Neonates with overwhelming sepsis often develop neutropenia, which illustrates some of the differences between adult and neonatal neutrophils. Neonates have fewer neutrophil progenitors and a diminished precursor storage pool, so neutrophils are easily depleted in stress conditions.[16] Following experimental sepsis with group B streptococci, adult rats respond with a transient decrease in circulating neutrophil counts, followed by significant neutrophilia associated with a twofold to threefold increase in the progenitor pool (colony-forming unit–megakaryocyte) and an increase in the proliferative rate to 75% of the maximal capacity.[17,18] In contrast, neonatal rats under the same conditions had a decrease of 50% of their progenitor pool and failed to increase their myeloid proliferative rate, which, as discussed previously, was already at near maximal levels. Most important, during experimental sepsis, neonatal rats had further depletion of their already reduced NSP reserves by almost 80%, compared with a decline of 33% in adult rats.

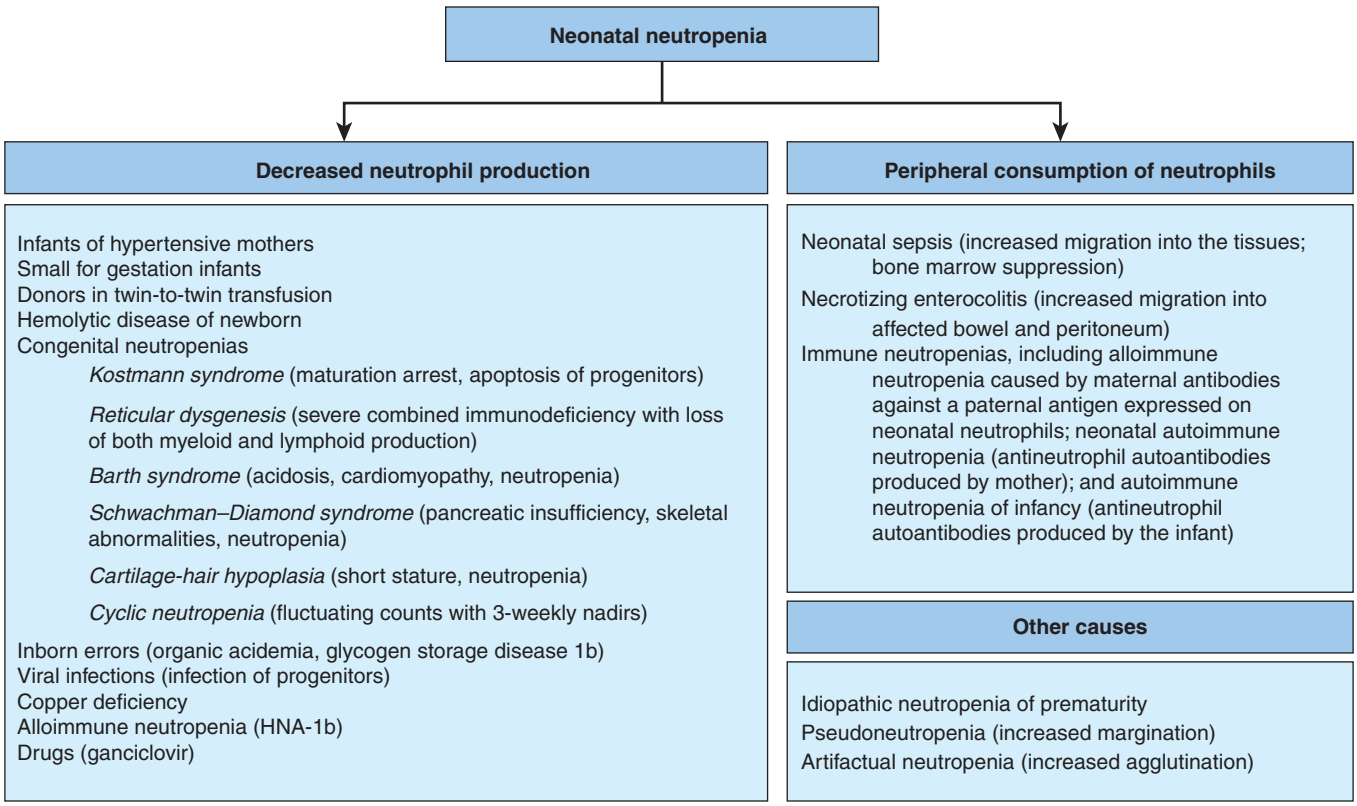
TABLE 71.1 Absolute Neutrophil Count in Neonates at 72–240 Hours of Age

Gestational Age	5th Percentile	95th Percentile
>36 weeks	2700/μL	13,000/μL
28–36 weeks	1000/μL	12,500/μL
<28 weeks	1300/μL	15,300/μL

From Schmutz N, Henry E, Jopling J, Christensen RD. Expected ranges for blood neutrophil concentrations of neonates: the Manroe and Mouzinho charts revisited. *J Perinatol.* 2008;28(4):275–281.

Immune-Mediated Neonatal Neutropenia

Immune-mediated neutropenia is important to consider as a diagnostic possibility in infants with persistent neutropenia. Alloimmune neonatal neutropenia occurs as a result of maternal sensitization to neutrophil antigens present on the infant's neutrophils (paternally acquired) that are not present on the maternal neutrophils, with subsequent production of immunoglobulin G (IgG). Neutrophil-specific antibodies are found in the maternal and infant sera, but the mother has a normal neutrophil count. Alloimmune neonatal neutropenia is estimated to occur at a frequency of 3% of live births.[19] The antigens most commonly involved in the United States are human neutrophil antigen (HNA)-1a, HNA-1b, and HNA-2a. Because the antibodies are IgG, which crosses the placenta, peripheral blood counts show profound neutropenia. The condition is self-limiting and typically resolves within 6 to 7 weeks, during which time the neonate is susceptible to infections, mostly cutaneous in nature. Most infections are mild, although infants with profound neutropenia are at risk of life-threatening infections and should be monitored closely.[20] Neonatal autoimmune neutropenia occurs when mothers have antineutrophil antibodies that cross transplacentally and bind fetal neutrophils. This form of neutropenia is generally milder in severity than alloimmune neutropenia.[21]



• **Fig. 71.2** Causes of Neonatal Neutropenia. *HNA*, Human neutrophil antigen.

Maternal Hypertension–Associated Neutropenia

One of the most common and well-described causes of transient neonatal neutropenia is maternal hypertension. Neonatal neutropenia is inversely related to birthweight and gestational age and directly related to the severity of hypertension. Infants of hypertensive mothers seem to have decreased production of neutrophils, but the cause is uncertain. Several studies have demonstrated a decrease in the numbers of neutrophil progenitor cells, decreased cycling of these cells, a relatively normal NPP and NSP, and the absence of a "left shift."[22] Studies show conflicting evidence for the risk of infection in these infants,[14,23,24] although the risk is probably low because neutropenia resolves in most cases within 72 hours, and almost always in 5 to 7 days.[25,26]

Idiopathic Neutropenia of Prematurity

This is generally a benign form of neutropenia that presents after the early neonatal period (weeks 4 to 10). Neutropenia is usually transient and recovers spontaneously in a majority of patients. Differential leukocyte counts show few immature neutrophils (in the presence of neutropenia), suggesting a transient suppression of neutrophil regeneration in these patients. In some premature infants, idiopathic neutropenia can be severe (sometimes ANC <500/μL) and prolonged, but even in these infants neutropenia resolves spontaneously.[27]

Treatment of Neonatal Neutropenia

Recombinant granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) are often used to treat neonatal neutropenia. G-CSF stimulates neutrophil production, maturation, and release from the marrow and also reduces neutrophil apoptosis. [28] GM-CSF generates both granulocyte and macrophage colonies from precursor cells.[29] G-CSF is the primary systemic regulator of the circulating neutrophil concentrations.[28] GM-CSF may not play a major role in the steady state but is induced in inflamed tissues.[30]

Recombinant G-CSF or GM-CSF has been used in neonatal sepsis with conflicting results.[31–33] In a meta-analysis of five studies, G-CSF was shown to reduce mortality (odds ratio 0.17, 95% confidence interval [CI] 0.03 to 0.70).[34] However, this protective effect was no longer significant when nonrandomized studies were excluded. The role of GM-CSF in the prevention or treatment of neonatal sepsis is also unclear.[35–37] Carr et al.[38] reviewed the efficacy and safety of G-CSF/GM-CSF in the treatment or prophylaxis of neonatal sepsis. In preterm infants with suspected sepsis, G-CSF or GM-CSF did not reduce mortality at 14 days after the start of therapy (relative risk [RR] of death 0.71, 95% CI 0.38 to 1.33). However, in a subgroup of 97 infants with sepsis and neutropenia (ANC <1700/μL), there was a significant reduction in mortality (RR 0.34, 95% CI 0.12 to 0.92; number needed to treat 6, 95% CI 3 to 33).

Recombinant G-CSF is highly effective in correcting immune-mediated neutropenia. Along with its effects on neutrophil production, G-CSF may decrease antigen expression on neutrophils, rendering them less vulnerable to circulating antibodies,[39] and also improve neutrophil function.[40] Similarly, G-CSF is also effective in many patients with congenital neutropenias.[41,42] Kostmann syndrome presents in early infancy with low ANCs, often less than 200/μL, and recurrent bacterial infections. These patients have mutations in the neutrophil elastase gene *ELANE*.[43] G-CSF can reduce the need for antibiotics and hospitalization[42] and can improve survival in these patients. Cyclic neutropenia is another rare hematologic disorder that may be modified by the use of G-CSF. Cyclic neutropenia is characterized by regular drops in ANCs to levels as low as 250/μL at 3-week intervals.[44] Although the marrow may look normal during periods of higher ANCs, it shows a characteristic "maturational arrest" of myeloid cells during or just before the onset of severe neutropenia. G-CSF treatment can be used to raise neutrophil counts during periods of severe neutropenia.[45] These patients may not respond to GM-CSF.[46] While neutropenia resolves spontaneously in most patients with idiopathic neutropenia of prematurity, in one study, G-CSF treatment induced a rapid rise in ANC, indicating an adequate marrow neutrophil reserve in these patients.[47]

G-CSF is administered intravenously or subcutaneously at a dosage of 5 to 10 μg/kg/day. The response to G-CSF therapy and a rise in ANC usually occurs within 24 to 48 hours. In an occasional patient, G-CSF therapy will not raise blood neutrophil counts. In such a patient, G-CSF doses can be increased in increments of 10 μg/kg at 7- to 14-day intervals if the ANC remains below 1000/μL.[48,49] Doses can be reduced or withheld once the ANC exceeds 5000/μL. G-CSF treatment is usually tolerated in neonates without adverse effects. Long-term G-CSF therapy in congenital neutropenias has been associated with splenomegaly, thrombocytopenia, osteoporosis, myelodysplastic syndrome/leukemia, and the development of anti–G-CSF antibodies.[50,51]

Intravenous immunoglobulin (IVIG) is effective in about 50% of infants with alloimmune and autoimmune neutropenia.[52–54] IVIG can mobilize neutrophils from the NSP, although repeated doses may be needed for a sustained effect.[55,56] While steroids are generally not effective in alloimmune neutropenia,[57,58] may raise the ANC for short periods in autoimmune neutropenia of infancy. Exchange transfusions are generally not effective in immune-mediated neutropenia.[59]

Monocyte Physiology and Dysfunction

Ontogeny

Embryonic macrophages are found among hematopoietic cells in the yolk sac at 3 to 6 weeks' gestation. The fetal liver becomes the primary site of hematopoiesis from 6 weeks until midgestation, and the bone marrow then becomes the lifelong center of blood cell production.[60] Monocytes are present in high proportions in the early hematopoietic tissues, with approximately 70% of hematopoietic cells at 4.5 weeks' gestation morphologically identifiable as monocytes. This proportion falls from 1% to 2% during the next 6 weeks as erythroid cells become predominant. The precursors of monocytes, monoblasts, and promonocytes continue to be present in the fetal liver; however, intravascular monocytes are not observed until the fifth month of gestation. Circulating monocytes do not appear with regularity until hematopoiesis is first established in the bone marrow after the 10th week of gestation.

During ontogeny, macrophages in the fetal liver express CD11b as early as 12 weeks' gestation. The classic monocyte marker, CD14, does not appear until about 15 to 21 weeks' gestation. CD14 expression on circulating mononuclear cells is equivalent in cord blood and adult peripheral blood. CD11a, CD11b, and CD11c are expressed in lower densities on cord blood monocytes than on adult cells. There is also a lower expression of class II major histocompatibility complex (MHC) antigens HLA-DR, HLA-DP, and HLA-DQ on neonatal monocytes compared with adult monocytes. The density of these class II MHC antigens has been correlated with the antigen-presenting capacity of monocytes

in vitro, although the effect of this deficiency on neonatal host defense is not clear. Other important monocyte markers are the receptors for the Fc moiety of IgG (FcγR) and the Toll-like receptors (TLRs). FcγR receptors are important in the process of monocyte and macrophage phagocytosis of microbes and antibody-dependent cytotoxicity. Monocytes constitutively express the high-affinity receptor FcγRI (CD64) and FcγRII (CD32). TLRs play a critical role in recognition of microbial pathogens. Term neonatal monocytes express normal basal levels of TLR2 and TLR4 but show reduced tumor necrosis factor (TNF) release in response to stimulation with a range of TLR agonists.[61–63] Cord blood monocytes of preterm neonates, however, have lower TLR4 expression than adult peripheral blood monocytes.[64]

Macrophage colony-stimulating factor (M-CSF) is a hematopoietic growth factor that regulates the proliferation, differentiation, and functional activation of monocytes. Normally detected in human serum, M-CSF plays an important role in enhancing the effector functions of monocytes and macrophages. Serum M-CSF levels are increased in cord blood and rise further during the neonatal period.

Circulating Monocytes

Term infants show a relative monocytosis that persists through the neonatal period. Although there is some disagreement about normal blood monocyte counts in neonates, we have described normal ranges of absolute monocyte counts (AMCs) using data from more than 62,000 blood counts.[65] In this cohort, blood monocyte concentrations increased almost linearly between 22 and 42 weeks' gestation. Monocyte concentrations also increased during the first 2 weeks postnatally. These data are consistent with previous kinetic studies in human fetuses that show a similar maturational increase in the concentrations of monocyte precursors.[66,67] In neonates, monocytosis has been associated with prematurity, blood transfusions, albumin infusions, and theophylline therapy. Monocytosis has also been described in infants with congenital infections such as candidiasis and syphilis.[68,69] and in association with immune-mediated neutropenia.[70] In contrast, monocytopenia is not seen frequently in neonates, except in growth-restricted preterm infants who may have low monocyte counts as part of an overall suppression of all leukocyte lineages.[71] Recently, we showed that a fall in AMCs can be a useful diagnostic marker of necrotizing enterocolitis (NEC) in VLBW infants.[72] In this study, we compared blood counts obtained at the onset of feeding intolerance with the last available counts obtained before the onset of symptoms. In an infant with feeding intolerance, a drop in AMC of more than 20% indicated NEC with a sensitivity of 0.70 (95% CI 0.57 to 0.81) and specificity of 0.71 (95% CI 0.64 to 0.77). The negative predictive value was 88%, indicating that the test may be valuable for exclusion of the diagnosis of NEC in infants with feeding intolerance due to other causes. Despite modest diagnostic accuracy, AMC is a convenient tool because the information is already available at no extra cost in complete blood counts from automated hematology analyzers.

Monocyte Subsets

Increasing evidence indicates that peripheral blood monocytes are a heterogeneous population comprised of two major subpopulations. The predominant subtype is "classic" $CD14^+CD16^-$ monocytes, which express C-C chemokine receptor (CCR)2, CD64, and CD62L and represent nearly 80% to 90% of all blood monocytes. The remaining fraction comprises the "nonclassic" $CD14^{low}CD16^+$ monocytes that lack CCR2.[73] Both subsets express the receptor for fractalkine, CX3C chemokine receptor (CX_3CR)1, but $CD14^{low}CD16^+$ monocytes characteristically express higher levels. $CD16^+$ monocytes are composed of at least two populations with distinct functions. Monocytes that express CD16 and CD14 ($CD14^+CD16^+$) also express the Fcγ receptors CD64 and CD32, have phagocytic activity and produce TNF and interleukin (IL)-1β in response to lipopolysaccharide (LPS). In contrast, monocytes that express CD16 but very low levels of CD14 ($CD14^{dim}CD16^+$) lack the expression of other Fc receptors, are poorly phagocytic and do not produce TNF or IL-1β in response to LPS.[74] This subset of "resident" monocytes patrol blood vessels in the steady state and extravasate during infection with *Listeria monocytogenes* or during tissue healing.[75]

Monocyte Function

Monocytes are capable of directed movement (chemotaxis) in response to chemoattractants produced by bacteria or by host cells at the site of injury or invasion. The chemotactic capabilities of neonatal and adult peripheral blood monocytes have been compared, and chemotaxis was found to be less pronounced in neonates than in adults (Table 71.2).

During an acute infection, circulating monocytes become activated and migrate into the tissues. During this process, monocytes adhere to the endothelium through the interaction of the integrins (CD11a, CD11b, CD11c, and CD18) expressed on the monocyte cell membrane, with ICAM-1 or ICAM-2 on the endothelial surface. Finally, the activated monocyte moves through the endothelium to the site of inflammation or infection. Preliminary studies demonstrate that the levels of monocyte adhesion molecule expression are comparable in neonate and adult peripheral blood.[76] The CD11b–CD18 complex (macrophage one antigen/complement receptor 3) promotes monocyte trafficking to the sites of infection by binding ICAM-1 and is also involved in the recognition of opsonized microbial pathogens.

TABLE 71.2 Function and Phenotype of Adult Versus Neonatal Mononuclear Cells

Cells	Function/Phenotype	Adult	Neonate
Monocytes	Chemotaxis	↑	↓
	Phagocytosis	↑	↓
	Adhesion	≈	≈
	Respiratory burst	≈	≈
Dendritic cells	Expression of CD83, CD86	↑	↓
	Mixed lymphocyte reaction	↑	↓
	IL-12 (p40) production	↑	↓
	IL-12 production	↑	↓
	IL-10 production	↓	↑
Natural killer cells	Expression of CD8, CD57	↑	↓
	Expression of ICAM-1, CD161	↑	↓
	Cytolytic activity	↑	↓

ICAM-1, Intercellular adhesion molecule1; *IL*, interleukin.

Antimicrobial activity of monocytes includes oxygen-dependent mechanisms such as the respiratory burst, which through a complex series of reactions forms highly reactive hydroxyl radicals that damage host and microbial membranes. The ability of fetal and neonatal monocytes to kill pathogens (*Staphylococcus aureus, Staphylococcus epidermidis, Escherichia coli*, and *Candida albicans*) is generally comparable to that of the monocytes in adult peripheral blood (see Table 71.2), although isolated preterm monocytes may show weaker superoxide production and degranulation in vitro than monocytes from term neonates.

On exposure to microbial antigens, monocytes and macrophages become activated by collaborative actions of soluble recognition proteins, including CD14 and TLRs, and produce several cytokines and chemokines contributing to the inflammatory process. IL-1β, interferon (IFN)-α, and TNF are synthesized at similar levels in adults and neonates. Kaufman et al.[77] detected lower TNF production in LPS-stimulated adherent monocytes from preterm infants compared with monocytes from term infants; however, no difference was seen in the production of IL-1β or IL-6. They also found lower expression of CD11b and CD18 adhesion receptor subunits in preterm monocytes. Although TLR expression of term neonatal monocytes is similar to that of adult monocytes, there are important functional differences. Levy et al.[78] reported that cord blood monocytes are less sensitive to TLR ligands than adult monocytes for TNF induction. The innate immune responses of neonatal monocytes to TLR agonists may be biased toward high IL-6 levels but low TNF levels in vitro because of distinct neonatal cellular (monocyte) and humoral (serum) factors, and such a pattern was also evident in vivo.[79]

Developmental Defects in the Phagocytic Immune System in Neonates

The immaturity of the phagocytic immune system predisposes neonates to increased morbidity and mortality during bacterial sepsis. This impairment is attributed to developmental deficiencies in both the innate immune system and the adaptive immune systems (see Fig. 71.1). In the following section, we use the term *phagocyte* to refer mainly to neutrophils and the monocyte/macrophage lineage. Although immature DCs also show phagocytic activity, there is limited information about these cells in the neonate. The phagocyte system depends on the presence of adequate numbers of phagocytes in circulation to function efficiently, the ability to respond to signals from the sites of inflammation, the ability of phagocytes to migrate to these sites, and the capability of phagocytes to ingest and kill invading microorganisms.

Several studies show important differences in TLR expression on neonatal versus adult leukocytes. The basal expression of TLR2 and TLR4 in neutrophils and monocytes from healthy adults and term neonates is similar.[16] During sepsis, neonates showed a sustained upregulation of TLR2 on monocytes but not on neutrophils, and there was no change in TLR4 expression on monocytes or neutrophils.[62] In VLBW infants, monocytes express TLR4 at much lower levels than in mature infants and adults and show significantly lower LPS-stimulated IL-1β, IL-6, and TNF release in vitro.[64] Further, CD14 and MD-2, co-receptors for gram-negative and gram-positive cell wall constituents alongside TLR2 and TLR4, respectively, are also expressed at lower levels on preterm infant monocytes.[80] Stimulation of newborn monocytes with LPS produced a significant decrease in the expression of MyD88, supporting the premise of impaired TLR4-mediated signaling[81] Belderbos et al.[82] compared TLR-induced cytokine responses of whole blood leukocytes from cord blood from healthy term neonates, neonatal venous blood at the age of 1 month, and adult venous blood. On TLR4 activation, neonatal leukocytes (both at birth and at 1 month of age) showed a skewed pattern of cytokine expression, with low levels of T-helper (T_h) type 1–polarizing cytokines such as IL12p70 and IFN-α and more of the anti-inflammatory cytokine IL-10. In contrast, cytokine responses to TLR3, TLR7, and TLR9 matured by 1 month of age.

Recent studies indicate that epigenetic changes during development may underlie the observed maturation in monocyte function with advancing gestational age. Histone modifications H3K4me3 and H3K4me1 affect promoter sites of various immune genes (IL1B, IL6, TNF) in monocytes. Increased H3K4me3 activation at these promoter sites (compared to H3K4me1 activity leading to increased H3K4me3/H3K4me1 ratio) is observed in monocytes with advancing gestational age and thought to be important in modifying the epigenetic landscape of monocytes to a more mature and functional state with age.[80]

The immaturity of neonatal host defense is also characterized by profound deficiencies in quantitative and qualitative phagocytic effector cell function, particularly during stress or bacterial sepsis. The initial step in mounting a host defense response is directed migration or chemotaxis (*chemo* refers to a chemical substance; *taxis* refers to rearrangement) of activated phagocytes toward the site of microbial invasion. Such movement occurs along concentration gradients of chemoattractants, which may include bacterial products such as *N*-formyl-L-methionyl-L-leucylphenylalanine (f-MLP), leukotriene B_4, complement products such as C5a, or chemokines. At the site of inflammation, the phagocytes ingest and kill the pathogens by oxygen-dependent and oxygen-independent mechanisms. Neutrophils from both preterm and term neonates show numerous qualitative abnormalities, including decreased deformability and impaired functions, including chemotaxis, phagocytosis, adherence, bacterial killing, aggregation, and oxidative metabolism. In contrast to neutrophils, neonatal monocytes are more comparable in function to the monocytes of adults.

GM-CSF increases adult neutrophil oxidative metabolism by augmenting superoxide anion production. Additionally, GM-CSF increases chemotaxis, promotes phagocytosis of *Staphylococcus aureus* and augments neutrophil aggregation by the increased expression of surface adhesion molecules.[83,84] GM-CSF is not a direct stimulant of neonatal neutrophil function, but cord blood leukocytes show increased superoxide production if primed with GM-CSF before exposure to f-MLP or opsonized zymosan particles.[85]

The diminished inflammatory response of neonatal neutrophils results in a high incidence of microbial invasion. Significant defects in the upregulation of surface-active glycoprotein receptors (C3bi) and reduced aggregation also predispose the neonate to impaired response to bacterial infection. C3bi expression has been compared in adult and neonatal neutrophils and was found to be significantly less in neonatal neutrophils when stimulated by f-MLP– or zymosan-activated serum. However, cord blood neutrophils incubated with GM-CSF demonstrated a significant induction of C3bi expression. Also, a significant increase in C3bi expression was seen when cord blood neutrophils were pretreated with GM-CSF and subsequently stimulated with the calcium ionophore A23187. The upregulation of the C3bi receptor by GM-CSF also appears to correlate with an enhancement of neutrophil aggregation. GM-CSF also primes neutrophils

for increased neutrophil aggregation following agonist (f-MLP) stimulation.

G-CSF and TNF have also been reported to modulate the function of adult and neonatal neutrophils in a manner similar to that of GM-CSF. Priming cord blood neutrophils with G-CSF or TNF and subsequent stimulation with f-MLP induces the expression of C3bi receptors and enhances the bacterial and phagocytic activity and superoxide generation.

Lymphocyte Contributing to Acquired Immunity

Lymphocytes form critical components of the acquired immune system and constitute 20% of blood leukocytes. There are two broad categories: (1) T lymphocytes, which mature in the thymus and subsequently seed peripheral lymphatic organs, including the spleen and lymph nodes; and (2) B lymphocytes, which are produced in the bone marrow, mature in secondary lymphoid organs, and subsequently differentiate into antibody-secreting plasma cells. The following sections outline the development and function of T and B lymphocytes in the neonate.

T-Lymphocyte Physiology and Function

Ontogeny

T-cell precursors undergo initial differentiation and maturation in the thymus, an organ that arises from the third branchial arch at approximately 6 weeks' gestation.[86] Hematopoietic stem cells destined to become T-cell precursors move to the thymus by 9 weeks' gestation, initially entering the subcapsular cortical areas, and then undergo a period of differentiation as they move from the cortex to the medulla of the thymus. Lymphoid progenitors entering the cortical area do not express the T-cell receptor (TCR) or the coreceptors CD4 and CD8 and are therefore referred to as *double-negative thymocytes*. These cells genetically rearrange α and β genes to generate a TCR with unique antigen specificity. In the next stage of differentiation, this newly rearranged TCR is expressed on the cell surface along with *both* CD4 and CD8, and the cells are termed *double positive*. T cells with TCRs that recognize MHC bound to microbial peptides are "positively selected." Following the double-positive stage, T cells lose expression of either CD4 or CD8 to become "single positive," and during this stage, T cells that recognize "self-peptides" are negatively selected to undergo apoptosis. At the end of this differentiation process, mature T cells that enter the medulla are either $CD4^+$ or $CD8^+$ and can bind host MHC but only when it is not bound to self-antigens. Approximately 98% of thymocytes are eliminated during this process.

T-Cell Receptor Repertoire

The TCR is composed of two different protein chains that are associated with CD3, a protein involved in signal transduction. Most T cells carry a TCR composed of α and β chains, but in about 5% of all T cells, the TCR comprises γ and δ chains instead. Each TCR protein chain contains an immunoglobulin-like extracellular region with a variable (V) domain at its N-terminal and a constant (C) domain at the C-terminal end. The variable domains contain hypervariable, complementary-determining regions (CDRs). The third CDR (CDR3) imparts affinity for a specific processed antigen.[87]

TCR diversity arises from genetic recombination of DNA encoding for a variable (V), diversity (D), and joining (J) gene segments in individual T cells using recombination activating gene (RAG)1 and RAG2 recombinases or gene conversion using cytidine deaminases. These recombinations create a diverse pool of T cells with a wide repertoire of antigen specificity.

T-Cell Subtypes

T cells are broadly categorized as $CD4^+$, $CD8^+$, or T cells that are neither $CD4^+$ nor $CD8^+$. $CD4^+$ T cells recognize antigens bound to class II MHC molecules and are further classified into T_h cells and T-regulatory cells, commonly referred to as T_{regs}.

T-Helper Cells

Naïve $CD4^+$ cells differentiate into three distinct effectors T_h subsets: T_h1, T_h2, and T_h17.[88] T_h1 cells are inflammatory cells that interact with mononuclear phagocytes and provide cellular immunity against intracellular pathogens and virus-infected cells. T_h1 cells produce IL-2, IFN-γTNF, IL-13, and GM-CSF. T_h2 cells associate with B cells and defend against helminths and play a role in allergic reactions through regulation of antibody isotype switching. T_h2 cells produce IL-4, IL-5, IL-9, IL-10, IL-12, and IL-13.[89] T_h17 cells protect against infections, where they take on a T_h1-like effector function to promote pathogen clearance by enhancing neutrophil recruitment to sites of infection, and by activating macrophages. These cells can also play a pathogenic role in allergic, autoimmune, and other chronic inflammatory diseases.[90–92] T_h17 cells produce cytokines such as IL-17A, IL-17F, IL-21, IL-22, and IL-26.

Regulatory T Cells

T_{regs} are derived from naïve T cells.[93] The transcriptional regulator forkhead box P3 (FoxP3) plays a critical role in the development of T_{regs} and is often used as a biomarker for these cells. T_{regs} downregulate the immune response by expressing inhibitory cytokines (IL-10, transforming growth factor β), cytotoxic molecules, modulators of cyclic AMP, and cytokine competition to limit effector and/or antigen-presenting cell function.[94]

Two populations of T_{regs} have been identified: thymus-derived T_{regs} (tT_{regs}) and peripherally derived T_{regs} (pT_{regs}). tT_{regs} develop in the thymus, whereas pT_{regs} develop in the periphery from naïve T cells.[95] $CD4^+CD25^+FoxP3^+$ T_{regs} are important contributors to the control of the immune response in the fetus/neonate. In the fetus, $CD4^+$ T cells have a predisposition to differentiate into tolerogenic T_{regs} that promote self-tolerance. During midgestation, $CD4^+CD25^+FoxP3^+$ T_{regs} may constitute 15% to 20% of all $CD4^+$ cells in the lymphoid tissues.[96,97] T_{regs} represent less than 5% of all $CD4^+$ cells in cord blood from term infants and in the adult peripheral blood.[97] Reductions in $CD4^+CD25^+$ T_{regs} numbers and/or functional impairment of these cells is thought to be important in the pathogenesis of necrotizing enterocolitis.[98,99]

Cytotoxic T Lymphocytes

Following antigen presentation and activation, $CD8^+$ T cells can differentiate into cytotoxic T lymphocytes (CTLs). These cells protect against intracellular pathogens and play a role in graft rejection and tumor surveillance.[100,101] CTLs cause cytotoxicity by releasing pore-forming mediators (perforin/granzyme system) or by activating the Fas/Fas ligand-dependent apoptotic pathway.[102,103]

Gamma-Delta (γδ) T Cells

γδ T cells are detectable in the fetal thymus and liver at 6 to 8 weeks' gestation. At 16 weeks' gestation, γδ T cells constitute 10%

of circulating T cells, but the proportion gradually declines to about 3% at term.[104,105] Postnatally, these cells are present mainly on skin and mucosal surfaces. A unique feature of the γδ T-cell sub-population is the characteristic T-cell receptor composed of a γ-chain and a δ-chain, genes that rearrange during γδ T-cell maturation in the thymus.[106] Although the role of γδ T cells remain unclear, these cells respond to nonpeptide microbial metabolites, show cytotoxicity, and produce various cytokines, including IFN-γ and TNF.[107,108] Recent studies indicate that IL-17A-producing γδ T cells are important to mediate protective immune responses to influenza infection during the neonatal period.[109] The cytotoxicity of neonatal γδ T cells is significantly less than that of their counterparts in adults,[110] although recent studies indicate an adult-like functional maturation in these cells by 2 years of age.[111]

Natural Killer T Cells

Natural killer (NK) T cells are a subset of T cells that express TCR αβ chains, as well as a variety of NK cell markers.[112,113] These cells recognize both exogenous and endogenous lipid antigens in the context of the MHC-like molecule CD1d. CD1d-restricted NK T cells are classified into two main subsets: type I or invariant NK T cells and type II or diverse NK T cells. Type I NK T cells express a conserved αβ TCR and constitute less than 1% of T cells in cord blood.[114,115] These cells have been identified in the human fetal small intestine.[116] Type II NK T cells are more abundant than type I NK T cells in humans and express relatively diverse TCR α and β chains.

Circulating T Cells

Term neonates have higher counts of $CD4^+$ T cells in peripheral blood than adults. The CD4/CD8 ratio is high (up to 4.9:1) in neonates and declines to adult values (2:1) by 4 years of age.[117,118] In cord blood, 85% of the T cells express CD38 (compared with less than 5% in adults) but lack other markers of activation.[119] Nearly 80% of all T cells in cord blood display a naïve CD45RA phenotype, compared with less than half of the circulating T cells in adults.[120,121] The proportion of memory CD45RO T cells reaches adult levels in the second decade.[120]

Neonatal T-Lymphocyte Function

T cells form a critical component of the adaptive immune defense system in the neonate. Although term infants have higher T-cell counts in peripheral blood than adults,[122] preterm neonates tend to have lower $CD4^+$ and $CD8^+$ lymphocyte counts than their term counterparts. This deficiency could, at least in part, place the preterm infant at risk of infection. In contrast to the $CD4^+$ effector T cells, preterm infants have more T_{regs} in cord blood than do term infants or adults in peripheral blood.[123]

Some studies suggest an altered function of $CD4^+$ T cells in neonates compared with adults. T_h1 cell function is decreased in human neonates. Neonatal $CD4^+$ T cells secrete less IL-12 and IFN-γ and express less CD154 (CD40 ligand) on their surface than their counterparts in adults.[124] Cord blood lymphocytes also show a limited capacity to produce IL-17.[125] Similarly, both preterm and term neonatal T_{regs} appear less functional than their adult counterparts. T_{regs} from neonates limits contact between DCs and conventional T cells, downmodulating the expression of costimulatory molecules by DCs. This results in decreased DC immunogenicity and impaired T-cell activation.[126] CTL function is also less efficient than in the neonate compared with the adult.[127] Neonatal CTLs express less perforin than their counterparts in adults. Circulating inhibitors, such as alpha-fetoprotein and prostaglandins, have been implicated as the cause of impaired CTL activity in neonates.[128]

In contrast, other studies indicate that neonatal T cells may not be truly deficient or immature versions of adult T cells but rather represent distinct populations of cells that are, in fact, well suited for adaptations during the perinatal period. These studies suggest a layered immune system model for CD4+ and CD8+ T cells where T cells that arise in the fetal and neonatal period have distinct characteristics and transcriptomic profiles from their adult counterparts. These cells continue to persist into adulthood (alongside the T cells originating in adulthood) and continue to maintain their cell-intrinsic behavior.[129] Critical features that may distinguish neonatal T cells from adult T cells include their origin from fetal hematopoietic stem cells, rapid capacity for proliferation and differentiation, low TCR diversity, increased expression of TLRs, and enhanced ability to respond to inflammation and danger signals and an impaired ability to form memory T cells.[129]

T-cell signals from antigen presentation and T-cell–derived cytokines such as IL-2, IL-4, IL-5, IL-6, IL-10, IL-13, and IFN-γ are required for B-cell proliferation, differentiation, and survival.[130] T-cell and B-cell cross-talk also involves receptor-ligand pairs such as CD40 (on B cell)–CD40 ligand (on T cell), which is critical during B-cell immunoglobulin isotype switch, and B7–CD28, CD11a (lymphocyte function-associated antigen–1)–ICAM-1, and CD58–CD2.[130] Neonatal T cells show lower CD40 ligand expression than adults and are less efficient at providing humoral and CD40-dependent activation signals to B cells.[131,132]

B-Lymphocyte Physiology and Function

Ontogeny

B-cell progenitors are derived from pluripotent hematopoietic cells in the bone marrow.[133] The first recognizable B-cell progenitor is the large pre-B cell, which is characterized by the presence of cytoplasmic μ heavy chains. Pre-B cells can be identified in the fetal liver as early as 7 weeks' gestation and in the marrow by 12 weeks. Immature B cells undergo a selection process analogous to T cells to eliminate self-identifying clones.[134,135] Once B cells begin to express surface IgM (sIgM), they are ready to leave the bone marrow to enter the peripheral circulation[136]; $sIgM^+$ B cells can be seen in the fetal liver by 9 weeks and in the bone marrow, peripheral blood, and spleen by 12 weeks. B cells with surface IgA, surface IgG, and surface IgD (sIgD) isotypes appear between 10 and 12 weeks.[137] IgM/IgD^+ B cells populate the lymph nodes at 16 weeks. Plasma cells are first seen around 20 weeks' gestation. By 22 weeks, the proportion of B cells in the spleen, peripheral blood, and marrow is similar to that in adults.[137,138] The bone marrow becomes the exclusive site for B-cell maturation by 30 weeks' gestation.

B-Cell Subtypes

In the fetus and neonate, most B cells express CD5, a T-cell antigen, on the cell surface. These $CD5^+$ B cells have been referred to as B1 cells to differentiate them from the conventional B2 cells seen in adults. These B1 cells show a greater capacity for bone marrow–independent self-renewal, display an unusual $CD11b^+$ $sIgM^{high}$ $sIgD^{low}$ phenotype, and show constitutive expression of the transcription factor signal transducer and activator of transcription 3.[139,140] These cells are the predominant B-cell type during fetal life and show a distinctive anatomic localization in the spleen and the peritoneal cavity.[141,142] In adults, CD5 expression can be found on about 25% to 35% of all B cells and on less than

5% of mononuclear cells in peripheral blood. In contrast, $CD5^+$ B cells represent 90% of all B cells in cord blood. The proportion falls to 75% to 80% during infancy and approaches adult levels only by late adolescence.[141,142]

The role of B1 cells in the fetus is still unclear. Their unique localization, their broad polyspecific specificities, and the restricted immunoglobulin repertoire suggest a role in innate immunity rather than in adaptive immunity.[139] Unlike follicular B2 cells, which respond to protein antigens and show immunoglobulin heavy chain class switching and affinity maturation, B1 cells respond mainly to T-cell–independent carbohydrate antigens.[143,144]

Regulatory B (Breg) cells are a rare B-cell subpopulation that is $CD19^+CD24^{hi}CD38^{hi}$ and known to promote tolerance and prevent unwanted immune responses. A greater number of Bregs (expressed as a proportion of all B cells) are present in cord blood compared to adult peripheral blood. Cord blood Bregs are also functionally more immunotolerant compared to their adult counterparts and produce higher levels of IL-10 and inhibit IFN-γ and IL-4 production by cocultured T cells.[145] These cells are thought to be important in the fetus to promote immune tolerance to the haploidentical mother, allowing for the normal continuation of pregnancy.

Circulating B Cells

Cord blood contains more B cells than adult peripheral blood, although the ratio of B cells to circulating T cells is similar.[146] B-cell counts peak at 3 to 4 months and then decline gradually to adult levels by 6 years of age[147]). Preterm infants have B-cell counts comparable to those of term infants, although the number may be smaller in growth-restricted infants.[148] Unlike adults, most B cells in cord blood express activation markers such as CD25, CD23, and transferrin receptors.[149]

Neonatal B-Lymphocyte Function

Immunoglobulin Production

The fetus and the neonate can mount an antibody response to antigenic challenges, although they may not be able to respond to all the antigens in a vaccine or may show other deficiencies, such as a delayed isotype switch.[150] Overall, postnatal age seems to be a better predictor of antibody response than gestational age. Both preterm and term infants immunized with diphtheria toxoid in the first 10 days after birth showed weaker antibody responses than similarly immunized adults, but the response was more robust when the vaccine was administered at 1 to 2 months of age.[150] Similarly, premature infants respond poorly to the hepatitis B vaccine in early infancy but show antibody responses comparable with those of their term counterparts in later infancy.[151]

Immunoglobulin Repertoire

Immunoglobulin diversity is generated by DNA recombination involving various V, D, or J gene segments, giving rise to a large number of V(D)J permutations.[152] Additional diversity is generated by imprecise gene segment joins, the addition of extra nucleotides to the splice junction of the VDJ joins, and somatic mutations.[153,154]

In the fetus and neonate, the immunoglobulin repertoire is relatively limited. During early gestation and midgestation, the heavy chain V (V_H) gene segments located closest to the J segments are utilized preferentially, resulting in shorter CDR3 regions than in adults. This altered architecture of the antigen-binding site has been postulated to allow greater polyspecificity of antigen binding, although at the cost of lower antibody affinity.[155,156] The utilization of V_H segments spreads out more evenly with increasing gestation but does not reach adult levels.[157] In general, the antibody response in neonates is of low affinity and restricted to the IgM isotype. Somatic mutation of the heavy and light immunoglobulin variable region genes and the selection of higher affinity antibody-producing B cells are also limited at birth and increase slowly after 10 days of age.[158]

Serum Immunoglobulin Levels

At birth, most of the Igs present in serum are derived from the transplacental transfer of maternal IgG (particularly IgG1 and IgG3) during the third trimester.[159,160] Serum IgG levels in term neonates (up to 1000 mg/dL) may be similar to or higher than those in maternal serum, although preterm infants, who did not receive the maternal antibody, have lower IgG levels.[161,162] During early infancy, Ig levels fall because of normal turnover to reach a nadir of 300 to 500 mg/dL at 3 to 5 months of age, when the infant starts producing increasing amounts of his or her own. This nadir is reached earlier and is typically lower in preterm infants.[163]

Dendritic Cell Physiology and Function

DCs are specialized mononuclear cells with highly developed antigen-presenting capabilities that play a pivotal role in humoral and cellular immunity by initiating T-cell responses. DCs have a distinct morphology and are noted for their irregular shape with veil-like ruffled cell membranes (lamellipodia), many pseudopods, and numerous membrane processes. Microscopic examination of DCs reveals prominent mitochondria, endosomes, and lysosomes within the cytoplasm, which are necessary for the processing of antigens. The morphology of DCs in cord blood and adult peripheral blood is identical, although cord blood contains a lower proportion of DCs (0.5%) than adult blood (1%).

Ontogeny

Most DCs are derived from pluripotent hematopoietic stem cells differentiating along myeloid or lymphoid lineages. An exception may be the *follicular DCs*, a nonmigratory population of DCs located in the paracortical areas of the spleen and lymph nodes, which may be of mesenchymal origin.[164]

Dendritic Cell Subtypes

In humans, DCs are usually classified into the following four subsets[165]:

1. *Myeloid DCs (mDCs) or conventional DCs (cDCs)* express typical myeloid antigens CD11c, CD13, CD33, and CD11b and are homologous to mouse $CD11c^+$ "classic" or "conventional" DCs. In humans, mDCs may be split into $CD1c^+$ and $CD141^+$ fractions.[166,167] $CD1c^+$ mDCs are the major population of human mDCs in the blood (1% of peripheral blood mononuclear cells), tissues, and lymphoid organs. In lymph nodes, $CD1c^+$ DCs are found as "interdigitating cells" of T-cell areas. The expression of CD141 (thrombomodulin) is seen in a smaller proportion of mDCs (0.03% of peripheral blood mononuclear cells). These cells show enhanced ability to take up necrotic cells, sense viral nucleic acids with TLR3 and TLR8, and cross-present antigen to $CD8^+$ T cells.[166]

2. *Plasmacytoid DCs (pDCs)* typically lack myeloid antigens and are distinguished by the expression of CD123 (IL-3 receptor), CD303 (C-type lectin domain family 4, member C), and CD304 (neuropilin). These cells are not related to plasma cells; the name reflects subtle lymphoid features and abundant secretory properties. Two populations of pDC are thought to exist based on their expression of CD2. While both subsets express CD123 and CD303, $CD2^+$ DCs lack the high IRF7 and IFN-I producing capabilities of $CD2^-$ DCs.[168] In quiescent tissues, there are few pDCs, but they may constitute up to 20% of MHC class II–positive cells in lymph nodes and are rapidly recruited to both sites during inflammation. Further, pDCs express high levels of TLR7 and TLR9 and release type 1 IFN in response to viruses.[169]
3. *$CD14^+$ DCs* are a third subset of $CD11c^+$ DCs found in tissues and lymph nodes. Originally described as "interstitial DCs," these cells are more monocyte-like than the other mDCs and may arise from classic $CD14^+$ monocytes.[170]
4. *Langerhans cells and microglia* are two specialized self-renewing DC populations found in stratified squamous epithelium and the brain parenchyma, respectively.

DC populations in the blood include pDCs and $CD1c^+$, and $CD141^+$ mDCs; these cells are immature forms of those found in tissues and lymph nodes. Most epithelial tissues contain "migratory" DC populations that acquire antigens and migrate via the afferent lymphatics to lymph nodes, where they present antigens to T cells. In the steady state, tissues contain $CD1c^+$ mDCs, $CD141^+$ mDCs, and $CD14^+$ DCs but few pDCs. Lymphoid tissue contains blood-derived nonmigratory "lymphoid" or "resident" DCs and some migratory DCs from the tissues.[171]

Mature DCs express high levels of CD80 and CD83 on the cell membrane. Several agents have been shown to increase CD80 and CD83 expression on DCs, including TNF, bacterial endotoxin, and monocyte-derived inflammatory signals. Interactions with other cells also can induce maturation of DCs, as demonstrated by T-cell–mediated cross-linking of CD40.

Morphology

DCs express numerous surface molecules commonly found on mononuclear cells, MHC molecules, CD4, CD45 isoforms, adhesion molecules (ICAM-1, ICAM-2, ICAM-3, and leukocyte function-associated antigen 1), and Fc receptors (FcγRI [CD64] and FcγRII [CD32]). Maturation of DCs is commonly associated with high expression of CD80 and CD83. On stimulation, DCs upregulate the costimulatory molecules CD40, CD80, and CD86. Cord blood DCs express lower levels of ICAM-1 (CD54), MHC class I (HLA-ABC), and MHC class II (HLA-DR), CD80, and CD40 antigens than DCs in adult peripheral blood.[172,173] Liu et al.[174] compared monocytes from cord blood and adult peripheral blood for the capacity to generate DCs; cord blood monocytes generated fewer DCs, which also showed lower MHC class II expression. The endocytotic ability and ability to stimulate CD3+ T cells were also reduced in cord blood DCs.

Function

The activation of TLR pathways has been shown to mediate DC maturation. Krutzik et al.[175] demonstrated that TLR activation of monocytes induces rapid differentiation to DCs that could be expanded by TLR-mediated upregulation of GM-CSF. Cord blood monocyte-derived DCs showed lower expression of the maturation markers CD83 and CD86 and produced fewer IL-12 (p40, p70) than adult DCs.[82,172,176] In mixed leukocyte culture with adult CD4+ T cells, neonatal DCs induced significantly lower levels of IFN-γ but higher levels of IL-10 than did adult DCs (see Table 71.2). Furthermore, neonatal DCs also performed poorly as accessory cells for T-cell mitogenic responses.[173]

Innate Lymphoid Cell Physiology and Function

ILCs include the classic cytotoxic NK cells and the recently described noncytotoxic ILC populations.[177] These cells are characterized by a classic lymphoid cell morphology but, unlike the adaptive T and B cells, do not show antigen specificity and function as a part of the innate immune system.

Natural Killer Cell Physiology and Function

NK cells have the ability to lyse target cells and secrete immunomodulatory cytokines.[178] These cells make up 10% of peripheral blood lymphocytes and are characterized by the lack of the lymphocyte marker CD3 but an expression of CD56.[179]

Ontogeny

NK cells develop from the committed lymphoid progenitors in the aortogonadomesonephron and later within the fetal liver.[180] Lineage-specific NK-cell progenitors are first identified in the fetal thymus and later in the bone marrow.[181,182] Human NK-cell development requires early growth factors such as FMS-like tyrosine kinase (Flt)-3 ligand or Kit ligand and later IL-15. Based on the expression profile of cell surface markers and functional maturity, distinct stages of NK-cell maturity have been recently described.[183]

Natural Killer Cell Subtypes

NK cells can be classified on the basis of the surface density of CD56 into $CD56^{bright}$ NK cells and $CD56^{dim}$ NK cells. Early NK cells are $CD56^{bright}$, which then undergo further differentiation into $CD56^{dim}$ NK cells. The $CD56^{dim}$ NK cells are the more cytotoxic of the two categories and represent 90% of the NK-cell population. These cells are also the predominant NK cell population in peripheral blood and express CD16 (FcγRIII), and show antibody-dependent cellular cytotoxicity.[183,184]

Function

NK cells mediate their effector immune function by cytotoxicity and/or expression of a plethora of pro-inflammatory cytokines.[183] NK cells express a repertoire of classes of receptors that bind to MHC class I or MHC class I–like molecules that regulate whether NK cells will be activated or inhibited.[179,185] When NK cells fail to interact with the MHC class I molecules and the activating receptor is activated, NK-cell–mediated cell lysis will ensue, as occurs in the case of infection.[186] After activation, lysosome-like vesicles containing perforin, serine esterases, and sulfated proteoglycans are secreted toward the target cell. Perforin forms pores in the target cell, leading to osmotic lysis. The serine esterases, including granzymes, induce apoptosis.[178,186,187] After stimulation with cytokines, $CD56^{bright}$ NK cells produce

positive feedback loops by secreting IFN-γ, TNF, and GM-CSF. In addition, these cells also produce chemokines that recruit macrophages and other antigen-presenting cells for more efficient control of the infection.[188,189]

Neonatal NK cells show functional immaturity, which leads to an impaired immune system. Cord blood NK cells show lower expression of CD8 and CD57, two markers associated with NK cell maturation[190] (see Table 71.2), but show higher levels of the immaturity marker NKG2A.[191] Cord blood NK cells express less ICAM-1 and CD161, which are involved in endothelial adhesion and activation, respectively, than adult NK cells.[190] Cord blood NK cells are also functionally deficient when compared to their adult counterparts. When challenged with MHC class I deficient cells, cord blood NK cells degranulate less and produce less IFN γ and TNFα compared to adult cells.[191] Neonatal NK cells also show less cytolytic activity, which results in impaired clearance of intracellular pathogens.[190,192]

Noncytotoxic Innate Lymphoid Cell Physiology and Function

Ontogeny

Similar to NK cells, noncytotoxic ILCs are also derived from the common lymphoid progenitor that differentiates into precursors committed to the various subsets. Recent studies have confirmed that NK cells and noncytotoxic helper ILCs belong to distinct cell lineages.[193,194]

Innate Lymphoid Cell Subtypes

Noncytotoxic ILCs are characterized by classic lymphoid cell morphology and express IL-2 receptor α and IL-7 receptor α, but unlike the adaptive T and B cells, ILCs do not exhibit antigen specificity. Noncytotoxic ILCs are largely tissue-resident cells and are divided into three main groups: group 1 ILCs (ILC1s), group 2 ILCs (ILC2s), and group 3 ILCs (ILC3s), including lymphoid tissue inducer (LTi) cells that are necessary for the formation of lymph nodes and intestinal Peyer patches during embryonic development.[195] These subsets are defined on the basis of differential requirements for transcription factors during development, expression of effector cytokines, and the acquisition of other distinct effector functions.[196] In addition to their direct role in mediating innate immune responses, ILCs interact closely with non-hematopoietic cells in the tissue microenvironment and also participate in metabolic homeostasis and tissue repair and remodeling.[197]

All three ILC subsets function in the absence of antigen specificity but exhibit remarkable functional similarity with the T_h cell subsets, T_h1, T_h2, and T_h17, respectively, in cytokine expression and effector function and are therefore thought to be innate counterparts to T lymphocytes.[177] ILC1s express the T-bet transcription factor and produce T_h1-associated cytokines such as IFN-γ and TNF to protect against intracellular bacteria and parasites. ILC2s express the transcription factor GATA-binding protein three and produce T_h2-associated cytokines (including IL-4, IL-5, IL-9, and IL-13) and/or the epidermal growth factor receptor ligand amphiregulin. ILC2s become activated in response to epithelial-cell derived cytokines IL-33, IL-25, and TSLP and promote type 2 inflammation seen during tissue repair, allergic disorders, and antihelminth immunity. Recent findings also implicate ILC2s in the development of inflammatory lung diseases such as asthma.[195]

ILC3s express the transcription factor RAR-related orphan receptor γT, have a cytokine signature similar to that of T_h17 cells, and produce IL-17A, IL-17F, IL-22, GM-CSF, and TNF, to promote antibacterial immunity, chronic inflammation, or tissue repair. ILC3s are a heterogenous group of cells that include the $CCR6^+$ ILCs and two other subsets of cells distinguished by their presence of the NK cell receptor (NCR).[195] $CCR6^+$ ILC3s encompass $CD4^+$ and $CD4^-$ LTi cells. Recent findings indicate that depending on specific pathogenic signals, ILC subsets retain the capacity to change phenotype and function and therefore exhibit some degree of plasticity.[197]

Function

There is limited information on ILCs in the fetus and neonate. ILC2 cells are detectable in cord blood and may be present in higher proportions in male neonates than in female neonates.[198] ILC2s influence adipocyte progenitor cells to differentiate into white or beige fat and can therefore affect thermal homeostasis.[199] In a murine model of gastroschisis, organs exposed to amniotic fluid were shown to contain high numbers of ILC2 and ILC3 and eosinophilia, which was reversed by the administration of an anti-IL5 antibody.[200] In another study, ILC3s were implicated as a source of increased IL-17 levels seen in patients with pre-eclampsia, and gestational/chronic diabetes was associated with ILC3s.[201]

ILC3s are abundant on mucosal surfaces, particularly in the gastrointestinal tract. There is evidence that the development and function of some subsets of ILC3s are induced in response to microbial colonization and are involved in enhancing B-cell IgA production.[202] IL-22 production by ILCs plays an important role in containing and shaping the composition of the intestinal microbiota.[203] Further, ILC3s also promote the proliferation of intestinal stem cells in certain conditions.[199] Yet, NCR^- ILC3s may also have a pathogenic role in colitis.[204] A fine balance of ILC3 function may therefore be important for intestinal homeostasis.

Summary

Immaturity of neonatal neutrophils, monocytes, lymphocytes, DCs, and ILCs predisposes newborns to an increased incidence and/or severity of infectious complications. An increased understanding of the genetic mechanisms responsible for these defects will provide insight regarding future treatment strategies to prevent and/or treat serious or overwhelming infection in the newborn.

Neonatal Hyperbilirubinemia and Kernicterus

W. CHRISTOPHER GOLDEN AND JON F. WATCHKO

KEY POINTS

- Early clinical jaundice or rapidly developing hyperbilirubinemia is often a sign of hemolysis, the differential diagnosis of which commonly includes immune-mediated disorders, red cell enzyme deficiencies, and red cell membrane defects.
- Knowledge of the maternal blood type and antibody screen is critical in identifying non-ABO alloantibodies in the maternal serum that may pose a risk for severe hemolytic disease of the newborn.
- Knowledge of the hour-specific predischarge bilirubin measurement, the infant's gestational age in weeks, and hyperbilirubinemia neurotoxicity risk factors are critical to determining appropriate timely postbirth hospitalization follow-up and evaluation.
- Hyperbilirubinemia in late-preterm neonates ($34^{0/7}$ to $36^{6/7}$ weeks' gestation) is more prevalent, more pronounced, and more protracted than in their term counterparts, and these immature neonates are more vulnerable to bilirubin-induced brain injury.
- Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a noteworthy cause of bilirubin encephalopathy worldwide. Clinicians everywhere must have a high index of suspicion for G6PD deficiency in neonates whose genetic heritage derives from Africa, the Middle East, the Mediterranean region, and Asia.

Hyperbilirubinemia

Hyperbilirubinemia is the most common clinical condition requiring evaluation and treatment in the newborn, and a frequent reason for hospital readmission during the first week of life. Although generally a benign, postnatal, transitional phenomenon, some neonates develop marked, potentially hazardous bilirubin levels that can cause serious brain injury.[1] Acute bilirubin encephalopathy (ABE) may ensue and evolve into kernicterus (chronic bilirubin encephalopathy), a permanent disabling neurologic condition classically characterized by (1) the movement disorders of dystonia and/or choreoathetosis, (2) hearing loss caused by auditory neuropathy spectrum disorders, and (3) oculomotor paresis.[1]

Total serum bilirubin (TSB) is the measure of albumin-bound bilirubin, whereas the small circulating fraction not bound to albumin or other serum proteins is indexed by the unbound or "free" (Bf) bilirubin level. There is a keen interest in circulating Bf, its measurement, and its ability to predict bilirubin-induced neurologic injury. Indeed, Bf is the vehicle of bilirubin's biologic effects in the brain. However, bilirubin-induced neurotoxicity depends on a complex interaction between the level and duration of the central nervous system (CNS), Bf exposure, and the innate cellular characteristics of the developing CNS that may predispose or protect against bilirubin-induced neuronal injury. At present, the measurement of circulating Bf is not generally available in clinical laboratories.[1] As a result, clinicians must rely on the TSB and the bilirubin/albumin (B/A) ratio, an imperfect surrogate of circulating Bf, to index the risk for ABE and drive treatment decisions.

