome 17 containing two genes for hCS, one hCS pseudogene and two GH genes.[148,149] SynTs produce hCS at a constant rate during gestation; thus, hCS levels reflect total placental mass and gross placental function. By term, hCS is made at 1 g/day, representing 10% of total placental protein synthesis.

hCS is considered one of the major diabetogenic factors of pregnancy, along with placental steroids, placental GH variant (hGH-V), and maternal cortisol. It is almost exclusively found in maternal rather than fetal circulation. This has led to the hypothesis that the primary role of hCS is to ensure adequate fetal nutrition because in maternal circulation it induces metabolic changes such as mobilization of fatty acids, insulin resistance, decreased utilization of glucose, and increased availability of amino acids through decreased maternal use of protein.[150] Circulating maternal glucose and free fatty acids are thus increased. While glucose readily crosses the placenta, fatty acids cross slowly, thus biasing glucose delivery toward the fetus and use of fatty acids for maternal energy, especially during maternal fasting. Within the placenta, hCS may regulate insulin-like growth factor (IGF-1)[151] and alter fetal growth through direct action on placental nutrient transport systems. In addition to its metabolic activity, the lactogenic activity of hCS may prepare the breast for lactation, working synergistically with PRL and steroids.[152] Most recently, a role for hCS as a placental angiogenic factor has been suggested.[153]

Placental Growth Hormone Variant

hGH-V is encoded in the same chromosome 17 gene cluster as hCS and pituitary GH. Two transcripts are generated from the hGH-V gene, a major form and an alternatively spliced version. Secreted hGH-V is translated from the major version and is produced in a highly bioactive 22 kD nonglycosylated form and to a lesser degree in a 25 kD glycosylated form.[152] Early in pregnancy, maternal pituitary GH is produced, but from 15 to 20 weeks' gestation to term hGH-V secretion increases, suppressing maternal GH. hGH-V peaks about a month before term delivery and disappears from maternal circulation immediately after delivery.[154] hGH-V is not detected in the fetal circulation. Much like hCS, hGH-V modifies maternal metabolism to meet fetal needs. hGH-V primarily appears to control maternal IGF-1 production.[154] In mice overexpressing hGH-V (not normally found in rodents), body weight was increased, IGF-1 levels were elevated, and insulin resistance developed, suggesting that hGH-V strongly contributes to the insulin resistance of pregnancy[155] and increases the risk of gestational diabetes and other pregnancy-related pathologies. This risk is counterbalanced by the placental lactogens hCS and PRL, which induce increased insulin secretion by pancreatic β-cell expansion. hGH-V secretion is tonic, in contrast to pulsatile pituitary GH, and is not regulated by hypothalamic-releasing factors.[154] Secretion is inhibited by elevated glucose and mildly increased by hypoglycemia, creating a feedback loop that may ensure constant delivery of nutrients to the developing fetus.

Insulin-Like Growth Factors

IGF1 and IGF2 are the primary somatotrophs in gestation. IGFs are highly homologous single chain polypeptides with similarities to pro-insulin made in human placental tissues.[156] The majority of the components of the insulin/IGF system are found in the placenta (IGF1, IGF2, and the IGF-binding proteins [IGFBP] 1–6)[157] except insulin itself, although maternal insulin has profound indirect effects on fetal growth and wellbeing. hGH-V levels regulate placental IGF levels,[151] and IGFBPs are carrier proteins expressed in the human placenta that prevent IGF from degradation while blocking bioactivity.[156,158,159] IGFBP1 is also produced by the decidua in large amounts. IGFBPs are themselves regulated by protease activity and through posttranslational modifications, adding a further layer of regulatory complexity.

IGF1 is expressed predominantly in SynT throughout gestation with some CTB expression, while IGF2 is expressed only in CTB with a declining level across gestation.[154,156–158] At physiologic concentrations, both IGF1 and IGF2 bind to the IGF1 receptor (IGF1R). The localization of IGF1R shifts during gestation; initially it is predominantly expressed on SynTs (closer to the maternal circulation), and by term it is mainly expressed on the fetal CTB side, reflecting the shifting activity from maternal to fetal growth control.[157] The IGF2 receptor (IGF2R; also known as the cation-independent mannose-6-phosphate receptor) controls extracellular IGF2 concentrations by mediating the endocytosis and degradation of IGF2, rather than by direct signaling via the receptor.[160] An additional receptor, possibly a variant of the insulin receptor, may mediate some of the fetal growth effects of IGF2.[161]

Information on the role of IGFs in fetal growth comes from genetic manipulation in mouse models as well as examination of human tissues, especially from fetal growth restricted pregnancies.[160] Disruption of mouse insulin-like growth factor (*Igf1*), *Igf2*, or insulin-like growth factor 1 receptor (*Igf1r*) genes retards fetal growth,[161] while disruption of Igf2r or overexpression of IGF2 enhances fetal growth.[162] In humans, mutations in the *IGF1* or *IGF1R* genes are extremely rare, and no *IGF2* gene deletions have been reported.[160] However, *IGF2* is an imprinted gene normally expressed exclusively from the paternal allele in placenta and fetal tissues. Changes in *IGF2* expression because of abnormal imprinting have been linked to both overgrowth (Beckwith–Wiedemann syndrome) and growth retardation (Russel–Silver syndrome).[160] Whether placentally derived IGFs—versus fetal IGFs—directly contribute to these fetal growth changes is uncertain since these

factors also have paracrine effects in the placenta that determine nutrient transport and placental growth.

IGF1 can promote SynT differentiation, while IGF2 does not appear to have this function despite its very early placental expression. In vitro experiments suggest that placental mass is regulated directly by placental IGFs[159]; in vivo, loss of IGF2 reduces the placental surface area available for gas and nutrient exchange more than IGF1 loss. Both IGFs increase nutrient transport, especially of amino acids, which may be reflected in elevated fetal amino acids associated with gestational diabetes.[159,163] IGFs may alter fetal growth through additional mechanisms since they potentiate EGF activity,[164] increase prolactin and progesterone production,[165,166] and inhibit placental thromboxane production.[167]

Other Secreted Growth Factors

Platelet-derived growth factor A, transforming growth factor (TGF)-α, and TGF-β[168] expression in blastocysts appear to be involved in implantation. Other growth factors, including EGF, basic FGF, nerve growth factor, granulocyte colony-stimulating factor, and hepatocyte growth factor as well as growth factor receptors are expressed by the placenta and membranes at later gestation stages.[169–172] The actions of many of these growth factors may be nonclassical autocrine actions. For example, EGF is made in SynTs, and EGF receptors on SynTs correlate with trophoblast differentiation rather than proliferation.[173–175] Additional growth factor actions on placental development are under intensive investigation.

Inhibin and Activin

Inhibin and activin, an antagonist and agonist of pituitary FSH, respectively, are expressed by CTBs and fetal membranes[176,177] while activin receptors are expressed in SynT.[178] Inhibin inhibits hCG and reduces progesterone production,[177] while activin has the opposite effect.[179] Inhibin elevation is associated with fetal trisomy 21, while elevated activin is associated with PE and gestational diabetes.[178] Thus, during pregnancy these hormones may serve as potential biomarkers of placental pathologies.

Proopiomelanocortin Hormones

Pituitary-like peptides derived from proopiomelanocortin (POMC), including adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone, β-endorphins, and β-lipoproteins, as well as full length POMC itself, are found in the human placenta.[180,181] The processing of POMC in the placenta is different from in the pituitary; POMC is released largely intact from the placenta while it is cleaved into several peptide hormones in the nonpregnant state. While pituitary POMC-derived peptides respond to and regulate physiologic stress, placental POMC is not inhibited by glucocorticoids nor do circulating levels correlate with ACTH or cortisol levels, although they do correlate with corticotrophin-releasing hormone (CRH) levels.[181] Chorionic CRH is produced by the placenta and stimulates the release of chorionic ACTH (see later).[182] The physiologic role of chorionic ACTH has not been defined, but it may affect placental cortisol production or maternal resistance of ACTH suppression by glucocorticoids.

Hypothalamic-Like Hormones

Every known hypothalamic-releasing or inhibiting hormone has a placental analogue.[140–142,183] These hormones act in placental paracrine–autocrine regulatory networks that control release of placental endocrine hormones.

Gonadotropin-Releasing Hormone

In the placenta, chorionic GnRH, which regulates the paracrine axis, is important for early pregnancy maintenance as well as regulating gonadal steroid production through stimulation of pituitary LH and FSH.[184] Two isoforms of GnRH (GnRH1 and GnRH2) are produced.[142,185,186] GnRH1 is encoded on chromosome 8 as a precursor protein that includes a signal sequence, the GnRH decapeptide, a processing sequence, and a GnRH-associated peptide.[187] GnRH2 is encoded on chromosome 20 and has 70% homology to GnRH1. GnRH1 and GnRH2 signal through the same G protein-coupled receptor, GnRHR1, expressed in SynTs, but may activate different intracellular signaling pathways.[185,188,189] Blocking GnRHs or GnRHR1 activity can lead to pregnancy failure,[190–193] possibly through alteration of hCG and placental steroids, whose production and release they modulate.[194] The release of placental GnRH1 is affected by cyclic adenosine monophosphate, PGs, epinephrine,[195] and inhibin,[146] while the expression of GnRHR1 is regulated by GnRH1, activin, and inhibin, creating a feedback loop.[185]

Corticotrophin-Releasing Hormone and Urocortins

Chorionic CRH and CRH receptors are expressed in placenta and fetal membranes.[196–199] Urocortins, members of the CRH-hormone family, are also produced and bind to CRH receptors as well.[200] Early in gestation, CRH family members may promote immune tolerance.[201] As gestation progresses, CRH and urocortin levels rise, peaking at term with delivery.[200] These hormones stimulate POMC-derived hormones, including ACTH and β-endorphinins[200,202] as well as PG release, suggesting roles in parturition.[203] CRH can also stimulate fetal adrenal estrogen and glucocorticoid production,[204] which may contribute to the timing of parturition. Glucocorticoids can increase placental CRH expression,[205] in contrast to glucocorticoid inhibition of CRH in the hypothalamus, creating a positive feedback loop that amplifies CRH activity.[206] Because of its tight association with delivery timing, CRH is often viewed as a *placental clock*[207] and may be biomarker of pregnancy pathology. In pregnancies complicated by hypertension, the maternal circulating levels of CRH are already elevated by 28 weeks of pregnancy, whereas local urocortin levels may be decreased.[200,208] CRH has been proposed as a predictor for preterm delivery,[207,209] but significant clinical utility has not yet been demonstrated.[210,211]

Thyrotropin-Releasing Hormone

Chorionic thyrotropin-releasing hormone[212] is made by the placenta and fetal membranes, but a clear role for either the mother or the fetus has not been identified. Pituitary TSH does not cross the placenta, nor does the placenta make thyroid hormone itself, but maternal T4 and triiodothyronine (T3) cross the placenta carried by placentally produced transthyretin.[213–215] The placental role in thyroid metabolism has been of considerable recent interest since thyroid disease is common in women of childbearing age and impacts pregnancy outcomes.[216] Early maternal hypothyroidism appears to be associated with lower intelligence quotient in offspring, but conflicting reports exist on the impact of maternal hypothyroidism after onset of fetal thyroid function in midgestation.[216,217] Maternal T4 continues to cross from maternal to fetal circulation in the second and third trimesters; even fetuses with complete thyroid dysgenesis have 30%–50% normal T4 levels in cord blood.[218] Placenta regulation of thyroid hormone transport and metabolism may play a critical role in fetal well-being, but the regulatory pathways remain to be defined.

Growth Hormone-Releasing Hormone, Somatostatin, and Ghrelin

Additional releasing factors are made in the CTB, including growth hormone-releasing hormone,[219] somatostatin,[220] and ghrelin[221] and may regulate hGH-V production as well as placental differentiation.[222]

Leptin

Leptin is normally secreted by adipocytes and decreases food intake through hypothalamic actions, but in pregnancy, the placenta is the primary leptin source.[223,224] The precise roles of leptin in the placenta, the mother, or the fetus are not known but may differ significantly from the nonpregnant state, as leptin levels in pregnancy do not correlate with body mass nor produce satiety.[225,226] Increased leptin levels are seen in PE and gestational diabetes.[227,228]

Oxytocin

OT is another hypothalamic hormone produced in the placenta and membranes.[229] OT is a potent uterotonic hormone used clinically to induce or speed labor. However, neither circulating maternal OT nor locally produced OT appears to increase markedly before labor; rather, uterine response to OT is increased through increases in OT receptor (OTR) expression and function.[230,231] Progesterone suppresses OTR signaling during gestation,[229] but a decline in progesterone activity at term (although not absolute progesterone levels in humans) increases OTR expression, making the uterus more responsive to OT.

Additional Placental Secreted Factors

Vasoactive Peptides

The angiotensin–renin system has been described in the placenta and is thought to be a factor in the regulation of vascular tone in the placental bed. Multiple vasoactive peptides—VEGF, endothelin, angiotensin, arginine vasopressin, and atrial natriuretic peptide—and their receptors are placentally expressed.[232–236] A balance of these factors is likely required for appropriate fetoplacental perfusion. For example, atrial natriuretic peptide inhibits the vasoconstrictive action of endothelin and angiotensin and induces vasodilatation in the uterus and the placenta.

Endogenous Opioid Peptides

Opioid peptides, enkephalins[237] and dynorphin,[238] and their receptors are expressed in placenta, with an increase in placental receptors at term.

Cytokines

Cytokines—interferons, tumor necrosis factor-α (TNF-α), leukemia inhibitory factor, and interleukins[239–243]—and their receptors are produced by the placenta as well as by uterine endothelial cells and invading macrophages.[242,244–246] Successful implantation requires a proinflammatory cytokine environment,[247,248] while pregnancy maintenance requires cytokine expression that suppresses the maternal immune response.[137,249] Before parturition, this balance again shifts back to proinflammatory cytokines.[244–246,249] The balance of cytokines and related factors, either proinflammatory or antiinflammatory, may be a key trigger for preterm labor caused by intrauterine infection or other types of inflammation.[137,245] Cytokine expression also regulates trophoblastic and vascular placental function.[250] Cytokines affect these activities by regulation of other cytokines, growth factors, hormones, and prostanoid production.[251–253]

Eicosanoids

Eicosanoids, such as thromboxanes (TXAs), PGs, and leukotrienes are inflammatory mediators expressed in placenta that are derived from arachidonic acid.[254,255] Human term placentas convert arachidonic acid primarily to TXAs and the PGs PGE2, PGF2α, and PGD2.[254,256] Much like cytokines, they play a role in trophoblast implantation[257] and in parturition.[258,259] After implantation, these factors, particularly prostacyclin (PGI2) and PGE2, appear to be vasoregulators of the fetal–placental unit.[259–261] PGI2 is a potent vasodilator in placental vessels, an inhibitor of platelet aggregation, and a uterine relaxing factor; its loss has been implicated in PE. TXA2 opposes PGI2, and production is increased in PE; low-dose aspirin preferentially inhibits TXAs in the placenta and may decrease development of PE.

Immunologic Function

Throughout pregnancy the risk of fetal infection must be balanced against fetal rejection. This balance is maintained on both the maternal and fetal sides of the placenta. Unique features of the cells at the placental interface are required to allow the genetically distinct fetal "graft" to inhabit the maternal host. Placental trophoblast cells directly encounter maternal immune cells: SynTs covering the placental villi are bathed in maternal blood and the invading trophoblasts exposed to the maternal decidua. Different strategies appear to be used at these sites to prevent destruction by cytotoxic maternal immune cells. For example, neither SynTs nor invading trophoblasts express classic human leukocyte antigen (HLA)-A or HLA-B class Ia major histocompatibility complex antigens nor HLA class II antigens. However, invading trophoblasts do express nonclassic HLA-G and HLA-C — HLA types that can actually suppress immune responses, especially through leukocyte inhibitory receptors on uterine natural killer (NK) cells and macrophages. A balance of innate immunity and modulation of adaptive immune responses is required, and this balance shifts throughout gestation.[262,263]

The decidua is replete with innate immune cells including T cells, regulatory T cells, macrophages, dendritic cells, and uterine NK (uNK) cells. The best-studied subtype is the NK population. NK cells peak and constitute the largest leukocyte population in the early pregnant uterus, accounting for 60% to 70% of total lymphocytes. These cells diminish in proportion as pregnancy proceeds. Despite being replete with cytotoxic perforin, granzymes A and B, and the natural cytotoxicity receptors (NKp30, NKp44, NKp46, NKG2D, NGK2B4, and LFA-1), these NK cells are tolerant cytokine-producing cells at the maternal–fetal interface.[264] The temporal occurrence around the SpAs and timed amplification of these specialized NK cells observed during the first trimester implicate their role in SpA remodeling. NK cell-deficient mice display abnormalities in decidual artery remodeling and trophoblast invasion, possibly because of a lack of uNK cell-derived interferon γ.[265] Other studies have shown that uNK cells are a major source of VEGF-C, angiopoietins 1 and 2, and TGF-β1 within the placental bed that decrease with gestational age.[266] These observations implicate uNK cells in promoting angiogenesis. Recent studies suggest that VEGF-C may induce the non-cytotoxic activity in maternal immune cells as well.[267] Additional molecules expressed on trophoblasts, such as members of the B7

family that alter lymphocyte activity and FasL, which interacts with Fas leukocyte receptors, may also modulate cytotoxicity in the placenta.

Both maternal macrophages and Hofbauer cells (macrophages in the villi that are derived from the fetus) are present in the placenta during pregnancy. These cells may prevent uterine infections or facilitate vascular remodeling and immune suppression.[268] Much like NK populations, alterations in macrophage activation, both maternal and fetal, have been linked to pregnancy complications such as IUGR, preterm birth, and PE.[269]

Maternal tolerance to fetal alloantigens was initially explored in the context of T-helper cells (Th)1/Th2 balance in mice, with Th2 cells and cytokines proposed to predominate over Th1 cellular immune response under normal pregnancy. In human pregnancy, the role of specialized T lymphocytes—termed *regulatory T cells* (Tregs)—in producing immune tolerance has emerged. Tregs are potent suppressors of T cell–mediated inflammatory immune responses and prevent autoimmunity and allograft rejection. $CD4^+CD25^+$ Tregs are found in the decidua throughout pregnancy. Fetal-specific Tregs persist between pregnancies, and they accumulate and reexpand their population rapidly in subsequent pregnancies, potentially providing a persistent protective regulatory memory to fetal antigen.[270] The specific role of these Tregs in human pregnancy loss remains to be defined.

Immunosuppressive immune modulators are also highly expressed at the placental interface. Many of the endocrine factors produced by the placenta (progesterone, PGE2, and interleukins) as described above appear critical to maternal immune modulation. For example, the antiinflammatory cytokine interleukin (IL)-10 is expressed by human trophoblasts and Tregs, increasing across the first two trimesters and then declining before delivery. Low IL-10 expression has been linked to pregnancy loss and preterm delivery as well as PE. However, how IL-10 protects the fetus is poorly understood. IL-$10^{-/-}$ mice are fertile if maintained pathogen-free but are highly susceptible to complications from infection, suggesting that IL-10 deficiency plus a "second hit" such as infection, environmental factors, or hormonal dysregulation may contribute to poor pregnancy outcomes.[271]

There is no generalized immunosuppression in pregnant women. Rather, there is a balance struck between specific types of immune suppression and activation. Indeed, cytokine production capacity is higher in pregnant than in nonpregnant women. It is the balance of proinflammatory to antiinflammatory cytokines that may determine outcome. When this balance is altered early in gestation, implantation could be affected, while immune alterations in late gestation may contribute to susceptibility to preterm birth, particularly in the face of an immune challenge. Similar shifts in the fetal immune response from tolerance to activation are being investigated across normal gestation.[272] The role of placental immune activation in poor neonatal outcome, particularly in neurologic complications, has become an area of active study in the past decade.[273,274] Defining and manipulating placental immune responses are key components of current efforts to improve pregnancy outcomes.

Regulation of Placental Function

Understanding placental dysfunction and disease during pregnancy is critical to improving neonatal and adult outcomes.[275,276] Healthy development of the placenta requires efficient metabolic, immune, hormonal, and vascular adaptation by the maternal system as well as the fetus. Abnormal placentation and placental infections can lead to preeclampsia, growth retardation, or preterm birth, which can have a lifelong bearing on health. Most major obstetric syndromes originate in early gestation because of abnormal trophoblast invasion or immune dysregulation but present clinically in late gestation. Maternal factors such as ascending infections, obesity, hypertension, diabetes, and environmental exposures also contribute to placental dysfunction.

Evaluation of Placental Dysfunction

Until recently, placental assessment was performed almost exclusively after delivery, using traditional anatomic pathology techniques. While significant correlations have been described between specific pathologic lesions and neonatal outcomes, our understanding of how and when these lesions develop during gestation and ultimately lead to poor outcomes remains limited. There has been a recent resurgence of interest in developing advanced tools to investigate placental function during gestation, particularly following the launch of the Human Placenta Project by the Eunice Kennedy Shriver National Institutes of Child Health and Disease.[277,278] In addition to promoting the development of new advanced imaging techniques[279,280] and biomarker methods for measuring placental function,[281] there has been a renewed interest in standardizing placental histopathologic classification and diagnosis. In 2014 an international group of placental pathologists met in Amsterdam to establish consensus guidelines for placental examination and classification of lesions;[282] these are summarized in Table 3.1.

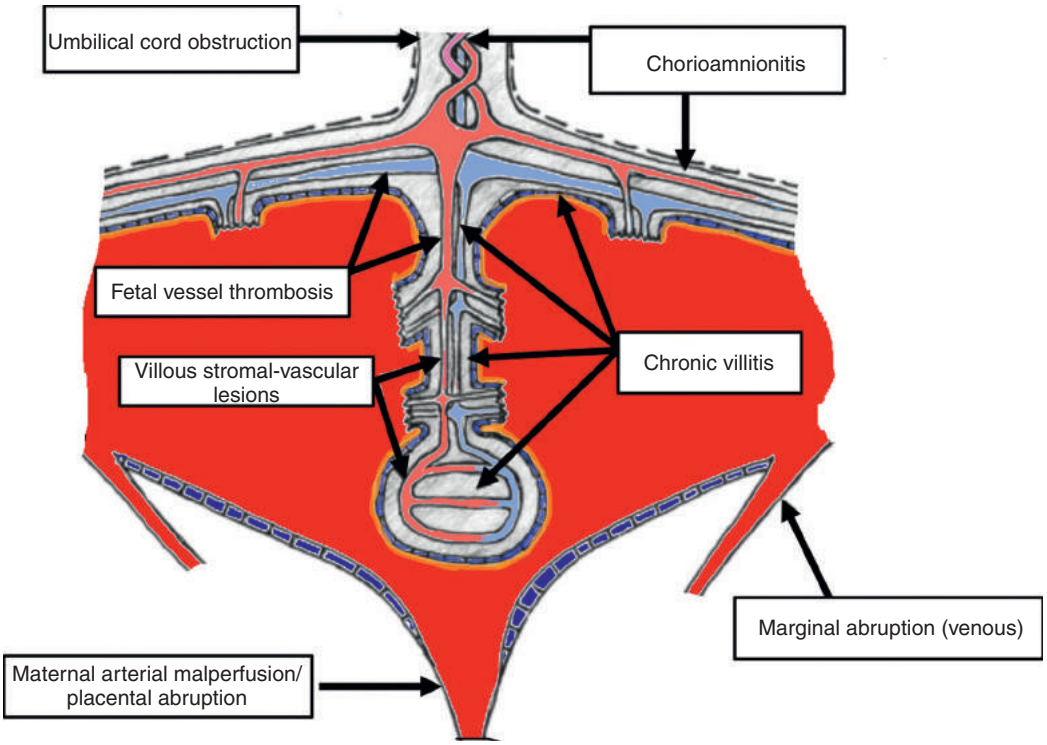
Placental Histopathology

Direct examination of the placenta after birth can give some clues to the timing and extent of important adverse prenatal or neonatal events. Some disorders are readily apparent in the delivery room (listeria lesions, placental abruption associated with large clots, abnormal cord insertion), and others require more detailed gross and microscopic examination. In a high-risk delivery service, approximately 50% of placentas qualify for pathologic examination.[283]

The majority of placental lesions described by pathologists involve either vascular or immunologic/infectious processes (Table 3.1). Vascular processes can be further localized as maternal or fetal lesions (Fig. 3.4 villous maternal stromal-vascular lesions versus fetal vascular lesions), potentially providing clues to both the underlying etiology of the lesion and its implications for maternal or fetal heath. Immune processes likewise can be subdivided into chronic or acute infections and also distinguished from inflammatory processes associated with immune activation without infection (see Fig. 3.4, chronic villitis). Links have been made between each major pathologic lesion type and different pregnancy complications (Table 3.2).

Placental Imaging

Ultrasound (US) imaging remains the standard imaging method used for placental evaluation during pregnancy because of its availability, safety, and relatively low cost. However, US evaluation of placental anatomy can be limited by placental implantation site, maternal body habitus, and amniotic fluid volume, and US-detected lesions correlate poorly with postnatal histopathology.[284] As a primary screening tool, placental US has proven very useful, but its use for functional placental assessment that can predict which pregnancies are at risk of later placental compromise is limited.



• **Fig. 3.4** Histopathologic Sites of Action of Major Placental Disease Processes. (Modified from Redline RW. The clinical implications of placental diagnoses. *Semin Perinatol.* 2015;39:2–8.)

TABLE 3.2 Common Placental Causes of Specific Adverse Pregnancy Outcomes

1. **Fetal Growth Restriction**
   Maternal stromal-vascular lesions: global/partial vascular malperfusion with accelerated villous maturation
   Fetal stromal-vascular lesions: developmental lesions (superficial implantation), global/partial vascular malperfusion (fetal thrombotic vasculopathy)
   Villitis of unknown etiology
2. **Spontaneous Preterm Birth**
   Maternal inflammatory response: acute chorioamnionitis
   Maternal vascular lesions: mild global/partial vascular malperfusion with accelerated villous maturation
   Acute marginal placental abruption
3. **Preterm Fetal Death**
   Maternal stromal-vascular lesions: global/partial vascular malperfusion with accelerated villous maturation
   Fetal global/partial vascular malperfusion (cord accidents/obstruction)
   Placental abruption
4. **Term Fetal Death**
   Fetal stromal-vascular lesions: developmental lesions (delayed villous maturation), global/partial vascular malperfusion (cord accidents/obstruction)
   Placental abruption
   Fetomaternal hemorrhage
5. **Term Neurologic Injury**
   Fetal stromal-vascular lesions: global/partial vascular malperfusion (fetal thrombotic vasculopathy or cord occlusion)
   Chronic villitis of unknown etiology with obliterative fetal vasculopathy
   Acute chorioamnionitis with severe fetal inflammatory response
   Presence of multiple placental lesions

Modified from Redline RW. Classification of placental lesions. *Am J Obstet Gynecol.* 2015; 213(4 Suppl):S21-8.

The placenta may be visible on US as early as 5 weeks' gestation.[285] It becomes readily visible by 15 weeks' gestation by US and undergoes progressive increases in thickness and diameter as well as changes in echogenicity and shape.[284] Both increased and decreased placental size are associated with abnormal development and risk of fetal complications. Many placental lesions can be seen by US as pregnancy progresses. Some, such as placental lakes, which are anechoic regions of low maternal blood flow, are very common but appear to be of limited clinical significance. Others, including echogenic areas of infarct, may be significant when large or centrally located. Placental calcifications increase across gestation. There appears to be an association between early development of calcifications and poor placental function, but use of early, high-grade calcification to predict pregnancy outcome has proved unreliable.[284] Doppler velocimetry is used in conjunction with anatomic US to functionally assess placental blood flow.[286] Fetal villous vascular damage results in high resistance in the umbilical artery (UA) circulation, and chronic fetal hypoxia decreases umbilical venous flow. Loss of UA end-diastolic flow is associated with severe IUGR and indicative of significant fetal compromise. Monitoring of placental blood flow allows detection of high resistance and poor circulation within the placenta but is usually apparent only when significant fetal compromise has already occurred. Additional US measures that may be more predictive of placental compromise, such as 3-dimensional placental volumes and vascularization indices[284] as well as new elastography and higher resolution US techniques, are under investigation.

Magnetic resonance imaging (MRI) is increasingly being used for anatomic placental evaluation, and advanced functional techniques may yield information on oxygenation, vascularization, and metabolism.[279,280] MRI benefits from having multiplanar images in a wider field of view as well as having higher spatial and

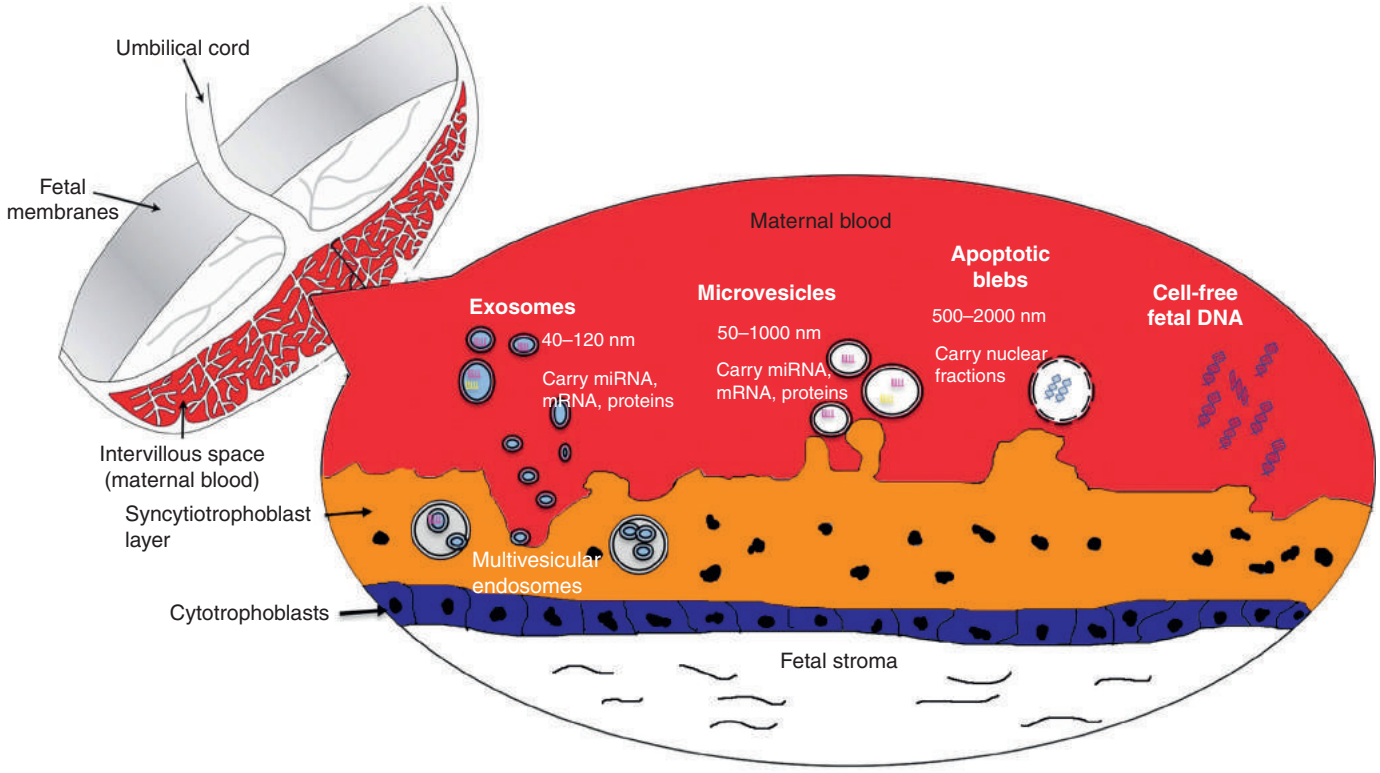
temporal resolution when compared with US. It is currently used primarily to assess fetal structural anomalies and, more recently, for improved detection of placenta accreta and other invasive placental anomalies.[287] Precise quantitation of placental volume is more readily performed using MRI than US and may allow earlier prediction of fetal growth retardation based on small placental size.[280,288] Use of standard MRI gadolinium-based contrast agents has been limited due to fetal safety concerns, but new agents are being developed. Placental application of noncontrast functional MRI methods, including diffusion-weighted imaging and diffusion tensor imaging, are being investigated along with methods that rely on endogenous contrast agents, such as hemoglobin-based detection of oxygen level changes measured by blood oxygen level-dependent MRI.[279,280] Use of placental MRI for real-time assessments is likely to provide new information about placental vascular development and function as well as new diagnostic tools for use in high-risk pregnancies.

Serum Biomarkers of Placental Disease

A major goal of pregnancy screening is to identify women early in gestation who will go on to develop placenta-mediated complications that threaten either fetal or maternal health so that targeted early therapies can be provided. Detection of factors released by the placenta into maternal circulation that predict disease is a longstanding area of investigation. In addition to physiologic secretion of placental factors into maternal circulation, cellular stress (i.e., oxidative, hypoxic, or inflammatory stress) can lead to increased villous trophoblast turnover with release of placental vesicles and cellular debris into the circulation.[281] Maternal serum analytes, circulating cell-free DNA, and extracellular vesicle contents derived from the placenta are under investigation as potential biomarkers of placental dysfunction.

Serum Analytes

Maternal serum screening has been applied successfully in the identification of fetuses at increased risk of aneuploidy or structural anomalies (open neural tube defects, abdominal wall defects). The association is less clear between pregnancies at risk of placental dysfunction and abnormal values for the most common first and second trimester serum screening markers: alpha fetoprotein, hCG, unconjugated estriol (uE_3), inhibin-A, and pregnancy-associated plasma protein-A (PAPP-A). Both single-serum analyte abnormalities and combinations have been assessed for their value as biomarkers of specific pregnancy complications with limited success.[289] For example, higher levels of second trimester inhibin-A levels are associated with PE, although no predictive cutoff level has been identified. Elevated inhibin-A in combination with UA Doppler abnormality, however, may be strongly predictive of



• **Fig. 3.5** Placental Products Circulate in Maternal Blood During Gestation. The placental syncytiotrophoblasts produce and secrete extracellular vesicles of various sizes, shapes, and functions into the maternal circulation in both healthy and compromised pregnancies. The function and cargo of these vesicles is not yet completely defined but likely plays a role in maternal–fetal cross-talk between cells during pregnancy. Circulating placental products may also provide biomarkers for placental function and pathologies. Exosomes are constitutively secreted products of the endosomal pathway that carry proteins, micro-ribonucleic acid (RNA), and messenger RNA that can modulate maternal cell functions, including immune and endothelial responses. Microvesicles and apoptotic bodies are larger vesicles produced by direct budding of the plasma membrane following alterations in cellular conditions (oxygen tension, glucose, or calcium level changes) or as part of apoptosis, respectively. These vesicles may carry unsorted protein and nucleic acid cargo picked up from the cell cytosol. They may have a proinflammatory role in pregnancy. Circulatory cell-free DNA can be up to 13% of cell-free DNA in maternal circulation. Circulatory cell-free DNA is fragmented and significantly smaller than maternal fragments, allowing fragment size and sequence to be used to distinguish fetal from maternal origin. *mRNA*, Messenger ribonucleic acid; *miRNA*, micro RNA; *nm*, nanometers.

PE.[290] Likewise, extensive studies of low PPAP-A and UA Doppler changes suggest an association with fetal growth restriction and PE.[291] Some alterations of these maternal serum markers have been associated with specific pathologies linked to poor placental function, but the strongest associations are serum marker abnormalities and a generalized increased risk of third trimester fetal death.[289] Increased surveillance or treatment of these pregnancies has not yet shown clinical benefit.

Additional maternal serum biomarkers of placental dysfunction, particularly in PE, include elevated circulating sFlt-1 and reduced PlGF. Syncytial stress leads to placental secretion of these and other angiogenic factors.[281] A recent meta-analysis suggested that the diagnostic accuracy of maternal sFlt-1/PlGF for early onset PE is high, but false positives and false negatives are both greater than 15%, limiting the utility of this ratio as a broad clinical screening tool.[292]

Circulating Cell-Free Fetal DNA

Direct measurement of DNA found in maternal serum has become possible in the past decade. Continuous turnover of placental villous trophoblasts releases placental microparticles and freely circulating nucleic acids (Fig. 3.5). These fragments are called fetal but actually originate from the placenta.[293] Noninvasive prenatal screening for aneuploidies and genetic mutations using circulating cell-free fetal DNA (cffDNA) screening from maternal serum has rapidly gained popularity in the past 5 years. Confined placental mosaicism with a normal fetal karyotype can confound these screening results, but the high sensitivity and specificity of these tests combined with their limited risk compared with chorionic villous sampling or amniocentesis have led to their rapid clinical adoption. Total cffDNA levels, rather than specific cffDNAs, may also be useful biomarkers for placental health and function. cffDNA is increased in PE both before and during the development of clinical symptoms, likely because of increased trophoblast apoptosis associated with oxidative stress.[294] High concentrations of cffDNA are also associated with increased preterm birth risk.[295] Cell-free RNA and miRNAs have also been found in maternal circulation, and their utility as biomarkers is actively being assessed.

Extracellular Vesicles

Multiple types and sizes of vesicles are shed by the placenta in both normal and compromised pregnancies (Fig. 3.5), but the amounts and contents vary with placental health.[281] Exosomes are a subtype of extracellular vesicle derived from endosomes that carry proteins and RNAs and that are released by exocytosis into the extracellular space. Exosomes play a significant role in intercellular signaling in multiple systems, and their role in pregnancy has garnered intense interest in the past few years.[296] Placentally derived exosomes carry SynT-specific proteins, including placental alkaline phosphatase and the miRNAs from H19 described previously, allowing their identification as placental vesicles in maternal circulation. Their release is regulated by multiple environmental factors including oxygen tension and glucose concentrations, making them particularly appealing as reporters of placental function. Exosomes mediate communication between the placenta and maternal immune cells, and widespread placental–maternal cellular communication using this mechanism has been proposed. There is a general increase in placental exosomes in maternal circulation across gestation, and these levels may vary with placental pathology; the vesicle contents may also reflect pathology, such as decreased cell fusion proteins in exosomes from preeclamptic placentas.[296] As placental exosome biology becomes better defined, use of exosomes as biomarkers of placental function is an exciting possibility.

Summary

The placenta is a complex organ that develops from many cell types to form a sophisticated interface between mother and fetus that integrates intrinsic and extrinsic signals to optimize fetal development. The consequences of impaired placental function have lifelong impact not only on individual offspring but potentially on multiple generations, effected by epigenetic changes. Understanding and optimizing placental health is critical, not just to newborns but also to improving health outcomes for the entire population.

Abnormalities of Fetal Growth

REBECCA A. SIMMONS

KEY POINTS

- Normal fetal growth is determined by a number of factors.
- The pattern of normal fetal growth involves rapid increases in fetal weight, length, and head circumference during the last half of gestation.
- Year-over-year increases in birth weight for gestational age are attributed to improvements in living conditions and maternal nutrition as well as changes in obstetric management.
- Variations in fetal growth have been identified in diverse populations and are associated with geographic location.
- There is no universal agreement on the classification of an SGA infant.

Definitions

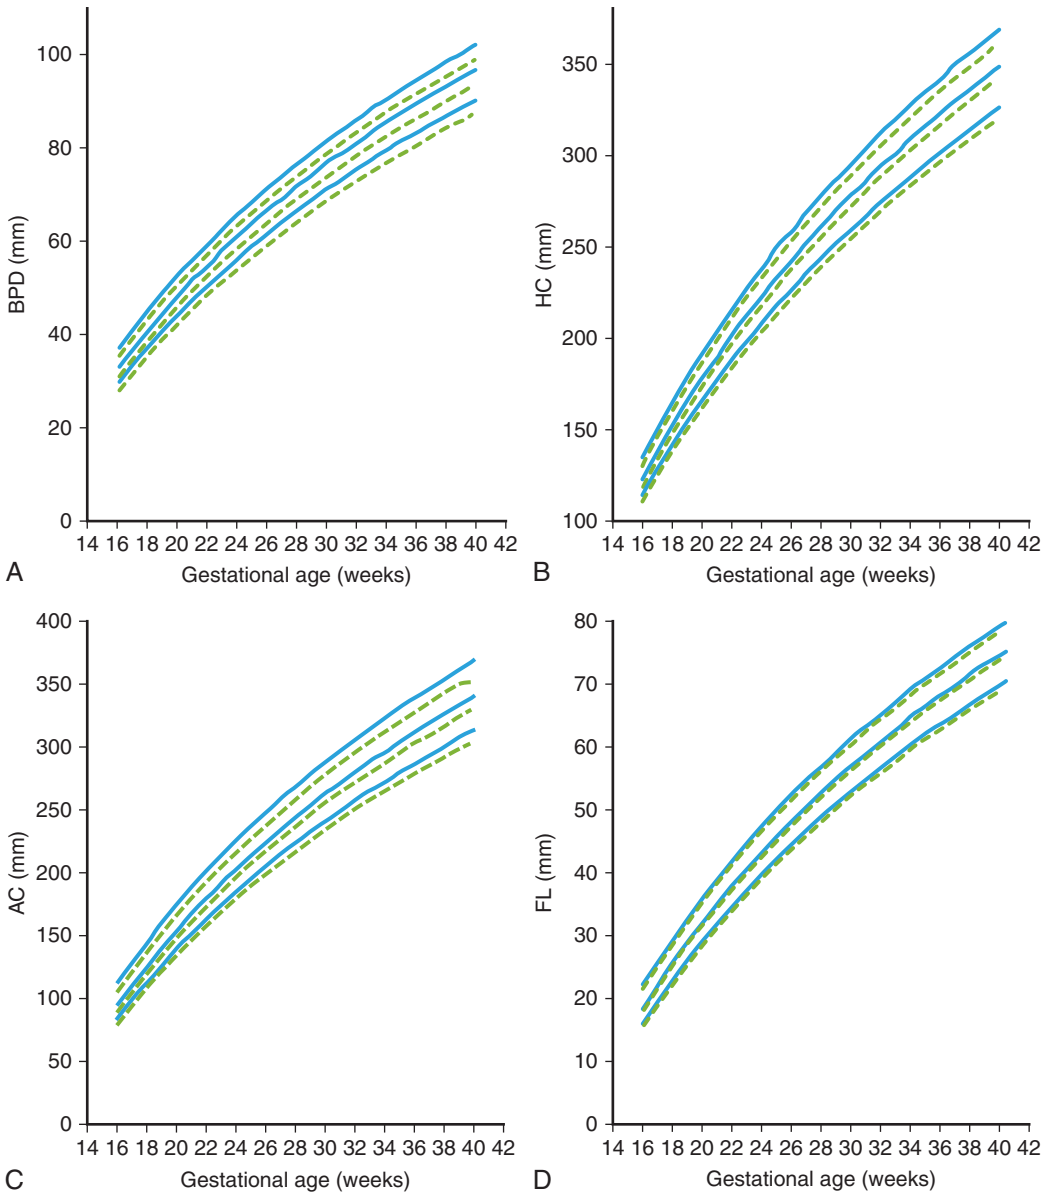
The duration of pregnancy is an integral component of prenatal growth assessment, and all currently prevailing definitions of fetal growth are gestational age specific. Assessing the gestational age accurately, however, can be challenging, and any error in dating will lead to misclassification of the infant, which can have significant clinical implications. In many instances, the method of gestational age determination has contributed to variations in the gestational age specific reference growth curves. For example, some nomograms are based on approximating the gestational age to the nearest week whereas others use completed weeks. The birth weight charts are also affected by other variables that may limit their reliability. Many of these, such as fetal sex, race, parity, birth order, parental size, and altitude, contribute to the normal biologic variations in human fetal growth. There is continuing controversy on whether the reference growth charts should be customized by multiple variables or developed from the whole population. The customized approach predicts the optimal growth in an individual pregnancy and therefore specifically defines suboptimal growth for that pregnancy. However, it has been argued that such an approach may lead to a profusion of standards and may not contribute to improving the outcome of small for gestational age (SGA) infants. In recognition of the utility of a national standard, a population-based reference chart for fetal growth was developed from all the singleton births (over 3 million) in the United States in 1991.[1] More recently, a similar national population-based fetal growth chart, which is also sex specific, has been developed in Italy. In a multicenter cross-sectional study, 8070 ultrasonographic examinations from low-risk singleton pregnancies between 16 and 40 weeks of gestation were used to develop growth curves: biparietal diameter (BPD), head circumference (HC), abdominal circumference (AC), and femur length (FL). Quantile regression was used to examine the impact of fetal sex across the biometric percentiles of the fetal measurements considered together with parents' height, weight, parity, and race[2] (Fig. 4.1).

There is no universal agreement on the classification of an SGA infant. Various definitions appear in the medical literature, making comparisons between studies difficult. Additionally, investigators have shown that the prevalence of fetal growth restriction varies according to the fetal growth curve used.[1] The most common definition of SGA refers to a weight below the 10th percentile for gestational age or birth weight less than 2 standard deviations (SD) from the mean. Some investigators also use measurements below the third percentile to define SGA. However, these definitions do not make a distinction between infants who are constitutionally small, growth-restricted and small, and those that are not small but growth-restricted relative to their potential. For example, as many as 70% of fetuses who weigh below the 10th percentile for gestational age at birth are small simply because of constitutional factors such as female sex or maternal ethnicity, parity, or body mass index; they are not at high risk of perinatal mortality or morbidity. In contrast, true intrauterine growth restriction (IUGR) is associated with numerous perinatal morbidities. This has clinical relevance to perinatologists and neonatologists, as many of the tiniest premature neonates in the neonatal intensive care units are probably growth restricted.

Increasing intervention for fetal growth restriction (FGR) is changing the definition of SGA as defined by population-derived birthweight centiles.[3] This was recently shown in Victoria, Australia, where improved detection of FGR reduced the proportion of babies with birthweight <3rd centile from 3.1% to 1.9%.[4] Over time, it is projected that this will cause the birthweight cutoff that defines the 3rd centile to increase. In that same Australian population, it has been projected that the birthweight defining the 3rd centile at 40 weeks' gestation will increase by 150 g over 35 years.[3] The authors of these studies proposed using the INTERGROWTH-21st birthweight charts that are derived from healthy populations specifically selected to demonstrate ideal fetal growth applicable across all countries.[5] This is an active and important area of research, and it is clear that there is not consensus around the world as to which growth charts should be utilized.

Patterns of Altered Growth

Neonates with intrauterine growth retardation can be classified as demonstrating either symmetrical or asymmetrical growth. Infants with symmetric IUGR have reduced weight, length, and



• **Fig. 4.1** Comparison of the 5th, 50th, and 95th centiles of the biometric measurements between male *(blue line)* and female sex *(green dashed line)* in a fetus with a paternal height of 180 cm, maternal height of 160 cm, maternal weight of 60 kg, mother nulliparous, and of white race. (A) Biparietal diameter. (B) Head circumference. (C) Abdominal circumference. (D) Femur length.

head circumference at birth. Weight (and then length) of infants with asymmetric growth retardation is affected, with a relatively normal or "head-sparing" growth pattern. Factors intrinsic to the fetus in general cause symmetrical growth restriction, whereas asymmetric IUGR is often associated with maternal medical conditions such as preeclampsia, chronic hypertension, and uterine anomalies. Asymmetrical patterns generally develop during the third trimester, a period of rapid fetal growth. However, now that fetal surveillance is more common, asymmetrical growth restriction is often diagnosed in the second trimester.

Factors that are well-recognized to limit the growth of both the fetal brain and body include chromosomal anomalies (e.g., trisomies), congenital infections (toxoplasmosis, rubella, cytomegalovirus, and herpes simplex [TORCH], malaria, human immunodeficiency virus [HIV], and parvovirus), dwarf syndromes, and some inborn errors of metabolism. Cardiac and renal structural anomalies are common conditions associated with SGA. These conditions retard fetal growth primarily by impaired cell proliferation. Recognized causes of IUGR are listed in Table 4.1.

Fetal Causes of Growth Restriction

Fetal factors affecting growth include fetal gender, familial genetic inheritance, and chromosomal abnormalities or dysmorphic syndromes. In one large population-based study, the frequency of IUGR among infants with congenital malformations was 22%. The majority of the infants affected had genetic abnormalities including chromosomal, submicroscopic single gene disorders and imprinting defects, such as Russell Silver.[6] Triploidies are the most common anomaly in fetuses below 26 weeks, and trisomy 18 above 26 weeks. Sometimes, the chromosomal anomaly can be confined to the placenta, and cause growth restriction in

TABLE 4.1 Causes of Intrauterine Growth Restriction

Genetic	Inheritance, chromosomal abnormalities, fetal gender
Maternal constitutional effects	Low maternal prepregnancy weight, low pregnancy weight gain, ethnicity, socioeconomic status, history of intrauterine growth restriction
Nutrition	Low prepregnancy weight (body mass index), low pregnancy weight gain, malnutrition (macronutrients, micronutrients), maternal anemia
Infections	TORCH infections (toxoplasmosis, rubella, cytomegalovirus, herpes simplex)
Decreased O_2-carrying capacity	High altitude, maternal congenital heart disease, hemoglobinopathies, chronic anemia, maternal asthma
Uterine/placental anatomy	Abnormal uterine anatomy, uterine fibroid, vascular abnormalities (single umbilical artery, velamentous umbilical cord insertion, twin-twin transfusion), placenta previa, placental abruption
Uterine/placental function	Maternal vasculitis (system lupus erythematosus), decreased uteroplacental perfusion, maternal illness (preeclampsia, chronic hypertension, diabetes, renal disease)
Toxins	Tobacco, ethanol, lead, arsenic

a chromosomally normal fetus. Mosaicism is defined as the presence of two or more different chromosomal complements in the fetoplacental unit developed from a single zygote. It is caused by a viable somatic postmitotic error occurring in an initially normal conceptus, or a meiotic error resulting in trisomy with subsequent postzygotic trisomic rescue.

Fetal gender also influences size, with male infants showing greater intrauterine growth than female infants.[7–9]

Placental Causes of Growth Restriction

In mammals, the major determinant of intrauterine growth is the placental supply of nutrients to the fetus.[10] Indeed, in many species, fetal weight near term is positively correlated to placental weight as a proxy measure of the surface area for materno-fetal transport of nutrients. The nutrient transfer capacity of the placenta depends on its size, morphology, blood flow, and transporter abundance.[10] In addition, placental synthesis and metabolism of key nutrients and hormones influences the rate of fetal growth.[11] Changes in any of these placental factors can therefore affect intrauterine growth. However, the fetus is not just a passive recipient of nutrients from the placenta. The fetal genome exerts a significant acquisitive drive for maternal nutrients through adaptations in the placenta, particularly when the potential for fetoplacental growth is compromised.

Placental maturation at the end of pregnancy is associated with an increase in substrate transfer, a slowing (but not cessation) of placental growth, and a plateau in fetal growth near term.[12] Fetal size and placental growth are directly related, and placentas from pregnancies yielding growth-restricted infants demonstrate a higher incidence of smallness and abnormality than those from pregnancies with appropriately grown infants. The difference in size is seen even in a comparison of placentas associated with growth-restricted infants and those associated with appropriate for gestational age (AGA) infants of the same birth weight.[13] Clinical conditions associated with reduced placental size (and subsequent reduced fetal weight) include maternal vascular disease (preeclampsia, eclampsia, and chronic maternal hypertension), uterine anomalies (fibroids, abnormal uterine anatomy), placental infarctions, unusual cord insertions, and abnormalities of placentation.

Multiple gestations are associated with greater risk for fetal growth restriction. The higher risk stems from crowding and abnormalities with placentation, vascular communications, and umbilical cord insertions. Divergence in fetal growth appears from about 30 to 32 weeks in twin gestation compared with singleton pregnancies, although this may occur earlier in gestation.[14] Abnormalities in placentation are also more common with multiple gestations.[12] Monochorionic twins can share placental vascular communication (twin-twin transfusion), leading to fetal growth restriction during gestation. Fetal "competition" for placental transfer of nutrients raises the incidence of growth restriction and discordance in growth between fetuses. The rate of birth weights less than the fifth percentile is higher in monochorionic twins. Placental growth is restricted in utero because of limitation in space, leading to a higher incidence of placenta previa in multiple-gestation pregnancies. Additionally, abnormalities in cord insertions (marginal and velamentous cord insertions) and occurrence of a single umbilical artery are more frequently found in multiple gestations.

Investigators have shown an effect of altitude on placenta function, thereby impairing fetal growth, with infants born at high altitudes having lower birth weights.[15,16] Differences in fetal growth are detected from about 25 weeks with pregnancies at 4000 m.[17] In these high-altitude pregnancies, the abdominal circumference is most affected.[18] Interestingly, investigators have shown that adaptation to high altitude during pregnancy is also possible. Tibetan infants have higher birth weights than infants of more recent immigrants of ethnic Chinese origin living at the same high-altitude (2700 to 4700 m) region of Tibet.[19] Tibetan infants also have less IUGR than infants born to more recent immigrants to the area.

Maternal Causes of Growth Restriction

Maternal health conditions associated with chronic decreases in uteroplacental blood flow (maternal vascular diseases, preeclampsia, hypertension, maternal smoking) are associated with poor fetal growth and nutrition. Infants born to women with preeclampsia are at substantial risk for IUGR.[20] Investigators have shown that the extent of growth restriction correlates with the severity and the onset during pregnancy of the preeclampsia.[21] Ødegård et al. showed that fetuses exposed to preeclampsia from early in pregnancy had the most serious growth restriction, and more than half of these infants were born SGA.[21] Chronic maternal diseases (cardiac, renal) may

decrease the normal uteroplacental blood flow to the fetus, and thus may also be associated with poor fetal growth.[22]

Maternal constitutional factors have a significant effect on fetal growth. Maternal weight (prepregnancy), maternal stature, and maternal weight gain during pregnancy are directly associated with maternal nutrition, and correlate with fetal growth.[23–25] Numerous studies show that these findings are often confounded by highly associated cultural and socioeconomic factors. The woman with a previous SGA infant has a higher risk of a subsequent small infant.[26] Investigators have shown a higher incidence of SGA infants to be associated with lower levels of maternal education.[27] Parity of the mother also affects fetal size, nulliparous women having a higher incidence of SGA infants.[28] A large population-based study in Sweden found that women who were older than 30 years and were nulliparous or had hypertensive disease were at increased risk of preterm and term growth-restricted infants.

Studies have shown differential fetal growth for women of diverse ethnicities, with Latina and white women having higher rates of large for gestational age (LGA) infants, and African-American and South Asian women having a higher incidence of small for gestational age (SGA) infants.[29–31] These gender and ethnic differences in birth weight become pronounced after 30 weeks of gestation.[32] Investigators in California have shown that US-born Black women have higher rates of prematurity and LBW infants than foreign-born Black women. Other researchers have found that even among women with very low risk of LBW infants (married, age 20 to 34 years, 13 or more years of education, adequate prenatal care, and absence of maternal health risk factors and tobacco or alcohol use), the risk of delivering an SGA infant is still higher for African-American women than for white women.[29,30] It is unclear whether these differences in fetal growth are due to inherent differences or differential exposure to environmental factors, including stress.

Maternal nutrition significantly impacts fetal growth, primarily in developing countries.[26,33–36] Although numerous factors interact with and affect fetal development, maternal malnutrition is assumed to be a major cause of IUGR in developing countries.

Teen pregnancy represents a special condition in which fetal weight is highly influenced by maternal nutrition. Teen mothers (<15 years) have been shown to have a higher risk for delivering a growth-restricted infant.[37] Teen pregnancies are complicated by the additional nutritional needs of a pregnant mother who is still actively growing, as well as by the socioeconomic status of pregnant teens in developed countries.[38]

The effects of micronutrients on pregnancy outcomes and fetal growth have been less well studied. Maternal intake of certain micronutrients has also been found to affect fetal growth. Zinc deficiency has been associated with fetal growth restriction as well as other abnormalities, such as infertility and spontaneous abortion.[39] Additionally, dietary intake of vitamin C during early pregnancy has been shown to be associated with an increase in birth weight.[40] Others have shown strong associations between maternal intake of folate and iron and infant and placental weights.[33] In developing countries, the effects of nutritional deficiencies during pregnancy are more prevalent and easier to detect. Rao and colleagues estimated that one third of infants in India are born weighing less than 2500 g, mainly because of maternal malnutrition.[41] These investigators have shown significant associations between infant birth weight and maternal intake of milk, leafy greens, fruits, and folate during pregnancy. However, many of these studies have not been replicated, and thus, the possible role of nutrient supplementation on fetal growth remains to be determined.

Although toxins such as cigarette smoke and alcohol have a direct effect on placental function, they may also affect fetal growth through an associated compromise in maternal nutrition. Other environmental toxins (lead, arsenic, mercury) are associated with IUGR and believed to affect fetal growth by entering the food chain and depleting body stores of iron, vitamin C, and possibly other nutrients.[42,43]

Numerous studies have shown associations between birth weight and maternal intake of macronutrients and micronutrients, but the effects of nutritional supplements used during pregnancy on fetal growth are equivocal.[44–47] This is underscored by the results of a large double-blind, randomized controlled trial including 1426 pregnancies that was carried out in rural Burkina Faso.[48] Pregnant women were randomly assigned to receive either iron and folic acid (IFA) or the United Nations International Children's Emergency Fund (UNICEF)/World Health Organization (WHO)/United Nations University (UNU) international multiple micronutrient preparation (UNIMMAP) daily until 3 months after delivery. Birthweight was only increased by 52 g and birth length by 3.6 mm. Unexpectedly, the risk of perinatal death was marginally but significantly increased in the UNIMMAP group (OR: 1.78; 95% CI: 0.95, 3.32; $P = .07$). However, another more recent study found that the effects of iron-containing supplements on birth weight depended on baseline hemoglobin concentrations. The iron-containing supplements improved birth weight in women with very high hemoglobin levels before 20 weeks of gestation in a large Chinese cohort.[49]

Maternal socioeconomic status and ethnicity have also been identified as risk factors for IUGR and poor health outcomes in infants in both developing and developed countries.[50] In the United States, low levels of maternal and paternal education, certain maternal and paternal occupations, and low family income are associated with lower birth weights in children of African-American, Hispanic, and white women.[51–53] In large population-based studies from Sweden, Brazil, France, and Denmark, investigators have similarly shown a higher incidence of fetal growth restriction in association with low maternal education.[27,54–56] The incidence of IUGR is also higher in women without medical insurance.[9,57,58] Interestingly, Mexican-born immigrants in California have better perinatal outcomes (including birth weight) than both African-Americans and US-born women of Mexican descent.[31] The reasons for this apparent paradox are unclear, but one postulate is the tendency of recent immigrants to maintain the favorable nutritional and behavioral characteristics of their country of origin.[59] These studies support the speculation that the differences in fetal growth between groups do not reflect inherent differences in fetal growth but rather stem from inequalities in nutrition, health care, and other environmental factors.[60,61]

Smoking

Maternal smoking during pregnancy is associated with a reduction in birth weight of approximately 250 g. In developed countries, cigarette smoking is the single most important cause of poor fetal growth.[62,63] However, the literature describing associations between maternal smoking and reduced fetal measurements is inconsistent. For example, maternal smoking is associated with reduced second trimester growth in some studies[64,65] but not all.[66] Abdominal and proximal muscle growth restriction has been linked to maternal smoking in one population[67] but to peripheral fetal growth (i.e., femur length) in others.[64,65] To address some of these inconsistencies, a recent meta-analysis was conducted of 16

studies from 8 populations.[68] They found that maternal smoking during pregnancy was associated with reduced fetal measurements after the first trimester, particularly reduced head size and femur length.[68] These effects were attenuated if mothers quit or reduced cigarette consumption during pregnancy. Kataoka and associates report that cigarette smoking also appears to have a dose-dependent effect on the incidence of IUGR, with this effect being seen especially with heavy smoking and smoking during the third trimester.[69] These investigators have shown that if women stop smoking during the third trimester, their infants' birth weights are indistinguishable from those of infants born to the normal population. Other researchers have shown that even a reduction in smoking is associated with improved fetal growth.[70,71] Numerous potential causes of the effects of smoking on fetal growth have been suggested, including direct effects of nicotine on placental vasoconstriction, decreased uterine blood flow, higher levels of fetal carboxyhemoglobin, fetal hypoxia, adverse maternal nutritional intake, and altered maternal and placental metabolism.[72,73]

Short-Term Outcomes

IUGR alters many physiologic and metabolic functions in the fetus and neonate that result in a number of morbidities. A large cohort study of 37,377 pregnancies found a five- to sixfold greater risk of perinatal death for both preterm and term fetuses that had IUGR.[74] Predictive factors for perinatal mortality in preterm IUGR fetuses reveal that of all antenatal factors examined, only oligohydramnios and abnormal umbilical artery Dopplers with absent or reversed diastolic flow were predictive of perinatal mortality.[75] Although the growth-restricted fetus may show symmetric or asymmetric growth at birth, it is unclear whether the proportionality of the fetus with IUGR truly affects outcomes or is related to the timing or the severity of the insult. Multiple studies have found that symmetric IUGR resulted in higher levels of prematurity and higher rates of neonatal morbidity.[76] In contrast, Villar and associates have shown that infants with asymmetric IUGR have higher morbidity rates at birth.[77] They found that infants with low ponderal index measurements (which they defined as weight/length^3) had higher risk for low Apgar scores, long hospitalization, hypoglycemia, and asphyxia at birth than infants with symmetric IUGR. Other investigators propose that IUGR represents a continuum, with asymmetric IUGR occurring as the severity of the growth restriction increases. Data also suggest that the more severe the growth restriction, the worse the neonatal outcomes, including risk of stillbirth, fetal distress, neonatal hypoglycemia, hypocalcemia, polycythemia, low Apgar scores, and mortality.[63,78]

Fetal growth restriction is associated with intrauterine demise. Almost 40% of term stillbirths and 63% of preterm stillbirths are SGA, and perinatal mortality for intrauterine SGA infants is higher overall than that for appropriately grown term and preterm infants.[25,76] Overall, intrauterine death, perinatal asphyxia, and congenital anomalies are the main contributing factors to the higher mortality rate in SGA infants. The effects of acute fetal hypoxia may be superimposed on chronic fetal hypoxia, and placental insufficiency may be an important etiologic factor in these outcomes. Investigators have described higher incidences of low Apgar scores, umbilical artery acidosis, need for intubation at delivery, seizures on the first day of life, and sepsis in SGA infants.[77,79]

Preterm infants with growth abnormalities have a much higher risk of adverse outcomes. Preterm SGA infants have a higher incidence of a number of complications, including sepsis, severe intraventricular hemorrhage, respiratory distress syndrome, necrotizing enterocolitis, and death, than normally grown preterm infants.[79–81] Additionally, SGA infants have a higher incidence of chronic lung disease at corrected gestational ages of 28 days and 36 weeks.

Neonatal hypoglycemia and hypothermia occur more frequently in growth-restricted infants.[82] These metabolic abnormalities presumably occur from decreased glycogen stores, inadequate lipid stores, impaired gluconeogenesis, and altered β-cell sensitivity to glucose in the growth-restricted neonate. Growth-restricted neonates have inadequate fuel stores and are at increased risk for hypoglycemia during fasting, and these risks are increased in preterm SGA infants. Infants with IUGR also have a higher incidence of hypocalcemia, the incidence correlating strongly with the severity of the growth restriction.[78]

Developmental Outcomes: Early Childhood

Neurologic outcomes, including intellectual and neurologic function, are affected by growth restriction. Overall, neurologic morbidity is higher for SGA infants than AGA infants. Even without identified perinatal events, SGA infants have a higher incidence of long-term neurologic or developmental handicaps. SGA infants born at term appear to have double or triple the risk for cerebral palsy: between 1 to 2 per 1000 live births and 2 to 6 per 1000 live births.[83] The rate of cerebral palsy is also higher in preterm growth-restricted infants than in preterm infants with appropriate fetal growth.[84] At 7 years of age, children whose birth was associated with hypoxia-related factors had a higher risk for adverse neurologic outcomes. Infants with symmetric IUGR (or perhaps more severe restriction) were at higher risk than infants with asymmetric IUGR. Other researchers have shown higher rates of learning deficits, lower IQ scores, and increased behavioral problems in children with a history of fetal growth restriction, even at 9 to 11 years of age.[85]

Long-Term Consequences: The Developmental Origins of Adult Disease

Programming

The period from conception to birth is a time of rapid growth, cellular replication and differentiation, and functional maturation of organ systems. These processes are very sensitive to alterations in the intrauterine milieu. *Programming* describes the mechanisms whereby a stimulus or insult at a critical period of development has lasting or lifelong effects. The "thrifty phenotype" hypothesis proposes that the fetus adapts to an adverse intrauterine milieu by optimizing the use of a reduced nutrient supply to ensure survival, but because this adaptation favors the development of certain organs over that of others, it leads to persistent alterations in the growth and function of developing tissues.[86] Also, although the adaptations may aid in survival of the fetus, they become a liability in situations of nutritional abundance.

Epidemiology

It has been recognized for nearly 70 years that the early environment in which a child grows and develops can have long-term effects on subsequent health and survival.[87] The landmark cohort study of 300,000 men by Ravelli and colleagues showed that men who were exposed in utero to the effects of the Dutch famine of 1944 and 1945 during the first half of gestation had significantly

higher obesity rates at age 19 years.[88] Subsequent studies demonstrated a relation between low birth weight and the later development of cardiovascular disease and impaired glucose tolerance in men in England.[89,90] Those men who were smallest at birth (2500 g) were nearly seven times more likely to have impaired glucose tolerance or type 2 diabetes than those who were largest at birth. Barker and colleagues also found a similar relationship between lower birth weight and higher systolic blood pressure and triglyceride levels.[91]

Valdez and associates observed a similar association between birth weight and subsequent glucose intolerance, hypertension, and hyperlipidemia in a study of young adult Mexican-American and non-Hispanic white men and women participants in the San Antonio Heart Study.[92] Normotensive, nondiabetic individuals whose birth weights were in the lowest tertile had significantly higher rates of insulin resistance, obesity, and hypertension than subjects whose birth weights were normal. In the Pima Indians, a population with extraordinarily high rates of type 2 diabetes, McCance and coworkers found that the development of diabetes in the offspring was related to both extremes of birth weight.[93] In their study, the prevalence of diabetes in subjects 20 to 39 years old was 30% for those weighing less than 2500 g at birth, 17% for those weighing 2500 to 4499 g, and 32% for those weighing 4500 g or more. The risk for development of type 2 diabetes was nearly fourfold higher for those whose birth weight was less than 2500 grams.[93] Other studies of populations in the United States,[94] Sweden,[95,96] France,[97,98] Norway,[99] and Finland[100] have all demonstrated a significant correlation between low birth weight and the later development of adult diseases.

Studies controlling for the confounding factors of socioeconomic status and lifestyle have further strengthened the association between low birth weight and higher risk of coronary heart disease, stroke, and type 2 diabetes. In 1976, the Nurses' Health Study was initiated and a large cohort of American women born from 1921 to 1946 established. The association between low birth weight and increased risks of coronary heart disease, stroke, and type 2 diabetes remained strong even after adjustment for lifestyle factors, such as smoking, physical activity, occupation, income, dietary habits, and childhood socioeconomic status.[101]

The Role of Catch-Up Growth

Many studies have suggested that the associations between birth size and later disease can be modified by body mass index (BMI) in childhood. The highest risk for the development of type 2 diabetes is among adults who were born small and become overweight during childhood.[102] Insulin resistance is most prominent in Indian children who were SGA at birth but had a high fat mass at 8 years of age.[103] Similar findings were reported in 10-year-old children in the United Kingdom.[104] In a Finnish cohort, adult hypertension was associated with both lower birth weight and accelerated growth in the first 7 years of life. A recent study from the UK of 259 children born SGA showed that catch-up weight gain in early childhood was associated with higher abdominal fat mass, blood pressure, and glycemia at age 6. Interestingly, in these children, less height gain was associated with reduced limb lean and fat mass.[105]

Interpretation of the findings of these studies is complicated by the vague definitions of *catch-up growth*. The term, which can encompass either the first 6 to 12 months only or as much as the first 2 years after birth, usually refers to realignment of one's genetic growth potential after IUGR. This definition allows for fetal growth retardation at any birth weight; even large fetuses can be growth retarded in relation to their genetic potential. However, postnatal factors can obviously affect infant growth in the first few months of life. For example, breast-feeding appears to protect against obesity later in childhood, yet breast-fed infants usually exhibit higher body mass during the first year than formula-fed infants. Although it is likely that accelerated growth confers an additional risk to the growth-retarded fetus, these conflicting results demonstrate the need for additional, carefully designed studies to determine just how childhood growth rates affect the later development of cardiovascular disease and type 2 diabetes.

Size at Birth, Insulin Secretion, and Insulin Action

The mechanisms underlying the association between size at birth and impaired glucose tolerance or type 2 diabetes are unclear. A number of studies of children and adults have shown that nondiabetic or prediabetic subjects with low birth weight are insulin resistant and thus are predisposed to development of type 2 diabetes.[23,95–97,103,106–110] IUGR is known to alter the fetal development of adipose tissue, which is closely linked to the development of insulin resistance.[111] In a well-designed case-control study of 25-year-old adults, Jaquet and colleagues demonstrated that individuals who were born SGA at 37 weeks or later had a significantly higher percentage of body fat in adulthood (15%).[98] Insulin sensitivity, even after adjustment for BMI or total fat mass, was markedly impaired in these SGA subjects. There were no significant differences between the SGA and control groups with respect to parental history of type 2 diabetes, cardiovascular disease, hypertension, or dyslipidemia. Of importance to generalization of the findings to other populations, the causes of IUGR in these subjects were gestational hypertension (50%), smoking (30%), maternal short stature (7%), congenital anomalies (7%), and unknown (6%).

The adverse effect of IUGR on glucose homeostasis was originally thought to be mediated through programming of the fetal endocrine pancreas. Growth-restricted fetuses and newborns have been shown to have a reduced population of pancreatic β-cells.[112] Jensen and colleagues measured insulin secretion and insulin sensitivity in a well-matched population of 19-year-old glucose-tolerant white men whose birth weights were either below the 10th percentile (SGA) or between the 50th and 75th percentiles (controls).[113] To eliminate the major confounding factors, such as "diabetes genes," the researchers ensured that none of the participants had a family history of diabetes, hypertension, or ischemic heart disease. They found no differences between the groups with regard to current weight, BMI, body composition, and lipid profile. When data were controlled for insulin sensitivity, insulin secretion was found to be lower by 30%. However, insulin sensitivity was normal in the SGA subjects. These investigators hypothesized that defects in insulin secretion may precede defects in insulin action and that once SGA individuals accumulate body fat, they demonstrate insulin resistance.

Epidemiologic Challenges

The data described in the preceding section suggest that low birth weight is associated with glucose intolerance, type 2 diabetes, and cardiovascular disease. However, the question remains whether these associations reflect fetal nutrition or other factors that contribute to birth weight and the observed glucose intolerance.

Because of the retrospective nature of the cohort identification, many confounding variables were not always recorded, such as lifestyle, socioeconomic status, education, maternal age, parental build, birth order, obstetric complications, smoking, and maternal health. Maternal nutritional status, either directly in the form of diet histories or indirectly in the form of BMI, height, and pregnancy weight gain, were usually not recorded. Instead, birth anthropometric measures were used as proxies for presumed undernutrition in pregnancy.

Size at Birth Cannot Be Used as a Proxy for Fetal Growth

Birth weight is determined by the sum of multiple known and unknown factors, including gestational age, maternal age, birth order, genetics, maternal prepregnancy BMI, and pregnancy weight gain plus multiple environmental factors, such as smoking, drug use, infection, and maternal hypertension. Some of these determinants may be related to susceptibility to adult disease and others may not. Conversely, some prenatal determinants of adult outcomes may not be related to fetal growth. A good example of how size at birth may potentially be a proxy for an underlying causal pathway is the hypothesis that essential hypertension in the adult is due to a congenital nephron deficit.[114] More recent studies have tended to support the association between low nephron number and increased susceptibility to hypertension.[115–117]

Genetics versus Environment

Several epidemiologic and metabolic studies of twins and first-degree relatives of patients with type 2 diabetes have demonstrated an important genetic component of diabetes.[118] The association between low birth weight and risk of type 2 diabetes in some studies could theoretically be explained by a genetically determined reduced fetal growth rate. In other words, the genotype responsible for type 2 diabetes may itself restrict fetal growth. This possibility forms the basis for the *fetal insulin hypothesis*, which suggests that genetically determined insulin resistance could result in insulin-mediated low growth rate in utero as well as insulin resistance in childhood and adulthood.[119] Insulin is one of the major growth factors in fetal life, and monogenic disorders that affect the fetus's insulin secretion or insulin resistance also affect its growth.[120–123] Mutations in the gene encoding glucokinase have been identified that result in low birth weight and maturity-onset diabetes of the young. However, such mutations are rare, and no analogous common allelic variation has yet been discovered, but it is likely that some variations exist that, once identified, will explain a proportion of the cases of diabetes in LBW subjects.

There is obviously a close relationship between genes and the environment. Not only can maternal gene expression alter the fetal environment, but the maternal intrauterine environment also affects fetal gene expression. An adverse intrauterine milieu is likely to have profound long-term effects on the developing organism that may not be reflected in birth weight.

Cellular Mechanisms

Fetal malnutrition has two main causes: poor maternal nutrition and placental insufficiency. In the extensive literature about the fetal origins hypothesis, these two concepts have not been clearly discerned. Such a distinction is necessary, however, because maternal nutrition has probably been adequate in the majority of populations in which the hypothesis has been tested. Only extreme maternal undernutrition, such as occurred in the Dutch famine, reduces the birth weight to an extent that could be expected to raise the risk of adult disease.[124] Thus it is reasonable to assume that placental insufficiency has been a main cause of low birth weight in these populations. The oxygen and nutrients that support fetal growth and development rely on the entire nutrient supply line, beginning with maternal consumption and body size but extending also to uterine perfusion, placental function, and fetal metabolism. Interruptions of the supply line at any point could result in programming of the fetus for the future risk of adult diseases.

The intrauterine environment influences development of the fetus by modifying gene expression in both pluripotential cells and terminally differentiated, poorly replicating cells. The long-range effects on the offspring (into adulthood) are determined by which cells are undergoing differentiation, proliferation, or functional maturation at the time of the disturbance in maternal fuel economy. The fetus also adapts to an inadequate supply of substrates (such as glucose, amino acids, fatty acids, and oxygen) through metabolic changes, redistribution of blood flow, and changes in the production of fetal and placental hormones that control growth.

The fetus's immediate metabolic response to placental insufficiency is catabolism, consuming its own substrates to provide energy. A more prolonged reduction in availability of substrates leads to a slowing in growth. This enhances the fetus's ability to survive by reducing the use of substrates and lowering the metabolic rate. Slowing of growth in late gestation leads to disproportion in organ size because the organs and tissues that are growing rapidly at the time are affected the most. Placental insufficiency in late gestation may, for example, lead to reduced growth of the kidney, which is developing rapidly at that time. Reduced replication of kidney cells may permanently reduce cell numbers because there seems to be no capacity for renal cell division to catch up after birth.

Substrate availability has profound effects on fetal hormones and on the hormonal and metabolic interactions between the fetus, placenta, and mother. These effects are most apparent in the fetus of the mother with diabetes. Higher maternal concentrations of glucose and amino acids stimulate the fetal pancreas to secrete exaggerated amounts of insulin, and the fetal liver to produce higher levels of insulin-like growth factors (IGFs). Fetal hyperinsulinism stimulates the growth of adipose tissue and other insulin-responsive tissues in the fetus, often leading to macrosomia. However, many offspring of diabetic mothers with fetal hyperinsulinism are not overgrown by usual standards, and many with later obesity and glucose intolerance were not macrosomic at birth.[125,126] These observations suggest that birth weight is not a good indicator of intrauterine nutrition.

Molecular Mechanisms: Epigenetics

Epigenetic programming occurs during early development at two critical time points that involve preimplantation embryos and primordial germ cell development. These modifications influence lineage and tissue-specific gene expression, are biologically stable, and are generally maintained throughout the lifetime of the organism. However, some of these modifications have a potential

to be influenced by extrinsic (environmental factors, such as diet, physical activity, in utero environment, chemical exposure, and stress) and intrinsic (genetically determined) factors and hence can be reprogrammed by being erroneously erased, reestablished, maintained, or reversed. These abrupt epigenetic changes theoretically could increase disease susceptibility later in the life of the organism.

Epigenetic modification is typically described as heritable changes in gene function that occur without a change in the nucleotide sequence.[127] Epigenetic regulation includes DNA methylation, histone modifications, and noncoding RNAs. DNA methylation, specifically cytosine methylation of palindromic CpG sequences, is the most studied epigenetic mark so far and occurs mainly at the fifth position of the cytosine ring. DNA methylation is necessary for cell-specific gene expression, plays an important role during embryonic development, and establishes imprinting and X chromosome inactivation.[128–130] DNA methylation in promoter regions has been associated with transcriptional silencing. However, emerging data show that the effect of DNA methylation depends on the genomic location, and it may also affect alternative splicing, genomic stability, transcriptional elongation, and transcription of noncoding RNAs. Thus, DNA methylation may also be associated with increased gene expression.

Most CpG islands remain unmethylated in normal cells; however, under some circumstances, such as cancer and oxidative stress, they can become methylated de novo.[131] It is not known why particular CpGs are susceptible to aberrant methylation. A study by Feltus et al. suggests that there is a "sequence signature associated with aberrant methylation."[132]

The NH_2-terminal tail of histones can be covalently modified by histone methyltransferases, histone deacetylases (HDACs), and histone acetylases. Histone modifications alter chromatin compaction, and influence the recruitment of transcriptional regulators, which modulate gene expression.[133] Multiple histone modifications have been described, including acetylation, methylation, phosphorylation, ubiquitination, and SUMOylation of amino acid residues (e.g., lysine or arginine).[134] Many of these modifications act in concert to regulate gene expression.

The metabolic or nutritional state of the organism directly influences epigenetic modifications as essentially all known epigenetic modifications rely upon substrates derived from intermediary metabolism, such as S-adenosyl methionine (SAM), acetyl CoA, a-ketoglutarate, and nicotinamide adenine dinucleotide (NAD^+).[135]

There are numerous studies in humans examining the relationship between fetal nutrient availability and epigenetic modifications in the offspring.[136] Many of these are confounded by small sample size, cellular heterogeneity of tissues examined, and lack of validation. Moreover, most DNA methylation assays are performed in total peripheral blood monocytes, where the unique methylation profiles of the various cellular lineages complicate interpretation of the data. Furthermore, most changes appear to be stochastic and not reproducible in other cohorts. Despite these issues, multiple studies in diverse populations repeatedly show changes in DNA methylation associated with low birth weight and/or altered nutrient availability. Thus, it is likely that an adverse in-utero milieu does indeed induce epigenetic modifications in the offspring, but whether these modifications have biological relevance remains to be determined. The field of "epigenetic epidemiology" remains an active and growing field of investigation.

Macrosomia

Excessive fetal growth (macrosomia, being large for gestational age) is found in 9% to 13% of all deliveries and can lead to significant complications in the perinatal period.[137] Maternal factors associated with macrosomia during pregnancy include increasing parity, higher maternal age, and maternal height. Additionally, the previous delivery of a macrosomic infant, prolonged pregnancy, maternal glucose intolerance, high pre-pregnancy weight or obesity, and large pregnancy weight gain have all been found to raise the risk of delivering a macrosomic infant.[138]

Maternal complications of macrosomia include morbidities related to labor and delivery, including prolonged labor, arrest of labor, and higher rates of cesarean section and instrumentation during labor. Also, the risks of maternal lacerations and trauma, delayed placental detachment, and postpartum hemorrhage are higher for the woman delivering a macrosomic infant.[137] Complications of labor are more pronounced in primiparous women than in multiparous women.[138] The neonatal complications of macrosomia include traumatic events, such as shoulder dystocia, brachial nerve palsy, birth trauma, and associated perinatal asphyxia. Other complications for the neonate are elevated insulin levels and metabolic derangements, such as hypoglycemia and hypocalcemia.[139] In a large population-based study in the United States, macrosomia (defined as birth weight greater than 4000 g) was detected in 13% of births. Of these, shoulder dystocia was noted in 11%.[137]

Macrosomia is often not detected during pregnancy and labor. The clinical estimation of fetal size is difficult and has significant false-positive and false-negative rates. Ultrasonography estimates of fetal weight are not always accurate, and the literature reports a wide range of sensitivity estimates for the ultrasound detection of macrosomia. Additionally, there is controversy in how to define macrosomia and which ultrasound measurement is most sensitive in predicting macrosomia. Stirnemann and colleagues have demonstrated a linear relation between abdominal circumference and birth weight.[140] They showed that the equations commonly used for estimated fetal weight (EFW) have a median error rate of 7%, with greater errors seen with larger infants. Using receiver operating characteristics (ROC) curves to measure the diagnostic accuracy of ultrasound, O'Reilly-Green and Divon reported sensitivity and specificity rates of 85% and 72%, respectively, for estimation of birth weight exceeding 4000 g.[141] In their study, the positive predictive value (i.e., a positive test result representing a truly macrosomic infant) is about 49%. Chauhan and associates found lower sensitivity for the use of ultrasound measurement of abdominal and head circumference and femur length (72% sensitivity), similar to the sensitivity of using clinical measurements alone (73%).[142] Other investigators have shown that clinical estimation of fetal weight (43% sensitivity) had higher sensitivity and specificity than ultrasound evaluation in predicting macrosomia.[143] In a retrospective study, Jazayeri and coworkers showed that ultrasound measurement of abdominal circumference of greater than 35 cm predicts macrosomia in 93% of cases and is superior to measurements of biparietal diameter or femur.[144] Other researchers have reported an abdominal circumference of either more than 37 cm or more than 38 cm to be a better predictor.[145,146]

Numerous investigators have also questioned whether antenatal diagnosis improves birth outcomes in macrosomic infants. Investigators point to the low rates of specificity of antenatal tests

resulting in high rates of false-positive results.[141,147] Antenatal identification of macrosomia (or possible macrosomia) may lead to a higher rate of cesarean section performed for infants with normal birth weights.[138,143,148] Macrosomia is a risk factor for shoulder dystocia, but the majority of cases of shoulder dystocia and birth trauma occur in non-macrosomic infants.[143] A retrospective study of infants weighing more than 4200 g at birth showed a cesarean section rate of 52% in infants predicted antenatally to have macrosomia, compared with 30% in infants without such a antenatal prediction. The antenatal prediction of fetal macrosomia is also associated with a higher incidence of failed induction of labor and no reduction in the rate of shoulder dystocia.[149] Using retrospective data from a 12-year period, Bryant and colleagues estimated that a policy of routine cesarean section for all infants with estimated fetal weight greater than 4500 g would require between 155 and 588 cesarean sections to prevent a single case of permanent brachial nerve palsy.[147]

Summary

There are many identified biologic and genetic factors associated with fetal growth and abnormalities of fetal growth. Physicians are limited in their ability to identify a causative agent in every case. Modification of fetal growth is possible and occurs from such diverse influences as socioeconomic status, maternal nutrition, and maternal constitutional factors. Abnormal fetal growth influences not only acute perinatal outcomes but also health during infancy, childhood, and, intriguingly, adulthood. In schools of public health, students are taught to search "upriver" for solutions to health problems. Solutions for ill health in adulthood may lie in the identification of methods to improve the health of the fetus.

Multiple Gestations and Assisted Reproductive Technology

ALLISON S. KOMOROWSKI AND EMILY S. JUNGHEIM

KEY POINTS

- The multiple birth rate has increased by 76% in the past three decades; however, it has recently started to stabilize or even decline.
- Increased utilization of assisted reproductive technologies and women delaying childbearing are the main contributors to the high rate of multiples.
- Multiple gestations are at high risk for both maternal and fetal morbidity and mortality, which increase as fetal number increases.
- Most neonatal complications in multiple gestations are sequelae of prematurity, including low birthweight, respiratory distress syndrome, neonatal intensive care unit (NICU) admission, intraventricular hemorrhage, and necrotizing enterocolitis.
- Up to 80% of women with multiple gestations experience antepartum complications, which include preterm labor, preterm premature rupture of membranes (PPROM), and placental abruption.
- Strategies for decreasing the rate of multiples resulting from assisted reproductive technology (ART) include increasing the number of single embryo transfers performed in in vitro fertilization (IVF) and using "low and slow" protocols for superovulation cycles with gonadotropins.

Epidemiology of Multiples

There are multiple factors influencing the increase in multiple births in the United States in the past half-century. The incidence of multiples was stable through the 1970s at 2% of all births.[1] We then began to see an "epidemic of multiples," with the twin birth rate increasing by 76% from 1980 to 2009.[1] The overall proportion of total national births that were multiples increased from 1.8% in 1971 to 3.30% in 2019.[2–4] Recently, twin birth has started to decline, and from 2014 to 2019, the twin birth rate declined 5%.[4] In 2019, the lowest number of twin births was reported since 2002.[4]

Twins continue to account for the vast majority of multiple pregnancies, comprising 97% in 2019.[4] The growing use of assisted reproductive technology (ART), in addition to delayed childbearing until age-related fertility issues become apparent, has contributed greatly to multiple birth rates. The rate of women delaying childbearing has dramatically increased, with women over the age of 30 accounting for 20% of births in 1980, compared with more than 45% in 2019.[1,4] Increased maternal age is associated with increased rates of twinning, and compared to mothers under 20, mothers aged 30 to 39 are twice as likely and mothers aged 40 and over are three times as likely to have a twin birth.[5] Between 1980 and 2009, the twin birth rate increased by 100% in women 30 to 35 years old and by more than 200% in women aged 40 and older.[1] On the other hand, recent declines in twin births have been limited to mothers aged 30 and older, and mothers aged 40 and over had a 23% decline in twinning from 2014 to 2018.[5] Despite the decline in twinning rate, in 2018, more than 5% of births to women aged 40 or older were multiple births.[2] Spontaneous twinning is more common as women age, perhaps related to higher follicle-stimulating hormone (FSH) levels in the follicular phase leading to ovulation of more than one oocyte, with a peak at age 37.[6] However, the increasing age of childbearing women is estimated to account for only one-third of the rise in twinning, with ART responsible for the remainder.[1] Since the birth of the first in vitro fertilization (IVF) baby in 1978, the numbers of IVF clinics, ovarian stimulation cycles, and live births from ART have all steadily increased. In 2017, ART contributed to the births of 1.9% of total infants, 14.7% of multiple birth infants, and 17.3% of triplet and higher order multiple (HOM–four or more) infants.[7] About 3.4% of all US births are multiples, yet in 2017, the ART twin birth rate was 26%, and the ART HOM birth rate was 0.9%.[7]

It is important to note that since 1997, IVF has *not* been the leading contributor to the multiple birth rate, contributing to under 15% of multiple births in 2017.[7,8] Non-IVF treatment options, including ovulation induction with oral medications and superovulation with injectable gonadotropins, were responsible for 19% of twins and 45% of triplets or HOMs in 2011.[3] These modalities involve less monitoring and are subject to less control than IVF and thus less susceptible to efforts to decrease the multiples rate. The proportion of triplet or HOM births arising from medically assisted conceptions has been declining in recent years: from 84% in 1998 to 77% in 2011.[3] The incidence of triplet and HOM births increased by a factor of 6.7 from 1971 to 1998 but has since decreased by 29% from 1998 to 2013.[3] This is largely due to a decrease in the number of embryos transferred per cycle of IVF and to the reticence of providers to use superovulation with injectable gonadotropins.

Given the maternal, perinatal, and neonatal complications associated with multiples, the goal of infertility treatment is one healthy child. Multifetal pregnancies drastically affect individuals, families,

and public health systems. Of particular importance in both maternal and fetal outcomes are fetal number and placentation.

Diagnosing Zygosity and Chorionicity

Zygosity refers to the number of oocytes and spermatozoa involved in conception while chorionicity refers to the type of placentation. Determining zygosity and chorionicity is important medically, genetically, and psychosocially for the individual and family. The chorion–amnion arrangement is crucial to antepartum management, as it determines risks of complications such as twin-twin transfusion syndrome (TTTS), intrauterine growth restriction (IUGR), growth discordance, congenital anomalies, and cord accidents. Chorionicity also guides next steps in cases of one fetal demise or desired selective reduction. Dizygotic twins result from fertilization of two separate ova by two spermatozoa, and these comprise 67% of spontaneous twins.[9] Monozygotic twins (MZTs) are identical and result from fertilization of a single ovum with one spermatozoon and subsequent postzygotic division.[10] The timing of this division-splitting determines the number of fetuses, chorionic plates, and amniotic sacs.

To determine zygosity, we can use prenatal determination of fetal gender and, more recently, single-nucleotide polymorphism-based noninvasive prenatal testing has been used to evaluate fetal genome components at as early as 9 weeks' gestation.[11] In the postnatal period, fetal blood typing and DNA analysis can be used to determine zygosity.[6,12] Diagnosing chorionicity is possible using ultrasound markers, including the number of placental sites, thickness of the dividing membrane, and the lambda sign. The lambda sign indicates dichorionicity and is a triangular projection of tissue that extends beyond the chorionic surface of the placenta.[13]

A first trimester screening ultrasound is essential in diagnosing multiple pregnancy. In a large randomized trial, in the cohort of women that did not have a screening ultrasound, 37% were not diagnosed as having a twin pregnancy until 26 weeks, and 13% were not diagnosed until the time of delivery.[14] Current ultrasonographic technology is very effective at diagnosing chorionicity, and amnionicity and first trimester ultrasounds are most accurate. In one study, the reported sensitivity, specificity, and positive and negative predictive values for ultrasonography at less than 14 weeks gestation for chorionicity were 89.8%, 99.5%, 97.8%, and 97.5%, respectively.[15] Overall, chorionicity was correctly diagnosed antenatally in 95% of cases.[15]

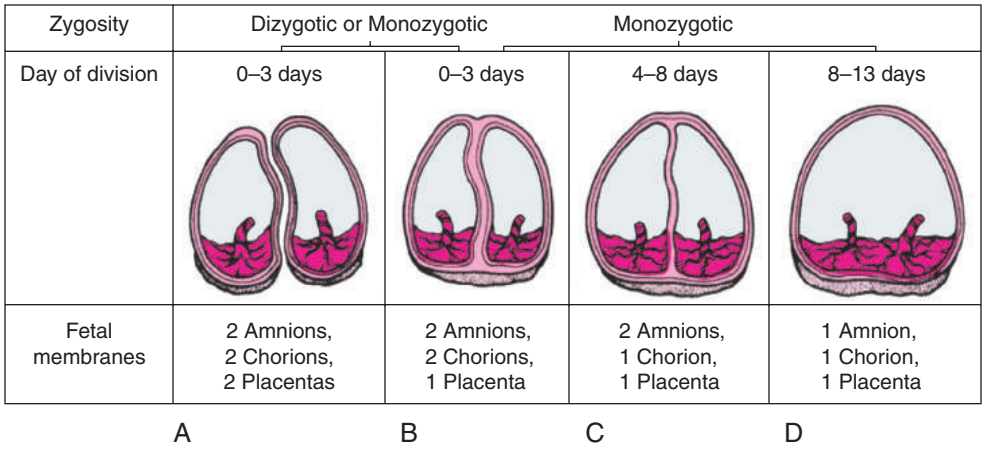
The Effect of Chorionicity

Chorionicity and placentation greatly affect fetal morbidity and mortality in multifetal pregnancies. Dizygotic twins (DZTs), with few exceptions, lead to a dichorionic, diamniotic (DCDA) arrangement in which the placenta can be separate or fused. Rare cases of dizygotic, monochorionic, diamniotic (MCDA) twins have been reported.[16] Theories as to the etiology of this include fusion of two genetically distinct zygotes or fertilization of a binovular follicle.[10]

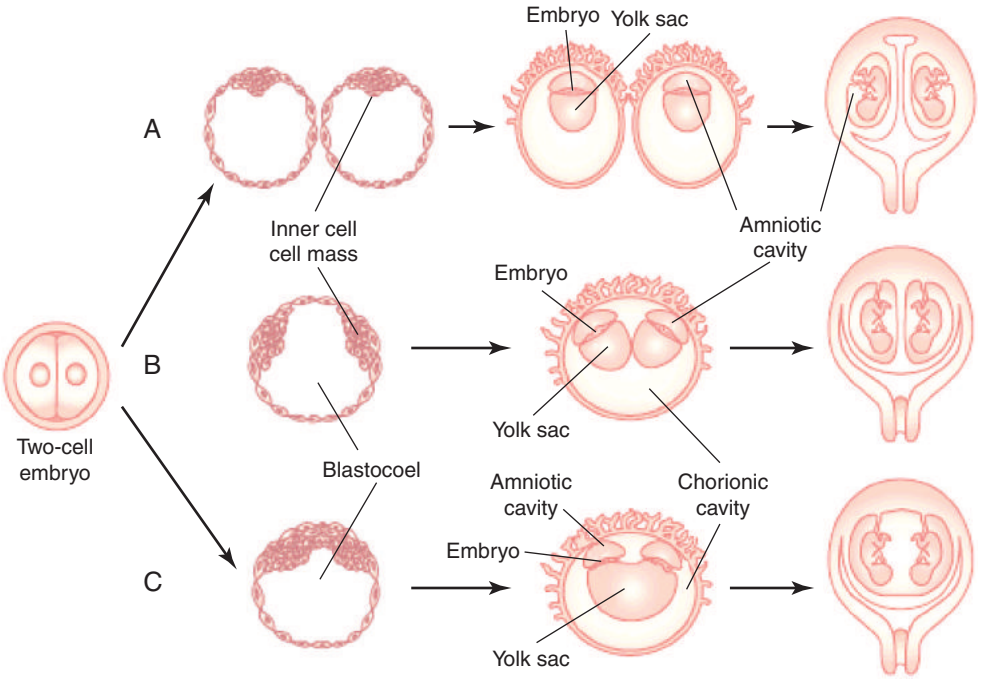
The highest rates of spontaneous twinning are in Nigeria, where 1 out of every 12 persons is a member of a twin pair, and the lowest twinning rates are seen in China, where 1 in every 70 persons is a member of a twin pair. North American and European countries are considered to have an intermediate prevalence of spontaneous dizygotic twinning.[17] Risk factors for DZT include advancing maternal age, increased parity, female relatives with DZT, taller height, and higher body mass index.[17,18] Historically, a seasonal trend in DZT has been seen, with higher rates among conceptions in the summer and autumn months.[17]

The true incidence of MZTs is difficult to ascertain because of its rarity, inaccuracies in diagnosis, and lack of confirmatory studies at birth, but spontaneous MZT rates are estimated to occur in 0.3% to 0.5% of all pregnancies and in less than 30% of all twins.[6,18,19] This rate was geographically constant prior to the advent of ART,[6] Unlike DZT, it is unclear whether MZT is related to genetics or environment.[17,20] Familial association has been seen but is very rare.[6,21]

Chorionicity in monozygotic gestations is determined by the timing of the embryonic division (Figs. 5.1 and 5.2). In 18% to 36% of MZTs, the zygote divides within 72 hours of fertilization, resulting in a DCDA gestation (the placenta can



• **Fig. 5.1** Placentation and Membranes Based on Timing of Embryonic Division. (A) Two amnions, two chorions, and separate placentas from the division of either a dizygotic or monozygotic embryo within 3 days of fertilization.[1] (B) Two amnions, two chorions, and one fused placenta from the division of either a dizygotic or monozygotic embryo within 3 days of fertilization.[2] (C) Two amnions, one chorion, and one placenta from monozygotic embryonic cleavage, days 4 to 8 after fertilization. (D) One amnion, one chorion, and one placenta from a monozygotic embryo splitting days 8 to 13 after fertilization. (Modified from Gibbs R, Karlan B, Haney A, et al. *Danforth's Obstetrics & Gynecology*. 10th ed. Philadelphia: Lippincott, Williams & Wilkins, 2008.)



• **Fig. 5.2** Types of Monozygotic Placentation. (A) Dichorionic diamniotic pregnancy.[1] (B) Monochorionic diamniotic pregnancy.[2] (C) Monochorionic monoamniotic pregnancy. (Adapted from Hall JG. Twinning. Lancet. 2003;362:735–743; and Benirschke K, Kim CK. Multiple pregnancy. *N Engl J Med*. 1973;288:1276–1284.)

be separate or fused); 60% to 75% split between days 4 and 8, leading to an MCDA unit; and 1% to 2% separate between days 8 and 13, leading to a monochorionic, monoamniotic (MCMA) pregnancy.[6,9,10,22] Embryonic division after day 13 results in conjoined twins that are MCMA.[22]

There are no naturally occurring animal models of MZT with the exception of armadillos. Models of MZT can be induced in laboratory animals by exposure to toxins or manipulation of the zona pellucida.[6] The cause of spontaneous monozygotic twinning in humans is unknown. An uneven sex ratio has been noted, with 0.484 male:female pairs in all monozygotic twins and 0.231 in monoamniotic twins, leading to the theory that skewed X inactivation may play a role.[6,23] The development of two inner cell masses (ICM) at the blastocyst stage can lead to MZT, either from damage or through immune-mediated cell-to-cell crosstalk.[6]

Although the majority of ART MZTs are MCDA, any of the three monozygotic, placental arrangements can transpire after ART, implying that the timing and mechanism of embryonic splitting are variable.[24,25]

Increase in Monozygotic Twins With Assisted Reproductive Technology

The first reported association between ART and MZT preceded numerous accounts of similar findings.[26] The majority (>90%) of ART twins are dizygotic secondary to transferring multiple embryos; however, the rate of MZTs per pregnancy after fertility treatment is higher (0.7% to 2%) versus the general population (0.3% to 0.5%).[9,24,27–31] A recent population-based study found a 60% higher risk of MZT for ART conceptions compared to natural conceptions.[32] It is also suspected that the incidence of MZT in ART may be underestimated because DCDA gestations after transfer of more than one embryo are often assumed to be dizygotic, and genetic analysis is rarely performed postnatally.[25] Several theories to explain the mechanism responsible for elevated MZTs with ART have been proposed. There follows a discussion of those theories.

Age

As mentioned previously, spontaneous dizygotic twinning increases with advancing maternal age, but the connection between age and MZTs is controversial.[18–20] Some studies report trends toward elevated MZT rates in older women, whereas others found no association with increasing maternal age and MZT.[19,20,33] A recent meta-analysis found that the MZT risk following IVF is significantly higher in women younger than 35 years, while other studies have found no association between MZT risk and age.[34,35] Overall, the correlation between age and MZT in ART remains unclear.

Zona Pellucida Manipulation

The zona pellucida (ZP), an acellular protein surrounding the ovum, provides a species-specific sperm barrier and decreases polyploidy by inhibiting penetration by multiple sperm.[36] It has been shown that the thickness and hardness of the ZP can vary in relation to stimulation protocol, elevated FSH or estradiol (E2) levels, and culture conditions. There is debate as to whether ZP manipulations performed during IVF affect MZT risk. Manipulation of the ZP in IVF occurs via both intracytoplasmic sperm injection (ICSI) and assisted hatching.[27] The injection of one sperm into a mature oocyte (i.e., ICSI) is most commonly performed for male factor infertility. AH is achieved with an artificial breach in the ZP by laser, chemical,

or mechanical methods and has been shown to increase clinical pregnancy rates, although not live birth rates, in patients with a poor prognosis.[37] A Cochrane review demonstrated that AH is associated with an increase in multiple pregnancy, with an odds ratio of 1.39.[38] However, the increase in MZT with AH was not statistically significant, and this was confirmed in other large studies.[27,31,38,39] However, the data are conflicting, with a retrospective review of over 35,000 IVF cycles showing a threefold risk of MZT with AH, a finding also demonstrated in a recent meta-analysis.[35,40] Similarly, there are mixed data regarding the association between ICSI and the risk of MZT. One study noted ICSI to be an independent predictor of MZT with an odds ratio of 2.42, with an even higher risk of MZT when ICSI was combined with day 5 embryo transfer.[41] However, more recent data have called this into question, with a recent study examining twinning after single embryo transfer finding a decrease in rates of MZT with ICSI.[42] The defect created in the ZP for ICSI is much smaller than for AH, lending plausibility to other recent studies that have shown no association.[35,39,43]

Blastocyst Transfer

After oocyte retrieval and insemination, embryos undergo intrauterine transfer at either the cleavage stage (day 2 to 3 after retrieval) or the blastocyst stage (day 5 to 6 after retrieval). Blastocyst-stage embryo transfer yields higher live birth rates, and lowers overall multiple rates because of an increase in single embryo transfer at the blastocyst stage.[44,45] However, several studies have supported the increased incidence of MZTs with extended culture to the blastocyst stage.[31,35,39,41–43] One theory is that extended culture may alter the integrity of the ZP, leading to an increased risk of splitting of the inner cell mass.[35] Another theory is that differences in culture media modify the odds of MZT. One institution initially noted increased MZT after blastocyst transfer (5.6% vs. 2%), but a follow-up study 3 years later demonstrated similar MZT rates between blastocyst and day 3 embryos (2.3% vs. 1.8%), indicating that changes in culture media and an experienced embryology team may affect the rate of MZTs.[46,47] Another recent study noted that use of sequential media was associated with higher rate of MZT in fresh, but not frozen, embryo transfers.[48] Elevated glucose levels in extended culture and subsequent glucose-induced apoptotic remodeling of the ICM and ICM splitting in extended culture in murine and human embryos may explain the phenomenon of MZTs in blastocysts.[49,50]

Higher quality embryos are more likely to be cultured out to the blastocyst stage, which may be confounding when comparing day of transfer. Recent data also indicate that younger oocyte age, another marker of embryo quality, is related to higher incidence of MZT.[25,31,51] Another environmental factor that may affect MZTs is temperature variation in frozen-thawed embryo cycles. Although rare evidence links frozen embryo transfers and temperature fluctuations to MZTs, most studies show no difference between fresh and frozen-thawed embryos and multiple rates or MZT rates.[35,39,48,52,53]

Ovulation Induction and Superovulation

Human studies of ovarian stimulation with clomiphene citrate and gonadotropins reveal a twofold increased risk of MZTs compared with the general population. MZT incidences of 1.5% after ovulation induction with gonadotropins compared to 0.72% after IVF, and 0.87% with IVF with ICSI and AH suggest that elevated levels of steroid hormones may increase rates of MZTs regardless of ZP manipulation.[28] However, this finding may be confounded by a higher baseline risk of MZT in patients with infertility.[54]

Neonatal Complications Associated With Multiples

Multiple pregnancies account for a small percentage of overall live births but are responsible for a disproportionate amount of morbidity and mortality. This is largely attributable to complications of prematurity, as women with multiple pregnancies are six times more likely to deliver preterm and 13 times more likely to deliver before 32 weeks than those with a singleton.[55] Of twin pregnancies, 61% are delivered preterm (i.e., before 37 weeks), compared with 8.5% of singleton pregnancies, and 20% of twins are delivered before 34 weeks.[4] Triplet and higher-order gestations are at even higher risk of prematurity, with 63% of triplets and 85% of quadruplets delivered before 34 weeks.[4] The risk of low birth weight (<2500 g) and very low birth weight (<1500 g) is also increased in multiple gestations. Of twin pregnancies, 9% are very low birth weight and 55% low birth weight, compared to 1% and 7% of singletons, respectively.[4] As a consequence, multiples have a fivefold increased risk of stillbirth and a sevenfold increased risk of neonatal death.[56] The average gestational ages at delivery for twins, triplets, and quadruplets are 35.3, 31.9, and 29.5 weeks, respectively, corresponding to neonatal intensive care unit (NICU) admission rates fivefold higher in twins and 17-fold higher in triplets and HOMs.[55,57]

Neonatal and maternal complications are more common in twin pregnancies, and this risk increases with triplets and HOMs (Table 5.1). Multiples have increased risks of intraventricular hemorrhage, periventricular leukomalacia, cerebral palsy, sepsis, necrotizing enterocolitis, and respiratory distress syndrome.[58–61] Surviving infants of preterm multifetal pregnancies have higher rates of developmental handicap.[60,62] Higher fetal number correlates with increased risk of growth restriction, earlier delivery, low birth weight (LBW), NICU admission, length of stay, risk of major handicap and cerebral palsy, and death in first year of life.[61–63] A recent retrospective cohort of 82 triplet gestations from 2007 to 2014 (65 conceived with ART) revealed that 88% required antepartum admission, 65% experienced preterm labor (PTL), 10% had congenital anomalies, and 5% died in the perinatal period.[64]

It is important to note that singleton pregnancies after assisted conception have increased complications, including preterm delivery, LBW, and perinatal mortality and for mothers, higher rates of antepartum hospital admission, cesarean delivery and blood transfusion.[65–69] Similar to ART singleton versus spontaneous singleton outcomes, ART multiples may have higher morbidity compared with spontaneous multiples. Assisted-conception twins have been shown to have increased risk for LBW, preterm delivery, cesarean delivery, NICU admission, longer length of stay, respiratory distress syndrome, and birth weight discordance versus spontaneously conceived twins in several studies.[70–75] In contrast, other studies suggest comparable outcomes in assisted conception and spontaneous multiples.

TABLE 5.1 Morbidity and Mortality in Multifetal Gestations

Characteristic	Singleton	Twins	Triplets	Quadruplets
Mean birth weight	3285 g	2345 g	1680 g	1419 g
Mean gestational age	38.5 weeks	35.0 weeks	31.7 weeks	30.3 weeks
Percentage less than 34 weeks of gestation	2.1	19.5	63.1	82.6
Percentage less than 37 weeks of gestation	8.2	60.3	98.3	97.4
Rate of cerebral palsy (per 1000 live births)	1.6	7	28	—
Infant mortality rate (per 1000 live births)	5.4	23.6	52.5	96.3

From American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 231: Multifetal gestations: twin, triplet, and high-order multifetal pregnancies. *Obstet Gynecol.* 2021;137:e145–e162.

Rates of pregnancy-induced hypertension, gestational diabetes mellitus, preterm premature rupture of membranes (PPROM), placenta previa, placental abruption, congenital malformations, and severe morbidity were similar in IVF twins versus spontaneous twins.[66,71,73,76]

A common phenomenon in ART is the "vanishing twin," an arrest of development and subsequent absorption of one or more fetuses of a multiple gestation in the first trimester.[77] Estimates of the incidence of a vanishing twin after ART range from 10% to 30% and are increased in HOMs.[10,78,79] The majority of vanishing twins (80%) occur prior to 9 weeks.[10] Demise of a twin after the first trimester is more common in monozygotic gestations.[80] Recent evidence suggests that the surviving twin is at increased risk for LBW, preterm birth, and perinatal mortality.[81–83] The risk of LBW is related to the gestational age at the time of a twin demise, with later gestations conferring more risk.[84]

Fetal Complications

Besides fetal number, another critical factor in pregnancy outcome is placental architecture. Monochorionic multiples experience higher rates of morbidity and mortality, largely because of placental factors.[22,85,86] Negative outcomes such as stillbirth, neonatal mortality, congenital malformations, necrotizing enterocolitis, and cerebral palsy are higher in monochorionic twins compared with dichorionic twins.[85–88] These complications are thought to be related to placental sharing and the vascular anastomoses that may cause unequal distribution of placental blood flow, causing TTTS.[88]

TTTS affects 10% of MCDA gestations and usually presents in the second trimester with oligohydramnios of the donor twin and polyhydramnios in the recipient twin.[55,89] Overall, TTTS accounts for half of perinatal deaths in MCDA twins, and surviving infants are at risk for long-standing adverse neurologic outcomes.[90–92] The severity of TTTS can be assessed using the Quintero staging system, which ranges from stage I to stage V. The most severe sequelae of TTTS are fetal hydrops and death of one or both twins.[93] Laser fetoscopic ablation can be utilized to treat TTTS by interrupting the vascular anastomoses and functionally dividing the placenta into two regions.[89] The incidence of progression from stage I to more severe stages of TTTS is 10% to 27%.[94–96] The optimal management strategy for stage I TTTS remains debated as there are similar survival rates of 85% to 86% for cases managed expectantly and those managed with fetoscopic laser photocoagulation.[95,97] The prognosis for advanced TTTS that is stage III or higher is poor, with a loss rate of 70% to 100% for untreated cases.[89] Even advanced cases treated with laser ablation have a 5% to 20% risk of neurologic handicap long-term and a 30% to 50% risk of perinatal mortality.[89]

MCMA twins are very rare, occurring in 1 in 10,000 pregnancies, but they suffer the highest risk of perinatal morbidity and mortality.[55] Similar to MCDA twins, MCMA twins are susceptible to TTTS, growth discordance, IUGR, preterm delivery, and congenital anomalies, but they also face the unique complication of cord entanglement.[98] These factors historically account for perinatal mortality rates of up to 80%.[55] However, lower morbidity and mortality rates (2% to 25%) reported in recent articles may be attributed to increased prenatal diagnosis and fetal surveillance.[98–101]

Maternal Complications

Approximately 80% of women pregnant with multiples experience antepartum complications versus 25% of those with singletons.[55,102] Pregnancies with multiples are at increased risk of hyperemesis gravidarum, hypertensive disorders, gestational diabetes, PTL, placental abruption, cesarean delivery, and postpartum hemorrhage.[55] The risk of severe acute maternal morbidity, including intensive care unit admission, uterine rupture, eclampsia, major obstetric hemorrhage, and peripartum hysterectomy, is elevated fourfold.[103,104] Approximately 20% of the elevated risk for maternal morbidity in twin gestations may be mediated by cesarean deliveries.[104] Mothers with two or more fetuses are at increased risk for three of the major causes of maternal mortality: postpartum hemorrhage, venous thromboembolism, and hypertensive disorders.[104–106] Hypertensive disorders occur in 12.7% of twin and 20% of triplet pregnancies compared with 6.5% of singletons.[107]

Plurality correlates with maternal morbidity, with triplets and HOMs experiencing significantly increased maternal morbidity compared to twins; one study found a maternal complication rate of 65% among triplet gestations and 71% among quadruplet gestations.[108] They have higher rates of PPROM, postpartum hemorrhage, gestational diabetes, placental abruption, cesarean delivery, and hypertensive disorders.[61,107,109] Results of a retrospective triplet cohort showed that 29% of gestations were complicated by PPROM, 26% by PTL, 19% by pre-eclampsia or HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome, and 10% by gestational diabetes.[110]

Psychosocial Factors

As would be expected, psychosocial stressors increase with pregnancy and delivery of multiples. As fetal number increases, parents report decreased quality of life, increased social stigma, increased

parenting stress, and decreased marital satisfaction.[111–114] Studies have also demonstrated an increased risk of postpartum depression in mothers of multiples with up to a threefold increase compared to mothers of singletons.[115–117] It is estimated that adequately caring for 6-month-old triplets and performing household duties would require 197.5 hours per week, clearly exceeding the 168 hours available.[118] Additionally, many multiple pregnancy infants are born preterm and have ongoing health issues, further exacerbating parental stress. Most studies have not demonstrated a psychosocial difference between naturally conceived multiples and multiples conceived with ART.[111,114,119]

Cost

Multiple gestations have a large economic impact, both for individual families and society. As previously discussed, multiples have increased risks of preterm delivery and LBW, which are the major drivers of short-term and long-term costs.[120] The average first-year medical costs for preterm infants are up to 10 times higher than for term infants.[55] According to gestational age, the mean initial hospital charge for infants born between 26 and 28 weeks gestation is approximately $240,000 compared with approximately $4800 for a term infant.[120] By birth weight, infants weighing less than 1250 g cost on average approximately $250,000 compared with infants weighing more than 2500 g, who cost on average $5800.[120] Daily NICU costs are over $3500 per infant, and many prolonged stays exceed $1,000,000.[121] Overall, the cost of a twin gestation is fourfold to fivefold that of a singleton, and this increases to 10- to 20-fold for triplets and HOMs.[122,123]

ART multiples and their associated comorbidities have a significant role in healthcare expenditures. The estimated financial cost of ART-associated preterm deliveries in the United States is $1 billion annually.[124] Women with ART pregnancies have higher rates of antenatal hospitalization with longer length of stay than women who conceived naturally, contributing to increased costs.[65] A Dutch study showed that multiples conceived with IVF were 3.3 times more costly than singletons conceived with IVF through 5 years of life.[125] If iatrogenic multiples were singletons in future, the estimated cost savings would be $6.3 billion in the first year of life.[126] Data also indicate that ART-conceived infants, especially in the case of multiples, have higher risks of hospital admission in the first 1 to 2 years of life, incurring additional costs.[76,127]

Decreasing the Risk of Multiples

Primary forms of preventing multiples include canceling ovulation induction cycles in which multifollicular development occurs, or converting those cycles to IVF, and limiting the number of embryos transferred in IVF cycles. Embryo transfer policies vary significantly on the global stage, ranging from strict legislation to recommendations from professional societies that are not binding. In some countries, single embryo transfer (SET) is mandatory with rare exceptions.[128,129] The American Society for Reproductive Medicine (ASRM) and the Society for Assisted Reproductive Technology (SART) established transfer guidelines in the United States, beginning in 1998, to assist in determining an appropriate number of embryos to transfer and help decrease the rate of multiples. Recommended limits are based on age, prognosis, and embryo stage, and further differentiate between a favorable prognosis (euploid embryos, high-quality embryos, expectation of high-quality embryos for potential cryopreservation, previous live birth after an IVF cycle, and frozen embryo transfer) and less favorable prognosis.[130]

In the most recent 2017 guidelines, ASRM highly recommends consideration of SET in patients younger than 38 with favorable prognosis.[130] In all age groups, transfer of a euploid embryo is recommended to be limited to one as prognosis is most favorable.[130] Recommendations state that the number of embryos transferred in a frozen cycle should not exceed the recommended limits in a fresh cycle.[130] These transfer guidelines are not legally binding, and they are subject to interpretation or adjustment based on clinical experience and unique patient characteristics.[130]

The rates of SET in the United States have been increasing in response to the epidemic of multiples, with the proportion of fresh autologous cycles reported to the CDC in which one embryo was transferred increasing from 9.3% in 2005 to 28.8% in 2014.[131] Among all embryo transfer procedures in the United States in 2017, 67.3% were SETs.[7] Similarly, the proportion in which three or more embryos were transferred decreased from 79% in 1998 to 24% in 2011, which corresponded to a 33% reduction in the proportion of IVF-conceived triplet and higher-order gestations.[3] The term "elective SET" (eSET) refers to couples who have more than one quality embryo available for transfer but elect to transfer only one. The rate of eSET in the United States has historically been quite low but increased from 1% of good-prognosis patients in 2005 to 15.3% in 2012, though there is significant variation by state.[3,132] These efforts have resulted in an increase in the singleton birth rate after IVF with 2005 marking the first year that the majority of IVF deliveries were singletons; in 2017, 73.6% of ART-conceived infants were singletons.[3,7] The goal outcome of ART is a non-low birth weight, term singleton, and eSET is most strongly associated with this outcome.[133]

There are many factors contributing to the increase in SET and stabilization of the multiple birth rate. These include revised guidelines from ASRM that lowered the recommended number of embryos to transfer, improved technology leading to more blastocyst transfers, and expanded insurance coverage for ART.[3] The overall number of embryos transferred each year has steadily declined since publication of the initial ASRM guidelines in 1998, and it is estimated that from 1998 to 2012, between 13,500 and 16,300 HOM deliveries were prevented, yielding a cost saving of more than $6 billion.[134,135] A cost-effectiveness model in a system with no infertility coverage incorporating neonatal and obstetrical cost estimates demonstrated that SET saves approximately $3.5 million per 250 patients.[136]

A recent retrospective cohort analysis of the SART outcomes between 2004 and 2013 showed a decline in live birth rate (LBR) of 10% to 15% for SET compared to double embryo transfer (DET).[132] For example, in autologous first cycles for women aged 35 to 37 years, the LBR for SET was 46.8% compared to 56.2% for DET.[132] Notably, the multiple birth rate (MBR) increased from approximately 2% with SET to greater than 49% with DET.[132] LBR was significantly higher for blastocyst embryo transfer compared to cleavage embryo transfer; this is reflected in the ASRM transfer guidelines.[132] A study of the national IVF outcomes data for 2013 demonstrated that clinics with higher eSET rates in women less than 38 years of age had lower MBRs with no significant difference in cumulative LBR.[137] Overall, there were very comparable pregnancy rates for younger

good-prognosis patients undergoing eSET compared to DET on day 5 to 6.[137,138] Preimplantation genetic screening may be another tool to improve embryo selection to reduce the rate of multiple gestations.[130] A randomized controlled trial found that in women under 43 years of age, transfer of a single euploid blastocyst resulted in similar ongoing pregnancy rate to transfer of two untested blastocysts, however the rate of twins was impressively 0% compared to 53%.[139]

Expanding insurance coverage for ART is another strategy that may help to decrease multiple births. As of early 2021, 17 states have enacted infertility insurance mandates that vary in coverage of infertility diagnosis and ART treatment. State-mandated IVF insurance coverage is associated with fewer embryos transferred per cycle.[140] Additionally, women with IVF insurance coverage are more likely to choose eSET, possibly because of less personal financial risk to patients with coverage.[130,133]

Patient education is a powerful tool to increase the acceptability of eSET. Many patients are undereducated as to the risks and complications associated with multiples and elect to have more than one embryo transferred because of a desire for twins. In studies of patient preference, the majority of couples with infertility reported a preference for having twins to having one child at a time.[141,142] It is incumbent upon providers to explain the multitude of reasons that one healthy liveborn infant is the goal of every IVF cycle. Educational programs targeted to improve attitudes toward SET have shown some success.[143,144]

Strategies for reducing multiples caused by non-IVF infertility therapy should also be considered. As previously discussed, ovulation induction and superovulation contribute to nearly 20% of twin births in the United States.[3] During superovulation cycles with gonadotropin stimulation, follicular growth is monitored with ultrasound, and E2 levels are serially measured in an attempt to minimize multifollicular development. Overall, the risk of multiples correlates with younger age, increasing E2 levels, and the size and number of follicles.[77,145,146] However, attempts to define thresholds at which couples are at low risk for multiples have been unsuccessful.[146–148] A strategy that has shown promise is the use of "low and slow" protocols, using low-dose gonadotropin stimulation over a longer period of time. Studies examining these protocols have documented multiple rates of 5% or less.[149–151] Lastly, some have advocated for the elimination of superovulation as an intermediary step between oral ovulation induction and IVF, given the associated high rate of multiples and HOMs, and this has been adopted as a cost-effective strategy by some health plans.[8,152]

Multifetal Pregnancy Reduction

As the rates of ART procedures, multiple pregnancies, and prematurity-related sequelae have increased, so has the use of selective reduction. Primary prevention of multiple gestations is optimal; however, in reality, multifetal pregnancies continue to occur. Multifetal pregnancy reduction (MFPR) provides an option to reduce the risk of fetal or neonatal morbidity and mortality.[55,77] First developed in the 1980s, termination of one or more fetuses is performed to reduce the final fetal number. The procedure most often involves passage of a needle transabdominally into the thorax of the fetus and subsequent injection of potassium chloride.[153] Selective termination refers to reduction of an abnormal fetus that is part of a multifetal gestation. The majority of patients choose to reduce a triplet or HOM pregnancy to twins, but the number reducing to singletons is increasing with heightened awareness of the morbidity associated with twins.[153,154] Improvements in MFPR techniques have enhanced success rates such that quadruplets or triplets reduced to twins have comparable outcomes to natural twins.[153] Studies have shown that pregnancies reduced from triplets to twins deliver at higher gestational ages and have lower rates of miscarriage, PTL, gestational diabetes, LBW, cesarean delivery, and neonatal death compared to nonreduced triplet pregnancies.[155–157] The average pregnancy loss rate currently quoted as a complication of MFPR is about 4%, down from 13% in the 1990s.[153,154] It is important to consider that MFPR is not without medical and psychological risks, and the ethical framework of each individual will guide decision making.[158] A discussion regarding the ethical and medical implications of MFPR should be undertaken with all patients prior to undergoing ART.[55]

Summary

Over the last three decades, advances in ART have helped countless infertile couples achieve parenthood. This has had the unintended consequence of causing an epidemic of multiple births, which are associated with maternal, fetal, and neonatal morbidity and mortality. The subsequent psychosocial and economic costs are significant. Births attributable to ART are likely to continue to increase with improvements in both effectiveness and accessibility, and strategies aimed at primary prevention of multiples should be a major focus going forward.

Prematurity and Stillbirth: Causes and Prevention

JULIA JOHNSON AND MANEESH BATRA

KEY POINTS

- Preterm birth, defined as birth prior to 37 weeks gestation, is the leading cause of under-five child mortality worldwide.
- Preterm birth can be spontaneous or medically indicated, in which cesarean delivery or induction of labor is performed to avoid the risks of continued pregnancy.
- Preterm birth and stillbirth should be considered as occurring on a spectrum rather than distinct entities, due to overlapping physiology and prevention strategies.
- Significant disparities in preterm birth and stillbirth exist by race reflective of long-standing effects of structural racism.
- Preterm birth and stillbirth have been associated with multiple risk factors, including demographic, environmental, genetic, placental, nutritional, microbial, and infectious factors.
- Further study of these factors and their associated pathways may lead to discovery of more direct ways to control the biology of pregnancy and, ultimately, the prevention of preterm birth and stillbirth.
- Global efforts to reduce preterm birth and stillbirth are critical for improving perinatal and child mortality globally and will require continued sustained and coordinated efforts.

Preterm Birth and Stillbirth: Burden in the United States and Global Estimates

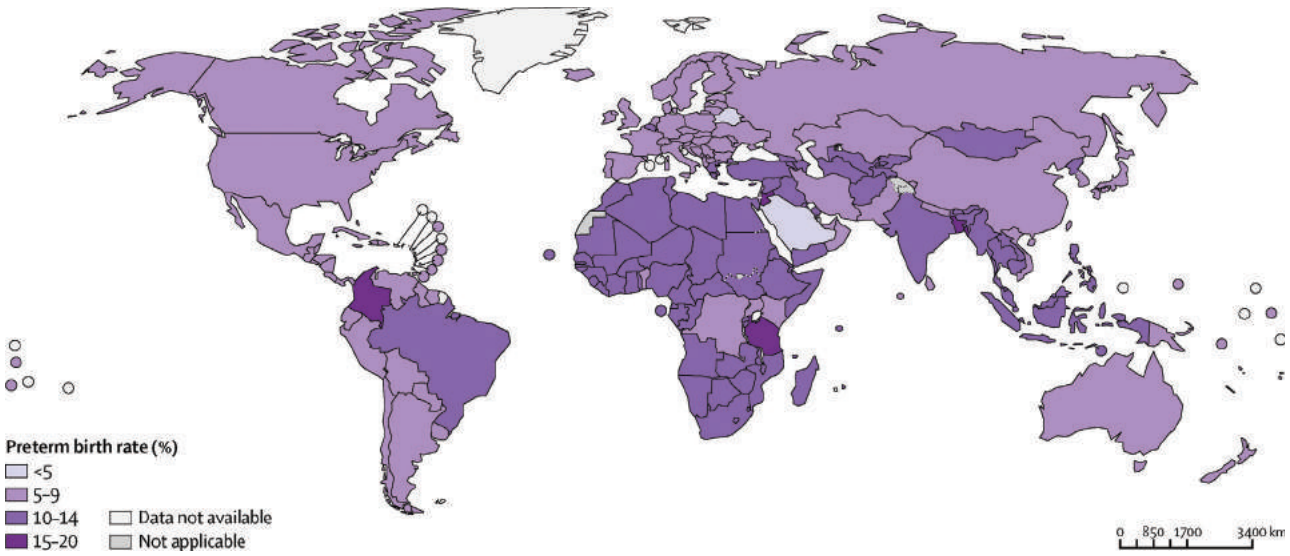
Preterm birth, defined as birth prior to 37 weeks gestation, affects 15 million newborns globally every year.[1] It is the leading cause of under-five child mortality worldwide and accounts for one million deaths annually.[2] More than 10% of newborns in the United States are born preterm, the annual cost of which exceeds $26 billion.[3,4] Globally, among survivors, preterm birth is a major cause of disability-adjusted life years due to lifelong neurologic and developmental sequelae.[5] The rate of preterm birth in the United States increased dramatically in the late 20th century from less than 7% in the 1960s to a peak of 12.8% in 2006; the preterm birth rate was 10.2% in 2019.[4] Globally, the preterm birth rate was estimated at 10.6% in 2014, though significant regional and country variation exists (Fig. 6.1).[1]

In the United States, stillbirth is typically defined as a fetal death at 20 weeks gestation or later or at a birth weight greater than or equal to 350 g. Estimates of stillbirth in the United States are complicated by inconsistent reporting criteria by state, with variable gestational age and birth weight cutoffs used. In 2019, there were 21,478 stillbirths reported in the United States via the National Vital Statistics System; annual stillbirths in the United States exceed the number of neonatal deaths.[6] Comparison of stillbirth rates across countries and regions are challenging given differential reporting mechanisms and metrics and difficulty differentiating between fresh stillbirths or fetal deaths during labor and delivery and early neonatal deaths in very low resource settings.[7,8] The World Health Organization (WHO) definition of stillbirth incorporates both early fetal deaths (500 to 999 g or 22 0/7 to 27 6/7 weeks) and late fetal deaths (≥1000 grams or ≥28 0/7 weeks; Fig. 6.2).[7,9] In 2020, the United Nations Inter-agency Group for Child Mortality Estimation released its first-ever report on the global burden of stillbirths, reporting an estimated 2 million late fetal deaths globally in 2019.[8] Approximately half of stillbirths occur in six countries: India, Pakistan, Nigeria, the Democratic Republic of the Congo, China, and Ethiopia; 27% of global stillbirths occur in low income countries, which account for only 16% of the world's live births.[8]

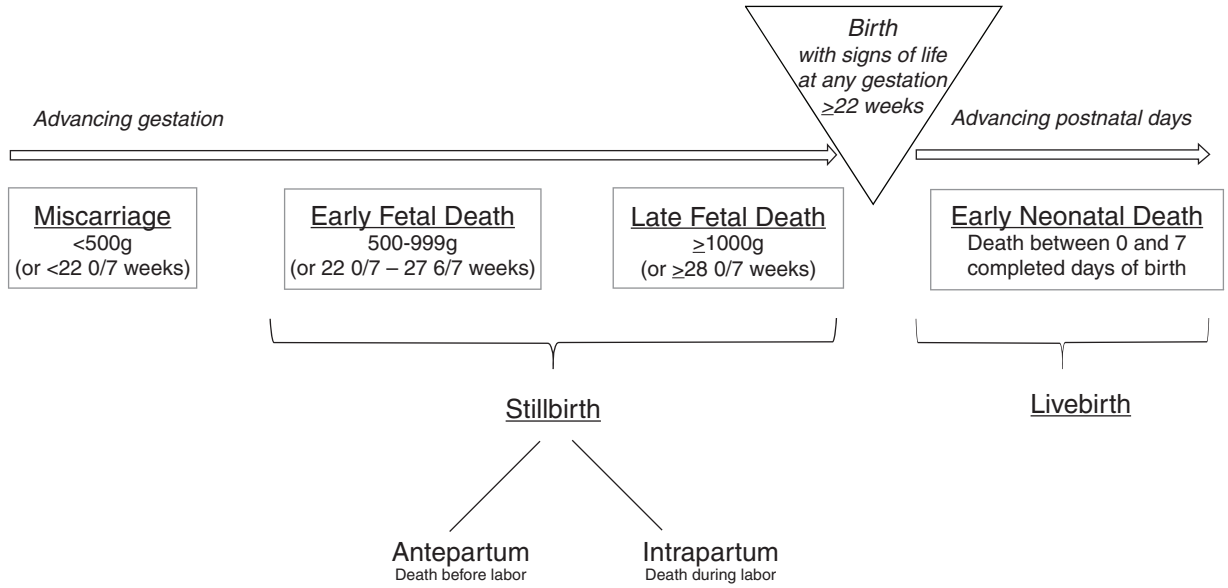
Preterm birth and stillbirth should not be considered distinct entities but rather as occurring along the same spectrum, both in terms of overlapping pathophysiology and targets for prevention. This is particularly true in the case of fresh stillbirths, a significant proportion of which could be averted with improved access to care and earlier obstetric intervention. Approximately 40% of stillbirths worldwide occur during labor (Fig. 6.3).[8]

Pathophysiology of Preterm Birth and Stillbirth

Preterm birth can be spontaneous, in which labor starts too soon, or medically indicated, in which cesarean delivery or induction of labor is performed to avoid the risks of continued pregnancy to the mother or fetus, e.g., due to preeclampsia or intrauterine growth restriction. Another subtype of spontaneous preterm birth is associated with premature preterm rupture of membranes (PPROM), in which rupture of amniotic membranes occurs both prior to 37 weeks gestation and prior to the onset of labor (Fig. 6.3).[10] Approximately 45% of preterm births result from spontaneous preterm labor, 30% from medically indicated delivery, and 25% from PPROM, though recent data suggest a rise in



• **Fig. 6.1** Map Representing Country-Level Preterm Birth Rates in 2014. (From Chawanpaiboon S, Vogel JP, Moller AB, et al. Global, regional, and national estimates of levels of preterm birth in 2014: a systematic review and modelling analysis. *Lancet Glob Health*. 2019;7[1]:e37–e46.)



• **Fig. 6.2** Classification of fetal and neonatal mortality based on timing of death, World Health Organization recommendations. (From Patterson JK, Aziz A, Bauserman MS, et al. Challenges in classification and assignment of causes of stillbirths in low- and lower middle-income countries. *Semin Perinatol*. 2019;43:308–314.)

medically indicated preterm deliveries.[10–12] The extent to which the etiologic pathways leading to each type of preterm delivery are distinct versus overlapping is uncertain. Etiologic differences also exist between early preterm birth (e.g., <28 weeks gestation) and late preterm birth, although the definition of "early" versus "late" preterm birth is somewhat arbitrary in the context of continuous gestational progression.

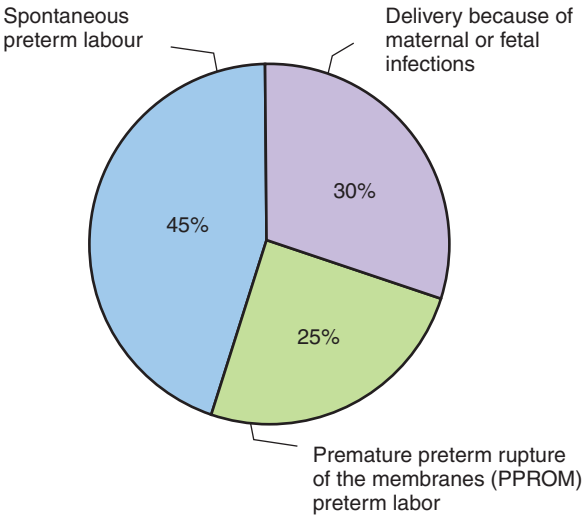
Spontaneous preterm birth is an exceedingly complex phenomenon that is not well understood. Physiologic or disease processes that induce uterine contractility, cervical dilatation, or rupture of amniotic membranes prior to 37 weeks gestation can lead to preterm birth (Fig. 6.4).[13,14] There is evidence that spontaneous preterm birth may be related to perturbations in the maternal-fetal environment, such as abnormal placental development, infection, uterine overdistension, and inflammation. While the majority of preterm births remain unexplained, the biology underlying disease states that contribute to preterm birth is beginning to be elucidated.[15–19]

Stillbirth, preterm delivery, and growth restriction exist along a spectrum, with overlapping etiologies. Fetal growth restriction is a marker of placental insufficiency, which is often implicated in both stillbirth and preterm delivery (Fig. 6.5).[20,21] Other common clinical antecedents of stillbirth and preterm delivery include spontaneous preterm labor or rupture of membranes and infection. Increasingly, inflammation is implicated as a common pathway contributing to stillbirth and preterm birth.[18,22–25] However,

approximately 40% of stillbirths are unexplained.[20] Further understanding of gestational biology and preterm birth will likely provide insight into the etiology of stillbirth. More frequent inclusion of stillbirth in studies of preterm delivery—especially early preterm delivery—will be important to fully understanding either outcome.

Demographic Factors and Disparities

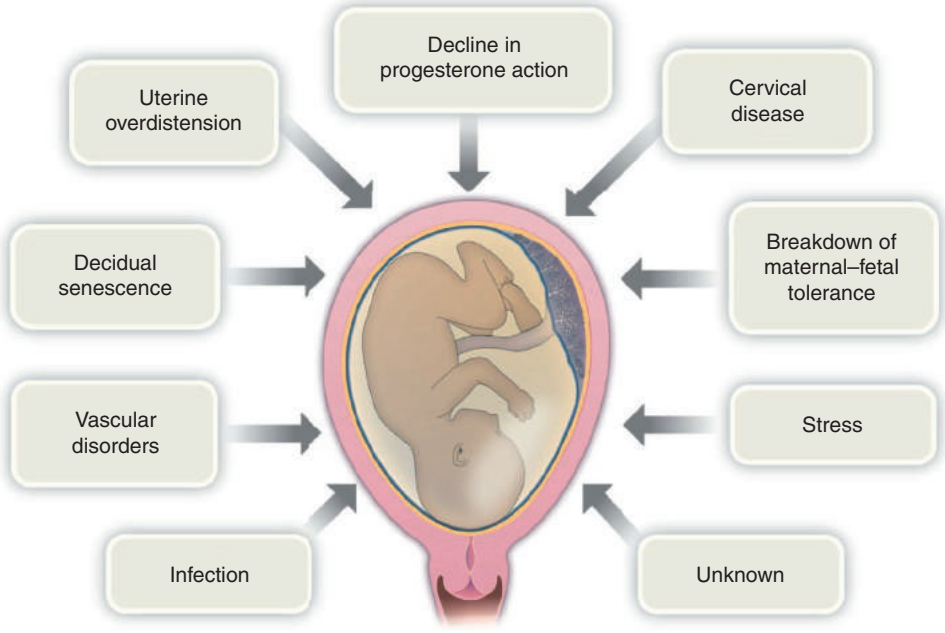
Multiple studies have demonstrated elevated risk of preterm birth among black women. The rate of preterm birth among non-Hispanic black women is as high as 14.4%, compared with 10.2% in the general United States population.[4] From 2015 to 2017, preterm births in the United States were most common among non-Hispanic black mothers and non-Hispanic black fathers and least common among non-Hispanic white mothers and non-Hispanic white fathers (10.8% vs. 6.5%).[26] Such disparities are augmented in early preterm birth (<28 weeks gestation), with preterm birth rates up to three to four times higher among black women.[26–28] Elevated risk remains after controlling for socioeconomic status and psychosocial risk factors, which themselves are associated with preterm birth.[11,26,29–31] Disparities are more modest to nonexistent for Hispanic women, despite social disadvantage within this group.[10] Other studies have found that the rate of preterm birth varies greatly based on geographic location and is driven by socioeconomic and demographic characteristics of those locales but possibly less so for blacks than whites.[32–34] Other factors associated with lower socioeconomic status, including educational background, extremes of maternal age, short interval between pregnancies (<6 months), and single marital status, have been independently associated with preterm birth.[35–41]



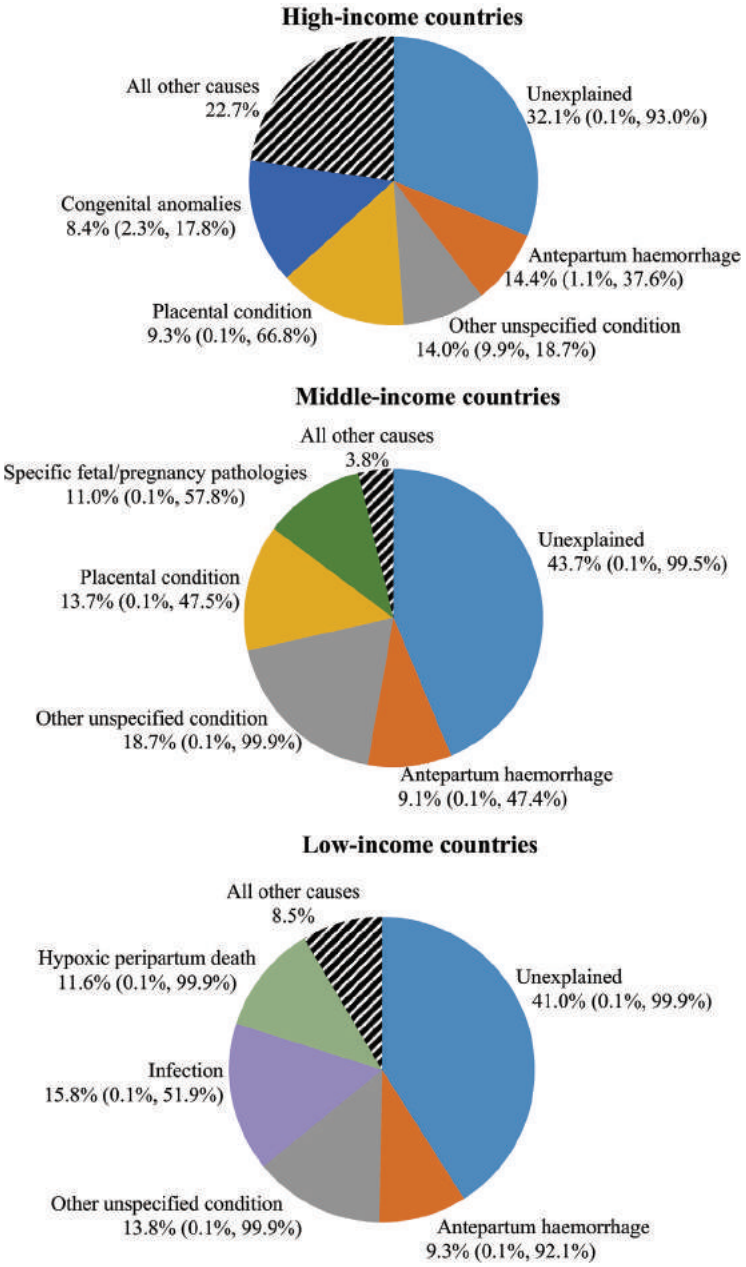
• **Fig. 6.3** Obstetric Precursors of Preterm Birth. (From Goldenberg RL, Culhane JF, Iams JD, Romero R. Epidemiology and causes of preterm birth. *Lancet*. 2008;371:75–84.)