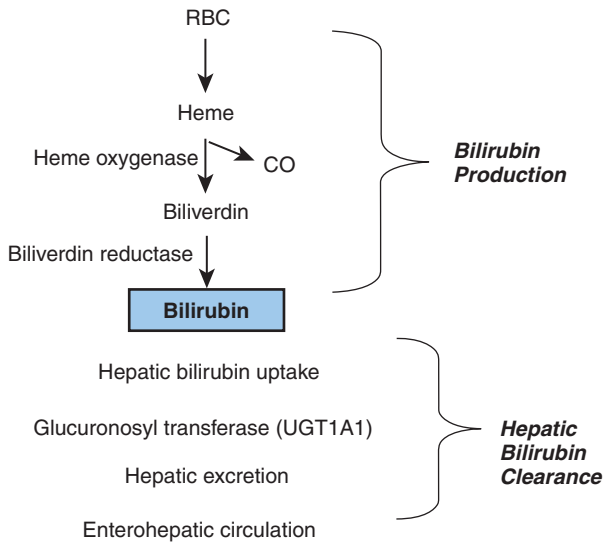
The genesis of neonatal hyperbilirubinemia reflects the interplay of developmental red blood cell (RBC), hepatic, and gastrointestinal immaturities that result in an imbalance favoring bilirubin production over hepatic enteric bilirubin clearance (Fig. 72.1). The equation below summarizes the interactions among the rates of bilirubin production (a), the enterohepatic circulation of bilirubin (b), and bilirubin elimination (c), in determining the TSB at any postnatal time point t, where TSB_0 is the cord blood TSB.[2]

$$TSB_t = TSB_0 + \sum [a(t) + b(t) - c(t)]^{\Delta t}$$

A variety of clinical conditions can increase the bilirubin load or decrease bilirubin clearance and thereby contribute to neonatal hyperbilirubinemia in any given infant (Box 72.1). In a small fraction of neonates, a constellation of conditions may lead to hazardous levels of hyperbilirubinemia that pose a neurotoxic risk. Accelerated RBC turnover (hemolysis) plays a pivotal role in increasing the risk for subsequent severe hyperbilirubinemia and in potentiating the risk of bilirubin neurotoxicity. Treatment interventions are therefore recommended at a lower bilirubin level whenever hemolysis is present.

Increased Hepatic Bilirubin Load: Hemolytic Disease

The causes of hemolysis in the neonatal period can be broadly grouped into five major categories: (1) abnormalities in red cell membrane structure, (2) red cell enzyme defects, (3) hemoglobinopathies, (4) acquired causes of hemolysis, and (5) immune-mediated mechanisms (see Box 72.1).



• **Fig. 72.1** Schematic of Bilirubin Production and Hepatic Bilirubin Clearance in Neonates. Heme, produced largely by the breakdown of red blood cells (RBCs), is catabolized by heme oxygenase to produce an equimolar amount of carbon monoxide (CO) and biliverdin; the latter is reduced to unconjugated bilirubin by biliverdin reductase. Unconjugated bilirubin is taken up by the hepatocyte via facilitated diffusion, bound to glutathione S-transferase (ligandin), and conjugated with glucuronic acid by hepatic uridine diphosphate-glucuronosyltransferase 1A1 (UGT1A1). Conjugated bilirubin is excreted into bile via multidrug resistance protein-2, a portion of which may be deconjugated by intestinal β-glucuronidase and reabsorbed into the portal circulation, enhancing the hepatic bilirubin load (enterohepatic circulation).

Red Cell Membrane Defects

Of the many red cell membrane defects that lead to hemolysis, only hereditary spherocytosis, elliptocytosis, stomatocytosis, and infantile pyknocytosis manifest themselves in neonates.[3–5] Establishing a diagnosis of these disorders is often difficult because newborns normally exhibit a marked variation in red cell membrane size and shape.[3,6] Spherocytes, however, are not often seen on RBC smears of hematologically normal newborns, and when prominent, suggest a diagnosis of hereditary spherocytosis, as does an elevated mean corpuscular hemoglobin concentration (MCHC >36.5 to 37 g/dL) or MCHC to mean corpuscular volume (MCV) ratio (MCHC/MCV >0.36).[7] Given the likelihood of autosomal dominant inheritance, a positive family history can often be elicited. The diagnosis of hereditary spherocytosis can be confirmed using the incubated osmotic fragility test coupled with fetal red cell controls or eosin-5-maleimide flow cytometry.[7] Symptomatic ABO hemolytic disease must be excluded by performing a direct Coombs test, as affected infants can manifest prominent microspherocytosis. Moreover, hereditary spherocytosis and symptomatic ABO hemolytic disease can occur in the same infant and result in anemia and severe hyperbilirubinemia.[8]

Hereditary elliptocytosis and stomatocytosis are rare but reported causes of hemolysis in the newborn period.[3] Infantile pyknocytosis is a transient red cell membrane abnormality manifesting itself during the first few months of life. The pyknocyte, an irregularly contracted red cell with multiple spines, can normally be observed in premature infants, whereas many as 5% of red cells may manifest this morphologic variant.[5] In newborns affected with infantile pyknocytosis, however, up to 50% of red cells may exhibit the morphologic abnormality with anemia that may necessitate transfusion, and hyperbilirubinemia that can be severe enough to require control by exchange transfusion.[5] Whatever the mechanism underlying infantile pyknocytosis, the disorder tends to resolve after several months of life. Pyknocytes may also occur in other conditions, including glucose-6-phosphate dehydrogenase (G6PD) deficiency and hereditary elliptocytosis, and these must be excluded before a diagnosis of infantile pyknocytosis is made.

• BOX 72.1 Causes of Indirect Hyperbilirubinemia in Neonates

A. Increased Hepatic Bilirubin Load

1. Hemolytic disease—immune mediated (positive direct Coombs test)
   a. Rhesus isoimmunization
   b. ABO incompatibility
   c. Minor blood group incompatibility
2. Hemolytic disease—red blood cell enzyme abnormalities
   a. Glucose-6-phosphate dehydrogenase deficiency
   b. Pyruvate kinase deficiency
3. Hemolytic disease—red blood cell membrane defects
   a. Hereditary spherocytosis
   b. Elliptocytosis
   c. Stomatocytosis
   d. Pyknocytosis
4. Hemolytic disease—hemoglobinopathies
   a. Alpha-thalassemia
   b. Gamma-thalassemia
5. Extravascular blood (e.g., cephalohematoma)
6. Polycythemia
7. Enhanced enterohepatic bilirubin circulation
   a. Intestinal obstruction, pyloric stenosis
   b. Ileus, meconium plugging, cystic fibrosis
   c. Breast-milk feeding

B. Decreased Hepatic Bilirubin Clearance

1. Prematurity including late-preterm gestation
2. Hormonal deficiency
   a. Hypothyroidism
   b. Hypopituitarism
3. Impaired hepatic bilirubin uptake
   a. Patent ductus venosus
   b. *SLCO1B1* gene polymorphisms
4. Disorders of bilirubin conjugation—*UGT1A1* gene variants
   a. Crigler-Najjar syndrome type I
   b. Crigler-Najjar syndrome type II (Arias disease)
   c. Gilbert syndrome
5. Enhanced enterohepatic circulation
   a. Intestinal obstruction, pyloric stenosis
   b. Ileus, meconium plugging, cystic fibrosis
   c. Breast-milk feeding

SLCO1B1, Solute carrier organic anion transporter 1B1; *UGT1A1*, uridine diphosphate glucuronosyltransferase 1A1.

Red Cell Enzyme Deficiencies

The two most common red cell enzyme defects that can lead to hyperbilirubinemia in the neonatal period are G6PD deficiency[9–14] and pyruvate kinase deficiency.[15,16] Of these, pyruvate kinase (PK) deficiency is far less frequent. PK deficiency is an autosomal recessive disorder largely confined to populations in which consanguinity is prevalent, including newborns of Amish descent and

other isolated communities.[16–18] Pyruvate kinase deficiency often presents with anemia, reticulocytosis, and severe hyperbilirubinemia.[15] A full third of affected infants require exchange transfusion to control their hyperbilirubinemia,[19] and kernicterus is a real risk.[16,18] The diagnosis of pyruvate kinase deficiency is often difficult, as the enzymatic abnormality is frequently not simply a quantitative defect but may involve abnormal enzyme kinetics or an unstable enzyme that decreases in activity as the red cell ages. The diagnosis of pyruvate kinase deficiency should be considered whenever marked hyperbilirubinemia and a picture of nonspherocytic, Coombs negative hemolytic anemia is observed.

Glucose-6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is an X-linked enzymopathy affecting hemizygous males, homozygous females, and a subset of heterozygous females (via X chromosome inactivation). G6PD deficiency is an important cause of hazardous hyperbilirubinemia and kernicterus worldwide, including the United States. Although most prevalent in Africa, the Middle East, East Asia, and the Mediterranean, G6PD deficiency has evolved into a global neonatal problem as a result of past and present migration patterns, the transatlantic slave trade, and intermarriage.[9,10,12–14,20] The condition is a noteworthy contributor to endemic rates of bilirubin encephalopathy in several developing countries[21] and accounts for a substantial and disproportionate number of neonates with kernicterus in the United States Pilot Kernicterus registry (20.8% of all reported cases).[22,23] The majority of these kernicterus cases have been in African-American neonates,[24,25] an at-risk population—given that the G6PD deficiency prevalence rates in the United States are 12.2% for African-American males and 4.1% for African-American females.[26] Other subgroups at risk for G6PD deficiency include newborns of East Asian, Greek, Italian (especially Sardinia and Sicily), and Middle Eastern descent.[13,20]

G6PD is remarkable for its genetic diversity (230 variants have been described),[14] and the mutations seen in the United States include among numerous others (1) the African A variants, a group of double-site mutations, all of which share a mutation in codon 126 (376A>G) known as *G6PD A* (which expressed alone is a nondeficient variant) coupled most commonly with the 202G>A mutation (202G>A;376A>G, known as *G6PD A−*) but on occasion with the 968T>C variant (968T>C;376A>G; also known as *G6PD Betica*), or the 680G>T mutation (680G>T; A376G); (2) the *Mediterranean* (563C>T) mutation; (3) the *Canton* (1376G>T) mutation; and (4) the *Kaiping* (1388G>A) variant.[9,14,27]

G6PD is critical to the redox metabolism of red blood cells. G6PD deficiency can result in acute severe neonatal hemolysis following exposure to oxidative stress, possibly even the stress accompanying perinatal transition to the extrauterine environment.[28] Reported hemolytic triggers in G6PD deficiency are outlined in Box 72.2. A sudden, often rapid exponential rise in TSB to potentially hazardous levels may occur and result in kernicterus that may not always be preventable.[10,12,13,24,29] Severe jaundice rather than anemia may predominate in the clinical presentation.[10,30] In some neonates, G6PD deficiency and the hepatic uridine diphosphate-glucuronosyltransferase 1A1 gene (*UGT1A1*) polymorphisms of Gilbert syndrome (that limit hepatic bilirubin conjugation) combine to significantly increase the risk of hyperbilirubinemia. Kaplan et al.[31] have demonstrated a dose-dependent genetic interaction between the *UGT1A1*28* promoter variant and G6PD deficiency that substantially increases neonatal hyperbilirubinemia risk. Details regarding this icterogenic genetic interaction and other aspects of *UGT1A1* gene variants in neonates are described later under Hepatic Bilirubin Conjugation. Coexistent nongenetic factors may also impact hyperbilirubinemia risk in G6PD-deficient neonates, as shown in those who are also late-preterm and breastfed.[32]

Caretakers must have a high index of suspicion for G6PD deficiency in populations at increased risk (Mediterranean region, Africa, the Middle East, southern and southeastern Asia) who demonstrate significant hyperbilirubinemia.[24,25] Although there has been discussion on the potential utility of screening for G6PD deficiency in the United States, no consensus has emerged on whether or how best to screen, and point-of-care testing during birth hospitalization is not routinely practiced.[33] Models of point-of-care testing have demonstrated the feasibility

• BOX 72.2 Agents Reported to Produce Hemolysis in Patients With Glucose-6-Phosphate Dehydrogenase Deficiency

Antimalarials
- Pamaquine
- Pentaquine
- Plasmoquine
- Primaquine
- Quinacrine
- Quinine
- Quinocide
  - Tafenoquine

Sulfonamides
- Sulfacetamide
  - Sulfadiazine
- Sulfamethoxazole/cotrimoxazole
- Sulfanilamide
- Sulfamethoxypyridazine
- Sulfapyridine
  - Sulfasalazine
- Sulfisoxazole
- Trisulfapyrimidine

Sulfones
- Nitrofurans
- Furaltadone
- Furazolidone
- Nitrofurantoin
- Nitrofurazone
- Thiazolesulfone

Antipyretics and Analgesics
- Acetophenetidin
- Acetylsalicylic acid
- Aminopyrine
- Antipyrone
- *p*-Aminosalicylic acid

Others
- Ascorbic acid
- Chloramphenicol
- Chloroquine
  - Ciprofloxacin
- Aniline dyes
- Dimercaprol
  - Dimercaptosuccinic acid
  - Dapsone-containing combinations
- Fava beans
  - Glibenclamide (glyburide)
  - Henna (cosmetic use)
- Methylene blue
  - Moxifloxacin
  - Nalidixic acid
- Naphthalene (used in mothballs)
- Naphthoquinones (used in mothballs)
  - Niridazole
  - Norfloxacin
  - Ofloxacin
- Paradichlorobenzenes (moth repellent, car freshener, bathroom deodorizer)
- Phenylhydrazine
  - Phenazopyridine
- Probenecid
- Quinidine
  - Rasburicase and pegloticase
  - Sulfonylureas
  - Tolbutamide
  - Tolonium chloride (toluidine blue)
- Vitamin K analogs
- Menadiol sodium phosphate

Infection
- Sepsis
- Urosepsis
- Necrotizing enterocolitis

Adapted from Oski FA, Naiman JL. *Hematologic Problems in the Newborn*, 2nd ed. Philadelphia, PA: WB Saunders; 1972 and updated from Valaes F. Severe neonatal jaundice associated with glucose-6-phosphate dehydrogenase deficiency: pathogenesis and global epidemiology. *Acta Paediatr Suppl.* 1994;394:58–76, and Luzzatto L, Ally M, Notaro R. Glucose-6-phosphate dehydrogenase deficiency. *Blood.* 2020;136(11):1225–40.

and utility of identifying G6PD-deficient newborns.[34,35] Data from other countries (e.g., Israel, Singapore, and Taiwan) show that point-of-care G6PD screening strategies are associated with reductions in the prevalence of severe hyperbilirubinemia and kernicterus.[36,37]

Hemoglobinopathies

Defects in hemoglobin structure or synthesis are rare disorders that infrequently manifest themselves in the neonatal period. Of these, the α-thalassemia syndromes are the most likely to be clinically apparent in newborns. Each human diploid cell contains four copies of the α-globin gene, and thus four α-thalassemia syndromes have been described reflecting the presence of defects in 1, 2, 3, or 4 α-globin genes. Silent carriers have one abnormal α-globin chain and are asymptomatic. Common in populations of African descent, the α-thalassemia trait (two α-thalassemia mutations) is not associated with hemolysis in newborns, but presents with an MCV of less than 95 μm^3 (normal 100 to 120 μm^3).[38] Hemoglobin H disease results from the presence of three α-thalassemia mutations and can cause hemolysis and anemia in neonates.[39] Homozygous α-thalassemia (total absence of normal α-chain synthesis resulting in hemoglobin Barts hydrops fetalis syndrome) is characterized by profound hemolysis, anemia, *hydrops fetalis*, and, without fetal transfusions, almost always stillbirth or death in the immediate neonatal period. Those few reported survivors have required lifelong transfusion and frequently evidence comorbidities including neurodevelopmental delays and associated congenital abnormalities.[40]

The pure β-thalassemias do not manifest themselves in the newborn period. In addition, γ-thalassemias are (1) incompatible with life in the homozygous form, (2) associated with transient mild-to-moderate neonatal anemia if one or two genes are involved that resolves when β-chain synthesis begins, or (3) in combination with impaired β-chain synthesis, and are associated with severe hemolytic anemia and marked hyperbilirubinemia.[41]

Acquired Causes of Hemolysis

Acquired causes of hemolysis comprise a miscellaneous group of disorders, which include among others the (1) microangiopathic hemolysis associated with disseminated intravascular coagulation or hemangiomas and (2) infection (bacterial sepsis or congenital infections). The mechanisms underlying the hemolytic process in the latter are not fully understood but may also serve as a hemolytic trigger in G6PD deficiency.

Immune-Mediated Hemolytic Disease

Immune-mediated disorders are the most common cause of hemolysis in neonates, and should be suspected when there is (1) a heterospecific mother–infant pair where the infant expresses a red cell antigen(s) foreign to the mother, (2) the presence of a maternal antibody directed to the infant RBC antigen, and (3) a positive direct Coombs test in the neonate, indicating maternal antibody bound to the infant RBC.

Non-ABO Alloantibodies

A priority in evaluating every newborn is knowledge of the maternal blood type and the maternal antibody screen (routinely performed at maternal registration upon pregnancy diagnosis) to identify non-ABO alloantibodies in the maternal serum that may pose a risk for hemolytic disease in the newborn.[42] In addition, Rhesus (Rh)-D negative women who have a negative antibody screen at registration will have a repeat screen at 24 to 28 weeks' gestation before Rh(D) immune globulin (RhIG) is administered, and a screen at delivery along with a blood type and direct Coombs test on the infant to determine the need for postpartum RhIG. If these maternal data are not known, the infant should have a direct antiglobulin test and blood type determined as soon as possible (from either umbilical cord or peripheral blood) to identify risk for hyperbilirubinemia due to hemolysis.[43]

In addition to the classic Rhesus hemolytic disease of the fetus and newborn secondary to Rh-D isoimmunization, alloantibodies directed to non-D Rhesus antigens and a broad range of non-Rhesus blood group (minor) antigens are seen. Increasingly, the latter two categories comprise a clinically relevant proportion of hemolytic disease. The incidence of clinically significant sensitization to the minor blood group antigens (as determined by meta-analysis) approximates 1:330 pregnancies.[44] Only a review of the maternal antibody screen and the direct Coombs test on the infant will uncover such cases. Fig. 72.2 outlines an approach to the evaluation and management of the neonate born to a mother with a positive antibody screen.[42] A blood type and direct Coombs test are indicated at delivery (cord or infant blood) for all infants born to women with a positive antibody screen.[42]

Interpreting the results of the maternal antibody screen by neonatal caregivers is critical in identifying mothers who carry a non-ABO alloantibody, several of which can cause moderate-to-severe hemolytic disease. Table 72.1 outlines several clinical scenarios in which the maternal antibody screen is positive, accompanied by the likely clinical explanation for the positive screen.[45] The only scenario shown that does not indicate maternal sensitization is that which is secondary to RhIG administration. The latter positive anti-D maternal antibody screen must be distinguished from the occurrence of late Rh-D sensitization by confirming that the mother was anti-D antibody negative before RhIG administration and that she received RhIG. At times, the infant will also have a positive direct Coombs test secondary to maternal RhIG administration.[46–49] This finding is generally not thought to indicate a hemolytic risk.[46–50]

It is also important to note that Rh-D positive infants delivered to Rh-D negative women during the first isoimmunized pregnancy (conversion from negative to positive maternal antibody titer in that pregnancy) are at an approximately 20% risk of developing hemolytic disease requiring treatment, including the possibility of an exchange transfusion.[51] An infant born of a pregnancy during which maternal antibody conversion occurs will by definition carry the foreign antigen and may have a positive direct Coombs test. Such infants are at risk of hemolytic disease and should be monitored closely for severe hyperbilirubinemia with serial TSB measurements and not discharged early from the birth hospital.

ABO Hemolytic Disease

Hemolytic disease related to ABO incompatibility is generally limited to mothers who are blood group O and infants of blood group A or B.[52] Although this association exists in approximately 15% of pregnancies, only a fraction of infants born in this context will develop significant hyperbilirubinemia.[52,53] The diagnosis should be considered in infants who develop marked jaundice in the context of ABO incompatibility accompanied by a positive direct Coombs test, and on occasion microspherocytosis on red cell smear. The hyperbilirubinemia seen with symptomatic ABO hemolytic disease is often detected within the first 12 to 24 hours

of life ("icterus neonatorum praecox").[54] Although usually controlled with intensive phototherapy alone, a few affected infants develop hyperbilirubinemia to levels requiring exchange transfusion.[45,55] Routine screening of all ABO-incompatible cord blood is common practice in many nurseries.[56] The literature,[52,56–59] however, suggests that such routine cord blood screening is not warranted given the low yield and cost, consistent with the position of the American Association of Blood Banks.[60] This recommendation assumes appropriate surveillance for early jaundice, universal birth hospitalization bilirubin screening, and hyperbilirubinemia risk assessment before discharge and in follow-up.[43,53,59,61,62] A blood type and Coombs test are indicated in the evaluation of any newborn with early and/or clinically significant jaundice.

Infants born of ABO-incompatible mother-infant pairs who have a negative direct Coombs test appear to be at no greater risk for developing hyperbilirubinemia than their ABO-compatible counterparts[52] and the development of significant hyperbilirubinemia in such neonates should prompt an evaluation for a cause other than isoimmunization.[63] Similarly, group A or B infants born to incompatible group B or A mothers are not likely to manifest symptomatic ABO hemolytic disease, and less than 1% will have a positive direct Coombs test.[52]

Decreased Hepatic Bilirubin Clearance

Hepatic Bilirubin Uptake

During intrauterine life, fetal bilirubin is removed by the placenta and metabolized and excreted by the maternal liver. Blood flow through the newborn's hepatic arteries develops only in the first week of extrauterine life, and the ductus venosus may remain partially patent for several days, allowing blood to bypass the liver. Unconjugated bilirubin may also be a substrate for the solute carrier organic anion transporter 1B1 (SLCO1B1), a sinusoidal transporter that facilitates the hepatic uptake of a broad range of substrates in an adenosine triphosphate-independent fashion.[64] It follows that delayed developmental expression of *SLCO1B1* and nonsynonymous *SLCO1B1* gene variants may adversely impact hepatic bilirubin uptake and clearance in neonates.[65]

Hepatic Bilirubin Conjugation

The bilirubin-conjugating capacity of infants is dependent on the activity of hepatic uridine diphosphate-glucuronosyltransferase 1A1 (UGT1A1), which is developmentally expressed at 0.1% of adult levels at 17 to 30 weeks' gestation, increasing to 1% of adult values between 30 and 40 weeks' gestation, and reaching adult levels only at 14 weeks of postnatal life.[66,67] A graded upregulation of hepatic UGT1A1 activity over the first few days of life is induced by TSB itself independent of the newborn's gestational age at birth. Phenobarbital induces *UGT1A1* via the phenobarbital responsive enhancer module (PBREM) in the *UGT1A1* gene promoter element. A nonsynonymous polymorphism of *UGT1A1* PBREM (*UGT1A1*60*) is associated with an increased risk of hyperbilirubinemia.[68]

In addition to the developmentally modulated postnatal transition in hepatic bilirubin UGT1A1 activity, there are congenital inborn errors of *UGT1A1* expression, commonly referred to as the indirect hyperbilirubinemia syndromes.[69] These include the Crigler-Najjar type I and II (Arias) syndromes and Gilbert syndrome (Table 72.2).[69] Infants with Crigler-Najjar type I have complete absence of bilirubin UGT1A1 activity and are at

TABLE 72.2 Congenital Nonhemolytic Unconjugated Hyperbilirubinemia: Clinical Syndromes

	SEVERITY		
Characteristic	**Marked Crigler-Najjar Type I**	**Moderate Crigler-Najjar Type II**	**Mild Gilbert Syndrome**
Steady-state serum total bilirubin	>20 mg/dL	<20 mg/dL	<5 mg/dL
Range of bilirubin values	14–50 mg/dL	5.3–37.6 mg/dL	0.8–10 mg/dL
Total bilirubin in bile	<10 mg/dL (increased with phototherapy)	50–100 mg/dL	Normal
Conjugated bilirubin in bile	Absent	Present (only monoglucuronide)	Present (50% monoglucuronide)
Bilirubin clearance	Extremely decreased	Markedly decreased	20%–30% of normal
Hepatic bilirubin uptake	Normal	Normal	Reduced
Bilirubin UGT1A1 activity	None detected	None detected	Decreased
Genetics	Autosomal recessive	Heterogeneity of defect distinctly possible	Genetic polymorphisms: 1. Thymine-adenine $(TA)_7$ and $(TA)_8$ repeats in the *UGT1A1* promoter region. 2. G211A (Gly71Arg) *UGT1A1* coding sequence mutation identified in the Asian populations. 3. Linkage disequilibrium between $(TA)_7/(TA)_7$ and T-3279G PBREM *UGT1A1* promoter polymorphisms.

PBREM, Phenobarbital responsive enhancer module; *UGT1A1*, uridine diphosphate glucuronosyltransferase 1A1 isoenzyme.

significant risk for bilirubin encephalopathy and kernicterus.[70–72] Inherited in an autosomal recessive pattern, at least 85 different genetic mutations have been identified in Crigler-Najjar type I syndrome, typically nonsense or "stop" mutations in nature.[73]

Phototherapy is the mainstay of treatment for infants and children with Crigler-Najjar type I syndrome, although neonates may develop hazardous hyperbilirubinemia necessitating exchange transfusion. Liver transplantation is the only current definitive therapeutic intervention for this disorder.[71,72] Human hepatocyte transplantation to enhance hepatic UGT1A1 activity has shown limited success in these patients.[74] Stem cell and gene therapy strategies hold promise for treatment of this condition.[75,76]

In contrast, the Crigler–Najjar type II syndrome, typified by more moderate levels of indirect hyperbilirubinemia as well as low but detectable hepatic bilirubin UGT1A1 activity, appears in most cases to be mediated by missense mutations in the *UGT1A1* gene.[73] Phenobarbital can be trialed to induce residual UGT1A1 activity. These rare but important clinical syndromes must be included in the differential diagnosis of prolonged marked indirect hyperbilirubinemia.

Gilbert Syndrome

Gilbert syndrome is far more common and characterized by mild, chronic, or recurrent unconjugated hyperbilirubinemia in the absence of liver disease or overt hemolysis.[77] Hepatic *UGT1A1* activity is reduced at least 50% in affected subjects, and more than 95% of their total serum bilirubin is unconjugated.[77] Gilbert syndrome affects approximately 9% of the population, and its genetic basis in Caucasians and African Americans is an abnormal, two base pair addition to the *UGT1A1* TATAAA box promoter element giving rise to 7 ($A[TA]_7TAA$) rather than the more usual 6 ($A[TA]_6TAA$) repeats—the *UGT1A1*28* variant allele.[78]

Pediatricians have long speculated that Gilbert syndrome might contribute to indirect hyperbilirubinemia in the newborn period, and reports now show that neonates homozygous for the *UGT1A1*28* allele have accelerated jaundice, decreased fecal excretion of bilirubin monoglucuronides and diglucuronides,[79] and modestly elevated postnatal TSB levels.[80] Others have failed to demonstrate a clinically significant effect of *UGT1A1*28* alone on peak TSB. However, the coupling of *UGT1A1*28* with icterogenic conditions, e.g., G6PD deficiency and hereditary spherocytosis, markedly increases a newborn's risk for severe hyperbilirubinemia.[31,81] Several studies clearly demonstrate that the $A(TA)_7TAA$ promoter variant is prevalent in breastfed infants who develop prolonged neonatal indirect hyperbilirubinemia.[80,82] In Asian populations the nucleotide 211 guanine to adenine mutation in the coding sequence of *UGT1A1 (UGT1A1*6)* underlies a Gilbert syndrome phenotype and contributes to neonatal hyperbilirubinemia risk, including that associated with breast milk jaundice.[65,83,84]

Enhanced Enterohepatic Circulation of Bilirubin

Intestinal reabsorption of bilirubin excreted into the intestine is enhanced in neonates, adding to their hyperbilirubinemia risk. Conjugated bilirubin, as either the monoglucuronide or diglucuronide, is unstable and can be spontaneously or enzymatically hydrolyzed back to unconjugated bilirubin via intestinal β-glucuronidase and readily reabsorbed through the mucosa. Two other factors accelerating the deconjugation of bilirubin glucuronides in the newborn intestine are the mildly alkaline pH of the proximal intestine, which facilitates nonenzymatic hydrolysis, and the predominance of monoglucuronides as the main excretion form of bilirubin in the first few days of life. Neonates also lack normal intestinal flora, which metabolize conjugated bilirubin to the water-soluble and readily excretable breakdown products urobilin and stercobilin.

Other Clinically Relevant Icterogenic Conditions

Certain demographic, environmental, and genetic/inherited risk factors, among a myriad of icterogenic contributors, merit special clinical attention in addition to hemolytic conditions (Box 72.3).[43] Although each holds the potential to be a singularly important contributor to an infant's hyperbilirubinemia, more often multiple risk factors are observed in combination in marked hyperbilirubinemia.[65,85] Indeed, in infants with peak TSB levels greater than or equal to 25 mg/dL (428 µmol/L), 88% had a least two and 43% had three or more identified risk factors in one report.[85] Several merit additional comment.[43,85–87]

Late-Preterm Gestation

Late-preterm ($34^{0/7}$ to $36^{6/7}$ weeks' gestation) infants evidence lower UGT1A1 enzyme activity and a slower increase in UGT1A1 enzyme activity than their term counterparts during the first week of life.[66,88] This exaggerated hepatic immaturity contributes to the greater prevalence, severity, and duration of neonatal jaundice in late-preterm infants.[89] Indeed, there is an approximately eightfold increased risk of developing a TSB of greater than or equal to 20 mg/dL (342 µmol/L) in infants born at 36 weeks' gestational age (5.2%) as compared with those born at 41 weeks' gestation (0.7%).[90] This gestational age effect is even more evident when examined as a function of hour-specific TSB risk zones using the Bhutani nomogram,[91] as shown in Fig. 72.3.[86] The reported difficulty in visually assessing jaundice in late-preterm newborns[92]

• BOX 72.3 Risk Factors for Development of Significant Hyperbilirubinemia in Infants of Greater Than 35 Weeks' Gestation

- Lower gestational age (i.e., risk increases with each additional week less than 40 weeks)
- Jaundice in the first 24 h after birth
- Predischarge TcB or TSB concentration close to the phototherapy threshold
- Hemolysis from any cause, if known or suspected based on a rapid rise of increase in the TSB or TcB of greater than 0.3 mg/dL/h (in the first 24 h) or greater than 0.2 mg/dL/h thereafter
- Phototherapy before discharge
- Parent or sibling requiring phototherapy or exchange transfusion
- Family history or genetic ancestry suggestive of inherited red blood cell disorders, including G6PD deficiency
- Exclusive breastfeeding with suboptimal intake
- Scalp hematoma or significant bruising
- Down syndrome
- Macrosomic infant of a diabetic mother

Combining clinical risk factors with serum bilirubin levels to predict hyperbilirubinemia in newborns. *Arch Pediatr Adolesc Med*. 2005;159(2):117.)

underscores the importance of routine birth hospitalization TSB or transcutaneous bilirubin (TcB) screening.[61]

Late-preterm neonates, because of their immaturity, often demonstrate less effective sucking and swallowing and may have difficulties achieving consistent nutritive breastfeeding, predisposing to varying degrees of lactation failure.[89,93] Suboptimal feeding was the leading reason for discharge delay during birth hospitalization in late-preterm neonates.[89,93] Late-preterm, breastfed infants merit timely post birth-hospitalization discharge follow-up and lactation support, given these risks.[61,89,94] A shortened hospital stay (<48 hours after delivery), although permitted for selected healthy term neonates, is not recommended for late-preterm neonates.[95]

Late-preterm infants are disproportionately overrepresented in the United States Pilot Kernicterus Registry, a database of voluntarily reported cases of kernicterus.[22,23,96] Moreover, the registry demonstrates that late-preterm neonates show signs of bilirubin neurotoxicity at an earlier postnatal age than term newborns, indirectly suggesting a greater vulnerability to bilirubin-induced brain injury.[96] Clinical hyperbilirubinemia management guidelines for late-preterm infants, therefore, recommend treatment at lower TSB thresholds than term newborns, an important distinction in the American Academy of Pediatrics' (AAP) practice guideline on neonatal jaundice.[43] It is also important to note that the management of late-preterm newborns born between $34^{0/7}$ and $34^{6/7}$ weeks' gestation is not addressed by the AAP guideline but set forth in an approach to management of preterm neonates.[97]

Breast-Milk Feeding

Not coincidentally, almost every reported case of kernicterus over the past three decades has been in a breastfed infant.[22] As such, exclusive breast-milk feeding, particularly in the setting of ineffective nursing and excessive weight loss, is listed as a hyperbilirubinemia risk factor by the AAP.[43,61] What does the association between exclusive breast-milk feeding and kernicterus imply with respect to the etiopathogenesis of marked neonatal jaundice? Numerous studies have reported an association between breastfeeding and an increased incidence and severity of hyperbilirubinemia, both in the genesis of early and prolonged neonatal jaundice.[65,98–101] A pooled analysis of 12 studies comprising over 8000 neonates showed a threefold greater incidence in TSB of greater than or equal to 12.0 mg/dL (205 µmol/L) and a sixfold greater incidence in levels of greater than or equal to 15 mg/dL (257 µmol/L) in breastfed infants as compared with their formula-fed counterparts.[101] Others, however, report that if adequate breastfeeding is established and sufficient lactation support is in place, breastfed infants should be at no greater risk for hyperbilirubinemia than their formula-fed counterparts.[102,103] The later studies suggest that many breastfed infants who develop marked neonatal jaundice do so in the context of a delay in lactation or varying degrees of lactation failure. Indeed, an appreciable percentage of the breastfed infants who develop kernicterus have been noted to have inadequate intake and variable but substantial degrees of dehydration and weight loss.[22,23,104] Inadequate breast-milk intake, in addition to contributing to dehydration, can enhance hyperbilirubinemia by increasing the enterohepatic circulation of bilirubin and resultant hepatic bilirubin load.[100,105] Breastfeeding-associated jaundice, however, is not associated with increased bilirubin production.[106]

Lactation failure, however, is not uniformly present in affected infants, suggesting that other mechanism(s) may be operative in breastfeeding-associated jaundice. Breast-milk feeding may act as an environmental modifier for selected genotypes and thereby potentially predispose to the development of marked neonatal jaundice.[107] In one report, the risk of developing a TSB greater than or equal to 20 mg/dL (342 µmol/L) associated with breast-milk feeding was enhanced 22-fold when combined with expression of *UGT1A1*6* or *SLCO1B1*1b* and increased 88-fold when breast-milk feedings were combined with *both UGT1A1* and *SLCO1B1* variants.[65] Several others have reported an association between prolonged (>14 days) breast-milk jaundice and expression of Gilbert syndrome variants *UGT1A1*28* and *UGT1A1*6*.[82–84] Indeed, breast-milk jaundice is now recognized as a prevalent Gilbert syndrome phenotype.[108] While recognizing the relationship between breast-milk feeding and jaundice, the benefits of breast-milk feeds far outweigh the related risk of hyperbilirubinemia. Cases of severe neonatal hyperbilirubinemia with suboptimal breast-milk feedings underscore the need for effective lactation support and timely follow-up examinations.

East Asian Ethnicity

Neonates of East Asian ethnicity, encompassing the populations of mainland China, Hong Kong, Japan, Macau, Korea, and Taiwan demonstrate a higher incidence of hyperbilirubinemia than others[107–109] and an overall increased risk for a TSB of greater than or equal to 20 mg/dL (342 µmol/L) (odds ratio [OR] 3.1, confidence interval [CI] 1.5 to 6.3).[85] Investigators have speculated as to the nature of this phenomenon, invoking potential population differences in the incidence of ABO hemolytic disease and G6PD deficiency, as well as environmental exposures to Chinese herbal medicines, among others.[110] There is little doubt that G6PD deficiency is an important contributor to hyperbilirubinemia risk in East Asian newborns.

Innate ethnic variation in hepatic bilirubin clearance also contributes to the hyperbilirubinemia risk in Asian newborns, as revealed by genetic analysis of enzymatic variants that modulate bilirubin metabolism.[110] Four different *UGT1A1* coding sequence variants: 211(G>A) (*UGT1A1*6*), 1456 (T>G) (*UGT1A1*7*), 686(C>A) (*UGT1A1*27*), and 1091(C>T) (*UGT1A1*73*) have been

described in East Asian populations, each associated with a Gilbert syndrome phenotype.[65,111] Of these, the *UGT1A1*6* variant is predominant, with an allele frequency of 11% to 13% in East Asians[111] (as high as 30% in neonates with hyperbilirubinemia ≥15 mg/dL [257 µmol/L])[112] and an associated significant decrease in UGT1A1 enzyme activity[113] greater than that seen in *UGT1A1*28*.[108] Indeed, studies of *UGT1A1*6* and **28* variants suggest a spectrum of neonatal hyperbilirubinemia risk across Gilbert syndrome genotypes.[108]

Hepatic *SLCO1B1* gene variants are also prevalent in East Asian populations,[65,114] and the *SLCO1B1*1b* variant was demonstrated to enhance neonatal hyperbilirubinemia risk.[65] Coupling *UGT1A1* and *SLCO1B1* variants together enhances hyperbilirubinemia risk, one that is further increased when that infant is also exclusively breastfed.[65]

Jaundice Observed in the First 24 Hours of Life

Jaundice appearing in the first 24 hours of life is an abnormal clinical finding[43] and an indication for immediate serum bilirubin measurement. Approximately 2.8% of newborns will evidence jaundice within 18 hours and 6.7% within 24 hours of life.[115] As contrasted with nonjaundiced newborns on the first day of life, newborns with overt jaundice in the first 24 hours of life are more likely to receive phototherapy (18.9% vs. 1.7%; relative risk [RR] 10.1, 95% CI 4.2 to 24.4) and to develop a TSB greater than or equal to 25 mg/dL (428 µmol/L) (OR 2.9, 95% CI 1.6 to 5.2).[115] Hemolytic disease, immune-mediated and otherwise, should be considered in any infant with early clinical jaundice.

Hemorrhage or Significant Bruising

Internal hemorrhage, ecchymosis, and other extravascular blood collections will enhance bilirubin production and the bilirubin load on the liver. Extravascular red cells have a markedly shortened life span, and their heme fraction is quickly catabolized to bilirubin by tissue macrophages that contain heme oxygenase and biliverdin reductase.[116] Thus cephalohematoma, subdural hemorrhage, subgaleal hemorrhage, massive adrenal hemorrhage, and marked bruising can be associated with increased serum bilirubin levels that typically manifest 48 to 72 hours following the extravasation of blood.[116] This temporal pattern is consistent with the evolution of ecchymosis and bilirubin formation in situ and also accounts for why extravascular blood can cause prolonged indirect hyperbilirubinemia.[116] An unusual but dramatic example of how extravascular blood can contribute to the genesis of hyperbilirubinemia is found in reports of marked jaundice associated with the delayed absorption of intraperitoneal blood in infants who received fetal intraperitoneal red cell transfusions.[117,118] In one such case, 13 exchange transfusions were necessary to control the hyperbilirubinemia that resolved only when approximately 87 cc of packed red cells were evacuated from the intraperitoneal cavity.[117] In this instance, the intraperitoneal blood hematocrit of 60% had the potential to contribute up to approximately 600 mg of bilirubin to the infant's bilirubin load over time.

Previous Sibling Treated With Phototherapy

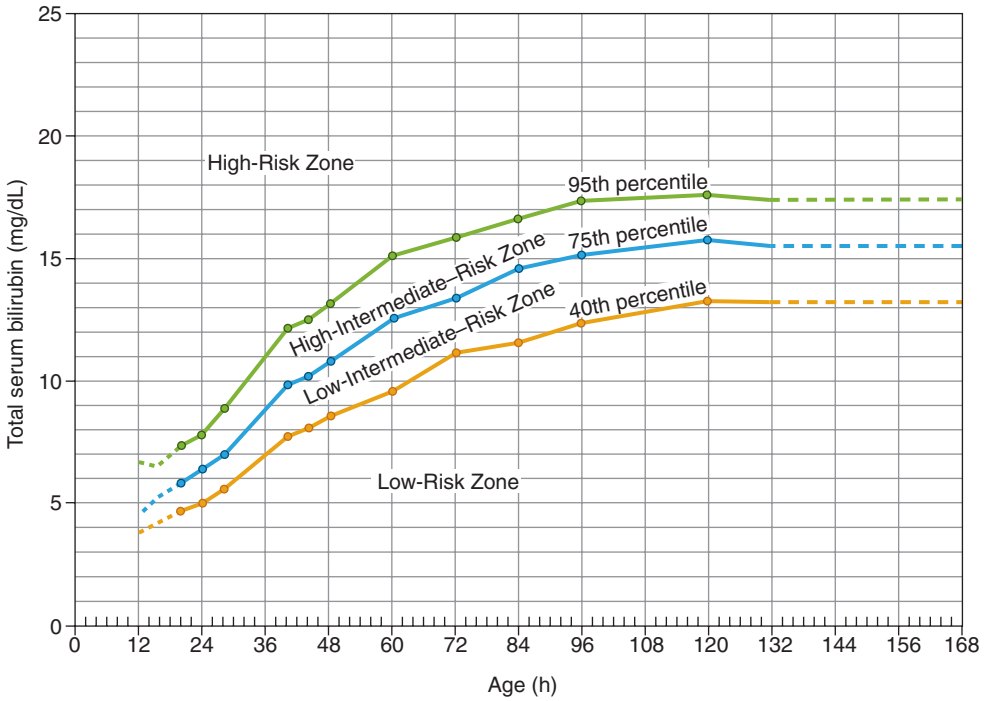
A history of a previous sibling treated with phototherapy is an identified risk factor for hyperbilirubinemia,[85,119] including concentrations greater than 15 mg/dL (257 µmol/L).[120] This relationship may reflect recurrent ABO or Rh hemolytic disease or exposure to a common environmental factor in addition to a shared genetic background.[119,121] The recurrence rate of ABO hemolytic disease is high: 88% in those infants of the same blood type as their index sibling, with almost two-thirds of the affected infants requiring treatment.[122] An excess risk in siblings independent of hyperbilirubinemia risk factors expected to recur in siblingships including breastfeeding, lower gestational age, and hemolytic disease suggests that genetic effects play an important role.[119,120] Consistent with this hypothesis, there is a higher concordance level in TSB between monozygotic (identical) than dizygotic (fraternal) twins when controlled for confounders that modulate neonatal bilirubinemia.[123]

African Ethnicity

African-American neonates demonstrate a lower overall incidence of significant hyperbilirubinemia, a lower risk for TSB greater than 20 mg/dL, comprise approximately 12% of the US population, and yet account for more than 25% of kernicterus cases in the United States.[24,25] A study using a large neonatal cohort reported that African-American newborns, despite having a reduced risk of TSB greater than 20 mg/dL, actually have a fourfold increased risk for a TSB greater than or equal to 30 mg/dL than other groups.[124] African ancestry also has been demonstrated as a risk factor for hazardous hyperbilirubinemia in infants born outside the United States.[125] G6PD deficiency is a plausible contributor to this pattern, but no effect modification by sex expected in an X-linked disorder was observed.[124] Regardless, African ancestry can no longer be considered a factor associated with decreased hyperbilirubinemia risk (as noted in the 2004 AAP Clinical Practice Guidelines for management of neonatal hyperbilirubinemia),[126] and African-American infants must be monitored for hyperbilirubinemia at least as closely as other neonates.[24,25,124] Some would caution that African-American neonates with jaundice merit special attention and follow-up.[24,25,127] Notably, Kaplan et al. report that 48.4% of G6PD-deficient African-American neonates developed a TSB greater than 75%, and 21.9% developed a TSB greater than 95% (high-intermediate and high risk zones on the Bhutani nomogram, respectively).[128] In contrast, Keren et al. report that neither the presence of a G6PD mutation or overt clinical jaundice was associated with the development of significant hyperbilirubinemia in African-American infants or African-American male infant cohorts.[87]

Combining Clinical Risk Factor Assessment With Predischarge Bilirubin Measurement

Several clinical studies show that combining clinical risk factor analysis with a birth hospitalization predischarge measurement of TSB or TcB significantly improves the prediction of subsequent hyperbilirubinemia risk.[60,85–87] An hour-specific prebirth hospitalization discharge TSB or TcB level in the high-risk zone (>95%) using the Bhutani nomogram (Fig. 72.4)[91] or close to the phototherapy threshold are risk factors for severe hyperbilirubinemia,[43,84,91,129] and the clinical factors most predictive of hyperbilirubinemia risk when combined with the risk zone characterization are lower gestational age and exclusive breastfeeding.[60,85–87] Coupling predischarge TSB or TcB measurement with gestational age and the presence of hyperbilirubinemia neurotoxicity risk factors (Box 72.4) is central to the recommendations for management and follow-up outlined in the current AAP



• **Fig. 72.4** Nomogram for Designation of Hyperbilirubinemia Risk Based on Hour-Specific Bilirubin Value. (Adapted from Bhutani V, Johnson L, Sivieri EM, et al. Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics*. 1999;103:6–14.)

• BOX 72.4 Risk Factors for Hyperbilirubinemia Neurotoxicity

- Gestational age less than 38 weeks, and this risk increases with the degree of prematurity
- Albumin less than 3.0 g/dL
- Isoimmune hemolytic disease (i.e., positive direct antiglobulin test), G6PD deficiency, or other hemolytic conditions
- Sepsis
- Significant clinical instability in the previous 24 h

G6PD, Glucose-6-phosphate dehydrogenase

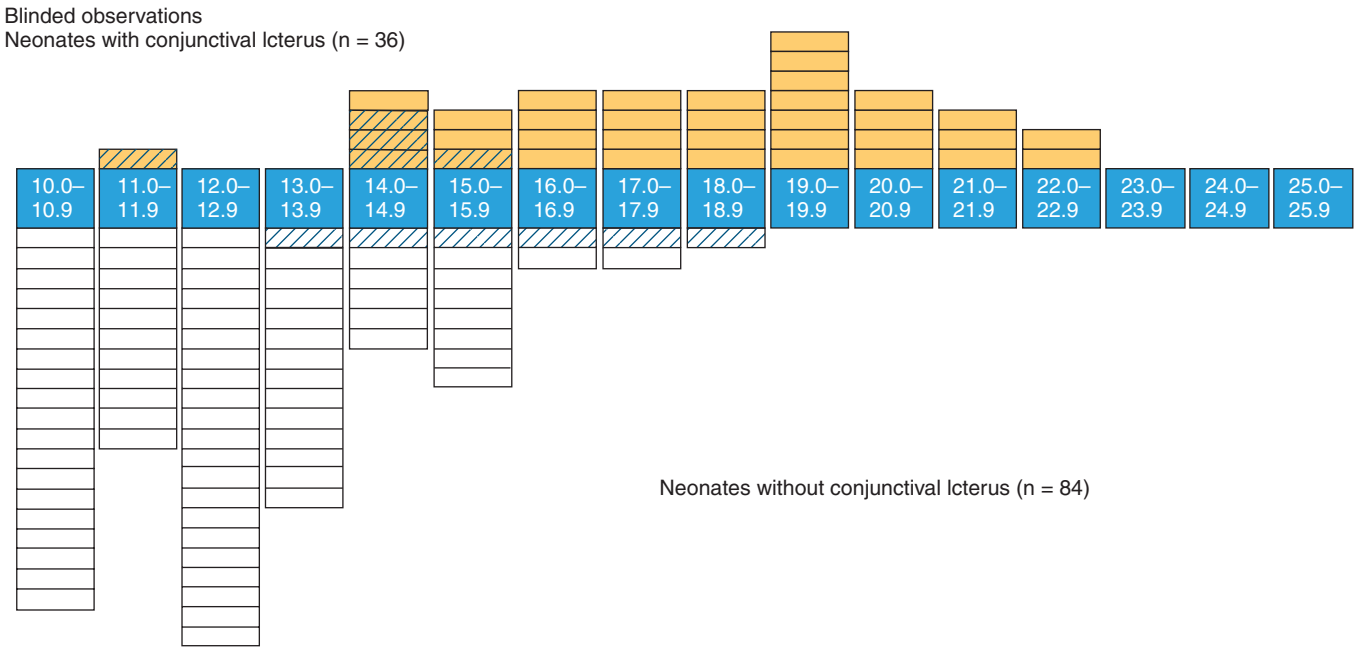
Adapted from Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2022;150(3):e2022058859.

clinical practice guideline on the management of hyperbilirubinemia in the newborn infant ≥35 weeks' gestation (see Clinical Efforts at Kernicterus Prevention later).[43] Published data show that predischarge bilirubin screening is associated with a significant reduction in the incidence of TSB greater than or equal to 25 mg/dL (428 µmol/L)[130–134] possibly by increasing the use of phototherapy.[131,134]

Clinical Evaluation of Jaundice

Jaundice is the visible manifestation in the skin of elevated serum concentrations of bilirubin. Although most adults are jaundiced when TSB levels exceed 2.0 mg/dL (34 µmol/L), neonates characteristically do not appear jaundiced until the TSB exceeds 5.0 to 7.0 mg/dL (86 to 120 µmol/L). Some degree of jaundice develops in approximately 85% of neonates,[92] and chemical hyperbilirubinemia, defined as a TSB greater than or equal to 2.0 mg/dL (34 µmol/L), is virtually universal in newborns during the first week of life. Jaundice in neonates becomes evident first on the face and progresses in a cephalocaudal fashion, with increasing hyperbilirubinemia, as classically characterized by Kramer.[135] The pattern and intensity of jaundice during the birth hospitalization, however, may not be as reliable an indicator of hyperbilirubinemia degree as previously thought.[92,136] Therefore, the AAP cautions that "*visual estimation of bilirubin levels can lead to errors*."[43] A transcutaneous bilirubin (TcB) or TSB is recommended as a complement to the clinical jaundice assessment in *every* neonate during the birth hospitalization to assist in hyperbilirubinemia detection and management.[60]

The absence of jaundice has excellent negative predictive value (99%) for developing a TSB that merits phototherapy[92]; jaundice limited to the face and upper chest likely predicts a TSB of less than 12.0 mg/dL (205 µmol/L).[136] More recent observations suggest that the presence of conjunctival icterus may be a sign of significant hyperbilirubinemia, often associated with elevations in TSB greater than 14.9 mg/dL (255 µmol/L) and greater than 95% on the Bhutani nomogram (Fig. 72.5).[137,138] Others, while confirming a strong correlation with elevated bilirubin levels, noted conjunctival icterus in neonates at lower bilirubin levels.[139] The AAP recommends that parents who detect conjunctival icterus should call their physician, who in turn should evaluate the infant, including a bilirubin measurement.



• **Fig. 72.5** Plot of individual neonates (each block = one subject) as a function of total serum bilirubin (mg/dL) and presence *(top/yellow)* or absence *(bottom/white)* of conjunctival icterus. Blinded observations of two clinicians; concordant examinations in open bars; the 11 discordant examinations are indicated by hatched bars. (Adapted from Azzuqa A, Watchko JF. Bilirubin concentrations in jaundiced neonates with conjunctival icterus. *J Pediatr*. 2015;167:840–844.)