Some portion of the racial/ethnic and socioeconomic disparities in preterm birth can be explained by increased psychosocial stress among these populations.[42,43] Several studies have found that maternal stress, as measured by a survey of life events and/or biomarkers of activation of the hypothalamic-pituitary-adrenal axis, is also strongly associated with preterm birth.[44–46] However, interventions to reduce stress have had limited success in preventing preterm birth.[47] Other factors proposed to contribute to disparities include nutrient deficiencies and infection, although further research is needed to clarify their roles.[48,49]

The longstanding disparities in preterm birth and perinatal outcomes which have been observed and studied over the last several decades have illuminated the role of structural racism on equity in health and health outcomes. While "race" has been considered in medical research as a demographic characteristic, it should be noted that "race" is not a biological construct per se but rather a sociopolitical construct that reflects the impacts of generational oppression, discrimination, and racism.[50] Maternal exposure to interpersonal racism has been associated with preterm



• **Fig. 6.4** Proposed Mechanisms of Disease Implicated in Spontaneous Preterm Labor. (From Romero R, Dey SK, Fisher SJ. Preterm labor: one syndrome, many causes. *Science*. 2014;345:760–765.)



• **Fig. 6.5** Causes of stillbirth, top five pooled estimates from representative country reports by income setting. (From Reinebrant HE, Leisher SH, Coory M, et al. Making stillbirths visible: a systematic review of globally reported causes of stillbirth. *BJOG*. 2018;125:212–224.)

birth rates and very low birth weight, and further, chronic "worry" about racial discrimination among African-American women was associated with elevated preterm birth rates.[51–53] The effect of structural racism on birth outcomes can also be gleaned from studies of preterm birth disparities by region. For example, in the United States, states with higher rates of police killings among unarmed black people were observed to have higher disparities in preterm birth rates.[54] Generational effects of racism, discrimination and oppression have affected economic mobility, housing security, access to education, exposure to stress and violence, environmental exposures, access to healthcare, quality of healthcare, and other factors which have been associated with adverse perinatal outcomes.[55–61]

Environmental Factors

Exposure to toxins—both self-inflicted and environmental—has been shown to increase the risk of preterm birth. Tobacco smoking during pregnancy is one of the most significant of these exposures.[62,63] The mechanism is unclear but may involve systemic inflammation (leading to spontaneous preterm birth) or placental vasoconstriction from nicotine causing fetal growth restriction, which, in turn, may lead to a medically indicated preterm birth.[10] Environmental tobacco smoke exposure has also been linked to adverse birth outcomes, including preterm birth.[64,65] Electronic nicotine delivery systems have been insufficiently studied in pregnancy, though increased risk of preterm

birth was described in electronic cigarette users participating in the United States Pregnancy Risk Assessment Monitoring System, a large nationally representative surveillance program for adverse pregnancy outcomes.[66] Marijuana use during pregnancy has been linked to preterm birth, including when used simultaneously with tobacco.[67–69]

Alcohol has not been consistently linked to risk of preterm birth, although cocaine and other illicit substances increase preterm birth risk, likely via alteration of placental blood flow and/or placental abruption.[70–72] Polysubstance use, including concurrent tobacco smoking and use of either stimulant or depressant drugs, is associated with preterm birth.[72,73]

Caffeine use during pregnancy has been associated with stillbirth in several observational studies; findings regarding its association with preterm birth have been inconsistent.[74] Higher levels of caffeine use are more frequently associated with these adverse pregnancy outcomes, suggesting possible causation.[74] American College of Obstetrics guidance, most recently reaffirmed in 2020, states that moderate caffeine consumption–less than 200 mg/day–is safe in pregnancy.[75]

Environmental air pollution has been associated with increased risk of preterm birth. There are myriad air pollutants that have been investigated, including ozone, carbon monoxide, sulfur dioxide, and lead, among others.[44,76–78] Both cumulative air pollution over the course of the pregnancy and during the week prior to delivery have been linked to increased risk of preterm birth.[78,79]

Exposure to other toxicants, including various pesticides and heavy metals, such as lead and cadmium, has also been associated with preterm birth.[80–82] Heavy metals can induce oxidative stress and inflammation in the placenta, thereby increasing risk of preterm birth.[82] Per- and polyfluoroalkyl substances (PFAS), which can be found in food packaging, commercial household products, and drinking water, have been linked to disruption of placental vasculogenesis and a proinflammatory state, though association with increased preterm birth has not been consistently demonstrated in studies to date.[83] Further studies are needed to examine the relationship between these exposures and risk of preterm birth and other adverse pregnancy outcomes.

Nutrition and Maternal Body Weight

Obesity, defined as body mass index (BMI) greater than or equal to 30 kg/m^2, is a major global health problem, affecting hundreds of millions of people worldwide. Prepregnancy obesity is a known risk factor for preterm birth.[84–88] Comorbidities associated with obesity, such as diabetes and hypertension, may contribute to this obesity-preterm birth association.[89–91] The biologic mechanisms behind the association may involve pathologic inflammation and altered vascular development.[92–95] Exercise during pregnancy for women who are overweight or with prepregnancy obesity is associated with a lowering of the risk of preterm birth and gestational diabetes.[96] Low maternal BMI is also a risk factor for spontaneous preterm birth.[97] Poor nutrient intake is associated with both low and high BMI and serves as one potential explanation for their association with preterm birth. Iron deficiency anemia, lower intakes of nutrients, such as folic acid and other B vitamins, zinc, calcium, magnesium, and polyunsaturated fatty acids, and higher dietary glycemic index have all also been associated with an increased risk.[33,48,98]

Infection and Microbiota

More than one-fourth of preterm births can be attributed to intra-amniotic infection, in which microorganisms perturb maternal-fetal homeostasis and trigger a cascade of biologic signals that initiate spontaneous preterm labor (PPROM) or fetal distress that leads to indicated preterm delivery.[99–103] Microorganisms and their immunogenic cellular components activate toll-like receptors, chemokines, and cytokines, which tips the balance of maternal-fetal tolerance and leads to uterine contractility, rupture of amniotic membranes, and preterm delivery.[13,104] Activation of the intra-amniotic, inflammasome, cytoplasmic, multiprotein complexes responsible for the inflammatory response has been implicated in both preterm labor with intact membranes and PPROM and is associated with intraamniotic microbial burden.[105–108]

The role of microorganisms in preterm birth is often subclinical, in which there are no signs or symptoms of overt maternal infection. One study showed that more than one fifth of preterm newborns have umbilical cords colonized by *Mycoplasma* spp.[109] *Ureaplasma* spp. have been isolated in the cervical fluid of women with preterm labor and confirmed intraamniotic infection as well as those without infection but with documented, sterile, intraamniotic inflammation.[110] Asymptomatic bacterial vaginosis was described as a risk factor for preterm birth in a 2007 metaanalysis, although treatment of bacterial vaginosis has not been shown to reduce risk of preterm delivery.[111,112] Asymptomatic vaginal *Candida* spp. colonization has not been associated with preterm birth.[113]

Sexually transmitted infections that have been associated with increased risk of preterm birth include chlamydia, gonorrhea, syphilis, and new human immunodeficiency virus (HIV) infection.[114–117] Urinary tract infections are a known risk factor for preterm birth.[118] Additionally, treatment of asymptomatic bacteriuria during pregnancy is associated with decreased risk of subsequent preterm birth; screening for asymptomatic bacteriuria in pregnancy thus is recommended in the United States.[119,120] Periodontal disease also increases the risk of preterm birth.[121,122] Unfortunately, treatment of periodontal infections does not reduce the rate of preterm birth.[123–125]

Infection has also been implicated in stillbirth. In a prospective population-based cohort study in the United States, infection was a probable or possible cause in 12.9% of stillbirths, with *Escherichia coli*, GBS, and *Enterococcus* spp. among the identified pathogens.[126] These bacterial pathogens were also associated with stillbirth in the context of fetal infection in a South African study.[127] Historically, listeriosis has been associated with stillbirth, although incidence of pregnancy-related listeriosis is declining in the United States and other high-income countries.[128,129] Syphilis rates during pregnancy, on the other hand, are on the rise in the United States, and maternal syphilis may increase the odds of stillbirth as much as five-fold.[115]

There is also evidence that the microbiome, and perturbations therein, plays an important role in maternal-fetal tolerance and preterm birth.[130–134] In particular, reduced prevalence of vaginal *Lactobacillus* spp. and resultant vaginal dysbiosis are associated with increased risk of preterm birth.[17,135] Recent advances have enabled sequencing and amplification of deoxyribonucleic acid (DNA) from myriad microbial communities, revealing complex potential interactions between these microbial communities and

clinical pregnancy outcomes.[17] Study of microbial communities during pregnancy, and microbiota in general, represents an important and exciting frontier in the effort to further our understanding of preterm birth.

SARS-CoV-2 Infection in Pregnancy

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection in pregnancy deserves special consideration. Other betacoronaviruses responsible for Middle East respiratory syndrome (MERS) and SARS were associated with adverse pregnancy outcomes, including fetal demise and preterm birth, although there are limited reports of these infections in pregnancy and no documented vertical transmission.[136,137] While vertical transmission of SARS-CoV-2 appears to be a rare outcome of maternal coronavirus disease 2019 (COVID-19), cases of both preterm birth and stillbirth with positive SARS-CoV-2 polymerase chain reaction (PCR) testing of the placenta, amniotic fluid, and cord blood have been described.[138] A multi-country cohort study revealed increased risk of preterm birth, including medically indicated preterm birth, among pregnant women with COVID-19 when compared to noninfected pregnant women controls.[139] Stillbirth, including in the context of maternal critical illness, has been reported with COVID-19, although it is unclear how stillbirth rates due to COVID-19 compare to the population incidence of stillbirth.[138] The broader impact of the COVID-19 pandemic on pregnant women, including on population-level preterm birth rates, continues to be explored, with some reports of decreased preterm birth rates and others suggesting no effect. [140–142]

Genetic Factors

Preterm birth tends to run in families and appears to be inherited across generations.[143,144] The heritability of preterm birth has been estimated to be 15% to 40%.[15,145] Women with a prior history of preterm birth have more than a twofold increased risk of preterm birth in the subsequent pregnancy, although environmental factors may also explain this finding.[146]

Advances in our ability to conduct genome-wide association studies—and to do so in a cost-effective manner—have led to increased interest in the study of single-nucleotide polymorphisms. Several large genome-wide association studies were recently conducted and found no definitive evidence of association between preterm birth and any one single nucleotide polymorphism.[147–151] However, additional analyses suggest that gene-gene interactions, particularly those related to cell motility and migration, glucocorticoid response, inflammation, and metabolic disorders, may affect the risk of preterm birth.[147,150,151] Several candidate genes have been identified by other investigators, but there are many inconsistencies in the data and findings.[152–155]

These inconsistencies may arise from the complex gene-gene and gene-environment interactions related to preterm labor and/or delivery.[149,155–157] One study found an association between a tumor necrosis factor-alpha allele, bacterial vaginosis, and preterm birth, although neither maternal carrier status nor bacterial vaginosis alone was associated with preterm birth.[158] Similar interactions with bacterial vaginosis were reported in a study on maternal carrier status of an interleukin-6 allele among black women.[153] Genomic studies exploring preterm birth lag behind progress for many other multifactorial diseases.[159] As we refine our ability to conduct genetic and epigenetic research and to do so more affordably, we will continue to take incremental steps toward solving the puzzle of preterm birth.

Placental and Pregnancy Factors

Several factors associated with disruption of the uterine environment during pregnancy have been associated with preterm birth.[14] Abnormal vascular development of the placenta is a frequent occurrence among women who deliver before term.[160,161] Abnormal placental villous maturation has been implicated in spontaneous preterm labor.[162] Perturbations of placentation may also account for many other adverse pregnancy outcomes that are seen in clinical practice and often cooccur with preterm birth, such as intrauterine growth restriction and preeclampsia.[163] Vaginal bleeding, isolated or associated with placental abruption or placenta previa, also carries increased risk of preterm delivery.[164]

Overdistension of the uterus, caused by multiple gestation or polyhydramnios, substantially increases the risk of preterm birth.[165–168] More than half of twin pregnancies result in delivery prior to 37 weeks gestation, likely because of mechanical distension from increased fetal mass and other comorbidities associated with multiple gestation. Among twin pregnancies, monochorionicity is a risk factor for preterm birth, as is twin-to-twin transfusion syndrome.[169,170] Anatomic abnormalities of the uterus and previous uterine or cervical surgical intervention also increase the risk of preterm birth.[171,172] Likewise, short cervix and cervical insufficiency carry increased risk, which varies greatly depending on degree of shortening.[173,174]

Prevention of Preterm Birth

Efforts to prevent—and predict—preterm birth have largely failed, although several targeted interventions, including low-dose aspirin and 17-hydroxyprogesterone, have been shown to reduce the risk of preterm birth among women at high risk for adverse pregnancy outcomes, such as women with a personal history of preterm birth or stillbirth.[175–179] Use of cervical cerclage among patients with short cervix and a history of preterm birth has effectively reduced the risk of preterm birth among this small subset of women.[179–181] Population-level interventions that address underlying disparities, such as improving access to prenatal care or other public policies related to smoking cessation or environmental pollution, may reduce the overall rate of preterm birth.[182] A recent systematic review of interventions during pregnancy to prevent preterm birth identified four interventions with clear evidence of benefit: midwife-led continuity models of care versus other models of care for all women; screening for lower genital tract infections for pregnant women less than 37 weeks gestation and without signs of labor, bleeding or infection; and zinc supplementation for pregnant women without systemic illness.[183]

Other obstetrical interventions have been successful at mitigating the neonatal morbidity and mortality associated with preterm birth, such as antibiotics, antenatal betamethasone, magnesium sulfate, and tocolytic agents, but these interventions rarely prevent delivery prior to 37 weeks gestation.

Over the last 25 years, considerable global attention has emerged on the plight of newborns in the world, starting with the inclusion of targets to reduce child mortality in the Millennium Development Goals (MDGs) in 2000 and more explicit targets for newborn mortality reduction in the Sustainable Development Goals in 2015. In addition to providing a "north star" for health

and development until 2015, the MDGs were successful at leveraging the attention, political will, and resources of the global community, nations, regions, researchers, aspiring innovators, and initiative leaders, all working toward a common goal. The Sustainable Development Goals (SDGs) were built on the successes and lessons learned from the MDGs and represented a new era of global health and development. While the SDGs are much more comprehensive, holistic, and ambitious and extend beyond the health and development sectors into a more integrated whole, some critics are challenged by the differences in their design, context, concept, scope, significance, targets, and approach. In 2016, a large array of countries and their newborn stakeholders, including Ministries of Health and Finance, academics, programmers, NGOs, funders, policymakers, clinicians, and, most importantly, civil society groups came together to develop and launch the Every Newborn Action Plan that galvanized efforts to reduce both neonatal mortality and stillbirths globally (Box 6.1).[184] Figure 6.6 outlines the estimated effect of intervention packages in 2014 on numbers of neonatal lives saved and the costs according to levels of care by the year 2025, with available interventions estimated to reduce deaths due to prematurity by 58% and prevent approximately 550,000 stillbirths.[185] While prevention of preterm birth

	Preconception nutrition care	Antenatal care	Care during labor and childbirth including complications	Immediate newborn care	Care of the healthy neonate	Care of the small and ill neonate

Can available interventions end preventable deaths in mothers, newborn babies, and stillbirths, and at what cost? *Lancet*. 2014;384:347–370.)

• BOX 6.1 The Every Newborn Action Plan

Vision

A world where there are no preventable deaths of newborns or stillbirths, where every pregnancy is wanted, every birth celebrated, and women, babies, and children survive, thrive, and reach their full potential.

Every Newborn Action Plan Goals and Targets

- End preventable newborn death: by 2035, all countries should have a neonatal mortality rate of 10 or less per 1000 live births
- End preventable stillbirth: by 2035, all countries should have stillbirth rates of 10 or less per 1000 total births
- A global neonatal mortality rate of 7 deaths per 1000 live births by 2035

Strategic Objectives

- Strengthen and invest in care during labor, childbirth, and the first day and week of life
- Improve the quality of maternal and newborn care
- Reach every woman and every newborn to reduce inequities
- Harness the power of parents, families, and communities
- Count every newborn: measurement, program tracking, and accountability

Guiding Principles

- Country leadership
- Integration
- Equity
- Accountability
- Innovation

and mortality attributable to preterm birth are not specific targets of global efforts, it is clear that targeted reductions in child and neonatal mortality cannot be achieved without specific focus on improving survival among preterm newborns. While *prevention* of premature delivery by a mother remains somewhat elusive and continues to attract ongoing research attention primarily in high-income countries, *management* of premature babies in all settings, particularly low- and middle-income countries, has received increasing attention over the past 15 years.

There are numerous inequities that must be combated in the global struggle to improve newborn health. In general, regions that have the highest neonatal mortality rates also have the lowest healthcare worker density.[186] Three-quarters of the world's physicians are working in high-income countries, serving approximately one-third of the world's population. Further analysis suggests that in Africa, 3% of the world's healthcare workforce has 1% of the world's expenditure on health to tackle approximately 24% of the global burden of disease.[187] Without a clear and concerted effort to address these long-standing inequities, the disparities in perinatal outcomes globally will persist.

Summary

Further study of the causal pathways of preterm birth and stillbirth, many of which are shared, may lead to discovery of more direct ways to control the biology of pregnancy. Preliminary evidence already exists for effective prevention of preterm birth through interference with some of these pathways.[177] Future interventions may take the form of targeted pharmaceuticals or community-based interventions that indirectly affect the biology, such as implementation of policies related to socioeconomic disparities or nutrition. Understanding when and where we are able to intervene to prevent preterm birth will require collaboration on large and transdisciplinary scales with concomitant integration of data from multiple levels of inquiry.[188] In particular, continued progress in prevention of preterm birth and stillbirth in low resource settings will require sustained investment in building capacity for maternal and child health on a global scale.

Nonimmune Hydrops

DALAL K. TAHA AND SCOTT A. LORCH

KEY POINTS

- Nonimmune hydrops fetalis results from many etiologies.
- Management involves correcting the underlying cause.
- The condition is associated with significant morbidity and mortality.
- Some etiologies are amenable to treatment in utero.

A newborn with hydrops has an abnormal accumulation of fluid. The condition varies from mild, generalized edema to massive anasarca with effusions in multiple body cavities and with peripheral edema so severe that the extremities are fixed in extension. Fetuses with severe hydrops may die in utero; if liveborn, they may die in the neonatal period from the severity of their underlying disease or from severe cardiorespiratory failure.

The first description of hydrops in a newborn twin may have appeared in 1609.[1] Ballantyne[2] suggested that the finding of hydrops was an outcome from many different causes, in contrast to the belief at that time that hydrops was a single entity. Potter[3] was the first to make the distinction between nonimmune hydrops and hydrops secondary to erythroblastosis fetalis by describing a group of infants with generalized body edema who did not have hepatosplenomegaly or abnormal erythropoiesis. Potter's description of more than 100 cases of hydrops included two sets of twins in which one had hydrops and the other did not, thus presenting the first description of twin–twin transfusion syndrome. With the nearly universal use of anti-D globulin and refinement of the schedule and doses for its administration, the occurrence of immune-mediated hydrops has steadily declined and may be as low as 6% to 10% of all cases of hydrops.[4]

Incidence

Determining the incidence of nonimmune hydrops in the general population is difficult because of biases in the pregnancy cohorts selected, as well as the accuracy of coding for nonimmune hydrops in those pregnancies. Most published studies come from single institutions with the at-risk populations ranging from that of a high-risk pregnancy clinic to infants in a neonatal intensive care unit and generally predating the more routine use of ultrasound investigation in the late first trimester of pregnancy.[5] Incidence rate of hydrops reported in those studies has been highly variable and generally higher than other studies, ranging from 6 per 1000 pregnancies in a high-risk referral clinic in the United Kingdom between 1993 and 1999[6] to 1 in 4000 pregnancies,[7] 6 per 1000 pregnancies,[8] 1.3 per 1000 pregnancies,[9] and 1 per 1700 pregnancies.[10] Two recent publications using population-based data found lower overall rates: a recent publication from Sweden using more than 1.9 million births extracted from the Swedish Birth Register for 1997–2015 found 309 cases of nonimmune hydrops at birth, which corresponded to an incidence of 1.6 per 10,000 births,[11] while data from California identified 1037 cases using ICD-9CM diagnosis codes from 4,090,950 live births, which corresponded to an incidence of 2.5 per 10,000 births between 2005 and 2012.[12] However, these lower rates may suffer from lack of information on fetuses who died in utero and from potential undercoding of the disorder in live birth infants. Geography also affects the incidence; for example, several causes of nonimmune hydrops, such as α-thalassemia, are more common in certain areas of the world. Hence, the actual incidence of nonimmune hydrops likely falls within a wide range of values reported from population and single center-based estimates.

Etiology

Nonimmune hydrops has been associated with a wide range of conditions (see Table 7.1). In many of these conditions, edema formation results from one of the following possible processes:

- Elevated central venous pressure (CVP) in which the cardiac output is less than the rate of venous return
- Anemia, resulting in high-output cardiac failure
- Congenital lymphatic flow disorder
- Capillary leak

The actual pathophysiology of hydrops for many of the conditions in Table 7.1, however, is still not understood.

The most common causes of nonimmune hydrops are chromosomal, lymphatic, cardiovascular, hematologic, thoracic, infectious, and conditions related to twinning.[11–15] As with reported incidence rates, the relative contribution of these causes varies by study. The studies that focus on early fetal presentation of hydrops (postconceptional age of less than 24 weeks' gestation) have found that chromosomal abnormalities, such as Turner syndrome and trisomies 13, 18, and 21, contribute 32% to 78% of all cases of hydrops.[5,6,10,16,17] For fetuses whose hydrops becomes evident after 24 weeks' gestation, cardiovascular and thoracic causes are most prevalent, with rates ranging between 30% and 50%.[17,18] Studies from Asia have noted a higher percentage of cases from hematologic causes, probably because of the higher rates of α-thalassemia in the population.[19,20]

A review of studies published between 2008 and 2013 suggests a potential change in the etiologies of nonimmune hydrops when compared with studies published between 1979 and 2008.[4] These more recent studies reported a higher rate of lymphatic etiologies

TABLE 7.1 Conditions Associated With Hydrops Fetalis

Condition Type	Specific Conditions
Hemolytic anemias	Alloimmune, Rh, Kell, α-chain hemoglobinopathies (homozygous α-thalassemia) Red blood cell enzyme deficiencies (glucose phosphate isomerase deficiency, glucose-6-phosphate dehydrogenase)
Other anemias	Fetomaternal hemorrhage Twin–twin transfusion Diamond–Blackfan
Cardiac conditions	Premature closure of foramen ovale Ebstein anomaly Hypoplastic left or right heart Subaortic stenosis with fibroelastosis Cardiomyopathy, myocardial fibroelastosis Atrioventricular canal Myocarditis Right atrial hemangioma Intracardiac hamartoma or fibroma Tuberous sclerosis with cardiac rhabdomyoma
Cardiac arrhythmias	Supraventricular tachycardia Atrial flutter Congenital heart block
Vascular malformations	Hemangioma of the liver Any large arteriovenous malformation Klippel–Trénaunay syndrome Idiopathic infantile arterial calcification
Vascular accidents	Thrombosis of umbilical vein or inferior vena cava Recipient in twin–twin transfusion
Infections	Cytomegalovirus, congenital hepatitis, human parvovirus, enterovirus, other viruses Toxoplasmosis, Chagas disease Coxsackie virus Syphilis Leptospirosis
Lymphatic abnormalities	Congenital lymphatic dysplasia Lymphatic malformations Lymphangiectasia Cystic hygroma Noonan syndrome Multiple pterygium syndrome Congenital chylothorax Hereditary lymphedema type 1
Nervous system lesions	Absence of corpus callosum Encephalocele Cerebral arteriovenous malformation Intracranial hemorrhage (massive) Holoprosencephaly Fetal akinesia sequence
Pulmonary conditions	Cystic adenomatoid malformation of the lung Mediastinal teratoma Diaphragmatic hernia Lung sequestration syndrome Lymphangiectasia
Renal conditions	Urinary ascites Congenital nephrosis Renal vein thrombosis Invasive processes and storage disorders Tuberous sclerosis Gaucher disease Mucopolysaccharidosis Mucolipidosis
Chromosome abnormalities	Trisomy 13, trisomy 18, trisomy 21 Turner syndrome 46, XX/XY chimerism
Bone diseases	Osteogenesis imperfect Achondroplasia Asphyxiating thoracic dystrophy
Gastrointestinal conditions	Bowel obstruction with perforation and meconium peritonitis Small bowel volvulus Other intestinal obstructions Prune-belly syndrome
Tumors	Neuroblastoma Choriocarcinoma Sacrococcygeal teratoma Hemangioma or other hepatic tumors Congenital leukemia Cardiac tumors Renal tumors
Maternal or placental conditions	Maternal diabetes Maternal therapy with indomethacin Multiple gestation with parasitic fetus Chorioangioma of placenta, chorionic vessels, or umbilical vessels Toxemia Systemic lupus erythematosus
Miscellaneous	Neu–Laxova syndrome Myotonic dystrophy Hereditary lymphedema type 1
Idiopathic	

(15.0% compared with 5.7% in older studies) and a lower rate of thoracic or chromosomal etiologies. Idiopathic hydrops, or hydrops of unknown etiology, remained constant at between 18% and 20% of all cases. As with older studies, papers published between 2008 and 2013 varied widely in the prevalence of specific etiologies depending on the ability of the clinicians to complete their diagnostic evaluation, geography, and the inclusion of fetal deaths in the analysis.* Finally, population-based data from California births between 2005 and 2012 found similar etiological results for live-born infants. Aneuploidy was found in 116 of 1037 infants with nonimmune hydrops (11.2%), lymphatic causes in 9.2% of all cases, and 29.1% of cases with a diagnosis of hydrops of unknown etiology.[12] It is likely that with increased understanding and the availability of genetic testing for many of the conditions listed in Table 7.1, the number of infants diagnosed with idiopathic, nonimmune hydrops will continue to decline.

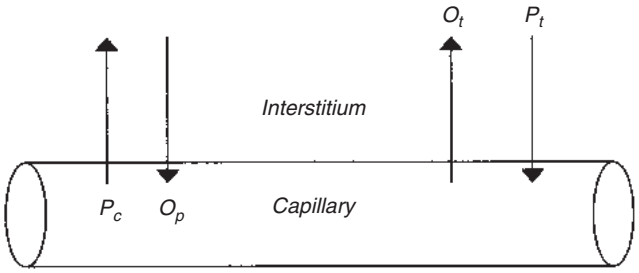
Pathophysiology

Normal Fluid Homeostasis

Abnormal body fluid homeostasis is the underlying cause of edema, whether localized or generalized. To understand the pathogenesis of hydrops, the clinician must consider the forces underlying normal fluid homeostasis that underpin a general pathophysiologic pathway for this disorder (Fig. 7.1) as proposed by Bellini et al.[24] The regulation of net fluid movement across a capillary membrane depends on the Starling forces, which were first described by E. H. Starling.[25] Flow between intravascular and interstitial fluid compartments is determined by the balance among (1) capillary hydrostatic pressure, (2) serum colloid oncotic pressure, (3) interstitial hydrostatic pressure or tissue turgor pressure, and (4) interstitial osmotic pressure, which depends on lymphatic flow. The Starling equation defines the relationship among these forces and their net effect on net fluid movement, or filtration, across a semipermeable membrane (such as the capillary membrane) as:

$$\text{Filtration} = K([P_c - P_t] - R[O_p - O_t])$$

where K = capillary filtration coefficient, representing the extent of permeability of a membrane to water and thus describing capillary integrity; P_c = capillary hydrostatic pressure; P_t = interstitial hydrostatic pressure or tissue turgor pressure; R = reflection coefficient for a solute, representing the extent of permeability of the capillary wall to that solute; O_p = plasma oncotic pressure as determined by plasma proteins and other solutes; and O_t = interstitial osmotic pressure (Fig. 7.2).



• **Fig. 7.2** Starling Forces and Net Effect on Fluid Homeostasis. *Arrows* represent net effect of movement of fluid across the capillary membrane for each factor under normal conditions. P_c, Capillary hydrostatic pressure; P_t, interstitial hydrostatic pressure or tissue turgor pressure; O_p, plasma oncotic pressure as determined by plasma proteins and other solutes; O_t, interstitial osmotic pressure.

Although an abnormality of any of the components of this equation may, in theory, result in the accumulation of edema fluid, the fetal–placental unit presents a unique physiologic condition that effectively eliminates two of the factors, assuming unimpeded fetal–placental flow and an appropriately functioning maternal–placental interface. Because approximately 40% of fetal

cardiac output is allocated to the placenta, there is rapid transport of water between the fetus and mother. Any condition resulting in elevated fetal capillary hydrostatic pressure or low plasma colloid oncotic pressure would likely cause the net flow of water from fetal villi in the placenta to the maternal blood stream where it can be effectively eliminated. This elimination of fluid would counteract the accumulation of interstitial fluid by the fetus. Although the placenta of a fetus with hydrops is also edematous, these changes are believed to occur with, and not before, fetal fluid accumulation.

Derangements in Fluid Homeostasis

Elevated Central Venous Pressure

The most commonly diagnosed causes of nonimmune hydrops that appear in fetuses older than 24 weeks' gestation are cardiac disorders. Any state in which cardiac output is lower than the rate of venous return results in an elevated CVP that raises capillary filtration pressures and, if high enough, restricts lymphatic return. Both of these mechanisms may then contribute to an interstitial accumulation of fluid. Structural cardiac causes of elevated CVP include right-sided obstructive lesions and valvular regurgitation. The most common and easily reversible cause of nonimmune hydrops is supraventricular tachycardia (SVT). In general, cardiac output rises with heart rate. At the increasingly high rates seen in SVT, however, cardiac output plateaus and then diminishes over time. The heart rates observed with SVT are often associated with decreased cardiac output. Impaired cardiac output results in elevated CVP, which can give rise to edema through mechanisms discussed previously.[26]

Infants with alloimmune hydrops (and several of the nonimmune hydropic conditions as well) have significant anemia that may also result in elevated CVP. It has been proposed that anemia leads to congestive heart failure with increased hydrostatic pressure in the capillaries, causing vascular damage that results in edema. However, the hematocrit values of infants with and without hydrops overlap significantly, suggesting that anemia alone is not the only explanation. A rapid decrease in hemoglobin concentration requires increased cardiac output in order to maintain adequate oxygen delivery. This increased cardiac output results in higher oxygen demands by the myocardium, which may be difficult to meet because of the anemia. The hypoxic myocardium can become less contractile and less compliant, with ventricular stiffness causing increased afterload to the atria. High-output congestive heart failure may then develop, resulting in elevated CVP. Raised CVP leads to increased capillary filtration pressures and impaired lymphatic return.[27]

An intrathoracic mass such as a pulmonary malformation may also increase CVP, resulting in impaired filling of the right ventricle and consequent increased capillary hydrostatic pressure. While the underlying reason for the elevated CVP differs between these two conditions, the resulting clinical presentations are similar.

Congenital Lymphatic Flow Disorders

If the rate of fluid filtration from plasma to tissues exceeds the rate of lymph return to the central venous system or if there is obstruction to lymphatic flow from the thoracic duct, then edema and effusions may form. To determine the effects of alterations in CVP on lymphatic return, Gest[28] inserted a catheter into the thoracic duct of fetal lambs and applied an opposing hydrostatic pressure by varying the height of the catheter. Thoracic duct flow was nearly constant over the physiologic range of CVP but sharply decreased at elevated pressures; therefore, lymphatic flow may be reduced or essentially blocked in pathologic states associated with elevated CVP.

Lymphatic causes of hydrops include congenital lymphovenous atresia—in which the thoracic duct outlet is not anatomically connected to the venous circulation—or complete absence of the thoracic duct. Pulmonary lymphangiectasia or pulmonary lymphatic perfusion syndrome may also result in hydrops fetalis if fetal pleural effusions are significant enough to cause mediastinal shift and compression of the heart and lungs.

Recent advances in the radiographic evaluation of the lymphatic system using magnetic resonance imaging (MRI) and lymphangiography have improved the assessment of this system and led to classification of neonatal lymphatic flow disorders.[29] In 1995 Constantin Cope showed that percutaneous transabdominal access of the thoracic duct through the cisterna chyli was not only feasible but led to better opacification of the thoracic duct in cases of chylothorax.[30] This method of imaging the lymphatic system has been used in neonates with congenital lymphatic flow disorders to diagnose abnormalities of the thoracic duct and/or the thoracic duct outlet.

Decreased Oncotic Pressure

A third potential etiology for nonimmune hydrops is hypoalbuminemia. The most convincing evidence for this etiology is in conditions where reduced compliance of a right ventricle may result in flow reversal in the inferior vena cava, which may in turn cause end-organ damage to the liver with consequent hypoalbuminemia and portal hypertension, enhancing formation of both edema and ascites. Hydrops has been produced in fetal lambs[31] in which the hemoglobin content was lowered in 12 fetuses through exchange transfusion using cell-free plasma; six became hydropic. Anemia developed more rapidly with a higher CVP in fetuses with hydrops than in the fetuses without hydrops. In the most severely anemic fetuses, it is probable that decreased oxygen transport causes tissue hypoxia, which in turn increases capillary permeability to both water and protein. These changes in capillary permeability may contribute to the development of hydrops.

However, human fetuses with hypoproteinemia as a result of nephrotic syndrome or analbuminemia rarely experience hydrops, supporting the hypothesis that hypoproteinemia alone is not sufficient to cause hydrops. To elucidate the role of isolated hypoproteinemia in the genesis of hydrops, Moise et al.[32] induced hypoproteinemia in sets of twin fetal lambs. One twin from each set underwent serum protein reduction through repeated removal of plasma and replacement with normal saline; the other twin served as the control. Over 3 days, plasma protein concentrations were reduced by an average of 41% with a 44% reduction in colloid osmotic pressure in experimental subjects. No fetal animals became edematous, and total body water content values were similar in experimental and control animals. Thus hypoproteinemia alone was insufficient to cause hydrops fetalis over the course of the study. Transcapillary filtration probably increased with hypoproteinemia but was compensated for by lymphatic return. Hypoproteinemia may lower the threshold for edema formation in the presence of impaired lymphatic return or increased intravascular hydrostatic pressures.

Increased Capillary Leak

One final potential etiology for hydrops is increased capillary leak. Increased capillary leak is typically identified not as a primary mechanism for hydrops but as part of the pathway between nonimmune hydrops and other insults, such as infection, hypoxic injury, or increased capillary hydrostatic pressure seen with elevated CVP or decreased or abnormal lymphatic flow.[24]

Prenatal Diagnosis

The prenatal diagnosis of hydrops fetalis is typically made via the ultrasonographic finding of excess fluid in the form of ascites, pleural or pericardial effusions, skin edema, placental edema, or polyhydramnios. Several definitions for ultrasonographic diagnosis based on quantity and distribution of excess fluid have been proposed. One widely accepted set of criteria consists of the presence of excess fluid in any two of the previously listed compartments. A 2015 study suggested that the involvement of more body compartments is associated with higher mortality.[33] Because this definition is based on the presence of excess fluid alone, the degree of severity is generally subjective.

Swain et al.[34] and Bellini and Hennekam[24] each outlined a multidisciplinary approach to the evaluation and management of a mother and fetus with hydrops. Table 7.2 provides recommendations for the antenatal investigation of fetal hydrops. Patient history should focus on ethnic background, familial history of consanguinity, genetic or congenital anomalies, and complications of pregnancy, including recent maternal illness and environmental exposures. Maternal disorders such as diabetes, systemic lupus erythematosus, myotonic dystrophy, and any type of liver disease should also be noted. Initial laboratory investigation includes blood typing and a Coombs test to rule out immune-mediated hydrops. Additional studies may include screening for hemoglobinopathies, a Kleihauer–Betke test to eliminate fetal–maternal hemorrhage, and testing for TORCH (i.e., toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex), including syphilis and parvovirus B19.

Rapid evaluation is necessary to determine whether fetal intervention is possible and to estimate the prognosis for the fetus. Many conditions, such as arrhythmias, twin–twin transfusion, large vascular masses, and congenital diaphragmatic hernias and other chest-occupying lesions, are discovered during the initial ultrasonographic evaluation.[35] Middle cerebral artery peak systolic velocity measurement can aid in detecting the presence of fetal anemia.[36] If the initial ultrasonic examination is not helpful in identifying a cause, it may be helpful to repeat it at a later date to reassess fetal anatomy, monitor progression of the hydrops, and evaluate the well-being of the fetus. Fetal MRI is being employed more commonly in cases of hydrops fetalis where the sonographic examination is unable to present a clear picture regarding etiology or to further delineate the anatomy in cases with a known anatomic etiology.

Fetal echocardiography should also be performed to evaluate for cardiac malformations and arrhythmia. Amniotic fluid can be obtained for fetal DNA analysis, cultures, and lecithin-to-sphingomyelin ratio to assess lung maturity. Fetal blood sampling allows for other tests, such as a complete blood cell count, routine chemical analyses, DNA analysis, bacterial and viral cultures, metabolic studies, and serum immunoglobulin measurements. Fetal thoracentesis may be done to establish a diagnosis. A pleural effusion cell count with a lymphocyte predominance would be suggestive of a lymphatic etiology of hydrops.

TABLE 7.2 Antenatal Investigation of Fetal Hydrops

Area	Testing
Maternal	History, including: Age, parity, gestation Medical and family histories Recent illnesses or exposures Medications Complete blood count and indices Blood typing and indirect Coombs antibody screening Hemoglobin electrophoresis Kleihauer–Betke stain of peripheral blood Syphilis, TORCH, and parvovirus B19 titers Anti-Ro and anti-La antibodies, systemic lupus erythematosus preparation Oral glucose tolerance test Glucose-6-phosphate dehydrogenase, pyruvate kinase deficiency screening
Fetal	Serial ultrasound evaluations Middle cerebral artery peak systolic velocity Limb length, fetal movement Echocardiography Fetal MRI Thoracentesis for pleural fluid cell count Thoracoamniotic shunt
Amniocentesis	Karyotype Alpha-fetoprotein Viral cultures; polymerase chain reaction analysis for toxoplasmosis, parvovirus 19 Establishment of culture for appropriate metabolic or DNA testing Lecithin-to-sphingomyelin ratio to assess lung maturity
Fetal blood sampling	Genetic testing Complete blood count Hemoglobin analysis Immunoglobulin M test; specific cultures Albumin and total protein measurements Measurement of umbilical venous pressure Metabolic testing

MRI, Magnetic resonance imaging; *TORCH*, toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex.

Prenatal Management

The goals of antenatal evaluation and management of fetal hydrops depend on the underlying cause. In diagnoses for which therapy is futile, management goals include avoiding unnecessary invasive testing and procedures and informing parents of the prognosis and their options—such as pregnancy termination or a perinatal palliative care plan in the event of a live birth. If the underlying cause is amenable to fetal therapy, the risks and benefits of such therapy, as well as the warning that diagnostic error is possible, should be discussed with the family.

SVT is one of the most common known causes of nonimmune hydrops, and it is the most amenable to treatment.[37,38] Usually the mother is given antiarrhythmic agents, and the fetus is monitored closely for resolution of the SVT. Digoxin is most commonly administered, although other antiarrhythmics have been used, such as sotalol or flecainide, because transplacental transfer of digoxin may be impaired in the setting of hydrops. In extreme circumstances, such as fetal tachyarrhythmia refractory to maternal treatment, direct fetal administration of antiarrhythmic agents via percutaneous umbilical blood sampling or intramuscular injection, although untested and highly risky, has met with some success.

If anemia is the cause of hydrops, transfusions of packed red blood cells may be administered to the fetus. Often a single transfusion reverses the edema, although serial transfusions may be necessary. Parvovirus B19[39] and fetal–maternal hemorrhage are examples of diagnoses that are amenable to this therapy. Transfusions should be given with the use of ultrasonographic guidance into the intraperitoneal space or umbilical vein. Blood instilled into the abdominal cavity is taken up by lymphatics, but elevated CVP present in hydropic fetuses may impair this uptake. If uptake of intraperitoneal blood is incomplete, treatment for the hydrops is less successful. In addition, degeneration of the remaining hemoglobin may create a substantial bilirubin load, necessitating phototherapy or exchange transfusion after the fetus is delivered. Other diagnoses involving anemias that are refractory to transfusions, such as α-thalassemia, may require neonatal stem cell transplantation.

High morbidity and mortality rates in severe twin–twin transfusion with associated hydrops led to multiple international trials of laser photocoagulation of interfetal vascular connections. A systematic review of 34 studies of 3868 patients published between 1990 and 2014 found improved survival comparing the 1990–1995 with the 2011–2014 epoch. Of pregnancies requiring laser photocoagulation, both twins survived in 65% of the pregnancies in the more recent epoch, with an additional 23% of pregnancies reporting a survival of one of the fetuses.[40] However, there is limited data on the impact of treatment on the neurodevelopmental outcomes in survivors. As a result, a Cochrane review recommends considering treatment with laser coagulation at all stages of twin–twin transfusion using results from three studies,[41,42] even though further research is needed to assess the effect of treatment on milder versus more severe forms of the syndrome.

Fetal intervention has met with some success in surgical defects and other conditions associated with hydrops.[43–45] While fetal lung lesions such as congenital cystic pulmonary malformation (CPAM) and pulmonary sequestration frequently involute and may disappear before delivery, in the most extreme cases they can result in mediastinal shift, pulmonary hypoplasia, cardiovascular compromise, and hydrops. The highest risk lesions for the development of hydrops include those lesions with a CPAM volume ratio greater than 2, an everted hemidiaphragm, or a mass-to-thorax ratio greater than 0.56.[46,47] Early surgical resection for these most severe lesions has occurred in several centers. The latest therapy involves ex utero intrapartum therapy—or EXIT delivery—where the resection of the CPAM occurs immediately after delivery but before separation of the placenta. Reported outcomes vary widely between centers. Thoracoamniotic shunts for large unicystic lesions and pleuroamniotic shunts for hydrothorax have reportedly enhanced survival in extreme cases. Similarly, in cases of massive urinary ascites, urinary diversion via peritoneal shunts has been reported.

There are complications associated with fetal interventions. Preterm birth can be as high as 80% under 37 weeks' gestation and 15% under 30 weeks' gestation, particularly for open surgical procedures.[48,49] Maternal morbidities related to fetal intervention range from spontaneous and/or premature rupture of membranes, oligohydramnios, and uterine wound infection with dehiscence to mild postoperative interstitial pulmonary edema, especially in mothers with longer operative times.[48,50,51]

In cases in which the cause of hydrops can be corrected by appropriate care at the time of delivery, such as elimination of a chorioangioma, as well as those cases in which no cause can be ascertained, close observation for fetal demise is the focus of prenatal management. Many cases of nonimmune hydrops manifest in the third trimester as preterm labor. It is difficult to decide whether to attempt tocolysis and delay delivery so as to allow the potentially beneficial administration of steroids before birth or to deliver the fetus immediately. If tocolysis is possible, expectant management should include usual biophysical testing, although fetal decompensation may be difficult to assess. Abnormal fetal heart tracings, oligohydramnios, decreased fetal movement, and poor fetal tone are all ominous signs. Prolonging the pregnancy beyond attainment of a mature lung profile is not generally recommended unless there is evidence of clinical improvement or resolution of the hydrops.

Neonatal Evaluation

Table 7.3 summarizes the diagnostic evaluations recommended for newborns with nonimmune hydrops of unknown cause. There are a few key points:

- Prenatal test results may help guide initial evaluation.
- Early cardiac and hematologic evaluations will determine most known etiologies.
- A multidisciplinary approach is essential.
- Response to interventions may help guide the evaluation.

TABLE 7.3 Diagnostic Evaluation of Newborns With Nonimmune Hydrops

System	Type of Evaluation
Cardiovascular	Echocardiogram, electrocardiogram
Pulmonary	Chest radiograph, pleural fluid examination
Hematologic	Complete blood cell count, differential platelet count, blood type and Coombs test, blood smear for morphologic analysis
Gastrointestinal	Abdominal radiograph, abdominal ultrasonography, liver function tests, peritoneal fluid examination, total protein and albumin levels
Renal	Urinalysis, blood urea nitrogen, and creatinine measurements
Genetic	Chromosomal analysis, skeletal radiographs, genetic consultation
Congenital infections	Viral cultures or serologic testing, including TORCH agents and parvovirus
Pathologic	Complete autopsy, placental examination
Lymphatic	MRI, lymphoscintigraphy, ICG lymphography

ICG, Indocyanine green; *MRI*, magnetic resonance imaging; *TORCH*, toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex.

Intensive Care of the Infant With Hydrops Fetalis

After newborn resuscitation, stabilization, and placement of umbilical catheters, the clinical management should address both the cause and the complications of hydrops. Morbidity and mortality may result from the hydropic state, the underlying conditions giving rise to hydrops, or both. A fetus with hydrops that is delivered prematurely is subject to the additional complications of prematurity. If there is massive ascites or pleural effusions, initial resuscitation may require thoracentesis or peritoneal tap. Because of pulmonary edema, newborns with hydrops are susceptible to pulmonary hemorrhage and may require high levels of positive end-expiratory pressure.

Respiratory Management

Virtually all hydropic newborns will require mechanical ventilation because of pleural and peritoneal effusions, pulmonary hypoplasia, surfactant deficiency, pulmonary edema, poor chest wall compliance caused by edema, and likely persistent pulmonary hypertension of the newborn. The presence of persistent pleural effusions may necessitate the placement of chest tubes. Ascites may also compress the diaphragm and impair lung expansion. Breath sounds, chest wall movement, blood gas levels, and radiographs must all be monitored frequently so that ventilator support can be reduced in response to improvements in lung compliance and fluid clearance. Pneumothoraces and pulmonary interstitial emphysema remain potential complications as long as ventilator support is continued. Neonates who need a prolonged course of ventilation, particularly those born prematurely, may develop bronchopulmonary dysplasia. Chronic lung disease results in a longer and more complicated hospital course and contributes to the late mortality of neonatal hydrops.

Fluid, Electrolyte, and Medical Management

A primary goal of fluid management is resolution of the hydrops itself. Maintenance fluids should be restricted, with volume boluses given only in response to clear signs of inadequate intravascular volume. The hydropic newborn has an excess of free extracellular water and sodium. Fluids given during resuscitation further increase the amount of water and sodium that must be removed during the immediate neonatal period. Initial maintenance fluids should contain minimal sodium. Serum and urine sodium levels, urine volume, and daily weights should be monitored carefully to guide administration of fluids and electrolytes. Urinary sodium levels may help differentiate between hyponatremia caused by hemodilution and urinary losses.

If the hydrops is secondary to a lymphatic disorder, peritoneal or pleural fluid that is drained will contain white blood cells, immunoglobulins, albumin, and coagulation factors, and may also contain triglycerides if the neonate is fed. Fluid replacement may be necessary to replete ongoing losses. Fresh frozen plasma may be considered for volume resuscitation to restore coagulation factors. Fluid replacement using hypo-oncotic (4%) albumin or iso-oncotic (5%) albumin should be used cautiously, as they may worsen peripheral and pulmonary edema without correcting serum levels of albumin. Hyper-oncotic (20% or 25%) albumin can be used intermittently to correct hypoalbuminemia, although there is limited data on this practice in neonates with hydrops.[52]

Medical management of neonatal lymphatic disorders typically includes furosemide to decrease pulmonary lymphatic flow, particularly in cases of PLPS. A low long chain fatty acid diet should also be used to reduce lymphatic fluid burden. Octreotide, a somatostatin analog that causes splanchnic vasoconstriction, decreases hepatic lymphatic flow and has been used to treat patients with lymphatic flow disorders. However, there is insufficient data to support its use in hydropic neonates given the risk of pulmonary hypertension and necrotizing enterocolitis.

Cardiovascular Management

Hydropic infants may develop hypovolemia as a result of capillary leakage, poor vascular tone, impaired myocardial contractility from hypoxia or infection, impaired venous return caused by shifting or compression of mediastinal structures, and/or pericardial effusion. Thus, these infants may present in shock. Adequate intravascular volume must be maintained, and correctable causes of impaired venous return should be addressed. Peripheral perfusion, heart rate, blood pressure, and acid–base status should be monitored carefully.

Lymphatic Evaluation and Interventions

Advances in the use of T2-weighted MRI, dynamic contrast-enhanced magnetic resonance lymphangiograms (DCMRL), and lymphangiography have identified a group of infants with nonimmune hydrops who have abnormal lymphatic systems. These infants, most of whom have congenital anomalies of the thoracic duct or abnormally conducting pulmonary lymphatic channels,[29] may benefit from new procedures to relieve these obstructions.[29,53,54] There are few studies in neonates, although data from older infants—many of whom had single-ventricle physiology—suggest that the use of percutaneous lymphatic interventions after a bilateral intranodal lymphangiogram may be useful in these infants.[55,56]

Pinto et al.[29] categorized neonates with lymphatic disorders into two subgroups: neonatal chylothorax secondary to pulmonary lymphatic perfusion syndrome (PLPS) and central lymphatic flow disorder (CLFD). CLFD, which is a generalized lymphatic disorder characterized by abnormal lymphatic flow or lymphatic leak into more than one body compartment, is often characterized by dermal backflow through lymphatic collaterals seen on DCMRL. Two recent studies have shown that neonatal chylothorax secondary to isolated PLPS can be successfully treated with intranodal injection of ethiodized oil and is considered standard of care in some centers.[29,57] Ethiodized oil, a radiopaque contrast agent, has a high viscosity and results in a mechanical occlusion of abnormally conducting pulmonary lymphatic channels. A universal treatment strategy has not been established for CLFD given the various etiologies for this disorder. Finally, neonates born with hydrops may have congenital atresia of the thoracic duct outlet. In these cases, surgical thoracic duct-to-vein (lymphovenous) anastomosis has been used to relieve thoracic duct outlet obstruction.[29,58] Other treatment options once thought to be useful in hydropic infants with CLFD can worsen disease. There is some evidence that surgical thoracic duct ligation in patients with CLFD develop worsening anasarca from dermal backflow. As such, some experts recommend avoiding this procedure in infants.[57] Further work is needed in the neonatal population with nonimmune hydrops, specifically with central lymphatic flow disorder, to identify those infants who may benefit from established interventions as well the development of newer therapeutic options.

Clinical Course and Outcome

Despite improvements in diagnosis and management, mortality from nonimmune hydrops remains high. For example, one study of 92 infants born with nonimmune hydrops between 2000 and 2012 reported a 45% fetal death rate and a 36% survival rate at 1 year.[59] Other studies have reported survival rates between 20% and 30%.[60,61] Recently published population data, though, present a more optimistic set of outcomes. Swedish data from 1997–2015 found that 58.7% of live-born children with nonimmune hydrops were alive at 12 months of age,[11] while California population data from 2005 to 2012 found a 1-year survival rate of 56.8%.[12]

The best predictors of survival are the cause of the hydrops, the gestational age of the child at delivery, and the condition of the neonate at birth. Highest survival rates are seen in infants with parvovirus infection, chylothorax, and SVT. The lowest survival rates are for hydrops associated with a chromosomal diagnosis. While the figures may be biased because a significant number of pregnancies in such cases are terminated, several studies have reported elevated risk of mortality in live-born infants with nonimmune hydrops that resulted from aneuploidy, especially those with a cardiac diagnosis.[6,10,12] A review of 598 patients with nonimmune hydrops found other risk factors for increased mortality, including younger gestational age, lower 5-minute Apgar score, and the need for increased respiratory support,[13] and a smaller study from Taiwan also found that lower albumin levels were associated with a higher mortality rate.[62]

Interventions to improve outcomes in hydrops are limited by the rarity of the disease. Most hydropic neonates lose a minimum of 15% of their birthweight, and some lose as much as 30%. Ordinarily, diuresis begins on the second or third day after birth and continues for a period of 2 to 4 days. Once the edema has resolved, the neonates have normal levels of circulating protein and eventually recover from their apparent capillary leak syndrome. No specific management strategies during the neonatal period, such as the use of high-frequency oscillatory ventilation, have been shown to improve outcome.[23] However, extracorporeal membrane oxygenation may be a reasonable option for some infants with nonimmune hydrops, with one study showing a 54% survival rate in 28 cases.[63] More recent data have not been published.

For infants who survive the immediate neonatal period, long-term outcomes largely depend on the etiology of the condition. For example, an older study from Japan found that 13 of 19 surviving infants with nonimmune hydrops had normal development at 1 to 8 years.[20] More recent data, though, found only a 45% to 50% survival rate without developmental delay by 1 year.[59,64] In both these studies, hydropic infants with mild or severe delays had other morbidities, such as extreme prematurity, structural cardiac lesions, or chromosomal anomalies. Thus similar to mortality, long-term morbidities from nonimmune hydrops result primarily from the underlying cause of the hydrops, gestational age at delivery, and complications arising immediately after delivery.

8 Maternal Diabetes

EMILY FAY, LAVONE SIMMONS, AND COLLEEN BROWN

KEY POINTS

- The incidence of diabetes in pregnancy is steadily rising, likely in parallel with the rising incidence of obesity among pregnant patients.
- Pregnant patients with diabetes are at increased risk for fetal complications (such as congenital malformations, fetal growth abnormalities, and stillbirth) and perinatal/neonatal complications (such as prematurity, respiratory distress, and metabolic abnormalities, including hypoglycemia and electrolyte derangements).
- Tight maternal glycemic control, achieved preconception and maintained throughout pregnancy, is key to optimizing fetal and neonatal outcomes.
- Breastfeeding should be encouraged and supported as it may reduce some of the possible adverse effects of intrauterine programming in the context of maternal diabetes.

Diabetes mellitus is an increasingly common disorder in the United States and around the world. According to 2018 data from the US Centers for Disease Control and Prevention (CDC), 26.8 million adults aged 18 years or older had diabetes and approximately half of these were women (Table 8.1).[2] An estimated 88 million adults—roughly 34.5% of the adult US population—have prediabetes, a condition associated with an elevated risk of developing type 2 diabetes. The rapidly rising rate of diabetes parallels the rising rates of obesity in counties across the United States (Figs. 8.1–8.3). Similarly, there has been a significant increase in the prevalence of gestational diabetes mellitus (GDM, elevated blood sugars due to insulin resistance diagnosed for the first time in pregnancy). Data from 2010 derived from birth certificates, as well as the Pregnancy Risk Assessment Monitoring System, estimated the prevalence of GDM in the United States to be as high as 9.2%.[1] Increasing rates of GDM are hypothesized to be due to increasing rates of obesity, which is a known risk factor (see Fig. 8.1), older maternal ages at delivery, as well as physical inactivity, smoking, and diets high in saturated fats.[3]

Given the statistics noted above, diabetes represents one of the most common medical diagnoses in pregnancy and is associated with profound implications on fetal and neonatal outcomes. Maternal pregestational diabetes is associated with an increased risk of congenital anomalies, abnormalities in fetal growth, and neonatal complications such as hypoglycemia, electrolyte abnormalities, respiratory distress, and cardiomyopathy. Additionally, the intrauterine environment, in the context of maternal diabetes, may impact pediatric neurodevelopmental outcomes as well as increase the risk of chronic disorders in exposed offspring such as obesity and metabolic syndrome.

Types of Diabetes

Type 1 Diabetes

Type 1 diabetes is characterized by insulin deficiency resulting from autoimmune destruction of pancreatic insulin-producing beta cells. Typically, people with type 1 diabetes will develop clinical signs and symptoms of diabetes in childhood. However, immune-mediated diabetes can arise at any time through adulthood. Immune-mediated diabetes in adults is characterized by a slower destruction of beta cells and subsequent progression to insulinopenia. People with type 1 DM are dependent on exogenously administered insulin. The underlying pathophysiology

TABLE 8.1 Diagnosed and Undia gnosed Diabetes Among People Aged 18 Years or Older in the United States 2018

	Number with Diabetes (Million)	Percentage with Diabetes
Total		
≥18 years old	34.1	12.3
Age		
1–44 years old	4.9	4.1
45–64 years old	14.8	16.2
Gender		
Women	16.2	11.2

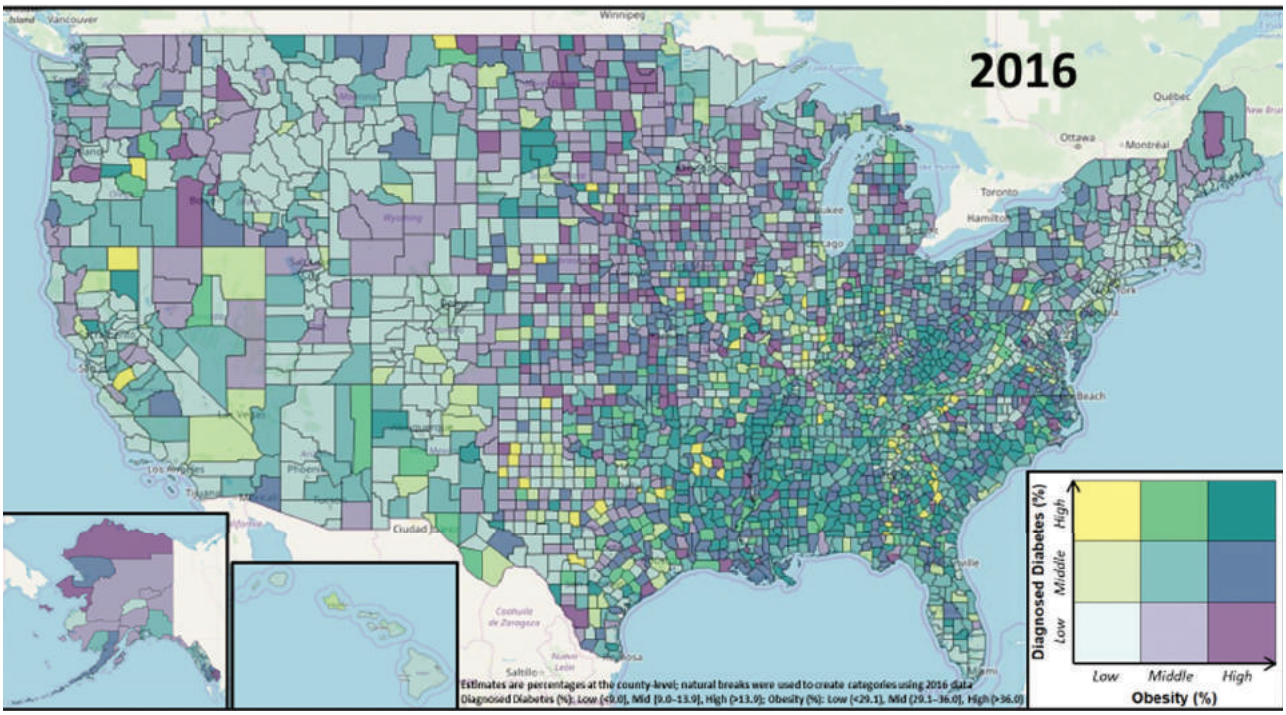
of type 1 diabetes and the physiological changes of pregnancy place pregnant patients at elevated risk for diabetic ketoacidosis (DKA). DKA is associated with a significant impact on perinatal morbidity, contributing to higher rates of fetal demise, preterm birth, and NICU admission.[4]

Type 2 Diabetes

Type 2 diabetes is the most common form, accounting for 95% of cases in the United States. Type 2 diabetes is characterized by insulin resistance and is more significantly associated with obesity.



• **Fig. 8.3** Map of diabetes and obesity, by county, U.S. Year 2016. Diagnosed Diabetes (%): Low (<9.0), Mid (9.0–13.9). Obesity (%): Low (<29.1), Mid (29.1–36.0), High (> 36.0). (https://www.cdc.gov/diabetes/data/center/slides.html)

Other risk factors include advancing age, sedentary lifestyle, history of gestational diabetes, and comorbidities including hypertension and dyslipidemia. Historically, type 2 diabetes is associated with adult onset, however, there have been increasing rates of diagnoses of type 2 diabetes among children and adolescents that appear to parallel the rise in obesity rates in these age groups.[5]

Monogenic Diabetes

The etiology of ~1% to 2% of diabetes diagnoses are genetic, also referred to as monogenic diabetes (MODY: maturity-onset diabetes of the young). Multiple types of monogenic diabetes exist; all of the genes involved share the common feature of affecting beta cell development, function, or regulation. Clinical presentations of monogenic diabetes are heterogeneous, with phenotypes varying according to the specific mutation (Table 8.2). Most forms share the following clinical features: affected individuals are typically diagnosed before the age of 25 years and are not insulin dependent. Frequently, pregnant patients with monogenic diabetes may be first identified and diagnosed with diabetes during pregnancy. A notable difference from GDM, they are often found to have continued hyperglycemia postpartum. Genetic testing is prompted by the recognition of a strong family history of diabetes (often two or more consecutive affected generations), as well as an absence of obesity or other clinical features suggestive of insulin resistance.

Neonatal Consequences of MODY

The genetic mutations leading to monogenic diabetes are inherited in an autosomal dominant fashion, so there is a 50% risk of inheritance in the offspring. Fetal MODY mutations may impact intrauterine growth. Macrosomia and neonatal hypoglycemia are associated with *HNF4A* mutations. In an analysis of siblings discordant to the *HNF4A* mutation, affected infants had birth weights that were on average 790 g higher than unaffected infants; 56% of affected infants were macrosomic (birth weight >4000 g), as compared with 13% of those who were unaffected. Fifteen percent of affected infants demonstrated evidence of neonatal hypoglycemia.[6]

In contrast, fetuses who have inherited the *GCK* mutation do not appear to demonstrate the excessive fetal growth that typically results from maternal hyperglycemia; studies have reported that affected fetuses may have a birth weight that may be 500 to 600 g lower than unaffected fetuses of mothers with monogenic diabetes due to *GCK* mutations.[7] Fetuses inheriting the *GCK* mutation may demonstrate a decreased insulin response to hyperglycemia. Therefore, they may experience less macrosomia. Unaffected fetuses have a normally functioning glucokinase enzyme, are at risk for hyperinsulinemia in response to maternal hyperglycemia, and have a greater risk of macrosomia. Knowledge of the fetal genotype during pregnancy might theoretically allow providers and patients to tailor diabetes management. Definitive diagnosis of *fetal* genotype requires invasive testing such as first trimester chorionic villus sampling (CVS) or second trimester amniocentesis, with the associated risks of these procedures.

The management of diabetes during pregnancy may also have long-term effects on fetuses who inherit mutations associated with diabetes. Studies have demonstrated that individuals with maternally-inherited *HNF1A* mutations often have earlier age at diabetes diagnosis and at initiation of insulin therapy than those paternally-inherited mutations[8]; this observation may suggest that the intrauterine environment may impact the phenotype associated with these mutations, and further highlights the importance of tight maternal metabolic control during pregnancy in optimizing long-term outcomes.

TABLE 8.2 Maturity-Onset Diabetes of the Young

Gene	Associated Function	Associated Effect	Effect of Mutation	Patient Presentation and Considerations for Care
Glucokinase (GCK)	Glucokinase enzyme catalyzes the 1st (rate-limiting) step in glycogen storage and glycolysis	Links insulin secretion to elevations in serum glucose	Inactivation of GCK raises the glucose setpoint for insulin secretion	• Stable, mild hyperglycemia; prominent elevated fasting levels • Fetal inheritance associated with lower birthweight compared to unaffected • Unaffected fetus is at higher risk for macrosomia • Associated with suboptimal glucose control/ treatment failure[3]
Hepatocyte nuclear factor (HNF1A) ~50% of MODY cases	Transcription factor	Beta cell differentiation, development and function	Progressive beta cell dysfunction and decreased insulin secretion	• Relatively high penetrance: 63% of patients with HNF1A develop diabetes by age 25 and 79% by age 35.2 • More responsive to sulfonylureas (e.g., glyburide) than to biguanides (metformin)
Hepatocyte nuclear factor (HNF4A) ~10% of MODY cases	Transcription factor	Beta cell differentiation, development and function	Progressive beta cell dysfunction and decreased insulin secretion	• More responsive to sulfonylureas (e.g., glyburide) than to biguanides (metformin) • Associated with macrosomia and neonatal hypoglycemia
Hepatocyte nuclear factor (HNF1B) <1% of MODY cases (also known as *renal cysts and diabetes* [RCAD] *syndrome*)	Transcription factor	Beta cell differentiation, development and function	Progressive beta cell dysfunction and decreased insulin secretion	• Early-onset non-insulin dependent diabetes • Developmental renal disease (typically cystic) • Genitourinary abnormalities • Atrophy of the pancreas • Hyperuricemia • Gout

Data from Naylor and Philipson, 2011[130]; Murphy et al., 2008[131]; Bacon et al., 2015[7]; Diabetes Care 2022[5]

Gestational Diabetes

The reported incidence of diabetes in pregnancy is up to 9.2% with 80% to 90% of cases due to gestational diabetes (GDM).[1] GDM is defined by the presence of elevated blood sugars, resulting from insulin resistance diagnosed for the first time during pregnancy. The physiologic changes of pregnancy are associated with hyperglycemia in pregnant patients with GDM, prediabetes and diabetes. In pregnancy, insulin resistance increases with advancing gestation in response to increasing levels of human placental lactogen, progesterone, cortisol, and prolactin. Human placental lactogen and prolactin antagonize the effects of insulin at the cellular level. Progesterone decreases gastrointestinal motility, which may enhance carbohydrate absorption. It is believed that insulin resistance in pregnancy is likely a physiologic adaptation to maintain a steady supply of nutrients to the growing fetus.

Given the underlying pathophysiology of insulin resistance, there is likely some overlap between pregnant patients with type 2 diabetes and those diagnosed with GDM. Because of the likelihood that underlying type 2 diabetes may be first diagnosed in pregnancy (and therefore mistaken for GDM), early screening in pregnancy is recommended for pregnant patients with risk factors for type 2 diabetes (Table 8.3). Risk factors that merit early diabetes testing include the following: a previous history of GDM, history of impaired glucose tolerance, and obesity (body mass index [BMI] ≥30 kg/m^2). In conjunction with American Diabetes Association recommendations, to facilitate early diagnosis, diabetic screening is recommended for patients with BMI ≥25 kg/m^2 and have one of the following additional risk factors: physical inactivity, a first-degree relative with diabetes, history of delivery of a macrosomic infant (defined as birth weight ≥4 kg), or history of polycystic ovarian syndrome or chronic hypertension. A negative early screen for

diabetes should be retested later in pregnancy at the recommended universal testing window: 24 to 28 weeks.

Currently in most of the United States, two-step testing is recommended with a 50-g glucose challenge test as the initial screen, followed by definitive diagnostic testing with a 100-g three-hour oral glucose tolerance test; this testing approach is endorsed by the American College of Obstetricians and Gynecologists (ACOG).[9] The International Association of Diabetes and Pregnancy Study Groups (IADPSG) recommends a one-step testing strategy utilizing a 75-g 2-hour oral glucose tolerance test; the diagnostic thresholds were selected based on odds ratio for various adverse outcomes evaluated in the Hyperglycemia and Adverse Pregnancy Outcome study.[10] Using a one-step approach may diagnose GDM in as many as 18% of pregnant patients. A recent randomized control trial evaluated the one- vs. two-step approach to diagnosis. The one-step approach did diagnose 16.5% of participants with GDM, as compared to 9.2% using the two-step. However, there were no significant between-group differences in primary outcomes related to perinatal and maternal complications.[10,11] In light of these findings, choice of screening test is left to each provider and/or practice based on the needs and adherence of their unique patient population.

Maternal Obesity

The obesity epidemic is contributing to the global rise in type 2 diabetes and GDM, thus resulting in an increased risk of the perinatal complications attributable to diabetes. Importantly, maternal obesity, even in the absence of diabetes, has been found to be an independent risk factor for adverse obstetric, fetal, and neonatal outcomes. Specifically, maternal prepregnancy obesity has been associated with an increased risk of congenital anomalies, stillbirth, macrosomia, hypertensive disorders of pregnancy (e.g., preeclampsia), stillbirth, cesarean delivery, as well as pediatric obesity.[12]

Pregnancies complicated by obesity are associated with increased odds of fetal open neural tube defects, hydrocephalus, cardiovascular anomalies, cleft lip and/or palate, and limb reduction anomalies.[13,14] The elevated risk of congenital malformation is likely compounded by the presence of suboptimal control of pregestational diabetes. There is an elevated risk of congenital malformations in offspring of obese pregnant patients with diabetes, and the detection of anomalies by ultrasound evaluation for fetal anomalies is more challenging in this population; studies estimate a 20% lower detection rate for anomalies.[15,16]

In several studies, the risk of perinatal mortality, including stillbirth, was shown to increase with increasing severity of maternal obesity.[17] Maternal prepregnancy obesity, as defined by a BMI of greater than or equal to 30 kg/m^2, has been identified as an independent risk factor for macrosomia and LGA birth weight.[18] In a cohort of singleton pregnancies, both maternal diabetes and maternal obesity were identified as independent risk factors for LGA birth weight; in the case of maternal obesity, the adjusted odds ratio for delivering an LGA infant is 1.6, while for pregestational diabetes, the adjusted odds ratio is 4.4.[19] Given the greater prevalence of obesity as compared with pregestational diabetes, it is likely that the proportion of LGA infants delivered by obese pregnant patients will exceed that of diabetic pregnant patients. Similar to what is observed in macrosomic infants of diabetic mothers (IDMs), LGA infants born to pregnant patients with obesity appear to have increased adiposity as compared with infants of patients without associated obesity; these children may go on to have an increased risk of childhood obesity and metabolic abnormalities.[20,21]

Association Between Perinatal Outcomes and Periconception Glycemic Control

In the setting of pregestational diabetes, suboptimal periconceptional glycemic control has been associated with a significantly increased risk of embryopathy. Embryopathy is associated with pregnancy loss and congenital anomalies. The background rate of congenital anomalies in the general population is around 2% to 3% compared to 6% to 9% among pregnant patients with pregestational diabetes.[22] Studies in the early 1980s demonstrated an association between congenital anomalies and increasing maternal periconception hemoglobin A_{1c} (HbA_{1c}); a first trimester HbA_{1c} greater than or equal to 7.5% is associated with a ninefold increased risk of congenital anomalies compared to optimal periconception glycemic control.[23] Extremely elevated maternal HbA_{1c} levels (i.e., ≥10%) in early pregnancy are associated with fetal anomaly rates of 20% to 25%, while periconception HbA_{1c} levels in the normal range are associated with a congenital anomalies rate similar to a nondiabetic population.[24,25] Contemporary studies have demonstrated similar associations. A nationwide population study of the United States demonstrated a 2.44 adjusted relative risk for congenital anomalies among patients with prepregnancy diabetes compared to patients without diabetes.[26] In a Danish prospective cohort study of 933 singleton pregnancies in patients with type 1 diabetes, 10.9% of the offspring with a periconceptional HbA_{1c} ≥10.4% had a major congenital anomaly as compared with 2.8% of the background population.[27]

There is no anomaly that is pathognomonic for pregestational diabetes. A wide range of congenital anomalies affecting multiple organ systems has been reported in pregnancies complicated by pregestational diabetes. Pregestational diabetes confers a 26-fold increase in odds of caudal regression syndrome, yet a large retrospective cohort study demonstrated that only 17% of all caudal regression cases occurred in pregnant patients with diabetes.[28] The most frequently encountered anomalies in the setting of maternal diabetes affect the cardiovascular system (3.5 times increase in odds in patients with diabetes as compared to the background population) as well as the CNS (Table 8.4). In one analysis, 13.6% of infants of diabetic patients have multiple congenital anomalies.[28]

The association of congenital anomalies in the setting of pregestational diabetes is thought to be due to teratogenic effects of glucose and ketone bodies. High levels of glucose and ketone bodies (e.g., β-hydroxybutyrate) are associated with teratogenicity in animal models. Hyperglycemia leads to the increased production of reactive oxygen species, which can alter cell membranes, cause mitochondrial dysfunction, or promote pathologic apoptosis; all of these alterations may contribute to embryopathy.[29] Animal studies have demonstrated that hyperglycemia-induced excessive apoptosis may affect neural progenitor cells, contributing to nervous system anomalies.[29] Hyperglycemia-related oxidative stress may demonstrate a direct effect on the proliferation and migration of neural crest cells, which play a critical role in the development of the fetal heart. In animal models, these changes resulted in cardiac outflow tract defects.[30]

Congenital malformation risk in patients with pregestational diabetes may be further compounded by exposure to medications that may be teratogenic. Patients with diabetes have a greater risk of comorbid medical conditions such as chronic hypertension or

TABLE 8.4 Congenital Anomalies Reported in Fetuses of Diabetic Mothers

Organ System	Anomalies
Central nervous system	Spina bifida Anencephaly Hydrocephalus
Cardiovascular system	Ventricular septal defect Tetralogy of Fallot Transposition of the great arteries Hypoplastic left heart syndrome Coarctation of the aorta Atrial septal defect Pulmonic stenosis Double-outlet right ventricle Truncus arteriosus
Genitourinary tract	Hydronephrosis Renal agenesis Ureteral duplication Hypospadias
Gastrointestinal tract	Intestinal atresias Anal atresia

complications of long-standing diabetes (e.g., nephropathy). In this setting, angiotensin-converting enzyme (ACE) inhibitors may be prescribed outside of pregnancy, however, these medications are known to be teratogenic and thus have limited application in pregnancy: in a nondiabetic population, first trimester exposure has been associated with a 2.7-fold increased risk of major congenital malformations, including a fourfold increase in the risk of CNS anomalies and a 3.7-fold increase in the risk of cardiovascular anomalies.[31] Exposure to ACE inhibitors beyond the first trimester of pregnancy also has adverse effects, including fetal renal failure, oligohydramnios with its associated consequences (e.g., pulmonary hypoplasia if early oligohydramnios is severe and persistent), fetal growth restriction, and increased risk of stillbirth.

Antenatal detection of congenital malformations usually requires a detailed second trimester ultrasound evaluation. Systematic reviews evaluating the accuracy of ultrasound diagnosis at GAs less than 24 weeks report detection rates of 16% to 44% for all anomalies[32,33]; the overall detection rate of major lethal anomalies is higher, at 84%.[34] Rates of detection may vary on GA at the time of ultrasound exam, expertise of the sonographer, and patient factors (e.g., maternal obesity).

Cardiac anomalies comprise up to 40% to 50% of congenital malformations encountered in IDMs; it is estimated that there is a fivefold increase in risk of congenital cardiac anomalies in IDMs as compared with infants of pregnant patients without diabetes.[35] In a case-control study of around 8000 live and stillborn infants weighing greater than or equal to 500 g and greater than or equal to 20 weeks' gestation, the absolute risk of a major cardiovascular system defect was 8.5 per 100 live births in offspring of insulin-dependent diabetic patients; in that population, the absolute risk of a cardiovascular malformation in infants born to nondiabetic patients was 0.8 per 100 live births.[36] A 2018 population-based historical Swedish cohort study using health registers demonstrated among liveborn infants of patients with type 1 diabetes, increasingly worse glycemic control in the periconception time was associated with a progressively increased risk of major cardiac defects with an adjusted risk ratio >2 for HgbA1c <6.5 and adjusted risk ratio >6 for HgbA1c >9.[37]

Given the increased risk of neonatal morbidity and mortality with some cardiac malformations, antenatal diagnosis appears vital for optimization of obstetric and neonatal care. Some studies have suggested that an antenatal diagnosis of complex cardiac malformations may be associated with improved neonatal outcomes as compared with infants in whom these malformations were first diagnosed postnatally. Given the increased risk of cardiac malformations in fetuses of patients with pregestational diabetes, many institutions recommend screening fetal echocardiography in addition to a detailed second trimester fetal anatomical survey. These established associations speak to the importance of preconception care to optimize periconception glucose control for optimal maternal, fetal, and neonatal outcomes.

Fetal Growth and Macrosomia

Maternal diabetes is associated with an increased risk for abnormal fetal growth. Pregestational diabetes with microvascular complications (especially diabetic nephropathy) or concomitant chronic hypertension may have an increased risk of intrauterine growth restriction, potentially related to abnormalities in placental structure or perfusion.[38]

Excessive fetal growth is an aberrant pattern more commonly encountered in diabetic pregnancies. Large for gestational age (LGA) is commonly defined as birth weight greater than the 90th percentile for GA. Macrosomia is more variably defined: birth weight greater than 4000 g or greater than 4500 g without adjustment for GA. Both pregestational and gestational diabetic pregnancies have a greater prevalence of LGA and macrosomic infants. Birth weights greater than or equal to the 90th percentile have been reported to occur in 42% to 62% of type 1 diabetic pregnancies, 30% to 56% of type 2 diabetic pregnancies, and in 10% to 20% of pregnancies complicated by gestational diabetes.[39] For infants born to patients without diabetes, the rate of macrosomia (when defined as birth weight ≥4 kg) has been reported to be 7% to 8%, and the rates of LGA have been reported to be 8% to 14%.[40]

Excessive fetal growth is probably stimulated by maternal hyperglycemia as explained by the classic Pedersen hypothesis. Maternal glucose readily crosses the placenta by facilitated diffusion; fetal glucose levels are maintained at a level that is approximately 70% to 80% of the maternal concentration of glucose. Maternal insulin does not cross the placenta. Fetal hyperglycemia stimulates fetal pancreatic beta cell hypertrophy and increased insulin production. Insulin acts as a potent growth factor in utero; thus, fetal hyperinsulinemia and concomitant increases in insulin-like growth factors (IGFs) probably result in increased protein, lipid, and glycogen synthesis contributing to increased fetal growth.[40] The excess fetal growth appears to be characterized by increased fat deposition and visceral enlargement. Fetal insulin activity in response to fetal glucose levels becomes evident at around 20 weeks' gestation. Insulin receptor levels in target organs such as the fetal liver appear to become maximal in the mid-trimester, with insulin receptor binding affinities increasing as pregnancy progresses.

Maternal glycemic control has been identified as a predictor of fetal growth. Studies have demonstrated a positive linear association between maternal glucose levels and risk of LGA birth weights.[41] Elevated maternal HbA_{1c} levels and nonfasting as well as mean glucose levels have been associated with risk of abnormal fetal growth.[39,42] However, reducing maternal hyperglycemia does

not always reduce LGA. More recent evidence from studies using continuous glucose monitoring suggest an association between glycemic variability, particularly in the second and third trimesters, and accelerated fetal growth.[43]

The clinical pattern of abnormal fetal growth in the context of maternal diabetes appears to be characterized by accelerated disproportionate growth in the second half of pregnancy. Studies evaluating fetal growth utilizing ultrasound assessment demonstrated pregnancies with evidence of accelerated growth as early as 17 to 24 weeks' gestation, with maximal growth occurring late in the third trimester. Observations of accelerated fetal abdominal circumference growth have been made in patients with diabetes, and associated with LGA birth weights.[44–46] In an evaluation of LGA neonates, IDMs had significantly increased fat mass and increased percentage body fat as compared with infants whose mothers had normal gestational glucose tolerance.[47] In general, fetal fat deposition seems to occur almost entirely within the third trimester and appears to be sensitive to the effects of fetal insulin.

Antenatal diagnosis of macrosomia is limited by the accuracy of fetal sonographic estimations of fetal weight. Measurements of the fetal head (head circumference and biparietal diameter), abdominal circumference, and femur length are incorporated into a formula (usually derived from nonlinear regression analysis) to estimate fetal weight; fetal weight percentiles are then determined from one of several fetal growth curves that, historically, have been derived from various geographic locations using representative subpopulations. Most experts consider a mean percent error in estimated fetal weight of ±10% to be clinically relevant for accuracy. Studies evaluating the accuracy of third-trimester ultrasound estimates of fetal weight show that sonographic estimates fall within 10% of birth weight in 50% to 75% of cases; the reported mean percentage differences between ultrasound-predicted and actual birth weight have ranged from 6% to 15%.[48]

Sensitivities for the antenatal diagnosis or prediction of birth weight greater than or equal to 4000 g has been estimated to be as low as 53% to 59%.[49] In a cohort of patients with gestational diabetes, third-trimester ultrasound estimation of fetal weight significantly overestimated the prevalence of LGA infants; of those patients identified as having an estimated fetal weight greater than or equal to the 90th percentile, only 23% actually delivered an LGA neonate.[50] Some data suggest that prediction of clinically relevant LGA (e.g., LGA infants who will have the greatest risk of shoulder dystocia) may be improved by the use of customized fetal growth curves, by taking into account clinical factors such as suspected fetal sex, maternal height, weight, and parity that are physiologic determinants of fetal growth.[51]

Pregnancies complicated by pregestational diabetes and suspected macrosomia have a greater risk of shoulder dystocia, birth trauma, cesarean delivery, and neonatal complications such as hypoglycemia requiring treatment and hyperbilirubinemia.[52] Shoulder dystocia is defined as difficulty and delay in delivery of the fetal shoulders/body following delivery of the fetal head; this often results from impaction of the anterior fetal shoulder behind the maternal pubic bone. Shoulder dystocia requires additional obstetric maneuvers to effect delivery, and delayed delivery is associated with an increased risk of perinatal asphyxia (potentially related to impaired oxygenation from occlusion of the umbilical cord during delayed delivery), and maternal birth trauma. Macrosomia and maternal diabetes have been identified as independent risk factors for shoulder dystocia. In a nondiabetic population, macrosomia, when defined as birth weight greater than 4500 g, was associated with a 13-fold increase in the odds of shoulder dystocia as compared with fetuses without suspected macrosomia; the rate of shoulder dystocia in a nondiabetic population with macrosomic infants was 23%.[53] When controlling for birth weight and other confounders, diabetes (pregestational and gestational) is an independent risk factor for shoulder dystocia, with a threefold increase in odds.[54] Shoulder dystocia rates as high as 35% have been reported in pregnant patients with diabetes who deliver an infant with a birth weight between 4750 and 5000 g.[55] In deliveries complicated by shoulder dystocia, pregnant patients with insulin requirement have a greater rate of birth trauma than infants of nondiabetic patients; in a review of shoulder dystocia cases in the state of California, 24% of neonates delivered to patients with diabetes experienced reported birth trauma and 7.3% of infants of nondiabetic patients had evidence of birth trauma.[54]

Birth trauma appears to occur at an increased rate in suspected macrosomic infants, even in the absence of shoulder dystocia. In a cohort of infants with a birth weight greater than or equal to 4000 g, 7% had evidence of a traumatic birth injury—most commonly Erb's palsy and clavicular or humeral fractures.[56] Birth trauma risks appear to increase on a continuum as the birthweight increases.[57,58] Macrosomic infants also have an increased risk of requiring cesarean delivery; cesarean delivery rates as high as 50% to 60% for infants with birth weights greater than or equal to 4 kg have been reported.[56]

Stillbirth and Perinatal Mortality

Pregnancies complicated by diabetes have been noted to have an increased risk of stillbirth (usually defined as fetal demise diagnosed at GAs at or beyond 20 weeks) as well as perinatal mortality. Perinatal mortality has varying definitions; the most inclusive definition is a fetal death at 20 weeks or more or an infant death before 28 days of life.[59] The most recent US National Vital Statistics Report from 2013 demonstrated a fetal death (stillbirth) rate of 5.96 per 1000 live births. The perinatal mortality rate was 9.98 per 1000 live births plus fetal deaths for the time period of evaluation.[60] This report did not specify fetal death rates or perinatal mortality rates for pregnancies complicated by specific medical or obstetric comorbidities. Studies evaluating the risk of perinatal mortality in pregnancies complicated by diabetes may have been limited by variable definitions of perinatal mortality as well as a lack of uniform agreement regarding how to determine if maternal diabetes was a direct contributor to the demise.

The stillbirth risk among patients with pregestational diabetes has been reported to be as high as five times the risk of stillbirth noted in the general population.[61,62] In the United States, a multicenter population-based case-control study identified maternal diabetes as an independent risk factor for stillbirth, accounting for 5.6% of all stillbirths in the cohort (for stillbirths occurring at GAs of ≥24 weeks, the adjusted odds ratio of stillbirth in patients with diabetes was a 3.47, 95% confidence interval [CI] 1.86 to 6.49).[63]

The reported risk of stillbirth may differ in patients with type 1 diabetes as compared with those with type 2 diabetes. In a large Danish cohort study, incidences of stillbirth among patients with type 1 diabetes was 28 per 1000 births as compared with a rate of 4.5 per 1000 births in the general population.[64] The risk of stillbirth is similarly elevated in patients with type 2 diabetes, although the magnitude of risk that has been reported has varied, with some studies suggesting worse outcomes in type 2 diabetes while others suggest comparable outcomes in both type 1 and

type 2 diabetes. Large retrospective cohort studies conducted in Denmark and in New Zealand demonstrated perinatal mortality rates two to three times higher in patients with type 2 diabetes as compared with those who have type 1 diabetes.[65,66] It is possible that the risk of perinatal mortality may be increased in pregnancies complicated by type 2 diabetes due to association with maternal obesity. Obesity has been shown to be an independent risk factor for adverse pregnancy outcomes, including stillbirth and gestational hypertensive disorders, which can also impact fetal growth and risks of prematurity.[17,67,68] A systematic review evaluating population-based studies reporting on risk factors for stillbirth in high-income countries (such as the United States, Canada, the United Kingdom, Australia, and the Netherlands) demonstrated that diabetes is a maternal medical comorbidity with one of the strongest associations with stillbirth. In this systematic review, patients with preexisting diabetes had an adjusted odds of stillbirth 2.9 times that of patients without diabetes; however, the calculated population-attributable risk of diabetes to stillbirths is 3% to 5%. In comparison to diabetes, maternal diagnoses of obesity and overweight (defined as BMI >25 kg/m^2) had a higher population-attributable risk for stillbirth (8% to 18%). Maternal overweight and obesity were identified as the highest ranking modifiable risk factor for stillbirth in high-income countries.[69]

The risk of perinatal mortality in pregnancies complicated by GDM is not clear. Some studies have reported an increased risk of perinatal mortality with GDM, while other studies have not. Patients may be misclassified as GDM when in reality they are type 2 diabetics first identified during pregnancy leading to discrepant results. A large retrospective cohort study evaluating outcomes of singletons delivered in California at 36 to 42 weeks' gestation demonstrated that there was an increased risk of stillbirth in women with GDM as compared with women without diabetes, though the absolute risks are low: women with GDM experienced 17.1 stillbirths per 10,000 deliveries, whereas nondiabetic women had 12.7 stillbirths per 10,000 deliveries (RR 1.34, 95% CI 1.2 to 1.5). This same study also evaluated the risk of expectant management in pregnancies complicated by GDM and concluded that at 39 weeks' gestation, the risk of expectant management (stillbirth and infant mortality risks) appears to exceed the risks of delivery.[70] Results from similar studies inform recommendations for consideration of delivery at 39 to 40 weeks' gestation in pregnancies complicated by GDM requiring medical therapy. Patients with diet-controlled GDM have not been shown to have greater risk of stillbirth.[71]

Several studies evaluating risks of adverse outcomes in the setting of maternal diabetes have identified an association between poor glycemic control and increased risk of perinatal mortality. The etiologies of perinatal morbidity that may be relevant include severe congenital malformations, growth abnormalities (e.g., fetal growth restriction in women with microvascular complications of diabetes), prematurity, and intrauterine asphyxia.[72] These etiologies are anticipated to occur with increased frequency in the setting of poor maternal glycemic control and diabetes severity. Poorly controlled diabetes early in pregnancy may contribute to abnormalities in placental development: high glucose levels have been shown to have an inhibitory effect on human trophoblast invasion.[73] Placental pathology of this nature might be hypothesized to impact placental function and therefore impact risk of intrauterine demise.

Intrauterine asphyxia may result from fetal hyperinsulinemia that is thought to increase fetal oxygen consumption and therefore decrease fetal oxygen tension; this proposed pathophysiology seems supported by the observation that some fetuses of patients with type 1 diabetes have higher plasma lactate levels and lower blood pH levels than normal when evaluated by third-trimester cordocentesis.[74] This lactic acidemia observed in some of the fetuses of diabetic patients may contribute to the risk of perinatal mortality.

One etiology of fetal death that is unique to diabetes is maternal diabetic ketoacidosis (DKA). Pregnancy represents a time of increased risk of DKA as several of the physiologic changes of pregnancy predispose to DKA.[75] Pregnancy results in increased insulin resistance, enhanced lipolysis, and ketogenesis. Pregnant patients are also in a state of compensated respiratory alkalosis; therefore, there is decreased buffering capacity (lower plasma bicarbonate levels) in the setting of acidosis. Complications unique to pregnancy such as nausea and vomiting, further increase risk of DKA.

The perinatal mortality rate in the setting of maternal DKA has been reported to be as high as 9% to 35%. The exact mechanism of fetal death in the setting of maternal DKA is not completely understood. It is known that maternal ketone bodies freely cross the placenta and contribute to fetal acidosis. Maternal DKA is also characterized by significant maternal hypovolemia (resulting from osmotic diuresis), which likely results in decreased uteroplacental perfusion. Maternal acidemia also shifts the maternal oxyhemoglobin dissociation curve leftward, thus further compromising oxygen delivery to the fetus. Decreased fetal oxygenation and metabolic acidemia are likely significant contributors to fetal mortality in this setting. Pregnant patients who develop DKA are often critically ill, and fetal status often reflects maternal illness. Fetuses often demonstrate evidence of intrauterine distress during monitoring. In this setting, obstetric management prioritizes maternal stabilization; emergent cesarean delivery for fetal distress resulting from DKA before adequate maternal treatment and stabilization is associated with high risk of maternal morbidity and mortality. Fortunately, early recognition of maternal DKA and aggressive, efficient initiation of treatment can lead to maternal improvement and effective intrauterine resuscitation of the fetus.

Prevention of perinatal mortality in pregnancies complicated by diabetes primarily relies on ensuring good maternal glycemic control throughout gestation. Increased antenatal surveillance to try to identify at-risk fetuses is also an accepted part of the obstetric management of pregestational diabetic patients. Given the conflicting data regarding risks of perinatal mortality in GDM patients, current expert guidelines recommend antenatal testing for GDM patients requiring medication therapy, and may be deferred with GDM patients controlled on dietary therapy alone who are otherwise at low risk for perinatal complications.

Maternal Preeclampsia

Preeclampsia is a gestational hypertensive disorder; the diagnosis of preeclampsia is made with the onset after 20 weeks' gestation of persistent elevations in systolic blood pressure (≥140 mmHg) or diastolic blood pressure (≥90 mmHg) in patients with previously normal blood pressure as well as the new onset of proteinuria, defined as greater than or equal to 300 mg of protein per 24-hour urine collection or a protein/creatinine ratio greater than or equal to 0.3. The diagnosis of preeclampsia may also be made in the absence of proteinuria if there are other complications such as thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, or neurologic symptoms (such as cerebral or visual symptoms) or HELLP syndrome.[76] In addition to the aforementioned maternal complications, preeclampsia is also associated

with an increased risk of fetal complications such as fetal growth restriction and oligohydramnios that are likely to reflect altered placental perfusion in the setting of preeclampsia. Patients with severe forms of preeclampsia are also at increased risk of placental abruption. Delivery is the only definitive treatment for preeclampsia. In the setting of maternal or fetal complications resulting from preeclampsia, delivery is medically indicated as the risk of perinatal and maternal morbidity and mortality is elevated.[77]

Patients with pregestational diabetes are at increased risk for developing preeclampsia. The prevalence of preeclampsia in the diabetic population has been estimated at 17%, which is five to six times higher than the general population.[78] Among diabetic patients, the risk of preeclampsia appears to increase with increasing duration of diabetes as well as with the presence of microvascular complications. In a US prospective observational cohort study, 11% of patients with a duration of diabetes of less than 10 years developed preeclampsia as compared with 22% of patients with diabetes of duration >10 years. Thirty-six percent of patients with proliferative diabetic retinopathy and/or diabetic nephropathy developed preeclampsia in this cohort. Patients with diabetic nephropathy with a baseline level of proteinuria ≥300 mg in a 24-hour urine collection had an increased risk of small for GA infants and of preterm delivery.[79]

Obstetric Management of Diabetes in Pregnancy

Preconception Care

Care of the pregestational diabetic patients should ideally begin before pregnancy. As discussed previously, preconception care of diabetic patients can improve outcomes; if good glycemic control is achieved and maintained throughout conception and early pregnancy, rates of miscarriage and congenital malformations are often indistinguishable from the general population in patients with uncomplicated diabetes.[80] Preconception care also allows for identification of teratogenic medications and hopefully substitution with safer alternatives (e.g., discontinuation of ACE inhibitors and transition to other antihypertensives that are compatible with pregnancy). Given the elevated risk of neural tube defects in diabetic pregnancies, folic acid supplementation should be initiated before conception. Identification of microvascular complications of diabetes such as retinopathy and nephropathy before pregnancy allows opportunities for treatment of these conditions (e.g., laser therapy for treatment of cases of proliferative retinopathy); optimization of these conditions will hopefully prevent progression of disease during pregnancy. Diabetic patients with microvascular complications also appear to have an additional increased risk of adverse pregnancy outcomes; for example, patients with diabetic nephropathy have an increased risk of having a fetus who develops fetal growth restriction and also have a risk of gestational hypertensive disorders such as preeclampsia that exceeds the risk conferred by diabetes alone. Low-dose aspirin has been evaluated as a possible intervention to reduce the risk of preeclampsia in patients who have an a priori elevated risk of developing this obstetric complication, and its use has been found to confer a modest reduction in the risk of developing preeclampsia. Low-dose aspirin in pregnancy appears to have a good safety profile. The U.S. Preventive Services Task Force has recommended the use of low-dose aspirin in patients at elevated risk of developing preeclampsia, including pregestational diabetic patients (type 1 or type 2).[81,82]

Identification of patients who have additional risk factors for adverse pregnancy outcomes may allow for pregestational optimization of medical comorbidities as well as closer maternal and fetal monitoring during pregnancy.

Medical Therapy for Diabetes in Pregnancy

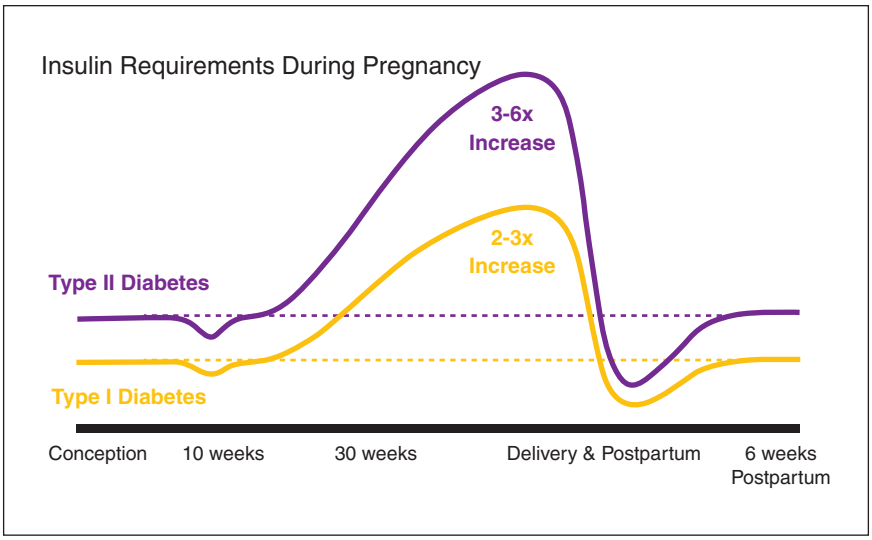
In general, maintaining tight glycemic control is a primary goal of the management of diabetes in pregnancy. The ideal target range for maternal blood glucose in pregnancy is not clear. Currently, expert consensus recommendations indicate the following targets for glycemic control in women with gestational and pregestational diabetes: fasting capillary blood glucose (CBG) of less than 95 mg/dL, 1-hour postprandial CBG levels below 140 mg/dL, or 2-hour postprandial levels less than 120 mg/dL; pharmacologic therapy is strongly recommended for patients with CBGs exceeding these thresholds.[5]

Results from the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study raised the question of whether stricter glucose levels should be targeted. The HAPO study was a prospective multinational study that evaluated the relationship between maternal hyperglycemia and adverse pregnancy outcomes that has been attributed to maternal diabetes. The relationship between results from a 2-hour, 75-g oral glucose tolerance test and the following primary outcomes were evaluated: birth weight greater than the 90th percentile for GA; cord blood C-peptide levels greater than the 90th percentile; primary cesarean delivery; and clinical neonatal hypoglycemia. Maternal glucose values at each time point (fasting, 1 hour, and 2 hours after glucose challenge) were positively associated with the primary outcomes in a linear fashion. There was no apparent threshold glucose level above which risk for an adverse outcome was clearly elevated; frequencies of adverse outcomes rose steadily with worsening maternal hyperglycemia.[41]

As many adverse fetal/neonatal outcomes such as macrosomia and neonatal hypoglycemia are thought to result from fetal hyperinsulinemia in response to maternal hyperglycemia, it may be relevant to consider the maternal blood glucose levels in patients without diabetes. A review of 12 studies evaluating the glycemic profile of nondiabetic patients demonstrated fasting glucose levels of 71 ± 8 mg/dL (mean ±1 standard deviation); 1-hour postprandial levels of 109 ± 13 mg/dL; 2-hour postprandial levels of 99 ± 10 mg/dL; and 24-hr mean glucose of 88 ± 10 mg/dL, suggesting that further clinical study of maternal goals for glycemic control is warranted.[83]

Maintaining maternal glycemic control is made more difficult by physiologic changes of pregnancy that lead to worsening insulin resistance with advancing GA. Increasing levels of human placental lactogen and changes in levels of cortisol and prolactin are likely to exacerbate insulin resistance. Insulin sensitivity has been demonstrated to decrease by as much as 56% by 36 weeks' gestation. For patients with pregestational diabetes, third-trimester insulin requirements may be two to three times greater than prepregnancy doses (Fig. 8.4). Obese patients with type 2 diabetes may demonstrate extreme levels of insulin resistance.

The changing landscape of diabetes management brings new opportunities for improvement in maternal glycemic control, safety, and neonatal outcomes. Insulin pumps deliver insulin using a small, externally worn, computerized device to deliver micro-boluses of (typically) rapid-acting subcutaneous insulin over the course of 24 hours. Pump users can alter basal insulin rates throughout the day, rather than relying on the fixed



• **Fig. 8.4** Insulin Requirements During Pregnancy. (Courtesy LaVone Simmons, MD.)

pharmacokinetic curves of injectable insulin. Users inject a bolus for mealtime insulin using the same pump, allowing for fewer injections, flexibility in meal-timing and the ability to optimize and manage glucose control for individual exercise habits and diurnal variation. The continuous glucose monitor (CGM) is a separate device which assesses interstitial glucose values every 1 to 5 minutes, allowing the user far fewer needlesticks and the ability to evaluate temporal trends in glycemia throughout the day. The devices may be worn separately, or in some cases paired to allow for sensor-augmented and hybrid closed loop therapies.

Several studies note the safety and benefit of Continuous Glucose Monitoring during pregnancy. CGM use during pregnancy remains "off-label" in the United States; however, it is approved for use in Europe. A large, multicenter, randomized control trial, named the CONCEPTT study, demonstrated significant improvement in neonatal outcomes with use of real-time CGM as compared to self-monitored blood glucose (SMBG). Infants born to mothers in the CGM group were less likely to be large for gestational age, had lower rates of neonatal hypoglycemia, fewer NICU admissions, and shorter hospital stays.[84] While there was no significant impact on maternal outcomes or HgbA1C values, the study suggests that other glycemic factors, like the time spent in normal glycemic range (TIR), glucose variability, and temporal profiles may have a significant impact on neonatal outcome.[85] Spending 5% more time in normal range (63 to 140 mg/dL) each day, and 5% less time above range (>140 mg/dL) in the second and third trimesters, improves neonatal outcomes such has neonatal hypoglycemia, LGA, and NICU admission.[86] As advances in the use of diabetes technology in the perinatal period continue, researchers have the opportunity to gain clarity in the specific glucose variables that contribute to maternal and neonatal outcomes.

All diabetic patients require dietary therapy during pregnancy. Consultation with a registered dietician is an important part of care to ensure that the nutritional requirements of pregnancy are met and the distribution of calories from carbohydrates, proteins, and fats contributes to optimal glycemic control. In obese patients, in particular, attention to dietary therapy is also critical to the goal of preventing excessive weight gain. Excessive weight gain appears to be an independent contributor to some adverse outcomes such as fetal macrosomia.

Medical management of maternal hyperglycemia in patients with pregestational diabetes commonly relies on subcutaneous insulin, regardless of the method of insulin delivery. Insulin does not cross the placenta. Insulin has been well studied in pregnancy and has been shown to be effective in achieving good maternal glycemic control and in reducing the risk of adverse obstetric outcomes.

Patients with GDM or mild type 2 diabetes may be treated with oral medications such as metformin instead of insulin. The use of oral medications, especially for the treatment of GDM, has become increasingly popular following the publication of clinical trials that demonstrated the effectiveness of these medications. Metformin has long been used in type 2 diabetes; it acts primarily by decreasing hepatic glucose production, decreasing intestinal absorption of glucose, and by improving insulin sensitivity in peripheral tissues. Metformin has a low risk of producing hypoglycemia. In a randomized clinical trial comparing metformin with insulin for the treatment of GDM, there was no significant difference in neonatal outcomes, including hypoglycemia, birth trauma, respiratory distress, or hyperbilirubinemia.[87] It was notable that 46% of women in the metformin group ultimately required insulin in order to maintain glycemic control; these women were more likely to be overweight and appeared to have had higher fasting glucose values at study entry. Metformin therapy has the additional benefit of being associated with significantly less maternal weight gain than insulin therapy alone.[88]

Treatment conversations, particularly with regard to oral medications, require finesse. Both metformin and glyburide have been shown to cross the placenta. Patients should be counseled on the limited safety data of all oral medications in pregnancy. Evidence exists on the short-term consequences of fetal exposure to metformin, and is reassuring.[88] However, meta-analyses of infants exposed to glyburide vs. insulin for the treatment of GDM remain concerning. Infants exposed to glyburide had significantly higher rates of respiratory distress, macrosomia, hypoglycemia, and birth injury, despite no difference in maternal glycemic control.[89] Furthermore, smaller observational studies show higher rates of preeclampsia, hyperbilirubinemia, and stillbirth when glyburide is used, as compared with insulin. Therefore, numerous governing bodies do not recommend use of glyburide for treatment of gestational diabetes.

The choice between insulin and metformin is less clear. While insulin does not cross the placenta, its injectable nature makes adherence difficult for many when compared with oral medications. Unfortunately, long-term data on glucose homeostasis and the progression to type 2 DM in infants exposed to metformin in utero is lacking, despite reassuring short-term data in the neonatal period. Seven- to nine-year follow-up exists for infants exposed to metformin vs. insulin in the Metformin in Gestational Diabetes Trial (MiG). The results showed similar total body fat percentages and other metabolic measures.[87] The Society for Maternal Fetal Medicine continues to endorse metformin as a reasonable and safe first-line alternative to insulin in patients whom medical nutrition therapy fails.[90] Maternal and perinatal outcomes continue to be influenced by factors beyond drug choice. Those include timing of screening, screening test chosen, treatment protocols (initiation, adjustment, addition, or medication), as well as genetic predisposition. Continued investigation of not just long-term consequences of pharmacologic choice, but also of these other factors, is required.

Antenatal Monitoring

As discussed previously, pregnancies complicated by diabetes are at increased risk for abnormal fetal growth as well as perinatal asphyxia and stillbirth. These complications warrant increased antenatal surveillance in the third trimester. Results of testing or changes in the pattern of testing may help to inform decisions regarding timing and mode of delivery.

Fetal acidemia may produce characteristic changes on biophysical tests. Tests currently utilized include maternal assessment of fetal movement, fetal heart rate testing (nonstress test or contraction stress test), and ultrasound biophysical profile testing.

Maternal assessment of fetal movement is a frequently recommended component of fetal monitoring programs. Studies have noted that decreased fetal movement may be perceived in the period preceding fetal death, however, there does not appear to be a superior method. A suggested protocol considers 10 distinct movements within 2 hours reassuring.[91] Fetal heart rate testing relies on a mature and normally functioning fetal autonomic system, and assessment of heart rate baseline, variability, and the presence of accelerations and decelerations. Fetal gestational age is an important consideration, as the likelihood of a nonreactive fetal heart rate test is greater at preterm GAs. Given these considerations, most centers do not initiate these screening tests until 32 to 34 weeks unless there are indications for earlier testing (e.g., concern for fetal growth restriction, poorly controlled maternal diabetes, or hypertension, etc.). Biophysical profile testing relies on sonographic evaluation of amniotic fluid volume, fetal movement, demonstration of fetal tone, and fetal breathing movements. Each component of this examination is given a score, with a low score considered abnormal and requiring further assessment and, potentially, intervention.

It is not clear that antenatal fetal testing as described above is useful in preventing stillbirth or perinatal asphyxia, but these tests may be clinically useful in providing reassurance that fetal status is stable so as to allow for continued expectant management until a favorable term GA is reached. If stillbirth within 1 week of testing is used as the primary outcome of interest for antenatal fetal testing, both fetal heart rate testing and biophysical profile testing appear to have high negative predictive values (>99%) for reactive nonstress tests and biophysical profile scores of 8 to 10. In diabetic pregnancies (especially if poorly controlled), more frequent testing may be warranted as the fetal testing strategies above may miss fetal compromise precipitated by acute maternal metabolic changes. The appropriate frequency of fetal testing in pregnancies complicated by diabetes has been difficult to establish. Twice-weekly testing is commonly recommended in most centers. This testing strategy has been evaluated in a large retrospective cohort that demonstrated an overall low stillbirth rate, with the observation that none of the stillbirths occurred within 4 days of the last antepartum test.[92]

Evaluation of fetal growth also contributes to the assessment of fetal status. As discussed previously, third-trimester evaluation of fetal growth is significantly limited by increasing inaccuracy of predicted fetal weights as gestation progresses. Despite these limitations, third-trimester ultrasound assessment of growth is commonly recommended, given the risk of pathologic growth in diabetic pregnancies. For patients with microvascular complications of diabetes, concomitant chronic hypertension, and preeclampsia, fetal growth restriction may confer further elevated risk of perinatal morbidity and mortality, thus necessitating additional antenatal testing (e.g., fetal umbilical Doppler studies) to help inform obstetric management. While fetal macrosomia has been difficult to accurately diagnose antenatally, findings suggestive of predicted birth weight above 4500 g appear to be associated with an increased risk of shoulder dystocia. In this setting, it may be reasonable to consider cesarean delivery in an attempt to avoid shoulder dystocia and resultant birth trauma.

Delivery Planning

Patients with diet-controlled gestational diabetes appear to have a low risk of perinatal complications; therefore, early delivery is not indicated, and expectant management is usually appropriate. For pregestational diabetics and gestational diabetics requiring medication management, timed early delivery has been considered in an attempt to reduce perinatal morbidity and mortality. Strategies of scheduled delivery at 38 to 39 weeks for women with GDM have been evaluated in clinical trials; results have suggested that while there may be some potential reduction in macrosomia or LGA with earlier delivery, there does not seem to be a significant reduction in shoulder dystocia, neonatal hypoglycemia, or perinatal death.[92,93] Given recent evidence that suggests early term births (at 37 to 39 weeks) may be associated with differences in rates of neonatal complications (such as respiratory complications) as compared with deliveries at term (39 to 40 weeks)[94], it is probably reasonable for most well-controlled pregestational and gestational diabetics to plan for a delivery at around 39 weeks' gestation. Delivery at GAs greater than 40 weeks' gestation may be associated with a greater risk of macrosomia and shoulder dystocia and does not appear to be associated with other improvement in neonatal or maternal outcome.[95] Elective cesarean delivery in fetuses suspected of macrosomia has also been considered. As discussed previously, macrosomic infants have a greater risk of shoulder dystocia and IDMs have a greater risk of birth trauma resulting from shoulder dystocia. Based on evaluation of reported rates of shoulder dystocia and birth trauma at different birth weights, it has been proposed that it may be reasonable to consider cesarean delivery for fetuses with estimated fetal weights greater than 4500 g. The potential neonatal benefit of cesarean delivery in these cases must be balanced against potential maternal morbidity associated with cesarean delivery. Studies evaluating potential benefit of cesarean delivery for presumed macrosomia estimate that up to 588 elective cesarean deliveries for an estimated fetal weight of

4500 g may need to be performed to prevent one case of a permanent brachial plexus palsy.[96]

Intrapartum Diabetes Management

The goals of intrapartum diabetes management are to maintain strict glycemic control and to avoid ketosis. Titration of an intravenous infusion of short-acting insulin is a common strategy for maintaining blood sugars at less than 140 mg/dL (some expert opinions recommend levels <120 mg/dL). Maintenance of blood sugars at this level may be helpful in reducing neonatal hypoglycemia. Maternal hyperglycemia intrapartum has been shown to be associated with higher rates of neonatal hypoglycemia, probably by worsening the fetal hyperinsulinemic response. After delivery, the neonate will no longer have a steady supply of maternal glucose as a fuel, but higher insulin levels persist.

Neonatal Considerations

Hypoglycemia

Neonatal hypoglycemia is one of the more common neonatal morbidities encountered in diabetic pregnancies, with reports citing rates of neonatal hypoglycemia as high as 25% to 50%. Studies in which good maternal glycemic control were reportedly achieved suggest a lower incidence of neonatal hypoglycemia in the range of 5% to 15%.[56] The reported rates of neonatal hypoglycemia have varied in the medical literature; this is probably due to the continued debate about clinically meaningful definitions of hypoglycemia. Severe or persistent hypoglycemia is known to cause adverse neurologic and endocrine sequelae; however, it is not clear what levels of neonatal glucose are optimal to minimize risk of these complications. Defining these optimal newborn glucose levels is likely further confounded by the observation that preterm and low birth weight neonates are more likely to have lower blood sugars.[97,98]

Most studies have defined neonatal hypoglycemia as blood glucose (BG) levels below 35 to 45 mg/dL, but clearly not all infants who have hypoglycemia as defined by these levels demonstrate evidence of adverse effects.[98] In a large prospective cohort study evaluating neonates born at GAs of 35 weeks or older, hypoglycemia (defined as a BG < 47 mg/dL) when treated did not appear to be associated with an increased risk of neurosensory impairment when assessed at 2 years of age. It was also notable that the lowest BG concentration observed in these neonates as well as the number of hypoglycemic episodes did not predict the child's neurodevelopmental outcome at age 2 years.[99] Many infants with hypoglycemia (defined as BG <40 mg/dL) may initially be asymptomatic. Symptoms attributable to hypoglycemia may include tremor, jitteriness, irritability, lethargy, and hypotonia; severe cases of hypoglycemia may also lead to convulsions, apnea, or cyanosis.

Neonatal hypoglycemia resulting from diabetic pregnancies is most likely due to fetal hyperinsulinism, i.e., a response to fetal hyperglycemia resulting from maternal hyperglycemia. After birth, the infant no longer receives a steady supply of maternal glucose; if there is hyperinsulinemia originating in utero, then the neonatal period is characterized by a relative imbalance of insulin as compared with neonatal glucose supply. This imbalance leads to a risk of hypoglycemia evolving within the first few hours of life with a nadir in blood glucose levels reported at 1 to 3 hours of life in most infants.

Neonates with hypoglycemia have been observed to have elevated cord blood C-peptide and serum insulin levels at birth.[100] Based on the pathophysiology, it is not surprising that poor maternal glycemic control in the third trimester and in the intrapartum period is a predictor of neonatal hypoglycemia.[100,101] Maternal plasma glucose levels at delivery have been shown to correlate strongly and negatively with neonatal glucose concentrations at 2 hours of life; in observational studies, rates of neonatal hypoglycemia were significantly lower if maternal blood glucose levels were less than 130 mg/dL.[100,102] Intrapartum maternal hyperglycemia and resulting fetal hyperglycemia probably stimulate the fetal pancreas to release more insulin, with this effect persisting through delivery and for the first few hours thereafter. Macrosomia has also been shown to be a risk factor for neonatal hypoglycemia, with some studies suggesting a prevalence of 30% to 50% in LGA IDMs; this observation is not surprising, as excessive fetal growth has also been attributed to the effects of fetal hyperinsulinemia.[102,103]

In addition to optimizing maternal glycemic control throughout gestation, strict maternal glycemic control in labor or in the hours immediately preceding delivery (e.g., if scheduled cesarean section) will help to prevent or reduce rates of neonatal hypoglycemia. Current expert recommendations for maternal intrapartum glycemic control vary; ACOG recommends maintaining maternal blood glucose levels between 70 and 110 mg/dL for pregestational diabetics.[104] Attention to early neonatal feeding within the first hour with promotion of breastfeeding (and/or access to colostrum/supplementation) may also help to prevent neonatal hypoglycemia.[105–107]

Respiratory Distress

Neonates of diabetic patients may also be at greater risk of respiratory complications and respiratory distress syndrome (RDS) as compared with same GA infants born to nondiabetic patients. This increased risk of respiratory compromise appears to affect even late-preterm and early-term neonates, though studies evaluating risk of respiratory distress at GAs greater than 38 weeks vary in their results. In a large retrospective cohort evaluating infants born at GAs of 34 weeks or greater, gestational diabetes was identified as an independent risk factor for severe neonatal respiratory failure (requiring admission to the neonatal intensive care unit or the need for ventilator support at 24 hours of age).[108] The pathophysiology of neonatal respiratory distress related to perinatal diabetes is thought to result from a delay in pulmonary maturation and surfactant production, leading to a relative surfactant deficiency.[109] Insulin appears to have a role in regulating fetal lung maturation; in a cell culture model of type 1 alveolar cells, exposure to elevated levels of insulin reduced choline incorporation into surfactant phosphatidylcholine.[110] Fetal hyperinsulinemia may have an inhibitory effect on glycogenolysis, which contributes to a decrease in the synthesis of phosphatidylglycerol (PG).

Delivery prior to 39 weeks may be considered clinically when there is persistent suboptimal or worsening maternal glycemic control that is not responsive to usual medical therapy or when there is concern for significant risk of adverse fetal outcomes (e.g., in the setting of macrosomia and polyhydramnios), and this is usually performed without an amniocentesis to confirm fetal lung maturity.

Antenatal Corticosteroids for Reduction in Risk of Respiratory Distress Syndrome

In clinical settings in which early preterm birth (at GAs <34 weeks) is anticipated, antenatal corticosteroids may be considered to reduce the risk of RDS and other neonatal complications of

prematurity. In the setting of maternal diabetes, the decision to administer antenatal corticosteroids must also take into consideration the potential maternal impact of these medications. Corticosteroid administration can lead to maternal hyperglycemia by promoting hepatic gluconeogenesis and impairing insulin sensitivity.[111] Significant maternal hyperglycemia resulting from the administration of antenatal corticosteroids must be anticipated because if left untreated there may be an increased risk of maternal complications such as DKA in patients with type 1 diabetes.[112,113] An evaluation of the impact of antenatal corticosteroid use in pregnant diabetic patients demonstrated a significant increase in insulin requirements for the 5 days following medication administration. Peak insulin requirements were noted on days 2 to 3 after administration, with an approximate 40% increase in insulin dosage needed to achieve glycemic control.[114]

Because of the potentially adverse maternal effects resulting from corticosteroid administration, women with diabetes were excluded from the recent National Institute of Child Health and Human Development multicenter trial evaluating the role of corticosteroid therapy in pregnancies at risk of late preterm birth between 34 + 0 and 36 + 5 weeks' gestation. This trial demonstrated a significant decrease in the need for neonatal respiratory support and a decrease in the rate of severe respiratory complications in those infants exposed in utero to corticosteroids prior to delivery; however, neonatal hypoglycemia was significantly more common in the group of exposed infants (24% in the betamethasone group vs. 15% in the placebo group, RR 1.60, 95% CI 1.37 to 1.87).[115] These results have led ACOG to advise the consideration of betamethasone administration in singleton pregnancies at risk for late preterm birth. However, ACOG acknowledges that patients with pregestational diabetes were not included in the Antenatal Late Preterm Steroids trial, so the effect of late preterm corticosteroids in this population is unknown.[116] In this setting, the potential adverse effects of late preterm corticosteroids are likely difficult to justify in patients with pregestational diabetes.

Hypertrophic Cardiomyopathy

Neonates of diabetic patients have an increased risk of developing hypertrophic cardiomyopathy. The most common echocardiographic findings include asymmetric interventricular septal enlargement, with hypertrophy of the ventricular free walls noted to a lesser extent. On average, most series reporting on the prevalence of hypertrophic cardiomyopathy note that 30% to 40% of neonates of diabetic patients have evidence of these cardiac changes on imaging, but only approximately 5% of infants will manifest symptoms suggestive of congestive heart failure. Heart failure may be caused by interventricular septal hypertrophy, leading to obstruction of the left ventricular outflow tract. Most symptomatic infants require only supportive care. In almost all cases, the myocardial hypertrophy is found to resolve spontaneously within 6 to 12 months of life.

The underlying etiology of hypertrophic cardiomyopathy is still incompletely understood; it is hypothesized to be related to fetal hyperinsulinemia.[117] As noted in other organs, increased insulin and related factors such as IGFs have been found to stimulate hyperplasia and hypertrophy. In myocardial cells, insulin inhibits the enzyme glycogen synthase kinase-3, which is a negative regulator of myocardial growth; its inhibition might contribute to abnormal myocardial hypertrophy. Further evidence in support of fetal hyperinsulinemia in the pathogenesis of hypertrophic cardiomyopathy comes from the observation that infants with congenital hyperinsulinism (in the absence of maternal diabetes) also appear to have an increased risk of hypertrophic cardiomyopathy. In a series of 25 infants with congenital hyperinsulinism who required neonatal echocardiogram evaluation for symptoms (e.g., arrhythmias, auscultated murmurs, etc.), 40% were found to have evidence of hypertrophic cardiomyopathy with features similar to that found in neonates of diabetic parturients.[118] Findings from serial fetal echocardiographic evaluations have also raised the hypothesis that structural cardiac changes may represent an adaptive response to altered fetal cardiac function early in gestation. Fetuses of diabetic parturients demonstrated impaired diastolic function (prolonged isovolumetric relaxation time and lower early/atrial [E/A] ratio) and poorer global cardiac function (increased myocardial performance index or Tei index) as compared with fetuses of nondiabetic parturients. The fetuses of diabetic parturients went on to develop evidence of interventricular septal thickening in the third trimester but had no persistent evidence of cardiac dysfunction later in gestation.[119] Maternal metabolic control during organogenesis is known to have a significant impact on fetal cardiac development, as discussed earlier in this chapter.

Predictors of symptomatic cardiomyopathy in neonates of diabetic parturients are limited at this time. Despite evidence that supports a role for fetal hyperinsulinemia in the development of hypertrophic cardiomyopathy, the association between maternal glycemic control and this fetal/neonatal complication is not clear. Clinical studies evaluating the correlation between fetal/neonatal hypertrophic cardiomyopathy and maternal HbA_{1c} values have been mixed in their conclusions. Investigators have reported evidence of septal hypertrophy even in fetuses of parturients with well-controlled diabetes. Third-trimester fetal echocardiography has been used to measure the myocardial performance index (as an indicator of global cardiac function) and the E wave/A wave peak velocity (E/A) ratio at the mitral valve, as an indicator of ventricular diastolic function, in an attempt to identify fetuses of diabetic parturients who are at increased risk of adverse perinatal outcome (including symptomatic cardiomyopathy). In a small series, these fetal echocardiographic measurements appeared to have reasonable sensitivity and specificity for the prediction of a composite of adverse perinatal outcomes, but given the low prevalence of the most serious of these outcomes (symptomatic cardiomyopathy, perinatal death), the predictive value and the cost-effectiveness of these measures are probably limited at this time.[120]

Hypocalcemia and Hypomagnesemia

Calcium and magnesium are actively transported across the placenta to the fetus throughout gestation. At delivery, the transfer of these minerals is terminated and neonatal levels of these minerals are expected to decrease in most infants, but IDMs appear to have an increased risk of more significant declines in levels of calcium and magnesium.

Neonatal hypocalcemia is often defined as a serum calcium level less than 7 mg/dL or an ionized calcium level less than 4.4 mg/dL (1.1 mmol/L). Studies have historically reported that up to 50% of IDMs may have hypocalcemia in the neonatal period, though more recent reports suggest a lower prevalence of 4% to 5%.[56] Most affected infants will be asymptomatic. This condition is often found to resolve spontaneously. It is suspected that neonatal hypocalcemia may result from a delayed transition from fetal to

neonatal parathyroid action in calcium metabolism as fetal parathyroid glands are relatively inactive until after delivery. The risk of neonatal hypocalcemia is further increased in the setting of prematurity as well as perinatal asphyxia.

Neonatal hypomagnesemia is defined as a serum magnesium level below 1.5 mg/dL. Hypomagnesemia has been reported to affect as many as 40% of neonates of diabetic parturients, although most usually remain asymptomatic. Neonatal hypomagnesemia appears to be most clinically relevant in the context of significant hypocalcemia, as concurrent hypomagnesemia makes the treatment of hypocalcemia more difficult. Magnesium deficiency probably has adverse effects on parathyroid function, thus exacerbating hypocalcemia. The pathophysiology underlying neonatal hypomagnesemia is not clear. Some experts have hypothesized that fetal hypomagnesemia may result from lower maternal magnesium levels in the setting of diabetes from increased maternal urinary losses or renal dysfunction.

Clinical signs and symptoms of hypocalcemia and hypomagnesemia are similar to those of hypoglycemia and include jitteriness, irritability, tachypnea, and possibly seizures in severe cases. Unlike hypoglycemia, which often presents within the first few hours of life, symptoms of hypocalcemia and hypomagnesemia typically present later at 24 to 72 hours after birth.[121]

Polycythemia

Polycythemia, defined as a venous hematocrit above 65% or hemoglobin greater than 20 g/dL, is also observed more often in IDMs. Polycythemia has been observed in approximately 3% of all infants born at sea level, with a slightly higher prevalence of 5% in infants born at higher altitudes. Among neonates of diabetic parturients, the reported prevalence has ranged from 5% to 40%.[122] Fetal hyperglycemia leads to increased catabolism and increased oxygen consumption resulting in decreased oxygen tension. If chronic, this relative fetal hypoxemia is thought to stimulate erythropoiesis, resulting in polycythemia. Some small series have reported an association between maternal diabetic control (as represented by HbA_{1c} levels) and neonatal hematocrit. Higher erythropoietin levels have been noted in the amniotic fluid of patients with diabetes. Neonates of diabetic parturients have also been shown to have increased erythropoietin levels at birth; erythropoietin levels in neonates of diabetic parturients have also been shown to correlate with amniotic fluid glucose and insulin levels, as well as cord blood insulin levels.

Infants with polycythemia may be at greater risk of complications resulting from hyperviscosity; reported complications include ischemia and infarction such as within the kidneys or within the CNS. These complications attributable to hyperviscosity may explain the increased incidence of renal vein thrombosis and stroke that have previously been reported in IDMs. Polycythemia in utero may also lead to deficient iron stores in the liver, brain, and heart; iron deficiency in these organs may then predispose to myopathies and altered neurodevelopment.

Infants with clinically significant polycythemia are likely to appear plethoric and may demonstrate sluggishness or lethargy. Treatment is currently initiated on the basis of symptoms and clinical status; treatment is not recommended on the basis of hematocrit value alone as the hematocrit level does not appear to correlate well with clinical hyperviscosity. Reported therapies include intravenous fluid administration and possible consideration of partial volume exchange transfusion in some severe cases.

Hyperbilirubinemia

Neonates of diabetic parturients also appear to be at greater risk for hyperbilirubinemia than infants born to nondiabetic patients. In studies that defined hyperbilirubinemia as a serum bilirubin level greater than 12 mg/dL, or any bilirubin level requiring phototherapy, the prevalence of hyperbilirubinemia in neonates of diabetic parturients was 25%[56]; other series report a hyperbilirubinemia prevalence of 10% to 13%. This increased risk might be attributable to polycythemia (larger source of bilirubin to be conjugated by the liver prior to excretion), ineffective erythropoiesis with an increased red blood cell turnover, as well as to immaturity of hepatic bilirubin conjugation and excretion. Macrosomic neonates of diabetic parturients appear to have the greatest risk of hyperbilirubinemia[123]; this probably reflects the role of poor maternal glycemic control during pregnancy as neonates of diabetic parturients are more likely to be macrosomic and polycythemic.

Breastfeeding

Breastfeeding is important to the health and well-being of all children; the benefits of breastfeeding may be greater in neonates of diabetic parturients. Early feeding in the immediate neonatal period may help to prevent hypoglycemia or effectively treat mild cases of hypoglycemia.

The positive effects of breastfeeding for neonates of diabetic parturients are likely to extend significantly beyond the neonatal period. Intrauterine exposure to maternal diabetes and/or obesity appears to be associated with an increased risk of childhood obesity; successful breastfeeding of durations greater than or equal to 6 months may mitigate some of this risk. There has been increasing evidence of the long-term impact of the intrauterine environment on the development of adulthood diseases. Several cohort studies have suggested an increased risk of diabetes and obesity in childhood or adolescence in the offspring of diabetic patients.[124–126] Studies conducted in the Pima Indian population demonstrated that offspring of diabetic patients had a significantly increased risk of type 1 diabetes (12-fold increased odds) when compared to offspring of nondiabetic patients.[127] Offspring of diabetic patients also were noted to be heavier than offspring of nondiabetics when evaluated at ages 5 to 9 years and at 10 to 14 years; the greater risk of obesity in offspring of diabetic patients persisted even among those who had a normal birth weight.[127]

A longer duration of breastfeeding has been associated with a decreased risk of offspring childhood obesity. A meta-analysis of studies conducted in general populations demonstrated that each month of breastfeeding was associated with a 4% decrease in risk of being overweight in childhood.[128] In offspring of diabetic parturients, breastfeeding duration of greater than or equal to 6 months has also been associated with decreased measures of adiposity such as waist circumference and measures of visceral and subcutaneous abdominal fat.[129] The obstetric community has increasingly recognized the importance of recommending and advocating for breastfeeding among diabetic parturients, as they are anticipated to benefit as well. During lactation, postpartum patients with diabetes have a significant decrease in insulin or oral hypoglycemic medication requirements; in fact, postpartum diabetic patients (especially type 1) are at an increased risk of hypoglycemia while breastfeeding. Predelivery counseling by their obstetric and/or endocrinologic providers can help to facilitate an

appropriate medical management and safety plan during lactation; close follow-up during the postpartum period with attention to issues unique to lactation in the context of diabetes can help to optimize breastfeeding success.

Maternal Medical Disorders of Fetal Significance

JERASIMOS BALLAS AND THOMAS F. KELLY

KEY POINTS

- Diagnostic imaging carries a risk of fetal radiation exposure. However, in most cases the actual fetal dose is low. While x-ray and computed tomography imaging should be avoided during pregnancy if possible, these studies are not contraindicated if needed.
- Adverse pregnancy outcomes in patients with lupus are more frequently seen in those with renal disease, antiphospholipid antibody syndrome, thrombocytopenia, and active disease.
- Cardiovascular disease in pregnancy is increasing in frequency and has become a major contributor to maternal mortality.
- The evaluation and management of most cancers should not be delayed for the sake of pregnancy. Surgery and most chemotherapeutic agents have been successfully used during the second and third trimesters.
- Epilepsy is associated with an increased rate of poor reproductive outcomes regardless of medication use. Medications used to control seizures do incur an increased rate of fetal anomalies, but the benefits to mother and fetus usually outweigh their risk.
- Selective serotonin reuptake inhibitors are considered first-line medication therapy for depression in pregnancy.

Pregnancies complicated by an underlying maternal medical condition increase the potential of a suboptimal perinatal outcome. Obstetricians are increasingly faced with patients affected by a medical problem that is unrelated to pregnancy. While diagnostic and therapeutic options for a nonpregnant adult in most cases can be effectively applied during pregnancy, there are concerns about whether these will adversely affect the fetus or newborn. Furthermore, the alterations of anatomy and physiology during pregnancy may require adjustments to therapeutic options.

Two questions should be addressed when a specialist is caring for a pregnant patient with a known medical problem. First, is the condition itself affected by the anatomic or physiologic alterations of pregnancy? Second, how does the medical problem potentially affect the patient, the fetus, or the ultimate perinatal outcome? A further concern is how to evaluate a newly suspected medical problem during pregnancy. Pregnancy itself can be a confounder as many symptoms experienced are similar to those of certain medical or surgical conditions, leading to either a lack of or delay in diagnosis. Providers may be reticent to perform needed imaging studies, proceed with indicated surgical procedures, or prescribe medications over concerns regarding risk to the fetus. Delays of diagnoses of de novo medical problems due to pregnancy have been reported. Unfortunately, in some cases, a lack of timely recognition and initiation of appropriate therapy may result in poor maternal or fetal outcomes.

General Principles in the Diagnosis and Management of Medical Complications During Pregnancy

Diagnostic Imaging

Ultrasonography and magnetic resonance imaging (MRI) are not associated with fetal risk and should be considered the imaging of choice for pregnant patients.[1] Diagnostic radiography, computed tomography (CT) scans, and nuclear medicine studies may be associated with fetal radiation exposure, even when studies target specific anatomy remote from the pregnant uterus (Table 9.1).[2] The fetal consequences of radiation exposure are both dose and time dependent (Table 9.2).[3] However, for most diagnostic procedures, actual fetal exposure is relatively low.

If possible, the practitioner should limit the amount of radiographic testing performed during pregnancy, but indicated studies should never be withheld because of pregnancy. Lead shielding of the abdomen and pelvis and careful selection of the type of study should be undertaken to minimize the fetal dose. To simplify the various measures of exposure, 1 radiation absorbed dose (rad), 1 Roentgen equivalents man (rem), 10 milliGray (mGy), and 10 milliSievert (mSv) can be considered equivalent.[4]

If the amount of fetal exposure is less than 5 rad, there appears to be no significant increased risk of malformations. While an increased risk of childhood cancer has been reported in case-control studies with prenatal radiation doses of greater than 10 mGy, prospective studies and larger meta-analyses have not consistently replicated this association between fetal radiation exposure and risk of cancer.[5,6] Iodinated contrast agents have not been shown to be teratogenic. Despite a theoretical concern about fetal hypothyroidism, there have been no reported cases resulting from the use of these agents.[3]

MRI has not been shown to have adverse effects on the fetus and there are no precautions or contraindications specific to pregnant patients. While historically it was recommended that MRI be avoided in the first trimester, the American College of

TABLE 9.1 Estimated Fetal Radiation Doses During Common Radiologic Examinations

Type of Examination	Fetal Dose (mGy)
Very Low Dose (<0.1 mGy)	
Cervical spine (anteroposterior, lateral)	<0.001
Extremities	<0.001
Mammography (two views)	0.001–0.01
Chest (posteroanterior, lateral)	0.0005–0.01
Low to Moderate Dose (0.1–10 mGy)	
Radiography	
Thoracic spine (anteroposterior, lateral)	0.003
Abdomen (anteroposterior)	0.1–3.0
Lumbar spine (anteroposterior, lateral)	1.0–10
Limited IV pyelogram	5–10
Double contrast barium enema	1.0–20
CT Scan	
Head CT	0
Chest CT or CT pulmonary angiography	0.01–0.66
Limited CT pelvimetry	<1.0
Nuclear Medicine	
Very Low Dose <0.1 mGy)	
Low-dose perfusion scintigraphy for PE	0.1–0.5
Pulmonary digital subtraction angiography	0.5
Technetium-99m bone scintigraphy	4–5
High Dose (10–50 mGy)	
Abdominal CT scan	1.3–35
CT scan of the abdomen/pelvis	10-50
^{18}F PET/CT whole-body scintigraphy	10-50

CT, Computed tomography; *IV*, intravenous; PET, positron emission tomography; *mGy*, milliGray.
Adapted from Tremblay E, Thérasse E, Thomassin-Naggara I, et al. Quality initiatives: guidelines for use of medical imaging during pregnancy and lactation. *Radiographics*. 2012;32:897–911.

Radiology has stated no special consideration is recommended for any trimester in pregnancy.[7–9] The use of gadolinium contrast in pregnancy remains controversial given its ability to cross the placenta and concentrate in amniotic fluid. A large, retrospective study found prenatal gadolinium exposure associated with rheumatologic, inflammatory, or infiltrative skin disorders (adjusted hazard ratio, 1.36; 95% confidence interval [CI] 1.09 to 1.69) and increased risk of stillbirth and neonatal demise (adjust RR, 3.70; 95% CI 1.55 to 8.85) when compared to unexposed pregnancies.[10] Ultimately, gadolinium contrast should only be used during pregnancy when close consultation with radiology specialists determines that the benefits for diagnosis far outweigh the aforementioned risks.[11] In the postpartum period, the use of all contrast agents, including gadolinium, is considered safe during lactation and the American College of Obstetricians and Gynecologists (ACOG) recommends that breastfeeding not be interrupted.[1]

Surgery During Pregnancy

Approximately 2% of pregnant patients require surgery for a nonobstetrical condition. The most common indications are appendicitis and cholecystitis followed by orthopedic procedures.[12–14] Indicated surgery during pregnancy is relatively safe. While the potential for adverse perinatal outcomes is slightly increased when compared with patients not requiring surgery, the delay of necessary procedures clearly increases the risk of poor maternal or fetal outcomes. A review of 54 studies regarding surgery during pregnancy concluded the following:[15]

1. The risk of maternal death is low.
2. Surgery and general anesthesia do not appear to be major risk factors for spontaneous abortion.
3. Elective termination rates are similar to the general population.
4. The rate of congenital anomalies does not appear to be increased.
5. Acute appendicitis, particularly with peritonitis, appears to be a risk of surgery-induced labor or fetal loss.
6. Urgent surgical procedures should be performed when needed.

Since appendectomy is the most common nonobstetric surgery performed during pregnancy (1 in 766 births), the data regarding outcomes are relatively robust. Anatomic changes in pregnancy can confound the diagnosis while a reluctance to operate on a pregnant patient can delay treatment and worsen outcomes. The negative appendectomy rate in pregnancy is higher when compared with nonpregnant cases (23% vs. 18%). The rates of fetal loss and early delivery are higher for complex appendicitis (6% and 11%, respectively) versus simple appendicitis (2% and 4%, respectively). Unfortunately, surgery for appendicitis and the finding of a normal appendix is still associated with an increased risk of loss (3% to 4%).[16,17] While laparoscopy is being utilized increasingly during pregnancy, there may be an associated increased risk of loss when compared with laparotomy for suspected appendicitis.[18] Ultimately, the type of surgical procedure, whether laparoscopic versus open, should be determined by the surgeon, in consultation with the obstetrics team.