Kernicterus Spectrum Disorders

Kernicterus spectrum disorders (KSDs) define the permanent clinical sequelae of bilirubin toxicity that become evident in the first years of life.[140] These include the extrapyramidal movement disorders (dystonia and/or choreoathetosis), hearing loss caused by auditory neuropathy, and paresis of vertical gaze.[140–142] The CNS sequelae reflect the regional topography of bilirubin-induced neuronal damage distinguished by remarkably selective involvement of the globus pallidus, subthalamic nucleus, hippocampus, red nuclei, the dentate nuclei and Purkinje cells of the cerebellum, and select brainstem nuclei.[143–145] Infants with KSD often demonstrate abnormal bilateral, symmetric, high-signal intensity on T2-weighted magnetic resonance imaging (MRI) of the globus pallidus and subthalamic nucleus, consistent with the neuropathology of kernicterus (Fig. 72.6).[142,146]

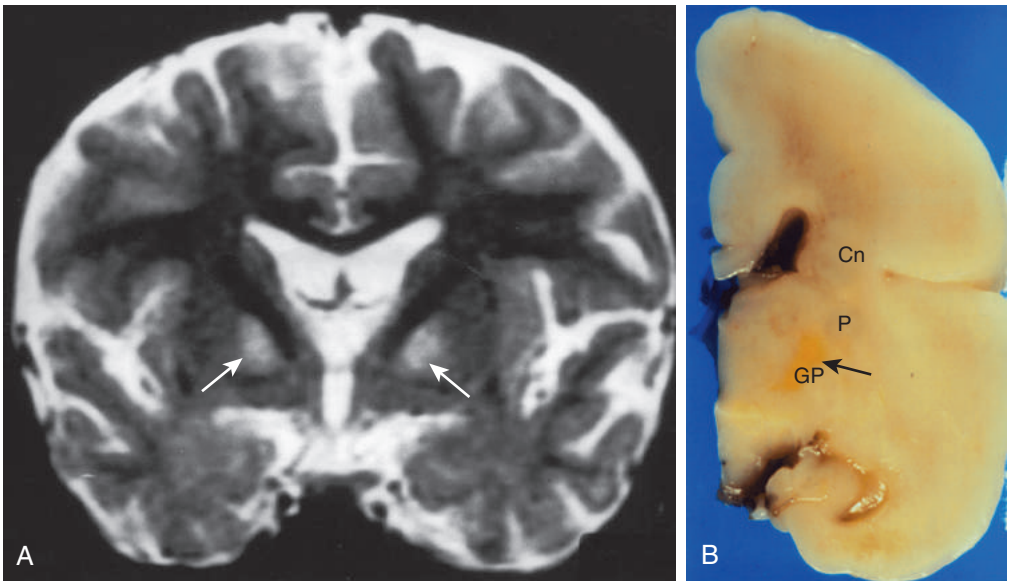
Originally described in the context of severe hyperbilirubinemia secondary to Rh hemolytic disease, kernicterus has also been reported in other hemolytic conditions (e.g., hereditary spherocytosis and pyruvate kinase deficiency), G6PD deficiency, premature neonates, and in otherwise healthy term and late-preterm gestation breastfed infants without evident hemolysis.[22,23,104] Population-based kernicterus incidence estimates for term neonates in developed countries range from approximately 0.4 to 2.7 per 100,000[147]; higher rates have been reported for (1) preterm newborns and (2) infants born in low- and middle income countries where kernicterus is a serious *endemic* problem, e.g., Nigeria, where approximately 3% of neonatal hospital admissions evidence bilirubin encephalopathy.[21,148]

Bilirubin toxicity usually does not become clinically evident until high TSB levels have been established for several hours. Acute bilirubin encephalopathy (ABE) defines an encephalopathic state characterized by a constellation of abnormal clinical signs typically progressive in their severity. In term and late-preterm gestation infants, stupor (lethargy), hypotonia, and poor sucking are seen in the initial phase.[142,149] These signs are nonspecific but in a hyperbilirubinemic infant should raise the possibility of early ABE. Clinical signs of intermediate to advanced stages of ABE are increasingly more specific to bilirubin-induced neurotoxicity and herald a marked increased risk for permanent injury.[142,149] These include hypertonia often manifested by retrocollis and opisthotonos, fever, and high-pitched cry. Inability to feed and apnea may ensue.[23] A bilirubin-induced neurologic dysfunction (BIND) score quantifies this progression and is strongly correlated with the risk of kernicterus.[150,151] Infants less than 34 weeks' gestation less frequently show these abnormal neuromotor signs. Recurrent apnea and desaturations may be the only clinical manifestations of ABE in preterm infants during the neonatal period, if any appear at all.[152,153]

Although a preponderance of the literature suggests that evidence of advanced ABE in an infant portends permanent CNS damage,[151,154,155] more recent reports suggest that at least some such infants, if treated aggressively, may escape unscathed.[156,157] The latter support the AAP recommendation for urgent exchange transfusion in any infant who is jaundiced and manifests the signs of intermediate to advanced stages of ABE (hypertonia, arching, retrocollis, opisthotonos, fever) even if the TSB is falling.[43]

Molecular Pathogenesis

Although no one disputes the neurotoxic potential of bilirubin, the cellular and molecular events that cause bilirubin-induced neurotoxicity only have been partially characterized, and there is little agreement as to which, from a mechanistic standpoint, may be the most clinically relevant. Fig. 72.7 highlights the multiple reported



• **Fig. 72.6** (A) Coronal T2-weighted MRI at the level of the basal ganglia, demonstrating bilateral, symmetric high-intensity globus pallidus (*GP*) signals *(arrows)*. (B) Deep orange-yellow staining of the *GP* of the coronal section at postmortem in another neonate. Note unstained putamen (*P*) and caudate nucleus (*Cn*). These findings illustrate the selective vulnerability and regional topography of kernicterus and concordance of neuroimaging and neuropathology in this disorder. (A from Blackwell Publishing Asia; from Shah Z, Chawla A, Patkar D, et al. MRI in kernicterus. *Austr Radiol*. 2003;47:55–57; B from *Monographs in Clinical Pediatrics*. 2000;11:78. Available at www.tandf.co.uk.)

effects of bilirubin on neurons and glial cells.[1] Bilirubin-induced neuronal cell injury probably reflects the adverse effects of hazardous unbound ("free") unconjugated bilirubin concentrations on plasma and mitochondrial and/or endoplasmic reticulum membranes (Fig. 72.8).[1,149,158,159] These membrane perturbations, in turn, precipitate untoward cellular events that culminate in increased intracellular calcium concentrations ([iCa^{2+}]). Downstream events triggered by increased [iCa^{2+}] may include the activation of proteolytic enzymes, apoptosis, necrosis, as well as abnormalities of cell cycle progression, including cell cycle arrest. Bilirubin-induced excitotoxicity, neuroinflammation, and oxidative stress have all been hypothesized to play important roles in potentiating bilirubin-induced neuronal injury. Innate cellular characteristics of the CNS may predispose or protect against bilirubin-induced neuronal injury.[1] Prematurity, hemolysis, and sepsis play key roles in enhancing bilirubin neurotoxicity risk.[43,151,160,161]

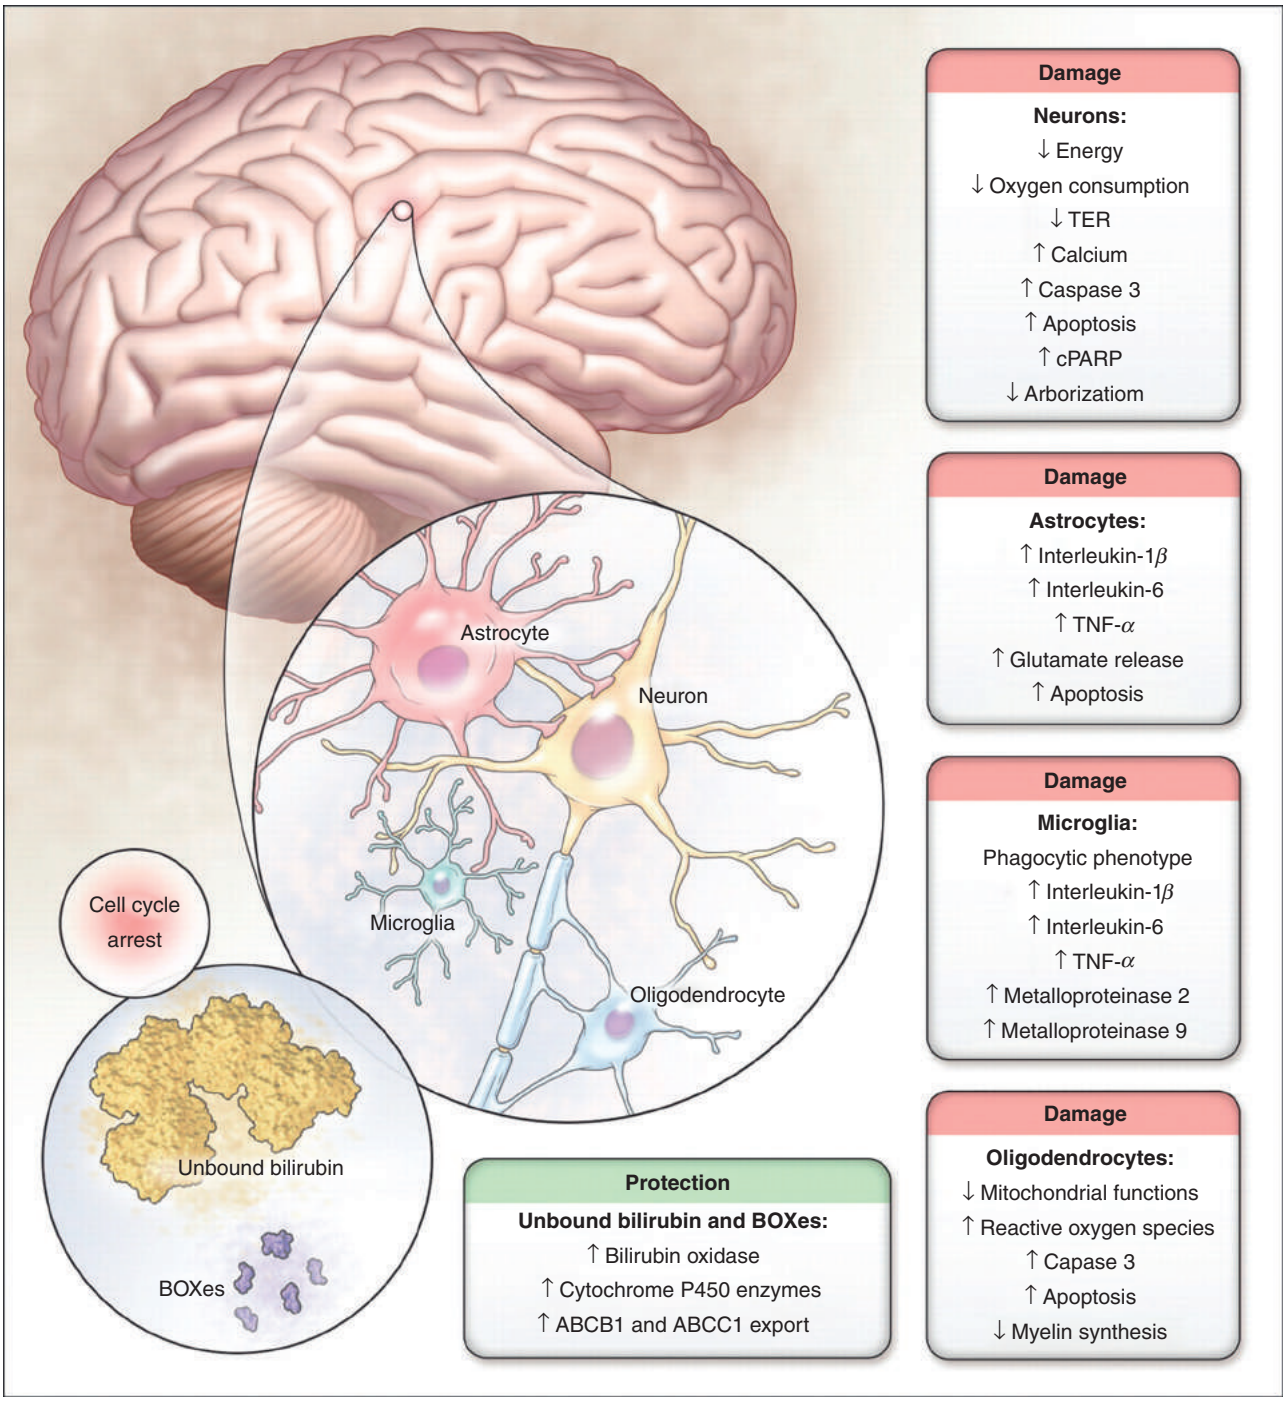
Preterm Neonates and Low-Bilirubin Kernicterus

Preterm newborns are more vulnerable to kernicterus secondary to CNS immaturity and concurrent adverse clinical conditions that may potentiate bilirubin neurotoxicity.[160] There remains some uncertainty, however, on how to quantify that risk and when to intervene with phototherapy or exchange transfusion in preterm neonates.[97,162,163] In this regard, low-bilirubin kernicterus, that is, bilirubin-induced neuronal damage at TSB levels generally thought to be nonhazardous (i.e., those below double volume exchange transfusion thresholds) continue to occur in preterm neonates. The CNS free bilirubin exposure resulting in neurotoxicity in premature infants suggests either (1) an albumin problem, that is, an abnormally low serum albumin and/or impaired albumin-bilirubin binding that results in a hazardous unbound unconjugated bilirubin concentration, and/or (2) a vulnerable neuronal pool resulting from cellular immaturity coupled with antecedent or concurrent insults that potentiate bilirubin neurotoxicity.[160,164–166] Hypoalbuminemia is common in preterm neonates[166] Conditions that predispose to a vulnerable neuronal pool are infection/inflammation, including chorioamnionitis and necrotizing enterocolitis, and comorbid CNS injuries including hypoxic–ischemic encephalopathy, intraventricular hemorrhage, and periventricular leukomalacia.[160,164,165] Oftentimes both an albumin problem and a vulnerable neuronal pool are evident in a given neonate with low bilirubin kernicterus, suggesting this injury is a two-hit (or multi-hit) phenomenon.[160,165]

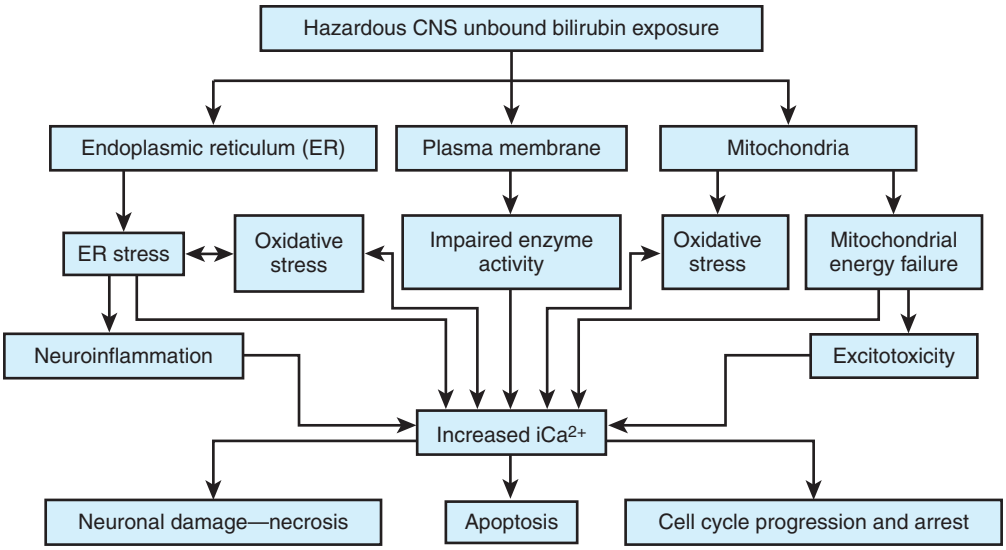
Important causes of hypoalbuminemia include leakage of albumin into the extravascular, extracellular interstitial space (reported in association with several conditions in sick preterm newborns), and significant albumin loss secondary to fetal perinatal hemorrhage. Marked neonatal hypoalbuminemia can be seen in (1) fetal–maternal transfusion, (2) the donor twin in twin–twin transfusion syndrome (TTTS) and the twin anemia–polycythemia sequence (TAPS), and (3) neonatal anemia associated with malformations of the placenta and cord.[160] Whenever anemia is present in the immediate neonatal period, measurement of the serum albumin concentration and bilirubin/albumin ratio are prudent.

Clinical Efforts at Kernicterus Prevention

The key elements to preventing kernicterus in term and late-preterm neonates are (1) hyperbilirubinemia risk assessment, (2) appropriate and timely birth hospitalization follow-up, and (3) timely and effective treatment of marked hyperbilirubinemia with phototherapy and/or exchange transfusion. Support of successful breastfeeding is also an important part of hyperbilirubinemia control.



• **Fig. 72.7** Cell Types and Metabolic Processes Affected by Bilirubin in the Central Nervous System. The main effects of bilirubin on neurons are decreased oxygen consumption and increased release of calcium and caspase 3, resulting in apoptosis. There is also decreased dendritic and axonal arborization. A similar pattern is observed in oligodendrocytes with increased apoptosis, impairment of the redox state (oxidative stress), and reduced synthesis of myelin. Microglia react to toxic injury associated with bilirubin by increased release of proinflammatory cytokines and metalloproteinase activity as cells manifest a phagocytic phenotype. A similar proinflammatory pattern is observed in astrocytes, with enhanced release of glutamate and apoptosis. At the same time, cells may reduce the intracellular concentration of bilirubin either by extruding the pigment through the ABC transporters and/or by increasing the formation of the less toxic products through bilirubin oxidation products (BOXes) and/or cytochrome P450 enzymes (1a1 and 1a2 in particular). These responses are protective, whereas all others result in cell damage; this suggests that once the intracellular concentration of bilirubin exceeds a toxic threshold (still to be defined) the polymorphic metabolic cascade leading to neurotoxicity ensues. *ABCB1*, ATP-binding cassette B1 transporter; *ABCC1*, ATP-binding cassette C1 transporter; *cPARP*, cleaved poly(adenosine diphosphate-ribose) polymerase; *TNF-α*, tumor necrosis factor α; *TER*, transcellular resistance. (From Watchko JF, Tiribelli C. Bilirubin-induced neurologic damage—mechanism and management approaches. *N Engl J Med*. 2013;369:2025.)



• **Fig. 72.8** Schematic of Several Hypothesized Pathophysiologic Mechanism(s) in Bilirubin-Induced Neuronal Injury. Hazardous unbound bilirubin exposure in the central nervous system *(CNS)* exerts direct effects at level of the plasma membrane, mitochondria, and/or endoplasmic reticulum *(ER)*, leading to ER stress, oxidative stress, impaired enzyme activity, and mitochondrial energy failure, culminating in neuroinflammation, excitotoxicity, and increased intracellular calcium levels *(iCa^{2+})*. If CNS free bilirubin exposure is of sufficient degree and/or duration than irreversible neuronal damage, i.e., necrosis, and/or cell cycle arrest may ensue.

A TSB or TcB measured 18 to 36 hours after birth interpreted according to the infant's age in hours significantly improves the prediction of subsequent severe hyperbilirubinemia[86,87,147,167] and is associated with a marked reduction in the incidence of extreme hyperbilirubinemia.[130–134] As outlined in Fig. 72.9,[43] the current AAP guideline recommends using the difference between the bilirubin concentration and the phototherapy threshold at the time of measurement to determine the interval between hospital discharge and follow-up and the need for additional TSB or TcB measurement. This approach incorporates both gestational age at birth and other hyperbilirubinemia neurotoxicity risk factors (see Box 72.4), which allows for formulation of a plan for birth hospitalization management and timely post-birth hospitalization follow-up (see Fig. 72.9).[43]

Clinicians are key to improving parental health literacy on neonatal jaundice, ensuring appropriate, timely follow-up and in navigating obstacles to parental care seeking when neonatal jaundice is present.[25,168–170] An example of specific written counselling and follow-up planning for parents during the birth hospitalization prior to discharge is shown in Fig. 72.10.[25]

Treatment Considerations

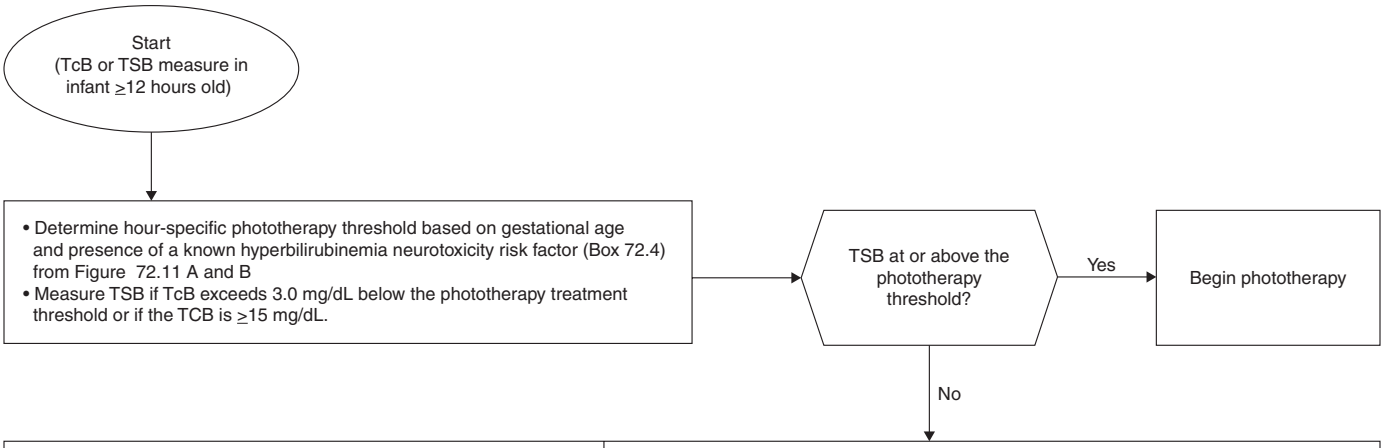
Phototherapy and exchange transfusion are the mainstays of intervention for neonatal hyperbilirubinemia. Current (2022) AAP phototherapy and exchange transfusion treatment thresholds for infants greater than or equal to 35 weeks' gestation are shown in Fig. 72.11 and 72.12, respectively.[43] These guidelines provide clinicians with TSB thresholds for both interventions in hyperbilirubinemic infants based on their gestational age (in weeks), chronologic age (in hours), and the presence or absence of hyperbilirubinemia neurotoxicity risk factors aside from gestational age. Notably, thresholds for phototherapy and exchange transfusion are incrementally higher in the 2022 AAP guideline based on evidence that neurotoxicity does not occur until bilirubin levels are well above the prior 2004 AAP guideline exchange transfusion thresholds.[43]

Tables 72.3 to 72.6[97,171] illustrate a range of TSB levels for intervention in varying circumstances for preterm neonates. Phototherapy is generally quite effective and capable of controlling the bilirubin levels in almost all infants, with the exception of the occasional infant with severe hemolysis. Indeed, a rising TSB on phototherapy should raise the concern that the neonate has significant hemolysis. The 2022 AAP Guidelines also provide direction for an escalation of care (Fig. 72.13), including preparations for exchange that should be made if the TSB is rising close to the exchange threshold.[43]

Phototherapy

The most effective phototherapy units deliver output in the blue to blue-green region of the visible spectrum, including the commercially available special blue fluorescent tubes and increasingly blue light-emitting diode (LED) units.[172–174] Phototherapy effectiveness is further enhanced by increasing the irradiance (the radiant flux [optical power] received by a surface per unit area) and the surface area exposed.[172,173] Irradiance increases dramatically as the distance between the light source and infant decreases. The efficacy of phototherapy is also closely related to the surface area of the infant exposed to the phototherapy lights. Previous clinical studies comparing intermittent versus continuous phototherapy have produced conflicting results, but in many circumstances, phototherapy does not need to be continuous.[172] As long as the serum bilirubin level is being controlled, phototherapy can be interrupted during feeding or short parental visits.[172]

Recent studies show that phototherapy converts bilirubin to more polar photoisomers quite rapidly, and it accounts for about 10% of TSB by 15 minutes of treatment, increasing to 20% to 25% of TSB by 2 hours of exposure.[175,176] In theory, these polar



Phototherapy threshold minus TcB or TSB		Discharge Recommendations
0.1-1.9 mg/dL	Age <24 hours	Delay discharge. Consider phototherapy, measure TSB in 4 to 8 hours
	Age ≥24 hours	Measure TSB in 4 to 24 hours[a] Options: • Delay discharge and consider phototherapy • Discharge with home phototherapy if all considerations in the guideline are met • Discharge without phototherapy but with close follow-up
2.0-3.4 mg/dL	Regardless of age or discharge time	TSB or TcB in 4 to 24 hours[a]
3.5-5.4 mg/dL	Regardless of age or discharge time	TSB or TcB in 1-2 days
5.5-6.9 mg/dL	Discharging <72 hours	Follow-up within 2 days; TcB or TSB according to clinical judgment[b]
	Discharging ≥72 hours	Clinical judgment[b]
≥7.0 mg/dL	Discharging <72 hours	Follow-up within 3 days; TcB or TSB according to clinical judgment[b]
	Discharging ≥72 hours	Clinical judgment[b]

• **Fig. 72.9** Flow diagram for infants during the birth hospitalization to determine postdischarge follow-up for infants who have not received phototherapy. [a]Use clinical judgment and shared decision making to determine when to repeat the bilirubin measure within this 4- to 24-hour time window. [b]Clinical judgment decisions should include physical examination, the presence of risk factors for the development of hyperbilirubinemia (see Box 72.3) or hyperbilirubinemia neurotoxicity risk factors (see Box 72.4), feeding adequacy, weight trajectory, and family support. (Adapted from Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2022;150[3]:e2022058859.)

stereoisomers should be less able to cross the blood-brain barrier and enter the CNS, reducing the risk for neurotoxicity.[175,176] Preliminary in vitro evidence also suggests that compared with unconjugated bilirubin, bilirubin photoisomers have no direct adverse effect on neuronal cell viability.[177]

Complications of phototherapy are exceptionally rare. Reported associations of neonatal phototherapy with an increased risk of subsequent seizures[178] and childhood cancers[179] have garnered attention. However, the absolute risk of seizures is small and limited to males,[178] and on balance not felt to be a contraindication to treatment when the TSB is at or above the phototherapy threshold.[43] The risk of childhood cancers is also small and tempered by data, suggesting that additional factors such as congenital and chromosomal anomalies, prematurity, or hyperbilirubinemia itself may contribute.[180–182] A more recent study from a large cohort of 139,100 children did not confirm associations between phototherapy and adjusted risk for any cancer, nonlymphocytic leukemia, or brain and/or central nervous system tumors in later childhood.[183] Another large study on early aggressive versus conservative phototherapy for infants with extremely low birth weight raised concerns that aggressive phototherapy may increase mortality while reducing neurological impairment in the birthweights of the 501 to 750 g subgroup.[184,185] Alternative approaches to bilirubin management, including cycling of phototherapy, are being tested in this vulnerable group of infants.[185,186] Collectively, these studies suggest that phototherapy should be used judiciously as set forth in established guidelines.[43,60,97]

The most overt complication of phototherapy is the dark, greyish-brown discoloration of the skin, serum, and urine (the "bronze baby syndrome") observed when treating neonates with direct hyperbilirubinemia or cholestatic jaundice.[187,188] The pathogenesis of this syndrome is unknown but is not related to copper porphyrins as previously hypothesized.[189] Although few deleterious consequences of the bronze baby syndrome have been described, there are case reports of infants with this syndrome who developed kernicterus.[190,191] Impaired binding of bilirubin to albumin has been detected in three infants with this syndrome[192,193] and in infants with cholestasis.[193] If there is a need for phototherapy, the presence of direct hyperbilirubinemia is not a contraindication to its use.[43,191] Treatment decisions

Parent Handout on Newborn Jaundice

Things you should know about neonatal jaundice:

- Jaundice is the yellowing of the skin and sometimes the whites of the eyes
- Severe, uncontrolled jaundice can cause permanent brain damage
- Severe jaundice can be prevented by early treatment with phototherapy

Important things you can do:

- Treat jaundice seriously
- Examine your baby for jaundice twice a day
- Call your provider if you observe jaundice anytime
- Seek care if the whites of the eyes become yellow
- Seek emergency help if jaundice extends to hands and feet or your baby becomes very fussy, sleepy, stops feeding, cries without being comforted, or stiffens when held
- Seek immediate care if jaundice recurs at home following hospital phototherapy

Avoid the following as they can produce severe jaundice in some babies:

- If breast feeding, mothers should not eat fava beans (broad beans)
- Do not use baby clothes, blankets, or bedding stored in moth balls (naphthalene)
- Avoid sulfa-containing antibiotics (e.g. Bactrim), henna, and herbal remedies (both for breastfeeding mothers and baby)

Review the result of your baby's bilirubin test (below) with your baby's provider, and ask whether a repeat test is necessary before leaving the hospital or in outpatient follow-up.

Pre-discharge bilirubin level:_____ mg/dL at_____ hours of life

Is a repeat bilirubin test necessary following discharge?	**Yes**	**No**
Late-preterm gestation ($34^{0/7}$-$36^{6/7}$ weeks)?	**Yes**	**No**
Positive direct antiglobulin test (DAT)?	**Yes**	**No**

Follow-up appointment: Dr. _____ on (date): _____; (time): _____
Office location:_____ Contact phone: _____

Take this report with you to your appointment with the baby's follow-up provider.

• **Fig. 72.10** An example of parental handout on neonatal jaundice to be reviewed with parents by hospital staff prior to birth hospital discharge. A copy should be given to the parents as it includes the birth hospital bilirubin screening result(s) and written details on the scheduled follow-up appointment with the baby's provider. Parents should be instructed to take this report with them to their appointment with the baby's follow-up provider. (From Okolie F, South-Paul JE, Watchko JF. Combatting the hidden health disparity of kernicterus in Black infants. A review. *JAMA Pediatr*. 2020;174(12):1199–1205.)

should be based on the TSB in cholestatic neonates when the direct fraction is < 50% of the total.[43,191] In the far less frequent circumstance where the direct bilirubin level is >50% of the total, consultation with an expert in the bilirubin field is recommended regarding treatment.[43,191] Rarely, purpuric bullous eruptions have also been described in infants with severe cholestatic jaundice who are receiving phototherapy.

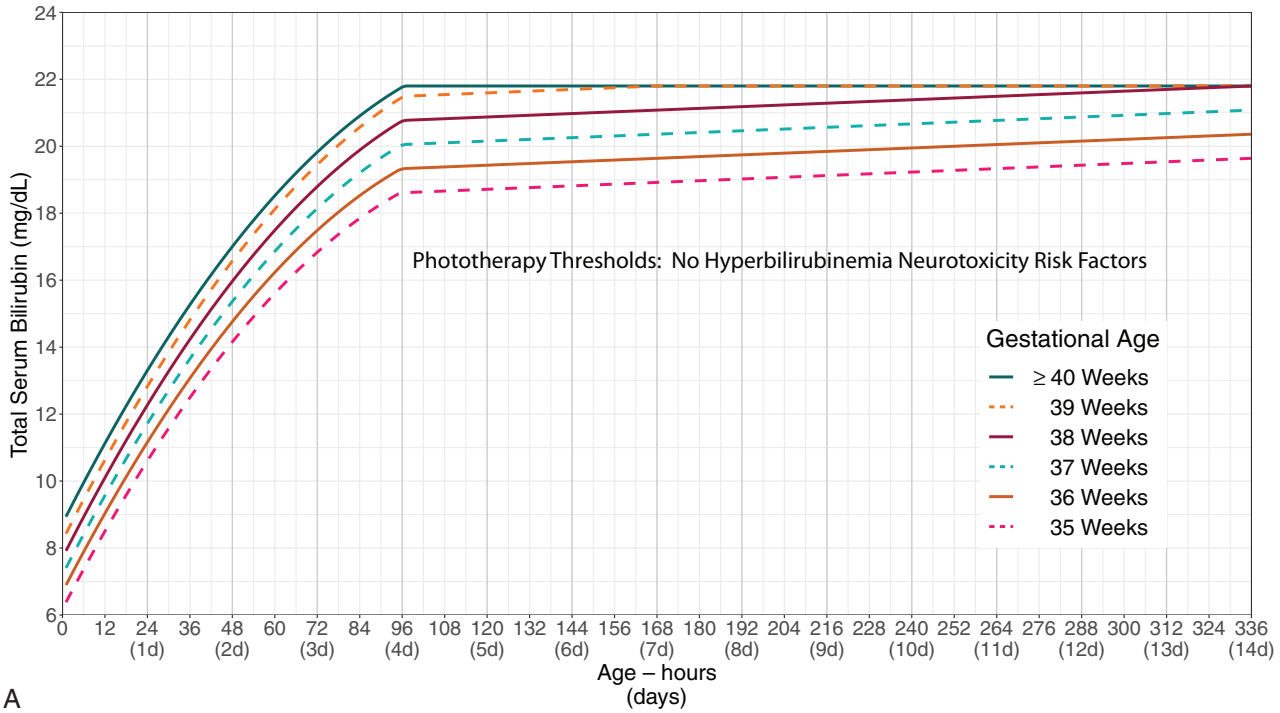
Intravenous Immunoglobulin

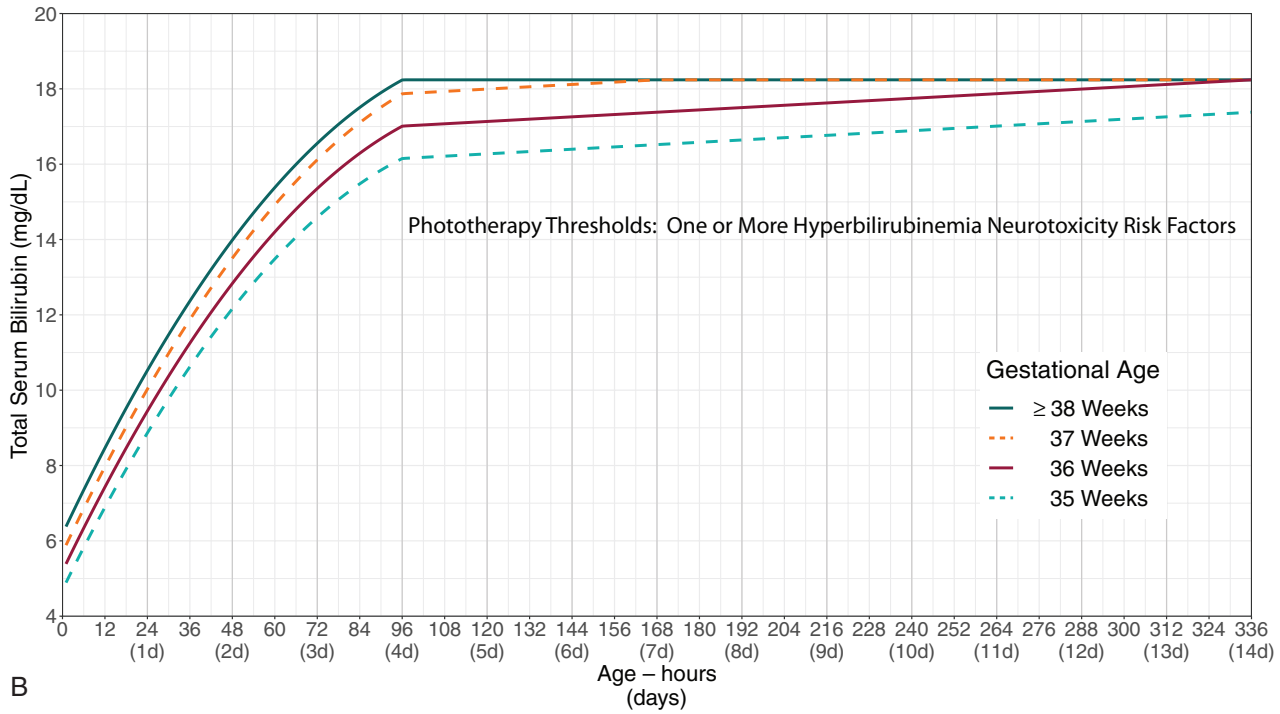
Intravenous immunoglobulin (IVIG) inhibits hemolysis in immune-mediated hemolytic disease possibly by blocking Fc receptors.[194] Although earlier studies and a systematic review suggested that IVIG administration to direct Coombs positive infants with alloimmune hemolytic disease reduces the need for exchange transfusion,[194–196] more recent investigations using early prophylactic IVIG do not support this benefit.[197–199] Routine IVIG administration in alloimmune hemolytic disease is not recommended; however, its targeted use in direct Coombs positive neonates in whom the TSB is rising—despite intensive phototherapy or the TSB level—that is within 2 to 3 mg/dL (34 to 51 μmol/L) of the exchange level remains prudent.[43]

Exchange Transfusion

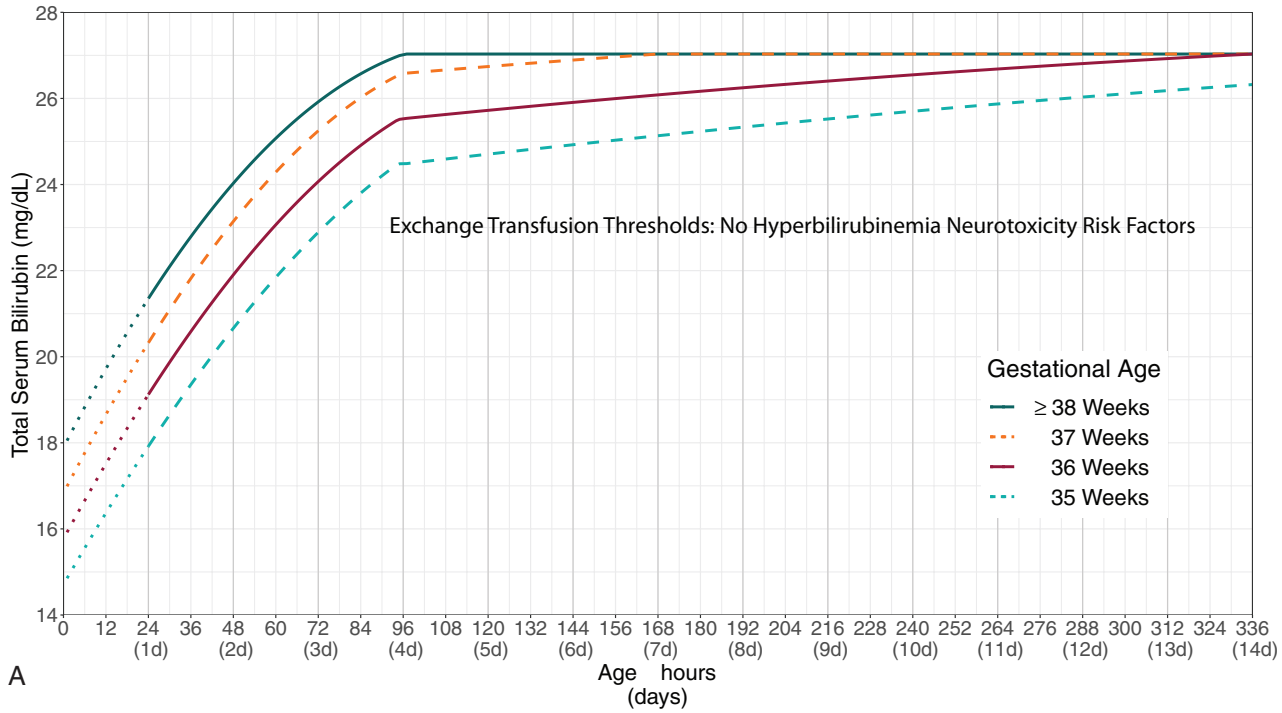
In addition to the TSB exchange transfusion thresholds outlined in Fig. 72.12, an exchange transfusion may be considered when the bilirubin-to-albumin ratio measured as TSB (in mg/dL) divided by serum albumin (in g/dL) exceeds the treatment thresholds outlined in Table 72.7.[43,171]

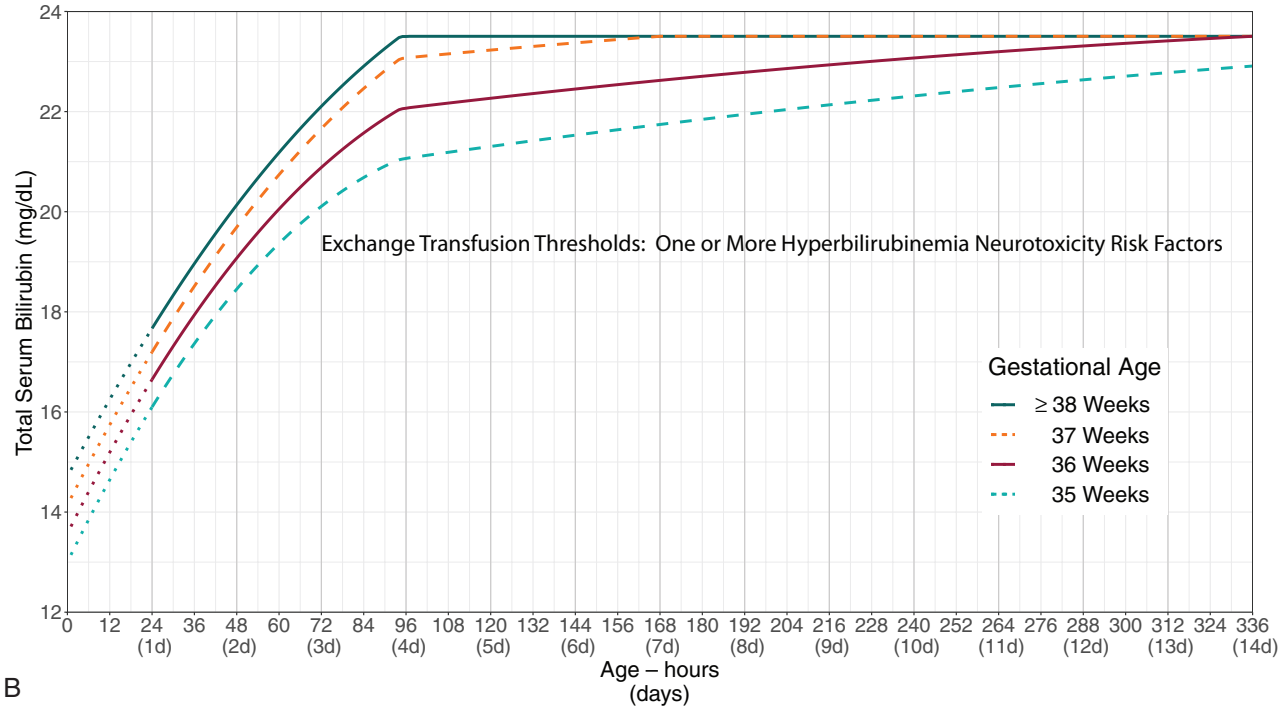
Historically, exchange transfusion was the first intervention to permit effective control of severe hyperbilirubinemia and prevent kernicterus. In addition to managing hyperbilirubinemia, an exchange transfusion in immune-mediated hemolytic disease also (1) removes antibody-coated red blood cells (a source of "potential" bilirubin), (2) corrects anemia (if present), and (3) removes maternal antibody. A "double volume" exchange refers to an exchange of twice the neonate's blood volume, or approximately 170 to 200 mL/kg, removing approximately 110% of circulating bilirubin (extravascular bilirubin





• **Fig. 72.11** Phototherapy thresholds by gestational age and age in hours for infants with no (A) and with any (B) recognized hyperbilirubinemia neurotoxicity risk factors other than gestational age. These thresholds are based on expert opinion rather than strong evidence on when the potential benefits of phototherapy exceed its potential harms. Use total serum bilirubin concentrations; do not subtract direct-reacting or conjugated bilirubin from the total serum bilirubin. In rare cases of severe hyperbilirubinemia in which the direct-reacting or conjugated bilirubin exceeds 50% of the total serum bilirubin (TSB), consult an expert. Note that infants less than 24 hours old with a TSB at or above the phototherapy threshold are likely to have a hemolytic process and should be evaluated for hemolytic disease. Hyperbilirubinemia neurotoxicity risk factors include gestational age less than 38 weeks; albumin less than 3.0 g/dL; isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency, or other hemolytic conditions; sepsis; or any significant clinical instability in the previous 24 hours. (Adapted from Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2022;150:e2022058859.)





• **Fig. 72.12** Exchange transfusion thresholds by gestational age for infants with no (A) and with any (B) recognized hyperbilirubinemia neurotoxicity risk factors (other than gestational age). See Fig. 72.13, which describes escalation of care, including initiation of exchange transfusion. These thresholds are based on expert opinion rather than strong evidence on when the potential benefits of escalation of care exceed its potential harms. The stippled lines for the first 24 hours indicate uncertainty because of the wide range of clinical circumstances and responses to intensive phototherapy. Use total serum bilirubin concentrations; do not subtract direct bilirubin from the total serum bilirubin. In rare cases of severe hyperbilirubinemia in which the direct-reacting or conjugated bilirubin exceeds 50% of the TSB, consult an expert. Hyperbilirubinemia neurotoxicity risk factors include albumin <3.0 g/dL; isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency, or other hemolytic conditions; sepsis; or any significant clinical instability in the previous 24 hours. (Adapted from Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2022;150[3]:e2022058859.)

TABLE 72.3 Guidelines for the Use of Phototherapy and Exchange Transfusion in Low Birth Weight Infants Based on Birthweight[a]

	Total Bilirubin Level (mg/dL [μmol/L][b])	
Birthweight (g)	Phototherapy[c]	Exchange Transfusion[d]
≤1500	5–8 (85–140)	13–16 (220–275)
1500–1999	8–12 (140–200)	16–18 (275–300)
2000–2499	11–14 (190–240)	18–20 (300–340)

[a]Note that these guidelines reflect ranges used in neonatal intensive care units. Lower bilirubin levels should be used for infants who are sick (e.g., presence of sepsis, acidosis, hypoalbuminemia) or have hemolytic disease.
[b]Consider initiating therapy at these levels. Range allows discretion based on clinical conditions or other circumstances. Note that bilirubin levels refer to total serum bilirubin concentrations. Direct reacting or conjugated bilirubin levels should not be subtracted from the total.
[c]Used at these levels and in therapeutic doses, phototherapy should, with few exceptions, eliminate the need for exchange transfusions.
[d]Levels for exchange transfusion assume that bilirubin continues to rise or remains at these levels despite intensive phototherapy.
From Maisels MJ. Jaundice. In: Avery GB, Fletcher MA, MacDonald MG (eds), *Neonatology: Pathophysiology and Management of the Newborn*. Philadelphia: Lippincott; 1999: 765–819.

enters the blood during the exchange); however, the procedure removes only 25% of total body bilirubin as the majority of the infant's bilirubin is in the extravascular compartment.[200] Post-exchange bilirubin levels are approximately 60% that of pre-exchange levels, but the rapid (~30 minutes) reequilibration of bilirubin between the vascular and extravascular compartments produces a rebound of serum bilirubin levels to 70% to 80% pre-exchange levels.[200,201]

Exchange transfusions are most readily performed via the umbilical vein using a 5- or 8-French umbilical catheter inserted just far enough to obtain free flow of blood (usually no more than the distance between the xiphoid process and umbilicus). The "push-pull" method with a single syringe and special *four-way stopcock* assembly permits a single operator to complete the procedure (Fig. 72.14).[202] Given that the efficacy of a double volume exchange is a direct function of the mass of albumin exchanged,[200,203] the ideal replacement fluid should have both a high plasma volume and a high albumin concentration to optimize the amount of bilirubin-free albumin introduced into the infant's circulation.[200,203,204] Accordingly, reconstituted whole blood, that is, packed red blood cells mixed with fresh frozen plasma to a hematocrit approximating 40%, is preferred.[200,203,204] The adult fresh frozen plasma ensures a high albumin concentration and the hematocrit a high plasma volume. Reconstituted whole blood

Gestational Age (Weeks)	**Initiate Phototherapy Total Serum Bilirubin (mg/dL)**	**Total Serum Bilirubin (mg/dL)**
$<28^{0/7}$	5–6	11–14
$28^{0/7}$–$29^{6/7}$	6–8	12–14
$30^{0/7}$–$31^{6/7}$	8–10	13–16
$32^{0/7}$–$33^{6/7}$	10–12	15–18
$34^{0/7}$–$34^{6/7}$	12–14	17–19

This table reflects the authors' recommendations for operational or therapeutic total serum albumin (TSB) thresholds—bilirubin levels at, or above which, treatment is likely to do more good than harm. These TSB levels are not based on good evidence and are lower than those suggested in recent UK and Norwegian guidelines.

The wider ranges and overlapping of values in the exchange transfusion column reflect the degree of uncertainty in making these recommendations.

Use the lower range of the listed TSB levels for infants at greater risk for bilirubin toxicity: e.g., (1) lower gestational age; (2) serum albumin levels less than 2.5 g/dL; (3) rapidly rising TSB levels, suggesting hemolytic disease; and (4) those who are clinically unstable. When a decision is being made about the initiation of phototherapy or exchange transfusion, infants are considered to be clinically unstable if they have one or more of the following conditions: (1) blood pH less than 7.15; (2) blood culture positive sepsis in the previous 24 hours; (3) apnea and bradycardia requiring cardiorespiratory resuscitation (bagging and or intubation) during the previous 24 hours; (4) hypotension requiring pressor treatment during the previous 24 hours; and (5) mechanical ventilation at the time of blood sampling.

Recommendations for exchange transfusion apply to infants who are receiving intensive phototherapy to the maximal surface area, but whose TSB levels continue to increase to the levels listed.

For all infants, an exchange transfusion is recommended if the infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, or/and high-pitched cry), although it is recognized that these signs rarely occur in very low birth weight infants.

Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin from the total.

For infants less than or equal to 26 weeks' gestation, it is an option to use phototherapy prophylactically starting soon after birth. Use postmenstrual age for phototherapy: e.g., when a $29^{0/7}$ week neonate is 7 days old, use the TSB level for $30^{0/7}$ weeks.

Discontinue phototherapy when TSB is 1–2 mg/dL below the initiation level for the infant's postmenstrual age.

Discontinue TSB measurements when TSB is declining and phototherapy is no longer required.

Measure the serum albumin level in all infants.

Measure irradiance at regular intervals with an appropriate spectroradiometer.

The increased mortality observed in infants who weigh less than or equal to 1000 g and are receiving phototherapy suggests that it might be prudent to use less intensive levels of irradiance in these infants. In such infants, phototherapy is almost always prophylactic—it is used to prevent a further increase in the TSB, and intensive phototherapy with high irradiance levels usually is not needed. In infants who weigh less than or equal to 1000 g it is reasonable to start phototherapy at lower irradiance levels. If the TSB continues to rise, additional phototherapy should be provided by increasing the surface area exposed (phototherapy above and below the infant, reflecting material around the incubator). If the TSB, nevertheless, continues to rise, the irradiance should be increased by switching to a higher-intensity setting on the device or by bringing the overhead light closer to the infant. Fluorescent and light-emitting diode light sources can be brought closer to the infant, but this cannot be done with halogen or tungsten lamps because of the danger of a burn.

On the other hand, in the first National Institute of Child Health and Human Development (NICHD) trial, irradiance levels were quite low, yet there was a 19% increase in mortality in infants who weighed less than 1000 g who received phototherapy ($P = .112$). One alternative to using lower irradiance is to decrease the length of exposure by using intensive phototherapy for a short period. Another option is to consider intermittent (cyclical) phototherapy. In one recent preliminary study, infants who weighed less than 1000 g who received phototherapy for 15 minutes in the hour had mean peak bilirubin levels (6.5 ± 1.6 mg/dL) that were virtually identical to those receiving continuous phototherapy (6.3 ± 1.3 mg/dL).

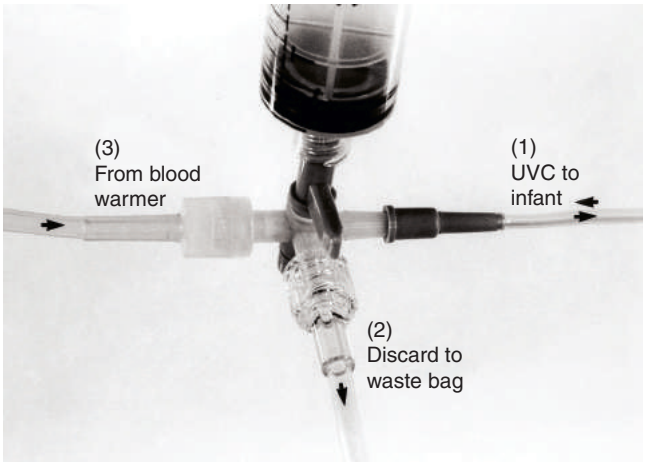
• **Fig. 72.13** Approach to escalation of care when an infant's bilirubin level is approaching 2 mg/dL below the exchange transfusion threshold. *B/A*, Bilirubin to albumin ratio; *IVIG*, intravenous immunoglobulin. (Adapted from Kemper AR, Newman TB, Slaughter JL, et al. Clinical practice guideline revision: management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2022;150:e2022058859.)

TABLE 72.7 Bilirubin to Albumin Ratio Thresholds at Which to Consider Exchange Transfusion

Risk Category	B/A RATIO AT WHICH EXCHANGE TRANSFUSION MAY BE CONSIDERED	
	TSB (mg/dL)/ Alb (g/dL)	TSB (μmol/L)/ Alb (μmol/L)
Infants ≥$38^{0/7}$ week	8.0	0.94
Infants $35^{0/7}$–$37^{6/7}$ week and well or ≥$38^{0/7}$ week if at least one hyperbilirubinemia neurotoxicity risk factor present	7.2	0.84
Infants $35^{0/7}$–$37^{6/7}$ week if at least one hyperbilirubinemia neurotoxicity risk factor present	6.8	0.80



• **Fig. 72.14** Special Four-Way Stopcock Assembly. (1) Male adapter to umbilical venous line (*UVC*); (2) female adapter to waste bag; and (3) attachment to blood bag and warmer. The stopcock handle points to the port that is open to the syringe, and the stopcock handle is rotated in a clockwise fashion when correctly assembled (e.g., first, withdraw aliquot from infant; second, discard to waste container; third, draw fresh blood from bag; and fourth, infuse into infant to complete one cycle). (From Watchko JF. Exchange transfusion in the management of neonatal hyperbilirubinemia. In: Maisels MJ, Watchko JF, eds. *Neonatal Jaundice*. Amsterdam: Harwood Academic; 2000:169–176.)

should be less than 72 hours old and devoid of the offending antigen in the case of immune-mediated hemolytic disease.

The risk for graft-versus-host disease following an exchange transfusion is extremely rare; however, blood for exchange transfusion should be irradiated. The blood should be warmed to body temperature by a blood/fluid warmer. The actual exchange should be performed slowly in aliquots of 5 to 10 mL/kg body weight with each withdrawal-infusion cycle approximating a 3-minute duration.[205] Using this approach, a double volume exchange should take approximately 1.5 ± 0.5 hours and avoids deleterious hemodynamic changes.[205]

During the exchange transfusion, the infant's vital signs should be monitored closely, including electrocardiogram, respiration, oxygen saturation, temperature, and blood pressure. Supplemental calcium gluconate administration during the exchange transfusion has little effect on serum ionized calcium,[206–208] and too rapid infusion of calcium may cause bradyarrhythmias or cardiac arrest. If symptomatic hypocalcemia develops, temporary cessation of the procedure will allow recovery toward normal calcium levels as the citrate (which binds calcium) is metabolized by the liver. Postexchange studies should include bilirubin, hemoglobin, platelet count, ionized calcium, serum electrolytes, and serum glucose.

The unintended consequences of exchange transfusion include cardiovascular, hematologic, gastrointestinal, biochemical, and infectious hazards, among others.[202] Reported overall mortality rates approximate 0.5 to 1 per 100 exchange trasnfusions.[209,210] These rates may be higher in ill infants[211,212] and in those born prematurely,[212] but lower in healthy term neonates.[211] In one series of 81 hyperbilirubinemic but otherwise healthy term neonates, there were no procedure-related deaths.[211] Most reported that adverse events associated with exchange transfusion are treatable laboratory abnormalities.[212,213] Nevertheless, because significant morbidity (apnea, cyanosis, vasospasm, thrombosis) can occur, an exchange transfusion should be performed by experienced individuals in a neonatal intensive care unit with continuous monitoring prepared to respond to potential adverse events. Finally, the risks per tested packed red blood cell unit for known transfusion-transmitted viruses in the United States are 1:1,467,000 for the human immunodeficiency virus (HIV); 1:1,149,000 for the hepatitis C virus, and 1:282,000 for the hepatitis B virus.[214]

73 Congenital Malignant Disorders

TIFFANY L. LUCAS, BENJAMIN HUANG, AND ELIZABETH ROBBINS

KEY POINTS

- The spectrum of malignancies in neonates differs from that in children.
- Malignancies in neonates are often associated with a genetic predisposition.
- Neuroblastoma and leukemia are the most common malignancies in neonates.
- Cancer treatment in neonates poses unique challenges, including the likelihood of significant late effects.
- Congenital solid tumors are often diagnosed in utero by ultrasonography.

Neonatal malignancies differ in incidence, clinical behavior, and heritable features from cancers seen in older children. While acute leukemia is the most common malignancy in young children, most neonatal tumors are solid tumors, many of which are detected prenatally during routine ultrasonography. Some childhood malignancies that carry excellent prognoses, such as acute lymphoblastic leukemia (ALL), are often fatal in neonates. In contrast, neuroblastoma, which responds poorly to treatment in older children, can spontaneously regress in newborns.

Treatment of cancer in the neonatal period presents special challenges. Among these are differences in drug metabolism in newborns, the sensitivity of rapidly growing normal tissues to chemotherapeutic agents and radiation, and the increased possibility of late effects, including neurocognitive sequelae, impaired reproductive capacity, growth disturbances, and secondary malignancies. The epidemiology, etiology, and diagnosis of neonatal malignancy are reviewed here, followed by a discussion of commonly encountered malignancies.

Epidemiology, Etiology, and Diagnosis of Neonatal Malignancy

Epidemiology: Incidence and Mortality

Neonatal tumors are rare, with an incidence of 1 per 27,500 live births in the United States; they compose 2% of childhood malignancies.[1] Although trend analyses suggest that the incidence of malignancy in the pediatric population may be increasing,[2] a number of factors affect incidence rates, including improvements in molecular methods of diagnosis, changes in population characteristics, screening fetal ultrasonography practices, and case ascertainment by cancer registries.[3]

The most common malignancy in infants is neuroblastoma, followed by leukemia, central nervous system (CNS) tumors, retinoblastoma, and germ cell tumors.[2] Female and male infants have similar cancer incidence rates. The distribution of the major types of cancers in newborns, infants, and children is depicted in Table 73.1. Incidence rates for the most common types of malignancy in infants are shown in Table 73.2.

The mortality rates for infants with cancer exceed those for older children, even among identical diseases.[4] Despite cure rates exceeding 85% for children older than 1 year with a diagnosis of ALL, newborns with ALL have cure rates of less than 50%.[5] Poorer survival patterns for infants are also seen with rhabdomyosarcoma (RMS) and CNS tumors, including primitive neuroectodermal tumor (PNET), atypical teratoid/rhabdoid tumor (ATRT), and ependymoma. Two notable exceptions are neuroblastoma, for which the 5-year survival rate in newborns with disseminated disease is more than 90%, and infantile fibrosarcoma, for which cure rates in newborns often exceed those achieved in older children or adults.

Etiology

Genetic Predisposition Syndromes and Congenital Defects

The cause of cancer in children is multifactorial, involving both genetic and environmental factors. However, in neonates, predisposing genetic factors more often play an important role. An acquired or inherited abnormality of a cancer-predisposing gene that is critical during embryogenesis underlies some cases of neonatal cancer, and the malignant transformation of normal cells results from the activation or suppression of these cancer-predisposing genes. The retinoblastoma gene at 13q is an example of a constitutional chromosomal abnormality that results in a high risk of malignancy.

A number of defined hereditary conditions and genetic defects are associated with an increased incidence of specific neoplasms; these are listed in Table 73.3.[1] Except for retinoblastoma, hepatoblastoma, and Wilms tumor, the neoplasms associated with these syndromes seldom manifest themselves in the neonatal period, but the associated abnormalities may be recognized early, allowing regular screening. A lack of a family history should not dissuade the clinician from investigating these syndromes, as both spontaneous germline mutations and parental mosaicism occur. The genetic defect in many of these neoplasms has been identified. For

example, the *NF1* gene, located at 17q11.2, encodes a protein, neurofibromin, that normally acts as a guanosine triphosphatase–activating protein that downregulates the Ras signaling pathway. Children with neurofibromatosis 1 (NF1) are at increased risk of developing juvenile myelomonocytic leukemia (JMML), a rare but aggressive myeloproliferative neoplasm that is treated with hematopoietic stem transplant but has also been seen to spontaneously regress.[6] In children with NF1 and JMML, the hematopoietic cells display loss of the wild-type *NF1* gene and duplication of the mutant allele, thus resulting in the complete loss of the normal

neurofibromin protein in the leukemia cells.[7] This promotes cell growth because there is no functional "off" switch.

A large number of childhood tumors occur in association with congenital defects. For instance, Down syndrome has an increased association with both leukemia and transient myeloproliferative disorders (TMDs). Children with congenital aniridia have an increased incidence of Wilms tumor. Although aniridia is found in only 1 in 75,000 persons, it is found in as many as 1 in 75 children with Wilms tumor. Children with abnormalities of the Wilms tumor 1 gene *(WT1)*, located at chromosome band 11p13, also have an increased risk of developing Wilms tumor.[8] Most individuals with constitutional *WT1* defects have associated phenotypic syndromes that include combinations of genitourinary abnormalities, renal dysfunction, and mental retardation. Beckwith-Wiedemann syndrome (BWS) and hemihypertrophy syndromes are associated with several neoplasms. This syndrome is typified by macroglossia, gigantism, and abdominal wall defects; patients may also have visceromegaly, flame nevus, neonatal hypoglycemia, microcephaly, and retardation.[8] Approximately 8% of infants with either the complete syndrome or the partial syndrome develop neoplasms, including Wilms tumor, adrenal cortical carcinoma, and hepatoblastoma—tumors of the same organs in which visceromegaly develops. Also reported are RMS, neuroblastoma, ganglioneuroma, and adenomas and hamartomas. BWS is linked with abnormalities of 11p15; this is the location of the insulin-like growth factor II gene *(IGF2)* and the tumor suppressor gene *H19*.[9]

Transplacental Tumor Passage

An exceedingly rare cause of cancer in neonates and infants is the transplacental passage of tumor cells from the mother. Rare cases of transplacentally transmitted cancer have been reported.[10] The malignancies transmitted include leukemia, melanoma, lymphoma, hepatic carcinoma, and lung cancer. The diagnosis of transplacentally acquired neoplasm usually occurs at birth but has been reported as late as age 8 months. The frequency of concurrent maternal malignancy in pregnant women is estimated at 1 per 1000 pregnancies,[11,12] and alternative treatment plans or delays in treatment are options for pregnant women. That transplacental transmission is so rare is attributed to the protective function of the placenta.

Twin-to-Twin Transmission

The risk of development of leukemia is increased in a monozygotic twin. If one monozygotic twin has leukemia, the cotwin has an approximately 25% chance of developing leukemia, usually within weeks or months of the diagnosis in the sibling. In contrast, a dizygotic twin has only a slightly increased risk of developing leukemia. This increased incidence is likely due to in utero twin-to-twin transmission of a preleukemic clone rather than the simultaneous development of a shared germline mutation facilitating the later development of leukemia.

Environmental Factors

Environmental factors are probably less important in the development of neonatal cancer compared with their role in the development of cancer in older children and adults. Nonetheless, there is evidence that environmental influences, including radiation exposure, maternal medication use, and various environmental exposures, may affect the incidence of neonatal cancer.[1]

Exposure to ionizing radiation during pregnancy is known to increase the risk of a number of tumors, including acute leukemia, in exposed offspring. There appears to be a dose-response relationship between the dose of ionizing radiation received by the fetus in utero and the subsequent development of cancer in childhood, with doses on the order of 10 milliGray sufficient to produce an increase in risk. Mixed evidence comes from atomic bomb survivors who were exposed to radiation in utero. Maternal exposure to ionizing radiation should be used sparingly and only for diagnostic purposes if required.[13]

Maternal exposure to some drugs during pregnancy has been associated with the subsequent development of cancer in offspring. Maternal use of diethylstilbestrol has been strongly associated with the development of clear cell adenocarcinoma of the vagina and cervix in daughters born from those pregnancies. Some substances and exposures known to be teratogenic may also be carcinogenic to offspring. Excessive maternal alcohol consumption may be linked to an increased risk of developing cancer in the newborn period, particularly acute myeloid leukemia (AML). The use of fertility drugs does not appear to increase the risk of cancer in the exposed offspring.[14]

Environmental exposures of the mother or father to hydrocarbons, dyes, and other chemicals and solvents may be related to the development of neonatal tumors, but there is only a weak association for most of the risk factors identified.[15] The association of neoplasms with other environmental factors, such as maternal use of tobacco, has not been conclusively proven.[16]

Diagnosis and Evaluation

The diagnostic evaluation of a newborn suspected of having cancer is guided by the signs and symptoms of the disease. Symptoms of malignancy in neonates can be nonspecific, such as irritability, poor feeding, failure to thrive, and fever. Table 73.4 lists clinical features associated with the more common malignancies found in the neonatal period. Most neonatal tumors present as a mass at birth; often the mass has previously been identified by prenatal ultrasonography. Postnatal imaging with magnetic resonance imaging (MRI) is usually required to better delineate the lesion.