Guidelines to optimize outcomes for pregnant patients undergoing surgery are relatively straightforward. Anesthetic options are unchanged when compared with nonpregnant patients, as both regional and general anesthesia can be safely administered. If general anesthesia is being used, extra care must be taken to protect the maternal airway from aspiration given the anatomic and physiologic oropharyngeal changes, reduced gastrointestinal motility, and displaced stomach that may contain significant residual contents hours after eating. In the second and third trimesters, a lateral decubitus position is preferred to reduce venacaval compression, thus optimizing both maternal venous return and uteroplacental perfusion. Preoperative counseling with an obstetrician and neonatologist is recommended, particularly if the gestational age is greater than or equal to 22 weeks to give the surgical team direction regarding interventions should fetal distress be encountered. Fetal heart rate monitoring, if feasible, can also facilitate the assessment of fetal status.

TABLE 9.2 American College of Radiology Summary of the International Commission on Radiological Protection Suspected in Utero-Induced Deterministic Radiation Effects

		RADIATION DOSE		
Menstrual or Gestational Age	Conception Age	<50 mGy (<5 rad)	50–100 mGy (5–10 rad)	>100 mGy (>10 rad)
0–2 weeks (0–14 days)	Before implantation	None	None	None
3rd and 4th week (15–28 days)	1st–2nd week (1–14 days)	None	Probably none	Possible spontaneous abortion
5th–10th week (29–70 days)	3rd–8th week (15–56 days)	None	Potential effects are scientifically uncertain and probably too subtle to be clinically detectable	Possible malformations increasing in likelihood as dose increases
11th–17th week (71–119 days)	9th–15th week (57–105 days)	None	Potential effects are scientifically uncertain and probably too subtle to be clinically detectable	Increased risk of deficits in intelligence quotient or mental retardation that increase in frequency and severity with increasing dose
18th–27th week (120–189 days)	16th–25th week (106–175 days)	None	None	Intelligence quotient deficits not detectable at diagnostic doses
>27 weeks (>189 days)	>25 weeks (>175 days)	None	None	None applicable to diagnostic medicine

mGy, MilliGray; *rad*, radiation absorbed dose.

Medication Usage

Maternal medication use during pregnancy requires the provider to understand two basic principles:

- Alterations of maternal anatomy and physiology may alter the effective dose.
- Maternal medications may enter the fetal circulation with resulting fetal exposure.

There are significant physiologic alterations in pregnancy that may affect the bioavailability, distribution, clearance, and half-life of a medication. Absorption is altered due to nausea and vomiting, gastric volume and pH changes, increased gastrointestinal transit time, and differences in the activity of drug-metabolizing enzymes in the gut. Increased body weight and plasma volume as well as reduced albumin alter the volume of distribution. Hepatic and placental enzymatic activity and increased glomerular filtration rates will influence drug clearance.[19] Examples of medication classes that often require increased dosing through gestation include thyroid function modulators, antiepileptics, antihypertensives, and medication assisted therapies (MAT) for substance use disorder.

With the discovery that certain medications may induce congenital malformations, notably thalidomide in the early 1960s, the Food and Drug Administration (FDA) developed a maternal drug classification system with escalating categories (A through D) signifying increased fetal risk, and a standalone Category X denoting medications that were contraindicated in pregnancy. Most drugs (65% to 70%) were labeled category C, meaning that animal studies had shown potential adverse effects, however, no adequate human studies were available to corroborate.[20] With half of all pregnant women receiving prescription drugs in categories C and D, the actual utility of this classification system became questionable.[21] In 2015 the FDA published the "Pregnancy and Lactation Labeling Rule," eliminating the ABCDX classification for any new drug applications and retroactively labeling prescription drugs approved after 2001.[22] The new labels include a summary of known fetal and newborn risks, considerations for lactation and breastfeeding, latest available data, and information for pregnant patients to participate in ongoing registries for the medication. In addition to pregnant patients, the expanded labeling also includes information on the potential impact medications may have on both male and female reproductive potential. Ultimately, such information should be utilized by both patients and physicians as part of a shared decision-making process, with the understanding that maternal benefit will most often outweigh weak or theoretical fetal risks when it comes to recommending indicated medical treatments in pregnancy.

Autoimmune Disorders

Systemic rheumatoid illnesses are seen more commonly in women than men and with presentations commonly in young adulthood and middle age. Therefore pregnancy complicated by an autoimmune condition is common. There are an estimated 4500 pregnancies complicated by systemic lupus erythematosus (SLE) in the United States annually.[23] Other autoimmune conditions seen during pregnancy include rheumatoid arthritis and scleroderma. While perinatal implications may differ, depending on the diagnosis, there are enough similarities among most rheumatologic disorders that there are common themes in maternal management, including work-up, medication usage, and fetal screening. Furthermore, some patients may have findings consistent with an autoimmune condition but lack enough criteria to warrant a specific diagnosis. Finally, there are individuals lacking clinical rheumatologic manifestations that exhibit autoantibodies that have maternal, fetal, or neonatal implications. The nuances of all

autoimmune disorders are too broad to allow discussion in this chapter. Therefore the focus will be on SLE and common antibody disorders with specific perinatal implications.

Systemic Lupus Erythematosus

SLE or lupus is a chronic multiorgan disease with a wide clinical spectrum. Advancements in reproductive and autoimmune care have improved maternal and fetal outcomes, reflected by the reduction of fetal loss rates from 43% to 17% between 1960 and 2000.[24] In the absence of antiphospholipid antibody syndrome (APS) or significant renal insufficiency, fertility does not seem impacted.[25] As with most autoimmune conditions, there is no uniform agreement on whether pregnancy alters the disease course. However, risk factors associated with a lupus flare include active disease within 6 months before conception, history of multiple flares, and discontinuation of hydroxychloroquine.

Risk factors for poor pregnancy outcomes in patients with lupus include proteinuria, renal insufficiency, APS, thrombocytopenia, or active maternal disease at the time of conception (Table 9.3).[26] Those with nephritis, APS, or who have anti-Sjögren syndrome related-antigen A (anti-SSA or anti-Ro antibodies) may have increased risks of altered perinatal outcomes.[27] Adverse outcomes include spontaneous abortion and intrauterine growth restriction (IUGR), and the risk of superimposed preeclampsia and stillbirth are potentially increased. Therefore, assessment of the patient's baseline disease activity, as well as exploration for evidence of multiorgan system dysfunction, is vital to aid in counseling and management. Comanagement with rheumatologists and/or nephrologists is vital to improving maternal and fetal outcomes.

Initial prenatal evaluation of a patient with lupus includes taking a history, such as disease activity, organ system involvement, and current medical therapy. The latter is important in determining whether there is an increased fetal risk, as some medications used are generally contraindicated during pregnancy (methotrexate, mycophenolate mofetil). Fortunately, most patients planning pregnancy are not using these agents. Prednisone, azathioprine, and hydroxychloroquine are more commonly used medications with reasonable safety profiles during pregnancy.

Chemical screening for disease activity should be performed. This includes anti-double-stranded DNA and complement levels. Antiphospholipid antibodies, anti-Ro, and anti-La (otherwise known as anti-Sjögren syndrome related-antigen B or anti-SSB) antibodies should be measured. The patient should also have baseline assessments for proteinuria, renal function, hepatic enzymes, and platelet count not only to assess her status but also to formulate a baseline profile (Table 9.4). Since a lupus flare may mimic preeclampsia, a comparison of her repeated studies against those obtained earlier may be helpful, as the management of these two conditions differs.

Medication management, including type and amount, is dictated by disease activity and the presence of APS. Most patients are managed with steroids, hydroxychloroquine, or azathioprine, and alterations of these should probably not be dictated by pregnancy. While there may be theoretical concerns with their usage, these drugs have to be balanced against the risk of uncontrolled lupus (Table 9.5).[28–30]

Disease activity should include serial assessment of maternal symptoms as well as complement and anti-double-stranded DNA levels. Fetal evaluation includes serial ultrasounds and antepartum testing. An increase in the patient's blood pressure or level of proteinuria may represent either a lupus flare or preeclampsia. Differentiation between the two is challenging, but every effort should be made to do so, as therapies for both are different.

Antiphospholipid Antibody Syndrome

APS was originally described as an autoimmune disease characterized by circulating antiphospholipid antibodies (aPL) and venous thrombosis, recurrent pregnancy loss, and occasionally thrombocytopenia.[31] This disorder may be isolated or associated with other autoimmune diseases. The presence of aPL is found in about 1% to 5% of healthy women. However, these antibodies are found in 15% of women who have recurrent abortions and in 30% to 40% of those with SLE.[32,33] The presence of aPL in the latter is a risk factor for a poor pregnancy prognosis.

Few women with aPL will develop the disease, and the prevalence of APS is estimated to be only 50/100,000.[34] The diagnosis of APS must include clinical criteria (vascular thrombosis, unexplained death of a morphologically normal fetus >10 weeks' gestation, premature birth <34 weeks due to preeclampsia or placental insufficiency, or ≥3 weeks otherwise unexplained abortions <10 weeks), as well as the presence of aPL (lupus

TABLE 9.3 Systemic Lupus Erythematosus and Adverse Pregnancy Outcomes

	Adverse Outcome	Percentage	OR
Systemic Lupus Erythematosus ± Antiphospholipid Syndrome			
	Prematurity	25%–35%	
	Preeclampsia	10%–15%	
	Eclampsia / HELLP	1%–1.5%	
Antiphospholipid ± Systemic Lupus Erythematosus			
	Prematurity	25%–30%	
	Preeclampsia	10%–20%	
	Eclampsia / HELLP	3%—5%	
Systemic Lupus Manifestations That Adjust Perinatal Risk			
Active flare	Preeclampsia		12.7
	Emergent cesarean		19
	Early fetal loss		3
	Preterm birth		5.5
Active nephritis	Any		5.3
Hypertension	Preeclampsia		4.8–7.3
Prednisone >10 mg/day	Preterm birth		3.5

EULAR recommendations for women's health and the management of family planning, assisted reproduction, pregnancy and menopause in patients with systemic lupus erythematosus and/or antiphospholipid syndrome. *Ann Rheum Dis.* 2017; 76:476–485.

TABLE 9.4 Laboratory Testing of Patients With Systemic Lupus Erythematosus During Pregnancy

Timing	Purpose	Test	Comment
Preconception or initial prenatal visit	Screen for organ system dysfunction and baseline for comparison should a lupus flare or preeclampsia be suspected	Urinalysis	Assessment of renal disease activity
		24-h urine for total protein or urine protein:creatinine ratio	24-h urine collection for proteinuria recommended if abnormal protein:creatinine ratio
		Complete blood count	Assess for thrombocytopenia
		Chemistry panel	
	Screen for risk of neonatal lupus syndrome	Anti-SSA (Ro) and Anti-SSB (La) antibodies	If present, screen for fetal congenital heart block
	Screen for disease activity and baseline for comparison should a lupus flare or preeclampsia be suspected	Anti-double-stranded DNA antibody Complement levels	Complement levels may increase in a normal pregnancy
Monthly		Urinalysis	Urine protein:creatinine ratio if urinalysis suspects proteinuria
		Creatinine	If prior history of lupus nephritis or prior renal dysfunction is noted
Every trimester		Anti-double-stranded DNA antibody Complement levels	
		Complete blood count	
		Chemistry panel	

anticoagulant, anticardiolipin antibody, or anti-β_2-glycoprotein antibody) on greater than two occasions, at least 12 weeks apart.[35] For those with a prior history of venous or arterial thrombosis, prophylactic anticoagulation with heparin throughout pregnancy and continuing through 6 weeks' postpartum is usually recommended. In patients with recurrent pregnancy loss, low-dose aspirin and heparin may reduce pregnancy loss by 50%.[36] Therefore even in the absence of a thrombotic history, in those with a history of stillbirth or recurrent pregnancy loss, prophylactic heparin and low-dose aspirin should be offered during pregnancy for up to 6 weeks' postpartum. [37]

Neonatal Lupus

Anti-Ro and anti-La antibodies can be present in asymptomatic women. The former are more often seen in women with Sjögren syndrome but can be also found in women with other autoimmune disorders.[38] These antibodies cross the placenta and have been associated with congenital heart block. In the absence of a prior infant with congenital heart block, the prospective fetal risk is low, at 2%. However, in patients with a prior history of an affected fetus or neonate, the recurrence risk is 15% to 20%.[39,40] The morbidity and mortality of these infants are significant, the latter ranging between 10% and 29%.[41] Other consequences include the potential need for a pacemaker or cardiac transplantation.

The injury to the atrioventricular node most often occurs between 16 and 24 weeks, and there is the potential for fibrosis that can extend to the endocardium and myocardium. No prenatal interventions have been shown to reverse complete heart block.[42] However, there may be some improvement in outcome with the use of fluorinated steroids if second-degree heart block is detected. There are potential fetal consequences of maternal steroids, including adrenal insufficiency, as well as neurodevelopmental and growth abnormalities.[41] It is suggested that women exhibiting these antibodies undergo fetal echocardiography beginning in the second trimester (16 to 18 weeks) and repeated every 1 to 2 weeks until 28 weeks.[43] In those with a prior child affected with congenital heart block, the use of hydroxychloroquine may be associated with a reduced risk of recurrence.[39]

Immune Thrombocytopenia

Approximately 7% to 10% of pregnancies are complicated by thrombocytopenia.[44] The most common etiology is gestational thrombocytopenia (75%), followed by preeclampsia (15% to 20%) and immune thrombocytopenia (ITP) (3%). By definition, ITP is immune mediated, and the responsible antibody may cross the placenta. The incidence is approximately 1/1000 pregnancies, but more significant disease (maternal platelet count $<50 \times 10^9$/L) is rare occurring in 0.85/100,000 pregnancies.[45,46] ITP is associated with an increased risk of neonatal thrombocytopenia, with 15% to 50% of newborns having platelets less than 100×10^9/L, 8% to 30% less than 50×10^9/L, and 1% to 5% less than 20×10^9/L.[44] Unfortunately, there is no variable that accurately predicts the potential for neonatal thrombocytopenia. There is no correlation between the maternal and neonatal platelet count, nor does the use of steroids or IVIg not seem protective. A history of a prior affected child or maternal splenectomy may increase the neonatal risk of thrombocytopenia.[46] Over the years, a number of interventions had been proposed in the past to reduce the risk of spontaneous fetal or neonatal bleeding. Strategies such as performing a routine cesarean section, fetal scalp platelet assessment in labor, or percutaneous fetal scalp platelet counts were not found to be helpful and were potentially associated with increased maternal or fetal

TABLE 9.5 Medications Used for Rheumatologic Disorders

Drug	Maternal and Fetal Outcomes	Recommendations
Commonly Used During Pregnancy		
Prednisone, prednisolone	Possible risk for orofacial clefts	Treatment of flares or maintenance therapy
Fluorinated corticosteroids (betamethasone, dexamethasone)	Cross the placenta. May be associated with poor fetal growth or adverse neurologic outcomes if used in multiple doses	Use only if fetal treatment is being considered (neonatal lupus syndrome)
Hydroxychloroquine	Considered safe in doses commonly used in SLE and RA	Safe to continue in pregnancy
Azathioprine	May be associated with IUGR, transient immune alterations	Long track record of use in pregnancies complicated by SLE. Safe to continue if necessary
Nonsteroidal anti-inflammatory drugs	May be associated with fetal ductus arteriosus constriction and impaired renal function with third trimester use	Avoid in third trimester. Limit use to very short duration (48–72 h)
Sulfasalazine	No increased risk in doses commonly used in RA	Use folic acid supplementation preconception and during pregnancy
Heparin	Does not cross placenta	If using low-molecular-weight heparin, may require changing to unfractionated heparin after 36 weeks for maternal anesthesia
IVIG	No identifiable fetal risk	May be used in refractory cases of immune thrombocytopenia
Contraindicated		
Methotrexate	Increased risk for congenital malformations	Conception should be delayed for at least 3 months after last dose
Leflunomide	Embryotoxicity	Discontinue 2 years prior to conception
Mycophenolate mofetil	Increased risk for congenital malformations	
May Be Used		
Cyclosporine	Often used in patients with organ transplants. No increased risk of congenital malformations	May be used in patients with SLE
Cyclophosphamide	Use in first trimester associated with fetal anomalies or loss. Second- and third-trimester use may be associated with fetal growth issues and impaired neurologic development	Use only if mother's life is at risk and other options have been exhausted
Rituximab	Associated with transient B-cell depletion in the second and third trimesters	Inadequate safety data to support routine use in pregnancy Neonatal live virus vaccination should be delayed by 6 months

morbidity. Therefore it is recommended that the delivery mode should not be altered for the diagnosis of ITP.[47]

Maternal management for this condition in the first and second trimesters of pregnancy is essentially unchanged when compared with a nonpregnant patient.[48] If the maternal platelet count is greater than 30,000/μL, no treatment is necessary. Below this threshold, or if there is evidence of spontaneous bleeding, corticosteroids and intravenous immunoglobulin are usually first-line therapies. Both are relatively safe during pregnancy and usually associated with a good maternal response. Refractory cases are difficult to manage. Large-dose anti-D antibody administration and splenectomy are options when initial therapy fails.[48]

Gestational thrombocytopenia (GTP) is a benign condition that sometimes can be difficult to delineate from ITP. However, the salient features include a lack of prior maternal history of severe thrombocytopenia and a maternal platelet count that is usually above 80,000/μL. Other potential causes for a low platelet count should be explored, including severe preeclampsia, autoimmune disease, medication usage, and viral illness. True GTP has no associated risk of neonatal thrombocytopenia. One potential consequence of GTP may be the reluctance of some anesthesiologists to place a regional anesthetic if the platelet count is too low.

Cardiovascular Disease

Cardiovascular disease in pregnancy has become a leading cause of morbidity and mortality, affecting 1% to 4% of pregnancies in the United States and contributing to 26% of maternal deaths.[49,50]

While this increase may be explained, in part, by improved reporting and evaluation of maternal deaths, the general consensus is that higher rates of advanced maternal age accompanied by comorbidities such as diabetes, hypertension, and obesity have contributed the most to increasing rates of cardiovascular mortality in pregnancy. In 1970, approximately 1% of first-time mothers were greater than 35 years old. Four decades later, this incidence has increased to 9.1%.[51]

Hemodynamic alterations of pregnancy begin early in gestation. Maternal blood volume increases by 50%, with an accompanying decrease in systemic vascular resistance. The cardiac output increases by 30% to 50% and heart rate by 15%. The labor process further increases cardiac output.[52,53] Furthermore, there are intra- and extravascular fluid shifts that occur after delivery. A previously compromised heart may not tolerate these changes. Attempts to stratify maternal risk have resulted in various scoring systems. The World Health Organization (WHO) risk stratification system has been validated in pregnancy and defines risk based on the presence of cardiac lesions, overall cardiac function, and current health status (Table 9.6).[54] The highest risk (WHO IV) includes individuals with pulmonary hypertension, severe left ventricular dysfunction, previous peripartum cardiomyopathy with residual impairment of left ventricular dysfunction, left heart obstruction, or Marfan syndrome with a dilated aorta.[55] In these patients, pregnancy is not advisable given the high risk of maternal mortality.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy (PPCM) refers to the onset of idiopathic dilated heart failure within 1 month prior to delivery or within 5 months after. The incidence of PPCM in the United States is increasing and is estimated to occur in 1/968 live births.[56] Risk factors include advanced maternal age, hypertension, preeclampsia, parity, and multiple gestations.[53] While the exact etiology is unknown, potential mediators include inflammation, autoimmune processes, endothelial dysfunction, oxidative stress, and underlying genetic mutations.[57,58] African-American race has long been associated as a risk factor for PPCM but without much biologic explanation. More contemporary analysis suggests that negative social determinants of health contribute to proinflammatory states and hypertensive disorders. When combined with delayed diagnosis and inadequate treatment due to socioeconomic barriers,

TABLE 9.6 Modified WHO Risk Stratification for Pregnant Patients With Cardiovascular Disease

Modified WHO Risk Classification (Cardiac Event Risk)	Examples of Cardiac Lesions	Suggested Follow-up and Delivery Planning
Class I (2%–5% risk)	• Small or mild pulmonary stenosis, patent ductus arteriosus, or mitral valve prolapse • Successfully repaired lesions	Cardiology 1–2 times in pregnancy
Class II (6%–10% risk)	• Unrepaired atrial or ventricular septal defect • Repaired tetralogy of Fallot • Most supraventricular arrhythmias • Turner syndrome *without* congenital cardiac disease	Cardiology every trimester Multidisciplinary cardiac team for delivery planning
Class II–III (11%–19% risk)	• Mild left ventricular impairment • Hypertrophic cardiomyopathy • Native/tissue valvular heart disease • Marfan syndrome without aortic dilation • Heart transplantation	Cardiology every trimester Multidisciplinary cardiac team for delivery planning
Class III (20%–27% risk)	• Mechanical valve • Systemic right ventricle (i.e., congenitally corrected transposition or simple repair) • Cyanotic heart disease • Post Fontan operation • Complex congenital heart disease	Cardiology every 1–2 months Multidisciplinary cardiac team for delivery planning

Class IV (>27% risk)
Pregnancy contraindicated
	• Pulmonary arterial hypertension
	• Severe systemic ventricular dysfunction
	  • Ejection fraction <30%, NYHA III-IV
	• Previous peripartum cardiomyopathy with residual left ventricular dysfunction
	• Severe mitral stenosis
	• Severe, symptomatic aortic stenosis
	• Systemic right ventricle with decreased ventricular function
	• Aortic dilation
	  • >45 mm in Marfan syndrome
	  • >50 mm in bicuspid aortic valve or tetralogy of Fallot
	  • Aortic size index (ASI) >25 mm/m^2 in Turner syndrome
	  • Vascular Ehlers-Danlos
	  • Severe re-coarctation
	  • Fontan circulation with any complication
		Cardiology monthly
		Multidisciplinary cardiac team for delivery planning
		Consider termination of pregnancy

these factors likely contribute to the racial disparities observed in PPCM incidence and recovery.[59]

Presentation of PPCM may be indolent, as symptoms such as fatigue, shortness of breath, tachycardia, tachypnea, and lower extremity edema can mimic those commonly encountered in pregnancy and the immediate postpartum period. Furthermore, patients with preeclampsia can have significant left-ventricular dysfunction and pulmonary edema, albeit transiently, which may delay diagnosis. Initial workup includes an electrocardiogram. There is a high prevalence of abnormalities in peripartum cardiomyopathy, including evidence of left-sided changes, conduction delays, reduced voltage, and abnormal Q waves. Echocardiography provides the best sensitivity for diagnosis, often revealing depressed left-ventricular function, significant ventricular dilation, and an ejection fraction less than 45%.[53] B-type natriuretic peptide levels, though normally increased in pregnancy, may be significantly increased as a consequence of left-ventricular end-diastolic pressure.[57] Treatment is supportive and similar to that of preexisting dilated cardiomyopathy. Complications include cardiogenic shock, arrhythmias, thromboembolism, and death. While 25% to 50% of patients with peripartum cardiomyopathy may recover by 6 months, one-quarter do not improve. The mortality may approach 15%.[57] There is an increased risk in subsequent pregnancies, particularly in those who have not had full recovery of reduced ejection fraction and heart failure.[60]

Congenital Heart Disease

Congenital heart disease (CHD) occurs in 81 in every 10,000 live births, affecting approximately 1% of the population.[61] The prevalence of CHD complicating deliveries is approximately 9 per 10,000 hospitalizations.[62] This represents a significant increase over the last two decades due to the improved diagnosis and treatment of CHD allowing more patients to reach childbearing age. With the exception of hypertensive disorders and thromboembolic events, obstetric complications do not seem to be increased in these patients. However, cardiac complications are found in about 11% of patients and include arrhythmias, heart failure, and cardiovascular events. [63] Myocardial infarction, cerebrovascular accidents, and mortality were noted in about 2% of patients. In those patients with more complex CHD, including Ebstein anomaly, transposition of the great vessels, pulmonary atresia with ventricular septal defects, and Eisenmenger syndrome, the preterm delivery rate ranged between 22% and 65%. The offspring mortality is higher, probably caused by prematurity. The infants have a higher incidence of CHD, between 0.6% and 8%, depending on the maternal lesion.[63]

Women with CHD should be evaluated before conception to advise them of the maternal and fetal risks of pregnancy. Many patients have limited or inaccurate knowledge of their disease. The history of the actual defect and subsequent surgical and other interventions should be obtained. Electrocardiography and echocardiography should be performed. The latter should focus on ventricular and valve functions, pulmonary artery pressure, and the presence of any prosthetic material. Since about 18% of patients have a defined chromosomal or Mendelian abnormality, formal genetic screening should be performed.[64]

Pregnancy management requires a multidisciplinary team, including cardiology, high-risk obstetrics, and anesthesiology. If necessary, cardiac catheterization or percutaneous interventions can be considered. Cardiopulmonary bypass can be performed during pregnancy, but there is an increased risk of prematurity and fetal death, particularly with urgent, high-risk surgery and maternal comorbidity.[65] Medical control of arrhythmias, if necessary, is usually safe. However, the use of β-blocker or calcium channel blocker may be associated with suboptimal fetal growth. In most cases, vaginal delivery is preferred. Cesarean section may be considered for women with severe aortic stenosis or pulmonary hypertension.

Coronary Artery Disease

Coronary artery disease (CAD) is a significant cause of maternal mortality and may account for up to 20% of maternal cardiac deaths.[66] Acute myocardial infarction may complicate up to 6/100,000 pregnancies.[67] It appears that spontaneous coronary artery dissection is more common during pregnancy. In one review of maternal deaths in the UK, all of the women who died had at least one risk factor for CAD. Unfortunately, in half of these cases, their care was deemed substandard due to delay in diagnosis or reluctance to treat due to pregnancy.[66] Patients with ST-segment elevation myocardial infarction should be treated similarly to those who are not pregnant. This includes percutaneous coronary intervention.[68] If stenting is required, bare metal stents are preferred in order to minimize the need for long-term dual antiplatelet therapy.[69] Aspirin and clopidogrel appear to be safe in pregnancy. Longer-duration antiplatelet therapy is generally recommended if a drug-eluting stent is placed. Once clopidogrel is no longer deemed necessary, single-agent antiplatelet therapy with aspirin is appropriate. β-Blockers are relatively safe to use in pregnancy but carry a theoretical risk of suboptimal placental perfusion.

Renal Disease

Chronic kidney disease (CKD) is a heterogeneous group of disorders with alterations in renal function. The prevalence in women of childbearing women is estimated between 0.1% and 4%.[70] It is estimated that 1/750 pregnancies is complicated by stages 3 to 5 CKD.[71] Since there is no accurate ability to measure glomerular filtration rate in pregnancy, women with CKD have been arbitrarily classified into three categories based on the serum creatinine level: mild, less than 1.5 mg/dL; moderate, 1.5 to 2.5 mg/dL; and severe, greater than 2.5 mg/dL (Table 9.7).[72] Whether the newer staging of CKD is better than the latter classification in

TABLE 9.7 Stages of Chronic Kidney Disease

Stage	Description	Glomerular Filtration Rate (mL/mm²)
1	Kidney damage with normal or raised GFR	>90
2	Kidney damage with mildly lower GFR	60–89
3	Moderately lower GFR	30–59
4	Severely low GFR	15–29
5	Kidney failure	<15 or dialysis

GFR, Glomerular filtration rate.

predicting pregnancy outcomes is unknown, but Table 9.8 summarizes maternal and pregnancy outcomes.[73]

Pregnancy may influence the rate of decline of renal function. While it appears unlikely when the baseline creatinine is less than 1.5 mg/dL, patients with hypertension are more likely to develop progressive disease.[74] However, the same cannot be said for those with moderate impairment (creatinine >1.5 mg/dL). A significant risk of deterioration of maternal renal function can be seen in up to 40% of patients with progression to end-stage disease in 10%.[75] The risk of irreversible deterioration of renal function is significant in those with marked impairment of renal function irrespective of the type of disease when accompanied by uncontrolled hypertension.[76]

When compared with women without CKD, those with kidney disease have a 52% increased odds of preterm delivery, 33% increased odds of cesarean section, 71% increased odds of neonatal intensive care unit (NICU) admission, and twofold increased odds of low birth weight.[77] The effect of mild-to-moderate CKD on pregnancy is dependent on the degree of renal impairment and the presence of underlying hypertension. In patients with mild renal dysfunction, successful outcomes are usually above 80% but with a complication rate of 26%.[78] However, there are increased rates of IUGR, preterm birth, and preeclampsia. In those with severe renal impairment, there are increased rates of infertility, miscarriage, and poor perinatal outcome. These pregnancies are complicated by growth restriction (65%), preterm birth (90%), preeclampsia (60%), and perinatal death (10%).[71]

Ideally, patients are evaluated prior to pregnancy. Preconception counseling regarding maternal and perinatal outcomes is dependent on the patient's baseline renal function, degree of hypertension, and various comorbid conditions. For example, those with severe renal impairment should consult with a nephrologist to determine whether medication therapy or dialysis should be considered. Implementing therapies that may optimize her medical status in the non-gravid state is recommended to improve outcome. Antihypertensive medication adjustments may be necessary to reduce fetal consequences, particularly with the use of angiotensin-converting enzyme inhibitors or receptor blockers that are known teratogens. If the degree of renal impairment is unknown, a 24-hour urine for creatinine clearance and total proteinuria should be performed. Furthermore, screening for active renal processes such as glomerulonephritis, lupus nephritis, reflux, and infection is advisable, as treatment may improve the degree of renal dysfunction. Low-dose aspirin (100 to 150 mg/day) starting at 16 weeks is recommended to potentially reduce the rate of preeclampsia.

Management of pregnancy includes initial office visits every other week and then weekly after 32 weeks, as well as serial ultrasounds to evaluate fetal growth. The urine should be evaluated every 4 to 6 weeks for infection, proteinuria, and hematuria. The blood pressure targets should ideally be between 120/70 mmHg and 140/90 mmHg, making adjustments to antihypertensive medications as necessary. Maternal creatinine and hemoglobin levels are also regularly assessed, the frequency dependent on the patient's baseline renal dysfunction.[71]

Hemodialysis in pregnancy has become more common. It appears that more intensive dialysis (36 to 43 hours/week) is associated with improved perinatal outcomes, increased birth rate and decreased risks of preterm birth and IUGR.[79] Pregnancy outcomes after renal transplantation are thought to be superior when compared to women undergoing dialysis. However, these patients remain at high risk for hypertension, preeclampsia, gestational diabetes, low birth weight, cesarean delivery, and neonatal intensive care admissions when compared with the general population.[70]

Cancer

Principles

Cancer complicating pregnancy is rare, with an estimated frequency of 1 case per 1000 live births. The trend of delaying childbearing to later maternal age and the increased rates of cancer, in general, have increased the incidence over the past four decades.[80] The sites or types of cancer in pregnancy, in descending order of frequency, are cervical, breast, ovarian, lymphoma, melanoma, brain, and leukemia (Table 9.9).[81–83] Pregnancy potentially complicates the diagnosis, given the overlap with normal maternal symptoms, compromised physical examination, hesitation to

TABLE 9.8 Renal and Pregnancy Outcomes According to Chronic Kidney Disease Stage

Outcome	Control	Stage 1	Stage 2	Stage 3	Stage 4-5
Progressed to next stage of CKD	N/A	7.6	12.6	16.2	20
New onset HTN	5.5	7.9	17.6	47.1	50

TABLE 9.9 Cancers That Can Complicate Pregnancy

Site/Type	Incidence (Per Number of Gestations)
Cervix	1:2,000–1:10,000
Breast	1:3,000–1:10,000
Melanoma	1:1,000–1:10,000
Ovary	1:10,000–1:100,000
Colorectal	1:13,000
Leukemia	1:75,000–1:100,000
Lymphoma	1:1,000–1:6,000

Data from Pentheroudakis G, Pavlidis N, Castiglione M, ESMO Guidelines Working Group. Cancer, fertility and pregnancy: ESMO clinical recommendations for diagnosis, treatment and follow-up. *Ann Oncol.* 2009;20(Suppl 4):S178–S181.

obtain testing, and restrictions of imaging and biochemical markers. All of these factors may contribute to a delay in diagnosis.

Malignancy complicating pregnancy presents a unique set of issues. Will the gestation accelerate the malignant process? Are the accepted therapies safe for the unborn fetus? Will delay of therapy adversely affect the mother? Should the pregnancy be terminated, or should the child be delivered prematurely to maximize treatment of the mother with no resultant risk to the child?

Few pregnancy conditions require a multidisciplinary approach as cancer. Providers unaccustomed to managing pregnant women may be reticent in recommending definitive cancer therapy, for fear of the surgical or teratogenic risks to the fetus. Therefore input regarding diagnosis and treatment must be acquired not only from an oncologist but also from the obstetrician, perinatologist, pediatrician, neonatologist, and dysmorphologist. The patient and her family must be involved in decision making. Information should include the risks of the disease and its potential therapies, as well as the limitations of current knowledge about cancer in pregnancy and any uncertainties of outcomes. Furthermore, depending on the gestational age at diagnosis, discussions regarding termination and potential iatrogenic prematurity are important.

In most cases, there should not be any delays in diagnostic procedures. Most imaging modalities are relatively safe in pregnancy but can be modified to lessen the risk of fetal exposure, providing there is no reduction in an ability to make a diagnosis. Biopsies and indicated surgery should not be delayed for the sake of the pregnancy.

Chemotherapy

The fetal impact of chemotherapy is dependent on the gestational age of exposure and the agent administered. The rates of congenital malformations are 16%, 8%, and 6% in the first, second, and third trimester respectively.[84] The impact of exposure is dependent on the agent. Alkylating drugs and antimetabolites appear to have the highest rates of adverse outcomes, while platinums, taxanes, and antibiotics have the lowest.[80] The literature regarding most chemotherapeutic agents is limited, consisting of a few collected series. For a list of the more common chemotherapeutic agents that have been used in pregnancy, refer to Table 9.10.[85,86]

Little is known regarding the long-term outcomes of fetuses exposed to chemotherapeutic agents. The National Cancer

TABLE 9.10 Common Chemotherapeutic Agents and Uses

Class	Drug	Common Uses
Alkylating Agents		
Bind covalently to DNA, causing cross-links and strand breaks	Busulfan	Leukemias
	Chlorambucil	Lymphomas, leukemias
	Cyclophosphamide	Breast, ovary, lymphomas, leukemias
	Melphalan	Ovary, leukemia, myeloma
	Procarbazine	Lymphomas
Antimetabolites		
Act as a false substrate during DNA and RNA synthesis, resulting in truncated proteins	5-Fluorouracil	Breast, gastrointestinal
	6-Mercaptopurine	Leukemias
	Methotrexate	Trophoblastic disease, lymphomas, leukemias, breast
	6-Thioguanine	Leukemias
Antibiotics		
Bind with DNA, prevent RNA synthesis, generate highly reactive free radicals	Bleomycin	Cervix, lymphomas
	Daunorubicin	Leukemias
	Doxorubicin	Leukemias, lymphomas, breast
Antimitotic Agents		
Stop mitosis in M phase of cell cycle	Vincristine	Leukemias, lymphomas
	Vinblastine	Breast, lymphomas, choriocarcinomas
Taxanes		
Inhibit disassembly of microtubules	Tamoxifen	Breast, lymphomas, choriocarcinoma
	Paclitaxel	Breast, ovarian
Platinum Compounds		
Bind to DNA, causing cross-links and apoptosis	Cisplatin	Ovary, cervix, sarcoma
Other		
	L-Asparaginase	Leukemias
	Hydroxyurea	Leukemias
	All-*trans*-retinoic acid	Leukemias

TABLE 9.11 Principles in Management of Cancer in Pregnancy

Diagnostic	Therapeutic	Prenatal Care	Delivery and Postpartum
Standard diagnostic procedures should not be delayed	If possible, delay surgery until the second trimester	Ultrasound prior to interventions to confirm dating and screen for fetal malformations	Delivery timing should preferably based on obstetrical indications
Multidisciplinary discussion regarding further diagnostic, staging and therapeutic options	Surgery ≥23 weeks requires discussion regarding need for intraoperative fetal monitoring	Assess fetal well-being after each cycle of chemotherapy	Chemotherapy should not be administered within 3 weeks of delivery
	Chemotherapy should be avoided if possible in the first trimester	Serial ultrasounds for fetal growth	Placenta should be evaluated for evidence of metastatic disease
	Radiation therapy should be avoided if possible during pregnancy	Neonatology consultation, particularly if preterm birth is being considered	Breast feeding is contraindicated with chemotherapy

Institute in Bethesda, Maryland, USA, maintains a registry in the hopes of determining the delayed effects. A small series of fetuses exposed to chemotherapeutic agents for acute leukemia revealed normal mental development with follow-up between 4 and 22 years.[87] A recent case-control study involving 129 children, 96 of whom were exposed to chemotherapy in utero, suggested that maternal cancer with or without treatment did not impair cognitive, cardiac, or general development.[88]

The risk of teratogenicity does not appear to be higher with combination chemotherapy than with single-agent therapy.[84] Studies performed thus far involve small numbers of patients, with power insufficient to show a statistical difference, but there seems not to be a trend. There is an increased rate of small for gestational age babies and premature labor in mothers receiving cytotoxic chemotherapy.[89] Theoretical consequences include bone marrow or immune suppression. As a result, the timing of chemotherapy should account for the anticipated date of delivery. Data regarding safety for breastfeeding the neonate of a mother receiving cancer chemotherapy are limited. For this reason, the majority of agents are contraindicated in nursing mothers (Table 9.11).

Radiation Therapy

The deleterious effects of fetal irradiation have been discussed previously. Adjuvant radiation during pregnancy should be avoided if possible. However, there are small case series of radiotherapy in pregnancy, primarily for lymphoma.[90] There are considerations regarding radiation therapy during pregnancy. The dose used in estimating risk should be the amount that the fetus actually receives. For example, axillary or neck irradiation for lymphoma involves a lower direct fetal exposure than direct pelvic irradiation for cervical cancer. Secondly, the magnitude of radiation scatter to the pelvis should be estimated. External shielding does not prevent the internal reflection of the ion beam. Thirdly, the advancing size of the uterus actually increases the amount of radiation exposure to the fetus, because of the closer proximity of the nonpelvic irradiation. Therefore an 8-week-old fetus may actually receive a smaller radiation dose from supraclavicular irradiation than a 30-week-old fetus. Fourthly, will the fetus concentrate the radiation and therefore increase its delivered dose? This is exemplified by the use of radioactive iodine (^{131}I) for maternal thyroid conditions. The actual rad dose is markedly higher in the fetus because the fetal thyroid concentrates the iodine.

Cervical Cancer

Cervical cancer is one of the more common gynecologic malignancies in pregnancy. The incidence of cervical intraepithelial neoplasia is approximately 130 per 100,000 gestations and of invasive disease, 3.3 per 100,000 gestations.[91] Colposcopy with cervical biopsy remains the mainstay of diagnosis. The latter may be associated with increased bleeding given the increased blood flow to the uterus and cervix. However, if cancerous invasion is suspected, or uncertain, a biopsy is necessary. If microinvasive disease is confirmed, cone biopsy is required to rule out frankly invasive disease. This procedure is undertaken with caution during pregnancy, because of the associated high rate of bleeding complications and miscarriage. Cervical conization may raise the risk of incompetence or preterm labor.

The therapy is dictated by the disease stage and gestational age as well as the patient's decision regarding pregnancy continuation and future fertility. Treatment options include external beam radiation, internal radiotherapy (brachytherapy), or surgery. In most cases, delay of definitive therapy by 4 to 14 weeks may be acceptable. Pregnancy does not seem to accelerate the growth of the tumor. Shared decision making is important. In the extremely previable gestation, the likelihood of achieving a safe gestational age for the fetus without worsening the stage or spread of the cancer in the mother must be balanced against parental desires based on ethical or religious beliefs. Conversely, it might be reasonable to delay definitive therapy until a time when delivery would not likely result in a long-term disability because of extreme prematurity.

Breast Cancer

Breast cancer is the most common malignancy of women, with approximately 1 in 8 women affected in their lifetimes: 0.2% to 3.8% of cases are diagnosed during pregnancy.[92,93] The incidence of breast cancer during pregnancy or within a year of delivery is 1.3 in 10,000 live births or 10 to 30 per 100,000 pregnancies.[94,95] Pregnancy does not seem to influence the actual course of the disease; however, there appears to be a higher risk of diagnostic delay and a trend toward more advanced stages in pregnant, compared with nonpregnant, women.

The diagnostic procedures for breast cancer should not be altered during pregnancy. Any suspicious mass should undergo a biopsy. Mammography, although discouraged for routine screening

in pregnancy, can be used safely if indicated. The fetal radiation exposure is negligible – approximately 0.001 to 0.01 mGy.[96] Mammography may be more difficult to interpret due to the physiologic changes of pregnancy, and ultrasound examination may be a useful alternative. Metastatic evaluation may also be limited because of a reluctance to utilize bone and liver scans during pregnancy. MRI can be used safely in the second and third trimesters.

Surgical therapy for breast cancer should not be delayed because of pregnancy. The risks of mastectomy and axillary node dissection appear to be low.[94] Radiation therapy is usually not recommended during pregnancy. If the patient has evidence of tumor invasion in the lymph nodes, adjuvant chemotherapy is often given. The timing of delivery should account for the following factors:

- When would the fetus have a reasonable chance for survival with a low risk of severe permanent morbidity?
- Can the number of cycles of chemotherapy be minimized with an earlier delivery? In addition, avoiding delivery just before or just after administration of chemotherapy is important to reduce the risk of immunosuppression and infection.
- How long can radiotherapy be safely delayed without increasing the risk of metastatic spread of the tumor?

Approximately 10% of women treated for breast cancer become pregnant, the majority within 5 years of diagnosis. Data suggests that pregnancy does not influence recurrence rate.[97] It seems reasonable to delay childbearing for at least 1 to 2 years, which is the time of the highest rate of recurrence.[98]

Ovarian Cancer

Most ovarian cancer occurs in women older than 35 years. Delayed childbearing has been more widely accepted, exemplified by British birth rates doubling in women older than 30 years and tripling in women older than 40 years since 1975, in addition to a twofold increased birth rate among US women older than 40 years since 1981.[99,100] It would not be surprising for the rate of ovarian and other cancers during pregnancy to increase. However, the current estimate of actual ovarian malignancies in pregnancy is low and estimated to range from 1 in 10,000 to 1 in 50,000 deliveries.[99] Whereas most ovarian cancers are epithelial in origin, borderline epithelial and germ cell tumors (dysgerminomas and malignant teratomas) are more common in pregnancy.

The widespread use of ultrasonography, particularly in the first two trimesters, has been helpful in identifying adnexal masses. Fortunately, most are functional cysts (13% to 17%) or benign teratomas, serous or mucinous cystadenomas, endometriomas, or paraovarian cysts.[101] Actual malignancy is rare and is estimated at 5% of the ovarian masses found. Surgery for an adnexal mass occurs in approximately 1 per 1000 pregnancies. Most procedures are performed not for suspected malignancy but because of concern about torsion or rupture. The incidence of adnexal torsion ranges between 7% and 22%, with increasing rates in masses greater than 6 cm.[102,103] Often these events occur at the end of the first trimester when the uterus elevates beyond the true pelvis, and at the time of delivery.

The characterization of an ovarian process can be aided by ultrasonography or MRI, but these modalities are not definitive. Ultrasound scoring systems that use size and character poorly predict malignancy but have a better negative predictive value.[104] Although an ovarian cyst, particularly if it is simple in nature, is probably not cancer, however, malignancy cannot be excluded. Indications for surgical exploration include a complex mass, a persistent simple cyst greater than 8 cm, or one that is symptomatic.[105] The optimal time for laparotomy is during the second trimester. If patients opt for more conservative management, they should be counseled that they have a potential risk of requiring emergent surgery for an acute event such as torsion or rupture.

If a malignancy is confirmed, staging and therapy are no different than for a nonpregnant woman. Frozen-section diagnosis, peritoneal washings, omentectomy, and sub-diaphragmatic biopsy are performed. Depending on the cell type and the stage, treatment can range from removal of the affected adnexa to complete hysterectomy and bilateral oophorectomy. Fortunately, most epithelial ovarian cancers found in pregnant women are usually of a lower stage, with 59% of reported cases being stage I.[99]

Survivors of Childhood Cancer

Given the improvements of therapy for childhood cancer, a large number of these individuals have survived into adulthood. Some are unable to conceive because of high-dose radiation or cytotoxic chemotherapy. The risk of decreased fertility for patients exposed to pelvic radiation therapy may be as high as 32%.[106] Those who remain fertile may have concerns regarding whether their treatment increases the risk of adverse pregnancy outcomes. Although data are limited, female cancer survivors treated with radiation therapy appear to have increased risks of premature delivery, low birth weight, and miscarriage. There is no evidence that female partners of male cancer survivors treated with radiation have these excess risks.[107]

Maternal Seizure Disorders

Epilepsy is the most common major neurologic disorder in pregnancy. Approximately 18 million women are affected worldwide, and 40% of those are of childbearing age. The estimated prevalence in pregnancy is 0.2% to 0.7%.[108] The pattern of maternal seizures ranges from complex partial to generalized tonic-clonic (grand mal) and generalized absence (petit mal) seizures. Physiologically, seizures arise from paroxysmal episodes of abnormal brain electrical discharges; when associated with motor activity, they are termed convulsive.

The effect of pregnancy on the frequency and severity of the seizure disorder has been difficult to ascertain because of limited prospective data. EURAP, an international registry of Antiepileptic Drugs and Pregnancy, reported on more than 3,700 patients whose seizure frequency and treatment were recorded. Sixty-six percent of patients had no seizures during their pregnancy. When using first-trimester seizure activity as a reference, 71% had no change in frequency in the second and third trimester, 13% improved, and 16% deteriorated.[109] In patients with worsening seizure activity, decreased plasma concentrations of antiepileptic drugs (AEDs) have been hypothesized as causative. The fall in plasma drug levels during pregnancy may be due in part to increased protein binding, reduced absorption, and increased drug clearance. The adequacy of prepregnancy seizure control can influence a patient's course during gestation. Patients whose seizures were poorly controlled tended to have more frequent seizures during pregnancy, whereas patients who had no seizures for 2 years before pregnancy had only a 10% chance of experiencing seizures during gestation. These latter patients may be candidates for stopping therapy or considering monotherapy if they have previously required multiple antiepileptic drugs.[110,111]

Perinatal Risk

For reasons that are not clear, women with seizures have more obstetric complications and a higher rate of poor perinatal outcomes. A recent systematic review comparing women with epilepsy to those without revealed increased odds of spontaneous miscarriage, antepartum and postpartum hemorrhage, hypertensive disorders, labor induction, cesarean section, preterm birth, and fetal growth restriction.[112] Preexisting conditions may play a role in these outcomes, as one large population-based study found significant associations between pregestational diabetes, hypertension, psychiatric diagnoses, and substance use disorders among pregnant patients with epilepsy compared to those without epilepsy.[113]

Earlier publications suggested an increased risk of congenital malformations in children of mothers with epilepsy even without prenatal use of AED. More recent data from larger, registry-based sources refute this. A study comparing patients with epilepsy to matched controls revealed that women receiving no medication had no increased rate of congenital malformations; however, monotherapy was associated with an increased risk of embryopathy (odds ratio [OR] 2.8). Furthermore, the frequency was even higher with the use of two or more drugs (OR 4.2).[114] A meta-analysis revealed the OR of malformations in those with untreated epilepsy was similar to nonepileptic controls (OR 1.92, 95% CI 0.92 to 4) but a higher prevalence of a major congenital malformation in those exposed to antiepileptic medications (OR 3.26, 95% CI 2.15 to 4.93).[115]

Malformation risk correlates with the number of medications used and is dose-dependent in those receiving monotherapy Recent updates from five international registries have reported malformation rates ranging from 1.8% to 13.8% with monotherapy and 6% to 9.8% with polytherapy.[116,117] Historically, malformations associated with AED include a fivefold rise in the rate of orofacial clefts, an increase in the rate of congenital heart disease, particularly with trimethadione, and a 3.8% incidence of neural tube defects in fetuses exposed to valproic acid.[118–120] Facial abnormalities (e.g., midface hypoplasia) are not specific to any particular AED; they have been seen with phenytoin, carbamazepine, and trimethadione. Some antiepileptic medications can adversely affect postnatal cognitive development. Although conclusive data are lacking, there may be an increased adverse effect, particularly with valproate.[121,122]

Overall rates of congenital malformations have declined as prescribing patterns of AED have changed. In a large observational study from the EURAP study group examining AED use from 2000 to 2013, as the rate of valproic acid and carbamazepine monotherapy decreased (25.9% to 6.7% and 41.1% to 13.5%, respectively), there was a 27% decrease in congenital malformations over the same time period.[123]

Fetal Hydantoin Syndrome

The classic features of the fetal hydantoin syndrome are facial clefting, a broad nasal ridge, hypertelorism, epicanthal folds, distal phalangeal hypoplasia, and growth and mental deficiencies; however, these effects also result from the use of other antiseizure medications (Table 9.12).[124] The postulated cause of this syndrome is the teratogenic action of a common epoxide intermediate of these medications. The hydantoin syndrome was found to develop in fetuses with inadequate epoxide hydrolase activity.[125] This enzymatic deficiency appears to be recessively inherited. It appears that preconception folic acid supplementation can reduce the risk of major congenital malformations in women prescribed AED.[126]

Management

Management of the pregnant patient with epilepsy centers on minimizing seizure activity to reduce physical risk and lower the incidence of fetal complications. Preconception counseling is vital and should entail (1) adjusting medication doses into the therapeutic range, (2) attempting to utilize monotherapy, if possible, and (3) choosing an agent with the least risk of teratogenesis. If the patient's disease is adequately controlled with a specific agent, changing medications based solely on teratogenicity risk should be weighed against the risk of increasing seizure activity. Typically, the benefit of preventing seizure activity outweighs the potential for reducing congenital malformations, though ultimately this must be a shared decision between patient and provider. Levetiracetam has increasingly been utilized as a first-line AED in pregnancy given its clinical effectiveness, convenient range of dosing, and favorable malformation risk profile.

Folic acid supplementation reduces the risk of open neural tube defects in the general population. Given the known inhibition of folate synthesis by many AED, patients with epilepsy on antiepileptic therapy should be encouraged to take folic acid supplementation (400 μg daily) at least 3 months prior to conception. Data remain insufficient about the efficacy of high dose folic acid (e.g., 4 mg daily) in patients taking AEDs, therefore both the American Academy of Neurology (AAN) and American College of Obstetricians and Gynecologists (ACOG) continue to recommend 400 μg daily supplementation for patients prescribed AED.[127] Additionally, there is some evidence of potential drug–drug interactions and animal evidence that high levels may have adverse effects on fetal brain development.[128] Maternal serum alpha-fetal protein (MsAFP) screening for neural tube defects, a fetal anatomic ultrasound, and a targeted fetal echocardiogram in the mid-trimester should be considered for all patients prescribed AED.

TABLE 9.12 Clinical Features of the Fetal Hydantoin Syndrome

Craniofacial abnormalities	Broad nasal ridge
	Wide fontanel
	Low-set hairline
	Broad alveolar ridge
	Metopic ridging
	Short neck
	Ocular hypertelorism
	Microcephaly
	Cleft lip with or without palate
	Abnormal or low-set ears
	Epicanthal folds
	Ptosis of eyelids
	Coloboma
	Coarse scalp hair
Limb abnormalities	Smallness or absence of nails
	Hypoplasia of distal phalanges
	Altered palmar crease
	Digital thumb
	Dislocated hip

Data from Briggs GC, Freeman RK, Yaffe SJ. *Drugs in Pregnancy and Lactation*. 7th ed. Baltimore: Lippincott Williams & Wilkins; 2005.

Serum AED levels should be checked monthly, and the dose adjusted accordingly to maintain therapeutic levels, particularly with the use of lamotrigine, carbamazepine, and phenytoin.[126] Although the evidence is less clear with other agents such as phenobarbital, valproate, primidone, and ethosuximide, serial level assessment should not be discouraged. Medications should not be changed unless they prove ineffective at the optimal serum level. If a patient reports greater seizure activity, the serum drug level should be checked immediately. A common reason for increased seizures is discontinuation or inconsistent use due to patient hesitancy towards AED use in pregnancy. As with any chronic medical condition, continuous reinforcement of the benefits of treatment combined with ongoing dialogue about patient concerns can often mitigate potential interruptions in care.

Mothers taking older generation AED, such as phenytoin, phenobarbital, or primidone, may have a higher incidence of neonatal coagulopathy as a result of vitamin K-dependent clotting factor deficiency. Although maternal vitamin K supplementation in the third trimester may be reasonable, there is insufficient evidence to determine whether it will reduce neonatal hemorrhagic complications.[126] Pediatricians should be made aware of maternal epilepsy and AED use in order to adequately assess the newborn for AED side effects, reassure patients about the safety of breastfeeding with AED, and counsel patients about the importance of maintaining their therapy to ensure safe care of the newborn. Additionally, when counseling about postpartum contraception, in particular oral combination pills (OCP), care must be taken to assess whether an AED reduces their efficacy, or conversely if the OCP reduces AED concentrations. For this reason, long-acting reversible contraception such as an intrauterine device or subcutaneous implant should be considered first-line options.[129]

Perinatal Mood and Anxiety Disorders

Perinatal mood and anxiety disorders (PMADs), including depression, anxiety, obsessive-compulsive disorders, posttraumatic stress disorder, bipolar disorders, and psychosis, affect approximately one in five pregnancies, including up to 1 year postpartum. It is estimated that maternal mental health conditions contribute to nearly 13% of all maternal deaths in the United States, with suicide accounting for 5% to 7% of these deaths.[130] Coexisting factors such as substance use disorders, socioeconomic barriers, and racial disparities often delay the diagnosis and treatment of PMADs, leading to worse perinatal outcomes and suboptimal parent-child bonding. (Table 9.13).[131] Routine screening of all pregnant patients for PMADs in both the antepartum and postpartum periods is recommended by ACOG, as well as the American Academy of Pediatrics (AAP), and U.S. Preventive Services Task Force.[132–134] Additionally, screening for thyroid dysfunction or substance use disorder may aid in addressing coexisting medical conditions. Ultimately, a multidisciplinary approach is advantageous, including social work, licensed therapists, addiction specialists, peer support groups, and in cases of incarceration or question of competency, legal professionals, and ethics boards.

Depression

Depression remains one of the leading causes of disability worldwide, with prevalence continuing to rise.[135] Rates of depression during pregnancy are 7% to 11% in the first trimester, 9% to 13% in the second trimester, and 9% to 12% in the third trimester. The prevalence over the entire pregnancy course is 18.4%.[136,137] Risk factors for perinatal depression include a history of depression or anxiety, unintended pregnancy, lower socioeconomic and education status, domestic violence, single status, and limited social support network.[138] The presence of a chronic medical condition in conjunction with side effects from various medications has also been associated with perinatal depression. All pregnant patients should be screened routinely with a validated screening tool at their first prenatal visit and during the postpartum period, at a minimum. Additional screening should be considered at 1, 2, 3, and 6 months postdelivery, or with any significant negative pregnancy event or change in mood or health status (Table 9.14).[134]

TABLE 9.13 Impact of Psychiatric Illness on Pregnancy Outcome

Illness	Teratogenic Effects	IMPACT ON OUTCOME		Treatment Options
		Obstetric	Neonatal	
Anxiety disorders	N/A	Increased incidence of forceps deliveries, prolonged labor, precipitate labor, fetal distress, preterm delivery, and spontaneous abortion	Decreased developmental scores and inadaptability; slowed mental development at 2 years of age	Benzodiazepines Antidepressants Psychotherapy
Major depression	N/A	Increased incidence of low birth weight, decreased fetal growth, and postnatal complication	Increased newborn cortisol and catecholamine levels, infant crying, rates of admission to NICUs	Antidepressants Psychotherapy ECT
Bipolar disorder	N/A	See *Major depression* entry above	See *Major depression* entry above	Lithium Anticonvulsants Antipsychotics ECT
Schizophrenia	Congenital malformations, especially cardiovascular	Increased incidence of preterm delivery, low birth weight, small for gestational age, placental abnormalities, and placental hemorrhage	Increased rates of postnatal death	Antipsychotics

Cognitive behavioral therapy (CBT) should be considered a first-line treatment to address perinatal depression. Oftentimes, CBT alone is not effective for major depression. Adding medication to regular therapy is the most common and effective adjunct treatment for major depression. However, due to concerns about fetal exposure to antidepressants, patients or providers commonly limit or discontinue medication use when pregnancy is diagnosed. Unfortunately, these patients have a 68% risk of relapse of major depression as opposed to a 26% risk in those who continue their medication regimen. Of those who discontinued medication, half will relapse in the first trimester and 90% by the second trimester.[139] Another study found that among those who discontinued antidepressants, over half had to restart them in pregnancy.[140]

Medical treatment of depression is effective in approximately 70% of cases. The most commonly prescribed antidepressants during pregnancy are selective serotonin reuptake inhibitors (SSRIs). As a group, SSRIs have not been consistently associated with specific birth defects.[141] Paroxetine has been associated with an increased risk of congenital heart defects, particularly with doses greater than 25 mg daily in the first trimester, and should be avoided as a first-line antidepressant, if possible.[142]

Persistent pulmonary hypertension of the newborn (PPHN) has been associated with SSRI use in pregnancy. Initial studies placed the incidence of PPHN at 10 in 1000 in fetuses exposed to SSRIs after 20 weeks.[143] A subsequent metaanalysis from pooled studies accounting for varying study sizes and quality estimated a far lower risk estimate of 1 case of PPHN for every 1000 pregnant patients exposed to SSRIs.[144] In reviewing the potential relationship between SSRI and PPHN, there are also a number of risk factors for PPHN that are also associated with depression, including obesity, smoking, cesarean section, and early delivery.[145] When assessing the potential link between SSRIs, prematurity, and low birth weight, systematic evaluation suggests that the medication is not the most likely cause, but rather one of the many confounders that accompany both a diagnosis of depression and risk for prematurity.

Approximately 30% of newborns exposed to SSRIs prior to birth develop poor neonatal adaptation syndrome (PNAS).[146] This is usually transient and most often does not require specific medical care. PNAS affects the central nervous system, motor function, and the gastrointestinal and respiratory systems. NICU admissions are more common.[147] Reduction of medication dose in the latter third trimester in the hope of reducing adverse neonatal outcomes does not appear to be beneficial.[148] Long-term outcome data suggest that maternal antidepressants do not cause autism or affect the neurodevelopment of offspring.[149] Therefore given the lack of consistent data suggesting significant fetal harm, SSRIs are currently considered the first-line antidepressant for use in pregnancy.[146] Furthermore, reducing the dose or discontinuing SSRIs in the latter part of pregnancy does not appear to improve neonatal outcome.

Electroconvulsive therapy (ECT) has been used in pregnancy, usually for refractory severe cases of psychotic depression, schizophrenia, and bipolar disease. There are some potential complications with ECT, including fetal bradycardia (2.7%), preterm contractions, or labor (3.5%), and potential complications of anesthesia including aspiration.[150]

There have been concerns regarding the use of SSRIs during breastfeeding. Fluoxetine has an active metabolite with a long half-life and is found in higher concentrations in infants.[151] Short-term neonatal effects have been reported, including increased crying, decreased sleep, and irritability, particularly with fluoxetine and citalopram. However, the relative infant dose is less than 10% of the maternal dose, and this level is lower than the fetal exposure.[146] In cases of prematurity, where there is immaturity of drug elimination pathways in the newborn, there may be potential for relative toxicity leading to irritability, agitation, and sleep disturbances. However, this is usually mitigated with medication adjustment or change, if possible, or supplementing breastfeeding with donor milk. The benefits of breastfeeding must be accounted for in decisions regarding the use of SSRIs, especially considering the

significant risk for postpartum depression. The currently available data do not support a contraindication for lactation.[146]

Postpartum Psychosis

Postpartum psychosis is rare, with a recent metaanalysis placing the incidence at between 0.89 to 2.6 per 1000 live births.[152] This condition is distinguishable from postpartum depression by a patient's inability to discern reality from periods of delirium. Patients at risk for postpartum psychosis typically have an underlying major depressive disorder, mania, or schizophrenia. Other risk factors include younger age and family history. The recurrence rate is approximately 25%. The peak onset of symptoms is between 10 and 14 days after delivery. Common clinical features of postpartum psychosis include confusion, disorganization, depersonalization, insomnia, irritability, delusions or hallucinations, and mood abnormalities such as mania, agitation, or depression.[153] Recognition of this disorder is extremely important to the protection of the patient and her family. Prompt hospitalization and intensive pharmacologic therapy are the mainstays of early intervention.

Schizophrenia

The prevalence of schizophrenia in a general population ranges between 4 and 7 per 1,000 persons, depending on the estimate used.[154] It is most commonly associated with delusions, hallucinations, and incoherence. Morbidity is higher than that of any other PMAD. There appears to be a genetic component to the etiology, with schizophrenia developing in approximately 10% of offspring of an affected person. Concordance of schizophrenia in identical twins reaches 65%. In a large, contemporary case-control study, schizophrenia was associated with higher rates of adverse pregnancy outcomes, including preeclampsia, venous thromboembolism, preterm birth, and both small and large for gestational age newborns.[155]

With a peak age of incidence of approximately 20 years, a higher incidence in women than men, and lower rates of routine primary or gynecologic care, obstetricians often face complicated situations of unintended pregnancies, discontinued or suboptimal psychiatric treatment, and situations where a patient may not fully grasp that they are pregnant. There appear to be higher rates of cesarean section and operative vaginal delivery in affected patients.[156] Offspring of women with schizophrenia may have a higher rate of sudden infant death syndrome and congenital malformations.[157] However, it is difficult to ascertain whether these risks are independent of other factors such as smoking, low socioeconomic status, poor social support, and the use of certain medications.

Treatment is achieved primarily using psychotropic medication. While antipsychotic medications cross the placenta, the potential for teratogenesis appears low and is often outweighed by the benefits of maintaining treatment. Lithium, used primarily in mania, is associated with a higher rate of Ebstein anomaly. Although the incidence of this consequence is low, either safely deferring the medication in the first trimester or continuing its use with careful counseling is a viable alternative.[158] Fetal echocardiography should be performed in women who have used lithium in early pregnancy.

As with antidepressants, the benefits of continuing most antipsychotic medications during lactation and breastfeeding appear to outweigh the minimal newborn risks reported in the literature (Table 9.15).[151,159]

TABLE 9.15 Summary of Current Knowledge of Drug Excretion Into Breast Milk, Drug Concentrations in Infant Serum, Adverse Effects in the Child, and Breastfeeding Recommendations for Different Psychotropic Drugs

Class or Drug	Drug Transfer Into Breast Milk	Infant Plasma Concentrations	Adverse Effects in the Child	Breastfeeding Recommendations
SSRIs	Low	Low plasma concentrations	Case reports of adverse effects in infants exposed to fluoxetine and citalopram	Compatible with breastfeeding; however, fluoxetine and citalopram may not be drugs of first choice
TCAs	Low	Low plasma concentrations (except doxepin)	No suspected immediate adverse effects observed (except doxepin)	Compatible with breastfeeding; however, doxepin should be avoided
Other antidepressants	Limited data	Limited data	Limited data	Insufficient data
Benzodiazepines	Low	High plasma concentrations with longer-acting drugs with active metabolites	Case reports of CNS depression reported for diazepam	Sporadic use of short-acting benzodiazepines unlikely to cause adverse effects
Lithium	Low	Dose received by the infant is high	Limited data; some reports of toxicity in the infant	Limited data; however, breastfeeding should be avoided
Carbamazepine, sodium valproate	Low	Low plasma concentrations	Some case reports of various adverse effects in the infant	Generally more compatible with breastfeeding than lithium
Lamotrigine	High	High plasma concentrations	Limited data	None able to be made
Novel antipsychotics	Moderate	Variable plasma concentrations	Limited data	None able to be made

CNS, Central nervous system; *SSRIs*, selective serotonin reuptake inhibitors; *TCAs*, tricyclic antidepressants.

Hypertensive Complications of Pregnancy

THOMAS R. MOORE

KEY POINTS

- Hypertensive disorders of pregnancy are classified as chronic hypertension, gestational hypertension, preeclampsia with and without severe features, and chronic hypertension with superimposed preeclampsia.
- Pharmacologic management of chronic hypertension should be reserved for women with sustained elevations in blood pressure at or greater than 160 mm Hg systolic or 110 mm Hg diastolic.
- Magnesium sulfate administration to prevent eclampsia is used for those preeclampsia cases with severe features.
- Daily low-dose aspirin is recommended in women at high risk of preeclampsia, initiated between 12 and 16 weeks of gestation and continued until delivery.
- When preeclampsia without severe features is diagnosed, delivery should be accomplished at or beyond 37 completed gestational weeks. When severe features are present, delivery should be accomplished expeditiously (regardless of gestational age) once maternal stabilization has been achieved.

Hypertension is the most common medical problem in pregnancy, affecting 10% to 15% of all pregnant women. As the third most common cause of maternal mortality after thromboembolic disease (15%) and hemorrhage (11%), hypertensive disorders account for almost 10% of maternal deaths in the United States.[1] Complications arising from hypertensive disorders have profound effects on the fetus and neonate and thus are a major source of perinatal mortality and morbidity. Preeclampsia (PE) is a leading cause of perinatal morbidity and mortality, with an estimated 50,000 to 60,000 PE-related deaths per year worldwide. With the greatest morbidity and mortality, preeclampsia affects 5% to 7% of all pregnant women but is responsible for more than 70,000 maternal deaths and 500,000 fetal deaths worldwide every year. In the United States, it is a leading cause of maternal death, severe maternal morbidity, maternal intensive care admissions, cesarean section, and prematurity.

Unfortunately, the incidence of preeclampsia has increased by 25% in the United States during the past two decades.[2] Furthermore, because preeclampsia has been shown to be a risk factor for future cardiovascular and metabolic disease in women, recognizing the importance of proper perinatal management and prevention is essential.[3]

Classification of Hypertensive Disorders of Pregnancy

The diagnostic criteria for the hypertensive complications of pregnancy have undergone significant revision in the past several years.[4–7] The American College of Obstetricians and Gynecologists (ACOG) has recently summarized the current consensus regarding the definitions of hypertensive disorders encountered in pregnancy.[8,9] Hypertension during pregnancy is currently defined into four categories (Table 10.1):

1. Chronic hypertension which predates pregnancy or is present prior to 20 weeks of gestation
2. Gestational hypertension which occurs after 20 weeks of pregnancy and resolves postpartum
3. Preeclampsia
4. Chronic hypertension (predating 20 weeks of gestation) with superimposed preeclampsia

Importantly, proteinuria is no longer required for the diagnosis of preeclampsia if other abnormal findings are present. Preeclampsia is now defined as hypertension plus proteinuria *or* hypertension plus other systemic abnormalities noted as follows.

Hypertension in pregnancy is defined when blood pressure is:

- ≥140 mm Hg systolic or ≥90 mm Hg diastolic on two occasions at least 4 hours apart after 20 weeks' gestation in a woman with a previously normal blood pressure.
- The requirement for documenting hypertension twice over an interval of at least 4 hours is shortened to minutes if systolic pressure is ≥160 mm Hg or diastolic pressure is ≥110 mm Hg.

Proteinuria is defined when urinary protein is:

- ≥300 mg per 24-hour urine collection

or

- Protein/creatinine ratio ≥0.3

or

- Dipstick reading of 1+ in a voided urine specimen if more precise laboratory-based results are not readily available

When the hypertension criteria above are present but proteinuria is absent or not tested, preeclampsia is diagnosed when any of the following are present:

- Platelet count <100,000/μL.
- Liver transaminase levels are twice normal values or higher

TABLE 10.1 Classification of Hypertensive Disorders of Pregnancy

Category	Definition
Hypertension in pregnancy	Systolic blood pressure ≥140 mm Hg or diastolic BP ≥90 mm Hg, or both, measured on two occasions at least 4 hours apart
Chronic hypertension	Hypertension diagnosed or present before pregnancy or before 20 weeks of gestation, or hypertension diagnosed for the first time during pregnancy and that does not resolve in the postpartum period
Gestational hypertension	New-onset hypertension after 20 weeks of gestation in the absence of proteinuria that normalizes postpartum. Blood pressure elevation first noted after 20 weeks that does not resolve after delivery is defined as chronic hypertension.
Preeclampsia	New-onset hypertension with new-onset proteinuria (300 mg/24 hours or a protein/creatinine ratio of ≥0.3) or one or more of the following: thrombocytopenia ($<100 \times 10^9$/L) elevated liver transaminases (twice normal) renal insufficiency (serum creatinine >1.1 mg/dL or doubling creatinine level without preexisting renal disease) pulmonary edema new-onset headache or visual disturbances
Chronic hypertension with superimposed preeclampsia	Preeclampsia occurring in a woman with hypertension predating 20 weeks of pregnancy

Data from American College of Obstetricians and Gynecologists' Committee on Practice Bulletins—Obstetrics. ACOG practice bulletin No. 203: chronic hypertension in pregnancy. *Obstet Gynecol.* 2019 and Gestational hypertension and preeclampsia. ACOG Practice Bulletin No. 222. American College of Obstetricians and Gynecologists. *Obstet Gynecol.* 2020;135:e237–e260.

- Newly elevated serum creatinine is >1.1 mg/dL or a doubling in the absence of other renal disease
- Pulmonary edema
- New-onset cerebral or visual disturbances

Because fetal growth restriction is managed similarly in pregnant women with and without preeclampsia, it has been deleted as a criterion for severe preeclampsia.

Chronic Hypertension

Up to 5% of pregnant women have chronic hypertension, which is diagnosed when hypertension is present before pregnancy or recorded before 20 weeks of gestation. However, when hypertension is first noted in a patient after 20 weeks' gestation, it may be difficult to distinguish chronic hypertension from preeclampsia. In such cases, the precise diagnosis might not be made until after delivery and well into the postpartum period. Hypertension that is first diagnosed during the second half of pregnancy and persists postpartum is diagnosed as chronic hypertension.

Chronic hypertension has adverse effects on pregnancy outcome. A report of 55 studies of chronic hypertension comprising 795,221 pregnancies found that 26% of women entering pregnancy with chronic hypertension developed superimposed preeclampsia, 41% required cesarean section, and 28% had preterm delivery. Of the neonates, 17% had birth weight less than 2500 g, NICU admission occurred in 21%, and perinatal death occurred in 4.0%.[10] The adverse fetal and maternal perinatal outcomes are related to the severity of the preexisting hypertension. When chronic hypertension is secondary to maternal chronic renal disease, a large (506,000 pregnancies) systematic review found significantly elevated odds for preeclampsia (odds ratio [OR] 10.36), premature delivery (OR 5.72), small for gestational age (OR 4.85), and pregnancy failure (OR 1.80).[11] Women with untreated severe chronic hypertension are also at increased risk for cardiovascular complications during pregnancy, including stroke.[12]

The majority of cases of chronic hypertension seen in pregnancy are idiopathic (essential hypertension), but other causes should always be sought because pregnancy outcome is worse in women with secondary hypertension. Renal disease (e.g., chronic renal failure, glomerulonephritis, renal artery stenosis), cardiovascular causes (coarctation of the aorta, Takayasu arteritis), and, rarely, Cushing disease, Conn syndrome, and pheochromocytoma should be excluded through physical examination, history, and more detailed testing if needed.

Patients with chronic hypertension should be evaluated thoroughly early in pregnancy with serum urea, creatinine, and electrolyte measurements, urinalysis, and 24-hour urine collection for protein and creatinine clearance determinations. Reassessment of renal function should be performed in each trimester and more frequently if the patient's condition deteriorates.

Antihypertensive Treatment of Chronic Hypertension in Pregnancy

A 2014 Cochrane review of 49 trials found that treatment of mild-to-moderate hypertension reduced the risk of developing severe hypertension but had no effect on the incidence of preeclampsia, preterm birth, fetal death, fetal growth restriction, or any other measured outcome.[13] However, a recent multicenter trial[13a] (chronic hypertension in pregnancy study [CHAP]; 2408 women before 23 weeks' gestation with mild chronic hypertension randomized to receive antihypertensive medications if blood pressure was >140/90 mm Hg [active treatment] versus no treatment unless severe hypertension developed [SBP >160 or DBP >=105]) documented a reduction in composite outcome (severe preeclampsia, medically indicated delivery <35 weeks' gestation, placental abruption, or fetal/neonatal death) with maternal antihypertensive medication treatment–30.2% versus 37.0%; adjusted risk ratio (RR), 0.82; 95% CI, 0.74–0.92; P<.001. Importantly, antihypertensive medication treatment had no effect on birth weight <10th percentile and other serious maternal and neonatal complications.

The CHAP study demonstrated for pregnant women with chronic hypertension that a treatment threshold of 140/90 mm Hg yields improved outcomes compared to initiating medication

only when blood pressure rises above 160/105 mm Hg, as previously recommended. One strength of the CHAP study includes the fact that the majority of enrolled patients had chronic hypertension on medication at the time of trial entry (56%) and 41% were enrolled prior to 14 weeks' gestation.

Thus, while antihypertensive medications were reserved in the past for patients whose blood pressures placed them at significant risk of maternal stroke (systolic blood pressure of ≥160 mm Hg or diastolic pressure of ≥110 mm Hg), the American College of Obstetricians and Gynecologists recently published a Practice Advisory[13b] recommending 140/90 as the threshold for initiation or adjustment of medical therapy for chronic hypertension in pregnancy, rather than the previous threshold of 160/110 mm Hg. Patients taking blood pressure medications at the start of pregnancy should be maintained on their medications, rather than discontinuing them and waiting to initiate treatment for blood pressures in the severe range.

Antihypertensive Medications in Pregnancy

The choice of antihypertensive agent for use in pregnancy is governed by reducing risk of severe maternal sequelae (e.g., cerebral hemorrhage, myocardial infarction) while avoiding adverse effects on the fetus. Because lowering of maternal systolic blood pressure to <140 mm Hg or diastolic to <90 mm Hg can compromise uterine perfusion and fetal growth and oxygenation, maternal pressures should be maintained in the 120 to 155 mm Hg systolic and 90 to 105 mm Hg diastolic range.[8]

The antihypertensive medications most commonly used in pregnancy are listed in Table 10.2.

α- and β-Adrenergic Blockers

Labetalol is a mixed α_1-adrenergic, β_1-adrenergic, and β_2-adrenergic blocker and is the most frequently used medication for chronic hypertension in pregnancy. Pure β-blockers have been associated with increased risk of IUGR (e.g., atenolol), and the mixed adrenergic blockade produced by labetalol is thought to mitigate this unwanted effect.[14] Labetalol is also used intravenously to manage severe hypertension accompanying preeclampsia.

Calcium Channel Blockers

Nifedipine in extended-release forms is effective in managing chronic hypertension in pregnancy.[15] In immediate-release form, nifedipine 10 to 20 mg orally or as a constant infusion of 0.5 to 10 mg/hr is recommended for urgent management of severe-range maternal blood pressures exceeding 160/110 mm Hg.

Methyldopa

α-Methyldopa is a centrally acting antihypertensive agent, it has a slow onset of action with prolonged time to therapeutic effect (days), and compliance with methyldopa therapy may be impeded by side effects such as sedation in some patients.

Hydralazine

Hydralazine, a potent peripheral vasodilator, is used intravenously to treat acute hypertensive emergencies in pregnancy (blood pressure >160/110 mm Hg). Its role as an oral agent in the management of chronic hypertension is limited to a second- or third-line choice. Long-term use of hydralazine may be associated with a lupus-like syndrome in some patients.

Diuretics

Diuretics are often used in hypertension in nonpregnant adults, but there is little role for their use in pregnant women with hypertension. Because diuretics can reduce the plasma volume expansion of normal pregnancy and thus impede fetal growth, use of diuretics in pregnant patients should be limited to those with cardiac dysfunction or frank pulmonary edema.[16]

Angiotensin-Converting Enzyme (ACE) Inhibitors and Angiotensin Receptor Blockers (ARBs)

ACE and ARBs should not be used during pregnancy because of their association with fetal renal failure, oligohydramnios, pulmonary hypoplasia, and intrauterine or neonatal death.[17] Transitioning women taking these agents in the prepregnancy period is recommended. Patients who conceive while taking an ARB or ACE inhibitor should be switched to a safer alternative as soon as possible.

Low-Dose Aspirin

Low-dose aspirin prophylaxis (81 mg/day) after 12 weeks of gestation has been shown to modestly reduce the risk of preeclampsia in women at increased risk, without adverse fetal or maternal effects. The US Preventive Services Task Force and ACOG recommend daily low-dose aspirin for women with a history of early-onset preeclampsia requiring delivery <34 weeks of gestation, or with more than one prior pregnancy complicated by preeclampsia.[18] The guidelines recommend initiating aspirin prophylaxis (81 to 162 mg daily) between 12 and 28 weeks of gestation (optimally before 16 weeks) and to continue until delivery.

Antenatal Fetal Surveillance in Chronic or Gestational Hypertension

Because women with chronic hypertension are at increased risk of slowing of fetal growth and of superimposed preeclampsia, antenatal surveillance in women with chronic hypertension is recommended. However, limited data exist regarding optimal timing and intervals of testing.

The procedures of providing antenatal fetal biophysical testing in chronic hypertension should also include maternal screening for signs of superimposed preeclampsia.

Detection of tapering fetal growth requires periodic sonographic fetal growth assessments, typically every 3 to 4 weeks from 24 weeks

TABLE 10.2 Drugs Commonly Used to Treat Chronic Hypertension in Pregnancy and Their Modes of Action

Drug	Mode of Action	Typical Dose
Methyldopa	Centrally acting antihypertensive	0.5–3 g/day in 2–3 divided doses
Labetalol	Mixed α- and β-adrenergic blockers	200–2400 mg/day in 2–3 divided doses
Nifedipine	Calcium channel blocker	30–120 mg/day in slow-release form

Adapted from American College of Obstetricians and Gynecologists; Task Force on Hypertension in Pregnancy. Hypertension in pregnancy. Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. *Obstet Gynecol.* 2013;122:1122–1131.

onward. Because arrest of fetal growth is an indication for delivery, tapering of growth on sonogram should prompt more frequent and intensive evaluations. If the sonographic estimated fetal weight tapers below the 20th percentile or the abdominal circumference is at a significantly smaller percentile than the head circumference, more intensive growth sonography and frequent fetal biophysical surveillance is indicated. In such cases, sonography is typically performed at 10- to 21-day intervals with attention to amniotic fluid volume, trending of each biometric parameter (especially abdominal circumference), and umbilical artery Doppler waveforms.

Weekly fetal biophysical testing in IUGR has been shown to reduce perinatal mortality while not increasing labor induction or cesarean delivery.[19] Indications for delivery in the hypertensive patient with fetal IUGR include absence of growth of the head and abdomen over a 10-day interval, oligohydramnios, biophysical score of less than 6, or reversal of end-diastolic velocity on the umbilical Doppler waveform.

Women with renal impairment and chronic hypertension have a markedly higher risk of poor perinatal outcome than women without renal impairment. The incidence of impaired fetal growth is closely related to the degree of renal impairment, and women undergoing dialysis are at particular risk for fetal growth failure, preterm delivery, and fetal death, even with optimal management. Those who start dialysis during pregnancy are at the greatest risk, with only a 50% chance of a surviving infant.[20]

Gestational Hypertension

Management of women with gestational hypertension and preeclampsia is summarized in Box 10.1.

Gestational hypertension is defined as new-onset hypertension occurring after 20 weeks of pregnancy in the absence of signs of preeclampsia.[4,9] During pregnancy, gestational hypertension is indistinguishable from preeclampsia-in-evolution. Because a woman with apparent gestational hypertension at 36 weeks of gestation can rapidly devolve into preeclampsia at 39 weeks of gestation, the diagnosis of gestational hypertension should always evoke caution and vigilance. Only if the patient's blood pressure returns to normal postpartum, without development of signs of preeclampsia during the pregnancy, should the final diagnosis of gestational hypertension be applied.

The earlier that gestational hypertension is evident, the greater the risk of preeclampsia. When the diagnosis is made before 32 weeks' gestation, more than one-third of patients will develop preeclampsia, whereas the risk is less than 10% when the diagnosis is made after 38 weeks of gestation. Use of antihypertensive agents to treat patients with gestational hypertension should be avoided, given the risk of concurrent preeclampsia and the lack of evidence supporting improved fetal outcome. Gestational hypertension tends to recur in subsequent pregnancies and predisposes women to hypertension in the future.[21]

Preeclampsia-Eclampsia

Apparently unique to humans, the underlying causes of preeclampsia remain poorly elucidated. It is evident that the clinical manifestations of preeclampsia arise from vascular endothelial dysfunction that ultimately involves the maternal central nervous, renal, hepatic, and cardiovascular systems. In its full-blown form, preeclampsia can produce a profound coagulopathy and liver, respiratory, or cardiac failure and maternal death.

Preeclampsia is categorized as having severe features when systemic complications (e.g., renal, hepatic, pulmonary, or hematologic) are present (Box 10.2). This distinction is important because, if the presence of severe features is documented at any gestational age, the only appropriate treatment option is delivery, whereas expectant management may be acceptable in a woman who has mild disease and is remote from term.

• BOX 10.1 Management of Pregnant Women With Chronic Hypertension

Monitoring
- Daily home BP monitoring with a validated cuff after 5 minutes in sitting position
- Fetal growth sonography every 4 weeks
- Fetal biophysical testing at least weekly from 32–34 weeks

Avoid
- Low sodium diets
- Weight loss prescriptions
- Limitations of moderate exercise

Prophylaxis
- If prior pregnancy had preeclampsia with severe features and delivery was <34 0/7 weeks, begin daily low-dose aspirin (81–162 mg) at 8–16 weeks of gestation

Antihypertensive Medications
- Maintain systolic BP 120–160 mm Hg; diastolic BP 80–105 mm Hg
- Use labetalol, nifedipine, or methyldopa if antihypertensives needed
- Avoid ACE inhibitors, ARBs, renin inhibitors, and mineralocorticoid receptor antagonists

Delivery
- At 37 0/7 weeks unless preeclampsia with severe features
- If <37 0/7 weeks, administer antenatal corticosteroids
- If preeclampsia with severe features
  - Promptly after maternal stabilization if uncontrollable BP, eclampsia, pulmonary edema, abruptio placentae, nonreassuring fetal status
  - Administer magnesium sulfate antepartum and postpartum

ACE, Angiotensin-converting enzyme; *ARBs*, angiotensin receptor blockers; *BP*, blood pressure.

Etiology

Although the precise etiology of preeclampsia remains uncertain, numerous factors are associated with elevated risk (Table 10.3). Up to 10% of primigravid patients have mild disease, and approximately 1% have severe disease. The most widely accepted theory for the pathophysiology of preeclampsia is based on pathologic observations in the placenta indicating hypoperfusion in the maternal spiral arteries with resultant hypoxia. The placenta then releases substances into the maternal circulation that adversely affect maternal endothelial function, leading to the clinical syndrome of widespread vascular dysfunction, which is recognized as the syndrome of preeclampsia.[22] Individual responses to the process of progressive maternal vascular dysfunction vary in severity and timing in a manner that seems to have genetic, familial, and immunologic components. For example, preeclampsia occurring in a first-degree relative confers a fourfold increase in risk of the disease in siblings and children.[23] Population studies have suggested that women exposed to the antigenic effects of sperm before conception have a lower rate of preeclampsia than do women who conceive with lower degrees of exposure, although the evidence is inconclusive.[24]

The endothelial dysfunction that characterizes preeclampsia[25] manifests as greater reactivity to circulating vasoconstrictors such

• BOX 10.2 Management of Pregnant Women With Gestational Hypertension or Preeclampsia

Women With Gestational Hypertension or Preeclampsia Without Severe Features

Monitoring and Management

- BP checks twice weekly
- Renal and liver function tests and platelet counts weekly
- Antepartum testing weekly from 32 weeks of gestation
- Fetal growth sonography every 2–4 weeks after 24 weeks of gestation
- If fetal growth restriction is diagnosed, monitor umbilical artery Doppler
- Antihypertensive medications if blood pressures >140/90 mm Hg
- Avoid strict bed rest

Delivery

- At or beyond 37 0/7 weeks unless preeclampsia with severe features
- Magnesium sulfate for the prevention of eclampsia
- Regional neuraxial anesthesia (spinal or epidural) may be performed
- Monitoring of BP should be performed for the first 72 h and again at 7–10 days

Women With Preeclampsia and Severe Features

- Administer parenteral magnesium sulfate and continue without interruption until at least 24–48 h postpartum
- If 34 0/7 weeks or more, deliver after maternal stabilization
- If less than 34 0/7 weeks
  - Delivery may be delayed in facilities with adequate maternal and neonatal intensive care while antenatal corticosteroids for fetal lung maturity are administered
  - Delivery should not be delayed if there is uncontrolled hypertension, eclampsia, pulmonary edema, abruptio placentae, or nonreassuring fetal status
- If previable gestational age, deliver promptly after maternal stabilization
- If sustained systolic BP >160 mm Hg and/or diastolic BP >110 mm Hg, administer antihypertensive medication

Prevention of Recurrent Preeclampsia

- If preeclampsia in prior pregnancy, begin daily low-dose aspirin (81–162 mg) prior to 16 weeks

BP, Blood pressure.

TABLE 10.3 Risk Factors for Development of Preeclampsia

Factor	Relative Risk
Primigravida	3
Age >40 years	3
African-American race	1.5
Family history	5
Chronic hypertension	10
Chronic renal disease	20
Antiphospholipid syndrome	10
Insulin-dependent diabetes mellitus	2
Multiple gestation	4

as angiotensin, reduced production of endogenous vasodilators such as prostacyclin and nitric oxide, increased vascular permeability, and an increased tendency toward platelet consumption and coagulopathy.[26] The end result is hypertension, proteinuria secondary to glomerular injury, edema, and a tendency toward extravascular fluid overload with intravascular hemoconcentration.

Prediction

Perhaps one of the most important contributions that prenatal care makes to maternal and fetal outcomes is the timely detection of preeclampsia and the prevention of eclampsia.[27] A wide variety of biochemical and physical tests have been proposed as screening tools for early detection of preeclampsia, but even the most widely used biochemical tests have poor predictive values.[28] Uric acid levels are elevated in many cases of preeclampsia, but the sensitivity of the measurement is low.[29] Clinicians should be aware of the limitations of routine urine testing for detection of proteinuria, with standard dipstick testing being notoriously inaccurate.[30]

Doppler ultrasonographic assessment of the vascular dynamics in the uterine arteries during the second trimester has been proposed as a screening tool in populations in which obstetric ultrasonography is routine.[31] Up to 40% of women who develop preeclampsia have abnormal waveforms, and this finding was reported to be associated with a sixfold rise in the risk of preeclampsia.[32] As no randomized trials to date have demonstrated convincingly the ability of uterine artery Doppler studies to predict preeclampsia, its use is currently not recommended.[9]

The role of angiogenic factors in the pathophysiology of preeclampsia has become increasingly clear. Vascular endothelial growth factor (VEGF) and placental growth factor (PlGF), which bind to fms-like tyrosine kinase-1 (Flt-1) and soluble fms-like tyrosine kinase-1 (sFlt-1) receptors, have a critical role in angiogenesis and placental development. Flt-1, VEGF, and PlGF factor promote angiogenesis and placental vasculogenesis, whereas sFlt-1, VEGF, and PlGF inactivate those proteins, resulting in disordered angiogenesis and endothelial dysfunction. Levels of sFlt-1 are elevated in women with preeclampsia, and these elevated levels of sFlt-1 precede the features of clinical preeclampsia.

Zeisler et al.[33] recently reported a multicenter, prospective study of the ratio of sFlt-1 to PlGF in women between 24 and 37 weeks' gestation who presented with a clinical suspicion of preeclampsia or the HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelet count) syndrome.[33] An sFlt-1:PlGF ratio of 38 was the optimal cutoff in distinguishing between women in whom preeclampsia would develop and those in whom it would not develop in the next week. In a validation cohort of 550 women, a ratio of 0.38 or lower had a negative predictive value of 99.3% (95% confidence interval [CI], 97.9 to 99.9).

Despite the clear negative predictive value of an sFlt-1:PlGF ratio of less than 38 for preeclampsia diagnosis in the subsequent week, the clinical utility of this fact in managing pregnant women remains unclear. Thus at present, serum screening for preeclampsia risk is not recommended.[9]

Prevention

If an accurate predictor of preeclampsia could be identified, the next logical step would be the application of a preventive or ameliorative treatment. Unfortunately, attempts to identify an effective treatment have proven equally difficult. Given the recognized association between vascular endothelial dysfunction and preeclampsia, prostaglandin inhibitors have been proposed as a candidate for prophylaxis or treatment. Numerous trials[34] have been conducted with low-dose aspirin, based on the idea that the ability of aspirin to irreversibly inhibit production of the vasoconstrictive prostaglandin thromboxane would promote greater activity of

prostacyclin, a vasodilatory prostaglandin. This ability of aspirin would help to maintain patency in the maternal placental vascular bed and limit or prevent the evolution of preeclampsia.

In a recent systematic review of 34 randomized controlled trials of women at risk for recurrent preeclampsia, low-dose aspirin started at 16 weeks or earlier was associated with a significant reduction in preeclampsia (9.3% treated vs. 21.3% control) and IUGR (7% treated vs. 16.3% control), whereas aspirin started after 16 weeks was not.[35] Low-dose aspirin started at 16 weeks or earlier also was associated with a reduction in severe preeclampsia (0.7% treated vs. 15.0% control) and preterm birth (3.5% treated vs. 16.9% control). Of note, all studies for which aspirin had been started at 16 weeks or earlier included women identified to be at moderate or high risk for preeclampsia.

Calcium supplementation has been proposed as a preventive treatment on the basis of the known vasodilatory effect of calcium and impressive results in earlier, small studies.[36] Similarly, it has been suggested that antioxidants may have a role in preeclampsia prevention, but the only available trial to date showed mixed results, with improvements in biochemical indices in women receiving vitamins C and E, although perinatal outcomes were not different in treated and untreated groups.[37] Of concern was the finding that women in whom preeclampsia developed despite vitamin therapy had markedly worsened preeclampsia than controls in whom the disease developed.

A recent Cochrane systematic review[38] found that calcium supplementation commencing before conception may make little or no difference to the risk of preeclampsia (69/296 versus 82/283, risk ratio [RR] 0.80, 95% CI 0.61 to 1.06). For preeclampsia or pregnancy loss or stillbirth (or both) at any gestational age, calcium may slightly reduce the risk of this composite outcome; however, the 95% CI met the line of no effect (RR 0.82, 95% CI 0.66 to 1.00). Supplementation may make little or no difference to the severe maternal morbidity and mortality index, stillbirth, or cesarean, but the existing data neither confirm nor refute the value of early-pregnancy calcium supplementation.

Antepartum Management

Given the current inability to predict or prevent preeclampsia in the majority of cases, clinicians should actively manage established disease to minimize maternal and fetal morbidity. The recognition that preeclampsia has a form with severe features is of great value in escalating management and minimizing morbidity (Box 10.3).

• BOX 10.3 Preeclampsia With Severe Features

- Systolic blood pressure of 160 mm Hg or more, or diastolic blood pressure of 110 mm Hg or more on two occasions at least 4 hours apart (unless antihypertensive therapy is initiated before this time)
- Thrombocytopenia (platelet count < 100,000 × 109/L)
- Impaired liver function not accounted for by alternative diagnoses and as indicated by abnormally elevated blood concentrations of liver enzymes (to more than twice the upper limit of normal concentrations), or by severe persistent right upper quadrant or epigastric pain unresponsive to medications
- Renal insufficiency (serum creatinine concentration > 1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease)
- Pulmonary edema
- New-onset headache unresponsive to medication and not accounted for by alternative diagnoses
- Visual disturbances
- Eclampsia

From Gestational hypertension and preeclampsia. ACOG Practice Bulletin, No. 222. American College of Obstetricians and Gynecologists *Obstet Gynecol.* 2020;135(6):e237–e260.

Mild disease is generally managed expectantly until 37 weeks with frequent fetal and maternal biophysical assessments or until severe features are identified, whereupon prompt delivery is indicated regardless of gestational age.

Patients with preeclampsia should undergo regular laboratory evaluation for severe features, including urine collection for protein/creatinine ratio, complete blood count with platelet measurements, serum uric acid, blood urea nitrogen, creatinine levels, and liver transaminases. Fetal size and interval growth should be determined ultrasonographically at least monthly. Although no longer a criterion for severe preeclampsia, the diagnosis of intrauterine growth restriction with estimated fetal weight less than the 10th percentile is a sign of fetal jeopardy.

At 37 weeks of gestation, patients with mild disease should be delivered because prolonging pregnancy further increases the risks of maternal and fetal morbidity. Patients at earlier gestational ages should be closely monitored with sequential clinical and laboratory evaluations. Fetal well-being should be evaluated once or twice weekly by means of nonstress tests or biophysical profiles. Because antihypertensive therapy may mask worsening preeclampsia, oral antihypertensive therapy should be avoided or held constant during expectant management.

However, severe hypertension (>160/110 mm Hg) requires prompt intervention with rapid-acting antihypertensive agents if stroke and placental abruption are to be avoided. Intravenous hydralazine is well established as a first-line drug for this purpose, although there is a growing experience with intravenous labetalol and oral nifedipine (Table 10.4).[39] The aim of treatment is to lower blood pressure into the mild preeclampsia range (<160/100 mm Hg) to reduce the risk of maternal stroke and cardiovascular complications. Parenteral magnesium sulfate to prevent eclampsia should be administered in all cases of severe disease.

Severe features of preeclampsia can also present with atypical central nervous system abnormalities including headache, visual deficits, confusion, seizures, and in the most severe cases, intracranial hemorrhage. This constellation of findings, when demonstrated on brain magnetic resonance imaging, has been termed the *posterior reversible encephalopathy syndrome* (PRES). Neuroimaging typically demonstrates cerebral edema in the parietal and occipital lobes. The long-term sequelae of PRES after preeclampsia/eclampsia and other PRES-related conditions are inadequately understood.[40]

More commonly, patients show evidence of intravascular microangiopathy leading to the hemolysis, elevated liver enzymes, and low platelets of HELLP syndrome. The full-blown clinical syndrome of HELLP carries a significant maternal risk related to coagulopathy and hepatic dysfunction, even hepatic rupture.[41] Most patients with HELLP never experience catastrophic features

TABLE 10.4 Drugs for Acute Treatment of Hypertension in Severe Preeclampsia

Drug	Dosage
Hydralazine	5 mg IV or IM, then 5–10 mg every 20–40 min as required, to a total of 30 mg or Constant intravenous infusion 0.5–10 mg/h
Labetalol	10–20 mg IV, then 20–80 mg every 20–30 min to a maximum of 300 mg or Constant intravenous infusion 1–2 mg/min
Nifedipine	10–20 mg PO, repeat in 30 min, then 10–20 mg every 2–6 h

of the syndrome because delivery is initiated before their condition deteriorates to a critical level.

Preeclampsia and Fetal Risk

While prompt delivery in cases of severe preeclampsia optimizes both maternal and newborn outcome, this practice increases the incidence of prematurity and its attendant complications. IUGR is not uncommon in severe preeclampsia, and there may be evidence of progressive deterioration in fetal well-being, with progressive placental dysfunction. Infants delivered before 36 weeks' gestation will benefit from as little as 8 hours of antenatal steroid therapy.[42] The incidence of respiratory distress syndrome is lower in infants of mothers with preeclampsia than in those of age-matched controls without antenatal steroid exposure.[43] Venkatesh et al. performed an analysis from the US Consortium on Safe Labor Study of deliveries <34 weeks with preeclampsia with severe features.[44] Among 2217 deliveries assessed, 50% had a maternal or neonatal comorbidity, namely chronic hypertension (30%), pregestational diabetes (8%), gestational diabetes (8%), twin gestation (10%), and fetal growth restriction (7%). Pregnancy complicated by fetal growth restriction (adjusted risk difference: 12.2%, 95% CI: 5.48 to 19.03) was more likely to result in adverse neonatal outcome but not with other comorbid conditions.

Intrapartum Management

Patients with preeclampsia and severe features should be delivered expeditiously once the maternal condition is stabilized. In most cases, induction of labor can be undertaken, reserving cesarean section for obstetric indications such as breech presentation, placenta previa, and concerning fetal status. The only exception to prompt delivery may be a case of severe preeclampsia limited to proteinuria and intermittently severe hypertension but remote from term (<28 weeks' gestation). Such patients may be managed conservatively within a high-risk center while antenatal corticosteroids are administered.[45] Patients with severe preeclampsia at less than 24 weeks' gestation should be offered termination of the pregnancy.

All women with preeclampsia and severe features should receive magnesium sulfate as seizure prophylaxis (Box 10.4). Current guidelines do not require magnesium sulfate for those with gestational hypertension/preeclampsia lacking severe findings. The safety and therapeutic superiority of magnesium sulfate over other agents (e.g., diazepam) have been validated in multiple randomized trials.[46]

Intrapartum blood pressure should be maintained in the mild preeclampsia range (<160/105 mm Hg) using intravenous antihypertensive agents (labetalol, hydralazine, or nifedipine). Careful attention to fluid balance, especially avoiding overload, should be maintained. After delivery, the preeclamptic process typically begins to resolve rapidly.

• BOX 10.4 Magnesium Sulfate Therapy for Prevention of Eclampsia

- Bolus 4–6 g IV over 20 min
- Continuous infusion 1–2 g/h
- Follow magnesium levels every 6–8 h to maintain serum level 4–6 mEq/L
- Continue infusion for 24 h after delivery or 24 h after seizure

Eclampsia

Eclampsia, by definition a "severe feature," is the occurrence of generalized tonic-clonic seizures in association with preeclampsia and affects approximately 1 in 2500 deliveries in the United States. Eclampsia is much more common in developing countries, affecting as many as 1% of parturients. Up to 10% of maternal deaths in the United States are due to eclampsia.[47]

Most cases of eclampsia occur immediately prior to or within 24 hours of delivery. Almost half of seizures occur before the patient's admission to labor and delivery, approximately 30% are intrapartum, and the remainder are postpartum. There is a considerable drop in the risk of eclampsia by 48 hours postpartum, with seizures occurring in less than 3% of women beyond that time. Most patients have antecedent symptoms that are suggestive of preeclampsia, although in some cases eclampsia may occur without warning. If eclampsia is left untreated, repetitive seizures become more frequent and of longer duration, and ultimately status eclampticus may develop. Maternal and fetal mortality are as high as 50% in severe cases, especially if the seizures occur while the patient is remote from medical care.

Randomized controlled trials have demonstrated the clear superiority of magnesium sulfate for the treatment of eclampsia over all other anticonvulsants.[48–50] Intravenous magnesium sulfate is given as a 4-g bolus over 5 minutes followed by a maintenance infusion of 1 to 2 g/h for 24 to 48 hours after delivery. Subsequent seizures can be treated with further bolus injections. In refractory cases, second-line treatment with other anticonvulsants may be required. Rarely, the patient may require pharmacologic paralysis and mechanical ventilation.

Delivery after an eclamptic seizure should take place expeditiously but in a controlled, careful manner. There is little value in performing an emergency cesarean section in response to a seizure.[51] Stabilization and optimization of both maternal and fetal status are important prerequisites for delivery procedures. Once magnesium sulfate has been administered and maternal vital signs controlled, vaginal delivery is preferable in most cases. Potential indications for cesarean include a significantly unfavorable cervix, evidence of ongoing fetal compromise, or inability to achieve acceptable blood pressure control. Infants born to mothers after eclampsia require careful observation after birth.

Intrauterine Drug Exposure: Fetal and Postnatal Effects

GERRI R. BAER, RACHANA SINGH, AND JONATHAN M. DAVIS

KEY POINTS

- Substance use remains at epidemic proportions, both nationally and globally.
- Increasing legalization of marijuana has resulted in new concerns for fetal and infant exposure, with limited understanding of the short- and long-term effects in this population.
- The recent focus of perinatal substance use has grown to include widely prescribed substances, including opioids and other psychotropic drugs.
- The importance of establishing and maintaining consistent protocols in managing neonatal abstinence syndrome (NAS) has been clearly demonstrated.
- The choice to breastfeed is challenging and healthcare professionals have difficulties making recommendations for specific mother-infant dyads. The known benefits of breastfeeding must be weighed against any potential risks to the infant, most of which are not well understood.
- A comprehensive postnatal discharge care plan for the mother-infant dyad should be instituted to provide ongoing support and to improve health and psychosocial outcomes.

Introduction

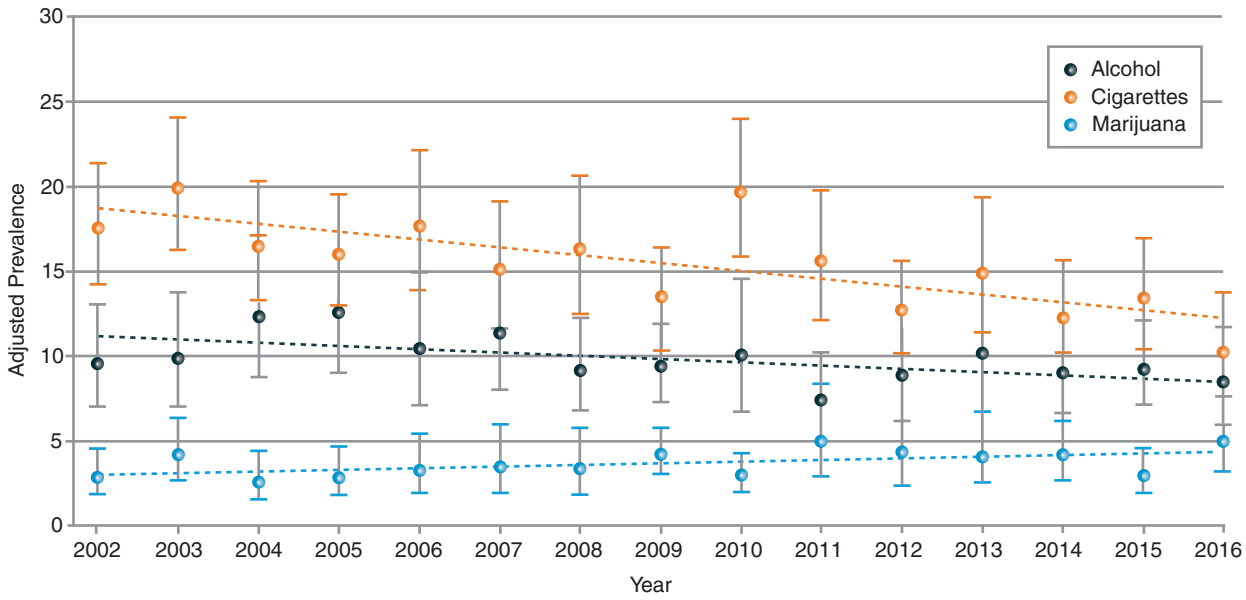
Substance use and misuse during pregnancy has been recognized as a problem for more than a century, but the problem has reached epidemic proportions in the United States in the past two decades. Prenatal exposure to psychotropic substances, both licit (e.g., alcohol, nicotine, opioids, cannabis) and illicit (e.g., heroin, cocaine, methamphetamines), is associated with significant maternal, fetal, and neonatal complications. These include poor fetal growth, preterm birth, placental abruption, stillbirth, fetal malformations, neonatal neurobehavioral dysfunction, and sudden infant death syndrome (SIDS).[1] Although substance use disorders (SUD) occur in all socioeconomic classes, illicit drug use is observed more frequently in populations with poor access to prenatal care, untreated medical conditions, poverty, food insecurity, stress, and psychiatric disorders. Confounding makes it difficult to distinguish effects of drug exposure from socioeconomic and environmental factors. This chapter addresses (1) epidemiology of perinatal substance use, (2) known effects of specific intrauterine exposures on the fetus and neonate, (3) maternal comorbidities and their effects on the neonate, (4) identification of pregnancies and infants considered to be at high risk, (5) smanagement of drug-exposed neonates, and (6) the long-term effects of intrauterine substance exposures. The discussion focuses on substances that are known to be associated with significant perinatal and neonatal morbidity.

Epidemiology of Perinatal Substance Exposure

Among people aged 12 or older in 2019 in the United States, 60.1% (165.4 million people) used tobacco, alcohol, or an illicit drug in the previous month.[2] This includes 50.8% (139.7 million) who drank alcohol, 21.1% (58.1 million) who used a tobacco product, and 13.0% (35.8 million) who used an illicit drug. Data on drug use during pregnancy in 2019 indicate that many pregnant women had a SUD with 120,000 (5.8%) using illicit drugs, 198,000 (9.6%) tobacco products, 197,000 (9.5%) alcohol, and 112,000 (5.4%) cannabis.[3] The prevalence of opioid use disorder (OUD) at delivery significantly increased from 1.5 per 1000 in 1999 to 6.5 per 1000 delivery hospitalizations in 2014.[4] While alcohol and cigarette use during pregnancy has declined over the past several years, the use of cannabis products and e-cigarettes has actually increased (Fig. 11.1).[5] This is largely due to individuals believing that these products are safer and not harmful to the fetus.

Determining accurate prevalence rates of perinatal substance use is extremely difficult. Under-reporting of substance use by pregnant persons, unreliable drug use survey and detection methods, polysubstance use, and negative stigma are just some of the challenges. In particular, SUDs are known to be more common in adolescents and adults with psychiatric disorders (e.g., anxiety disorders, major depressive and other mood disorders) that also require treatment. Thus, it is not uncommon for pregnant persons to receive multiple psychotropic drugs simultaneously, often without adequate safety data being available.

Updated resources for perinatal substance exposure and the impact on the mother-infant dyad are available online. The Substance Abuse and Mental Health Services Administration (SAMHSA) conducts an annual U.S. National Survey on Drug Use and Health (NSDUH) and also has a Center for Behavioral Health Statistics and Quality (codified after passage of the



• **Fig. 11.1** Alcohol, cigarettes, and cannabis use in pregnancy (2002–2016). Derived from a 2019 publication, this figure demonstrates contemporary trends in the use of alcohol, tobacco, and cannabis during pregnancy. (From Agrawal A, Rogers CE, Lessov-Schlaggar CN, et al. Alcohol, cigarette, and cannabis use between 2002 and 2016 in pregnant women from a nationally representative sample. *JAMA Pediatr*. 2019;173[1]:95–96.)

21st Century Cures Act) that tracks substance use closely. The Pregnancy Risk Assessment Monitoring System (PRAMS) provides comprehensive information on substance exposure before, during, and after pregnancy. PRAMS is designed to monitor maternal behaviors and experiences among persons who deliver live born infants, covering approximately 81% of all births. PRAMS surveillance data have historically demonstrated wide geographic, age-related, and racial/ethnic variation in tobacco, alcohol, and illicit drug use.

Health Policy

Pregnant persons who use opioids or other substances without a prescription are considered to have SUD, and the dyad is at much higher risk without treatment. Martin et al. found that only 9.3% of reproductive age women with a SUD needing treatment were able to access it.[6] Pregnant and parenting persons had similar or poorer access to treatment than the general population. Black and Latina pregnant and parenting persons were less likely to receive necessary treatment than white populations.

Health policy interventions for SUD during pregnancy should focus on treating SUD as an illness and not a criminal offense. This is crucial since up to 55,000 pregnant persons are incarcerated in the United States each year, many for crimes related to their SUD.[7] Incarceration is known to exacerbate mental illness, increase psychological distress, promote financial instability, and harm the parent-child bond. The need for appropriate treatment programs is growing as the number of pregnant persons with SUD increases. The effectiveness of these treatments is well established, with multiple studies demonstrating decreased morbidity and mortality in the mother and infant.[8] Current healthcare policy should focus on providing appropriate care for pregnant persons with SUD, including medical management and psychosocial support, and stigmatization of individuals with SUD must change. Schiff et al. examined existing public attitudes toward pregnant women with SUD with 85% of 1227 respondents agreeing that a pregnant person with SUD was "responsible for their opioid use" and "addiction was caused by poor choices, putting the baby in danger."[9] It is also important to recognize that illicit drugs may not be more harmful to the fetus than licit drugs. Future efforts need to include better education on the significant impact of these substances on the fetus, preferably initiating treatment before pregnancy occurs.

There are promising legislative efforts addressing the opioid epidemic and the problem of NAS.

- The Protecting Our Infants Act of 2015 aims to reduce the number of neonates exposed to antenatal opioids developing NAS. This act requires the development of recommendations, programs, strategies, data, and research relevant to prenatal opioid use.
- The Child Abuse Prevention and Treatment Act (CAPTA) provides funds to improve states' child protective services.
- The Comprehensive Addiction and Recovery Act of 2016 (CARA) identified limited physical capacity to care for neonates with NAS; coordination of care for mothers and neonates with NAS; and gaps in research and data on NAS.

Finally, private groups such as the National Advocates for Pregnant Women combine legal advocacy, education, and organizing to defend and protect pregnant persons with a variety of conditions including alcohol use disorder and OUD.[10] It is essential for health care providers to treat pregnant women with SUD in a respectful and non judgmental manner in order to build therapeutic relationships which will ultimately benefit the parent-infant dyad.

Perinatal Exposure to Specific Substances

Alcohol

Introduction

Alcohol consumption during pregnancy can cause a range of disorders, known as the fetal alcohol spectrum disorders (FASDs). FASDs include fetal alcohol syndrome (FAS), alcohol-related neurodevelopmental disorder (ARND), alcohol-related birth defects

(ARBDs), partial FAS, and neurobehavioral disorder associated with prenatal alcohol exposure (ND-PAE). Intrauterine alcohol exposure also is associated with growth restriction that persists postnatally.[11] The classic features of FAS were initially described by a French pediatrician in 1968 who observed a common pattern of birth anomalies in children born to alcoholic mothers.[12] In the 1970s, two U.S. reports were published describing similar features in children born to women consuming alcohol while pregnant.[13,14] This recognition led to the U.S. federal law placing warning labels on all alcoholic beverage containers regarding the increased risk of alcohol-related birth defects. In 2005, the Surgeon General reissued an advisory for people who are or might become pregnant, urging abstinence from alcohol to eliminate the risk for FASD.

Data from the NSDUH in 2015–2018 indicated that nearly 10% of pregnant respondents had admitted to alcohol consumption and 4.5% to binge drinking within the past 30 days.[15] Prevalence differed, with greater consumption and binge drinking in the first trimester compared to the second and third trimesters. Overall, nearly 20% of pregnant respondents reported drinking any alcohol and using tobacco within the past 12 months. The objective set by Healthy People 2030 is to increase abstinence from alcohol among pregnant persons to 92.2%.[16] The rate of FAS in the United States has been estimated to vary from 0.5 to 2 cases per 1000 live births, but its true prevalence is unknown and is likely underdiagnosed worldwide.[17–21]

Pediatricians often do not recognize FAS in the neonatal period and do not always inquire about alcohol exposure during pregnancy.[22] There are prenatal alcohol exposure screening instruments that are appropriate for use in pregnant persons as well as expert guidelines to clarify the diagnosis of FASD and aid in the earlier recognition and referral of affected infants and children.[18,23,24]

Diagnosis and Classification

The Institute of Medicine defined FASD in 1996 as an umbrella term for a range of sequelae of prenatal alcohol exposure.[25] A scientific task force led by the Centers for Disease Control (CDC) confirmed and refined the diagnostic criteria in 2004. FASD includes FAS as well as additional classifications for patients with variations on the classic FAS presentation. A diagnosis of FAS requires evidence of: (1) all three facial abnormalities (see description below), (2) growth deficits, and (3) central nervous system (CNS) abnormalities (structural, neurological, and/or functional).

Additional classifications include:

- Partial FAS (pFAS)—some, but not all of the physiologic features of FAS,
- ARND, where there are no facial deformities but features of CNS injury,
- ARBD, presenting primarily with physical malformations (cardiac, renal, bone, visual, and/or hearing),
- ND-PAE.[17]

A diagnosis of FASD is made using maternal history, the infant's physical findings, and neurobehavioral testing results. Although biomarkers such as fatty acid ethyl ester levels in meconium have been evaluated for use in diagnosis of prenatal alcohol exposure, no laboratory tests are available and validated for clinical use to quantify the extent of fetal alcohol exposure.[26] There are also no clinical methods for validating maternal self-reporting of alcohol use, quantifying the level of fetal exposure, or predicting future disability after fetal exposure.

Pharmacology and Biologic Actions

Alcohol is a mood-altering substance that enhances the effects of the inhibitory neurotransmitter γ-aminobutyric acid while reducing the effects of the excitatory neurotransmitter glutamate. This results in dose-dependent depressant or sedative effects on the CNS. Alcoholic beverages contain ethanol, which is metabolized in the liver to acetaldehyde by alcohol dehydrogenase (ADH). Acetaldehyde is then metabolized to acetate by aldehyde dehydrogenase and eventually eliminated as water and CO_2. A small amount of oxidation in the liver is catalyzed by the cytochrome P450 enzyme CYP2E1.

Ethanol readily diffuses across the placenta and can be rapidly detected in the fetus. The placenta expresses an isoform of ADH that has a low affinity for ethanol and a reduced metabolic rate. The fetal liver expresses CYP2E1 by mid-gestation, but at lower levels and less metabolic capacity than adult liver. Despite the presence of fetal and placental metabolic activity, fetal ethanol clearance largely relies on maternal metabolism. Toxic effects of alcohol during pregnancy appear to be related to the peak and circulating alcohol concentrations.[27] Undernutrition and alcohol exposure may interact to cause greater fetal toxicity, due to slower maternal metabolism.[27]

Fetal and Neonatal Effects

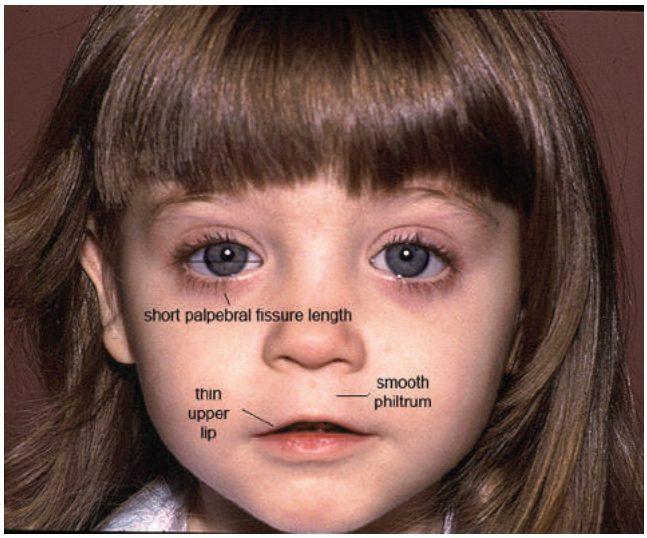
It is unclear how much alcohol exposure is necessary to cause fetal teratogenicity and even high consumption levels do not always result in the birth of a child with FASD.[28] The adverse effects of alcohol on the fetus are related to gestational age (GA), duration of exposure, amount of alcohol consumed, pattern of consumption (e.g., binge drinking), maternal peak blood alcohol concentrations, and maternal alcohol metabolism.[29] Studies show that maternal blood alcohol levels are affected by body size and genetic disposition, with poor maternal nutritional status a significant risk factor for FASD.[27,30,31] A variety of additional risk factors increase susceptibility to FASD, including increased maternal age, poverty, and socioeconomic status.[28,32,33]

Growth Restriction

Fetal growth restriction (FGR) is one of the most consistent sequelae of prenatal alcohol exposure. The diagnostic criteria for FAS require birth weight and/or length to be below the 10th percentile (adjusted for age, sex, gestational age, and race or ethnicity).[34] Restricted growth begins in utero and continues postnatally, with high levels of alcohol exposure causing greater impact on head and body growth. Fetal and childhood growth deficits appear to be multifactorial, with etiologies including abnormal placentation, abnormal vascular development, and impaired production of insulin-like growth factors that are involved in somatic growth and placental function.[35,36] Growth deficiency may persist through childhood, particularly in those children with the highest levels of intrauterine exposure.[37,38]

Dysmorphology

Key features of FAS include characteristic facial dysmorphology, including a smooth philtrum (using University of Washington Lip-Philtrum Guide), a thin vermillion border, and small palpebral fissures.[17,34] Characteristic features also may include midface hypoplasia, broad flat nasal bridge, and thin upper lip (Fig. 11.2). Patients with FAS also have a higher risk of microcephaly, micrognathia, and cleft palate. Genetic syndromes must be excluded because some of their dysmorphic features can overlap with FAS. The facial features and growth restriction may become



• **Fig. 11.2** Child with three diagnostic facial features of fetal alcohol syndrome. (From Williams JF, Smith VC. AAP committee on substance abuse. Fetal alcohol spectrum disorders. *Pediatrics*. 2015;136[5]:e1395–e1406; copyright 2022 Susan (Astley) Hemingway PhD, University of Washington.)

less distinctive during adolescence and puberty.[39] While skeletal anomalies, abnormal hand creases, and ophthalmologic, renal, and cardiac anomalies[40] have been described in children with FAS, they are less frequent than the facial dysmorphology.[41]

Central Nervous System Abnormalities

Children with FASD are at higher risk of seizure disorders as well as significant cognitive, motor, and neurobehavioral problems.[42] A host of CNS abnormalities are associated with FASD. Table 11.1 lists some of the more common findings.[20,42]

Long-Term Effects

FASDs are associated with lifelong social, behavior, intellectual, and psychological difficulties, and deficits in reading, spelling, and math are common.[43] In a cohort of 76 children and young adults with FASD, high rates of attention deficit/hyperactivity disorder (ADHD; 62%), oppositional defiant disorder (43%), and developmental coordination disorders (41%) were noted. Visual and/or ocular abnormalities were also found in 86% of the children. Of the adults evaluated, 70% had ADHD, 52% had an anxiety disorder, 42% had experienced a depressive episode, and 24% had engaged in self-injurious behavior.[44] Adolescents and young adults who were exposed prenatally to alcohol are at an increased risk for earlier alcohol use and subsequent abuse.[45,46]

Researchers using the Canadian National FASD Database reported on a sample of 726 adolescents and adults (mean age 19.8 years [range 12 to 60]) who had prenatal alcohol exposure. Impairments in adaptive behavior, social skills, executive functioning, academic achievement, and attention were seen in approximately 2/3 of the sample, and 40% had an intelligence quotient less than 70. Difficulties included independent living needs (63%), substance misuse (46%), employment problems (37%), legal problems (30%), and housing problems (21%), with 81% experiencing at least one such difficulty at the time of assessment.[47] Earlier recognition and intervention for children with FAS and its variants may help mitigate eventual adulthood disabilities and help to prepare affected adolescents and young adults for independent living.[17,18]

Cigarette Smoking, Electronic Cigarettes

Introduction

Nicotine in the form of cigarettes (including electronic cigarettes—ECIGS and electronic nicotine delivery systems—ENDS), smokeless tobacco, and nicotine replacement patches, is the most commonly used substance during pregnancy which negatively affects perinatal outcomes. Cigarette smoking in the United States has decreased significantly over the past 25 years, due to effective public health strategies. Unfortunately, these efforts have not been as effective for pregnant persons. Since the 2019 NSDUH survey revealed that 9.6% of pregnant persons used tobacco, targets set by the Healthy People 2020 initiative to decrease tobacco use to less than 2% of pregnant people have not been reached.[2,16] These targets are becoming even more tenuous with the use of ECIGS steadily increasing during pregnancy, likely because they are believed to be a safer alternative than conventional cigarette smoking.[48] Pregnant persons who use nicotine products are more likely to use opioids, alcohol, cocaine, amphetamines, and marijuana.[2] Cigarette smoking is especially prevalent among pregnant persons with OUD (85% to 95%) and smoking cessation programs should improve both maternal and neonatal outcomes.

Pharmacology and Biological Actions

Cigarette smoke contains a mixture of approximately 4000 compounds (93 of which are considered toxic), including nicotine and carbon monoxide. Nicotine stimulates the reward center of the brain through activation of nicotinic acetylcholine receptors. It readily crosses the placenta and concentrates in fetal blood and amniotic fluid, where levels can significantly exceed maternal blood concentrations.[49] The maternal serum concentration of cotinine (the primary metabolite of nicotine) is used to quantitate smoking and fetal exposure. Cotinine has a half-life of 15 to 20 hours with serum levels 10-fold higher than nicotine.[50]

Smoking during pregnancy can impact fetal growth and development; nicotine and its metabolites are potent vasoconstrictors which decrease uterine and placental blood flow.[51,52] Carbon monoxide crosses the placenta, forming carboxyhemoglobin in the fetus and resulting in significant hypoxemia.[51] Serum erythropoietin levels are significantly higher in cord blood from neonates who were exposed to cigarette smoke, a finding likely reflecting fetal hypoxia.[53] Nicotine may also act as a developmental toxin targeting the placenta as well as the brain and other organ systems in the fetus.[51] Since the amount of nicotine delivered by ECIGS is similar to conventional cigarettes, potential toxicity would be expected to be similar.[48]

Long-Term Effects of Perinatal Exposure to Cigarettes and Electronic Cigarettes

Maternal smoking has been shown to increase the risk of stillbirth, miscarriage, and preterm delivery. Liu et al. studied over 25 million pregnancies in the U.S. National Vital Statistics System from 2011 to 2018.[54] They demonstrated that smoking during the first or the second trimester of pregnancy (even 1 to 2 cigarettes per day) was associated with an increased risk of preterm birth, which was in part due to increased placental abruption and placenta previa.[54–56] Cigarette smoking is also well recognized to cause FGR in a dose-dependent manner.[51] Reductions in weight, fat mass, and other anthropometric measurements occur through impaired placental blood flow, tissue

TABLE 11.1 Central Nervous System Abnormalities Associated With Fetal Alcohol Spectrum Disorders

Abnormality	Organ or Function	Specific Examples
Sensory	Visual	Strabismus Refractive errors Impaired oculomotor control Microphthalmia Coloboma Optic nerve hypoplasia Retinal dysplasia Retinal vascular tortuosity
	Auditory	Hearing loss—sensorineural, conductive, central Impaired auditory processing
Neurological	Gross motor	Delayed walking Slowed motor reaction timing
	Fine motor	Visual-motor integration Poor graphomotor skills
	Coordination	Gait ataxia Impaired static postural control
	Sensory integration and processing	Auditory and visual processing dysfunction
Neuropsychological	Cognitive	Intellectual impairment Executive function Learning and memory Attention deficits Decreased processing speed Speech and language Reading and spelling Numerical processing/estimation
	Behavioral/emotional	Problem behaviors—externalizing and internalizing Attention deficit hyperactivity disorder Impulse control problems Aggression Anxiety Depression
	Social/adaptive	Decreased interpersonal skills and social competence Decreased social problem solving Poor social judgment
	Sleep

hypoxia, and alterations in protein metabolism and enzyme activity in the placenta. When these children are followed to 3 years of age, body weights are increased, consistent with early childhood obesity.[57] Although nicotine replacement therapy (NRT) and ENDS do not show clear evidence of effectiveness and safety in pregnant women, those who stopped smoking before or during early pregnancy had appropriate fetal and childhood growth.

Fetal exposure to cigarette smoke can impact lung development, putting preterm neonates at increased risk of bronchopulmonary dysplasia (BPD) and longer-term pulmonary dysfunction termed chronic pulmonary insufficiency of prematurity (CPIP).[58,59] Term neonates are at increased risk of diminished lung function, altered central and peripheral respiratory chemoreception (e.g., SIDS), and asthma during childhood.[60] Possible mechanisms also include dysregulated cytokine production, oxidative stress, and the direct effects of nicotine on lung receptors resulting in altered lung development. Genetic (upregulation of asthma susceptibility genes) and epigenetic (alterations in DNA methylation) factors have been identified that may influence the risk for long-term lung disease. Pregnant persons who smoke during pregnancy often continue to smoke postnatally, exposing their children to secondhand smoke exposure.[60] This can further increase the risk of morbidity and mortality throughout childhood.

Finally, alterations in developmental patterning of DNA methylation and gene expression can be detected in the fetal brain following antenatal exposure to cigarette smoke. This can result in reduced mature neuronal content, fetal brain growth, and smaller volume of cortical gray matter.[61] This may explain the increased incidence of behavioral problems and impaired executive function that can be seen later in childhood.

Cannabis and/or Cannabidiol

Introduction

Cannabis is a potent psychoactive agent used commonly during pregnancy.[62] Between 2016 and 2019, the NSDUH reported a rate of cannabis use in pregnant persons aged 15 to 44 years ranged from 4.9% to 7.1%, with frequent use in 1.5% to 3.1%.[3] Another analysis found increased cannabis use occurring despite cigarette and alcohol use in pregnancy declining.[5] The majority of cannabis use is recreational and probably underreported due to recall bias.[2,63] Surveys of pregnant persons and non pregnant persons indicate that 70% believe that there is slight or no risk of harm from using cannabis.[64] The increased potency of cannabis products is of particular concern. Chandra et al. reported that mean Δ^9-tetrahydrocannabinol (Δ^9-THC; the active component of the endocannabinoid system) concentrations have increased from 8.9% in 2008 to 17.1% in 2017 and the mean Δ^9-THC: Cannabidiol (CBD) ratios from 23 to 104.[65] The greatest reported use occurs in the first trimester, often before the person is aware of being pregnant.

Pharmacology and Biological Actions

Endocannabinoids and phytocannabinoids activate cannabinoid receptors in the endocannabinoid system. CB1 is primarily found in the central nervous system and CB2 in immune cells and the retina.[66] Cannabinoid signaling is necessary for normal placental implantation and receptors are expressed early in the fetal brain, particularly in white matter and areas with high cellular proliferation.[67] During pregnancy, cannabis readily crosses the placenta and the fetal blood-brain brain barrier since it is highly lipophilic, altering normal endocannabinoid signaling, synaptogenesis, development of neuronal interconnections, and developing neurotransmitter systems.[68] All of these effects can potentially influence embryogenesis and fetal development by disrupting normal angiogenesis, increasing cellular apoptosis, and reducing cellular migration and DNA replication.[69]

Cannabis use during the postpartum period can increase neonatal exposure through breast milk and secondhand exposure.[70–72] THC may remain in breast milk up to 6 weeks after ingestion and up to eight times the maternal serum level.[73,74] Recent studies have suggested that cannabis use during pregnancy is associated with placental abruption, preterm birth, fetal growth restriction, admission to a neonatal intensive care unit, and lower 5-minute Apgar scores which can significantly impact both short- and longer-term outcomes.[75]

Long-Term Effects of Perinatal Cannabis Exposure

Lee and colleagues evaluated cardiovascular structure and function in rat pups born to pregnant dams exposed to Δ^9-THC. At birth, Δ^9-THC exposed pups were noted to have more FGR, lower cardiac output, and cardiac remodeling (increased in cardiac collagen content).[76] This cardiac dysfunction could persist throughout the lifespan and contribute to long-term cardiovascular morbidity and mortality. These findings in conjunction with potential epigenetic and biochemical alterations in the placenta and fetal brain highlight the potential impact on short- and long-term health outcomes.[77,78] Additional studies focusing on epigenetics and long-term outcomes associated with cannabis use in pregnancy are urgently needed to better understand the impact of fetal exposure on the life long risk of cardio-metabolic disorders.[79,80]

The longitudinal Adolescent Brain and Cognitive Development (ABCD) Study recruited 11,875 children aged 9 to 11 years between 2016 and 2018. Compared to unexposed children and those exposed in utero prior to knowledge of the pregnancy, children exposed to cannabis during gestation had higher rates of psychopathology. Cannabis-exposed children had lower cognitive scores, birth weight, and brain volumes and increased sleep problems, but these associations weakened after adjusting for confounding factors.[81] Other studies have suggested that antenatal cannabis exposure is associated with increased impulsivity, hyperactivity, delinquent behavior, memory dysfunction, and decreased intelligence quotient (IQ) scores in children.[82] While more definitive evidence is needed, these recent studies indicate that cannabis use should be avoided during pregnancy and lactation.

Opioids (Including Prescription Drugs)

Introduction

Opioids may be used in pregnancy either for illicit or recreational use, or for therapeutic reasons such as treatment of OUD or chronic pain. Pregnant persons are not a uniform group and their perinatal outcomes are variable. Approaches to the care of the dyad should be tailored according to the clinical scenario such as chronic pain, illicit use, or medication-assisted treatment (MAT) for OUD.[83]

Pharmacology and Biologic Actions

All opioids bind to opiate receptors, including natural derivatives from opium poppy (e.g., morphine, narcotine, codeine, thebaine, papaverine, narceine) or synthetically manufactured opioids. Semisynthetic and synthetic derivatives include heroin, fentanyl, hydromorphone, methadone, buprenorphine, and others.[84] Specific opioid receptors (μ, δ, κ) have been identified in the CNS and bowel that are activated by endogenous opioids (e.g., endorphins, enkephalins).[85,86] As modulators of the sympathoadrenal system, endogenous opioids are important during periods of

stress with receptor activation producing analgesia and alterations in multiple organ systems. Synthetic opioids have similar physiologic and adverse effects.[83] The chronic use of opioids can result in tolerance, physiologic dependence, and addiction. Tolerance leads to a shortened duration of the action followed by the need for higher doses to obtain the same clinical effect.[87]

Fetal and Neonatal Effects

Studies to evaluate the impact of early fetal opioid exposure on the incidence of congenital anomalies have yielded variable results.[88–90] Although there may be a marginally increased risk, the benefits of a healthier pregnancy with prescribed opioids (i.e., MAT) greatly outweigh any potential risks associated with uncontrolled substance use. Obstetric complications of untreated OUD may include spontaneous abortion, preterm delivery, placental abruption, chorioamnionitis, and placental insufficiency.[83] Antenatal illicit opioid exposure is associated with a smaller head circumference (with increased risk of white matter lesions), higher rates of meconium-stained amniotic fluid, perinatal asphyxia, lower Apgar scores, and an increased incidence of infections such as syphilis, HCV, and HIV at birth.[91–93] The etiology of these complications is multifactorial with poor prenatal care, ongoing illicit opioid use, poor nutrition, infections, and polydrug use likely contributing.

Long-Term Effects of Perinatal Opioid Exposure

Key knowledge gaps exist regarding longer-term neurocognitive and mental health outcomes after antenatal exposure to opioids. While numerous studies suggest that exposure during fetal development may produce lifelong alterations in brain development, many have significant limitations such as: (1) not delineating antenatal/postnatal drug exposure (single or polydrug); (2) using large datasets with coded diagnoses that may not be accurate and variables that may be statistically significant, but not clinically relevant; (3) not describing if prenatal toxicology testing was performed; and (4) poorly matched comparison groups. All the confounding variables may be impossible to control for in a single follow-up study and all of these factors need to be considered when interpreting long-term studies.[94]

Significant neurobehavioral differences have been found between neonates prenatally exposed to methadone who either did or did not require pharmacotherapy for NAS, demonstrating variable impact on clinical outcomes.[95] Emerging data also suggest an increased risk for behavioral and/or developmental disorders in infants born to mothers with OUD when followed to school age.[96,97] While one study found that infants exposed to methadone or buprenorphine had normal measures of cognition, sensory processing, and behavior, other investigators have shown normal development for opioid-exposed infants during the first 2 years of life after data were controlled for a variety of socioeconomic and environmental influences.[94,98,99]

Cocaine

Introduction

Cocaine and its metabolites readily cross the placenta and enter the amniotic fluid and fetus.[100] The amniotic fluid may serve as a reservoir for cocaine and its metabolites and prolong exposure to vasoactive compounds. The confounding effects of multiple other drugs (e.g., tobacco, alcohol), nutritional deficits, and poor prenatal care complicate the establishment of causal relationships between antenatal cocaine exposure, intrauterine growth, and subsequent neurobehavioral development.[101]

Pharmacology and Biologic Actions

Cocaine is a highly psychoactive stimulant with a long history of abuse. Two forms of cocaine are commonly used—cocaine hydrochloride and cocaine base (crack). Cocaine hydrochloride is used orally, intranasally, or intravenously with intravenous users more likely to have a history of heroin use. Crack is the most widely available form of freebase and when smoked, it readily enters the bloodstream to produce levels similar to intravenous administration. Cocaine rapidly reaches the blood stream and the brain to produce its psychological effects. The pharmacologic actions of cocaine include inhibition of postsynaptic reuptake of norepinephrine, dopamine, and serotonin neurotransmitters by sympathetic nerve terminals.[102] Tryptophan uptake is similarly inhibited, altering serotonin pathways with resultant effects on sleep. In adults, cocaine has been associated with cerebral hemorrhage, hyperthermia, cardiac arrest, cardiac arrhythmias, myocardial infarction, intestinal ischemia, and seizures. Chronic use is associated with anorexia, nutritional problems, and paranoid psychosis.[103]

Fetal and Neonatal Effects

Adverse perinatal outcomes associated with cocaine use are primarily due to vasoconstrictive properties of cocaine on maternal blood vessels in the uterus and placenta.[104,105] Cocaine increases maternal mean arterial blood pressure, decreases uterine blood flow, raises fetal systemic blood pressure, and causes fetal hypoxemia in an ovine model.[106] These effects contribute to the higher risks of stillbirth, spontaneous abortion, placental abruption, preterm delivery, and FGR seen in cocaine-exposed infants.[107,108] Cocaine is hypothesized to reduce fetal growth via constriction of uteroplacental vessels with consequent decreased fetal substrate and oxygen delivery. Neonates exposed to cocaine in utero have lower birthweight and length and smaller head circumference.[101,108] In the Maternal Lifestyle Study, cocaine-exposed neonates had lower birthweight (151 g), length (0.71 cm), and head circumference (0.43 cm) at 40 weeks' gestation.[109]

To date, no well-defined cocaine-associated malformation syndrome has been identified and the teratogenic potential of cocaine remains controversial. Early reports had suggested that cocaine-exposed neonates had a higher rate of limb reduction anomalies, heart defects, ocular anomalies, intestinal atresia or infarction, and other vascular disruption sequences. However, more recent data has failed to demonstrate higher rates of congenital anomalies among cocaine-exposed infants.[107]

Subtle neurobehavioral abnormalities have been reported using the NICU Network Neurobehavioral Scale (NNNS) in the month after birth. Cocaine-exposed neonates manifest a range of neurobehavioral abnormalities that are present at birth and wane as the cocaine and metabolites are cleared from plasma. Neonates may present with signs of central and autonomic dysfunction such as hypertonicity, irritability, tremulousness, and abnormal crying, sleep, and feeding patterns.[110,111] The intoxicant effects of cocaine that have been reported in two controlled studies include tachycardia, tachypnea, apnea, and elevations in cardiac output, stroke volume, mean arterial blood pressure, and cerebral artery flow velocity which typically resolve by day 2 of age.[112,113] Cocaine-exposed neonates may also have

abnormal electroencephalograms or clinical seizures which may be the result of direct toxicity or delayed and/or impaired neuronal myelination.[114–116]

Long-Term Effects of Prenatal Cocaine Exposure

Evidence from preclinical and clinical studies, including adults who had prenatal cocaine exposure, suggests that there is persistence of behavioral and cognitive deficits secondary to multiple cellular and molecular mechanisms.[116] The neurodevelopmental problems among children exposed to cocaine may occur from direct drug effects during gestation or from postnatal environmental influences, or both.[117] Using family case management as an intervention for cocaine-exposed infants resulted in improved verbal development at 36 months in those children who remained with their birth mothers.[118] Cocaine-exposed infants in a prospective longitudinal cohort (with a masked comparison group) were studied at an urban teaching hospital and were twice as likely to have significant cognitive but not motor delays at 2 years of age.[119] Language development appears to be affected into adolescence in a dose-dependent manner.[120]

Prenatal cocaine exposure is associated with increased externalizing behaviors and a doubling of the risk for SUD in adolescence, even after controlling for other prenatal drug exposure and environmental influences.[121,122] In mid-adolescence, girls who were exposed have impaired executive functioning compared to unexposed peers and exposed boys.[123] Both direct and indirect impact of prenatal cocaine exposure have been detected in long-term follow-up, including emotional regulation problems, arrest history, and conduct disorder.[104] Early screening and appropriate intervention in adolescents with mental health and behavioral problems can improve outcomes.

A study of volumetric magnetic resonance imaging (MRI) in thirty-five 12-year-old children exposed to cocaine in utero found smaller total parenchymal volumes, lower cortical gray matter volumes, and smaller head circumferences (HC) compared to controls.[124] Akyuz and colleagues conducted a longitudinal cohort study in 11 children with antenatal cocaine exposure and 10 controls (6 with noncocaine polysubstance exposure and 4 with no reported substance exposure) and found decreased HC in cocaine-exposed infants and trends toward reduced cerebral cortical volumes that persisted into the teenage years.[125]

Amphetamines

Introduction

The use of amphetamines, including illicit and prescription amphetamines, has increased worldwide in the past two decades. Methamphetamine (also known as "speed," "ice," "crystal meth," or "crank") is abused most often because it can be produced cheaply using over-the-counter decongestants and cough medicines. Amphetamines also include ecstasy (3,4-methylenedioxy methamphetamine, or MDMA) and prescription amphetamine stimulants that may be misused or abused, especially among adolescents and persons of childbearing age.[126] In a large national sample of hospital deliveries between 2004 and 2015, 1.7/1000 deliveries included a diagnosis related to amphetamine use. The rate of amphetamine-related diagnoses was trending higher and by 2015 affected 2.4/1000 birth.[127]

Pharmacology and Biologic Actions

Methamphetamine (or "crystal") is increasingly abused because it readily dissolves in water for injection, inhalation, or rectal administration.[126] The amphetamine isomers are CNS stimulants that provide an intense euphoria and increased energy. Amphetamines were initially marketed for the treatment of obesity and narcolepsy and continue to be used for the treatment of ADHD. Amphetamines are classified as schedule II drugs, similar to cocaine and narcotics.

Like cocaine, amphetamines are sympathomimetics and potentiate the actions of norepinephrine, dopamine, and serotonin. In contrast to cocaine, amphetamines appear to exert their CNS effects primarily by enhancing the release of neurotransmitters from presynaptic neurons. Amphetamines also can block reuptake of released neurotransmitters and can exert a weaker direct stimulatory action on postsynaptic catecholamine receptors.

The clinical effects and toxicity of these agents are difficult to distinguish from those of cocaine. While the psychotropic effects of cocaine are of short duration (5 to 45 minutes), the effects of amphetamines can last from 2 to 12 hours. Amphetamine withdrawal is characterized by prolonged periods of hypersomnia, depression, and intense, often violent paranoid psychosis.

Obstetrical and Fetal Effects, Including Fetal Growth Restriction

Amphetamines cross the placenta and are detectable in umbilical cord, placenta, and amniotic fluid.[128] Animal studies suggest that the increased rate of FGR, prematurity, and fetal demise derive from increases in maternal and fetal blood pressure and uterine vascular resistance.[129] These changes restrict oxygen and nutrient delivery to the fetus and may be further complicated by diminished maternal nutrient intake from the anorectic effect of amphetamine. Methamphetamine exposure has direct and indirect effects on the fetus, many of which are confounded by comorbidities, other drugs, smoking, poverty, and poor prenatal care.[126] A meta-analysis of eight studies showed statistically significant decreases in gestational age, birth weight, head circumference, body length, and Apgar scores in exposed neonates.[130] A population-based study using California's mother-infant linked datasets also showed that methamphetamine use significantly increased the odds of preterm delivery as well as gestational hypertension and preeclampsia, abruption, intrauterine fetal demise, neonatal death, and infant death (controlled for maternal age, race/ethnicity, insurance status, prenatal care, education, parity, chronic hypertension, drug and alcohol exposure, and diabetes).[131]

The Infant Development, Environment, and Lifestyle (IDEAL) study, published in 2006, followed 84 methamphetamine-exposed and 1534 unexposed infants (confirmed by screening for meconium). Both groups included alcohol, tobacco, and marijuana use but excluded opioids, phencyclidine (PCP), and lysergic acid diethylamide (LSD). Cocaine, tobacco, alcohol, and marijuana use were also more frequent in methamphetamine users. Methamphetamine-exposed infants were 3.5-fold more likely to be small for gestational age after adjusting for confounders such as low socioeconomic status, GA, and tobacco exposure.[132] Methamphetamine is neurotoxic to the developing brain, and prenatal exposure is associated with smaller subcortical brain volumes, including putamen, globus pallidus, and hippocampus.[133,134]

Neonatal and Infant Neurobehavioral Effects

Although the IDEAL study reported no increase in dysmorphism or other congenital anomalies, there was a higher rate of NICU admission.[127] Amphetamine exposure was associated with poor suck and less likelihood of breast feeding, but no specific withdrawal

syndrome requiring treatment has been noted.[135] Prenatal methamphetamine exposure is linked to abnormal NNNS scores and underarousal, low tone, poorer quality of movement, and increased stress.[136] It is important to note that by 1 month of age, stress and arousal were significantly improved in exposed neonates.[137]

Long-Term Effects

Height trajectories are lower in methamphetamine-exposed infants during the first 3 years of life.[138] In a Swedish cohort evaluated at age 14 to 15 years, amphetamine-exposed boys were taller and heavier and girls were smaller and lighter than national standards.[139] Although by age 3 the IDEAL cohort had no differences in receptive or expressive language, gross motor skills, or mental development between exposed and unexposed children, at age 5 differences in externalizing behavioral problems, attention processing, and risk of ADHD were noted. By including an adversity index score over the first 3 years, the investigators found that the effects of methamphetamine on neurobehavior were primarily due to early adversity, caregiver stress, and/or psychological symptoms.[135,140]

Prenatal Medication Exposures That May Be Associated With Neonatal Withdrawal

Pregnant persons may require medication to treat preexisting medical conditions, including neurological or psychiatric conditions. In a prospective U.S. cohort including nearly 10,000 nulliparous pregnant persons (2010–2013), 73.4% took at least one medication (excluding vitamin or mineral supplements) during pregnancy with 55% taking a medication in the first trimester.[1] The most commonly prescribed were antiemetics or gastrointestinal medications (34.3%), antibiotics (25.5%), and analgesics (23.7%). Antidepressants were taken in 6.1% of the sample and antipsychotics in 0.5%.[141]

Selective Serotonin Reuptake Inhibitors

The prevalence of major depressive disorder (MDD) during pregnancy has been estimated to be 14% to 23%.[142] Untreated depression during pregnancy is associated with increased odds of preterm birth and low birth weight.[143] While a 2003 study indicated that 13.4% of pregnant persons were prescribed antidepressant medications, primarily selective serotonin reuptake inhibitors (SSRIs) (the most commonly prescribed antidepressants), the more recent nuMoM2b study found that 6.1% of pregnant persons were treated with antidepressants between 2010 and 2013.[141,142] It is unclear whether this is a true decrease in prescribing or differences in the populations sampled, but the increased recognition of potential effects of SSRIs on the neonate may have influenced prescribing patterns.

SSRIs selectively inhibit reuptake of serotonin in presynaptic nerve terminals and increase the synaptic concentrations of serotonin. They are better tolerated and have fewer side effects than tricyclic antidepressants because they do not affect other neuroreceptors. Animal studies have shown that serotonin appears as a neurotransmitter in the early fetal brain, but its role in development is not clearly delineated. Although fluoxetine and its active metabolite cross the placenta and enter the fetal brain, the impact on brain development is not clearly understood.[144]

Studies of SSRI use in pregnancy have not shown patterns of fetal malformations with first trimester use, except for congenital heart defects.[143] Fetal losses, lower birth weights, and preterm birth appear to be more common in pregnancies exposed to antidepressants, but confounding has prevented full understanding of causality.[144,145] After intrauterine exposure, neonates are more likely to require NICU admission and are at risk for a self-limited syndrome of poor neonatal adaptation that may include tachypnea, irritability, jitteriness, hypertonia, sleep disturbance, temperature instability, poor feeding, hypoglycemia, and/or seizures.[146] There is a small absolute risk but increased relative risk of persistent pulmonary hypertension of the newborn (PPHN) associated with SSRI exposure in later pregnancy.[147]

Benzodiazepines

Insurance claims data from 2015 in the United States indicated that benzodiazepines were prescribed for 2.9% of pregnant persons, which was increased from 1.3% in 2007.[148] Worldwide prevalence of benzodiazepine use during pregnancy was found to be 1.9%, with the highest prevalence (3.1%) during the third trimester.[149] Benzodiazepine exposure in early pregnancy is associated with an increased risk of spontaneous abortion.[150]

Gamma-aminobutyric acid (GABA) is the primary inhibitory neurotransmitter in the brain. Benzodiazepines bind to the GABA type A receptor, increasing its affinity for GABA. Relaxation, fatigue, lethargy, and sedation are short-term effects. Tolerance and dependence result from long-term use of benzodiazepines and withdrawal may occur.[151] There are multiple oral benzodiazepines available in the United States with varying pharmacokinetic properties.

Benzodiazepines readily cross the placenta. A 2019 meta-analysis found that prenatal benzodiazepine use alone is not associated with an increased risk of congenital anomalies, but used concurrently with antidepressants, there was an increased risk of congenital malformations (OR 1.4; 95% CI, 1.09 to 1.8).[152] Signs of benzodiazepine withdrawal overlap with those of neonatal opioid withdrawal and benzodiazepine co-exposure increases the severity of NAS.[153]

Gabapentin

Gabapentin is indicated for management of postherpetic neuralgia in adults and for treatment of partial onset seizures in children and adults. It is widely prescribed off-label for multiple indications, including neuropathic pain, bipolar illness, hyperemesis gravidarum, and restless leg syndrome.[154] Co-prescription of gabapentin with opioids is common and it is used to potentiate the effects of opioids and other CNS depressants. [155,156] Umbilical cord tissue sent for drug screening has shown a positivity rate of 2% for gabapentin, with 70% of the gabapentin-positive specimens testing positive for at least one other drug.[157]

Gabapentin is structurally related to GABA but does not appear to act via the GABA receptor. It is a CNS depressant that binds to voltage-gated calcium channels, inhibiting release of neurotransmitters. It recently has been found to modify the action of NMDA-sensitive glutamate receptors as well as other proteins that mediate its effects.[158]

In a prospective cohort, gabapentin was not associated with increased rates of fetal malformations, but exposed neonates had a higher rate of preterm delivery, low birth weight, and NICU admission.[159] Neonates born after co-exposure to opioids and gabapentin appear to have more severe NAS. A recent case series of 19 co-exposed neonates described a specific pattern of withdrawal including tongue thrusting, back arching, wandering eye movements, and continuous movements of the extremities. Treatment with gabapentin and subsequent tapering improved signs of withdrawal.[160]

Stimulant Therapy for Attention Deficit Hyperactivity Disorder (ADHD)

The use of stimulant medications for the treatment of ADHD (such as methylphenidate and amphetamines) in pregnant persons (both adolescent and into adulthood) is uncommon but has increased in the past two decades.[161,162]

Although most data do not suggest a serious risk, associations have been noted between early pregnancy ADHD medication use (unspecified medications) and gastroschisis, omphalocele, transverse limb deficiency, and cardiac malformations (specifically associated with methylphenidate).[161,163,164] No substantive data are published that describe abnormal neonatal or childhood neurodevelopment secondary to intrauterine exposure to ADHD medications.[163]

Screening Pregnant Persons for Substance Use Disorder

Maternal and neonatal outcomes of any pregnancy depend on multiple factors including parental health, socioeconomic factors, family infrastructure, community support, genetic and metabolic factors, treatment medications, infant feeding type, parental education, and the degree of parental involvement in infant care. Early identification of potential negative exposures and appropriate management in the prenatal period can improve the outcomes for the dyad. Thus, early identification and treatment of maternal OUD and associated comorbidities with an empathic and comprehensive approach are imperative.[165] However, stigma and legal concerns make pregnant women less likely to initiate prenatal care and/or to access treatment for their SUD.[166–168]

The American College of Obstetricians and Gynecologists (ACOG) recommends early universal screening for substance use during all pregnancies, preferably at the first prenatal visit.[83] Nonuniversal screening based on previous pregnancy outcomes, adherence to care, socioeconomic status, and race or ethnicity is unreliable and creates further mistrust between the caregiver and the patient.[169] A number of screening tools have been developed including 4Ps, NIDA Drug Use Screening Tool: NIDA-Modified Assist, and CRAFFT—Substance Abuse Screen for Adolescents and Young Adults.[170–172] The 4Ps questionnaire focuses on Parents, Partner, Past, and Present as related to problems with alcohol and/or drugs (including prescription drugs). If there is a positive response to any of these tools, further relevant inquiries, toxicology testing, and referral for treatment are needed. Therefore a history of drug and alcohol use should be routinely included in the initial contact with every pregnant patient. The person taking the history should be prepared to offer preliminary counseling on risk reduction and referrals for treatment programs, as available and feasible in the given geographic locations.

Although screening works well for persons who seek prenatal care, it is not as useful for pregnant persons who do not seek prenatal care. For these patients, it is more helpful to identify risk indicators for perinatal substance abuse at the time of delivery. Use of one of the screening questionnaires (in addition to urine toxicology testing) increases the likelihood of identifying at-risk pregnancies and neonates, allowing for earlier referral for treatment or specialized interventions.[83] While urine toxicology testing with the patient's consent may assist in pregnancy management, caution must be exercised due to occurrence of false positive and false negative results.

Pregnancy Management

Establishing comprehensive and consistent preconception, antenatal, postnatal care, and counselling programs for families affected by SUD is paramount (Fig. 11.3). Making the dyad an active participant in their care enables them to achieve optimal health status and positive outcomes.[165,173] Screening procedures and counseling should always include the following topics:

Preconception

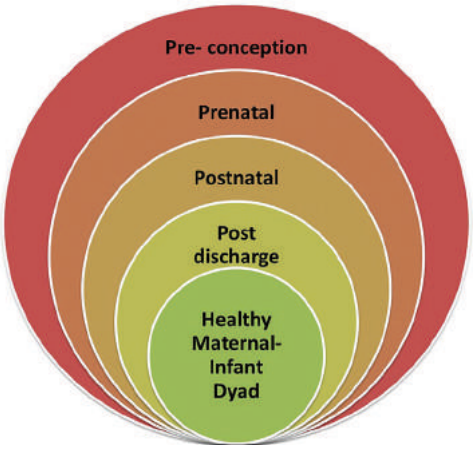
- Many pregnancies in persons with SUD are unintended (though not undesired) and discussions with healthcare providers may proactively assist with reproductive plans to achieve healthy pregnancy outcomes.[174,175] These discussions should be incorporated into all routine healthcare visits.

Antepartum

- Attention should focus on routine pregnancy counseling per ACOG guidelines, including smoking cessation (tobacco, cannabinoids) as indicated.
- Initial screening for hepatitis, HIV, syphilis, tuberculosis (if not part of routine prenatal care), and ongoing screening for other sexually transmitted infections
- Referral to drug dependency/addiction treatment programs, if appropriate
- Mental health counseling, if warranted
- Discussion of possible drug effects on the fetus and neonate, potential for the development of NAS/neonatal opioid withdrawal syndrome (NOWS)
- A multidisciplinary prenatal consulting team including obstetrics, psychiatry, addiction medicine, neonatology/pediatrics, pain services/anesthesiology, and social work to prepare families for potential outcomes
- Discussion of breastfeeding related to alcohol and drug use
- Establishing connections with community resources (e.g., early intervention) to help provide peer and family support which is crucial to successful transitioning home

Intrapartum

- Effects of recent drug use on labor and fetal well-being
- Pain management



• **Fig. 11.3** Comprehensive prenatal and postnatal care for the dyad. Paradigm for developing comprehensive clinical practice guidelines for holistic care provision to pregnant people with the goal of achieving a healthy maternal-infant dyad. (Rachana Singh, MD, personal communication, 2021.)

- Intrapartum prophylaxis for HIV and herpes simplex virus infections
- Need for social services involvement

Postpartum

- Breastfeeding (related to both drug use and infection)
- Contraception and pregnancy prevention
- Support for initiation or continuation in a drug treatment program
- Screening, counseling, and referral for postpartum depression, exacerbation of mental health disorders, OUD relapse, and/or overdose
- Notification of Child and Family Services
- Referral to community support resources (e.g., early intervention) and peer support programs

Human Immunodeficiency Virus and Other Viral Infections

Nationwide, intravenous drug users are a high-risk group for HIV and hepatitis C virus (HCV) infections. In the United States from 2015 to 2019, HIV diagnoses were stable among people who inject drugs (PWID) overall. In 2018, PWID accounted for 7% (2508) of the 36,801 new HIV diagnoses. Men who inject drugs accounted for 4% of the new HIV diagnoses, while women who inject drugs accounted for 3% of new HIV diagnoses.[176] The rate of vertical transmission has decreased significantly due to implementation of antenatal HIV testing and treatment during pregnancy, labor, and in the neonatal period.[177] However, most vertical transmission occurs during the intrapartum period and there is a risk of transmission through breastfeeding.[178] The AAP Committee on Infectious Diseases recommends rapid HIV testing of any mother whose HIV status is not known, with appropriate consent as required by local law.[178] Many states have now adopted a policy promoting testing with an "opt out" approach, rather than requiring consent for testing.[179]

HCV infection is also spread by exposure to infected blood and can be acquired in the perinatal period. The most common route for HCV infection is vertical transmission. The 2018 AAP Red Book indicates that seroprevalence of HCV during pregnancy has been estimated at 1% to 2% and the risk of perinatal transmission 5% to 6% from pregnant persons who are HCV-RNA positive at the time of delivery.[180] Maternal co-infection with HIV has been associated with increased risk of perinatal transmission of HCV. Although antibodies to HCV and HCV RNA have been detected in colostrum, the risk of HCV transmission is similar in breastfed and formula fed infants. Breastfeeding is currently allowed, with specific education needed about breast/nipple health.

Medication-Assisted Treatment for Opioid Use Disorder During Pregnancy

OUD is defined as a pattern of opioid use involving tolerance, cravings, inability to control use, and ongoing use despite negative consequences. Opioid agonists prevent signs of withdrawal and reduce the risk of relapse and obstetrical complications (e.g., preterm delivery). Improved perinatal outcomes are believed to be the result of a stable intrauterine environment uncomplicated by periods of intoxication and withdrawal, as well as less stress and better nutrition during pregnancy.

Population-based data from Massachusetts (2003–2007) demonstrated that one third of pregnant persons with OUD did not receive treatment prior to delivery.[181] Methadone and buprenorphine are the mainstays of treatment for OUD during pregnancy.[83] Substantial differences between the two in key maternal and neonatal outcomes have not been established in randomized controlled trials.[182] Small studies have suggested that treatment with buprenorphine may be associated with better fetal activity and heart rate variability than methadone.[8] An observational study that evaluated singleton neonates born at term and diagnosed with NAS after delivery found that prenatal exposure to buprenorphine was associated with a shorter length of hospital stay than methadone (21 vs. 24 days).[183] An analysis of Massachusetts Medicaid data (adjusted for confounding) found a similar decreased length of stay for neonates prenatally exposed to buprenorphine compared to methadone, as well as reductions in preterm birth and low birth weight.[184]

Methadone

Methadone is a long-acting mu-opioid agonist. Benefits of maternal methadone maintenance include the prevention of opioid withdrawal in the mother, improved health and growth of the fetus, and decreases in the use of illicit drugs and the potential for perinatal infections. For the greatest benefits, methadone maintenance treatment should be part of a comprehensive approach including addiction treatment specialists, counseling, nutritional education, and other medical and psychosocial support services.[83]

The current recommendation for methadone initiation in pregnancy is to titrate the methadone dose until the person is asymptomatic and adjust as needed to avoid signs of withdrawal.[83] Alterations in methadone dosing may be required during pregnancy (especially in the third trimester) because of physiologic and pharmacokinetic changes. Rapid metabolism may require split dosing (rather than once daily) in some pregnant persons to control withdrawal.[83,185] Disadvantages of methadone include drug-drug interactions and potential QTc prolongation. Several investigators have found that the incidence and severity of NAS, birthweight, length of pregnancy, and the duration of NAS treatment do not correlate with maternal methadone dosage.[186]

Buprenorphine

Buprenorphine is a partial μ-agonist and κ-antagonist with approximately 50% oral bioavailability due to extensive first-pass metabolism.[187] Its advantages over methadone include fewer drug-drug interactions, fewer dose adjustments during pregnancy, and options for outpatient treatment without daily visits. Disadvantages include the lack of long-term data on infant outcomes, potential risk of precipitated withdrawal with induction, and increased diversion. Buprenorphine treatment can be considered for patients who can administer the drug safely without the structure and multidisciplinary support of a daily methadone treatment program.[83]

The Maternal Opioid Treatment: Human Experimental Research (MOTHER) trial was a randomized, controlled trial comparing buprenorphine with methadone for treatment of OUD during pregnancy. There were more dropouts in the buprenorphine arm compared to methadone (33% vs. 18%), potentially related to dissatisfaction with treatment effects. The investigators found that although the neonates exposed to buprenorphine and methadone were treated for NAS at the same rate, neonates exposed to

buprenorphine received significantly lower total amounts of morphine and had a shorter hospital length of stay.[188] Follow-up of children born in the MOTHER trial showed comparable growth, development, and behavior at 3 years of age.[98]

Buprenorphine Plus Naloxone

Buprenorphine can be prescribed as monotherapy or in a combination product containing naloxone. There are insufficient data to recommend this combination in pregnancy, although small observational studies have not raised significant safety concerns.

Medically Supervised Withdrawal

The standard of care for pregnant persons with OUD is opioid agonist pharmacotherapy. Detoxification during pregnancy is associated with higher relapse rates and poorer outcomes.[189] Historically there have been concerns about fetal deaths, but a recent retrospective analysis of 301 pregnant persons described several scenarios of detoxification and recorded no fetal deaths in the second or third trimester. There were four fetal deaths among the 28 persons detoxified during the first trimester.[190] Significant concerns remain about the safety of this practice and its potential impact on fetal brain development.

Neonatal Management After Gestational Substance Exposure

Introduction

It is important for practitioners to understand the difference between a substance-exposed neonate and one with NAS. (Note: For the purposes of this chapter, NAS is considered a general description of withdrawal from prenatal exposure to opioids, other substances, or opioids plus other substances that produces a broad range of signs of withdrawal in the neonate. An alternative designation, NOWS can be considered a subset of NAS when the withdrawal is believed to result primarily from prenatal opioid exposure.)

Identification of substance-exposed neonates usually occurs by:

- A documented history of maternal substance use during pregnancy or
- Laboratory confirmation of maternal use of selected controlled substances within the 30 days preceding delivery or
- Positive toxicology screen (urine, meconium, umbilical cord, hair) in the neonate

Identification of infants with NAS occurs by:

- Confirmed neonatal substance exposure,
- A Finnegan/modified Finnegan score ≥8, and/or
- A diagnosis of NAS entered in the infant's medical record by a medical practitioner

The lack of a standardized definition of NAS, both for clinical and research purposes, has been an ongoing issue as the number of infants with NAS continues to increase.[191,192] To address this, 20 clinical experts caring for substance-exposed mother-infant dyads explored including some key evidence-based clinical elements defining opioid withdrawal in the neonate and leading to a diagnosis of NAS. This panel concluded the following were required for diagnosis: (1) in utero exposure (by history or toxicology) to opioids with or without the presence of other psychotropic substances, and (2) the presence of at least two of the most common clinical signs characteristic of withdrawal (excessive/continuous crying, fragmented sleep, tremors, increased muscle tone, and gastrointestinal dysfunction).[193]

A better understanding of maternal and neonatal risk factors is essential to optimize management (Table 11.2). Neonatal toxicology testing with a comprehensive panel including fentanyl and gabapentin should be considered. Testing neonates for in utero drug exposures is complicated by variations in neonatal liver metabolic activity, screening methodologies, and immunoassay cutoffs.[194] For urine testing, there is a poor correlation between maternal and neonatal testing and the earliest urination may be missed. While some drugs such as cocaine may be present for 4 to 5 days, cannabis may persist for weeks. The utility of neonatal urine drug testing is limited because most substances are detectable only with recent use, and alcohol is nearly impossible to detect. Meconium drug testing (at term) reflects substance exposure during the second half of gestation, has a high sensitivity for opioids and cocaine, and can detect more drugs than urine testing. Other neonatal drug tests include hair (high sensitivity for cocaine, amphetamines, opioids) and umbilical cord segments. These tests are becoming more widely available and detect earlier exposure, with results similar to meconium testing.[195] However, both meconium and umbilical cord testing can be negative for exposures in a significant percentage of neonates with a diagnosis of NAS.[196] If indicated by neonatal or maternal risk indicators, toxicology testing should be performed on neonatal urine, meconium, and/or umbilical cord segments as soon as possible after birth.

Although at higher risk for medical complications, most substance-exposed neonates do not require intensive care. However, caring for infants with moderate to severe NAS does require additional resources and adds to healthcare costs. A detailed physical examination on admission should include a gestational age assessment, anthropometrics, and evidence of any congenital malformations and/or dysmorphisms. Neonates whose mothers had limited prenatal care require screening for HIV, hepatitis B, HCV, and syphilis. In some states, rapid testing of the neonate for HIV is required by law if the mother refuses to be tested so that appropriate neonatal treatment can be started before 12 hours of age.

TABLE 11.2 Risk Indicators for Gestational Substance Exposure

Maternal	Neonatal
No or late prenatal care	Jittery, with normal serum electrolyte levels
Precipitous labor	Marked irritability with excessive crying
Placental abruption	NEC in otherwise healthy term/near-term infant
Repeated spontaneous abortions	Neurobehavioral abnormalities
Hypertensive episodes	Significant hypotonia or hypertonia
Severe mood swings	Unexplained IUGR
Previous unexplained fetal demise	Unexplained poor suck and feeding
Myocardial infarction or stroke	Unexplained seizures or apneic spells
	Clinical signs of narcotic withdrawal

IUGR, Intrauterine growth restriction; *NEC*, necrotizing enterocolitis.

Breastfeeding and Drug Exposure

Multiple organizations support breastfeeding to provide optimal neonatal nutrition and to promote bonding and attachment.[83,197,198] Breastfeeding is generally supported for women with SUD, especially those who have had a confirmed period of abstinence (from street drugs) prior to delivery. Similarly, women who are dependent upon opioids for chronic pain or other conditions are encouraged to breastfeed if they are medically able. Concentrations of methadone and buprenorphine in human milk are low and there is increasing evidence supporting a reduction in the severity and duration of NAS when mothers breastfeed.[199]

For women with SUD, the choice to breastfeed is often challenging. In addition, most healthcare professionals have not been adequately educated and are equally challenged in making recommendations, especially when addressing racial disparities that may be seen in this population.[200] Wachman et al. reported that only 24% of 276 opioid-exposed neonates had any breast milk during their hospital stay with 60% stopping after an average of 6 days.[201] There are many issues to consider including lactation and pharmacology issues, coexisting risk factors or conditions, polydrug use/abuse, and infection. In neonates, numerous factors may affect drug clearance, accumulation, and/or toxicity. The most current/comprehensive information regarding drug transfer into human milk, bioavailability, and potential toxicity are available at NIH's Drugs and Lactation Database (LactMed).[202] For many drugs, this information is limited to data from animal studies or anecdotal case reports. For neonates whose mothers engage in ongoing use of illicit drugs, the risks of breastfeeding often outweigh any potential benefits. In addition, use of illicit drugs is associated with a higher risk for drug overdose, so breastfeeding is not currently recommended in women with active illicit drug use at the time of delivery.[203]

Alcohol levels in human milk generally parallel maternal blood alcohol levels. Heavy alcohol use during lactation has been associated with decreased milk production via interference with the milk ejection reflex. Studies evaluating the effects of maternal alcohol consumption during breastfeeding on the infant have yielded mixed results, including mild effects on infant sleep. Women are generally advised to wait 90 to 120 minutes after consuming alcohol before breastfeeding.[197] Maternal smoking is not an absolute contraindication to breastfeeding, although there are measurable levels of nicotine and cotinine in breast milk. However, lactating women are encouraged to stop smoking (if they can) as exposure to nicotine increases the severity and duration of NAS for infants with in utero opioid exposure.[204] Finally, cannabis may remain in breast milk for up to 6 weeks after use and can reach up to eight times the maternal serum level. [73,74] Most medical organizations highlight the importance of eliciting a history of cannabis use during prenatal care visits and recommend counseling the mother to avoid the drug during pregnancy and breastfeeding.

Neonatal Abstinence Syndrome

The incidence of neonatal opioid withdrawal has been steadily increasing in the United States. From 2000 to 2014, there was a sevenfold increase in the number of neonates with documented NAS which accounted for $2.5 billion in medical costs.[205] Exposed infants may be hospitalized for 5 to 7 days to monitor for signs of NAS, incurring significant hospital charges.[206] The signs of NAS usually manifest within 72 hours of birth, with severity that can vary significantly depending on drug(s) exposure. A number of maternal, neonatal, and environmental factors are known to contribute to this variable expression.

Clinical Findings and Biomarkers

NAS results from fetal exposure to licit (prescription) and/or illicit opioids. Neonates exposed in utero to opioids develop physical tolerance and dependence through placental transfer of the drug. The abrupt cessation of the drug transfer at the time of birth causes a drug withdrawal syndrome characterized by dysregulation of both the autonomic and central nervous systems. Clinical signs are summarized in Table 11.3. If untreated, these signs can progress to seizures and become life-threatening.[207] These signs are most often related to gestational opioid exposure but are relatively non specific, with the differential diagnosis including infection, meningitis, hypoglycemia, hypocalcemia, hyponatremia, intracranial hemorrhage, seizures, and stroke.[111]

The incidence and severity can be influenced by other psychotropic agents such as antidepressants (SSRIs), anxiolytics (benzodiazepines), atypical agents such as gabapentin, nicotine, and other substances.[111,153,157,160] With almost 30% to 40% of women with OUD also taking a variety of other psychotropic substances, the signs of opioid withdrawal may overlap with "atypical withdrawal" from gabapentin, SSRIs, amphetamines, nicotine, and cannabis.[208] These agents have different mechanisms of action, pharmacokinetics, pharmacodynamics, receptor activation, and neurotransmitter production with drug-drug interactions potentially impacting the severity of NAS.

The timing of withdrawal from specific drug exposures can often be anticipated. While heroin withdrawal usually occurs within 24 hours of birth, methadone has a longer half-life and withdrawal typically begins approximately 48 to 72 hours after birth. The incidence of NAS in neonates born to pregnant persons using opioids is steadily increasing, with 30% to 60%

TABLE 11.3 Clinical Signs of Neonatal Abstinence Syndrome

Central nervous system dysfunction	Excoriation (from frantic movement) Hyperactive reflexes Increased muscle tone Irritability, excessive crying, high-pitched cry Jitteriness, tremulousness Myoclonic jerks Seizures Sleep disturbance
Autonomic dysfunction	Excessive sweating Frequent yawning Hyperthermia
Respiratory problems	Nasal stuffiness, sneezing Tachypnea
Gastrointestinal and feeding disturbances	Inadequate oral intake Diarrhea (loose, watery, frequent stools) Excessive sucking Hyperphagia Regurgitation

Adapted from Patrick SW, Barfield WD, Poindexter BB. Neonatal opioid withdrawal syndrome. *Pediatrics*. 2020;146(5). e2020029074.

receiving pharmacologic treatment and inpatient stays averaging 2 to 3 weeks.[192] Although preterm birth is a known complication of maternal SUD, severe NAS is unusual in preterm neonates (potentially due to shorter exposure to opioids and fewer opioid receptors in the brain). Some signs of NAS (e.g., feeding problems, tachypnea) overlap with typical findings in preterm neonates. Allocco et al. reported that preterm neonates were less likely to be scored for signs of neurologic and/or autonomic dysfunction compared to term neonates.[209]

An important aspect of monitoring for NAS is the method of assessment and the scores assigned. Many tools have been developed to determine the severity of NAS and need for treatment (Table 11.4).[210] The Finnegan Neonatal Abstinence Scoring Tool (FNAST) has been the most widely used since its development over 40 years ago. When first developed, the FNAST was a research tool which provided some degree of uniformity in monitoring NAS severity. Even though training programs were introduced to increase inter rater reliability, the FNAST remains subjective and somewhat nonspecific.[211] This includes elevated scores for non-opioid drug exposure (e.g., nicotine, benzodiazepines) seen in almost 30% to 40% of affected pregnancies. Several modified versions of the FNAST have been reported, reducing items for scoring from 21 to 8 to 10 items, with revised thresholds for treatment. For example, Devlin et al. studied 424 term opioid-exposed neonates and found that 8 items of the FNAST (sleeps ≤3 hours after feeds, any tremors, increased muscle tone, temperature ≥37.2°C, respiratory rate >60, excessive suck, poor feeding, regurgitation) were independently associated with pharmacologic treatment.[212] External validation was conducted with thresholds of four on the simplified scale correlating with FNAST thresholds of eight. These data suggest that eight signs of NAS may be sufficient to assess whether a neonate meets criteria for pharmacologic therapy.

The Lipsitz score was also developed and is simpler to use, with a score greater than 4 indicating significant signs of withdrawal.[213] The emergence of a new approach to NAS monitoring and treatment—Eat, Sleep and Console (ESC)—has gained increasing popularity. This tool consists of 3 items including eating at least 1 ounce/feed or breastfeeding well, sleeping undisturbed for ≥1 hour, and being able to be consoled when irritable within 10 minutes.[214] When comparing results and determining protocols, it is notable that a single validated objective tool is still not universally accepted or utilized. In an effort to provide more objective assessments for NAS, new physiologic and neurobehavioral indictors of NAS severity are being examined. These include measurement of skin conductance reflecting autonomic regulation through sympathetic-mediated filling of sweat glands, changes in pupillary diameter, alterations in sleep patterns, and a computer-based cry analysis system.[215–218]

Another novel concept being studied focuses on serial measurements of biochemical markers of stress, inflammation, and oxidation in neonates with NAS. Rodrigues and colleagues measured salivary cortisol levels and reported: (1) significantly higher cortisol levels in neonates who required treatment within the first week of life, (2) significant decreases 72 hours after birth

*Only 8 infants were opioid exposed.

for neonates not requiring pharmacotherapy, and (3) no circadian rhythm demonstrated for either group.[219] Animal studies have demonstrated that opioid exposure may be associated with increased oxidative stress and disruptions to glutamate and glutathione homeostasis that could be measured at the time of birth and modified by antioxidants such as *N*-acetylcysteine (NAC).[220] These studies and many more support the need for better biomarkers that are more definitively associated with the severity of NAS and correlate with short- and long-term neurodevelopmental outcomes.[221] The role of additional testing such as EEG and MRI is still being explored. Neuroimaging data from in utero opioid-exposed neonates demonstrate structural as well as functional brain alterations that may persist into adolescence and young adulthood.[93,222,223]

Finally, genetic differences and epigenetic changes in opioid-exposed neonates may place them at higher risk of developing severe NAS. Studies in neonates with antenatal opioid exposure have found an association (in both mothers and their neonates) of specific single nucleotide polymorphisms (SNPs) in the OPRM1, COMT, and PNOC genes with a shorter length of hospital stay and less need for treatment.[224] Increased DNA methylation of opioid receptor gene OPRM1 may be associated with increased NAS severity.[225] In the future it may be possible to link comprehensive clinical and demographic data to genetic and epigenetic information to allow for more targeted management of neonates at risk for NAS.

Management

The goal of NAS management is to maintain physiologic stability and avoid complications such as failure to thrive, inability to sleep, poor feeding, and/or seizures. Strategies to begin treatment, escalate treatment, and to wean treatment once started should be influenced by the neonate's age, comorbidities, other conditions leading to abnormal behavior, and constant evaluation of the clinical elements observed in the relevant scoring system.[226] Standard medical practice is to combine both developmental and behavioral methods with pharmacologic interventions as necessary to control signs of opioid withdrawal. Recent work has confirmed that use of a standard protocol for management of NAS decreases length of hospital stay and use of multidrug therapy.[165,227]

Nonpharmocologic Treatment

Although treatment for opioid withdrawal should always begin with nonpharmacologic measures, pharmacologic management should be adopted when medically necessary.[228] In 2016 and again in 2020, the American Academy of Pediatrics Committee on Fetus and Newborn released a clinical guideline for the care of neonates with NAS. Nonpharmacologic bundles included swaddling, rocking, cuddling, frequent feedings, and skin-to-skin contact as the first line of treatment.[111,165,226,228] Work done by several perinatal quality collaboratives provides additional evidence supporting the use of these nonpharmacologic bundles in minimizing the need for pharmacologic treatment and reducing the length of hospital stay.[227,229] Nonpharmacologic care, especially swaddling and cuddling, requires prolonged involvement of parents or other personnel to soothe the infant. However, not all parents can "room in" and provide this care (especially 24 hours/day). In these situations, trained volunteers can be very helpful. Location of care is equally important and care should ideally be provided to these infants in a non-NICU environment, especially when parental rooming-in is feasible.[165,207] Rooming-in also allows mothers to directly care for their neonate, initiate breast feeding, enhance their parenting skills in a safe environment (facilitating parental retention of custody), and judiciously utilize hospital resources.[165]

Pharmacologic Treatment

Many neonates exhibiting signs of NAS will receive pharmacologic treatment.[230] The mainstay of pharmacologic treatment for opioid withdrawal is opioid replacement, either alone or in combination with other medications.[111,226] Each of the opioid replacement therapies and adjunctive therapies has unique pharmacokinetic properties in neonates, which may vary significantly from that of older children and adults and may vary significantly between individuals.[231] Medication is titrated for each neonate according to the severity of the signs of withdrawal as assessed by various scoring systems. Various threshold scores have been reported for initiating pharmacologic treatment, with common approaches of FNAST scores 8 to 12, or a positive score on 1 component of the ESC scoring tool.[207] NIH-supported trials comparing short- and longer-term outcomes in opioid-exposed neonates managed by the ESC versus the more traditional FNAST approach are ongoing.

Morphine and methadone are the most common initial drugs of choice for NAS, with phenobarbital or clonidine as second-line therapies if clinical signs continue to worsen despite opioid replacement.[226] A small, randomized, controlled trial comparing morphine to phenobarbital for primary treatment of NAS suggested that opioids are superior at decreasing treatment duration and lowering NAS scores.[232] A typical starting dose of morphine is 0.03 to 0.05 mg/kg given orally every 3 to 4 hours. This dose can be increased in increments of 0.03 to 0.1 mg until the signs are controlled.[111] Methadone is increasingly being used as a first-line agent for treatment of NAS. Methadone has a long duration of action and can be administered by either the oral or parenteral route.[231] The initial recommended methadone dose is 0.05 to 0.1 mg/kg followed by 0.025 to 0.05 mg/kg every 8 to 12 hours until signs are controlled. In a recent randomized clinical trial, methadone as compared to morphine was associated with decreased length of stay by 14% and length of treatment by 16%.[233] Study participants' neurobehavioral and developmental outcomes at 18 months were similar in the morphine and methadone arms.[234]

Sublingual buprenorphine also appears safe and effective for short-term outcomes when used to treat NAS. It has a low intrinsic activity which results in less physiological effects than seen with other complete μ-agonists.[235] Because there is no appropriate marketed formulation for neonates, an extemporaneous formulation containing 30% ethanol was developed to conduct clinical trials.[236] In neonates with NAS, pharmacokinetic data are available to inform model-based dosing strategies.[237] Kraft and colleagues conducted a single-site randomized, double-blind, double-dummy controlled trial and demonstrated that in neonates with significant NAS, buprenorphine was associated with a shortened treatment duration compared with morphine as first-line therapy.[238].

Phenobarbital is a commonly used second-line therapy, especially when maternal multidrug use is suspected.[231] However, phenobarbital does not reduce most physiologic signs of opioid withdrawal such as diarrhea and seizures. Czynski and colleagues demonstrated that the use of phenobarbital was associated with a variety of neurobehavioral problems when infants with NAS were assessed at 18 months of age.[234] It is unclear if this was due to an effect of phenobarbital (and the specific formulation) or related to more severe NAS that required second-line pharmacologic treatment. The doses of phenobarbital that have been used are 5 to 20 mg/kg in the first 24 hours, followed by 2 to 4 mg/kg every

12 hours; however, the optimal dosing and therapeutic blood level of phenobarbital for treatment of NAS are not known. A National Institutes of Health (NIH)-funded cohort study that compared phenobarbital versus clonidine as a second-line therapy found that the phenobarbital-treated infants had fewer morphine treatment days and shorter length of stay. However, many infants were discharged home on phenobarbital therapy, which may result in a longer total pharmacologic treatment time, and raises questions about long-term neurodevelopment and safety.[239]

Clonidine is an α_2-adrenergic receptor antagonist used in treating opioid withdrawal in older children and adults. In 2009, a randomized, controlled trial showed that adding clonidine to an opioid for the treatment of NAS significantly reduced the number of treatment failures, the median length of opioid therapy, and the number of neonates requiring high-dose opioids.[240] There were reportedly no significant cardiovascular or other adverse events related to clonidine use.[239,240] In 2015, another randomized, controlled pilot study compared clonidine to morphine as a first-line, single-drug therapy for NAS and found that patients receiving morphine required significantly longer duration of treatment. In addition, measurement of NNNS at 1 week and 2 to 4 weeks of age improved significantly with clonidine, but not with morphine. One-year follow-up did not show significant differences in motor, cognitive, or language scores between treatment groups.[241]

Once the drug(s) have been titrated to control the manifestations of NAS, tapering of the dose should begin 12 to 24 hours later. A common method is to decrease the opioid dose by 10%–20% of the highest dose, with continued assessments to ensure the neonate tolerates the decrease. Signs of opioid withdrawal may increase during the medication tapering, but the goal of weaning is to allow the neonate to acclimate to a lower dose of medication while ensuring that they are able to maintain physiologic stability. Whether opioid replacement can safely be weaned more rapidly in neonates is currently under investigation. Clonidine must be carefully weaned in the hospital because of the risk of rebound autonomic activity with possible hypertension and tachycardia; recent studies have proposed stepwise clonidine weans.[241]

Challenges With Polysubstance Exposure and Nonopioid Withdrawal

About 30% to 40% of pregnant women with OUD are taking more than one psychotropic drug which may increase NAS severity.[242,243] Intrauterine polysubstance exposure could be due to prescribed medications as well as illicit drugs. Psychiatric comorbidities are common in pregnant persons with OUD, and awareness of fetal exposures can help identify infants at risk for complex withdrawal syndromes to allow a tailored management approach. (See Prenatal Medication Exposures That May Be Associated with Neonatal Withdrawa for additional information.)

Postdischarge Infant Follow-Up

Well-designed postdischarge medical and neurodevelopmental follow-up for all neonates with prenatal substance exposures is essential. Since family support is critical for success, postdischarge community support programs should be readily available with referrals in place prior to discharge. If the infant is being discharged home on any medications (phenobarbital), then parents, caregivers, and primary care providers should be given clear, precise written instructions about administration and storage of medications and a proposed weaning schedule. There should be provision for regular postdischarge follow-up visits with the primary care providers to ensure monitoring of medication weaning, following up HIV and HCV testing, and longitudinal growth monitoring. An early intervention (EI) referral should be made prior to discharge and routine neurodevelopmental screenings should be performed at each well child visit as opioid-exposed infants are significantly more likely to have neurodevelopmental impairments in early childhood.[96,243] A significant number of neonates with NAS have long-term neuromotor, cognitive, and/or behavioral morbidities, including insecure and disorganized attachment, impaired speech and language development, aggressive behavior, peer conflicts, hyperactivity, inattention, anxiety, depression, and substance abuse.[244] Even though early identification and intervention has been shown to improve outcome, fewer than half of the eligible infants with NAS enroll in EI services.[245] Efforts to improve EI referral rates during the birth hospitalization, particularly among infants discharged into foster care, and close follow-up for infants with shorter hospital stays are needed to enhance the developmental supports for infants with NAS.

Conclusions

While significant concerns exist with illicit maternal substance use during pregnancy related to observed perinatal outcomes, the number of exposed infants pales in comparison to the established health and developmental risks associated with licit substances such as tobacco and alcohol as well as diversion of prescription drugs. The greatest impact of continued illicit substance use may be the risks of neglect, maltreatment, and disruptions in the home environment. Health policy must be directed at reducing all these complex factors associated with perinatal substance use and providing support for families and children with in utero substance exposure. Most importantly, providing support to the mother-infant dyad following birth (when the risk of relapse is highest) with comprehensive psychosocial services is essential to improving maternal and child health outcomes and reducing the stigma associated with perinatal substance use.

12 Assessment of Fetal Well-Being

CHRISTIAN M. PETTKER AND KATHERINE H. CAMPBELL

KEY POINTS

- Fetal assessment demands a view into the somewhat inaccessible intrauterine environment; the primary tools are ultrasound and fetal heart rate monitoring.
- It is important to make the distinction between intrapartum (during labor) and antepartum (before labor) fetal assessment; the latter is the focus of this chapter.
- Current debate centers on who should undergo sonographic examination and what type of evaluation these patients should have.
- Fetal assessment in the third trimester is centered on prediction and/or detection of fetal hypoxemia and academia.
- Antepartum fetal testing in high-risk pregnancies includes the nonstress test, amniotic fluid volume measurement, biophysical profile, and Doppler velocimetry.
- The primary difficulty with antepartum fetal testing is the as-yet unproven utility to improve outcome.

A primary objective of obstetric care is the assessment and prevention of adverse fetal and neonatal outcomes. Maternal care is an integral step toward this goal. Optimization of the maternal state, through monitoring and treatment of chronic conditions such as diabetes or hypertension or acute states like preeclampsia or preterm labor, is one important facet of care to achieve desirable perinatal outcomes. Monitoring and management of the fetus, although a more obvious step toward this goal, is somewhat less straightforward. Fetal assessment demands a view into the somewhat inaccessible intrauterine environment. The ability to gain access to this space to gauge the needs and health of the fetus improved dramatically with developments in technology and increased understanding of fetal physiology over the past several decades. As a result, perinatal morbidity and mortality decreased considerably over that time (Fig. 12.1).

In general, antepartum fetal assessment utilizes various techniques to assess fetal health and well-being in pregnancies that are at increased risk of fetal death due to preexisting maternal conditions (chronic hypertension) or pregnancy-related complications (fetal growth restriction [FGR]). Selecting appropriate patients at risk for adverse perinatal events can enhance the prediction of these events, although some tests may be appropriate even for a low-risk population. The assessment may allow for certain therapeutic options—often, timely delivery—to prevent fetal harm. The overall goal of these efforts is to reduce perinatal mortality, although the reduction of morbidities such as cerebral palsy or preventable birth injury is intertwined with this objective. In antenatal assessment in the third trimester, the prediction and detection of fetal acidemia and hypoxemia form a central principle underlying these efforts.

It is important to make the distinction between antepartum and intrapartum fetal assessment: the latter is specifically related to monitoring the fetus during labor. The nature of labor affords certain advantages (e.g., dilation allows blood samples from the fetus) and restrictions (the lack of fluid after rupture of membranes creates difficulties for ultrasound examination) that do not occur in the antenatal period. As a result, this chapter focuses only on events and assessments preceding labor.

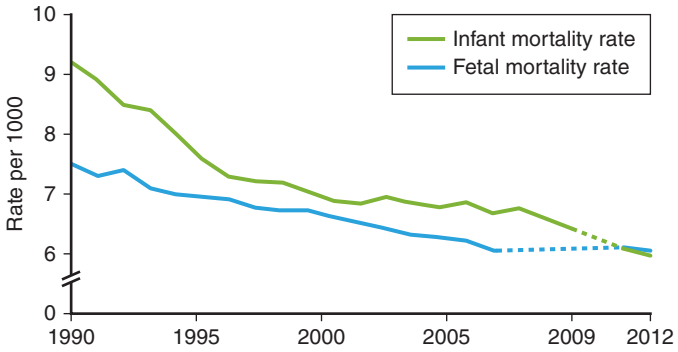
General Principles

Principles of Testing

Many of the tests used for antepartum fetal assessment are screening tests that will lead to further testing allowing for diagnosis and decision making; therefore it is important to note the principles guiding such tests. The outcome, principally perinatal morbidity and mortality, is a significant burden to both the individual and the overall healthcare system. The primary tools for assessment, ultrasound examination and fetal heart rate (FHR) monitoring, are generally easy, safe, and acceptable to patients. Screening has the potential to allow important and timely interventions, such as antenatal steroid administration or delivery. The predominant difficulty with fetal testing comes in the unproven utility of testing to improve outcomes. Furthermore, some tests, such as the nonstress test (NST), have high false-positive rates; therefore when used as a diagnostic test (e.g., to decide on delivery), they can lead to the overuse of interventions. The specificity and sensitivity of the tests vary, and the critical step to enhancing test performance is patient selection. The utility of fetal surveillance involves the judicious application of the tests in patients with specific risk profiles.

Fetal Physiology and Behavior

The first trimester (≤14 weeks' gestation) is mainly a time of system development and organogenesis. The hyperplastic enlargement during the first 11 weeks produces standard rates of growth, with deviation being rare. At the completion of the first trimester, the major organ systems have developed, allowing the opportunity during the second trimester to assess for anomalies in development.



• **Fig. 12.1** Fetal and Infant Mortality Rates in the United States, 1990–2012. Infant mortality rate is the number of infant deaths per 1000 live births. Fetal mortality rate is the number of fetal deaths of 20 weeks' gestation or later per 1000 live births and fetal deaths. (From CDC/NCHS, National Vital Statistics System.)

The second and third trimesters involve the maturation of these systems. Fetal assessment, primarily performed in the third trimester, is concerned with the prediction or detection of fetal hypoxemia and acidemia. Integration of the fetal neurologic and cardiovascular systems as they relate to acid-base status is the cornerstone of this assessment. By the beginning of the third trimester, there is usually adequate maturation present in the neurologic and cardiovascular systems to enable meaningful fetal assessment. We are thus able to monitor the manifestations of hypoxemia and acidemia as shown by neurologic and cardiovascular changes. In pregnancies at extremely high risk for adverse perinatal outcome or stillbirth, a fetal assessment may be performed in the second trimester, as early as 23 to 24 weeks' gestation.

Technology

The technologic underpinning of fetal assessment is ultrasound. FHR monitoring during the antepartum period depends on a Doppler cardiogram; movements of the fetal heart, in particular the sounds of the valves, are detected by this monitor. The time between the beats is translated into a heart rate, which is then graphically represented on a chart over time. This process produces the FHR monitoring strip that becomes the NST or contraction stress test (CST).

Contemporary ultrasound imaging technology involves a wide array of features, including B-mode (basic imaging), M-mode (mapping the movement of structures over time), pulsed Doppler (demonstrating flow velocity in a particular area, such as a vessel), color Doppler (showing intensity and direction of flow through shades of red and blue), and power Doppler (a more sensitive form of colorized Doppler). Magnetic resonance imaging is often used to supplement ultrasound imaging, especially for imaging of the fetal brain.

Indications and Timing

Most fetal testing protocols involve a stepwise approach, and the first step is the selection of the appropriate patient. Suggested assessments for low-risk pregnancies include one ultrasound examination for dating and one for the basic anatomic survey. Prenatal risk assessments for chromosomal disorders, such as cell-free fetal DNA analysis, first-trimester risk assessment with maternal serum analysis and fetal nuchal translucency assessment, or the second-trimester maternal quadruple serum screen, are additional options (see Chapter 26, Prenatal Diagnosis and Counseling, for additional discussion of these tests). Whereas up to 30% of perinatal morbidity may occur in low-risk patients, routine fetal testing beyond that described previously in a low-risk pregnancy is an ineffective use of resources.

High-risk pregnancies are those at greater peril for perinatal morbidity and mortality. These pregnancies often have more justification for targeted or detailed anatomic ultrasound examinations and for regular assessment of fetal growth or FHR. Common conditions requiring increased fetal surveillance are shown in Box 12.1.

Pregnancy dating should be confirmed at the earliest possible moment, and fetal anatomic screening is best accomplished in the second trimester, specifically at 18 to 20 weeks' gestation, when visualization of the anatomic features is adequate. However, standards for the timing of antepartum fetal assessment to survey for fetal compromise do not exist. Certainly, assessment with NST or biophysical profiles (BPP) would have little utility before viability (approximately 23 to 24 weeks' gestation). Guidelines for initiating fetal testing for specific indications are largely based on the risk of fetal loss at a particular gestational age (GA). Most fetal testing algorithms begin antepartum fetal testing no earlier than 32 weeks' gestation. However, the most at-risk pregnancies may be monitored at earlier GAs when delivery would be considered for fetal benefit.

• BOX 12.1 Common Indications for Antepartum Fetal Assessment: High-Risk Pregnancies

Fetal
- Abnormal fetal testing, fetal distress
- Decreased fetal movement
- Fetal growth restriction
- Monochorionic multiple gestation
- Oligohydramnios

Maternal–Fetal
- Placental abruption (abruptio placenta)
- Alloimmunization
- Late term or postterm pregnancy
- Gestational hypertension or preeclampsia
- Gestational diabetes
- History of fetal death

Maternal
- Advanced maternal age (>40 years old)
- Cyanotic cardiac disease (severe)
- Hypertension, chronic
- Morbid obesity
- Pulmonary disease (severe)
- Chronic renal disease
- Systemic lupus erythematosus
- Hyperthyroidism

Fetal Assessment in Low-Risk Pregnancies

Ultrasound: Pregnancy Dating

The *estimated date of delivery* is defined at the beginning of pregnancy based on the best available information, including menstrual history, ultrasound data, and assisted reproduction technology. The median duration of a singleton pregnancy is

280 days (40 weeks) from the first day of the last menstrual period or 266 days (38 weeks) from the time of ovulation. *Term* is defined as 37 to 41 + 6 weeks' (259 to 294 days) gestation. This definition is further broken down into two subgroups: early term (37 weeks 0 days to 38 weeks 6 days) and late term (41 weeks 0 days to 41 weeks 6 days). Preterm is defined as delivery prior to 37 weeks. This definition is further broken down into the late preterm subgroup (34 weeks 0 days to 36 weeks 6 days). Postterm pregnancies are defined as delivery at 42 weeks and beyond (Box 12.2). Given that the preterm and postterm periods are associated with increased risks to the fetus and newborn, pregnancy dating provides an approximate expectation for the completion of the pregnancy and serves as a basis for the efficient and appropriate use of fetal surveillance, testing, and treatment. Accurate pregnancy dating by ultrasound has been associated with reduced diagnoses of growth restriction,[1] reduced use of tocolysis for preterm labor,[2] and a reduced need to intervene in postterm pregnancies.[3,4] Additionally, early ultrasound assessment is associated with an increased diagnosis of multifetal pregnancies.[4]

In a spontaneous pregnancy in a woman with regular cycles and normal menstrual periods, the last menstrual period is often an accurate way of dating a pregnancy. Menstrual dating is less accurate in women who are taking oral contraceptives, were recently pregnant, or have irregular periods or intermenstrual bleeding. In these cases, and others in whom there is uncertainty, ultrasound dating in the first trimester is accurate and effective. A fetal pole may be seen beginning at 6 weeks' gestation, and the fetal heartbeat should be visualized by 6 to 7 weeks' gestation.[5] In the first trimester, measurement of the crown-rump length is accurate to within 5 to 7 days; therefore this measurement should take priority in dating a pregnancy when the timing of the last menstrual period suggests a GA outside this range of variation.[6–9] A first-trimester ultrasound examination is indicated to confirm an intrauterine pregnancy (i.e., exclude ectopic pregnancy), confirm fetal viability, document fetal number, and estimate GA. During this ultrasound, the maternal pelvis and ovaries may be assessed to look for the presence of abnormalities, including uterine fibroids, müllerian anomalies, and ovarian masses, such as a dermoid cyst. In the second trimester, ultrasound dating is less accurate (discrepancy from 7 to more than 14 days) but can nonetheless be helpful. Measurement of the biparietal diameter (BPD) of the fetal head, the most accurate parameter, can be accurate to within 7 to 10 days.[10,11] The BPD is also a parameter of choice because it is less affected by chromosomal anomalies, in particular Down syndrome.[12] Usually in the second or third trimesters, several biometric measurements—such as BPD, head circumference, abdominal circumference (AC), and femur length—are recorded, and a computerized algorithm can generate an estimated GA. Additional fetal measurements, including other fetal long bones (i.e., humerus, ulna, and tibia) and transverse cerebellar diameter may also assist with estimating fetal GA.[13,14]

Ultrasound: Second and Third Trimesters

Perinatal ultrasound examination in the second and third trimesters can be classified broadly into three types: the basic or standard examination, the specialized (detailed) examination, and the limited examination. The standard or basic examination includes the determination of the fetal number, fetal viability, fetal position, fetal biometry, placental location, amniotic fluid volume, the presence or absence of a maternal pelvic mass, and the presence of gross fetal malformations (Box 12.3).[15,16] Most pregnancies can be evaluated adequately by this basic examination. If the patient's history, physical examination, or basic ultrasound examination suggests the presence of a fetal malformation, a specialized or detailed examination should be performed by a sonographer who is skilled in fetal evaluation. During a detailed ultrasound, which is best performed at 18 to 20 weeks' gestation, fetal structures are examined in detail to identify and characterize any fetal malformation. In addition to identifying structural abnormalities, a specialized ultrasound examination can identify sonographic markers of fetal aneuploidy. In some situations, a limited examination may

• BOX 12.2 Definition of Gestational Age Categories

Term Pregnancy	37 + 0 to 41 + 6 weeks
Early	37 + 0 to 38 + 6 weeks
Late	41 + 0 to 41 + 6 weeks
Preterm Pregnancy	<37 weeks
Late	34 + 0 to 36 + 6 weeks

• BOX 12.3 Images and Information Obtained During a Standard Second- and Third-Trimester Ultrasound

Fetal cardiac activity
Fetal number including chorionicity and amnionicity
Fetal position
Fetal biometry
Placental location and umbilical cord insertion
Amniotic fluid volume
Assessment of maternal adnexa, uterus, and cervix
Fetal anatomy
Head, face, neck
- Lateral cerebral ventricles
- Choroid plexus
- Midline falx
- Cavum septi pellucidi
- Cerebellum
- Cistern magna

- Right ventricular outflow tract
- Three-vessel view and 3-vessel trachea view

Abdomen
- Stomach
- Kidneys
- Urinary bladder
- Umbilical cord insertion site into the fetal abdomen
- Umbilical cord vessel number

Spine
- Cervical, thoracic, lumbar, and sacral spine

Extremities
- Legs and arms
- Hands and feet

Sex
- In multiple gestations and when medically indicated

be appropriate to answer a specific clinical question (such as fetal viability, amniotic fluid volume, fetal presentation, placental location, or cervical length) or to provide sonographic guidance for an invasive procedure (such as amniocentesis).

Current debate centers on who should undergo sonographic examination and what type of evaluation these patients should have. Advocates of routine sonography cite several advantages of universal ultrasound evaluation, including more accurate dating of pregnancy and earlier and more accurate diagnosis of multiple gestation, structural malformations, and fetal aneuploidy (discussed later in Ultrasound section). Opponents of routine sonographic examination argue that it is an expensive screening test ($100 to $250 for a standard examination) and that the cost is not justified by published research, which suggests that routine ultrasound examinations do not significantly change perinatal outcome.[2,17,18] However, subsequent cost-benefit analyses regarding the routine use of ultrasound in low-risk pregnancies have concluded both cost savings,[19] if the ultrasound is performed in a tertiary care setting, and net loss, if the ultrasound is performed by less experienced providers. Ultrasound performed in a country with socialized medicine proved cost saving.[20] Thus it may be the more-tempered approach to ultrasound screening with the utilization of highly skilled sonographers and sonologists that allows the routine ultrasound screening of pregnancies to be both effective and economical. Nonmedical use of obstetric ultrasound is not supported by either the American College of Obstetricians and Gynecologists or the American Institute of Ultrasound in Medicine for many reasons, including the potential for false reassurance at the time of the ultrasound, as well as no formal process for follow-up if an abnormality is identified.[21]

Second-trimester ultrasound examination may be indicated for various reasons, including uncertain dating, a uterine size larger or smaller than expected for the estimated GA, vaginal bleeding, suspected multiple gestation, a medical disorder that can affect fetal growth and development (e.g., diabetes, hypertension, collagen vascular disorder), a family history of an inherited genetic abnormality, a suspected fetal malformation or growth disturbance, or suspected fetal death.[15,16] In the United States, most patients undergo a standard examination at 18 to 20 weeks' gestation to screen for structural defects. An understanding of normal fetal physiology is critical to the diagnosis of fetal structural anomalies. For example, extra-abdominal herniation of the midgut into the umbilical cord occurs normally in the fetus at 8 to 12 weeks' gestation and can be misdiagnosed as an abdominal wall defect. The placental location should be documented with the bladder empty because overdistension of the maternal bladder or a lower uterine contraction can give a false impression of placenta previa. If placenta previa is identified at 18 to 22 weeks' gestation, serial ultrasound examinations should be performed to follow placental location. The presence of placenta previa at 15 to 17 weeks has about a 12% risk of being present at term, while presence later in the second trimester (24 to 27 weeks) confers a 49% risk of persistence at term.[22] The umbilical cord should also be imaged, including the number of vessels and its fetal and placental insertion.

The indications for third-trimester ultrasound examination are similar to that for second-trimester ultrasounds. Fetal anatomy survey examinations and estimates of fetal weight become less accurate as GA increases, especially in obese women or in pregnancies complicated by oligohydramnios. However, fetal biometry and an anatomic survey should still be performed, because certain fetal anomalies, such as achondroplasia, may become evident for the first time later in gestation.

Fetal Movement Counting

Fetal movement (quickening) is typically perceived by the mother at 16 to 22 weeks' gestation. Fetal hypoxemia is typically associated with a reduction in fetal activity; the fetus is essentially conserving energy and oxygen for vital activities. A typical procedure for fetal movement counting consists of having the patient record the interval taken to feel 10 fetal movements, usually after a meal when the fetus is more active. If 10 movements are not detected in 1 hour, further testing is often recommended. The data supporting fetal movement counting are mixed. A large UK and Ireland cluster-randomized trial involving more than 400,000 pregnancies demonstrated no benefit,[23] and a Cochrane analysis found insufficient evidence to support this technique to prevent stillbirth.[24] However, a Norwegian study found a significant reduction in the number of stillbirths without a subsequent increase in the number of hospital visits for decreased fetal movement when a standardized approach to patient education regarding the recommended approach to decreased fetal movement[25] was implemented. Fetal movement counting represents a low-technology screening test that can be applied easily to all pregnancies. Although its effectiveness in improving perinatal outcomes is debatable, it can be used as a cost-effective first-line strategy.

Fetal Assessment in High-Risk Pregnancies

Cardiotocography

Cardiotocography is the visual representation of FHR and uterine contractions. FHR has been recognized as an important indicator of fetal status since the 19th century, with Lejumeau Kergaradec of Switzerland being credited with the first accounts of direct fetal auscultation and the uterine souffle in 1821. FHR monitoring is based on the principle that the fetal neurologic system, through its afferent and efferent networks, serves as a key mediator to demonstrate fetal well-being. Oxygenation, acidemia, and other vital functions are monitored by peripheral chemoreceptors and baroreceptors, which provide input on fetal status through afferent neurologic networks to the central nervous system (CNS). This information is processed by the CNS, and signals are conducted through efferent networks to produce peripheral changes, particularly to the heart via direct parasympathetic vagal neurons, direct sympathetic signals, or indirect sympathetic stimulation of catecholamine release. In this way, fetal cardiac activity can be seen as a surrogate for fetal oxygenation and acid-base status.

For many years, assessment of the FHR was limited to the fetoscope, a direct stethoscope attributed to Adolphe Pinard in 1876. In 1957, Orvan Hess and Ed Hon at Yale University (New Haven, CT) introduced electronic FHR monitoring as a window into the status of the fetus.[26] This technology relied on direct monitoring through a scalp electrode; only years later would Doppler technology allow cardiac signals to be detected noninvasively. FHR monitoring became a tool for fetal assessment, as it was recognized that certain FHR patterns were associated with fetal compromise and poor fetal outcomes.

The basic elements of an FHR strip are baseline, variability, accelerations, and decelerations. A baseline of 110 to 160 beats/min is normal. Variability is determined by the irregular fluctuations in amplitude and frequency in the baseline, and variability of fewer than 6 beats/min is often abnormal. Accelerations are classified as visually apparent abrupt increases that peak at

15 beats/min or more above the baseline and last 15 seconds or longer. Fetal movements often coincide with FHR accelerations. Finally, decelerations, often classified as early, variable, or late, are decreases in the FHR that have specific pathologic and physiologic associations. Although primarily focused on intrapartum monitoring, the 2008 National Institute of Child Health and Human Development workshop report on fetal monitoring provides an excellent summary of the nomenclature and interpretation involved (Table 12.1).[27]

Nonstress Test

A normal result of an NST is defined as a 20-minute FHR tracing that contains two heart rate accelerations lasting 15 seconds or longer that peak 15 beats or more above the baseline: often this is called a *reactive NST* (Fig. 12.2). Modifications are made in reference to GA. NSTs for fetuses at less than 32 weeks' gestation are often considered reactive if the acceleration is 10 beats/min or more above the baseline and lasts for at least 10 seconds.[28,29] Furthermore, to account for the periodicity of 20- to 30-minute sleep cycles in the fetus, an NST that is not reactive over the first 20 minutes may be continued for an additional 20 to 40 minutes. A nonreactive NST or an NST with specific abnormalities (e.g., high or low baseline, decelerations) should be followed by a BPP. It is important to note that some abnormal states, such as a fetal CNS abnormality or maternal drug ingestion, may contribute to a nonreactive NST. In these cases, ultrasound examination may provide appropriate information to determine the diagnosis or required management.

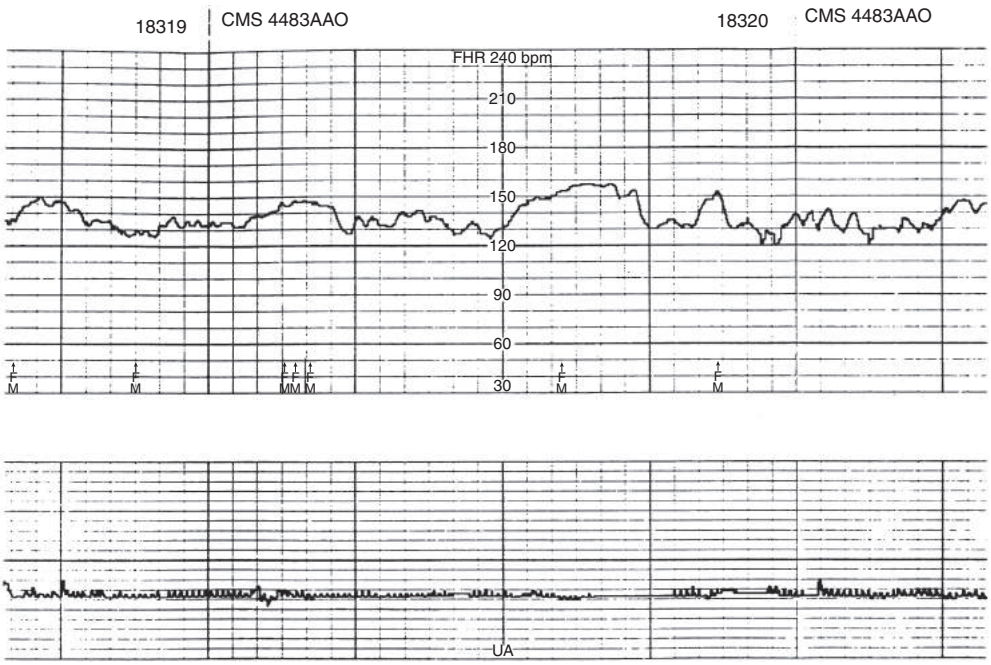
Falsely normal NSTs occur at a rate of 3 to 5 per 1000 tests, although this does not account for a baseline rate of unpreventable fetal deaths.[30] The difficulty with the NST really lies in its lack of specificity for fetal death or compromise; the false-positive rate may be as high as 50%.[30]

The rather modest false-negative rate is likely because of the NST being a measurement of short-term hypoxemia. Indeed, longer-term fetal status can be measured through amniotic fluid assessment, because the amniotic fluid is correlated with fetal urinary output, which is a surrogate for renal perfusion. When combined with an assessment of amniotic fluid level, the false-negative rate of the NST is reduced to 0.8 per 1000, although a 60% false-positive rate remains.[31] Thus when the amniotic fluid level is combined with the NST—sometimes known as the *modified BPP*—the risk of fetal death is reduced to negligible levels in high-risk populations.[32] For these reasons, the modified BPP is a modality of choice for monitoring high-risk pregnancy.

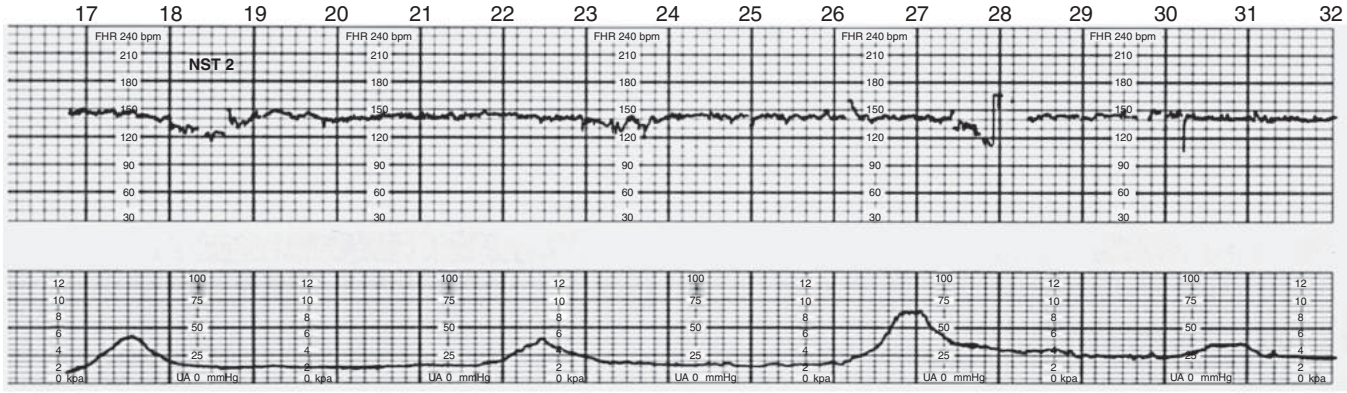
TABLE 12.1 Interpretation of Antepartum Cardiotocography

Term	Characteristic	Description
Baseline	Definition	Mean FHR, rounded to increments of 5 beats/min (e.g., 140, 145); need baseline duration of ≥2 min during a 10-min segment, between periodic or episodic changes, to determine baseline
	Bradycardia	<110 beats/min for >10 min
	Tachycardia	>160 beats/min for >10 min
Variability	Definition	Fluctuations of the baseline heart rate; measured from peak to trough
	Absent	Undetectable
	Minimal	Undetectable to ≤5 beats/min
	Moderate	6–25 beats/min
	Marked	>25 beats/min
Acceleration	Definition	Abrupt increase ≥15 beats/min lasting ≥15 s
	Prolonged	≥2 min and <10 min (≥10 min is a baseline change)
Deceleration	Definition	Decreases in the FHR
	Variable	Abrupt decrease onset to nadir <30 s; decrease ≥15 beats/min lasting ≥5 s to <2 min
	Early	Gradual decrease onset to nadir ≥30 s with contraction
	Late	Gradual decrease onset to nadir ≥30 s; nadir of deceleration occurring after peak of contraction
	Prolonged	Decrease ≥15 beats/min lasting ≥2 min, but <10 min (≥10 min is a baseline change)
	Recurrent	Occur with ≥50% of uterine contractions in any 20-min window
	Intermittent	Occur with <50% of uterine contractions in any 20-min window
Contractions	Considerations	Frequency, duration, intensity, and relaxation
	Normal	≤5 contractions per 10 min averaged over a 30-min window
	Tachysystole	>5 contractions per 10 min averaged over a 30-min window; should always be qualified as to the presence or absence of associated FHR decelerations

FHR, Fetal heart rate.



• **Fig. 12.2** Normal Nonstress Test. Note two fetal heart rate accelerations exceeding 15 beats/min and lasting at least 15 seconds during the monitoring period. *FHR*, Fetal heart rate.



• **Fig. 12.3** Contraction Stress Test. The fetal heart rate is plotted above the uterine contraction signal. Note the late decelerations after the contractions; this is a positive, or abnormal, test result. *FHR*, Fetal heart rate; *NST*, nonstress test.

Contraction Stress Test

The CST assesses the FHR response in the presence of contractions. This test improves on the specificity and sensitivity of the NST by assessing the fetal response to stress. In fact, the CST preceded the NST, although the NST became more favorable because of fewer contraindications, ease of administration, and reduced time and supervision necessary. Compared with the NST, there is a much lower incidence of falsely normal tests (0.4 per 1000), representing an eightfold reduction in the risk of fetal loss in one study.[33]

Contractions are stimulated by the administration of intravenous oxytocin or through maternal nipple stimulation. Of course, the CST is contraindicated in patients in whom contractions should not be provoked, such as threatened preterm delivery or preterm premature rupture of membranes, prior classical cesarean delivery, or placenta previa. A minimum of three contractions over a 10-minute period of continuous FHR assessment are necessary for a satisfactory test interpretation. An unsatisfactory test should be followed by continued testing with a modification of the mode of contraction stimulation. A negative (i.e., normal) test result demonstrates no late decelerations, whereas a positive test result shows late decelerations after 50% or more of contractions (Fig. 12.3). A positive test result requires immediate further testing or evaluation, if not delivery. An equivocal test demonstrates late decelerations with less than 50% of contractions and requires further testing or monitoring. A test that encompasses a hyperstimulatory contraction pattern (e.g., five contractions within 10 minutes or contractions lasting longer than 90 seconds) is also considered equivocal and requires further testing.

Ultrasound

Although routine sonography for low-risk pregnant women is controversial, few would disagree that the benefits far outweigh the costs for high-risk patients. Given the higher risk for fetal complications such as anatomic anomalies or growth disturbances,

a specialized examination is performed between 18 and 20 weeks' gestation in most high-risk pregnancies.

Additional ultrasound modalities are also available, including fetal echocardiography, three-dimensional (3D) sonography, and Doppler. Cardiac anomalies are the most common major congenital defects encountered in the antepartum period. A four-chamber view of the heart at the time of fetal anatomy survey at 18 to 20 weeks' gestation will detect only 50% of congenital cardiac anomalies, although the detection rate can be increased to approximately 65% to 90% if the four-chamber and outflow tract or outlet tract and three vessels with trachea views are adequately visualized,[34] but this still leaves 10% to 35% of all congenital cardiac anomalies undiagnosed. Factors that affect the sensitivity include the type of practice (university-based vs. community-based), operator training and experience, GA at the time of the scan, maternal weight, fetal position, and type of defect present.[35] For this reason, fetal echocardiography should be performed by a skilled and experienced sonologist at 20 to 22 weeks' gestation in all pregnancies at high risk of a fetal cardiac anomaly; this includes pregnancies complicated by pregestational diabetes mellitus, a personal or family history of congenital cardiac disease (regardless of the nature of the lesion or whether it has been repaired), maternal use of potential cardiac teratogens (e.g., lithium and valproic acid),[36] monochorionic twins, and pregnancies conceived by in vitro fertilization, but not if the pregnancy was conceived using clomiphene citrate or ovarian stimulation or intrauterine insemination alone.[37]

Compared with standard two-dimensional (2D) ultrasound, 3D ultrasound (or four-dimensional [4D] if fetal movements are included) allows for visualization of fetal structures in all three dimensions concurrently for the improved characterization of complex fetal structural anomalies and for storage of scanned images with 3D reconstruction at a later date or remote location (telemedicine). Unlike 2D ultrasound, 3D images are greatly influenced by fetal movements and are subject to more interference from structures such as fetal limbs, umbilical cord, and placental tissue. Because of movement interference, visualization of the fetal heart with 3D ultrasound is suboptimal.

In addition to the rapid acquisition of images that can be later reconstructed and manipulated, 3D ultrasound has other potential advantages:

- Surface rendering mode can provide clearer images of many soft tissue structures. Such images can improve the diagnosis of certain fetal malformations, especially craniofacial anomalies (cleft lip and palate, micrognathia, ear anomaly, facial dysmorphism, club foot, finger and toe anomalies), intracranial lesions, spinal anomalies, ventral wall defects, and fetal tumors.
- 3D ultrasound may be useful in early pregnancy by providing more accurate measurements of the gestational sac, yolk sac, and crown-rump length. It may also allow for a more accurate midsagittal view of the fetus for measuring nuchal translucency.
- 3D ultrasound can also be used to measure tissue volume. Preliminary data suggest that the assessment of cervical volume may predict the risk of cervical insufficiency,[38] and measurement of placental volume in the first trimester may predict fetuses at risk of FGR.[39]

Despite these advantages and the fact that 3D ultrasound has been available since the early 1990s, it has yet to live up to its promises. Although 3D ultrasound is unlikely to replace standard 2D imaging in the near future, it is a valuable complementary modality in obstetric imaging. Areas amenable to 3D evaluation include fetal facial anomalies, neural tube defects, fetal tumors, and skeletal malformations.

Growth Assessment

Normal fetal growth is a critical component of a healthy pregnancy and the subsequent long-term health of the child. A systematic method of physical examination of the gravid abdomen was first described by Leopold and Sporlin.[40] Although this examination has several limitations, particularly in the setting of maternal obesity, multiple pregnancy, uterine fibroids, or polyhydramnios, it is safe, low cost, and well tolerated and may add valuable information to assist in antepartum management. Palpation is divided into four separate Leopold maneuvers. Each maneuver is designed to identify specific fetal landmarks or to reveal a specific relationship between the fetus and mother. For example, the first maneuver involves measuring fundal height. The uterus can be palpated above the pelvic brim at approximately 12 weeks' gestation. Thereafter, fundal height should increase by approximately 1 cm/week, reaching the level of the umbilicus at 20 to 22 weeks' gestation. Between 20 and 32 weeks' gestation, the fundal height (in centimeters, from the superior edge of the pubic symphysis) is approximately equal to the GA (in weeks) in healthy women of average weight with an appropriately grown fetus. However, there is a wide range of normal fundal height measurements. One study has shown a 6-cm difference between the 10th and 90th percentiles at each week of gestation after 20 weeks.[41] Moreover, fundal height is maximal at approximately 36 weeks' gestation, at which time the fetus drops into the pelvis in preparation for labor, and the fundal height decreases. For these reasons, reliance on fundal height measurements alone will fail to identify more than 50% of fetuses with FGR.[42] Serial fundal height measurements by an experienced obstetric care provider are more accurate than a single measurement and will lead to an improved diagnosis of FGR, with reported sensitivities as high as 86%.[41] However, a more recent systematic review failed to conclude that serial fundal height measurements were superior to abdominal palpation alone due to a lack of randomized controlled trials.[43]

If the clinical examination is not consistent with the stated GA, an ultrasound examination is indicated to confirm GA and to establish a more objective measure of fetal growth. Ultrasound examination may also identify an alternative explanation for the discrepancy, such as multiple pregnancy, polyhydramnios, oligohydramnios, fetal demise, or uterine fibroids.

For many years, obstetric sonography has used fetal biometry to define fetal size by weight estimation, although this approach has a number of key limitations. For example, regression equations used to create weight estimation formulas are derived primarily from cross-sectional data that rely on infants delivering within an arbitrary period of time after the ultrasound examination, and they assume that body proportions (i.e., fat, muscle, bone) are the same for all fetuses. Moreover, growth curves for healthy infants from 24 to 37 weeks' gestation rely on data collected from pregnancies delivered preterm, which should not be regarded as normal pregnancies and are likely to be complicated by some element of uteroplacental insufficiency, regardless of whether the delivery was spontaneous or iatrogenic. Despite these limitations, if the GA is well validated, the prevailing data suggest that prenatal ultrasound can be used to verify an alteration in fetal growth in 80% of cases and exclude abnormal growth in 90% of cases.[44]

Sonographic estimates of fetal weight are commonly derived from mathematical formulas that use a combination of fetal measurements, especially the BPD, AC, and femur length.[45] Whereas the BPD may be the most accurate indicator of GA in the second or third trimesters, fetuses gain weight in their abdomen, making the AC the single most important measurement for fetal size. The

AC is thus given more weight in these formulas. Unfortunately, the AC is also the most difficult measurement to acquire, and a small difference in the AC measurement will result in a large difference in the estimated fetal weight (EFW). The accuracy of the EFW depends on a number of variables, including GA (in absolute terms, EFW is more accurate in preterm or FGR fetuses than in term or macrosomic fetuses), operator experience, maternal body habitus, and amniotic fluid volume (measurements are more difficult to acquire if the amniotic fluid volume is low). Although objective, sonographic EFW estimations are not particularly accurate and have an error of 15% to 20%, even in experienced hands.[46] Indeed, a sonographic EFW at term is no more accurate than a clinical estimate of fetal weight by an experienced obstetric care provider or the mother's estimate of fetal weight if she has delivered before.[47] Sonographic estimates of fetal weight must therefore be evaluated within the context of the clinical situation and balanced against the clinical estimate of fetal weight. Serial sonographic evaluations of fetal weight are more useful than a single measurement in diagnosing abnormal fetal growth. The ideal interval to evaluate fetal growth is every 3 to 4 weeks, with a minimum 10-day to 14-day interval necessary to see significant differences. Because of the inherent error in fetal biometric measurements, more frequent ultrasound determinations of EFW may be misleading. Similarly, the use of population-specific growth curves, if available, will improve the ability of the obstetric care provider to identify abnormal fetal growth. For example, growth curves derived from a population that lives at a high altitude, where the fetus is exposed to lower oxygen tension, will be different from those derived from a population at sea level. Abnormal fetal growth can be classified as insufficient (i.e., FGR) or excessive (fetal macrosomia).

The definition of FGR has been a long-standing challenge for modern obstetrics. Distinguishing the healthy, constitutionally small fetus, defined as an EFW below the 10th percentile for a given week of gestation, from the nutritionally deprived, truly growth-restricted fetus has been particularly difficult. Fetuses with an EFW less than the 10th percentile are not necessarily pathologically growth restricted. Conversely, an EFW greater than the 10th percentile does not mean that an individual fetus has achieved its growth potential, and such fetuses may still be at risk of perinatal mortality and morbidity. As such, the most widely utilized definition of FGR is EFW less than the 10th percentile for GA in a well-dated pregnancy.[48,49] More restrictive definitions of FGR (EFW less than the 5th or 3rd percentiles) can identify fetuses at higher risk for pathologic growth restriction as opposed to constitutionally small fetuses. An AC below the 10th percentile can also be used to define FGR.[50] Additional findings suggestive of fetal compromise like oligohydramnios or abnormal umbilical artery Doppler velocimetry increase the likelihood of pathologic FGR.

FGR can be classified into maternal, fetal, or placental etiologies. These distinct pathophysiologic mechanisms associated with FGR may occur in isolation or collectively but result in the common final pathway of suboptimal fetal growth and compromised fetal nutrition. Fetuses affected by poor antepartum growth may be further categorized as having symmetric or asymmetric FGR. In cases of symmetric FGR, both the fetal head size and body weight are reduced, indicating a global insult that probably occurred early in gestation. Symmetric FGR may reflect an inherent fetal abnormality (e.g., fetal chromosomal abnormality, inherited metabolic disorder, early congenital infection) or long-standing severe placental insufficiency caused by an underlying maternal disease (e.g., maternal hypertension, long-standing pregestational diabetes, or a significant collagen vascular disorder). Asymmetric FGR is characterized by suboptimal body growth with preserved head growth. It is more commonly observed in the third trimester and is thought to result from a later pathologic event, such as chronic placental abruption leading to uteroplacental insufficiency, in an otherwise uncomplicated pregnancy and healthy fetus.

Currently, patients with risk factors for FGR, those who develop obstetric complications, and those identified with lagging symphysial fundal height measurements are subsequently screened with ultrasound to assess fetal growth. This screening algorithm is in place in the United States, the UK, and various other countries; however, it is known to be imprecise and many fetuses at risk for growth restriction as well as perinatal mortality are not identified with this system. For this reason, a prospective cohort study evaluated screening for FGR with a universal third-trimester ultrasound to assess fetal growth.[51] The authors found that standard screening for FGR identified 20% of small for gestational age (SGA) infants, and implementation of universal screening identified 57% of SGA infants. The increased sensitivity resulted in a decrease in specificity from 98% to 90%, resulting in an increased number of false-positive cases. Therefore the implementation of a universal screening program to identify fetuses at risk for growth restriction and increased perinatal mortality would have to take into consideration the issue of over-identification of possible at-risk fetuses and subsequent overtreatment.

Early and accurate diagnosis of FGR coupled with the appropriate intervention will lead to an improvement in perinatal outcome. If FGR is suggested clinically and by ultrasound examination, thorough evaluations of the mother and fetus are indicated. Referral to a maternal-fetal medicine specialist should be considered. Every effort should be made to identify the cause of FGR and to modify or eliminate contributing factors. Up to 20% of cases of severe FGR are associated with fetal chromosome abnormalities or congenital malformations, 25% to 30% are related to maternal conditions characterized by vascular disease, and a smaller proportion are the result of abnormal placentation. However, in a substantial number of cases (50% or more in some studies), the cause of the FGR will remain uncertain even after a thorough investigation.[52]

Fetal macrosomia is defined as an EFW (not birthweight) of 4500 g or greater, measured either clinically or by ultrasound, and is independent of GA, diabetic status, or actual birthweight.[21] Fetal macrosomia refers to a single cutoff EFW; this should be distinguished from the large for GA fetus, which is one in whom the EFW is greater than the 90th percentile for GA. By definition, 10% of all fetuses are large for GA at any given GA. Fetal macrosomia is associated with an increased risk of cesarean delivery, operative vaginal delivery, and birth injury to both the mother (including vaginal, perineal, and rectal trauma) and the fetus (orthopedic and neurologic injury).[21,53–56] Shoulder dystocia with resultant brachial plexus injury (Erb palsy) is a serious consequence of fetal macrosomia and is further increased in the setting of diabetes because of the increased diameter of the upper thorax and neck of those fetuses.

Fetal macrosomia can be determined clinically, by abdominal palpation using Leopold maneuvers, or by ultrasound examination; these two techniques appear to be equally accurate.[57] However, EFW measurements are less accurate in large (macrosomic) fetuses than in normally grown fetuses, and factors such as low amniotic fluid volume, advancing GA, maternal obesity, and the position of the fetus can compound these inaccuracies. Clinical examination has been shown to underestimate the birthweight by 0.5 kg

or more in almost 80% of fetuses with macrosomia.[58] For these reasons, the prediction of fetal macrosomia is not particularly accurate, with a false-positive rate of 35% and a false-negative rate of 10%.[57,58] A number of alternative sonographic measurements have therefore been proposed in an attempt to better identify the macrosomic fetus, including fetal AC alone, umbilical cord circumference, cheek-to-cheek diameter, and upper arm circumference; however, these measurements remain investigational and should not be used clinically.

Despite the inaccuracy in the prediction of fetal macrosomia, an EFW should be documented either by clinical estimation or ultrasound examination in all women at high risk for fetal macrosomia at approximately 38 weeks' gestation. Suspected fetal macrosomia is not an indication for induction of labor prior to 39 weeks of gestation, because the evidence is lacking that the benefits of reducing shoulder dystocia risk would outweigh the harms of early delivery.[21] However, if the EFW is excessive, elective cesarean delivery should be considered to prevent fetal and maternal birth trauma. Although controversy remains as to the precise EFW at which an elective cesarean delivery should be recommended, a suspected birthweight in excess of 4500 g in women with diabetes or 5000 g in women without diabetes is a reasonable threshold.[21,59]

Amniotic Fluid Assessment

Amniotic fluid plays a key role in the health and development of a growing fetus. Once considered an afterthought during the ultrasound examination of the fetus, evaluation of the amniotic fluid is now considered an integral part of ultrasound evaluation for fetal well-being. The amniotic fluid serves a number of important functions for the developing embryo and fetus. It provides cushioning against physical trauma; creates an environment free of restriction and or distortion, allowing for normal growth and development of the fetus; provides a thermally stable environment; allows the respiratory, gastrointestinal, and musculoskeletal tracts to develop normally; and helps to prevent infection.[60]

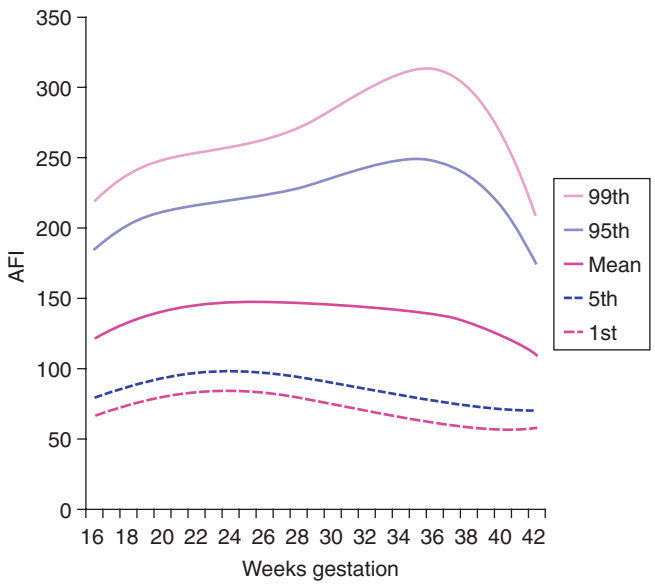
The chorioamnion acts as a porous membrane early in pregnancy, allowing the passage of water and solutes across the membrane; there is little contribution from the small embryo. As the pregnancy progresses into the late first trimester, diffusion of fluid across the fetal skin occurs, increasing the volume of amniotic fluid. In the second half of the pregnancy, the main sources of amniotic fluid come from fetal kidneys and lungs. The primary sources for removal of fluid are fetal swallowing and absorption into fetal blood perfusing the surface of the placenta. As more fluid is produced than is resorbed by the fetal–placental unit, the volume of amniotic fluid increases throughout the first 32 weeks of pregnancy (Fig. 12.4). The volume peaks at approximately 32 to 33 weeks' gestation, and at this GA, equal amounts of fluid are produced and resorbed. After term, the amniotic fluid declines at a rate of 8% per week.[61]

Because amniotic fluid plays a critical role in the normal development of a fetus, the assessment of amniotic volume is an essential component of the ultrasound evaluation for fetal well-being. Subjective estimates of the amniotic fluid volume have been validated, but two ultrasound measurements—amniotic fluid index (AFI) and maximum vertical pocket (MVP)—have been developed to quickly and accurately assess the quantity of amniotic fluid surrounding the fetus.

The AFI is a semiquantitative method for assessing the amniotic fluid volume with ultrasound. The gravid uterus is divided into four quadrants using the umbilicus, linea nigra, and external landmarks.[62] The deepest amniotic fluid pocket is measured in each quadrant with the ultrasound transducer perpendicular to the floor. The four measurements are added together, and the sum is regarded as the AFI. Pockets filled with the umbilical cord or fetal extremities should not be used for generating the AFI.[63] Researchers and clinicians have used a variety of measurements to define abnormalities in amniotic fluid volume. However, the normal range of the AFI most commonly used in clinical practice is greater than 5 to less than 24 cm of fluid. Pregnancies with an AFI of greater than 5 are described as having oligohydramnios, and pregnancies with measurements greater than 24 cm are described as having polyhydramnios.[64]

The MVP is another semiquantitative method for assessing fluid volume. The technique involves scanning the gravid uterus for the single deepest pocket of amniotic fluid that is free of the umbilical cord and fetal parts and, with the transducer perpendicular to the floor, measuring the pocket of fluid.[65] Oligohydramnios is defined as a single measurement of less than 2 cm. Polyhydramnios is defined as a single measurement greater than 8 cm. In contrast to AFI, this method can be used for both singleton and multiple gestation pregnancies. Currently, MVP is preferred to AFI for assessment of amniotic fluid volume and clinical decision-making not only because of its ease to perform but also because the use of MVP compared with AFI results in fewer obstetric interventions without a significant difference in perinatal outcome.[66]

Otherwise normal pregnancies affected by oligohydramnios are at increased risk for perinatal mortality as decreased amniotic fluid volume can be used as a proxy for declining uteroplacental perfusion and increasing placental dysfunction. Decisions to intervene in a pregnancy affected by oligohydramnios are based upon several factors such as GA, fetal condition, and maternal characteristics. First, rupture of membranes must be ruled out, as a low amniotic fluid volume in the setting of ruptured membranes is no longer predictive of poor placental perfusion. Expert opinion recommends delivery after 36 to 37 weeks' gestation in the setting of isolated and persistent oligohydramnios (MVP <2 cm) in an otherwise uncomplicated pregnancy.[67]



• **Fig. 12.4** Amniotic Fluid Index (in mm) Plotted Against Gestational Age. The curves represent percentiles. *AFI*, Amniotic fluid index.

Biophysical Profile

An NST alone might not be sufficient to confirm fetal well-being; in such cases, a BPP may be performed. The BPP refers to a sonographic scoring system performed over a 30- to 40-minute period designed to assess fetal well-being. The BPP was initially described for testing postterm fetuses but has since been validated for use in both term and preterm fetuses.[68–73] Notably, BPP is not validated for use in active labor. The five variables described in the original BPP were gross fetal body movements, fetal tone (i.e., flexion and extension of limbs), amniotic fluid volume, fetal breathing movements, and NST (summarized in Table 12.2).[74] More recently, however, BPP is interpreted without the NST.

The individual variables of the BPP become apparent in healthy fetuses in a predictable sequence: fetal tone appears at 7.5 to 8.5 weeks, fetal movement at 9 weeks, fetal breathing at 20 to 22 weeks, and FHR reactivity at 24 to 28 weeks' gestation. Similarly, in the setting of antepartum hypoxia, these characteristics typically disappear in the reverse order in which they appeared (i.e., FHR reactivity is lost first, followed by fetal breathing, fetal movements, and finally fetal tone).[72] The amniotic fluid volume, which is composed almost entirely of fetal urine in the second and third trimesters, is not influenced by acute fetal hypoxia or acute fetal CNS dysfunction. Rather, oligohydramnios (decreased amniotic fluid volume) in the latter half of pregnancy and in the absence of ruptured membranes is a reflection of chronic uteroplacental insufficiency, increased renal artery resistance leading to diminished urine output, or both;[75] it predisposes to umbilical cord compression, thus leading to intermittent fetal hypoxemia, meconium passage, or meconium aspiration. Adverse pregnancy outcome (including abnormal FHR tracing, low Apgar score, and neonatal intensive care unit admission) is more common when oligohydramnios is present.[75–78] Serial (weekly) screening of high-risk pregnancies for oligohydramnios is important because amniotic fluid can become drastically reduced within 24 to 48 hours.[79]

Although each of the five features of the BPP is scored equally (2 points if the variable is present or normal and 0 points if absent or abnormal, for a total of 10 points), they are not equally predictive of adverse pregnancy outcome. For example, amniotic fluid volume is the variable that correlates most strongly with adverse pregnancy events. The recommended management based on the BPP is summarized in Table 12.3.[74] A score of 8 to 10 out of 10 is regarded as reassuring; a score of 4 to 6 is suspicious and requires reevaluation, and a score of 0 to 2 suggests abnormal fetal testing—previously referred to as *fetal distress*.[65,68] Evidence of abnormal fetal testing or oligohydramnios in the setting of otherwise normal fetal testing should prompt evaluation for immediate delivery.[72,73]

It is important to recognize that administration of maternal systemic steroids to promote fetal maturity may result in fetal behavioral changes. Subsequent to systemic steroid administration, fetal body movements may decrease, FHR variability may decrease, and fetal breathing episodes may be less frequent.[80,81] These changes in fetal activity and FHR patterns are important to take into consideration when interpreting the various components of the fetal BPP.

TABLE 12.2 Fetal Biophysical Profile

Element	Criterion (2 Points for Each Element Satisfied)
Breathing	≥1 episode of breathing movements lasting 30 s
Movement	≥3 discrete body or limb movements
Tone	≥1 episode of active extension and flexion of limbs or trunk
Amniotic fluid	≥1 pocket of amniotic fluid measuring ≥2 cm in two perpendicular planes
NST	≥2 FHR accelerations lasting ≥15 s over 20 min

FHR, Fetal heart rate; *NST*, nonstress test.

TABLE 12.3 Interpretation and Management of Biophysical Profile

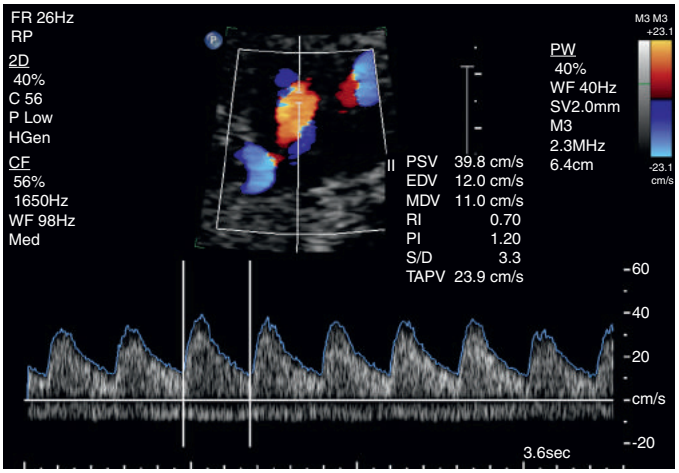
Score	Comment	Perinatal Morbidity or Mortality Within 1 Week (No Intervention)	Management
10/10	Normal	<1/1000	No intervention
8/8	Normal	—	No intervention
8/10 (abnormal NST)	Normal	—	No intervention
8/10 (abnormal amniotic fluid)	Suspect chronic fetal compromise, renal anomaly, or rupture of membranes	89/1000	Rule out renal abnormality or rupture of membranes; consider delivery or prolonged observation if dictated by gestational age
6/8 (other)	Equivocal, possible asphyxia	Variable	If fetus is mature, deliver; if immature, repeat test within 4–6 h
6/8 (abnormal amniotic fluid)	Suspect asphyxia	89/1000	Repeat 4–6 h; consider delivery
4/8	Suspect asphyxia	91/1000	If ≥36 weeks' gestation or documented pulmonary maturity, deliver immediately; if not, repeat within 4–6 h
2/8	High suspicion of asphyxia	125/1000	Immediate delivery
0/8	High suspicion of asphyxia	600/1000	Immediate delivery

NST, Nonstress test.
Adapted from Manning FA, Morrison I, Harman CR, et al. Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. *Am J Obstet Gynecol.* 1987;157:880–884.

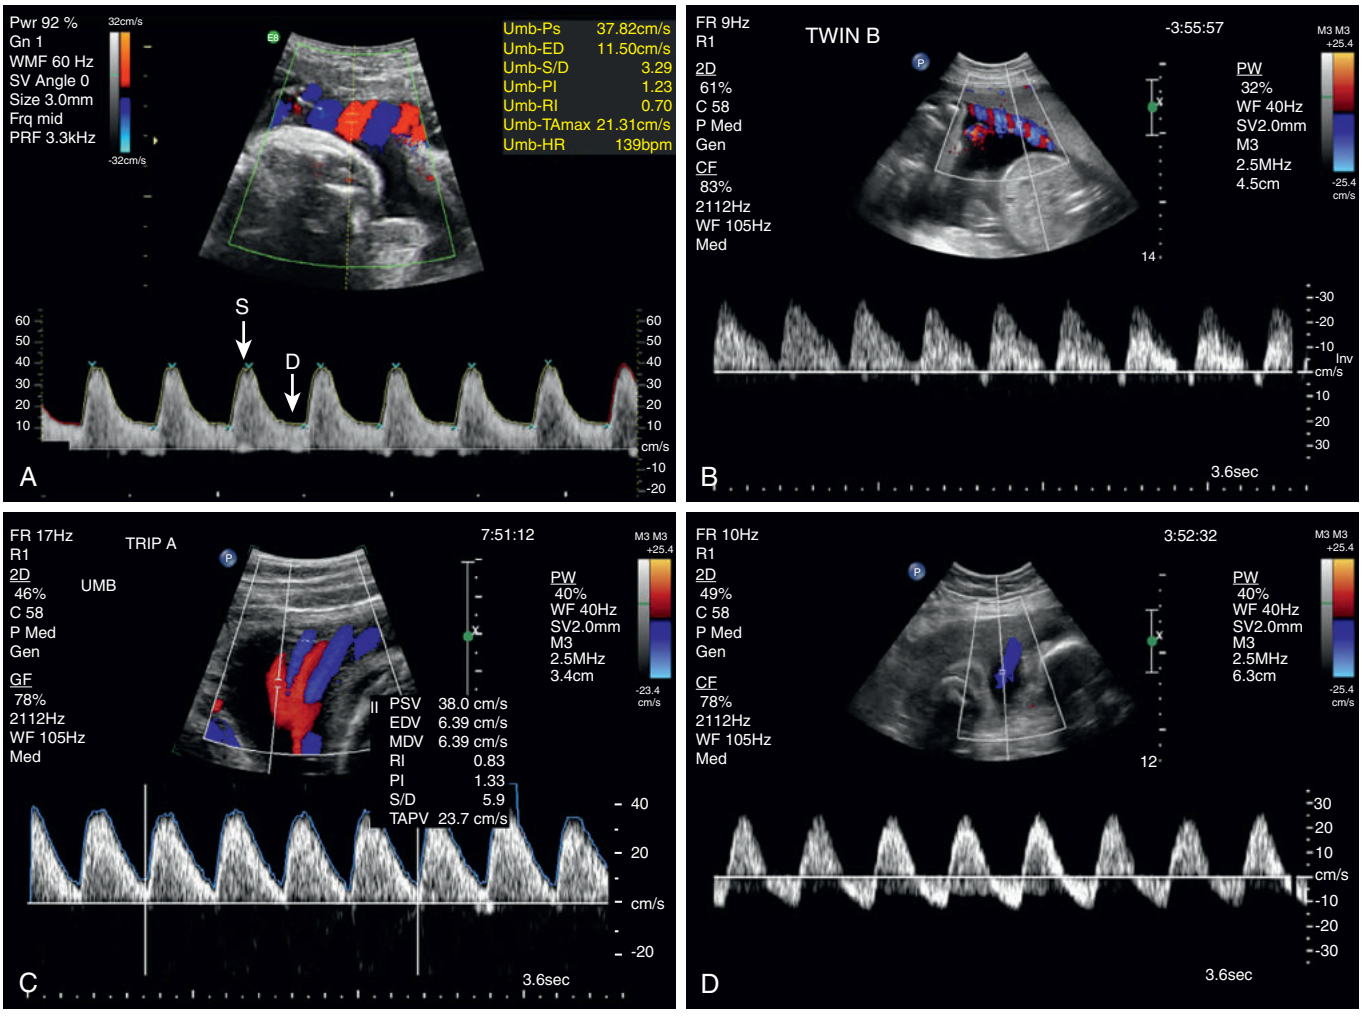
Doppler

Doppler velocimetry shows the direction and characteristics of blood flow, and it can be used to examine the maternal, uteroplacental, or fetal circulations. Because of placental capacitance, the umbilical artery is one of the few arteries that normally has forward diastolic flow, and it is one of the most frequently targeted vessels during pregnancy (Fig. 12.5). Umbilical artery Doppler velocimetry measurements reflect resistance to blood flow from the fetus to the placenta. Factors that affect placental resistance include GA, placental location, pregnancy complications (placental abruption, preeclampsia), and underlying maternal disease (chronic hypertension).

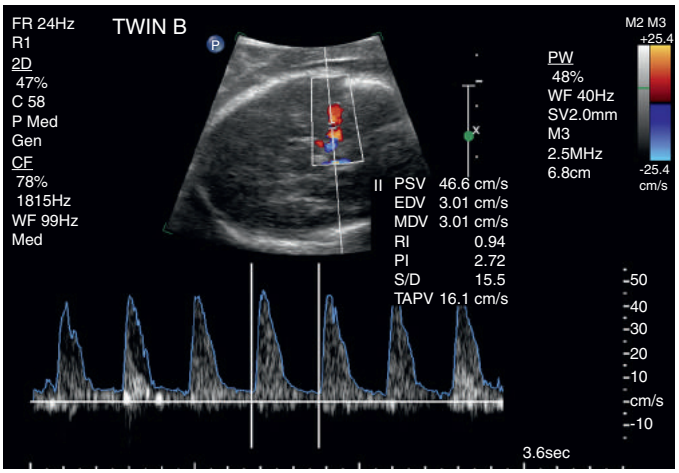
Doppler velocimetry of umbilical artery blood flow provides an indirect measure of placental function and fetal status.[82] Decreased diastolic flow with a resultant increase in systolic-to-diastolic ratio suggests increased placental vascular resistance and fetal compromise. Severely abnormal umbilical artery Doppler velocimetry (defined as absent or reversed diastolic flow) is an especially ominous observation and is associated with poor perinatal outcome, particularly in the setting of FGR (Fig. 12.6A–D).[83–88] The overall mortality rate for fetuses with absent or reversed flow may be



• **Fig. 12.5** Normal Fetal Umbilical Artery Doppler Recording. *EDV*, End diastolic velocity; *PSV*, peak systolic velocity; *S/D*, systolic/diastolic ratio.



• **Fig. 12.6** Uterine Artery Doppler to Assess Growth Restriction. Increasing levels of placental resistance as seen in the umbilical artery at the time of diastole (*D*) as it relates to systole (*S*). Normal end-diastolic flow (A), decreased end diastolic flow (B), absent end-diastolic flow (C), and reversed end-diastolic flow (D). *EDV*, End diastolic velocity; *PSV*, peak systolic velocity; *S/D*, systolic/diastolic ratio.



• **Fig. 12.7** Middle Cerebral Artery Peak Systolic Velocity for Fetal Anemia Assessment. *EDV*, End diastolic velocity; *PSV*, peak systolic velocity; *S/D*, systolic/diastolic ratio.

near 30%.[89] It should be noted that abnormal Doppler studies are often seen in cases of anatomic anomalies or chromosomal abnormalities, which should be noted when managing a case. A 2013 systematic review[90] found evidence that the use of umbilical artery Doppler ultrasound in high-risk pregnancies (FGR/suspected placental insufficiency) reduced the risk of perinatal deaths and resulted in fewer obstetric interventions.

The role of ductus venosus and middle cerebral artery (MCA) Doppler in the management of FGR pregnancies is not well defined. As such, urgent delivery should be considered in FGR pregnancies when the results of umbilical artery Doppler studies are severely abnormal, regardless of GA. However, it is unclear how to interpret these findings in the setting of a normally grown fetus. For these reasons, umbilical artery Doppler velocimetry should not be performed routinely on low-risk women. Appropriate indications include FGR, cord malformations, unexplained oligohydramnios, suspected or established preeclampsia, and possibly fetal cardiac anomalies. Umbilical artery Doppler velocimetry has not been shown to be useful in the evaluation of a variety of high-risk pregnancies, including diabetic and postterm pregnancies, primarily because of its high false-positive rate.[91–94]

As such, in the absence of FGR, obstetric management decisions are not usually made on the basis of Doppler velocimetry studies alone. An application that has proved extremely useful is the noninvasive evaluation of fetal anemia resulting from isoimmunization. When a fetus develops severe anemia, cardiac output increases and there is a decline in blood viscosity, resulting in an increase in MCA blood flow, which can be demonstrated by measuring the peak velocity using MCA Doppler velocimetry (Fig. 12.7).[95] This demonstration can help the perinatologist to better counsel such patients about the need for cordocentesis and fetal blood transfusion. Doppler studies of other vessels—including the uterine artery, fetal aorta, ductus venosus, and fetal carotid arteries—have contributed considerably to our knowledge of maternal-fetal physiology but as yet have resulted in few clinical applications.

Summary

There are a variety of testing modalities available to the obstetrician for assessing fetal well-being in the antepartum period, each with specific applications, advantages, and disadvantages. As such, it is difficult to apply generalized protocols to the assessment of the fetus. A stepwise approach entails applying the appropriate tests for low-risk patients and identifying those patients, from the results of those tests or from historical factors, for whom further testing is needed. Although many tests, including NST, fetal weight assessment, and uterine artery Doppler, may be somewhat nonspecific and may have misleading false-positive rates, combining those tests with others increases the specificity. Test results that raise concerns require further investigation or active management.

Complicated Deliveries

KARA K. HOPPE AND BRAD BOSSE

KEY POINTS

- Cesarean section occurs in approximately one-third of all births in the United States, with substantial variation among hospitals that cannot be entirely accounted for by preexisting maternal or fetal comorbidities.
- Multidisciplinary team training can reduce infant morbidity after shoulder dystocia.
- Operative vaginal birth with either forceps or vacuum has declined to a multi-decade low despite the low frequency of infant complications directly attributable to this method of delivery.
- Regardless of mode of delivery, both the obstetrician and pediatrician must be aware that the infant in breech presentation requires careful attention upon birth for the presence of hip dislocation and traumatic morbidity (soft tissue trauma, fracture, facial nerve paralysis, and brachial plexus palsy).
- Twin gestations account for 3% of total births, however the twin birth rate decreased from 2018 (32.6/1000 births) to 2019 (32.1/1000 births). Twin gestations account for 17% of preterm births and approximately 25% of infants of low birth weight and very low birth weight.
- Vaginal birth after cesarean (VBAC) section should occur in delivery facilities capable of rapidly performing an emergent cesarean section because this improves the likelihood of minimizing adverse neonatal sequelae.

Overview

Historically, childbirth was often regarded as a perilous undertaking. However, over the past century in the United States, many advancements in perinatal medicine have improved modern obstetric care, such as widespread use of antibiotics, easy access to expedient cesarean delivery, and better understanding of the proper use of instruments, such as forceps and vacuum extraction.[1] Despite the improvements in obstetric care, and in contrast to the global trend in decreased maternal mortality, maternal mortality has been increasing in the United States (from 10 deaths per 100,000 livebirths in 1990 to a high of 18 deaths per 100,000 live births in 2014).[2] Indeed, adverse outcomes are generally uncommon in modern obstetrics and, unlike in the past, most labor and delivery concludes with a healthy mother and neonate. Nevertheless, complicated deliveries still exist, and knowledge of their conduct and sequelae is still required for the administration of proper maternal and infant care.

In this chapter we will address:

Brief overview of normal labor and delivery. A comprehensive discussion of labor and delivery is beyond the scope of this chapter, and the interested reader is directed to *Williams Obstetrics*, 25th ed., Chapter 22 on normal labor.[3]

The complicated vaginal delivery, with particular attention to neonatal outcomes.

Cesarean delivery and vaginal birth after cesarean (VBAC) delivery and associated neonatal implications.

Vaginal Delivery

Labor begins with the onset of regular uterine contractions with concomitant cervical dilation and effacement. The first stage of labor is subdivided into a latent phase, the length of which is variable and can last for several hours, and an active phase. Historically, the active phase was defined as beginning when the cervix is dilated 4 cm and is marked by more rapid cervical dilation (Fig. 13.1).[4] The second stage begins with complete cervical dilation and terminates with expulsion of the fetus from the birth canal. The third stage of labor concludes with delivery of the placenta (Table 13.1).

In 2010, data from the Consortium on Safe Labor stimulated debate regarding whether the 60-year-old data of Friedman apply to currently laboring women.[5] Based on this research, the active phase became defined as beginning at 6 cm of cervical dilation (Fig. 13.2). In 2012, a summary was published by a joint committee including the Eunice Kennedy Shriver National Institute of Child Health and Human Development, Society for Maternal-Fetal Medicine, and American College of Obstetricians and Gynecologists (ACOG), regarding labor management guidelines largely based on the work of Zhang, and these guidelines have been largely adopted as the standard of care for labor management.[6]

Disorders of labor progress involve either protraction, with a slower rate of cervical dilation or fetal descent than expected, or arrest. Both disorders are addressed by operative delivery if they are unresponsive to active medical management; this can be performed abdominally through cesarean section or vaginally by obstetric forceps or vacuum extraction if the cervix is fully dilated and specific criteria are fulfilled (see later discussion on operative vaginal delivery). All these modalities can have neonatal and maternal adverse effects, and the choice of instrument or mode of delivery must always be selected when taking these potential morbidities into account.

TABLE 13.1 Stages of Labor

Stage	
First (latent and active phase)	Onset of labor to complete (10 cm) cervical dilation
Second	Complete cervical dilation to fetal expulsion
Third	Fetal expulsion to placental expulsion

Cesarean Section

A cause-and-effect relationship between cesarean delivery and improved neonatal outcomes in the United States has never been demonstrated. Currently, almost one in three mothers gives birth by cesarean section in the United States. The rate of cesarean delivery in the United States, which peaked in 2009 at 32.9%, had declined to 31.7% in 2019.[7] Since 1985, the World Health Organization (WHO) had recommended cesarean section rates not exceed 10% to 15%. However, international data called the safety of this low projection into question, demonstrating that national cesarean section rates up to 19% were associated with lower maternal and neonatal mortality among WHO member states.[8] Recent recommendations from the US Department of Health and Human Services Healthy People 2030 have targeted a cesarean section rate of 23.6% for first-time pregnancies.

There are, however, wide variations in cesarean delivery rates among individual states within the United States[7] and among individual hospitals within a given state.[9] This cesarean section variability was shown to be 10-fold (7% to 70%) among birthing hospitals in the United States and varied from 17.5% to 31.8% among the 50 states. This suggests that factors other than pregnancy risk indicators may heavily influence the current cesarean delivery rate. Liability fears have been suggested as a leading cause of the variability in cesarean section rates. One study has lent validity to this concern, showing that higher cesarean section rates were associated with reduced risk of litigation.[10] The incidence of cesarean delivery on maternal request and its contribution to the overall increase in cesarean delivery rate are not well known, but it has been estimated that 2.5% of all births in the United States are due to maternal request for cesarean delivery. The ACOG has recommended that, in the absence of a maternal or fetal indication for cesarean delivery, vaginal delivery should be recommended. After counseling the patient about risks, benefits, and alternatives to cesarean delivery, if the patient decides to pursue an elective cesarean delivery, the delivery should not be performed before 39 weeks gestation. Women should also be informed that the risk of placental complications (which could lead to a gravid hysterectomy) will increase with each subsequent cesarean delivery.[11] This rise in cesarean delivery has been associated with a parallel drop in the vaginal operative delivery rate to less than 5%.

Cesarean section is usually performed through either a Pfannenstiel or vertical skin incision. The uterine incision is often made transversely in the lower uterine segment because it minimizes intraoperative blood loss and future risk of rupture during subsequent labor, compared with a vertical or classical incision. The risk of rupture in future labor is thought to be 0.5% to 0.9% for a low transverse incision.[12] However, risks of uterine rupture with previous classical incision have ranged from 1% to 12% in women undergoing a trial of labor.[13–15]

Cesarean delivery is also performed for disorders of protraction or arrest in the first stage of labor when conservative measures, such as oxytocin or amniotomy, fail to augment delivery or in the second stage when assisted or operative vaginal delivery is deemed unfeasible or unsafe.

A partial list of other accepted indications for cesarean delivery is as follows:

- Fetal malpresentation (e.g., shoulder or breech)
- Placenta previa
- Prior classical uterine incision
- Fetal status not reassuring, remote from vaginal delivery
- Higher-order multiple gestation (triplet or greater)
- Fetal contraindications to labor (alloimmune thrombocytopenia)
- Maternal contraindication to labor (e.g., history of rectal or perineal fistulas from inflammatory bowel disease, large lower-uterine segment, or cervical leiomyoma preventing vaginal delivery).
- Maternal choice after counseling regarding risks versus benefits.

Operative Vaginal Delivery: Obstetric Forceps and Vacuum Extraction

Description of the Obstetric Forceps

Obstetric forceps have been used to facilitate vaginal deliveries since 1500 BCE. More recently, their invention has been credited to Peter Chamberlen and his brother, both obstetricians from England. Designed originally as a means of extracting fetuses from women who were at high risk of dying during childbirth, forceps now are an alternative to cesarean delivery in women with a protracted second stage of labor. Originally, many of these instruments were furnished with hooks and other accessories of destruction, and they were intended to save the mother but not the fetus. Over the last 500 years, the modern instruments in current use have been through hundreds of modifications, safer techniques have been established, and the overriding goal now includes delivering an intact, living baby and a healthy mother.[16,17]

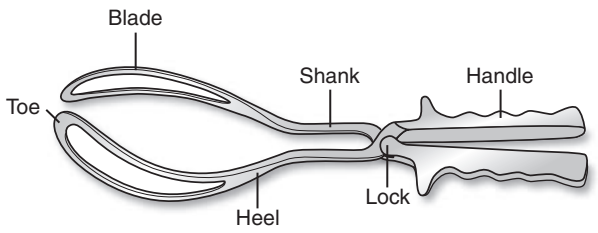
Current obstetric forceps were first devised for practical use in the 16th and 17th centuries and were perfected over the past 300 years into the models in current use. Although there are many variations on the standard blueprint, depending on the indication for its use, all obstetric forceps have a similar design.

Forceps are made of stainless steel and consist of two blades (each approximately 37.5 cm long, crossing each other), a lock at the site of crossing, and a handle, whereby the instrument is grasped by the obstetrician. The part of the forceps that grasps the fetal head is the blade; this is further divided into the heel, which is the part closest to the lock, and the toe, which is the most distal part of the blade. The blade can be either fenestrated—meaning the body of the blade is hollow—or solid to prevent fetal head compression. A further modification is pseudofenestration, in which a solid blade has a ridged edge, combining the advantages of easier applicability and reduced fetal trauma that a solid blade affords with the ease of traction of a fenestrated blade. Obstetric forceps also possess a rounded cephalic curve, which accommodates the fetal vertex, and a pelvic curve that mirrors the maternal pelvic curve (Fig. 13.3).

There are more than 60 different types of obstetric forceps described in the literature, but most of them are not used currently. The forceps used most often today are described in Table 13.2, along with their indications for use and the variations in anatomy, which distinguish one from the other.

Indications for Use of Obstetric Forceps

To an individual without obstetric training, the use of forceps can appear to be a dangerous and difficult undertaking, fraught with potential trauma for both the mother and fetus. It is true that the use of this instrument, if not performed carefully or appropriately, can have serious consequences. Nevertheless, with properly trained hands, and a proper appreciation of its use, forceps have traditionally been lifesaving for both mother and fetus.



• **Fig. 13.3** Simpson forceps: a standard obstetric forceps with features common to all such instruments.

TABLE 13.2 Types of Obstetric Forceps in Most Common Use

Type	Anatomic Modification	General Use
Classic		
Tucker–McClane	Solid blade	Nonmolded vertex
Simpson	Parallel shanks	Molded vertex or significant caput
Elliot	Convergent shanks	Nonmolded vertex
Laufe	Pseudofenestrated blade; divergent shanks	For preterm infants or EFW <2500 g
Rotational		
Kielland	English lock; absent pelvic curve	For rotation of fetal vertex ≥45°
Breech		
Piper	Long handles with no pelvic curvature	For after-coming head in breech vaginal delivery

EFW, Estimated fetal weight.

The criteria for the safe application of obstetric forceps are as follows:

- The cervix must be fully dilated.
- The position of the fetal vertex must be known. Forceps should not be applied when the fetal presentation is in doubt.

The fetal vertex must be engaged within the maternal pelvis. Often in difficult or challenging labors, significant caput can lead to the false impression that fetal station is lower than it actually is. For this reason, the obstetrician must be confident that the biparietal diameter has passed the pelvic inlet (engagement) as evidenced by the leading part of the fetal skull beyond the level of the ischial spines. In addition, when the presentation is occiput posterior, the leading point of the fetal skull may appear to be lower in the pelvis, although the biparietal diameter has not yet passed through the pelvic inlet, and can lead to an erroneous conclusion about fetal station. When the forceps are properly applied, the sagittal suture must be exactly midway between the blades, and the lambdoidal sutures should be equidistant from the edge of the blade. If these conditions are not met, the delivery with forceps should be reconsidered.

ACOG has revised its 1988 classification of the type of forceps delivery, according to the station of the fetal vertex before forceps application[17] which are as follows:

- Outlet forceps—the fetal vertex is visible at the labia without manually separating them, and the fetal skull has reached the pelvic floor.
- Low forceps—the leading point of the fetal skull is greater than 2 cm beyond the ischial spines.

- Mid forceps—the fetal head is engaged (0 to +1 station). The forceps should be applied only if cesarean delivery is not quickly or imminently possible with the fetus in distress, or there should be a high likelihood that the forceps operation will be successful.
- High forceps—the vertex is not engaged (leading part not at the level of the ischial spines or beyond). Under these circumstances, the forceps must never be applied.

The usual indications for use of the obstetric forceps are:

- Maternal exhaustion or inability to push (endotracheal intubation with sedation or paralysis, neuromuscular disease)
- Fetal heart tracing not reassuring
- Maternal contraindications to pushing (cardiopulmonary disease, cerebrovascular aneurysm)
- After-coming head in a vaginal breech delivery

Forceps and Potential Neonatal Morbidity

Forceps were used for hundreds of years without regard to fetal survival and were primarily needed to facilitate or terminate difficult labors for maternal benefit. Today, with the widespread availability of cesarean delivery, considerations turn to providing the best neonatal outcome possible; therefore, the difficult forceps deliveries of the past have largely been abandoned. Nevertheless, forceps can still play a role in modern obstetrics if judiciously used and in some circumstances can provide a safer alternative to cesarean delivery for both mother and baby.

The difficulty in interpreting the obstetric literature, in regard to neonatal morbidity incurred by forceps, is that the classification for type of forceps was revised by the ACOG in 1988; therefore, prior studies do not use the same clinical criteria used currently to select appropriate candidates for forceps use. Furthermore, residency training in operative vaginal delivery has dramatically decreased over the past 30 years, potentially increasing fetal risk. Consequently, for modern interpretation of adverse outcomes, one must look to studies performed after the 1988 ACOG revision of the classifications.

The incidence of operative vaginal delivery in the United States has declined to 3.1% of births, ranging by hospital from 1% to 23%.[7] Forceps deliveries have declined to 0.5%, while vacuum deliveries account for the majority of operative births (2.6%).[7] In a systematic review of randomized trials, failed operative delivery occurred in approximately 9% of forceps deliveries and 14% of vacuum deliveries (RR 0.65, 95% CI 0.45 to 0.94; seven trials, n-2419 deliveries).[18] In general, the failure rate increases as the station from which delivery is attempted decreases. The indication for forceps use varies widely by clinical situation, and the neonatal morbidity that can result from a "difficult pull" in a patient with a transverse arrest with marked fetal asynclitism may be different from the quick delivery of a 2600 g fetus whose mother is unable to push, even if both deliveries are by low forceps. Asynclitism refers to the position of a baby in the uterus such that the head of the fetus is presenting first and is tilted to the shoulder, causing the fetal head to no longer be in line with the birth canal.

There are few randomized prospective trials specifically addressing the issue of neonatal morbidity arising from forceps operations, and many of those are several decades old. In addition, there appears to be a substantial difference regarding frequency of operative delivery and outcomes between the United States and other English-speaking countries (UK and Australia),[19] which is likely related to higher rates of litigation in the United States.

The primary outcome that birth attendants wish to avoid when considering operative vaginal birth is birth trauma to the baby, primarily, and secondarily to the mother. A large population-based study in the United States describing over 11 million births showed that birth trauma (facial nerve injury, cephalhematoma, intracranial hemorrhage, need for mechanical ventilation) was more likely with operative vaginal birth than spontaneous birth and even higher if sequential (vacuum and forceps) operative attempts had been made.[20] When comparing forceps, vacuum, and spontaneous vaginal delivery, the rates of neonatal death were 5.0, 4.7, and 3.7/10,000 deliveries; assisted ventilation less than 30 minutes was 250, 295, and 147/10,000 deliveries, birth injury was 75.1, 109.1, and 21.4/10,000 deliveries, and neonatal seizures were 250, 293, and 147/10,000 deliveries.[20] A large population-based study in California, however, found no differences in outcome with forceps versus vacuum except for a higher incidence of facial nerve palsy with forceps delivery.[21] The absolute frequencies of birth trauma in these two large series were very similar and, although the rate of birth trauma was higher than for spontaneous vaginal birth, the overall frequencies were quite low. Table 13.3 shows the incidence of intracranial injury by delivery mode.[21]

The hazard of making such comparisons is that in most instances the decision facing the birth attendant is not operative delivery versus spontaneous birth but operative birth versus cesarean delivery. In this regard, the data from Towner provided some important information. When comparing fetal outcomes after successful operative vaginal birth, unsuccessful operative vaginal birth, and cesarean section done for labor disorder without attempt at operative vaginal birth, the latter two were similar. The primary finding of this study was that there appeared to be an irreducible number of fetal injuries associated with labor rather than the method of delivery.

The clinical dilemma that has probably changed the frequency of operative delivery in the United States also comes from data presented by Towner and Ciotti (2007)[21] as well as others.[22,23] The dilemma is what to do in the instances in which operative vaginal birth fails. Towner showed that fetal injury was higher in sequential vaginal birth, even if successful, than with successful single operative attempts. Gardella et al. (2001)[22] found the same thing and expended the excess morbidity to the mother as well. However, Towner found that the excess morbidity to the baby after failed vaginal birth was not reduced by cesarean section. Another study looking at outcomes of failed operative delivery

TABLE 13.3 Risk of Neonatal Intracranial Hemorrhage[a] According to Type of Delivery

Mode of Delivery	Incidence of Intracranial Injury
Vacuum	1 in 860
Forceps	1 in 664
Combined vacuum and forceps	1 in 256
Cesarean, in labor	1 in 907
Cesarean, not in labor	1 in 2750
Spontaneous vaginal delivery	1 in 1900

[a]Intracranial hemorrhage was defined as subdural, cerebral, intraventricular, or subarachnoid. Adapted from Towner D, Castro MA, Eby-Wilkens E, et al. Effect of mode of delivery in nulliparous women on intracranial injury. *N Engl J Med.* 1999;341:1709–1714.

also found worse neonatal outcomes, but these were nearly all in infants who had fetal heart rate abnormalities listed as either the primary or secondary reason for operative delivery.[24] The knowledge of morbidity associated with failed vaginal births by most obstetricians in the United States has appeared to have changed behavior regarding forceps attempts. In the second stage of labor, if efforts to achieve spontaneous vaginal birth are unsuccessful, cesarean delivery is increasingly offered rather than attempted vaginal birth with the risk of failure and increased fetal morbidity. In many hospitals in the United States, the percentage of labor-related cesarean sections done in the second stage of labor exceeds 40%.

Vacuum Delivery: Indications, Uses, and Comparison With Forceps Procedures

Operative vaginal delivery for the indications listed previously can also be performed by the vacuum extractor. The situations that indicate the use of the vacuum and the requirements that must be fulfilled for its correct use are identical to those for the obstetric forceps. Care must be taken in its application to ensure that an adequate seal with the fetal head has been created and that no maternal soft tissue is trapped between the suction device and the fetus. Traction is then applied to the fetal head in the line of the birth canal to assist delivery. It is also cautioned that rocking movements or torque to the cup should not be used. The premature infant (<34 weeks) is a relative contraindication to vacuum application. It is generally advised that no more than three detachments occur before attempts at vacuum extraction are abandoned.[1]

In a laboratory experiment, Duchon et al. (1988)[25] compared the maximum force at suggested vacuum pressures (550 to 600 mm Hg) prior to detachment for different types of vacuum devices. They found that the average force of traction exerted before detachment ranged from 18 to 20 kg. This result is interesting to bear in mind when one considers the older data of Wylie, who estimated the average tractive force required for delivery of infants was 15.95 kg for a primigravida and 11.33 kg for a multipara (Fig. 13.4).[26,27]

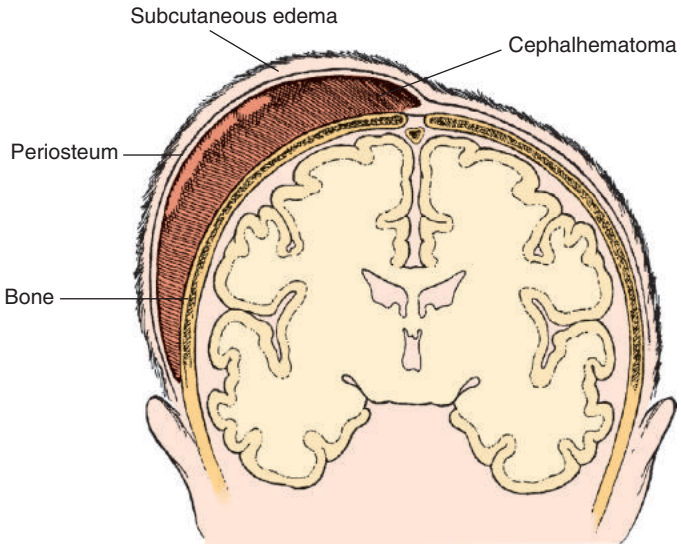
• **Fig. 13.4** A soft, bell-shaped vacuum extractor *(top)* and a rigid, mushroom-shaped vacuum extractor *(bottom).* (Courtesy Cooper Surgical, Trumbull, CT, USA.)

A 1994 metaanalysis of 1375 women in nine trials comparing soft and rigid vacuum extractor cups demonstrated that soft cups were more likely to fail to achieve a vaginal delivery, because of more frequent detachments (odds ratio [OR] 1.65, 95% confidence interval [CI] 1.19 to 2.29), but were associated with fewer scalp injuries (OR 0.45, 95% CI 0.15 to 0.60) and no increased risk of maternal perineal injury.[28] For example, the risk of scalp laceration with the rigid Kiwi OmniCup (Clinical Innovations, Murray, Utah) was reported to be 14.1%, compared with 4.5% using a standard vacuum device ($P = .006$). These and other authors concluded that handheld soft bell cups should be considered for more straightforward occiput-anterior deliveries, and that rigid M cups should be reserved for more complicated deliveries, such as those involving larger infants, significant caput succedaneum (scalp edema), occiput-posterior presentation, or asynclitism.

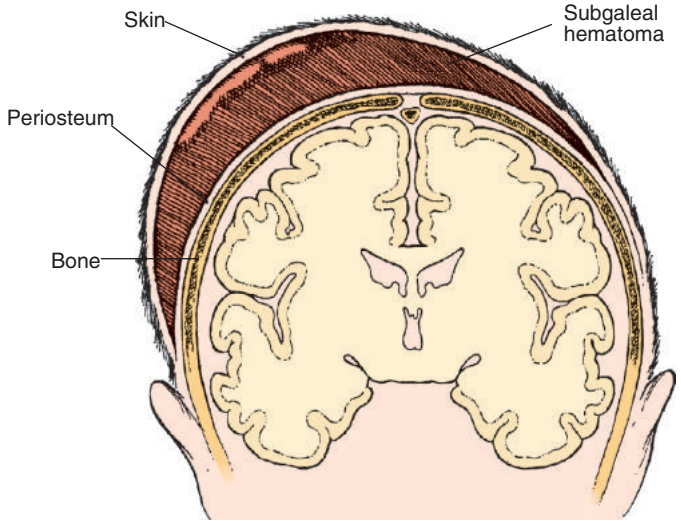
The vacuum extractor is used in the United States but is not free from neonatal injury. In addition to superficial scalp lacerations or abrasions, the use of the vacuum has been associated with cephalhematoma and subgaleal hemorrhages.

Cephalhematoma occurs when the force created by the vacuum results in the rupture of diploic or emissary vessels between the periosteum and outer table of the skull; this fills the potential space that exists between the two with blood. Although cephalhematomas are often cosmetically alarming, they are limited to traveling along one cranial bone, because the firm periosteal attachments limit further extravasation of blood across suture lines. Thus, large amounts of blood cannot usually collect in this space, and serious neonatal compromise from this bleeding is rare. In a randomized trial of continuous and intermittent vacuum application, Bofill et al. examined factors associated with increasing the risk of cephalhematoma; it was found that only asynclitism and traction time were independently related to this complication.[29] There was a clear relationship between increasing time of vacuum application (up to 6 minutes) and cephalhematoma. Interestingly, Hartley and Hitti did not find a significant independent association of neonatal injury with continuous versus intermittent vacuum, or with decreasing gestational age or increasing birth weight. Furthermore, the number of detachments was not correlated with cephalohematoma.[30] These results were further corroborated by Teng et al., who conducted a prospective observational study of 134 vacuum extractions and found that only increasing total duration of vacuum application was associated with neonatal injury.[31] Meta-analysis of randomized trials comparing vacuum to forceps extractions showed that vacuums are more likely to fail to deliver the baby and lead to increased rates of cephalhematoma and retinal hemorrhage (Fig. 13.5).[32]

Subgaleal hemorrhage poses much more risk for the neonate. It occurs when emissary veins above the skull and periosteum rupture, with blood dissecting through the loose tissue underlying the cranial aponeurosis, unimpeded by suture lines. A tremendous amount of blood, potentially the entire neonatal blood volume (approximately 250 to 350 mL), can fill this space and thus can compromise the neonate's condition.[28] Much of the literature about this rare complication of vacuum extraction was published in the 1970s and early 1980s, with few recent studies to detail associated risk factors. Plauche, in his classic paper published in 1979 on vacuum-related neonatal injury, identified only 18 cases of subgaleal hematomas among 14,276 cases of vacuum-assisted births, in contrast to a mean incidence of cephalhematoma of 6%.[33] These morbidity estimates are derived from data that are approximately 30 to 40 years old; nevertheless, Teng et al. noted an incidence of cephalhematoma of 8%, and 0.7% for subgaleal hemorrhage in



• **Fig. 13.5** A cephalhematoma is a hemorrhage that occurs under the periosteum of the skull and is thus confined to a defined space with limited capacity for expansion. (Adapted from Gilstrap LC, Cunningham FG, Hankins GDV, et al. *Operative Obstetrics*. 2nd ed. Stamford, CT: Appleton and Lange; 2002.)



• **Fig. 13.6** A subgaleal hematoma spreads along subcutaneous soft tissue planes and has no immediate barrier to expansion, creating the potential for significant neonatal hemodynamic compromise. (Adapted from Gilstrap LC, Cunningham FG, Hankins GDV, et al. *Operative Obstetrics*. 2nd ed. Stamford, CT: Appleton and Lange; 2002.)

their more recent investigation, which agrees well with Plauche's estimates.[34] The incidence in the United States in the last two decades is unknown as there was no specific Current Procedural Terminology code to distinguish subgaleal hemorrhage from cephalhematoma or other forms of minor scalp injury until after 2010.

A study from Australian investigators evaluated 37 cases of subgaleal hemorrhage at a single tertiary care center accrued over a period of 23 years, with an estimated prevalence of 1.54/10,000 total births. The finding was that this complication occurred most often in primigravidae, and that a large proportion of these infants (89.1% compared with 9.8% of the general control population) had an attempted vacuum extraction (Fig. 13.6).[35] Failed vacuum extraction has been identified as a risk factor for subgaleal hemorrhage when comparing infants born after a successful vacuum extraction (OR 7.3, 95% CI 5.5 to 9.7).[36]

The choice of which instrument to use, forceps or vacuum, is usually determined by the obstetric care provider, depending on the skill level and experience with either method. There have been several randomized trials exploring the instrument used for operative vaginal delivery.[16,37,38] In 2002, the Cochrane Library pooled the results from 10 randomized trials comparing neonatal morbidity and successful vaginal delivery between these two devices. This analysis found that the vacuum was more likely than forceps to fail (OR 1.69, 95% CI 1.31 to 2.19) and was associated with a greater likelihood of cephalhematoma (OR 2.38, 95% CI 1.68 to 3.37) and retinal hemorrhage (OR 1.99, 95% CI 1.35 to 2.98). However, the overall serious complication rate was low, and there was no difference in long-term morbidity between groups.[39]

A significant problem with the use of vacuum extraction is the difficulty some providers experience in abandoning the procedure and opting for cesarean delivery. One of the best cohort studies found that 82% of successful vacuum extractions occurred with the first three pulls.[40] When more than three pulls were necessary, signs of trauma were present in 45% of babies. Without clear progress toward vaginal delivery, as evidenced by progressive descent with each pull, attempts at further vaginal birth are not supported by the literature.

Shoulder Dystocia

Shoulder dystocia is arguably the most dreaded complication in obstetrics. The problem posed by this entity is that although it may be highly anticipated, it is also unpredictable and can appear despite the most cautious measures taken to prevent it. *Shoulder dystocia* is defined as the delivery of the fetal head with an impaction of the fetal shoulder girdle against the pubic symphysis, making subsequent delivery either difficult or impossible without performing auxiliary delivery maneuvers. In some cases, the posterior shoulder may be lodged behind the sacral promontory—a bilateral shoulder dystocia.