Laboratory and pathologic evaluations should be directed at making the diagnosis efficiently, sparing the newborn unnecessary procedures that could result in acute and chronic morbidity. Routine laboratory studies, including a complete blood count (CBC) and liver and renal function tests, should be performed. Urine catecholamine excretion should be measured when neuroblastoma is being considered. Serum alpha fetoprotein (AFP) and beta human chorionic gonadotropin (β-hCG) levels should be measured in infants suspected of having a germ cell tumor or teratoma; these can serve as tumor markers, although the normally elevated levels in infancy can complicate the interpretation of these values (Table 73.5).[17] Surgeons and pathologists should submit biopsy tissue for histologic examination, immunoperoxidase staining, flow cytometry, cytogenetic analysis, and tumor banking.

Specific Neoplasms

Neuroblastoma

Overview

Neuroblastoma is the most common malignant tumor of infancy. It is of embryonal origin, derived from neural crest cells that have committed to the sympathoadrenal lines. The tumor can present in utero, in infancy, and in childhood; the age of presentation significantly affects the prognosis and treatment plans. Because,

TABLE 73.4 Differential Diagnosis of Malignant and Nonmalignant Conditions in Infancy

Feature	Malignancy	Nonmalignant Condition
Skin nodules	Neuroblastoma	Congenital viral infections

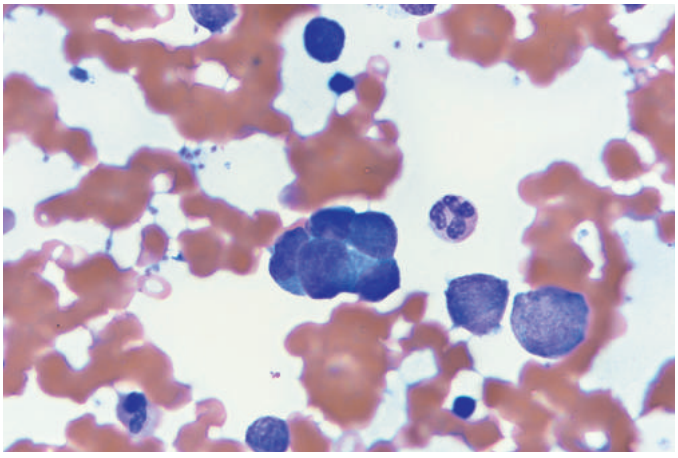
in part, of improvements in prenatal ultrasonography, neonatal neuroblastoma is now diagnosed in more children; neuroblastoma is diagnosed in approximately 100 children per year in North America prenatally or at age less than 3 months.[18] Neonatal neuroblastoma (defined as age younger than 28 days) represents 5% of neuroblastoma cases.

Etiology

Neuroblastoma can be associated with genetic disorders but does not have a single cause.[19] The incidence is increased in patients with Turner syndrome, Noonan syndrome (in 50% of Noonan syndrome patients the *PTPN11* gene is mutated, which is associated with an increased risk of leukemia and neuroblastoma), and Costello syndrome. While *NF1* mutations have been detected in neuroblastoma cell lines, patients with germline *NF1* mutations do not have a predisposition to neuroblastoma. Neuroblastoma is seen in BWS and other overgrowth disorders; abdominal ultrasonography is recommended quarterly until age 8 years for early detection. Congenital central hypoventilation syndrome (specifically the *PHOX2B* mutation) and Hirschsprung disease are associated with increased risk of neuroblastoma and ganglioneuroblastoma. There are cases of familial neuroblastoma; in 80% of these cases the anaplastic lymphoma kinase *(ALK)* receptor has been found to be mutated, although there are no phenotypic abnormalities.[20] In addition to germline mutations in the familial cases, somatic *ALK* mutations are found in up to 12% of sporadic neuroblastoma tumors.[21]

Presentation

In children, symptoms of neuroblastoma are often due to a mass effect in the compartment of tumor origin. Among all pediatric neuroblastoma cases, two-thirds of cases occur within the abdominal cavity; most of these occur in the adrenal glands. Abdominal distention is a common initial presentation. However, neuroblastoma can occur anywhere along the sympathetic chain and is sometimes incidentally found on chest x-rays. Neuroblastoma in the posterior mediastinum can present as bronchial obstruction. Neuroblastoma arising in the sympathetic paraspinal ganglia may invade the neural foramina, causing spinal cord compression with associated neurologic symptoms. Tumor cells can also rarely be found circulating on review of the peripheral blood smear (Fig. 73.1).



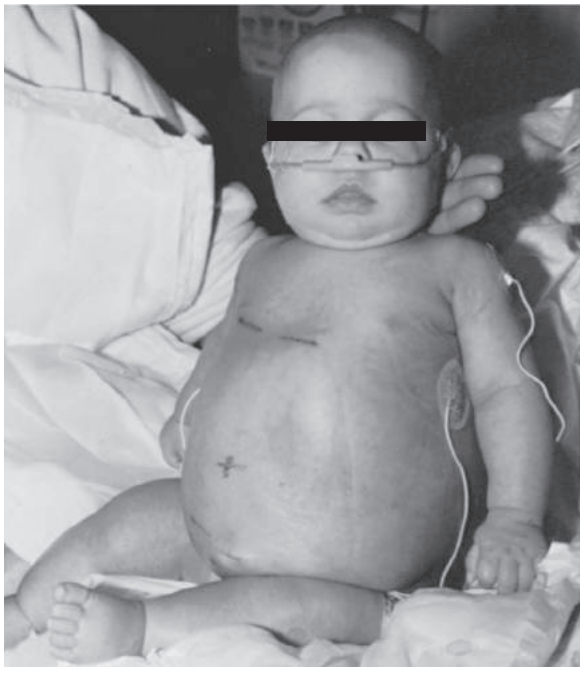
• **Fig. 73.1** Clump of Neuroblastoma Cells in Bone Marrow Aspirate. (Courtesy Kristie White, UCSF, San Francisco.)

In the newborn, neuroblastoma presents commonly as an asymptomatic adrenal mass found on routine ultrasonography in the third trimester, but it most often manifests as stage 4S (now referred to as stage MS and inclusive of patients up to 18 months of age) neuroblastoma with hepatomegaly, seen in 65% of cases, followed by subcutaneous metastases, seen in 32% of cases. This metastatic pattern is different from that seen in older infants and children. Metastases to the lungs, bones, skull, and orbit are rare in the newborn, although clumps of tumor cells are often found in the bone marrow. In the newborn the primary site of disease often cannot be identified or may be a small adrenal primary tumor. Liver involvement can cause massive hepatomegaly, which can be a cause of dystocia during vaginal delivery. This massive involvement can also cause abdominal distention, coagulopathy, heart failure, and life-threatening respiratory distress (Fig. 73.2), necessitating immediate chemotherapy.[22] Subcutaneous skin nodules can be present; these are typically bluish, and palpation of the nodules leads to transient erythema followed by blanching, presumably because of the vasoconstriction caused by the release of catecholamines from the tumor cell.

The neoplasm may also arise in the neck or pelvis. Involvement of the stellate ganglion may result in Horner syndrome, which includes ptosis of the upper eyelid, slight elevation of the lower eyelid, meiosis, narrowing of the palpebral fissure, anhidrosis, and enophthalmos (Fig. 73.3). Neuroblastoma arising from the paravertebral sympathetic ganglion has a tendency to grow into the intervertebral foramina, causing spinal cord compression and resultant paralysis. Careful periodic neurologic evaluation should be performed in a child with neuroblastoma in this region to evaluate the child for the onset of cord compression, which may necessitate emergency intervention with chemotherapy, surgery, or irradiation.

Unusual Presentations

Intractable diarrhea can be the sole presenting manifestation of neuroblastoma. Secretion of vasoactive intestinal peptide by the



• **Fig. 73.2** Stage 4S neuroblastoma causing abdominal distention and respiratory distress secondary to hepatic infiltration.

• **Fig. 73.3** Horner syndrome in an infant with neuroblastoma arising from the left cervical sympathetic ganglion.

tumor has been postulated to be the cause of the diarrhea, which resolves following surgical removal of the tumor.[23]

Opsoclonus and *myoclonus* ("dancing eyes, dancing feet") are associated with neuroblastoma, although this presentation is only rarely seen in the neonatal period.[24] Patients have rapid multidirectional eye movements (opsoclonus), myoclonus, and truncal ataxia (OMA) in the absence of increased intracranial pressure (ICP). The condition may be due to an autoimmune reaction, as the presence of antineuronal antibodies has been shown to be significantly more common in children with neuroblastoma and OMA than in case-controlled neuroblastoma patients.[25] Removal of the tumor usually results in a decrease in neurologic signs and symptoms, but the use of steroids, intravenous (IV) gammaglobulin, and other immunosuppressive therapy such as cyclophosphamide or rituximab is frequently required for complete resolution.[26,27] In general, the prognosis for survival of children with OMA is excellent, although long-term neurologic deficits and learning delays are common and can be quite debilitating.

Catecholamine Secretion

A hallmark of neuroblastoma cells is the ability to store and secrete catecholamines. Patients with neuroblastoma usually have elevated urinary levels of norepinephrine as well as its biochemical precursors and their metabolites. More than 90% of patients have an elevated urinary excretion of vanillylmandelic acid (VMA) or homovanillic acid (HVA) or both. VMA and HVA determinations can be made on random urine samples when values are normalized for creatinine concentration. In the occasional case with no elevation of catecholamine levels, a 24-hour urine collection is necessary. Catecholamine secretion can be used not only as a diagnostic aid but also as a means to assess the response to therapy and to detect tumor recurrence. Thus urine catecholamine levels should be measured before surgical removal of the tumor or before initiation of therapy.

Diagnosis

Clinical evaluation should include a physical examination with particular attention paid to detecting an abdominal mass, hepatomegaly, lymphadenopathy, Horner syndrome, and skin lesions; a baseline neurologic examination is also performed. Laboratory evaluation should include a CBC, tests for urine levels of VMA and HVA, and tests for serum ferritin and lactate dehydrogenase. While the initial imaging study in an infant is often abdominal ultrasonography, additional imaging to better delineate the tumor and to evaluate the infant for metastatic disease is needed; this should include computed tomography (CT) or MRI of the primary lesion. MRI of the spine should be performed for paraspinal and posterior mediastinal lesions. An [^{123}I]metaiodobenzylguanidine (MIBG) scan is particularly important for diagnosis and follow-up. MIBG, a norepinephrine analogue specifically taken up by neuroblastoma in bone and soft tissue, serves as a sensitive modality (90% sensitive) for disease localization.[28] Bilateral bone marrow aspiration (along with bilateral bone marrow biopsy in patients older than 6 months) is also part of the initial evaluation.

Histologic evidence provides confirmation of the diagnosis of neuroblastoma. Tissue may be obtained from a primary lesion or a metastatic site. Because tumor-specific biologic information plays a critical role in risk classification and treatment recommendations, obtaining adequate tissue for biologic studies is essential.

Pathologic Classification

Neuroblastoma is made up of small round blue cells that are uniformly sized and contain dense, hyperchromatic nuclei and scattered cytoplasm with stroma around it. Immunohistochemistry is positive for neurofilament protein, synaptophysin, neuron-specific enolase, ganglioside GD2, and chromogranin A, which distinguishes it from the other small round blue cell tumors of childhood. The histopathologic appearance of neuroblastoma ranges from undifferentiated neuroblasts, to more mature ganglioneuroblastoma, to fully differentiated and benign ganglioneuroma. The most widely used morphologic classification system is based on the system proposed by Shimada et al.[29] in which tumors are classified as favorable or unfavorable. It is based on age, the amount of stroma, degree of neuroblastic differentiation, and the mitosis-karyorrhexis index. Further clarification with international agreement followed with the International Neuroblastoma Pathology Classification, which separates neuroblastoma into four categories: (1) neuroblastoma that is undifferentiated, poorly differentiated (<5% exhibiting differentiation), or differentiating (>5%); (2) ganglioneuroblastoma, intermixed; (3) ganglioneuroblastoma, nodular; and (4) ganglioneuroma.

Genetic Prognostic Factors: Tumor Biology

In addition to clinical factors and histology, a number of biologic factors have been shown to correlate with prognosis (Table 73.6). Genomic data currently used in risk classification schemes include the status of the *MYCN* oncogene, tumor cell DNA content (ploidy), and the allelic status of chromosome arms 1p, 11q, 14q, and 17q.[30] More recently, it has been found that any segmental chromosomal abnormality indicates a less favorable outcome.[31]

Amplification of the *MYCN* oncogene is present in 16% to 25% of primary neuroblastomas and has been shown to correlate with poor prognosis independent of age, stage, and other genetic alterations.[32] Patients with stage 1, 2, or 4S disease demonstrate *MYCN* amplification only rarely; when present, it has been associated with rapid disease progression in these normally favorable stages. In a Children's Cancer Group study of stage 4 neuroblastoma in infants, the progression-free survival rate after 3 years was less than 10% in infants with tumors that demonstrated *MYCN* amplification, compared with 93% for those with single-copy tumors.

Total cellular DNA content also predicts response to therapy in infants with neuroblastoma.[33] Diploid DNA content is an unfavorable prognostic factor, particularly in infants younger than 12 months. Infants with hyperdiploid tumors have a significantly

TABLE 73.6 Features That Affect Prognosis in Neuroblastoma

Feature	Favorable	Unfavorable
Age at diagnosis	<18 months	>18 months
INRG stage	L1, L2, MS	M
MYCN status	Nonamplified	Amplified
Histologic appearance	Ganglioneuroma, ganglioneuroma maturing, ganglioneuroblastoma intermixed	Ganglioneuroblastoma nodular or neuroblastoma
DNA ploidy (DNA index)	>1 or <1	1
Allelic status of 11q	Normal	11q deletion or LOH at 11q or any segmental chromosome loss

INRG, International Neuroblastoma Risk Group; *LOH*, loss of heterozygosity.

TABLE 73.7 International Neuroblastoma Risk Group Staging System

Stage	Definition
L1	Localized tumor not involving vital structures as defined by the list of image-defined risk factors[a] and confined to one body compartment
L2	Locoregional tumor with the presence of one of more image-defined risk factors[a]
M	Distant metastatic disease (except stage MS)
MS	Metastatic disease in children younger than 18 months with metastases confined to the skin, liver, and/or bone marrow

[a]Image-defined risk factors are specific to each body compartment. For example, risk factors within the neck include tumor encasing the carotid and/or vertebral artery and/or internal jugular vein, tumor extending to the base of the skull, or tumor compressing the trachea.
Data from Monclair T, Brodeur GM, Ambros PF, et al. The International Neuroblastoma Risk Group (INRG) staging system: an INRG Task Force report. *J Clin Oncol*. 2009;27:298–303.

better response to therapy than those with diploid tumors. Diploidy often correlates with tumor *MYCN* amplification, although in rare cases of hyperdiploidy with *MYCN* amplification, the *MYCN* amplification portends an unfavorable outcome.

Tumor karyotype also influences outcome. Loss of heterozygosity (LOH) of 1p occurs in up to 36% of primary tumors, and LOH at 11q23 is seen in 44% of primary neuroblastomas.[34] Both are associated with poor outcomes, older age at presentation, and advanced-stage disease. Gain of 17q occurs in 60% of neuroblastomas and is associated with metastatic disease and unfavorable prognosis. Comprehensive genome-wide approaches such as comparative genomic hybridization are becoming increasingly useful in refining the prognostic accuracy of chromosomal alterations.[35]

Staging

Neuroblastoma has traditionally been staged according to the International Neuroblastoma Staging System (INSS). Staging is based on age, disease site(s), and degree of surgical resection. New guidelines for a pretreatment risk classification system have been developed by the International Neuroblastoma Risk Group (INRG) Task Force and are being used in addition to the INSS summarized in Table 73.7[36]; this system is undergoing evaluation in risk-based clinical trials. INRG stages include L1, localized tumor not involving vital structures (corresponds to INSS stages 1 and 2); L2, locoregional tumor with one or more image-defined risk factors (corresponds to INSS stage 3); M, metastatic disease (corresponds to INSS stage 4); and MS, metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone marrow (corresponds to INSS stage 4 S). Two important differences in the INRG system compared with the INSS are that it is a radiologic rather than a surgical staging system and that the upper age limit for stage MS has been extended from 12 to 18 months.

Stage 4 S (MS) comprises a unique group of patients with disseminated disease but a good prognosis. This combination occurs exclusively in infants. In this special group of patients, typical findings include a small primary tumor that does not cross the midline and remote spread involving the liver, skin, or bone marrow (<15% of marrow replacement by tumor), without radiographic evidence of skeletal metastases. There is lack of MYCN oncogene amplification in most INSS stage 4 S tumors, in contrast to INSS stage 4 tumors. Infants with INSS stage 4 S disease have a very good prognosis despite having disseminated disease (5-year survival rate >90%); spontaneous regression occurs without cytotoxic therapy in approximately 50% of cases.[37]

Treatment

Treatment modalities for neuroblastoma include observation alone, surgery, chemotherapy, and radiation therapy or a combination of these. Patients with INSS stage 1 and INSS stage 2 neuroblastoma have a 96% to 100% survival rate with surgery alone.[38] Isolated adrenal masses, the more common presentation among infants with neuroblastoma diagnosed prenatally, can be monitored closely for spontaneous regression if a tumor diameter meets the size criteria and if urine VMA and HVA levels are decreasing.[39] Infants with INSS stage 3 and INSS stage 4 disease have a poorer survival, even with aggressive chemotherapy, although the outcome, with better than 70% surviving overall, is far better than the survival rate of 10% to 20% reported for older children with disease of these stages.[22]

The unpredictable course of neuroblastoma, with its occasional spontaneous maturation or regression, not only makes this tumor unusual but also requires careful assessment of clinical and biologic risk factors in planning therapy. The type and intensity of treatment are determined by identification of infants with relatively good, intermediate, and poor prognoses on the basis of stage, international pathology classification, ploidy, segmental chromosomal abnormalities, and *MYCN* amplification. Patients who have localized disease (L1 or L2) without amplification of *MYCN* have an excellent prognosis, and such patients should undergo surgical resection or partial resection, but they likely will not derive any additional benefit from postoperative chemotherapy or radiation therapy. An exception to this is in the case of spinal cord compression, in which prompt decompression with chemotherapy (preferred), laminectomy, or local irradiation may be used to preserve function. The combination of extensive laminectomy with

postoperative irradiation should be avoided because later spinal deformity is almost inevitable. Infants with stage 3 and stage 4 disease are usually treated with a combination of chemotherapy and local surgery, with radiation therapy given only as necessary to eradicate residual disease. The active drugs that are most commonly used include cisplatin or carboplatin, etoposide, doxorubicin, cyclophosphamide, and vincristine. Infants with stage 4 disease with amplification of the *MYCN* oncogene have a very unfavorable prognosis; standard chemotherapy regimens are not sufficient for cure. In these high-risk patients, intensive chemotherapy followed by myeloablative therapy with stem cell support may offer additional benefit.[40] In addition, the use of the differentiation agent isotretinoin and the anti-GD2 antibody ch14.18 has been shown to improve outcome in patients with advanced-stage, high-risk neuroblastoma.[41,42]

Infants with INSS stage 4S disease have a highly favorable prognosis and may require minimal or no therapy. Because many patients undergo spontaneous regression, therapy should be directed toward supportive care, with use of chemotherapy and surgery restricted to relieving symptoms.[43] The main cause of death in these patients is massive hepatic involvement resulting in respiratory insufficiency or compromise of renal or gastrointestinal function. Symptomatic patients are treated with chemotherapy. When there is a risk of organ impairment due to tumor bulk not responding to initial chemotherapy, low-dose radiotherapy can be considered (450 centiGray given in three fractions; in some cases not all three fractions are needed).[22]

Prenatal Diagnosis

Neuroblastoma is increasingly being detected prenatally by screening ultrasonography. Newborns with adrenal or other mass lesions detected prenatally should be evaluated by urine catecholamine levels (although this has a low specificity) and follow-up ultrasonography. Careful observation may be adequate for infants with localized tumors, which frequently regress.

Congenital Leukemia

Epidemiology

Although leukemia is the second most common malignancy in infants, congenital leukemia, defined as leukemia diagnosed in the first 4 weeks of life, is quite rare. The incidence of leukemia in the first 3 months is approximately five cases per million.[44] Two-thirds of congenital leukemia cases are classified as AML, in contrast to older infants and children, in whom ALL predominates. Congenital leukemia is associated with a high mortality with an overall survival rate at 24 months of only 20%,[45] which is due to the aggressive biology of these leukemias and age-related treatment complications.

The cause of leukemia is unclear. In infants and older children a number of factors are associated with the development of leukemia; these include genetic factors, environmental influences, and immunodeficiencies. Genetic epidemiologic studies of infant leukemia indicate that most, if not all, cases are initiated in utero and involve acquired, noninherited genetic rearrangements; chromosome band 11q23 (*KMT2A*, previously known as *MLL*) is frequently involved. Leukemia-associated gene rearrangements have been retrospectively identified in archived newborn screen blood spots of children who subsequently developed leukemia.[46–48] The Children's Oncology Group has reported a trend toward higher incidence of AML, but not ALL, in infants of mothers who consumed larger amounts of naturally occurring topoisomerase 2 inhibitors, such as those in foods high in flavonoids and phytates.[49]

Clinical Manifestations

Clinical signs of leukemia may be evident at birth and include hepatosplenomegaly, petechiae, and ecchymoses. Myeloid leukemic cell infiltration of the skin *(leukemia cutis)* is present in 25% to 30% of patients with congenital leukemia; a skin nodule may be the first clinical sign of leukemia (Fig. 73.4). Patients typically have multiple nodules that are freely movable over the subcutaneous tissue with a greenish-blue or dark pink discoloration of the overlying skin. It is important to perform flow cytometry and cytogenetic studies on the skin biopsy specimen because infants found to have an *KMT2A* rearrangement have a poor prognosis even in the absence of bone marrow involvement and should be treated aggressively.[50] When chloromas are present on the head or neck, imaging studies should be performed to assess the patient for the presence of intracranial or skull involvement. Infants may present with respiratory distress from very high numbers of circulating leukemia blasts and resultant leukemic infiltration in the lungs. Some infants with leukemia may appear somnolent or have periodic apnea as a result of CNS leukostasis, caused by sludging of leukemic cells in blood vessels.

Laboratory Manifestations

Hemoglobin levels may be normal initially, but anemia soon develops as the normal postnatal decrease in red blood cell production is combined with the leukemic proliferation and expansion within the bone marrow. Total white blood cell (WBC) counts may be normal or decreased, but leukocytosis is more often present. WBC counts of 150,000/mm^3 to 250,000/mm^3 or higher are common, and counts as high as 1,300,000/mm^3 have been reported. There is usually a predominance of blast cells on the CBC differential. Auer rods, characteristic intracellular inclusions, may be present and are pathognomonic of AML (Fig. 73.5).

Differential Diagnosis

A number of conditions can mimic congenital leukemia. Leukocytosis, hepatosplenomegaly, and thrombocytopenia can be seen in congenital infections such as syphilis, cytomegalovirus

• **Fig. 73.4** Extensive Leukemia Cutis in a Newborn. (From Zhang IH, Zane LT, Braun B, et al. Congenital leukemia cutis with subsequent development of leukemia. *J Am Acad Dermatol*. 2006;54:S22–S27.)

(CMV) infection, herpes simplex virus infection, toxoplasmosis, and bacterial sepsis. Congenital human immunodeficiency virus infection may rarely be confused with leukemia. Clonal B-cell expansion in such patients may cause lymphadenopathy. A marked but transient leukemoid reaction may occur during the newborn period in the setting of suspected or proven infection, particularly in very low birthweight neonates.[51] Severe erythroblastosis fetalis can mimic leukemia. Affected infants usually have hepatosplenomegaly, large numbers of nucleated erythroblasts in the peripheral blood, and, occasionally, thrombocytopenia. Small infiltrates of extramedullary erythropoiesis in the skin are a rare manifestation, resembling leukemia cutis.

A transient leukemoid reaction *(TMD)* occurs in many infants with Down syndrome. The leukemoid reaction usually resolves, but these infants sometimes require low-dose chemotherapy to reduce the risk of death because of end organ injury and failure. Furthermore, infants diagnosed with transient myeloproliferative disorder are at higher risk of later development of acute leukemia (see later). Infants with neonatal neuroblastoma may have symptoms similar to those of congenital leukemia, with hepatomegaly and discolored skin nodules. CBCs are usually normal, without circulating blasts. Bone marrow biopsies and aspirates sometimes show clusters of neuroblastoma cells (see Fig. 73.1). Increased excretion of catecholamine metabolites and the presence of a primary tumor, most often intraabdominal, are other clues that point to the diagnosis of neuroblastoma rather than leukemia.

Cellular Morphology and Immunophenotype

The bone marrow of a newborn with leukemia shows extreme hypercellularity and a marked predominance of immature cells, either myeloid or lymphoid. AML and ALL are differentiated on the basis of typical morphologic characteristics, such as the presence of granules or Auer rods (in AML), histochemical stains, immunophenotyping by flow cytometry, and chromosomal analysis. Terminal deoxynucleotidyl transferase, a DNA polymerase that catalyzes the polymerization of deoxynucleotides in thymocytes, is usually present in lymphoblasts but is only rarely present in myeloblasts. Myeloblasts are usually positive for myeloperoxidase, whereas lymphoblasts are not. AML is primarily subclassified on the basis of recurrent genetic abnormalities as described in the most recent World Health Organization classification system.[52] Leukemias that do not have a genetic abnormality are classified according to the international French-American-British (FAB) classification based on morphology and histochemistry (Table 73.8).

TABLE 73.8 World Health Organization 2008 and Immunophenotypic Classification of Childhood Acute Leukemia

WHO 2008 Classification	Antigen Expression*
Acute Lymphoblastic Leukemia	
B-cell acute lymphoblastic leukemia	HLA-DR, CD10, CD19, CD20, CD24
T-cell acute lymphoblastic leukemia	CD2, CD5, CD7
AML and Related Neoplasms	
AML with recurrent genetic abnormalities†	
AML with t(9;11)(p22;q23); *MLLT3–MLL*	
AML, Not Otherwise Specified	
AML with minimal differentiation (M0)	CD13, CD33, CD34
AML without maturation (M1)	CD13, CD33, CD34
AML with maturation (M2)	CD13, CD33, CD34
Acute myelomonocytic leukemia (M4)	CD11b, CD13, CD14, CD15, CD33, CD34
Acute monocytic leukemia (M5)	CD11b, CD13, CD14, CD15, CD33, CD34
Acute erythroid leukemia (M6)	Glycophorin CD34
Acute megakaryoblastic leukemia (M7)	CD34, CD41, CD42, CD61
Myeloid Proliferations Related to Down Syndrome	
Transient myeloproliferative disorder	CD34, CD41, CD42, CD61
Myeloid leukemia associated with Down syndrome	CD34, CD41, CD42, CD61

*The indicated diagnosis may express some or all of the indicated antigens.
†Other genetic abnormalities omitted because of rarity in neonatal and infantile acute myeloid leukemia.
AML, Acute myeloid leukemia; *WHO*, World Health Organization.
Modified from the 2008 revision of the WHO classification of myeloid neoplasms and acute leukemia.

The immunophenotype, determined with a panel of fluorescently labeled monoclonal antibodies most often against cluster of differentiation (CD) antigens, is critical for differentiating AML and ALL.[53] Myeloid leukemia cells are usually positive for CD13/CD33 antigens, which are markers of myeloid and monocytic differentiation. A notable exception is acute megakaryoblastic leukemia, which expresses the CD41/CD42 platelet glycoproteins and CD61, and is most commonly seen in patients with Down syndrome. Most neonatal and infant lymphoblastic leukemia cells exhibit an early precursor B-cell phenotype and often are CD1a, CD19, CD24, and CD15 positive and CD10 negative.[54] In addition, coexpression of myeloid antigens is often present, suggesting that these leukemias arise from very immature lymphoid progenitors. Surface antigen expression is summarized in Table 73.8.

Genetics

A number of cytogenetic abnormalities have been found in association with congenital leukemia; many of these abnormalities are independent prognostic indicators. The most frequent abnormalities involve disruptions of the *KMT2A* gene at 11q23. Abnormalities of 11q23 are found in approximately 50% of infant AML cases and 70% to 80% of infant ALL cases.[45,55,56] These are nonhereditary, nonconstitutional abnormalities that occur in utero. In mice and in humans, the *KMT2A* protein positively regulates *HOX* genes, which are critical for hematopoietic development.[57] Rearrangements in the *KMT2A* gene confer a poor prognosis, which worsens with decreasing age.[5,58] Gene expression analysis studies demonstrate a unique early hematopoietic progenitor genetic signature that distinguishes infant ALL with *KMT2A* rearrangements from ALL and AML in older children.[57]

Treatment and Prognosis

The course of congenital leukemia is usually characterized by rapid deterioration and death from hemorrhage or infection. Although cure rates have increased significantly in older children with leukemia, improvements have been modest in neonates with ALL. Infants with leukemia frequently present with hyperleukocytosis (blast cell count in excess of 100,000/mm^3), which may result in sludging of blast cells in capillaries with resultant intracranial hemorrhage, respiratory distress, or tumor lysis syndrome, which is characterized by hyperkalemia, hyperphosphatemia, hypocalcemia, hyperuricemia, and acute renal failure. Disseminated intravascular coagulation is another common complication, especially with monocytic subtypes. Leukemic blast cells release procoagulants, causing a consumptive coagulopathy that places the neonate at risk of either bleeding or thrombotic sequelae and may be exacerbated by further leukemia cell lysis induced by chemotherapy.

Initial supportive care includes correction of metabolic and hemorrhagic complications. Transfusion of platelets and fresh frozen plasma is frequently required. Rasburicase, a recombinant urate oxidase enzyme, has been safely used in neonates with hyperuricemia[59,60] but is contraindicated if glucose 6-phosphate dehydrogenase deficiency is suspected or diagnosed as precipitation of severe hemolysis and death have been reported.[61]

Intensification of chemotherapy regimens has resulted in increased rates of remission and survival in both infants and older children diagnosed with AML. The contemporary chemotherapy regimens used in infants are similar to those used in older children and usually include daunorubicin and cytarabine, and outcomes for infants with AML are similar to those for older children, with overall survival rates of 65% to 75%.[62,63] Importantly, molecular features, in particular certain partner genes that fuse with *KMT2A* and a rare form of leukemia characterized by *CBFA2T3-GLIS2*, have been closely associated with poor survival outcomes in AML.[64]

Conversely, young infants with ALL fare worse than do older children with ALL, in whom chemotherapy results in a disease-free survival rate of more than 85%. Studies of infant ALL have reported rates of disease-free survival of 28% to 47%,[65] which is a significant improvement from previous trials and has been associated with the introduction of hybrid regimens that combine elements from standard ALL and AML protocols, addressing the more primitive nature of *KMT2A*-rearranged ALL. Unfortunately, patients with congenital ALL continue to have higher relapse rates, with a disease-free survival rate of less than 20%.[45]

Because CNS involvement is common in infants with AML and ALL, intrathecal chemotherapy is an important part of treatment. Radiation therapy, which can cause neurocognitive sequelae and secondary malignancies, is no longer routinely used. The use of hematopoietic stem cell transplant is controversial and remains an area of research in the treatment of congenital leukemia.

Transient Myeloproliferative Disorders and Leukemia in Patients With Down Syndrome

The incidence of acute leukemia in children with Down syndrome is 20-fold higher than in the general population. In children with Down syndrome younger than 3 years, a rare megakaryoblastic subtype of acute leukemia predominates and is classified by the World Health Organization as myeloid leukemia associated with Down syndrome (ML-DS). ML-DS is characterized by *GATA1* transcription factor mutations and is distinct from conventional acute megakaryoblastic leukemia, which occurs in older non–Down syndrome patients, on the basis of molecular features and prognosis.[52] The prognosis of myeloid leukemia associated with Down syndrome is favorable[66] and is associated with blast hypersensitivity to traditional chemotherapy agents such as cytarabine and daunorubicin.[67]

Transient Myeloproliferative Disorder

TMD, which occurs in 4% to 10% of neonates with Down syndrome, is clinically indistinguishable from AML.[68] Although most cases of TMD occur in patients with Down syndrome, TMD is also rarely seen in patients with no constitutional chromosomal abnormalities or with trisomy 21 mosaicism. TMD is a clonal disorder typically manifested by hepatomegaly, splenomegaly, and circulating myeloblasts. There may or may not be associated anemia or thrombocytopenia. In general, the blast count of the peripheral blood exceeds that of the bone marrow. Blast cells often have cell surface antigens characteristic of megakaryoblasts. Somatic mutations in *GATA1* have been detected in nearly all cases of TMD and myeloid leukemia associated with Down syndrome.[69]

Most neonates with Down syndrome and TMD experience complete clinical and hematologic recovery without systemic therapy, usually within 3 months. The blast count slowly decreases over a period of 2 to 3 weeks, and the hemoglobin and platelet counts normalize. However, in some cases, spontaneous resolution does not occur, and the neonate may experience clinical deterioration manifested by progressive hepatosplenomegaly, hepatic dysfunction, coagulopathy, ascites, and pleural or pericardial effusions. Approximately 20% of Down syndrome TMD cases are fatal, usually due to hepatic or cardiopulmonary failure.[70] Treatment with low-dose cytarabine has been shown to reduce the risk of early death in the setting of high-risk TMD. The indications for starting treatment differ but generally include a WBC count of more than 50,000/mm^3 to 100,000/mm^3, platelet count of less than 100,000/mm^3, renal or hepatic dysfunction, or cardiopulmonary compromise.[71,72] In some instances, complications from TMD occur in utero, and various degrees of hydrops fetalis can result.

Infants with Down syndrome and a history of TMD should undergo careful follow-up because TMD is considered to be a preleukemic syndrome: approximately 20% of neonates with TMD develop ML-DS within 4 years.[68] The administration of low-dose cytarabine does not appear to alter the risk of ML-DS development.

Germ Cell Tumors

Germ cell tumors are neoplasms derived from primordial germ cells. They are a heterogeneous group of tumors, differing in site, age at presentation, histopathologic features, and malignant potential. They can occur in both gonadal and extragonadal sites—although primarily in extragonadal sites in neonates.[73] Normal pluripotent primordial germ cells migrate from the yolk sac to the embryo, and persistence and abnormal migration of these cells or lack of normal erasure of parental methylating imprinting is thought to lead to these tumors.[74]

Germ cell tumors make up 35% to 40% of all neoplasms in the neonate, but only 5% of those contain a malignant component.[74] Benign germ cell tumors in the fetus and newborn are classified as either mature or immature teratomas.[75] However, one or more of the germ layer derivatives may develop malignant characteristics. Germ cell tumors may arise in a variety of locations in the body, usually along the axial midline. Common sites in children include the pineal gland, neck, mediastinum, retroperitoneum, and sacrococcygeal region. In the neonatal period, most teratomas occur in the sacrococcygeal region (40% of all germ cell tumors), followed next by tumors in the neck. Yolk sac tumor (endodermal sinus tumor) is the most common malignant germ cell tumor in neonates and young children. In the neonate it most often occurs within a teratoma, often in the sacrococcygeal region (see later). Of note, patients with undervirilization syndromes have a 5.5% prevalence of germ cell tumors which increases to 33% by puberty, so gonadectomy is recommended before puberty in these patients.

Pathology

By definition, teratomas contain tissue arising from all three layers of the embryonic disk. Ectodermal components, including glial tissue, are a major component of teratomas occurring at birth, in particular, sacrococcygeal tumors. There are often skin, hair, and tooth elements. Mesodermal components, including fat, bone, and muscle, also are present. Endodermal components include digestive tract tissue; this component generally forms a smaller portion of the tumor. The levels of hormonal markers, including serum AFP and β-hCG, are often elevated in the presence of malignant tissue within the teratoma and are useful to follow as therapy progresses. Elevated serum AFP level indicates the presence of immature endodermal sinus tissue or yolk sac elements, whereas elevated β-hCG level indicates the presence of embryonal carcinoma. Choriocarcinoma, which is rarely seen in newborns, manifests itself with an extremely elevated β-hCG level. Immature teratomas are defined and graded on a scale of 1 to 3 depending on the amount of embryonal tissue present.[74]

Evaluation

MRI or CT of the primary tumor is indicated to evaluate the extent of disease. Sacrococcygeal tumors should be imaged by MRI because of the possible involvement of the spinal cord. The entire abdomen is included in the imaging study to assess the extent of any local invasion, particularly involvement of the rectal wall. Chest imaging is performed to rule out metastasis. Baseline levels of serum AFP and β-hCG, which are normally elevated in newborns, are measured. Because of the variation in the levels at birth and the variation in the rates at which the levels decline to normal, these tumor markers can be difficult to interpret as measures of residual disease or recurrence. Normal AFP values for age are shown in Table 73.5. The half-life of AFP is 5 to 7 days; that of β-hCG is 24 to 36 hours.

Sacrococcygeal Teratomas

Sacrococcygeal teratomas are the most common solid tumors in newborns. The estimated incidence is 1 in 27,000 live births.[76] A minority are malignant: 10% to 17% of sacrococcygeal teratomas contain yolk sac tumor.[75] Malignancy is less common, only 7% to 10%, in infants younger than 2 months.[74] Females are affected 2 to 4 times more frequently than males, but the malignancy rate is similar. Half of sacrococcygeal teratomas are diagnosed prenatally by ultrasonography. Polyhydramnios, nonimmune fetal hydrops, and dystocia have all been described in association with sacrococcygeal teratomas. Lack of prenatal diagnosis has been reported to carry a 20% risk of death in the first hour after birth secondary to hemorrhage.[76] Congenital anomalies, including genitourinary, hindgut, and lower vertebral malformations, are present in 15% of patients.[75] In most cases the tumor manifests itself as a mass protruding between the coccyx and rectum; the mass may be quite large (Fig. 73.6). Approximately 10% of these tumors are found only by rectal examination. Nearly all arise at the tip or inner surface of the coccyx.

Differential Diagnosis

Sacrococcygeal teratomas may be confused with meningomyelocele, rectal abscess, pelvic neuroblastoma, pilonidal cyst, and a variety of very rare neoplasms that may occur in the sacral region. Most benign teratomas in this area produce no functional difficulties, even when marked intrapelvic extension is present. Bowel or bladder dysfunction, painful defecation, and vascular or lymphatic obstruction suggest that the lesion is malignant.

Treatment

Treatment of sacrococcygeal tumors is primarily surgical.[73] The tumor should be radically excised as soon as possible because small, undifferentiated foci may proliferate and become aggressive. Removal of the entire coccyx is required. Failure to remove the coccyx carries a 30% to 40% risk of local recurrence, which is sometimes accompanied by malignant elements. The survival rate for neonates with sacrococcygeal teratoma is 85%.

Sacrococcygeal teratomas diagnosed prenatally by ultrasonography (approximately 50% of cases) are associated with a worse outcome; the survival rate is only 30% to 50%.[75,77] Fetal hydrops and prematurity are the main factors contributing to the low survival rate. If hydrops occurs before fetal pulmonary maturity, open

• **Fig. 73.6** Large Sacrococcygeal Teratoma in a Newborn.

fetal surgical intervention to debulk and devascularize the tumor is an option.[77]

Infants with sacrococcygeal teratoma containing malignant yolk sac elements are treated with surgery followed by chemotherapy with cisplatin, etoposide, and bleomycin. Immediate and late complications of this regimen can be significant and include hearing loss, pulmonary fibrosis, and secondary malignancy.

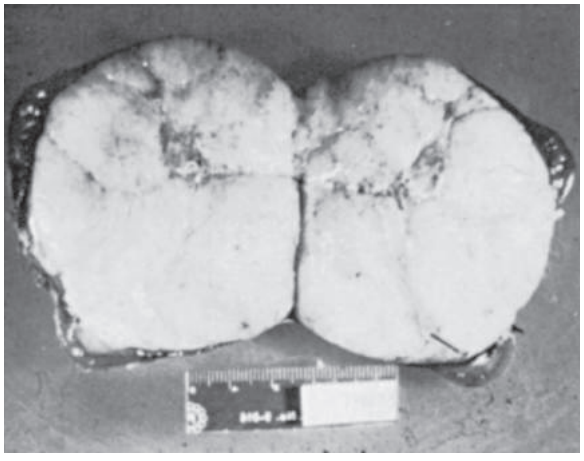
Renal Neoplasms

Approximately two-thirds of intra-abdominal masses in the neonatal period arise from the kidney. The vast majority of these neoplasms are nonmalignant and include polycystic or dysplastic kidney disease, hydronephrosis, renal vein thrombosis, and ectopic kidneys. The most common intrarenal neoplasm manifesting itself at birth is congenital mesoblastic nephroma (CMN), followed by Wilms tumor and nephroblastomatosis. Less common intrarenal neoplasms diagnosed during infancy include rhabdoid tumor, clear cell sarcoma of the kidney, renal cell carcinoma, RMS, and lymphoma.[78] The typical clinical presentation is an asymptomatic abdominal mass detected on physical examination or by ultrasonography.

Congenital Mesoblastic Nephroma

CMN is the most common intrarenal neoplasm in the neonate. It usually behaves as a benign neoplasm, but the histopathologic subset, cellular CMN, occasionally recurs or metastasizes. The typical clinical presentation is an asymptomatic abdominal mass detected on physical examination or by ultrasonography, but hypertension due to a mass effect on the renal vasculature and hypercalcemia due to elevated renin levels are also common findings. The tumor infiltrates into normal renal parenchyma and is not encapsulated (Fig. 73.7). Specific sonographic features can help to differentiate CMN from Wilms tumor. The tumor may be diagnosed prenatally by ultrasonography, which reveals a greatly enlarged kidney distorted by the tumor. There is an increased incidence of polyhydramnios (71%) and premature labor.[78]

Two histologic subtypes of CMN have been identified: the classic subtype and the cellular variant. The cellular variant usually manifests itself at an older age (>3 months) than the classic type (mean age at presentation of 1 month). Cytogenetic analysis of the cellular variant shows a translocation t(12;15)(p13;q25) that results in an *ETV6–NTRK3* gene fusion that is identical to that found in infantile fibrosarcoma.[78,79]



• **Fig. 73.7** Congenital Mesoblastic Nephroma Compressing and Nearly Totally Replacing the Kidney.

Complete surgical resection is usually an effective treatment for the classic form of CMN. Patients with the cellular variant are also treated with complete resection, but local and distant recurrences to the lungs and brain can rarely occur. Positive surgical margins or tumor rupture during resection are risk factors for recurrence, which usually occurs within the first year following surgery. Resection and chemotherapy can successfully treat recurrent disease.[78] The overall survival rate for CMN is 95% to 98%.[80]

Wilms Tumor

Wilms tumor, or nephroblastoma, is the most common intra-abdominal tumor of childhood, affecting 1 in 8000 children, but it is relatively rare in the neonatal period. In subsets of children with aniridia and hypospadias, the incidence is much higher. Wilms tumor is thought to arise from abnormal proliferation of metanephric cells, referred to as *nephrogenic rests*, without normal tubular and glomerular differentiation. Nephrogenic rests normally occur in 1% of newborn kidneys but often regress early in childhood.

Clinical Manifestations

Wilms tumor arises from one or both kidneys, and most children present with an abdominal or flank mass. It seldom extends beyond the midline, even though it may grow downward beyond the iliac crest. In 5% to 10% of all cases, tumors involve both kidneys. Gross hematuria is a rare presenting symptom, but microscopic hematuria is found in approximately 25% of cases. Wilms tumor is seldom diagnosed at birth or during the neonatal period. Characteristics associated with an earlier presentation include bilaterality, associated aniridia or hypospadias, and a family history.[81]

Hereditary Associations and Congenital Anomalies

Although most cases of Wilms tumor are sporadic, a number of conditions are associated with an increased risk of developing the tumor. These include *WT1*-associated phenotypes caused by deletions and mutations of the *WT1* gene (11p13), overgrowth syndromes, and constitutional chromosomal disorders.[8]

WAGR syndrome (*W*ilms tumor, *a*niridia, *g*enitourinary abnormalities, mental *r*etardation) predisposes to Wilms tumor because of a deletion in *WT1* and aniridia because of a deletion of *PAX6*, which are both encompassed within a deleted region at 11p13.[82] From a clinical perspective, if an infant has aniridia, chromosome analysis should be undertaken. If a deletion of chromosome 11p13 is found, the child should be monitored for the development of Wilms tumor with serial renal ultrasound examinations. Wilms tumor develops in approximately half of these patients. Denys-Drash syndrome, caused by missense mutations within the *WT1* gene, classically describes the triad of Wilms tumor, genitourinary anomalies, and nephropathy. The genitourinary anomalies may be severe enough to result in pseudohermaphroditism.

Hemihypertrophy, which can be either isolated or associated with various genetic syndromes, is associated with an increased risk of the development of Wilms tumor. BWS, an overgrowth disorder caused by dysregulation of imprinted genes

at chromosome 11p15, is associated with an increased risk of Wilms tumor, particularly bilateral disease. Between 1% and 8% of individuals with BWS develop Wilms tumor.[8] Other characteristic clinical findings include macroglossia, anterior abdominal defects, ear creases and pits, neonatal hypoglycemia, and hemihypertrophy.

Between 1% and 2% of Wilms tumor cases occur within families, but the underlying cause of familial Wilms tumor is heterogenous and mostly unknown.[8]

Prognostic Factors

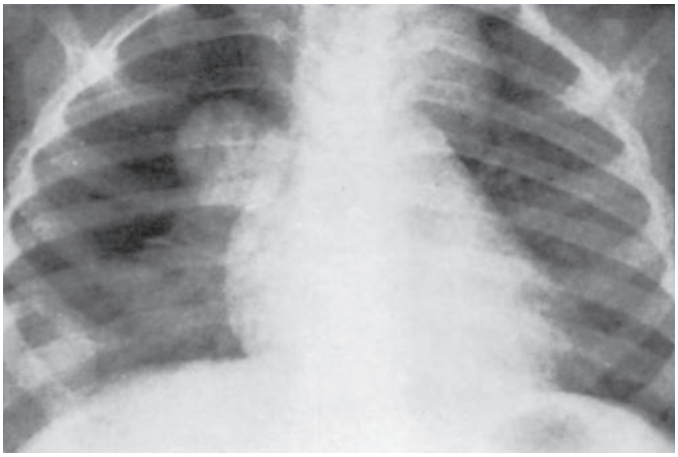
Important prognostic factors include the histologic assessment, the extent of disease, and chromosomal abnormalities. The presence of anaplasia is an important predictor of adverse outcome, and patients who have tumors with diffuse anaplasia fare worse than those with focal anaplasia. The presence of tumor-specific LOH for chromosome arms 1p and 16q is associated with a worse prognosis.[83] Patients younger than 2 years have fewer relapses, especially of distant sites, than older children.

Evaluation and Staging

Clinical staging, which includes a CT scan of the abdomen and chest, is an important factor in predicting survival; tumors with more extensive spread carry a poorer prognosis. The most common sites of metastasis are the liver and the lungs (Fig. 73.8). Tumor thrombus is occasionally noted in the inferior vena cava.

Treatment

Patients with low-stage Wilms tumor have a cure rate of more than 90%. Patients with small tumors limited to the kidney can be cured with surgery alone. Patients with intermediate-risk Wilms tumor are treated with a short course (12 weeks) of chemotherapy with vincristine and dactinomycin. More extensive disease or high-risk features, such as anaplasia, require the addition of doxorubicin and possibly other chemotherapy agents. Radiation therapy is indicated in children with diffuse abdominal disease; tumor spillage, including percutaneous biopsies, which is not a recommended diagnostic approach for pediatric renal tumors; or nonresponsive pulmonary metastases. Even patients with metastatic disease have a good prognosis, with a 70% long-term overall survival rate. Recurrent disease, which can be local or may involve metastases to the liver, lungs, or brain, is treated with additional chemotherapy and radiation therapy.



• **Fig. 73.8** Pulmonary Metastases from Wilms Tumor.

Persistent Nephrogenic Rests and Nephroblastomatosis

Nephrogenic rests are residual immature metanephric tissue within a fully developed mature kidney. They normally occur in 1% of newborn kidneys but typically regress during early childhood. Although benign, nephrogenic rests have been confused with Wilms tumor in the past and are believed to have the potential for neoplastic transformation to Wilms tumor. Histologically, nephrogenic rest cells may resemble Wilms tumor and occasionally present a diagnostic dilemma, although the presence of mitoses favors Wilms tumor. Radiographically, when imaged with MRI, nephrogenic rests tend to appear less heterogeneous, demonstrate less contrast enhancement, and are smaller than Wilms tumor. Bilateral or multicentric Wilms tumors are associated with a high incidence of synchronous nephrogenic rests. When nephrogenic rests are multifocal or diffuse, they are referred to as *nephroblastomatosis*. Children with massive bilateral nephroblastomatosis often respond to therapies for Wilms tumor.[84]

Rhabdoid Tumor of the Kidney

Rhabdoid tumor of the kidney (RTK) is an uncommon tumor of children that is one of the most lethal neoplasms of early neonatal life, with a mortality rate exceeding 80%. RTK is the second most common malignant neoplasm of the kidney in neonates, after Wilms tumor. It has a predilection for males and for infants, with median age at diagnosis of 11 months. It is often widely metastatic at diagnosis; metastatic sites include lung, abdomen, lymph nodes, liver, bone, skin, and brain. Homozygous inactivating deletions or mutations of the *INI1* gene, located in chromosome band 22q11.2, are responsible for most rhabdoid tumors[85] and can be detected immunohistochemically. The prognosis for infants with RTK is extremely poor. The survival rate at 2 years for infants with a diagnosis before 6 months of age is less than 15%.[86] Virtually all patients with distant metastases will have a fatal outcome. Treatment modalities have included surgical resection, chemotherapy, and radiation therapy.

Retinoblastoma

Retinoblastoma is a malignant ocular tumor that arises from embryonic retinal cells. It occurs in the setting of hereditary and nonhereditary disease. The incidence of retinoblastoma is approximately 1 in 18,000 live births; between 250 and 350 cases are diagnosed in the United States each year.[87,88] Bilateral involvement, which occurs in the setting of heritable disease, is observed in 20% to 35% of patients. Although the incidence of heritable retinoblastoma is constant among various population groups, the incidence of sporadic, nonhereditary, unilateral retinoblastoma is increased in poorer, tropical, and subtropical regions.[87]

Genetics

Approximately one-third of patients have hereditary disease, which is often bilateral. Patients with hereditary disease have a germline mutation in the retinoblastoma gene, *RB1*, a tumor suppressor gene located on chromosome band 13q14. The mutation is inherited from a parent or occurs during embryonic development. There is autosomal transmission with high penetrance, approximately 90%. Patients with nonhereditary disease tend to have unilateral retinoblastoma. Their disease is the result of acquired somatic mutations in both *RB1* alleles.

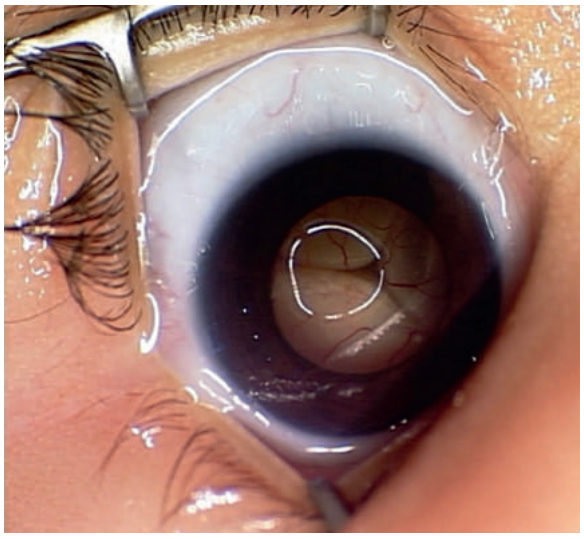
Approximately 5% of retinoblastoma patients are born with a constitutional deletion of chromosome 13, 13q−. These patients have associated constitutional anomalies, including

microencephaly, macrognathia, malformed ears and thumbs, hypertelorism, microphthalmia, ptosis, short stature, cleft palate, and developmental delay. In children with the bilateral and hereditary form, diagnosis is often at 1 year of age as opposed to on average at 2 years of age in children with the nonhereditary form.[88] This is due in part to early screening initiated because of the family history. In rare instances, a family history of retinoblastoma may be lacking; hereditary bilateral retinoblastoma may result from germline mosaicism in the parent.

Clinical Manifestations

Patients with retinoblastoma commonly present with leukocoria ("cat's eye"), squinting, or strabismus caused by loss of vision in the affected eye. Multifocal retinal involvement is common, occurring in 84% of cases. Intraocular spread may fill the vitreous body by extension or seeding, whereas exophytic tumors arise from the outer retinal layer and cause retinal detachment (Fig. 73.9). Extraocular spread is seen in less than 15% of patients, usually occurring by direct invasion of the optic nerve and eventually leading to subarachnoid involvement and intracranial spread. In such cases the cerebrospinal fluid may contain tumor cells. Rarely, tumors may spread by invasion of the orbit or by hematogenous dissemination to bone and bone marrow. Children with bilateral retinoblastoma are at risk of tumor dissemination to the pineal gland, a condition known as *trilateral retinoblastoma*. All patients with retinoblastoma should be evaluated initially by brain MRI for this condition. Patients with bilateral retinoblastoma are typically evaluated by brain MRI annually until age 5 or 6 years. Retinoblastoma can variably be detected in utero by ultrasonography or MRI in patients known to carry the mutated *RB1* gene.[88] Infants born to a parent with a known *RB1* mutation should be screened by an ophthalmologist from the time of birth.

The diagnosis of retinoblastoma is made by fundoscopic examination and orbital ultrasonography performed with the patient under general anesthesia. MRI of the orbit is useful to determine tumor extent and optic nerve involvement. A lumbar puncture for cerebrospinal fluid cytology is performed if there is optic nerve invasion, but more extensive evaluation with bone marrow biopsy or bone scan is not usually necessary. Tumors are staged according to the International Classification of Retinoblastoma, on the basis of tumor size and location and the extent of vitreus and subretinal seeding.[87]



• **Fig. 73.9** Retinoblastoma Filling the Orbit. (Courtesy Bertil Damato and Andrew Kao, UCSF, San Francisco.)

Treatment

Because extraocular spread and death from dissemination are rare, the main goal of treatment is local control and preservation of vision. Surgical enucleation is used only when there is no chance for useful vision, if glaucoma is present, or if conservative measures fail to control the tumor. Small tumors confined to the retina can often be controlled with focal consolidative therapies such as cryotherapy and laser photocoagulation. Systemic chemotherapy with agents such as carboplatin, vincristine, and etoposide is frequently used concurrently with cryotherapy and laser therapy. Intra-arterial chemotherapy with agents such as melphalan can provide directed therapy. External beam radiation therapy is effective, but because of the late effects of radiation on bone growth and the potential for second tumor induction, aggressive local therapy and systemic and/or intra-arterial chemotherapy are preferable. Decisions about management involve multidisciplinary discussion because of the various treatment modalities.

Prognosis

The prognosis for children with unilateral retinoblastoma is excellent, with cure rates of 85% to 90%. However, patients with bilateral disease have a much lower long-term survival rate because of the high incidence of second malignancies, which may occur at any point in the life span. Patients with hereditary disease can develop secondary sarcomas in the area treated with radiation therapy; they are also at increased risk of developing sarcomas in other, nonirradiated areas. Local extension of retinoblastoma confers a poor prognosis, with survival rates of less than 10% with orbital extension or distant dissemination.

Central Nervous System Tumors

Incidence and Epidemiology

Congenital brain tumors are rare (2% of childhood CNS tumors), with an incidence of approximately 1 to 3 per million live births.[89,90] The incidence is likely underreported as 30% of neonates with brain tumors are delivered stillborn. Most brain tumors in infants are supratentorial, in contrast to pediatric CNS tumors. Half are gliomas, including astrocytomas (low-grade gliomas). PNETs, choroid plexus tumors (associated with Aicardi syndrome), and medulloblastomas also occur. Atypical teratoid or rhabdoid tumor of the CNS is associated with a high mortality rate. In general, brain tumors presenting in the perinatal period carry a very poor prognosis. Mortality from congenital CNS tumors has been reported to be from 72% to 93%.[90] Discussion with the family regarding prognosis and alternatives to therapy should be undertaken prenatally if CNS tumors are identified.

Clinical Manifestations

Macrocephaly is often the first sign of a congenital CNS tumor if the tumor has not been identified in utero. Signs and symptoms of increased ICP may be present. In infants these include a bulging fontanelle, split sutures, or rapidly increasing head size. Poor feeding, vomiting, lethargy, and irritability can also be symptoms of increased ICP. Fundoscopic examination may or may not show papilledema. Specific neurologic abnormalities include Parinaud syndrome (impaired upward gaze secondary to increased pressure

in the dorsal midbrain), cranial nerve palsies, and nystagmus. Head tilting can occur in patients with posterior cerebellar masses secondary to cervical root irritation.