Once shoulder dystocia occurs, a series of maneuvers—which have never been tested in a prospective fashion, because of the sporadic and unpredictable nature of this complication—are used to resolve it. The first step to resolving shoulder dystocia is usually the McRoberts maneuver, which consists of hyperflexing the maternal thighs onto the abdomen. This maneuver flattens the pubic symphysis and sacral promontory and facilitates delivery of both the anterior and posterior shoulders. The only prospective randomized study of prophylactic McRoberts maneuver in anticipation of shoulder dystocia showed no benefit to this strategy.[41] If the McRoberts maneuver is unsuccessful, the next intervention is typically applying suprapubic pressure to remove the anterior shoulder from its impacted state behind the pubic symphysis. If these two maneuvers fail, either rotational maneuvers or extraction of the posterior fetal arm are usually tried. The Woods screw rotational maneuver or the Rubin rotational maneuver is used in an attempt to rotate the infant's shoulders to relieve the impaction of the shoulder against the pubic bone. Alternatively, delivery of the posterior arm can be accomplished by inserting the operator's hand into the vagina and grasping the fetal wrist of the posterior arm, then guiding it through the vaginal introitus. It is often necessary to perform an episiotomy to have sufficient room in the vagina to accomplish this maneuver. An alternative maneuver to fetal manipulation is the Gaskin maneuver, where the mother is

moved from the lithotomy position to a hands and knees position. Next, the posterior fetal shoulder, which is now at the 12 o'clock position, is delivered with gentle downward traction. If the dystocia remains unresolved, the Zavanelli maneuver (cephalic replacement) can be performed. After the fetal head is rotated from occiput transverse to occiput anterior, it is flexed and pushed back in the birth canal, and the child is delivered by emergent cesarean section. McRoberts maneuver, suprapubic pressure, or both will relieve shoulder dystocia in more than 50% of instances. Cephalic replacement should be rarely necessary.

Greater attention has been on enhanced practitioner training for shoulder dystocia by means of simulation.[42] Multiple studies have demonstrated multidisciplinary, simulation-based training of shoulder dystocia increases recognition of shoulder dystocia and reduced the incidence of fetal injury and brachial plexus injury.[43–45] At the current time, multidisciplinary team training with a standard management protocol and postevent debrief appears to offer the best strategy to minimize brachial plexus injury once shoulder dystocia has occurred.

The prevalence of shoulder dystocia varies depending on the population studied and the presence of various risk factors known to predispose women to this obstetric emergency. Estimates range from 0.2% to 1% in a low-risk population to 20% in higher-risk groups.[1,27,30,34] Maternal obesity, fetal macrosomia, history of prior shoulder dystocia, and maternal diabetes mellitus are the most common associated variables, but are not of sufficient prognostic power to be clinically useful in predicting shoulder dystocia.[1,34]

Because shoulder dystocia has the potential to cause significant neonatal morbidity and mortality, efforts have been made to predict its occurrence; unfortunately, no clinical guidelines have been clinically tested or proved. Ultrasound examination is commonly used in patients with suspected fetal macrosomia or diabetes to detect large birth weight infants who might be more likely to suffer shoulder dystocia. Third-trimester sonographic examination has an accuracy of ±10% to 15% in the prediction of fetal weight and is thus not highly reliable.[27,28,33] In addition, if ultrasound examination were completely reliable, the fetal weight cutoff that would prompt an elective cesarean section has not yet been determined.

If practitioners use ultrasound to evaluate estimated fetal weight (EFW), then two strategies have been suggested to avoid shoulder dystocia: labor induction or cesarean section. A recently published randomized clinical trial in France based on ultrasound evaluation of EFW has clarified the risks and benefits of labor induction to avoid shoulder dystocia and subsequent fetal injury.[45] In this trial 800 patients with EFWs greater than the 95th percentile for gestational age were randomized to either induction of labor or observation at 37 to 39 weeks gestation. At study conclusion, shoulder dystocia was reduced from 8% to 4% (OR 0.47, CI 0.26 to 0.86). Predetermined composite of fetal injury was also reduced from 6% to 2% (CI 0.15 to 0.71). There were, however, no brachial plexus injuries or deaths in either group. In addition, the occurrence of cesarean delivery was similar in both groups (28% induced versus 32% expectant management: OR 0.89, CI 0.72 to 1.09). Currently in the United States, labor induction prior to 39 weeks is an adverse quality metric and has financial consequences for both the hospital and obstetric provider. Whether this indication will gain acceptance as an exception to this quality metric remains to be determined.

Rouse et al. (1996)[46] elaborated further on the use of ultrasound to prevent shoulder dystocia. In their decision analysis, they showed that if one chose to perform an elective cesarean section for all women without diabetes but who had sonographically predicted macrosomia (EFW >4000 g), 2345 cesarean sections would need to be performed to prevent one permanent brachial plexus injury. If the 4500-g cutoff were selected, 50% more cesarean deliveries would be needed to prevent one permanent brachial plexus injury. In the mother with diabetes, if one chooses a cutoff of 4500 g or greater, 443 cesareans would need to be done to prevent one permanent injury, a trade-off that most practitioners now believe is acceptable. The conclusions from this decision analysis have been borne out by several other investigators who have established that the risk of nerve injury certainly increases with rising birth weight, but the large number of macrosomic infants who have a normal, spontaneous vaginal delivery without sequelae does not justify a policy of elective cesarean for macrosomia alone in a nondiabetic population.[37,47–49] Some believe that an EFW of greater than 5000 g provides an acceptable cutoff in nondiabetic patients to offer elective cesarean.

The ideal management of shoulder dystocia would minimize the occurrence of permanent fetal injury or death. According to one systematic review, the risk of permanent brachial plexus impairment, if recognizable at birth, was 15% to 20%.[49] In another study, a prospective investigation evaluated the natural history of recovery following a birth-related brachial plexus injury of infants referred to a tertiary care, multidisciplinary neurologic center. Enrollment required identification of injury in the newborn period, initial evaluation at the center between 1 and 2 months of age, and lack of antigravity movement in the shoulder or elbow persisting until 2 weeks of age. In this group of children subject to ascertainment bias (as those injuries resolving before 2 weeks of age would not have been included in the results), complete neurologic recovery was documented in 66%, 20% had minimal impairment, and 14% had persistent, severe weakness.[50]

At present there is no universally accepted method to prevent shoulder dystocia. A previous study demonstrated that operative vaginal delivery, especially vacuum delivery, of a fetus weighing greater than 4 kg could increase the risk of shoulder dystocia.[51] Thus it is prudent to consider avoiding difficult forceps or vacuum delivery if a patient is thought to have an infant weighing more than 4000 g, especially if she has diabetes or a past history of shoulder dystocia.

Prospective studies have shown that brachial plexus injury is related to the extent of provider-applied traction to the fetal head and neck.[52] However, there is a large variation in the provider assessment of traction used in deliveries of infants with brachial plexus injuries recognizable at birth.[52] Several studies evaluating simulated shoulder dystocia measured traction forces applied by the birth attendant.[53–55] Provider experience, gender, and body habitus were not associated with the amount of force applied during delivery. Family medicine providers applied more force than obstetrics/gynecology providers. A significant number of all providers (19/47, 40%) applied greater than 100 newtons to the fetal neck, a suggested but not proven threshold for brachial plexus injury.[55]

Currently, delivery training emphasizes that only axial traction be applied to the fetal neck, which should minimize stretch on the brachial plexus during delivery. Unfortunately, some infants are injured with minimal or no force being applied to the fetal neck, which suggests that some injuries occur as a result of a combination of labor and the standard techniques used to deliver all infants, and are therefore not provider-dependent.[55]

The documentation of the events surrounding shoulder dystocia is important, as is the discussion of the current and future

status of an infant delivered with a birth injury after shoulder dystocia. The recurrence risk of shoulder dystocia is approximately 10% to 15%, which is similar to the risk of shoulder dystocia with a known fetal weight of 4500 g. Both obstetric and pediatric providers should debrief a shoulder dystocia event immediately after the delivery. Regardless of whether fetal injury has occurred, it is optimal for both providers to discuss the delivery events and subsequent newborn treatment plans if necessary with the mother before discharge. The diagnosis of shoulder dystocia is an obstetric diagnosis made at the time of delivery, which is based upon delivery findings as defined above. There is a published update on the acute management of shoulder dystocia that can be reviewed for those readers interested in further detail on this topic.[56]

Finally, it is important to note that **shoulder dystocia is not a diagnosis that can or should be made by the pediatric team or based on observations of the neonate after delivery**.

Vaginal Breech Delivery

Three to four percent of all infants at term will present in the breech position at the time of delivery.[56,57] There are three main types of breech presentations as follows:

1. Footling breech with one (single footling) or both (double footling) lower extremities presenting.
2. Frank breech with both thighs flexed, but legs extended.
3. Complete breech with both thighs and legs flexed.

The vaginal delivery of a singleton footling breech carries attendant risks of cord prolapse and head entrapment, and the consensus among obstetricians is that this presentation should be delivered by cesarean section (unless the fetus is a second twin: see later discussion on Twin Delivery). The frank breech has a lower risk of these adverse events occurring and thus could potentially be delivered vaginally. The complete breech presentation will convert to frank or footling during labor, and the appropriate management scheme for delivery depends on which leading fetal part will descend.

The mechanics of vaginal breech delivery are as follows. The frame of reference for the presenting part is the sacrum (i.e., sacrum anterior, posterior, or transverse). In the absence of urgent fetal indications, the singleton breech is allowed to deliver passively with maternal expulsive efforts until the infant has been delivered past the umbilicus. At this point the legs are gently reduced, and the trunk and body are gently rotated to bring the sacrum anteriorly. With the appearance of the scapula below the maternal symphysis, the arms are then delivered by gently sweeping them across the chest. Every effort is then made to keep the neck from extending during the delivery of the after-coming head; this is accomplished during delivery of the body by an assistant exerting suprapubic pressure on the fetal head to keep it flexed. Once the body has delivered, the delivery of the head is accomplished by either the Mauriceau–Smellie–Veit maneuver or with Piper forceps directly applied to the fetal vertex. In the Mauriceau–Smellie–Veit maneuver, one hand extends along the posterior neck and occiput and applies pressure to prevent hyperextension, while the other hand gently applies downward traction against the maxilla to flex the head forward as the head is delivered.

The feasibility of vaginal breech delivery and its safety have been the subject of much debate throughout the past half century. With the advent of safe, expedient cesarean delivery in the United States, many obstetricians have favored cesarean section as the method of choice for management of the breech presentation at term. However, even in institutions with availability for expedient cesarean deliveries, there are situations such as precipitous delivery, out-of-hospital delivery, severe fetal anomalies, fetal death, or a mother's preference for vaginal birth that make it essential for clinicians to maintain the skills needed for a vaginal breech delivery. The literature to support this point of view has produced conflicting conclusions, and its interpretation is consequently difficult. Unfortunately, there are only two randomized trials that have explored the question of which delivery route is best for the term singleton frank breech fetus.[58,59]

Collea et al. (1980)[58] randomized 208 women with a singleton frank breech presentation at term to vaginal delivery or cesarean section; they found a low overall risk of permanent birth injury or neonatal morbidity in the vaginal delivery group, although the incidence of neonatal morbidity was higher in the vaginal delivery group. Of note, a majority of conditions listed as morbidities (hyperbilirubinemia, meconium aspiration, mild brachial plexus injury) had resolved by hospital discharge. In addition, decreased neonatal morbidity with cesarean section was offset by a striking increase in higher maternal risk in the operative group. It must be remembered that this study was published in 1980, and standards of maternal and neonatal care have changed dramatically since then.

Hannah et al. (2000)[59] published a large, multicenter, multinational trial that randomized 2088 women at 121 centers in 26 countries to planned vaginal birth or planned elective cesarean section. Criteria for enrollment were frank or complete term singleton breech with no evidence of fetal macrosomia. The investigation was halted when preliminary results showed that there were significantly increased neonatal mortality and severe morbidity in the vaginal breech arm compared with the cesarean arm (5.0% vs. 1.6%). This conclusion was not altered by the experience of the delivering obstetrician or maternal demographic factors such as parity and race. Maternal morbidity between both groups was comparable. The difference in outcome was even more striking in countries such as the United States, with a low national perinatal mortality rate (5.7% vs. 0.4%).

Criticisms of this study are that the patients enrolled did not have computed tomography (CT) pelvimetry performed, which in some institutions is standard practice before considering a vaginal breech delivery. Furthermore, subjects did not have continuous fetal monitoring, but rather intermittent fetal auscultation every 15 minutes. In addition, the capability of various centers to perform emergent cesarean sections differed markedly, and this could have potentially affected the neonatal morbidity and mortality rate. Nevertheless, it is unlikely that another large study will ever be performed to examine this issue, and the ultimate results are difficult to dispute given the excellent study design and adequate sample size.

The Term Breech Trial Collaborative Group published outcomes of children after planned cesarean birth versus planned vaginal birth for breech presentation at term. In this analysis they followed 923 of the 1159 enrolled subjects (79.6%) to 2 years of age. The risk of death or neurodevelopmental delay was no different between the planned cesarean section versus the planned vaginal groups (14 children [3.1%] vs. 13 children [2.8%]; RR 1.09, 95% CI 0.52 to 2.30).[59]

In addition, there are several large retrospective series describing neonatal outcomes with the vaginal approach, most of which suggest that vaginal delivery in carefully selected patients carries a low risk of long-term neonatal morbidity and mortality.[28,34,60–62]

A recent metaanalysis assessing the risks of planned vaginal breech delivery versus planned cesarean section for term breech birth included studies between 1993 and 2014 and included 27 articles with a total sample size of 258,953 women and reported the relative and absolute risks of perinatal mortality and morbidity in relation to mode of delivery. They reported that the absolute risks of perinatal mortality, fetal neurologic morbidity, birth trauma, a 5-minute Apgar score less than 7, and neonatal asphyxia in the planned vaginal delivery group were 0.35%, 0.7%, 0.7%, 2.4%, and 3.3%, respectively. They concluded that perinatal mortality and morbidity in planned vaginal breech delivery was significantly higher than with planned cesarean delivery, which is consistent with the aforementioned authors.[63] The truly interesting point raised by all these investigators is that, aside from the issue of cesarean versus trial of labor, singleton breech infants regardless of mode of delivery have an increased risk of morbidity compared with their vertex counterparts. Breech infants had higher incidences of neonatal intensive care unit (NICU) admissions, eventful hospital courses, hip dislocation, and traumatic morbidity (soft tissue trauma, fracture, facial nerve paralysis, and brachial plexus palsy). Thus both the obstetrician and pediatrician must be aware that the infant in breech presentation requires careful attention upon birth for the presence of these potential factors. Furthermore, the risk of developmental hip dysplasia is increased in infants born in breech presentation. The American Academy of Pediatrics has a clinical practice guideline for early detection of developmental dysplasia of the hip in these infants.[64]

Diro et al. (1999)[60] evaluated 1021 term singleton breech deliveries occurring at their institution over a 4-year period. Infants with a clinically adequate pelvis and frank breech presentation with an EFW less than 3750 g were allowed a trial of labor. They found an overall cesarean rate of 85.6%; however, for women allowed to deliver vaginally, the success rate, defined as vaginal delivery, was 50% (19 of 38 patients) for nulliparous women and 75.8% (116 of 153 patients) for multiparous women. The length of NICU stay was higher for the group delivered vaginally (17.4% vs. 12.1%; $P = .036$), but major morbidities between operative and vaginal delivery were not significantly different. Long-term outcome was not evaluated. Of note, the women in this cohort had pelvic dimensions evaluated clinically, and not by x-ray or CT pelvimetry, as has been performed in other studies.

Norwegian investigators examined the neonatal outcomes of 30,681 singleton term breech deliveries, between 1991 and 2011, identified using the Medical Birth Registry in Norway. They compared planned vaginal deliveries with planned cesarean deliveries across two time periods: January 1991 to November 2000 and November 2000 to December 2011. They identified an increase in cesarean delivery from 34.4% to 51.3% across these study periods. They also found that early neonatal mortality in the first 0 to 6 days after delivery declined from 0.10% to 0.04% ($P = .04$). During the second time period, 30.7% of term breech presentations delivered vaginally. There were eight deaths in the planned vaginal and four in the planned cesarean groups, although the difference was not statistically significant (OR 2.11, 95% CI 0.64 to 7.01). Neonatal outcomes were significantly worse in the planned vaginal delivery groups across both time periods.[62]

The delivery of the vaginal breech is an emotional issue; physicians trained in the art of the vaginal breech delivery maintain that for an appropriately selected candidate, vaginal breech delivery has acceptable neonatal risk and has the advantage of sparing the mother significant operative morbidity. Proponents of cesarean delivery further state that the level of resident training in the art of the singleton vaginal breech delivery has markedly diminished, with most graduating senior residents having performed few such births. Nonetheless, many practitioners will be required to assist in vaginal birth of a breech infant in unplanned situations. The acquisition of skills necessary to competently perform this procedure may need to be learned and practiced with simulation-based training, because the opportunities for training in most residency programs are few. ACOG has recommended that the decision regarding the mode of delivery should depend on the experience of the healthcare provider. However, cesarean delivery will be the preferred mode of delivery for most physicians because of the diminishing expertise in vaginal breech delivery.

Multifetal Delivery

Twin births account for 3% of births in the United States.[65] With the advent of assisted reproductive technologies, the incidence of multifetal pregnancies has increased, particularly higher-order multiples. The incidence of twin gestations in patients undergoing in vitro fertilization is approximately 20% in the United States,[66] and it is 1% to 3% for higher-order multiples. However, the frequency of twin gestation in the United States has most recently decreased from 2018 (32.6/1000 births) to 2019 (32.1/1000 births).[65] Of twin gestations, 80% are dizygotic and 20% are monozygotic. Twin gestations account for 17% of preterm births and approximately 25% of infants of low birth weight and very low birth weight. The perinatal mortality rate of twins is sevenfold that of singletons, of which a small fraction is due to problems associated with delivery. The mode of delivery for twins is well delineated by several studies, and the issues surrounding the choice of vaginal birth versus cesarean delivery are outlined in the following sections.[67]

Twin Delivery

Vertex–Vertex

Approximately 40% of twin gestations will be in a vertex–vertex presentation prior to delivery.[68] It is almost universally accepted that the appropriate method of delivery is vaginal if both twins are vertex. The first infant is delivered like a singleton infant. The second infant is delivered in a similar fashion, but care must be taken not to rupture membranes before the head is well engaged, because this may increase the risk of cord accident. Of note, the delivery of the second twin does not necessarily occur immediately after the first.

Vertex–Nonvertex

Vertex–nonvertex presentation occurs 38.4% of the time prior to delivery.[68] The first twin is usually delivered vaginally. The options for delivery of the second twin are as follows: cesarean section, breech extraction, or attempts at external cephalic version and vertex delivery of the second twin if successful. The optimal delivery choice for the second twin has been the subject of much controversy. Many obstetricians claim that cesarean section is the safest approach to the nonvertex twin,[69] whereas others claim that vaginal delivery affords equivalent neonatal outcome, sparing the mother from an unnecessary surgical procedure.[70] There is only one randomized trial including 60 vertex-nonvertex twin deliveries of planned vaginal delivery with plan for breech extraction of the second twin versus cesarean section in this situation. Maternal morbidity and hospital stay were increased in the surgical group, but there were no differences in neonatal outcome.[70]

Hogle et al. (2003)[71] performed a metaanalysis to determine whether a policy of planned cesarean or planned vaginal birth is preferable for twins. They found only four studies with a total of 1932 infants that met their inclusion criteria. There were no significant differences in maternal morbidity, perinatal or neonatal mortality, or neonatal morbidity between the two groups. They did find significantly fewer low 5-minute Apgar scores in the planned cesarean group, principally because of a reduction among breech first twins. They concluded that, if twin A is vertex, "there is no evidence to support planned cesarean section for twins." In contrast, Smith et al. (2005)[67] published a retrospective cohort study of 8073 twin births after 36 weeks gestation in Scotland between 1985 and 2001. There was a death of either twin in two of 1472 (0.14%) deliveries by planned cesarean and in 34/6601 (0.52%) deliveries by other means ($P = .05$; OR for planned cesarean 0.26, 95% CI 0.03 to 1.03). They concluded that planned cesarean may reduce the risk of perinatal deaths of twins at term by 75% despite the lack of statistical significance in outcomes between the two groups. The data also suffer from the fact that 30 of the 36 deaths were in second twins, and there were no data regarding fetal presentation.[72]

There are several large cohort studies examining the issue of feasibility and safety of total breech extraction of the nonvertex second twin. These studies have almost unanimously reached the similar conclusion that the neonatal outcome for nonvertex second twins delivered vaginally is similar to the vertex first twin, but is not statistically different from those second twins delivered by cesarean section, regardless of birth weight or gestational age.[1,27,28,30,33,34] Hartley and Hitti (2005)[30] conducted a retrospective analysis of birth certificates and fetal and infant death certificates for 5138 twin pairs selected from those born in Washington State from 1989 to 2001. They concluded that if prompt vaginal delivery of twin B does not occur, the benefits of vaginal delivery for twin A might not outweigh the risks of distress and low Apgar scores in twin B and vaginal plus cesarean delivery for the mother.[30]

The available body of evidence supports attempts at vaginal delivery of the nonvertex second twin. Of course, the responsible obstetrician must choose a management plan most compatible with his or her experience and training. For those not versed in the techniques of successful vaginal breech extraction, cesarean delivery might be a more prudent plan. As in the case of the singleton vaginal breech, simulation training may play a role in the acquisition and maintenance of skills for safe vaginal breech birth.[55]

In addition to cesarean delivery and total breech extraction, there is the option of external cephalic version (i.e., attempting to turn a nonvertex fetus to vertex by abdominal manipulation). Studies have shown that this option is associated with a higher failure rate at successful vaginal delivery and other complications (such as cord accident and malpresentation not amenable to vaginal delivery) when compared with primary breech extraction or cesarean section.[28,44]

If the vaginal approach is chosen, once the first twin is delivered the obstetrician inserts a hand into the uterine cavity and, under sonographic guidance if necessary, finds the feet of the second twin. Once the feet are firmly grasped, they are brought down into the vagina, and the membranes are then ruptured. Traction is applied to the fetus along the pelvic curve; once the body has been delivered through the introitus, delivery of the arms, shoulders, and after-coming head proceed in a fashion similar to that of a singleton breech.

Nonvertex–Nonvertex

The most uncommon combination for presenting position at birth is nonvertex–nonvertex, which occurs 19.1% of the time.[68] Because of the theoretical risk of interlocking twins, as well as the recent data showing the greater morbidity for the singleton vaginal breech (see the preceding discussion), cesarean section is the recommended choice for delivery of the nonvertex–nonvertex presentation.

Monochorionic, Monoamniotic Twins

Monochorionic, monoamniotic twins share a single intraamniotic space and thus have a higher risk of cord and extremity entanglement during delivery. It is commonly accepted that the optimal mode of delivery is a planned cesarean section before labor ensues.

Higher-Order Multiple Gestations

Most perinatologists would suggest cesarean delivery for triplets and higher-order multiples.[48] Although this practice is common, the data mandating cesarean delivery are far from conclusive.

A Dutch study compared the outcomes of triplets delivered vaginally and abdominally at two institutions.[50] One hospital favored cesarean section, whereas, at another, trial of labor was offered to all appropriate candidates. The success of vaginal delivery was relatively high (34 of 39 women [87%]). There was a higher incidence of neonatal mortality and postdelivery depression (as estimated by Apgar score) in the hospital favoring operative delivery compared with the vaginal delivery group. The biases inherent in this study are obvious, although the reported findings have been corroborated by several other reports from single institutions that offer trial of vaginal delivery to triplet gestations.[16,17,37] Vintzileos et al. (2005)[73] attempted to estimate the risks of stillbirth and neonatal and infant deaths in triplets, according to mode of delivery; they used the "matched multiple birth" data file that was composed of triple births that were delivered in the United States during 1995 through 1998 and found that 95% of all triplets were delivered by cesarean delivery. Vaginal delivery (all vaginal) was associated with an increased risk for stillbirth (RR 5.70, 95% CI 3.83 to 8.49) and neonatal (RR 2.83, 95% CI 1.91 to 4.19) and infant (RR 2.29, 95% CI 1.61 to 3.25) deaths. They concluded that cesarean delivery of all three triplet fetuses is associated with the lowest neonatal and infant mortality rate and that vaginal delivery among triplet gestations should be avoided.[73] Most of the data on triplet births consist of small cohort studies and not randomized trials, and the possibility of type II or beta errors exists in the interpretation of many of these studies.[27,33] Thus, delivery of triplet gestations vaginally, while not an unreasonable approach, has nearly disappeared from the practice of modern obstetrics in favor of routine cesarean delivery. Currently, quadruplets and other higher-order multiples are usually delivered by cesarean section.[74]

Vaginal Birth After Cesarean: Neonatal Concerns

The overall cesarean delivery rate in the United States increased 60% from 1996 to 2009, from 20.7% to 32.9%. Since 2009, the rate has declined slightly to 31.7% in 2019, but nearly one-third of births continue to be delivered by cesarean each year.[65] Surgery carries the maternal risks of increased blood loss, prolonged hospital stay, and longer recovery time compared with vaginal delivery.

During the 1980s to 1990s, efforts were made to encourage women to attempt a trial of labor after a prior cesarean delivery because the success rates of a VBAC are reasonable, varying from 60% to 80%, depending on the indications for the prior cesarean delivery.[75]

Whereas VBAC rates remained relatively high in the United Kingdom at 33% (range 6% to 64%), VBAC rates in the United States underwent a dramatic decrease, from a high of 28.3% in 1996 to less than 1% in 2006.[76,77] This decrease occurred primarily because VBAC can result in uterine dehiscence, in which the prior scar asymptomatically separates or, more seriously, uterine rupture occurs. In 2010, the Eunice Kennedy Shriver National Institute of Child Health and Human Development and the Office of Medical Applications of Research of NIH convened a Consensus Development Conference that sought to address the national trend away from VBAC in the United States. The conference highlighted the relative efficacy and safety VBAC and concluded that a trial of labor may be a reasonable option for appropriately selected patients.[78] As a result, VBAC rates in the United States have continued to rise in recent years, with reports as high as 13.3% in 2018, a 7% increase from 2016.[79]

A full discussion of VBAC, the studies supporting its safety, and the controversies surrounding its feasibility is beyond the scope of this chapter, and the interested reader is urged to consult *Williams Obstetrics*, 25th ed., for further details. This discussion instead focuses on neonatal risks from VBAC, particularly from its most dreaded complication, uterine rupture. There are no randomized controlled trials comparing neonatal outcomes among women undergoing a trial of labor after previous cesarean delivery versus an elective repeat cesarean delivery.

Observational studies have uniformly shown a risk of uterine rupture with VBAC on the order of 0.5% to 1%.[27,77] Feingold et al. (1988)[27] performed a large retrospective study evaluating 20,095 women with a history of prior cesarean delivery and found the following risk of uterine rupture:

- 0.16% if the woman elected for a repeat cesarean delivery
- 0.52% if VBAC occurred as a result of spontaneous labor
- 0.77% if labor was induced without prostaglandins
- 2.5% if labor was induced with prostaglandins

Thus, VBAC carries the lowest risk if labor is spontaneous. However, it is currently a well-accepted practice to induce and augment labor during a VBAC using mechanical dilation and/or oxytocin as the risk of uterine rupture remains less than 1%. The use of prostaglandins is not recommended during any portion of the labor process in patients with a prior uterine scar because of the increased risk of uterine rupture.[80]

There are few large, well-designed studies specifically evaluating neonatal rather than maternal outcomes after VBAC. Kamath et al.[81] performed a retrospective cohort study of 672 women who had one prior cesarean section and then underwent a trial of labor. They found that infants born by cesarean delivery had higher rates of admission to the NICU (9.3% compared with 4.9%) and higher rates of oxygen supplementation for delivery room resuscitation (41.5% compared with 23.2%).

Yap et al. (2001)[82] retrospectively evaluated 38,027 deliveries occurring at a single tertiary care institution and found 21 cases of uterine rupture; 17 occurred after a history of a prior cesarean delivery. The two neonatal deaths that occurred were a result of either prematurity (23-week-gestation fetus) or multiple congenital anomalies. All liveborn infants were discharged from the hospital without neurologic sequelae. Thus, the ultimate neonatal outcome despite uterine rupture was favorable. However, all deliveries occurred in a tertiary care institution with readily available obstetric anesthesiologists, neonatologists, and obstetricians. Most deliveries after diagnosis of rupture occurred within 26 minutes.

A third group of investigators retrospectively identified 99 cases of uterine rupture occurring over a period comprising 159,456 births.[28] Thirteen of these ruptures occurred before the onset of labor. There were six neonatal deaths, but four of these occurred in women with uterine rupture at admission and thus were never given a trial of labor. There were five cases of perinatal asphyxia, but once again it is not detailed whether these occurred in women allowed a trial of labor or in those who had ruptured on presentation to the hospital. Moreover, many of these women had an undocumented prior scar, which in some institutions would warrant an elective repeat cesarean section. The aforementioned study evaluating 20,095 women with a prior cesarean delivery and their subsequent risk of rupture found a neonatal mortality of 5.5%.[83] However, because this was a population-based study, it was not specified whether these deliveries occurred in tertiary care institutions with the capability of performing emergent operative rescue procedures in the event of uterine rupture.

A summary document was published by the Agency for Healthcare Research and Quality in 2010 on the infant benefits and harms after VBAC using relevant studies from 1966 to 2009.[84] The composite neonatal morbidity from elective repeat cesarean delivery compared to trial of labor after previous cesarean delivery in term infants demonstrated: antepartum stillbirth 0.21% vs 0.1%; intrapartum stillbirth 0% to 0.004% vs. 0.01% to 0.04%; hypoxic ischemic encephalopathy 0% to 0.03% vs. 0.089%; neonatal mortality 0.06% vs. 0.11%; NICU admission 1.5% to 17.6% vs. 0.8% to 26.2%; and respiratory morbidity 2.5% vs. 5.4%. In addition, in comparison to an elective repeat cesarean delivery, there is evidence that vaginal delivery after a previous cesarean delivery is associated with greater risks of long-term neurodevelopmental impairment and upper-extremity motor impairment, caused, respectively, by greater risks of perinatal hypoxic-ischemic encephalopathy and brachial plexus injury.[85] Available information does not provide a precise estimate of the relative risks for infants delivered after a trial of labor versus elective cesarean delivery.

It is appropriate to offer women VBAC, but they must be counseled carefully about the potential risk of uterine rupture. Careful documentation of the informed consent and labor management must be completed. When uterine rupture occurs, timely delivery is essential. Among 36 cases of uterine rupture, it was demonstrated that umbilical cord pH levels and 5-minute Apgar scores were normal in neonates delivered within 18 minutes after suspected uterine rupture compared to the occurrence of poor long-term outcomes when the decision-to-delivery times was greater than 30 minutes.[86] Moreover, VBAC should occur in delivery facilities capable of rapidly performing an emergent cesarean section because this improves the likelihood of minimizing adverse neonatal sequelae.[80]

Umbilical Cord Abnormalities

The term *cord accident* usually refers to adverse events affecting the fetus that occur as a result of an umbilical cord abnormality that leads to obstruction of blood flow through the umbilical cord and ultimately stillbirth. This heterogeneous term encompasses umbilical cord prolapse, in which the cord delivers through the cervix and compression by a fetal part results in a significantly increased

risk of asphyxia; it also includes such entities as compromised fetal microcirculation, cord entrapment, knots, torsions, and strictures which can lead to fetal compromise.

The incidence of in utero cord accidents is not clearly known, because the diagnosis is often one of exclusion after an in utero fetal demise. However, in one retrospective review of 496 stillbirths, 94 cases were associated with umbilical cord abnormalities: 45 (48%) had compromised fetal microcirculation; 27 (29%) had cord entrapment; 26 (27%) had knots, torsions, or stricture; and 5 (5%) had cord prolapse.[87]

Because cord prolapse is the only cord abnormality where prompt intervention can prevent fetal death, it will be the focus of the rest of this discussion. The standard of care in cases of cord prolapse is to proceed immediately with cesarean section as quickly as possible while an assistant elevates the presenting fetal part with a hand in the vagina to prevent compression of the umbilical cord. It is also of paramount importance to have appropriate pediatric support available at the time of delivery because the newborn is likely to be depressed and require resuscitation. One large, population-based study compared 709 cases of cord prolapse occurring among 313,000 deliveries to matched controls and found that low birth weight, male sex, multiple gestations, breech presentation, and congenital anomalies all increased the risk of umbilical cord prolapse.[88] Not surprisingly, cord prolapse was associated with a high neonatal mortality rate (10%), which was reduced if cesarean rather than vaginal delivery was performed.

Obstetric Analgesia and Anesthesia

EMILY E. SHARPE, MARK A. ROSEN, AND MARK D. ROLLINS

KEY POINTS

- Labor results in significant pain for many women that is individualized, dynamic, and unpredictable.
- Although the effects of obstetric analgesia and anesthesia on the fetus and neonate are typically benign, there is potential for adverse neonatal effects.
- During pregnancy, labor, and delivery, women undergo fundamental changes in anatomy and physiology that affect all organ systems, significantly alter pharmacokinetic and pharmacodynamics responses to many drugs commonly used in anesthesia, and have important implication for anesthetic administration.
- Opioids are commonly used systemic medications for labor and delivery but are administered with limitations on both dose and timing because they readily cross the placenta and are associated with a risk of neonatal respiratory depression in a dose-dependent fashion.
- Neuraxial analgesia (epidural, spinal, combined spinal-epidural, and dural puncture epidural techniques) is the most widely used and most effective method for labor analgesia. Epidural labor analgesia is a catheter-based technique that provides continuous analgesia during labor using administration of medication into the epidural space. Neuraxial analgesia does not increase the risk for cesarean delivery, and with use of more current techniques is no longer associated with an increased use of instrumented vaginal delivery (forceps or vacuum).
- For the patient without an epidural catheter, spinal anesthesia is the most common regional anesthetic technique used for cesarean delivery. Use of general anesthesia for cesarean delivery is typically reserved for situations where neuraxial anesthesia is contraindicated or emergent delivery is needed.

Labor results in significant pain for many women that is individualized, dynamic, and unpredictable. Modern techniques for labor analgesia and obstetric anesthesia, essential for operative and cesarean delivery, provide an effective and safe alternative to women seeking reduced pain with childbirth. Although the effects of obstetric analgesia and anesthesia on the fetus and neonate are typically benign, there is potential for adverse neonatal effects. This chapter introduces some of the scientific background and clinical techniques used in providing obstetric analgesia and anesthesia, as well as some of the potential maternal and neonatal complications.

Anatomy of Labor Pain

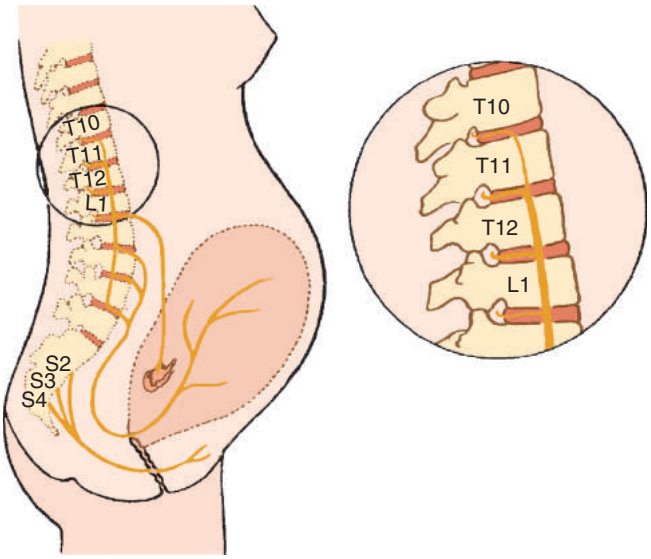
Labor is a continuous process divided into three stages. The first stage of labor begins with cervical dilation accompanied with regular uterine contractions. The second stage of labor begins when the cervix is fully dilated and concludes with the delivery of the neonate. The third stage ends with the delivery of the placenta. Contraction of the uterus, dilation of the cervix, and distention of the perineum cause pain during labor and delivery. Somatic and visceral afferent sensory fibers from the uterus and cervix travel with sympathetic nerve fibers to the spinal cord (Fig. 14.1). These fibers pass through the paracervical tissue and course with the hypogastric nerves and the sympathetic chain to enter the spinal cord at T10 to L1. During the first stage of labor (cervical dilation), the majority of painful stimuli are the result of afferent nerve impulses from the lower uterine segment and cervix, as well as contributions from the uterine body causing visceral pain (poorly localized, diffuse, and usually described as "a dull but intense aching"). These nerve cell bodies are located in the dorsal root ganglia of levels T10 to L1. During the second stage of labor (pushing and expulsion), afferents innervating the vagina and perineum cause somatic pain (well localized and typically described as "sharp"). These somatic impulses travel primarily via the pudendal nerve to dorsal root ganglia of levels S2 to S4. Pain during this stage is caused by distention and tissue ischemia of the vagina, perineum, and pelvic floor muscles, associated with descent of the fetus into the pelvis and delivery. Neuraxial analgesic techniques that block levels T10 to L1 during the first stage of labor must be extended to include S2 to S4 for effective pain relief during the second stage of labor.

Changes in Maternal Physiology and the Implications

During pregnancy, labor, and delivery, women undergo fundamental changes in anatomy and physiology. These alterations are caused by changing hormonal activity, biochemical shifts associated with increasing metabolic demands of a growing fetus, placenta, and uterus, and mechanical displacement by an enlarging uterus.[1–3]

Maternal Circulatory System

Cardiac output increases during pregnancy, reaching an output 50% greater than the prepregnant state by the third trimester. The increase in cardiac output is due in part to both increases in heart rate (15% to 25%) and stroke volume (25% to 30%).[4] During labor, maternal cardiac output increases during the first and second stages, reaching an additional 40% above prelabor values in the second stage.[5] Each uterine contraction results in the autotransfusion of 300 to 500 mL of blood back into the maternal



• **Fig. 14.1** Parturition pain pathways. Nerves that accompany sympathetic fibers and enter the neuraxis at the T10, T11, T12, and L1 spinal levels carry afferent pain impulses from the cervix and uterus. Pain pathways from the perineum travel to S2, S3, and S4 via the pudendal nerve. (From Miller RD, Pardo MC. Basics of Anesthesia. 6th ed. Philadelphia: Elsevier Saunders; 2011, Fig. 33.3.)

central circulation. The greatest increase in cardiac output occurs immediately after delivery, when values can increase as much as 75% above predelivery levels. This abrupt increase in cardiac output is secondary to the loss of aortocaval compression, autotransfusion from the contracted uterus, and decreased venous pressure in the lower extremities.[6]

Maternal systemic vascular resistance decreases 20% in normal pregnancy by term gestation. This results in a 5% to 20% decrease in systemic blood pressure starting near mid-gestation with diastolic pressures decreasing more than systolic. Reduced cardiac output and hypotension can occur when a pregnant woman is in the supine position because of aortocaval compression by the gravid uterus. Significant supine aortoiliac artery compression occurs in 15% to 20% of term pregnancies and vena caval compression is universal, often as early as 13 to 16 weeks gestation. Therefore, supine positioning is avoided during anesthetic administration in the second and third trimesters. Vena caval compression also contributes to lower extremity venous stasis and increased risk of thromboembolus. Significant lateral tilt is typically employed during cesarean delivery as 30 degrees is often required to relieve venacaval compression.[7] This improves cardiac output and preserves uterine blood flow. Because neuraxial blockade can impair compensatory increases in sympathetic tone that facilitates maintenance of blood pressure during supine positioning, maternal tilt positioning is also frequently employed with administration of neuraxial labor analgesia to help preserve uterine blood flow.

Physiologic (dilutional) anemia of pregnancy occurs as a result of a greater increase in plasma volume (45% to 55%) than in red blood cell volume (20% to 30%) by term gestation. Average blood loss at delivery—approximately 500 mL for vaginal delivery and 1000 mL for cesarean delivery—is well tolerated because of this expanded blood volume and autotransfusion (about 500 mL) from the contracted uterus after delivery.[1]

Maternal Airway and Respiratory Systems

Beginning early in pregnancy, maternal capillaries become engorged causing mucosal edema and tissue friability throughout the pharynx, larynx, and trachea. These changes can make ventilation by mask, laryngoscopy, and tracheal intubation more challenging. In addition, the presence of comorbidities such as preeclampsia, upper respiratory tract infections, and active pushing with increased venous pressure during the second stage of labor further exacerbate airway tissue edema.[8]

At term, minute ventilation is increased approximately 45% to 50%, as a result of an increase in tidal volume and a small increase in respiratory rate. In addition, oxygen consumption is increased by more than 20%, and functional residual capacity is decreased by 20%. The combination of these changes (increased oxygen consumption and decreased oxygen reserve) result in a state promoting rapid desaturation during periods of apnea. The changes in both airway and respiratory physiology during pregnancy make ventilation and intubation more difficult and increase the potential for complications.[9] A multi-institutional database of adverse obstetric anesthesia events noted rates of failed maternal intubation for cesarean delivery were approximately 1:533, although none of these 10 failed obstetric intubations resulted in maternal mortality.[10]

Maternal Gastrointestinal System

The gravid uterus increases intragastric pressure and causes the stomach and esophagus to reposition, resulting in decreased competence of the esophageal sphincter. Elevated progesterone and estrogen levels further reduce esophageal sphincter tone and placental gastrin decreases gastric pH. Consequently, most pregnant women experience symptoms of gastric reflux.[11] Furthermore, gastric emptying is delayed by active labor, pain and administration of opioids. Delayed gastric emptying and decreased competence of the esophageal sphincter cause an increased risk of pulmonary aspiration with induction of general anesthesia, which has important implications for airway management that are discussed in detail in the General Anesthesia section.

Uterine and Fetal Circulation

Uterine weight and blood flow increase throughout gestation from approximately 100 mL/min before pregnancy to approximately 700 mL/min (10% of cardiac output) at term gestation, with 80% of the uterine blood flow perfusing the intervillous space (placenta) and 20% supporting the myometrium. Uterine vasculature has limited autoregulation and remains (essentially) maximally dilated under normal conditions during pregnancy.

Maternal uterine blood flow decreases as a result of either reduced uterine arterial perfusion pressure or increased arterial resistance. Decreased perfusion pressure can result from systemic hypotension secondary to reduced cardiac preload from hypovolemia, aortocaval compression, or significant decreases in vascular resistance from the initiation of neuraxial anesthesia or induction of general anesthesia. Uterine perfusion pressure can also decrease from increased uterine venous pressure associated with vena caval compression (e.g., supine position), uterine contractions (particularly during prolonged contractions and uterine tachysystole), or significant increase in intra-abdominal pressure (pushing during second stage or seizure activity). Despite these

potential effects, phenylephrine (alpha-adrenergic) is useful for treating maternal hypotension secondary to neuraxial anesthesia, and it has been demonstrated to result in less fetal acidosis and base deficit compared to treatment with ephedrine (primarily beta-adrenergic) in many clinical trials.[12–14] If treated promptly, transient maternal hypotension does not lead to fetal depression or neonatal morbidity. Additionally, phenylephrine is the vasopressor of choice for preventing and managing hypotension during cesarean delivery.[15]

Placental and Fetal Drug Transfer

Exchange of drugs across the placenta occurs by passive diffusion, facilitated diffusion, transporter-mediated mechanisms, and vesicular transport. Most drugs less than 1000 Da molecular weight, if not ionized, cross the placenta by diffusion. The maternal drug concentration is usually the primary determinant of maternal-fetal transfer but maternal protein binding, molecular weight, lipid solubility, and drug ionization also contribute to maternal-fetal exchange. Although there is at least some placental transfer of most drugs, placental transfer of a variety of drugs is severely limited. During administration of anesthesia, drugs employed with significantly reduced placental transfer include succinylcholine, nondepolarizing muscle relaxants, heparin, and glycopyrrolate. Anesthetic drugs that readily cross the placenta include volatile anesthetic agents, opioids, and benzodiazepines. Local anesthetics and meperidine cross the placenta in a nonionized state, but once in the fetal circulation with a relatively lower pH, they become more ionized and can accumulate. (See the Neuraxial Local Anesthetics section.)

Analgesic Options for Labor and Vaginal Delivery

The pain of labor is highly variable and described by many women as severe. Factors influencing the patient's perception of labor pain include duration of labor, maternal pelvic anatomy in relation to fetal size, use of oxytocin, parity, participation in childbirth preparation classes, fear and anxiety about childbirth, attitudes about and experience of pain, and coping mechanisms. The choice of analgesic method resides primarily with the patient. The medical condition of the parturient, stage of labor, urgency of delivery, condition of the fetus, and availability of qualified personnel are also factors. Many different techniques are available to alleviate labor and delivery pain, and none appears to increase the risk of cesarean delivery.[16–19] Analgesia refers to pain relief without loss of consciousness; regional analgesia denotes partial sensory blockade in a specific area of the body, with or without partial motor blockade. Regional anesthesia is the loss of sensation, motor function, and reflex activity in a limited area of the body. General anesthesia results in the loss of consciousness, and the goals for providing general anesthesia typically include hypnosis, amnesia, analgesia, and skeletal muscle relaxation.

Techniques for labor analgesia must be safe for both mother and fetus and individualized to satisfy the analgesic requirement and desires of the parturient; they also must accommodate the changing nature of labor pain and the evolving, varied course of labor and delivery (e.g., spontaneous vaginal delivery, instrumentally assisted vaginal delivery, and cesarean delivery). The current approaches to pain relief are outlined in Box 14.1.

Nonpharmacologic Analgesia

There are a variety of nonpharmacologic techniques for labor analgesia. Although many seem to reduce labor pain perception, most lack the rigorous scientific methodology for the useful comparison of these techniques to pharmacologic methods. Although data are limited, acupuncture, acupressure, transcutaneous electrical nerve stimulation, relaxation, and massage all demonstrate a modest analgesic benefit during labor.[20,21] Other techniques such as hypnosis and intradermal water injections have not been shown to be more effective than placebo. A meta-analysis reviewing the effectiveness of a support individual (e.g., doula, friend, hospital staff, family member) noted that parturients with a support individual used fewer pharmacologic analgesia methods, had a decreased length of labor, experienced less dissatisfaction, had a lower incidence of operative or cesarean deliveries, and had improved 5-minute neonatal Apgar scores.[22]

Systemic Medications

Opioids are the only commonly used systemic medications for labor and delivery, but are administered with limitations on both dose and timing because they readily cross the placenta and are associated with a risk of neonatal respiratory depression in a dose-dependent fashion. Although pain relief from the administration of systemic opioids is frequently inadequate for the duration of labor, this option can be beneficial for short-term analgesia, particularly in early labor. Opioids are inexpensive, easy to administer, and do not require a trained anesthesia provider. However, they have a high rate of maternal side effects (sedation, respiratory depression, dysphoria, nausea, pruritus), can decrease fetal heart rate variability and fetal movements, and carry a potential risk of neonatal respiratory depression and changes in neurobehavior. Systemic administration of opioids at doses that are safe for mother and newborn provides some labor pain relief, but do not have the analgesic efficacy of regional techniques. Systemic opioids are recommended for administration in the smallest doses possible with minimization of repeated dosing to reduce the accumulation of drug and metabolites in the fetus. Larger doses would risk excessive maternal sedation, maternal respiratory depression, loss of protective airway reflexes, newborn respiratory depression, and impairment of both early breastfeeding and newborn neurobehavior.

Opioids differ in pharmacokinetics, pharmacodynamics, method of elimination, and the presence of active metabolites, but all readily cross the placental barrier through passive diffusion. Systemic opioids are most useful for patients with minimal

to moderate pain, precipitous labor, or contraindications to neuraxial blockade, such as a coagulopathy.

Meperidine remains the most widely used opioid worldwide for labor analgesia. Maternal half-life of meperidine is 2 to 3 hours, with the half-life in the fetus and newborn being significantly greater and more variable at values between 13 and 23 hours.[23] In addition, meperidine is metabolized to an active metabolite (normeperidine) that has a longer maternal half-life of 13 to 23 hours and significantly accumulates in the fetus after repeated doses. With increased dosing and shortened time interval between dose and delivery, there is greater neonatal risk of lower Apgar scores and newborn oxygen saturations as well as prolonged time to sustained respiration, abnormal neurobehavior, and more difficulty initiating successful breastfeeding.[24,25]

Morphine was used more frequently in the past but is rarely used today. Its onset of action is about 20 minutes with a prolonged duration of analgesia (3 to 4 hours). The half-life is longer in neonates compared with adults, and it produces significant maternal sedation. Although mostly metabolized into an inactive metabolite (morphine-3-glucuronide), about a third of administered morphine is transformed into an active metabolite (morphine-6-glucuronide) with significant analgesic properties. Obstetricians sometimes administer intramuscular morphine (10 to 15 mg) in combination with 25 mg of promethazine in latent labor to provide analgesia and facilitate rest. A recent prospective cohort study found that use of this "morphine sleep" did not impact the mode of delivery, maternal complications, or cause adverse neonatal outcomes.[26]

Fentanyl is a synthetic opioid with a short duration of action (approximately 30 minutes), no active metabolites, and a ratio of fetal to maternal plasma concentrations of approximately 1:3. In small intravenous (IV) doses of 50 to 100 μg over an hour, there were no significant differences in Apgar scores, respiratory depression, or neurobehavior scoring compared with newborns of mothers who did not receive fentanyl.[27] In addition, a comparison of equianalgesic doses of IV fentanyl compared with IV meperidine[28] demonstrated a decreased frequency of maternal nausea, vomiting, and prolonged sedation in the fentanyl group. Furthermore, neonates whose mothers received meperidine required naloxone more often compared with the fentanyl-exposed infants. There was no difference in the neuroadaptive testing scores of the two groups of infants. Fentanyl administration by a patient-controlled analgesia (PCA) device is occasionally used during labor for patients with contraindications to neuraxial analgesia. In a retrospective study, neonatal depression correlated with maternal dose even when the fentanyl PCA was terminated approximately 20 minutes prior to birth.[29]

Remifentanil, an ultra-short-acting opioid rapidly metabolized by nonspecific serum esterases, is significantly metabolized by the fetus, with umbilical artery–to–vein ratios of approximately 0.3.[30] Remifentanil administered by a PCA device is an analgesic option for women who have contraindications to neuraxial blockade. The primary benefit of choosing this rapidly metabolized drug is to minimize opioid-related side effects on the neonate. Remifentanil can be used effectively for labor with PCA dosing, but it is difficult to achieve satisfactory analgesia without potential of significant maternal respiratory depression, requires more intensive monitoring and nursing, and is therefore typically reserved for patients with contraindications to epidural anesthesia.[31] In a prospective randomized controlled trial comparing the effectiveness of epidural analgesia to a remifentanil PCA with optimized settings, epidural analgesia was significantly more effective than PCA for labor analgesia. In addition, they observed more sedation and oxygen desaturation during remifentanil analgesia, but there was no difference between groups in fetal and neonatal outcomes.[32] A meta-analysis of randomized controlled trials comparing epidural analgesia with remifentanil PCA found improved pain scores among parturients randomized to epidural analgesia.[33] A more recent equivalence trial performed between remifentanil PCA and epidural analgesia found remifentanil was inferior to epidural analgesia for satisfaction of pain relief and pain relief scores.[34] A retrospective study comparing use of remifentanil and fentanyl PCA for labor analgesia found a greater rate of transient maternal desaturation with remifentanil, but use of fentanyl resulted in greater need for assisted neonatal ventilation or administration of supplemental oxygen.[35]

Inhaled Nitrous Oxide

The use of nitrous oxide is widespread in Canada, Australia, Scandinavia, the United Kingdom, and other parts of the world, and recently its use has increased in the United States.[36] Nitrous oxide is a weak analgesic but can provide satisfactory pain relief and anxiolysis for some parturients. It is inhaled intermittently in a 50% mixture with oxygen and provides satisfactory labor analgesia for some women but is a much less effective analgesic compared to epidural analgesia. Side effects are minimal with nausea, dizziness, and drowsiness among the most common. Uterine contractility is not affected, and the degree of maternal cardiovascular and respiratory depression is very mild. At a 50% concentration (without co-administration of opioids or other sedatives), nitrous oxide is insufficient to cause unconsciousness or loss of protective airway reflexes. Nitrous oxide provides a safe analgesic option for laboring women when administered with appropriate equipment by trained personnel, essential to ensure safety (i.e., limiting the nitrous oxide concentration, avoiding administration of a hypoxic mixture, avoiding co-administration of other agents).[37] It can be used during the first, second, or third stage of labor. The effects of nitrous oxide are quickly reversed with discontinuation because of its rapid respiratory elimination, and it does not cause neonatal depression regardless of duration of administration.[38] When administered with appropriate scavenging equipment, there does not appear to be concern regarding occupational exposure.[37,39] Despite its historical use, rigorous scientific studies are lacking to adequately assess its overall efficacy, safety, and long-term effects on the fetus and newborn. Use of nitrous oxide for labor analgesia has no adverse impact on neonatal Apgar scores and there are no data to suggest adverse effects on fetal heart rate, umbilical cord gases, newborn respiration, or neonatal neurobehavioral measures.[40] Additionally, in comparing large populations with low rates of fetal nitrous oxide exposure during labor (United States) and high rates (Australia, Canada, Scandinavia, and United Kingdom), there is no evidence of cognitive differences.[41]

Neuraxial (Regional) Analgesia

Neuraxial analgesia, including epidural, spinal, dural puncture epidural (DPE), and combined spinal-epidural (CSE) techniques, is the most widely used method for labor analgesia in the United States.[42] Neuraxial techniques typically involve epidural and spinal administration of local anesthetic agents, and often the co-administration of epidural and spinal opioid analgesics. Administration of other adjuvants, such as epinephrine and clonidine, decrease the dose of local anesthetics required for

analgesia but are used much less frequently than opioids and do not appear to offer a significant advantage in most situations.[43,44] Lower blood pressures observed with use of clonidine as a neuraxial adjunctive resulted in the US Food and Drug Administration (FDA) issuing a "black box" warning for its use during labor.

Neuraxial Local Anesthetics

Local anesthetics reversibly block nerve impulse conduction via voltage-gated sodium channels. Their chemical structures are secondary or tertiary amines, which are weak bases. Local anesthetics differ in their onset, peak plasma concentration, potency, and duration based on their lipid solubility, protein binding, site of injection, and concentration. Vascular absorption of local anesthetics limits the safe dose that can be administered. Bupivacaine and ropivacaine are the most commonly used local anesthetics for neuraxial labor analgesia and are extremely safe when appropriately used for epidural or intrathecal administration. An accidental, large intravascular dose of any local anesthetic can result in local anesthetic systemic toxicity (LAST) that can lead to seizure, cardiac arrest, and/or death. If LAST occurs, administration of a lipid emulsion and initiation of advanced cardiac life support is critical to optimizing outcome.[45]

Local anesthetics have a high lipid solubility and a low ionized fraction. However, the lower pH of the fetus has the potential to increase the fraction of ionized molecules, decrease lipid solubility, and result in ion trapping. Therefore in a distressed acidotic fetus, higher concentrations of local anesthetic can accumulate (ion trapping) and result in decreased neonatal neuromuscular tone. If a direct intravascular or intrafetal injection of local anesthetic occurs, significant toxicity and depression can develop, signified by bradycardia, ventricular arrhythmia, and severe cardiac depression with acidosis.

Neuraxial Opioids

Epidural administration of lipid-soluble opioids (e.g., sufentanil, fentanyl) provides rapid analgesia equivalent to that of systemic administration but remains inferior to that of dilute concentrations of local anesthetics. When lipid-soluble opioids are co-administered with local anesthetics in the epidural space, they decrease the total local anesthetic dose required and lower the minimum local anesthetic concentration needed to achieve adequate labor analgesia.[46,47] The most common maternal side effects of conventional doses of epidural fentanyl or sufentanil are pruritus and nausea. Typical doses used for labor analgesia do not adversely affect the neonate. However, much of the opioid administered in the epidural space crosses to the maternal plasma and the potential for respiratory depression is both dose-dependent and a function of the time between administration and birth.

Subarachnoid (i.e., spinal, intrathecal) opioid injections provide effective maternal labor analgesia. Analgesic effects of spinal opioids are more potent than epidural or systemic opioid administration but are of limited duration (2 hours or less). Spinal fentanyl or sufentanil administration is often performed as part of a CSE technique (discussed in the following section). Intrathecal opioids are often combined with small doses of local anesthetic (e.g., 2.5 mg bupivacaine), decreasing the dose of opioid needed and the incidence of pruritus and nausea.[48,49] Use of high-dose intrathecal opioids (e.g., sufentanil 7.5 µg) is associated with increased risk of fetal bradycardia and severe pruritus even without the presence of hypotension.[50] The mechanism for fetal bradycardia is uncertain but may be from uterine hyperactivity following the rapid analgesia. A systematic review of studies comparing intrathecal opioids to other methods of labor analgesia noted an increase in fetal bradycardia (odds ratio [OR] 1.8; 95% CI, 1.0 to 3.1) and increased maternal pruritus (RR, 29.6; 95% CI, 13.6 to 64.6), but the risk of cesarean delivery because of FHR abnormalities was similar.[51]

Neuraxial Techniques for Labor Analgesia

Neuraxial techniques represent the most effective form of labor analgesia, and they achieve the highest rates of maternal satisfaction.[40,52] The patient remains awake and alert without sedative side effects, maternal catecholamine concentrations are reduced, hyperventilation is avoided, cooperation and capacity to participate actively during labor are facilitated, and predictable analgesia can be achieved, superior to the analgesia provided by all other techniques.

Epidural Analgesia

Epidural labor analgesia is a catheter-based technique that provides continuous analgesia during labor by administration of medication into the epidural space. A catheter is inserted through a specialized needle (Fig. 14.2) that is directed between vertebral spinous processes in the mid to lower lumbar region. The needle traverses the skin and subcutaneous tissues, supraspinous ligament, interspinous ligament, and the ligamentum flavum, and is advanced into the epidural space (Fig. 14.3). The tip of the needle does not penetrate the dura, which forms the boundary between the intrathecal or subarachnoid space and the epidural space. To locate the epidural space, a tactile technique called "loss of resistance" is used. The tactile resistance noted with pressure on the plunger of an air- or saline-filled syringe dramatically decreases as the tip of the needle is advanced through the ligamentum flavum (dense resistance) into the epidural space (no resistance). The epidural space has an average depth of approximately 5 cm from the skin. Once the needle is properly positioned, a catheter is inserted through the needle, and the needle is removed. The catheter is secured and analgesia is achieved by administration of local anesthetics, opioids, or both (see Neuraxial Local Anesthetics and Neuraxial Opioids sections) and maintained throughout the course of labor and delivery. The catheter can also be used for administration of anesthesia for cesarean delivery and postoperative analgesia when necessary.

After epidural placement, the catheter is aspirated to help ensure inadvertent intravascular or intrathecal placement has not occurred. Additionally, a "test dose" of lidocaine (e.g., 45 mg) and epinephrine (e.g., 15 mcg) is typically administered. If the catheter is inadvertently placed into an epidural vein, the epinephrine causes transient maternal tachycardia and the lidocaine can cause maternal tinnitus and metallic taste. If the catheter is inadvertently positioned into the subarachnoid space, the small dose of lidocaine results in the rapid onset of profound maternal analgesia and significant lower extremity weakness. By test dosing the catheter, possible disastrous complications such as total spinal anesthesia or cardiovascular collapse are significantly minimized.

Epidural medications can be administered in bolus doses or by continuous infusion. Patient-controlled epidural anesthesia (PCEA) is a delivery technique allowing the patient to self-administer small boluses of epidural analgesics with or without a background infusion. Studies comparing PCEA with continuous infusion technique have found decreased local anesthetic

Regional anesthesia for labor and delivery. In Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's Anesthesia for Obstetrics*. 4th ed. Baltimore: Lippincott Williams & Wilkins; 2002:125.)

requirements, less anesthesia provider intervention, equivalent or improved patient satisfaction, equivalent or decreased motor blockade, and no significant differences in effects on the fetus or neonate.[18] Using PCEA delivery with a background infusion compared to PCEA alone further improves labor analgesia, reduces the need for clinician boluses, and does not increase maternal or neonatal adverse effects.[53]

More recently, programmed intermittent epidural bolus (PIEB) delivery provides automated fixed epidural boluses at scheduled intervals. Similar to continuous infusions, PIEB can be used alone or with a PCEA dosing technique. A recent systematic review of the literature comparing PIEB with continuous epidural infusion found PIEB reduces the risk of breakthrough pain, reduces local anesthetic usage, and improves maternal satisfaction.[54]

Dilute solutions of bupivacaine or ropivacaine are typically chosen for epidural labor analgesia, while more potent concentrations of 2% lidocaine or 3% chloroprocaine are often administered for cesarean delivery. As an example of the difference in concentrations, bupivacaine solutions of 0.1% or less are typically used for labor analgesia, while 0.5% bupivacaine would be needed to produce adequate surgical anesthesia for a cesarean delivery. Dilute solutions of local anesthetics minimize the motor blockade and preserve the perception of pelvic pressure with descent of the fetus during labor. Most practitioners routinely use low concentrations of local anesthetics with co-administration of an opioid (e.g., 2 µg/mL fentanyl) for its synergistic effect.

Effects on the Progress of Labor and Rate of Operative Delivery

The use of epidural analgesia has been associated with a prolonged second stage of labor and increased rates of assisted and cesarean delivery. A recent systematic review of the literature found neuraxial analgesia was associated with a modest increase in the mean duration

of the second stage (approximately 15 minutes) when compared to use of systemic opioids for labor analgesia.[52] This increase in the duration of the second stage is not harmful to the mother or infant and does not require intervention when the fetal status remains reassuring and labor continues to progress[55]; however, allowing a longer duration of the second stage for women who receive epidural analgesia may provide significant benefit on an individual basis.[56]

In addition, this systematic review found neuraxial labor analgesia was associated with an increased rate of instrumented vaginal delivery (RR 1.44, 95% CI 1.29 to 1.60, 30 trials, 9948 women); however, a secondary analysis of trials conducted after 2005 found this effect was no longer present (RR 1.19, 95% CI 0.97 to 1.46).[52] The use of epidural analgesia has no effect on the rate of cesarean delivery.[52] Although it was previously believed that placement of an epidural early in labor (<4 cm dilation) increased cesarean delivery rates, randomized controlled clinical trials comparing women receiving either systemic opioids or neuraxial analgesia in early labor (both spontaneous and induced), demonstrated no difference in rates of cesarean delivery.[16,17] Consequently, both American College of Obstetricians and Gynecologists (ACOG) and the American Society of Anesthesiologists guidelines recommend that maternal request is sufficient justification for epidural analgesia, and should not depend on an arbitrary amount of cervical dilation.[18,57]

Spinal Analgesia

Spinal analgesia can be administered as either a single injection or by a continuous infusion. In parturients without epidural analgesia, single injection spinal analgesia can be administered in the second stage of labor near the time of anticipated delivery. A small dose of a local anesthetic, opioid, or both is injected into the subarachnoid space. This dose of local anesthetic is far less than that used for spinal anesthesia for cesarean delivery, and it has minimal effects on motor nerve function. Compared with epidural analgesia, it has the benefits of a more rapid onset, a lower failure rate, and is technically easier and quicker to perform. It has the significant disadvantage of a finite effective duration (approximately 90 minutes). Single injection analgesia is usually reserved for multiparous women with spontaneous onset of labor and advanced cervical dilation,[58] but also can be useful in certain circumstances such as forceps-assisted delivery for a woman without epidural analgesia.

When inadvertent dural puncture occurs during epidural placement, a catheter can be inserted into the intrathecal space. Although the incidence of headache is high after dural puncture with the 17 to 19 gauge needle used for epidural catheter placement, a metaanalysis of 13 studies with 1044 obstetric patients found placement of an intrathecal catheter reduced the incidence of postdural puncture headache, when compared to relocating the epidural catheter following inadvertent dural puncture (RR = .82, $P = .018$).[59] Placement of an intrathecal catheter also decreased the need for treatment with an epidural blood patch (RR = .62, $P = .004$).[59] An intrathecal catheter provides excellent analgesia and also can be used to provide surgical anesthesia if cesarean delivery is required. However, care must be taken to ensure the spinal catheter is not mistaken for an epidural catheter since dosing errors could result in significant maternal morbidity.

Combined Spinal-Epidural Analgesia

CSE labor analgesia is a variation of neuraxial analgesia that combines the lumbar epidural technique and use of a single intrathecal dose to initiate spinal analgesia. After placement of the epidural needle, but before insertion of the epidural catheter, a spinal needle is passed through the indwelling epidural needle (see Fig. 14.2), puncturing the dura, and a small dose of local anesthetic and/or opioid is administered. Segmental analgesia results more rapidly than with epidural administration of local anesthetics. Comparing CSE to epidural labor analgesia, CSE has a faster onset of effective analgesia (especially in spread to sacral roots), decreased catheter failure for both labor analgesia and conversion to anesthesia for cesarean delivery, and increased maternal satisfaction.[40] However, CSE is associated with more pruritus and fetal heart rate changes, including fetal bradycardia with accompanying uterine hypertonus associated with higher doses of intrathecal opioids.[60–62] There is no difference seen for mode of delivery, maternal hypotension, postdural puncture headache rate, or need for blood patch.

Dural Puncture Epidural Analgesia

Similar to CSE, DPE involves use of the epidural needle to locate the epidural space and a spinal needle passed through the indwelling epidural needle to puncture the dura (see Fig. 14.2). However, no medication is administered into the intrathecal space. After the dural puncture, the spinal needle is withdrawn and a catheter is advanced into the epidural space. The dural puncture facilitates migration of epidural administered medications into the intrathecal space. The dural puncture is usually performed with a 25 g pencil-point needle since the smaller 27 g needle has not shown benefit.[63,64] Compared to an epidural without intentional dural puncture, DPE has a higher incidence of bilateral sacral analgesia, lower incidence of asymmetric block, and reduced need for top-up doses.[65] In addition, compared to the CSE technique, DPE results in less maternal pruritus, hypotension, or uterine tachysystole.

Contraindications and Complications of Neuraxial Techniques

Certain conditions contraindicate neuraxial procedures; these include patient refusal, infection at the needle insertion site, significant coagulopathy, hypovolemic shock, increased intracranial pressure from mass lesion, and inadequate provider expertise. Other conditions such as systemic infection, neurologic disease, and mild coagulopathies should be evaluated on a case-by-case basis. Human immunodeficiency virus infection is not a contraindication to regional technique in the pregnant patient.[66]

Rare but life-threatening complications can result from administration of regional anesthesia. Current rates of injury secondary to epidural catheter placement include epidural abscess/meningitis (1:63,000), epidural hematoma (1:250,000), and serious neurologic injury (1:36,000).[10] Other serious complications result from accidental IV or intrathecal injections of local anesthetics. An unintended bolus of IV local anesthetic causes dose-dependent consequences ranging from minor side effects (e.g., tinnitus, perioral tingling, mild blood pressure and heart rate changes) to major complications (e.g., LAST manifesting as seizures, loss of consciousness, severe arrhythmias, and cardiovascular collapse). The severity depends on the dose, type of local anesthetic, and preexisting condition of the parturient. Measures that can minimize the likelihood of accidental intravascular injection include careful aspiration of the catheter before injection, administration of a test dose, and incremental administration of therapeutic doses.

A "high spinal" (or total spinal) can result from an unrecognized epidural catheter placed subdural, migration of the catheter

during its use, or an overdose of local anesthetic in the epidural space (i.e., high epidural). Both high spinals and high epidurals can result in severe maternal hypotension, bradycardia, loss of consciousness, and blockade of the motor nerves to the respiratory muscles. An analysis of serious complications in over 250,000 obstetric anesthetics noted high neuraxial block (1:4300), respiratory arrest (1:10,000), and anesthesia related cardiac arrest (1:128,000).[10]

Treatment of complications resulting from both intravascular injection and high spinal is directed at restoring maternal and fetal oxygenation, ventilation, and circulation. Intubation, vasopressors, fluids, and advanced cardiac life support algorithms are often required. LAST is treated with administration of a lipid emulsion in addition to basic and advanced cardiac life support.[45] In any situation of maternal cardiac arrest with unsuccessful resuscitation, the fetus should be delivered by cesarean delivery if the mother is not resuscitated within 4 minutes of the arrest. This guideline for emergent operative delivery increases the chances of survival for both the mother and neonate.[67–69]

A variety of less severe complications such as inadequate analgesia, headache, and hypotension can occur with neuraxial blockade. The retrospective rates of inadequate epidural analgesia or inadequate CSE analgesia requiring catheter replacement were 7% and 3%, respectively, at a US academic center.[70] Interestingly, a recent meta-analysis found no difference in the need for catheter replacement between DPE and epidural techniques.[71] The rate of accidental dural puncture during epidural catheter placement is 1.5%, and approximately half of these will result in a severe headache,[72] which is typically managed with analgesics or an epidural blood patch if necessary. Hypotension (decrease in systolic blood pressure greater than 20%) secondary to sympathetic blockade is the most common complication of neuraxial blockade for labor analgesia, with rates approximately 14%.[60] Prophylactic measures include left uterine displacement and hydration. Although standards for timing, amount, and hydration fluid remain controversial, dehydration should be avoided, and there may be a reduction in hypotension following spinal anesthesia if a co-load of IV crystalloid or colloid preload is administered.[15] Hypotension treatment consists of further uterine displacement, IV fluids, and vasopressor administration. A prophylactic phenylephrine infusion and small boluses of either phenylephrine or ephedrine can be used to treat hypotension.[15] Although ephedrine (primarily β-adrenergic) was historically used, phenylephrine (primarily α-adrenergic) is associated with less fetal acidosis. If treated promptly, maternal hypotension does not lead to fetal depression or neonatal morbidity.

A rise in core maternal body temperature and fever are associated with labor epidural analgesia. Although it was originally believed that all women who had epidural analgesia gradually increased their core temperature, more current studies suggest that only about 20% of women who receive epidural labor analgesia develop a fever and the remaining 80% have no increase in core body temperature.[73] Although the etiology of the maternal temperature rise remains uncertain, an association with noninfectious inflammation mediated by proinflammatory cytokines is supported most consistently in the literature.[74] It is not associated with a change in white blood cell count or with an infectious process, and treatment is not necessary.[73] In addition, the fever associated with epidural labor analgesia does not increase the incidence of neonatal sepsis and need not affect neonatal sepsis evaluation.

Other potential side effects from neuraxial blockade during labor include pruritus, nausea, shivering, urinary retention, motor weakness, and a prolonged block.

Paracervical and Pudendal Blocks

A paracervical block is rarely used to provide pain relief during the first stage of labor and is no longer mentioned in the current ACOG guidelines on obstetric analgesia and anesthesia.[57] A paracervical block is associated with a 15% rate of fetal bradycardia,[75] which is usually limited to less than 15 minutes, and treatment is supportive. A pudendal block is infrequently used to provide pain relief during the second stage of labor at the time of delivery. In most centers this technique is used when epidural or spinal techniques are unavailable. A sheathed needle is guided to the vaginal mucosa and sacrospinous ligament just medial and posterior to the ischial spine, blocking sensation of the lower vagina and perineum. The technique can provide analgesia for vaginal delivery or uncomplicated instrumental delivery, but the rate of failure is high.[76] For parturients with cervical dilation ≥7 cm, administration of spinal analgesia with low-dose bupivacaine and fentanyl provided better labor pain relief and maternal satisfaction than administration of a pudendal block.[77] Complications include LAST, ischiorectal or vaginal hematoma, and, rarely, fetal injection of local anesthetic.

Anesthesia for Cesarean Delivery

In the United States, the vast majority of cesarean deliveries are performed with neuraxial anesthesia. It offers the advantages of less anesthetic exposure to the neonate, has the benefit of an awake mother at the delivery, allows for placement of neuraxial opioids to decrease postoperative pain, and avoids the risks of maternal aspiration and difficult airway associated with general anesthesia. However, the use of general anesthesia is sometimes required if regional anesthesia is contraindicated (e.g., coagulopathy, hemorrhage) or for emergent deliveries (e.g., fetal bradycardia, uterine rupture). Benefits of general anesthesia compared with regional anesthesia include a secure airway, controlled ventilation, rapid and reliable onset, and potential for less hemodynamic instability.

Epidural Anesthesia for Cesarean Delivery

Epidural anesthesia is an excellent choice for surgical anesthesia when an indwelling, functioning labor epidural catheter is in place. Epidural anesthesia provides the ability to titrate the desired level of anesthesia and extend the block time if needed. The volume and concentration of local anesthetic agents used for surgical anesthesia are larger than those used for labor analgesia. Typically the anesthesiologist attempts to provide a dense block from the T4 level to the sacrum. This technique does not always alleviate the visceral pain and pressure sensation associated with peritoneal manipulation, and adjuvant drugs are occasionally necessary. Epidural block failure rates for cesarean delivery following use of a labor epidural are known to be greater in the urgent setting compared to elective cases and range between 1.7% to 19.8%.[78] A systematic review of observational trials found the risk of failed labor epidural conversion to surgical anesthesia was increased with an urgent need for cesarean delivery, care by a nonobstetric anesthesiologist, and a greater number of top-up boluses.[79] In some cases,

conversion to general endotracheal anesthesia may be required. Antiemetics are frequently administered to decrease nausea and vomiting associated with the cesarean delivery and hemodynamic effects from the dense neuraxial blockade. Epidural morphine is typically administered near the end of the procedure to decrease postoperative pain for up to 24 hours.

Spinal Anesthesia for Cesarean Delivery

For the patient without an epidural catheter, spinal anesthesia is the most common regional anesthetic technique used for cesarean delivery. The block is technically easier than epidural blockade, more rapid in onset, and more reliable in providing surgical anesthesia from the midthoracic level to the sacrum.[80] The risk of profound hypotension is greater with spinal anesthesia than with epidural anesthesia because the onset of the sympathectomy is more rapid. However, this risk can be nearly eliminated by avoidance of aortocaval compression, cohydration, and appropriate use of vasopressors.[15] Data suggest that spinal anesthesia can be used safely for patients with preeclampsia.[81] A typical spinal anesthetic often consists of hyperbaric bupivacaine with fentanyl and morphine added to improve the block quality and decrease postoperative pain. A hyperbaric solution facilitates appropriate local anesthetic spread in the cerebral spinal fluid to a position near T4. The duration of a single injection spinal anesthetic is variable but normally provides adequate surgical anesthesia for greater than 90 minutes. In selected circumstances, the use of a CSE technique offers the advantage of a spinal anesthetic, with rapid onset of a dense block and the ability to administer additional local anesthetic through the epidural catheter if the procedure lasts for an extended time.

General Anesthesia

Use of general anesthesia for cesarean delivery is typically reserved for situations when emergent delivery is needed or neuraxial anesthesia is contraindicated. Based on data from 1997 to 2002, the case fatality risk ratio attributed to general anesthesia is 1.7 times that of neuraxial anesthesia, with two-thirds of the mortality associated with general anesthesia caused by intubation failure or induction problems.[82] Appropriate airway examination, preparation for unanticipated events, and familiarity with techniques and algorithms for difficult intubation are critical for providing a safe general anesthetic. A multiinstitutional database of adverse obstetric anesthesia events noted rates of failed intubation to be approximately 1:533, although none of these 10 failed obstetric intubations resulted in maternal mortality.[10]

After denitrogenation of the lungs (i.e., preoxygenation), general anesthesia is induced by rapid-sequence administration of an IV induction agent, followed by a rapidly acting muscle relaxant. The trachea is intubated with a cuffed endotracheal tube, and a surgical incision is made after confirmation of tracheal intubation and adequate ventilation. Anesthesia maintenance can include a combination of inhaled halogenated agents (e.g., sevoflurane), propofol, opioid analgesics, nitrous oxide, benzodiazepines, and additional muscle relaxants if needed. These additional IV agents are normally administered after the baby is delivered to avoid placental transfer to the neonate. Before delivery of the baby, the primary anesthetic for the incision and delivery is the IV induction agent because there is little time for uptake and distribution of the inhaled agents into the mother or fetus.[83] If intubation attempts fail, the cesarean delivery may proceed if the anesthesiologist communicates that it is possible to reliably ventilate the mother's lungs with either facemask or laryngeal mask airway.[18] Halogenated agents are often partially replaced with other anesthetic agents following delivery to decrease the adverse effects on uterine muscular tone (atony).

Induction Agents

Anesthesiologists use a variety of agents to rapidly induce unconsciousness. Among the most common are propofol, etomidate, and ketamine. Each agent represents a different biochemical class, and each has specific advantages and cardiovascular effects.

Propofol is rapid in onset with an umbilical artery to umbilical vein (UV) ratio of 0.7.[84] Propofol administration has no significant effect on neonatal behavior scores with typical induction doses of 2.5 mg/kg, but larger doses (9 mg/kg) are associated with newborn depression.[85] The lack of neonatal effects is unclear but may be caused by redistribution into maternal vascular-rich tissue beds, first-pass metabolism by the neonatal liver, additional dilution by the fetal circulation, and higher fetal brain water content. Among patients with hemodynamic compromise (e.g., maternal hemorrhage), typical doses of propofol can result in significant hypotension and decreased cardiac output.

Etomidate also has a quick onset of action because of its high lipid solubility. It rapidly crosses the placenta and rapid hydrolysis and redistribution results in a relatively short duration of action. Unlike propofol, etomidate has minimal effects on the cardiovascular system and is often used for parturients with hemodynamic instability. In addition, etomidate can cause involuntary muscle tremors, has higher rates of nausea and vomiting, and can increase the risk of seizures in patients with decreased seizure thresholds. At typical induction doses (0.3 mg/kg), etomidate administration can cause decreased neonatal cortisol production (<6 hours), but the clinical significance remains uncertain.[86]

Ketamine, a structural analogue to phencyclidine, is an analgesic, hypnotic, and amnestic with minimal respiratory depressive effects. In contrast to propofol, sympathomimetic characteristics of ketamine increase arterial pressure, heart rate, and cardiac output through central stimulation of the sympathetic nervous system. Similar to etomidate, it is an appropriate choice for a patient in hemodynamic compromise. With typical induction doses (e.g., 1.5 mg/kg) no neonatal depression is noted.[87] Larger doses can increase uterine tone and reduce uterine arterial perfusion. Even in low doses, ketamine has profound analgesic effects.

Nitrous Oxide

Inhaled nitrous oxide is often used as part of maintenance for general anesthesia because of its minimal effects on maternal hemodynamics and uterine tone. Alone, it is insufficient to provide adequate anesthesia for cesarean delivery. It rapidly crosses the placenta with increasing UV-to-maternal artery ratios of 0.37 in the first 2 to 9 minutes increasing to 0.61 at 9 to 14 minutes.[88] The effects of nitrous oxide on the neonate for such brief exposures are not significant.[37] (Additional information about nitrous oxide is found in the section Inhaled Nitrous Oxide section.)

Inhaled Halogenated Anesthetics

Isoflurane, sevoflurane, and desflurane are all halogenated hydrocarbons that differ in chemical composition, physical properties, biotransformation, potencies, and rates of uptake and elimination.

In clinical use, specialized vaporizers deliver these volatile liquid agents so that the inhaled concentrations can be carefully titrated by anesthesiologists because of the relatively profound cardiovascular effects and potential for uterine muscle relaxation. These agents are important components of general anesthesia for cesarean delivery but readily cross the placenta. Placental transfer of inhalation agents is rapid because these are nonionized, highly lipid-soluble substances of low molecular weight. The concentrations of these agents in the fetus depend directly on the concentration and duration of anesthetic in the mother. Although general anesthesia is often utilized when emergent cesarean delivery is required, neonatal depression is more likely due to the previously compromised fetus than the impact of anesthesia. A depressed fetus will likely become a depressed neonate. A Cochrane review of 16 studies comparing neuraxial blockade versus general anesthesia in otherwise uncomplicated cesarean deliveries found that "no significant difference was seen in terms of neonatal Apgar scores of six or less and of four or less at five minutes and need for neonatal resuscitation."[89] The authors concluded that there was no evidence to show that neuraxial anesthesia was superior to general anesthesia for neonatal outcome.

Experimental animal studies have demonstrated neuronal apoptosis in the developing brain when a variety of agents are administered to induce and maintain general anesthesia.[90,91] Implications for the fetus and neonate from the extremely brief anesthetic exposures associated with cesarean delivery are currently unknown because of a lack of human studies and difficulties extrapolating animal study methodology to humans. The FDA published a warning in 2016 that "repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than three years or in pregnant women during the third trimester may affect the development of children's brains."[92] This warning is based on concern that anesthetic or sedative drugs that bind to GABA or NMDA receptors could result in long-term effects on children's learning and behavior, although nitrous oxide was not included in the list of agents. No specific anesthetic agent (e.g., halogenated anesthetics, propofol, ketamine) is known to be safer than another, and there is no association known between use of general anesthesia for urgent cesarean delivery and neurocognitive disability later in life.[93]

For neonatal outcome, the "induction-to-delivery" interval is not as important as the uterine "incision-to-delivery" interval, during which uterine blood flow can be compromised and fetal asphyxia can occur. A long induction-to-delivery time can result in a neonate who is lightly anesthetized but should not be associated with fetal asphyxia. If inhaled anesthetics are administered to the mother for a prolonged period, neonatal anesthesia evidenced by flaccidity, cardiorespiratory depression, and decreased tone can be anticipated.[94] In such cases, the infant would be lightly anesthetized and should easily respond to basic, supportive treatment measures focused on effective ventilation; cardiopulmonary resuscitation should not be necessary. Ventilation will allow elimination of the inhalation anesthetic by the infant's lungs. Rapid improvement of the infant should be expected. Otherwise, a search for other causes of depression is imperative. For these reasons, it is critical that clinicians experienced with neonatal ventilation are present at cesarean deliveries during which the mother receives general anesthesia and the time from skin incision to delivery is expected to be prolonged (e.g., known percreta, large fibroids), or maternal condition necessitates an atypical induction and maintenance of anesthesia. A discussion of the operative and anesthetic plan by the neonatologist, obstetrician, and anesthesiologist is crucial for optimizing the outcome of neonates in these situations.

Neuromuscular Blocking Agents

Succinylcholine remains the skeletal muscle relaxant of choice for obstetric anesthesia because of its rapid onset and short duration of action. In appropriate doses (1 to 1.5 mg/kg), intubating conditions are achieved within 45 seconds. Because it is highly ionized and poorly lipid-soluble, only small amounts cross the placenta. Side effects include increased maternal potassium levels and myalgias. Succinylcholine is also a known trigger agent for malignant hyperthermia in susceptible individuals. This depolarizing neuromuscular blocking agent is normally hydrolyzed in maternal plasma by pseudocholinesterase and usually does not interfere with fetal neuromuscular activity. Although pseudocholinesterase activity is decreased in pregnancy, neuromuscular blockade by succinylcholine is not significantly prolonged. If large doses are administered (2 to 3 mg/kg), it results in detectable levels in umbilical cord blood, and extreme doses (10 mg/kg) are needed for the transfer to result in neonatal neuromuscular blockade.

Rocuronium is a rapid-acting, nondepolarizing neuromuscular blocker that is an acceptable alternative to succinylcholine. It has the benefit of not being a triggering agent of malignant hyperthermia or elevating serum potassium levels. It provides adequate intubating conditions in approximately 60 to 90 seconds in appropriate doses. Unlike succinylcholine, it has a much longer duration of action, decreasing maternal safety in the event the anesthesiologist is unable to intubate or ventilate the patient. However, with a large IV dose of sugammadex (16 mg/kg), neuromuscular block with rocuronium can be rapidly reversed.[95] Sugammadex is a α-cyclodextrin that inactivates aminosteroid nondepolarizing neuromuscular blocking drugs. Studies have found sugammadex to be effective and safe to use at the conclusion of a cesarean delivery.[96] The Society for Obstetric Anesthesia and Perinatology currently recommends avoidance in pregnant woman undergoing nonobstetric surgery.[97] Sugammadex reduces unbound progesterone in pharmacologic studies and could theoretically impact the length of pregnancy, however there is insufficient evidence regarding the safety of its use during pregnancy.

During cesarean delivery under general anesthesia, nondepolarizing neuromuscular blocking agents are typically not required but can be titrated to improve operating conditions. Under normal circumstances, the poorly lipid-soluble, highly ionized, nondepolarizing neuromuscular blockers (i.e., rocuronium, vecuronium, cisatracurium) do not cross the placenta in amounts significant enough to cause neonatal muscle weakness.[98] This placental impermeability is only relative, however, and neonatal neuromuscular blockade can be present when large or repeated doses are administered.[99]

The diagnosis of neonatal depression secondary to neuromuscular blockade can be made on the basis of the maternal history (e.g., prolonged administration of neuromuscular blockers, history of atypical pseudocholinesterase), the response of the mother to neuromuscular blocking drugs, and the physical examination of the newborn. The paralyzed neonate has normal cardiovascular function and good color, but lacks spontaneous ventilatory movements, has muscle flaccidity, and shows no reflex responses. The anesthesiologist can place a nerve stimulator on the neonate and demonstrate the classic signs of neuromuscular

TABLE 14.1 Perioperative Drugs and Breastfeeding Compatibility

Drug Class	Compatible	Limited Data[a]	Avoid
Anesthetics	Bupivacaine, etomidate, lidocaine, midazolam, nitrous oxide, propofol, ropivacaine, volatile agents	Dexmedetomidine, ketamine	Diazepam
Analgesics	Acetaminophen, fentanyl, hydromorphone,[b] morphine,[b] neuraxial opioids, NSAIDs (oral), oxycodone, remifentanil	Ketorolac	Codeine, meperidine, tramadol
Antiemetics	Dexamethasone, metoclopramide, ondansetron	Droperidol, haloperidol	
Other	Atropine, gadolinium, glycopyrrolate, iodinated contrast, NDMRs, neostigmine, succinylcholine, sugammadex[c]		

[a]Limited studies available; recommend monitoring infant for adverse effects.
[b]Close monitoring is recommended.
[c]The effects of sugammadex on breast feeding in the early postpartum period are currently unknown, and may affect the patient's ability to establish breastfeeding successfully.
Based on table in Kraus MB, Dodd SE, Sharpe EE. "Sleep and keep": dispelling myths of "pump and dump" from an anesthesiologist's perspective. *J Womens Health (Larchmt)*. 2020 Oct;29(10):1243–1245. NSAIDs, Nonsteroidal antiinflammatory drugs; *NDMRs*, nondepolarizing muscle relaxants.

blockade. Treatment consists of ventilatory support until the neonate excretes the drug, up to 48 hours. Reversal of nondepolarizing relaxants with cholinesterase inhibitors may be attempted (e.g., neostigmine, 0.06 mg/kg), but adequate ventilatory support is the mainstay of treatment. Concomitant administration of an anticholinergic (e.g., atropine, glycopyrrolate) with neostigmine is normally necessary to prevent severe bradycardia from muscarinic side effects of the increased acetylcholine.

Breastfeeding and Perioperative Medications

It is considered safe for a mother to breastfeed after general and/or neuraxial anesthesia.[100] Recommendations for the safety of anesthetics are guided by pharmacologic data. Breast milk drug levels follow passive diffusion and maternal plasma concentrations. After surgery, once the patient is awake and able, she can breastfeed or pump her breasts. Resumption of normal mentation occurs once medications have redistributed from the plasma compartment (and milk). Additionally, the dose the infant receives is affected by bioavailability, and peripartum drugs that are administered intravenously to the mother have a different bioavailability when consumed orally by the infant. Medications commonly used for anesthesia and their compatibility with breastfeeding are summarized in Table 14.1. It is not recommended that women pump and discard milk after exposure to anesthetic medications.

Mothers can also safely breastfeed when standard prescribed doses of opioids are administered for postoperative analgesia after cesarean delivery. However, caution is recommended if larger opioid doses are required, the infant is premature or susceptible to apnea, or for mothers also taking other sedating medications. Meperidine and codeine carry increased risk. Meperidine use among breastfeeding mothers can result in neonatal respiratory depression; cases of neonatal cyanosis, bradycardia, and apnea have been reported.[101] (Cobb 2015). Codeine is also avoided since there is significant transfer to breast milk and infants with genetic polymorphisms are at risk for respiratory depression.[102] A resource for clinicians to obtain current information is the Drugs and Lactation Database (LactMed) website, part of the National Library of Medicine's Toxicology Data Network.[103]

Summary

This chapter serves as a general overview of the changes in maternal physiology during pregnancy and briefly discusses options and techniques for both labor analgesia and anesthesia for cesarean delivery. Its purpose is to allow the pediatrician and neonatologist a better understanding of the decisions and concerns of the anesthesiologist and the implications of his or her interventions. To provide the best care for mother and child, excellent communication is required between the obstetrician, pediatrician, anesthesiologist, and nursing staff. Only by facilitating these lines of communication and obtaining input from each discipline can patient care and safety be optimized.

Perinatal Transition and Newborn Resuscitation

NOORJAHAN ALI AND TAYLOR SAWYER

KEY POINTS

- Preparation prior to delivery helps ensure timely and effective newborn resuscitation.
- Delayed umbilical cord clamping following delivery may have a significant impact on newborn outcomes.
- Establishing adequate ventilation is key to the perinatal transition.
- The laryngeal mask airway is an alternative to intubation in newborns at ≥34 weeks' gestation and > 2000 g.
- Devices such as carbon dioxide detectors, pulse oximetry, electrocardiography, and respiratory function monitors can be helpful during resuscitation.
- Postresuscitation care is critical to ensure optimal outcomes after newborn resuscitation.

The transition from fetal to neonatal life is a dramatic and complex process. Individuals who care for newborns must monitor the progress of this transition and be prepared to intervene when necessary. In most births, the perinatal transition occurs without the need for assistance. However, when assistance is needed, the presence of healthcare providers skilled in neonatal resuscitation can be lifesaving. Globally, 2.9 million neonates die every year.[1] Approximately 1 million of those babies die on the day they are born.[2] While newborn resuscitation cannot eliminate all early neonatal deaths, properly performed newborn resuscitation can save lives and reduce subsequent morbidities.[3]

Attempts to revive nonbreathing newborns have been described throughout recorded time.[4,5] In the past 50 years, significant attention has been focused on improving the scientific evidence behind the process of newborn resuscitation. Although the sophistication of resuscitation efforts has changed over time, the basic goal of inflating the newborn's lungs and initiating spontaneous breathing has remained constant.[4,5] With collaboration between the American Heart Association (AHA) and the American Academy of Pediatrics, the Neonatal Resuscitation Program (NRP) was started in 1987 to address the specific needs of the newborn.[6] The goal of the NRP is to teach healthcare providers the cognitive, technical, and behavioral skills needed for newborn resuscitation.[7]

To ensure that resuscitation methods taught in resuscitation training programs are based on the best available scientific evidence, the International Liaison Committee on Resuscitation (ILCOR) was formed. ILCOR meets on a regular basis to review the world's literature on resuscitation.[8] The findings form ILCOR reviews are translated into AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Major changes to resuscitation guidelines generally occur every 5 years. The 2020 AHA guidelines on neonatal resuscitation[9] and the content of the 2021, 8th edition, *Textbook of Neonatal Resuscitation* are referenced throughout this chapter.[10]

Transition from Fetal to Extrauterine Life

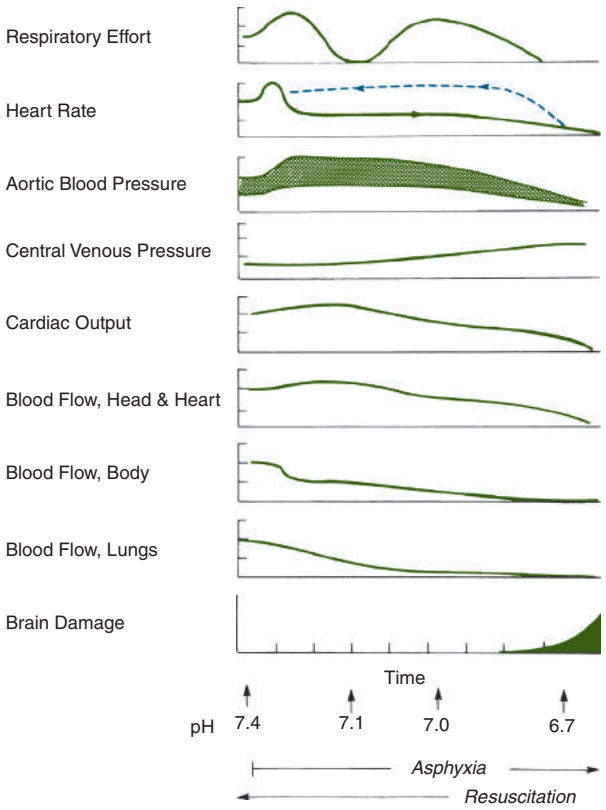
The fetus exists in the protected environment of the uterus, where temperature is closely controlled, the lungs are filled with fluid, continuous fetal breathing is not essential, and the gas exchange organ is the placenta. The transition that occurs at birth requires the newborn to increase heat production, initiate continuous breathing, replace lung fluid with air/oxygen, and significantly increase pulmonary blood flow so that gas exchange can occur in the lungs. Understanding this transitional process and knowing how to effectively assist the process helps guide the practice of newborn resuscitation. The key elements necessary for a successful transition to extrauterine life involve changes in thermoregulation, respiration, and circulation.

In utero, the fetal core temperature is approximately 0.5°C greater than the mother's temperature.[11] Heat is produced by metabolic processes and is lost through the placenta and skin.[12] After birth, the temperature gradient between the newborn and the environment becomes much greater, and heat is rapidly lost through radiation, convection, conduction, and evaporation. To adapt to the increased heat loss, the newborn must produce heat through other mechanisms, such as lipolysis of brown adipose tissue.[13] If heat is lost faster than it is produced, the newborn will become hypothermic. Preterm newborns are at particular risk of increased heat loss because of immature skin, a greater surface area to body weight ratio, and decreased brown adipose tissue stores.

The fetus lives in a fluid-filled environment, and the developing alveolar spaces are filled with lung fluid. Lung fluid production decreases in the days before delivery,[14] and the remainder of lung fluid is reabsorbed into the pulmonary interstitial spaces after delivery.[15] As the newborn takes its first breaths after birth, a negative intrathoracic pressure of approximately 50 cm H_2O is generated.[16] The alveoli become filled with air, and with the help of pulmonary surfactant, the lungs retain a small amount of air at the end of exhalation that is known as the functional residual capacity (FRC).

Although the fetus makes breathing movements in utero, these intermittent efforts mobilize fluid in physiologic dead space and are not required for fetal gas exchange. Continuous spontaneous breathing is maintained after birth by several mechanisms, including the activation of chemoreceptors, decrease in hormones that inhibit respirations, and the presence of natural environmental stimulation.

Spontaneous breathing can be suppressed at birth for several reasons, most critical being the presence of acidosis due to fetal hypoxia. Dawes described the fetal breathing response to acidosis in different animal species.[17] The physiologic effects that occur with worsening acidosis are shown in Fig. 15.1. When the pH is decreased, animals have a relatively short period of apnea followed by gasping. The gasping rate then increases until breathing ceases again for a second period of apnea. The first apnea period (e.g., "primary apnea") can be reversed with tactile stimulation. The second apnea period (e.g., "secondary apnea") requires assisted ventilation to establish spontaneous breathing. At birth, the timing of the onset of acidosis is unknown, and therefore apnea in the newborn could be either primary or secondary. Therefore, tactile stimulation should be attempted in the presence of apnea at birth to resolve primary apnea, but if it is not quickly successful, assisted ventilation should be started to resolve secondary apnea. In the absence of acidosis, a newborn can develop apnea because of exposure to respiratory-suppressing medications such as maternal anesthetics, narcotics, and magnesium.



• **Fig. 15.1** The sequence of cardiopulmonary changes with asphyxia and resuscitation. Time is on the horizontal axis. Asphyxia progresses from left to right; resuscitation proceeds from right to left. Units of time are not given. If there is complete interruption of respiratory gas exchange, the entire process of asphyxia from extreme left to right could occur in approximately 10 minutes. It could take much longer with an asphyxiating process that only partly interrupts gas exchange or does so completely but only for repeated brief periods. With resuscitation, the process reverses, beginning at the point to which asphyxia has proceeded. The blue dotted line is the reversal of asphyxia with resuscitation. (Modified from Dawes G. *Foetal and Neonatal Physiology*. Chicago: Year Book; 1968; and Avery GN. *Neonatology*. Philadelphia: JB Lippincott; 1987.)

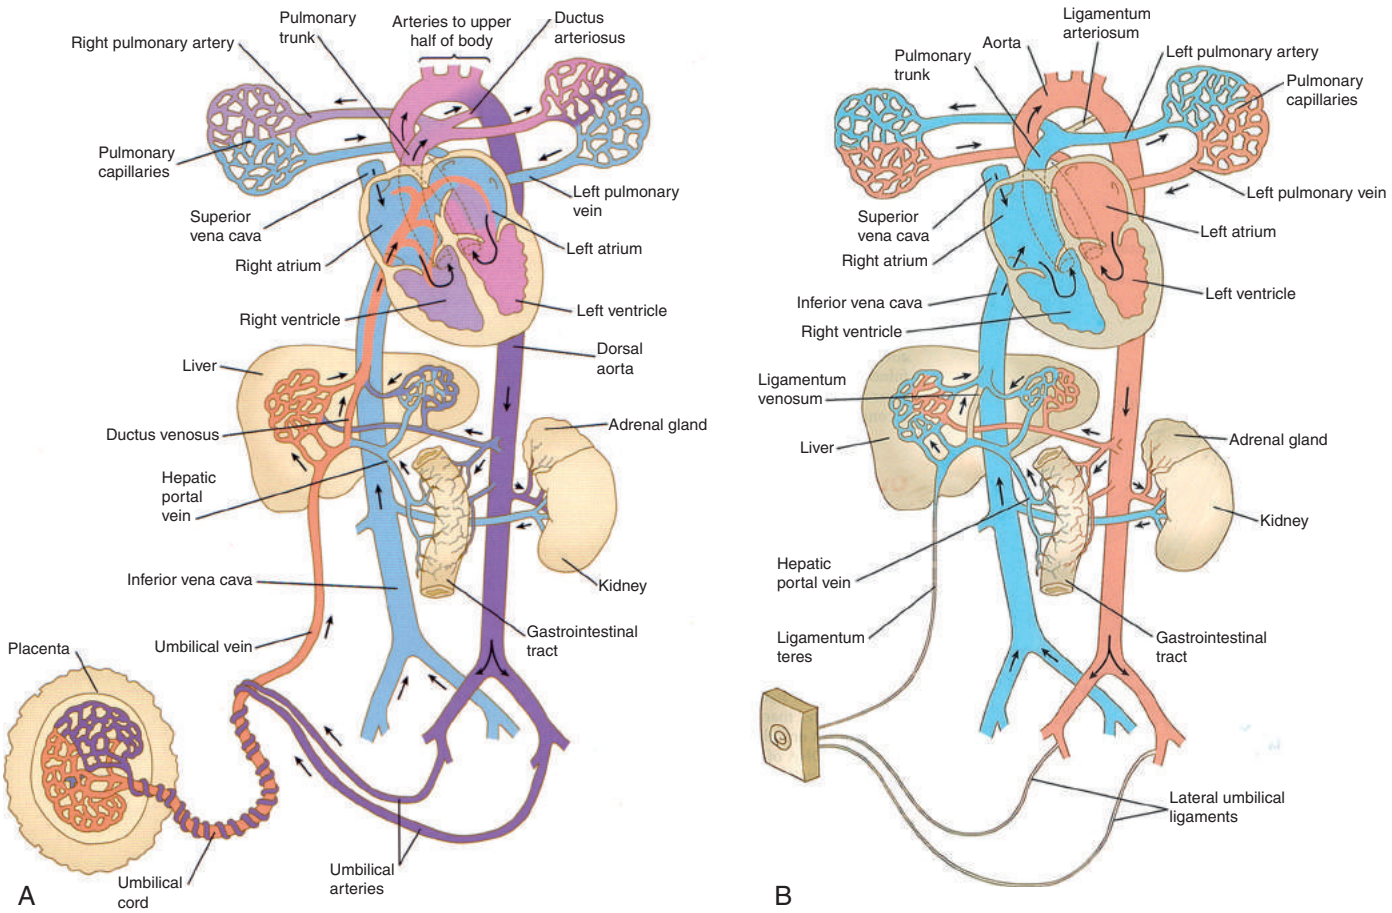
The fetal circulation is unique because gas exchange occurs in the placenta. Fig. 15.2 outlines the changes from fetal to neonatal circulation around the time of birth. Fetal channels, including the ductus arteriosus and foramen ovale, allow most of the blood flow to bypass the lungs. In the fetus, pulmonary blood flow is approximately 8% of the total cardiac output. With the closure of the ductus arteriosus and foramen ovale after birth, the neonatal lungs receive 100% of the cardiac output. When the low-resistance placental circulation is removed after birth, the newborn's systemic vascular resistance rises, while the pulmonary vascular resistance falls because of lung expansion, increased arterial and alveolar oxygen tension, and the release of local vasodilators.

The average fetal oxyhemoglobin saturation averages around 50% with a range between 20% to 80% at different points in the fetal circulation.[18,19] After birth, the oxyhemoglobin saturation rises gradually over the first 5 to 15 minutes of life to 90% or greater as the air spaces are cleared of fluid.[10] In cases of disordered transition secondary to asphyxia, meconium aspiration, pneumonia, or extreme prematurity, the lungs may not be able to develop efficient gas exchange, and thus the oxygen saturation may not increase as expected. Also, in some situations the normal drop in pulmonary vascular resistance may not fully occur, resulting in decreased pulmonary blood flow, and continued right to left shunting through the aforementioned fetal channels, a phenomenon known as persistent pulmonary hypertension of the newborn.

Birth Environment and Preparation for the Delivery

The birth environment should facilitate the transition to neonatal life and accommodate the needs of a newborn resuscitation. Hospitals and birthing centers differ in their physical layouts of the birth environment and the procedures used to prepare for delivery. Wherever the resuscitation is performed, a few key elements must be considered. The room should be warm enough to prevent excessive newborn heat loss, bright enough for assessment of the newborn's clinical status, and large enough to accommodate the necessary personnel and equipment to care for the baby. When a preterm birth is expected, the temperature in the birth environment should be set to approximately 23°C to 25°C (74°F to 77°F).[10]

In most cases, it is possible to use perinatal risk factors to predict which newborns will need resuscitation. According to the *Textbook of Neonatal Resuscitation*, every birth should be attended by at least one qualified provider skilled in the initial steps of newborn care and positive pressure ventilation (PPV), whose only responsibility is managing the newborn.[10] If risk factors are present, at least two qualified people should be present to manage the newborn.[10] If the need for extensive resuscitation is anticipated, then a qualified team capable of performing endotracheal intubation, chest compressions, emergency vascular access, and medication administration should be present at the time of birth.[10] Table 15.1 lists several risk factors associated with the need for mask ventilation or intubation.[20] Using these risk factors can



• **Fig. 15.2** The fetal circulation at term: (A) before birth and (B) after birth. (A) The path of oxygenated blood returning from the placenta is shown in *orange*. It mixes with deoxygenated blood returning from the fetal systemic veins shown in *light blue*. There is intracardiac mixing of blood as shown. The upper body receives a higher oxygen content than the lower body, as deoxygenated blood enters the descending aorta via right to left flow at the ductus arteriosus. After birth, the pulmonary and systemic circulations are completely separated as shown in (B). (From Carlson BM. *Human Embryology and Developmental Biology*. 5th ed. Philadelphia, PA: Mosby; 2014:436, 469.)

TABLE 15.1 Risk Factors Associated With the Need for Mask Ventilation or Intubation[a]

	High-Risk Deliveries[b]	Very High-Risk Deliveries[c]
Preterm delivery	34–37 weeks' gestational age	<34 weeks' gestational age
Birth weight	2.0–2.5 kg	<2 kg
Antepartum factors	Intrauterine growth restriction Fetal anemia or isoimmunization Polyhydramnios Gestational diabetes	Fetal hydrops Other major fetal anomalies Conditions that compromise respiratory transition
Intrapartum factors	Chorioamnionitis/maternal fever Maternal general anesthesia Emergency cesarean section Intrapartum hemorrhage Placental abruption Meconium-stained amniotic fluid Fetal heart rate trace concerns Forceps or vacuum delivery Breech presentation Shoulder dystocia	Fetal bradycardia Cord prolapse Uterine rupture Acute or severe complication of labor

[a]There is insufficient data to determine risk factors for chest compressions or medication administration; however, the same risk factors likely apply.
[b]Odds ratio less than 5 as compared to term controls.
[c]Odds ratio ≥5 as compared to term controls.
Adapted from Sawyer T, Lee HC, Aziz K. Anticipation and preparation for every delivery room resuscitation. *Semin Fetal Neonatal Med.* 2018 Oct;23(5):312–320.

guide delivery attendance decisions and may improve resource utilization.[20]

Institutions can improve newborn resuscitation team readiness in several ways. These include simulation-based training, encouraging task-oriented role assignment, reviewing resuscitation videos, using delivery room checklists, and debriefing after resuscitations. A systematic review of simulation-based team training in neonatal resuscitation found improved team performance and technical performance in simulation-based evaluations 3 to 6 months later.[21] Task-oriented role assignments include specific role(s), list of tasks, and the location where each newborn resuscitation team member should stand. Task-oriented role assignment training has been associated with improved behavioral skills during simulated neonatal resuscitation.[22] Many institutions regularly review videos of newborn resuscitations as a quality improvement process to identify areas of resuscitation performance that need improvement.[23,24] Current neonatal resuscitation guidelines recommend the use of a standardized checklist before every birth.[9] An example of a checklist is shown in Fig. 15.3. Checklist use during neonatal resuscitation has been found to be helpful in improving overall

DR Resuscitation Check list Patient Label Here

Pre-Resuscitation Briefing

Leader _____

MD(s) _____

RN(s) _____

RT(s) _____

☐ Introductions/Roles

☐ Discuss Plan, communication expectations

- Special considerations?
- Additional personnel/equipment?
- **"If any team member sees any developing problem or concern, I want to have it brought to my attention as soon as possible."**
- **Please call back all orders from Leader (e.g. "PIP is now 40")**

Pre-Resuscitation Checklist

Lead Resuscitator

- ❖ **Need urgent assistance, call x10770**
- ☐ Ensure briefing completed and introductions done
- ☐ Ensure RT checklist done
- ☐ Ensure RN checklist done
- ☐ Check status with resident receiving infant

Respiratory Therapy

- Brings RT bag (bring surfactant for < 28 weeks)
- Sets up Neopuff (30/5 and FiO2 .40, flow 8-10), appropriate masks
- Pedicap
- Sets up hand bag, checked (black bag if expecting difficult resus.)
- Intubation equipment checked, appropriate sized tubes
- Suction set at 80-100 mmHg, catheters, meconium aspirator if needed
- Pulse ox on and probe out
- NICO ET CO2 sensor
- Turn on video recorder

Nursing

- If crash C/section (call 2nd RN/MD) ensure line is set up, Epi drawn up.
- Barney bag
- Radiant warmer on MANUAL at 100%, probe and cover available, hat
- Stethescope
- Plastic wrap for < 28 weeks, Chemical mattress for <25 weeks
- ECG Leads

Debrief

Did we have all the information we need to admit this patient? Y/N

What did we do well? (Resident, Nurse, RT, Fellow, Attending in that order)

_____

What can we improve upon? _____

Do we need follow-up on any items? _____

• **Fig. 15.3** Delivery room resuscitation checklist. *DR*, Delivery room; *ET*, endotracheal; *FiO_2*, oxygen concentration; *MD*, medical doctor; *NICO ET*, NICO Monitor (Philips-Respironics, Inc.; Wallingford, CT); *PIP*, peak inspiratory pressure; *RN*, registered nurse; *RT*, respiratory therapist.

communication and rapidly identifying issues to be addressed by institutional leaders.[25] A performance-based postresuscitation debriefing should be completed after every resuscitation.[26] The debriefing is a critical opportunity for teams to identify what went well, what could be improved, and what issues require follow-up.

Umbilical Cord Management

After birth, blood flow in the umbilical arteries and vein usually continues for a few minutes. The additional blood volume transferred to the baby during this time is known as a placental transfusion. During the first 30 seconds after birth, the newborn's blood volume can increase by at least 12 mL/kg because of placental transfusion.[27–31] The timing of umbilical cord clamping influences the amount of placental transfusion and subsequent plasma and red blood cell volume of the newborn.[32,33]

The benefits and risks of delayed cord clamping (longer than 30 seconds) at birth have been closely examined. Cord clamping within 30 seconds may interfere with normal transition because it leaves fetal blood in the placenta that could have gone to the newborn. Delayed cord clamping is associated with higher hematocrit after birth and better iron levels in infancy.[34–46] Although developmental outcomes after delayed cord clamping have not been comprehensively assessed, iron deficiency is associated with impaired motor and cognitive development.[47–49] Based on the perceived benefits, the American College of Obstetricians and Gynecologists recommends delayed cord clamping for at least 30 to 60 seconds after birth in vigorous term and preterm infants.[50] For uncomplicated term or late preterm births, neonatal resuscitation guidelines include deferring cord clamping until after the newborn is placed on the mother and assessed for breathing and activity.[9] Delaying cord clamping may also be reasonable in preterm newborns because it reduces the need for blood pressure support, blood transfusions, and may improve survival.[51–58] Early cord clamping should be considered in cases when placental transfusion is unlikely to occur, such as maternal hemodynamic instability/hemorrhage, placental abruption, or placenta previa.[50] There is insufficient data at this time to make a recommendation on delayed cord clamping for newborns requiring PPV after birth, but this is an area of active research.[9]

Cord milking is an alternative to delayed cord clamping and can be used when the cord must be cut immediately after birth for medical reasons.[59] Cord milking is performed by gently squeezing a short segment of the cord with the thumb and forefingers and slowly pushing the blood within the cord towards the newborn's abdomen three to four times. Cord milking may be helpful for full-term newborns born by cesarean delivery, where there is a concern that delayed cord clamping may not provide an adequate placental transfusion.[27] Compared with delayed cord clamping, cord milking results in greater blood flow to and from the heart, higher hemoglobin levels, and higher blood pressure in neonates born by cesarean delivery.[60] Studies are ongoing to investigate the risks and benefits of umbilical cord milking in preterm newborns and in newborns requiring resuscitation. At the time of this writing, cord milking should be avoided in babies less than 28 weeks' gestational age, because it has been associated with brain injury.[61]

Newborn Resuscitation

Fig. 15.4 shows the neonatal resuscitation algorithm from the 8th edition (2021) *Textbook of Neonatal Resuscitation*.[10] Here, we examine several concepts and interventions in the practice of neonatal resuscitation and review the evidence that supports the current neonatal resuscitation guidelines.

Initial Steps

Preparing for the birth includes antenatal counseling, a team briefing, and an equipment check using a checklist. Before delivery, the following four "prebirth questions" should be asked of the obstetric team.[10]

What is the gestational age?
Is the amniotic fluid clear?
Are there any additional risk factors?
What is the plan for umbilical cord management?

After the birth, an initial assessment includes a visual inspection of the newborn to determine if it is term gestation, has good muscle tone, and if it is breathing or crying. If the newborn is preterm, has poor muscle tone, or is not breathing or crying, it should be moved to the radiant warmer and the initial steps of newborn resuscitation should begin.

The initial steps of newborn resuscitation include warming, drying, tactile stimulation, and positioning the airway. Radiant warmers are used to maintain the newborn's body temperature between 36.5°C and 37.5°C.[10] For preterm and low-birth-weight newborns, warming adjuncts including plastic wraps or bags, hats, exothermic mattresses, and warmed humidified inspired gases may reduce the risk of hypothermia.[9] Drying the newborn is done by placing the baby on a warm towel or blanket and gently drying fluid on the skin. Drying is not necessary for newborns less than 32 weeks' gestation. Preterm infants less than 32 weeks' gestation should be immediately covered in plastic or their torso and extremities placed inside a plastic bag to reduce evaporative heat loss.[10] Tactile stimulation should be limited to drying and rubbing the back and soles of the feet. Appropriate positioning of the airway includes placing the newborn supine with the head in a neutral or "sniffing" position to facilitate maintenance of an open airway.

Routine suction of the airway is not indicated in newborns that are vigorous or crying.[10] Avoiding unnecessary suctioning helps prevent reflex bradycardia resulting from laryngeal stimulation.[9] The mouth and nose may be suctioned with a standard bulb syringe if there is visible fluid obstructing the airway, if the baby is having difficulty clearing their secretions, or if there is concern for obstructed breathing. Suctioning of secretions from the airway should be performed if the baby is not breathing, is gasping, has poor tone, and before PPV is given.[10]

Neonates born through meconium-stained amniotic fluid are at risk of aspirating meconium and developing meconium aspiration syndrome. For many years, routine management of nonvigorous newborns with meconium-stained amniotic fluid included endotracheal intubation and tracheal suctioning to remove meconium from the trachea in hopes of preventing meconium aspiration syndrome. In 2015, after careful deliberation, the neonatal resuscitation guidelines were changed to eliminate routine tracheal intubation and suctioning due to insufficient evidence of clinical benefit and concern for possible harm. A specific concern with routine tracheal suctioning was that it delayed the start of PPV in nonvigorous newborns. Neonatal resuscitation guidelines continue to recommend against routine direct laryngoscopy and tracheal suctioning for nonvigorous newborns born through meconium-stained fluids.[9] However, tracheal suction with a meconium aspirator can be beneficial in newborns who have evidence of airway obstruction while receiving PPV.[62]

Positive Pressure Ventilation

Assisted ventilation with PPV is the most important step in newborn resuscitation. Approximately 3% to 5% of newborns require PPV to initiate spontaneous respirations at birth. The need for PPV is more common in preterm newborns than term newborns. The indications for PPV include apnea, gasping, and bradycardia (heart rate less than 100 bpm).[10] A PPV rate of 40 to 60/min is recommended in newborns.[9,10] PPV can be delivered noninvasively with a pressure delivery device and face mask or with a laryngeal mask airway (LMA). PPV can be delivered invasively using an endotracheal tube (ET). Pressure delivery devices used for newborn resuscitation include self-inflating bags, flow-inflating (e.g., anesthesia) bags, and T-piece resuscitators. Each device has its advantages and disadvantages. Currently, there is insufficient evidence to recommend one type of PPV device over another.[9]

Proficiency is needed to perform effective PPV with a face mask. This is especially true when administering PPV to extremely low birth weight newborns. It is important to maintain an open airway for pressure to be transmitted to the lungs. This is done by

keeping the head in a neutral position and lifting the jaw towards the mask, as opposed to pushing the mask down onto the face. The mask must make a good seal on the face for air to pass to the lungs. Leakage around the mask and airway obstruction from suboptimal airway positioning are common issues with face mask PPV. Signs that the airway is open and the face mask is well-sealed include visible chest rise with each breath and, most importantly, improvement in the newborn's heart rate.[10]

It is important to provide adequate pressure for ventilation; however, excessive pressure can contribute to lung injury. Initial inflation pressures of 20 to 25 cm H_2O are recommended.[9,10] If there is no visible chest rise or improvement in the newborn's heart rate at the initial inflation pressures, the pressures can be increased in 5 to 10 cm H_2O increments. In term newborns, a peak inflation pressures of 30 cm H_2O is usually sufficient to inflate the lungs.[63–70] In preterm newborns, peak inflation pressures of 20 to 25 cm H_2O are usually sufficient.[63–70] In some cases, however, higher inflation pressures are required. The *Textbook of Neonatal Resuscitation* recommends a maximum peak inspiratory pressure (PIP) of 40 cm H_2O.[10]

Immaturity and surfactant deficiency result in lung collapse in preterm newborns. In animal studies, positive end expiratory pressure (PEEP) has been shown to maintain FRC during PPV and thus improve lung function and oxygenation.[71] PEEP may be beneficial during neonatal resuscitation; however, the evidence from human studies is limited.[9] In clinical practice, PEEP is commonly used when providing PPV to both term and preterm newborns with either a flow-inflating bag or T-piece resuscitator. The optimal PEEP has not been determined.[9] All current human studies have used a PEEP of 5 cm H_2O.[72–76]

Continuous Positive Airway Pressure (CPAP)

Both term and preterm newborns need to establish a FRC as part of the transition from fetal to extrauterine life. The use of continuous pressure throughout the breathing cycle is helpful in establishing FRC and improves surfactant function.[77–79] Continuous positive airway pressure (CPAP) is a form of continuous pressure that helps newborns keep their lungs open and lessens breathing difficulty in preterm infants.[80] CPAP should only be used in spontaneously breathing newborns. CPAP is not appropriate in newborns that are apneic, gasping, or have a heart rate less than 100 bpm.[10] CPAP is administered during resuscitation using a face mask attached to either a T-piece resuscitator or a flow-inflating bag. CPAP cannot be administered with a self-inflating bag. The desired CPAP level is achieved by adjusting the PEEP dial on the cap of the T-piece resuscitator or the flow-control valve on the flow-inflating bag. If CPAP is administered for a prolonged period, the interface can change to nasal prongs or a nasal mask attached to a CPAP device or a mechanical ventilator.[10]

Studies comparing initial respiratory management with CPAP to endotracheal ventilation report a reduction in death and bronchopulmonary dysplasia in preterm infants < 30 weeks' gestation.[81–84] Thus, it is reasonable to use CPAP rather than intubation in spontaneously breathing preterm newborns who require respiratory support at birth.[9] The recommended level of CPAP is 5 to 6 cm H_2O.[10]

Sustained Inflation

CPAP is one method to establish FRC. Another method is to use sustained inflation. Sustained inflation is performed using either a T-piece resuscitator or a flow-inflating bag to deliver a prolonged PIP at a level of 20 to 25 cm H_2O for 15 to 20 seconds.[85] Animal studies suggest that a sustained inflation may be beneficial for short term respiratory outcomes.[86] However, a 2020 ILCOR systematic review and metaanalysis on sustained lung inflations during neonatal resuscitation at birth did not find benefit in using sustained inflations.[87] In that analysis, sustained inflations were associated with an increased risk of death before discharge in newborns < 28 weeks' gestation. A 2020 Cochrane systematic review examining sustained versus standard inflations during neonatal resuscitation also found no evidence to support the use of sustained inflation.[88] The current newborn resuscitation guidelines recommend against the routine use of sustained inflations in the delivery room.[9]

Laryngeal Mask Airways

A laryngeal mask airway (LMA)—also called a supraglottic airway device—is a small elliptical mask that is attached to an airway tube. Several types and brands are available. Some include an inflatable mask while others use a soft-gel mask that does not need inflation; some have a separate port through which to insert a gastric drainage tube.

An LMA is inserted into the baby's mouth using the operator's index finger and advanced into the throat until it sits over the laryngeal opening. The soft LMA mask conforms to the shape of the hypopharynx creating a seal that occludes the esophagus and provides a channel for air to enter the lungs via the glottis. The LMA makes a better seal than a face mask and thus may improve the effectiveness of ventilation. The LMA allows both the support of spontaneous breathing and the delivery of PPV. Unlike endotracheal intubation, the LMA does not require other instruments for insertion and the newborn's vocal cords do not need to be visualized during insertion.

Using an LMA for neonatal resuscitation was first described in 1994.[89] The LMA was introduced in the neonatal resuscitation guidelines in 2000. Over the past two decades, the utility of LMAs for neonatal resuscitation has been increasingly appreciated. A 2018 Cochrane systematic review noted that LMAs were more effective than face-mask ventilation.[90] Current guidelines recommend LMA use in newborns >34 weeks' gestational age with a birth weight >2000 g when attempts at face-mask ventilation or endotracheal intubation are not feasible or are unsuccessful.[9] Because the smallest commercially available LMAs are too large for very preterm newborns, there is lack of evidence on the use of LMAs in premature infants.

Endotracheal Intubation

Endotracheal intubation is the insertion of an ET through either the mouth or nose, and into the trachea. Endotracheal intubation is performed during newborn resuscitation to assist with breathing and inflating the newborn's lungs. Endotracheal intubation (or LMA placement) should be considered in newborns with a heart rate less than 100 beats/min after initial PPV and should be performed in newborns with a persistent heart rate less than 60 beats/min after adequate ventilation with face mask PPV. Endotracheal intubation can also be performed at delivery in newborns who are difficult to ventilate with a face mask and for those with respiratory failure requiring mechanical ventilation or intratracheal surfactant administration.

Intubation of the newborn trachea has been a part of newborn resuscitation for over 200 years.[91–94] The procedure was originally

performed using a long flexible tube directed into the newborn's airway by the operator's fingers (digital intubation).[94] The first laryngoscope for neonatal intubation was developed by the New York anesthesiologist Paluel Flagg in 1928.[95] The laryngoscope blade lifts the newborn's tongue out of the way to allow visualization of the glottis, so the ET can be visualized passing through the vocal cords. In recent years, the laryngoscope has been modified to include a video camera which allows better visualization of the glottis and provides the opportunity for other team members to see into the airway and confirm ET placement.[94] A photograph of a newborn's airway, obtained from a video laryngoscope, is presented in Fig. 15.5.

Neonatal intubation is technically challenging and often associated with adverse events. Recent studies from the multicenter National Emergency Airway Registry for Neonates report an average first intubation attempt success rate of 46% in the delivery room.[96,97] Tracheal intubation-associated events—including esophageal intubation, mainstem bronchial intubation, airway trauma, hypotension, pneumothorax, and cardiac arrest—ranged from 9% to 50% across centers.[96,97] Severe oxygen desaturation, defined as a drop in oxygen saturation during intubation by ≥20% from preintubation baseline occur in 29% to 69% of intubations.[96,97] In a recent study, the median time to a saturation decrease to <90% during neonatal intubation was only 22 seconds.[98] The low success rates, high adverse event rates, and frequent oxygen desaturations during intubation are concerning. Failed intubation in premature infants is associated with an increased incidence of severe intraventricular hemorrhage and neurodevelopmental impairment.[99,100] Concerns around intubation safety have caused the LMA to be increasingly considered as the primary advanced airway device during newborn resuscitation in near term and term infants.[10] If endotracheal intubation is performed, it should be done by an experienced provider skilled in the procedure to optimize the chance of success and to minimize adverse events.

Supplemental Oxygen

After birth, healthy newborns make the transition from the low oxygen environment of the womb to the oxygen-rich environment of room air (21% oxygen) over the course of several minutes. During that time, blood oxygen saturation levels slowly rise from approximately 60% at birth to around 90% by 10 minutes of life. When blood oxygen levels do not rise as expected, or fall after birth, supplemental oxygen is used to prevent harm from inadequate oxygen delivery to tissues (e.g., hypoxia).

• **Fig. 15.5** View of the glottis and vocal cords as the laryngoscope is gently lifted. (From Kattwinkel J, ed. *Neonatal Resuscitation Textbook*. 5th ed. Elk Grove Village: American Heart Association and American Academy of Pediatrics; 2006.)

Before 2000, neonatal resuscitation guidelines recommended a supplemental oxygen concentration of 100% for all newborns, regardless of gestation. Studies over the past two decades have raised concerns about exposure to high oxygen concentration during neonatal resuscitation.[101,102] A 2005 Cochrane systematic review found a reduction in short-term mortality for newborns resuscitated with room air (21% oxygen) as compared with 100% oxygen.[103] A 2019 ILCOR systematic review with meta-analysis reported a 27% relative reduction in short-term mortality for newborns ≥35 weeks' gestation receiving respiratory support at birth with room air as compared with 100% oxygen.[104] No difference was found in neurodevelopmental outcome of survivors.[104] Based on the short-term benefits, current neonatal resuscitation guidelines recommend room air for the initial resuscitation of newborns ≥35 weeks' gestation.

The data on supplemental oxygen use in preterm newborns <35 weeks' gestation is less clear. A 2019 ILCOR meta-analysis of randomized trials enrolling preterm newborns showed no difference in short-term mortality with low oxygen (21% to 30%) as compared with high oxygen (60% to 100%) concentrations.[105] There was also no difference in neurodevelopmental outcomes, retinopathy of prematurity, bronchopulmonary dysplasia, necrotizing enterocolitis, or major cerebral hemorrhage between the low oxygen and high oxygen groups.[105] Of note, all preterm babies who started off on 21% oxygen required supplemental oxygen during resuscitation to reach target oxygen saturations.[105] Based on a lack of evidence to support a specific initial oxygen level, current newborn resuscitation guidelines recommend anywhere between 21% and 30% for the resuscitation of newborns <35 weeks' gestation.[9,10] To ensure the safe use of oxygen, pulse oximetry with oxygen saturation targeting is recommended.

During cardiopulmonary resuscitation with chest compressions, higher oxygen concentrations may be needed to deliver adequate oxygen to the body. Also, during cardiopulmonary resuscitation with chest compressions, peripheral circulation may be so poor that the pulse oximeter will not give a reliable signal. For these reasons, neonatal resuscitation guidelines recommend that supplemental oxygen be increased to 100% when chest compressions are started.[9,10] Once the heart rate is greater than 60 beats/min and a reliable pulse oximeter signal is achieved, supplemental oxygen levels should be adjusted to achieve the target oxygen saturation based on minutes life.[10]

Chest Compressions

The need for chest compressions during newborn resuscitation is rare. It is estimated that 0.1% (1/1000) of term infants and around 15% (15/100) of preterm infants receive chest compressions—with or without epinephrine—in the delivery room.[106] Chest compressions are indicated if the newborn's heart rate remains less than 60 beats/min after at least 30 seconds of PPV that inflates the lungs.[9,10] Chest compressions mechanically pump blood through the body by either direct compression of the heart between the sternum and vertebral column ("cardiac pump theory") or via phasic increases in intrathoracic pressure ("thoracic pump theory").[106] Optimized chest compressions generate around 30% of normal organ perfusion, with preferential perfusion of the heart and brain.[107]

Performing chest compressions on a newborn is best done using the two thumb–encircling hands technique.[9] With this technique, the compressor's thumbs are placed on the lower third of the sternum, just below an imaginary line connecting the newborn's nipples. The thumbs can be placed either on top of the other or side-by-side.[10] Using two thumbs, the sternum is pressed downward to a depth of approximately one-third of the anterior–posterior diameter of the chest. The compression distance depends on the size of the newborn. One chest compression consists of the downward stroke plus the release. The release phase is critical because it allows the myocardium and coronary blood vessels to refill with blood.

Chest compressions are typically started by a team member standing at the side of the warmer near the neonate's feet. Once an advance airway is established, the team member performing chest compressions can move to the head of the bed. Having the compressor at the head of the bed frees up space for another team member to place an umbilical catheter.

The optimal approach to chest compressions and ventilation in an asphyxiated newborn is unknown.[106] The recommended compression rate in newborns is 90 compressions per minute. The recommended chest compression to PPV ratio is 3 compressions and 1 ventilation, with 90 compressions and 30 ventilations provided per minute. It is important to avoid unnecessary interruptions in chest compressions to optimize coronary and cerebral perfusion. Once started, coordinated compressions and ventilation should be continued for at least 60 seconds before pausing compressions to reassess the heart rate.[9,10] Chest compressions can be stopped when the newborn's heart rate is 60 beats/min or greater.[9,10]

Epinephrine

Epinephrine (adrenaline) is recommended for newborns with a sustained heart rate <60 beats/min after adequate assisted lung ventilation with 100% oxygen (preferably through an ET) and chest compressions.[9,10] Epinephrine produces beneficial effects during cardiac arrest primarily through its α-adrenergic receptor-stimulating properties, which increase both myocardial and cerebral blood.[108,109] The beneficial effects of epinephrine's β-adrenergic-stimulating properties during cardiac arrest are controversial because they may increase myocardial work and reduce subendocardial perfusion.[110]

The acceptable intravenous (IV) dose of epinephrine is 0.02 mg/kg.[9,10] A normal saline flush of 3 mL is recommended after the IV dose.[9,10] The acceptable endotracheal dose of epinephrine is 0.1 mg/kg. No flush is needed with endotracheal epinephrine. The dosage interval for epinephrine, either IV or endotracheal, is every 3 to 5 minutes if the heart rate remains less than 60 beats/min.[9,10] However, an intravenous dose may be given as soon as IV access is obtained if an initial dose of endotracheal epinephrine was already given.

The preferred route of epinephrine is IV. This is because IV is believed to be more effective than endotracheal administration.[111] A low-lying umbilical venous catheter provides the most rapid and reliable medication delivery method at birth.[9] If the need for advanced resuscitation is suspected prior to birth, the necessary equipment for umbilical venous catheter placement should be prepared before delivery. One method to ensure rapid IV epinephrine administration is to assign one resuscitation team member to place the emergency umbilical catheter as soon as chest compressions are initiated. In cases where IV access via a low-lying umbilical venous catheter fails or is not feasible, an intraosseous line is an acceptable alternative.[10]

Volume Expanders

Hypovolemic shock at delivery can result from extensive vaginal bleeding, acute fetal-maternal hemorrhage, bleeding vasa previa, a placental laceration, umbilical cord prolapse, a tight nuchal cord, and blood loss from a ruptured umbilical cord.[10] Newborns with hypovolemic shock may appear pale, and have delayed capillary refill and weak pulses. A persistently low heart rate that does not respond to effective ventilation, chest compressions, and epinephrine may be seen in newborns with hypovolemic shock.[9]

Volume expanders are indicated for newborns with signs of shock or a history of acute blood loss that does not respond to resuscitation. The preferred route for volume expanders is IV. However, the intraosseous route is an acceptable alternative. Volume expanders should be avoided in the absence of shock or a history of acute blood loss because large volumes of IV fluid can worsen cardiac output and further compromise the newborn.[10] Normal saline (0.9% sodium chloride) is the crystalloid volume expander of choice.[9] In cases of substantial blood loss, uncrossmatched type O, Rh-negative blood is preferred.[9] The recommended dose of volume expanders is 10 mL/kg given over 5 to 10 minutes.[9] This dose may be repeated if there is inadequate response.

Apgar Score

The assessment of a newborn was first quantified by the anesthesiologist Virginia Apgar in the 1950s and henceforth known as the Apgar score.[112] The score is based on a 10-point scale with a maximum of 2 points assigned for each of the following categories: respirations, heart rate, color, tone, and reflex irritability (Table 15.2). The Apgar score is assigned at 1 minute, 5 minutes, and then every 5 minutes thereafter if the total score is less than 7. The score was initially intended to provide a uniform, objective assessment of the newborn's condition and to compare different practices, especially obstetric anesthesia. Despite the intent of objectivity, there is often disagreement in score assignment among practitioners.[113] Low scores are associated with increased risk of neonatal death,[114] but have not been predictive of neurodevelopmental outcome.[115] Interpreting the score when interventions are being provided may be difficult. Current recommendations suggest that clinicians document the interventions used at the time the score is assigned.[116]

Delivery Room Monitoring

The modern delivery room is becoming more like the NICU with advanced patient monitoring devices used to track important physiological measures. Exhaled carbon dioxide (CO_2) detectors, pulse oximetry, electrocardiogram (ECG), and respiratory function monitors (RFM) are some of the most used monitoring devices in the delivery room. Here, we briefly examine the use of each.

Exhaled CO_2 Detector

Detection of exhaled CO_2 confirms ventilation and perfusion of the lungs. Exhaled CO_2 is evaluated by either color change

TABLE 15.2 The Apgar Score

Feature Evaluated	0 Points	1 Point	2 Points
Heart rate (beats/min)	0	<100	>100
Respiratory effort	Apnea	Irregular, shallow, or gasping respirations	Vigorous and crying
Color	Pale, blue	Pale or blue extremities	Pink
Muscle tone	Absent	Weak, passive tone	Active movement
Reflex irritability	Absent	Grimace	Active avoidance

of a colorimetric device or as an expiratory waveform using capnography. A lack or color or waveform alerts the operator to an obstructed airway, blocked ET, displaced ET, or lack of perfusion to the lungs. Airway obstruction is common when providing face mask PPV to newborns.[117,118] The site of obstruction may be laryngeal or supralaryngeal and can be alleviated with ventilation corrective steps. The use of a CO_2 detector during face mask ventilation provides visual confirmation that gas exchange is occurring in the lungs.[119] The *Textbook of Neonatal Resuscitation* supports the use of colorimetric CO_2 detectors during face mask ventilation and during ventilation corrective steps.[10]

It is important to remember that CO_2 detectors will not change color or display a waveform in the absence of pulmonary blood flow, as occurs during cardiac arrest or inadequate cardiac output. If the newborn has cardiac arrest or severe bradycardia, the CO_2 detector may not detect exhaled CO_2 even though the lungs are being ventilated. In cases of newborn cardiac arrest or severe bradycardia where chest compressions are given, the presence of exhaled CO_2 provides some evidence of effective chest compressions.

Pulse Oximetry

Pulse oximeters measure the absorption of red light passing through capillaries in the skin to estimate the percentage of hemoglobin that is saturated with oxygen. The pulse oximeter displays the oxygen saturation ranging from 0% to 100%. Oxygen saturation is different from the partial pressure of oxygen (PaO_2) measured on a blood gas, but both provide evidence of blood oxygenation. The pulse oximeter also displays the newborn's heart rate by sensing pulsatile blood flow in the capillaries. Pulse oximetry at delivery is indicated when resuscitation is anticipated, to confirm the presence of central cyanosis, when supplemental oxygen is administered, and when positive-pressure ventilation is required.[10]

The recommended location for a pulse oximeter is on the newborn's right hand or wrist. This "pre-ductal" position is preferred because it measures the blood flow from the arteries supplying the baby's right arm, which normally attach to the aorta before the patent ductus arteriosus. Oxygen saturations from "post-ductal" locations (left arm or either leg) may be lower than those from the pre-ductal location because the former receives blood from the aorta after it mixes with venous blood that bypasses the lungs through the patent ductus arteriosus. When properly placed on a newborn with adequate pulsatile capillary flow, the pulse oximeter should accurately display the heart rate and oxygen saturation within approximately 1 to 2 minutes after birth.[10] If the baby has a very low heart rate or poor perfusion, the oximeter may not be able to detect oxygen saturations or heart rate. In such cases, electrocardiography may be helpful to determine the heart rate.

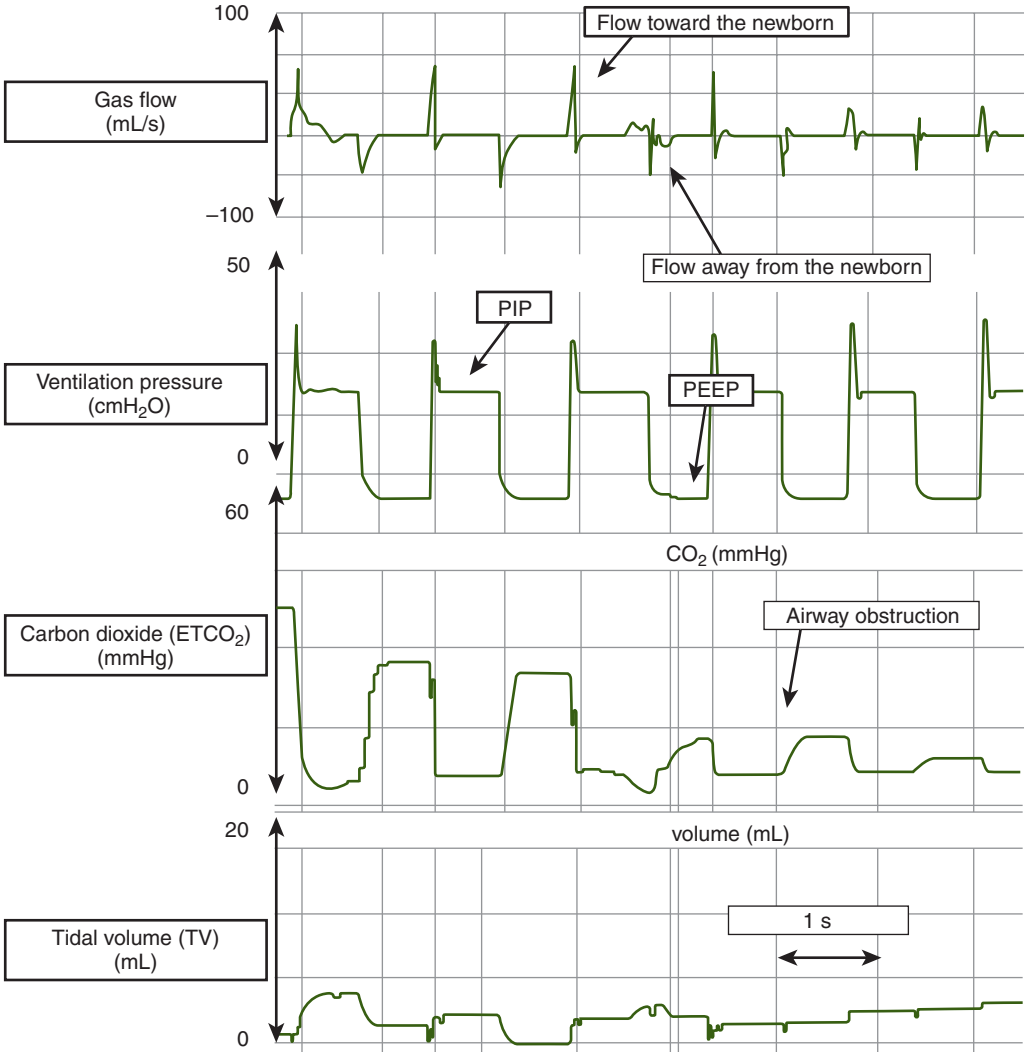
Electrocardiography

Electrocardiography (ECG) detects the electrical activity of the heart, and so is not dependent on the circulation. Placement of the 3-lead ECG electrodes includes just below the right clavicle, just below the left clavicle, and just above and left of the umbilicus. ECG provides a rapid and accurate estimation of heart rate in low perfusion states. In randomized clinical trials comparing oximetry with ECG during newborn resuscitation, ECG was faster and more accurate for newborn heart assessment compared with pulse oximetry.[120,121] Use of ECG for heart rate detection does not replace the need for pulse oximetry to evaluate oxygen saturation.[9] Neonatal resuscitation guidelines suggest that ECG be consider with the initiation of PPV and should be used after placement of an alternative airway and during chest compressions to confirm heart rate.[9,10]

Respiratory Function Monitors

A respiratory function monitor (RFM) measures delivered pressures and gas flow in and out of the lungs.[122] From pressures and gas flow data, inflation and expired volumes are calculated. Most RFMs shows continuous graphical displays of airway pressure, gas flow, tidal volumes (VT), and expired CO_2, and gas leak (Fig. 15.6).[123] Studies have shown that using an RFM during neonatal resuscitation is associated with reduced mask leak, less variation in VT, and improved ability to determine whether an ET is properly inserted in the trachea.[123]

Three types of RFMs are currently available to measure lung function at birth.[122] The devices use different techniques to measure gas flow and unique software to calculate tidal volume. At this time, none of these devices are approved for use in the United States by the Food and Drug Administration (FDA). Therefore, AHA neonatal resuscitation guidelines do not include recommendations regarding RFM use. RFMs are mentioned in the 2021 European Resuscitation Council guidelines on newborn resuscitation[124] and the clinical impact of RFM use is being examined as part of ILCOR's continuous evidence review process. RFMs may be included in future AHA guidelines if devices become FDA-approved.