Treatment

Treatment depends on the pathologic characteristics of the tumor, which usually cannot be ascertained until after birth and further imaging. An important component of therapy in neonates is surgical resection of the tumor. The degree of surgical resection is the single most important predictor of survival.[89] Complete resection is often not possible because tumors in infants tend to be large, highly malignant, and invasive. They are also highly vascular, making it difficult to remove the tissue without significant morbidity. Many patients require ventriculoperitoneal shunt placement for relief of hydrocephalus.

Radiation therapy, a backbone of treatment for older children with malignant brain tumors, is avoided if possible in young infants because infants experience devastating late effects, including neurocognitive deficits and growth impairment. Adjuvant chemotherapy can play a role in treatment; this may allow necessary radiation therapy to be delayed until the child is older. Most tumor types are treated similarly to childhood CNS tumors, although the efficacy of these treatments is not clear especially given the desire to limit radiation therapy.

Sarcomas

Soft tissue sarcomas are rarely seen in newborns. The most commonly diagnosed soft tissue sarcoma in the neonatal age group is infantile or congenital fibrosarcoma, which is classified as a low-grade non-RMS soft tissue sarcoma. The incidence in infants between age 1 month and age 12 months is five cases per million infants.[4] In general, infantile fibrosarcoma is treated by complete surgical excision, although neoadjuvant chemotherapy with a variety of agents has been successfully used for tumor shrinkage, with subsequent reduction in the morbidity related to radical surgical procedures.[91] The cure rates for infantile fibrosarcoma approach 100%.[92,93]

The initial evaluation of a patient with a congenital fibrosarcoma includes imaging of the primary tumor by MRI or CT and a chest CT scan. Diagnosis is made by biopsy of the lesion. The chemotherapy regimens used successfully for treatment of this tumor include vincristine, dactinomycin, and cyclophosphamide, as well as etoposide and ifosfamide. Doxorubicin, while efficacious, is generally avoided because of the risk of cardiac toxicity. The duration of therapy depends on the size, location, and response of the tumor, but the general goal is to reduce the tumor size to maximize the chances of surgical local control. Radiation therapy is usually avoided to spare the infant the associated late effects of poor growth and secondary cancers.

RMS, the most common soft tissue sarcoma in children, is rarely seen in neonates: less than 1% of RMS cases are diagnosed in the first month of life. Congenital RMS often involves the genitourinary tract and is frequently of the embryonal subtype. Congenital embryonal RMS appears to be associated with a specific translocation, t(2;8)(q35;q13).[94]

Histiocytosis

The histiocytoses are a diverse group of disorders characterized by the accumulation and proliferation of cells derived from the monophagocytic system—macrophages and dendritic cells.[95] Taken as a whole, histiocytoses can occur throughout life but peak incidence is in 1- to 3-year-old patients. Class I disorders, which are dendritic cell related, include Langerhans cell histiocytosis (LCH) and pure cutaneous histiocytosis. Class II disorders, which involve macrophage-derived cells, include familial hemophagocytic lymphohistiocytosis (FHL) and infection-associated hemophagocytic syndrome (IAHS). Class III disorders are malignant disorders of mononuclear phagocytes and include acute monocytic leukemia, malignant histiocytosis, and histiocytic lymphoma. In addition to these three classes, other rare, noncategorized histiocytoses can occur in newborns, in particular, juvenile xanthogranuloma (JXG). The pathophysiology of the histiocytic disorders appears to be related to abnormal regulation of histiocyte activation resulting in cell proliferation and cytokine production.[95]

The most common histiocytic disease seen in the fetus and neonate is LCH. About half of newborns with LCH have disease confined to the skin, while the other half have disseminated disease with resultant organ dysfunction, usually involving bone marrow, liver, or lung. Presenting symptoms of LCH in neonates can include skin lesions, hepatosplenomegaly, lymphadenopathy, and respiratory distress. Natal teeth can be a sign of lesions in the maxilla or mandible. Histologically, both cutaneous and disseminated LCH are characterized by granuloma-like lesions. Diagnosis is made by biopsy; Langerhans cells are positive by immunohistochemistry for CD1a and S-100.

The course of LCH is unpredictable. The pure cutaneous form of LCH usually resolves spontaneously in 2 to 3 months, whereas disseminated LCH carries a poor prognosis, with 57% mortality;[96] prognosis depends on level of organ involvement, age of diagnosis, and progression of disease. To complicate matters, newborns with skin lesions may not develop the symptoms of disseminated disease for several weeks to months. Disseminated LCH is usually treated with chemotherapy, including vinblastine and prednisone. Recently, genetic findings in LCH include *BRAF* V600E mutations; treatment with vemurafenib (BRAF inhibitor) has been effective.[97]

FHL and IAHS are also seen in the newborn period. FHL has an incidence of approximately 1 in 50,000 liveborn children[98] and is more common in neonates than IAHS. The overall survival rate for newborns with FHL is only 9% unless a stem cell transplant is performed; the survival rate for newborns with IAHS is 59%.[95] Newborns with these disorders commonly have fever, hepatosplenomegaly, and cytopenias. Other symptoms include liver dysfunction, neurologic symptoms, hypertriglyceridemia, elevated serum ferritin levels, and hypofibrinogenemia. Diagnostic criteria are listed in Box 73.1. Hemophagocytosis is found in the bone marrow in 76% of patients. Natural killer cell and cytotoxic T-cell activity is reduced or absent. Thirty percent of patients with FHL harbor constitutional mutations in the *PRF1* gene, which encodes an essential protein for cellular immune activation. Other mutations, in *UNC13D* and *STX11*, have been reported, and additional genetic predispositions are being discovered, thus whole exome sequencing is indicated for patients without a known genetic predisposition.[99] Patients with FHL are usually well at birth, then develop clinical symptoms by age 2 to 6 months. Constant fever, cytopenias, marked hepatosplenomegaly, and progressive cerebromeningeal symptoms characterize the disease course. Initial treatment is with steroids and etoposide. Progressive disease usually leads to death within 4 months of diagnosis, but hematopoietic cell transplant can increase the 3-year survival rate to 64%.[100]

Patients with IAHS, whose symptoms are similar to those of patients with FHL, experience a high recovery rate (59%)

• BOX 73.1 Diagnostic Criteria for Hemophagocytic Lymphohistiocytosis

The diagnosis can be established if:

1. The patient has a molecular diagnosis consistent with hemophagocytic lymphohistiocytoses (pathologic mutations of *PRF1, UNC13D, STXBP2, RAB27A, STX11, SH2D1A*, or *BIRC4*).
2. The patient has five of the following eight diagnostic criteria:
   a. Temperature ≥38.5°C
   b. Splenomegaly
   c. Cytopenias (affecting at least two of three lineages in the peripheral blood): hemoglobin level <9.0 g/dL (<10 g/dL in infants younger than 4 weeks), platelet count $<100 \times 10^9$/L, neutrophil count $<1.0 \times 10^9$/L
   d. Hypertriglyceridemia and/or hypofibrinogenemia: fasting triglyceride level ≥3.0 mmol/L (i.e., ≥265 mg/dL), fibrinogen level ≤1.5 g/L
   e. Hemophagocytosis in bone marrow or spleen or lymph nodes; no evidence of malignancy
   f. Low or absent natural killer cell activity (according to local laboratory reference)
   g. Ferritin level ≥500 μg/L
   h. Elevated soluble CD25 level (i.e., alpha chain of soluble IL-2 receptor) ≥2400 IU/mL

Other findings consistent with the diagnosis include cerebromeningeal symptoms, lymph node enlargement, jaundice, edema, rash, hepatic enzyme abnormalities, hypoproteinemia, hyponatremia, elevated VLDL level, and decreased HDL level.

HDL, High-density lipoproteins; *IL-2*, interleukin-2; *VLDL*, very low-density lipoprotein.
From Henter J-I, Horne A, Arico M, et al. HLH-2004: diagnostic and therapeutic guidelines for hemophagocytic lymphohistiocytosis. *Pediatr Blood Cancer*. 2007;48:124–131.

when appropriate antibiotic or antiviral treatment is promptly administered.[95]

JXG, a disorder of dendritic-related cells, is less common in neonates than LCH. Two forms are recognized: cutaneous and extracutaneous. Patients have one or multiple cutaneous nodules, which are reddish to yellow-brown papules on the head, neck, and extremities. Three-quarters of neonates with cutaneous JXG have a solitary nodule. The nodules, which are present at birth in 34.5% of cases, typically resolve spontaneously within approximately 2 years.[101] Survival is excellent for neonates with JXG limited to the skin and subcutaneous tissue, with no deaths reported in one series.[95] Treatment is not generally indicated. Extracutaneous or disseminated JXG can involve the subcutaneous and soft tissues, liver, lung, spleen, eye, lymph nodes, and brain. Immunohistochemical stains may be required to differentiate this from LCH. Twenty-five percent of neonates with disseminated JXG do not have cutaneous lesions. Jaundice, hepatosplenomegaly, and thrombocytopenia can be seen. Although most cutaneous and extracutaneous lesions resolve spontaneously without treatment, disseminated JXG has an 11% death rate.[95] Ocular and CNS involvement can cause significant morbidity. Systemic JXG is usually treated with chemotherapy and/or corticosteroids.

Hepatoblastoma

Hepatoblastoma, the most common malignant tumor of the liver in children, is an embryonal neoplasm composed of malignant epithelial tissue. Besides hepatoblastoma, the differential diagnosis of hepatic lesions in neonates includes metastases from other malignant tumors (a more common cause than hepatoblastoma) and benign vascular tumors of the liver (see later). The incidence of hepatoblastoma in infants is 11.2 cases per million; premature infants with low birthweights have a particularly high incidence.[102] In neonates the female-to-male ratio is 1:6.[103] Treatment of hepatoblastoma in neonates is similar to that in young children. Histologic subtype is associated with outcome, with pure fetal histology having the best prognosis. Hepatoblastoma is associated with a number of genetic abnormalities and malformation syndromes, including BWS and trisomy 18.[104] Patients with sporadic hepatoblastoma have tested positive 10% of the time for a germline mutation in the tumor suppressor *APC*, the gene associated with familial adenomatous polyposis.[105]

The most common presenting symptom in neonates is abdominal distention. Even in the absence of distention an abdominal mass can sometimes be palpated. Anemia, fetal hydrops, and respiratory distress are other initial findings. Serum AFP level is elevated above neonatal norms in half of patients. Hepatoblastoma is occasionally diagnosed prenatally by screening ultrasonography. Tumor rupture can occur during birth, resulting in massive hemorrhage, often necessitating birth by cesarean delivery.[105]

Ultrasonography is useful to distinguish cystic and solid masses from diffuse hepatic enlargement. CT scan of the abdomen demonstrates the extent of tumor involvement, anatomic landmarks, and operability; MRI most accurately shows tumor margins and vessel involvement. Use of the PRETEXT system, which uses imaging findings to stage hepatoblastoma, helps guide decisions about resection and need for liver transplant.

The goal of therapy is complete surgical resection. Infants with pure fetal histology whose tumors are completely resected have a 92% 24-month survival rate; the overall survival rate in a case series of 52 patients was 86%.[105] A lobectomy of the involved portion of the liver is performed if one lobe is free of malignancy and there is no evidence of distant metastases. For unresectable but nonmetastatic tumors, initial treatment consists of chemotherapy with cisplatin and vincristine. If adequate tumor shrinkage results, the tumor is then resected. Orthotopic liver transplant has been used in patients with unresectable, nonmetastatic hepatoblastomas in conjunction with chemotherapy.

Hepatic Hemangioendothelioma

Hepatic hemangioendothelioma, also referred to as *hepatic hemangioma*, is a benign vascular tumor of the liver; it is the most frequent liver tumor of infants.[106] The disease is classified into three subtypes: focal, multiple, and diffuse hepatic lesions. Some patients also have cutaneous hemangiomas. While some infants with small tumors are asymptomatic, infants with larger tumors can have multiple symptoms, including abdominal distention, respiratory distress, high output cardiac failure, and consumptive coagulopathy. The diagnosis is often suspected prenatally when a hepatic mass is detected by ultrasonography. The diagnostic evaluation usually includes abdominal ultrasonography and CT or MRI. If imaging studies fail to provide a diagnosis, then a biopsy can be considered. Infants with focal or multifocal disease without evidence of cardiac failure can usually be carefully observed with periodic physical examinations and ultrasound examinations. Various modalities have been used for symptomatic infants, including use of corticosteroids, use of corticosteroids with vincristine, sirolimus, embolization or artery ligation, surgical excision, and use of antiangiogenic chemotherapy agents.[107,108] Propranolol, which is used for treatment of cutaneous hemangiomas, may also be effective for treatment of hepatic hemangiomas.[109] The overall

survival rate for focal hemangioma is 86%; the overall survival rate for multifocal disease is 71%.[103]

Treatment Considerations in Infants

Chemotherapy Dosing

Neonates and infants experience more frequent and more severe side effects and late effects from chemotherapy compared with older children and adults. This is likely due to age-related differences in body composition, drug bioavailability, and drug metabolism. Infants have an increased amount of total body water, decreased activity of drug-metabolizing enzymes, particularly cytochrome P450, and less efficient renal function. To compensate for these differences, specific chemotherapy dosing protocols have been developed for neonates and infants. The doses for systemic chemotherapy are reduced overall and are frequently calculated by weight instead of by body surface area. Paradoxically, the volume of the cerebrospinal fluid in relation to body surface area is much greater in young children than in adults. Accordingly, the doses of intrathecal chemotherapy are adjusted for age to avoid the underdosing of young infants with leukemia.

Radiation Effects

The use of radiation therapy in newborns is reserved for acute life-threatening situations in which the benefits of radiation therapy clearly outweigh the risks of adverse late effects, which include growth impairment, cognitive impairment, and the risk of secondary malignancies. The goal is to minimize the use of radiation as much as possible, while not compromising disease-related outcomes, to spare the infant potentially morbid treatment-related side effects.

Pain Management

Infants experience pain and should be treated with adequate pain medication. Signs of pain in the neonate can be subtle and can include crying, grimacing, poor feeding, tachycardia, and high blood pressure. Acetaminophen can be an effective analgesic in infants, but it must be used judiciously to avoid the masking of a fever that could signify an infection, particularly if a central line is in place or in the setting of neutropenia. Use of nonsteroidal antiinflammatory medications is usually avoided in patients with cancer because of the risks of bleeding due to interference with platelet function in the setting of chemotherapy-induced thrombocytopenia. Narcotics can be used as needed provided that adequate monitoring of side effects such as respiratory depression is in place. Narcotics can produce physical dependence when used for more than 1 week, and the doses may need to be tapered to avoid withdrawal symptoms.

Nutrition

Adequate nutrition is particularly important for neonates and infants. Patients might require supplemental nutrition via a nasogastric tube or IV parenteral nutrition. A nutritionist should be consulted to help assess the infant's nutritional needs. Breastfeeding can usually be continued in neonates with malignancy.

Intravenous Access

Most neonates and infants with diagnosed cancer will require a central venous catheter to facilitate delivery of chemotherapy, blood product support, and parenteral nutrition. Some chemotherapy agents, such as vincristine and doxorubicin, are vesicants and can cause severe skin and subcutaneous burns if inadvertently infiltrated underneath the skin, which is a more common occurrence with peripheral IV access. The type of central line inserted depends on the size of the infant and the specific needs associated with the chemotherapy regimen.

Transfusions

Cancer patients frequently require blood product support to correct life-threatening cytopenias and coagulopathies, which can be secondary to the underlying malignancy or treatments directed against the malignancy. To minimize the risk of transfusion-associated infections and complications, a number of guidelines exist. These include the use of CMV-negative blood to prevent transmission of CMV, which is potentially life-threatening in an immunocompromised infant; the use of irradiated blood products to prevent the possibility of life-threatening graft-versus-host disease; and the use of leukocyte-depleted blood products to minimize nonhemolytic febrile and allergic reactions. Use of donor-designated blood is usually discouraged in infants with congenital leukemia, given the possible need for future related-donor hematopoietic stem cell transplant.

Immunizations

Immunizations are generally avoided until the patient has not been receiving chemotherapy for at least 6 months. In addition, close contacts of the patient should receive the inactivated polio vaccine rather than the live oral polio vaccine. There is no contraindication to immunization of first-degree relatives with the varicella vaccine. However, any person in whom a rash develops after the vaccination should be kept away from the patient.

Psychosocial Considerations

Social services and psychological support are essential for families. These services are usually best coordinated through the efforts of a multidisciplinary team composed of nurses, social workers, case managers, and the pediatric oncologist.

Late Effects

Infants who receive treatment for cancer during the first year of life are at risk of many late effects directly related to chemotherapy, surgery, and radiation therapy. Infants in the neonatal period will be particularly susceptible to therapies affecting normal growth and development. Information about late effects of treatment and suggested screening after childhood cancer may be found on the Children's Oncology Group website (http://www.childrensoncologygroup.org). Infants require follow-up evaluations at routine intervals by a pediatric oncologist (or multidisciplinary cancer survivor team), who can help identify appropriate screening tests and support.

Conclusion

Cancer in the neonatal period is rare but must be diagnosed and treated promptly with careful attention to the epidemiologic and clinical features that differ from those of older children with similar malignancies. There are special challenges in treating the neonate with cancer, including the newborn's unique physiologic status, which results in marked susceptibility to immediate and late adverse effects of treatment. Careful teamwork is necessary among the neonatologist, pediatric oncologist, surgeon, radiation therapist, nurse, and social worker to support and treat the patient and the family.

Developmental Abnormalities of the Kidneys

RACHEL M. ENGEN AND SANGEETA HINGORANI

KEY POINTS

- Kidney malformations account for 20% to 30% of all prenatally diagnosed developmental anomalies and are responsible for 31% of all childhood end-stage kidney disease.
- Patients with unilateral kidney agenesis are at risk for hypertension in childhood and chronic kidney disease in adulthood.
- Multicystic dysplastic kidney typically presents as a collection of large kidney cysts on ultrasound, and patients generally do well. Autosomal recessive polycystic kidney disease presents as bilaterally enlarged hyperechoic kidneys, often without cysts, and patients may have significant pulmonary and kidney complications.
- The outcome for patients with kidney dysplasia depends significantly on the amount of functioning kidney tissue and the associated congenital anomalies.
- Infant dialysis has improved rapidly over recent years, and 2-year survival outcomes as high as 80% are now reported by multinational dialysis databases.

Normal kidney development begins with two precursor organs, the pronephros and mesonephros, followed by the definitive metanephros at approximately 5 weeks' gestation. The metanephros develops from an interaction between a branch of the mesonephric (wolffian) duct, called the ureteric bud, and the surrounding metanephric mesenchyme. The repeatedly branching ureteric bud will become the collecting system, including the collecting ducts, kidney pelvis, ureter, and bladder trigone. The metanephric mesenchyme will form the glomerular podocytes, proximal tubule, loop of Henle, and distal convoluted tubule. Nephrogenesis begins at 9 weeks' gestation and is complete by 32 to 36 weeks' gestation. A complex and carefully timed web of signaling "crosstalk" between the mesonephric duct, metanephric mesenchyme, and surrounding tissue is necessary to coordinate proper kidney development. Any interruption of this process can lead to abnormalities in kidney structure and function.[1]

Developmental abnormalities of the kidney and the urinary tract affect 3 to 6 per 1000 births[2] and account for 31% of all children with end-stage renal disease (ESRD) in the United States.[1] Renal malformations represent 20% to 30% of all prenatally diagnosed developmental anomalies; prenatal ultrasound allows malformations that are asymptomatic at birth to be detected. Long-term outcomes for children with development anomalies of the kidney depend on the amount of functional renal tissue at birth, associated urinary tract anomalies, degree of prematurity, urine output, and presence of additional congenital anomalies.

With advances in neonatal critical care, nutritional therapy, and peritoneal dialysis techniques, many children who previously would have died in early infancy are surviving, growing, and receiving a kidney transplant. Reviews of multinational dialysis databases have reported 2-year survival rates as high as 80% in infants who start dialysis.[3] Successful provision of care requires a multidisciplinary team approach that includes the neonatologist or pediatrician, nephrologist, surgeon, urologist, nutritionist, nurse, and social worker. Above all, it requires close communication with and strong support of the child's family, who may bear enormous emotional and financial burdens in caring for their child.

Abnormalities of Kidney Number

Unilateral Kidney Agenesis

Unilateral kidney agenesis, or a congenital solitary kidney, results from a unilateral early and complete failure in the signaling interaction between the ureteric bud and metanephric mesenchyme. The estimated incidence is 1 in 500 to 1 in 1000 children.[4] Approximately 30% to 40% of children with unilateral kidney agenesis will have other developmental anomalies; approximately 25% will have vesicoureteral reflux, with the remainder having ureter-pelvic junction obstruction and gastrointestinal, cardiac, and musculoskeletal anomalies.[5]

Kidney agenesis was once thought to be a benign condition if the contralateral kidney appeared healthy. However, there is now increasing concern that unilateral kidney agenesis increases the risk for chronic kidney disease in adulthood.[6,7] The "hyperfiltration" hypothesis suggests that compensatory hyperfiltration in the healthy kidney leads to single-nephron hypertension, glomerulosclerosis, and nephron loss over time.[8] Recent studies of outcomes for children with congenital solitary kidney identified proteinuria and hypertension in 5% to 25% of patients during childhood,[9,10] while chronic kidney disease affects approximately 13% to 30% of adults with a solitary kidney.[4,9] The presence of other urinary tract abnormalities or any dysplasia in the remaining kidney worsens the prognosis.

TABLE 75.1 Syndromes With Kidney Agenesis and Ectopia

Syndrome	Inheritance	Genes	Kidney Disease (%)	Type of Kidney Involvement	Key Features
Fraser	AR	*FRAS1, FREM1, FREM2, GRIP1*	67	Bilateral or unilateral kidney agenesis	• Failure of eyelid formation • Syndactyly • Genital anomalies • Laryngeal stenosis
Kallman	XR	*KAL-1*	30	Unilateral or bilateral kidney agenesis Horseshoe kidney Vesicoureteral reflux	• Hypogonadism • Olfactory defects • Mirror movements of arms • Sensorineural hearing loss
Mayer-Rokitansky-Küster-Hauser	Sporadic or familial	*WNT4*	20–40	Unilateral kidney agenesis	• Congenital absence of uterus and upper two-thirds of vagina • Vertebral, cardiac, skeletal, ocular, and ear involvement
OEIS complex	Sporadic	Unknown	36	Kidney agenesis Vesicoureteral reflux	• Omphalocele • Cloacal extrophy • Imperforate anus • Spinal defects
Turner syndrome	Sporadic	XO karyotype	33	Kidney agenesis Horseshoe kidney Ectopic kidney	• Coarctation of aorta • Bicuspid aortic valve • Short webbed neck • Ovarian failure
Thrombocytopenia-absent radius	AR	*RBM8A*	23	Horseshoe kidney	• Bilateral absent radii • Bilateral thumbs present • Thrombocytopenia • Cardiac malformations

AR, Autosomal recessive; *OEIS*, omphalocele-exstrophy-imperforate anus-spinal defects; *XR*, X-linked recessive.[96–103]

Unilateral kidney agenesis is asymptomatic in infants with a healthy, nonobstructed contralateral kidney. The routine use of voiding cystourethrogram (VCUG) to screen for vesicoureteral reflux in infants without evidence of a urinary tract infection is now controversial. Children with unilateral kidney agenesis should be monitored for appropriate compensatory hypertrophy of the healthy kidney during infancy and should have annual screening for proteinuria and hypertension during childhood (Table 75.1).[9]

The same embryologic insult that led to failure of kidney development can also cause abnormalities of other mesonephric duct derivatives, including the seminal vesicles, vas deferens, and epididymis and müllerian duct organs.[4] Approximately 32% to 50% of girls with unilateral kidney agenesis will have genital tract abnormalities, including unicornate or didelphic uterus and vaginal obstruction.[11,12] The syndrome of obstructed hemivagina and ipsilateral kidney agenesis (OHVIRA), presumed to be due to the arrest of müllerian and mesonephric ducts around week 8 of gestation, can lead to unnecessary surgeries for evaluation of misdiagnosed pelvic mass and complications such as abscess formation and endometriosis.[13] Therefore uterine ultrasound screening for genital tract abnormalities in girls with a solitary kidney is recommended[11] but may be technically challenging.

Bilateral Kidney Agenesis

Bilateral kidney agenesis occurs in 1 in 3000 births. It may be an isolated finding or part of a syndrome, such as the brachio-oto-renal dysplasia syndrome or a hereditary kidney adysplasia. It is typically diagnosed prenatally in a pregnancy complicated by severe oligohydramnios or anhydramnios and nonvisualization of the fetal kidneys and bladder. Bilateral kidney agenesis is responsible for approximately 20% of cases of the oligohydramnios sequence (Potter syndrome),[14] in which decreased amniotic fluid causes compression of the fetus. Patients have the classic low-set ears, wide-set eyes with epicanthal folds, flat nose, and receding chin (Fig. 75.1). Historically, infants were typically born alive but died within the first hours to days of life because of pulmonary hypoplasia. There are now multiple case reports of prenatal treatment with serial amniotransfusion that resulted in the birth of infants who survived and received peritoneal dialysis followed by a kidney transplant with minimal respiratory support.[15,16] As of writing, there is an ongoing clinical trial in the United States to evaluate amnioinfusions with normal saline or lactated ringers solution for management of bilateral kidney agenesis (https://clinicaltrials.govNCT03101891).

Abnormalities of Kidney Position

Ectopic Kidney

Kidney ectopia occurs when the kidney fails to ascend from its embryologic position in the fetal pelvis to its final position in the kidney fossa. Ectopia can be simple, with the kidney located ipsilateral to its ureteral insertion, or crossed, with the kidney

located contralaterally. Crossed ectopic kidneys typically fuse to the orthotopic kidney.[17] It is found in 1 in 1000 individuals on autopsy and is typically asymptomatic; approximately 90% of patients are never diagnosed, and ectopic kidneys with ectopic ureters can become obstructed or associated with incontinence.[18] Approximately 20% to 30% of patients will have vesicoureteral reflux usually into the orthotopic kidney,[17,19] which may be associated with infections. Ectopia is not associated with hypertension, proteinuria, or chronic kidney disease. Patients are typically not followed closely if there is no evidence of reflux or obstruction.

Horseshoe Kidney

A horseshoe kidney occurs when the two kidneys are fused, typically at the lower poles, by a parenchymal or fibrous isthmus. This fusion impedes the embryologic ascent of the horseshoe kidney past the origin of the inferior mesenteric artery. It occurs in 1 in 400 children. Twenty-two percent of cases are associated with other systemic abnormalities, including vertebral anomalies, anorectal malformations, and Turner syndrome, and 20% to 30% of children will have vesicoureteral reflux. Urinary tract infections and kidney stones are common. The risk of progression to chronic kidney disease is primarily dependent on the amount of kidney damage suggested by proteinuria, hypertension, and kidney scarring.[20]

Kidney ectopia occurs when the kidney fails to ascend from its embryologic position in the fetal pelvis to its final position in the kidney fossa. Ectopia can be simple, with the kidney located ipsilateral to its ureteral insertion, or crossed, with the kidney located contralaterally. Crossed ectopic kidneys typically fuse to the orthotopic kidney.[17] It is found in 1 in 1000 individuals on autopsy and is typically asymptomatic; approximately 90% of patients are never diagnosed, and ectopic kidneys with ectopic ureters can become obstructed or associated with incontinence.[18] Approximately 20% to 30% of patients will have vesicoureteral reflux usually into the orthotopic kidney,[17,19] which may be associated with infections. Ectopia is not associated with hypertension, proteinuria, or chronic kidney disease. Patients are typically not followed closely if there is no evidence of reflux or obstruction.

Abnormalities of Kidney Organization

Multicystic Dysplastic Kidney

A multicystic dysplastic kidney (MCDK) develops when there is an impairment of nephrogenesis, resulting in branched ducts surrounded by connective tissue and undifferentiated cells. Occasionally there will be areas of recognizable kidney tissue, but the ureter is not patent and the kidney is nonfunctional.[21] MCDK is typically a sporadic and unilateral finding that occurs in 1 in 4300 births. It is the second most common cause of a flank mass in newborns. MCDK can be accurately diagnosed on ultrasound as a collection of large cysts that do not communicate with the kidney pelvis[22]; a nuclear medicine scan is not necessary for diagnosis (Fig. 75.2).[23–25] Bilateral MCDK is functionally

• **Fig. 75.2** Multicystic Dysplastic Kidney. (A) Gross pathology specimen of a multicystic dysplastic kidney. (B) Prenatal ultrasound image of a multicystic dysplastic kidney. Note the many large cysts. (A courtesy Dr. Laura Finn, Seattle Children's Hospital, Seattle; B courtesy Jennifer McBroom, Seattle Children's Hospital, Seattle.)

similar to bilateral kidney agenesis, with similar management and outcomes.

Approximately 20% of patients with MCDK have vesicoureteral reflux in the contralateral kidney; 40% of these children will have severe (grade III to V) reflux.[21] However, given the low rate of clinical intervention in some recent cohorts, the need for routine screening VCUG is controversial. If VCUG is not performed, the parents should be given instructions on monitoring for urinary tract infections.[26] Five percent of MCDKs are associated with a contralateral ureteropelvic or ureterovesical junction obstruction; approximately 15% will have other developmental abnormalities.[21]

MCDKs undergo spontaneous involution over time, with 5% of prenatally detected MCDKs no longer visible at birth and 40% to 55% involuted by age 5 years. If the contralateral kidney is normal, MCDK is usually asymptomatic, with a prognosis similar to unilateral kidney agenesis (see earlier). In rare cases MCDK may be a bilateral finding; these infants generally die soon after birth because of pulmonary hypoplasia. Patients should have routine ultrasound monitoring in infancy to ensure involution of the MCDK and appropriate compensatory hypertrophy of the contralateral kidney, with annual screening throughout childhood for hypertension and proteinuria. Lack of compensatory hypertrophy of the contralateral kidney is a risk factor for progressive kidney disease.[25] Nephrectomy is generally only performed if there is a clear indication. Older studies associated MCDK with an increased incidence of Wilms tumor, but more recent cohorts have not found an association.[27,28] Currently, routine tumor monitoring is not recommended for MCDK.[25]

Isolated Kidney Dysplasia

Kidney dysplasia occurs when either failure of ureteric bud-metanephric mesenchyme signaling or early urinary flow obstruction disrupts the normal development and differentiation of the fetal kidney.[29] The tissue is made up of primitive ducts, branches of the ureteric bud, surrounded by a ring of fibromuscular tissue and disorganized lobar development.[30] Kidney dysplasia may be unilateral or bilateral, isolated or syndromic, and sporadic or genetic. Mutations in *ITGA8*, an integrin important to cell structure and signaling, and *FGF20*, a fibroblast growth factor with a variety of functions in growth and development, have been associated with dysplasia and/or agenesis. Kidney dysplasia occurs in 0.1% to 3% of births and is the most common cause of childhood ESRD.[29]

Kidney dysplasia is typically diagnosed prenatally or postnatally with the appearance of large, bright kidneys on ultrasound. Cysts may or may not be present. Treatment and prognosis depend on the degree of dysplasia and associated findings. Children with unilateral kidney dysplasia and a normal contralateral kidney may have outcomes similar to children with unilateral kidney agenesis. Children with bilateral kidney dysplasia have variable outcomes depending on the degree of residual kidney function. Mild bilateral dysplasia may result in adequate amniotic fluid production for lung development; however, in general, there is a progressive decline in kidney function in infancy or childhood. Severe bilateral dysplasia has significantly worse postnatal outcomes, particularly if children develop the oligohydramnios sequence (Potter syndrome) with pulmonary hypoplasia.[31] Treatment may include dialysis, but the appropriateness of dialysis is typically determined on a case-by-case basis after discussion of the multidisciplinary care team and parents.

Prognosis for children with kidney dysplasia associated with genetic syndromes often depends on the patient's other developmental abnormalities. Some of the more common syndromes are presented as follows and in Table 75.2.

Renal Coloboma Syndrome

Renal coloboma syndrome (a.k.a. papillorenal syndrome) is an autosomal dominant disorder caused by mutations in *PAX2*, a transcription factor involved in development. Affected children have optic nerve coloboma (dysplasia) and small dysplastic kidneys.[32] Vesicoureteral reflux, high-frequency hearing loss, and central nervous system anomalies may also be present. Most patients have progressive kidney dysfunction, although the timing is highly variable, even in families with the same *PAX2* mutation.[32,33] *PAX2* mutations have also been associated with congenital anomalies of the urinary tract and autosomal dominant childhood-onset focal segmental glomerulosclerosis (FSGS).[34]

Brachio-Oto-Renal Syndrome

Branchio-oto-renal syndrome is an autosomal dominant condition affecting 1 in 40,000 newborns. It is caused by mutations in *EYA-1, SIX1*, or *SIX5*, which interact in the development of the branchial arches, inner ear, and kidney.[35] Clinical manifestations include branchial arch anomalies (clefts, fistula, cysts), preauricular pits, hearing impairment (conductive or sensorineural), and kidney anomalies ranging from unilateral dysplasia to bilateral agenesis.[36]

Hypothyroidism-Deafness-Renal Dysplasia Syndrome

Hypoparathyroidism-deafness-renal dysplasia syndrome (a.k.a. Barakat syndrome) is an autosomal dominant disorder with variable penetrance caused by mutations in *GATA3*, a transcription factor involved in embryologic development.[37] Patients can present at any age with symptomatic hypocalcemia secondary to hypoparathyroidism or early-onset bilateral sensorineural hearing loss that worsens with age. The associated kidney abnormalities include unilateral or bilateral kidney dysplasia or agenesis, although vesicoureteral reflux, proteinuria, and progressive chronic kidney disease have been described.[38,39]

VACTERL

The VACTERL association consists of vertebral defects, anal atresia, cardiac anomalies, trachea-esophageal fistula, kidney malformations, and limb abnormalities; diagnosis is made by the presence of three of the component features. The genetics of VACTERL are heterogeneous, and many of the currently identified mutations are related to the sonic hedgehog signaling cascade.[40] Kidney anomalies are one of the most common component features of VACTERL, found in approximately 65% to 80% of affected children, and typically consist of unilateral kidney agenesis or dysplasia. There is an increased risk of chronic kidney disease in childhood. Twenty-seven percent of those with kidney anomalies and 12% of children without visible kidney anomalies will have vesicoureteral reflux.[41]

TABLE 75.2 Syndromes With Kidney Dysplasia

Syndrome	Inheritance	Genes	Kidney Disease (%)	Type of Kidney Involvement	Key Features
Alagille	AD	*JAG1, NOTCH2*	40 with *JAG1*	Kidney dysplasia Kidney tubular acidosis Vesicoureteral reflux	• Paucity of intrahepatic bile ducts • "Butterfly" vertebrae
Brachio-oto-renal	AD	*EYA-1, SIX1, SIX5*	67	Unilateral dysplasia Bilateral kidney agenesis	• Branchial arch anomalies • Hearing impairment
Cornelia de Lange	AD, XD	*NIPBL, SMC1A, SMC3, RAD21, HDAC8*	36	Kidney dysplasia Kidney ectopia Vesicoureteral reflux	• Short stature • Hirsutism, low hairline • Limb abnormalities • Hearing loss
DiGeorge	AD	22q11.2 deletion	30	Kidney dysplasia Kidney agenesis MCDK Vesicoureteral reflux	• Facial dysmorphia • Cardiac malformations • Congenital hypoparathyroidism • Absent thymus
Ecterodactyly, ectodermal dysplasia, and cleft lip/palate (EEC1)	AD	7q11.2–q21.3	20	Kidney dysplasia Ureterocele Vesicoureteral reflux	• Absent digits, "split" hand/foot • Fair hair • Hyperkeratotic skin • Cleft palate, cleft lip
Fanconi anemia	XR	Heterogeneous	5	Kidney dysplasia Kidney agenesis	• Microcephaly • Café au lait spots • Absent radii • Thumb malformations
Fryns	AR	Unknown	35	Kidney dysplasia	• Congenital diaphragmatic hernia • Pulmonary hypoplasia • Distal finger hypoplasia • Craniofacial anomalies
Hypoparathyroidism-deafness-renal dysplasia	AD	*GATA3*	>60	Kidney dysplasia Kidney agenesis Nephrotic syndrome Vesicoureteral reflux	• Hypoparathyroidism • Bilateral hearing loss
Pallister-Hall	AD	*GLI3*	21–36	Kidney agenesis Kidney dysplasia Vesicoureteral reflux	• Hypothalamic hamartoma • Polydactyly • Imperforate anus
Prune-belly	AR	Unknown	>97	Hydronephrosis Kidney dysplasia	• Absent abdominal wall muscle • Bilateral cryptorchidism
Renal coloboma	AD	*PAX2*	>90	Kidney dysplasia Vesicoureteral reflux	• Optic nerve coloboma • Hearing impairment • Central nervous system anomalies
Townes-Brocks	AD sporadic	*SALL1*	27–42	Kidney dysplasia Chronic kidney disease	• Imperforate anus • Dysplastic ears • Hearing loss • Thumb anomalies
VACTERL	Sporadic	Unknown	65–80	Kidney dysplasia Kidney agenesis Vesicoureteral reflux	• Vertebral defects • Anal atresia • Tracheoesophageal fistula • Limb abnormalities
Wolf-Hirschhorn	Sporadic	4p16 deletion	40	Kidney dysplasia Kidney hypoplasia	• Seizures • Cognitive disabilities • Growth delay

AD, Autosomal dominant; *AR*, autosomal recessive; *MCDK*, multicystic dysplastic kidney; *XR*, X-linked recessive.[32,36,38,41,44,104–112]

• **Fig. 75.3** Eagle-Barrett Syndrome.

Eagle-Barrett Syndrome

Eagle-Barrett (prune-belly) syndrome is the triad of deficient abdominal wall musculature, bilateral undescended testes, and urinary tract abnormalities including kidney dysplasia and an enlarged, hypotonic bladder (Fig. 75.3). It affects 3.7 per 100,000 live male births; females comprise fewer than 5% of cases. The etiology is unknown, but familial recurrence suggests a genetic cause. Autosomal copy number variants involving candidate genes involved in mesodermal, muscle, and urinary tract development have been identified[42] but not reproducibly.[43] Cardiac, gastrointestinal, and musculoskeletal abnormalities are common; 10% of children have respiratory insufficiency related to oligohydramnios and pulmonary hypoplasia. Ten to 25% of children die in the neonatal period of respiratory failure or prematurity. Because of poor bladder tone, most patients have vesicoureteral reflux and develop urinary tract infections. Urologic management with intermittent catheterization or surgery is important to allow adequate bladder drainage and preserve kidney function. Forty to 50% of children develop chronic kidney disease, and 15% will ultimately require dialysis or kidney transplantation, often before school age.[44]

Abnormalities With Kidney Overgrowth

Beckwith-Wiedemann syndrome is an overgrowth disorder caused by abnormal methylation in two gene regulation regions, *IC1* and *IC2*, or paternal uniparental disomy of chromosome 11p15.5.[45] It occurs in 1 in 10,000 live births, and most cases are sporadic; in rare cases there is autosomal dominant inheritance. Patients are large at birth with hemihyperplasia, abdominal wall defects, enlarged tongues and internal organs, hyperinsulinemic hypoglycemia, *nevus flammeus* capillary malformations, and dysmorphic facial features. Nephromegaly is the most common kidney finding, although kidney cysts, nephrolithiasis, and urinary tract malformations have also been reported.[46] The kidneys contain nephrogenic rests, areas of embryonic kidney tissue that are at high risk for malignant transformation. Ten percent of patients with Beckwith-Wiedemann syndrome develop embryologic cancers before 10 years of age, and 40% to 60% of these cases are Wilms tumor (nephroblastoma). Tumor screening by abdominal ultrasound is recommended for all patients every 3 to 4 months until age 8 years.[47]

Simpson-Golabi-Behmel syndrome is an X-linked condition associated with mutations in *glypican3*, which may be involved in regulating embryologic growth. Affected children have many of the same findings as in Beckwith-Wiedemann syndrome, although hemihypertrophy and *nevus flammeus* are typically absent. There is a similar risk for Wilms tumor, and a similar screening schedule is typically recommended.[48]

Perlman syndrome is an autosomal recessive congenital overgrowth disorder caused by mutations in *DIS3L2*, a gene involved in ribonucleic acid processing, that leads to upregulation of insulin-like growth factor 2 (IGF-2).[49] Patients are large at birth with poor muscle tone and characteristic facial features. There is often polyhydramnios in utero and nephromegaly. In one case series, 29% of children with Perlman syndrome developed Wilms tumor, half of those tumors were bilateral, and the average age at diagnosis was less than 2 years.[50] More than half of patients with Perlman syndrome die of respiratory or kidney failure within the first month of life.[51]

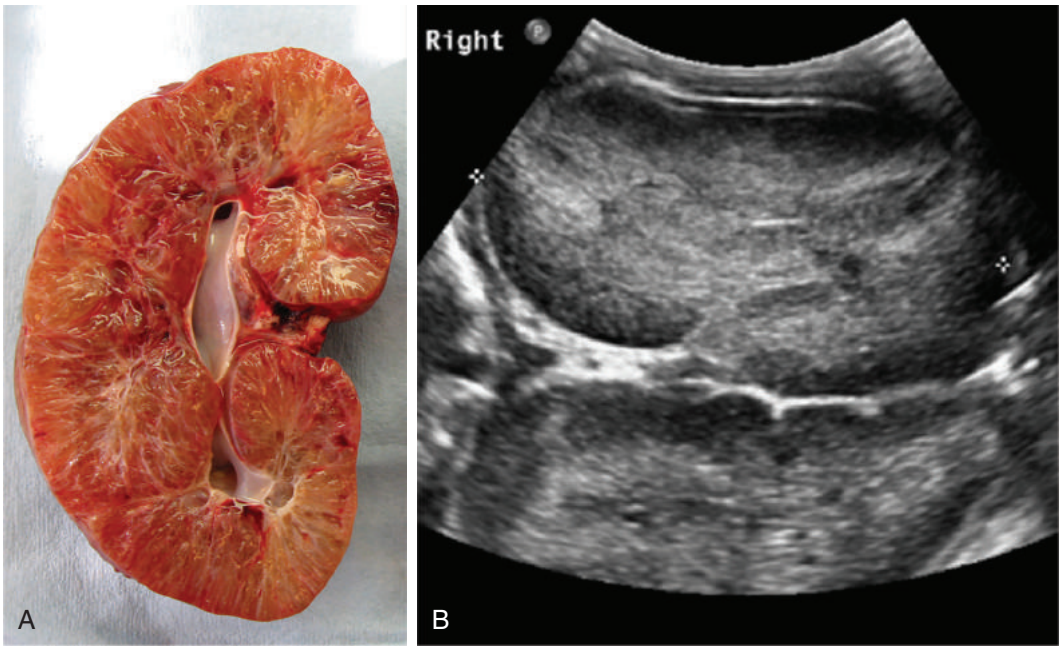
Abnormalities Predominated by Kidney Cysts

Ciliopathies

Primary cilia are protrusions of the cell membrane overlying a microtubule-based axon core. At the base of the cilium is a basal body, which is one of the two centrioles of the centrosome. Primary cilia sense the extracellular environment and transmit signals to the center of the cell, and they are critical to maintaining coordinated cell polarity.[52] Failure to maintain cell polarity in kidney tubular cells results in the development of kidney cysts, which is why diverse kidney cystic syndromes are now being grouped as ciliopathies. Except for a few diseases, including autosomal recessive and autosomal dominant polycystic kidney disease (ADPKD), the ciliopathies are highly heterogeneous genetically. Many syndromes are associated with a dozen or more genes, and single genes are often associated with multiple syndromes depending on the exact mutation and the presence of other cilia gene abnormalities. This genetic diversity can also lead to a high degree of clinical variability within any one syndrome and significant overlap between genetically related syndromes.

Autosomal Recessive Polycystic Kidney Disease

ARPKD is an autosomal recessive hepatorenal fibrocystic syndrome associated with mutations in fibrocystin *(PKHD1)*, which encodes a transmembrane protein of unknown function that localizes to the primary cilia, mitotic spindle, and apical membranes of kidney tubule and biliary duct cells. *PKHD1* is expressed in a number of tissues during fetal development, including the ureteric bud, mesonephric tubules, and immature hepatocytes and probably has a role in organogenesis and tubule formation. In the kidney the abnormality causes dilation of collecting ducts, forming cysts. Recently, mutations in a second gene, *DZIP1L*, have also been associated with an ARPKD phenotype with a more moderate clinical course.[53,54]



• **Fig. 75.4** Autosomal Recessive Polycystic Kidney Disease. (A) Autosomal recessive polycystic kidney disease. Many microcysts without large cysts. (B) Ultrasound image of an autosomal recessive polycystic kidney measuring 9.1 cm in length, twice the normal length for age. Note the significant increased echogenicity. (A courtesy Dr. Laura Finn, Seattle Children's Hospital, Seattle.)

ARPKD affects 1 in 20,000 live births, and carrier rates as high as 1:70 have been suggested.[55] Most patients present at or before birth with enlarged echogenic kidneys with poor corticomedullary differentiation; macrocysts are generally not visible on ultrasound at birth but do develop later in life (Fig. 75.4). Severely affected patients may have the oligohydramnios sequence with pulmonary hypoplasia, but oligohydramnios alone is not predictive of a poor neonatal outcome.[56] A small subset of patients present in childhood or adolescence with liver disease.

The kidneys may be so enlarged as to compromise respiratory function after birth, and 20% to 30% of affected infants will die due to respiratory insufficiency. The kidneys are often palpable, and the abdomen may be grossly distended. Most patients have abnormal kidney function from birth. Hypertension can be severe. As blood flow to the kidney increases after birth, polyuria may develop due to a urinary concentrating defect. All patients with ARPKD have liver disease due to bile duct malformation, and some will develop congenital hepatic fibrosis. Portal hypertension and ascending cholangitis are common complications, and some infants will have fat malabsorption due to abnormal bile flow. The enlarged kidneys may also compress other abdominal organs, further complicating enteral nutrition.[56] Hepatic synthetic and metabolic functions generally remain normal until late in the disease course.[55]

Initial management is focused on respiratory support and the initiation of peritoneal dialysis, if necessary.[57] Polyuric patients require high levels of daily fluid intake to match their excessive urine output, and some may require sodium supplementation.[57] Hypertension is often treated with angiotensin-converting enzyme inhibitors.[58] Infants with fat malabsorption may require supplementation of their fat-soluble vitamins (A, D, E, and K).

If the enlarged kidneys are causing respiratory failure, intractable hypertension, or feeding intolerance, simultaneous or staged bilateral nephrectomy may be performed. However, bilateral nephrectomy necessitates dialysis, which can be challenging in neonates. It may cause refractory hypotension due to the absence of renin production,[56] which animal models suggest is a significant early regulator of blood pressure while the sympathetic nervous system matures postnatally.[53] One cohort study of children with ARPKD and bilateral nephrectomy within the first 3 months of life reported a higher incidence of neurologic complications (63%), including seizures, hypoxic brain damage, severe neurodevelopmental disorder, and optic neuropathy with vision loss, compared with those whose second nephrectomy was performed at 4 to 15 months of age (22%) or who had initiation of dialysis within the first 3 months of life (17%). This association was seen despite similar total kidney volumes between groups and was independent of the incidence of severe hypotensive episodes.[53] There is one case report of using midodrine to treat an infant with refractory hypotension after bilateral nephrectomy,[59] but this has not been widely studied. In addition, kidney function in ARPKD may improve over the first several months of life. Therefore the decision to perform bilateral nephrectomy should be approached with caution based on individual clinical circumstances.[60]

Approximately 70% to 75% of patients with ARPKD survive the newborn period; among those survivors, the 15-year survival rate is 67% to 79%.[57] More than 50% of affected patients require kidney replacement therapy, either dialysis or a kidney transplant, during childhood, and 7% to 10% require a liver transplant.[61]

Autosomal Dominant Polycystic Kidney Disease

ADPKD is the most common inherited kidney disease, affecting 1 in 500 to 1 in 1000 live births. It is associated with mutations in *PKD1* and *PKD2*, with *PKD1* mutations being more frequent and associated with earlier onset of symptoms. *PKD1* encodes polycystin-1, a membrane protein involved in cell-matrix interactions and possibly calcium homeostasis. *PKD2* encodes polycystin-2, a

nonselective cation channel that increases membrane permeability to calcium and interacts physically with polycystin-1 at the primary cilia. ADPKD has an autosomal dominant inheritance pattern but is recessive at the molecular level; it is now generally understood that cells must develop a second, somatic mutation to begin forming a cyst.[57]

ADPKD generally presents with bilateral kidney cysts in early adulthood followed by progressive cyst development, kidney enlargement, hypertension, and kidney function decline. Patients may also have cysts in the liver, pancreas, spleen, and seminal vesicles and are at increased risk for vascular abnormalities, including cerebral aneurysms, aortic dilatation, and aortic dissection. Two to 5% of patients with ADPKD present prenatally or in early childhood with symptoms ranging from asymptomatic kidney cysts on ultrasound to the oligohydramnios sequence. A history of early-onset ADPKD in a family member portends a high risk of early-onset disease in the patient.[57] Biallelic abnormalities in *PKD1* or *PKD2* or a mutation in one allele of *PKD1* or *PKD2* with a mutation in a second kidney cystic disease gene may also cause early, severe disease, suggesting a gene-dosage effect.[62] Most infants diagnosed with ADPKD are asymptomatic at birth and remain so throughout childhood. Chronic kidney insufficiency has been reported in 8% of children and hypertension in 19% of children by adolescence.[63]

It may be difficult to differentiate severe early ADPKD from ARPKD by ultrasound. There are no diagnostic criteria for ADPKD in children younger than 15 years old; the kidneys of affected infants may be enlarged and hyperechoic with or without visible cysts and have increased corticomedullary differentiation. Children rarely have liver or pancreatic cysts, but 10% will have inguinal hernias. Screening the patient's parents for kidney cysts may be helpful in determining the correct diagnosis, although normal parental ultrasound does not rule out a diagnosis of ADPKD, because 8% to 10% of cases are associated with new mutations. Management of early ADPKD is guided by clinical presentation; severe cases may require nephrectomy and dialysis similar to children with ARPKD, whereas asymptomatic cases may need only outpatient follow-up. There is one case report of a 31-day-old infant with early, severe ADPKD who was treated with tolvaptan, a selective vasopressin V_2-receptor antagonist, for hyponatremia and edema, but this drug is not generally approved for use in children in the United States.[62]

Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is an autosomal dominant condition associated with mutations in either *TSC1*, encoding hamartin, or *TSC2*, encoding tubulin. *TSC1* and *TSC2* are important regulators of the mechanistic target of rapamycin (mTOR) kinase, a key signaling molecule involved in cell proliferation. Patients develop uncontrolled cellular proliferation, leading to hamartomas of the brain, skin, heart, lungs, and kidneys. Hypomelanotic skin macules (ash leaf marks) may be the only skin manifestation in infants, and the presence of three or more ash leaf marks at birth is suggestive of TSC. Shagreen patches, angiofibromas, and nail fibromas tend to develop later in childhood.[64] Seizures and kidney angiomyolipomas are common; simple kidney cysts are a minor feature of TSC but can be seen. *TSC2* is physically located near *PKD1* on chromosome 16, and 2% of patients with TS will also have ADPKD secondary to a contiguous gene deletion.[65,66] The cysts in ADPKD-TSC appear earlier, are larger, and are more numerous than the simple kidney cysts of isolated TSC. Enlarged kidneys also raise the concern for ADPKD-TSC.[67] ESRD is rare in patients with isolated TSC but may occur before age 30 years in patients with ADPKD-TSC.

Bardet-Biedl Syndrome

Bardet-Biedl syndrome is an autosomal recessive ciliopathy caused by mutations in any of at least 17 genes whose products are involved in the "BBsome," a complex involved in signaling receptor trafficking to the primary cilia. It affects 1 in 125,000 to 1 in 175,000 children. The abnormal primary cilia signal trafficking that leads to nonspecific glomerular and tubulointerstitial changes in the kidney, with or without kidney cysts, and reduced nephron mass. Retinitis pigmentosa, obesity, kidney anomalies, learning disabilities, polydactyly, and hypogonadism are the cardinal features.[68] Hearing loss, developmental or behavioral problems, diabetes, hypertension, cardiac defects, and limb anomalies have also been reported.

Kidney anomalies may be both structural and functional. Fetal ultrasound may show enlarged hyperechoic kidneys without corticomedullary differentiation. Cysts and abnormalities of the kidney pyramids may be seen. By 3 months of age there is inversion of the corticomedullary differentiation with a hyperechoic medulla. Kidney size normalizes over time, and kidney cysts may disappear. In childhood, one-third of patients will have polyuria and polydipsia; kidney tubular acidosis and other signs of tubular dysfunction are less commonly seen. Hypertension is also common. Approximately 10% of children will develop ESRD, and 25% will require dialysis or transplant by 40 years of age.[69]

Jeune Syndrome

Jeune syndrome, also called asphyxiating thoracic dystrophy, is an autosomal recessive skeletal ciliopathy affecting 1 in 126,000 live births and is associated with mutations in a large number of genes, including *IFT80*, *DYNC2H1*, *WDR19*, and *TTC21B*, that are involved in transport along the axon of primary cilia. Since 2006 it has been considered one of the short-rib thoracic dysplasias. Patients have characteristic skeletal abnormalities, including a small narrow chest with short ribs, short squared iliac wings, and short digits and extremities that can typically be diagnosed on prenatal ultrasound. Liver and eye abnormalities may be present. Approximately 40% of patients will have kidney anomalies, including cystic dysplasia, kidney hypoplasia, or hydronephrosis causing a tubulointerstitial nephropathy and tubular dysfunction.

The abnormal chest development in Jeune syndrome prevents the intercostal muscles from contributing to respiration, and half of children with Jeune syndrome die before 6 months of age secondary to respiratory failure. Surgical techniques for chest wall reconstruction, such as using a vertical expandable prosthetic titanium rib, which allows for ongoing chest growth, are currently being explored.[70] In limited case series, outcomes appear good if surgery is performed after 1 year of age but demonstrate 50% mortality before 1 year of age.[71] If affected children have mild respiratory involvement and live past infancy, they develop a urinary concentrating defect, polyuria, and polydipsia. After 3 years of age, kidney failure is the leading cause of death among children with Jeune syndrome.[72]

Nephronophthisis

Nephronophthisis is an autosomal recessive ciliopathy associated with at least 14 different genes involved in primary cilia structure and function, the most common being *NPHP1*. Nephronophthisis

is a tubulointerstitial nephropathy with tubular atrophy, corticomedullary cysts, and interstitial fibrosis that presents as polydipsia and polyuria around age 6 years, progressing to kidney failure in early adolescence. Infantile nephronophthisis progresses to ESRD around 1 year of age. It has similar pathologic findings as polycystic kidney disease, including cysts seen throughout enlarged kidneys,[73] and is typically associated with mutations in *NPHP2* and *NPHP3*.[74] It has been reported in isolation but is more common as a component of a number of genetic syndromes, including Meckel-Gruber syndrome, Joubert syndrome, and the Joubert-related disorders.

Meckel-Gruber Syndrome

Meckel-Gruber syndrome is an autosomal recessive disorder associated with mutations in any of at least 11 genes, all of which are associated with proper functioning of the primary cilia. It occurs in 2.6 per 100,000 live births and is more common if there is parental consanguinity. Patients have the characteristic triad of bilateral kidney cystic dysplasia, occipital encephalocele, and polydactyly. Hepatic fibrosis may also be present. More than 90% of cases are diagnosed prenatally by ultrasound, and 80% of cases result in fetal death or termination of pregnancy. Outcomes are poor; only about one-third of patients survive the first week of life, and the longest recorded survival is 28 months.[75]

Joubert Syndrome and Joubert-Related Disorders

Joubert syndrome is an autosomal recessive disorder associated with mutations in any of 35 genes that are associated with the primary cilia and basal body.[76] Patients have developmental delay, hypotonia, an irregular neonatal breathing pattern (episodic apnea and/or tachypnea), and abnormal eye movements including nystagmus and oculomotor apraxia. Facial features may be dysmorphic with a broad forehead, arched eyebrows, ptosis, wide-spaced eyes, and polydactyly. Magnetic resonance imaging shows the characteristic "molar tooth sign," an unusual combination of cerebellar vermis hypoplasia/dysplasia, elongated superior cerebellar peduncles, and a deep interpeduncular fossa. The molar tooth sign has now been associated with seven other conditions, including some cases of Senior-Løken syndrome, COACH syndrome, Dekaban-Arima syndrome, orofaciodigital (OFD) syndrome type VI (Varadi-Papp) syndrome, and Malta syndrome, all of which have variable levels of ocular and kidney involvement.

Kidney disease in Joubert syndrome and Joubert-related disorders may present as cystic dysplasia or nephronophthisis, with corticomedullary cysts and tubulointerstitial nephritis. Ultrasound shows increased kidney echogenicity in normal-sized kidneys with poor corticomedullary differentiation. Affected infants may be asymptomatic at birth but develop urinary concentrating defects, polyuria, and progressive kidney dysfunction during childhood. ESRD is common in the teenage years. Rarely, patients will present with a clinical picture similar to ARPKD; this is more common in patients with COACH syndrome and *MKS3* mutations.