• **Fig. 15.6** Display from a respiratory function monitor (rfm) showing complete airway occlusion during mask positive pressure ventilation. Adequate positive pressure ventilation is provided, and suddenly the inflation and expiratory flow curves both display fewer flow movements and no tidal volume, and reducing expiratory CO_2 is displayed. The peak inspiratory pressure and positive end-expiratory pressure are maintained during positive pressure ventilation. *$ETCO_2$*, End-tidal carbon dioxide; *PEEP*, positive end-expiratory pressure; *PPV*, positive pressure ventilation. Specific Problems Encountered During Resuscitation

Neonatal Response to Maternal Anesthesia/Analgesia

Medications administered to the mother during labor can affect the fetus by transfer across the placenta. The most discussed complication of intrapartum medication exposure is newborn respiratory depression after maternal opiate administration. The fetus can develop respiratory depression from the direct effect of opiates. Naloxone has been used during neonatal resuscitation as an opiate receptor antagonist to reverse the effects of acute fetal opiate exposure. However, newborns chronically exposed to opiates in utero (which may not be known at delivery) may have acute withdrawal, including seizures, if they receive a narcotic antagonist. Therefore, neonatal resuscitation guidelines do not recommend naloxone as part of the initial resuscitation of newborns with respiratory depression, regardless of whether they have been acutely exposed to opiates.[10] Such newborns should be treated with assisted ventilation.

Conditions Complicating Resuscitation

There are many perinatal and congenital conditions that can complicate newborn resuscitation. Any time a resuscitation has proceeded through the neonatal resuscitation algorithm without improvement in the newborn's clinical condition, other problems should be considered. Some of these problems may be modifiable with interventions that could improve the course of the resuscitation. For example, a pneumothorax could prevent adequate pulmonary inflation and if under tension impair cardiac function. If the pneumothorax is recognized and drained, both gas exchange and circulation can be improved.

Many other congenital anomalies can also lead to a difficult resuscitation. A complete review of the management

TABLE 15.3 Special Considerations and Modifications of Neonatal Resuscitation Guidelines for Newborns With Select Congenital Anomalies

Congenital Anomalies	Specialized Equipment and Personnel to Consider	Neonatal Resuscitation Guideline Modifications
Airway Anomalies		
Micrognathia, TEF, CHAOS, Airway mass, lymphatic malformations	Video laryngoscope, flexible fiberoptic bronchoscopy, tracheostomy, otolaryngology and/or anesthesia assistance	Rapid progression to intubation if face mask PPV is difficult; consider ex-utero intrapartum treatment (EXIT) in high-risk cases
Lung Anomalies		
CDH	Replogle to decompress stomach	Immediate intubation, "gentle ventilation" with lower pressures and tidal volumes
Congenital Heart Disease		
TGA, HLHS, uncontrolled arrhythmias	Cardiologist for possible early balloon septostomy in case of restricted atrial level shunt, PGE, defibrillator, equipment for thoracentesis, and paracentesis in cases of fetal hydrops	For mixing lesions, targeted SpO2, 75%–80%
Gastrointestinal Anomalies		
Gastroschisis, omphalocele, duodenal/intestinal atresia	Gastroschisis: Replogle, sterile bowel bag Omphalocele: Replogle, sterile bowel bag if concern for rupture Duodenal/Intestinal atresia: Replogle	Caution with positive pressure, intubate early in cases of respiratory distress
Neurological Anomalies		
Neural tube defects	Sterile nonstick gauze, foam donut or a gauze rolled into a circle for placement around the defect, latex-free dressing and gloves	Positioning on the side or in a prone position to avoid putting pressure on the lesion.
Multiples		
Conjoined twins	Duplicate equipment to accommodate both twins	Individualized assessment for placement of ECG leads, pulse oximetry, and position for optimal delivery of PPV and chest compressions

CHAOS, Congenital high airway obstruction syndrome; *CDH*, congenital diaphragmatic hernia; *HLHS*, hypoplastic left heart syndrome; *TEF*, tracheoesophageal fistula; *TGA*, transposition of great arteries.

of all the varied congenital anomalies that can complicate newborn resuscitation is outside the scope of this chapter. However, Table 15.3 provides a summary overview of special considerations in newborn resuscitation adapted from a recent review.[125]

Limits of Viability

The lower limit of viability has been an ongoing debate since the specialty of neonatology began. The limit has changed over time with the advent of newer equipment and increasing comfort with the care of extremely premature newborns. In the 1972 (3rd edition) of the Avery's textbook, Drs. Avery and Schaffer wrote "the lower limit of viability is probably about 28 weeks, at which time most infants weigh 2 pounds 4 ounces (1000 g)."[126] Today, the lower limit is probably a gestational age less than 22 weeks and/or birth weight less than 350 g.[127] Because of ethical and legal implications of publishing guidelines for the noninitiation of resuscitation based on gestational age or birth weight, the AHA neonatal resuscitation guidelines and the *Textbook of Neonatal Resuscitation* do not mention a lower limit of viability.[9,10] Instead, they acknowledge that decision-making should be individualized with consideration to the likelihood of survival and acceptable health outcomes.

Noninitiation and Discontinuing of Resuscitation

Even with optimal neonatal resuscitation, some babies are too sick or immature at birth to survive. Also, some conditions are so severe that the burdens of the illness and treatment outweigh the likelihood of survival. In cases where such conditions are identified at or before birth, it is reasonable not to initiate resuscitative efforts.[9,10] What is best for the newborn is the primary consideration for decisions around newborn resuscitation. Factors that should be considered include the following[10]:

The chance that the therapy will succeed.
The risks involved with treatment and nontreatment.
The degree to which the therapy, if successful, will extend life.
The pain and discomfort associated with the therapy.
The anticipated quality of life for the newborn with and without treatment.

Making the decision to discontinue resuscitation efforts after resuscitation is started is challenging. Variables to consider include the circumstances before birth, whether the resuscitation process was optimal, the availability of advanced neonatal care such as therapeutic hypothermia, and the wishes of the family.[10] Neonatal resuscitation guidelines suggest that if the heart rate remains undetectable (e.g., persistent asystole) at about 20 minutes after birth, and all steps of the resuscitation algorithm have been completed, it may be reasonable to stop resuscitation.[9,10] The decision to continue or discontinue resuscitative efforts should, however, always be individualized. The 20-minute time frame is based on case series showing small numbers of intact survivors after 20 minutes of resuscitation with no detectable heart rate.[9]

Post-resuscitation Care

While effective resuscitation is critical, optimal care after the resuscitation is also paramount. Post-resuscitation monitoring in a neonatal intensive care unit or a triage area is needed for any newborn who received prolonged PPV or advanced resuscitation (e.g., intubation, chest compressions, and/or epinephrine) at birth.[9] Frequent complications following resuscitation include hypoglycemia, hypothermia, hypotension, and persistent metabolic acidosis.

Hypoglycemia is a common problem in newborns who have received advanced resuscitation and hypoglycemia in the post-resuscitation period is associated with poorer outcomes.[128] Thus, all newborns that received prolonged PPV or advanced resuscitation should be monitored for hypoglycemia and treated appropriately.[9]

During resuscitation, many newborns experience unintentional hypothermia (temperature less than 36°C). Therefore, temperature should be monitored closely after stabilization. Hypothermic newborns should be rewarmed to avoid complications associated with low body temperature, which including increased mortality, brain injury, hypoglycemia, and respiratory distress.[9] Neonatal resuscitation guidelines suggest that warming can be done either rapidly (0.5°C/h) or slowly (less than 0.5°C/h) with no significant difference in outcomes.[9] Caution should be taken to avoid overheating during post-resuscitation care.

Newborns 36 weeks or greater who receive advanced resuscitation should be examined for clinical evidence of hypoxic-ischemic encephalopathy (HIE). The pathophysiology of HIE and its treatment with therapeutic hypothermia are discussed in detail elsewhere in this textbook. Therapeutic hypothermia decreases the secondary injury that occurs after a hypoxic-ischemic insult. The therapy is most beneficial when started as soon as possible after birth, ideally within 6 hours. Thus, a thorough assessment for HIE during the immediate post-resuscitation period is critical to determine if a newborn meets treatment criteria. Therapeutic hypothermia is not recommended in newborns less than 36 weeks' gestational age since the impact is unclear. It is the subject of ongoing research.[9]

Acknowledgment

The authors would like to acknowledge Dr. Anup Katheria and Dr. Neil Finer for their work on this chapter in the previous edition.

16 Care of the Newborn

MICHELLE M. GONTASZ, AMARIS M. KEISER, AND SUSAN W. AUCOTT

KEY POINTS

- Prenatal ultrasonography can diagnose multiple newborn conditions early. However, the natural history of many common ultrasound findings is variable, and the findings may or may not represent markers of serious disease.
- The short-term and long-term benefits of breastfeeding are clear. The effects on breastfeeding rates from interventions such as formula supplementation, frenotomy, and restriction of pacifiers remain controversial, as does breastfeeding among HIV-positive mothers.
- Comprehensive guidelines for the management of common newborn conditions such as jaundice, suspected sepsis, and hypoglycemia allow standardization of care. Ongoing research is needed to optimize guidelines to improve long-term outcomes.
- With the implementation of universal maternal screening for group B streptococcus and the use of intrapartum antibiotic prophylaxis, rates of sepsis in term newborns have fallen significantly. Online aids are available to assist clinicians in assessing the risk of sepsis and developing institutional guidelines for the identification and management of infants at risk for sepsis.
- Pulse oximetry screening for critical congenital heart disease is recommended for healthy newborns.
- Late preterm infants are at risk of complications associated with prematurity and require close monitoring for respiratory problems, feeding issues, hypoglycemia, hyperbilirubinemia, infection, and thermoregulation in the postnatal period.

Introduction

Optimal newborn care facilitates a successful transition from intrauterine to extrauterine life without overmedicalization of care, provides low-risk preventive care, and identifies "high-risk" infants who would benefit from increased monitoring, testing, or intervention, thereby decreasing early preventable morbidity and mortality. Systems of care should be designed to align with the concept that the majority of newborns are healthy and require little intervention beyond the promotion of breastfeeding, and interventions for which there is clear evidence that benefits outweigh risks should be provided as unobtrusively as possible. Simultaneously, the system must maintain space and opportunity for healthcare providers to quickly and efficiently identify those neonates at risk of developing serious or life-threatening conditions.

The goal of this chapter is to provide a framework for developing an approach to the initial assessment of the apparently well newborn. This includes the identification of common neonatal problems, indications for additional monitoring, and risk-benefit analysis of testing and treatments commonly employed in the newborn nursery. Rather than providing a comprehensive prescription on how to care for healthy newborns, we hope that the reader will integrate the information provided in this chapter with expert opinion and his or her own clinical experience to provide thoughtful, evidence-based management for this unique patient population.

Initial Newborn Evaluation

In the mother-baby unit or well-baby nursery, the primary goal is to identify the small minority of babies with significant problems that may cause serious morbidity if not detected promptly, including psychosocial problems that may adversely impact both "normal" and "at risk" newborns. This goal must be accomplished with the understanding that the vast majority of babies encountered in the newborn nursery are completely healthy, despite wide variations in presentation and findings.

The Initial Assessment

The timing of the initial assessment of a healthy-appearing newborn is dependent on the condition of the newborn and parental preference. In most instances, a healthcare professional who is present at the birth will make a general appraisal of the newborn and alert the child's provider if there is an acute problem necessitating an immediate evaluation. The newborn's weight, length, and head circumference should be measured and plotted on a standardized chart; the WHO growth chart is used for term (≥37 weeks) infants, and the Fenton growth chart for preterm infants (<37 weeks).[1,2] This assessment can usually be timed so as not to interfere with breastfeeding, bonding with the family, and routine care.

The Newborn History

Before a well newborn is examined, the maternal medical history should be reviewed to identify issues that could affect the care or prognosis of the newborn. For example, a history of diabetes (gestational or prepregnancy) would lead to glucose monitoring in the newborn; and maternal medication use may prompt an assessment for possible teratogenic effects or signs of neonatal drug withdrawal or compatibility with breastfeeding. It is equally

important to review the pregnancy history, including the estimated gestational age (GA), the results of prenatal screening for genetic conditions, and the results of prenatal ultrasound examinations. Positive findings on the prenatal ultrasound deserve particular attention, as they may have implications for postnatal management. Perinatal events such as the type of delivery, length of time that membranes were ruptured, and Apgar scores should also be reviewed. Finally, it is critical to review the mother's social history to identify psychosocial risk factors that may preclude safe discharge home, or for which interventions are indicated before, or shortly after, discharge from the newborn nursery. An outline of relevant prenatal and newborn history is presented in Table 16.1.

TABLE 16.1 Key Components of the Maternal Medical, Pregnancy, and Perinatal History

Category	Components
Maternal identification	Age, gravida, parity, weeks in gestation
Maternal medical history	Significant co-morbidities, illness, medications
Current pregnancy	Singleton or multiple fetuses
	Pertinent results of laboratory tests and imaging studies
	Fetal growth (IUGR; LGA; hydrops)
Labor	Rupture of membrane (duration)
	Amniotic fluid (oligohydramnios/polyhydramnios; bloody; purulent; meconium; foul smelling)
	Signs of infection (maternal fever, elevated WBC count, tachycardia, uterine tenderness)
	Fetal tracing (tachycardia, decelerations, etc.)
Delivery	Indication if emergent delivery (abruption; preeclampsia, fetal distress/intolerance to labor)
	Route of delivery
	Method of anesthesia (general versus local)
	Medications administered
Newborn	Apgar scores and resuscitation at delivery
	Growth parameters
	Desired feeding method

IUGR, Intrauterine growth restriction; *LGA*, large for gestational age; *WBC*, white blood cell.

Prenatal Ultrasound Findings

Ultrasound screening for fetal anomalies has become increasingly routine. Major fetal organ system abnormalities can be identified, for the most part, and the mother can be referred for counseling and appropriate fetal and neonatal management. There are, however, a number of ultrasound findings that have a variable natural history and may or may not be markers for serious conditions. Moreover, these ultrasound findings may or may not result in a definitive prenatal diagnosis, highlighting the importance of postnatal assessment and management. Here we present common prenatal ultrasound findings, organized by organ system, including recommendations for prenatal and postnatal evaluation.

Central Nervous System Findings

Choroid plexus cysts are found in 2% to 4% of second-trimester fetal ultrasound examinations. They are transient, functionally benign in nature, and generally resolve spontaneously before term. Isolated choroid plexus cysts on prenatal ultrasound examination are not associated with adverse effects on fetal growth or development. Thus, without other risk factors, no further evaluation is needed in an infant with this isolated finding who has had a benign prenatal and a normal postnatal course.[3] Choroid plexus cysts may be a soft marker for aneuploidy (particularly trisomy 18) when associated with other fetal anomalies or with maternal risk factors, such as advanced maternal age. In such situations, current recommendations are to begin an appropriate prenatal evaluation, such as karyotyping.[4–6]

Agenesis of the corpus callosum is reported to occur in 0.3% to 0.7% of unselected postnatal populations. Aneuploidies have been reported in 10% to 20% of children with this prenatal ultrasound finding, and major organ system abnormalities are reported in up to 60% of affected fetuses. Therefore, fetal magnetic resonance imaging can be considered to further assess for associated anomalies and offer enhanced risk stratification. Encouragingly, the absence of the corpus callosum in an otherwise anatomically normal fetus is associated with a normal developmental outcome in 50% to 75% of cases. Postnatal management for infants with a history of agenesis of the corpus callosum on prenatal ultrasound should include a thorough physical examination, close clinical assessment, and consideration of additional imaging if not already completed prenatally.[7–10]

Mild, isolated ventriculomegaly is a relatively uncommon fetal ultrasound finding and may be a soft marker for aneuploidy, fetal infection, or other central nervous system abnormalities. As such, serial prenatal imaging studies and, in some cases, more extensive work-up are recommended. In the presence of a benign fetal assessment, most newborns appear to do well following delivery. It is important to consider close developmental follow-up and serial imaging studies, often beginning with an early postnatal cranial ultrasound, if there are additional concerns.[11–13]

Cardiac Findings

Echogenic cardiac focus is an incidental ultrasound finding in 3% to 4% of normal fetuses. Notably, there is an increased incidence (10% to 30%) in Asian populations. It may be a soft marker for chromosomal abnormalities (trisomy 21 and trisomy 13) when associated with other screening abnormalities. Further work-up may be indicated in high-risk populations. If the physical examination findings for a newborn are unremarkable and there are no other ultrasound findings, no further evaluation is suggested.[14–18]

Gastrointestinal Findings

Grade 0 or 1 echogenic bowel on a second-trimester ultrasound examination (i.e., less echogenic than bone) is considered a normal variant with a good prognosis. No special prenatal or postnatal work-up is recommended. Anything of density equal to or greater than that of bone (grade 2–3) is abnormal; differential diagnoses include cystic fibrosis (CF), trisomy 21, gastrointestinal anomalies, in utero infection, bowel ischemia or bleeding, intrauterine growth restriction, and/or impending in utero demise. Oftentimes, further prenatal work-up will have been performed, including parental CF testing, maternal serologic testing for

cytomegalovirus (CMV) and toxoplasmosis, and amniocentesis, which allows for narrowing of the differential. If unrevealing, postnatal assessment should include consideration of aneuploidy, congenital infection, and identification of associated structural anomalies. Management often entails close monitoring for feeding tolerance, with or without abdominal imaging and additional targeted testing.[3,19,20]

Cholelithiasis is an uncommon third-trimester fetal ultrasound finding that needs to be differentiated from hepatic calcification. Cholelithiasis is considered a benign condition requiring no special evaluation or treatment prenatally or postnatally, but careful clinical follow-up is recommended. An imaging examination at 1 year of age for a child with this prenatal finding may be helpful in documenting expected resolution.[21,22]

Hepatic calcifications are uncommon fetal ultrasound findings. They are often isolated, single, and, in a low-risk mother, of no significance. However, when numerous, hepatic calcifications may be markers for fetal aneuploidy, infection, meconium peritonitis, hepatic tumor, or vascular insult. A significant percentage are associated with some form of fetal disease. Neonatal management depends on the prenatal work-up and the clinical presentation in the newborn period.[23,24]

Urinary Tract Findings

Mild fetal pelviectasis is one of the more common abnormalities detected by second-trimester ultrasound, with a reported incidence of 0.5% to 5%. Diagnostic criteria differ but generally include a second-trimester renal pelvis diameter of 4 to 10 mm or a third-trimester renal pelvis diameter of 7 to 10 mm; renal pelvis diameters of ≥10 mm are always considered abnormal. Some experts consider mild fetal pelviectasis to be a soft marker for aneuploidy, especially trisomy 21. When mild fetal pelviectasis is an isolated finding, the prognosis is good, and the condition often resolves either in utero or during early childhood. In fact, the majority of children with a prenatal finding of hydronephrosis demonstrate no postnatal disease.[25–28] Experts thus recommend a postnatal follow-up renal ultrasound examination approximately 1 week after birth and, if necessary, at 1 month of life to document resolution.[3,29,30]

Evidence of hydronephrosis on prenatal ultrasound will need a postnatal evaluation with a renal ultrasound in order to identify obstructive lesions and determine the need for further evaluation for urinary reflux. The ultrasound is recommended to occur at greater than 48 hours after birth, as earlier evaluation can lead to false-negative results due to the relative oliguria that occurs on the first day of age in newborns. An ultrasound should be considered immediately after birth if evidence of obstructive uropathy is seen on the prenatal ultrasound.[29]

The Physical Examination

For the healthy newborn, the admission examination is done after the newborn completes transition and within 24 hours of birth. A complete physical examination at this time—in an orderly sequence—is designed to efficiently detect problems that were initially unapparent or are likely to soon develop (Box 16.1). The pediatrician should review the infant's growth chart to determine whether there are discrepancies in the weight, height, and head circumference percentiles and stated GA. Although the most common reason for a discrepancy is an inaccurate measurement, a valid discrepancy warrants close clinical observation or testing. If the estimated GA of the newborn is inconsistent with the growth parameters, a formal evaluation by a Dubowitz–Ballard

• BOX 16.1 Example Examination Sequence

1. Observation (is the baby sick or well?)
2. Auscultation of the anterior chest and abdomen (if the newborn is quiet and cooperative).
3. Inspect and palpate the head (the back of the head and neck will be inspected later).
4. Gently turn the head to each side (noting any restricted range of motion).
5. Inspect each ear when the head is turned.
6. Palpate the neck and clavicular areas (for masses and/or crepitus).
7. Determine overall features of facial shape and symmetry.
8. Confirm the presence or absence of abnormal findings involving skin, eyes, nose, mouth, and oral cavity.
9. Assess respiratory pattern.
10. Inspect and palpate the anterior chest and abdomen (including the umbilicus).
11. Open the diaper and palpate the femoral pulses.
12. Examine the genitalia and perineum.
13. Inspect the lower extremities for abnormal positioning to check alignment, plantar grasp, and the Babinski reflex (start by placing the thumbs on the soles of the feet with the fingers around the back of the ankles).
14. Perform the Barlow and Ortolani maneuvers.
15. Lift and abduct the legs into a frog-leg position to provide a full view of the perineum and anus. Evaluate the newborn for appropriate positioning of the anus and its patency.
16. Inspect the genitalia by gently retracting the labia majora in females or depressing the skin at the base of the penis in males. Inspect and palpate the scrotum and testes. Refasten the diaper.
17. Take an unobstructed observation of the overall shape, symmetry, and movements of the arms and hands (shirt/clothing removed).
18. Palpate each whole arm gently, starting with one of the examiner's hands on each of the baby's shoulders, and then slide down to the baby's hands, noting any swelling or discontinuities.
19. With the newborn supine, turn the head to elicit the asymmetric tonic neck reflex on each side.
20. Inspect the hands, fingers, nails, and palms. If the newborn's hand is tightly fisted, do not attempt to pry the fingers open. Instead, gently flex the wrist to 90 degrees, which will cause the fingers to relax naturally. Inspect the palms, and then elicit the palmar grasp reflex.
21. Without releasing the baby's hands, one can then perform the pull-to-sit maneuver. The pediatrician places his/her hand behind the newborn's head and neck to provide support as the newborn is gently lowered back toward the bed. When the newborn's head and shoulders are a few inches from the bed, the examiner drops his/her hand rapidly to elicit the Moro reflex. (Parents may be alerted to this portion of the examination to avoid unnecessary distress/anxiety.)
22. Next, place the hands on either side of the chest, under the arms at the shoulders, and raise the baby to an upright position. Note the strength and tone of the shoulder muscles.
23. Lower the newborn, still in an upright position, and try to elicit the supporting and stepping reflexes.
24. Turn the newborn to a prone position, suspended on the examiner's hand. Observe the newborn's posture and tone, and elicit the incurvation response (again, explanation in advance of these actions to parents who may be observing is helpful).
25. Inspect the newborn's back, from the vertex of the head down to the sacrum (pulling the diaper down, if needed).
26. Gently place the newborn back in the crib, and fully redress the newborn. Attempt to successfully soothe newborn by swaddling if the newborn has cried during the more active portions of the examination.
27. Red reflex examination can be performed at this time or at any suitable time when the eyes are open spontaneously.

assessment should be performed.[31] This scoring tool is probably the most widely used GA assessment tool in contemporary practice.[32] Detailed descriptions and a video demonstration of this examination are available online.[33,34] For greater detail on organ-specific aspects of the newborn physical exam, readers are referred to relevant sections and chapters in this textbook.

Routine Management of the Newborn

Prevention of Ophthalmia Neonatorum and Conjunctivitis

Approximately 1% to 12% of babies will develop conjunctivitis in the first 4 weeks of life.[35] Conjunctivitis can be caused by a sexually transmitted bacterium, normal skin or nasopharyngeal flora, or chemical irritation. In addition, eye discharge can be caused by obstruction of the nasolacrimal duct rather than from conjunctivitis.[36] The most worrisome infection is that of *Neisseria gonorrhea*, which can invade the cornea in a matter of hours and lead to blindness. Despite effective preventive measures known since the 1880s, thousands of children are still blinded by this infection worldwide each year.[37]

Most states in the United States have laws or regulations requiring the administration of topical antibiotic ointment to the conjunctivae of babies within a few hours of birth. This practice has been effective in reducing the cases of blindness caused by gonococcal conjunctivitis. It is moderately effective in preventing conjunctivitis caused by chlamydia. The main risk of antibiotic ointment application is chemical conjunctivitis. Silver nitrate solution instilled into both eyes immediately after birth was the standard of care for many years, but it caused a high rate of chemical conjunctivitis.[37]

A search for alternative, non-ointment-based prophylaxis that causes less irritation is ongoing. A variety of prophylactic treatments have been recommended, including 1% nitrate solution, 1% tetracycline solution, 1% erythromycin solution, 2.5% povidone-iodine solution, fusidic acid, and freshly expressed breast milk. Among those, tetracycline has been reported as the most effective.[38] There is lay literature recommending the instillation of colostrum or breast milk into the eyes of babies to prevent or treat conjunctivitis,[39,40] and limited scientific literature addressing the feasibility and efficacy of this approach.[41–43] A randomized controlled trial from Iran comparing the efficacy of colostrum versus erythromycin ointment versus placebo in preventing neonatal conjunctivitis demonstrated some degree of protection conferred by colostrum, but results should be interpreted cautiously and are insufficient to recommend practice change in the United States.[44]

Studies demonstrate that povidone-iodine solution is more effective and causes less irritation than erythromycin ointment. It is also less expensive but is not yet approved for this use by the US Food and Drug Administration.[45] A major concern is that medical errors can occur if povidone-iodine soap is mistakenly substituted for the solution; it can cause eye damage. Fusidic acid has been used for preoperative prophylaxis for a number of surgical procedures in adults; however, data on its use in newborns are limited.[38]

Vitamin K Prophylaxis

Vitamin K is necessary for biologic activation of several human proteins, most notably coagulation factors II (prothrombin), VII, IX, and X. Since placental transfer is limited, umbilical cord blood levels of vitamin K_1 (phylloquinone) are 30-fold lower than maternal levels. Intestinal bacteria synthesize menaquinone (vitamin K_2), which has 60% of the activity of phylloquinone. However, neonates have a decreased number of bacteria in their gut that manufacture vitamin K_2; thus, newborns are deficient in vitamin K at birth and are at risk of significant bleeding within the first days to months of life. There are three presentations of vitamin K–deficient bleeding (VKDB) in the neonate, with the risk dramatically reduced when intramuscular (IM) vitamin K is administered shortly after birth.

"Early" VKDB presents in the first 24 hours after birth, is not prevented by postnatal administration of vitamin K, and usually occurs in newborns born to mothers who are taking medications that cross the placenta and interfere with vitamin K metabolism. The most common of these medications include many anticonvulsants (such as phenytoin), isoniazid, rifampin, warfarin, and some antibiotics (especially cephalosporins). Early VKDB is frequently serious because of intracranial or intraabdominal hemorrhage. It is estimated that in neonates at risk of early VKDB, the incidence is as high as 12%.[46]

"Classic" VKDB occurs in newborns during the first week of life. Although the presentation is often mild, blood loss can be significant, and intracranial hemorrhages have been reported. Although estimates differ, the incidence of classic VKDB, in the absence of vitamin K supplementation, is 0.25% to 1.7%.[47]

"Late" VKDB occurs between the ages of 2 and 12 weeks and is usually severe. The mortality rate from late VKDB is approximately 20%, and half of infants with this disorder develop intracranial hemorrhages. Late VKDB is associated with exclusive breastfeeding. Human milk contains only 1 to 4 μg of vitamin K per liter, while commercially available formula contains 50 μg/L or more. In exclusively breastfed neonates who do not receive supplemental vitamin K, the incidence of late VKDB is estimated at 4.4 to 7.2 per 100,000 (or 1 per 15,000 to 1 per 20,000).[46]

IM vitamin K administered shortly after birth is effective in preventing classic and late VKDB by rapidly activating clotting factors. Since 1961, the United States has recommended 1 mg IM vitamin K for term newborns. In the early 1990s, controversy about this recommendation began after a study was published suggesting an association between IM vitamin K given at birth and childhood cancer.[48,49] The results of subsequent studies strongly suggested that there is no increased risk of solid tumors in children given IM vitamin K.[50] However, enough concern was raised over this possible association that in some countries vitamin K prophylaxis was transitioned to an oral preparation. While helping to allay fears about childhood malignancies, it was unclear whether an oral dosing regimen provided the same degree of protection against all forms of VKDB as the IM injection. Specifically, studies demonstrate that the efficacy of a single oral dose of vitamin K is similar to that of an IM dose in preventing classic VKDB, but offers less protection against late VKDB.

In a multination review, the rate of late VKDB in infants receiving various regimens of orally administered vitamin K ranged from 1.2 to 1.8 per 100,000, compared with no cases in 325,000 children receiving an IM dose.[51] The rates of VKDB in newborns receiving 2 mg orally at birth plus repeated doses over the ensuing weeks are relatively low, but still higher than in neonates administered a single dose of IM vitamin K.[52,53] Early data from the Netherlands suggested that infants receiving an oral vitamin K regimen of 1 mg at birth and 25 μg daily for up to 12 weeks was as effective as a single IM dose at birth in preventing both classic and late VKDB.[51] However, a subsequent study

from the Netherlands documented a higher rate of late VKDB (3.2 per 100,000) with the 1 mg/25 μg dosing regimen among a group of infants later diagnosed with biliary atresia,[54] a significant risk factor for VKDB. This study raised questions about the ability of an oral vitamin K regimen to offer adequate protection against VKDB for higher-risk populations when the identification of risk factors may be delayed. Finally, no cases of late VKDB were found among 396,000 Danish infants who received an oral dose of 2 mg of vitamin K at birth and 1 mg weekly until the age of 3 months.[55]

Highlighted by the reports of intracranial hemorrhages in four newborns from Tennessee who did not receive vitamin K at birth, there are concerns that the rate of parental refusal of vitamin K in the United States has been increasing.[56,57] Although there has been little widespread surveillance of the rates of vitamin K refusals, recent studies suggest that rates in North America may range from 0.5% to 3%,[58] and that rates are higher for newborns born in birthing centers than in hospitals.[59,60] Rather than being concerned about the reports linking vitamin K with childhood cancers, parents who refuse vitamin K treatment for the newborn are also more likely to refuse vaccines for their children at later ages and share many of the beliefs of other parents refusing vaccines for their children.[60] In one study the most commonly cited reason for parents refusing vitamin K treatment for their newborns was "synthetic or toxic ingredients," followed by concerns about an "excessive dose" and side effects; only 7% of those surveyed were concerned about the risks of cancer.[60]

The risks of IM vitamin K include pain at the injection site and the possibility of a serious medication error. The risks of a significant complication from the injection are probably negligible; in one study, no significant complications were reported after 420,000 injections.[61] In the United States, oral administration is complicated by the lack of an oral vitamin K preparation licensed for newborns. In some settings, infants have received the IM preparation orally. However, tolerability may be a problem, and the efficacy of this preparation when given orally may not be comparable with the oral formulations used in Europe. In addition, adherence to repeated doses of orally administered vitamin K in infants may be suboptimal. Finally, it is unknown whether the use of repeated administration of an oral vitamin K preparation in the dose range of 1 to 2 mg each week is associated with an increased risk of childhood cancers.

For parents who have questions regarding the best method to prevent classic and late VKDB, we suggest the clinician discuss the pros and cons of IM versus oral administration of vitamin K. If the parents decline IM vitamin K administration but agree to oral administration, a dose of 2 mg should be given shortly after birth, with subsequent doses until the newborn is at least 4 weeks old if breastfed. These recommendations are based on a policy report developed by the American Academy of Pediatrics (AAP) addressing prophylactic vitamin K administration, which states that *if an oral vitamin K formulation becomes licensed for use in the United States*, providers may administer 2 mg by mouth at birth, at 1 to 2 weeks of age, and at 4 weeks of age.[62]

Universal Hepatitis B Immunization

The implementation of routine hepatitis B virus (HBV) immunization during infancy has been associated with a dramatic decrease in the incidence of this infection. Between 1990 (before routine vaccination of infants) and 2004, the overall incidence of acute hepatitis B infection in the United States declined by 75% and by 94% among children and adolescents, respectively.[63] Both the Centers for Disease Control and Prevention and the AAP recommend that the initial dose of the three-dose HBV immunization series be given within the first 24 hours of life for medically stable infants with birth weight ≥ 2 kg and at day of life 30 or discharge (whichever is sooner) for infants with birth weight less than 2 kg.[64]

There are at least two advantages of providing the first dose of HBV vaccine during the initial hospital stay. First, newborns who receive a birth dose are more likely to complete their HBV immunization series on time than those who receive the first dose later.[65] Second, since a dose of HBV vaccine given within 12 hours of birth can prevent vertical transmission of HBV infections in 75% to 90% of cases, early provision of immunization serves as a "safety net" in cases where there has been an error in identifying a mother who is HBV surface antigen positive.[63] There is no evidence that administration of a birth dose of HBV vaccine leads to more evaluations for sepsis because of adverse events related to the immunization.

Newborn Feeding

Breastfeeding

There is voluminous evidence that the optimal nutrition for healthy neonates is human milk provided via the mother's breast. Growing evidence supports the role of human milk in the prevention of the early onset of allergies, prevention of adult obesity, reduction in severity and frequency of infections (including those leading to hospitalization in developed countries and those leading to death in developing countries), and increased intellectual functioning.[66] It is a public health imperative and incumbent on our society to provide systems that support breastfeeding.[67]

Support of Breastfeeding

Breastfeeding is not always the "easy and natural" undertaking it is touted to be. Primiparous mothers report more difficulties than multiparous mothers. Breastfeeding support begins with encouragement and education at prenatal visits. After birth, in-person lactation support is helpful in promoting both initiation and continuation of nursing.[68] Places of employment should provide support by having adequate maternity care leave policies, improving facilities for nursing women, and having policies allowing time and space for nursing and pumping for lactating women at the workplace.[69] Fathers and grandparents should provide a supportive social network by performing home care tasks to facilitate rest for lactating mothers.[70] Problems with nursing should trigger additional intervention with lactation specialist evaluation and advice.

In 1991, the WHO and the United Nations Children's Fund developed a program to promote breastfeeding called the Baby-Friendly Hospital Initiative (BFHI). As a comprehensive program, implementation of the 10 steps of the BFHI (Box 16.2) has been shown to significantly increase the rates of breastfeeding.[71] In addition, there is evidence of a "dose-response" relationship between the number of BFHI steps that women are exposed to and improved breastfeeding outcomes.[72]

For some of the individual steps of the BFHI, such as excluding the use of pacifiers, the evidence is contradictory.[73,74] There are a number of epidemiologic studies showing cessation of breastfeeding is associated with pacifier use, but the few randomized prospective trials done give different results. The authors of a review

• BOX 16.2 Baby-Friendly Hospital Initiative: Ten Steps to Successful Breastfeeding

1. Maintain a written breastfeeding policy that is routinely communicated to all healthcare staff.
2. Train all healthcare staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within 1 h of birth.
5. Show mothers how to breastfeed and how to maintain lactation, even if they are separated from their newborns.
6. Give newborns no food or drink other than breast milk unless medically indicated.
7. Practice "rooming-in"—allow mothers and newborns to remain together 24 h/day.
8. Encourage unrestricted breastfeeding (breastfeeding on demand).
9. Give no pacifiers or artificial nipples to breastfeeding newborns.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on their discharge from the hospital or clinic.

concluded that among mothers who were motivated to breastfeed, pacifier use did not significantly affect the prevalence or duration of breastfeeding.[75] Sucking is a primitive brain self-soothing process. Babies with certain temperaments may benefit more than others by using sucking to self-soothe. Pacifier use has been shown in some studies since the 1970s to decrease the risk of sudden infant death syndrome (SIDS), and in premature infants, nonnutritive sucking actually enhances weight gain. The AAP developed a policy statement supporting pacifier use but recommended waiting until approximately 1 month of age.[66] The important issue is whether or not the use of a pacifier is replacing feedings, so if a mother is motivated to breastfeed and maintains a frequency of 8 to 12 feedings per day, the use of a pacifier between meals is reasonable.

Another contentious issue is the use of supplemental formula during the initial newborn period. The results of a randomized prospective trial indicated that use of limited supplemental formula was associated with increased breastfeeding rates at 3 months of age.[76] That seems contradictory to earlier studies showing a decline in nursing when formula samples or discharge packages were given to families. One key difference is that in the trial, formula use was limited to 10 mL after feedings, administered via a syringe, and supplement was discontinued once mature milk was produced. More research is needed to determine which mother–infant dyads will benefit from supplement while avoiding sabotage of breastfeeding.

From a practical standpoint, there are several evidence-based interventions during the newborn nursery stay that increase the rate and/or duration of breastfeeding. These include the use of frequent demand feedings as opposed to a rigid feeding schedule, early skin-to-skin contact between the mother and the newborn, professional advice on breastfeeding techniques, and exclusion of commercial formula from discharge packs.[77–80]

Challenges With Breastfeeding

Breast milk development is divided into three phases. The first, lactogenesis I, begins during pregnancy with breast enlargement due to the proliferation of ducts and lobules and concludes with colostrum production. Lactogenesis II occurs usually about 56 to 72 hours after delivery; gonadotropin and progesterone levels decline and prolactin level increases.[81] This phase is characterized by a rapid increase in milk volume—sometimes this is exuberant to the point of engorgement. Lactogenesis III occurs after approximately one month of nursing when the milk composition and volume are responsive to the reciprocal relationship between the mother and her baby—a demand and supply feedback loop. Some experts combine lactogenesis II and lactogenesis III into one phase.

Delays in lactogenesis II may occur after cesarean birth, in poorly controlled diabetic mothers, when there is stress during delivery, when there are retained placental fragments, and when there is pituitary failure. There are some situations when no milk production occurs, leading to frustration and feelings of failure in mothers. The timing of lactogenesis II is biologically fixed and cannot be accelerated by pumping or frequent nursing.[82,83]

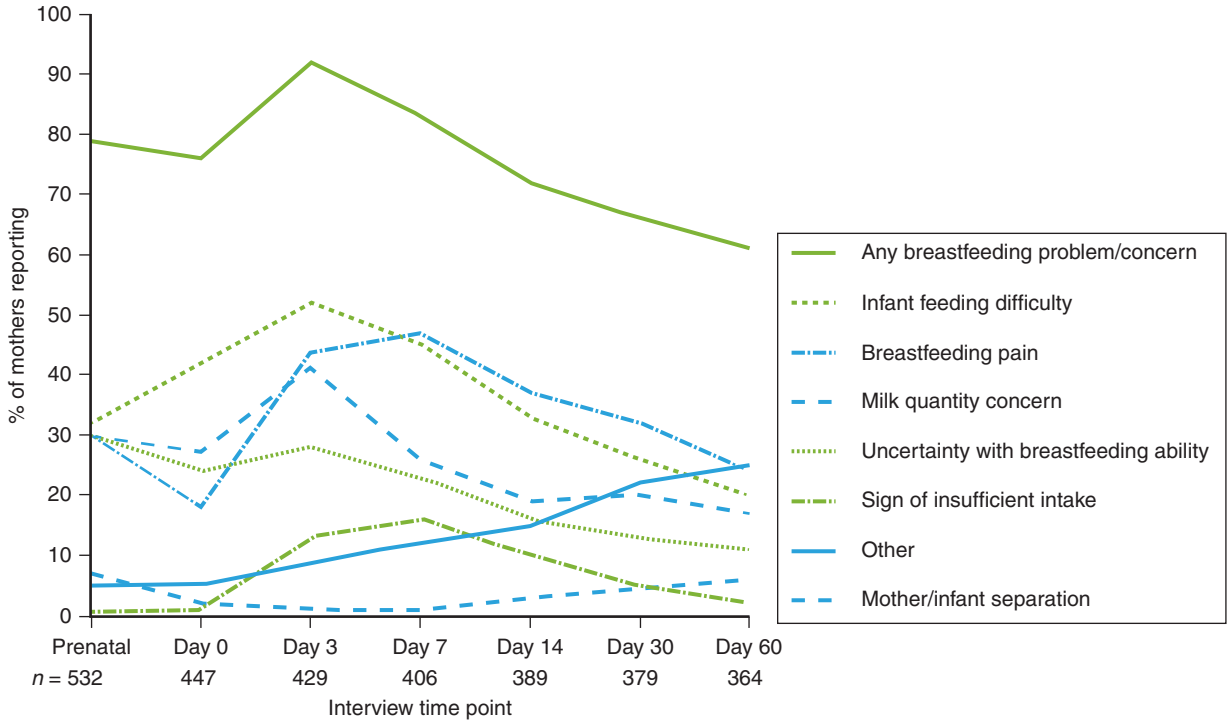
More than 90% of mothers report concern and difficulty with nursing during the first 10 days after delivery (Fig. 16.1).[84] Combined with hormonal changes and sleep deprivation, this can compound the risk of postpartum depression and early cessation of nursing. Postpartum depression screening should be conducted at pediatric health supervision visits until the infant is 6 to 12 months of age.[85]

Common issues that may lead to early cessation of breastfeeding include nipple pain, newborn jaundice, excessive weight loss or poor weight gain, concern about maternal medications, and lack of social support. There are also conditions associated with low milk volume production, including maternal factors (lack of social support, prenatal confidence and expectations about breastfeeding, timing of return to work, inadequate frequency of nursing, inadequate breast tissue, flat or inverted nipples, large breasts) and infant factors (hypotonia, drug withdrawal, asymmetric jaw, high arched palate, poor tongue motor abilities, temperamental issues).

For nipple pain, there is no treatment that is clearly advantageous (e.g., hydrogel, lanolin, breast milk, shields), but education on latch position is helpful. For most, the pain decreases within the first 7 days regardless of the treatment selected.[86] Nipple shields can be used to help decrease nipple pain, but there is some concern that their use could interfere with milk transfer.[87]

There has been a recent increase in the use of frenotomy to alleviate pain with nursing, presumably due to a tight lingual frenulum (tongue-tie or ankyloglossia). With the use of objective rating scales, the rate of tongue-tie in newborns is about 1% to 4%, but more infants are undergoing frenotomy, and there are concerns that this may be more due to anecdotal reports rather than more rigorous study.[88] Sometimes frenotomy is done to alleviate the frustrations of mothers (and lactation specialists) who are dealing with breastfeeding problems of unknown origin. There are few prospective studies evaluating frenotomy, and two recent systematic reviews did not find a consistent positive effect of lingual frenotomy on infant breastfeeding.[89,90] It may be prudent to wait until the physiologic process of lactogenesis II and early nipple pain have passed before frenotomy is considered. Although the procedure is simple and relatively free of side effects, unnecessary interventions should be avoided in newborn care whenever possible. Frenotomy for posterior tongue-tie has received extra scrutiny because evidence is lacking to support improved outcomes after treatment, and the procedure is more invasive.[91]

Jaundice became more prevalent with the resurgence of breastfeeding and is discussed in more detail elsewhere in this textbook. Consistent with efforts to promote breastfeeding, a rising bilirubin level should serve as a call for action to emphasize lactation



• **Fig. 16.1** Prevalence of reported breastfeeding concerns by mothers by newborn age. (Modified from Wagner EA, Chantry CJ, Dewey KG, et al. Breastfeeding concerns at 3 and 7 days postpartum and feeding status at 2 months. *Pediatrics*. 2013;132:e865–e875.)

support rather than lead to a separation of the newborn from the mother and artificial feeding to lower the bilirubin level.

The normal newborn is born with a surplus of extracellular free water, and in cesarean delivery births, mothers are often given additional boluses of fluids that may further hydrate the newborn.[92] It is normal, expected, and perhaps preferable that babies will lose this free water in the first 72 hours of life. This free water is protective of the newborn's fluid balance while the mother's milk comes in.[93] In cases of extra hydration, extra weight loss may be expected. The average term newborn loses about 7% of birthweight, with 12% of newborns born vaginally losing more than 10% of birthweight (Fig. 16.2).[94] The loss during the first 24 hours of life can predict those who will lose more. This is not a state of dehydration but is a normal physiologic adaption to extrauterine life, so healthcare providers should not alarm parents or suggest that there is something wrong with their baby.

With the onset of copious production of mature milk, neonates begin to gain weight and their serum sodium levels fall.[95] Newborns fed human milk regain their birthweight, on average, by the age of 8.3 days; 97.5% have regained their birthweight by 21 days.[96] In newborns who lose substantially more than 10% of their birthweight because of breastfeeding difficulties, there is the potential for significant hypernatremia, and these infants should be monitored closely.[97]

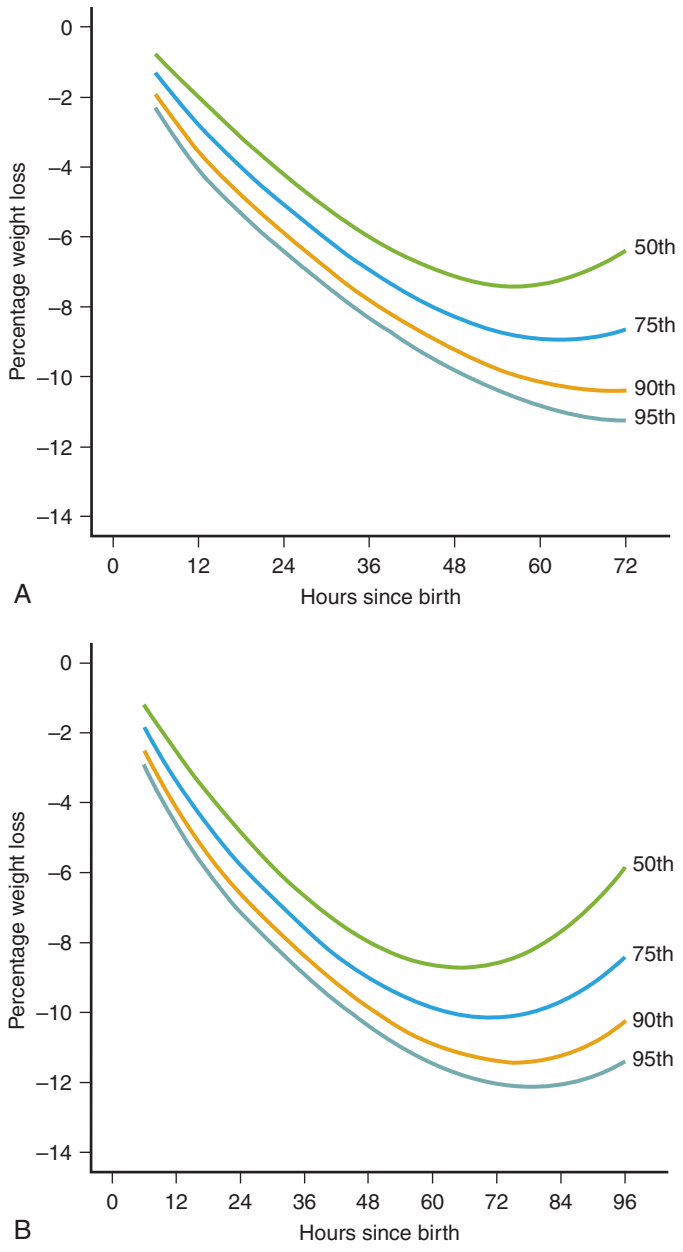
Supplementation of Breastfeeding

It is usually unnecessary to provide any nutrition or fluid to breastfed term newborns beyond human milk. Oral dextrose or commercial formula may be needed in neonates with hypoglycemia whose blood glucose levels are not responsive to breastfeeding alone. Supplementation may also be indicated in newborns who have lost more than 10% of their birthweight and/or have decreased urine and stool output or in the presence of significant hyperbilirubinemia. Supplementation should be considered a temporary intervention, and its provision should not interfere with the initiation of successful breastfeeding.

Temporary supplemental formula or expressed breast milk when available can be provided via a supplemental nursing system, finger feeding, or a bottle. Of greatest importance is close monitoring of the change in weight of the baby and continued lactation support. The use of banked or donor milk is increasing, and human milk banks have now been established in over 60 countries globally. However, there remains little authoritative guidance on the implementation, operation, and regulation of human milk banks and appropriate the use of donor milk. The importance of safe operational guidelines and a coordinating body to collate and communicate data have been recently highlighted by the milk-banking community,[98] and efforts to create the evidence base necessary for guideline development are ongoing. However, in the absence of existing evidence and guidelines, there remains concern about the routine use of donated human milk outside of the hospital setting, especially for otherwise healthy term newborns for whom there is a paucity of evidence to support its value in promoting health and mitigating illness.

Contraindications to Breastfeeding

The few absolute contraindications to breastfeeding include untreated maternal tuberculosis, evidence of current maternal cocaine use or antimetabolite drugs, and neonatal galactosemia.[99,100] Hepatitis C virus RNA has been found in the milk of mothers infected with this virus; however, the transmission of infection via breastfeeding has not been documented. Therefore, maternal hepatitis C is not considered a contraindication to breastfeeding.[99]



• **Fig. 16.2** Nomograms of weight loss in exclusively breastfed newborns born vaginally (A) or by cesarean delivery (B). (Modified from Flaherman VJ, Schaefer EW, Kuzniewicz MW, et al. Early weight loss nomograms for exclusively breastfed newborns. *Pediatrics*. 2015;135:e16–e23.)

Maternal HIV infection has historically been considered an absolute contraindication to breastfeeding. However, in more recent years, there has been an increase in the number of HIV-positive mothers expressing a desire to breastfeed. Oftentimes, mothers are from low- and middle-income countries where the risk-benefit analysis of breastfeeding is different, due to high rates of infant mortality and limited access to safe water and affordable infant formulas. In this context, although the risk of HIV transmission with breastfeeding is present, it is lower than the risk of infant morbidity and mortality from other causes, especially with strict maternal adherence to an antiretroviral medication regimen and persistently undetectable viral loads. In many instances, these mothers have breastfed previous children in their home country, and are confused or resistant when breastfeeding is not recommended upon relocation to the United States. Lastly, in some cultural communities, especially enclaves of families originally from Africa, the maternal HIV diagnosis is not disclosed to the extended family, and the mother choosing to formula feed and avoid breastfeeding raises suspicion of maternal HIV infection and stigmatizes the mother.

Although breastfeeding among HIV-positive mothers in the United States remains strongly discouraged, there are some mothers who will decide to breastfeed, despite extensive counseling. In these instances, risk-reduction strategies should be implemented to reduce the possibility of HIV transmission. For more detail, readers are referred to Chapter 34, Viral Infections of the Fetus and Newborn. In addition, comprehensive recommendations and further details regarding risk-reduction strategies can be found on the Center for Disease Control and Prevention's website.[101] Due to the complexity and clinical equipoise surrounding this issue, decision-making should include outpatient pediatric providers who will be responsible for follow-up care.

There are a number of drugs that raise concern for adversely impacting infant long-term neurodevelopment. Selective serotonin reuptake inhibitors are commonly used to treat depression and anxiety in young women. Among the drugs in this category, sertraline and paroxetine are thought to be the safest for use in breastfeeding mothers, while fluoxetine and citalopram are felt to have the most potential for toxicity in the neonate.[100] Overall, few adverse effects have been noted with the use of any of these drugs, and generally the potential risks associated with these medications are thought to be outweighed by the benefits of breastfeeding.[100] Similarly, although methadone is detectable in the breast milk of women receiving this medication, serum levels in neonates are quite low and unlikely to have a significant effect.[102] Online references are available detailing the current scientific knowledge of the effects of toxins and medications in breast milk.[103]

Formula Feeding

Commercial formula that provides adequate nutrition, vitamins, and minerals is available for infants of mothers who do not choose (or are unable) to breastfeed their infants or in those rare instances when breastfeeding is contraindicated. There are three major categories of formula used in neonates: cow's milk-based, soy, and hydrolyzed formula. Of these, cow's milk-based formula is the most commonly used. The main carbohydrate in cow's milk-based formula is lactose. Soy formulas were developed for infants with suspected cow's milk allergy. Because the main carbohydrate in soy formulas is sucrose or corn syrup, soy formula can be used in neonates with suspected galactosemia. Protein hydrolysate formulas were initially developed for use in infants who are highly intolerant to cow's milk protein.[104] They are purported to lead to fewer allergies in babies and children than cow's milk-based formula, but the evidence for this is limited.[105] All extensively hydrolyzed formulas are lactose-free.[104] Extensively hydrolyzed formulas are indicated in infants with definitive evidence of cow's milk protein allergy because 10% to 14% of such children also have a soy allergy.[106]

Traditionally, standard preparations of formulas available for use in healthy term neonates provided 0.67 kcal/mL. This caloric density was based on the calories in human milk. However, the results of some studies indicate that the average caloric density of human milk may be closer to 0.64 to 0.65 kcal/mL. Based on

these additional data, some infant formulas have been modified to provide 0.643 kcal/mL (19 kcal/oz).[107] Most commercially available formulas are fortified with iron at a concentration of 10 to 12 mg/L and vitamin D at a concentration of 400 IU/L.[108]

Mothers who elect to give their babies formula report feeling unsupported in their decision by healthcare professionals, and up to 50% feel pressured to breastfeed.[109] Although the benefits of breastfeeding should be provided to mothers who have not decided how to feed their babies, the role of healthcare providers is also to support the decision of those who have elected to provide formula feedings to their babies. It is also important to provide practical education about formula feeding to these parents; this is frequently not done in many newborn nurseries.[109]

Newborns who are fed formula can feed ad lib beginning shortly after birth. The average formula intake in term newborns during the first day of life is 15 to 20 mL/kg and is 40 to 45 mL/kg during the second day.[110] Term newborns who are formula fed during their birth hospitalization typically lose less weight than breastfed infants.[94,111] The median weight loss in formula-fed term newborns at 48 hours of life has been reported to be 2.9% of birthweight for those born vaginally and 3.7% among those born by cesarean delivery; weight loss of 7% or more during a typical newborn nursery stay in formula-fed infants is uncommon.[111]

Umbilical Cord Care

Bacterial colonization of the umbilical cord can lead to omphalitis, and in some cases may be associated with thrombophlebitis, cellulitis, or necrotizing fasciitis. To decrease the risk of bacterial infection and serious illness, many methods of umbilical cord care have been developed worldwide. Although various topical substances continue to be used, the more recent practice in high-resource settings has been towards dry umbilical cord care. Based on the results of multiple meta-analyses, dry cord care without the application of topical substances is currently recommended for hospital births and those in high resource settings; for infants born outside of the hospital in communities with high neonatal mortality rates, application of topical chlorhexidine is recommended.[112] Regardless of the method of cord care used, parents and healthcare providers should monitor for redness around the umbilical cord stump, and seek medical attention and further intervention to avoid serious bacterial illness.

Tetanus neonatorum, with the infection occurring via the umbilical cord, continues to be reported in more than 20 developing countries, resulting in 58,000 neonatal deaths per year. The condition is related to low vaccination rates in women of childbearing age, home deliveries, and certain cultural care practices. Public health efforts focusing on effective vaccination programs and the use of "clean bed" deliveries are needed to eliminate the disease.[113]

Circumcision

Neonatal circumcision is a polarizing issue for both healthcare professionals and parents. Those who favor routine circumcision highlight health benefits such as the decreased risk of urinary tract infections (UTIs), reduced risk of penile cancer, and possibly lower rates of sexually transmitted infections, including HIV.[114] Those who oppose the procedure point out that the number of circumcisions needed to be performed to prevent one of these outcomes (number needed to treat) is large, that the risks of the procedure balance out the benefits, that circumcision may lead to loss of sexual sensation, and that subjecting a neonate to a painful procedure without clear benefits may be unethical.[115] In 2012, the AAP published a policy statement concluding that the benefits of circumcision outweighed the risks of the procedure. However, these health benefits were not great enough to recommend routine circumcision in all male neonates.[116]

It is clear that circumcision reduces the risk of UTI by 3- to 10-fold.[117] However, given the low incidence of UTI in male newborns, 100 boys need to be circumcised to prevent one UTI. Similarly, although circumcision has been shown to prevent penile cancer, this is an extremely rare condition, and the number needed to treat is about 900.[118] The results of studies in three African countries indicate that circumcision reduces the risk of HIV infection by 56%.[119] In the United States, where HIV infection rates are lower, it has been estimated that circumcision might decrease the acquisition of HIV through heterosexual transmission by 16%; 298 boys would need to be circumcised to prevent one case of HIV infection.[120] There is also limited evidence suggesting that circumcision might reduce the risk of other sexually transmitted infections, including syphilis and genital herpes. However, there is no compelling evidence that circumcision reduces the risk of chlamydia or gonorrhea.[117]

Circumcision is generally a safe procedure. Although some increased bleeding is reported after 1% of circumcisions, the rate of significant complications is about 0.2%.[118,121,122] Bleeding, sometimes requiring suturing of a vessel, is the most common significant complication, followed by penile injury and infection. Infection is more common following a circumcision using a Plastibell rather than a Gomco clamp; the incidence of hemorrhage is reportedly similar after either technique.[121]

Circumcision is an uncomfortable experience for the neonate. Small amounts of sucrose solutions can be offered to the baby for soothing. Pain from the actual surgery can be significantly decreased with the use of a dorsal penile nerve block or ring block.[117] In one study, 65% of newborns who received a dorsal nerve block had no or minimal response to the initial clamping of the foreskin.[123] However, the results of a randomized controlled trial suggest that ring block provides superior analgesia compared with a dorsal penile nerve block.[124] Although topical anesthesia may be better than no anesthesia, it provides inferior pain relief compared with a dorsal penile nerve block.[125]

A poor cosmetic outcome can be caused by the removal of too little foreskin. It has been estimated that 1% to 9.5% of circumcisions are redone because of parental concern regarding the appearance. In a prospective study among boys younger than 3 years who had been circumcised with the use of either a Plastibell clamp or a Mogen clamp, the glans were fully exposed in only 35.6%. However, in older circumcised boys, the glans was fully exposed in more than 90%.[126] This suggests that parents of a circumcised infant should be counseled that the vast majority of properly done circumcisions will lead to an acceptable cosmetic appearance over time.

In the United States, the Gomco clamp is the most commonly used apparatus for performing circumcisions, followed by the Plastibell clamp and the Mogen clamp.[127] The use of the Mogen clamp, which was designed by a Jewish mohel, leads to shorter procedures and, reportedly, less pain and bleeding than the other techniques.[123,128,129] However, less foreskin is removed with the use of the Mogen clamp than with the other two techniques.[130]

Newborn Metabolic Screening

Newborn screening (NBS) for metabolic disorders began in 1962 when 29 states participated in a trial of testing for phenylketonuria (PKU). The advent of tandem mass spectrometry in the 1990s revolutionized newborn metabolic screening by increasing the number of conditions that could be tested for using a small sample of blood. In 1995, the average number of conditions included in state-mandated screening programs was 8; by 2005 this had increased to 19, with some states testing up to 46 conditions. However, this increase in conditions included in the NBS has been controversial. Not all of the conditions included meet the established criteria for screening in that there are no known effective treatments, and, in some cases, it is not known whether the targeted condition always leads to disease. In addition, increased testing results in more false-positive results, which leads to increased parental anxiety and potential overuse of medical services for confirmational testing.[131,132]

In an attempt to define a rational list of disorders for which NBS is appropriate, the American College of Medical Genetics used an iterative process to identify "core conditions" that should be included in mandatory screening programs.[133] Subsequently, federal legislation was passed to facilitate standardization of NBS across the United States. This legislation led to the development of the Recommended Universal Screening Panel, which initially included 29 core disorders. All US states currently provide testing for all of these disorders.[132] The recommended screening panel has now been expanded to include 32 core disorders and 26 secondary disorders. In addition to newborn hearing screening and screening for critical congenital heart disease (CCHD), there are nine organic acids, five fatty acid oxidation, six amino acids, two endocrine, three hemoglobin, and four other conditions included in the list of core disorders. Information on state-by-state screening programs can be found online.[134]

The most common disorders included on newborn metabolic screens in the United States are congenital hypothyroidism (1 case per 3000 to 4000 newborns) and sickle cell disease.[135,136] The incidence of PKU is approximately 1:15,000.[137] For many of the core conditions for which screening is now recommended, the incidence rates are in the range of 1:100,000 to 1:200,000.[135] For additional information, see Chapter 18, Newborn Screening.

Hearing Screening

Newborn hearing screening has become universal in the United States, with more than 98% of newborns screened in 2018, the most recent year for which national statistics are available. Every state and territory in the United States has now established an early hearing detection and intervention program and is required to provide tracking data. Newborns who do not "pass" the hearing screen in the newborn nursery should be referred for definitive outpatient testing in a timely manner. The prevalence of hearing loss among screened infants is 1.7 per 1000. Of those infants who did not pass their final screening (1.6%), 53.4% had no documented hearing loss, 10.7% had documented hearing loss, and 35.9% had no documented diagnosis.[138,139] Many other countries have adopted or are in the process of adopting universal hearing screening. Experts from the WHO endorsed universal newborn hearing screening in 2009. It is reported that 80% of early childhood hearing loss is congenital and that most cases have genetic origins or are a result of CMV infection.[140,141]

There is growing evidence that early intervention with amplification or cochlear implants can improve childhood reading, language, and communication skills.[142–145] These treatments are effective when implemented by 6 months of age, preferably younger. For infants who do not pass the hearing screen, medical providers and families should act swiftly to complete definitive diagnostic testing and refer the infant to specialists with expertise in the treatment of early hearing loss. This process is particularly challenging in rural areas and in countries with limited access to these services.[146]

It is recommended that the term "refer" be used instead of "fail" when the screen results are being discussed with families. Babies have an increased "refer" rate when born by cesarean delivery or screened during the first day of life, so performing the screen on the third or fourth day of life, or at least after 4 hours of age, will aid in decreasing false positives.[147–149] Many nurseries have adopted a two-step process using an automated otoacoustic emissions (OAE) test for the first step followed by a brainstem auditory evoked potential test in those who do not pass the automated OAE test. This process has been shown to decrease the false-positive rate.[150,151] False-negative rates are low, occurring in an estimated 0% to 2% of newborns, and are further minimized with the use of auditory brainstem response (ABR) screening.[152,153]

All newborns who are at high risk of early hearing loss should be sent directly for ABR screening. High-risk factors include premature birth, family history of early childhood or infant hearing loss, craniofacial anomalies or abnormal ear examination findings (includes microtia but not tags), and prolonged exposure to aminoglycoside antibiotics.

Screening for Critical Congenital Heart Disease

It has been estimated that approximately 25% of newborns with complex congenital heart disease (CCHD) have "critical" lesions, defined as a lesion requiring surgery and/or cardiac catheterization in the first year of life.[154] Overall, CCHD is diagnosed in fewer than half of newborns prenatally, and in only 70% to 75% of affected newborns during the birth hospitalization.[155] Further, some neonates with lesions that are amenable to surgical intervention who are not identified as having CCHD before discharge from their birth hospitalization may die from their CCHD before a clinical diagnosis is made.[155] Because of this, it is recommended that all newborns be screened with pulse oximetry for CCHD prior to discharge from their birth hospital.[156]

Pulse oximetry, a relatively inexpensive and noninvasive method of determining peripheral oxygen saturation, was chosen as the screening modality for CCHD based on the idea that most (but not all) CCHD lesions cause hypoxemia. To minimize false-positive results, pulse oximetry screening should be delayed until newborns are 24 hours or older, if possible. Conversely, since some newborns with CCHD have different oxygen saturation levels when measured preductally or postductally, false negative results are reduced by screening newborns both in the right hand (preductal) and in a lower extremity (postductal). Newborns with a measured oxygen saturation level of less than 90% at either site are classified as having a positive screen and should be evaluated by a pediatric provider on an urgent basis. Repeated screening is recommended for newborns with oxygen saturation levels between 90% and 95% or with a difference of 3 or more percentage points between the right hand and the lower extremity; if either of these findings persists after three screenings, the screen is considered positive.[157] Alternative algorithms, using only the lower extremity

as the initial screen, or modifications for high altitudes, have been adapted in some states.[158]

There were initially concerns that widescale implementation of universal pulse oximetry screening would result in a high proportion of false-positive results, leading to unnecessary and expensive evaluations of normal newborns. These concerns have been largely unfounded; a recent Cochrane systematic review including 19 studies conducted from 2002 to 2017 found routine CCHD screening to have a false-positive rate of 0.14%, with sensitivity of 77% and specificity of 99.9%. Of note, the false-positive rate for detection of CCHD was lower when newborn pulse oximetry was performed after 24 hours of age compared to when it was performed within 24 hours of birth.[159] Although an excellent screening test, because the sensitivity of pulse oximetry screening is not 100%,[160] a diagnosis of CCHD should remain high on the differential for a young infant with signs or symptoms consistent with cardiac disease, even if a negative CCHD screen was documented during the birth hospitalization.

Common Problems in Newborn Care

Hypoglycemia

Fetal blood glucose levels are approximately 70% of maternal levels. Following birth and separation from its major energy supply, the newborn's glucose level falls by half. Over the next several hours, it gradually increases to a level approaching that of older newborns. The critical factors involved in this normal adaptive process include transient inhibition of the newborn's insulin secretion and an increase in levels of the counter-regulatory hormones growth hormone, cortisol, catecholamines, and glucagon.[161] This results in the promotion of liver glycogen breakdown, gluconeogenesis, and tissue lipolysis.

Risk Factors

Infants with increased risk for hypoglycemia and who may benefit from early glucose screening and possible therapeutic intervention include:

- Newborns of diabetic mothers
- Large for GA newborns
- Small for GA newborns
- Premature newborns
- Newborns delivered following in utero or intrapartum distress
- Family history of congenital hyperinsulinism
- Newborns with midline facial anomalies (possible marker of pituitary deficiency)

Clinical Presentation

Screening infants with risk factors is essential as those with hypoglycemia may be asymptomatic. Infants with symptomatic hypoglycemia exhibit clinical signs and symptoms including poor feeding, lethargy, hypotonia, irritability, tremor, high-pitched cry, seizure-like activity, and apnea. An infant exhibiting any of these signs should be evaluated by a medical provider and should have serum glucose checked immediately.

Differential Diagnosis

Causes of neonatal hypoglycemia—both transient and persistent—are shown in Box 16.3.

Initial Management

The treatment approach to confirm hypoglycemia depends on the glucose level and the presence of clinical signs. Newborns with symptomatic hypoglycemia require immediate intervention.[162] However, while it is apparent that severe and symptomatic hypoglycemia can result in brain injury leading to neurodevelopmental issues, the effects of less severe and asymptomatic hypoglycemia on the neonatal brain are much less clear.[163,164] Thus there is considerable debate regarding the definition of hypoglycemia and an actionable glucose level in this early transition period in asymptomatic newborns. The HypoEXIT (Hypoglycemia-Expectant Monitoring versus Intensive Treatment) trial,[165] a randomized controlled trial comparing two accepted glucose value thresholds, demonstrated that in otherwise healthy newborns with asymptomatic moderate hypoglycemia, a lower glucose treatment threshold (36 mg/dL) was noninferior to a traditional threshold (47 mg/dL) with regard to psychomotor development at 18 months. This study may provide support for less aggressive diagnostic and treatment interventions for managing asymptomatic hypoglycemia, which could be beneficial for minimizing disruptions to parental bonding and promoting the establishment of maternal breastfeeding. However, these results are not generalizable to infants at higher risk of impaired developmental outcomes or those with persistent hypoglycemia. Depending on institutional policies, glucose levels, and presence or absence of symptoms of hypoglycemia, management may include offering additional enteral feedings, supplementation of breastfeeding, buccal administration of dextrose gel,

• BOX 16.3 Causes of Hypoglycemia

Transient Hypoglycemia

Maternal conditions

- Glucose infusion in the mother
- Preeclampsia
- Drugs (tocolytic therapy, sympathomimetics)
- Infant of a diabetic mother

Neonatal conditions

- Prematurity
- Respiratory distress syndrome
- Twin gestation
- Neonatal sepsis
- Perinatal hypoxia-ischemia
- Temperature instability (hypothermia)
- Polycythemia
- Specific glucose transporter deficiency
- Isoimmune thrombocytopenia, Rh incompatibility

Persistent Hypoglycemia

Endocrine disorders

- Pituitary insufficiency
- Cortisol deficiency
- Congenital glucagon deficiency

Inborn errors of metabolism

- Carbohydrate metabolism (glycogen storage disease, galactosemia, fructose 1,6-diphosphatase deficiency)
- Amino acid metabolism (maple syrup urine disease, propionic acidemia, methylmalonic acidemia, hereditary tyrosinemia)
- Fatty acid metabolism (acyl coenzyme A dehydrogenase defect, defects in carnitine metabolism, β-oxidation defects)
- Defective glucose transport

and glucose-containing intravenous fluids. For more detail, see Chapter 87 which discusses evaluation, diagnosis, and treatment of neonatal hypoglycemia.

Respiratory Distress

The vast majority of term or late preterm newborns accomplish the transition from dependency on the placenta to the newborn cardiorespiratory system without incident. After birth, pulmonary blood flow increases, fetal shunts reverse and begin to close, spontaneous breathing effort is initiated, and fetal lung fluid is cleared. Effective cardiorespiratory function is usually established by several hours of age.[166,167]

Perinatal Risk Factors

- Preterm birth
- Prolonged rupture of membranes
- Oligohydramnios or anhydramnios
- Chorioamnionitis
- Meconium-stained amniotic fluid
- Intrapartum distress
- Delivery via unlabored cesarean section
- Exposure to maternal medications (magnesium, anesthetic agents)
- Infant of a diabetic mother

Clinical Presentation

Respiratory distress, including nasal flaring, grunting, chest wall retractions, tachypnea (respiratory rate >60 breaths/min) and hypoxia (oxygen saturation <95%), occurs in 5% to 7% of live births at term gestation and in 2% to 8% of infants born at 34 weeks' gestation or later.[168–171] The initial presenting symptoms can range from mild to severe, are relatively nonspecific, and may indicate the presence of a very common or an extremely rare condition. Therefore, any neonate with respiratory distress should be examined promptly and supportive measures implemented while completing initial studies and determining a management plan.

Differential Diagnosis

- Transient tachypnea of the newborn (TTN)
- Respiratory distress syndrome (RDS)
- Meconium aspiration syndrome
- Spontaneous pneumothorax
- Sepsis
- Congenital pneumonia
- Persistent pulmonary hypertension of the newborn (PPHN)
- Pulmonary hypoplasia
- Complex congenital heart disease
- Congenital diaphragmatic hernia
- Inherited primary lung diseases (primary ciliary dyskinesia, congenital surfactant deficiencies, alveolar capillary dysplasia)

Initial Management

In most cases, initial diagnostic efforts for a term newborn with unexpected respiratory distress should include a chest X-ray and an arterial blood gas, including an assessment of the arterial oxygen saturation. The results of these studies, in combination with the clinical exam and maternal history, should provide information helpful to (1) establish the initial management, such as the need for supplemental oxygen and/or continuous monitoring; (2) determine the need for further work-up or treatment, possibly including an echocardiogram, laboratory testing, and treatment for possible sepsis; or (3) in severe cases, refer the newborn for further specialty consultation and management. For additional information, refer to Chapter 42, Acute Neonatal Respiratory Disorders.

Cardiovascular Concerns

Congenital heart disease is a relatively common condition in newborns, with an estimated incidence of 81 per 10,000 live births.[172] The increasing accuracy of prenatal ultrasound examinations has greatly improved the early diagnosis of complex congenital heart disease (CCHD). The results of population-based reviews indicate that the sensitivity of routine prenatal ultrasound examinations in identifying selected congenital defects is as high as 70% to 85%.[173,174] For mothers at high risk of delivering a newborn with CCHD, the use of fetal echocardiography is helpful for delineating the anatomy and predicted clinical significance of specific lesions.

Perinatal Risk Factors

- Product of in-vitro fertilization
- Infants born to mothers with pregestational diabetes
- Family history of congenital heart disease
- Maternal history of autoimmune disorders (especially systemic lupus erythematosus)

Clinical Presentation and Initial Management

At birth, many babies have loud murmurs, often due to the closing ductus arteriosus or tricuspid regurgitation.[175] These murmurs are transient and not indicative of disease. Conversely, murmurs associated with VSDs may not be heard for several days, when the pulmonary vascular resistance has dropped enough to permit a significant shunting of blood from left to right across the ventricular septum. Although the ratio of pathologic to benign murmurs is higher in newborns than in older children, most of the murmurs heard during the birth hospitalization in a healthy neonate are not clinically significant. Characteristics that increase the likelihood that a murmur is pathologic include a harsh quality, auscultation during all of systole or into diastole, and loudest at the lower sternal border or right upper border.[176] In a healthy newborn the most common presentation of CCHD is a harsh systolic murmur heard best at the left lower sternal border in an asymptomatic newborn, corresponding to a VSD.

In addition to auscultation, it is helpful to assess a newborn with a murmur for dysmorphic features or other anomalies, as these findings increase the likelihood that the murmur is indicative of CCHD. It is important to evaluate the adequacy of femoral pulses to rule out coarctation of the aorta. Femoral pulses may be difficult to palpate in a neonate; if there is uncertainty, upper and lower extremity blood pressures can be measured. Chest radiographs and electrocardiograms are usually of limited value in evaluating healthy newborns with murmurs. For more detail, readers are referred to Chapter 50, Congenital Heart Disease.

Term neonates frequently have alterations in cardiac rhythm and rate. Heart rates in term newborns may be as high as 200 beats/min (particularly when agitated) or as low as 80 beats/min (when in deep sleep). These values are usually indicative of normal variation and are not clinically meaningful unless there are other signs of illness or if there is a lack of variability in rate with stimulation or attempts at calming the newborn. Arrhythmias

are relatively common, occurring in approximately 1% of newborns.[177] By far the most common arrhythmia in a well-appearing term newborn is from premature atrial contractions.[177] These are usually benign and transient, and in most cases, no further workup is indicated. If there is concern about an irregular rhythm in a newborn, an electrocardiogram can be obtained. The maternal history should be reviewed for risk factors for arrhythmia, such as autoimmune diseases, which are associated with congenital heart block.[178] For more information about the electrocardiographic features and management associated with different arrhythmias, readers are referred to Chapter 49, Perinatal Arrhythmias.

Early-Onset Sepsis

Although early-onset sepsis (EOS) is a rare occurrence in term neonates, early identification of a newborn with EOS is a central focus of newborn care and a source of considerable anxiety for clinicians. This anxiety is driven by two unique features of EOS. First, the phenomenon of an apparently healthy newborn becoming moribund from overwhelming sepsis in a matter of hours is well described. Second, the earliest signs of infection are frequently subtle and nonspecific. Fortunately, with the advent of screening mothers for group B streptococcus (GBS) colonization prenatally and providing intrapartum antibiotics for those colonized, rates of EOS have fallen dramatically.

Perinatal Risk Factors

- Prematurity
- Prolonged rupture of membranes
- Maternal fever
- Chorioamnionitis
- Maternal GBS colonization without adequate intrapartum antibiotic prophylaxis
- Sibling with a history of EOS

Clinical Presentation

Early identification of a newborn with EOS based on clinical and laboratory findings is challenging. A number of signs and symptoms have been reported to be present in neonates with EOS, including fever, hypothermia, temperature instability, hypotension, lethargy, irritability, pale or mottled skin, cyanosis, apnea, hypoglycemia, acidosis, tachycardia, tachypnea, grunting respirations, nasal flaring, and inspiratory retractions. Unfortunately, there is a paucity of information delineating the frequency of symptoms in term newborns with EOS versus those without, as well as how often infected infants demonstrate symptoms early versus later on in the disease course. Therefore, the efficacy and reliability of most clinical signs and symptoms in diagnosing EOS are unknown. Of note, while creating a predictive model to quantify the risk of sepsis in infants ≥ 34 weeks' gestation, researchers did identify four specific and objective clinical signs of sepsis: temperature of 38.0°C or greater or less than 36.4°C; heart rate of 160 or more beats per minute; respiratory rate of 60 or more breaths per minute; and respiratory distress (grunting, flaring, and retractions).[179]

Initial Management

Infants born at $\geq 35^{0/7}$ weeks' gestation can be stratified by the level of risk for EOS. Per the 2018 AAP recommendations, acceptable approaches to risk stratification include categorical algorithms in which threshold values for intrapartum risk factors are used, multivariable risk assessment based on both intrapartum risk factors and infant examinations, and serial physical examination to detect the presence of clinical signs of illness after birth.[180] These approaches provide guidance in determining which infants are at higher risk of EOS and how to decide next steps based on the infant's clinical appearance and symptoms. The Neonatal EOS Risk Calculator[181] is an example of this approach, which synthesizes the risk factors and clinical symptoms previously identified as predictive of EOS into an interactive, user-friendly calculator for use in daily clinical practice.[179,182–184] In addition, local guidelines are important for determining when to escalate to higher levels of care, such as observation in the nursery or admission to the neonatal intensive care unit (NICU). For more detail, readers are referred to Chapter 33, Neonatal Bacterial Sepsis and Meningitis.

Hyperbilirubinemia

Bilirubin is a molecule formed from the breakdown of heme, the iron-containing, nonprotein component of hemoglobin. Normal levels of bilirubin for older children and adults range from 0.3 to 1.0 mg/dL,[185] but in newborn infants, there is an expected transient elevation of these levels due to increased red blood cell turnover as the infant transitions from fetal to neonatal life. Clinically, elevated serum bilirubin levels manifest as jaundice, a yellowing of the skin, sclera, and mucous membranes. Jaundice is typically visible when the total serum bilirubin (TSB) is greater than 5 mg/dL.[186]

TSB is composed of two parts: indirect (unconjugated) bilirubin and direct (conjugated) bilirubin. Transient indirect hyperbilirubinemia is an almost universal finding in the newborn period.[187] This physiologic indirect hyperbilirubinemia is normal and benign and requires no additional intervention beyond assuring that enteral feedings are established and the infant remains hydrated with adequate elimination patterns. However, a subset of neonates will develop severe indirect hyperbilirubinemia warranting treatment. In cases of severe and untreated indirect hyperbilirubinemia, free bilirubin can cross the blood–brain barrier and cause brain injury. In its initial presentation, this injury is known as acute bilirubin encephalopathy and may be reversible or permanent; long-term injury, known as chronic bilirubin encephalopathy or kernicterus, is permanent and develops gradually, with most infants demonstrating clinical manifestations within the first year of life.

Hyperbilirubinemia is often categorized as benign or pathologic. Direct hyperbilirubinemia, also known as cholestasis, is always considered pathologic and deserves an appropriate and timely evaluation and treatment. Indirect hyperbilirubinemia is considered pathologic under the following conditions, and similarly requires timely evaluation and intervention:

- Jaundice observed within the first 24 hours of life
- Jaundice persisting beyond 2 to 3 weeks of life in a term infant
- TSB greater than 95th percentile for age based on an hour-specific nomogram
- TSB level increasing by greater than 5 mg/dL/day or greater than 0.2 mg/dL/h

Even when not classified as pathologic, indirect hyperbilirubinemia may be severe enough to require treatment, including IV hydration, medication (such as intravenous immunoglobulin), phototherapy, or exchange transfusion. Because hyperbilirubinemia evolves over time, it is important to risk stratify infants to identify those who would benefit from more frequent monitoring and prompt initiation of treatment if indicated.

Risk Factors

Perinatal and neonatal risk factors for severe hyperbilirubinemia are shown in Box 16.4.

Initial Management

AAP has long recommended universal bilirubin screening in all neonates within the first 72 hours of life,[188] as well as assessment for the presence of risk factors for hyperbilirubinemia soon after birth. Even when this screening recommendation is met, newborns are often discharged from the hospital before TSB levels peak at 3 to 4 days of age. Therefore, predictive models were developed to assess the risk of severe hyperbilirubinemia in the first week of life and to help guide how closely infants should be followed after discharge. In the late 1990s, using a cohort of infants greater than 35 weeks' gestation, Bhutani and colleagues obtained serial serum bilirubin measurements and found that newborns with initial bilirubin levels above the 95th percentile at any time point (in hours) were more likely to have "significant hyperbilirubinemia" when the levels were measured subsequently than those newborns with lower initial bilirubin levels (Fig. 16.3).[189] This nomogram was subsequently used by the AAP to develop their 2004 practice guidelines for the management of hyperbilirubinemia in term and near-term infants. These practice guidelines contain hour-specific bilirubin level thresholds for initiation of phototherapy and exchange transfusions, to help guide and standardize the timing of screening and intervention for hyperbilirubinemia. For each nomogram, infants are categorized as low, medium, or high risk based on the presence of risk factors that increase the likelihood of either severe hyperbilirubinemia or neurotoxicity (see above). Based on this categorization, infants' TSB levels are plotted on their appropriate risk curve, thereby standardizing the management of hyperbilirubinemia. The 2004 AAP practice guideline[188] provides clinicians with guidance on when to initiate, continue and discontinue phototherapy or to perform an exchange transfusion, as well as assists with the identification of risk factors that may alter the serum bilirubin level at which intervention is warranted (Fig. 16.4).[190] Internet tools based on the Bhutani nomogram and the 2004 AAP guidelines are available to assist in determining the appropriate management for a newborn based on hour-specific TSB level.[191] For more detail, readers are referred to Chapter 72, Neonatal Hyperbilirubinemia and Kernicterus.

• BOX 16.4 Risk Factors for Severe Hyperbilirubinemia

- Prematurity (<38 weeks)
- Exclusive breastfeeding
- Older sibling with jaundice
- East Asian or Native American ancestry
- Cephalohematoma or other significant bruising
- Polycythemia
- Immune or non-immune mediated hemolytic disease (including ABO, Rh, minor red cell antigens)
- Glucose-6-phosphate dehydrogenase deficiency
- Predischarge bilirubin screening level in the high risk or high-intermediate risk zone for age (in hours)
- Asphyxia
- Acidosis
- Sepsis
- Albumin <3 g/dL (<30 gL)

Adapted from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114(1):297–316.

Ineffective Thermoregulation

Being too cold or too hot causes metabolic stress to the newborn, so efforts to maintain a steady and neutral thermal environment should be part of routine newborn care. The best practice is to dry the baby immediately after delivery and place the newborn skin-to-skin with the mother. Although the AAP and the American College of Obstetricians and Gynecologists jointly recommend keeping newborns' core temperatures within the narrow range of 36.5°C to 37°C, in one study of healthy term newborns the average temperature was 36.5°C, with a normal range from 36.0°C to 37.9°C.[192] Thin babies tend to have lower body temperatures, and heavier babies tend to have higher body temperatures. Bathing a newborn can cause hypothermia; this is less likely when bathing is performed from trunk to head or when a bath is used versus washing with a cloth.

An elevated body temperature at birth usually reflects the intrauterine temperature and is not necessarily a sign of sepsis.[193] Isolated hyperthermia during labor is associated with neonatal encephalopathy, occurring in approximately 1 in 2000 births.[194] After the first 3 to 4 days of life, increased temperatures are most likely caused by dehydration from suboptimal breast milk supply.[195] A single increased temperature in an otherwise well-appearing newborn is not a strong predictor of infection, but has been reported as a sign of intracranial hemorrhage.[196]

Risk Factors

- Premature infants (hypothermia)
- Small for GA infants (hypothermia)
- Infants with neonatal abstinence syndrome (hyperthermia)

Initial Management

Standard practice at most nurseries is to measure axillary temperatures, probably because of reports in the 1960s and 1970s of rare perforations caused by rectal thermometers; however, axillary temperatures may not always accurately reflect core temperature.[197] Importantly, axillary temperatures are not the standard used in studies of sepsis in infants younger than 2 to 3 months of age.

Many nurseries worldwide have adopted policies to delay bathing to avoid hypothermia, allow time for initial bonding, and promote breastfeeding. Early skin-to-skin contact between the newborn and the mother is useful both to prevent and treat early hypothermia, but attention to positioning and frequent checks by nursing staff are required.[198] Hypothermia should be managed by the baby being placed skin-to-skin with a parent or under a radiant warmer. Additional information about temperature regulation in the newborn can be found in Chapter 17, Temperature Regulation.

Abnormal Voiding Patterns

Urination

Approximately 15% of healthy newborns void at the time of delivery, and 95% void by 24 hours of age. Delayed voiding is often a consequence of stress on the newborn during labor and delivery, which is a protective mechanism for the baby.[199,200] Normally, no intervention is needed once homeostatic adaption to extrauterine life has been established.

The differential diagnosis of delayed voiding (defined as no urine output by 24 to 48 hours of age) includes renal and postrenal causes. With the frequent use of prenatal ultrasound examination, it is unusual for a significant renal anomaly to be unknown before birth. In the absence of antenatal intervention, infants with bilateral renal agenesis have additional findings, such as anhydramnios, Potter sequence, and early, severe respiratory failure due to pulmonary hypoplasia and PPHN. Unilateral renal agenesis does not manifest as decreased urine output. Renal vascular thrombosis can cause anuria, and babies with this condition are usually ill. Severe cystic kidney disease can involve urinary outflow obstruction. The diagnosis of cystic kidneys is usually made after the newborn period or is found incidental to the evaluation of other anomalies and not because of delayed voiding.

Postrenal causes of delayed voiding include neuropathic bladder dysfunction and anatomic obstruction of urinary flow by anomalies in the ureters, bladder, or urethra. Persistent or recurrent bladder distention after catheterization is found with occult lower spinal cord anomalies. Presacral teratoma or other tumors can cause compression and urinary blockage as well. In male newborns, there is the possibility of posterior urethral valves. Congenital lower urinary tract obstruction occurs in 1 in 3000 births, with two-thirds of these due to posterior urethral valves. Physical findings of loose abdominal skin or musculature and a distended bladder, most often accompanied by respiratory distress, suggest this diagnosis.[201]

In a healthy-appearing newborn who has a normal physical examination and a history of a normal prenatal ultrasound, allowing up to 72 hours for a spontaneous first void will avoid excessive testing. In fussy neonates and neonates with other genitourinary

abnormalities, enlarged kidneys, or a distended bladder, testing should begin immediately. Ultrasound examination of the bladder, kidneys, and urethra is often diagnostic.

Normal newborns have decreased renal concentrating ability and excessive extracellular free water at birth. As a result, they will continue to void despite a low intake of fluids. This process is normal. Newborns maintain normal hydration despite weight loss. Conversely, delayed voiding is not indicative of dehydration in the first 72 hours after birth. When mothers undergo a cesarean section, the fluid boluses given to prevent hypotension may result in additional free water in their newborn. This can lead to greater than 7% birthweight loss with extra voiding (i.e., a physiologic diuresis).[202] Hearing about weight loss in their newborn creates stress, guilt, and anxiety in parents, which may be counterproductive to breastfeeding success. It is important for providers to emphasize the normalcy of weight loss.[76]

Stooling

The first passage of meconium occurs at an average of 7 hours of age. One-third of newborns pass meconium before their first feeding. Late preterm newborns tend to pass meconium later than term newborns, and 32% of preterm newborns do not pass meconium within 48 hours after birth. Although intake is not well correlated with meconium output, the number of wet and soiled diapers does reflect the adequacy of breast milk production by day 4. Fewer than four soiled diapers on day 4 correlate with inadequate milk production.[203] By 2 weeks of age, breastfed newborns stool more frequently than formula fed newborns; they also have larger variability in the time between bowel movements.[204,205] After the first month, breastfed and formula-fed infants have about the same rate of defecation.

Because 99.7% of healthy newborns pass meconium by 48 hours of age, those whose passing of meconium is delayed beyond that time deserve extra vigilance during the examination to avoid obstructions being missed, such as an imperforate anus. A baby with abdominal distention or vomiting and delayed stooling deserves evaluation for a possible gastrointestinal tract obstruction.

Discharge of the Newborn

Anticipatory Guidance

A primary duty of newborn care providers is to ensure that the newborn's caregivers (usually the parent or parents) have the knowledge and skills to support their baby's normal growth and development outside of the hospital setting. Anticipatory guidance should be provided to help prepare new parents for the common tasks of newborn care and to educate them about the many normal variations in newborn behavior.

Because most parents have questions about infant feeding, elimination, bathing, umbilical cord care, genital care, jaundice, and common rashes, attempts should be made to provide education about these topics during the birth hospitalization. However, addressing all of the information at once using a single format may be overwhelming and not the preferred learning style for some families. Therefore, it may be prudent for practitioners to focus on a few key points of anticipatory guidance rather than reciting a litany of instructions. There is also a philosophical choice in deciding whether to emphasize the overall health of a newborn or to concentrate on the prevention or identification of illness. There is little evidence about the efficacy of most anticipatory guidance provided to parents during the newborn nursery stay, with the notable exception of the "Back to Sleep" campaign to reduce the risk of SIDS. There is also evidence that education regarding the normality of inconsolable crying in newborns helps parents deal with this stressful situation and may reduce the risk of shaken baby syndrome.[206–208]

Postpartum depression is present in at least 10% of mothers, and depression also occurs in about 10% of fathers during early infancy. Depression is linked to sleep deprivation and has a major and long-lasting impact on infant homeostasis and development.[209] Parental depression screening should occur at all well-child visits during the first 6 to 12 months of life.

Parents who display concerning behaviors during the birth hospitalization that raise concern for future child abuse or neglect should be identified, and a plan made to assure the infant's safety after discharge. The plan may include supervision by another responsible adult, mandatory participation in community-based parenting interventions, temporary placement in foster or kinship care, or—as a last resort—termination of parental rights.[210,211]

Safe Sleep

With the exception of immunizations, no child health intervention in the past three decades has resulted in a larger decrease in postneonatal infant mortality than the "Back to Sleep" campaign. The remarkable change in the predominant sleep position of infants from prone to supine has led to a 30% to 50% reduction in the rate of SIDS in the United States.[212] A multipronged effort including brochures, public service announcements, and education provided by healthcare professionals was used to promote the recommended change in infant sleep position.[213] The education provided to parents during the newborn nursery stay is a crucial determinant of the sleep position of an infant. In addition to providing education, there is evidence that parents model sleep position for their babies after how they saw nurses and physicians place their neonate in the bassinet in the newborn nursery.[212,214] There is no evidence that placing newborns on their side during the first few hours after birth decreases the risk of aspiration.[215] Therefore it is crucial that neonates are placed on their backs to sleep in the newborn nursery. In addition, there is an additive effect from physicians and nurses both recommending and demonstrating the supine sleep position.[213]

In addition to the supine position, there are other factors related to the sleep environment that may impact the risk of SIDS. It is recommended that infants sleep on firm surfaces and without excessive bedding such as pillows, crib bumpers, or stuffed animals. Although a controversial topic, the results of a metaanalysis strongly indicate that co-sleeping increases the risk of SIDS by nearly threefold. The risk of co-sleeping is highest in infants of mothers who smoke.[216] In addition, although the use of a pacifier has been found to reduce the risk of SIDS, there is a reluctance to recommend these devices because of concerns about a negative impact on breastfeeding.[212,215]

Infant Car Seats

All states have laws that require the use of car seats for children. It is important that parents purchase only approved car seats, so bargain-hunting at used child equipment stores should be done with caution. Lists of approved car seats are available online.[217]

Pediatrician Follow-Up

In an era of early hospital discharge for healthy newborns (average length of stay 48 to 52 hours),[218–220] it is particularly

important to have in-home or clinic follow-up at 3 to 4 days of age. This is when the newborn's weight reaches its nadir, bilirubin levels peak, lactogenesis II is starting, and mothers are sleep deprived from tending to the around-the-clock needs of the newborn. Breastfeeding mothers may need extra encouragement during this time and continued vigilance to ensure that breastfeeding is established. The AAP recommends that newborns discharged before 48 hours after birth have a follow-up appointment with a provider within 48 hours.[221] This follow-up can be accomplished either by a visit to a healthcare provider or by a home nursing visit.

The risk factors for readmission following an initial hospital stay of less than 48 to 72 hours include GA less than 39 weeks (and especially <37 weeks), primiparous mother, and Asian ethnicity (presumably due to an increased risk of hyperbilirubinemia).[219,222–224] Consideration of a longer nursery stay is suggested for newborns with one or more of these risk factors. In addition, early discharge is not recommended for term newborns who have not voided, passed at least one stool, or demonstrated adequate breastfeeding.[221]

Special Considerations for Late Preterm Infants

With nearly 3.75 million live births in 2019,[225] the United States has one of the highest birth rates among industrialized countries while simultaneously having a disproportionately high rate of preterm birth. Decades of efforts to reduce preterm births have made little headway. In 2007, the AAP Committee on the Fetus and Newborn published guidelines to help standardize and optimize care for this vulnerable population, changing the term from "near term" to "late preterm" infant (those occurring between $34^{0/7}$ and $36^{6/7}$ weeks' gestation), and "early term" infants being those born between $37^{0/7}$ and $38^{0/7}$ weeks gestation. Late preterm and early term account for approximately 32% of live births.[226]

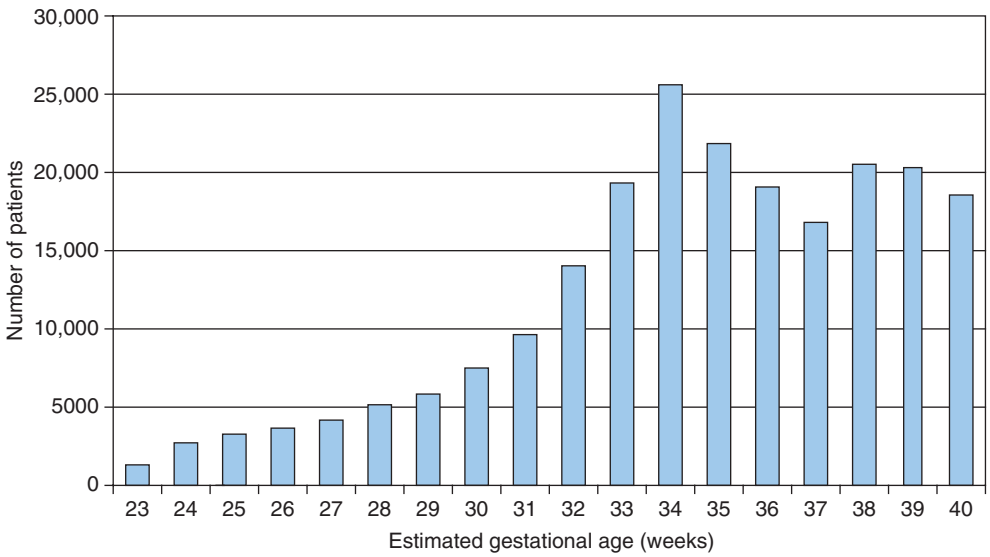
Hospitalization

As the number of late preterm infants has grown, so has the awareness of their unique set of medical challenges. In fact, late preterm newborns account for up to one-third of all NICU admissions (Fig. 16.5).[227,228] Unlike the smaller, visibly immature early preterm infant, late preterm infants appear mature because they are larger, and the tendency has been to treat them no differently than full term infants. However, they have a higher incidence of many neonatal pathologies, including TTN, RDS, PPHN, respiratory failure, prolonged physiologic jaundice, late neonatal sepsis, impaired thermoregulation, hypoglycemia, feeding difficulties, and risk of injury to the developing brain with later neurodevelopmental impairment.[229–234] This increased susceptibility to illness accounts for the increased rates of NICU admissions within the late preterm population (Fig. 16.6).

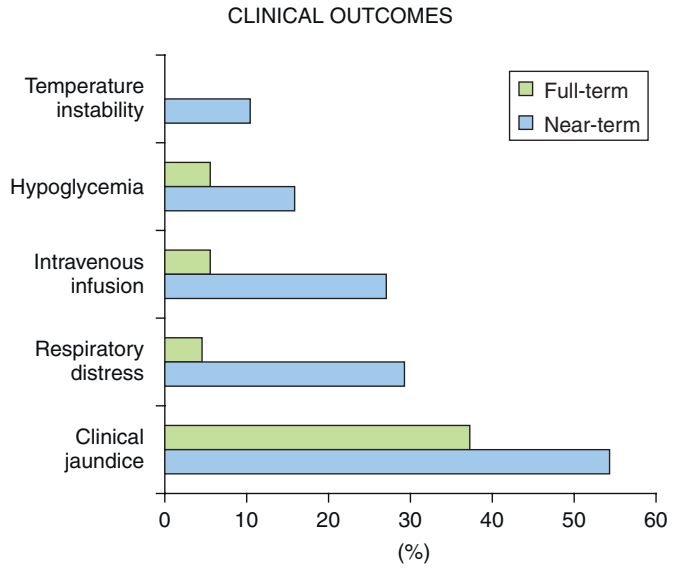
The most common reasons for admission include temperature instability, jaundice, respiratory distress, dehydration, poor feeding, and hypoglycemia.[229,235] Studies have shown that 88% of infants born at 34 weeks' gestation, 12% born at 37 weeks' gestation, and 2.6% born at 38 to 40 weeks' gestation were admitted to the NICU.[236]

In general, nutritional experts recommend that 34- and 35-week late preterm infants receive nutrient-enriched (22 kcal/oz) milk, whereas older 36- and 37-week late preterm infants with an uncomplicated neonatal course should be fed unfortified milk after discharge.[237] These nutrient-enriched formulas have a higher protein content (1.9 g/dL vs. 1.4 g/dL), increased energy (22 kcal/oz vs. 20 kcal/oz), and additional calcium, phosphorous, zinc, trace elements, and vitamins compared with standard formulas.[237]

Those late preterm infants not admitted to the NICU may require a longer hospital stay. Because of the morbidities and risk factors associated with late preterm babies, they should not be discharged before 48 hours after birth. When in the



• **Fig. 16.5** Distribution of neonatal intensive care unit admissions by gestational age, highlighting the contribution made by late preterm and early preterm infants. Data were obtained from a large consortium of neonatal intensive care units under a common management. (Modified from Clark RH. The epidemiology of respiratory failure in neonates born at an estimated gestational age of 34 weeks or more. *J Perinatol*. 2005;25:251–257.)



• **Fig. 16.6** Clinical outcomes in near-term infants (350/7 to 366/7 weeks) and full-term infants as a percentage of the patients studied. (Modified from Wang ML, Dorer DJ, Fleming MP, et al. Clinical outcomes of near-term infants. *Pediatrics*. 2004;114:372–376.)

newborn nursery, discharge criteria should reflect criteria similar to the NICU.

Newborn Car Seat Challenge

The observation that preterm newborns had episodes of hypoxia when monitored in car seats led the AAP to recommend in 1991 that preterm newborns be observed and monitored for apnea, bradycardia, or oxygen desaturation in their car safety seat prior to hospital discharge—the so-called car seat challenge.[238–240] In the United States, the car seat challenge expanded to include late preterm newborns, most of whom did not have respiratory problems during their hospital stay. It has been reported that 25% of late preterm newborns do not fit securely into standard car safety seats, and 12% of healthy late preterm newborns have apneic or bradycardic events in their car seats.[241] The rate of failure (about 4%) has been found to be about the same in small for GA babies as those born late preterm.

The authors of a Cochrane systematic review questioned whether or not car seat trials actually prevent morbidity or mortality and whether there might be adverse effects from not passing this "screen," such as prolonging the hospital stay or creating parental anxiety. Their review did not discover any randomized trials, and they concluded that "it is unclear whether undertaking a car seat challenge is beneficial or indeed whether it causes harm."[242]

Follow-Up After Discharge

After discharge from the hospital, it is recommended that the late preterm baby be brought for a checkup by its pediatrician within 24 to 48 hours. In addition, because of their increased risk of developmental delays, these infants should be monitored closely to ensure that all milestones are achieved appropriately and that early intervention (e.g., physical therapy, occupational therapy, speech therapy) is in place if needed. Early developmental testing can also be useful in determining any cognitive delays, which can then be addressed with individualized educational programs.

Primary care physicians caring for late preterm infants in an outpatient setting should also be cognizant that the higher risk of morbidities may persist beyond the neonatal period and into early childhood. One recent study showed that 30% of children younger than 2 years who were admitted to the pediatric intensive care unit for respiratory diseases were born prematurely. Of that group, 17% were former early preterm babies, and 12% were late preterm infants.[243]

Readmission to the Hospital

The late preterm infant is at increased risk of readmission to the hospital, with rates of 4.4% compared to 2% for full-term infants,[244] with common causes including dehydration, feeding problems, respiratory distress, apnea, fever, infection, and jaundice[245] In addition, 34- to 36-week infants who were never admitted to the NICU (or if admitted, their NICU stay lasted less than 24 hours) had nearly a threefold and 1.3-fold higher risk of readmission compared with full-term infants, respectively.[244,246] Because late preterm infants are at a much higher risk of rehospitalization, they need close follow-up after discharge to assess breastfeeding and nutrition and to monitor them for jaundice.

Acknowledgments

We wish to thank Valencia P. Walker, James A. Taylor, Jeffrey A. Wright, David Woodrum, Sowmya S. Mohan, and Lucky Jain for their invaluable contributions to the previous edition of this textbook, on which this chapter is based.

Temperature Regulation

JANESSA B. LAW AND W. ALAN HODSON

KEY POINTS

- Providing an appropriate and stable thermal environment is important for newborns regardless of size or gestational age.
- Neutral thermal environment (NTE) refers to the ambient temperature necessary to maintain normal metabolism.
- Newborn (admission) hypothermia continues to be a global challenge, particularly in resource-limited settings.
- Radiant warmers, warm blankets, thermal mattresses, head covering, plastic wrap (without drying), delayed bathing, and skin-to-skin care have been recommended to reduce neonatal hypothermia.
- Interhospital transport, particularly for critically ill and/or low birth weight (LBW) neonates, increases the risk of thermal instability.

All newborns are at risk of experiencing physiologic instability due to aberration of their core temperature. Providing an appropriate and stable thermal environment is important for newborns regardless of size or gestational age (GA). Most of the temperature needs of the full-term infant will be associated with birth, or in rare circumstances with the development of an illness or environmental instability. It is imperative that providers involved with delivery or subsequent care understand the various causes and consequences of heat loss, the mechanisms of heat production by the infant, and the multiple management options for providing the correct thermal environment. A variety of clinical conditions present different management challenges depending upon the degree of immaturity, birth weight, and concurrent illness such as respiratory distress, sepsis, or asphyxia. Temperature regulation is an essential and important component of neonatal intensive care.

Nearly a century ago, long before the development of intensive care nurseries, research demonstrated an association between temperature control and increased survival in premature infants. Incubators first appeared in the 19th century in Europe, but it was not until the 1930s that they were incorporated into the care of premature infants at Michael Reese Hospital in Chicago. However, the concept that premature infants were unharmed by hypothermia (acting as if they were similar to a poikilothermic animal) prevailed until controlled trials demonstrated the associated morbidity and mortality of cooling in various birth weight groups.[1] Often referred to as "cold stress," a number of studies demonstrated the metabolic cost of hypothermia, resulting in a doubling or tripling of oxygen consumption, particularly in early-gestation infants.[2–5] These studies were the first attempts at defining the optimal environmental temperature for maintenance of a normal body temperature and physiology, known as the neutral thermal environment (NTE). This quest has resulted in ever-increasing refinements of protective management techniques including hybrid incubators, radiant heaters, heated gel mattresses, plastic wrapping, heat shields, a laminar flow device, clothing, caps, room temperature control, and protocols for skin-to-skin care (SSC). Appropriate incorporation of the many management options will depend upon the needs of the individual infant related to his or her birth weight, maturity, degree of illness, and postnatal age.

Mechanisms of Heat Loss

The most vulnerable time for heat loss occurs during the first minutes after birth. It is of interest to consider the thermal environment of the fetus and how a stable body temperature is maintained despite variations in fetal metabolic activity associated with sleep cycles, muscular activity, respiratory movements (fetal breathing), and changes in maternal temperature. Maternal-fetal heat exchange occurs primarily via the umbilical vessels. Although the fetus maintains a differential of 0.5°C above maternal temperature, the extra heat is transferred from the umbilical artery to the umbilical vein as it courses back to the placenta such that the temperature of the blood returning to the placenta is nearly equal to the temperature of the blood leaving through the umbilical vein.[6,7] Thus, the fetal environment is primarily dependent upon the maternal temperature. Significant elevations in maternal temperature have the potential to cause fetal harm, hence the standard advice given to pregnant women to avoid hot tubs. Maternal fever as a result of inflammation or infection is likely of higher risk to the fetus than moderate maternal exercise or ambient heat stress. The temperature gradient between the fetus and the mother may increase beyond 0.5°C during labor, uterine contractions, and it widens slightly with advancing GA.[8]

There are four major mechanisms of heat loss that will vary over progressive days of nursery care (depending upon the maturity of the infant, growth, illness, and environmental factors). These are evaporation, radiation, convection, and conduction, each with variable contributions to heat loss (Table 17.1; Fig. 17.1).

Evaporation

Evaporative losses at birth may result in a fall of 2°C to 3°C within the first 30 to 60 minutes after birth if the newborn is extremely premature or if no wrapping, drying, or clothing is applied in a larger newborn.[9] Delays in warming may occur if resuscitation or other medical care postpones drying. The first minutes after birth are already stressful because of the physiologic adaptions required

for onset of breathing, absorption of fetal lung fluid, and circulatory changes.

The major cause of heat loss from evaporation following delivery is exposure of the infant's large surface area of skin relative to his or her body mass while wet from amniotic fluid. The more immature the newborn, the larger the relative surface area (Table 17.2). In full-term newborns, evaporation of water from the skin decreases until a body temperature of 36.6°C to 37.1°C is reached. Concomitant increase in skin blood flow does not appear to influence evaporative heat loss.

Insensible water loss through the skin continues to contribute to evaporative heat loss, but this decreases over the first few days after birth. The rate of evaporative water loss depends upon the ambient humidity and increases at humidity levels below 50%. Evaporation is somewhat greater under a radiant warmer compared to an incubator. Studies have demonstrated large losses from transepidermal water evaporation over the first few days after birth in extremely LBW newborns (Fig. 17.2). This suggests that the skin permeability of very premature neonates, especially during the first hours after birth, is very different from that of neonates born beyond a GA of 32 to 34 weeks.[10]

Radiation

Radiation is a major source of heat loss, thus it has been the focus of the majority of research studies which has led to the development of many devices to minimize that loss and to protect the infant from excessive energy expenditure. Radiant heat loss from the skin can be responsible for 40% or more of the daily heat loss (when air movement is low). Many variables can influence the degree of heat loss, including body surface area, environmental temperature, the type of external heat source, clothing, blankets, caps, heat shields, and swaddling. The full-term infant should not present ongoing concerns with radiant heat loss if certain measures of care are provided such as room temperature of 24°C to 26°C, appropriate SSC, clothing, and blankets. Premature infants and those who are growth restricted or ill with cardiorespiratory

distress, sepsis, asphyxia, or other disorders will be at continued risk of radiant heat loss. This mechanism of heat loss is influenced by the mean temperature of the skin and the mean temperature of the surrounding walls, as well as the temperature gradient to a nearby object of lesser warmth even if the object is outside but near the incubator or the warmer.

Convection

Heat loss due to convection is determined by the airflow around the infant, the mean temperature of the ambient air, the mean temperature of the skin, and the exposed surface area of the infant. Different incubators have different airflow, humidity, and wall temperature capacities that can influence the degree of convective heat loss.

Conduction

Conductive heat loss contributes minimally to energy expenditure and primarily depends upon the thermal conductivity of the mattress, which is low in incubators and under radiant warmers. Skin adjacent to a colder object such as a radiograph plate or other cold instrument will result in some conductive heat loss.

Mechanisms of Thermoregulation

Our understanding of thermoregulation in the human infant comes from translational studies in animal models. From these studies we know that temperature sensors are located throughout the surface of the neonatal body. These receptors transmit signals to a central temperature controller within the hypothalamus which in turn regulates temperature homeostasis via multiple mechanisms. Thermoneutrality in response to hypothermia in the newborn is primarily accomplished via nonshivering thermogenesis as discussed below.

The optimal temperature for an infant is defined by a range of measurable skin temperatures that indicate a central or core temperature. Measurement sites include the axilla, rectum, and skin (the small size of the ear canal precludes tympanic measurement). The recommended range for normal axillary and rectal temperatures is 36.5°C to 37.5°C for full-term infants, 35.6°C to 37.3°C for preterm infants, and 36.7°C to 37.3°C for LBW infants. Axillary temperature measurement is intermittent with minimal errors related to placement of the thermometer, while rectal temperatures have a risk of trauma and inaccuracies due to depth or duration of insertion of the thermometer as well as passage of stool. Continuous temperature monitoring with an infrared skin probe placed over the midline of the upper abdomen or on the back below the scapulae permits accurate assessment of core temperature under various external heating arrangements.

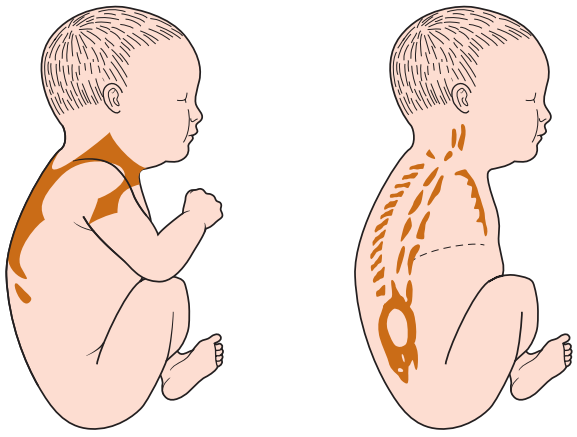
The NTE refers to the ambient temperature necessary to maintain normal metabolism. For the average naked adult it is 25°C to 27°C, and for the full-term naked newborn it is 32°C to 34°C.[11] For premature infants it will differ with GA and weight. Infants of 25 weeks' GA or less will require an ambient temperature close to that in utero (i.e., 35°C to 37°C) until they are placed in an appropriate protective environment. LBW infants are particularly susceptible to temperature instability because of the absence of subcutaneous fat for insulation, decreased levels of brown fat for heat production, increased evaporative losses from a large body surface area relative to body weight, poor vasoconstrictor control, decreased spontaneous muscle activity, and transepidermal insensible water loss. Additionally, small for GA infants have a higher metabolic rate for weight. An increase in activity and ingestion of food in growing preterm infants will also increase the metabolic rate through altered energy expenditure (see Table 17.2).

Nonshivering Thermogenesis

The newborn is unable to reduce heat loss or increase heat production by shivering or increasing voluntary muscle activity. Nonshivering thermogenesis produces energy output and heat production, largely from brown fat. Brown fat is located in six major sites near major arterials and organs, and demonstrates increased oxidation within minutes of birth (Fig. 17.3).[12] Although it appears as early as 25 weeks in the fetus, the substrates detailed below that are necessary for thermogenesis are markedly decreased in the premature infant.[13]

Temperature receptors sensing a low temperature stimulate the sympathetic nervous system to release norepinephrine and ATP adjacent to brown fat cells.[14] These in turn stimulate β-adrenergic and adenosine activated A_{2A} receptors, respectively, resulting in increased cyclic AMP (cAMP) activation of protein kinase A (PKA). PKA drives heat production by (1) release of cytoplasmic stores of fatty acids that either combust or activate uncoupling proteins (i.e., thermogenin), and (2) promoting transcription of genes involved in heat production. These genes are also regulated by thyroxine, triiodothyronine, and thyroid stimulating hormone via the hypothalamic-pituitary-thyroid axis as well as by adrenocorticoid hormone and glucocorticoids via the hypothalamic-pituitary-adrenal axis.[13,15]

During the 1960s, considerable clinical and animal research helped to define the NTE for newborns in relation to changes in environmental and core temperatures. Environmental temperatures that progressively decreased below 34°C resulted in a steady increase in oxygen consumption to values that were two to three times the resting state. Increases in oxygen consumption and metabolic output are considered important contributors to increased morbidity and mortality, especially in extremely LBW infants. Extended periods of cold stress have been associated with hypoglycemia, respiratory distress, hypoxemia, metabolic acidosis, necrotizing enterocolitis, and death. If environmental cooling



• **Fig. 17.3** Distribution of brown fat deposits in the newborn from 28 to 42 weeks' gestation. (Redrawn from Aherne W, Hull D. Brown adipose tissue and heat production in the newborn infant. *J Pathol Bacteriol*. 1966;91(1):223–234. doi:10.1002/path.1700910120.)

exceeds the infant's thermoregulatory response of energy output, the core temperature will drop along with a decrease in oxygen consumption (Fig. 17.4). This "Q_{10} effect" of decreased metabolism when the environmental temperature falls below a critical point is the basis for the use of induced hypothermia in certain clinical situations.

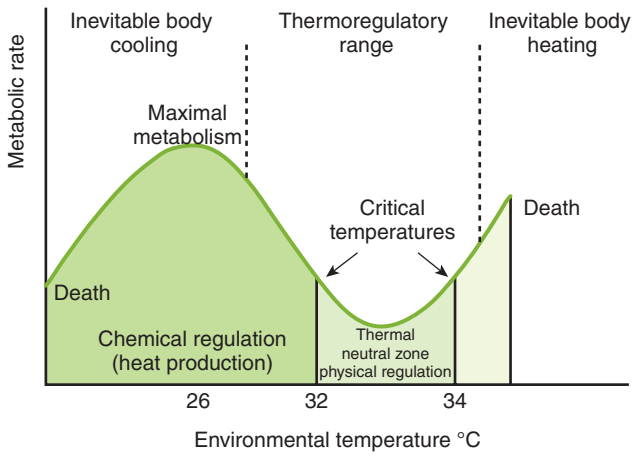
Thermal Management Strategies

Understanding heat loss, nonshivering thermogenesis, and the consequences of cold stress have led to a variety of protective and therapeutic options. Much controversy has arisen regarding various warming devices and techniques, resulting in new or modified equipment and strategies. The goal of estimating and maintaining the NTE for each infant is supported by evidenced-based trials. The indication and timing of interventions have driven evolution of management protocols applicable to various clinical settings including transport, delivery rooms, nurseries with "rooming-in" policies, and neonatal intensive care units (NICUs).

Delivery Room Environment

Hypothermia soon after birth has been associated with increased morbidity and mortality, prompting organizations such as the Neonatal Resuscitation Program and the World Health Organization (WHO) to stress the importance of preventing early postnatal hypothermia.[16] Maternal temperature at delivery should be noted on the infant's birth record along with an axillary temperature. The room temperature, including operative rooms, should be kept at 26°C. Ideally, a preheated gel mattress, a warm bassinette, warm blankets, and a radiant heat source should be in place. Immediate drying, placement of a cap, and swaddling (once stabilized) will reduce evaporative heat loss. The full-term newborn will maintain a normal body temperature with appropriate clothing and blankets in an environment of at least 24°C. Preterm newborns need additional protection from heat losses, including higher ambient temperature and the use of plastic wraps (without drying) especially in infants less than 1500 g at birth.[17] Early skin-to-skin care (SSC), once the infant has been stabilized, can be very effective in preventing hypothermia—particularly in resource-limited settings.[18]

Delayed umbilical cord clamping in very preterm newborns initially raised concern regarding thermal management. However, multiple reviews and meta-analyses of studies done in newborns of all gestational ages have found no differences in admission temperature.[19,20]



• **Fig. 17.4** Variations in metabolic rate with changes in environmental temperature in human newborns, including the neutral thermal environment and extremes of cooling and heating. (Redrawn from Baumgart S. Incubation of the human newborn infant. In: Pomerance JJ, Richardson CJ, eds. *Neonatology for the Clinician*. Norwalk: Appleton & Lange; 1993:139–150.)

Care of the Extremely LBW Infant

The neonate born before 28 weeks' gestation presents a major challenge to the prevention of heat loss. Hypothermia is reported in extremely LBW neonates upon admission to the NICU and is especially hard to prevent in neonates born at less than 25 weeks' gestation. Furthermore, it is associated with an increased risk of early and late neonatal death.[21] Studies support the use of plastic bags and caps in the delivery room with the newborn immediately wrapped in a clear plastic bag up to the neck without drying and placed under a radiant warmer.[22,23] The head is dried and covered with a plastic cap. Resuscitation can proceed with the bag in place. This provides initial thermal stability for transfer to the NICU or transport to another facility. The first 12 hours is important in preventing further heat loss. Possible contributors to cold stress are the temperature of the inspired airflow, evaporative loss under radiant heat, cold hands, weight scales, the temperature of intravenous infusions and fluid boluses within syringes, and procedural interventions such as intubation, imaging, and vessel cannulation. The duration of vessel cannulation determines the length of time the newborn is covered with a sterile drape that interferes with warming. Expediency in completing this procedure is therefore vital.

Warming Infants

Incubators and radiant warmers have been in use in the NICU for several decades and remain the focus of heat management. Each of these warming devices has undergone sophisticated evolution and remain effective in providing a NTE for infants of differing sizes and with differing illnesses. Both devices provide enhanced observation and access when needed. There are slight variations between incubators and radiant warmers in the degree of evaporative and radiant heat loss, but no significant differences in outcomes have been demonstrated.

Incubators Versus Radiant Warmers

The prototype of the modern incubator, using the principal of convective heating of air, came into widespread use in newborn nurseries in the 1960s. Since then there have been many modifications allowing precise control of air temperature, airflow, humidity, and limitation of heat loss due to convection, radiation, and conduction within the incubator.[24] There are three options to achieve a stable and desirable skin temperature of 36.0°C to 36.5°C: (1) servo control of incubator air temperature, (2) servo control of abdominal skin temperature (using an abdominal skin probe), and (3) manual control of incubator temperature with knowledge of abdominal skin temperature. The advantage of servo control with an abdominal skin probe is that it ensures maintenance of a constant body temperature despite perturbations caused by a decreased environmental temperature from open portholes or opening of the incubator top. Overheating can occur if the probe becomes detached or covered with a blanket.

Thermal blankets have been used over the infant within the incubator to reduce insensible water loss. Heat shields are employed when using single-walled incubators to reduce radiant heat loss. The rationale for creating the double-walled incubator was to reduce radiant heat loss. While double-walling incubators have become standard for contemporary NICUs, several studies demonstrate only small differences in heat loss and heat production between the two types of incubators, and they have not shown a difference in clinical outcome if skin temperature servo control is used.[25]

Overhead radiant heaters were first used in delivery rooms, particularly for support during resuscitation procedures. These evolved into the Sierracin Cradle Warmer, which fits over an open bassinet. This warmer was used to observe naked infants for signs of distress over the first few hours after birth, commonly referred to as the transition or observation period. The "observation nursery" is now a thing of the past and has been replaced by the "intermediate care nursery" for infants with a minor degree of instability such as mild respiratory distress, irritability, jaundice, or risk for sepsis. Monitoring these infants with temperature probes as well as by means of vital signs facilitated the provision of an NTE without needing a NICU admission. These devices prompted development of the current radiant warmers now in common use in NICUs. They produce overhead heat in the infrared range distributed in a uniform fashion to the infant and controlled by an abdominal skin thermistor. As expected, evaporative heat loss is large with radiant warmers and increases if humidity falls below 50%, however these losses can be minimized by swaddling the infant. Open access under the warmer is excellent and advantageous in the assessment and management of the seriously ill infant upon admission.

Comparisons of the superiority of either the incubator or the radiant warmer have shown no differences in outcome. Both methods are effective, safe, and appropriate for care of the extremely LBW newborn, with recognition of small differences in insensible water loss. The more recent development of a hybrid incubator allows the intermittent use of a vertically adjustable radiant heater as well as drop-down incubator walls to improve access. Advocates for its use suggest that the incidence of severe bronchopulmonary dysplasia may be lessened and that better fluid balance and growth velocity may be achieved.[26]

Weaning to an Open Crib

The continuing need for an incubator is relevant to discharge planning and home care. Body weight attainment serves as a useful indicator for open crib readiness. Infants weighing 1500 g transferred to an unheated open crib demonstrate satisfactory growth velocity and a stable temperature without other adverse effects.[27,28] However, earlier transfer to an open crib does not necessarily correlate with an earlier discharge. Crib nursing of full-term infants requires a room temperature of at least 24°C, while infants of 1500 g should be in an environment of 26°C to 28°C. Smaller infants should be fully dressed, including a head covering, and may require a room temperature of 30°C.

Skin-to-Skin Care

SSC, a component of "Kangaroo mother care," was originally described as an effective way for mothers to keep their full-term infants warm while breastfeeding, and subsequently as an alternative method of caring for LBW infants in resource-limited settings.[29] In these original versions, the infant is placed skin-to-skin in a vertical position between the mother's breasts and under her clothes and is exclusively (or almost exclusively) breastfed. Intermittent SSC provided by a caregiver has been introduced in resource-rich settings for infants requiring neonatal intensive care—even extremely premature infants and those on ventilators. Several guidelines regarding SSC in the NICU have been published, but because it requires intensive staffing support, resources, and parent participation, development of individualized unit guidelines has been recommended.[27,30]

When first introduced, temperature regulation during SSC was a concern for both care providers and parents; however, thermal balance even in very and extremely preterm neonates before, during, and after SSC during the first week after birth has been demonstrated to be safe.[31,32] It is likely that the conduction of heat from caregiver to infant is sufficiently high to compensate for the increases in evaporative and convective heat losses. The vast majority of studies, including a 2016 Cochrane review, have demonstrated better growth and exclusive breastfeeding rates with decreased incidence of hypothermia, hypoglycemia, sepsis, and mortality in infants who experience SSC compared to standard bassinet, radiant warmer, or incubator care.[33,34] Improvements in social and behavioral outcomes even 20 years later have been shown.[35] The Committee on Fetus and Newborn of the American Academy of Pediatrics does acknowledge, however, that NICU infants should be continuously monitored during SSC and that "any infant who requires careful temperature regulation or a high-humidity environment might have SSC delayed until he or she is more stable."[27]

Additional Considerations

Transport

Temperature instability during transport to a NICU remains a challenging problem, particularly for extremely LBW neonates. Neonates born at less than 25 weeks' gestation, even those delivered within a tertiary care center, have been noted to have a drop in core temperature within 12 hours of admission to a NICU.[36] A review of several thousand LBW infants in the National Institute of Child Health and Human Development Neonatal Research Network who were admitted directly from the delivery room to the NICU revealed an association between lower admission temperature and lower birth weights as well as the need for immediate intubation. Admission temperature was inversely related to mortality (28% increase per 1°C decrease) and the incidence of late-onset sepsis (11% increase per 1°C decrease).[37]

Interhospital transport, particularly for critically ill and/or LBW infants, increases the risk of thermal instability. Infants may be exposed to a cooler, draftier non-NICU environment at the referring hospital and during transfer to and from the transport incubator. Evaluation and stabilization efforts, often accompanied by the movement of multiple care providers and equipment, can also increase convective heat loss. Intubation equipment, vascular access instruments, cold inspired air, unheated intravenous solutions or medications, and cold hands may increase conductive heat losses. One level III referral NICU used transport risk index of physiologic stability (TRIPS) scores to evaluate the impact of transport on the physiologic stability of very LBW infants. They found that more than half the transported infants demonstrated deterioration in their TRIPS score primarily because of a decrease in temperature, and the likelihood increased with longer duration

of transport. They concluded that better temperature regulation during transport may decrease the risk of clinical deterioration in such infants.[38]

As discussed previously, the use of occlusive plastic wraps and a cap is advocated while evaluation, resuscitation, and/or stabilization measures are occurring. However, additional warming methods are often needed and may be provided by a heated gel mattress and a radiant warmer. The urgency of cardiopulmonary stabilization and other life support measures may take priority over the many details of heat loss prevention. Thus development of standard temperature care protocols and team training in their use for every neonatal transport is recommended.

Hypothermia

Induced hypothermia by controlled cooling of the body or head for the treatment of neonatal encephalopathy is discussed extensively elsewhere.

For the most part, a nontherapeutic decrease in core temperature is indicative of an infant's inability to generate sufficient heat by increasing metabolism. How best and how quickly should rewarming occur to reach a core temperature of 36°C without increasing oxygen consumption or metabolism? Few data exist to support the optimal rate of rewarming. Current protocols favor a rapid return to a NTE with extra heat provided by radiant heat and a heated mattress or an incubator. A decrease in core temperature in LBW infants, especially in the first hours of life, remains an important risk factor for increased morbidity and mortality.

The World Health Organization (WHO), concerned that neonatal hypothermia is prevalent around the world as a contributor to inadequate newborn care, has developed a classification system to underscore the importance of intervention. Three levels are defined: Mild hypothermia (aka cold stress) from 36.0°C to 36.5°C, moderate hypothermia between 32.0°C to 35.9°C, and severe hypothermia for temperatures below 32.0°C. A retrospective study assessing these criteria found that approximately 56% of very LBW newborns were moderately hypothermic in the first few hours of life and had an associated adjusted risk factor for an increase in intracranial hemorrhage (odds ratio [OR] 1.3) and death (OR 1.5).[39] Therefore, emphasis on the need for rewarming has been focused on the care of infants at risk of "moderate" hypothermia.

Where available, rewarming involves setting a skin thermistor at a desired level of 37°C or 38°C. Under a radiant warmer, heat core temperature of 37°C can be achieved in 4 hours with a set point of 37°C or 2 hours with a set point of 38°C. Although there is minimal evidence for an increase in apnea or hypoglycemia, both should be monitored. In resource-limited settings, the WHO recommends SSC for treatment of moderate hypothermia.[40]

Hyperthermia

Overheating (core temperature above 37.3°C) can result in "heat stress," manifested by tachycardia, tachypnea, and restlessness. It is important to assess whether the cause is environmental or secondary to infection. Measurement of the abdominal skin temperature and that of the foot or toe should normally reveal a difference of 2.0°C. As infection progresses, vasoconstriction of the periphery will occur in an effort to support the body's effort to increase core temperature. Therefore, a toe-to-abdominal skin temperature difference of greater than 2.5°C would indicate an infection rather than an environmental cause. If the abdomen-to-toe temperature gap is less than 1°C or reversed, this indicates excess heat is being applied. Environmental temperature should be reduced by 0.5°C at intervals of about 30 minutes, with excess layers of clothing removed. The abdomen-to-toe temperature gap in the LBW infant may be unreliable because of impaired control of microvascular perfusion, and thus monitoring for other signs of overheating is more important.

Bathing

There is a tendency for all neonates, large and small, to be bathed soon after birth. In some cultures, customs and rituals associated with birth dictate the timing of naming, cord separation, first feed, and first bath, among other events. Should early bathing be performed, it is recommended that newborns be bathed starting with the trunk and concluding with the head with its greater evaporative surface area, thus minimizing heat loss.

Although early bathing is probably of limited value and can safely be delayed, there is often a desire to rid the skin of its coating of vernix. The vernix is made up of a thick coat of mostly lipids, including triglycerides, free fatty acids, and cholesterol esters. One of the many functions of the vernix is to provide barrier function against transepidermal water movement in utero.[41] It may have a similar role after birth as well as providing mechanical protection during birth. There is no evidence that it plays a role in thermal protection, but it may provide some benefit to the premature neonate.

There is recent evidence that one benefit of a vaginal delivery is the transfer of organisms in the maternal microbiome to the infant, leading to the suggestion that smearing infants born by cesarean delivery with vaginal secretions would be of benefit to establishing a microbiome pattern akin to that of the mother.[42] Bathing may interfere with that goal.

Summary

Body temperature homeostasis is but one element of the normal adaptation to extrauterine life for all newborns. Prevention of heat loss is especially important in reducing morbidity and mortality in premature and LBW newborns. Hypothermia in critically ill infants whether due to prematurity, respiratory distress, sepsis, asphyxia, congenital anomalies, or other abnormalities will result in increased energy expenditure and oxygen consumption. Protocols and guidelines have been developed for protective management strategies based on clinical trials and physiologic rationale and are periodically revised by medical and technical staff. The use of sophisticated equipment requires constant monitoring of heat output and the neonate's core temperature with the goal of providing the appropriate NTE. It is particularly important for care providers to understand the consequences of heat loss in fragile neonates.

Several challenges remain, particularly in the maintenance of body temperature of extremely LBW newborns in the delivery room, during transport to the NICU, and in the first few hours after birth. This is due in part to resuscitative and stabilization efforts that may take priority over wrapping and other temperature control procedures. However, there is room for improvement in the coordinated and simultaneous approach to the prevention of unintended cooling without delaying or impeding necessary resuscitation and stabilization procedures.

There is also need for improvement in standards for the optimal level and duration of humidification for incubators and radiant warmers. For infants 26 weeks' GA and older, incubator humidity set at 60% to 70% during the first week of life and at 50% to 60% until 32 weeks' corrected age reduces transepidermal water loss and electrolyte disturbances.[26] However, prolonged and high levels (>80%) of humidity, often used in infants less than 26 weeks' GA, have been associated with impaired phototherapy delivery, enhanced microbial growth, and delayed maturation of the stratum corneum.[43–46] Significant practice variation persists.[25,47]

Future modifications of existing equipment will probably be directed toward improving safety and efficacy in maintaining strict and accurate control of the appropriate NTE. The use of noncontact infrared thermography to measure multiple skin sites simultaneously is being evaluated.[48,49] Different areas of the skin may demonstrate temperature fluctuations under different conditions, such as during movement from an incubator to SSC and back, phototherapy, times of vasomotor instability, and at sites of conductive heat loss. Infrared thermal imaging can provide minute-to-minute information from various sites and may be useful in studying the developmental changes in the neural control of temperature (central and peripheral receptors) with advancing gestational and postnatal age.

Perhaps the larger and more important need for future work is toward reducing newborn morbidity and mortality in lower-income and middle-income countries. While temperature management with SSC in these areas has been demonstrated to significantly reduce death in premature and LBW infants, cultural beliefs, lack of education or buy-in, and insufficient resources have all been identified as barriers to implementation of SSC.[18,50–53] Ongoing global efforts by multiple groups including Helping Babies Survive and the Kangaroo Mother Care Acceleration Partnership are focused on overcoming these barriers to improve infant outcomes in resource-limiting settings.[54,55]

Newborn Screening

INDERNEEL SAHAI

KEY POINTS

- Newborn screening (NBS) provides an opportunity for early identification of newborns with disorders in which the clinical complications develop postnatally and may remain unrecognized prior to irreversible clinical damage.
- Since its inception nearly six decades ago, with screening for a single disorder, NBS has expanded substantially to more than 60 disorders in the current screening panels.
- NBS is a "screen," and individuals should not be labeled as having a disorder before diagnostic testing confirms the condition.
- Once a disorder has been confirmed, however, treatment should be initiated without delay to prevent irreversible clinical complications.
- False positives are inevitable; false negatives are possible.
- The clinical spectrum of disorders is wider than expected.
- The disorder detected is not always the one that was sought.
- Numerous methods are used in NBS, ranging from simple to complex, such as isoelectric focusing and enzymatic assays to tandem mass spectrometry and high-throughput genomic sequencing.
- Many factors will continue to transform NBS, including rapidly advancing technology and new and increasingly available therapeutic approaches to previously untreatable disorders.

Newborn screening (NBS) is directed at identifying congenital disorders in which the clinical complications develop postnatally. In metabolic and many other conditions considered appropriate for NBS, complications result from biomarker abnormalities that appear after birth, when the infant is no longer protected by fetal-maternal exchange or the fetal physiology. Initiation of treatment in the pre-symptomatic or early stages thus reduces the morbidity and mortality associated with the conditions. For example, the infant with phenylketonuria (PKU) has a normal blood phenylalanine level at birth but within a few hours demonstrates hyperphenylalaninemia. The infant with congenital hypothyroidism (CH) is also protected in utero, most likely from placental transfer of maternal thyroxine (T4). If the hyperphenylalaninemia in PKU is not controlled by diet or the hypothyroidism in CH is not corrected by supplemental T4, the infant begins to show signs of developmental delay and subsequently becomes intellectually disabled. If therapy begins during the first few weeks of life, intellectual disability in both disorders is prevented.

The association between mental retardation and PKU was initially recognized in the 1930s. Subsequently, it became evident that dietary therapy could prevent intellectual disability if initiated in the neonatal period. Detecting PKU in all affected newborns at that early age, before irreversible brain damage occurred, then became the challenge. Meeting this challenge required screening for a biochemical marker of the disease, which was accomplished in 1962 when Guthrie developed a simple bacterial assay for phenylalanine in filter paper saturated with a few drops of blood.[1] Newborns could therefore be routinely screened for PKU by measuring phenylalanine in dried blood spot specimens (DBS), obtained by lancing the heel and blotting the drops of blood onto a filter paper card, and mailed to a central laboratory for testing. An increased concentration of phenylalanine in the specimen indicated the possibility of PKU in the infant. By the mid-1960s many states had established routine NBS programs for PKU using the Guthrie method. Infants with PKU were identified in larger numbers than anticipated and showed normal development while receiving treatment.[2]

The success of PKU screening led to the addition of tests for other metabolic diseases, including galactosemia, maple syrup urine disease (MSUD), and homocystinuria. These additional tests could be performed on the same blood specimen obtained for PKU screening. Within a decade, NBS expanded to include the endocrine disorders CH and congenital adrenal hyperplasia (CAH), the hemoglobinopathies, and later biotinidase deficiency, cystic fibrosis (CF), and other diseases.

In 1990, the technology of tandem mass spectrometry (MS/MS) was applied to the DBS, opening a new era in NBS.[3] This method allowed for the accurate detection of numerous biochemical markers for metabolic disorders with a single assay, thereby replacing several assays traditionally used in screening for metabolic disorders and adding additional biomarkers not detectable by previous methods, thus greatly expanding the spectrum of conditions identifiable in the neonate.[4–6] Currently, all programs in the United States and many screening programs in Europe and elsewhere have integrated MS/MS into NBS to screen numerous biochemical disorders with high specificity and extremely low rates of false-positive results; some are screening newborns for more than 60 individual conditions.[7]

In 2006, to standardize screening panels nationwide, the American College of Medical Genetics recommended a panel of 29 core conditions for screening, and an additional 25 secondary conditions for which test results could be reported.[8] These secondary conditions are those that are identified through screening for the 29 core conditions, but either their clinical spectrum is not well-known, or effective treatment is unavailable. Currently, the task of reviewing and recommending conditions nominated for inclusion in the Recommended Uniform Screening Panel (RUSP) is performed by the Advisory Committee on Heritable Disorders in Newborns and Children.[9] The committee completes a systematic evidence-based review, deliberates on the evidence available, and votes to recommend or not recommend adding the nominated condition to the RUSP for consideration by the secretary of Health

and Human Services. The secretary makes the final decision on whether to add, or not to add, a recommended condition to the RUSP. Mucopolysaccharidosis (MPS-I), X linked adrenoleukodystrophy (X-ALD), and Spinal Muscular Atrophy (SMA) are the most recent additions to the RUSP. At the time of publication, the RUSP includes 35 core disorders and 26 secondary disorders (Tables 18.1 and 18.2).[10] In addition, the advisory committee has recently completed a review of two disorders—mucopolysaccharidosis (MPS-II) and cerebral creatine deficiency syndromes (CCDS)—and deemed that the conditions meet criteria for inclusion in the RUSP. Review of Krabbe disease to judge its suitability for inclusion in the RUSP has also begun.

TABLE 18.1 Core Disorders in the Recommended Universal Screening Panel

Condition	Acronym	Primary Biomarker
Organic Acid Disorder		
Propionic acidemia*	PA	C3
Methylmalonic acidemia (methylmalonyl-CoA mutase)*	MMA-Mut	C3
Methylmalonic acidemia (cobalamin defects: A,B)*	MMA-Cbl	C3
Isovaleric acidemia*	IVA	C5
3-Methylcrotonyl-CoA carboxylase deficiency	3 MCC	C5OH
3-Hydroxy-3-methyglutaric aciduria*	3 HMG	C5OH
Holocarboxylase synthase deficiency* (Multiple carboxylase deficiency)	MCD	C5OH, C3
β-Ketothiolase deficiency	BKT	C5:1, C5OH
Glutaric acidemia type I	GA-I	C5 DC
Fatty Acid Oxidation Defects		
Carnitine uptake defect/carnitine transport defect	CUD	C0 (Low)
Medium-chain acyl-CoA dehydrogenase deficiency*	MCAD	C8
Very long-chain acyl-CoA dehydrogenase deficiency*	VLCAD	C14:1
Long-chain L-3 hydroxyacyl-CoA dehydrogenase deficiency*	LCHAD	C16OH/C18:1OH
Trifunctional protein deficiency*	TFP	C16OH/C18:1OH
Amino Acid Disorders		
Argininosuccinic aciduria*	ASA	Argininosuccinic acid
Citrullinemia, type I*	CIT-I	Citrulline
Maple syrup urine disease*	MSUD	Leucine
Classical homocystinuria (cystathionine ß-synthase deficiency)	CBS	Methionine
Classic phenylketonuria	PKU	Phenylalanine
Tyrosinemia, type I	TYR-I	Succinylacetone
Other Inborn Errors of Metabolism		
Biotinidase deficiency	BIO	Biotinidase activity
Classic galactosemia*	GALT	Galactose1-phosphate uridyltransferase activity; Galactose (Total)
Glycogen storage disease type II (Pompe disease)	Pompe	Lysosomal acid α-glucosidase activity
Mucopolysaccharidosis type I	MPS-I	α-L-iduronidase activity
X-linked adrenoleukodystrophy	X-ALD	C 26:0 lysophosphatidylcholine
Endocrine Disorders		
Primary congenital hypothyroidism	CH	Thyroid-stimulating hormone; thyroxine
Congenital adrenal hyperplasia*	CAH	17-hydroxyprogesterone

(Continued)

TABLE 18.1 Core Disorders in the Recommended Universal Screening Panel—Cont'd

Condition	Acronym	Primary Biomarker
Hemoglobin Disorders (Sickling Disorders)		
S,S disease (Sickle cell anemia)	HbSS	Hemoglobin pattern—FS
S, β-thalassemia	HbS/β-thal	Hemoglobin pattern—FS or FSA
S, C disease	HbSC	Hemoglobin pattern—FSC
Other Genetic Disorders		
Cystic fibrosis	CF	Immunoreactive trypsinogen
Severe combined immunodeficiencies	SCID	T-cell receptor excision circles
Spinal muscular atrophy	SMA	Absence of Exon 7 of *SMN-1* gene
Other Congenital Disorders†		
Critical congenital heart disease	CCHD	Oxygen saturation by pulse oximetry
Hearing loss	HEAR	Failed hearing screen; diagnostic testing

Notes:
The markers for the organic acid disorders and fatty acid oxidation disorders are acylcarnitines; the number after the "C" represents the number of carbon atoms in the acylgroup in the acylcarnitine.
Numerous secondary markers, ratios, indices and second-tier tests employed in increasing the specificity of the primary markers are not listed.
*Disorders more likely to manifest acutely in the first week of life.
†Not screened by blood spot analysis.

TABLE 18.2 Secondary Disorders in the Recommended Universal Screening Panel

Condition	Acronym	Biomarker*
Organic Acid Disorder		
Methylmalonic acidemia with homocystinuria	Cbl C, D	C3
Malonic acidemia	MAL	C3 DC
Isobutyrylglycinuria (isobutyryl-CoA dehydrogenase deficiency)	IBG	C4
2-Methylbutyrylglycinuria (short/branched chain acyl-CoA dehydrogenase def)	2MBG SBCAD	C5
2-Methyl-3-hydroxybutyric aciduria	2M3HBA	C5OH
3-Methylglutaconic aciduria–type 1	3 MGA	C5OH
Fatty Acid Oxidation Defects		
Carnitine palmitoyltransferase IA deficiency	CPT-I	C0 (High)
Carnitine palmitoyltransferase II deficiency†	CPT-II	C16, C18:1
Carnitine acylcarnitine translocase deficiency†	CACT	C16, C18:1
2,4-Dienoyl-CoA reductase deficiency	DER	C10: 2
Glutaric aciduria II† (multiple acyl-CoA dehydrogenase deficiency)	GA II MADD	C4, C5, C5DC, C8, C14, C16
3-Hydroxyacyl-CoA dehydrogenase deficiency (medium/short-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency)	HAD M/SCHAD	C4 OH
Medium-chain ketoacyl-CoA thiolase deficiency	MCKAT	C8
Short-chain acyl-CoA dehydrogenase deficiency	SCAD	C4
Amino Acid Disorders		
Arginase deficiency	ARG	Arginine

(Continued)

TABLE 18.2 Secondary Disorders in the Recommended Universal Screening Panel—Cont'd

Condition	Acronym	Biomarker*
Citrullinemia, type II (citrin deficiency)	CIT-II	Citrulline
Hypermethioninemia	H-MET	Methionine
Benign hyperphenylalaninemia	H-PHE	Phenylalanine
Biopterin defect in cofactor biosynthesis	BIOPT (BS)	Phenylalanine
Biopterin defect in cofactor regeneration	BIOPT (REG)	Phenylalanine
Tyrosinemia, type II	TYR-II	Tyrosine
Tyrosinemia, type III	TYR-III	Tyrosine
Other Disorders		
Galactose epimerase deficiency	GALE	Galactose
Galactokinase deficiency	GALK	Galactose
Various other hemoglobinopathies	—	Various hemoglobin patterns
T-cell-related lymphocyte deficiencies	—	T-cell receptor excision circles

*The markers for the organic acid disorders and fatty acid oxidation disorders are acylcarnitines; the number after the "C" represents the number of carbon atoms in the acylgroup.
†Disorders more likely to manifest acutely in the first week of life.

Molecular techniques (i.e., DNA analysis) are commonly used in NBS. At the outset, molecular assays were limited to "second-tier" testing to specify disorders, suspected because of a primary screening abnormality, such as by targeting known pathogenic mutations on the *CFTR* gene in samples with an increased concentration of immunoreactive trypsinogen (IRT), the primary biomarker for CF, or a panel of mutations in the *GALT* gene in specimens with decreased galactose1-phosphate uridyltransferase (GALT) activity in screening for classical galactosemia. Implementation of screening for severe combined immunodeficiency (SCID) and more recently for SMA, with low T-cell receptor excision circles (TREC) and absence of Exon 7 of the *SMN1* gene as the respective markers, extended the application of molecular assays into first-tier analysis in NBS. Sequencing of individual genes as second-tier testing has already been adopted by a few programs and the role of Next Generation Sequencing (NGS) in NBS is being evaluated.[11]

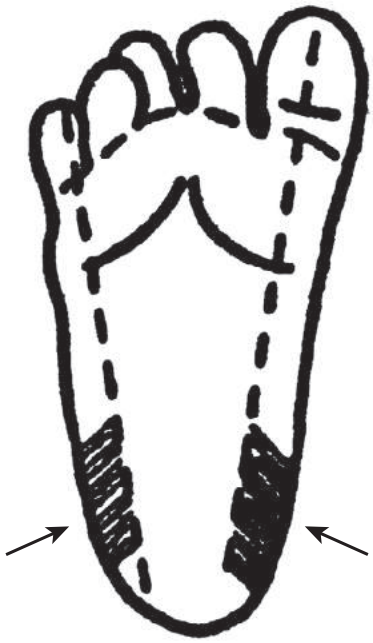
Screening Procedure

Specimen

Currently, almost all disorders on the RUSP are screened by laboratory analysis of the DBS specimen of the newborn. The two exceptions are a point-of-care hearing test and pulse oximetry that are performed directly on the newborns to screen for hearing loss and critical congenital heart disease (CCHD), respectively.

Specimen Collection Procedure

The blood specimen is generally obtained from the heel of the infant. This simple sampling method conceived and introduced by Guthrie and Susi,[1] has made NBS feasible since blood is easily obtained and can be easily and inexpensively delivered to a central testing facility by mail or courier. There are no serious complications from obtaining these newborn specimens, contrary to early fears that their collection would lead to infection or result in excessive bleeding.



• **Fig. 18.1** Hatched areas on the medial and lateral sides of the heel of the sole indicate the proper sites for a heel stick in the newborn.

The blood specimen should be obtained from the lateral or the medial side of the heel (Fig. 18.1). Blood should be applied to only one side of the filter paper card, but it should saturate each circle on the card. Contamination of the filter paper specimen

with iodine, alcohol, petroleum jelly, stool, urine, milk, or a substance such as oil from the fingers can adversely affect the results of the screening tests. In addition, exposure to heat and humidity can inactivate enzymes and produce false results. The specimen should be dried in air at room temperature for at least 3 hours before being placed in an envelope.

Specimens are sometimes collected in capillary tubes, by venipuncture of a dorsal vein or from a central line, and then spotted on filter paper. There is little or no substantial difference in analyte levels between blood collected directly from the heel and that collected by any of these other methods. However, there is the danger of introducing amino acids into the specimen in infants receiving total parenteral nutrition (TPN) if the blood is collected from a central line, resulting in a false-positive increase in the levels of amino acids or interference in some molecular assays by the heparin within the line. In general, it is preferable that a blood screening be spotted on filter paper directly from the heel.

Timing of the Collection

Specimen collection timings differ around the world. In the United States, most specimens are collected between 24 and 48 hours after birth. In Europe and Australia, screening specimens are collected within 48 to 72 hours, and in the United Kingdom the specimen is not collected until the newborn is 5 to 8 days old.[12] The specimen should be obtained from every newborn before nursery discharge or by the third day of life, whichever is first. In newborns whose initial specimen was obtained within the first 24 hours after birth, as may happen with the practice of early nursery discharge, a second blood specimen should be obtained at no later than 7 days old to be certain that a diagnosis is not missed.[13]

NBS encompasses a gamut of conditions, each with its own ideal screening period during which there is the greatest chance of diagnosing the disorder before the onset of symptoms. As a result, it is worth noting that recommendations on the timing of specimen collection, although appropriate for most conditions, may not be ideal for all conditions on the screening panel. For instance, for CAH, in which the symptoms can manifest themselves within the first week of life, the optimal time for collection of the specimen is within 24 to 48 hours after birth. Conversely, there remain concerns that with the NBS specimen collected early, often during the first day of life, some newborns with metabolic disorders or with CH might not have a sufficient degree of abnormality for identification. The MS/MS method with its increased sensitivity and specificity has considerably increased the reliability of screening for metabolic conditions in early specimens.[14] Furthermore, use of thyroid-stimulating hormone (TSH) as the primary marker for CH, or as a second-tier test when T4 is the primary marker, has similarly allowed early screening for CH to be more acceptable.

Special circumstances require specific attention to newborn blood specimen collection. Premature newborns or those with low birthweight (LBW), and newborns who are sick and those in neonatal intensive care units (NICU), are at risk of unreliable screening owing to factors such as the unique physiology of the newborn, therapeutic interventions, and a focus on critical activities in caring for the very sick neonate. Consequently, a single specimen is inadequate for screening newborns in this subpopulation, and additional specimens should be collected for retesting. Serial screening with collection of three specimens, (1) on admission to the NICU prior to interventions regardless of age, (2) between 24 and 48 hours after birth, if a prior specimen was collected at less than 24 hours of birth and, (3) at discharge or at 28 days old, whichever is sooner, has been proposed as an adequate and efficient protocol for this population.[13] In addition, some programs recommend that screening be performed every month until discharge for babies who continue to remain in the NICU.

A blood specimen should be collected from any infant who is being transferred to a different hospital or to an NICU, regardless of age. The first specimen should be collected before transfer, and a second specimen should be collected at the receiving hospital by 4 days of age. This dual collection policy covers the child from whom a newborn specimen might not have been obtained in the turmoil that frequently accompanies the transfer of neonates.

In a newborn who is to receive a blood transfusion within 24 hours of birth precluding collection of an ideal routine specimen, a screening specimen should ideally be collected before transfusion, and a second specimen should be collected 2 days after the transfusion. If a pretransfusion specimen has not been obtained, a screening specimen should be obtained 2 months after the last transfusion, when most of the donor red blood cells have been replaced, to ensure reliable testing for analytes present in red blood cells.

Screening Tests

NBS tests are usually performed in a centralized state, provincial, or regional laboratory. In a regional program, the specimens may be received by the state program and then delivered to the regional state or private laboratory, or they may be sent directly to the regional laboratory. In either case, the individual state programs serve as the state data and follow-up centers.

The testing procedure begins with punching small discs (each usually 3 mm in diameter) from the screening specimen. These small discs are then analyzed by various methods for the individual markers being sought. Amino acids (AA) and acylcarnitines (AC), the markers for a large proportion of the screened metabolic conditions, are simultaneously measured by MS/MS. MS/MS is superior in terms of accurate measurement of the individual analytes when compared with alternative methods originally used for screening the AA, such as bacterial assays or fluorometric techniques. Immunoassays, including fluoroimmunoassay and enzyme-linked immunosorbent assays, are used to test for endocrinopathies such as CH and CAH, for infectious diseases such as congenital toxoplasmosis, and for CF. Hemoglobin analysis of blood eluted from the filter paper can be performed by high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), or isoelectric focusing (IEF) to identify abnormal hemoglobin variants (Hb) associated with the sickling hemoglobinopathies. An enzyme-based assay is often used to screen newborns for galactosemia and is always used to screen newborns for biotinidase deficiency and the lysosomal storage disorders (LSD).

A molecular assay, quantitative polymerase chain reaction (qPCR), is employed to identify SCID by quantifying TRECs, a marker of newly formed, antigenically naïve thymic emigrant T cells,[15] and another qPCR-based assay is used to identify homozygous absence of Exon7 of *SMN1*, expected in 95% of individuals with SMA.[16] TREC analysis was the first NBS test to use DNA as the primary analyte. Before implementation of screening for SCID, molecular assays were used only as second-tier tests to detect targeted mutations in disorders such as CF following an

out-of-range biomarker. Several platforms, DNA microarrays, and microsphere-based assays can multiplex several molecular and immunologic assays for high-throughput screening and are used by screening programs.[17–19] NGS with the high-throughput and massively parallel DNA sequencing technologies has substantially reduced the cost and time required for sequencing and made it possible to sequence the whole exome and entire coding regions of a gene/genes.[20] NGS has already been adopted by a few screening laboratories to provide supplemental genotyping information as a second-tier test,[21] and offers the prospect of becoming a first-tier test to screen newborns for genetic disorders that do not have a biomarker identifiable by current screening.

Secondary Tests

An abnormal finding on an NBS test is not diagnostic. Abnormalities in the newborn specimen can be transient or artifactual. Accordingly, when an abnormality is identified, the original specimen is retested for the primary analyte that was abnormal. In addition, secondary tests, biochemical or molecular, can be performed by the screening laboratory to substantiate the finding and increase the specificity of screening.[22] However, it should be noted that the primary analyte(s), the second-tier tests, and even the testing algorithms applied vary across screening programs.

In screening for CH, many programs have adopted protocols in which the primary analysis is for TSH, and T4 is measured as a second-tier test in specimens with high concentrations of TSH to improve specificity. Some programs initially measure T4. Specimens in which a low T4 level is found are further tested for an increased level of TSH, which would indicate CH.[23] Similarly, in screening for galactosemia, in some laboratories an elevated galactose measurement in a specimen can trigger the analysis of GALT activity as a second-tier test, while in others, a decreased GALT activity prompts galactose measurement as the second-tier test.

An out-of-range IRT, the primary marker for CF, could prompt second-tier molecular testing to identify pathogenic mutations on the *CFTR* gene.[24,25] However, the IRT concentration that prompts the molecular analysis, methods used for mutation selection and detection, and the number of mutations in the screening panel vary greatly, with some regions testing only for the most common mutation (F508del) and others for more than 400 mutations.[26] Sensitivity and specificity consequently vary across regions, but screening programs following this two-tier IRT-DNA approach can identify up to 99% of patients with CF and report a positive predictive (PPV) value ranging between 1/9.5 and 1/25.[27] Molecular assays to detect disease-causing mutations are currently used as second-tier tests for several other disorders, and their use continues to expand with advances in DNA technology. Some examples include testing for a panel of several *GALT* mutations in galactosemia screening and sequencing the relevant genes in screening for X-ALD and the LSD.

The final interpretation of the screening results is based on the primary analysis and, if available, the results of second-tier testing. The second-tier tests are used to either reduce the number of positive screens reported, or to provide supplemental information and categorize results based on probability of the disorder. However, it is important to realize that screening is not intended to be diagnostic; abnormal screening results must be supported by confirmatory investigations. These studies require additional specimens and are performed by clinical laboratories or sometimes by the screening laboratory.

Physician Contact for Abnormal Results

Tables 18.3 and 18.4 indicate disorders or other reasons for abnormal screening results, sorted according to the primary analyte usually used to screen the newborn for the condition. For example, a low T4 level together with an elevated TSH concentration indicates CH, and a marked elevation of 17-hydroxyprogesterone (17-OHP) level indicates the likelihood of CAH. An elevation of an acylcarnitine could indicate an organic acid or fatty acid oxidation disorder.

Any infant for whom an abnormal screening result is reported should be evaluated by the primary healthcare provider as soon as possible to facilitate the next steps toward the confirmation and management of the disorder. However, several conditions screened are extremely rare, and primary healthcare professionals might not have sufficient information available to direct appropriate intervention in screen-positive infants. To overcome the challenge, one-to-two-page explanations of the possible disorders, suggested follow-up action and confirmatory diagnostic investigations for the screening abnormality, known as ACTion (ACT) Sheets and Algorithms, are readily available on the website of the American College of Medical Genetics and Genomics (ACT Sheets and Algorithms [https://acmg.net]).[28] Similar explanations are often included with the screening report.

Although all screening results with a metabolite concentration that crosses its threshold are considered screen positive, all screen-positive results are not associated with the same likelihood of being associated with a disorder. Most infants with a positive screening result that is only mildly abnormal are less likely to have a disorder (see the later discussion of false-positive results) than are infants with analyte concentrations that are severalfold above the cutoff. Applying a uniform approach for all screen-positive results because of urgency of intervention or battery of tests suggested can result in unnecessary parental anxiety and medical costs. However, if recommendations for further action and workup are customized in accordance with the potential significance of the abnormality, both parental anxiety and the costs associated with false-positive results can be reduced. To achieve this goal, some programs subcategorize positive screening results and the primary care providers are supplied with category-based, customized fact sheets when a positive screening result is reported (personal communication). These sheets include information on disorders associated with the marker, the estimated likelihood of being affected, clinical presentations of likely disorders, factors contributing to false positives, and recommendations for further management. The follow-up recommendations can range from immediate admission to a hospital to simply repeating the analysis on a DBS specimen collected a few days later. Other programs approach this problem differently, but with the same goal of providing the primary care providers with the information needed to put the result in the appropriate context for the family.

When specific guidelines based on the individual results are not provided by the screening program, and the infant is ill or the likely disorder is among those that manifest acutely within the first few days of life (indicated in Tables 18.1 and 18.2), a specialist should be contacted. The infant may need to be admitted to the hospital, where further evaluation and therapy for the illness can be initiated without delay.

If the infant is clinically well on initial evaluation and the suspected disorder does not require immediate attention, a second DBS can be obtained and sent to the screening laboratory for

TABLE 18.3 Disorders and Other Factors Associated With Positive Screens for Acylcarnitines and Amino Acids

Marker	Disorders (Targeted and Incidental)	Possible Causes of False Positives
↓C0 (Free carnitine)	Carnitine uptake disorder (CUD); Other organic acid disorders	Poor feeding; Rx with valproic acid; CUD carrier; Maternal CUD/carnitine deficiency
↑C0 (Free carnitine)	Carnitine palmitoyl transferase I deficiency (CPT-I)	Carnitine supplementation
↑C3 (Propionylcarnitine)	Propionic acidemia (PA); Methylmalonyl-CoA mutase (MMA-Mut); Cobalamin disorders—A, B, C, D, F, J	Hemolysis or hyperbilirubinemia in infant; Carrier of associated disorder; Maternal cobalamin deficiency
↑C4 (Butyrylcarnitine)	Short-chain acyl-CoA dehydrogenase deficiency (SCAD); Ethylmalonic encephalopathy (EE); Glutaric aciduria (GA II); Isobutyryl-CoA dehydrogenase deficiency/isobutyrylglycinuria (IBG).	Hypoglycemia; FIGLU elevation; Carrier of associated disorder
↑C5:1 (Tigylcarnitine)	β-Ketothiolase deficiency (BKT)	VLBW neonate; Exposure of sample to heat/humidity
↑C5 (Isovalerylcarnitine)	Isovaleric acidemia (IVA); 2-Methylbutyrylglycinuria (2MBG)	VLBW neonate; TPN/HA; IVA carrier; Receiving antibiotics containing pivalic acid; FAS hemoglobin profile
↑C5-DC (Glutarylcarnitine)	Glutaric aciduria-I (GA-I)	GA-I carrier; MCAD carrier [with derivatized methods]
↑C5-3M-DC (Methylglutarylcarnitine)	3-Hydroxy-3-methyglutaric aciduria (HMG)	Severe respiratory distress; Neonates receiving ECMO
↑C5OH (Hydroxyisovalerylcarnitine)	3-Methylcrotonyl-CoA carboxylase deficiency (MCC); 3-Hydroxy-3-methyglutaric aciduria (HMG); Holocarboxylase synthase deficiency (MCD)	Carrier of associated disorder; Maternal 3MCC deficiency; Maternal biotin deficiency
↑C8 (Octanoylcarnitine)	Medium-chain acyl-CoA dehydrogenase deficiency (MCAD); Glutaric aciduria-II (GA II); Medium-chain ketoacyl-CoA thiolase deficiency (MCKAT)	MCAD carrier; GA-II carrier; MCT supplementation
↑C14:1 (Tetradecenenoylcarnitine)	Very long-chain acyl-CoA dehydrogenase deficiency (VLCAD)	VLCAD carrier
↑C16OH (Hydroxyhexadecanoylcarnitine) ↑18:1 OH (Hydroxyoctadecenoylcarnitine)	Long-chain L-3 hydroxyacyl-CoA dehydrogenase deficiency (LCHAD); Trifunctional protein deficiency (TFP)	LCHAD/TFP carrier; Renal dysfunction
↑C16 (Hexadecanoylcarnitine) ↑C18:1(Octadecenoylcarnitine)	Carnitine palmitoyl transferase II deficiency (CPT-II)	CPT-II carriers; Severe hemolysis
↑Arginine	Arginase deficiency (ARG)	TPN/HA; Arginase carrier
↑Argininosuccinic acid	Argininosuccinic aciduria (ASA)	Contamination
↓Citrulline	N-acetylglutamate synthase (NAGS) deficiency; Carbamylphosphate synthetase (CPS) deficiency; Ornithine transcarbamylase (OTC) deficiency; Pyrroline-5-carboxylate synthetase (P5CS) deficiency.	Poor feeding; Intestinal atresia or bowel resection
↑Citrulline	Citrullinemia, type I (CIT-I); Citrullinemia, type II (CIT-II); Pyruvate carboxylase deficiency (PC)	CIT I/CIT II carriers; Sample contamination (watermelon)
↑Phenylalanine	Classic phenylketonuria; Benign hyperphenylalaninemia; Biopterin defect in cofactor biosynthesis/regeneration BIOPT (BS/REG)	TPN/HA; Sample contamination (aspartame-artificial sweetener)
↑Leucine	Maple syrup urine disease	TPN/HA; Hydroxyprolinemia (benign disorder)
↓Methionine	Remethylation Defects— Methylenetetrahydrofolate reductase deficiency; Cobalamin defects—C, D, E, F, G, J	Poor feeding
↑Methionine	Classical homocystinuria (CBS); Methionine adenosyltransferase (MAT) I/III deficiency; Glycine N-methyltransferase deficiency	TPN/HA; Liver dysfunction
↑Tyrosine	Tyrosinemia, type II; Tyrosinemia, type III; Hawkinsinuria	Prematurity; Transient immaturity of enzymes; Liver dysfunction
↑Succinylacetone	Tyrosinemia, type I (TYR I)	—

HA/TPN—Hyperalimentation or Total parenteral nutrition containing amino acids. VLBW—Very Low Birth Weight —numerous secondary markers, ratios, and indices, employed for increasing the specificity of the primary markers, are not listed.

TABLE 18.4 Disorders and Factors Associated With Positive Screens for Primary Markers

Marker	Disorders (Targeted and Incidental)	Possible Causes of False Positives
↓Biotinidase activity	Biotinidase deficiency (profound or partial)	Exposure of sample to heat/humidity; Transient deficiency common in premature infants
↑Galactose (Total)	GALT deficiency (classical galactosemia and Duarte/benign variants); Galactose epimerase deficiency; Galactokinase deficiency; Citrin deficiency	Contamination with milk/cream; Portosystemic shunts
↓Galactose1-phosphate uridyltransferase (GALT) activity	GALT deficiency (classical galactosemia; Duarte/benign variants)	Exposure of sample to heat
↓Lysosomal acid α-glucosidase (GAA)	Glycogen storage disease aka Pompe	Pseudodeficiency
↓α-L-iduronidase (IDUA)	Mucopolysaccharidosis type 1	Pseudodeficiency
↑C26:0 lysophosphatidylcholine (LPC-C26:0)	X-linked adrenoleukodystrophy; Zellweger spectrum disorders	Omagaven supplementation; Carriers of associated disorders
↑Thyroid-stimulating hormone (TSH)	Primary congenital hypothyroidism	Transient elevations; Therapeutic hypothermia; Exposure to betadine
↓Thyroxine (T4)	Primary congenital hypothyroidism Secondary hypothyroidism (central); Thyroxine-binding globulin deficiency	Hypothyroxinemia of prematurity; Euthyroid sick syndrome
↑17-Hydroxyprogesterone (17 OHP)	Congenital adrenal hyperplasias	Neonatal stress (seen commonly in neonatal intensive care unit babies); very low birth weight; EDTA in specimen
Hemoglobin pattern analysis* FA [Normal in neonate]	*Sickling Disorders:* FS [HbS/S; HbS/β^0thal; HbS/HPFH]; FSC [HbS/C]; FSA [HbS/β+thal]; FSD [HbS/D^{Punjab}]; FSE [HbS/E]; FSX [HbS/OtherVariant] *Thalassemia & Other Hemoglobinopathies*: F only [β^0thal]; FABart's [HbH disease]	*Sickle Traits:* FAS[HbS]; FAC [Hb C]; FAD [Hb D^{Punjab}]; FAE[Hb E]; FAX [Other Hb Variant]
↑Immunoreactive trypsinogen (IRT)	Cystic fibrosis; CFTR-related metabolic syndrome	Cystic fibrosis carriers; Neonatal stress
↓T-cell receptor excision circles (TREC)	Severe combined immunodeficiencies; Other T-cell lymphopenias	Prematurity; Contamination (Heparin); Hydrops; Chylothorax; Gastroschisis; s/p thymectomy
Absence of Exon 7 of SMN-1	Spinal muscular atrophy	—

*The Hb variant pattern is shown outside [with the associated Hb disorder inside the brackets]. Complete listing of variants is beyond the scope of the chapter. Secondary markers, ratios and indices, and second-tier assays are employed for increasing the specificity of positive screens.

repeat testing, or confirmatory testing can be performed on a less urgent basis. In many cases, confirmatory testing or referral to a specialist is required only if the second specimen also indicates the presence of the disorder. However, the follow-up of an initial positive screening result can differ. In some cases, specific confirmatory testing is the appropriate first response to a positive newborn screen, with a less intense time frame for individuals in whom the level of suspicion is lower.

The physician should contact the screening laboratory when an infant whose screen has been reported as normal or whose screening results have not yet been reported has symptoms that suggest a disorder on the NBS panel. The screening laboratory can check the results in the infant's newborn specimen. If the testing has been completed and the newborn specimen is retained in storage, the laboratory may wish to recover the specimen and repeat the tests. The physician should also contact the screening laboratory for the repeated test results and inform the family of the results as soon as possible. If the second result is normal, the family's anxiety may be shortened.

Disorders Screened

The disorders included in the RUSP and the primary markers typically employed in NBS are listed in Tables 18.1 and 18.2. Majority of disorders on the RUSP are included in the individual state NBS panels, although implementation of screening for the newer conditions could lag behind the recommendation by a few years. Some states also screen for additional disorders. Some relevant NBS specifics related to the disorders are provided in the following sections. However, there is no attempt to describe any of the disorders in detail or their rare variants as they are covered extensively in other chapters of the book.

Every infant identified with a positive screen with a high probability of a disorder should be referred directly to the specialty center for confirmatory testing and prompt consideration of treatment. High probability positive screens, with disorders that are likely to present acutely in the first week of life, require immediate action that could include evaluation in the emergency room (ER) and admission to the NICU at a medical center with the

appropriate specialty service. Such fulminant disorders are marked in Tables 18.1 and 18.2.

Metabolic Disorders

Disorders With an Amino Acid or Acylcarnitines as the Primary Marker

The amino acid disorders, urea cycle disorders (UCD), organic acid disorders (OA), and fatty acid oxidation disorders (FAOD) detectable by NBS have a characteristic AA or AC as the primary marker. These AA and AC are analyzed simultaneously using MS/MS assays; however, the specific assays across different screening laboratories may vary in the preanalytical processing or internal standards employed. The simultaneous analysis of these numerous AA and AC in the assay has the advantage of allowing analysis of biochemical profiles in conjunction with the primary analyte, rather than the primary analyte alone. This biochemical profile, quantitated in the form of various ratios, indices, and scores by the NBS programs, can aid in differentiating the true positives from the false positives and in determining the most likely disorder when an analyte is associated with more than one disorder.[29] For instance, propionylcarnitine (C3) is the primary marker for several disorders: propionic acidemia (PA), methylmalonic acidemia (MMA), and cobalamin defects C, D (Cbl C, D). However, methionine the primary marker for homocystinuria, can be easily evaluated in an infant who screens positive for C3, and if low, would suggest Cbl C, D as the most likely disorder. Another relevant factor to be considered in analysis of AA and AC, by MS/MS based assays used in NBS is that the signal quantitated, is the combination of all ions with the same mass-to-charge ratio (m/z) as that of the analyte targeted. As an example, the concentration of an acylcarnitine (abbreviated as a "C" followed by a number indicating the number of carbon atoms in the acyl group in the carnitine ester), C4, represents the combined concentration of both butyrylcarnitine and isobutyrylcarnitine. Consequently, disorders that are not the primary target for screening are also identified in the process. Table 18.3 shows the disorders and other factors associated with positive screens for the primary AA or AC markers.

Amino Acid Disorders: The amino acid disorders are caused by an enzymatic defect in the catabolic pathway of the AA, causing an accumulation of specific AA above the block. Screening relies on the detection of these elevated AA in the DBS. The clinical manifestations may occur because of the toxic effects of the accumulating AA or metabolites produced by alternative pathways, a deficiency of products of the normal pathway, or both.

PKU is the best-known example of an AA disorder and is the paradigm for screened disorders in the newborn. In addition to PKU, MSUD and homocystinuria are historically significant in the context of screening because they are among the original metabolic conditions for which screening was performed before the expansion of NBS through the introduction of MS/MS technology. Screening for other AA disorders such as the UCD became possible only with the advent of MS/MS technology.

In PKU, the cardinal screening feature is an increased level of phenylalanine. With screening by MS/MS, PKU can reliably be identified as early as the first day after birth.[14] Not all infants with an elevation of phenylalanine level have PKU. Occasionally, an infant with elevated phenylalanine level will have one of the cofactor deficiency (pterin) disorders. Liver disease, such as that associated with galactosemia, tyrosinemia type I, or citrin deficiency, can also produce increased levels of phenylalanine.

The primary indicator for MSUD in the NBS specimen is an increase in the leucine level. Classical forms of MSUD are unlikely to be missed by NBS, but milder variants of MSUD can be missed,[30] as the increase in the leucine level may be so mild as to be below the cutoff value in the first few days of life when the NBS sample is collected. In the intermittent form of MSUD, the blood leucine concentration is normal in the newborn period, becoming elevated only in later infancy or childhood during acute metabolic episodes precipitated by febrile illness or surgery. Hydroxyproline at an increased level, as seen in a benign metabolic disorder known as hydroxyprolinemia, can be mistakenly identified as leucine in NBS. Second-tier analysis of hydroxyproline or quantitative plasma AA analysis will differentiate the condition from MSUD. To increase the specificity for MSUD of an abnormal leucine measurement, some screening programs also perform second-tier analysis of alloisoleucine, a leucine enantiomer pathognomonic for MSUD.[22] MSUD is one of the disorders that can present acutely in the first week of life and thus all high probability positive screens for MSUD require immediate action.

Majority of the characteristic metabolite for homocystinuria, homocysteine (Hcy), exists as S-linked Hcy in plasma, either bound to proteins or as disulfides. Accurate measurement of Hcy requires preanalytical deproteinization and reduction, and therefore cannot be analyzed simultaneously with the other AA and AC by the high throughput MS/MS assays utilized in NBS. Thus, NBS for classical homocystinuria, caused by cystathionine β-synthase deficiency (CBS), is based on identifying an increased concentration of methionine. The diagnosis of CBS is missed if the blood methionine concentration is not sufficiently elevated to be reportable by the screening laboratory. Adjusting the cutoff downwards has not been successful in eliminating false-negative occurrences completely, predominantly for the pyridoxine responsive forms. Some screening programs measure Hcy, methylmalonic acid and 2-methylcitric acid in a second-tier analysis to increase specificity of the primary methionine screen.[31] Although this two-tier strategy offers the advantage of substantially reducing the burden of false positives, there is a risk of missing cases of CBS with an increased concentration of methionine but without the expected increase in Hcy at the time of screening.[32] It is debatable whether the pyridoxine responsive forms of CBS is identified even when assays to measure Hcy as a primary marker are used. Strikingly high methionine levels can be seen in several other rare inborn errors of metabolism: isolated hypermethioninemia (methionine *S*-adenosyltransferase I/III deficiency), *S*-adenosylhomocysteine hydrolase deficiency,[33] glycine *N*-methyltransferase deficiency associated with liver disease,[34] and nonmetabolic causes of liver disease. Hypermethioninemia secondary to liver disease owing to tyrosinemia type I or to nonspecific liver disease is usually accompanied by increased tyrosine level.

More recently, screening programs have started reporting decreased concentrations of methionine to identify neonates with homocystinurias secondary to the remethylation defects—methylenetetrahydrofolate reductase deficiency and cobalamin defects—C, D, E, F, G, J (personal communication).[31]

Tyrosinemia type I (TYR-I) is identified in the newborn by the finding of increased levels of succinylacetone in the screening specimen using an MS/MS assay.[35] It is notable that in this eponymous disorder, caused by a deficiency of fumarylacetoacetate hydrolase the terminal enzyme in the tyrosine catabolic pathway, tyrosine is typically not increased in a well-timed NBS specimen. High concentrations of tyrosine in TYR-I are usually noted later in the neonatal period or after liver dysfunction is evident. The

other forms of tyrosinemia, type II and III, caused by deficiency of enzymes in the initial steps of the tyrosine catabolic pathway, tyrosine aminotransferase and 4-hydroxyphenylpyruvate dioxygenase respectively, are identified by an increased level of tyrosine in NBS. Another disorder caused by certain heterozygous mutations in the gene encoding the 4-hydroxyphenylpyruvate dioxygenase enzyme, hawkinsinuria,[36] has been identified in neonates with elevated tyrosine levels in the screening specimens. However, majority of positive screens for tyrosine are transient, seen in preterm newborns due to an immaturity of enzymes in the tyrosine pathway or secondary to vitamin C deficiency. Neonates with liver dysfunction with any underlying etiology often have an increased concentration of tyrosine.

Urea Cycle Disorders: The three UCD routinely screened by MS/MS analysis are citrullinemia, argininosuccinic acidemia, and arginase deficiency. All three may produce hyperammonemia in the neonate, although arginase deficiency usually presents in childhood with neurologic features such as spasticity and developmental delays in infancy and mild hyperammonemia rather than severe hyperammonemia in the neonate.[37] Severe hyperammonemia in the newborn is a medical emergency, thus high probability positive screens for these disorders should trigger prompt consultation with a metabolic specialist or referral to the ER at a metabolic center. Early identification through NBS with presymptomatic or early symptomatic therapy is critical to protecting patients with UCD. A decreased concentration of citrulline is used by the New England Newborn Screening Program, as an indicator to screen for the proximal UCDs, ornithine transcarbamylase deficiency, carbamylphosphate synthetase deficiency, and N-acetylglutamate synthase deficiency.

Fatty Acid Oxidation Disorders: The FAOD include those involving carnitine wherein the long-chain fatty acids cannot traverse the mitochondrial membranes to be oxidized within the mitochondrial matrix, and those in which there are defects in fatty acid oxidation per se. In either category the problem is the inability to fully oxidize fatty acids. The major clinical consequence of these disorders is fasting intolerance resulting in hypoketotic hypoglycemia, lethargy, hyperammonemia, metabolic acidosis, hepatomegaly, and sometimes sudden death. Each FAOD is associated with a specific or almost specific AC pattern on MS/MS analysis.

The most common FAOD is medium chain acyl CoA dehydrogenase deficiency (MCADD). Tragically, before NBS was available, this disorder was often diagnosed only retrospectively after a sudden unexplained death, usually when postmortem examination revealed a fatty liver. This devastating outcome and a frequency of 1:15,000 to 1:20,000, comparable with that of PKU, made MCADD the primary reason for the addition of MS/MS technology to NBS. The primary finding for MCADD in NBS is an elevation of octanoylcarnitine (C8) along with other medium chain ACs. Some programs pursue targeted testing of the c.985 A>G *ACADM* gene mutation as a second-tier analysis to provide supplementation information.[38] Because this mutation occurs in as many as 90% of individuals with MCADD, this additional analysis substantially increases the predictive value of the primary C8 screen, even though the absence of the mutation does not exclude the condition. Furthermore, in infants affected with a FAOD, when not metabolically stressed, the AC can be within the normal range. Thus, infants with a high probability AC pattern on the initial NBS specimen require a referral for diagnostic studies, regardless of the results on a subsequent specimen or any targeted mutation analysis. Most of these disorders are treatable, but screening enables early diagnosis and genetic counseling for the family even when early treatment may not be effective, such as in neonatal carnitine palmitoyltransferase II deficiency.[39] Short-chain acyl-CoA dehydrogenase deficiency is likely benign, although before NBS it was considered a serious disorder.[40]

Organic Acid Disorders: The OAs are a heterogenous group of disorders characterized by accumulation of organic acids. Many OA can be identified by NBS based on increased levels of their characteristic AC in the DBS. The major OAs identified in NBS are PA, MMA, the cobalamin (vitamin B_{12}) defects, and isovaleric acidemia. The classical OAs can manifest themselves in the neonatal period with a life-threatening, sepsis-like picture of feeding difficulties, lethargy, vomiting, and seizures. If a screening result suggests an OA, a metabolic specialist should be consulted immediately.

Biotinidase Deficiency

Biotin recycling is necessary for the maintenance of sufficient intracellular biotin to activate carboxylase enzymes. Biotinidase is a key enzyme in biotin recycling, and biotinidase deficiency is one form of an OA known as multiple carboxylase deficiency. NBS for the disorder is based on demonstrating deficient enzyme activity in the DBS.[41] Individuals with profound biotinidase deficiency have less than 10% of mean normal enzymatic activity, while those with the partial biotinidase deficiency variant have 10% to 30% of mean normal activity.[41] Clinical features of biotinidase deficiency, primarily seen in profound deficiency, include developmental delay, seizures, vision problems, hearing loss, and cutaneous abnormalities. Initiation of biotin therapy in the presymptomatic stage prevents all features of the condition. Occasionally, an individual with partial deficiency may develop symptoms when stressed, such as during infection. Transiently low biotinidase activity in some premature newborns results in false positive screens. Some newborns with partial biotinidase deficiency may be missed by NBS.

Galactosemias

Classical galactosemia due to GALT deficiency typically manifests itself in the neonatal period as failure to thrive, vomiting, and liver disease.[42] Death from bacterial sepsis, usually caused by *Escherichia coli*, occurs in a high percentage of untreated neonates.

Some screening programs use a metabolite assay for total galactose (galactose and galactose 1-phosphate) as the primary test to detect galactosemia. Other programs employ a semiquantitative enzyme assay in the first tier to measure the GALT activity, which is usually undetectable in classic galactosemia. A few programs use both tests as a primary screen. The enzyme assay identifies only galactosemia, whereas the metabolite assay also identifies other galactose metabolic disorders, such as deficiencies of galactokinase and epimerase. Severe neonatal liver diseases and portosystemic shunting caused by anomalies in the portal system can also increase the galactose level. NBS programs that use total galactose as the primary screen usually perform second-tier GALT testing in specimens with elevated galactose level. If the newborn specimen has markedly reduced or absent GALT activity, a few screening programs then perform targeted molecular testing for a panel of frequent mutations associated with galactosemia, particularly Gln188Arg and Asn314Asp; the Asn314Asp variant, commonly referred to as the Duarte (D or D2) allele, is associated with about half of the normal level of GALT activity, and is clinically benign. However, it is a common variant accounting for a large proportion of positive screens for GALT deficiency.

Infants having increased galactose and reduced GALT activity in NBS or those with no detectable activity when only the GALT assay is performed should immediately be seen at a metabolic center. Breastfeeding or lactose-containing formula feeding should be discontinued, and appropriate intravenous fluids with glucose should be given as needed.

Markedly increased galactose and normal GALT activity in NBS suggest the possibility of galactokinase deficiency. This disorder produces early-onset cataracts, which are prevented by removal of lactose from the diet. Moderately increased galactose with normal or somewhat reduced GALT activity could indicate uridine diphosphate (UDP)-galactose 4-epimerase deficiency, a largely benign disorder.

Lysosomal Storage Disorders

Lysosomes are organelles required for cellular turnover and contain more than 50 acid hydrolases that catabolize macromolecules. Deficiency of the individual enzyme or a combination of enzymes and transporters can result in accumulation of the substrate and progressive cellular and organ dysfunction. The disease phenotype is a consequence of the type of substrate and its sites of turnover, and severity generally correlates with the amount of residual enzyme activity. The incidence of these disorders as a group is estimated to be 1 in 7700 to 1 in 10,000 births. NBS for the LSD relies on the analysis of the specific enzyme activities by using artificial substrates in the DBS, either by fluorometry, MS/MS, or microfluidics combined with fluorometry. Screening assays are available for Fabry disease, Gaucher disease, Krabbe, MPS-I, MPS-II & IV-A, Niemann-Pick A/B disease and Pompe disease. As most laboratories screening for LSD using the MS/MS method screen for at least two LSDs simultaneously, the enzymatic activities can be evaluated in conjunction to ascertain sample quality and determine significance of a specific result and thereby risk of a disorder.[43] As indicated on the website of the Advisory Committee on Heritable Disorders in Newborns and Children,[9] until May 2021 five LSDs (Krabbe disease, Fabry disease, Niemann–Pick disease, Pompe disease, and MPS-I) had been evaluated by the Committee to be considered for inclusion in the RUSP. Only MPS-I and Pompe disease were approved for inclusion in the RUSP. The considerations underlying the decision to not approve the addition of Krabbe disease corresponded to many of the concerns expressed by the Krabbe Disease Consortium.[44] Although not included in the list of RUSP disorders, in August 2006, New York became the first state to initiate population-wide screening for early infantile Krabbe disease in response to a strong and organized advocacy. Previous high-throughput methods for the measurement of a lysosomal enzyme galactocerebrosidase (GALC) by MS/MS were adapted for NBS in blood spots.[45] Specimens with reproducibly low GALC activity were analyzed for *GALC* mutations as a second tier, particularly for homozygosity for the 30-kb deletion because of its strong association with early infantile Krabbe disease.[46] Early infantile Krabbe disease is a rare progressive neurodegenerative genetic disorder that usually leads to death in infancy. Studies had previously indicated that human stem cell transplantation (HSCT) was effective in improving survival and clinical outcomes when used before the onset of symptoms in infantile Krabbe disease. However, after more than 15 years of active screening in New York and introduction in other states, the efficacy of NBS for Krabbe disease has not been established. Some recommend placing a moratorium on mandatory NBS for Krabbe disease for now.[47] They argue that the current laboratory screening and diagnostic tools to identify infants, who are likely to develop Krabbe disease and need HSCT, are inadequate. Additional biomarkers such as psychosine that appear to be more specific than low GALC levels for diagnosing early infantile Krabbe disease, and new consensus guidelines for diagnosis and treatment following NBS have been developed that may improve screening and outcomes in the future.[48]

One challenge in screening for some LSDs is the phenomenon of pseudodeficiency that results in low activity of the specific enzyme in the in-vitro assays with no associated clinical phenotype. Pseudodeficiency is caused by certain variants in a gene, and its prevalence varies by disorder and ethnicity. Whether the presence of a pseudodeficiency variant could influence the effect of another variant is not completely understood at this time. Occurrence of pseudodeficiency could increase false-positive screens in the first-tier enzymatic assay and may complicate accurate identification of true cases. Gene sequencing is important for identification of pseudodeficiency alleles and confirmation of a diagnosis following the first-tier enzymatic assay, and thus is performed as a second-tier test for the LSDs in some screening programs.

Pompe disease, also known as *glycogen storage disorder II*, is characterized by accumulation of lysosomal glycogen, predominantly in muscles, resulting from the decreased activity of lysosomal acid α-glucosidase (GAA) due to pathogenic variations in the corresponding *GAA* gene.[49] Pompe disease exhibits a broad spectrum in regard to age of onset, cardiac involvement, and progression of skeletal muscle dysfunction. The severe infantile form manifests itself within the first few months of life and is characterized by cardiomyopathy and severe progressive muscle weakness. Without treatment, death occurs within the first year of life in the infantile forms. The overall incidence of Pompe disease is 1 in 28,000, with 28% being the infantile forms. NBS offers the opportunity to detect the infantile forms early (22 days vs. 3.6 months by clinical ascertainment) and thus justifies its inclusion in the RUSP. Decreased GAA activity in the screening blood spot should prompt molecular analysis for confirmation. Homozygosity for a "pseudodeficiency" allele c.(1726G>A; 2065 G>A) is associated with low GAA activity like that seen in patients with Pompe disease but does not cause disease. This genotype, seen in approximately 4% of individuals in the Asian population, will result in false-positive screens in enzymatic assays. Second-tier tests including GAA gene sequencing and measurement of the creatine/creatinine/α-glucosidase ratio are often utilized to improve the specificity of the first-tier enzymatic assay.[50] However, although gene sequencing can predict genotype-phenotype effects when known, the risk assessment is limited when the variants are novel or of unknown significance. Similarly, the creatine/creatinine/α-glucosidase ratio may not be reliable in accurately identifying the late onset forms of the disorder.

MPS-I is a progressive multisystem disorder with features ranging over a continuum of severity. It is caused by the deficiency of the lysosomal enzyme α-L-iduronidase (IDUA), encoded by the *IDUA* gene, which leads to an accumulation of glycosaminoglycans (or mucopolysaccharides) within lysosomes of the affected cells.[51] MPS-I is broadly categorized into Hurler syndrome (MPS I H; severe, incidence 1 in 100,000), Hurler–Scheie syndrome (MPS I H/S; attenuated; incidence 1 in 500,000), and Scheie syndrome (MPS I S). Newborns typically appear normal at birth. Decreased IDUA activity in the DBS suggests the possibility of MPS-I and needs to be confirmed by molecular analysis of the *IDUA* gene and/or confirmatory biochemical testing (urinary glycosaminoglycans, IDUA activity in leukocytes or fibroblasts). Unfortunately, the residual IDUA

activity is not predictive of the phenotype, and the presence of pseudodeficiency alleles renders interpretation of IDUA activity more difficult. Second-tier genotyping may help predict the expected phenotype if it reveals mutations with good genotype–phenotype correlation,[52] but the advantage is limited for novel variants or those of unknown significance. Second-tier analysis of glycosaminoglycans in the DBS has been incorporated by a few laboratories to improve specificity of the first-tier enzymatic assay.[53] However, the experience is limited in accurately identifying the late onset forms of the disorder.

X-linked Adrenoleukodystrophy

X-ALD is one of the most common monogenic forms of an inherited neurodegenerative disease. It is inherited in an X-linked manner, with a prevalence of approximately 1 in 21,000 in males or 1 in 16,800 with symptomatic heterozygous females included. The clinical phenotype is highly variable, but neurologic manifestations, as either the inflammatory cerebral form or adrenomyeloneuropathy only, are present in nearly all males by adulthood.[54] X-ALD can present as a primary adrenocortical insufficiency without evidence of neurologic abnormality in about 10% of males, with neurologic involvement occurring subsequently. Overall, adrenal function is abnormal in 90% of neurologically symptomatic boys and in 70% of men with adrenomyeloneuropathy. HSCT has been shown to arrest the inflammation in the early stages and thus provide an efficient treatment for the inflammatory cerebral form of X-ALD. Detection of X-ALD by NBS allows periodic reevaluation of adrenocortical function and MRI for detection of males with early cerebral disease, thereby providing an ideal window of opportunity for HCST to treat the cerebral form. NBS for X-ALD relies on measuring C26:0 lysophosphatidylcholine (C26:0LPC) using HPLC-MS/MS assays in the DBS.[55] Individuals with a positive screen require plasma very long chain fatty acid (VLCFA) analysis and sequencing of the *ABCD1* gene (performed as second-tier tests in some NBS programs) to confirm the diagnosis. However, the phenotype cannot be reliably predicted by the plasma VLCFA concentration or the *ABCD1* variants. Increased concentrations of C26:0 LPC in the screening specimen are also noted in other peroxisomal disorders, such Zellweger spectrum disorders, peroxisomal acyl-CoA oxidase 1 deficiency, and D-bifunctional enzyme deficiency.

Endocrine Disorders

Congenital Adrenal Hyperplasia

The rationale for screening for classic congenital adrenal hyperplasia (CAH) is to prevent deaths from delayed recognition and treatment of the salt-wasting form (SW-CAH), to prevent sex misassignment of affected female newborns that can occur with either the salt-wasting or simple-virilizing forms, and possibly to prevent premature epiphyseal closure in children with simple-virilizing CAH. Initial screening relies on an immunoassay for identifying increased levels of 17-OHP to detect CAH due to steroid 21-hydroxylase (CYP21) deficiency, which accounts for more than 95% of all cases.[56,57] Although screening is effective at identifying SW-CAH cases, there is a very high false-positive rate associated with the immunoassay. The finding may be due to a truly increased 17-OHP level, as in perinatal stress and early specimen collection (within the first 24 hours of life) or may be due to cross-reacting steroids present in prematurity and LBW neonates. Despite employing screening algorithms based on covariate (gestational or birth weight, gender, and age at collection) adjusted cutoffs, the PPV for the first-tier immunoassay performed on specimens collected within the first 2 days of life remains low (on average <10%).

To enhance specificity, second-tier liquid chromatography-MS/MS-based assays to measure 17-OHP and various combinations of additional steroids, is being increasingly employed by NBS programs. Most recently, PPV of 17% and reduction of false positives by 95% was demonstrated, by employing a screening algorithm including a first-tier immunoassay, second-tier multi-steroid quantification and profiling, in conjunction with stratification of population-based cutoffs by the time of specimen collection and birth weight.[58] On the other hand, the resounding success of the two-tier approach in reducing the false positives is dampened by reports of missed cases after second-tier analysis.[59]

However, the risk of missed CAH cases, whether after first or second-tier analysis, cannot be eliminated. Insufficient accumulation of 17-OHP at time of specimen collection as can occur with mild/simple virilizing forms or early collection of NBS specimens, and reduced flux through the steroidogenic pathway secondary to adrenocorticotropic hormone inhibition by exposure to glucocorticoids or maternal cortisol, and the lack of mature enzyme function, are some factors that contribute to the existence of false negatives. Several laboratories have demonstrated increased specificity after implementing molecular analysis as a second-tier test. However, thus far second-tier molecular analysis has not been implemented in routine screening. The 2018 Endocrine Society Clinical Practice Guidelines specify that NBS programs employ second-tier liquid chromatography-MS/MS (LC-MS/MS) in preference to all other methods (e.g., genotyping) to improve PPV of screening for CAH.[60] Classic CAH, caused by CYP21 deficiency, occurs in 1 in 16,000 to 20,000 births, of whom 75% are estimated to have the salt-wasting form and 25% the non-salt-wasting or simple virilizing form.[57]

Congenital Hypothyroidism

Early detection by NBS and thereby early treatment of infants with CH has essentially eliminated the neurodevelopmental disabilities associated with this disorder. The NBS strategies for CH, directed mainly towards identifying primary hypothyroidism, have evolved since its inception in the mid-1970s and vary regionally.[23,61] Currently, immunoassays are employed for analysis of both T4 and TSH. Screening programs employ algorithms in which either TSH or T4 is measured as the primary marker, and if out of range, proceed with T4 or TSH as a second-tier test to improve specificity. The primary T4 approach has the potential to detect neonates with secondary (central) CH. Only a few screening laboratories pursue simultaneous T4 and TSH testing. All approaches have similar accuracy in detecting severe primary hypothyroidism. Nevertheless, affected infants can be missed with either approach, because of lack of the identifying marker abnormality at the time of specimen collection. Specifically, the T4 level during the first 24 hours after birth in an affected newborn might not yet be sufficiently decreased for identification because of persistence of maternally transmitted T4 Moreover, in some infants it might take 2 weeks or more for a TSH level elevation to develop.[23,62] This pattern of a delayed TSH rise is particularly common in infants who are preterm, LBW, or acutely ill, and proposed mechanisms include immaturity of the hypothalamic–pituitary–thyroid axis, nonthyroidal illness, and exposure to medications that may suppress TSH secretion (e.g., dopamine or glucocorticoids). To avoid missing CH, screening programs test additional blood specimens in specific subgroup of infants a few weeks after the initial screen.

The reported false-positive rates of screening for CH range from approximately 0.05% to as high as 4%.[63] Newborns with false-positive results have transiently low T4 or elevated TSH levels. Many of those with low T4 levels are premature neonates with a normal TSH concentration or infants with perinatal stress and elevated TSH levels. Analysis of the markers adjusted for parameters such as age at collection, weight, and location may improve the performance of NBS for hypothyroidism. In addition to false-positive results, a low T4 level with a normal TSH value can result from benign T4-binding globulin deficiency or hypothyroidism secondary to pituitary deficiency.

The incidence rates of CH detected by NBS recently (1:1400 to 1:2800) are substantially higher than the incidence rates (1:3000 to 1:4000) reported in the initial years of NBS for CH.[64,65] Numerous factors, including shifting demographics and modifications in screening protocols (lowered TSH cutoffs, testing additional specimens in specific subgroups) that allow detection of mildly affected patients or those with a delayed TSH rise, probably explain the increase. The majority of increased occurrence, in addition to the mildly affected patients, is due to those with transient CH, which brings forth new dilemmas about the diagnosis and optimal management of such cases.[66]

Cystic Fibrosis

The frequency (1 in 2000 to 3000 live births in the white population) and severity of CF explains its inclusion in routine NBS. The primary screen for CF relies on detection of elevated levels of IRT, a biomarker indicative of pancreatic damage, in the first week of life. A transient increase of IRT is not uncommon in premature neonates and neonates with perinatal asphyxia or other stressors. Thus, to improve specificity of the elevated IRT on the initial screen, additional analyses are performed by NBS programs before the screen is reported as "positive" or the infant is referred for a sweat test to confirm the diagnosis. However, the approach for the subsequent analyses varies widely among NBS programs, both in regard to the specimen (initial or additional typically collected at 3 weeks of life) prompting the second-tier test, and the second-tier test performed (selected mutation analysis or sequencing of the *CFTR* gene or pancreatitis-associated protein) on the specimen, each with its own benefits and disadvantages.[67,68]

Second-tier DNA analysis on the initial specimen [IRT/DNA] protocols can reduce time to diagnosis substantially for infants carrying at least one mutation included in the panel, but a significant number of neonates who are carriers or unaffected undergo sweat testing. In other protocols, persistence of the IRT elevation on a second specimen collected, following an elevated IRT on the initial specimen [IRT/IRT], prompts a referral for sweat testing [IRT/IRT] or molecular testing [IRT/IRT/DNA]. As many screening protocols rely on mutation analysis, the impact on false negatives is determined by the number of mutations targeted and how closely the mutation panel represents the population being screened. In contrast, with the wide variety of CFTR mutations and mutation combinations identified, directly by screening or during diagnostic testing, genotype–phenotype correlations are difficult to predict and lead to increased diagnostic uncertainty. NBS commonly identifies infants who have an inconclusive diagnosis of CF following a positive screen, classified as CFTR-related metabolic syndrome or CF screen positive inconclusive diagnosis, and may need to be monitored.[69,70]

Early diagnosis and treatment of classic CF has shown to result in improved nutrition, growth, and survival compared with those diagnosed clinically (CF-related childhood mortality is lower by 5% to 10% in screened cohorts). The recent development of options that treat the underlying genetic defect bring forth the potential to substantially impact the course of the disease in individuals with specific mutations.

Sickle Cell Disease

Most programs in the United States screen newborns for the hemoglobinopathies with the objective of detecting the sickling hemoglobinopathies. Screening is based on the separation and quantification of the various hemoglobin variants (Hb), typically by IEF, CE or HPLC.[71] Other technologies using MS/MS, matrix-assisted laser desorption ionization-time of flight mass spectrometry, and DNA-based methods are also emerging. At a minimum screening assays can separate and identify the normal variants (HbF, HbA) and sickling variants (HbS, HbC). Hb Bart's, HbH and other Hb variants of clinical relevance, such as HbD, HbE, and HbO are also detected.

The typical neonatal pattern is FA, representing the Hb variants (HbF, HbA) listed in order of their fractional concentrations (highest to lowest). In NBS specimens, HbA levels range between 6% and 40% (average of 19%), showing variations based on gestational age and age at sampling, reflecting the stage of hemoglobin switch. Screening specimens showing atypical variants or profiles on the initial assay are retested using secondary assays to confirm the presence of the Hb variant or identify the abnormal Hb. Programs are increasingly adding genotyping for this purpose. Screening identifies sickling disorders (HbSS, HbSC, HbS/β^0 thalassemia), sickle cell traits, and several other hemoglobin variants. Cases identified by screening or those with unidentified Hb variants should have further diagnostic evaluation by a hematologist. Initiation of simple but effective prophylactic measures such as penicillin for pneumococcal sepsis, vaccination, and parent education, have shown to result in a significant reduction of mortality and mortality of the sickling disorders during the early years when risks are the greatest. The long-term complications are not yet preventable but, erythrocyte transfusion (for acute crises) and medications (hydroxyurea, oxbryta, L-glutamine) are some options to alleviate the morbidity and mortality. Additionally, hematopoietic stem cell transplantation and the emerging gene therapies raise the prospects of curative treatment.[72–75] Other than sickling disorders, most of the abnormalities are benign or are not impacted by early detection. It is especially important to differentiate the common and benign sickle cell trait from the much rarer sickle cell disease, to avoid the stigma attached and unnecessary medical treatment for the disease, but at the same time counseled appropriately about the risk of complications of sickle cell disease (pain crises, stroke, myolysis) with intense exercises under extreme circumstances.

The presence of a β-chain hemoglobinopathy can be missed in premature infants as they have lower percentage of HbA (and other β-chain variants) and in infants after a blood transfusion as the hemoglobinopathy may be masked by the higher proportion of the donor HbA. Screening programs thus request additional screening specimens under special circumstances.

Severe Combined Immunodeficiency

SCID is a group of at least 20 known rare genetic disorders, characterized by profound impairment in T-cell development and function and absence of antibody production. As SCID is

typified by absent or extremely low production of antigenically naïve T-cells from the thymus, a low concentration of TRECs (DNA fragments that are byproducts of thymic emigrant T-cell production) in a specimen with a valid result for an internal control (typically β-actin or RNase P gene) is used to screen newborns for SCID.[75] A high-risk positive SCID NBS result prompts further diagnostic testing, such as flow cytometry to measure specific T-cell markers and specialized immune function tests before the diagnosis is established or excluded. Majority of low-risk positive SCID NBS results are from neonates in the NICU and depending on the testing laboratory's algorithms may require only a repeat screen. Non-SCID lymphopenias and other disorders associated with T-cell impairment (e.g., DiGeorge syndrome, trisomy 21) or T-cell losses (e.g., vascular leakage, chylothorax), and infants with gastrointestinal anomalies or those who have had a thymectomy (most often during cardiac surgery) can show low TREC values.[75,76] Early treatment of SCID, using allogeneic hematopoietic cell transplantation and autologous gene therapy, has led to an improved survival with a high rate of full immune reconstitution in infants.[76,77] Genetic diagnosis is often needed for genetic counselling, prognostication, and modification of pretransplant chemotherapeutic agents. Sequencing a panel of SCID genes using NGS as a second-tier test in specimens with low TRECs is feasible and may be the norm in the future.[78]

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is an autosomal recessive disorder, characterized by progressive degeneration of alpha motor neurons in the spinal cord leading to muscular atrophy, caused predominately by bi-allelic deletions involving exon 7 of the *SMN1* gene. Molecular assays to detect absence of Exon 7 of *SMN1* in the DBS were developed and used to screen newborns for SMA since 2016. Its inclusion in RUSP occurred subsequently in 2018, when specific treatments directed at improving functional SMN protein expression for SMA became commercially available. Neonates who screen positive for SMA require confirmatory testing for the *SMN1* deletion. Furthermore, determination of *SMN2* (a paralog of *SMN1*) gene copy number is an integral part of confirmatory testing, as SMN2 dosage is highly prognostic of disease severity and predictive of neonates who would benefit from immediate intervention.[79] Further developments of molecular assays, allowing detection of *SMN1* deletions, *SMN2* copy numbers and *SMN1* sequencing in the DBS at the NBS laboratory are ongoing. Early data shows that some SMA-affected children have remained asymptomatic and are meeting developmental milestones expected for unaffected infants.[80]

Critical Congenital Heart Disease

Congenital heart disease (CHD) is the most common cause of death in the first year of life, accounting for 3% of all infant deaths. CHD affects about 7 in 1000 to 9 in 1000 live births; a fourth of these can be classified as CCHD, a term that encompasses the heart defects that cause severe and life-threatening symptoms and require intervention within the first year of life.[81,82] Currently, pulse oximetry, in conjunction with a clinical examination, is the recommended screening approach and will usually identify CHD that results in hypoxemia. This group accounts for approximately 17% to 31% of CHD cases and includes hypoplastic left-sided heart syndrome (HLHS), pulmonary atresia with intact septum, tetralogy of Fallot, total anomalous pulmonary venous return, transposition of the great arteries, tricuspid atresia, and truncus arteriosus. Each condition has palliative and surgical options, with a spectrum of standard interventions for each. Overall, the 5-year survival rates after intervention range from 65% to 97%, with five of the seven conditions having 5-year survival rates greater than 85%. The two conditions with the lowest long-term survival rates are pulmonary atresia with intact septum and HLHS. The sensitivity of screening for CCHD is 30.8%, 47%, and 77% by pulse oximetry, clinical examination alone, and both, respectively.

Hearing Loss

Hearing loss is the most common birth defect, with 1 in 500 newborns having confirmed hearing loss. Infants with hearing loss not identified before 6 months of age have delays in speech and language development, while intervention before 6 months of age allows an infant with impaired hearing to develop normal speech and language. This rationale prompted the National Institutes of Health to recommend screening for congenital hearing loss for all newborns in 1993. Typically, automatic auditory brainstem response or otoacoustic emissions testing is performed to detect hearing loss in the neonate. To maximize the benefits, the hearing screen should be performed before 1 month of age, preferably before hospital discharge; infants who screen positive should have a diagnostic audiologic evaluation before 3 months of age, and all infants identified with hearing loss should receive appropriate early intervention services before 6 months of age (medical, audiologic, and early intervention). Approximately 1.6% of all newborns do not pass the hearing screen and are referred for an audiologic evaluation, and among those 10.3% are confirmed as having hearing loss. Enrollment in early intervention services among children diagnosed with hearing loss is estimated to be 61.7%.

Specific Issues in Newborn Screening

Criteria for Newborn Screening

In 1968, under the auspices of the World Health Organization, Wilson and Jungner published a set of criteria for screening for conditions that have generally been accepted as those required for population screening.[83] These 10 criteria state that (1) the condition must be an important health problem, (2) there must be accepted treatment, (3) facilities for diagnosis and treatment must be available, (4) there must be a recognizable latent or early symptomatic stage, (5) there should be a suitable test, (6) the test should be acceptable to the population, (7) the natural history of the condition should be understood, (8) there should be a policy prescribing whom to treat, (9) the cost of case finding should be economically balanced in relation to medical care as whole, and (10) case finding should be a continuing process.

These criteria were developed at a time when NBS was in its incipient stages and with screening for adult disorders in mind but were also germane for NBS. Regarding the first criterion, Wilson and Jungner recognized that the term *important* is relative; whereas PKU was rare, and diabetes was prevalent, PKU warranted screening in the neonatal period because of the serious consequences that would be prevented by early diagnosis and treatment. Ideally all criteria should be applied for screening; however, continuing

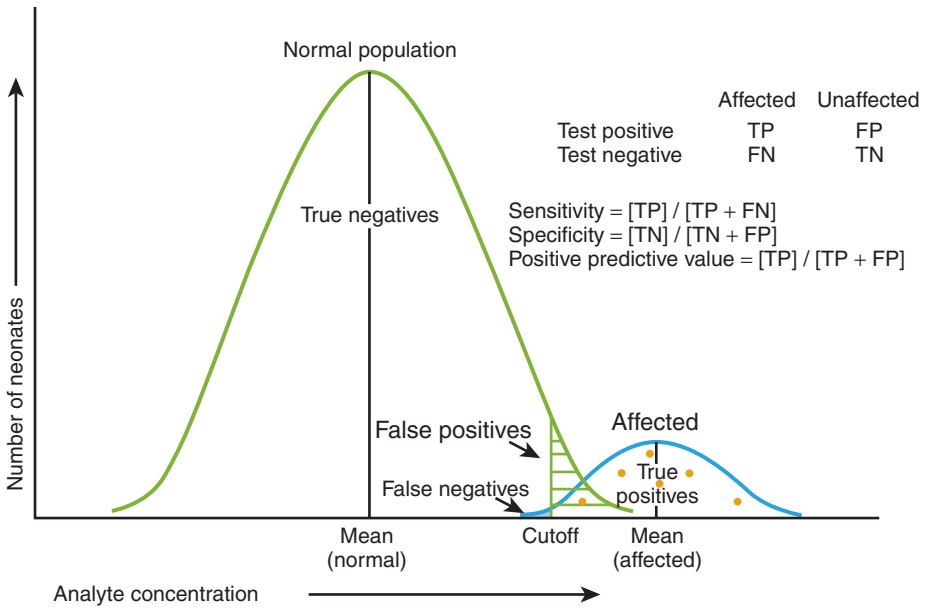
advances in technology challenge the current relevance of some Wilson and Jungner criteria for NBS.[84,85] As an example, current screening methodologies allow detection of serious disorders for which there may not be acceptable or agreed on therapy or for which the natural history is largely unknown, in conflict with the criterion that any disorder included in screening should have acceptable treatment. How is this dilemma resolved? A definitive answer is not yet available. It is hoped that the experience garnered from ongoing NBS for such disorders will be used to develop a new set of criteria that will apply to NBS. These criteria will likely retain the essence of the Wilson–Jungner compilation but with important modifications that could be applied to any new screening venture.

False-Positive Results

The majority of positive results in NBS, when the result is only mildly or moderately abnormal, are not due to a disorder. Unfortunately, such false-positive results are inevitable when relying on quantitative markers or qualitative genetic variations, for identifying all individuals at risk for a condition prior to onset of symptoms as is the essence of NBS.

The distribution of a quantitative primary metabolite concentration is expected to be different for affected individuals as compared to the unaffected population (Fig. 18.2). The primary analyte value that could distinctly differentiate individuals affected with the specified condition from unaffected individuals would be an ideal "cutoff." The cutoff is typically established by the individual screening laboratories and may differ among the laboratories, as is determined by the specific assay used and adjusted based on the marker distribution in the regional population.[86,87] Specimens in which the concentration crosses the established cutoff are considered screen positive. For disorders characterized by an increased (or decreased) metabolite concentration, the concentrations in most unaffected infants are below (or above) the cutoff value, but in a small proportion the metabolite concentration crosses this threshold. Screen-positive results in unaffected infants are considered false positives. Because of some degree of overlap in the distribution curves of the affected and unaffected populations, these false positives cannot be eliminated without compromising the sensitivity of screening. Furthermore, other physiologic factors, such as immaturity of metabolic enzymes, stress, and therapeutic interventions, can skew the concentrations of certain metabolites and lead to false-positive screening results.

Currently, the indicators measured by immunoassays (e.g., 17-OHP in CAH and T4 in CH) or enzymatic activity (low GALT activity in galactosemia) are associated with the highest false-positive rates. The false-positive results are more common in preterm and LBW infants than in term infants. For example, up to 85% of preterm infants have transiently low T4 levels.[88] Transient increases in 17-OHP level is another common abnormality in infants who are preterm or are LBW or have experienced perinatal stress. In addition, transient tyrosinemia is commonly observed in preterm and LBW infants, although it can also occur in term infants.[89] Artifacts produced in the collection or transport of the DBS account for some false-positive results. As previously mentioned in the specimen collection procedure, obtaining the specimen from a central line in infants receiving TPN can result in a false increase of the AA concentration in the specimen. Even with correct specimen collection, TPN can produce a transient AA level increase. Contamination with milk (or any drink containing milk) can result in a false elevation in galactose level and the mistaken suspicion of galactosemia. Prolonged exposure to heat can reduce the activity of GALT in the specimen and produce a false impression of galactosemia when the enzyme assay is used to screen an individual for this disorder. This error is common during the summer, especially when the specimen remains in a mailbox for some time.



• **Fig. 18.2** Distribution of quantitative markers measured in screening. For most conditions, the distribution in the unaffected or normal population overlaps that in the affected individuals. The number of false positives (*FP*), false negatives (*FN*), true positives (*TP*), and true negatives (*TN*) depends on the established cutoff.

Implementation of MS/MS has resulted in a significant reduction in false-positive screens for the AA disorders that were previously being screened using the traditional bacterial or specific assays. For PKU screening, the false-positive rate using MS/MS was reported at 0.05%, as compared to 0.23% with the earlier methods.[90] In addition, analysis of biochemical profiles instead of a single analyte, made feasible by MS/MS (e.g., phenylalanine/tyrosine ratio vs only a phenylalanine level for PKU identification) can further enhance specificity.[91] The average PPV for primary markers (AA and AC) analyzed by MS/MS reported to be 8% to 10%[92–94] can be improved substantially if the marker is evaluated in context with other metabolites that are screened or when a tiered approach is applied.[29]

Second-tier testing, either complementary quantitative metabolites (e.g., TSH testing prompted by low T4) or genetic variant analysis (e.g., sequencing the *IDUA* gene prompted by low IDUA activity), is commonly performed to reduce false-positive results. Notwithstanding, false positives will continue occur for the foreseeable future.

Some factors known to be associated with false-positive screens for the primary markers/disorders are mentioned in the previous sections and compiled in Table 18.3. The Newborn Screening Analyte Interference List (http://aphl.org) is another resource for a list of observed analyte interferences in NBS assays.[95]

Missed Cases

A few infants with one of the screened disorders, who were not identified on NBS, have been reported.[30,32,37,59] Laboratory error, suboptimal markers (primary or second-tier), specimen mix-up, and failure to collect an NBS specimen can result in missed cases. However, in screening for a multitude of disorders, each with its own biomarker that varies with time and physiological states, an occasional affected neonate may have normal biomarker concentrations in the newborn specimen simply because the timing of collection was not ideal for the particular condition that affected the baby. As examples neonates with CF-related meconium ileus may not show an elevation of IRT, or an infant with a FAOD may not have the characteristic AC pattern when not in the perinatal catabolic state.[96] Thus, physicians must exercise clinical judgment and not fall into the trap of excluding a diagnosis because an infant has presumably been screened. Clinical testing should be pursued in any infant or child with symptoms that suggest the presence of a disorder, regardless of the assumed or actual NBS result. Some conditions that could result in false-negative screens for the individual disorder are mentioned in the previous sections and found in the Newborn Screening Analyte Interference List (http://aphl.org).

Increased Detection of Cases

The number of infants identified by screening is greater than the numbers previously expected solely based on clinical identification for numerous disorders (inborn errors of metabolism, CF, CH).[66,70,93,97] Individuals who may have remained undiagnosed after a clinical presentation account for some, but the greater part of the difference represents infants with benign or milder forms of the disorders who may not have required clinical attention to have been identified prior to NBS.[98,99] Furthermore, some positive screens are not resolved despite diagnostic testing and clinical evaluation, due to inconclusive results on confirmatory metabolite testing or presence of variants of unknown significance on genetic testing or the existence of late onset forms of the disorder. Unfortunately, such individuals, although clinically asymptomatic may remain under medical surveillance for extended periods of time, and consequently experience anxiety associated with uncertainty and often interventions prompted by perceived risk of disease.[100]

The Future

Next generation sequencing (of the whole genome or exome), the dramatic technological advance allowing sequencing of nucleotides in the genome with an equally dramatic reduction in the cost for sequencing, is predicted to become an integral component in NBS in the future. Proponents envision the application of genetic screening for expansive second-tier testing, as an ideal primary modality for adding numerous genetic disorders to the screening panels, to potentially replace the assays for disorders that are currently identified reliably by primary metabolite-based screening, and as a resource that could be probed as needed throughout the individual's lifetime.

However, in an analysis of retrieved NBS specimens, primary NGS screening on its own performed poorly as compared to MS/MS-based screening for the current panel of metabolic disorders; overall sensitivity and specificity were 88% and 98.4% with NGS versus 99.0% and 99.8% with MS/MS.[101] Despite being inadequate to be a primary screen for most metabolic disorders, NGS as a second-tier test can substantially improve specificity and facilitate a timely and accurate diagnosis. Additionally, identification of genetic variants across numerous genes provides the opportunity to implement screening for a multitude of genetic disorders that do not have a biomarker identifiable by current screening.[102] Nonetheless, experience with NGS as a second-tier test augurs that primary genetic screening could be beset with a high risk of false negatives and a high false-positive rate due to the unreliable genotype-phenotype correlations and existence of numerous variants of unknown significance.[70] These challenges do not even address the medical genetic services needed that would far exceed the current availability, the greatly increased need for confirmatory tests, the increased number of infants with variants of uncertain significance in whom a diagnosis cannot be conclusively excluded and thereby would entail otherwise unnecessary follow-up or treatments, and the huge amount of uncertainty and anxiety in families that genetic screening would generate.[100,103] An overzealous implementation of primary genetic screening could thus lead to the implosion of NBS. Initial implementation of NGS in NBS is likely to be complementary to the current screening methodologies, as a second-tier test, and as the primary modality for adding on a limited number of variants for which the implications are known for some genetic disorders not identifiable by current screening.[104,105] The disorders targeted could include those in which early treatment might not be critical or even available but in which diagnosis would be important for defining the origin of illness and/or for family considerations. Other than the challenge of selecting genes and variants to detect the ethical, legal, and societal implications of sequencing in NBS need to be addressed. NGS-based screening would require informed consent that would have to be carefully constructed.

Many factors will continue to transform NBS, including rapidly advancing technology and new and increasingly available therapeutic approaches to previously untreatable disorders. Involvement

of family advocacy groups, influential citizens, or legislators who are heavily invested in individual disorders that may or may not be appropriate for NBS are additional determinants that impact NBS. Some disorders have been included in isolated state panels based on the political influences mentioned above, even though the disorders were not approved for inclusion in RUSP. Conversely, there is the issue of retention of blood spots for future study. Despite multiple safeguards in place to protect the identity and anonymity of individuals, parents and civil libertarians are concerned that retention of these blood spots poses a threat to the privacy of individuals, and therefore the specimens should be destroyed. If this view prevails, a resource of great value in the development of new and more effective tests, and one that is increasingly recognized as the avatar of personalized medicine, will be lost.

19 Neonatal Transport

ZEENIA C. BILLIMORIA AND GEORGE A. WOODWARD

KEY POINTS

- Regionalization of neonatal critical care improves outcomes.
- Highly effective transport systems feature centralized and standardized communications, experienced medical oversight and skilled teams trained to care for sick neonates.
- Appropriate transport care depends on the training and competency of the transport teams.
- The care delivered should not decrease in sophistication during the transport process.
- The referring provider is responsible (per Emergency Medical Treatment and Active Labor Act [EMTALA]) for ensuring the adequacy of the chosen mode of transport, but the receiving/transport teams can help inform decision-making.

Controversies

- Optimal transport team composition and configuration
- With proliferation of midlevel neonatal intensive care units, determining or anticipating which patients require transfer to higher levels of care and when
- Optimal method to achieve and monitor neonatal therapeutic hypothermia during transport
- Optimal timing and mode of transport of neonates likely to need extracorporeal membrane oxygenation (ECMO)

Regionalization of medical care enhances the ability to centralize resources and has improved patient outcomes.[1,2] For optimal coordinated care, however, an adequate medical transport infrastructure needs to be developed and continually refined to enable delivery of patients to regional centers and for specialized care to be delivered to patients in need. For centers that provide basic or specialized service, there will be times when subspecialty care is required, and for those who deliver subspecialty care, there may be times when transfer is indicated for reasons such as capacity or extraordinary care (i.e., extracorporeal membrane oxygenation [ECMO]). For hospitals that do not have birthing centers but to which neonates are brought for care, transfer may be indicated, and potential morbidity and mortality of these patients depend on high-quality and efficient neonatal transport. Although transfers to neonatal centers in the 1960s and early 1970s often occurred in an ad hoc manner, such as in a police car or a general ambulance, transfer programs today offer a more sophisticated level of care. Many transport services and centers have grown around individual center needs, without clear attention to coordination and regionalization of services. Competitive systems, often located in similar areas or vying for similar patient populations, have resulted in the duplication of services at the ground and air levels and at times increased risk and cost to patients and providers as part of the efforts to maintain or increase patient volume and revenue. Furthermore, national and international standards of care in neonatal and pediatric transport medicine are evolving. Transport guidelines and standards are available through the Commission on Accreditation Medical Transport Systems (CAMTS), Joint Commission Resources International (JCRI), and The Ground Air Medical qUality Transport (GAMUT) quality improvement collaborative.[3–6]

When considering the transport of neonatal patients, several situations can occur: *intrafacility* for services within a particular institution and *interfacility*, often between organizations with lower and higher levels of service capability, as well as between relatively equivalent levels of service because of capacity, geography, or other issues. Transported patients may be of high acuity, relatively stable, or in various stages of convalescent care. Each type of transport requires anticipatory planning, skilled, qualified, and certified transport personnel, adequate modalities (e.g., transport vehicles), and strong communication and relationships between referring and receiving providers. As noted in the next section, transfer agreements may help minimize inefficiencies and enable rapid approval and eventual transport of patients.

This chapter will review considerations and requirements for neonatal transport; discuss issues involved in transport team operation, including equipment, personnel, mode of transport, and medical legal issues; and present general and specific topics, including quality improvement opportunities, that might be encountered in a neonatal transport system.[7,8]

Regionalization of Neonatal Care, Care in the Community, and Transfer Agreements

Historical Perspective

The concept of regionalization of neonatal care and transport developed from the formation of neonatal stations, areas within hospitals, in the 1920s and 1940s[9] that had additional resources to care for premature neonates. One consequence of the formation of these stations was the development of equipment and protocols to transport premature neonates from other area hospitals to those with specialty services.

In the 1960s and 1970s, as interest in neonatal care grew, so did the number of hospitals offering services for premature

infants. To help optimize the care being delivered, the March of Dimes produced *Toward Improving the Outcome of Pregnancy: Recommendation for the Regional Development of Maternal and Perinatal Health Services* in 1976.[10] The report stratified maternal and neonatal care into levels based on complexity, and it proposed the referral of high-risk patients to centers with sufficient personnel and resources to provide care. The goal was to create standard definitions so that comparisons of health outcomes, resource utilization, and costs among regional institutions could be made. High-risk maternity patients would be able to actively participate in selecting a delivery service, and businesses would be able to select appropriate healthcare resources for their employees. The subsequent March of Dimes publication in 1993, *Toward Improving the Outcome of Pregnancy: The 90s and Beyond*, reiterated the importance of regionalized care and further delineated care levels.[11] The concepts of regional care were adopted and incorporated into the Guidelines for Perinatal Care.[12,13] While the original driving forces for regionalization in the 1970s were the shortage of centralized trained personnel to care for low birth weight (LBW) neonates and the economic expense to maintain these skills, during the late 1980s and 1990s, technology and clinical expertise disseminated outside the regional tertiary centers, resulting in proliferation of the number of intermediate-care neonatal intensive care units (NICUs). This proliferation has blurred many of the original distinctions between various care systems. Whether driven by third-party payers or other factors, with various interpretations and applications of what "regional care" means, the results have been the creation of a variety of care options[14] but without necessarily improved or optimal outcomes for all patients. For example, Kastenberg et al. found that very low birth weight (VLBW) neonates with necrotizing enterocolitis had significantly increased mortality when cared for in low-volume mid-level NICUs compared with higher-volume units and those with higher acuity status.[15] While there is limited robust evidence that demonstrates a clear causal relationship between improved outcomes and regionalized systems of neonatal care, understanding the impact of de-regionalized systems on quality of care and patient outcomes will help inform which neonates require transfer to regional, high-volume, high-acuity centers and how to optimize use of the neonatal transport system to meet these needs.[15,16] Tanem et al. present a descriptive review of the transport workforce, including transport training and team configuration in their 2016 paper.[17]

Care in the Community and Back Transport

Regionalization of care, space limitations, and longitudinal care coordination contribute to a current system in which neonates are being both transported to higher levels of care for acute and/or critical needs and also transported back ("back transport") to appropriate centers, perhaps closer to home, once their critical condition has resolved or stabilized.[18–20] Regionalization guidelines should support the return to community facilities for patients who no longer need the highest level of care. Patient selection for back transport and care in another facility should match the capabilities and expertise of the community hospital.[21] The increasing application of telemedicine and technologies that allow real-time assessment and medical guidance may enhance not only the capacities of more remote facilities and providers during initial stabilization but also assist those providing ongoing care of high-risk neonates. In addition, telemedicine applications may augment the assessment and care provided by the transport team when at the patient bedside when they are able to communicate in real time with specialty providers at a receiving facility. Kim et al. (2013) conducted a prospective study to assess the impact of telemedicine in Arkansas on regionalized care and infant mortality.[22] They found that there were fewer VLBW neonates born in hospitals without NICUs and an overall decline in infant mortality statewide. Webb et al. (2013), in a multicenter study assessing the impact of telemedicine on neonates with suspected congenital heart disease (CHD), observed improvements in the diagnosis of CHD, fewer patient transfers, reductions in the length of stay, and use of inotropes and indomethacin.[23] In a single center study on simulated newborn transport calls, Umoren et al. showed change in perception of newborn stability and increased provider confidence in recommendations made following video-based telemedicine simulations as compared to telephone only encounters.[24] Telemedicine is a rapidly growing area in medicine, with increasing presence in NICUs, and an area of continued opportunity for development for infant transport.

Transfer Agreements

Although third-party payers often drive decision-making, transport relationships can develop between various institutions by formalized transfer/preferred provider agreements and/or by historical and personal relationships.[20] Transfer agreements can help to define the roles, understanding, and expectations between institutions and the transport service; they may also help to detail reimbursement issues. These agreements set the expectations for participating facilities, with the ultimate goal of the timely movement of patients from one facility to another.[8,13] Agreements should be reviewed by legal counsel to ensure compliance with state law.[8]

A neonatal transport system must also determine if maternal transport is part of its purview. It is clear that preterm neonates who are born outside hospitals and require transfer to tertiary care centers or transfer between tertiary care centers have worse outcomes, which include increased mortality and morbidity such as intraventricular hemorrhage.[25–29]

Several investigators have shown that mortality is lowest for deliveries of VLBW neonates that occurred in hospitals with tertiary care NICUs.[30–33] In 2003, Clark supported the idea that, whenever possible, women in early preterm labor should be moved to the regional hospital rather than the neonate being transferred after birth.[34] The study was insufficiently powered, however, to make a recommendation regarding the difference between regional and large community NICUs.[34] In trying to discern which LBW neonate might be better cared for in tertiary regional care centers, Vieux et al. showed that there were factors associated with both increased and decreased need for neonatal intensive care.[35] These data can help inform guideline development for transporting women in preterm labor and optimize the use of transport and local community resources to ensure timely transfer and optimal patient outcome.

Transport Communication

When one is developing and maximizing transport capabilities, a key concept is centralized communication, often in the form of a communication center. While a call from a referring provider directly to a receiving provider might seem to be the most efficient way to initiate a clinical conversation about a potential transport, there are more effective means of communication. Those who have

transported or referred patients in systems without centralized access understand the challenges in working through operators, unit coordinators, multiple providers, and often multiple services to enable a singular transport. This process is time-consuming and often frustrating for the referring provider, and the time could be better spent in direct assessment and care of the patient. When one is communicating with the transport system, there are key elements that must be considered and appreciated on both sides to initiate and complete a successful patient transfer:

- Appreciation and recognition of the need for transfer
- Awareness of appropriate and available transport modality and options
- Identification of appropriate receiving facility and acceptance by receiving provider
- Verification of regional and local bed capacity
- Review of current medical issues
- Determination of required transport services, including personnel
- Dispatch of transport team and potential limitations

Centralized access through a communication center can allow all those functions to occur simultaneously, enabling more rapid transport response and appropriate involvement of all individuals required for the care of a particular patient (Box 19.1).[12,13]

Medical Supervision

A key requirement for any system is to have appropriately skilled and immediately available medical command physicians (MCPs) (also referred to equally as *medical control physicians*).[8,12,13] An MCP should be literate and expert in the medical area of concern, as well as up to date on transport capabilities. In most cases involving neonatal transport, this provider should be a neonatologist. There may be instances, however, when the referring or receiving physicians may request or desire additional medical expertise. For example, a cyanotic newborn with CHD may be temporarily stabilized by the referring provider and additional medical advice may be provided by the receiving MCP, as well as a partnering cardiac intensive care physician. A communication center can facilitate an initial call in which multiple providers are linked, allowing the highest level of advice to be presented and discussed among providers. These telephone calls should ideally be recorded for quality control and/or for review if verification of information is needed and should include the transport personnel so that background information and care plans are communicated directly.

BOX 19.1 Features of a Highly Functional Centralized Communication Center

- Centralized number with immediate access to transport system or center personnel 24/7
- Contact number advertised, easily recalled, monitored 24/7
- Single call or point of contact for referring provider to accomplish all transport needs
- Dedicated communication center personnel with transport-specific training
- Recorded calls for quality assurance and quality improvement activities

Data from Southard PA, Hedges JR, Hunter JG, et al. Impact of a transfer center on interhospital referrals and transfers to a tertiary care center. *Acad Emerg Med.* 2005;12:653–657.

Mode of Transport

Once the transport referral has been made and discussions have been started with the MCP, the transport process begins in earnest. A decision on mode of transport is an important consideration at this juncture and is ultimately the responsibility of the referring provider, although it can be appropriately influenced by the MCP with informational guidance from the transport team and communication center (Table 19.1).

In addition to distance from the referring and receiving facilities, which will impact the total transport time, the decision regarding the mode of transport is influenced by several additional considerations when aiming to arrange and dispatch the most appropriate team for a given patient, including:

- Available mode of transport
- Staffing and medical expertise of providers involved in each mode
- Patient's current stability and potential illness progression during the projected transport time
- Capabilities of referring facility and personnel
- Urgency of need for intervention and definitive care of patient
- Geography and weather

In a study examining the decision-making factors around the mode of transport, Quinn et al. found that the decision to activate a helicopter versus a ground unit was made in the face of not only prolonged distance (>45- to 60-minute drive time) but also the presence of perceived high-risk clinical conditions, specifically neurovascular and respiratory concerns, even more so than blood pressure or heart rate.[36]

Currently, there are guidelines but no national absolute criteria or standards to direct the choice of ground versus air transport. Each modality has its own general and more case specific benefits, constraints, and risks. First, with both air and ground transfer, concerns include potential physiologic stress and discomfort experienced by the neonate secondary to stimuli such as vibration and noise.[37–42] Therefore, adjuncts to minimize the stress and discomfort, such as gel mattresses and earmuffs, should be used as much as possible. Air transport can also present specific

TABLE 19.1 Characteristics of Mode of Transport

Transport Modality	Distance to Receiving Facility (Miles)	Features
Ground	10–20+	• Fewer weather restrictions • Door-to-door • Well-lighted care environment • Space for family, providers • Efficient in urban, short-range transfers
Rotor wing	>20–100	• More expeditious >50 miles, ideal efficacy 50–150 miles • Can access less accessible areas • Can potentially be door-to-door
Fixed wing	>100	• Expeditious over long distances, ideal efficacy >150 miles • Can circumvent weather issues • Potential space for family, provider • Ability to pressurize cabin • Requires ground transport to and from airports

stressful stimuli such as gravitational forces during acceleration and deceleration, temperature variations, and decreased humidity with altitude and introduces issues related to altitude physiology that can affect patients with respiratory issues or air trapping as well as air-containing equipment (e.g., endotracheal tube cuffs, laryngeal mask airways).[37,43–45] Dalton's law recognizes that ambient oxygen partial pressure decreases as altitude increases; therefore, there may be a need for pressurization and augmentation with increased fraction of inspired oxygen. Boyle's law states that as altitude increases, the volume of a gas also increases, as barometric pressure is inversely related to the volume of the gas. Thus, consequences of this law are potentially a serious issue for patients with an enclosed gas collection, such as a simple or developing pneumothorax or pneumatosis in suspected cases of necrotizing enterocolitis.

Second, weather and physical distance can make each mode of transport more or less accessible or reasonable at a given time. For instance, while ground transport may be more readily available than air transport because of fewer weather constraints and an increased number of vehicles, the overall transport time may be too long given the clinical needs of the patient.

Finally, each mode of transport has occupancy limitations associated with select vehicles, especially rotary air transport. These limitations can preclude extra passengers such as parents or family members or potentially crew members if weight and balance is an issue.

Transport Personnel, Education, and Team Composition

Awareness of the capabilities of the transport system and of the personnel involved is imperative in decisions regarding the mode of transport. Although it is ultimately the responsibility of the referring physician to identify the appropriate mode and personnel for transport (per the federal Emergency Medical Treatment and Active Labor Act [EMTALA]), opportunities exist for tertiary care and referral centers to help inform the referring providers regarding optimal transport and hospital planning and use.[46–48] In general, issues influencing transport decisions (as well as hospital care needs) include the patient's current level of care, urgency for a different level of medical capability or equipment, current provider capabilities, stability of the patient, options available to the provider and patient, and efficiency and quality of the transport process. Ideally, these issues are key determinants of appropriate transfer; however, referring providers are often overwhelmed, due to their lack of resources, by the severity or acuity of the patient and their primary desire may be to have the patient transferred from their facility as quickly as possible. Thus, the providers may focus on a transfer process based solely on the speed of transport rather than the quality of care. It is imperative for the receiving and tertiary care centers to educate the referring providers regarding the importance of stabilization, initiation and quality of the primary response, transport options, and definitive care to maximize patient outcome. When examining the transfer of patients, providers should ask a simple question: "Are we trying to deliver the patient to tertiary care, or are we trying to deliver tertiary care to the patient?" In most high-functioning transport and referral centers, the latter is true. The referring physician should expect to have tertiary care advice and direction delivered at the moment of the referral call and continued throughout the transport process.[12,13,47]

When considering the transport team composition, it is important to consider the quality of the personnel, their expertise and experience, and their ability to work in the transport environment.[49–51] There are many variations of transport teams in the United States and abroad.[52] These teams can be composed of a combination of physicians, nurse practitioners, nurses, respiratory therapists, paramedics, and other healthcare providers. Regardless of the formal educational background of an individual, there are several criteria that must be met to be optimally effective in the transport environment. First, the provider must have adequate certification, be licensed for the care he/she delivers, and be able to provide the assessments and interventions that a patient currently or potentially requires during the transport process. For example, a neonatal retrieval service must be able to manage acute and critical airways in the neonatal population, both at a referring hospital and during the transport. While transport team providers might not be credentialed to provide certain skills within their home hospital (i.e., intubation), they have been certified to provide them in the ambulance environment. In general, this must be done under the auspices of a physician's care, which may be from an accompanying physician or via online medical control (real-time medical advice during the transport process) or protocol-based care (off-line medical control). It is important to recognize that the transport time frame is somewhat limited; therefore, the personnel may not need to have the longitudinal or differential diagnosis expertise of a fully trained neonatologist. However, these personnel must have the acute care assessment abilities and intervention skills of an experienced neonatal caregiver.

From the transport and pediatric literature, patient outcomes are improved with specialty providers. While multiple studies have examined this issue,[53–56] the most compelling is the study by Orr et al., which examined transport by variable providers within the same system.[57] This study compared outcomes in patients whose care was delivered by specialized pediatric critical care teams with those whose care was delivered by general providers. Both teams had the same medical command oversight, equipment, and modalities. Patient outcomes were worse for those whose care was not delivered by specialized teams and were much improved for those whose care was delivered by specialized teams. While the study by Orr et al. and studies by others are compelling, a 2015 Cochrane review that focused specifically on neonatal specialty teams[58] concluded that in the absence of randomized controlled studies there is not good evidence to refute or support the use of neonatal specialized teams for high-risk neonates. Evidently, specialized teams and patient outcomes is an area for ongoing investigation.

In addition to training the transport personnel, MCPs should understand the opportunities and limitations of the transport services, the environment, and the risks and challenges that referring personnel can potentially encounter with situations and patients who exceed their own or their facility's management abilities. It is imperative that MCPs have clear and efficient communication, not only with referring providers and those from different disciplines but also within the transport team.

Quality Improvement

Throughout medicine, there is an increasing focus on measuring and improving the quality of care provided across all healthcare domains and patient experiences. Transport medicine offers an opportunity for potential quality improvement activities within the inpatient arena, in the transport system, and at the referring

facilities.[59–63] While there are guidelines of care and process recommendations such as those provided through the American Academy of Pediatrics and the Commission on Accreditation of Medical Transport Services, formal national transport benchmarks or standard quality-of-care metrics are still evolving. A 2015 consensus document on behalf of the American Academy of Pediatrics Section on Transport Medicine offered 12 core quality metrics for neonatal and pediatric transport.[64]

The authors proposed that these metrics serve as benchmarks and help guide individual program quality improvement. Details of their recommendations can be accessed at http://www.aap-sotm.org. This effort, which evolved as the GAMUT database/tools is a good place to start for of transport services and quality metrics (http://gamutqi.org/). Aspiotes et al. reviewed GAMUT's benchmarking process, noting the inclusion of more than 350 transport programs with more than 200,000 annual patient encounters.[65]

Neonatal and pediatric airway management may be one of the most important aspects of transport clinical care and historically is one of the more challenging areas for emergent and prehospital management. Examples of quality-based investigations reflect these challenges and provide information to guide improvements. Bigelow et al. retrospectively assessed first-pass intubation success for neonatal and pediatric patients across nine transport programs over a 6-month period.[66] The overall success rate was 64%, with a range of 35% to 87% but was highest for teams that had live-patient training for initial competency and lowest for those using simulation alone. Smith et al. considered risk factors for intubation failure among neonatal and pediatric specialized teams and found higher rates of intubation failure for neonates compared with pediatric patients, especially for the smallest neonates necessitating the use of tube sizes of 2.5 mm or less.[67] Additional risk factors for failure were the lack of use of sedation and neuromuscular blockade. Impact of environmental issues (altitude) on endotracheal use is reported by Orsborn et al. and Long et al.[68,69]

Quality improvement activities in the transport domain are diverse and range from assessment of the transport process by review of recorded calls to the monitoring of intubation success and vital signs in transport to improving communication through standard handovers.[70] However, this glimpse into facility/provider medical sophistication and capability is one that is privileged and should be used to identify educational opportunities for all providers involved rather than used as a judgmental review. Education by receiving physicians and transport teams can have a significant effect on the quality and outcome of patient care and the volume of future referrals. Ideally, once a referral call is made, a receiving physician or MCP will direct the care so that the job of the transport team is to verify that an appropriate working diagnosis has been made and adequate stabilization has been achieved. Systems that do not gather adequate information or offer appropriate advice, or in which the referring facilities do not follow that advice or choose not to perform needed interventions, can put the patient at risk by delaying potentially necessary interventions, prolonging the transport process, and delaying delivery of definitive care. The transport team that has invested several hours at a bedside stabilizing a newborn with medical or surgical issues may be spending time in a facility that is not ideal, has a limited number of skilled personnel, and has minimal backup, thus prolonging the transport process, delaying definitive care, and potentially putting that individual patient and the transport team at risk.[59,71] Furthermore, during this prolonged stabilization time, the entire system becomes at risk because the valuable resource of specialized neonatal transport personnel is not available for another patient.

Ideally, care delivery would be the same at referral and receiving centers, and the development of practice guidelines can help in this regard. Guidelines that are evidence-based, developed by regional and local experts, and disseminated to referring centers and transport teams will help standardize and promote consistent care across variable locations. It is necessary, however, to assess and reassess the quality of the guidelines and the competency of their use to ensure optimal results. Even in the best of hands, near-miss or realized adverse events may happen. It is clear that identification of those events, discussion with families where appropriate, and root cause analysis are imperative. Several studies have examined adverse events in transported patients. Van den Berg et al. examined adverse events that occurred over 13 years with their neonatal transport team in northern Sweden.[72] They found that such events had differing significance (53% low risk to 11% high or extreme risk), were common, and were often related to transport logistics and equipment failure. Ligtenberg et al. noted that one-third of patients had an adverse event, and 50% of adverse events resulted from the advice of the MCP not being followed.[73] Of that group, 70% of events were avoidable and 30% involved logistical issues. In a review of the London Neonatal Transfer Service, Lim and Ratnavel noted that 36% of their patients had one or more adverse events and that two-thirds of those were due to human error.[61] Half of the events occurred before the team arrived at the referral center and were due to patient preparation and communication issues.

Transport Administration

As a hospital develops and optimizes a neonatal transport program, experts in transport medicine are integral to the success of the program.[12,13] A quality medical director and program director, often a nurse or respiratory therapist, are essential for understanding the potentially complicated and challenging environment of transport medicine. These leaders should be instrumental in identifying expectations, roles, and responsibilities for the entire transport process, including oversight of the communication center and developing and disseminating referral center expectations.

The responsibilities of the referring center when transferring patients include the following:

- Stabilize and prepare the patient before transport
- Make an appropriate decision to transfer the patient
- Choose an appropriate transport process and destination
- Obtain family consent for transport, including the transport mode and the receiving facility
- Discuss and initiate a plan for stabilization with the medical command physician (MCP)
- Communicate clearly when suggested interventions are beyond the scope of the referring center or cannot be done
- Be present and participate in the transition of care to the transport team and to the receiving service.

In turn, there are also clear expectations of the receiving center and transport team:

- Be available immediately for patient care consultation
- Be able and qualified to provide clear and concise recommendations
- Have the ability to quickly determine if the receiving center is able to accept the patient for transfer
- Ensure that the receiving facility staff are prepared for both patient and transport team arrival
- Document interaction with—and recommendations to—the referring facility.

Most importantly, the team needs to ensure that appropriate skills and therapeutics are available and delivered throughout the process,

from the referral call through definitive placement, and ensure seamless transition at each point of care. The team needs to communicate well with the patient's physicians and document their advice, interventions, and activities in a clear, concise fashion to enable appropriate patient care and provide protection for the transport service.

Transport Team Safety Training and Protocols

Safety of the transport system and its providers is paramount and must be assessed and ensured before any patient is transported. Vehicles must be safe and meet the standards for air or ground transport; the personnel must be trained and skilled in the care of neonates, licensed, and competent; and the patients must be managed in the most appropriate and professional fashion. In addition, the logistics of travel must include a safe environment, including helmets and fire-retardant suits for those who fly in helicopters, three-point restraints, and appropriate ambulance seating arrangements. General equipment expectations for basic life support (BLS) and advanced life support (ALS) ambulances (often used as a platform for neonatal and pediatric critical care transport) can be found in the May 2021 multi-organizational joint position statement. These general vehicle equipment and supplies must be augmented to address the needs of the critical care transport system, providers, and patients.[74] Providers should not put themselves at risk by being unrestrained or being in an area where unsecured debris or inappropriately placed equipment may cause harm to them or the patient. Adherence to all rules and regulations of air and ground travel is essential.[75–80]

It is important to recognize that there are risks with both air and ground transport. In 2008, the air transport industry saw a spike in tragic and fatal air accidents.[78,81,82] This increase caused the industry, and the US government, to investigate these incidents and offer recommendations to improve transport safety.[83,84] Requirements such as duty hours for pilots, weather restrictions, flight under instrument flight rules with terrain avoidance equipment, and night vision goggles can help to minimize transport risk. While ground ambulances are used much more frequently and the risk of injury and death is evident, the fatality rate is lower in ambulance accidents than it is in aircraft accidents.[76,85,86] Many systems do not allow ambulances to exceed posted speed limits and allow them to use lights and sirens only as a way to identify an emergency response not to enable the vehicle to circumvent or ignore standard traffic laws.[75] The 2014 joint statement issued by the American College of Surgeons Committee on Trauma and the American Academy of Pediatrics regarding appropriate equipment for ambulances should also be reviewed by the providers and administrators of all transport systems.[87]

One challenge for transport teams is that the differentiation of medical resources, such as a neonatal specialty team, likely means that there may be a scarcity of resources and a potential need to ration those resources. It is possible to develop teams with a variety of personnel with complementary cognitive and procedural skill sets and work toward appropriate triage of transport requests to ensure the optimal level of onsite patient care and safe transport. There have been multiple attempts to develop triage tools for pediatric and neonatal care providers, including the Mortality Index for Neonatal Transport, the Modified Clinical Risk Index for Babies, the Risk Score for Transported Patients, and the Transport Risk Index of Physiologic Stability (TRIPS).[88–91] Notably, TRIPS is a validated tool that can be calculated in a single assessment and has been shown to correlate with NICU mortality. The original authors of TRIPS validated TRIPS-II, the application of TRIPS over 12 to 24 hours after NICU admission, and found it correlates with illness severity not only at admission but also up to 24 hours.[92] Given the simplicity and ease of use, TRIPS and TRIPS-II are examples of scoring tools that can be applied in both the transport environment and the hospital environment reflecting clinical deterioration or improvement over time.

Family-Centered Care

Transport team research has shown that family-oriented care, as in other areas of health care, is an important component of transport.[8,93–96] Families who have been formally surveyed appreciate the opportunity to participate in the care of their child and express increased stress and anxiety when they do not accompany their child during transport.[95,96] In neonatal transport, however, there are times when there are two patients who may require care in two disparate locations. A mother who has had a cesarean delivery and has delivered an acutely ill neonate who requires transfer to a specialty pediatric facility with neonatal intensive care capability is one such example. Transport teams should be sensitive to the challenges and opportunities for the family members and include them in the process when possible. It is evident that when parents attend or accompany transport team members during critical care transports, they are there not to assess the medical skill set of the provider but to provide support to their child. It is also a great opportunity for the transport team to demonstrate to the family that their patient is in focused, professional, caring, and capable hands.

Medical Legal Issues

There are many medical legal issues in transport medicine, just as there are elsewhere in the medical system.[8,97–100] The Health Insurance Portability and Accountability Act is a required component of transport planning and delivery. Discussion of patients should not happen in a public area or via public communication airways, where patient-specific information could be overheard. As noted earlier, a requirement of EMTALA is that the referring physician choose the appropriate mode of transport and ensure that the transport process and receiving hospital are appropriate for the patient. Patients should not be transferred if they are unstable and the ability to further stabilize them is available at the initial site of care. If a patient must be transferred for care while in an unstable condition—a frequent scenario for critically ill patients who need care not available at the referring institution—consent must be obtained from the family, which acknowledges their understanding of the potential risks and benefits of the process. In practice, there are often patients in an unstable condition who are transferred from lower to higher levels of care because the level of care that can be provided at the referring center is not optimal for the child. This reason is appropriate for transfer as compared with transfer of acutely unstable patients because of financial or other economic incentives.

The medical liability for transport is a shared process. Before the referring center contacts a receiving facility or transport team, the entire medical responsibility lies with the referring provider. Once the receiving team has accepted the patient and offered advice, medical liability becomes a shared process. The referring physician maintains most of the liability, as well as medical control of the patient, throughout the process until the transport team has left the referring hospital. It is important to recognize that most transport teams and personnel do not have privileges at referring

hospitals and are working under the guidance and supervision of the referring physician team. Transport teams that act independently or referring providers who are not available when the transport team arrives, put not only the patient but also the referring provider and transport team at risk.

There will be times, however, when there is disagreement regarding the optimal care to be delivered. This situation can be challenging, and it must be handled appropriately. It is never appropriate to have obvious provider conflict occur at a patient's bedside in front of family members. The appropriate way to handle a situation that cannot be easily mitigated is to involve the MCP with a telephone call to the referring physician in a discussion at a peer-to-peer level. Transport teams have been known to comply with the wishes of the referring providers to not perform advanced procedures at the referring hospital, only to perform those procedures in the ground or air ambulance, which is a much less desirable location. Ideally, all disagreements and considerations of different therapies should be discussed in a collegial fashion.

As noted previously, documentation of all information received, and advice offered is imperative. If there is a review or there are challenges regarding the care delivered before or during transport, clear and appropriate documentation should stand alone as an excellent defense. In addition, many centers use recorded (i.e., digital, tape, and other retrievable recording process) intake and advice lines; this is another way to review, educate, and ensure that appropriate information is delivered using an effective communication style. The use of recorded lines with frequent review, for educational and quality assurance purposes, can be invaluable. Review with legal advisors can help define the length of time the recorded materials should be maintained for quality improvement or patient record addendum.

Patient Care During Transport

The primary clinical goals for any neonatal transport include, but are not limited to, the following and should be established during the initial stabilization phase before departure from the referring facility and maintained until handover at the receiving facility:

- Secure and patent airway
- Adequate ventilation and oxygenation
- Thermoregulation, especially for premature neonates, goal 36°C to 37°C (except as indicated for hypoxic-ischemic encephalopathy)
- Normoglycemia
- Goal glucose level 50 to 200 mg/dL
- Adequate blood pressure and perfusion
- Appropriate condition-specific care such as for myelomeningocele

A team's ability to achieve these care goals may be impacted by the patient's clinical status but will also depend on the team's preparedness and skill and experience caring for critically ill neonates. Therefore, the general approach to any neonatal transport includes ensuring the availability of appropriate equipment, such as an isolette and endotracheal tubes for the smallest premature neonates, that there are skilled team members who can optimally care for a sick neonate, that there are appropriate medications for specific situations such as prostaglandin E_1 (PGE_1), and that there is smooth communication with the MCP.

Extreme Prematurity and the Limits of Viability

Of the approximately 4 million live births that occur annually in the United States, approximately 10% are preterm (<37 weeks gestation), and approximately 1.5% are VLBW (<1500 g).[101] The most effective method of transporting extremely premature neonates is before delivery with the mother serving as the transport vehicle, but sometimes this is not possible, and a very premature baby is delivered unexpectedly at a referral center. Neonates born at 23 to 26 weeks outside tertiary centers have higher mortality and morbidity than those delivered within specialty centers.[32,33,102–104] When delivered at a referral hospital, the premature neonate is exposed to all the variability of the extrauterine environment, with the added complexity of having to be transported to another facility capable of meeting the neonate's needs. Increased transport duration, lower gestational age, and severe acidosis before transfer have been associated with increased risk of clinical deterioration and mortality among transported VLBW neonates.[105,106] In one study the odds of deterioration increased 1.33 for every 5 minutes of transport time.[106] Most neonatal transport teams are regarded as extensions of the NICU. The team initiates and provides much of the same level of complex neonatal care as the receiving hospital, but in a changing environment. It is this changing environment that poses unique challenges for both the patient and the caregiver. These issues would be amplified in the case of a natural disaster with care and transfer required for premature neonates.[107,108]

Human viability is limited largely by the physiology of pulmonary development and currently appears to be at approximately 22 to 24 weeks gestation.[109,110] Unfortunately, for transport teams and providers at referring hospitals, it may be difficult to determine which neonates born at the margins of viability should be resuscitated and treated with aggressive neonatal care and which should not.[12,111] These decisions are best made collaboratively with the family, transport team members, and the referring and receiving physicians, and they may ultimately result in patient transport, even when the likelihood of survival is low. Telemedicine may be useful to help with decision making in these difficult cases.[112–114]

Thermoregulation

Problems in neonatal thermoregulation continue to be a major contributor to neonatal morbidity and mortality worldwide and can be especially problematic in neonatal transport. During transport, neonates often cross into and out of multiple different environments with wide temperature and humidity variations. Although a normal term neonate may be capable of significant homeothermic response by using its sympathetic nervous system to vasoconstrict peripherally, preterm neonates lack the subcutaneous fat insulation to protect their core temperature. Several studies using TRIPS found that temperature instability accounted for clinical deterioration during transport, with as many as 57% of neonates demonstrating clinical decline.[115,116] In one study, increased mortality was observed among those neonates with clinical deterioration.[115] Skiöld et al. identified factors associated with temperature instability before transport and found that VLBW neonates and the presence of respiratory support were predictors of temperature instability on arrival at the receiving center.[117] Clearly, steps should be taken to minimize temperature instability during transport, such as adequate isolette temperature and the use of chemical gel packs and polyethylene occlusive skin wrapping to help maintain temperature, especially of VLBW neonates.[118]

While humidity contributes to neonatal temperature control, especially for VLBW neonates, it is also important for gas delivery among those receiving mechanical ventilator support.[119] Ventilation with dry gases affects the airway epithelium in VLBW

neonates and can result in hypothermia secondary to their large surface area to body mass ratio and their relatively large respiratory minute volume.[120] While ventilator complications can be reduced, and thermoregulation can be improved by provision of exogenous heat and humidity to the gases, active heated humidification systems are used infrequently during neonatal transport. Passive hygroscopic heat and moisture exchangers have been used for short-term conventional mechanical ventilation and with some types of high-frequency ventilation.[120–122]

For all newborns, an equally important condition to avoid is hyperthermia. Although elevated temperatures in neonates occur with increased metabolic rates, prolonged seizures, dehydration, or infection, the most common cause of neonatal hyperthermia is high ambient air temperature and humidity.[123]

Surfactant

Surfactant replacement therapy has proven to be one of the most significant advances in neonatal critical care.[124–127] Benefits are achieved with both prophylactic (defined as within 10 to 30 minutes of birth) and rescue (within 12 hours of birth) surfactant administration, especially for extremely LBW neonates.[127–129] Surfactant administration can be complicated by airway obstruction, right mainstem bronchus or esophageal instillation, bradycardia, hypotension, and rarely pulmonary hemorrhage. These complications led the American Academy of Pediatrics Committee on Fetus and Newborn to recommend that "preterm and term neonates who are receiving surfactant should be managed by nursery and transport personnel with the technical and clinical expertise to administer surfactant safely and deal with multisystem illness."[130]

Given the potential for rapid physiologic changes and the risk of complications, surfactant administration should generally not be initiated en route between facilities. While investigations are still ongoing as to the optimal manner of surfactant administration, future technology might eventually allow surfactant to be delivered without tracheal intubation. The administration of surfactant via a small intratracheal catheter while the neonate breathes spontaneously while receiving continuous positive airway pressure (CPAP), a technique known as *minimally invasive surfactant therapy* (MIST),[131] has been shown to be equally effective as techniques involving tracheal intubation, and in some studies resulted in decreased morbidity.[132–135] Several studies, including NICU-based randomized controlled trials,[136,137] have shown success with the INSURE method[138,139]: *int*ubate-*sur*factant-*e*xtubate to CPAP to avoid the potential sequelae and complications of prolonged mechanical ventilation in preterm neonates. This method has not been studied in the transport environment; however, there are preliminary investigations into parameters that may serve as eligibility criteria to identify in which neonates extubation to CPAP could be could safe and successful before they depart from the referring center.[140] Aerosolized surfactant has yet to be shown to be superior to endotracheal tube administration.[141,142]

Currently, the most frequently used surfactant preparations in the United States are derived from animal lung extracts. These surfactants require refrigeration and are usually carried by transport teams in small containers cooled by gel packs. Lucinactant, a synthetic surfactant, requires a special warming cradle to convert it from a gel to a liquid before administration, adding a level of difficulty to its administration during neonatal transport.[143,144] Because smaller community hospitals may not have surfactant readily available, the transport team should carry it as part of their medical supplies.

After the surfactant has been administered, monitoring pulmonary compliance and adjusting the patient's ventilator while still at the referring facility may extend the transport time but also limit avoidable clinical complications.

Hypoxic Respiratory Failure

Hypoxic respiratory failure describes a heterogeneous group of neonatal disorders that have in common impaired oxygenation and the need for assisted ventilation, most commonly respiratory distress syndrome, meconium aspiration syndrome, and persistent pulmonary hypertension of the newborn (PPHN). Interfacility transport of the newborn with hypoxic respiratory failure is potentially hazardous, with a high risk of patient deterioration and complications of therapy.

Assisted ventilation during neonatal transport can be accomplished with a variety of devices, although not all modes of mechanical ventilators have been modified for use in a mobile setting. Newborns, including very preterm neonates born at 28 to 32 weeks' gestation with milder degrees of illness, may be managed successfully with CPAP[145] with a variety of interfaces, ranging from a face mask to nasal prongs or a nasal cannula.[146] In a systematic review of observational studies, Cheema et al. concluded that noninvasive ventilation (CPAP or high-flow nasal cannula) was relatively safe in pediatric and neonatal transport, with an in-transport adverse event rate of 1% to 4%. However, the studies included in that review did not contain information on severity of illness and were likely subject to selection bias, leading the authors to conclude that additional studies were needed.[147]

There have been a few case reports and a limited literature review that suggested a potential role for neonatal laryngeal mask airway during transport.[148] This modality is particularly interesting since the success of neonatal intubation is highly variable across transport programs, specialties, and individuals. The use of sedation and neuromuscular blockade has been shown to increase intubation success[67,149] and is recommended by the American Academy of Pediatrics.[150] However, caution is required when considering paralytic agents if the ability to establish the airway and/or ventilate the patient is at all in question, such as with a provider inexperienced in managing a neonatal or difficult airway.

Inhaled nitric oxide (iNO) is approved for use in term and near-term newborns with hypoxic respiratory failure with clinical or echocardiographic evidence of pulmonary hypertension.[151] Administration of iNO to newborns with PPHN reduces the need for ECMO.[152,153] With increasing availability in community NICUs, iNO therapy is often initiated before transport to a tertiary care center. Once iNO is administered, abrupt cessation of therapy can result in rapid clinical deterioration from rebound pulmonary hypertension, so it is essential to continue this therapy throughout the transport.[154] Transport teams may also consider initiating iNO therapy for term and near-term newborns with hypoxic respiratory failure in discussion with the MCP. If the referring facility does not have the capability to perform echocardiography, the transport staff should carefully consider the possibility of congenital heart lesions that can lead to clinical decompensation with iNO, including total anomalous venous return, and lesions with ductal-dependent systemic blood flow or severely diminished left ventricular function. While rare, some preterm infants may have PPHN despite adequate lung inflation resulting in severe hypoxemia and a need for iNO. Starting iNO in this population should be given due consideration and should be discussed with the MCP.[151]

The rationale for initiating iNO therapy for a transport is to reduce pulmonary vasoreactivity and increase stability during transport. However, there have been no prospective studies to determine whether this practice affects patient outcome. A retrospective study by Lowe and Trautwein evaluated initiation of iNO by the transport team in the field versus at the hospital following transport and showed similar death and ECMO rates, but an overall decrease in hospital length of stay at referring and receiving hospitals when iNO was started earlier.[155] During transport, iNO has been delivered by several different systems, such as the aeroNOX (Aeronox Technology Corporation, Quezon City, Philippines) iNOvent, and INOmax DS (INO Therapeutics, Hampton, New Jersey, United States) transport systems.[151,154,156–158] The use of iNO in combination with high-frequency ventilation in non-ECMO centers can complicate the transfer process. If the transport team does not have the capability to provide mobile high-frequency ventilation, it is recommended that the referring hospital perform a trial of conventional mechanical ventilation before transport to establish that the neonate can tolerate the transition.

Both high-frequency jet ventilation (Bunnell ventilators; Bunnell, South Salt Lake, Utah, United States) and high-frequency flow interrupter ventilation (Bird ventilators; CareFusion, Yorba Linda, California, United States) have been configured and used with nitric oxide during transport.[159,160] The high-frequency oscillator (SensorMedics 3100 A; CareFusion, Yorba Linda, California, United States) that is commonly used in many NICUs is impractical for ground transport and is not configured for helicopter or fixed-wing transport. However, even with these technologies, the conditions of 30% to 40% of critically ill neonates improve only temporarily with iNO therapy, and they will ultimately require a higher level of care.[157,161]

For patients with pulmonary or cardiac failure who are unresponsive to maximal medical therapy, ECMO is often used as a bridge therapy to allow either the lungs or heart, or both, to recover. Ideally, centers without ECMO capability should have prospective criteria to guide the transfer of newborns before the need for ECMO cannulation. The Extracorporeal Life Support Organization (ELSO) recommends ECMO for infants with severe hypoxemic respiratory failure on maximal medical therapy with potentially a reversible cause, if they have one or more of the following: (1) inadequate tissue oxygen delivery, (2) severe hypoxic respiratory failure (PaO_2 <40 mmHg), (3) oxygenation index with sustained elevation, and (4) severe pulmonary hypertension with evidence of right and/or left ventricular dysfunction.[162] It must be highlighted that earlier referral to an ECMO center of a patient with severe respiratory failure, may prevent significant morbidity and mortality, including the need for ECMO itself.[163] In some cases, the patient's condition is so unstable that conventional transport cannot be conducted safely. Select programs have the capability to provide mobile ECMO, during which patients are cannulated for ECMO either before transport or when the transport team arrives.[164] The ELSO provides guidelines for team composition and equipment that are based upon the need for patient cannulation at the referring hospital and on special considerations for modes of mobile ECMO transport.[165] In a recent study the most common diagnoses associated with the need for neonatal ECMO transport were meconium aspiration syndrome, persistent pulmonary hypertension, sepsis, and congenital diaphragmatic hernia.[166] Mobile ECMO can also benefit patients already receiving ECMO at a tertiary facility who are in need of transfer for advanced quaternary therapies, such as heart or heart-lung transplants.[167–169] Fixed-wing and ground ambulance transport predominate as primary modalities for ECMO transport, which is logical given the size of the equipment and the team involved. In a recent study, however, 5% of ECMO transports occurred in a helicopter.[166]

The resources and skill set necessary to perform ECMO safely and consistently in the transport environment have, by their complexity, restricted the number of transport programs with mobile ECMO capabilities,[166,169–171] and there are thus a limited number of such centers worldwide that have long-standing, relatively high-volume pediatric/neonatal ECMO transport programs. The amount of time from the decision to deploy the mobile ECMO team and the actual departure from the unit can vary depending on the mode of transport, availability of appropriate personnel, and the time of the call making mobile ECMO a lengthier process that can potentially impact patient outcome.[171] While there are no published data to set criteria for the number of ECMO transports needed to maintain competency or impact mortality, recent literature suggests that centers with at least 20 to 30 neonatal and pediatric ECMO cases annually have higher survival rates than centers with a lower volume.[166,169,171,172] These data support the regionalization of ECMO transport services to optimize transport team skills and performance as well as patient outcomes given the high-risk, low-frequency nature of these transports.

Neurologic Issues

Hypoxic-ischemic encephalopathy affects approximately 1 in 1000 to 2 in 1000 term neonates.[173,174] Therapeutic hypothermia (generally sustained core temperature of 33.5°C for 72 hours) for encephalopathic term neonates has demonstrated a reduction in the combined outcome of death and neurodevelopmental disability up to 7 years of age when neonates were cooled compared with a control population.[175–181] Clinical trials and current guidelines suggest that cooling should be initiated within 6 hours of delivery, after an acute perinatal event (Box 19.2). Several studies have demonstrated the feasibility of initiating passive (turning off radiant warmer heat) and/or active (using ice/gel packs) and device-controlled (cooling blanket with servo-control using rectal or esophageal probe) hypothermia during transport.[182–186] Passive and/or active hypothermia that is not device-controlled results in wider range of fluctuation in patient temperatures, with patients arriving at the receiving hospital outside of goal range and taking longer to reach the goal temperature.[83,186,187] Device-controlled hypothermia on transport results in patients reaching goal temperature faster which is important when considering distance of travel and time of initiation of patient transfer.[186,188]

Device-controlled hypothermia on transport is more favorable than passive and/or active hypothermia that is not device-controlled in achieving goal temperature within 6 hours of birth. This is not always achievable depending on the capabilities of the transport program and/or mode of transport. In the United Kingdom, 70% of transport teams use servo-controlled devices.[189] The US Food and Drug Administration approved servo-regulated cooling device weighs 7.2 kg and can be easily accommodated on most ground, helicopter, and fixed-wing ambulances.

Congenital Heart Disease

Transport of the neonate with CHD follows the same general approach as for the transport of any critically ill neonate. However, neonates with complex CHD often need therapeutic intervention, requiring the support of multiple subspecialty

BOX 19.2 Criteria for Neonatal Therapeutic Hypothermia on Transport

1. *Must* meet the following eligibility criteria:
   - ≥36 weeks' gestation
   - Birth weight >1800 g
   - Less than 6 hr of age
   - First-hour blood gas, if available: pH ≤ 7.15 and base deficit ≥10
   - No severe congenital anomalies
   - Plan for continued full care
2. Criteria additional to above eligibility:
   - *And* first-hour blood gas: pH ≤7.0 or base deficit or base deficit ≥16
   - Or no blood gas available or first-hour blood gas: pH 7.0–7.15 or base deficit 10–16
   - *And both:*
   - 10-minute Apgar score ≤5 or assisted ventilation required at birth ≥10 min
   - Acute perinatal event
     - Intrauterine distress
     - Cord rupture or prolapse
     - Uterine rupture
     - Maternal trauma/hemorrhage
     - Cardiopulmonary arrest
3. *And* either of the following:
   - Moderate to severe encephalopathy
   - Seizures

TABLE 19.2 Steps Toward Optimal Transport of the Neonate With Congenital Heart Disease

All Patients	Intubated Patients
• Secure vascular access. • Ensure vascular access for volume resuscitation that is not infusing inotropes or PGE1. • Avoid interruption of PGE1 infusion. • Maintain normothermia to minimize oxygen consumption.	• Secure and record endotracheal tube position. • Place nasogastric or orogastric tube for decompression. • Maintain NPO status including fluids and medications. • Provide appropriate sedation.

NPO, Nil per os; *PGE_1*, prostaglandin E_1.

services, including a pediatric cardiothoracic surgeon and cardiologist,[190,191] which may necessitate transport to a specialized center.[192,193] Importantly, the preoperative care of these patients affects their postoperative outcomes and mortality.[194–199] In some cases, the neonate will have a prenatal diagnosis of CHD and the team will have disease-specific management plans, for instance, initiation of PGE_1 therapy on arrival for a neonate with a clinically stable ductal-dependent lesion. In other cases, CHD may be suspected in a critically ill neonate with signs of cardiovascular collapse, and the transport team must be prepared to initiate treatment, such as PGE_1 therapy, or limit others, such as treatment with fluids, oxygen and iNO, to manage a potential but not yet confirmed diagnosis. Regardless of whether the presence of CHD is known or suspected, the transport team must be prepared to manage it.

To optimize management, early communication with the receiving specialty center is vital. Whenever possible, the pediatric cardiologist, neonatologist, and cardiac intensivist at the accepting hospital should be included in formulating the transport management plan while the neonate is still at the referring hospital, thereby guiding the timing and urgency of the transport, line placement, and recommendations for airway management and supplemental oxygen therapy (Table 19.2).

The neonatal resuscitation algorithm is applicable in the presence of CHD[200] but should be modified in certain circumstances. In presentations such as hypoxemia unresponsive to supplemental oxygen, congestive heart failure, or shock, attention is devoted simultaneously to the basics of neonatal ALS and to the assurance of a patent ductus arteriosus.

A stable airway must be maintained, allowing adequate alveolar oxygenation and ventilation before transport. In critically ill neonates with known CHD presenting with severe cyanosis or circulatory collapse, intubation should be performed by a skilled provider after premedication with sedation and neuromuscular blockade. Reliable venous access is important, and arterial monitoring is helpful for ongoing assessment of blood pressure, acid–base status, and gas exchange. Volume resuscitation, inotropic support, and correction of metabolic acidosis may be required to maximize cardiac output and tissue perfusion. In neonates with suspected but not confirmed CHD, an evaluation for sepsis is typically considered simultaneously, and empiric antibiotic therapy initiated.

Supplemental Oxygen

Supplemental oxygen is a potent pulmonary vasodilator and systemic vasoconstrictor, and it can adversely affect the physiology of neonates with a single ventricle, as well as those with two ventricles with an unrestrictive ventricular septal defect or great vessel communication. The oxygen-induced pulmonary vasodilation can decrease pulmonary vascular resistance and increase pulmonary blood flow at the expense of systemic blood flow, thus reducing systemic output in some cases. For known CHD, the use of oxygen therapy and goal oxygen saturations should be determined with the use of established guidelines for specific lesions or in consultation with the MCP. Titrating oxygen via a nasal cannula or a face mask to a target peripheral saturation of 75% to 85% usually corresponds to adequate blood flow in both the pulmonary system and the systemic system. Higher oxygen saturations are typically not necessary and in fact may ultimately result in decreased oxygen delivery to the peripheral tissues. In cases of undifferentiated neonatal hypoxemia where CHD is suspected, oxygen therapy should be continued until CHD is ruled out by echocardiogram since severe pulmonary hypertension is also in the differential diagnosis for which supplemental oxygen therapy is indicated.

Prostaglandin E_1 Therapy

PGE_1 therapy is the standard of care for stabilization of known ductal-dependent CHD (DDCHD) but is often initiated in

undifferentiated hypoxic neonates when DDCHD is possible but not confirmed. In a study examining the diagnostic accuracy for CHD based on the clinical findings of a transport team, Gupta et al. found that there was no single finding predictive of DDCHD, concluding that making this diagnosis outside a specialty center was challenging.[201] In a separate study, the same authors studied the effects of PGE_1 administered to both neonates with DDCHD and those with PPHN and found that when PGE_1 was administered to neonates with persistent pulmonary hypertension, they recovered faster, and no adverse events were observed during transport.[202]

In the instance of prenatally diagnosed CHD, ductal dependency is often already determined. In these cases, maintaining ductal patency is key. Whenever possible, PGE_1 infusions should be prepared ahead of arrival at the referring center and started promptly. PGE_1 may be given via a central or peripheral intravenous catheter or in emergent situations where intravenous access cannot be obtained via an umbilical catheter or intraosseous line. For neonates with suspected CHD whose duct has begun to close, usually after the first 24 hours after birth, PGE_1 is often required, and response is immediate if ductal patency is central to the neonate's hemodynamics. In all cases, failure to respond to appropriate dosing may mean that the initial diagnosis of DDCHD is incorrect, the ductus is unresponsive to PGE_1 therapy (which may occur in older neonates), or there is no ductus arteriosus present. Often the condition of the patient with a ductal-dependent lesion will improve greatly with the initiation of PGE_1 therapy, and the patient may not need to be rushed to the cardiac referral center as an emergent case.

On rare occasions, the neonate may have progressive instability after initiation of PGE_1 therapy. This important diagnostic finding strongly suggests a congenital heart defect with obstructed blood flow out of the pulmonary veins or the left atrium.

The following are types of CHD unresponsive to PGE_1 therapy:

- Hypoplastic left-sided heart syndrome with a restrictive foramen ovale or intact atrial septum
- Variants of mitral atresia with a restrictive foramen ovale
- Transposition of the great arteries with an intact ventricular septum and restrictive foramen ovale
- Total anomalous pulmonary venous return with obstruction of the common pulmonary vein

If the neonate clinically deteriorates despite receiving PGE_1 therapy, urgent echocardiography is indicated, followed by prompt transfer to a cardiac unit.[193] Controversy exists as to whether PGE_1 therapy should be continued in these rare instances, but most importantly, the apparent lack of response is a marker for rare forms of CHD that do not respond to medical management and require urgent surgical or catheter intervention.

Although PGE_1 is critical in the management of DDCHD, there are several potential adverse effects associated with PGE_1 that must be anticipated, particularly in the premature neonate, in which they occur more commonly (Table 19.3). Apnea and hypotension usually manifest themselves during the first few hours of administration but can occur at any time during the infusion. Judicious fluid resuscitation will generally normalize the blood pressure in cases of hypotension.[203] If hypotension is refractory to fluid administration, an alternative cause of hypotension should be considered (e.g., a restrictive ductus, pericardial effusion, myocardial dysfunction, sepsis), and inotropes should be prepared. Hypotension is a late finding in neonatal cardiogenic shock and ideally should be managed before transport during the stabilization phase. Standards for septic shock management should be followed regardless of the care environment.[204]

TABLE 19.3 Adverse Effects of Prostaglandin E_1 Infusion

Most Common	Less Common
• Hypotension due to vasodilation	• Seizures
• Apnea	• Gastric outlet obstruction
• Rash	• Cortical hyperostosis
• Fever	• Leukocytosis

Data from Kramer HH, Sommer M, Rammos S, et al. Evaluation of low dose prostaglandin E_1 treatment for ductus dependent congenital heart disease. *Eur J Pediatr*. 1995;154:700–707; Lewis AB, Freed MD, Heymann MA, et al. Side effects of therapy with prostaglandin E_1 in infants with critical congenital heart disease. *Circulation*. 1981;64:893–898; Arav-Boger R, Baggett HC, Spevak PJ, et al. Leukocytosis caused by prostaglandin E_1 in neonates. *J Pediatr*. 2001;138:263–265; Teixeira OHP, Carpenter B, MacMurray SB, et al. Long-term prostaglandin E_1 therapy in congenital heart defects. *J Am Coll Cardiol*. 1984;3:838–843.

The potential side effect profile of PGE_1 mandates the need for ongoing cardiorespiratory monitoring during transport; however, it does not in and of itself usually require intubation and mechanical ventilation without the presence of significant or recurrent apnea.[203,205] Low-dose PGE_1 infusions are unlikely to cause apnea requiring mechanical ventilation, and neonates can be safely transported without an artificial airway being established in most cases.[206]

Vascular Access

Umbilical venous catheters (UVCs) and umbilical arterial catheters (UACs) are useful in the stabilization and transport of critically ill neonates, including those with CHD. Placement of these lines is not without risk. Beyond the infectious risks, newborns with CHD are at a higher risk of thromboembolic events because of their immature clotting mechanisms, small-vessel lumens, and low flow states. There is also an ongoing risk of systemic embolization of air in babies with an intracardiac right-to-left shunt. There has been much controversy surrounding the optimal placement of a UAC in premature neonates, although there are scant data regarding term neonates with CHD. Historically, high UACs have been preferred due to a presumed lower risk of vascular complications (Table 19.4).

Catheter tip positions between the high-lying and low-lying designations are associated with increased risks of complications, as are placements below the L5 level.[207] The tip of the UVC should be placed, if possible, at the inferior vena cava/right atrial junction or in the atria. It might not be necessary to obtain ideal placement of either the UAC or the UVC for stabilization and transport, and manipulation of line position and reconfirmation can delay transport to the tertiary care center. The risk-benefit relationship for the use of umbilical lines in the neonate with ductal-dependent circulation has not been well delineated. The need for central access should be judged based on the clinical status of the neonate and stability for transport.

TABLE 19.4 Features of High-Lying Versus Low-Lying Umbilical Artery Catheters

High	Low
• Catheter tip above diaphragm, below left subclavian artery, ~T6–T10 • Decreased risk of vascular complications • No significant increase in adverse sequelae	• Catheter tip below renal arteries, above aortic bifurcation, ~L3–L5

Data from Barrington KJ. Umbilical artery catheters in the newborn: effects of position of the catheter tip. *Cochrane Database Syst Rev.* 2000;1999(2):CD000505; Hermansen MC, Hermansen MG. Intravascular catheter complications in the neonatal intensive care unit. *Clin Perinatol.* 2005;32:141–156.

Surgical Emergencies

Because most births occur in hospitals without a NICU or neonatal surgical services, the need for surgical evaluation or intervention is a common reason for interfacility transport. While some surgical conditions are relatively nonurgent, there are several diagnoses that represent truly life-threatening conditions for which stabilization and transport require expertise and specialized resources.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) presents along a spectrum of severity, is associated with pulmonary hypoplasia and hypertension, and can be isolated or accompanied by other congenital malformations. Prenatally diagnosed CDH are typically associated with larger size defects and have higher morbidity and mortality as compared to postnatally diagnosed CDH.[208] Protocolized management of CDH patients at high volume centers is likely to improve outcomes.[209,210]

The following are important in the transport of critically ill neonates with known or suspected CDH[211]:

- Secure the airway
  - For respiratory distress, use endotracheal intubation, not nasal CPAP or high-flow nasal cannula
- Use gentle ventilation approach:
  - Allow permissive hypercapnia
  - Limit peak airway pressures
  - Use low tidal volumes
  - Allow spontaneous breathing as much as possible with judicious use of sedation and neuromuscular agents
- Decompress the bowel with a nasogastric or orogastric tube connected to low intermittent suction
- Obtain central venous and arterial access prior to transport
- Maintain adequate systemic blood pressure with fluid and inotropes as needed

Transport to a high-volume center with ECMO capabilities is recommended since a subset of severe CDH patients will benefit from ECMO as a bridge to surgical repair while resting the lung and heart and avoiding the side effects of mechanical ventilation.[212]

Abdominal Wall Defects

The proper management of a newborn with gastroschisis or an omphalocele is critical during the first several hours after birth, and delivery in a tertiary care center has been associated with improved outcome.[213] In addition to the need for initial resuscitation and cardiorespiratory support, the correct treatment of the exposed bowel or sac may improve the newborn's chances of a successful repair and long-term intestinal function.

While current guidelines aim for at least 38 weeks estimated gestational age for elective cesarean delivery, the mean gestational age for newborns with gastroschisis in previous decades was 36 weeks.[214] Many affected neonates are small for their gestational age,[215] and as with other mildly premature and growth-restricted neonates, patients with gastroschisis are at risk for hypothermia and hypoglycemia. Heat loss is exacerbated by the large surface area of the exposed intestines, which also serve as a significant source of fluid loss. Prevention of both losses can be accomplished by placement of the lower part of the neonate's body, including the intestines, into a transport bag (i.e., bowel bag or Lahey bag) before placement of the neonate into the heated transport isolette. Significant fluid losses can still occur through the exposed mucosa, and the patient may require aggressive fluid administration (120 to 150 mL/kg/day). The use of antibiotics should be considered if risk factors for sepsis are present.

Neonates with gastroschisis are at risk for intestinal vascular compromise because the vascular pedicle containing the bowel's arterial supply and venous drainage must pass through the relatively small abdominal wall defect. Transport personnel must closely monitor the appearance of the bowel to detect signs of venous congestion or ischemia. Transporting the neonate in the lateral position, with support of the exposed intestines to avoid tension or torque, is recommended. The use of intestinal pulse oximetry has been described for monitoring the bowel for ischemia through a transparent silo but has not been studied as a tool during interfacility transport.[216] Vascular compromise of the intestine is a surgical emergency, and communication with the receiving facility is essential to coordinate urgent intervention.

The transport of a neonate with an omphalocele has similar considerations, although unless the sac has ruptured, there is minimal risk of heat and fluid loss. Neonates with an omphalocele are more likely than those with gastroschisis to have other birth defects (e.g., CHD). Furthermore, neonates with giant omphaloceles often have respiratory insufficiency caused by diaphragmatic dysfunction, pulmonary hypoplasia, or both and may require ventilatory assistance.