Orofaciodigital Syndrome

OFD syndrome is a heterogeneous ciliopathy of 14 subtypes that are grouped together by the common finding of malformations of the face, oral cavity, and digits. OFD1 is an X-linked dominant condition that is lethal in males and occurs in 1 in 50,000 to 1 in 250,000 live Caucasian births;[77] the other 13 OFD subtypes are autosomal recessive and linked to a variety of cilia-associated genes. Tooth and tongue abnormalities, a buccal frenulum, agenesis of the corpus colosseum, and brachydactyly are common findings. Cleft lip and/or cleft palate occur in approximately one-third of patients. Kidney cysts have been reported in 6% of children with OFD syndrome and in up to 70% of adults, and patients develop progressive kidney insufficiency that results in ESRD in early adulthood.[78] Case series suggest that kidney cysts are strongly associated with neurological structural anomalies in patients with OFD1.[77]

Cranioectodermal Dysplasia

Cranioectodermal dysplasia, also called Sensenbrenner syndrome, is an autosomal recessive or sporadic ciliopathy associated with mutations in *IFT122, WDR35, IFT43*, *WDR19*, and *IFT52*, all of which encode proteins that localize to the cilia; *IFT43* and *WDR35* are involved in axonal transport within the primary cilia.[79] Patients have frontal bossing, dolichocephaly, low-set ears, wide-spaced eyes with epicanthal folds, small and widely spaced teeth, sparse hair, abnormal nails, short stature, a narrow thorax, short humeri, and brachydactyly. The liver and eyes may also be affected. More than half of patients will develop nephronophthisis that progresses to ESRD.

Renal-Hepatic-Pancreatic Dysplasia

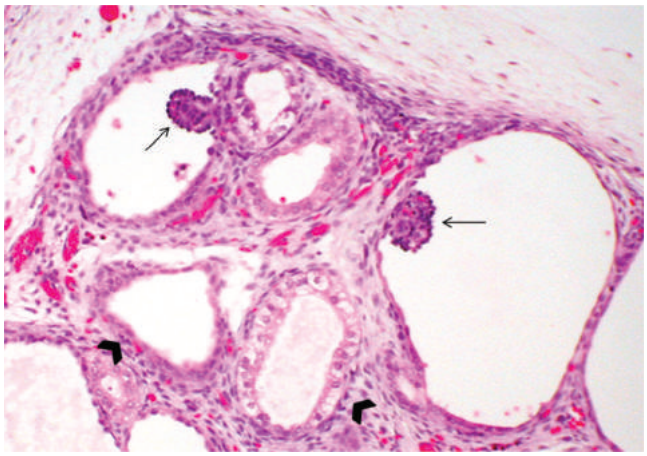
Renal-hepatic-pancreatic dysplasia (RHPD), also called Ivemark syndrome, is an autosomal recessive disorder associated with mutations in *NPHP3*, which encodes nephrocystin 3, a protein that localizes to primary cilia.[80] Patients often present in utero with oligohydramnios caused by kidney dysplasia with peripheral cortical cysts. Hepatic and pancreatic fibrosis is also present, and presentation may appear clinically similar to Alagille syndrome.[81] Most patients develop the oligohydramnios sequence and die of respiratory failure soon after birth, but there are a few reports of survival among patients who received a combined liver-kidney transplant in early childhood.[82]

Glomerulocystic Kidney Disease

Glomerulocystic kidney disease is defined as dilation of the Bowman capsule around the glomeruli with or without tubular dilatation and kidney cysts (Fig. 75.5). It is an autosomal dominant disorder associated with mutations in *UMOD* or *HNF1β* but may also be seen in ciliopathies, kidney dysplasia, or associated with severe fetal kidney damage. *HNF1β* encodes a transcription factor critical to embryologic development of the kidney, pancreas, liver, and müllerian duct. Mutations in *HNF1β* are also associated with maturity-onset diabetes of the young, as in the "renal cysts and diabetes syndrome." *UMOD* encodes uromodulin, which is linked to urinary tract defense but probably has other, currently unknown, functions in the kidney. Glomerulocystic kidney disease often presents in young children with kidney hyperechogenicity on ultrasound, but presentation may be delayed into adulthood. Patients may be hyperuricemic. The kidneys generally progress to ESRD, but the rate of progression is highly variable.[83–85]

Renal Tubular Dysgenesis

Renal tubular dysgenesis is an autosomal recessive disorder associated with mutations in genes for the renin-angiotensin system (*AGT, REN, ACE*, and *AGTR1*) that result in failure of kidney



• **Fig. 75.5** Glomerulocystic Kidney Disease. *Arrows* show glomeruli inside dilated Bowman capsule; *arrowheads* indicate normal tubules. (Courtesy Dr. Laura Finn, Seattle Children's Hospital, Seattle.)

proximal tubule development. Similar pathology may develop if kidney blood flow is interrupted in utero, such as in a major cardiac anomaly, kidney artery stenosis, twin-twin transfusion syndrome, or use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers during the second or third trimesters.

Patients present with severe oligohydramnios by 20 to 22 weeks' gestation, leading to the oligohydramnios sequence. The kidneys may appear normal on ultrasound, or there may be hyperechogenicity or decreased corticomedullary differentiation. The skull may have large fontanelles and sutures. Diagnosis is confirmed by kidney biopsy showing the absence or dramatic reduction in the number of differentiated proximal tubules.

Most patients die in utero or in the neonatal period because of pulmonary hypoplasia and hypotension that is not responsive to standard medical therapy. In cases of refractory hypotension, fludrocortisone may improve the blood pressure; fresh frozen plasma may also be helpful in patients with an angiotensinogen mutation. Of the 150 patients reported with kidney tubular dysgenesis, there are at least 10 reported cases of survivors past 18 months of age, 4 of whom have ESRD and 5 of whom have chronic kidney disease.[86]

Kidney Teratogens

A number of commonly used medications have been associated with abnormal kidney development. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers inhibit nephrogenesis when taken in the second and third trimesters, and they have been associated with kidney tubular dysgenesis, ureteropelvic junction obstruction, and kidney agenesis. Nonsteroidal antiinflammatory drugs, especially indomethacin, are linked to fetal and neonatal kidney failure, probably because of their effects on the ductus arteriosus. Mycophenolate mofetil is associated with a variety of organ anomalies, including kidney anomalies. Tacrolimus may cause a mild and transient decline in kidney function, but the placenta prevents an estimated 60% of the dose from reaching the fetus.[87] The breast cancer drug trastuzumab has been associated with oligohydramnios when used in the second or third trimester and is a US Food and Drug Administration pregnancy category D medication. Gentamicin has been associated with nephrotoxicity in animal studies and two human cases of cystic dysplasia; however, these findings were not confirmed by a large Swedish study.[87] Maternal diabetes is associated with kidney and urinary tract abnormalities, especially if it is present in the first trimester.[88]

Inborn Errors of Metabolism

Multiple Acyl-CoA Dehydrogenase Deficiency

Multiple acyl-CoA dehydrogenase deficiency (MADD), also called glutaric acidemia type II or glutaric aciduria type II, is an autosomal recessive defect in the mitochondrial electron transfer chain caused by mutations in *ETFDH, ETFA*, or *ETFB*. This causes degeneration of cells that use fatty acids as a primary source of energy, including kidney tubular epithelial cells. Affected children present in the neonatal period with lethargy, vomiting, a "sweaty feet" odor, nonketotic hypoglycemia, metabolic acidosis, and organic aciduria. Some will have other congenital anomalies, including a high forehead, low-set ears, wide-spaced eyes, a small midface, kidney dysplasia, and kidney cysts. Most patients who present near birth die within weeks to months despite attempts at treatment with dietary interventions, riboflavin, and L-carnitine. There is a milder, late-onset form of the disease, not associated with kidney anomalies, which may be treated with riboflavin.[89]

Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome is an autosomal recessive disorder of cholesterol synthesis associated with mutations in *DHCR7* affecting 1 in 20,000 to 1 in 70,000. The clinical spectrum is broad, ranging from asymptomatic cases to perinatal lethality. Affected children may have delayed growth, microcephaly with bitemporal narrowing, ptosis, a short nose with anteverted nares, micrognathia, epicanthal folds, and low-set ears. Mental retardation, clef palate, heart defects, genital anomalies, and syndactyly of the second and third toes are common. One-fourth of patients have kidney anomalies, including kidney hypoplasia or agenesis, kidney cortical cysts, or urinary tract anomalies. Due to inability to synthesize steroids, patients may have varying levels of adrenocortical hormone deficiency; however, presentation with acute adrenal crisis is rare.[90]

Zellweger Syndrome

Zellweger syndrome, also called cerebrohepatorenal syndrome, is an autosomal recessive condition associated with mutation in any of 12 pexin genes, usually *PEX1*, leading to peroxisome dysfunction. Affected infants have severe hypotonia, absent reflexes, a high forehead and large anterior fontanelle, small supraorbital ridges, a triangular mouth, and low-set ears with abnormal lobes. There are usually small kidney cysts and calcific stippling of the epiphyses. Severe liver dysfunction typically appears after 3 months of age. Some patients present with seizures caused by abnormal neuronal migration. Death before age 1 year is common, although some patients survive longer with varying developmental outcomes.[91,92]

Congenital Disorders of Glycosylation

The congenital disorders of glycosylation (CDG) are a family of autosomal recessive defects in the synthesis of the glycans of

glycoproteins.[93] Patients can present with a variety of symptoms, including developmental delay, seizures, hypotonia, liver disease, protein-losing enteropathy, and dysmorphic facial features. Patients may have enlarged hyperechoic kidneys on ultrasound and kidney tubular microcysts. Congenital nephrotic syndrome, associated with diffuse mesangial sclerosis pathology, has also been reported.[94] Due to the variability of the condition, management is individualized to a patient's specific clinical presentation.[95]

Acknowledgments

Thank you to Dr. Laura Finn, Seattle Children's Hospital Department of Pathology, for providing kidney pathology images. Thank you to Jennifer McBroom, Seattle Children's Hospital Department of Radiology, for providing ultrasound images.

Developmental Abnormalities of the Genitourinary System

COURTNEY K. ROWE AND PAUL A. MERGUERIAN

KEY POINTS

- A voiding cystourethrogram should be performed in infants with high-grade hydronephrosis or bilateral hydronephrosis.
- Vesicoureteral reflux is more common in male infants and has a high rate of spontaneous resolution.
- Bladder exstrophy repairs are currently delayed to 3 months of age and performed with a dedicated team.
- Nadir creatinine predicts future renal function in posterior urethral valves.
- Current American Urological Association guidelines do not recommend ultrasound for the evaluation of undescended testicles; instead, refer children to a pediatric urologist at approximately 6 months of age.
- Infants with bilateral nonpalpable testicles should be evaluated for possible congenital adrenal hyperplasia; infants with hypospadias and unilateral or bilateral undescended testicles should be evaluated for disorder of sexual development.
- Hydroceles are common in male infants and most resolve by one year of age.

Congenital anomalies of the kidney and urinary tract (CAKUTs) are found in around 0.5% of pregnancies and account for 20% to 30% of all prenatally diagnosed congenital anomalies. They are responsible for about two thirds of all children with chronic kidney disease in developed countries.[1] Ureteropelvic junction obstruction (UPJO) and vesicoureteral reflux (VUR) are the most common CAKUTs. Other forms of CAKUTs include multicystic dysplastic kidneys (MCDK), primary megaureter, duplicated collecting systems, ureterocele, renal dysplasia, and bladder outlet obstruction such as posterior urethral valves (PUVs).[2] There are well-recognized features related to these anomalies in infants, and they include higher incidence of UPJO and VUR in males; UPJO and MCDK are often unilateral; most of these anomalies are associated with VUR; most infants with high-grade reflux have renal dysplasia; and primary megaureter is overwhelmingly found in males. On the other hand, in older children there is a female preponderance of several of these CAKUTs. These anomalies are thought to be a result of defects in the same molecular pathways involved in kidney development. According to the Genitourinary Molecular Anatomy Project, there may be several hundred genes involved in the process of kidney development.[3] The phenotypic spectrum of these CAKUTs is shown in Box 76.1.

• BOX 76.1 Spectrum of Congenital Anomalies of the Kidney and Urinary Tract

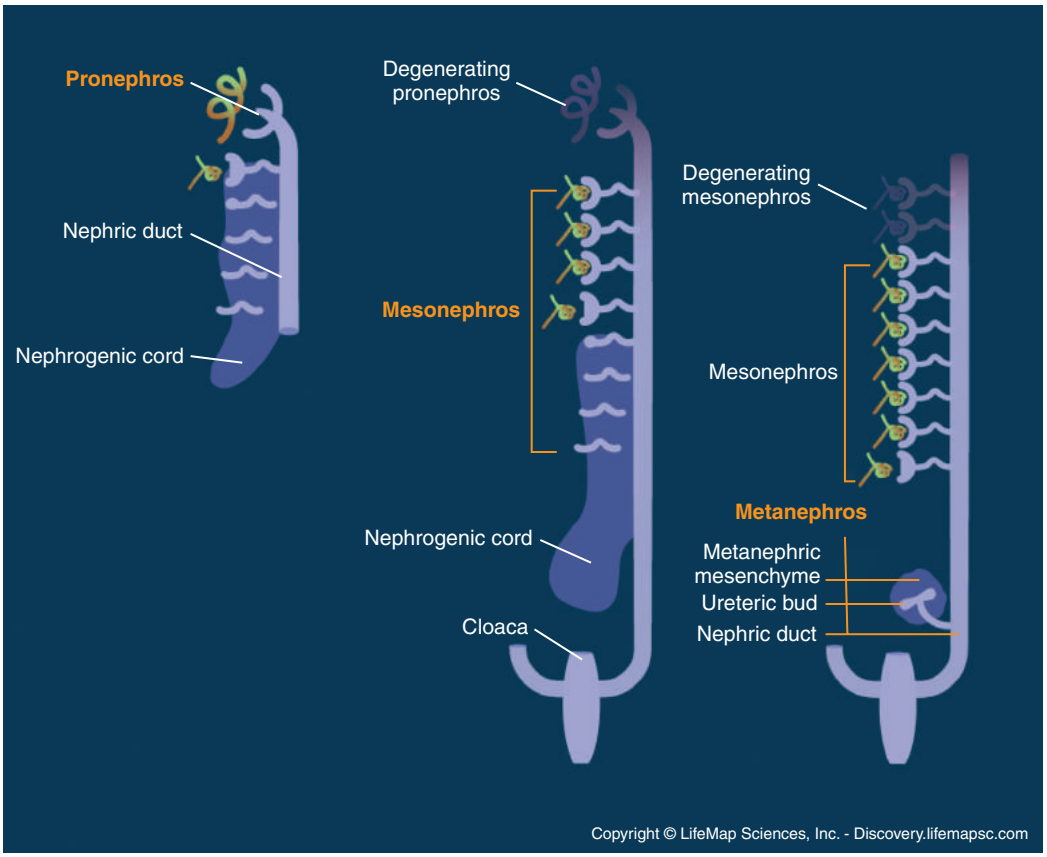
Renal agenesis
Renal dysplasia
Renal hypoplasia
Duplex kidney and ureter
Horseshoe kidney and other fusion anomalies (crossed fused ectopia)
Ureteropelvic junction obstruction
Megaureter (obstructing, refluxing, nonobstructing, nonrefluxing)
Ectopic ureter
Ureterocele

Early Kidney and Urinary Tract Embryologic Development

The development of the kidney and urinary tract begins when the nephric duct (ND) is formed from the intermediate mesoderm (Fig. 76.1). The ND extends caudally and induces the adjacent mesoderm to form two transient kidneys, the pronephros and the mesonephros. The pronephros contains nonfunctional tubules that open into the pronephric duct and disappears at the end of the fourth week of gestation.[4]

The mesonephros then begins to develop and contains well-developed nephrons with vascularized glomeruli connected to proximal and distal tubules draining into the mesonephric duct. The mesonephric duct then fuses with the cloaca and contributes to the formation of the bladder trigone. In the male, it also forms part of the genital system, including the vas deferens, seminal vesicles, epididymis, ejaculatory ducts, and the efferent ductules of the testis.[5] In females, the mesonephros forms vestigial structures, the epoophoron and the paroophoron.[6]

The metanephros is the final stage of renal development and is identified at around 5 to 6 weeks' gestation. This structure consists of two components: the ureteric bud and the metanephric mesenchyme. The ureteric bud forms from the nearby caudal mesonephric (Wolffian) duct and grows to penetrate the metanephric blastema. The reciprocal interaction between the ureteric bud and the metanephric mesenchyme results in branching of the ureteric bud to form the collecting system of the kidney.



• **Fig. 76.1** Development of the Human Kidney.

A mesenchymal-to-epithelial transition of the metanephric mesenchyme at each of the newly formed ureteric bud tips results in the development of the nephrons. With each division of the ureteric bud, a new layer of nephrons is induced from stem cells in the periphery of the organ.[4,7] As development proceeds, the metanephros extends laterally and cranially, ascending from the sacral to the lumbar position by 8 weeks' gestation.[8]

The main ureteric duct (future ureter) undergoes a process of temporary obliteration followed by recanalization of the lumen as the embryo grows. This process begins in the middle zone of the ureter and progresses proximally and distally. In embryos of approximately 17 mm in length the primary ureter forms a solid cord, and in a 23-mm embryo it is totally patent. These observations have given rise to the theory that UPJO and ureterovesical junction obstruction arise from incomplete recanalization of the ureter at its most proximal and distal ends.[9,10]

The ureteral orifice is also transposed from its original budding site on the Wolffian duct into the bladder. This transposition occurs with expansion of the terminal part of the duct and its incorporation into the base of the bladder as the hemitrigone. If, for example, the bud arises caudally on the duct, the orifice becomes incorporated onto a long cornu of the hemitrigone and is therefore laterally displaced. This lateral displacement causes the submucosal tunnel to be short, leading to VUR.[11]

All the branches of the ureteric bud and the nephrons are formed by 34 weeks' gestation.[7] However, these structures will continue to mature after birth. Once matured, humans have an estimated 210,000 to 2.7 million nephrons per kidney.[12]

Anomalies of the Kidney

Renal Agenesis

Renal agenesis is the congenital absence of the kidneys. Renal agenesis can be bilateral or unilateral. Bilateral renal agenesis occurs in roughly 1 in 4000 births, with male predominance.[13] Prenatally, it is discovered in the second or third trimester because of severe oligohydramnios on ultrasound. Findings of absent kidneys, no bladder filling, and lack of renal arteries on color Doppler ultrasonography support the diagnosis.[14] Postnatally, infants are noted to have the characteristic Potter facies with a prominent skin fold from the eye to the cheek, blunted nose, low-set ears, and orthopedic abnormalities, including clubbed legs or fused lower extremities. Lack of adequate amniotic fluid results in pulmonary hypoplasia and respiratory distress.[15] These findings, or lack of urine output within 24 hours, should prompt renal ultrasound. Bilateral renal agenesis is almost universally fatal, with 40% demise in utero due to cord compression, and those born alive surviving for less than 48 hours because of pulmonary compromise. There have been reports of survival of monoamniotic twins discordant for bilateral renal agenesis[16] and reports of bilateral renal agenesis managed with serial amnioinfusion with survival through delivery with successful initiation of peritoneal dialysis,[17] but in general prognosis remains poor.[18] There is an increased prevalence of congenital renal anomalies in relatives, and screening ultrasound has been recommended for parents and siblings of children with renal agenesis.[19]

Unilateral renal agenesis occurs in approximately 1 in 500 to 1000 births. The true incidence can be difficult to measure because of the frequent involution of multicystic dysplastic kidneys. In fetal ultrasounds with a unilateral empty renal fossa, 47% have an absent kidney, while most of the rest have renal ectopia.[20] Unilateral renal agenesis is associated with abnormalities of the paramesonephric and mesonephric ducts, including absence of the ipsilateral uterine horn or vas deferens. Due to the risk of obstruction at the time of menarche, screening for OHVIRA syndrome (obstructed hemivagina with ipsilateral renal agenesis) at puberty should be considered.[21] About a third of children with unilateral renal agenesis will have extra-renal anomalies including gastrointestinal, cardiac, and musculoskeletal;[22] there is also an association with a number of multisystem syndromes.[23] There is an increased risk of contralateral renal anomaly, including UPJO and VUR.[24,25]

Patients with unilateral renal agenesis have a higher risk of end stage renal disease than those with solitary kidney from donor nephrectomy or MCDKD, with 50% requiring dialysis by 30 years of age.[26] Because of the low risk of renal injury, the American Academy of Pediatrics recommends participation in sports for those with solitary kidney, particularly non-contact sports.[27] Children with unilateral renal agenesis should be followed regularly to monitor urine protein, blood pressure, and kidney function blood pressure.[28]

Renal Ectopia and Fusion

Renal ectopia describes a kidney that fails to reach its standard location. The kidney can be pelvic, iliac, abdominal, thoracic, and contralateral or crossed. Renal ectopia occurs in about 1 in 700 infants on ultrasound screenings.[29] Abnormalities of renal ascent during fetal development are thought to be the cause of ectopia. Most patients with renal ectopia are asymptomatic.

Half of ectopic kidneys are hydronephrotic, of which 50% are due to obstruction, 25% are due to vesicoureteral reflux, and 25% are due to abnormal rotation without obstruction.[30] There is a strong association with extrarenal anomalies, which are seen in almost half of patients.[31] An association with genital anomalies is common, and a large number of girls with müllerian anomalies, including cloacal anomalies, are also noted to have ectopic kidneys.[32,33] Because of this, the finding of an ectopic kidney in a female should prompt further investigation. Prognosis for the ectopic kidney is good, with no evidence of adverse effects on blood pressure or renal function.[34]

When the ectopic kidney is located on the opposite side from where its ureter enters the bladder, this is called *crossed renal ectopia*. This is found in 7.5 per 10,000 newborns, and 90% of these kidneys are also fused to the adjacent kidney.[35] The cause of crossed renal ectopia is unknown. The condition is found more commonly in males, and left-to-right crossover is most frequent. Approximately 20% to 40% of patients with crossed renal ectopia also have VUR, and there is a high incidence of associated cardiac, skeletal, genital anomalies with solitary crossed renal ectopia, although it is not known if this is due to the ectopia or the agenesis.[36]

The most common renal fusion abnormality is the horseshoe kidney, which consists of two renal masses on either side of the midline connected by an isthmus of tissue. Horseshoe kidney is found in approximately 1 in 600 on autopsy study.[37] There is male predominance, an association with syndromes such as Edwards syndrome, Down syndrome, and Turner syndrome, and an increase in associated genitourinary anomalies, including hypospadias, undescended testes, bicornuate uterus, septate vagina, and duplication of the ureter.[38] Up to half of children with horseshoe kidney have associated urologic anomalies including VUR and UPJO.[39]

Most patients with horseshoe kidney are asymptomatic, although the incidence of Wilms tumor is higher in patients with horseshoe kidney than in the average population,[40] and about a third develop stones in adulthood.[41] Neither risk is significant enough to justify routine screening of these patients.

Supernumerary Kidney

A supernumerary kidney is a separate or loosely attached renal mass with its own blood supply and collecting system. It is exceedingly rare, with only about 100 cases reported.[42] About 50% have a structural abnormality such as a duplicated system or hydronephrosis, and this condition is usually diagnosed due to infection, obstruction, or urinary incontinence.[43]

Cystic Disease of the Kidney

Cystic diseases of the kidney are classified as having inheritable or noninheritable causes (Box 76.2). Most cases present during the neonatal period.

Autosomal Recessive Polycystic Kidney

Autosomal recessive polycystic kidney disease presents as symmetric enlargement of the kidneys bilaterally due to collecting duct cysts and is associated with biliary dysgenesis and portal fibrosis. This disease used to be referred to as *infantile*; however, mild cases can present later in life. The incidence is estimated at 1 in 20,000 live births, with a mutation of *PKHD1* located on chromosome 6 responsible for this disease.[44] Ultrasound findings of bilateral hyperechoic kidneys with poor corticomedullary differentiation are suggestive, and infants often have Potter facies and respiratory issues due to oligohydramnios. Survival rates have improved overtime; despite this, about 20% of patients die shortly after birth of pulmonary complications.

• BOX 76.2 Cystic Diseases of the Kidney

Inheritable

- Autosomal recessive (infantile) polycystic kidney disease
- Autosomal dominant (adult) polycystic kidney disease
  - Juvenile nephronophthisis and medullary cystic disease complex
  - Juvenile nephronophthisis (autosomal recessive)
- Medullary cystic disease (autosomal dominant)
- Congenital nephrosis (familial nephrotic syndrome) (autosomal recessive)
- Familial hypoplastic glomerulocystic disease (autosomal dominant)
- Multiple malformation syndromes with renal cysts (e.g., tuberous sclerosis, von Hippel–Lindau disease)

Noninheritable

- Multicystic kidney (multicystic dysplastic kidney)
- Benign multilocular cyst (cystic nephroma)
- Simple cysts
- Medullary sponge kidney
- Sporadic glomerulocystic kidney disease
- Acquired renal cystic disease
- Calyceal diverticulum (pyelogenic cyst)

Modified from the American Academy of Pediatrics, Section on Urology.[218]

Those who survive have a high risk of developing childhood renal insufficiency, systemic hypertension, and portal hypertension, with 50% requiring early renal replacement, and many undergoing renal and/or liver transplants.[45]

Autosomal Dominant Polycystic Kidney

Autosomal dominant polycystic kidney disease involves progressive cystic enlargement of bilateral kidneys due to an abnormal form of the protein polycystin. It is the most commonly inherited renal disease, occurring in 1 in 1000 live births, and is attributed to a mutation in the genes *PKD1* and *PKD2* in 90% of cases.[46] While it used to be diagnosed late in life, advances in radiographic imaging have allowed early detection in fetuses and infants.[47] Renal failure progression is variable but typically occurs in adulthood; about 20% of children will have hypertension or proteinuria despite a normal glomerular filtration rate (GFR).[48] Because of this, children with family history or confirmed disease should have regular clinical screening with blood pressure monitoring and urinalysis; routine ultrasounds or "cyst counting" should be avoided in asymptomatic children.[49] There is no need to screen children for associated findings such as cerebral aneurysm or hepatic involvement. Presymptomatic testing to obtain a diagnosis in at risk children is controversial. Tolvaptan was recently approved to slow disease progression in adults and has been used for severe neonatal disease.[50]

Tuberous Sclerosis

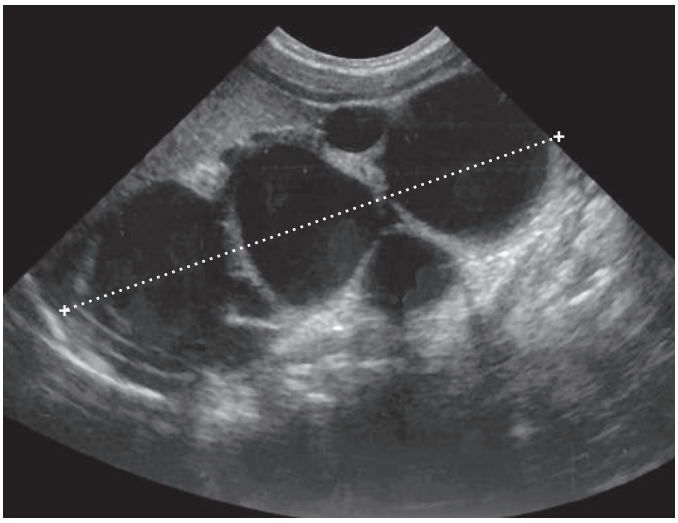
Tuberous sclerosis complex is a neurocutaneous disease that presents with benign hypopigmented skin lesions and is associated with epilepsy or autism. Renal manifestations are the primary source of morbidity in adult patients, and include angiomyolipoma, renal cysts, and oncocytomas.[51] Renal ultrasound should be performed at the time of diagnosis and then every 1 to 3 years to avoid missing a growing angiomyolipoma at risk of spontaneous hemorrhage.[52] First line treatment is with the mammalian target of rapamycin (mTOR) inhibitor everolimus, with surgery reserved for emergent situations.

Multicystic Dysplastic Kidney

Multicystic dysplastic kidney disease is the most common type of renal cystic disease, occurring in 1 in 4300 live births. It is diagnosed based on ultrasound findings of a collection of cysts of various sizes without any evidence of renal parenchyma (Fig. 76.2). There is a male and a left-sided predominance. The cause is unknown. Since 60% of MCDK will involute spontaneously with associated contralateral hypertrophy, early nephrectomy is rarely needed.[53] While vesicoureteral reflux is common in the contralateral kidney, it is rarely clinically significant and so a screening voiding cystourethrogram (VCUG) should be considered only if there are anomalies on the contralateral kidney.[54] Poor neonatal outcomes are generally only found when there are contralateral or extrarenal anomalies. Isolated multicystic dysplastic kidneys typically follow a benign course with hypertension and malignancy occurring at a similar proportion to general population.[55]

Renal Tumor

Malignancies are rare in neonates, and renal tumors make up 7% to 12% of neonatal malignancies.[56] The most common finding of renal tumor is a palpable abdominal mass, but more commonly they are noted on prenatal ultrasound, after which a fetal MRI can help characterize the lesion.[57] The first line of treatment is radical nephrectomy for all unilateral renal tumors. Biopsy before surgery is generally reserved for complex cases such as those with bilateral disease or metastases at presentation.



• **Fig. 76.2** Sonographic view of a multicystic dysplastic kidney in which multiple cysts that do not communicate with one another are grouped together, giving the typical "bunch of grapes" appearance. No function was noted on the patient's renal scan, confirming this diagnosis.

The most common renal tumor in neonates is congenital mesoblastic nephroma, generally diagnosed before 3 months of age. There is a male predominance of 1.5:1. The mainstay of treatment is a radical nephrectomy, and surgery is generally curative in stage I/II tumors, with rare need for chemotherapy. The overall survival rate for congenital mesoblastic nephroma is excellent, around 95%.[58]

Wilms tumor is the second most common neonatal renal tumor. It affects males and females equally and is associated with several syndromes, including Beckwith-Wiedemann syndrome, WAGR syndrome, Denys-Drash syndrome, and Perlman syndrome.[59] Treatment generally begins with radical nephrectomy, although there is increasing evidence that partial nephrectomy in appropriately selected patients is safe and may be preferred for those with bilateral masses or predisposing syndromes.[60,61] After surgery, treatment is based on risk stratification and may include chemotherapy and radiation therapy based on protocols from two international oncologic groups, the Children's Oncology Group and the International Society of Pediatric Oncology. The overall survival rate is high at 90%, but long-term survivors are at risk of cardiac disease, adverse pregnancy outcomes, and renal dysfunction, as well as secondary primary tumors in 16%.[62]

Malignant rhabdoid tumor of the kidney is a rare and aggressive cancer that generally presents at advanced stages. The overall survival rate in neonates is 16%. Other renal tumors in neonates include clear cell carcinoma of the kidney, which presents at advanced stage but for which there is an overall survival rate of 50%, ossifying renal tumor of infancy, which is generally benign, nephroblastomatosis, which is a premalignant condition requiring observation, and cystic nephroma, which is benign but indistinguishable from rare malignancies and therefore generally surgically removed.[63,64]

Renal Vein Thrombosis

The risk factors for renal vein thrombosis include umbilical vein catheterization, perinatal asphyxia, maternal diabetes, and dehydration, as well as the presence of prothrombotic states. The classic presentation is gross hematuria, a palpable flank mass, and thrombocytopenia.[65] Contrast angiography is the gold standard for diagnosis, but because of concerns regarding radiation, Doppler ultrasound is often used as an alternative. This will show enlarged and echogenic kidneys with either absent flow in the renal vein or increased resistance in the renal artery.[66] The current standard is treatment with anticoagulation; thrombolysis can be considered with life-threatening renal vein thrombosis.[67] Optimal targets for anticoagulation have not been established, so adult ranges are generally used.[68] Even with anticoagulation, over 60% of affected kidneys will become atrophic.[69]

Adrenal Hemorrhage

Adrenal hemorrhage occurs after birth in approximately 2 in 1000 live births. While presentation can include prolonged jaundice, palpable abdominal mass, anemia, or scrotal hematoma, these symptomatic cases are less common in the era of ultrasound diagnosis.[70] Predisposing factors include vaginal birth, macrosomia, perinatal hypoxia, birth asphyxia, and sepsis.[71] Treatment is generally supportive and adrenal insufficiency rare. Serial ultrasounds should be obtained to confirm resolution given the rare chance of a fetal neuroblastoma mimicking an adrenal hemorrhage.[72]

Anomalies of the Ureters

Duplication of the Ureters

Ureteral duplication can develop if there are duplicate ureteral buds or early division of these buds. Ureteral duplication occurs in between 0.8% and 1.67% of the population.[73] Ureteral triplication and even quadruple ureters have also been reported in the literature, but are much rarer. Complete duplication results in two separate ureters, while partial duplication results in a bifid renal pelvis with distal confluence into a single ureter. There is a strong genetic link to duplication of the ureter, which occurs in 12% of screened siblings and parents of affected patients.[74] Diagnosis is generally by ultrasound. Some clues can indicate a duplex kidney prenatally, including renal length greater than the 95th percentile with a cyst-like structure in the upper pole surrounded by a rim of parenchyma, two noncommunicating renal pelvises, or a cystic structure in the bladder consistent with a ureterocele.[14] The location of the ureters in the bladder of patients with complete ureteral duplication generally follows the Weigert-Meyer law, with the upper pole ureter found caudal to the lower pole ureter.

About half of patients with duplex kidneys are otherwise asymptomatic, and the anomaly by itself is not thought to have any clinical significance. Duplex kidneys is, however, associated with other conditions; a quarter of patients have upper pole obstruction, usually associated with a ureterocele, 10% have lower pole scarring, and 4% have lower pole VUR.[75] Both lower pole UPJO and rarely upper pole UPJO have been reported, as has upper pole ectopia. Long-term renal outcome is generally related to the presence of these associated conditions, although ureteral duplication itself is a risk factor for a slower rate of spontaneous reflux resolution.[76]

Ureteral Ectopia

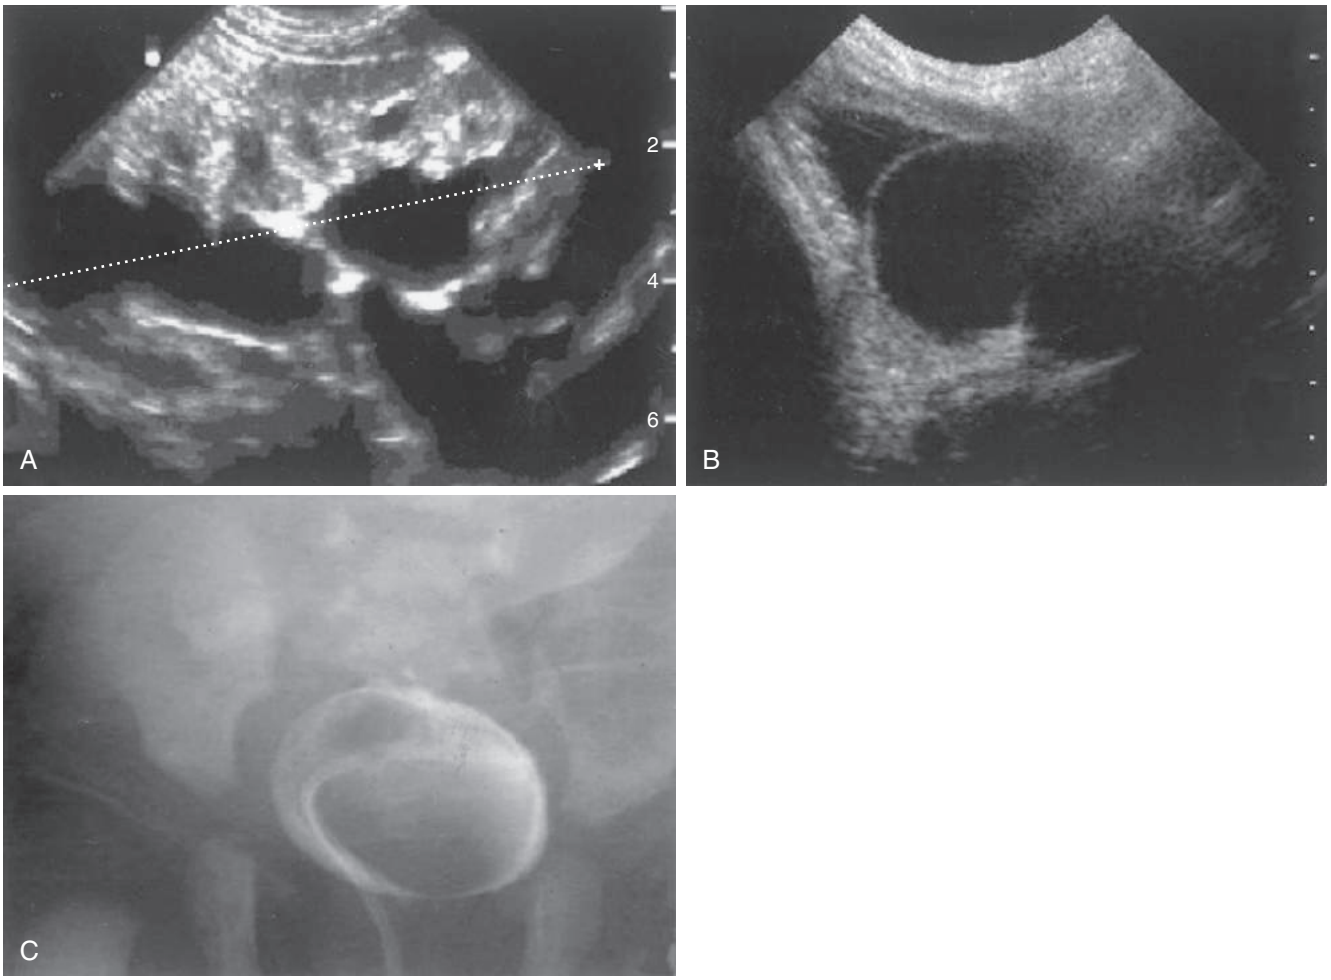
Ureteral ectopia occurs whenever the opening of the ureter is in a position other than the expected location in the bladder trigone. The incidence is 1 in 2000 to 4000 on autopsy study.[77] The cause is thought to be from ectopic location of the initial ureteric bud, and because of the predictable pathway of the bud during embryologic development, these ureters are generally found in predictable locations. The most common form is lateral migration, which is thought to cause vesicoureteral reflux. Medially located ureters are generally found along the path of the Wolffian duct. In males, an ectopic ureter can be found in the bladder neck, the posterior urethra, seminal vesicles, the vas deferens, or the epididymis. In females, an ectopic ureter can be found in the bladder neck, the urethra, the uterus, the proximal part of the vagina, or the Gartner duct.

In males, the ectopic ureter can present with dilatation or infection of the structure into which it inserts. In females, the ectopic position is more likely to be distal to the urethral sphincter, resulting in continuous incontinence, which is often discovered after failed attempts at toilet training. Ectopic ureters are generally from the upper pole of a duplex kidney. While single-system ureteral ectopia occurs, it is difficult to diagnose because of the association with poor renal function on that side. Single-system ureteral ectopia should be considered in females who present with continuous urinary incontinence and what appears to be a solitary or duplex kidney on conventional imaging.[78] Dimercaptosuccinic acid scanning and computed tomography are the most sensitive techniques for diagnosis, although ultrasound, MRI, and intravenous pyelogram can also detect a single-system ectopic ureter.[79]

Ureterocele

A ureterocele is a cystic dilatation of the distal submucosal or intravesical ureter that results in obstruction of urine flow. Ureteroceles occur within a single system or a duplex system. If the system is duplex, the ureterocele is associated with the ectopic upper pole. Ureteroceles occur in between 1 in 500 in autopsy series.[80] The cause is thought to be failure of apoptosis of a distal membrane at the ureteral orifice known as the *Chwalle membrane*. Because of familial occurrence a genetic cause is suspected.[81] Ultrasound of ureteroceles shows hydronephrosis associated with a cystic structure within the bladder (Fig. 76.3). Most ureteroceles are diagnosed prenatally and have been detected as early as 16 weeks.[82] Symptoms include infection, retention, or prolapse through the urethra in a female, which generally presents as a bulging vulvar mass.[83]

Multiple options have been described for management of ureteroceles, and there is no clear consensus.[84] If the child has no infections, minimal associated vesicoureteral reflux, and either no obstruction or an already nonfunctioning portion of the kidney, close observation without intervention can have good outcomes.[85] For patients who require treatment, transurethral incision or puncture provides decompression in a minimally invasive fashion, although it can result in secondary vesicoureteral reflux. It is most successful as a definitive operation in patients with intravesical single-system ureteroceles and can also be used as an urgent temporizing measure in septic, obstructed children.[86] Fetoscopic incision and puncture has been successful, as has bedside puncture without anesthesia.[87,88] More definitive surgical procedures include ureteroureterostomy, ureteropyelostomy, and ureterocele



• **Fig. 76.3** Images demonstrating upper pole hydronephrosis that is secondary to a dilated ureter (A), which empties into a larger ureterocele within the bladder, evident in (B). There is also secondary dilatation of the lower pole renal pelvis. The ureterocele is demonstrated as the cystic filling defect on bladder views from the ultrasound study (B) as well as the voiding cystourethrogram (C).

excision with reimplantation into the bladder for functioning renal units or nephrectomy or heminephrectomy for nonfunctioning renal units. Regardless of the management selected, most children do well in the long term, with low risk of major bladder dysfunction.[89]

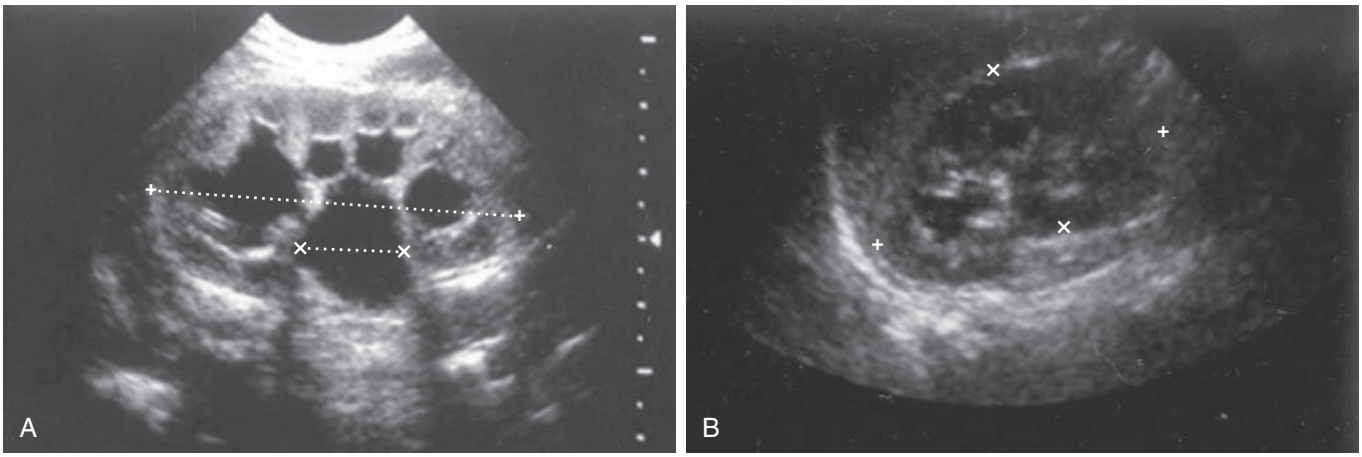
Ureteropelvic Junction Obstruction

Ureteropelvic junction obstruction (UPJO) refers to a blockage where the renal pelvis meets the ureter (Fig. 76.4). It occurs in an estimated 1 in 1500 live births and is the most common cause of prenatal hydronephrosis, accounting for 41% of cases.[90,91] UPJO in newborns and infants is generally caused by intrinsic narrowing of the area, while in childhood and adolescence it is generally caused by extrinsic compression by an accessory vessel to the lower pole of the kidney. Because of increased prenatal ultrasound screening, many cases are diagnosed prenatally. Delayed presentations can occur with flank pain, nausea, and emesis later in life. Diagnosis of functional obstruction is confirmed with a diuretic renogram or MR urography.

Between 23% and 51% of patients with UPJO will require intervention because of worsening hydronephrosis or decreasing renal function.[92,93] Surgery is still primarily performed in an open fashion, but laparoscopic or robotic surgery is at least as successful.[94,95] While surgical success rates are between 90% and 100%, patients are still at risk of later development of hypertension and proteinuria.[96] Half of patients with UPJO will have other urologic anomalies, including contralateral obstruction and VUR.[97] A routine VCUG is generally recommended if UPJO is present, although some pediatric urologists are questioning the benefit of this invasive test because of the high prevalence of clinically insignificant reflux.[98,99]

Ureterovesical Obstruction

Ureterovesical obstruction, also sometimes called an *obstructed megaureter*, refers to a blockage where the ureter meets the bladder. The cause is thought to be an adynamic segment of the distal ureter with insufficient peristalsis.[100] Megaureter accounts for 5% to 10% of prenatal hydronephrosis, and up to 80% of cases resolve without the need for intervention.[101,102] The true incidence of obstructed megaureter is not known. As with UPJO, ureterovesical obstruction is confirmed with the functional study of a diuretic renogram since not all megaureters are obstructed.



• **Fig. 76.4** An example of prenatal hydronephrosis consistent with a partial ureteropelvic junction obstruction (A) that spontaneously resolved over a 6-month period (B).

Surgical management can be with endoscopic treatment or open or robotic reconstruction.[103,104]

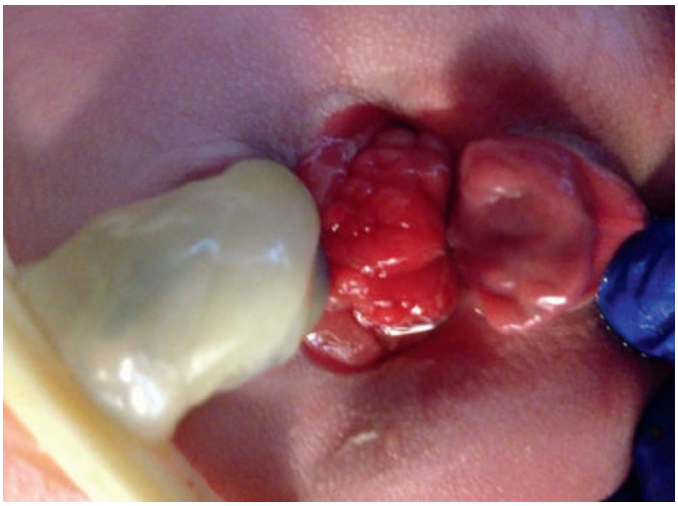
Vesicoureteral Reflux

Vesicoureteral reflux describes retrograde flow of urine from the bladder to the ureters. The normal ureterovesical junction is designed with a long intramural tunnel through which the ureter travels before reaching the bladder and prevents retrograde flow of urine. Primary VUR is thought to be due to an abnormal or immature formation of this area, allowing urine to reflux from the bladder into the ureters and kidneys.

As many as 17% of all children may have VUR, including 31% to 36% of those who develop a urinary tract infection.[105,106] The first sign of VUR is often hydronephrosis on the prenatal ultrasound, with 20% of these infants eventually found to have reflux.[107] Neonates with a history of unilateral prenatal hydronephrosis should undergo ultrasound again within the first week of life. If the hydronephrosis was bilateral or in a solitary kidney, the ultrasound should be done before discharge from the hospital.[101] Patients with high-grade hydronephrosis on late prenatal or postnatal imaging should be screened with a VCUG.[108]

VUR is graded after a VCUG from I to V. Lower-grade reflux is more likely to resolve spontaneously without the need for intervention, with early resolution rates of 13% yearly for grades I to III and 5% for grades IV and V.[109] Continuous antibiotic prophylaxis is recommended for infants with grade III to V VUR or any grade if the infant has a history of febrile urinary tract infection. There is evidence that prophylaxis prevents recurrent infections, but its benefit in terms of renal scarring is less clear.[110] Other options for reducing the risk of urinary tract infection are circumcision or early preputial retraction using a prescription steroid cream.[111,112] Breakthrough infections despite continuous administration of prophylactic antibiotics generally trigger a change in the antibiotic or surgical correction via an open or endoscopic approach.

About 27% of siblings and 36% of children of patients with VUR will have reflux. A screening ultrasound can be considered, with a VCUG pursued if there is evidence of renal scarring or a history of urinary tract infection.[113]



• **Fig. 76.5** Male patient with bladder exstrophy showing exstrophied bladder, low umbilicus, and penile and urethral defect.

Anomalies of the Bladder

Bladder Exstrophy

Bladder exstrophy and epispadias are congenital anomalies that have characteristic external physical manifestations. The anterior portion of the bladder and/or urethra and abdominal wall structures are deficient, and the symphysis pubis is widely separated from the midline (Figs. 76.5 and 76.6).

Bladder exstrophy has been described as "if one blade of a pair of scissors were passed through the urethra of a normal person; the other blade were used to cut through the skin, abdominal wall, anterior wall of the bladder and urethra, and the symphysis pubis; and the cut edges were then folded laterally as if the pages of a book were being opened."[114] Bladder exstrophy is usually found in isolation, with other organ systems, including the kidneys, rarely affected. The incidence of bladder exstrophy is an estimated 1 per 50,000 live births, and it is about twice as common in males than females.[115] The pathogenesis of exstrophy is thought to be caused

• **Fig. 76.6** Female patient with bladder exstrophy showing exstrophied bladder and bifid clitoris.

by persistence of the cloacal membrane during development. This, in return, prevents the mesoderm from fusing in the midline. The persistent cloacal membrane then ruptures to produce an exstrophic condition.[116]

Ultrasonography can reliably detect exstrophy with the following findings: (1) an absent or nonfilling bladder, (2) a mass protruding from the abdominal wall, (3) normal kidneys with a low-set umbilicus, (4) widened pubic diastasis, and (5) a smaller penis with anteriorly displaced scrotum.[117,118] Fetal MRI can also aid in diagnosis. Prenatal diagnosis allows better counseling of parents as the overall prognosis of these children is excellent if they are treated in specialized centers. Counseling of families by healthcare providers unfamiliar with the long-term outcomes is associated with an increase in the abortion rate for these fetuses.[119]

Management after delivery includes ligation of the umbilical cord with silk suture rather than plastic or metal clamp to prevent trauma to the exposed bladder. A transparent film, hydrated gel, or even plastic wrap placed on the exposed bladder protects it from superficial trauma. The dressing should be replaced daily, and the bladder irrigated with saline with each diaper change. A renal ultrasound and a pelvic radiograph should be performed to evaluate the kidneys and the pubic diathesis. If a sacral dimple is found, a spinal ultrasound should be performed to rule out spinal cord tethering.

Surgical management has evolved, with most centers today performing a complete primary repair of exstrophy, which includes closure of the bladder exstrophy, reconstruction of the bladder neck, repair of the dorsal chordee, repair of epispadias with urethroplasty, and bilateral iliac osteotomies. Some still advocate a staged repair with closure of the bladder exstrophy and bladder neck as the first stage and repair of the epispadias as a second stage.[120,121] Ureteral reimplantation is sometimes performed at the time of bladder closure; if not children develop VUR after surgery and are often given antibiotic prophylaxis for the first 18 months of life.[122]

The timing of repair has also undergone some recent changes. In the past these repairs were primarily performed at birth. Recently many have advocated delayed closure at around 3 months of age, and this was based on studies showing that delayed closure does not compromise the rate of bladder growth.[123–125] Delayed closure allows better coordination of care between the teams of urologists, orthopedic surgeons, anesthesiologists, and operating room staff. Moreover, it allows the child to bond with the parents and allows penile growth to occur because of the physiologic surge of testosterone.

The goal of reconstruction includes preservation of renal function, urinary continence with volitional voiding, and functional and cosmetically acceptable external genitalia. With the primary repair, volitional voiding can be achieved with a single operation in around 40% of children, with around 40% requiring further bladder neck reconstruction at age 4 to 5 years to achieve continence. A small percentage of patients with small bladders will require reconstruction, including bladder augmentation and use of intermittent catheterization.[126]

Cloacal Exstrophy

Patients with cloacal exstrophy have multiple organ systems affected, and as a result it is also referred to the *OIES complex* (omphalocele, exstrophy, imperforate anus, and spinal defects). Other organ systems affected may include the extremities, the upper urinary tract, and the cardiovascular, pulmonary, and craniofacial systems. In this condition the hindgut is also open to the abdominal wall and separates the hemibladder plates.

Before the 1960s cloacal exstrophy was considered incurable, with a very high mortality rate. In the past 2 decades, survival rates have increased to close to 100%.[127] The principles of management include neurologic evaluation for assessment of myelomeningocele, neonatal closure of omphalocele and intestinal diversion using the exstrophied hindgut, approximation of bladder halves, delayed bladder exstrophy closure with placement of the bladder deep in the pelvis, and iliac osteotomies.[128]

Patent Urachus

The urachus is a tubular structure that connects the urogenital sinus and the allantois. It begins to narrow at between 4- and 5-months' gestation, generally being obliterated before birth. A patent urachus is often diagnosed because of drainage of clear fluid from the umbilicus. While ultrasound will often show the anomaly, a VCUG or sinogram can be used to confirm the diagnosis.[129] Because the urachal remnant resolves spontaneously in up to 80% of cases, surgery is generally avoided in patients younger than 1 year.[130] While malignant transformation in adulthood is possible, it is so rare that these are generally only removed if symptomatic.[131] If a urachal anomaly is excised, this can be performed via the open or laparoscopic approach.

Posterior Urethral Valves

PUVs are a congenital obstruction of the posterior urethra. They are the most common cause of bladder outlet obstruction in newborn males, affecting approximately 1 in 4000 live births.[132] Importantly, PUVs occur only in males. PUVs have been classified into three types. Type 1 valves account for the majority of PUVs, with leaflets of tissue arising from the verumontanum and

fusing in the midline. Type 2 valves have not been described since the initial reports and likely do not exist. Type 3 valves are an annular ring thought to be due to persistence of the urogenital membrane.[133] This classification has been challenged, with some arguing that the different types are due to postnatal rupture or instrumentations.[134]

Prenatal ultrasound is often able to detect PUVs. The classic findings include a thickened, dilated bladder with bilateral hydroureter, especially in the presence of oligohydramnios and a dilatated posterior urethra with the "keyhole sign," although some of these anomalies may be present in urethral atresia as well.[135] A VCUG is used to confirm the diagnosis after birth and will clearly show the obstructing membranes in the urethra (Fig. 76.7).

PUVs have consequences for multiple organ systems. Pulmonary hypoplasia and Potter facies can be seen if the obstruction was severe enough to cause oligohydramnios. Renal dysplasia is common and can lead to progressive renal failure later in life, often associated with polyuria and nephrogenic diabetes insipidus. The bladder is generally small, with poor compliance that progresses to myogenic failure over time. The ureters often remain chronically dilated.[100]

Initial management of PUVs involves support in the neonatal intensive care unit and passage of a urinary catheter for drainage. There is some evidence that inflation of a catheter balloon can cause ureteral obstruction in the valve bladder, and so this should be avoided.[136] Once the infant is stable to undergo the procedure, the valves are ablated endoscopically. Vesicostomy is reserved for infants with urethras that are too small to accommodate the scope, though progressive urethral dilation via catheters has been described.[137]

Long-term renal outcomes with PUVs are poor, with 20% to 60% of boys progressing to end-stage renal disease. Nadir creatinine level is predictive of eventual renal outcome, with initial creatinine nadir level greater than 1.0 mg/dL generally used in modern series as the cutoff to predict a high risk of future renal damage.[138,139] The bladder decompensates to an overly large bladder with poor sensation and elevated postvoid residuals that often require overnight catheter drainage or clean intermittent catheterization.[140]

In the past decade several fetal interventions have been trialed for PUVs. These include vesicoamniotic shunting and fetoscopic valve ablation. While oligohydramnios abates and perinatal mortality is reduced, there is no evidence of a decrease in the percentage of patients who progress to end-stage renal disease.[141]

• **Fig. 76.7** This voiding cystourethrogram shows a classic posterior urethral valve, with narrowing of the urethra at the most distal end of the prostate. This area corresponds to a flap of tissue that serves as an obstructing valve leaflet.

Genital Abnormalities in Males

Cryptorchidism

Cryptorchidism, also known as *undescended testicle*, is one of the most common congenital anomalies. The incidence is variable and dependent on gestational age. The incidence ranges from 1% to 4.5% in full-term infants and from 30% to 45% in premature infants. During the first 3 to 6 months of life the testicle may spontaneously descend such that the incidence at 1 year of age is around 0.8% to 1.2%.[142] Diagnosis is made on physical exam. Ultrasound is not recommended given poor sensitivity and specificity.[143]

Cryptorchidism is commonly seen in healthy infants but can occur in conjunction with more than 400 syndromes.[144] Abnormal gubernacular attachment or migration is the theorized etiology, and the cause is thought to be multifactorial and includes familial predisposition and environmental exposure (phthalates, pesticides, flame retardants).[145] It has also been included in "testicular dysgenesis syndrome," a mechanism that interferes with normal fetal testicular development and includes undescended testicles and genitourinary disorders such as hypospadias, semen production abnormalities, and infertility.[146] A newborn who appears phenotypically male with bilateral nonpalpable gonads should be evaluated for possible difference of sexual differentiation (DSD) such as congenital adrenal hyperplasia (CAH). Patients with a unilateral nonpalpable testicle and hypospadias should also be evaluated for a DSD; namely, mixed gonadal dysgenesis or ovotesticular DSD.[147]

The most recent American Urological Association guidelines on the management of cryptorchidism state: "Providers should refer infants with a history of cryptorchidism (detected at birth) who do not have spontaneous testicular descent by six months (corrected for gestational age) to an appropriate surgical specialist for timely evaluation (Evidence Strength: Grade B)".[147] The main reasons for treatment are risk of impaired fertility potential, testicular cancer, and testicular torsion. The number of spermatogonia per tubule is adversely affected in boys with undescended testicles beyond 1 year of age, and therefore it is recommended that orchiopexy be performed early to minimize germ cell loss, ideally between 6 and 18 months of age.[148] Surgically bringing the testicles into the scrotum may reduce but does not prevent long-term sequelae such as reduced fertility and cancer.[147]

Testicular Tumors

There is a bimodal age distribution for the incidence of testis tumors, with one peak occurring during the first 2 years of life and a second, larger peak occurring in young adulthood. The incidence of pediatric testis tumors is 0.5 to 2.0 per 100,000 children, accounting for only 1% to 2% of all pediatric tumors.[149]

Teratomas are the most common benign tumors in prepubertal patients. Cases have been described from 6 days to 13 months.[150] Testis-sparing surgery is a consideration for prepubertal children, but frozen sections should be obtained to confirm the diagnosis. Orchiectomy is necessary if the entire testicle is involved.

Testicular Torsion

This is a rare event, and its management is controversial. The newborn presents with swelling of the hemiscrotum with or without discomfort. In this condition the testicle, epididymis, and tunica vaginalis twist around the spermatic cord (extravaginal torsion). This condition may be unilateral or bilateral, and the bilateral torsion can either be synchronous or asynchronous. The cause is unknown, but it is theorized that complicated pregnancies and vaginal delivery are predisposing factors.[151]

The presentation depends on when the torsion occurred. If torsion occurs several days before birth, the newborn will have a firm painless scrotal mass. If it occurred hours before birth, the newborn usually has a painful, enlarged, and high-riding testicle.[151] Diagnosis is usually made by physical examination and Doppler testicular ultrasonography showing no blood flow to the testicle.

Management of neonatal testicular torsion is controversial. Because of the low salvage rate and risk of surgical or anesthetic complications, some advocate conservative management.[152] Most pediatric urologists, however, advocate immediate surgical exploration. The rationale behind this recommendation is that viability of the testicle can be assessed only surgically. Moreover, asynchronous torsion has been described in 3% of cases, and fixing the normal testicle in place before this happens will prevent anorchia.[153]

Hydrocele

Hydroceles describe persistent fluid within the tunica vaginalis adjacent to the testicle. They occur in more than half of newborn male infants, and most at this age fluctuate in size due to a persistent communication of the processes vaginalis with the peritoneum.[154] In the absence of an associated hernia or undescended testicle, 90% of communicating hydroceles will resolve spontaneously by 12 months of age.[155] If surgery is needed, it can be performed open or laparoscopically.

Hypospadias and Chordee

Hypospadias and chordee is one of the most common abnormalities of the penis and occurs in 1 in every 250 to 300 male births worldwide, or around 0.3% of all male births.[156] From an analysis of all boys born in Denmark between 1973 and 2005, it was found that the relative recurrence risk for a brother to have hypospadias was 13.4 (95% confidence interval [CI] 11 to 16.4) and 10.4 (95% CI 7.54 to 14.4) for offspring of an affected male. The risk in same-sex twins was 50.8 (95% CI 34.2 to 75.5).[157]

The term *hypospadias* describes a urethral opening more proximal than the tip of the glans. This difference is a spectrum that includes an abnormal ventral curvature (chordee) of varied degree, a dorsally hooded foreskin, and penoscrotal transposition. The spectrum ranges mild chordee without hypospadias to severe chordee and hypospadias with the meatus in a perineal location. A small group of patients will have a normally formed foreskin such that the hypospadias is discovered at the time of circumcision or preputial retraction. These children also have a wide urethral plate and thus are described as having megameatus intact prepuce variation of hypospadias.[158]

In most patients, hypospadias is the only atypical finding. But there are over 200 syndromes that include hypospadias, including the Wilms tumor, aniridia, genitourinary malformations, and intellectual disability (WAGR) and the Denys-Drash syndrome.[159] The most common associated anomaly is cryptorchidism, which is reported in around 3% of infants with distal hypospadias and in up to 10% of infants with proximal hypospadias.[160] In one study chromosomal anomalies were found in 22% of patients with hypospadias and cryptorchidism.[161] DSD such as CAH and mixed gonadal dysgenesis should be considered when hypospadias is found with either a unilateral or bilateral undescended testicles.[162,163]

Hypospadias is usually classified based on the location of the meatus: distal portion of the shaft, midshaft, proximal portion of the shaft; penoscrotal, scrotal, perineal. This classification, however, is not sufficient to explain the complexity of the defect. Because of this, a classification system called the *GMS score* (glans, meatus, shaft) has been used that includes a scale of 1 to 4 for each component (glans size and urethral plate quality, meatal location, and degree of shaft curvature), with the more unfavorable characteristics assigned higher scores. This new scoring system provides a means by which hypospadias severity can be standardized and surgical outcomes better classified.[164,165]

Hypospadias repair is undertaken to allow for straight erections and standing to void. Surgery is generally performed between 6 and 18 months of age, with the more extensive repairs sometimes postponed until after the age of 1 year.[166,167] A two-stage repair is advocated for those with severe hypospadias and chordee (Fig. 76.8).[168] If the phallus is small, testosterone injections may be given to increase phallic size and facilitate repair, but it is unclear whether this increases or decreases postoperative complications.[169] Poor response to testosterone injections may reveal children with androgen insensitivity.[170] Reported outcomes after hypospadias repair have historically been limited by short follow-up; modern series report complications requiring an unplanned additional

• **Fig. 76.8** Severe Scrotal Hypospadias with Chordee. The opening is in between the scrotal folds.

surgery in 12% to 17% for distal hypospadias and around 50% to 60% for proximal hypospadias.[168,171,172]

Phimosis

Phimosis is a condition in which tight foreskin cannot be pulled back over the head of the penis. In phimosis, the prepuce forms as a roll of epithelium that fuses ventrally at the frenulum. Once formed, the inner preputial surface fuses with the glans epithelium and may not separate from it until later in childhood. In the process of separation, cystic spaces between the two layers may form and fill with desquamated epithelium that form white beads or infantile smegma. These may be quite large and present as a mass under the foreskin. They eventually drain spontaneously. Incomplete formation of the prepuce is associated with other penile anomalies such as hypospadias, chordee, and epispadias.

Current recommendations for phimosis are to allow the foreskin to separate from the glans and to consider management if the phimosis does not resolve during childhood or by 5 to 7 years of age. Forcible retraction of the foreskin is contraindicated as this produces tears in the foreskin that will result in scarring that leads to pathologic phimosis, inflammation, and infection (posthitis).

The benefits of circumcision at birth have been the subject of debate and controversy. An American Academy of Pediatrics statement indicates that circumcision may have benefits in reducing the risk of urinary tract infections (UTIs) and sexually transmitted diseases.[173] On the other hand, the Canadian Pediatric Society concluded that since the benefits do not exceed the risks, circumcision should be performed only in boys in high-risk populations or circumstances.[174]

The most common complications of newborn circumcision include bleeding, infection, formation of penile adhesions between the skin and the glans, and incomplete circumcision. Other less common complications include iatrogenic amputation of the glans, loss of penile skin, and injury to the urethra.[175] When newborn circumcision is being discussed with the parents, it is important to discuss the pros and cons of circumcision, including the possible benefits, risks, and complications.

Other Penile Anomalies

Webbed Penis

Webbed penis, also called *penis palmatus* or *penoscrotal fusion*, is a congenital condition where the scrotal skin extends to the ventral penile shaft with deficient ventral penile shaft skin. The penile shaft may be buried in the scrotum. The urethral meatus and the penile shaft are generally not impacted.[176]

If a circumcision is desired, it should not be performed as a newborn as outcomes will be poor. These infants should be referred to a specialist for repair after 6 months of age, which will include use of the foreskin to cover the ventral penile shaft and recreation of the penoscrotal and penopubic junction.[177]

Buried Penis

Buried penis, also known as *hidden penis*, is a congenital condition where the penis is partially or completely hidden below the surface of the skin, generally due to excessive prepubic fat or a lack of anchoring of the skin to the base of the penis. Large scrotal masses such as hernias or hydroceles can also lead to this appearance. Buried penis can sometimes lead to ballooning of the foreskin during voiding. Families may worry about the size of the penis, but the true length of the penis can easily be palpated through the skin when the suprapubic fat is depressed.[178]

If a circumcision is desired, it should be performed by a specialist after 6 months of age. Otherwise, if there are no symptoms, then no treatment is needed as most children lose their excessive prepubic fat with growth and puberty.

Micropenis

This is a congenital *condition* defined as a phenotypical male with expected internal and external genitalia with a stretched penile length 2.5 standard deviations below the mean (Table 76.1). Stretched penile length is measured by pressing the suprapubic fat pad down with a firm tool like a ruler, gently stretching the penis, and measuring from the pubic ramus to the top of the glans.[179] The reported incidence of this condition is 1.5 in 10,000 male births.[180]

Aphallia

Agenesis of the phallus is very rare and occurs in 1 in 10 million to 1 in 30 million live births. This suggests an early embryologic failure in development of the genital tubercle. The urethra is located in the perineum or rectum. The karyotype is mostly 46XY, but females have been described with absence of corporal bodies.[181] More than half of patients with aphallia will have an associated anomaly, such as renal agenesis, horseshoe kidney, skeletal and neural disorders, and imperforate anus. Male children were previously raised as females, but this practice has been abandoned. These children have normal testicles, with normal testosterone production and normal spermatogenesis, and should be raised as males. With improvements in phallic reconstruction and in vitro fertilization, these patients can father children and have the potential of having a functional phallus.[182]

Epispadias

Epispadias is characterized by failure of the urethral plate to tubularize on the dorsum, with a defect ranging from the glandular to the phallopubic location. Male patients also have dorsal curvature or chordee where females have a bifid clitoris.[183] This condition is usually associated with bladder exstrophy but can appear as an isolated defect. The incidence is around 1 in 117,000 males and 1 in 150,00 to 1 in 300,000 females.[184]

Those with the more proximal defects (penopubic) are incontinent because of incompetence of the bladder neck, but urinary incontinence has also been reported in the more distal defects.[185]

TABLE 76.1 Stretched Penile Length by Age

Age	Mean (cm)	SD (cm)	Mean − 2.5 SD (cm)
Preterm newborns, 30 weeks	2.5	0.4	1.5
Preterm newborns, 34 weeks	3.0	0.4	2.0
Term newborn	3.5	0.4	2.5

SD, Standard deviation.

There are different techniques for repairing this defect, with the proximal defects also requiring a bladder neck reconstruction for continence.[186] The current recommendation is to delay repair of these defects until 3 to 6 months of age. The more proximal defects (penopubic) will also require a bladder neck reconstruction including pelvic osteotomies to place the bladder neck area in an anatomically correct location, deep in the pelvis.

Urethral Duplication

This is an uncommon anomaly and can present as a complete or partial duplication. It is more common in males than in females. The two urethras are oriented in an anteroposterior plane, with the ventral urethral meatus being the functional urethra and the dorsal urethra being stenotic.[187] In females, urethral duplication may accompany cloacal anomalies and be associated with duplication of the bladder.[188]

Disorders of Sexual Differentiation

Chapter 85 in this text provides a full review of disorders of sexual differentiation. These patients pose a difficult diagnostic and therapeutic challenge and require a multidisciplinary approach to evaluation and management, including genetics, urology, gynecology, endocrinology, social work, and pediatric psychiatry.

Any phenotypically looking male, even if completely masculinized, with bilateral nonpalpable gonads should be evaluated for CAH. Failure to do so may result in an Addisonian crisis due to salt-losing adrenogenital syndrome.

Urinary Tract Infections

UTIs are the most common serious bacterial infection in infants, with a higher prevalence in males than females.[189] Uncircumcised male infants appear to be at increased risk, with a 2.15% incidence of UTIs during the first year of life, while females have a 2.05% incidence and circumcised males a 0.22% incidence.[190] A retractable foreskin appears to reduce UTIs, and steroid cream can be used if physiologic phimosis is present.[112,191]

Newborns with culture-documented UTI should be evaluated with at least a renal ultrasound. Some advocate a VCUG or DMSA in addition.[192] If any findings are abnormal, a VCUG should be performed.

Myelodysplasia

Spina bifida and meningomyelocele occur when the neural tube fails to close due to a lack of folic acid during pregnancy. They are found in approximately 36 per 100,000 live births in the United States.[193] The urinary tract is involved in most of these children given the location of the bladder nerves. Increased bladder pressures and impaired bladder function due to the neurologic deficit eventually result in hydronephrosis and ultimately renal damage. The urologic goal of treating children with myelomeningocele is preventing upper tract deterioration.

In utero closure of myelomeningocele has resulted in reduced need for shunting and improved motor outcomes.[194] Open prenatal surgery has not significantly reduced the need for clean intermittent catheterization, but fetoscopic treatment has shown more impact on urodynamic function.[195,196]

All children should be evaluated with a renal ultrasound. Urodynamic studies are currently recommended early in life to risk-stratify children into those at high risk of renal damage (those with high-pressure bladder, high leak point pressures, dyssynergic voiding) and those at low risk (normal bladder compliance, low leak point pressure).[197]

An indwelling catheter is placed in the immediate postclosure period, and clean intermittent catheterization is implemented every 3 to 4 hours. Parents should be taught to perform clean intermittent catheterization, but continuing catheterization if volumes are low is controversial. Early initiation of clean intermittent catheterization may decrease the need for future reconstruction such as bladder augmentation.[198,199]

These children should be treated by a multidisciplinary team that includes neurologists, neurosurgeons, urologists, and orthopedic surgeons.[200]

Prune-Belly Syndrome

Prune-belly syndrome, also known as *Eagle–Barrett syndrome*, is a rare defect occurring in about 1 in 40,000 births, 95% of them male (Fig. 76.9). This condition is usually characterized by the triad of abdominal wall deficiency, cryptorchidism, and dilatation of the urinary tract, including severe hydroureteronephrosis, bladder distension, and urethral dilatation.[201]

Prognosis ranges from death in utero to near normal life expectancy. Management of the disorder depends on the severity of the symptoms. Patients with incomplete bladder emptying and recurrent UTIs may require a vesicostomy. All male children will have to undergo bilateral orchiopexy before the age of 1 year. Some children will require urinary tract reconstruction or reconstruction of the abdominal wall, and up to 40% will develop chronic kidney disease.[202]

VACTERL Association

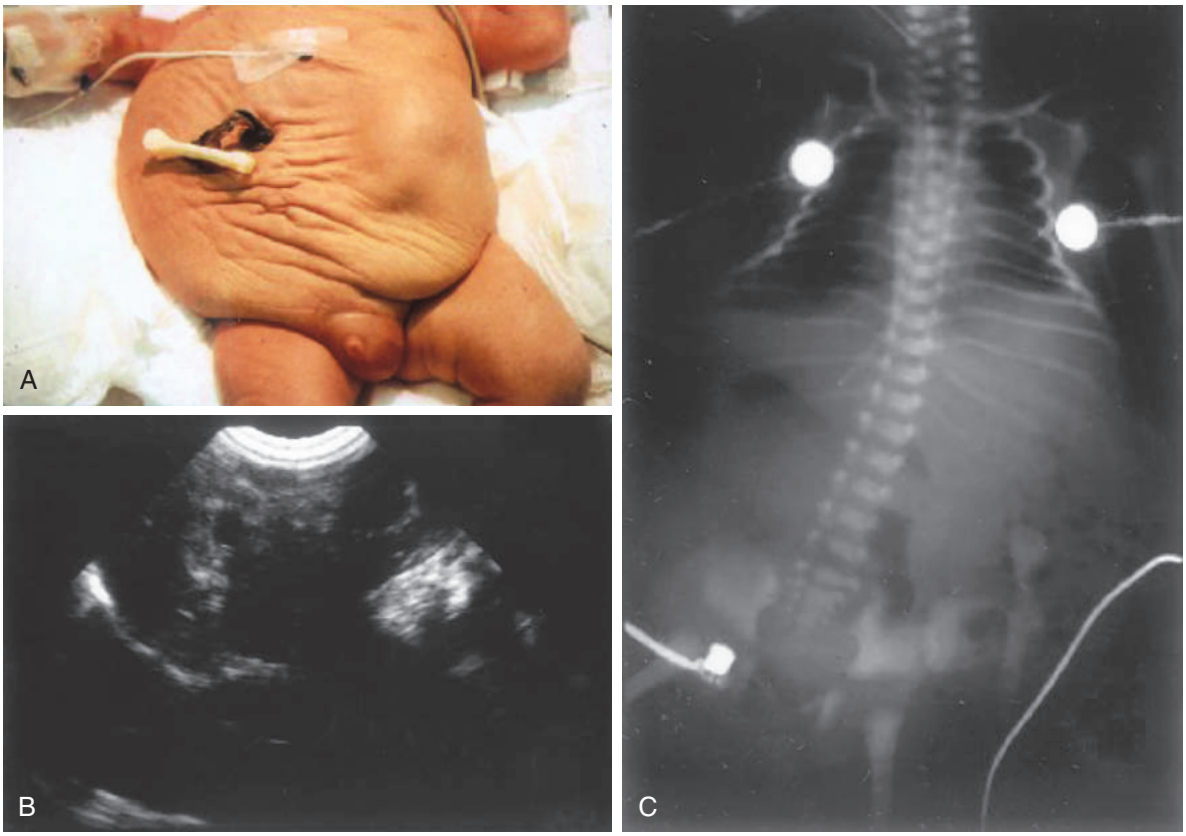
Since the 1970s, a co-occurrence of anomalies in multiple systems has been noted, and the heterogeneous group of these conditions is known as *VACTERL association* (vertebral, anorectal, cardiac, tracheal, esophageal, renal and/or radial, and limb).[203] Most clinicians agree that this condition is present if at least three systems are impacted. Urologic anomalies are frequently seen and can result in severe renal impairment if treated inadequately. The most common renal anomalies seen are hydronephrosis and VUR.[204] All children should undergo a renal and bladder ultrasound and, if the findings are abnormal, a VCUG. Sacral x-rays and ultrasound of the spine will further detect defects of the spinal cord that may also affect bladder function and cause renal impairment.

Female Genital Anomalies

Female Genital Tract Development

The female reproductive system is formed by the müllerian or paramesonephric ducts. The process is complex and involves many genes. Mostly because of the absence of müllerian inhibiting substance (produced by the testicle), there is involution of the wolffian ducts. The müllerian ducts form lateral to the wolffian duct at around 6 to 8 weeks' gestation. The müllerian ducts then migrate medially, fuse in the midline and are incorporated into the urogenital sinus to form the uterovaginal canal by the 10th week of gestation. The vagina forms from the fused müllerian ducts and the urogenital sinus. The upper four-fifths of the vagina is müllerian derived, and the lower fifth is of urogenital sinus in origin.

The external genitalia differentiate during the 12th to 16th weeks. The genital tubercle forms the clitoris, the urethral folds become the labia minora, and the genital swellings become the labia majora.[205]



• **Fig. 76.9** The classic wrinkled abdominal wall seen in prune-belly syndrome is accompanied by bilateral undescended testes (A). Affected patients will have marked hydronephrosis. In severe cases as illustrated here, these small kidneys may have a markedly dysmorphic sonographic appearance (B), and renal insufficiency may be present from the beginning. In cases with severe renal insufficiency, pulmonary development may be compromised, as evident on the radiograph (C); the patient required prolonged mechanical ventilation in the neonatal period.

Hydrocolpos and Hydrometrocolpos

Congenital hydrocolpos is an uncommon disorder characterized by vaginal distension with fluid. Hydrometrocolpos is associated with accumulation of fluid in both the vagina and the uterus. It is believed to be due to increased secretion by cervical mucous glands secondary to maternal hormone stimulation that expands and builds up into a pelvic mass because of vaginal outlet obstruction.[206] Hydrocolpos can be associated with genitourinary anomalies such as persistent urogenital sinus and cloacal anomalies (Fig. 76.10).[207] Vaginal atresia can be associated with several syndromes (e.g., McKusick-Kaufman syndrome and Bardet-Biedl syndrome).

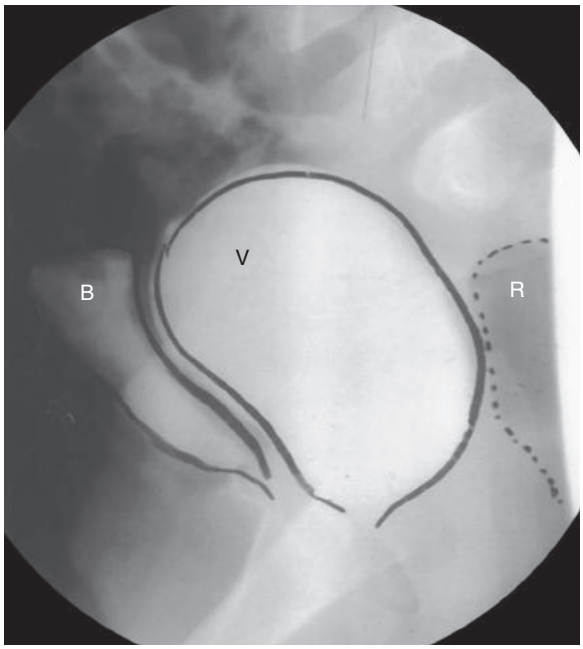
The most common complication of hydrocolpos is compression of the bladder, leading to urinary retention and hydronephrosis, which can ultimately cause kidney damage. This can be prevented by drainage of the accumulated fluid.[208] If the hydrocolpos is secondary to an imperforate hymen, incision with drainage is performed. If, on the other hand, the hydrocolpos is due to vaginal atresia or cloacal anomaly, drainage of the vagina can be accomplished either by clean intermitted catheterization or a transabdominal vaginostomy performed by an interventional radiologist under ultrasound guidance, which enables real-time evaluation without radiation exposure. The transabdominal drainage of hydrocolpos with an indwelling tube is more preferred than transvaginal drainage to prevent reaccumulation. In general, infants with hydrocolpos and urogenital sinus have increased risk of sepsis due to collection of urine in the vaginal vault. There have been reported deaths due to sepsis associated with hydrocolpos.

Vaginal Agenesis

Vaginal agenesis (Mayer-Rokitansky-Küster-Hauser syndrome) occurs in 1 in 5000 live female births and is due to failure in canalization of the vaginal plate.[209] Most of these patients present later in life with amenorrhea with normal secondary female sex features. The ovaries and external genitalia are normal, and the uterus may be rudimentary. Type I involves isolated ureterovaginal differences, while type II includes associated anomalies, including renal, skeletal, ear, or cardiac malformations. These have been termed *MURCS* (müllerian duct aplasia, renal aplasia, and cervicothoracic somite malformations).[210] Surgical correction is often delayed until the patient is mature enough to participate in postoperative care and individualized on the basis of the extent of atresia, development of the uterine and vaginal remnants, and goals of the patient.[211]

Cloacal Anomalies and Urogenital Sinus

A cloacal anomaly is defined when the urogenital sinus is combined with an anorectal malformation. A common urogenital



• **Fig. 76.10** This genitogram, performed by retrograde injection of contrast medium into a single sinus anterior to the patient's rectum, demonstrates the anteriorly placed bladder *(B)* and posteriorly placed vagina *(V)*. The vagina and urethra merged into a common sinus, which then traveled a distance of 2 cm before emerging on the perineal body. The rectum *(R)* was normally placed. The vagina distended as a result of urinary entrapment, and the patient presented with a lower abdominal mass.

sinus is a normal part of development of the fetus.[212] If müllerian duct development stops during the first trimester, a common urogenital sinus will persist at birth. The confluence of the vagina into the common channel varies and depends on when the development arrest occurred. The earlier the arrest, the higher the connection of the vagina will be. The anus will be normally located but sometimes is anteriorly displaced. On examination, only one opening is found in the introitus, and there is a second, anal opening.

Sometimes the vagina is distended, with urine causing compression of the ureters and hydronephrosis. This can be easily managed with initiation of intermittent catheterization, which will decompress the distended vagina.[208]

Evaluation includes an examination of the patient under anesthesia and determination of the length of the common channel and the length of the urethra from the bladder neck to the common channel. A cloacogram with three-dimensional CT reconstruction will also provide details of the anatomy, which aids in surgical planning.[213] Surgical repair is usually undertaken during the first year of life, and the approach for reconstruction depends on the location of the confluence of the vagina into the urogenital sinus.[214]

Infants with cloacal anomaly have only one opening into the perineum and confluence of the vagina, rectum, and urethra into a common channel.[215] The incidence is 1 in 35,000 to 50,000.[212] These children require a colostomy for stool divergence, and at the same time an examination under anesthesia can be performed to determine the extent of the common channel and the length of the urethra and vaginal channels. The reconstruction is usually performed at around 6 to 8 months of age or when the child is nutritionally stable. Multiple teams are involved in the reconstruction, including pediatric general surgery, pediatric urology, and pediatric gynecology teams.

Müllerian Duplication Anomalies

If fusion of the müllerian duct is incomplete, duplication anomalies occur. This can range from a septate vagina to vaginal duplication, where one or both vaginas are open to the perineum. These children may have a uterus that is partially fused (bicornuate uterus) to complete duplication with two cervices (uterus didelphys).[216]

Introital Masses in Children

These are seen on physical examination of the infant, and the differential diagnosis includes:

- Imperforate hymen
- Prolapsed ureterocele
- Urethra prolapse
- Skene or Gartner duct cysts
- Rhabdomyosarcoma[217]

Acute Kidney Injury

HEIDI J. STEFLIK, DAVID ASKENAZI, AND DAVID T. SELEWSKI

KEY POINTS

- Acute kidney injury (AKI) is common in critically ill neonates. AKI affects survival, hospital expenditures, and long-term outcomes, independent of the severity of illness and comorbidities.
- Kidney development continues until 34 weeks' gestation. Neonatal intensive care unit graduates, especially those with a history of AKI, those born prematurely, and those with intrauterine growth retardation, are at risk for long-term chronic kidney disease.
- New technological advancements are making the use of kidney replacement therapy (dialysis) more common, safer, and effective in neonates.

Acute Kidney Injury

Acute kidney injury (AKI) is characterized by a sudden impairment in kidney function, which may result in dysregulation of fluid balance, acid-base balance, electrolytes, and build-up of nitrogenous waste products. The term *injury* highlights the spectrum of organ injury and differentiates a damaged organ from an organ that has dysfunction to an organ that has failed. AKI is incrementally staged based on severity by oliguria or rise in serum creatinine (SCr).

The development and utilization of standardized definitions of AKI have created a commonality in defining AKI. Incremental degrees of AKI independently impact survival in critically ill neonates,[1] children,[2] and adults.[3] All three of the above multicenter cohort studies used the Kidney Disease: Improving Global Outcomes (KDIGO) AKI definition. In neonates, a modified version of this definition (Table 77.1) is the consensus, standard definition. This classification system utilizes the lowest SCr as a baseline and subsequent rise in SCr values to stage kidney injury. In April 2013, neonatologists and pediatric nephrologists participating in the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) workshop carefully scrutinized this definition and concluded that, although there are limitations inherent to utilizing SCr, the modified, neonatal KDIGO definition represents the current consensus definition of neonatal AKI for research purposes and clinical care.[4] This group also pointed out that this definition represents the first step in an iterative process to better define AKI, pointing to the need for neonatal-specific evidence to guide future definitions.

A critical component to understanding the shortcomings of the current AKI definitions is to recognize the limitations of SCr as a biomarker. Importantly, SCr is a marker of kidney function and detects damage that has occurred in the preceding 48 to 72 hours. Thus, the current AKI definitions utilizing SCr do not detect kidney damage; instead, they document changes in kidney function.[5] Table 77.2 details the limitations inherent to utilizing SCr.

Over the last decade, there has been a significant amount of work to identify urine and serum biomarkers of AKI. Ideally, novel AKI biomarkers will show acute damage hours after an insult, distinguish between different causes and locations of tissue injury, and prognosticate clinical outcomes. Potential biomarkers include cystatin C, urine and serum neutrophil gelatinase-associated lipocalin (NGAL), urine interleukin-18, kidney injury marker-1, copeptin, and liver fatty acid-binding protein among others.[6] Many of these were originally identified and studied in neonates undergoing cardiopulmonary bypass[7,8] and now are being studied in neonates in the neonatal intensive care unit (NICU) (Fig. 77.1). These serum and urine biomarkers notably vary based on gestational age (GA), day of life, and gender[9,10] but show promise in their ability to predict AKI in preterm infants,[11–13] very low birth weight (VLBW, i.e., birth weight <1,500 g) infants,[14,15] near-term/term neonates,[16,17] and neonates with perinatal asphyxia.[18,19] Future work is needed to determine how best these biomarkers can be used at the bedside.

Epidemiology

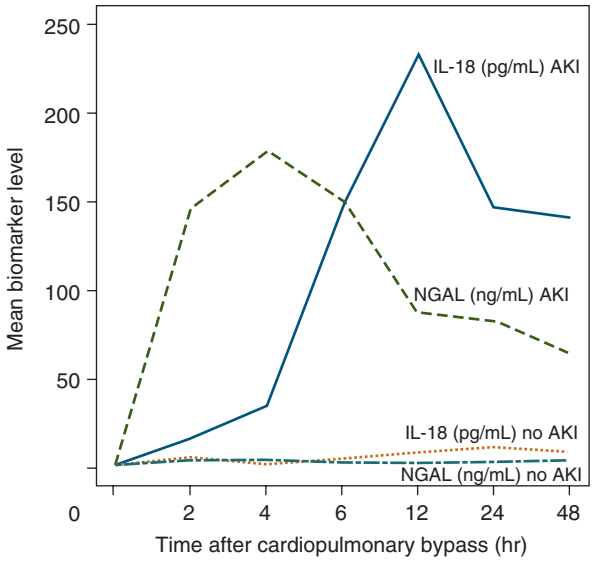
Over the past decade, there has been a significant amount of research utilizing modern staged definitions of AKI to evaluate the incidence and impact of AKI in the NICU. In the largest epidemiologic study to date, the Assessment of Worldwide Acute Kidney Injury Epidemiology in Neonates (AWAKEN) study, more than 2000 infants from 26 NICUs and 4 countries were enrolled allowing investigators to compare AKI incidences and associated outcomes across the GA spectrum in a multicenter, multinational cohort for the first time.[1] Using this general NICU cohort, AWAKEN investigators demonstrated that 30% of neonates admitted to the NICU develop AKI and that the incidence of AKI varied across GA groups. Importantly, they also demonstrated that neonatal AKI was independently associated with both morbidity and mortality.

In the NICU there are a number of high-risk patient sub-populations that warrant separate discussion, including neonates with perinatal asphyxia, those undergoing cardiac surgery or receiving extracorporeal membrane oxygen (ECMO), and VLBW and extremely low birth weight (ELBW, i.e., birth weight <1,000 g) infants (Table 77.3).

TABLE 77.1 Modified Neonatal, Kidney Disease: Improving Global Outcomes Definition and Classification of Neonatal Acute Kidney Injury

Stage	Serum Creatinine	Urine Output
0	No change in SCr *or* rise < 0.3 mg/dL	≥0.5 mL/kg/h
1	SCr rise ≥0.3 mg/dL rise within 48 hrs *or* SCr rise ≥1.5–1.9 × baseline SCr[a]	<0.5 mL/kg/h for 6–12 hr
2	SCr rise ≥2.0–2.9 × baseline SCr	<0.5 mL/kg/h for ≥12 hr
3	SCr rise ≥3 × baseline SCra *or* SCr ≥2.5 mg/dL[b] *or* Receipt of dialysis	≤0.3 mL/kg/h for ≥24 hr *or* Anuria for ≥12 hr

[a]Baseline SCr defined as lowest previous SCr value.
[b]SCr value of 2.5 mg/dL represents glomerular filtration rate of <10 mL/min/1.73 m^2.
SCr, Serum creatinine.
Adapted from Kidney Disease: Improving Global Outcomes (KDIGO) Acute Kidney Injury Workgroup. KDIGO clinical practice guideline for acute kidney injury. *Kidney Int Suppl.* 2012;2:1–138.



• **Fig. 77.1** Mean values of urine interleukin-18 (pg/mL) and neutrophil gelatinase-associated lipocalin (ng/mL) over the first hours after cardiopulmonary bypass in infants who develop acute kidney injury (50% increase in serum creatinine) compared with those who did not develop acute kidney injury. *AKI*, Acute kidney injury; *IL-18*, interleukin-18; *NGAL*, neutrophil gelatinase-associated lipocalin.

TABLE 77.2 Acute Kidney Injury Definitions: Limitations Inherent to Serum Creatinine

- Up to 50% kidney function is lost prior to SCr change
- It may take 48–72 hr for SCr to rise after an insult
- At a low GFR, SCr will overestimate renal function[a]
- Different measurement methods (Jaffee reaction vs. enzymatic) produce different SCr values
- Bilirubin can alter SCr Jaffee-based measurement
- SCr varies by muscle mass, diet, hydration, sex, age, gender
- Nephrogenesis continues until 34 weeks of gestation
- Dependent on the degree of prematurity, GFR improves steadily after birth:
  - To 10–20 mL/min/1.73 m^2 during the first week of life
  - To 30–40 mL/min/1.73 m^2 by 2 weeks of life
- Neonatal SCr values in the first days of life reflect maternal SCr values (Fig. 77.3)
- Unique, absolute SCr rise threshold values for different gestational ages improve the prediction of mortality.

[a]Due to tubular secretion.

Neonates With Perinatal Asphyxia

Infants with perinatal asphyxia represent a population at high risk for the development of AKI. Selewski et al. (2013) evaluated 96 newborns undergoing therapeutic hypothermia for perinatal asphyxia and found that 38% developed AKI.[20] In this cohort, AKI was associated with adverse outcomes, including prolonged mechanical ventilation by a mean of 4 days ($P < .01$) and prolonged hospitalization by 3.4 days ($P < .03$). In the same cohort, those with AKI were more likely to have abnormal brain magnetic resonance imaging (MRI) findings at 7 to 10 days of life, implicating AKI as a potential marker and/or mediator of poor neurologic outcomes.[21] Recently, in a randomized controlled trial (RCT) of 120 term neonates with perinatal asphyxia, those randomized to therapeutic hypothermia had lower rates of AKI (32% vs. 60%, $P < .05$), suggesting therapeutic hypothermia may protect against the development of AKI.[22]

When examining infants greater than 34 weeks of gestation with perinatal asphyxia within the AWAKEN cohort, Kirkley et al. (2019) found that 42% (47/113) developed AKI and that those with perinatal asphyxia and AKI remained in the hospital with an average of 8.5 days longer than those with asphyxia but no AKI.[23] More recently, Cavallin et al. (2020) demonstrated that AKI was associated with an increased likelihood of unfavorable neurodevelopmental outcomes at 24 months (100% vs. 59% in neonates without AKI; $P = .01$).[24]

Neonates Undergoing Cardiac Pulmonary Bypass Surgery

Several factors contribute to the risk of postoperative AKI in neonates undergoing cardiac pulmonary bypass (CPB) surgery, including prematurity, CPB characteristics and duration, surgical complexity, perioperative morbidities, hypotension, deep hypothermic circulatory arrest, and hypoxia.[25] Reported rates of post-CPB AKI in neonates range from 45% to 64%.[25–28] In this population, AKI is consistently found to be independently

TABLE 77.3 Neonatal Acute Kidney Injury Studies

Population	Study	Definition	Incidence of AKI	Findings
General NICU Population	Jetton et al. 2017 ($n = 2162$)	Neonatal modified KDIGO criteria	29.9%	AKI varies by gestational age • 22 to <29 WGA: 48% • 29 to <36 WGA: 18% • ≥36 WGA: 37% AKI is associated with higher mortality and longer length of hospital stay.
Perinatal Asphyxia/HIE	Selewski et al. 2013 ($n = 96$)	Neonatal modified KDIGO criteria	38%	AKI predicted prolonged mechanical ventilation, length of stay, and abnormal brain MRI findings at 7–10 days of life.
Cardiopulmonary Bypass Surgery	Alabbas et al. 2013 ($n = 122$)	AKIN criteria	62%	Severe AKI (stage III) was associated with increased mortality and length of stay after adjusting for severity of illness.
ECMO	Murphy et al. 2021 ($n = 446$)	KDIGO criteria	51%	AKI most common in those with cardiac disease but varies by diagnostic cause for ECMO. Risk of mortality differed by diagnostic category in the presence or absence of AKI; without AKI, CDH independently predicts mortality.
	Zwiers et al. 2013 ($n = 242$)	RIFLE criteria	64%	Increased risk of mortality at highest level of AKI (failure).
VLBW Infants	Rhone et al. 2014 ($n = 107$)	Neonatal modified KDIGO criteria	26.2%	AKI is associated with nephrotoxic medication exposure.
	Koralkar et al. 2011 (n = 229)	Neonatal modified KDIGO criteria	18%	Adjusting for severity of illness AKI was associated with increased mortality.
	Askenazi et al. 2009 ($n = 195$)	AKIN criteria	Matched case-control study	AKI is associated with increased mortality after adjustment for confounders.

AKI, Acute kidney injury; *AKIN*, acute kidney injury network; *CDH*, congenital diaphragmatic hernia; *ECMO*, extracorporeal membrane oxygenation; *HIE*, hypoxic-ischemic encephalopathy; *KDIGO*, Kidney Disease Improving Global Outcomes; *MRI*, magnetic resonance imaging; *NICU*, neonatal intensive care unit; *RIFLE*, risk, injury, failure, loss, end-stage; *VLBW*, very low birth weight; *WGA*, weeks' gestational age.

associated with morbidity, including prolonged length of intubation, postoperative ventilation days, ICU stay, and hospitalization,[26–28] as well as with the increased risk of mortality.[25,26]

Neonates Requiring Extracorporeal Membrane Oxygenation

Neonates on ECMO are predisposed to AKI for a number of reasons, including those inherent to their underlying critical illness (sepsis, ischemia, respiratory failure, cardiac failure, hypotension, nephrotoxic medications) and elements associated with ECMO (hemodynamic fluctuations, hemolysis, systemic inflammation). Several early studies of infants and children who received ECMO suggest AKI is associated with mortality.[29–33] In a retrospective cohort study of 7941 neonates in the Extracorporeal Life Support Organization (ELSO) registry, where AKI was defined as infants who had an SCr greater than 1.5 mg/dL or an ICD-9 code for acute renal failure, neonatal mortality was 2175/7941 (27.4%).[34] Nonsurvivors experienced more AKI than survivors (413/2175 [19.0%] vs. 225/5766 [3.9%]; $P < .01$), and more received renal replacement therapy (RRT, also known as kidney support therapy [KST]) (863/2175 [39.7%] vs. 923/5766 [16.0%]; $P < .01$). After adjusting for confounding variables, the adjusted odds ratio (OR) for mortality was 3.2 ($P < .01$) following AKI. Zwiers et al. (2013) evaluated AKI in 242 neonates on ECMO, reporting an AKI incidence of 64% and a mortality of 65% when AKI progressed to the highest stage.[35]

More recently, the multidisciplinary, international Kidney Intervention during Extracorporeal Membrane Oxygenation (KIDMO) study group has produced several manuscripts investigating the epidemiology and impact of AKI, fluid overload, and RRT utilization in neonates and pediatric patients receiving ECMO. Utilizing the KDIGO criteria, KIDMO investigators found that 66% of neonates receiving ECMO develop AKI.[36] In their cohort, AKI occurred by 48 hours of ECMO support in 93% of cases and was independently associated with increased duration of ECMO and increased odds of in-hospital mortality. When examining only neonatal patients within the cohort, they found that neonates receiving ECMO for cardiac diagnoses experienced higher rates of AKI than those cannulated for respiratory indications or congenital diaphragmatic hernia (CDH; cardiac 68% vs. respiratory 33% vs. CDH 38%; $P < .01$), and an interaction suggested that risk of mortality differed by diagnosis in the presence or absence of AKI in neonates receiving ECMO; in the absence of AKI, CDH independently predicted mortality while fluid overload and RRT receipt both independently predicted mortality regardless of the underlying diagnosis.[37] These findings suggest that physiologically distinct ECMO diagnoses warrant individualized treatment strategies.

Very Low Birth Weight and Extremely Low Birth Weight Neonates

There are now multiple single-center studies describing the epidemiology of AKI in VLBW and extremely low birth weight (ELBW) neonates with particular attention being paid to premature neonates. Rates of AKI in this population range from 12.5% to 56% and AKI is independently associated with increased morbidity and mortality.[38–43] In a recent 2020 study of an overlapping population, extremely low gestational age neonates (ELGANs), Askenazi et al. reported AKI occurred at least once in 38% of their cohort, and severe AKI, defined as KDIGO stage 2 or higher AKI, occurred at least once in 18.2%.[44]

Several studies examining the association between common morbidities of prematurity, including bronchopulmonary dysplasia (BPD) and necrotizing enterocolitis (NEC), and AKI have recently been published. One of the most common morbidities of prematurity is BPD, affecting 10% and 40% of surviving VLBW and ELBW infants, respectively.[45] In 2015, Askenazi et al. showed an association between AKI and BPD in premature infants; neonatal AKI was independently associated with a higher risk of oxygen requirement/death at 28 days old (RR 1.45, 95% CI 1.07 to 1.97; $P < .02$).[46] In the AWAKEN cohort, neonates born between 29 and 32 weeks of gestation who developed AKI had a higher likelihood of moderate or severe BPD/death than those without AKI after controlling for multiple factors (adjusted OR 4.21, 95% CI 2.07 to 8.61, $P < .01$).[47]

An association between AKI and NEC has also been reported. NEC is an inflammatory disease of the intestines that typically affects VLBW and ELBW infants and significantly increases the risk of mortality.[48] Bakhoum et al. (2018) studied a population of premature infants with NEC and found that AKI occurred in 42.9% of infants (Stage 1 NEC: 18.2%, Stage 2 NEC: 13.0%, Stage 3 NEC: 11.7%) and was independently associated with mortality (adjusted hazard ratio (HR) 20.3, 95% CI 2.5 to 162.8; $P < .01$).[49] Criss et al. (2018) found AKI in 54% (98/181) of neonates with NEC and reported that those with AKI experienced higher mortality (44% vs. 25.6%, $P < .01$) and a higher chance of death (HR 2.4, CI 1.2 to 4.8, $P < .01$).[50] When examining risk factors for and outcomes of severe AKI (i.e., stage 2 and 3 AKI), Garg et al. (2021) found severe AKI in 33% (66/202) neonates after NEC and in 58.7% (61/104) neonates after surgical NEC.[51] They also reported severe AKI was associated with significantly longer hospitalization (124 days [IQR 88 to 187] vs. 82 days [IQR 42 to 125]; $P < .01$).

Pathophysiology

Prerenal Azotemia

Prerenal azotemia occurs in response to decreased kidney blood flow (RBF). Causes of prerenal azotemia in neonates include loss of effective circulating blood volume, dehydration, capillary leak, increased abdominal pressures, and decreased cardiac output.[52] Nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin and angiotensin-converting enzyme inhibitors (ACE-Is) can also decrease RBF (Table 77.4).

TABLE 77.4 Causes of Acute Kidney Injury in the Newborn

Prenatal Azotemia	Intrinsic Acute Kidney Injury	Postrenal (Obstructive) Renal Failure

• Loss of effective blood volume
  • Perinatal blood loss
  • Hemorrhage
  • Dehydration
  • Diarrhea
  • Transepidermal free water losses
  • Poor intake
  • Gastric losses
  • Chest tube losses
• Capillary leak
  • Hydrops fetalis
  • Infection
  • Hypoalbuminemia
• Increased abdominal pressures leading to renal hypoperfusion
  • NEC
  • Repair or reduction of gastroschisis
  • Omphalocele
  • CDH
  • Ascites
• Decreased cardiac output
  • Sepsis
  • Cardiac surgery
  • CHF
  • ECMO
• Pharmacologic agents
  • NSAIDs such as indomethacin

		  • Hematocolpos
		  • Sacrococcygeal teratoma
		• Intrinsic obstruction
		  • Renal calculi
		  • Fungus balls

ACE, Angiotensin-converting enzyme; *ATN*, acute tubular necrosis; *CDH*, congenital diaphragmatic hernia; *CHF*, congestive heart failure; *ECMO*, extracorporeal membrane oxygenation; *NEC*, necrotizing enterocolitis; *NSAID*, nonsteroidal anti-inflammatory drug; *PUV*, posterior urethral valves; *RAT*, renal artery thrombosis; *RVT*, renal vein thrombosis; *UPJ*, ureteropelvic junction.

When low RBF occurs, kidney autoregulation preserves glomerular filtration rate (GFR) by increasing kidney sympathetic tone, activating the renin-angiotensin–aldosterone system, and increasing activation of hormones such as vasopressin and endothelin. An increase in filtration fraction (GFR/RBF × 100) increases peritubular oncotic pressure, resulting in enhanced proximal tubular sodium and water reabsorption.[53] These hemodynamic changes lead to a decrease in water and sodium losses which helps to maintain systemic volume expansion. In some newborns, anticipated oliguria does not develop because of poor vasopressin secretion and/or weak kidney responsiveness to vasopressin,[54] immature/poor tubular function, or prolonged/severe hypoperfusion. In prolonged states of kidney hypoperfusion, parenchymal damage occurs, and a pre-renal state may transition to kidney tubular cell damage (acute tubular necrosis, ATN).

Intrinsic Acute Kidney Injury

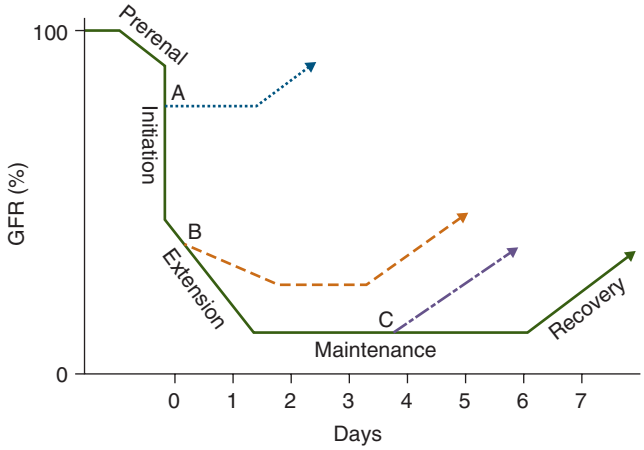
Prolonged or severe hypoperfusion leading to ischemic AKI and ATN is the most common cause of intrinsic AKI (see below). Other causes of intrinsic AKI in neonates include nephrotoxic medications and sepsis. Other rare causes of AKI include renal vein thrombosis (RVT), renal artery thrombosis (RAT), uric acid nephropathy, hemoglobinuria, myoglobinuria, and congenital malformations (Table 77.4).

Ischemic Acute Kidney Injury

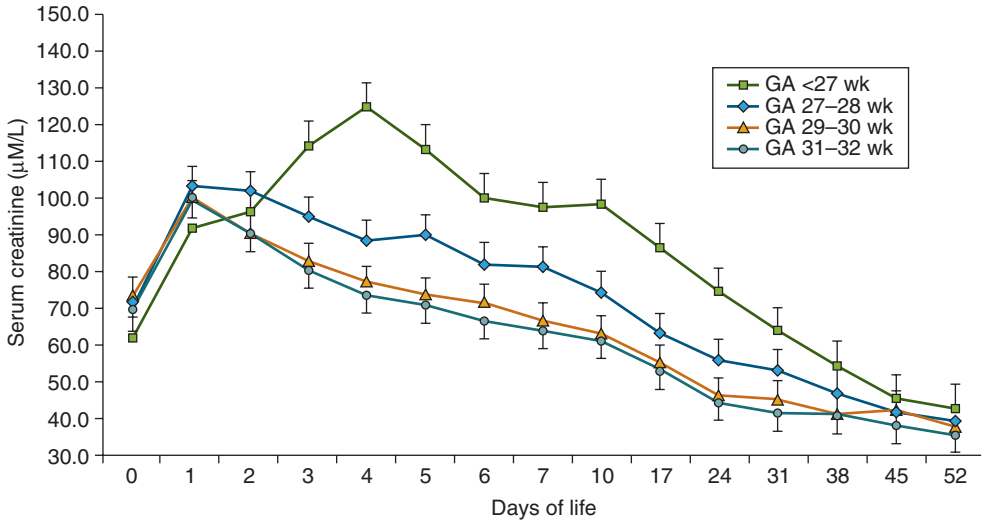
The presentation and course of the kidney damage after hypoxic-ischemic injury depends on the severity and duration of the insult. In contrast to prerenal azotemia, kidney function abnormalities in ischemic AKI are not immediately reversible. In states of prolonged hypoperfusion, kidney parenchymal damage develops, particularly to the tubular epithelium of the terminal medullary portion of the proximal tubule (S3 segment) and of the medullary portion of the thick ascending limb of the loop of Henle. The severity of intrinsic AKI ranges from mild tubular dysfunction to ATN, to kidney infarction and corticomedullary necrosis with irreversible kidney damage.[53]

The course of ischemic AKI may be subdivided into the prerenal, initiation, extension, maintenance, and recovery phases (Fig. 77.2).[55] If, during prerenal azotemia, restoration of RBF occurs, GFR can normalize. The initiation phase includes the original insult and the associated events resulting in a drop in GFR. The extension phase includes alterations in kidney perfusion, continued hypoxia, and inflammatory insults to the kidney's microvasculature. Tubular dysfunction with low GFR represents the maintenance phase. The duration of the maintenance phase depends, at least in part, on the severity and duration of the initial insult. The recovery phase is characterized by the gradual restoration of GFR and tubular functions, which may take months to occur. During the maintenance and recovery phases of ischemic AKI, the kidney is susceptible to further damage from additional insults. Recognition of the different phases of intrinsic, ischemic AKI is helpful in the diagnosis, clinical management, and prognostication of the disorder.

The histologic hallmark of severe ischemic AKI is damage to epithelial tubular cells with characteristic bleb formation, loss of brush border in the apical portion of the cell cytoskeleton, and loss of tight junctions between cells. If an injury is severe enough, apoptosis and necrosis will occur with the resultant desquamation of cells, which lead to tubular obstruction. Not only are tubular epithelial cells critical in the pathophysiology of ischemic AKI, but damage to the innermost lining of the kidney vascular system, the endothelial cells, has a critical role in the initiation, extension, maintenance, and recovery phases of ischemic AKI.[56]



• **Fig. 77.2** Stages of progression in acute kidney injury. *GFR*, Glomerular filtration rate.



• **Fig. 77.3** Serum creatinine concentrations (μM/L) during the first days of life, with values given as means and standard error for infants born at different gestational ages. *GA*, Gestational age; *wk*, weeks.

When endothelial cell damage occurs, activation of vasoconstriction, impaired vasodilation, and impaired leukocyte adhesion result in capillary obstruction and distorted peritubular capillary morphology and a cycle of increasing ischemia and vascular inflammation. The loss of endothelial cell function may represent an important therapeutic target in which vascular support and/or endothelial regeneration by progenitor cells may impact the short- and long-term consequences of AKI.[57]

Damaged endothelial and tubular cells not only lead to dysfunction within the kidney, but they produce a systemic inflammatory response. The inflammatory dysregulation is due (at least in part) to dysfunctional immune, inflammatory, and soluble mediator metabolism. AKI also has been shown to directly affect the brain, lung, heart, liver, bone marrow, and gastrointestinal tract.[58]

Nephrotoxic Acute Kidney Injury

Exposure to nephrotoxic medications is a potentially modifiable risk factor for intrinsic AKI. Table 77.5 lists commonly used nephrotoxic medications in the NICU and their mechanisms of nephrotoxicity. Until recently the epidemiology and burden of nephrotoxic medication exposure in neonates were unknown. Rhone et al. (2014) evaluated the cumulative nephrotoxic medication exposure of a cohort of 107 VLBW neonates.[59] In this study, 87% of the cohort was exposed to at least one nephrotoxic medication, and on average these neonates were exposed to over 14 days of nephrotoxic medications. In 2017, Barhight et al. reported that 84% of VLBW neonates in their single-center cohort received nephrotoxic medications, and antibiotics were the most common of these (80%).[60] In their regression modeling, these investigators found birthweight (OR 0.995, 95% CI: 0.991 to 0.998; $P = .004$) and number of nephrotoxic medication exposures (OR 1.83, 95% CI 1.33 to 2.53; $P = .0002$) were predictive of AKI.

TABLE 77.5 Nephrotoxic Medications and Mechanisms

Drug	Mechanism
Acyclovir	Urinary precipitation, especially with low flow and hypovolemia, with renal tubular obstruction and damage and decreased GFR • May cause direct tubular toxicity (metabolites)
Angiotensin-converting enzyme (ACE) inhibitors	Decreased angiotensin II production inhibiting compensatory constriction of the efferent arteriole to maintain GFR
Aminoglycosides	Toxic to the proximal tubules (transport in the tubule, accumulate in lysosome, intracellular rise in reactive oxygen species and phospholipidosis, cell death); intrarenal vasoconstriction and local glomerular/mesangial cell contraction
Amphotericin B	Distal tubular toxicity, vasoconstriction, and decreased GFR
NSAIDs	Decreased afferent arteriole dilatation as a result of inhibiting prostaglandin production resulting in reduced GFR
Radiocontrast agents	Renal tubular toxicity secondary to increase in reactive oxygen species; intrarenal vasoconstriction may play a role
Vancomycin	Mechanism of AKI unclear, possible mechanism includes proximal tubular injury with generation of reactive oxygen species

AKI, Acute kidney injury; *GFR*, glomerular filtration rate; *NSAID*, nonsteroidal antiinflammatory drug.

In the NICU, nephrotoxins can cause AKI by decreasing kidney perfusion, direct tubular injury, interstitial nephritis, and tubular obstruction. Although not a comprehensive review, some of the most common nephrotoxic medications in neonates are described below.

Indomethacin, a prostaglandin inhibitor used to treat patent ductus arteriosus (PDA) in premature infants, is a commonly used medication in the NICU. The potentiation of the vasoconstrictive and sodium- and water-retaining effects of angiotensin II, norepinephrine, and vasopressin by the indomethacin-induced inhibition of kidney prostaglandin production is the primary mechanism of the kidney actions of the drug which is accentuated by the dependence of immature neonatal regulatory mechanisms of RBF on prostaglandins. Ibuprofen, another prostaglandin inhibitor used to treat PDA in the NICU, has been shown to be equally efficacious in achieving PDA closure as indomethacin but with a reduced risk of kidney injury.[61]

Amphotericin B alters kidney function by directly affecting tubular function, resulting in renal tubular acidosis and increased urinary potassium excretion. Although these nephrotoxic effects are somewhat rare and most often reversible, cases of fatal neonatal AKI caused by amphotericin B toxicity have been reported.[62] A liposomal formulation of amphotericin B is available which has a higher affinity to fungal rather than mammalian cellular membranes and therefore is likely less nephrotoxic.[63,64]

Aminoglycosides inhibit lysosomal phospholipases, leading to primary proximal tubule cell damage,[65] although changes in the ultrastructure of the glomerulus also occur.[66] Aminoglycosides should be used with caution in any person with kidney dysfunction, concomitant nephrotoxic medication use, or poor kidney perfusion. Unfortunately, aminoglycosides are used concurrently with other nephrotoxins such as NSAIDs frequently in the NICU. In a single center study, neonates receiving concurrent aminoglycosides and NSAIDs experienced more AKI than infants receiving aminoglycosides alone (14.8% vs. 9.1%; RR 1.6, 95% CI 1.0 to 2.6), and the attributable risk of NSAID use was 5.7% (95% CI 0.5 to 11.0).[67] In those with kidney dysfunction, serial monitoring to assure proper clearance of the medication is needed to prevent AKI. Because aminoglycoside toxicity is usually nonoliguric, serial monitoring of SCr values is necessary, especially during prolonged administration of these antibiotics, to detect their potential nephrotoxicity in the newborn.

Acyclovir is used to treat neonatal herpes simplex virus infections. Acyclovir is an antiviral agent that is eliminated rapidly in the urine through glomerular filtration and tubular secretion. It is nearly insoluble in the urine and may precipitate, particularly in the distal tubular lumen. Intravenous high-dose acyclovir treatment may lead to intratubular crystal precipitation and AKI. Acyclovir-related nephrotoxicity can be limited by maneuvers to prevent crystallization including avoiding use in those with AKI or intravascular volume depletion, prolonged infusion (over several hours), and by maintaining a high urinary flow rate.[68]

Postrenal Acute Kidney Injury

The most common causes of postrenal or obstructive kidney dysfunction in the newborn are congenital malformations, including imperforate prepuce, urethral stricture, prune belly syndrome,

and posterior urethral valves. Other causes of acute obstruction include neurogenic bladder, extrinsic compression (e.g., hematocolpos, sacrococcygeal teratoma), and intrinsic obstruction from kidney calculi or fungal balls. Depending on the cause and associated damage to the kidneys, relief of the obstruction will markedly improve kidney function.

Evaluation and Management

There are three main goals in the care of neonates with AKI. The first is to understand the cause of the problem. The second is to take steps to intervene to prevent further deterioration in kidney function. The third is to manage the homeostatic functions that the kidney plays as it relates to electrolytes, fluids, acid/base balance, and waste product removal. If medical interventions and adjustments to nutritional contents do not achieve the proper homeostasis, artificial (dialysis) kidney support may be indicated.

Step 1: Understand the Cause of Acute Kidney Injury

The pregnancy history, timing, vital signs, changes in weight, physical examination, interventions, and medications prescribed provide important clues about the cause of neonatal AKI. SCr often does not rise until days after an injury, thus monitoring these values for several days after the inciting event is necessary to determine if AKI occurred. If possible, a urinalysis, urine culture, and a spot urine sample for sodium, creatinine, and osmolality should be collected as they can assist diagnostically.