All neonates with gastroschisis or an omphalocele require placement of a large-bore nasogastric or orogastric tube because of the functional ileus or intestinal obstruction that may occur with associated stenoses or atresias. In general, cannulation of the umbilical vessels is not recommended unless obtaining other means of vascular access are not successful.

Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia, with or without tracheoesophageal fistula, is typically diagnosed within the first day after birth because of increased secretions, poor feeding, and respiratory distress. General transport considerations include placing a large-bore sump-type tube for continuous aspiration of the proximal esophageal pouch; positioning prone with the head of the bed elevated; and providing respiratory support as needed. Direct aspiration of secretions into the trachea may occur with either a proximal or a distal tracheoesophageal fistula. Transport providers should be aware that neonates with a distal tracheoesophageal fistula (type C), characterized by the presence of air in the intestinal tract, are at risk of gastric and intestinal insufflation via the fistula when receiving positive pressure ventilation. Bag-mask ventilation and CPAP should be avoided. If the neonate requires endotracheal

intubation, the endotracheal tube should be positioned as close to the carina as tolerated to position the distal tip beyond the fistula and minimize direct inflation of the distal esophageal segment with pressurized gas. In extreme cases, gastric rupture with pneumoperitoneum has been reported, requiring emergency paracentesis, laparotomy, or both.[217]

Midgut Volvulus

Malrotation with midgut volvulus can be a catastrophic event resulting in intestinal ischemia and shock and represents a surgical emergency. The most common clinical presentation of midgut volvulus is bilious vomiting, which is a nonspecific sign of intestinal obstruction. Expeditious evaluation of the newborn with bilious vomiting is essential to facilitate prompt surgical intervention to prevent progression of vascular insufficiency to actual intestinal necrosis. An upper gastrointestinal tract series is the radiologic test of choice to diagnose malrotation and midgut volvulus, although some practitioners have reported success with the use of ultrasound examination to identify the relationship of the superior mesenteric vessels.[218,219]

A neonate with suspected midgut volvulus should be rapidly cared for in a facility with pediatric radiology and surgical capabilities. Care of the neonate with suspected midgut volvulus during interfacility transport is primarily supportive and includes circulatory interventions with intravenous fluid repletion, correction of metabolic abnormalities, and gastric decompression with a large-bore nasogastric or orogastric tube.

Necrotizing Enterocolitis

Necrotizing enterocolitis occurs primarily in premature neonates, and approximately 30% of affected newborns will require surgical intervention in the form of laparotomy or peritoneal drain placement.[220] Neonates with moderate or severe necrotizing enterocolitis should be transported to a facility with pediatric surgical capabilities. Care during transport is primarily supportive and includes intravenous fluids, administration of broad-spectrum antibiotics, correction of metabolic abnormalities, and gastric decompression. Respiratory failure is common because of disordered control of breathing and elevation of the diaphragm from abdominal distention. With significant free intraperitoneal air or pneumatosis and changes in altitude, neonates may be at risk of intra-abdominal hypertension and abdominal compartment syndrome. Transport providers should be aware of this and discuss potential interventions, such as a peritoneal drain, with the MCP and referring provider before departure from the referring facility. Abdominal decompression before transport has been previously recommended for the transport of neonates with pneumoperitoneum.[221]

Meningomyelocele

For purposes of transport, the newborn with myelomeningocele should be placed in the prone position, and the spinal defect covered with moist sterile dressings as well as some form of plastic wrap to maintain moisture. The lesion can be covered with a moistened nonadherent dressing and then loosely encircled with a gauze roll "donut," with the entire defect covered with a sterile drape. This dressing can be moistened as required during the transport process. The use of latex gloves should be avoided during care of these patients. If cerebrospinal fluid leakage is observed or suspected, there is an increased risk of infection, and empiric antibiotics should be considered. Neonates with a meningomyelocele may or may not have accompanying hydrocephalus at birth; approximately 25% of affected patients will require shunting in the immediate newborn period, with up to 85% eventually undergoing shunt placement.[222] In one institution, the percentage of patients necessitating shunt placement was reduced when stricter criteria were used, including permissive mild ventricular dilatation and the presence of symptomatic hydrocephalus.[223] Furthermore, the results of the Management of Myelomeningocele Study, which demonstrated reduced need for shunt placement and corresponded with improved neurologic and motor outcomes at 30 months following in utero repair of the spinal defect, may lead to additional practice changes in postnatal shunt placement.[224]

Future Directions

The field of transport medicine has grown substantially in the past several decades and will continue to grow and change, particularly in relation to its special and vulnerable patient population. The goals include rapid awareness of need, clear communications, and delivery of care that is similar to that in our level III/IV NICUs. Development of standards and guidelines will enable us to assess the impact of neonatal transport and the opportunity it provides for patients and clinicians. The role of developing technologies, such as telemedicine, will likely have an increasing presence in referral hospitals as well as for use by transport teams. In addition, there will likely be increasing attention paid to cost and value, especially of high-cost air transport, that may lead to stricter criteria and a greater push toward national transport guidelines, and potentially even drones may play a role at least in equipment and medication delivery to outlying hospitals. The transport of critically ill neonates is most often a high-risk, low-frequency event in the context of all patient transfers. Therefore, as systems move forward, it is imperative to ensure the highest level of skill and competence both in the transport team personnel and in the facilities that refer and receive these patients—be it through team specialization, regionalization of high level neonatal critical care, or support of telemedicine and outreach initiatives.

Fluid, Electrolyte, and Acid-Base Balance

CLYDE J. WRIGHT, MICHAEL A. POSENCHEG, AND ISTVAN SERI

KEY POINTS

- In the neonate, many pathologic states and/or their treatment are associated with disruptions in normal body fluid, electrolyte, and acid-base balance, which at times may in themselves become life-threatening.
- Conversely, many conditions may be negatively affected by disruptions of normal body fluid, electrolyte, and acid-base balance occurring independently of the condition itself.
- The maintenance of normal fluid, electrolyte, and acid-base balance is a cornerstone of appropriate management of the sick neonate.

Fluid and Electrolyte Balance

Maintenance of fluid and electrolyte balance is essential for normal cell and organ function during intrauterine development and throughout extrauterine life. In the newborn, pathologic conditions and/or their treatment often lead to disruption of the complex regulatory mechanisms maintaining homeostasis. In addition, pathologic conditions themselves may be negatively affected by disruptions of normal body fluid, electrolyte, and acid-base balance occurring independently of the condition itself. Therefore, a thorough understanding of the physiologic changes in the neonatal period and the provision of appropriate therapies, based on the principles of developmental fluid and electrolyte physiology, are among the cornerstones of modern neonatal intensive care.

Developmental Changes Affecting Fluid and Electrolyte Balance in the Fetus and Neonate

Developmental Changes in Body Composition and Fluid Compartments

Dynamic changes occur in body composition and fluid distribution during intrauterine life, labor and delivery, and the early postnatal period. Thereafter the rate of change in body composition and fluid distribution gradually decreases, with subtler changes occurring especially after the first year of age.[1,2]

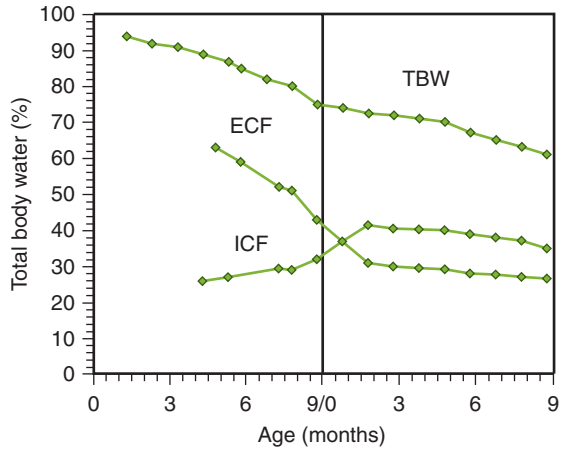
Changes During Intrauterine Development

In early gestation, body composition is characterized by a high proportion of total body water (TBW) and a large extracellular compartment.[3,4] As gestation advances, rapid cellular growth, accretion of body solids, and fat deposition and developmental changes in the production of hormones regulating body water homeostasis result in gradual reductions in TBW content and extracellular fluid (ECF) volume, while the intracellular fluid compartment increases (Fig. 20.1).[3] In the 16-week-old fetus, TBW represents approximately 94% of total body weight; approximately two-thirds and one-third of the TBW are distributed in the extracellular and intracellular compartments, respectively. After delivery, TBW decreases by 1.44% per week in preterm neonates.[2] By term gestation, TBW represents 75% of body weight, and approximately half of this volume is located in the intracellular compartment. Therefore, premature newborns have excess TBW and a larger extracellular volume compared with their term counterparts at birth, with most of the expanded extracellular volume being distributed in the interstitium.[5]

Changes During Labor and Delivery

Greater changes in TBW and its distribution occur during labor and delivery. Arterial blood pressure rises several days before delivery because of increases in plasma catecholamine, vasopressin, and cortisol levels, as well as translocation of blood from the placenta into the fetus. This rise in arterial blood pressure, along with changes in the fetal hormonal milieu and an intrapartum hypoxia-induced increase in capillary permeability, results in a shift of fluid from the intravascular to the interstitial compartment and an associated approximately 25% reduction in circulating plasma volume in the human fetus during labor and delivery.[5] If the cord is not clamped immediately after delivery of the body, placental transfusion tends to restore the circulating blood volume,[6] while the postnatal increase in oxygenation and changes in vasoactive hormone production act to restore capillary membrane integrity and favor absorption of interstitial fluid into the intravascular compartment. The return of interstitial fluid into the bloodstream aids in maintaining intravascular volume during the first 24 to 48 hours postnatally, when oral fluid intake may be limited. The return of interstitial fluid also triggers the release of atrial natriuretic peptide, which is—at least in part—responsible for the physiologic diuresis commencing on postnatal days 2 and 3.[7] However, prematurity, pathologic conditions, or both can disrupt this delicate process and interfere with the physiologic contraction of the ECF compartment in the immediate postnatal period.

In the fetus, body composition and fluid balance depend on the electrolyte and water exchange between the mother, fetus, and amniotic space.[8] Antenatal events can have significant effects on postnatal fluid balance. Maternal indomethacin treatment or excessive administration of intravenous (IV) fluids during labor



• **Fig. 20.1** Total body water content and its distribution between the extracellular fluid and intracellular fluid compartments in the human fetus, newborn, and infant from conception until 9 months of age. *ECF*, Extracellular fluid; *ICF*, intracellular fluid; *TBW*, total body water. (The data represent average values from Friis-Hansen B. Body water compartments in children: changes during growth and related changes in body composition. *Pediatrics*. 1961;28:169–181.)

can result in neonatal hyponatremia with expanded extracellular water content.[9] Placental insufficiency or maternal diuretic therapy can impair fetal extracellular volume, urine output, and amniotic fluid volume.[10]

Effect of Timing of Cord Clamping

The timing of cord clamping after delivery is another important factor significantly affecting total circulating blood volume and extracellular volume in the neonate. Immediate cord clamping does not allow placental transfusion and negatively influences hemodynamic transition, especially in preterm neonates.[11] However, if cord clamping is delayed, up to 25 to 50 mL of blood per kilogram is transfused into the neonate, representing an approximately 25% to 50% increase in the total blood volume.[6] In a metanalysis of term neonates, delayed cord clamping for at least 30 seconds was associated with increased iron stores and higher birth weight but with a higher need for phototherapy.[12] In a metanalysis in preterm neonates, delayed cord clamping was associated with significantly decreased rates of intraventricular hemorrhage (IVH) and necrotizing enterocolitis, and the need for inotropic support and blood transfusion.[13] The use of novel resuscitation trolleys[14] and a better understanding of the cardiorespiratory impact of resuscitating neonates with the cord unclamped[15] have led to a more widespread use of delaying cord clamping in the clinical practice.[16] Animal data[17] and earlier observations in term neonates[18] also suggest that the establishment of an appropriate functional residual capacity is the most relevant factor in determining the volume and rapidity of placental transfusion when cord clamping is delayed. Accordingly, neonates who do not establish effective respirations and who require resuscitation at birth may be at additional risk of lower circulating blood volumes. Although further data are still needed to understand whether increased blood volume at birth is associated with improved long-term outcomes, the American College of Obstetricians and Gynecologists now recommends delaying cord clamping for 30 to 60 seconds after birth in vigorous preterm and term neonates;[19] the World Health Organization recommends it for all newborns.[20]

Changes in the Postnatal Period

In the first few days and weeks after birth, the TBW content and distribution are affected by gestational and postnatal ages, pathologic conditions, the immediate environment (temperature, humidity), and the type of nutrition (enteral vs. parenteral). Normally, in the first few days after birth, an increase in capillary membrane integrity favors absorption of the interstitial fluid into the intravascular compartment.[21] The ensuing rise in circulating blood volume stimulates the release of atrial natriuretic peptide (ANP) from the heart, which in turn enhances renal sodium and water excretion,[22] resulting in an abrupt decrease in TBW and attendant weight loss. Although it is generally accepted that this postnatal weight loss is primarily due to the contraction of the expanded ECF compartment, some water loss from the intracellular compartment can also occur, particularly in infants with extremely low birth weight (ELBW) and increased transepidermal water losses (TEWLs).[21,23]

Healthy term newborns lose approximately 10% of their birth weight during the first 4 to 7 days of age[5] and, thereafter, they establish a pattern of steady weight gain. As preterm neonates have an increased TBW content and extracellular volume, they lose approximately 10% to 15% of their birth weight during this period[5,24] and, depending on the degree of prematurity and associated pathologic conditions, these neonates only regain their birth weight by 10 to 20 days after birth (Fig. 20.2). Neonates who have intrauterine growth retardation have a smaller initial weight loss and more rapidly regain their birth weight than their normally grown counterparts, whether term or preterm.[25] Although the mechanisms for these differences have not been well studied, they appear to be associated with less diuresis in the infant with intrauterine growth retardation.[25,26]

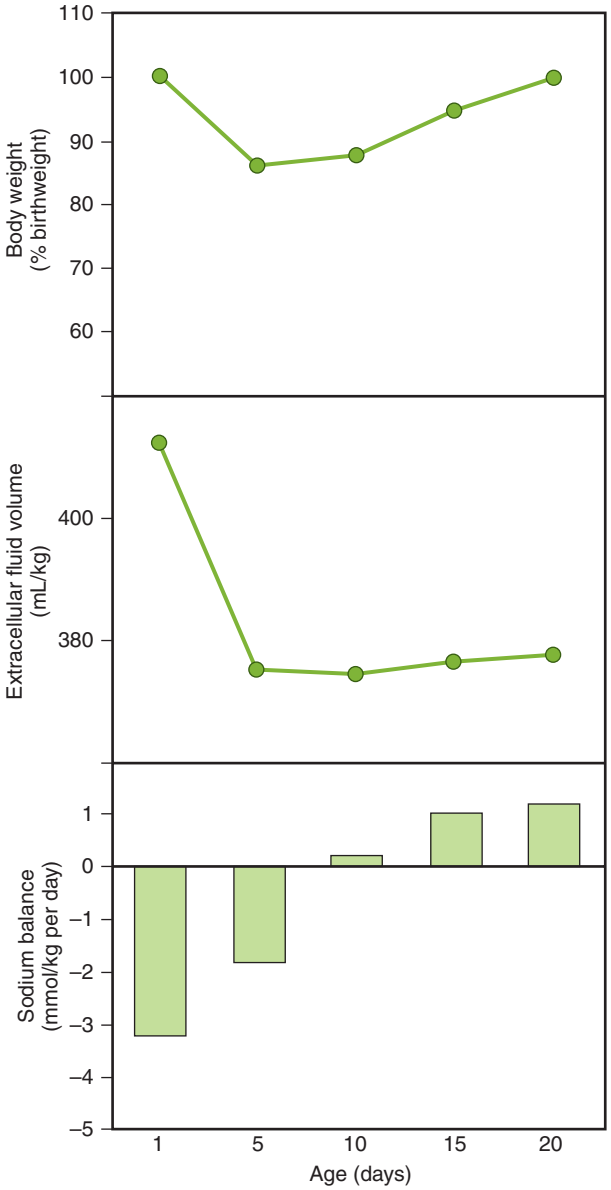
In the management of the neonate, it is important that the appropriate weight loss be anticipated and facilitated, if necessary, as the lack of the early postnatal weight loss has been associated with higher rates of persistency of patent ductus arteriosus (PDA), bronchopulmonary dysplasia (BPD), and necrotizing enterocolitis in low birthweight infants.[27–29]

Physiology of the Regulation of Body Composition and Fluid Compartments

Although human cells have the ability to adjust their intracellular composition, extracellular volume and osmolality affect intracellular conditions. If these changes are too dramatic, they may go beyond the cells' capacity to appropriately maintain the normal intracellular milieu. Therefore, monitoring and active regulation of extracellular volume and osmolality are necessary in sick infants and those born prematurely.

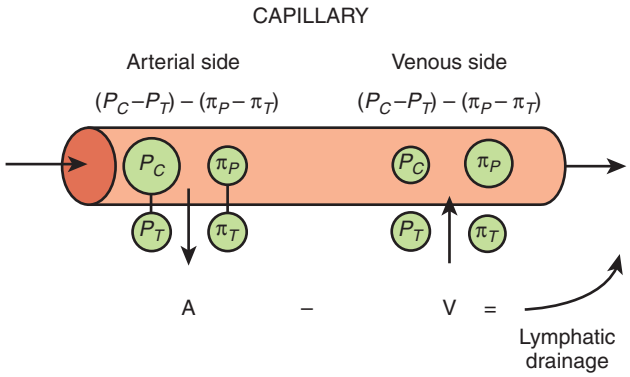
Regulation of the Intracellular Solute and Water Compartment

The major intracellular solutes include the proteins necessary for cell function, the organic phosphates associated with cellular energy production and storage, and the equivalent cations balancing the phosphate and protein anions.[30] As a consequence of the function of the cell membrane-bound sodium-potassium-ATPase enzyme, potassium is the major intracellular and sodium the major extracellular cation. The energy derived from the concentration differences for sodium and potassium between the intracellular and extracellular compartments is used for cellular work. Because changes in osmolality of the extracellular compartment are reflected as net movements of water into or out of the cell,



• **Fig. 20.2** Postnatal changes in body weight (expressed as a percentage of birth weight), extracellular fluid volume (estimated by the bromide dilution method), and sodium balance (defined as the difference between sodium intake and urinary sodium excretion). (From Shaffer SG, Weismann DN. Fluid requirements in the preterm infant. *Clin Perinatol*. 1992;19:233–250.)

regulation of ECF osmolality ultimately controls the intracellular compartment.[30] This physiologic principle must be kept in mind when managing sick term and preterm neonates with disturbances of sodium homeostasis. Rapid changes in serum sodium concentration, and thus in extracellular osmolality, directly affect the osmolality and size of the intracellular compartment and can lead to irreversible cell damage, especially in the central nervous system (CNS). Hyponatremia in the neonatal period has been associated with adverse long-term outcomes, especially in preterm neonates, while hypernatremia has been associated with short-term morbidities, including seizures and thrombosis.[31–33] These associations underscore the importance of maintaining appropriate fluid and electrolyte homeostasis in the neonatal period.



• **Fig. 20.3** Filtration and reabsorption of fluid along the capillary under physiologic conditions. *A*, Arterial; P_C, capillary hydrostatic pressure; P_T, tissue/interstitial hydrostatic pressure; *V*, venous; π_P, plasma oncotic pressure; π_T, tissue/interstitial oncotic pressure.

Regulation of the Intracellular–Extracellular Interface: The Interstitial Compartment

In the healthy term neonate, hydrostatic (P_C, capillary hydrostatic pressure; P_T, tissue/interstitial hydrostatic pressure) and oncotic (π_P, plasma oncotic pressure; π_T, tissue/interstitial oncotic pressure) pressures are well-balanced, with both being approximately half of those in the adult.[34] Under normal physiologic conditions, movement of fluid across the capillary is determined by the direction of the net driving pressure ($[P_C - P_T] - [\pi_P - \pi_T]$), the water permeability and the protein permeability, as well as transport characteristics of the capillary wall (Fig. 20.3). At the arterial end of the capillary, intracapillary hydrostatic pressure (P_C) is high and plasma oncotic pressure (π_P) is relatively low, resulting in a net movement of fluid out of the capillary. As filtration of relatively protein-poor fluid continues along the capillary, plasma oncotic pressure rises and intracapillary hydrostatic pressure drops; therefore on the venous side, fluid moves from the interstitium into the capillary and thus the majority (85% to 90%) of the filtered fluid is reabsorbed at the end of the capillary bed. The fluid remaining in the interstitium (arterial–venous side of the capillary) is drained by the lymphatic system. Interstitial hydrostatic (P_T) and oncotic (π_T) pressures remain virtually unchanged along the capillary bed. However, pathologic conditions readily disturb the delicate balance between the hydrostatic and oncotic forces, leading to an expansion of the interstitial compartment at the expense of the intravascular compartment. The increased interstitial fluid volume (edema) then further affects tissue perfusion by altering the normal function of the extracellular–intracellular interface. Box 20.1 summarizes the mechanisms for conditions resulting in interstitial edema formation in the neonate. There are also some important developmentally regulated differences between the newborn and the adult relating to the pathogenesis of edema formation. Capillary permeability to proteins is increased during the early stages of development.[5,35] Because neonatal capillary permeability is further increased under pathologic conditions (see Box 20.1), protein concentration in the interstitial compartment may approach that of the intravascular space, favoring further intravascular volume depletion and interstitial volume expansion. The findings of most[36,37] but not all[38] clinical studies suggest that 0.9% saline administration for suspected hypovolemia is associated with less fluid retention and similar improvements in the cardiovascular

• BOX 20.1 Mechanisms for Conditions Causing Interstitial Edema in the Neonate

Conditions Favoring Fluid Accumulation in Interstitial Space by Causing Disequilibrium Between Filtration and Reabsorption of Fluid by Capillaries

Increased hydrostatic pressure
Elevated capillary hydrostatic pressure
Increased cardiac output
Venous obstruction
Decreased tissue hydrostatic pressure
Conditions associated with changes in the properties of the interstitial gel (edematous states, effects of hormones including prolactin)
Decreased oncotic pressure gradient
Decreased capillary oncotic pressure
Prematurity, hyaline membrane disease
Malnutrition, liver dysfunction
Nephrotic syndrome
Increased interstitial oncotic pressure is usually the result of increased capillary permeability.
Elevation of the filtration coefficient
Increased capillary permeability
Organs with large-pore capillary endothelium (liver, spleen)
State of maturity (preterm infants > term newborns > adults)
Production of proinflammatory cytokines (sepsis, anaphylaxis, hypoxic tissue injury, tissue ischemia, ischemia–reperfusion, soft tissue trauma, extracorporeal membrane oxygenation)
Increased capillary surface area
Vasodilation

Conditions Associated With Decreased Lymphatic Drainage

Decreased muscle movement
Neuromuscular blockade and/or heavy sedation
Central and/or peripheral nervous system disease
Obstruction of lymphatic flow
Increased central venous pressure
Scar tissue formation (bronchopulmonary dysplasia)
Mechanical obstruction (dressings, high mean airway pressure in mechanically ventilated newborns)

status compared with 4.5% or 5% albumin infusion; however, the topic requires further investigation.

Even in the presence of hypoalbuminemia, when sick neonates are treated with frequent albumin boluses, much of the infused albumin rapidly leaks into the interstitium. This creates a vicious cycle of intravascular volume depletion and edema formation, resulting in vasoconstriction and disturbances in tissue perfusion and cellular function, exacerbating impairments in the regulation of extracellular volume distribution. If the cycle is not interrupted, anasarca develops, which is usually associated with an extremely poor prognosis. In summary, the sick neonate has limited capacity to maintain appropriate intravascular volume and to regulate the volume and composition of the interstitium, and high vigilance is thus required by the caretaker in appropriately managing intravascular volume, including avoiding routine use of albumin in the critically ill neonate.[39]

Regulation of the Extracellular Solute and Water Compartment

The osmolality of the extracellular compartment is tightly maintained within 2% of the osmolar set point, which lies between 275 and 290 milliosmoles (mOsm).[40] Blood pressure and serum sodium concentration (i.e., the main contributor to osmolality under homeostatic conditions) are monitored by baroreceptors and osmoreceptors, respectively. The effector limb of the regulatory system consists of the heart, vascular bed, kidneys, and intake of fluid in response to thirst. The inability of critically ill term and preterm neonates to maintain fluid balance by responding to thirst places increased importance on caregiver management of fluid administration. By regulating the function of the effector organs, several hormones play a role in the control of the extracellular compartment, including the renin–angiotensin–aldosterone system (RAAS), vasopressin, ANP, brain (B-type) natriuretic peptide (BNP), bradykinin, prostaglandins, and catecholamines. Effective regulation of the extracellular compartment and intravascular volume also depends on intact cardiovascular function and capillary endothelium integrity.[40] For example, under physiologic conditions, an increase in the extracellular volume is reflected by an increase in the circulating plasma volume, leading to increased blood pressure and renal blood flow. The ensuing increase in glomerular filtration and the hormonally mediated inhibition of renal tubular sodium and water reabsorption result in increased urine output returning the extracellular volume to a normal level. In critically ill neonates, however, the capillary leak and reduced myocardial responsiveness resulting from immaturity and underlying pathologic conditions limit the increase in the circulating blood volume when extracellular volume expands. Thus, especially in sick preterm neonates, blood pressure may rise only transiently,[41] and renal blood flow may remain low after volume boluses as fluid rapidly leaks into the interstitium. Inappropriate central regulation of vascular tone results in vasodilatation, further decreasing effective circulating blood volume and compromising tissue perfusion; this leads to impaired gas exchange in the lungs, resulting in hypoxia with further increases in capillary leak. Unless it is interrupted by appropriate therapeutic measures, a vicious cycle with further deterioration readily occurs in the sick neonate.

Maturation of Organs Regulating Body Composition and Fluid Compartments

The heart, kidneys, skin, and endocrine system play the most important roles in the regulation of ECF (and thus intracellular fluid) and electrolyte balance in the neonate. Immaturity of these organ systems, especially in infants with very low birth weight (VLBW), results in a compromised regulatory capacity, which must be noted in the estimation of daily fluid and electrolyte requirements in these patients.

Maturation of the Cardiovascular System

There is a direct relationship between gestational maturity and the ability of the neonatal heart to respond to acute volume loading.[42] The blunted Starling response of the immature myocardium primarily results from its lower content of contractile elements, immature intracellular calcium handling, and incomplete sympathetic innervations.[43] Because central vasoregulation and endothelial integrity are also developmentally regulated,[5,35] an appropriate intravascular volume is seldom maintained in the critically ill preterm neonate. Since regulation of the extracellular volume requires the maintenance of an adequate effective circulating blood volume, the immaturity of the cardiovascular system contributes to the limited capacity of sick preterm neonates to effectively regulate the total volume of their extracellular compartment.

Maturation of Renal Function

The kidney has a crucial role in the physiologic control of fluid and electrolyte balance. It regulates extracellular volume and osmolality through the selective reabsorption of sodium and water, respectively. Immaturity of renal function renders preterm neonates susceptible to excessive sodium and bicarbonate losses.[21,44] As described earlier, the inability of the preterm neonate to respond promptly to a sodium or volume load also results in a tendency toward extracellular volume expansion with edema formation. Because prenatal steroid administration accelerates maturation of renal function,[45] preterm neonates exposed to steroids in utero have a better capacity to regulate their postnatal ECF contractions. During the first few weeks postnatally, hemodynamically stable but extremely immature infants produce dilute urine and may develop polyuria because of their renal tubular immaturity. As tubular functions mature, their concentrating capacity gradually increases from the second to the fourth postnatal week. However, it takes years for the developing kidney to reach the concentrating capacity of the adult kidney.[46]

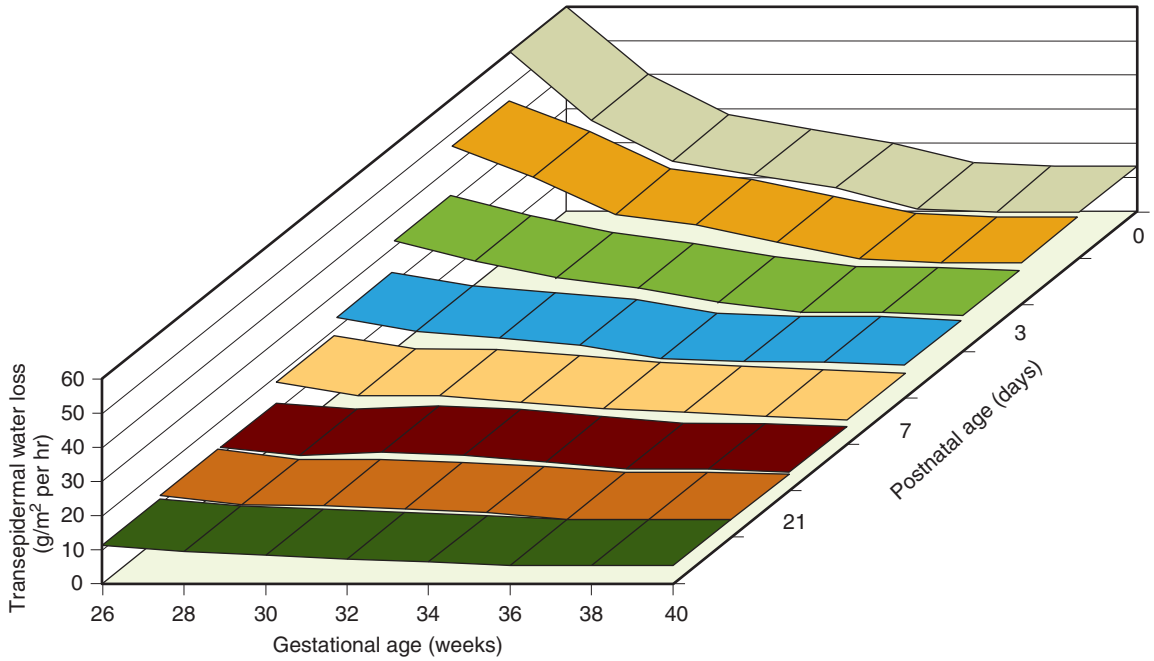
Maturation of the Skin

Although the epidermis of term neonates is well developed and cornified, in extremely immature neonates it consists of only two or three cell layers.[47] The absence of an effective barrier to the diffusion of water increases TEWL in the immature neonate. TEWL through immature skin can result in early postnatal hypertonic dehydration, with rapid changes in intracellular volume and osmolality. In many organs, especially the brain, these abrupt changes can result in cellular dysfunction and ultimately cell death. Gestational age, postnatal age, the pattern of intrauterine growth, and environmental factors (e.g., humidity and temperature) affect transepidermal free water loss (Fig. 20.4). Postnatal skin cornification occurs rapidly, but full maturation of the epidermis does not occur until 2 to 3 weeks of age.[48] Chronic intrauterine stress[49] and prenatal steroid treatment[50] also enhance maturation of the skin.

Maturation of End-Organ Responsiveness to Hormones Involved in the Regulation of Fluid and Electrolyte Balance

Several hormones directly regulate the volume and composition of the extracellular compartment by altering renal sodium and water excretion, as well as by inducing changes in systemic vascular resistance and myocardial contractility. These include the RAAS, vasopressin, ANP, and BNP. Other hormones, including the prostaglandins, bradykinin, and prolactin, acting via endocrine, paracrine, or autocrine mechanisms modulate the actions of many of the regulatory hormones.

Renin–Angiotensin–Aldosterone System. Decreases in renal capillary blood flow stimulate renin secretion from the juxtaglomerular cells of the kidney, which in turn catalyzes the conversion of angiotensinogen to angiotensin I. Angiotensin-converting enzyme hydrolyzes angiotensin I to angiotensin II, which can then bind to the cell membrane–bound receptors AT_1 and AT_2.[51] Angiotensin induces vasoconstriction, increased tubular sodium and water reabsorption, and the release of aldosterone.[51] Aldosterone increases potassium secretion and further enhances sodium reabsorption in the distal tubule; therefore the primary function of this system is to protect the volume of the extracellular compartment, maintain adequate tissue perfusion and mitigate the impact of the hypovolemia-induced metabolic acidosis on potassium homeostasis.[52] However, its effectiveness in the neonate is somewhat limited by the decreased responsiveness of the immature kidney to the sodium- and water-retaining effects of these hormones.[53] Vasodilatory and natriuretic prostaglandins generated



• **Fig. 20.4** Transepidermal water loss in relation to gestational age during the first 28 postnatal days in newborns who are appropriate for their gestational age. There is an exponential relationship between transepidermal water loss and gestational age, the water loss being higher in preterm newborns than in term newborns. Transepidermal water loss is also significantly affected by postnatal age, especially in the immature preterm newborn. The measurements were performed at ambient air humidity of 50% and with the newborns calm and quiet. (From Hammarlund K, Sedin G, Stromberg B. Transepidermal water loss in newborn infants. VIII: relation to gestational age and post-natal age in appropriate and small for gestational age infants. *Acta Paediatr Scand*. 1983;72:721–728.)

in the kidney[54] are the main counterregulatory hormones balancing the renal actions of the RAAS. Therefore, when prostaglandin production is inhibited by indomethacin, the unopposed vasoconstrictive and sodium-retentive actions of the RAAS contribute to the development of the drug-induced renal failure in the preterm neonate.[54,55]

Vasopressin. Vasopressin (antidiuretic hormone) regulates the osmolality of the extracellular compartment and directly affects vascular tone through the V_{1a} and V_2 receptors. Vasopressin selectively raises free water reabsorption through the upregulation of aquaporin-2 water channels in the collecting duct, resulting in blood pressure elevation.[46,56] Plasma levels of vasopressin are markedly elevated in the neonate, especially after vaginal delivery, and its cardiovascular actions facilitate neonatal adaptation.[46,57] Although the developing kidney is less sensitive to circulating vasopressin, the high vasopressin levels are in part also responsible for the diminished urine output of the healthy term neonate during the first day after birth as their renal response to vasopressin is less immature than that of their preterm counterparts. However, under certain pathologic conditions, the dysregulated release of and/or the end-organ unresponsiveness to vasopressin significantly affects renal and cardiovascular functions and electrolyte and fluid status in the sick preterm and term neonate.[58] In the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), an uncontrolled release of vasopressin occurs in sick preterm and term neonates, with resulting water retention, hyponatremia, and oliguria. In the syndrome of diabetes insipidus, the lack of pituitary production of vasopressin or renal unresponsiveness to the hormone results in polyuria and hypernatremia.

Atrial Natriuretic Peptide. Via its direct vasodilatory and renal natriuretic actions, the hormone ANP regulates the volume of the extracellular compartment in the fetus and neonate in a fashion opposite to that of the renin–angiotensin–aldosterone system.[59–61] ANP also has a direct inhibitory effect on renin production and aldosterone release.[62]

The stretch of the atrial wall caused by an increase in the circulating blood volume is the most potent stimulus for ANP release in the cardiovascular system. Plasma levels are high in the fetus[63] and, along with BNP, ANP likely plays a role in cardiac development.[64] There are a few specific conditions in which the actions of ANP are directly relevant for the neonatologist. For example, the hormone is involved in the regulation of both the fluid shifts during labor[5] and the extracellular volume contraction during postnatal transition.[7,65,66] Furthermore, the oliguric effects of positive end-expiratory pressure ventilation are due, in part, to a decrease in ANP secretion[62] along with the enhanced release of vasopressin.[67]

Brain (or B-Type) Natriuretic Peptide. BNP is released from the ventricular myocardium in response to increases in wall tension. Similarly to ANP, BNP causes natriuresis, diuresis, and vasodilatation, while inhibiting the RAAS.[68,69] Compared with ANP, BNP and its inactive N-terminal fragment (NT-proBNP) demonstrate longer half-lives and may thus be more useful clinical biomarkers as their levels are relatively more stable over time.[70] NT-proBNP is renally excreted, and renal function should be considered when interpreting its serum levels.[71]

BNP levels increase by up to 20-fold during the first postnatal day,[72,73] followed by a declining trend during the first postnatal week.[73,74] Not unexpectedly and unlike serum levels of ANP, decreasing BNP levels after the first postnatal day correlate with the downward trend in pulmonary arterial pressure.[75] By causing vasodilatation and diuresis, high levels of BNP play a critical role in the hemodynamic transition of the fetus. The usefulness of measuring BNP levels is limited by the variability of levels in the first few days after birth and, to a certain extent, by the variety of assays available to measure BNP levels. In summary, its clinical utility remains at best uncertain, especially since trending requires repeated measurements in the same patient over time with the same assay.

Prostaglandins. Prostaglandins have a well-documented, counterregulatory role for the renal vascular and tubular effects of renin–angiotensin–aldosterone and vasopressin.[76] The inhibition of prostaglandin synthesis by indomethacin results in clinically important and sometimes detrimental renal vascular and tubular effects especially in the preterm neonate managed with restricted fluid intake.[77] Interestingly, ibuprofen demonstrates fewer side effects than indomethacin on renal and mesenteric blood flow.[77] How prostaglandins modulate the effects of the other regulatory hormones of neonatal fluid and electrolyte homeostasis is less well studied.

Prolactin. Prolactin plays a permissive role in the regulation of fetal and neonatal water homeostasis.[78,79] High fetal plasma prolactin levels contribute to the increased tissue water content of the fetus. Postnatal prolactin levels remain high in the preterm neonate until approximately the 40th postconceptional week.[80] Low levels have been associated with increased risk of developing respiratory distress syndrome (RDS).[81,82] However, the clinical relevance of this observation is unclear.

Management of Fluid and Electrolyte Homeostasis

General Principles of Fluid and Electrolyte Management

Fluid and electrolyte management is one of the cornerstones of neonatal intensive care, and appropriate management requires an understanding of the previously outlined physiologic principles and careful monitoring of key clinical data. Requirements vary substantially from infant to infant and in the same infant over time; therefore, fluid prescription must be individualized and frequently reassessed. The primary goals are to maintain the appropriate ECF volume, extra- and intracellular fluid osmolality, and ionic concentrations.

Assessment of Fluid and Electrolyte Status

Maternal conditions during pregnancy, drugs and fluids administered to the mother during labor and delivery, and specific fetal and neonatal conditions all affect early fluid and electrolyte balance. Excessive administration of free water or oxytocin use in the mother can result in hyponatremia in the neonate. Maternal therapy with indomethacin, angiotensin-converting enzyme inhibitors, furosemide, and aminoglycosides can all adversely affect neonatal renal function. A newborn's history of oligohydramnios or birth asphyxia may also alert the clinician to the possibility of abnormal renal function. In young neonates, altered skin turgor, sunken anterior fontanel, and dry mucous membrane are not sensitive indicators of dehydration, but tachycardia and oliguria present relatively early and hypotension and metabolic acidosis somewhat later during the course of intravascular volume depletion. On the other hand, when there is volume overload or illness, edema usually occurs early. Serial measurements of body weight, intake and output, and serum electrolyte levels will usually provide the most precise and accurate information regarding overall fluid status.

Normally, both term and preterm neonates will void within the first 24 hours after birth.[83] In most neonates without hemodynamic compromise, urine output increases from 1 to 2 mL/kg/h on the first postnatal day to 3 to 5 mL/kg/h by the third to fifth postnatal day and is associated with a weight loss of 5% to 10% in term infants and 10% to 15% in preterm neonates.[84] Frequently, the onset of diuresis heralds the resolution of RDS.[85] However, this phenomenon has become less noticeable after the introduction of early surfactant administration. In critically ill newborns and in situations of altered homeostasis, additional clinical data that may help in diagnosis and management include blood urea nitrogen (BUN) levels, serum and urine osmolarity or specific gravity, and urine electrolyte and serum bicarbonate levels, along with close monitoring of cardiac output and organ blood flow, blood pressure, and heart rate. The frequency of monitoring depends on the extent of immaturity, the underlying pathologic condition, and the severity of the fluid and electrolyte disturbance.

Water Homeostasis and Management

Water Losses

Free water loss can be categorized as either *insensible* (skin and respiratory track) or *sensible* (urine and feces). Urine output is the most important source of sensible water loss. Extremely preterm neonates without systemic hypotension or renal failure usually lose 30 to 40 mL of water per kilogram per day in the urine on the first postnatal day and approximately 120 mL/kg/day by the third day. In stable, more mature preterm neonates born after 28 weeks' gestation, urinary water loss is approximately 90 mL/kg/day on the first postnatal day and 150 mL/kg/day by the third day.[86] Because of their renal immaturity, preterm neonates have a tendency to produce dilute urine, thereby increasing their obligatory free water losses. In term neonates, urinary water loss is considerably less, approximating 40 to 60 mL/kg/day by the third day.

Normal water losses in the stool are less significant, amounting to approximately 10 mL/kg/day in term neonates and 7 mL/kg/day in preterm neonates during the first postnatal week.[23] Water losses in the stool increase thereafter and are influenced by the type of feeding and the frequency of stooling, which is usually higher in breastfed neonates.

In the preterm neonate, consideration of daily insensible water losses (IWLs) through the skin is critical (see Fig. 20.4). During the first few postnatal days, in a nonhumidified environment, TEWLs may be 15-fold higher in extremely premature neonates born at 23 to 26 weeks' gestation than in term neonates.[23] Although the skin matures rapidly after birth, even in extremely immature neonates, insensible losses are still somewhat higher at the end of the first month than in the term counterparts. Prenatal steroid exposure is associated with substantially less IWL in preterm neonates.[50,87]

Appropriate management of the neonate's immediate environment most effectively counteracts the high degree of IWL through immature skin. Among environmental factors, ambient humidity has the greatest effect on TEWL. In extremely immature neonates, a rise in the ambient humidity in the incubator from 20% to 80% decreases the TEWL by approximately 75%.[23] However, the use of an open radiant warmer more than doubles TEWLs,[88] and it is now standard of care to maintain extremely immature neonates in humidified incubators. Other factors that increase transepidermal IWL include phototherapy, especially when the neonate is nursed under low humidity, activity, airflow, elevated body, and environmental temperature as well as skin breakdown and skin or mucosal defects (e.g., gastroschisis, epidermolysis bullosa).

IWLs from the respiratory tract depend mainly on the temperature and humidity of the inspired gas mixture and on the respiratory rate, tidal volume, and dead space ventilation. In a healthy term newborn, the water loss through the respiratory tract is approximately half the total IWL if the ambient air temperature is 32.5°C and the humidity is 50%.[23] However, in neonates undergoing mechanical ventilation, there will be no IWL through the respiratory tract if the ventilator gas mixture is humidified at body temperature.

Extraordinary water losses are also seen in the neonate requiring intensive care. The most commonly encountered extraordinary losses occur when a nasogastric tube is placed under continuous suction (discussed in Surgical Conditions). Large losses may also occur in association with phlebotomy, chest tubes, surgical drains, ostomies, and fistulas, as well as with emesis or diarrhea.

Management of Water Requirements

When managing the fluid status of the neonate, the clinician must consider fluid requirement dictated by three broad categories. First, any existing deficits or surpluses must be estimated. Secondly, ongoing maintenance needs to replace usual sensible and insensible losses, and support for growth must be calculated. Finally, additional needs as a result of extraordinary losses should be anticipated. Importantly, while administered together, the composition of each of these fluids is unique and must be considered individually. For example, fluids given to replace ongoing losses from a chest tube or ostomy will require a different electrolyte composition than simple maintenance fluids to maintain hydration, and these will differ again from fluids given to support growth. The neonate's prenatal history, birth weight, gestational age, and need for mechanical ventilation and the environment in which the neonate is to be cared for should be considered when initial fluid and electrolyte needs are being determined. Frequent reevaluations are necessary. The most useful parameter for monitoring fluid balance is the weight of the baby, as rapid changes in weight will reflect changes in water balance. Serial weights can be used to estimate the IWL with use of the following formulas:

$$\text{IWL} = \text{Fluid Intake} - \text{Urine Output} + \text{Weight Loss}$$

or

$$\text{IWL} = \text{Fluid Intake} - \text{Urine Output} - \text{Weight Gain}$$

It is reasonable to initiate fluid volume on the basis of the sum of an allowance for sensible water loss of 30 to 60 mL/kg/day and the estimated IWL. Fig. 20.4 shows usual IWL ranges by gestational and postnatal age. Factors previously outlined that predictably affect IWL should be considered when fluids are being prescribed. However, prevention of excessive IWL rather than replacement of increased IWL is associated with fewer complications in the preterm neonate and can usually be achieved by modification of the neonate's environment. See Table 20.1 for usual maintenance fluid administration based on birth weight. These numbers are guidelines for initial management only; the approach must subsequently be individualized on the basis of laboratory values and other clinical data.

It is important to remember that the TBW excess and extracellular volume expansion of preterm neonates imply that their negative water and sodium balance during the first 5 to 10 postnatal days (see Fig. 20.2)[24] represents an appropriate adaptation to extrauterine life and should not be compensated for by increased fluid administration and sodium supplementation. If this

TABLE 20.1 Estimated Maintenance Fluid Requirements

Birth Weight (g)	DAILY FLUID REQUIREMENTS (ML/KG)			
	Day 1	Day 2	Days 3–6	Day 7+
<750	100–140	120–160	140–200	140–160
750–1000	100–120	100–140	130–180	140–160
1000–1500	80–100	100–120	120–160	150
>1500	60–80	80–120	120–160	150

principle is not followed, and a positive fluid balance (i.e., weight gain) is achieved during the transitional period, preterm neonates have been shown to be at higher risk of a more severe course of RDS[89] and a higher incidence of PDA,[90] congestive heart failure,[90] pulmonary edema,[89] necrotizing enterocolitis,[27] and BPD.[29,91] However, most of the published studies on outcomes related to fluid balance were performed in the presurfactant era and before the widespread use of prenatal corticosteroids.

Neonates, especially very preterm infants with anticipated fluid problems should be weighed daily or twice daily. Serum sodium levels should be measured every 4 to 6 hours until they have stabilized, usually by 3 to 4 days after birth, and urine output should be recorded and reviewed every 6 to 8 hours. In ELBW infants, electrolyte levels should be checked by 12 hours of age to help guide fluid management. Once data are available, fluids should be increased if weight loss is greater than 1% to 2% per day in term neonates and 2% to 3% per day in preterm neonates if urine output is inappropriately low; if urine specific gravity is rising; and/or if serum sodium concentration is rising. Overall, expected and appropriate weight loss during the first week postnatally is up to 10% in term neonates and up to 15% in preterm neonates. Conversely, fluids should be decreased if weight is not falling appropriately and/or serum sodium concentration is decreasing. The goal is to reach 140 to 160 mL of fluids per kilogram per day by 5 to 10 days to allow adequate caloric intake.

Treatment of Fluid Overload

Fluid overload commonly occurs in sick neonates, often because of the use of fluid bolus administration for hypotension and/or poor perfusion. The diagnosis is based on weight gain, edema, and often hyponatremia. Overhydration can sometimes be prevented by the use of blood transfusions and/or careful vasopressor-inotrope (dopamine, epinephrine) administration instead of colloid or crystalloid, if appropriate, for blood circulatory support. Once overhydration has occurred, management is usually affected by 10% to 20% decrements of total daily fluid intake and with careful monitoring of clinical and laboratory signs to ensure maintenance of adequate intravascular volume as well as normal glucose and electrolyte status while the ECF contraction occurs. While administration of albumin followed by a diuretic (e.g., furosemide) may be used in an attempt to mobilize interstitial fluid, there is little evidence to support this practice, and it may be counterproductive because of the albumin leak into the interstitial space.[39]

Treatment of Dehydration

Dehydration in the neonate may be suspected on the basis of history or clinical signs and confirmed by laboratory studies. One may estimate the total water deficit by using weight changes, calculating total inputs and outputs, and following serial sodium levels. Appropriate treatment requires consideration of sodium status. For additional details of fluid correction and sodium management, see the discussion in Treatment of Hypernatremia.

Sodium Homeostasis and Management

Serum sodium values should generally be kept between 135 and 145 milliequivalent (mEq)/L.[92] As sodium urinary losses are both gestational and postnatal age-specific, recommended intakes vary depending on these two factors and range from 1 mEq/kg/day to 12 mEq/kg/day.[93] Sodium chloride supplementation should be started in preterm and sick term neonates only after completion of the postnatal extracellular volume contraction, usually after the first few days of age or after more than 5% of birth weight has been lost.[94] Appropriate supplementation ensures a positive sodium balance that is necessary for adequate growth.

Hyponatremia

Hyponatremia (serum sodium <130 mEq/L) represents a deficit of sodium in relation to body water content and may be caused by either total body sodium (TBS) deficit or free water excess. In either situation, TBW may be decreased (hyponatremia with volume contraction), normal, or increased (hyponatremia with volume expansion). While hyponatremia has been associated with various morbidities, it may primarily be a marker of severity of illness. Regardless, sodium supplementation in preterm neonates is associated with improved long-term outcomes, thus underscoring the importance of appropriate sodium management.[93,95]

It is important to determine the primary cause and duration of the hyponatremia in order to initiate appropriate therapy. Fig. 20.5 summarizes the clinical evaluation and therapy of neonates with hyponatremia. The most common cause of hyponatremia in the sick neonate is excessive administration and/or retention of free water. In these situations, the total body sodium content is normal, and the appropriate treatment is restriction of free water intake and not administration of sodium. In situations of true sodium deficit, one can estimate the deficits by assuming 70% of total body weight as the distribution space of sodium. The formula for calculating sodium (Na^+) deficit is:

$$Na^+ \text{ Deficit (or Excess) (mEq)} \approx 0.7 \times \text{Body Weight (kg)} \times ([Na^+]_{\text{desired}} - [Na^+]_{\text{current}}).$$

In this formula, (0.7 × BW) is the estimation of TBW.

In most situations of depletional hyponatremia (i.e., true sodium deficit), two-thirds of the replacement sodium should be provided in addition to maintenance sodium needs in the first 24 hours, and the remainder is to be provided over the next 24 hours. Frequent measurements of serum levels of electrolytes are needed to ensure that the correction is occurring appropriately. With severe hyponatremia (serum sodium concentration Na <120 mEq/L), regardless of whether the hyponatremia is due to free water overload or TBS deficit, the correction of the serum sodium concentration up to 120 mEq/L is recommended with administration of 3% saline solution (513 mEq of sodium per liter). This recommendation is due to concern of increased risk of neurologic complications associated with severe hyponatremia, although this relationship has not been explicitly demonstrated in large cohorts of neonatal patients.[96] This correction should be done over 4 to 6 hours, depending on the severity of

hyponatremia,[97] with the use of the preceding formula and with close monitoring of serum sodium changes. Although rapid IV bolus administration of 4 to 6 mL/kg of 3% saline solution has been effective in children with seizures or coma,[98] rapid and complete correction of low serum sodium concentration in adults with chronic hyponatremia have been shown to be associated with pontine and extrapontine myelinolysis.[99] Although this association has not been demonstrated in neonates, the potential risk of injury to the immature central nervous system necessitates caution with rapid correction of long-standing hyponatremia. Once the serum sodium concentration has reached 120 mEq/L, complete correction of hyponatremia should be performed more slowly over the next 48 hours. In patients with asymptomatic hyponatremia whose serum sodium concentration exceeds 120 mEq/L, hypertonic infusions are not indicated. Additional therapy should be directed toward fluid restriction if the hyponatremia is dilutional or sodium repletion if the hyponatremia is depletional. More stable infants with chronic sodium losses can also be corrected with enteral sodium chloride.

Hypernatremia

Hypernatremia (serum sodium concentration >150 mEq/L) reflects a deficiency of water relative to TBS and is most often a disorder of water rather than sodium homeostasis. The presence of hypernatremia does not reflect the TBS content, which can be high, normal, or low depending on the cause of the condition. Hypernatremia can also be associated with hypovolemia, normovolemia, or hypervolemia (Box 20.2). If hypernatremia is primarily due to changes in sodium balance, it can result from pure sodium gain or, more commonly, sodium gain coupled with a lesser degree of water accumulation or, rarely, water loss. It is important to recognize that neonates with hypernatremic dehydration often do not demonstrate overt clinical signs of intravascular depletion and dehydration until late in the course of the condition. The hypernatremia-induced hypertonicity causes water to shift from the intracellular to the extracellular compartment, resulting in intracellular dehydration but with relative preservation of the extracellular compartment. This fluid shift is the main reason that neonates with chronic hypernatremic dehydration often do not demonstrate overt clinical signs of intravascular depletion and dehydration until late in the course of the condition.

Compared with other organs, the CNS has a unique and more effective adaptive capacity to respond to the hypernatremia-induced hypertonicity, leading to a relative preservation of neuronal cell volume. The shrinkage of the brain stimulates the uptake of electrolytes such as sodium, potassium, and chloride (immediate effect). However, these electrolytes, at higher-than-normal intracellular concentrations, have severe adverse effects on intracellular enzyme functions. The synthesis of osmoprotective amino acids and organic solutes (delayed response, starting perhaps around 4 to 6 hours into the process) serves as a defensive mechanism to protect cellular functions. These idiogenic osmols, such as taurine, glycine, glutamine, sorbitol, and inositol aid in attenuating the volume loss in the cells of the central nervous system during longer periods of hyperosmolar stress and limit the accumulation of intracellular sodium and chloride.[100] As long as hypernatremia develops rapidly (within hours), as in accidental sodium loading, a relatively rapid correction of the condition is usually safe. Intracellular fluid accumulation does not occur because the accumulated electrolytes (sodium, potassium, and chloride) are rapidly extruded from the brain cells, and the development of cerebral edema is unlikely. In these cases, reducing serum sodium concentration by 1 mEq/L/h (24 mEq/L/day) is appropriate.[101]

In contrast to rapidly developing hypernatremia, in cases of chronic hypernatremia, the dissipation of idiogenic osmols in response to correction of the hypernatremia occurs slowly over several days.[101] Thus in these chronic cases, or in cases in which the time frame over which hypernatremia developed is unknown, the hypernatremia should be corrected more slowly, at a maximum rate of 0.5 mEq/L/h (12 mEq/L/day). If correction is performed more rapidly, the abrupt fall in the extracellular tonicity results in the movement of water into the brain cells, which have a relatively fixed hypertonicity because of the presence of the osmoprotective molecules. The result is the development of brain edema with potentially deleterious consequences.[101,102] A large population-based study, published in 2007, showed that neonates admitted to the hospital with dehydration (weight loss >12% of birth weight) and hypernatremia (serum sodium concentration ≥150 mEq/L), but without shock, respiratory failure, infarct, or gangrene and in a managed care setting, did not have increased rates of adverse neurodevelopmental outcome at 5 years.[31] The authors noted that these favorable outcomes may not be generalizable to neonates presenting with more severe symptoms.

In the breastfed term neonate, hypernatremia most commonly develops in association with dehydration secondary to inadequate breast milk intake.[102] In addition, it has also been associated with high sodium levels in maternal breast milk, especially from mothers of neonates who are not successfully lactating.[103,104] Reduction in breastfeeding frequency has been associated with a marked rise in the sodium concentration of breast milk.[104] Thus, the initial clinical presentation of neonates with breastfeeding-associated hypernatremia is a bodyweight loss of 10% or more, poor hydration state, lethargy, and poor feeding. Recognition may be delayed because these neonates may appear quiet, content, and without overt clinical signs of dehydration initially as the extracellular water loss is supplemented from the intracellular compartment. During this process, idiogenic osmols are being produced in the cells to follow the rise of osmolality in the extracellular compartment and protect the cells from a rapid

• BOX 20.2 Conditions Causing Hypernatremia

Hypovolemic Hypernatremia

Inadequate breast milk intake
Diarrhea
Radiant warmers
Excessive sweating
Renal dysplasia
Osmotic diuresis

Euvolemic Hypernatremia

Decreased Production of Antidiuretic Hormone

Central diabetes insipidus, head trauma, central nervous system tumors (craniopharyngioma), meningitis, or encephalitis

Decreased or Absence of Renal Responsiveness

Nephrogenic diabetes insipidus, extreme immaturity, renal insult, and medications such as amphotericin, hydantoin, and aminoglycosides

Hypervolemic Hypernatremia

Improperly mixed formula
Sodium bicarbonate administration
Sodium chloride administration
Primary hyperaldosteronism

and unsustainable water loss. However, once this compensatory capacity is overwhelmed, the full clinical presentation develops with oliguria, lethargy, irritability, and hypotonia. Finally, at the most advanced stages, seizures, and cardiovascular collapse with renal failure present. In general, once the clinical presentation of full-blown shock develops, treatment efforts usually fail as cellular volume contraction has reached an irreversible stage. Even before the irreversible phase, the presentation can be associated with serious CNS morbidity from both the hypertonicity (sagittal or other venous sinus thrombosis) and/or inappropriately rapid rehydration therapy (brain edema).[104] Although thorough follow-up studies of neonates with breastfeeding-associated severe hypernatremia are not available, observational studies suggest that up to 5% of neonates experience brain damage (cerebral hemorrhage, edema, thrombosis, or infarction).[103]

In the extremely immature neonate, early hypernatremia most commonly occurs from excessive transepidermal free water losses. The condition usually develops rapidly, within 24 to 72 hours after birth. The diagnosis is supported by a decrease in body weight, an increase in serum sodium concentration, and clinical signs of extracellular volume contraction. Appropriate adjustments of free water intake, the use of humidified incubators and frequent monitoring of serum electrolyte levels prevents this condition.[21] A recent retrospective single center study of VLBW neonates using multiple linear regression analysis with generalized estimating equations found that a peak serum sodium value over149 mmol/L is associated with poor cognitive outcomes at 24 months of age.[105] Further studies are needed to determine if this association is casual rather than a consequence of disease severity.

The central and nephrogenic forms of diabetes insipidus (DI) are much less common causes of hypernatremia and occur because of the lack of production of and renal responsiveness to vasopressin, respectively. Central diabetes insipidus can be congenital or can be acquired secondary to a neurologic insult.[106] Iatrogenic hypernatremia can also develop in response to excessive sodium supplementation, mainly in the sick neonate receiving repeated volume boluses for cardiovascular support or sodium bicarbonate for metabolic acidosis. In these cases, clinical signs of edema, increased body weight, and the history of volume boluses help to establish the diagnosis.

Treatment of Hypernatremia. Thorough analysis of the medical history and the changes in clinical signs, laboratory findings, and body weight are necessary to determine the major etiologic factor in hypernatremia and thus the appropriate treatment. In the critically ill neonate, the cause of the serum sodium abnormality may be multifactorial, making the treatment strategy less straightforward. Although some cases of hypernatremia are a result of sodium excess with normal or high TBW, most cases in neonates are due to hypernatremic dehydration. Treatment of this condition is generally divided into two phases: the *emergent phase*, where the intravascular volume is restored, usually by administration of a solution with a sodium concentration of 10 to 15 points lower than the that of the patient, and the *rehydration phase*, where the sum of the remaining free water deficit and the usual maintenance needs are administered evenly over at least 48 hours. To resuscitate the patient using a solution with a sodium concentration of 10 to 15 points lower than the that of the patient is especially important when serum sodium levels are greater than 175 mEq/L.[107]

The free water deficit can be calculated as follows:

$$\mathrm{H_2O\ Deficit\,(or\ Excess)\,(L)} \approx 0.7 \times \mathrm{Body\ Weight\,(kg)} \times \left(\frac{[\mathrm{Na^+}]_{\mathrm{current}}\ (\mathrm{mEq/L})}{[\mathrm{Na^+}]_{\mathrm{desired}}\ (\mathrm{mEq/L})} - 1 \right).$$

In this formula, (0.7 × body weight) is the estimation of TBW. When dehydration is diagnosed, correction should generally occur over 24 hours, with half of the correction occurring over the first 8 hours and the remainder over the next 16 hours. It is important to note that longer correction times are indicated when dehydration is accompanied by moderate (serum sodium concentration >160 mEq/L) to severe (serum sodium concentration ≥175 mEq/L) hypernatremia, particularly in cases with a more chronic presentation of hypernatremia.

Alternatively, one can consider the amount of free water required to decrease the serum sodium concentration by a desired amount. The amount of free water required to decrease the serum sodium concentration by 1 mEq/L is 4 mL/kg with moderate hypernatremia but only 3 mL/kg when the serum sodium concentration is as high as 195 mEq/L.[102] Therefore, the amount of free water required to decrease the serum sodium concentration by 12 mEq/L over a 24-hour period when hypernatremia is moderate (serum sodium concentration >160 mEq/L) is calculated as follows:

$$\mathrm{Free\ Water\ Required} = \mathrm{Current\ Weight\,(kg)} \times 4\,\frac{\mathrm{mL}}{\mathrm{kg}} \times 12\,\frac{\mathrm{mEq}}{\mathrm{L}}$$

or

$$\mathrm{Free\ Water\ Required} = \mathrm{Current\ Weight\,(kg)} \times 48\,\frac{\mathrm{mL}}{\mathrm{kg}}\,\mathrm{per\ Day}.$$

When hypernatremia is severe (serum sodium concentration >175 mEq/L), the amount of free water required to decrease the serum sodium concentration by 12 mEq/L over a 24-hour period is calculated as follows:

$$\mathrm{Free\ Water\ Required} = \mathrm{Current\ Weight\,(kg)} \times 36\,\frac{\mathrm{mL}}{\mathrm{kg\ per\ Day}}.$$

The free water contents of the common IV fluids are listed in Table 20.2. The selection of the correct replacement fluid requires consideration of the sodium content of the replacement fluid in relation to the serum sodium concentration. It is important to note that sodium must be delivered with the free water replacement to avoid the hypernatremia being corrected too rapidly. The relative free water content of an IV solution for a specific patient with sodium perturbations can be calculated with the formula:

$$\mathrm{Percentage\ of\ Free\ Water} = 1 - (\mathrm{Intravenous\ Fluid\ Sodium} \,/\, \mathrm{Serum\ Sodium}).$$

Serum electrolyte levels should be monitored every 2 to 4 hours until the desired rate of decline in serum sodium concentration is established. At this point, the frequency of the laboratory measurements can be relaxed to every 4 to 6 hours until the serum sodium concentration is less than 150 mEq/L. The speed of correction of hypernatremia also depends on the rate of its development. This approach provides a reasonable chance that the serum sodium concentration will gradually decrease to the normal range over 2 to 4 days. Except in cases of acute massive sodium overload, the goal should be to lower the serum sodium concentration at a rate of maximum 1 mEq/L/h. A slower pace of correction of 0.5 mEq/L/h is prudent in patients with severe hypernatremia of chronic or unknown duration to minimize the chances of iatrogenic CNS sequelae.

While free water deficits are being corrected, the usual maintenance fluids and electrolytes must also be provided. Of note is that appropriate supplementation of calcium and magnesium is of especially great importance in neonates with hypernatremic dehydration. Ongoing urine losses should be replaced volume for volume every 4 to 6 hours with a solution tailored to the urine's electrolyte concentration (usually 0.225% to 0.45% normal saline). Extraordinary losses caused by open wounds, tubes, drains, ostomies, emesis, and/or diarrhea should always be considered in the dehydrated or hypernatremic infant and also accounted for in fluid management. The composition of this latter replacement solution depends on the electrolyte concentration of the fluid loss. The most common extraordinary loss, gastric fluid, contains significant amounts of sodium and chloride. See Table 20.3 for approximate electrolyte compositions of body fluids. Because

TABLE 20.2 Free Water Content (as Volume Percent) of Common Intravenous Solutions at Normal and High Serum Sodium Concentrations*

	SERUM SODIUM CONCENTRATION			
	145 MEQ/L		195 MEQ/L	
Intravenous Fluid	Isotonic (%)	Water (%)	Isotonic (%)	Water (%)
5% dextrose in water	0	100	0	100
0.2% saline	22	78	17	83
0.45% saline	50	50	39	61
0.9% saline	100	0	79	21
Lactated Ringer's solution	86	14	68	32

*Isotonic saline provides 21% free water when given to a patient with a serum sodium concentration of 195 mEq/L and therefore will induce undesirable decreases in serum sodium concentration when used for volume resuscitation in the severely dehydrated hypernatremic neonate.

Modified from Molteni KH. Initial management of hypernatremic dehydration in the breastfed infant. *Clin Pediatr*. 1994;33:731–740.

TABLE 20.3 Approximate Electrolyte Composition of Body Fluids (mEq/L)

Body Fluid	Sodium	Potassium	Chloride
Gastric	20–80	5–20	100–150
Small intestine	100–140	5–15	90–130
Bile	120–140	5–15	80–120
Ileostomy	45–135	3–15	20–115
Diarrhea	10–90	10–80	10–110

of the association between hyponatremia and neurologic injury in hospitalized pediatric patients,[108] thoughtful consideration of fluid tonicity must be considered when the replacement fluid composition is being determined in the treatment of hypernatremia. Some have advocated routine administration of isotonic ("normal" saline) fluids regardless of sodium requirement to avoid "hospital-acquired hyponatremia" caused by overadministration of free water.[108,109] This approach is not without risk, given the overdose of sodium that may occur with administration of normal saline.[110,111] A reasonable approach may be to base the appropriate fluid prescription on accurately assessed fluid deficits and ongoing requirements, with thoughtful consideration of sodium requirements of each compartment, as well as frequent monitoring of serum sodium changes.[110,111]

Once serum sodium concentration, urine output, and renal function are normal, the patient should receive standard maintenance fluids, either intravenously or orally, depending on his or her condition. Potassium replacement (usually by addition of 20 to 40 mEq of potassium per liter of replacement fluid) should not begin until adequate urine output has been established. At this time, electrolyte status must still be monitored for an additional 24 hours to ensure that complete recovery has occurred. Hyperglycemia and hypocalcemia commonly accompany hypernatremia. The use of insulin to treat the hyperglycemia is not recommended because it can increase brain idiogenic osmol content. Hypocalcemia should be corrected with appropriate calcium supplementation.

Potassium Homeostasis and Management

Serum potassium concentration should be kept between 3.5 and 5 mEq/L. Neonates, especially the immature preterm infant, can experience a relative hyperkalemia in the early postnatal period due to developmentally regulated differences in renal function in general and renal potassium handling in particular, decreased Na^+, K^+-ATPase activity,[112] and hormonal milieu. Exposure to steroids prenatally in premature neonates is associated with a decreased incidence of hyperkalemia, believed to be due to improved renal function.[113]

In general, potassium supplementation should be started only after urine output has been well established, usually by the third postnatal day. Supplementation should be started at 1 to 2 mEq/kg/day and increased over 1 to 2 days to the usual maintenance requirement of 2 to 3 mEq/kg/day. Some preterm neonates may need more potassium supplementation after the completion of their postnatal volume contraction because of their increased plasma aldosterone concentrations, prostaglandin excretion, and disproportionately high urine flow rates. Most neonates will require additional potassium supplementation if they are receiving diuretics.

Hypokalemia. Hypokalemia in the neonate is usually defined as a serum potassium level of less than 3.5 mEq/L. Hypokalemia can occur from (1) inadequate potassium intake; (2) potassium loss due to diuretics, diarrhea, renal dysfunction, or nasogastric drainage; or (3) shift of potassium into the intracellular compartment in the presence of alkalosis. Electrocardiogram (ECG) manifestations of hypokalemia include flattened T waves, prolongation of the QT interval, or the appearance of U waves. Except in patients receiving digoxin, hypokalemia is rarely symptomatic until the serum potassium concentration is less than 2.5 mEq/L. This degree of hypokalemia can result in cardiac arrhythmias, ileus, and lethargy.

Treatment of Hypokalemia. Hypokalemia is treated by slow enteral of parenteral replacement. Rapid administration of IV potassium chloride is not recommended because it may be associated with life-threatening cardiac dysfunction. In extreme emergencies, potassium can be given as an infusion over 30 to 60 minutes of not more than 0.3 mEq of potassium chloride per kilogram. If hypokalemia is secondary to alkalosis, the total body potassium content is usually normal, and the alkalosis should be corrected before considering potassium replacement.

Hyperkalemia. Hyperkalemia in the neonate is defined as a serum potassium level greater than 6 mEq/L in a nonhemolyzed specimen. Hyperkalemia often presents without oliguria in the very preterm infant and occurs in more than 50% of neonates weighing less than 1000 g ("non-oliguric hyperkalemia of prematurity").[114] A common cause of hyperkalemia is renal dysfunction, of particular concern in very preterm neonates, and in neonates whose course is complicated by asphyxia or hypotension. In addition, hyperkalemia secondary to release of potassium from dying cells often complicates IVH, tissue ischemia (i.e., volvulus or necrotizing enterocolitis) and intravascular hemolysis. Less commonly, hyperkalemia may be one of the earliest manifestations of congenital adrenal hyperplasia or may occur because of other causes of neonatal acute adrenal insufficiency. Furthermore, because pH affects the distribution of potassium between the intracellular and the extracellular space, serum potassium levels may rise acutely during acidosis. The clinician should be aware of the potential for life-threatening arrhythmias to occur in infants with chronic lung disease on diuretics and potassium supplements who develop a sudden respiratory deterioration with acidosis.

It is important to understand that most of the body's potassium is contained within cells; therefore serum potassium levels do not accurately reflect total body stores. Even if total body stores are normal or low, serum potassium greater than 6.5 to 7 mEq/L can be life-threatening due to the vital role played by potassium in the electrophysiologic function of the heart. ECG manifestations of hyperkalemia include peaked T waves (the earliest sign), a widened QRS configuration, bradycardia, tachycardia, supraventricular tachycardia, ventricular tachycardia, and ventricular fibrillation.

Treatment of Hyperkalemia. When hyperkalemia is diagnosed, all potassium intake should be discontinued, and the ECG should be monitored. Table 20.4 presents medications used in the management of significant hyperkalemia. Calcium gluconate stabilizes cardiac membranes, and alkali therapy (sodium bicarbonate, tromethamine), insulin/glucose, and inhaled albuterol[115] all rapidly enhance cellular uptake of potassium and can cause a sharp drop in serum potassium levels in life-threatening situations but will not decrease total body potassium content. It is important to recognize that none of these therapies will decrease total body potassium and their effect will be temporary. Intravenously administered furosemide and rectally administered sodium polystyrene sulfonate (Kayexalate) enhance potassium excretion and will lower total body stores but require at least several hours to take effect. Furthermore, use of polystyrene sulfonate to treat hyperkalemia in preterm neonates (<29 weeks' gestational age or <1250 g birth weight) has been associated with intestinal complications, including hematochezia and necrotizing enterocolitis.[116,117] Dialysis or exchange transfusion may be used when the hyperkalemia is life-threatening and other measures do not result in relief.

TABLE 20.4 Medications Used for Treatment of Hyperkalemia

Medication	Dosage	Route	Onset	Duration of Effects	Mechanism of Action	Comments and Cautions
Calcium gluconate	100 mg/kg	Intravenously over 2-5 min	Immediate	30 min	Protects the myocardium from toxic effects of potassium; no effect on total body potassium	• Risk of precipitation when administered with sodium bicarbonate • Administer with caution when using peripheral venous access due to the risk of tissue injury with extravasation
Sodium bicarbonate	1-2 mEq/kg	Intravenously over 2-5 min	Immediate	Variable	By increasing pH, $NaHCO_3$ shifts potassium intracellularly; no effect on total body potassium	• Consider lower dose and infusion rate for very preterm infants in the first postnatal days • Risk of precipitation when administered with calcium gluconate
Tromethamine (THAM)	3-5 mL/kg	Intravenously over 1 hr	Immediate	Variable	By capturing H^+, THAM increases pH without increasing CO_2 and thus shifts potassium intracellularly; no effect on total body potassium	—
Insulin plus dextrose	*Insulin:* 0.1-0.15 U/kg *Dextrose:* 0.5 g/kg	Intravenously over 30 min	15-30 min	2-6 hr	By stimulating the Na^+,K^+-ATPase enzyme, it shifts potassium intracellularly; no effect on total body potassium	Monitor for hypoglycemia
Albuterol	0.4 mg (in 2 mL of NS)	Inhalation, up to every 2 hr	15-30 min	2-3 hr	By stimulating the Na^+,K^+-ATPase enzyme, it shifts potassium intracellularly; no effect on total body potassium	Should not be used as sole agent
Furosemide	1-4 mg/kg per dose Intravenously: 1-2 mg/kg per dose	Orally Intravenously	15 min to 1 hr (sooner with IV admin)	4 hr	Increases renal excretion of potassium	—
Sodium polystyrene	1 g/kg every 6 hr	Rectally or orally	1-2 hr (sooner with rectal admin)	4-6 hr	Removes potassium from gut in exchange for sodium	• Use with extreme caution in neonates, especially preterm neonates • Contains sorbitol • May be associated with bowel necrosis and sodium retention

Clinical Conditions Associated With Fluid and Electrolyte Disturbances

Extreme Prematurity

Infants born between 22 and 27 weeks' gestation, or with a birth weight of less than 1000 g (i.e., ELBW), are at particular risk of acute abnormalities of both fluid and electrolyte status in the immediate postnatal period. TEWL is much higher than in more mature preterm neonates (see Fig. 20.4), and thus it is difficult for water balance to be maintained unless this water loss is prevented. Neonates exposed to prenatal glucocorticoids often have fewer problems because prenatally administered glucocorticoids enhance maturation of the epidermis and cardiovascular and renal development and function, resulting in increases in urine output and fractional excretion of sodium.[87,118]

Table 20.1 shows suggested maintenance fluid requirements by birth weight and postnatal age. Critically ill, extremely immature neonates often receive excess sodium with volume boluses, medications, and the maintenance infusion of their arterial lines. Therefore, extra sodium supplementation should usually not be started during the first few postnatal days, to prevent a rise in TBS concentration and thus extracellular volume, which will hinder the appropriate postnatal diuresis. However, one must be careful as a positive sodium balance is a prerequisite for appropriate growth and, thus, after the transitional period, it must be ensured. Extremely premature neonates are at risk of the development of both oliguric and nonoliguric hyperkalemia, so the serum potassium concentration should be monitored closely, and supplementation should be discontinued if warranted by changes in serum potassium values or in renal function.

Many critically ill preterm neonates retain their originally high extracellular volumes, even when sodium and water intakes are restricted, and such neonates also tend to lose more bicarbonate in the urine. Proximal tubular bicarbonate reabsorption

is gestation-age appropriate even in the VLBW neonate despite the immaturity of its renal function, as long as extracellular volume contraction occurs.[119] Therefore, the presence of the extracellular volume expansion appears to be an important factor in the renal bicarbonate wasting in these neonates. The diagnosis of functional proximal tubular acidosis in such cases should not rely solely on the finding of an alkaline urine pH because the distal tubular function is usually mature enough to acidify the urine once the serum bicarbonate concentration has decreased to its new threshold. Provided that liver function is normal, daily supplementation of bicarbonate, in the form of sodium acetate, potassium acetate, or both, rapidly begins to normalize blood pH and serum bicarbonate concentration in these neonates and also increases urine pH, aiding in the diagnosis. Once extracellular volume contraction occurs, these neonates generally achieve a positive bicarbonate balance,[119] and further supplementation becomes unnecessary.

Other general guidelines in the fluid and electrolyte management of the extremely immature preterm neonate during the first postnatal week are daily calculation of fluid balance and measurements of body weight. The need to measure serum electrolyte levels, plasma glucose levels, urine glucose, osmolality, and specific gravity should be considered based on the severity of illness. The frequency of testing and the addition of other tests, including the measurement of serum albumin concentration and osmolality, depend on the clinical status, the severity of the underlying disease, and the fluid and electrolyte disturbance of the individual patient. Serum creatinine and especially BUN levels are not accurate measures of fluid status in the first postnatal weeks but following their trend can be helpful. There is little to no association between BUN levels and protein intake,[120] even when changes in renal function are taken into account.[121] In the stable infant, the information gained by these studies often do not justify the potential harms inflicted by overstimulation and blood draws, and testing must be tailored for individual patients.

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) is a self-limited respiratory complication in term and late preterm neonates caused by delayed clearance of fetal lung fluid during labor and in the immediate postdelivery period. Infants born by cesarian section or to mothers with diabetes are at higher risk for TTN. The maternal diabetes-associated delayed fetal maturation, the lack of labor-induced stress and the absence of the mechanical effects of vaginal delivery explain, at least in part, these findings.[122] These neonates present with mild to moderate respiratory distress frequently requiring respiratory support including supplemental oxygen, high-flow nasal cannula, or continuous positive end-expiratory pressure for a duration ranging from 24 to 96 hours. Fluid management is thought to impact the duration of illness in neonates with TTN. Although multiple studies have been performed evaluating whether fluid restriction is beneficial for neonates with TTN, a definitive answer is lacking.[123] However, maintaining adequate hydration is indicated for neonates with TTN.

Bronchopulmonary Dysplasia

BPD is a multifactorial disease. Many risk factors have been associated with the development of BPD, including a high fluid and salt intake during the first few days to weeks of postnatal life. Specifically, higher fluid intake and lack of appropriate weight loss during the first 10 postnatal days are associated with significantly higher risk of BPD, even after other known risk factors have been controlled for.[29] Furthermore, there is an association between cumulative fluid intake in neonates with an intake of more than 345 mL/kg in the second through fourth postnatal days and an increased incidence of severe BPD.[124] Therefore, careful fluid and electrolyte management during the first few weeks of life, allowing the appropriate degree of weight loss, are of great importance in decreasing the incidence and severity of this condition.

Patent Ductus Arteriosus and Treatment With Indomethacin/Ibuprofen

Fluid, electrolyte, and acid-base management can affect the closure of the ductus arteriosus and the hemodynamic impact of a PDA, as increased fluid administration, increases in extracellular volume, and metabolic acidosis prolong patency of the ductus arteriosus[125] and worsen the hemodynamic impact of left-to-right shunting. Accordingly, clinical management aimed at preventing the occurrence of ductal patency and mitigating its hemodynamic effects involve thoughtful management of fluid and electrolyte balance.[126] For more detail, see Chapter 48.

In the preterm neonate, indomethacin administration has been shown to have clinically significant, although mostly transient, renal side effects because of decreased prostaglandin production through inhibition of cyclooxygenase. In the indomethacin-treated neonate, the unopposed increased catecholamine and angiotensin production associated renal vasoconstriction and sodium and water reabsorption lead to decreases in renal blood flow and glomerular filtration rate and to increases in sodium and free water reabsorption. These side effects occur despite the diminishing left-to-right shunt through the closing ductus. Characteristic clinical findings include a rise in serum creatinine level, oliguria, and hyponatremia.[127] Hyponatremia occurs because the free water retention caused by the unopposed renal actions of high plasma vasopressin levels is out of proportion to the sodium retention induced by angiotensin and norepinephrine. Fluid management of the preterm neonate receiving indomethacin must focus on maintaining an appropriately restricted fluid intake and avoiding extra sodium supplementation until urine output increases and renal function recovers. As the prostaglandin inhibitory effects of indomethacin diminish following the last dose, renal prostaglandin production returns to normal, and the retained sodium and excess free water are usually rapidly excreted, especially with the improvement in cardiovascular status as the ductal shunt decreases.

Ibuprofen is an alternative inhibitor of cyclooxygenase for the treatment of PDA and appears to have equivalent efficacy in closing the symptomatic PDA, with fewer adverse effects.[128] Ibuprofen administration is specifically associated with less renal and gastrointestinal (GI) dysfunction[129] and no apparent effect on cerebral perfusion.[130,131] The lack of an effect on cerebral perfusion likely explains why prophylactic ibuprofen does not reduce the incidence of severe IVH.[128]

Oral or intravenous acetaminophen has also been recently used in the management of PDA in neonates either resistant to one of the COX-inhibitors or as a primary agent.[132] Acetaminophen blocks prostaglandin production by inhibiting the peroxidase segment of the prostaglandin synthetase enzyme. Interestingly, it appears to have less renal side effects than indomethacin or even ibuprofen,[133] but further studies are required for a more in-depth investigation of this topic.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

In the preterm and term newborn, SIADH may be associated with neurologic (birth asphyxia, intracerebral hemorrhage, meningitis) and pulmonary (RDS, pneumothorax, bronchiolitis, and pneumonia) insults.[67] The syndrome is characterized by oliguria, free water retention, decreased serum sodium concentration and serum osmolality, increased urine concentration, and weight gain caused by edema formation. However, because the urinary concentrating capacity of the newborn is limited, a less than maximally diluted urine satisfies the diagnosis of SIADH in the presence of the other symptoms. As a result of their more immature renal function, during the first few weeks of postnatal life, ELBW neonates do not usually exhibit the full-blown syndrome despite their sometimes excessively high plasma vasopressin levels.[134] Appropriate treatment requires fluid and sodium restriction despite the oliguria and hyponatremia, as well as on appropriate circulatory and ventilatory support. The clinician must remember that TBS content is normal, but TBW content is elevated, making treatment of the hyponatremia with large amounts of sodium dangerous.

Diminished vasopressin secretion or complete unresponsiveness of the renal tubules to vasopressin results in polyuria, dilute urine production, and increased serum osmolality,[135] otherwise known as *diabetes insipidus*. This condition is not common in neonates but can occur in association with CNS injury or disease, such as in meningitis, in cerebral hemorrhage affecting the pituitary gland (central diabetes insipidus), or in an inherited form (nephrogenic diabetes insipidus). In addition, diabetes insipidus is one of the features of congenital developmental abnormalities also affecting the pituitary gland, such as septo-optic dysplasia (de Morsier syndrome). The treatment of neonates with this condition consists of facilitating adequate free water intake and the use of desmopressin with or without chlorothiazide.[136]

Surgical Conditions

Surgery has a major effect on metabolism, fluid balance, and electrolyte balance in the newborn. Preterm neonates with acute or chronic lung disease are especially sensitive and respond to the procedure with significant catabolic responses, increases in capillary permeability, with the attendant shift of fluid into the interstitial space, and retention of sodium and free water.[137] The retention of sodium and free water is secondary to the decrease in effective circulating blood volume and to the increased plasma levels of sodium-retaining and water-retaining hormones, including catecholamines, renin–angiotensin–aldosterone, and vasopressin.

Preoperative management has a significant effect on outcome and should aim at maintaining adequate effective circulating blood volume as well as cardiovascular and renal function. In preterm neonates who have evidence of absolute or relative adrenal insufficiency,[138] as well as those who have received prolonged steroid therapy for hypotension or lung disease, the provision of stress doses of steroids may be necessary (see Chapter 84). In the postoperative period, close monitoring and maintenance of the integrity of the cardiovascular system is required. The judicious use of volume expanders and vasopressor–inotropic support, as well as meticulous replacement of ongoing surgical and nonsurgical fluid and electrolyte losses in addition to maintenance needs are essential to ensure a successful outcome. As capillary integrity improves, reabsorption and excretion of the expanded interstitial fluid volume occurs, with normalization in the secretion of hormones regulating fluid and electrolyte balance.

Carefully monitored post-surgical fluid management necessitates consideration of various sources of surgical water losses. These include fluid losses from chest tubes, ostomies, and nasogastric tubes placed under continuous suction to provide relief for the GI tract. Because these losses may be substantial, they should be monitored and a portion of the losses should be replaced every 6 to 12 hours to maintain appropriate water and electrolyte balance. However, free water retention often develops after surgery; therefore, full replacement of these losses is not usually recommended. One of the approaches to the fluid–electrolyte management of postoperative neonates may be to replace half of the removed/lost volume or increase the total fluid limit for a period to account for these loses. The composition of the replacement solution depends on the electrolyte concentration of the fluid loss. Gastric fluid usually contains 50 to 60 mEq of sodium chloride per liter, and therefore 0.45% sodium chloride with potassium is normally used as the fluid of choice for replacement. See Table 20.3 for estimated electrolyte compositions of body fluids.

Acid-Base Balance

Physiology of Acid-Base Balance Regulation

Like adults, newborns must maintain their extracellular pH, or hydrogen ion concentration, within a narrow range. A normal pH is essential for intact functioning of all enzymatic processes and therefore the intact functioning of all organ systems of the body. Newborns are subjected to many stresses that can affect their acid-base balance. In addition, neonates, especially if they are premature, have a limited ability to compensate for acid-base alterations; therefore acid-base disturbances are common in the neonatal period. An understanding of the principles of acid-base regulation is essential for proper diagnosis and treatment of these disturbances.

In healthy humans, the normal range of ECF hydrogen ion (H^+) concentration is 35 to 45 mEq/L. Because pH is defined as the negative logarithm of hydrogen ion concentration ($pH = -\log[H^+]$), these hydrogen ion concentrations correspond to a pH range of 7.35 to 7.45. Acidosis is a downward shift in pH to less than 7.35, and alkalosis is an upward shift in pH to more than 7.45. Alterations in normal pH are resisted by complex physiologic regulatory mechanisms. The main systems that maintain pH are the body's buffer systems, the respiratory system, and the kidneys. Some of these systems respond immediately to sudden alterations in hydrogen ion concentration, whereas others respond more slowly to changes but maintain the overall balance between acid and base production, intake, metabolism, and excretion over the long term.

The physiologic regulatory systems that respond immediately to changes in acid-base balance include the various intracellular and extracellular buffers as well as the lungs. A buffer is a substance that can minimize changes in pH when acid or base is added to the system. The extracellular buffers, which include the bicarbonate–carbonic acid system, phosphates, and plasma proteins, act rapidly to return the extracellular pH toward normal. The intracellular buffers, which include hemoglobin, organic phosphates, and bone apatite, act more slowly and require several hours to reach maximal capacity.

The most important extracellular buffer is the plasma bicarbonate–carbonic acid buffer system, in which the acid component (carbonic acid [H_2CO_3]) is regulated by the lungs, and the base component (bicarbonate [HCO_3^-]) is regulated by the kidneys. The buffer equation is as follows:

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 + H_2O + (CO_2)_d$$

where $(CO_2)_d$ represents the dissolved carbon dioxide. At equilibrium, the amount of dissolved CO_2 exceeds that of H_2CO_3 by a factor of 800:1; therefore, for practical purposes, dissolved CO_2 and H_2CO_3 can be treated interchangeably. The fact that CO_2 excretion can be controlled by the respiratory system markedly increases the efficiency of this buffer system at physiologic pH. The enzyme carbonic anhydrase allows rapid interconversion of H_2CO_3 to H_2O and CO_2. If the hydrogen ion (H^+) concentration increases for any reason, hydrogen combines with HCO_3^-, driving the buffer reaction toward greater production of H_2CO_3 and CO_2. CO_2 crosses the blood–brain barrier and stimulates CNS chemoreceptors, leading to increased alveolar ventilation and decreased concentration of extracellular CO_2. This respiratory compensation begins within minutes after a pH change and is complete within 12 to 24 hours. A similar compensation occurs in response to a decrease in H^+ concentration, leading to decreased alveolar ventilation and a resultant increase in extracellular CO_2 concentration.

The relationship between the two components of the bicarbonate–carbonic acid buffer system and pH is expressed by the Henderson–Hasselbalch equation:

$$pH = pK_a + \log\left(\frac{[HCO_3^-]}{[H_2CO_3]}\right).$$

Because H_2CO_3 is in equilibrium with the dissolved CO_2 in the plasma, and because the amount of dissolved CO_2 depends on the partial pressure of CO_2, the equation can be modified as follows:

$$pH = pK_a + \log\left(\frac{[HCO_3^-]}{0.03}\right) \times PaCO_2.$$

Both the original equation and the modified equation are clinically difficult to use; therefore the modified Henderson–Hasselbalch equation can be rewritten as the Henderson equation without logarithms for easier clinical use:

$$[H^+] = 24 \times \frac{PaCO_2}{[HCO_3^-]}.$$

This last equation clearly describes the clinically most important aspect of acid-base regulation by the bicarbonate–carbonic acid buffer system, that the change in the ratio of $PaCO_2$ to HCO_3^- concentration, and not in their absolute values, determines the direction of change in H^+ concentration and thus in pH. The status of the plasma bicarbonate–carbonic acid buffer system can be monitored easily by serial blood gas measurements, making understanding of this buffer system important in clinical care.

The physiologic regulation system that responds more slowly to changes in acid-base balance is the renal system. There must be a long-term balance between net acid increase caused by intake and production and net acid decrease caused by excretion and metabolism. Although infant formula and protein-containing IV fluids have small amounts of preformed acid, most of the daily acid load is derived from metabolism. A large amount of the acid produced is in the form of the volatile H_2CO_3, which can be excreted in the lungs. Nonvolatile or fixed acids are also produced and must be excreted through the kidneys. The nonvolatile acids are normally sulfuric acid produced in the metabolism of the amino acids methionine and cysteine and, to a lesser extent, phosphoric acid, lactic acid, hydrochloric acid, and incompletely oxidized organic acids. In addition to the excretion of nonvolatile acids, however, the kidneys have a role in long-term acid-base regulation by controlling renal HCO_3^- excretion.

Two regions of the kidney act to achieve urinary acidification: the proximal tubule and the collecting tubule. The proximal tubule acidifies the urine by two mechanisms. The first mechanism is by the reabsorption of any HCO_3^- already present in the blood that is being constantly filtered through the glomeruli. The proximal tubule reabsorbs 60% to 80% of all filtered HCO_3^- and performs this role through the exchange of Na^+ for H^+ across the luminal membrane of the proximal tubular cells via the Na^+/H^+ exchanger. The excreted H^+ combines with filtered HCO_3^-, producing H_2CO_3 through the activity of carbonic anhydrase in the cellular brush border. The H_2CO_3 is then quickly converted to CO_2, which crosses into the tubular cell, where HCO_3^- is regenerated and reabsorbed back into the bloodstream, mostly in exchange for chloride (Cl^-). The regenerated H^+ ion reenters the cycle at the Na^+/H^+ exchanger.

The second mechanism by which the proximal tubule acidifies urine is by the production of ammonia (NH_3). Inside the tubular cell, NH_3 is produced by the deamination of glutamine. The NH_3 is secreted into the tubular lumen where it combines with and traps free H^+ to form ammonium (NH_4^+).

The remaining urinary acidification occurs mostly in the collecting tubule. H^+ secreted in this region of the kidney is sufficient to combine with or titrate any remaining filtered HCO_3^- or any filtered anions, such as phosphate and sulfate. Hydrogenated phosphate and sulfate anions produce the titratable acid of the urine. The collecting tubule also takes up NH_3 from the medullary interstitium and secretes it into the urine where, again, it can combine with and trap H^+ as NH_4^+. This urinary NH_4^+ can act as a cation and can be excreted with urinary anions such as Cl^-, phosphate (PO_4^-), and sulphate (SO_4^-), thereby preventing loss of cations such as Na^+, Ca^{2+}, and K^+. Total acid secretion in the kidney can be represented by

$$\text{Titratable Acid} + NH_4^+ - HCO_3^-$$

and under normal conditions should equal the net production of acid from the diet and metabolism that is not excreted in the form of CO_2 through the lungs.

In adults, the steady state for renal compensation for respiratory alkalosis is reached within 1 to 2 days and that for respiratory acidosis is reached within 3 to 5 days. Newborns are able to compensate for acidemia through the previously described renal mechanisms, although the renal response to acid loads is limited, especially in premature neonates born before 34 weeks' gestation. Reabsorption of HCO_3^- in the proximal tubule and distal tubular acidification are also decreased, with a fairly rapid gestational age-dependent maturation of these functions after birth.[139]

To accomplish the tight regulation of pH necessary for survival, H^+ ions generated in the form of the volatile acid H_2CO_3 are excreted by the lungs as CO_2. H^+ ions generated in the form of nonvolatile acids are buffered rapidly by extracellular HCO_3^- and more slowly by intracellular buffers. HCO_3^- is then replenished by the kidneys via the reabsorption of much of the filtered HCO_3^- and by the excretion of H^+ in the urine as NH_4^+ and titratable acids.

Disturbances of Acid-Base Balance in the Newborn

General Principles

The evaluation of the acid-base status in a newborn is one of the most common laboratory assessments made in the neonatal intensive care unit (NICU). The status of this system can be monitored with blood gas measurements and should be the starting point for the evaluation of any acid-base disorder. In the blood gas measurement, the pH and $PaCO_2$ levels are directly measured; from these, the HCO_3^- level and base excess or deficit are calculated.

The whole blood buffer base, defined as the sum of the HCO_3^- and non-HCO_3^- buffer systems, is another important blood gas value used in evaluating acid-base disturbances. The difference between the observed whole blood buffer base of any blood gas sample and the expected normal buffer base of that sample is called the base excess or base deficit. The base excess and base deficit give an accurate measure of the amount of strong acid or base respectively that would be needed to titrate the pH back to normal once the respiratory contribution of the acid-base disturbance is also corrected. For example, a base excess of 10 mEq/L indicates that there is an additional 10 mEq of base per liter (or loss of 10 mEq of H^+ per liter) that is contributing to the acid-base abnormality. Conversely, a base deficit of 10 mEq/L indicates there is relatively more acid (or less base) in the ECF than expected after the effect of $PaCO_2$ on pH has been accounted for.

Acid-base disorders are classified according to their cause as being either metabolic or respiratory. Metabolic acidosis occurs as a result of the accumulation of increased amounts of nonvolatile acid or decreased amounts of HCO_3^- in the ECF. Metabolic alkalosis occurs as a result of increased amounts of HCO_3^- in the ECF. Respiratory acidosis is caused by hypoventilation and decreased excretion of volatile acid (CO_2), whereas respiratory alkalosis is caused by hyperventilation and increased excretion of CO_2.

Acid-base disorders are also classified according to the number of conditions causing the disorder. When only one primary acid-base abnormality and its compensatory mechanisms occur, the disorder is classified as a *simple acid-base disorder*. When a combination of simple acid-base disturbances occurs, the patient has a mixed (or complex) acid-base disorder. Because secondary physiologic regulatory mechanisms often compensate for the alteration in pH caused by primary disturbances, it is sometimes difficult to differentiate simple from mixed disorders or even a simple disorder from its resulting compensation. One important principle that allows the determination of primary acid-base disturbance is that the compensatory regulatory mechanisms do not completely normalize the pH.

Nomograms, such as the one shown in Fig. 20.6, can help in the diagnosis of the primary disturbance. The nomogram describes the 95% confidence limits of the expected compensatory response to a primary abnormality in either $PaCO_2$ or HCO_3^- concentration. Table 20.5 summarizes the expected respiratory and metabolic compensatory mechanisms for primary acid-base disorders.[140] If the compensation in a given patient differs from that predicted in Fig. 20.6 or Table 20.5, the patient either has not had enough time to compensate for a simple acid-base disturbance or has a mixed acid-base disorder. Furthermore, the complete correction of an acid-base disturbance occurs only when the underlying process responsible for the abnormality has been treated effectively.

For identification of the primary disturbance, the analysis of blood gas values must be considered in light of the patient's history and physical findings and with an understanding of expected compensatory responses. Further laboratory evaluation is indicated if the problem is not immediately obvious or if the response to therapy is not as expected. The evaluation of the acid-base disturbance should always involve efforts to determine the underlying cause of the disturbance, because adequate treatment requires correction of the underlying disorder, if possible.

Transitional Physiology After Birth

As part of a discussion of normal physiology, it is important to understand the in-utero environment just before delivery of the newborn and its effect on neonatal acid-base analysis shortly after birth. Hyperventilation of pregnancy is a known phenomenon with corresponding maternal $PaCO_2$ levels of approximately 31 to 34 mm Hg.[141] This relative respiratory alkalosis in the mother is compensated for by a corresponding metabolic acidosis in the mother and therefore in the fetus. As a result, umbilical arterial blood gases have a normal pH range of 7.20 to 7.28, with a corresponding base deficit ranging from 2.7 ± 2.8 mEq/L to 8.3 ± 4.0 mEq/L.[142,143] In other words, a mild metabolic acidosis in the newborn shortly after birth can be expected and explained by normal physiology. In particular, factors such as gestational age,[144] mode of delivery, type of anesthesia, the use of phenylephrine instead of ephedrine to maintain normal blood pressure during cesarean delivery, and maneuvers to decrease vena caval compression all can have impact on fetal acid production. The

TABLE 20.5 Expected Compensatory Mechanisms Operating in Primary Acid-Base Disorders

Acid-Base Disorder	Primary Event	Compensation	Rate of Compensation
Metabolic Acidosis			
Normal anion gap	Decreased HCO_3^- concentration	Decreased PCO_2	For 1 mEq/L decrease in HCO_3^- concentration, PCO_2 decreases by 1–1.5 mmHg
Increased anion gap	Increased acid production Increased acid intake	Decreased PCO_2	For 1 mEq/L decrease in HCO_3^- concentration, PCO_2 decreases by 1–1.5 mmHg
Metabolic Alkalosis			
	Increased HCO_3^- concentration	Increased PCO_2	For 1 mEq/L increase in HCO_3^- concentration, PCO_2 increases by 0.5–1 mmHg
Respiratory Acidosis			
Acute (<12–24 h)	Increased PCO_2	Increased HCO_3^- concentration	For 10 mmHg increase in PCO_2, HCO_3^- concentration increases by 1 mEq/L
Chronic (3–5 days)	Increased PCO_2	Increased HCO_3^- concentration	For 10 mmHg increase in PCO_2, HCO_3^- concentration increases by 4 mEq/L
Respiratory Alkalosis			
Acute (<12 h)	Decreased PCO_2	Decreased HCO_3^- concentration	For 10 mmHg increase in PCO_2, HCO_3^- concentration increases by 1–3 mEq/L
Chronic (1–2 days)	Decreased PCO_2	Decreased HCO_3^- concentration	For 10 mmHg decrease in PCO_2, HCO_3^- concentration decreases by 2–5 mEq/L

final common pathway for these factors is in optimizing uteroplacental blood flow.[145] The practice of delayed cord clamping appears to have minimal to no impact on umbilical cord gases in term newborns.[146]

Metabolic Acidosis

Metabolic acidosis is a common problem, particularly in the critically ill newborn. Metabolic acidosis occurs when the drop in pH is caused by the accumulation of acid other than H_2CO_3 in the ECF, resulting in loss of available HCO_3^-, or by the direct loss of HCO_3^- from body fluids. Patients who have metabolic acidosis are divided into those with an elevated anion gap and those with a normal anion gap.

The anion gap reflects the unaccounted acidic anions and certain cations in the ECF. The unmeasured anions normally include the serum proteins, phosphates, sulfates, and organic acids, whereas the unaccounted cations are the serum potassium, calcium, and magnesium ions. Thus, in clinical practice, the anion gap is estimated with the formula:

$$\text{Anion Gap} = [NH_4^+]_{serum} - ([Cl^-]_{serum} + [HCO_3^-]_{serum}).$$

The normal range of the serum anion gap in newborns is 8 to 16 mEq/L, with slightly higher values in very premature newborns. Accumulation of strong acids because of increased intake, increased production, or decreased excretion results in an increased anion gap acidosis, whereas loss of HCO_3^- or accumulation of H^+ results in a normal anion gap acidosis. A decrease in serum potassium, calcium, and magnesium concentrations, an increase in serum protein concentration, or a falsely elevated serum sodium concentration can also result in an increased anion gap in the absence of metabolic acidosis. In clinical practice, although a serum anion gap value greater than 16 mEq/L is highly predictive of the presence of lactic acidosis and a value less than 8 mEq/L is highly predictive of the absence of lactic acidosis, an anion gap value between 8 and 16 mEq/L cannot be used to differentiate between lactic and non-lactic acidosis in the critically ill newborn.[147] Therefore, if the anion gap is within this high normal range and lactic acidosis is suggested, measurement of serum lactate is indicated. At present, with the routine availability of measurement of lactic acid from low-volume blood samples by blood gas machines, the determination of the origin of acidosis ("anion gap," i.e., net strong acid gain, or "non-anion gap," i.e., buffer loss–induced acidosis) has become simpler in most clinical presentations of metabolic acidosis.

An increased anion gap metabolic acidosis in the newborn is most commonly caused by lactic acidosis secondary to tissue hypoxia, as seen in hypoxic-ischemic encephalopathy, hypothermia, hypovolemia, severe respiratory distress, sepsis, necrotizing enterocolitis, and other severe neonatal illnesses. Other important but much less common causes of an increased anion gap metabolic acidosis in the neonatal period are inborn errors of metabolism, renal failure, and intake of toxins (Box 20.3). Box 20.4 lists inborn errors of metabolism that can manifest themselves as increased anion gap metabolic acidosis in the newborn period.

In the syndrome of late metabolic acidosis of prematurity, first described in the 1960s, otherwise healthy premature infants at several weeks of age demonstrated mild to moderate increased anion gap acidosis and decreased growth. All the infants were receiving high-protein cow's milk formula and presented with higher net acid excretion compared with controls. However, this type of late metabolic acidosis is rarely seen today, likely because of the use of special premature infant formulas and changes in regular formulas with decreased casein-to-whey ratios and lower fixed acid loads.

A normal anion gap metabolic acidosis most commonly occurs in the newborn as a result of HCO_3^- loss from the extracellular

• BOX 20.3 Common Causes of Metabolic Acidosis

Increased Anion Gap

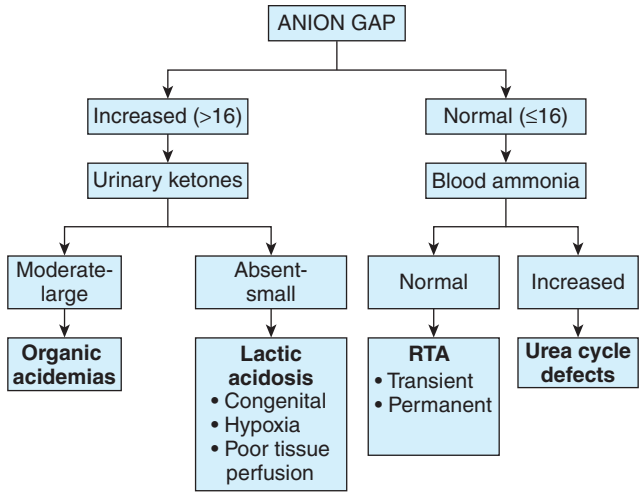
- Lactic acidosis caused by tissue hypoxia
  - Asphyxia, hypothermia, shock
  - Sepsis, respiratory distress syndrome
- Inborn errors of metabolism
  - Congenital lactic acidosis
  - Organic acidosis
- Renal failure
- Late metabolic acidosis
- Toxins (e.g., benzyl alcohol)

Normal Anion Gap

- Renal bicarbonate loss
  - Bicarbonate wasting caused by immaturity
  - Renal tubular acidosis
- Carbonic anhydrase inhibitors
  - Gastrointestinal bicarbonate loss
  - Small bowel drainage: ileostomy, fistula
  - Diarrhea
- Extracellular volume expansion with bicarbonate dilution
- Aldosterone deficiency
- Excessive chloride in intravenous fluids

• BOX 20.4 Inborn Errors of Metabolism Associated With Metabolic Acidosis

- Primary lactic acidosis
- Organic acidemias
- Pyruvate carboxylase deficiency
- Pyruvate hydroxylase deficiency
- Galactosemia
- Hereditary fructose intolerance
- Type I glycogen storage disease



• **Fig. 20.7** Diagnostic approach of increased anion gap and normal anion gap metabolic acidosis in the newborn. Newborns with lactic acidosis may not have an increased anion gap, and lactate concentration should be directly measured if this is suspected from the history and physical examination. *RTA*, Renal tubular acidosis. (Modified from Lorenz JM, Kleinman LI, Markarian K, et al. Serum anion gap in the differential diagnosis of metabolic acidosis in critically ill newborns. *J Pediatr*. 1999;135:751–755.)

space through the kidneys or the GI tract. Hyperchloremia develops with the HCO_3^- loss because a proportionate rise in serum chloride concentration must occur to maintain the ionic balance or to correct the volume depletion in the extracellular compartment. The most common cause of normal anion gap metabolic acidosis in the preterm newborn is a mild, developmentally regulated, proximal renal tubular acidosis with renal HCO_3^- wasting. In newborns with this disorder, the serum HCO_3^- concentration usually stabilizes at 14 to 18 mEq/L in the early postnatal period. The urinary pH is normal once the serum HCO_3^- has stabilized at this level because the impairment in proximal tubular HCO_3^- reabsorption is not associated with an impaired distal tubular acidification of similar magnitude.[139] The diagnosis of this temporary cause of acidosis can be established by the recurrence of a urinary alkaline pH when serum HCO_3^- concentration is raised above the threshold after HCO_3^- or acetate supplementation. Even term newborns have a lower renal threshold for HCO_3^- than adults with normal plasma HCO_3^- levels in the range of 17 to 21 mEq/L. In most infants, plasma HCO_3^- concentration increases to adult levels over the first year as the proximal tubule matures. Other common causes of normal anion gap metabolic acidosis seen in neonatal intensive care units are GI HCO_3^- losses, often caused by increased ileostomy drainage, diuretic treatment with carbonic anhydrase inhibitors, and dilutional acidosis, with rapid expansion of the extracellular space through the use of non-HCO_3^- solutions such as 0.9% sodium chloride in the hypovolemic newborn.

The presence of metabolic acidosis in the newborn may be suspected by the clinical presentation and the history of predisposing conditions, including perinatal depression, respiratory distress, blood or volume loss, sepsis, and congenital heart disease associated with poor systemic perfusion or cyanosis. Metabolic acidosis is confirmed by blood gas measurements. Specific laboratory evaluation of electrolytes, renal function, lactate, and serum and urine amino acids may be undertaken, depending on the diagnosis that is suggested clinically. Fig. 20.7 shows a simple flow diagram outlining an approach to diagnosis of metabolic acidosis in the newborn. It is important to emphasize that newborns might not manifest an increased anion gap in the setting of lactic acidosis.[147] However, the availability of lactic acid measurement along with the blood gas measurements in today's intensive care units aids in the rapid determination of the type of the lactic acidosis.

The morbidity and mortality associated with metabolic acidosis depend on the underlying pathologic process, the severity of the acidosis, and the responsiveness of the process to clinical management. By far, the most important intervention for a newborn with a metabolic acidosis is identification of the pathologic process responsible for the development of acidosis and the taking of measures to correct it. It is important to emphasize that the indiscriminate administration of a base, such as sodium bicarbonate, as supportive therapy for all types of metabolic acidosis is unproven in its efficacy.[148]

The question facing neonatal providers is: how low does the pH need to fall before base administration might be associated with improvement in clinical condition for newborns with metabolic or severe mixed acidosis? An early study suggested that $NaHCO_3$ administration to mechanically ventilated preterm and term neonates receiving neuromuscular blockade with an arterial pH of less than 7.25 *transiently* improved systemic and organ blood flow.[149] However, in a more recent study using more sophisticated

hemodynamic evaluation in hemodynamically stable preterm neonates born at 30 weeks' gestation or earlier, myocardial contractility was found to be unaffected by acidosis even at pH values close to 7.00 during the first 2 weeks postnatally. In the same study, similar to what is seen in adults, worsening acidosis in more than 3-day-old preterm neonates was associated with decreased systemic vascular resistance and increased left ventricular output. This effect was not seen on preterm neonates 3 days old or less.[150] It is clear that more data are needed to adequately address this question, especially because of the concern for harm associated with the administration of base. Indeed, a number of historical studies have shown an association between the use of base and increased mortality and incidence of IVH,[151–153] increased cerebral blood volume regardless of the rate of administration,[154] and decreased intracellular pH with cellular injury.[155] To assess the frequency of prevention or treatment of metabolic acidosis, a survey of 120 Italian NICUs with a 97.5% response rate revealed that 55% of NICUs routinely correct metabolic acidosis with sodium bicarbonate and 37.6% include buffer salts in parenteral nutrition in an attempt to prevent the occurrence of metabolic acidosis.[156]

If a decision has been made to administer base, the clinician has traditionally had three options: sodium bicarbonate, sodium (or potassium) acetate, and tromethamine. $NaHCO_3$ is the most widely used buffer in the treatment of metabolic acidosis in the neonatal period. Bicarbonate should not be given if ventilation is inadequate because its administration results in an increase in $PaCO_2$ with little to no increase in pH and an increase in intracellular acidosis. Therefore, $NaHCO_3$ should be administered slowly and in diluted form only to newborns with documented metabolic acidosis and adequate alveolar ventilation. Once a blood gas measurement has been obtained, the dose of $NaHCO_3$ required to fully correct the pH can be estimated with the use of the following formula:

$$\text{Dose of } NaHCO_3\,(\text{mEq}) = \text{Base Deficit}\left(\frac{\text{mEq}}{\text{L}}\right) \times \text{Body Weight}\,(\text{kg}) \times 0.3.$$

$NaHCO_3$ is confined mostly to the ECF compartment. Although there are controversies regarding the actual bicarbonate space in humans, body weight (kg) × 0.3 (or 30% of the infant's total body weight) represents its estimated volume of distribution in the neonate. Most clinicians would use half of the calculated total correction dose for initial therapy to avoid overcorrection of metabolic acidosis. Subsequent doses of $NaHCO_3$ are then based on the results of additional blood gas measurements.

When clinicians are faced with a chronic non–anion gap metabolic acidosis caused by a prematurity-related proximal renal tubular acidosis with bicarbonate wasting, many choose to replace these losses over time. In this instance, either sodium acetate or potassium acetate can be used as an alternative to $NaHCO_3$. Sodium acetate is a conjugate base of a weak acid (acetic acid) with a pK_b of 9.25; pK_b is a measure of the strength of a base, which depends on its base dissociation constant. Sodium acetate has been shown in one study to be an effective alternative to $NaHCO_3$ in correcting this type of acid-base abnormality when added to parenteral nutrition.[157] The median dosages of acetate used in this randomized controlled trial were 2.6 mmol/kg/day on postnatal day 4 of life and 4.1 mmol/kg/day on postnatal day 8. Neonates randomized to receive acetate had an increased base excess, pH, and $PaCO_2$, and they received less bicarbonate boluses compared with control neonates.

Historically, tromethamine has been used as an alternative buffer to sodium bicarbonate, but in recent times its commercial availability has been limited. In the United States, it appears to have been removed from the market; however, it continues to be available elsewhere.[158] The theoretical advantages of tromethamine over $NaHCO_3$ in the treatment of metabolic acidosis include its more rapid intracellular buffering capability, its ability to lower $Paco_2$ levels directly, and the lack of an increase in the sodium load.[159] Tromethamine lowers $Paco_2$ by covalently binding H^+ and thus shifting the equilibrium of the reaction

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow H_2O + CO_2$$

to the left, resulting in a decrease in the amount of CO_2 and an increase in the amount of HCO_3^-. Tromethamine administration has been associated with the development of acute respiratory depression, most likely secondary to an abrupt decrease in $PaCO_2$ levels, as well as from rapid intracellular correction of acidosis in the cells of the respiratory center.[160] In addition, when large doses of tromethamine are administered, hyponatremia,[161] hypoglycemia, hyperkalemia, an increase in hemoglobin oxygen affinity, and diuresis followed by oliguria can occur. As tromethamine is hyperosmolar, a slow infusion rate is recommended at a dose calculated from the formula:

$$\text{Dose of Tromethamine}\,(\text{mL}) = \text{Base Deficit}\left(\frac{\text{mEq}}{\text{L}}\right) \times \text{Body Weight}\,(\text{kg}).$$

Finally, during the correction of metabolic acidosis, regardless of the method chosen, particular attention should be paid to ensuring an appropriate potassium balance. Because potassium moves from the intracellular to the extracellular space in exchange for H^+ when acidosis occurs, the presence of a total body potassium deficit might not be appreciated during metabolic acidosis. Hypokalemia may become evident only as the pH increases and potassium returns to the intracellular space. Furthermore, intracellular acidosis cannot be completely corrected until the potassium stores are restored. Therefore, close monitoring of serum electrolyte levels and careful potassium supplementation are important during the correction of metabolic acidosis in the sick newborn.

Respiratory Acidosis

Respiratory acidosis occurs when a primary increase in $PaCO_2$ develops secondary to impairments in alveolar ventilation that result in an arterial pH of less than 7.35. Primary respiratory acidosis is a common problem in newborns and causes include hyaline membrane disease, pneumonia owing to infection or aspiration, PDA with pulmonary edema, chronic lung disease, pleural effusion, pneumothorax, and pulmonary hypoplasia. The initial increase in $PaCO_2$ is buffered by the non-HCO_3^- intracellular buffers without noticeable renal compensation for at least 12 to 24 hours (see Table 20.5). Renal metabolic compensation reaches its maximum levels within 3 to 5 days, and its effectiveness in the newborn is influenced mainly by the functional maturity of proximal tubular HCO_3^- transport. Management of respiratory acidosis is directed toward improving alveolar ventilation and treating the underlying disorder. This may include escalation of noninvasive respiratory support, intubation and mechanical ventilation, alternative modes of mechanical ventilation, and/or administration of surfactant.

Metabolic Alkalosis

Metabolic alkalosis is characterized by a primary increase in the extracellular HCO_3^- concentration sufficient to raise the arterial pH above 7.45. In the newborn, metabolic alkalosis occurs when there is a loss of H^+, a gain of HCO_3^-, or a depletion of the extracellular volume with the loss of more chloride than HCO_3^-. It is important to understand that metabolic alkalosis generated by any of these mechanisms can be maintained only when factors limiting the renal excretion of HCO_3^- are also present.

Metabolic alkalosis can result from a loss of H^+ from the body, from either the GI tract or the kidneys, that induces an equivalent rise in the extracellular HCO_3^- concentration. The most common causes of this type of metabolic alkalosis in the newborn period are continuous nasogastric aspiration, persistent vomiting, and diuretic treatment. Less common causes of H^+ losses are congenital chloride-wasting diarrhea, certain forms of congenital adrenal hyperplasia, hyperaldosteronism, post-hypercapnia, and Bartter syndrome.

Metabolic alkalosis can also result from a gain of HCO_3^-, such as occurs during the administration of buffer solutions to the newborn. In the past, a metabolic alkalosis was intentionally created when $NaHCO_3$ or tromethamine was used to maintain an alkaline pH to decrease pulmonary vasoreactivity in infants with persistent pulmonary hypertension, a practice not recommended anymore. Currently, iatrogenic metabolic alkalosis is primarily due to long-term excessive administration of HCO_3^-, lactate, citrate, or acetate in IV fluids and blood products. Because excretion of HCO_3^- is normally not limited in the newborn, metabolic alkalosis resulting from HCO_3^- gain alone should rapidly resolve after administration of HCO_3^- is discontinued. However, if the alkalosis is severe and urine output is limited, inhibition of the enzyme carbonic anhydrase by the administration of acetazolamide may enhance elimination of HCO_3^-.

Metabolic alkalosis can also result from a loss of ECF containing disproportionately more chloride than HCO_3^-, the so-called contraction alkalosis. During the diuretic phase of normal postnatal adaptation, preterm and term newborns retain relatively more HCO_3^- than chloride.[119] The obvious clinical benefits of allowing this physiologic extracellular volume contraction to occur, especially in the critically ill newborn, clearly outweigh the clinical importance of a mild contraction alkalosis that develops after recovery. No specific treatment is needed in such cases, because with the stabilization of the extracellular volume and renal function after recovery, acid-base balance rapidly returns to normal. Contraction alkalosis due to other causes, however, may require treatment.

As mentioned previously, for metabolic alkalosis to persist, factors limiting the renal excretion of HCO_3^- must be present. The kidneys are usually effective in excreting excess HCO_3^-, but this ability can be limited under certain conditions, such as decreased glomerular filtration rate, increased aldosterone production, and the more common clinical situation of volume contraction–triggered metabolic alkalosis with potassium deficiency. In the last condition, there is a direct stimulation of Na^+ reabsorption coupled with H^+ loss in the proximal tubule and an indirect stimulation of H^+ loss in the distal nephron by the increased activity of the RAAS. Contraction alkalosis responds to administration of saline to replace the intravascular volume in conjunction with additional potassium supplementation to account for renal potassium wasting. In the other disorders, however, the primary problem of reduced glomerular filtration rate or elevated aldosterone concentration must be treated for the alkalosis to resolve.

One of the most commonly encountered clinical scenarios of chronic metabolic alkalosis actually occurs in the form of a mixed acid-base disorder in a preterm neonate with chronic lung disease receiving long-term diuretic treatment. Such a newborn initially has a chronic respiratory acidosis that is partially compensated for by renal HCO_3^- retention. Prolonged or aggressive use of diuretics can lead to total body chloride and potassium depletion and contraction of the extracellular volume, thus exacerbating the metabolic alkalosis. By stimulating proximal tubular Na^+ reabsorption and thus H^+ loss, distal tubular H^+ secretion, and renal ammonium production, the diuretic-induced hypokalemia contributes to the severity and maintenance of the metabolic alkalosis. Furthermore, metabolic alkalosis per se worsens hypokalemia, because potassium moves intracellularly to replace hydrogen as the latter shifts into the extracellular space. Although the serum potassium concentration may be decreased, the serum levels in the newborn do not accurately reflect the extent of total body potassium deficit because potassium is primarily an intracellular ion, with approximately 98% of the total body potassium being in the intracellular compartment. In addition, the condition is accompanied by marked hypochloremia and hyponatremia. Hyponatremia occurs in part because sodium shifts into the intracellular space to compensate for the depleted intracellular potassium. If the alkalosis is severe, alkalemia (pH >7.45) can supervene and result in hypoventilation. In this situation, potassium chloride supplementation, and not sodium chloride supplementation, reverses hyponatremia and hypochloremia, corrects hypokalemia and metabolic alkalosis, and increases the effectiveness of diuretic therapy. Because chloride deficiency is the predominant cause of the increased pH, ammonium chloride or arginine chloride also corrects the alkalosis. These agents do not affect the other electrolyte imbalances such as the hypokalemia, so they should not be the only therapy given.

It is important to be proactive and stay ahead of the potassium losses in infants receiving long-term diuretic therapy rather than to attempt to replace potassium after intracellular depletion has occurred. Because the rate of potassium repletion is limited by the rate at which potassium moves intracellularly, correction of total body potassium deficits can require days to weeks. In addition, there is also a risk of acute hyperkalemia if serum potassium levels are driven too high during repletion, particularly in newborns in whom an acute respiratory deterioration may occur. Indeed, with worsened respiratory acidosis, potassium will move from the intracellular to the extracellular space. The routine use of potassium chloride supplementation and close monitoring of serum sodium, chloride, and potassium levels are therefore recommended during long-term diuretic therapy to prevent these common iatrogenic problems.

Respiratory Alkalosis

When a primary decrease in $PaCO_2$ results in an increase in the arterial pH beyond 7.45, respiratory alkalosis develops. The initial hypocapnia is acutely titrated by the intracellular buffers, and metabolic compensation by the kidneys returns the pH toward normal within 1 to 2 days (see Table 20.5). Respiratory alkalosis is the only simple acid-base disorder in which, at least in adults, the pH can be completely normalized by the compensatory mechanisms.[140] The cause of respiratory alkalosis is hyperventilation, which in the spontaneously breathing newborn is most often

caused by fever, sepsis, retained fetal lung fluid, mild aspiration pneumonia, CNS disorders, or urea cycle defects.

In the NICU, the most common cause of respiratory alkalosis is iatrogenic secondary to hyperventilation of the intubated newborn. Because findings suggest an association between hypocapnia and the development of periventricular leukomalacia (PVL)[162,163] and chronic lung disease[164] in ventilated preterm neonates, avoidance of hyperventilation during resuscitation and mechanical ventilation is of utmost importance in the management of sick preterm newborns. It appears that later onset of hypocarbia is more deleterious in terms of the development of PVL (at 26 hours of age vs. 15 hours of age), with 88% of these patients having poor neurodevelopmental outcome at a median age of 46 months.[165] Managing preterm neonates with permissive hypercapnia has made the incidence of hypocapnia and respiratory alkalosis much less common than it was in previous decades. However, it is of note that *hypercapnia in the transitional period* is associated with increased incidence of periventricular hemorrhage/IVH in very preterm neonates.[166,167] In one study of ventilated preterm neonates, the incidence of hypocapnia was 4%, and hypocapnia was more common in the first 3 days of age.[168] The treatment of neonatal respiratory alkalosis consists in the specific management of the underlying process causing hyperventilation.

Neonatal Pharmacology

KAREL ALLEGAERT, ROBERT M. WARD, AND JOHN N. VAN DEN ANKER

KEY POINTS

- The key feature of neonatal physiology is rapid maturation, resulting in extensive variability in pharmacokinetics and pharmacodynamics, further aggravated by other covariates, like pharmacogenetics or unique disease characteristics. Variability is the essence of neonatal care and neonatal pharmacology.
- Thorough understanding of these factors, especially developmental changes, that affect pharmacokinetics (absorption, distribution, metabolism, elimination) in neonates helps to provide accurate dose adjustments to assure effective drug therapy.
- Adverse drug reactions are common and important aspects of neonatal drug therapy. Pharmacovigilance is based on prevention, detection, and assessment, but all these issues need to be adapted to the specific characteristics of this population. Minimization or prevention of such events can usually be achieved.
- To stimulate neonatal drug development, product development should be based on neonatal physiology and pharmacology, while still incorporating already available knowledge from non-neonatal settings to facilitate neonatal drug development. Furthermore, the central role of nurses and families in research and the value of the entire neonatal team in the design, implementation, and interpretation of clinical therapeutic studies is crucial.

Dynamic changes related to growth and maturation in newborns create unique complexities in drug therapy that affect the variability in pharmacokinetics (PK) (absorption, distribution, metabolism, elimination) and pharmacodynamics (PD) (both desired efficacy and unwanted side effects). Pharmacologic studies during this period of rapid growth and physiologic maturation reveal diverse patterns of changes. These patterns also reflect the maturation of different drug-metabolizing enzymes or pathways of elimination throughout infancy. Therapeutic drug monitoring (TDM) is applied to only a limited number of drugs in neonatal care (e.g., phenobarbital, gentamicin), because the serum or plasma concentrations need to correlate with both effects and possible side effects. Dose adjustments to reach the desired concentrations can be estimated at the bedside with use of simple calculations, although we expect that such observations will be incorporated in model informed precision dosing (MIPD) concepts, tailored to neonates.[1] Pharmacogenetics (PGx) or pharmacogenomics of drug-metabolizing enzymes, transporters, or receptors explain a large part of the observed variations among individuals in their responses to drugs. Developmental expression of enzymes, receptors, and organ function add additional levels of complexity in drug disposition and effects in the immature, preterm, or critically ill newborn.

Principles of Neonatal Therapeutics

In neonates, thorough understanding of factors ("covariates") that influence drug concentrations enhance accurate and effective drug therapy and may help to identify causes of treatment failure or therapy-related toxicity. Many relevant covariates are not incorporated in a therapeutic plan, although the impact on effectiveness and safety of a given drug added to current drug therapy may be tremendous. Since PK (concentration–time profiles) and PD (concentration–effect profiles) in newborns follow the same general principles that govern drug actions in patients of all ages, the diagnosis, drug selection, and route of administration needed to achieve a therapeutic goal must consider the impact of absorption, distribution, metabolism, and elimination (ADME) on the dose–exposure relationship. In newborns these principles should include special consideration of the unique physiologic and pharmacologic features of these developmentally immature patients (Box 21.1).

Diagnosis

Effective treatment begins with an accurate diagnosis and assessment of symptoms. Although this applies to all areas of therapeutics, treatment in newborns presents specific challenges. Their small size and fragility may preclude useful, but inordinately invasive, diagnostic procedures. For example, newborns with chronic lung disease are treated for "bronchospasm" on the basis of the findings of decreased air entry, desaturation, and abnormal breath sounds. Relief of these symptoms with aerosolized bronchodilators may be interpreted as confirming this diagnosis. Although this may be correct, increased humidity or movement of the endotracheal tube bevel away from a pliable tracheal wall during aerosol treatment may also result in improvement. A similar argument can be made for suspected neonatal infection, the clinical diagnosis of a patent ductus arteriosus, neonatal pain management, drug-related renal or hepatic toxicity, or the claimed link between gastroesophageal reflux and apnea. Therefore, evaluation of an ineffective therapy should include reconsideration of the diagnosis, in the same way as conclusions about why a therapy succeeded should be made cautiously.

Absorption

Absorption is the movement of a drug into the systemic circulation. It generally requires the crossing of membranes or membrane barriers and is characterized by rate (time to peak) and

• BOX 21.1 Pharmacologic Principles and Pitfalls in the Management of Very Low Birth Weight Infants

Diagnosis
Limited diagnostic procedures

Absorption
Intravenous
- Drug injection away from patient
- Uneven mixing of drugs and intravenous fluids
- Delayed administration due to very low flow
- Part of the dose discarded with tubing changes

Intramuscular
- Poor perfusion limits absorption
- Danger of sclerosis or abscess formation
- Depot effect

Oral
- Poorly studied
- Affected by delayed gastric emptying
- Potentially affected by reflux
- Passive venous congestion may occur with chronic lung disease, decreasing absorption

Distribution (Affected by)
Higher (85%) total body water (vs. 65% in adults)
Lower body fat, i.e., about 1% body weight (vs. 15% in term newborns)
Low protein concentration
Decreased protein affinity for drugs

Metabolism
a. Half-life prolonged and unpredictable
b. Total body clearance decreased
c. Affected by nutrition, illness, and drug interaction
d. Affected by maturational changes

Elimination
Decreased renal function, both glomerular filtration rate and tubular secretion/absorption

extent (percentage of dose). The most commonly used route in neonates is *intravenous administration*. However, even this route of administration has challenges related to neonatal pathophysiology and limitations of intravenous infusion systems (e.g., low flow, small volume, dead space volume, limited flush volume).[2–4] Consequently, drugs should be infused into the patient as close as possible to the site of the venous access. If a drug is injected farther away from the infant and at a low rate, the drug may reach the patient far too slowly or incompletely to achieve effective concentrations. Infusion solution filters may further hamper drug delivery by blocking large molecules, by adsorption of the drug to the filter, or by allowing a heavier drug to settle in the filtration chamber and mix slowly.[2–4] For drugs in which the peak concentration matters (e.g., aminoglycosides) or when the driving force for tissue penetration is a concentration gradient between circulation and tissue (e.g., meningitis), these limitations may result in suboptimal therapy.

Intramuscular administration of drugs is used for slow release (e.g., vitamin A or K, palivizumab) but is a poor substitute for intravenous access and should be avoided for multiple doses. Absorption following intramuscular injection relates to muscle blood flow and depends on maturation and disease characteristics (e.g., hypothermia, shock). Furthermore, intramuscular administration may result in tissue sclerosis, causing sterile abscesses, or create large intramuscular collections, which are subsequently absorbed slowly, producing a "depot effect" in which serum concentrations evolve slowly (both rise and fall) over time.

Oral administration of drugs is preferred for treatment of chronic illnesses in newborns, but this route is not very well studied in acutely ill preterm neonates. Maturation affects gastric and intestinal pH and motility, pancreatic activity and bile acid secretion, or pre-systemic drug metabolism and transport (first pass) in the intestinal wall. The gastric fluid composition (bile salts, osmolarity, pH) displays age-dependent changes, further affected by type and frequency of feeding.[5] Many newborns experience gastroesophageal reflux and delayed gastric emptying. This prolongs and delays absorption, which reduces the peak concentration and may also reduce the total dose absorbed. Passive intestinal venous congestion caused by elevated right atrial pressure decreases drug absorption in adults and may do so in premature infants with severe bronchopulmonary dysplasia.[6] Co-administration of medications to newborns with small volumes of milk or during continuous gastric or duodenal feedings may also alter absorption. Volumes can affect drug solubility in the intestinal lumen while milk can affect bioavailability (e.g., iron or quinolone absorption when combined with milk).

Buccal, lingual, or rectal administrations are additional enteral routes that are all associated with variability. For clinicians, this means that if enteral drug therapy fails, the impact of the route or feeding patterns on drug absorption must be considered. Finally, unanticipated absorption of drugs or excipients intended for topical effects (e.g., cutaneous, inhalation, perineural) should be considered, as these can also be associated with relevant side effects.[7,8]

Distribution

Distribution is the partitioning of drugs among various body fluids, organs, and tissues. The distribution of a drug within the body is determined by several factors, including organ blood flow, pH and composition of body fluids and tissues, physical and chemical properties of the drug (e.g., lipid solubility, molecular weight, and ionization constant), and drug transporter activity but also by the extent of drug binding to plasma proteins (albumin, α_1-acid glycoprotein) and other macromolecules.[7,9]

Physiologic differences between fetuses, preterm neonates, children, and adults affect drug distribution. Total body water content ranges from 85% in premature newborns to 75% in term newborns to 65% in adults.[10–13] Conversely, body fat content ranges from 0.7% or less in extremely premature newborns to 12% in term newborns. These differences affect distribution of water-soluble (e.g., aminoglycosides, acetaminophen), lipophilic (e.g., propofol) or nonpolar drugs (e.g., fentanyl). The protein-binding capacity of drugs in the circulation is lower in early infancy because of lower circulating plasma protein concentrations (e.g., albumin, α_1-acid glycoprotein) and less binding affinity. Competitive binding with bilirubin is another specific issue to be considered in neonates.[7] With rare exceptions, only the free (unbound) drug crosses membranes, exerts pharmacologic actions, and undergoes metabolism and elimination. However, measurements of drug concentrations usually reflect total circulating drug concentrations, which consist of both free and protein-bound drug concentrations. Thus even when total circulating drug concentrations in

the newborn may be low by adult standards, the free drug concentrations may still be equivalent or even higher than those in the adult because of decreased protein binding. Disease (sepsis) or therapeutic interventions (extracorporeal circulation) can further affect distribution.

Metabolism

Drug-metabolizing enzymes are crucial in the extent of drug biotransformation. Although the liver is considered the major organ responsible for drug biotransformation, other organs such as the intestines, lungs, and kidneys also contribute to drug metabolism. These metabolizing enzymes can be classified as participating in non-synthetic phase I reactions (e.g., oxidation, reduction, hydrolysis) or synthetic phase II reactions (e.g., glucuronidation, sulfation, acetylation). Their metabolites can subsequently be eliminated by renal, biliary, or other elimination routes and may also be therapeutically active or contribute to adverse effects.

The primary type of enzymes involved in phase I reactions are cytochromes P450 (CYPs). CYPs mature at different rates and in different patterns with the highest impact in early infancy. In addition, single nucleotide polymorphisms (SNPs) or substitutions in the DNA sequence for a CYP may reduce its metabolizing activity or completely eliminate it if the polypeptide cannot be formed (cf. PGx). Conversely, some individuals inherit multiple copies of a CYP, producing "supermetabolizers" (CYP2D6). The phase II conjugation enzymes, such as the uridine 5-diphosphoglucuronosyltransferases (UGTs) have several forms with different substrate specificity (e.g., UGT1A1 for bilirubin, UGT2B7 for morphine) although they are not as absolutely selective as the CYPs.

All enzymes display isoenzyme specific maturation, and this affects drug metabolism throughout infancy. Consequently, the clearance of almost all drugs is decreased in neonates compared with older children and adults, but important variations in rates of maturation occur among drug classes and among individuals, which prevents simple generalization. Three patterns can be identified with (a) most CYPs being low at birth and increasing to adult levels in the first months or years (e.g., CYP2D6, UGT1A1), (b) high at birth and decreasing thereafter (e.g., CYP3A7), and (c) stable expression (e.g., plasma esterase, sulfation).[14] Although this classification is very helpful to explain and even predict maturational drug disposition, it should be used cautiously. We cannot simply miniaturize "major" and "minor" routes of elimination as documented in adults to (pre)term neonates. In the absence of an adult major route, a minor route, either metabolic or primary elimination, may be a more relevant route of clearance in neonates (e.g., caffeine elimination is renal in neonates and metabolic [CYP1A2] in adults). A similar argument can be made for acetaminophen. Glucuronide conjugation is usually low at birth. In contrast, conjugation through sulfation is usually active at birth. These different patterns are reflected in the developmental changes in acetaminophen metabolism in early life.[15]

Besides age-driven maturation, other factors such as nutrition, disease characteristics, PGx, or drug–drug interactions further affect the phenotypic activity of enzymes and organs responsible for drug metabolism in the newborn. Maturational changes in hepatic blood flow, drug transport into hepatocytes, synthesis of serum proteins, protein binding of drugs, and biliary secretion further confound accurate predictions about drug metabolism after birth.

Elimination

Drug elimination can occur through several mechanisms. Elimination occasionally occurs by the hepatobiliary route, transcutaneously, or by the lungs, but is most commonly by the kidneys. Renal elimination is the most important pathway for unchanged drugs or metabolites, either by glomerular filtration or by renal tubular transport (reabsorption, secretion).

Glomerular function increases steadily after birth, whereas tubular function matures more slowly, causing a glomerular-to-tubular imbalance.[16,17] Based on pooling of GFR estimates (polyfructose, Cr-EDTA, mannitol or iohexol), a quantitative description using weight and postmenstrual age (PMA) showed that half of the adult value is reached at 48 weeks PMA.[18] In a very recent analysis on differences between preterm and term neonates, Salem et al. documented that both postnatal and gestational age (GA) are relevant for GFR until 1.25 years.[19] This postnatal increase in glomerular function relates to higher cardiac output, reduced renal vascular resistance, redistribution of intrarenal blood flow, and changes in intrinsic glomerular basement membrane permeability. These age-dependent dynamics of neonatal renal function markedly influence drug elimination. Similar to drug metabolism, however, the variability in renal elimination capacity and drug clearance is further affected by other covariates, such as hypoxemia, nephrotoxic drugs, hypoperfusion, hypothermia, and intercurrent renal diseases.[20]

The maturation of biliary elimination capacity appears to be fast, attaining adult activity within the first months of life.[20,21] Drugs that are conjugated within the liver may also be eliminated, excreted through bile only to enter the intestinal tract, where they may be deconjugated and undergo enterohepatic recirculation, similarly to bilirubin. Although biliary elimination is not well studied in newborns, clinical conditions such as parenteral nutrition-associated cholestasis suggest that it may be quite variable among specific patients and conditions.

Transporters play important roles in the uptake or removal of drugs. Compared with enzymes, the ontogeny is still not well documented, although patterns have been described and incorporated in physiologically based PK models. A recent review suggests that different developmental patterns for individual transporters are emerging.[9] Organic anion transporter polypeptides provide facilitated transport of anions in many tissues, including the kidney and liver. P-glycoprotein (PGP), the permeability glycoprotein, is an efflux transporter that belongs to the adenosine triphosphate-binding cassette/multiple drug resistance family of transporters and prevents absorption of many compounds across the intestinal wall or into the brain. PGP expression has been described as limited at birth, reaching adult levels at 3 to 6 months of age.[22] To put these findings into perspective, the limited PGP efflux activity increases opioid concentrations in the central nervous system of newborns and likely explains the higher incidence of apnea in neonates following opioid exposure.

Pharmacogenetics and Pharmacogenomics

The Human Genome Project has described the structures of many proteins (enzymes, transporters, receptors, postreceptor signaling pathways) that have a role in the PK and PD of many drugs currently used in neonatal, pediatric, and adult pharmacotherapy. Genetic variants that alter activity have been identified, many based on SNPs in these proteins. As mentioned earlier, genetic

variation in drug-metabolizing enzymes can have a significant influence on the relative activity within a particular individual. Large interindividual variation occurs for several isoenzymes and is often explained by inherited differences in activity. Changes in a single nucleotide in the DNA for one of these enzymes is designated with an asterisk, such as CYP2C9*1, and these changes can alter the protein structure enough to decrease, completely inactivate, or increase its enzymatic activity. SNPs have been identified for many CYPs, and ethnic variations in these SNPs help predict when their activity is likely to be reduced or increased. A similar case can be built for drug transporters and/or receptors.

Knowledge of pharmacogenetic and pharmacogenomic factors that affect PK (metabolism, transport) or PD (receptor) has been important for understanding ways to avoid unanticipated drug effects in adults and to some extent in children. The aim to individualize pharmacotherapy with the use of PGx reflects the fact that specific effects/side effects are not just randomly distributed but relate to genetic variation in the level of activity of transporters, drug-metabolizing enzymes, and/or receptors.[23] Tailoring neonatal pharmacotherapy to individual patients with use of this knowledge holds great promise and serves as a model of precision medicine in newborns.[23,24]

The most commonly applied approach to evaluate PGx in neonates is to search for similar signals initially reported in adults or children (*from adult to newborn* approach). For drug-metabolizing enzymes such as CYP2C19 (pantoprazole dealkylation), CYP2D6 (tramadol O-demethylation, codeine), *N*-acetyl transferase 2 (isoniazid acetylation), or UGT2B7 (morphine glucuronidation), the impact of polymorphisms on neonatal drug metabolism has been documented.[23,25] However, drug-metabolizing enzymes also mature during the first months or years of life. Consequently, it can be difficult to determine to what extent the variability in drug metabolism is explained by genetic expression, maturation, or other covariates. Drug metabolism is often reduced in neonates, and scaling of drug dose by simple body weight or allometrically with an exponential function will not fully compensate for differences in clearance that exist in this newborn population. Clearance often differs several-fold among adults, and the same degree of variation is emerging among neonates, whether due to maturation of the expression of these enzymes by GA or due to induction of protein synthesis after birth.