One of the major goals in the initial evaluation of neonatal AKI is to determine if the kidney is hypoperfused. Several laboratory, clinical, and therapeutic interventions can help delineate prerenal azotemia from intrinsic AKI (Table 77.6). A decrease in body weight, tachycardia, dry mucous membranes, poor skin turgor, flattened anterior fontanel, and elevation of serum sodium can be seen in those with low intravascular volumes.

When the kidney is hypoperfused, the kidney will avidly retain sodium and water to preserve intravascular volume. Laboratory markers of prerenal azotemia include low urinary sodium excretion, low fractional excretion of sodium (FENa), low kidney/renal failure index, and high blood urea nitrogen: SCr ratio. However, it is important to recognize that the preservation of urine sodium and water is dependent on intact tubular function; therefore, disturbances of tubular function (diuretic use, tubular injury, or primary tubular diseases) can affect the results of urine electrolyte values. As premature infants have poor tubular function, these studies have important limitations. Normal FENa in preterm infants born at less than 32 weeks of gestation is usually higher than 3%.[69] Additionally, because of the developmentally regulated limitation of their concentrating capacity and the effects of low protein intake and urea excretion on urine osmolality, the urine-to-plasma creatinine ratio instead of the urine-to-plasma osmolar ratio should be used in newborns to evaluate their kidney tubular reabsorptive capacity.[53]

If the suspicion of kidney hypoperfusion is high, an appropriate fluid challenge with 10 to 20 mL/kg of isotonic fluids should be given. Close observation of vital signs and urine output (UOP) may serve to delineate if intravascular hypoperfusion is present. Several boluses may be necessary with careful prescription of fluid volume for the next 24 hours. Care to avoid fluid challenges is advised in those with suspected urinary outlet obstruction, lung pathology such as BPD, or congestive heart failure. In situations where there is low oncotic pressure (serum albumin levels <2.5 mg/dL), consideration for 20% to 25% albumin infusions should be considered. Medications to ensure adequate cardiac output is present to perfuse the kidneys are sometimes required.

TABLE 77.6 Diagnostic Indices Suggestive of Prerenal Azotemia Versus Intrinsic Acute Kidney Injury in the Newborn

Diagnostic Indices	Prerenal Azotemia	Intrinsic Acute Kidney Injury
Urine flow rate (mL/kg/h)	Variable	Variable
Urine osmolality (mOsm/L)	>400	≤400
Urine-to-plasma osmolar ratio	>1.3	≤1.0
Urine-to-plasma creatinine ratio (mean ± standard deviation)	29.2 ± 1.6	9.7 ± 3.6
Urine [Na^+] (mEq/L)	10–50	30–90
FENa[a] (%, mean ± standard deviation)	<0.3 (0.9 ± 0.6)	>3.0 (4.3 ± 2.2)
Renal failure index[b] (mean ± standard deviation)	<3.0 (1.3 ± 0.8)	>3.0 (11.6 ± 9.5)
Response to fluid challenge	• Improved tachycardia • Increased UOP	No effect on tachycardia or UOP

[a]Fractional excretion of sodium (FENa) = (urine [Na^+]/serum [Na^+])/(urine [Cr]/serum [Cr]) × 100.
[b]Renal failure index = urine [Na^+]/(urine [Cr]/serum [Cr]).
Cr, Creatinine; *UOP*, urine output.

Neonatal renal failure: usefulness of diagnostic indices. *Pediatrics*. 1980;65(1):57–60. See text for details.

Another important part of the evaluation of AKI is to rule out obstruction to urine flow. A kidney and bladder ultrasound should be performed without delay if an obstructive process is suspected and to determine if congenital kidney abnormalities are present. If hematuria or hypertension (or both) are present, the possibility of kidney/renal vascular disease should also be considered. Doppler ultrasound of the kidney vessels can be performed if renal vascular thrombosis is suspected.

Step 2: Intervene to Preserve or Prevent Further Acute Kidney Injury

For all neonates with AKI, the provision of fluid boluses (if appropriate) as part of the evaluation of prerenal azotemia also serves as the initial management of AKI. Careful evaluation of any potentially nephrotoxic medications to determine if they are necessary, and/or if alternatives are available, is crucial. The clinician can reverse or prevent further damage by maintaining adequate perfusion to the kidney, relieving abdominal compartment syndrome if present, assuring adequate oncotic pressure (keeping a serum albumin of 2.5 mg/dL or higher), and providing interventions to eliminate

any obstruction to urinary flow (if discovered). If systemic hypotension develops despite adequate volume administration, early initiation of blood pressure support often establishes appropriate kidney perfusion.[70,71] Other management goals include the maintenance of blood oxygen content, provision of blood products (as indicated), limiting severe acidosis, and maintenance of normal serum albuminemia (at least 2.5 mg/dL preferably).

Several therapies are commonly employed in AKI and consideration of these options should be given; however, little, if any, data are available to support the use of low-dose dopamine, fenoldopam, or diuretics for the treatment or prevention of AKI in neonates. Low-dose dopamine increases kidney perfusion in sick infants, however, well-powered RCTs have failed to demonstrate an improvement in survival, length of hospitalization, or dialysis receipt in adult patients.[71–76] Fenoldopam, a selective dopamine-1 receptor agonist, leads to kidney and splanchnic vasodilation with subsequent increased RBF and GFR, but results of small, single-center studies in neonates have conflicting results[77–79]; the single prospective, placebo-controlled trial of fenoldopam in infants failed to show kidney-related benefits.[79] Diuretics are commonly used to induce diuresis in critically ill neonates; however, studies in neonates, children, and adults have failed to demonstrate that diuretics are effective in preventing AKI or improving outcomes once AKI occurs.[74] Although diuretics have failed to improve outcomes, a time-limited trial of diuretics is reasonable as multiple studies demonstrate associations between fluid overload and morbidity.[80]

In neonates with perinatal asphyxia and hypoxic ischemic encephalopathy (HIE), several RCTs have suggested a single dose of theophylline after birth may protect against AKI (Table 77.7).[81–85] During episodes of acute kidney hypoxemia and ischemia, increased kidney adenosine content leads to afferent arteriole and intra-renal vasoconstriction with subsequent decreased RBF and GFR.[86–88] These changes suggest adenosine may play a role in the pathogenesis of hypoxia-related AKI, leading investigators to hypothesize that theophylline, an adenosine receptor antagonist, may block this vasoconstriction and preserve kidney function. Based on these studies, the KDIGO AKI guidelines state "we suggest that a single dose of theophylline may be given in neonates with severe perinatal asphyxia, who are at high risk of AKI."[89] Further, large multicenter RCTs are warranted before widespread adoption of prophylactic theophylline for neonatal asphyxia and AKI protection, particularly given none of the infants in the studies to date received therapeutic hypothermia.

Similarly, emerging evidence suggests adenosine receptor antagonists, including theophylline as well as caffeine, may prevent AKI in premature infants. In a retrospective, single-center study, Carmody et al. (2016) found that VLBW infants who received caffeine were less likely to develop neonatal AKI.[90] These findings persisted after controlling for confounders such as BW, GA, illness severity, and receipt of nephrotoxic medications (aOR 0.22; 95% CI 0.07 to 0.75; $P = .02$). Even more recently, a secondary analysis of the AWAKEN cohort, showed that AKI occurred less frequently among neonates who received caffeine (50/447 (11.2%) vs. 72/228 (31.6%); $P < .01$).[91] Again, after multivariable adjustment, caffeine receipt remained associated with reduced odds of developing AKI (aOR 0.20; 95% CI 0.11 to 0.34) suggesting that for every 4.3 neonates exposed to caffeine, 1 case of AKI was prevented. Caffeine receipt was also associated with a decreased likelihood of developing severe, KDIGO stage 2 or 3 AKI (aOR 0.20; 95% CI 01.2 to 0.34). Further research is needed to better understand how best to utilize caffeine in those neonates at the highest risk to develop AKI.

Given the lack of treatment options for neonatal AKI, significant efforts have been given to establishing protocols and guidelines to help prevent AKI. Quality improvement programs designed to prevent harm from nephrotoxic mediations called NINJA (Negating Injury from Nephrotoxins with Just-in-time Action) and Baby NINJA have been reported.[92,93] Stoops et al. (2019) reported a reduction in nephrotoxic medication exposures (16.4 to 9.6 per 1000 patient days; $P = .03$), a reduction in the percentage of nephrotoxin-associated AKI (30.9% to 11.0%; $P < .001$), and a reduction in AKI intensity (9.1 to 2.9 per 100 suspectable patient days; $P < .001$).[94] These authors estimated Baby NINJA prevented 100 AKI episodes during the 18-month sustainability era of their project.

Step 3: Manage Consequences of Kidney Failure

The clinician has an important role in helping to achieve homeostasis during episodes of AKI, and careful attention to the fluids and electrolytes being delivered to the patient is critical. Managing fluids in the critically ill neonate with AKI can be very difficult and requires close attention. Once adequate intravascular volume has been restored, prevention of severe fluid overload is paramount. Severe fluid restriction, limiting intake to insensible, gastrointestinal, and kidney losses, is sometimes required to prevent or treat fluid overload but is performed at the heavy price of inadequate nutrition. Trending of cumulative fluid overload on daily rounds should be reported. Decisions on the placement of dialysis access should be considered early in those with severe fluid overload as fluid overload is associated with adverse outcomes across critically ill patient populations.[37,95–98]

Although diuretics do not impact the course of AKI, they can be used to assist in maintaining fluid homeostasis. If an adequate dose of a loop diuretic (i.e., 1 mg/kg of furosemide intravenously) does not improve UOP, it is unlikely that higher doses, changing diuretic, and/or changing to continuous dosing will benefit the infant, and their use could have negative side effects. The KDIGO Clinical Practice Guidelines for AKI suggest "not using diuretics to treat AKI, except in the management of volume overload."[89]

Electrolyte abnormalities can vary depending on the cause of AKI. For example, aminoglycoside toxicity is commonly non-oliguric with ongoing potassium and magnesium losses. Alternatively, ischemic AKI causes oliguria/anuria, hyponatremia, hyperkalemia, hyperphosphatemia, and hypocalcemia. Polyuria with electrolyte (especially bicarbonate) losses may occur following the relief of a urinary obstruction. Management of electrolyte disorders can typically be managed by attention to electrolyte intake during the initial course of AKI, frequent evaluation, and specific therapies.

Most cases of hyponatremia are due to water overload and, less commonly, low total sodium body composition. Attention to fluid status is critical to determine the cause and proper treatment of hyponatremia. In cases of non-symptomatic hypervolemic hyponatremia (serum sodium concentrations usually between 120 and 130 milliequivalent [mEq]/L), restriction of free water intake is recommended. If hyponatremia at this level results in clinical signs and symptoms (lethargy, seizures) or serum sodium concentration falls below 120 mEq/L, the use of 3% sodium chloride over 2 hours should be considered, but caution should be used to assure that the sodium is not corrected too quickly. Possible complications of hypertonic saline administration include congestive heart failure, pulmonary edema, hypertension, intraventricular hemorrhage, and periventricular leukomalacia. Care should be taken not to increase serum sodium concentration more rapidly than 0.5 mEq/h.

TABLE 77.7 Randomized Controlled Trials of Theophylline in Neonatal Hypoxic Ischemic Encephalopathy

Study	Population and Study Design	Dose and Timing of Theophylline (vs. Placebo)	Findings and Kidney-Related Outcomes
Raina et al. 2016	Single center ($n = 159$ severely asphyxiated term newborns)	Theophylline 5 mg/kg IV × 1 during first hour of life	• Theophylline group had lower SCr levels[a] (0.83 ± 0.35 vs. 1.47 ± 0.61; $P = .00$) • Theophylline group had higher endogenous CrCl (32.16 ± 16.34 vs. 17.73 ± 7.92; $P = .00$) • More AKI in placebo group[b] (117 [48%] vs. 36 [15%]; $P < .01$)

Eslami et al. 2009	Single center ($n = 36$ severely asphyxiated term and post-term newborns, >2.5 kg at birth)	Theophylline 5 mg/kg IV × 1 during first hour of life	• At 24 h of life, fluid balance was more positive in infants in placebo group[b]
			• On DOL 3 and 5, significantly higher SCr noted in placebo group[b] ($P < .05$ all)
			  • DOL 3: 1.06 ± 0.47 vs. 0.63 ± 0.22
			  • DOL 5: 0.73 ± 0.14 vs. 0.56 ± 0.14
			• Severe kidney dysfunction more prevalent in placebo group[b] (8 [42.1%] vs. 2 [11.7%])
			• On DOL 3, GFR[c] increased in theophylline group[a] (42.4 ± 19.1 vs. 27.5 ± 10.7; $P < .05$)

Bhat et al. 2006	Single center ($n = 70$ severely asphyxiated term newborns)	Theophylline 8 mg/kg IV × 1 during first hour of life	• Plasma Cr (mg/dL) was higher on DOL 2–5 in control group[b] ($P < .01$)
			  • DOL 2: 1.56 ± 0.92 vs. 0.92 ± 0.65
			  • DOL 3: 1.59 ± 0.92 vs. 0.95 ± 0.50
			  • DOL 4: 1.62 ± 1.03 vs. 0.94 ± 0.45
			  • DOL 5: 1.57 ± 0.90 vs. 0.82 ± 0.47
			• From DOL 2–3, endogenous CrCl[c] higher in theophylline group[a] (20.54 ± 7.96 vs. 7.36 ± 3.52; $P < .01$)
			• Excretion of β2 M (mg/L) was lower in theophylline group[a] (6.7 ± 2.4 vs. 15.2 ± 5.6; $P < .001$)
			• The output/input ratio was higher in theophylline group[a] ($P < .001$ all)
			  • DOL 1: 0.34 ± 0.18 vs. 0.32 ± 0.16
			  • DOL 2: 0.55 ± 0.32 vs. 0.39 ± 0.21
			  • DOL 3: 0.63 ± 0.29 vs. 0.44 ± 0.22
			  • DOL 4: 0.81 ± 0.19 vs. 0.49 ± 0.24
			  • DOL 5: 0.88 ± 0.15 vs. 0.52 ± 0.22
			• Mean weight (grams) was higher in control group[b] ($P < .01$ all)
			  • DOL 1: 2900 ± 250 vs. 2730 ± 410
			  • DOL 2: 2870 ± 240 vs. 2680 ± 420
			  • DOL 3: 2830 ± 230 vs. 2640 ± 410
			  • DOL 4: 2800 ± 250 vs. 2610 ± 410
			  • DOL 5: 2740 ± 210 vs. 2560 ± 430
			• Urine output (mL/kg/h) on DOL 2–5 is higher in theophylline group[a]

Bakr 2005	Single center ($n = 49$ severely asphyxiated term and postterm newborns)	Theophylline 5 mg/kg IV × 1 during first hour of life	• SCr (g/dL) lower in theophylline group on days 2–5 of life[a] ($P < .05$ all)

TABLE 77.8 Medical Management of Hyperkalemia in the Newborn

Medication	Dose	Onset of Action	Duration of Action
Calcium gluconate (10%)	0.5–1 mL/kg (IV over 10 min)	1–5 min	15–60 min
Sodium bicarbonate (3.75% solution)	1–2 mEq/kg (IV over 10 min)	5–10 min	2–6 h
Insulin	1 IU/5 g glucose (IV bolus or continuous infusion)	15–30 min	4–6 h
Glucose	≤14 mg/kg/min (IV bolus or continuous infusion)	15–30 min	4–6 h
Furosemide	1 mg/kg dose or as continuous infusion	5–10 min	2–3 h
Sodium polystyrene sulfonate[a]	1 g/kg dose q 6 h as needed (orally/rectally)	1–2 h[b]	4–6 h
Dialysis	As per nephrology	Immediate	Duration of therapy

[a]Risk of gastrointestinal complications, specifically necrotizing enterocolitis, requiring cautious use.
[b]Onset of action may take up to 6 h, and the drug may be ineffective in preterm infants born at less than 29 weeks of gestation. See text for details.
IU, International unit; *IV*, intravenous.

Severe hyperkalemia is a life-threatening medical emergency. Signs of progressive hyperkalemia on the electrocardiogram, in order of severity, consist of tall, peaked T waves, heart block with widened QRS complexes, U wave formation, the development of sine waves, and finally cardiac arrest. Medications used to manage hyperkalemia, with their dose, onset, and duration of action, are listed in Table 77.8. Measures to remove potassium from the body include oral or rectal sodium polystyrene powder (Kayexalate), loop diuretics (if not anuric), and dialysis. Notably, sodium polystyrene powder should be used with caution given a known association with NEC, particularly when the suspension contains sorbitol.[99–103] Sodium polystyrene power can also be used to pretreat infant formula or expressed breastmilk to decrease the potassium load and decrease potential gastrointestinal complications.[104] Several methods to move potassium from the extracellular to the intracellular compartment are available including albuterol inhalation, sodium bicarbonate, and insulin with glucose. Adequate ionized calcium levels for cardio protection should be sought in the context of hyperkalemia.

Hyperphosphatemia is common in AKI and should be treated with low phosphorus intake. Breast milk and Similac 60/40 both contain low phosphorous and low potassium in comparison to other infant formulas. Significant elevations in serum phosphate pose a risk for the development of extra-skeletal calcifications of the heart, blood vessels, and kidneys in the newborn, especially when the calcium-phosphorus product exceeds 70.[29] Calcium carbonate may be used as a phosphate-binding agent in those whose phosphorous intake exceeds excretion. Although rarely an indication for dialysis without fluid overload or hyperkalemia, severe hyperphosphatemia can be treated with dialysis.

Hypocalcemia is possible in neonates with severe and prolonged AKI, especially those who develop an inability to convert 25-hydroxy-vitamin D to 1-25-hydroxy-vitamin D. Ionized calcium should be measured in those with low total calcium levels as concurrent hypoalbuminemia can affect total calcium levels. If ionized calcium is decreased and the newborn is symptomatic, 100 to 200 mg/kg of calcium gluconate should be infused over 10 to 20 minutes and repeated every 4 to 8 hours as necessary. Oral or intravenous calcitriol may be administered to increase intestinal reabsorption of calcium.

Normal acid-base homeostasis depends on the kidney's ability to reabsorb bicarbonate. Thus, infants with AKI commonly have a non-anion gap metabolic acidosis. Replacement with bicarbonate or acetate is indicated in those with AKI to avoid or treat metabolic acidosis. In infants with severe respiratory failure, large doses of bicarbonate should be avoided as this can result in respiratory acidosis.

Nutritional goals in infants with AKI are similar to those of infants without AKI. Commonly, parental nutrition and/or feeds will need to be concentrated to avoid excessive fluid gains. If

nutritional goals are unable to be achieved due to oliguria and ongoing fluid overload, the potential risks of dialysis therapy versus the potential risks associated with inadequate caloric and protein needs should be discussed. If a neonate is on continuous peritoneal dialysis (PD) or hemodialysis (HD), an additional 1 g/kg/day of protein is needed to supplement the protein losses that occur.[105,106]

In a neonate with AKI, careful assessment of medication dosing is imperative. Because many drugs are excreted in the urine, impaired metabolism or clearance from the kidneys can cause drug accumulation and adverse side effects. In those on dialysis, pharmacokinetic properties (volume of distribution, protein binding, size, charge) of drugs, dialysis modality (PD vs. HD), and interval of dialysis (intermittent vs. continuous) will affect drug availability.[107] Consultation with pharmacists and nephrologists familiar with drug dosing in kidney failure is invaluable for neonates with AKI.

Kidney Support Therapy With Dialysis

Kidney support therapy (KST; also known as renal support therapy, renal replacement therapy, or dialysis), either through the use of the peritoneal membrane or with extracorporeal blood systems, does not prevent or treat kidney failure; instead, it is used solely to support the infant who lacks the ability to maintain electrolyte, fluid, or acid/base homeostasis despite maximal medical management. KST can be provided via peritoneal access (i.e., PD) or intravenous access (i.e., HD) and can be provided continuously or intermittently. The decision to initiate KST (especially in those infants with severe congenital malformations of the kidney and urinary tract) is complex and requires a multidisciplinary approach (see later on decisions to initiate KST). Access placement and technical challenges make neonatal KST more difficult than KST in older children, but this therapy is feasible in experienced programs with dedicated pediatric nephrologists, neonatologists, dialysis nurses, and surgeons.

Indications for Dialysis Initiation

Absolute indications to initiate KST/dialysis include severe electrolyte abnormalities that are not correctable with medical interventions, life-threatening intoxications of medications that can be cleared with dialysis, inborn errors of metabolism that lead to hyperammonemia, fluid overload that leads to pulmonary edema or other organ dysfunction, and inability to provide adequate nutritional requirements because of oliguria and uremia. If kidney dysfunction and/or fluid overload occurs, discussions about dialysis initiation should occur early because prolonged fluid overload/uremia can worsen pulmonary edema and cardiopulmonary instability, making placement of access for dialysis very difficult.

The timing of initiation of dialysis for those with AKI is controversial. Most pediatric and neonatal AKI occurs due to impaired fluid homeostasis. Pediatricians have been at the forefront of identifying the degree of fluid overload at the initiation of continuous kidney replacement/support therapy as an independent risk factor for survival in critically ill children.[108–111] Further studies evaluating the impact of fluid overload on outcomes in neonates need to be performed. Advocates for early initiation of kidney support argue that critically ill patients benefit from early dialysis because they can remove excess fluid sooner, gain metabolic control faster, and provide maximal nutrition without progressive fluid overload. As technical access and machine advances have made neonatal dialysis safer and technically possible, early initiation of dialysis may improve outcomes in critically ill neonates with AKI. Further studies are needed before recommendations on the timing of dialysis can be made.

Access

The limiting factor in performing dialysis in the smallest of babies is access to the peritoneal space or the vascular space. The ideal acute PD access is a non-cuffed or single-cuffed coiled catheter specifically designed for neonatal PD. If this is not available, the use of a catheter that is typically used for chest tube drainage, or other catheters that may be available, can be lifesaving. The advantage of the straight uncuffed catheter is that it can be placed at the bedside and used soon after insertion. However, these catheters may be more likely to become infected and/or develop leakage of fluids around the insertion site. For the patient who requires chronic dialysis, a catheter with two subcutaneous cuffs and the use of a downfacing exit site away from the diaper area and away from a gastrostomy tube (if present) are recommended.[112] As with all pediatric surgery procedures, the exact type of catheter and the timing and location of catheter insertion need to be tailored to the individual patient.[33]

Vascular access for HD requires a rigid, large double lumen catheter (ideally ≥6.5 French [F]) placed in the femoral or internal jugular vein. Standard intravenous catheters are too flexible and too small to maintain patency with high blood flows; two 4 F or 5 F catheters in different sites can be lifesaving. If dialysis is anticipated to last more than one week, a cuffed catheter is preferred to decrease the likelihood of surgical revision. The length of the catheter should be chosen so that the tip of the catheter resides in the right atrium for internal jugular catheters and in the inferior vena cava (IVC) for femoral catheters. Unless no other choices are available, the subclavian artery should be avoided in infants who are likely to require long-term KST because a future forearm fistula of the ipsilateral arm can fail with "mild stenosis" of the subclavian vein.

Peritoneal Dialysis

Once PD access is placed and the decision to start dialysis has been made, small volume continuous cycles (10 mL/kg) are performed. The dialysate solution is left dwelling in the peritoneal cavity, during which time solute and fluid removal take place, and the solution is then drained. Continuous cycles are performed with each cycle lasting about an hour. The dextrose concentration in the dialysate fluid will determine the amount of net water loss (ultrafiltration). Complications associated with PD include peritonitis, leakage around the catheter exit site, tunnel infection, catheter malfunction, and catheter obstruction by the omentum.[113] Leakage of fluid into other compartments (including the chest in patients without an intact diaphragm) can occur, and, if suspected, the fluid composition of fluid removed from that compartment will reveal high glucose levels if a leak is indeed present. Absolute or relative contraindications to PD include NEC, abdominal wall defects, and the presence of an intraabdominal foreign body, such as a ventriculoperitoneal shunt or diaphragmatic patch.

Hemodialysis and Continuous Renal Replacement Therapy

Once reliable access to the vascular space is achieved, the HD procedure can be performed. The two types of HD, intermittent HD and continuous HD (i.e., continuous renal replacement therapy [CRRT]), differ mainly by the duration of the procedure.

Intermittent HD is significantly more efficient at solute removal than CRRT but technically challenging and often impossible in small neonates. The blood flow and time on therapy are the limiting factors for solute clearance on HD. Even with the smallest dialyzers and neonatal tubing, most infants need blood priming of the extracorporeal circuit for the therapy. Skilled pediatric HD nurses are required at the bedside during the entire procedure, which typically lasts 3 to 4 hours. Achieving the adequate fluid removal necessary for the entire day can be difficult to achieve in the few hours on dialysis, especially in hemodynamically unstable infants. This technique usually requires systemic heparinization, with activated clotting time usually kept at 180 to 200 seconds, rendering the technique risky in preterm newborns and others at high risk for intracranial bleeding.

The main advantage of a continuous modality is that lower blood flow and fluid removal rates can be used to accomplish the desired ultrafiltration and clearance goals. CRRT requires a double-lumen venous catheter whereby the CRRT pump pulls blood from one port of the catheter and returns the blood via the other side of the catheter. CRRT is slowly becoming a more common procedure in the pediatric and neonatal ICU.

Anticoagulation with CRRT is achieved with either systemic heparin or regional citrate anticoagulation. The advantage of regional citrate anticoagulation is that the patient is not systemically anticoagulated; however, this approach has the added risk of hypocalcemia caused by citrate excess (especially in those with impaired liver metabolism) and metabolic alkalosis.[114] Because citrate is metabolized by the liver, caution must be exercised when dialyzing premature infants or newborns with multiorgan failure who may have impaired liver function.

Outcome data in neonates who require CRRT are scarce. Symons et. al. (2003) reported a survival rate of 37.6% (32/85) in neonates who received CRRT in five large children's hospitals in the United States.[115] Between 2001 and 2007, the prospective pediatric CRRT group, a multicenter registry of 14 pediatric CRRT programs, reported outcomes for neonates in whom CRRT was initiated before 1 month of age.[110] About 8% (35 neonates) in the registry were dialyzed in the first month of life. In this group, the median age was 8 days old; the median weight was 3.2 kg, with the smallest infant weighing 1.3 kg. Of the 35 infants in the registry, 24 were dialyzed for either fluid overload, electrolyte imbalance, or both, and 11/35 were dialyzed for inborn errors of metabolism. Overall survival was 43%. Infants dialyzed for inborn errors had a better survival rate (73%) than the others (30%).

Several technical issues specific to infants arise when using CRRT for dialysis. The extracorporeal volume can incorporate greater than 50% of the infant's blood volume. For example, a 2 kg baby has a blood volume of ~80 mL/kg (160 mL); the smallest circuit volume available on the most commonly used machine in the United States has an extracorporeal volume of around 60 mL, about 37.5% of this example infant's blood volume. More recently, low extracorporeal volume CRRT machines have been developed for use in neonates.

The CARPEDIEM (Bellco Medtronic, Mirandola, Italy) is a machine designed for use in neonates.[116] It has been used across Europe and was US FDA approved for use in the United States in the Fall of 2020. The Nidus (Allmed, London, England) is currently being tested in five pediatric hospitals in England.[117] The Aquadex (CHF Solutions, Eden Prairie, MN) has been adapted for neonatal CRT in the United States.[118] With a circuit volume less than half of all other CRRT circuits available, these devices dramatically decrease the hemodynamic instability often experienced during circuit initiation. With less risk and fewer complications have come improved outcomes and broader acceptance of CRRT for neonates.

Priming the CRRT circuit with blood will minimize the risks of hypotension during circuit initiation, but additional complications (acidosis, hypocalcemia, thrombocytopenia, and dilution of coagulation factors) make initiation of CRRT challenging. The risk for the bradykinin reaction that can occur at the initiation of CRRT with AN69 dialyzer (Baxter, Chicago, IL) membranes can be reduced using several techniques that minimize exposure of acidotic blood to the membrane including blood buffering, transfusion of blood postfilter in a saline-primed circuit, and zero balance ultrafiltration.[119,120]

Hyperammonemia, due to an inborn error of metabolism such as a urea cycle enzyme defect, can rapidly lead to brain damage in a newborn and requires high index of suspicion to diagnose. Treatment involves both decreasing the production of ammonia and avoidance of protein but also removal of toxic metabolites via dialysis. An ammonia level exceeding 560 µg/dl (400 ummol/L) is an indication for dialysis.[121]

Acute Kidney Injury as a Cause of Long-Term Chronic Kidney Disease

Total GFR is determined by the filtration rate of single nephrons and the number of nephrons present. When the number of nephrons is diminished, single nephron GFR increases as the kidney works to compensate for low nephron numbers. This compensatory hypertrophy causes glomeruli to function under increased intracapillary hydraulic pressure, which, over time, causes damage to capillary walls. This abnormal process leads to progressive glomerulosclerosis, proteinuria, hypertension, and chronic kidney disease (CKD).[122] This hyperfiltration hypothesis has been applied and confirmed in autopsy data of hypertensive patients[123,124] and has been written about at length regarding infants with intrauterine growth restriction.[125–129] A systematic review and meta-analysis in 2009 concluded that low BW babies (≤5.5 lb) were 70% more likely to develop CKD later in life compared with individuals with normal birthweight.[129]

Nephrogenesis continues through 34 weeks' gestation. Premature infants are therefore born with low nephron numbers compared with term infants. Autopsy studies suggest that AKI in premature neonates impairs nephrogenesis.[130–133] Follow-up single-center studies in term and premature newborns suggest that AKI may lead to CKD.[134–139] For example, the Follow-Up of Acute Kidney Injury in Neonates during Childhood Years (FANCY) study evaluated 34 premature infants (20 with AKI and 14 without AKI) at an average of 5 years of age.[139] Those without AKI had higher rates of CKD (compared to those without AKI 13/20 [65%] vs. 2/14 [14%]; $P < .05$).

Renal Vascular Disease in the Newborn

Thromboembolic events in neonates usually result from an imbalance of the delicate homeostasis between bleeding and thrombosis. Some may be of genetic origin, some may relate to underlying stresses during pathologic processes, and some may relate to treatments for the pathologic processes. Both RAT and RVT occur in the neonate and pose a significant threat to short and long-term kidney function.

Renal Arterial Thrombus

The major risk factor for RAT is umbilical artery catheterization. However, shock, coagulopathy, and congestive heart failure all pose risks. The detection, and thus incidence rates of RAT vary depending upon the diagnostic test chosen. Doppler ultrasonography estimates the incidence of umbilical artery-related thromboembolism from 14% to 35%, whereas studies using angiography document incidences up to 64%; however, clinical symptoms of umbilical artery-related thromboembolism occur in only 1% to 3% of infants.[140] RAT in the neonate is far less common than RVT.

Clinical presentation varies with the extent and severity of thrombosis. Thrombosis of the abdominal aorta or renal arteries can manifest in any of the following ways: signs of congestive heart failure, hypertension, oliguria, kidney failure, decreased femoral pulses with lower limb ischemia, or bowel ischemia/frank NEC secondary to superior or inferior mesenteric artery thrombosis. Symptoms of RAT manifest within the first few postnatal days in a term neonate, compared with a median age of 8 days in a preterm neonate. Laboratory findings associated with RAT are thrombocytopenia, hypofibrinogenemia, elevated fibrin split products, variable prothrombin and thromboplastin times, conjugated hyperbilirubinemia, elevated blood urea nitrogen and creatinine, hyperreninemia, and hematuria.

Doppler ultrasonography is used as the first line of imaging for diagnosing RAT, although it usually fails to detect smaller intra-arterial thrombi.[141] If ultrasonography is inconclusive, radionuclide imaging can be used. Angiography is the standard diagnostic modality and should be performed through the umbilical artery line if surgical intervention or fibrinolytic therapy is being considered.

For asymptomatic or minimally symptomatic newborns, only supportive care is recommended, such as removal of the umbilical artery catheter and close ultrasonographic monitoring. Most of these thrombi resolve spontaneously. In newborns with mild signs of organ dysfunction and stable thrombosis, management of hypertension, transient kidney insufficiency/AKI, and mild congestive heart failure is recommended. Systemic heparin is given for anticoagulation. Close laboratory monitoring is done to avoid excessive heparinization, and clinical response is monitored by Doppler ultrasonography.

In case of potentially life-threatening complications of aortic or renal thrombosis, fibrinolytic therapy (systemic or intrathrombotic) along with supportive care is indicated. There are limited data on the efficacy, dose, and safety of fibrinolytic agents in infants.[142,143] The intrathrombotic infusion of a fibrinolytic agent, typically tissue plasminogen activator (tPA) reduces the cumulative dose and possible systemic adverse effects. Close monitoring by ultrasonography or angiography should be done to evaluate the response to this therapy.

The overall mortality rate with aortic thromboses and RAT is between 9% and 20%, with mortality being higher with major aortic thromboses and RAT.[144] Renovascular hypertension is the most common long-term complication. In most cases, these infants eventually are weaned from antihypertensive medications and remain normotensive.

Renal Vein Thrombosis

RVT is the most common thrombosis in infancy and occurs primarily in the newborn period with an incidence of 2.2 cases per 100,000 live births.[145] RVT has a male predominance of approximately 67%; it is unilateral in more than 70% of patients and more prevalent on the left side (approximately 63%). The thrombus also involved the IVC in approximately 43% of the cases, and it was associated with adrenal hemorrhage in approximately 15%.[146,147]

The cause of RVT is unknown, although a number of factors are associated with this disorder including maternal diabetes, traumatic delivery, prematurity, hyperviscosity, hypovolemia, hemoconcentration, sepsis, birth asphyxia, cyanotic congenital cardiac disease, congenital renal vein defects, and an indwelling umbilical venous catheter.[144,145,147,148] Prothrombotic conditions have a significant role in the pathogenesis of neonatal RVT.[147,149,150]

There are three cardinal signs of RVT: macroscopic hematuria, palpable abdominal mass, and thrombocytopenia; these signs have been found in approximately 56%, 45%, and 47% of cases, respectively.[147] Other signs and laboratory findings associated with RVT are oliguria or anuria, hemolytic anemia, metabolic acidosis, azotemia, and variable prothrombin and partial thromboplastin times.

Kidney/renal ultrasonography (RUS) is used to diagnose RVT, typically demonstrating unilaterally or bilaterally enlarged and echogenic kidneys with attenuation or loss of corticomedullary differentiation and little blood flow. In many cases, calcification and thrombus may be seen extending into the IVC.[148] Doppler studies are useful for detecting resistance or absence of flow in renal venous branches and collateral vessels. Although RUS is most commonly used, contrast angiography is considered the gold standard. MRI has also been reported to give excellent diagnostic findings in RVT, although it should be reserved for those cases in which Doppler findings are inconclusive.[151]

Treatment of RVT remains controversial as literature is lacking to compare therapies which include anticoagulation, fibrinolysis, or both. Supportive therapy should be provided to all affected infants. Hypertonic solutions, nephrotoxic medications, hyperosmotic radiographic contrast agents, and unnecessary use of diuretics should be avoided. In the case of a spontaneous, unilateral RVT without kidney impairment/AKI or extension, current guidelines recommend radiologic monitoring for thrombus extension or therapeutically dosed anticoagulation (unfractionated heparin [UFH] or low molecular weight heparin [LMWH][143]). Therapeutically dosed UFH or LMWH are recommended for spontaneous, unilateral RVT with renal impairment/AKI or RVT without renal impairment/AKI but with extension into the IVC. In the case of bilateral spontaneous RVT with renal impairment/AKI, anticoagulation with UFH or LMWH or initial thrombolytic therapy with TPA followed by anticoagulation with UFH or LMWH is recommended. Monitoring and continued therapy until resolution for a total duration of 6 weeks to 3 months is included in the guidelines. Surgical interventions such as thrombectomy or nephrectomy have not shown any benefit.

Affected neonates must be followed closely for kidney complications. Kidney scarring and atrophy are well-recognized complications of RVT. Approximately 19% of patients have a persistent elevation of blood pressure, which has been shown to be slightly higher—at 21% for those with bilateral RVT. The mortality rate for neonates with RVT is approximately 3%.[147] Because more than 80% of neonates with RVT have shown persistent abnormalities on kidney imaging and there are not enough data on long-term outcomes of such neonates, continued follow-up is strongly recommended.

74 Renal Development

IRENE MCALEER AND KAI-WEN CHIANG

KEY POINTS

- Renal organogenesis is a complex interaction between gene stimulation of planned growth and complementary apoptosis, allowing appropriate development of the functioning renal organ system, vascular bed, and intertwined genital system.
- The renin-angiotensin system (RAS) is critical to normal renal development through delicate interaction between the maternal–placental RAS and the developing fetal RAS, which has central hormone-specific and sex-specific configurations that help the developing vascular and renal organogenesis.
- Preterm birth (<37 weeks gestation), as well as low birth weight, are associated with chronic kidney disease (CKD), and the improved survival with treatment warrants more research into long-term health optimization of these patients.

The human kidney, specifically the metanephric kidney, is an extremely complex organ with more than 25 functionally and morphologically different distinct cell types performing vitally important functions for the developing human. These actions include filtering waste products, maintaining electrolyte and fluid homeostasis, facilitating bone mineralization, regulating blood pressure, and blood composition.[1] The nephron of the kidney performs these functions. The number of human nephrons range from 200,000 to 2,000,000 for each kidney with peak growth during the third trimester and complete nephrogenesis by 36 weeks' gestation.[2] Any further growth of the kidney is due to an increase in the size of the individual nephrons rather than an increase in nephron number.

Renal organogenesis is a complex and incompletely understood process. Factors affecting maternal and fetal health, including environmental factors in utero, can lead to failure of normal morphogenesis, resulting in congenital anomalies of the kidney and urinary tract. If the complement of nephrons is decreased by prematurity, low birth weight (LBW), or exposure to environmental agents causing damage to the developing renal system, adult renal disease and hypertension may occur.[2] Many steps in the development of the human kidney are unknown but are extrapolated from the study of animal models. This chapter will review known (and postulated) molecular and cellular mechanisms of renal development, the impact of environmental factors on the developing fetal kidney, and the long-term risks of CKD and other associated adult health outcomes.[2–4]

Factors Influencing Organogenesis

Organogenesis, or organ formation, begins with early patterning of cell groups through gene expression with transcription factors that act to determine cell fates specific to each given organ.[5]

Transcription factors, generally ribonucleic acids (RNAs) directed by DNA information, are incorporated into larger molecular networks and ultimately, direct downstream signaling pathways. Transcription factors may have different purposes in each developing organ system. Similarly, signaling pathways are used repeatedly in each different organ's development, and these pathways may also be used in multiple stages of differentiation in the same organ.

Signaling pathways establish epithelial morphogenesis by allowing cell polarity, bending, and folding to shape developing tissues and to allow these tissues to interact with the loose mesenchyme surrounding the epithelia through signaling. This reciprocal induction between epithelia and mesenchyme is well illustrated in kidney development, where expression of the transcription factor Wilms tumor 1 (WT1) in the metanephric mesenchyme leads to glial cell–derived neurotropic factor (GDNF) expression critical for the outgrowth of the developing epithelial ureteral bud. Reciprocally, the ureteral bud then signals back to the metanephric mesenchyme to induce formation of the renal nephron units. There is a delicate balance between the interplay between the ureteral bud and the developing mesenchymal metanephros to allow tissue differentiation into the final renal unit.

Enhanced imaging, ex vivo organ culture, and computational strategies have advanced our understanding of the physical forces inside and outside the cells in organ development.[5] Study of different species has led to better understanding of the role of extracellular matrix in regulating the mechanical properties of the developing tissues. The extracellular matrix also provides substrata for cell migration, rotation, and elongation necessary for organ development. Most of this research is in nonhuman tissue at present, but basic understanding of generalized organogenesis is important in determining the steps critical in human organ development, with potential implications for regenerative medicine as well.

Development of the Renal Vascular Bed

The vascular systems of all vertebrates are highly organized branched networks of arteries, veins, and capillaries. The circulatory system in combination with the hematologic system is the

first functioning physiologic system to develop in embryogenesis.[6] Development of the cardiovascular and hematologic systems must occur in tandem because simple diffusion of oxygen and nutrients would be insufficient for organ development as the embryo enlarges. Formation of the vascular system is therefore crucial for proper tissue growth and differentiation, delivery of oxygen and nutrients to the developing organism, and removal of waste.

Vasculogenesis and angiogenesis play a primary role in determining patterning of the developing embryo through the paracrine action of the endothelial cells. Blood vessels are critical for organ development, differentiation, and postnatal remodeling. There is a reciprocal relationship, with the developing organ providing signals to the endothelial cells of the developing vasculature, while the endothelial cells signal patterning instructions for organ formation. Vascular development begins shortly after gastrulation when the blood islets form in the yolk sac and angioblast precursors form in the head mesenchyme and the posterior lateral plate mesoderm. Vascular precursor cells are present in the metanephric blastema. Local environmental cues initiate differentiation of the endothelial layer in the developing kidney by forming the renal vascular tree after transplant of different extrarenal endothelial cells to the developing renal bed as studied in developing mouse kidneys. Angiogenesis generally occurs later in embryogenesis by increasing the previously laid vascular bed by sprouting, bridging, and intussusceptive growth. Ultimately, the primitive vessels branch, prune, and specialize to accommodate the probable function of each respective organ that they feed. Oxygen tension and hemodynamic forces are critical for developing the delicate patterns specific to the local vasculature. Angiogenic growth factors are necessary for vasculature development as well as for organ patterning. The most important factors responsible for angioblast differentiation and tube formation are vascular endothelial growth factors (VEGFs). VEGFs are found early in blood vessel patterning and later help modulate endothelial maintenance in normal tissues before and after birth. The endothelial cells themselves are the source of these proteins. VEGF also helps mobilize blood elements from the bone marrow through interactions with hematopoietic stem cells there.[6] The development of the area-specific branching pattern is likely due to local factors and different local progenitor cell populations. The podocyte epithelial cells in the developing glomerular region secrete large amounts of VEGF, stimulating increased branching of the vessels forming in this area (Fig. 74.1). Fibroblast growth factors (FGFs) are heparin-binding growth factors that interact with endothelial cell surface receptors. Their primary purpose is to help control branching morphogenesis of the vascular tree during organogenesis. The post-glomerular vascular bed is closely aligned to the vasa recta in the renal tubule structures and is likely regulated by angiogenic factors such as VEGF secreted by the tubules themselves. Postnatal development of the vasa recta has also been found to be mediated by VEGF. Renal vasculature development occurs through simultaneous vasculogenic and angiogenic processes. VEGF is critical in the regulation of blood vessel formation in the kidney and is also responsible for the coordinated development of the glomerulus and renal tubular development simultaneous to its regulating vasculogenesis. Animal model studies suggest that postnatal branching may be mediated by the renin-angiotensin system (RAS).

The renal vascular bed is unique compared with other organ systems. The kidneys compose less than 0.8% of the human body weight but receive 20% of the cardiac output at any given time.[7] The volume of blood sent to the kidney is critical for clearing the body of metabolic waste, as well as maintaining fluid and ion homeostasis in the bloodstream. The renal artery enters the kidney near the central portion of the kidney or hilum, which is close to the medulla of the kidney. Although the renal artery is proximal to the medulla of the kidney, 90% of the blood it delivers is sent directly to the glomerular capillary bed in the periphery of the kidney, and only 10% is delivered to the medulla.

The arterial structure of the kidney is critical for directing blood primarily to the glomerulus. The mechanisms for this patterning during development are not well understood, but as development proceeds, the medullary portion of the arterial tree has very little branching, whereas the cortical arteries have extensive branching, especially the afferent arterioles surrounding the glomeruli.

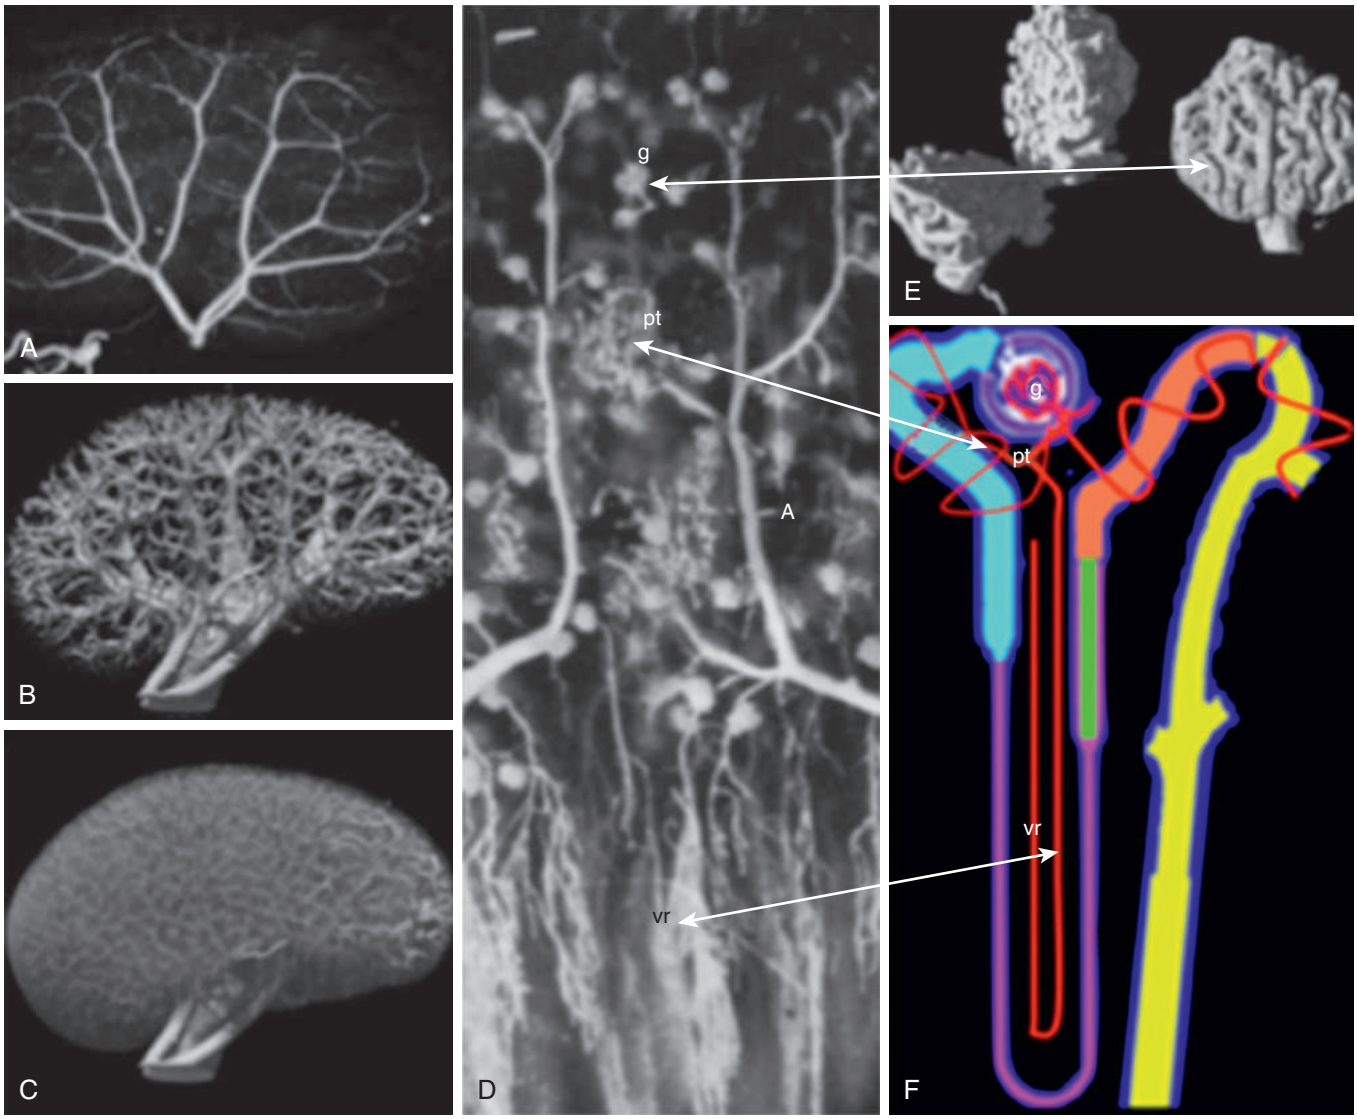
For appropriate renal function, the glomerulus endothelium is very permeable to fluids and low molecular weight solutes. The resistance of the renal vasculature surrounding the glomerulus is very high, to allow the ultrafiltrate produced to flow through the urinary space at 125 mL/min. These high-resistance arterioles allow the amount of fluid emanating from glomerular capillaries to be about 50 times greater than the fluid outflow of other capillary systems in the body. In contrast, the peritubular capillaries have high oncotic pressure, allowing them to reabsorb solutes and fluids that would otherwise be lost by this high glomerular filtration rate (GFR). There is a complementary interplay between the renal tubules reabsorbing fluid, electrolytes, and solutes from the glomerular filtrate and the peritubular capillaries returning these substances to the systemic circulation because of this high oncotic pressure pull.

The vasa recta is an additional renal capillary bed adjacent to the renal tubules in the medulla. These vessels act by delivering oxygen and nutrients to the medulla and return electrolytes and solutes reabsorbed by the medullary renal tubules. The long-looped arrangement of the vasa recta close to the loop of Henle is critical for urine concentration by conservation of water through increased osmolarity in this region in the renal medulla.[7] The blood is ultimately collected in the venous system at the cortical medullary region of the kidney and flows out of the kidney through the renal vein.

Renal Morphogenesis

The mammalian urogenital system develops from the intermediate mesoderm. Paired epithelial nephric ducts arise dorsally and elongate caudally on the right and left sides of the embryo until they induce development of the pronephric and mesonephric duct formation from intermediate mesenchymal mesoderm. These ducts elongate until they reach and fuse with the cloaca, which is the bladder and urethral precursor. Primitive tubules develop as the pronephros and mesonephros and are transient with minimal function, and only a portion remains of the mesonephric tubules as part of the male reproductive system.[1]

The metanephric kidney arises from the posterior nephric duct through reciprocal signaling induction between the metanephric mesenchyme and nephric duct causing the ureteral bud to form. Human metanephric differentiation starts at about 5 weeks' gestation, and the first functioning nephrons are formed at about week 8. The ureteral bud then invades the metanephric mesenchyme to initiate the mesenchymal to epithelial differentiation giving rise to the glomerulus–nephron–collecting duct system of the mature kidney. The requirement for intermediate mesoderm appears to

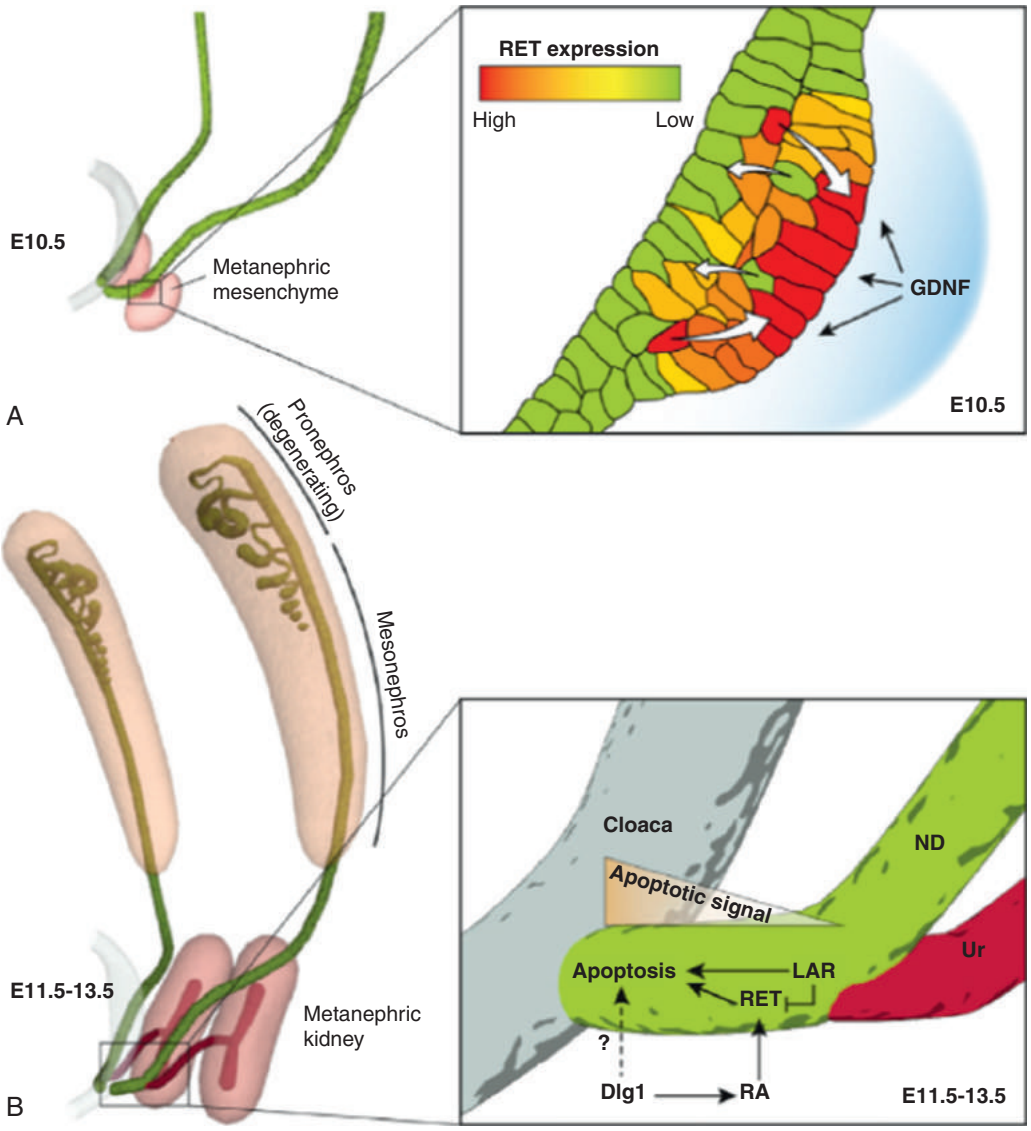


• **Fig. 74.1** Anatomy of the Renal Vascular Bed. Reconstructed scan of an entire mouse kidney corrosion cast by nano computed tomography (A–C). Thresholding for large vessels (A) illustrates the stereotypic architecture of the renal artery and its major branches. As thresholding is adjusted to visualize smaller vessels, the cortical arterial tree up to the level of the intralobular arteries is detected (B). Finer thresholding allows the visualization of the complex architecture of the cortical microvasculature (C). (D) Corrosion cast of rat kidney images by scanning electron microscopy. The glomeruli (*g*), peritubular capillaries (*pt*), and vasa recta (*vr*) are easily visualized. (E) A corrosion cast of an isolated glomerulus imaged by nano computed tomography illustrating the complexity of the capillary loops. Patterning the renal vascular bed. *Semin Cell Dev Biol*. 2014;36:50–56.)

be regulated by bone morphogenetic protein (BMP) signaling, which is also required for maintenance of the pronephric duct gene expression to allow survival and differentiation of the developing nephric duct.

Paired box genes (*PAX2* and *PAX8*) appear to be necessary to drive nephric duct development, elongation, and maintenance.[8] The final stage in early nephric development is the separation of the genital tract from the urinary tract. Once the ureteral bud extends from the nephric duct, the urinary tract separates the ureter from the common nephric duct through apoptosis to form the new ureterovesical junction into the cloacal structure that will be the urinary bladder. This apoptosis is most active at the caudal region and less so at the ureteral bud branching point. The apoptosis occurs through downregulation of RET (receptor tyrosine kinase) activity. RET is still needed for ureteral remodeling but at an expression level lower than that needed for generation of the ureteral bud branching off the nephric duct. Ultimate elimination of the common nephric duct is necessary for normal urinary tract function. Absence or delay in ureteral remodeling may result in ureteropelvic junction obstruction. Overactivation of apoptosis of the common nephric duct may result in vesicoureteral reflux (Fig. 74.2).[8]

Development of the ureteral bud requires an active RET–glial cell line-derived neurotrophic factor (GDNF) pathway. GDNF



• **Fig. 74.2** Interaction between mesenchymal and nephric duct epithelial tissues drives cell sorting to form the ureteric bud and programmed cell death during ureter maturation. (A) Ureteric bud evagination involves RET tyrosine kinase–dependent cell sorting *(white arrows)* to assemble the highest RET-responsive cells toward glial cell–derived neurotropic factor (*GDNF*) secreted from the metanephric mesenchyme. (B) A graduated apoptotic signal drives elimination of the common nephric duct. Apoptotic cell death involves Dlg1 and retinoic acid (*RA*) signaling from the mesenchymal compartment, which appear to act through RET within the common nephric duct. Apoptosis additionally requires the expression of LAR-family receptor protein tyrosine phosphatases in the common nephric duct, which act partially by down-regulating RET prosurvival signaling. *E*, Embryonic day; *ND*, nephric duct; *Ur*, ureter. is located in the metanephric mesenchyme adjacent to the nephric duct and activates ureteral bud development through interaction with RET located along the nephric duct. If RET is absent, ureteric induction fails, but the ureteral bud forms ectopically in studies where GDNF is cultured next to the nephric duct.[9] Wnt (Wingless/integrated) pathway factors, particularly factor 11, and FGFs upregulate GDNF to help with branching of the developing ureteral nephron tree.

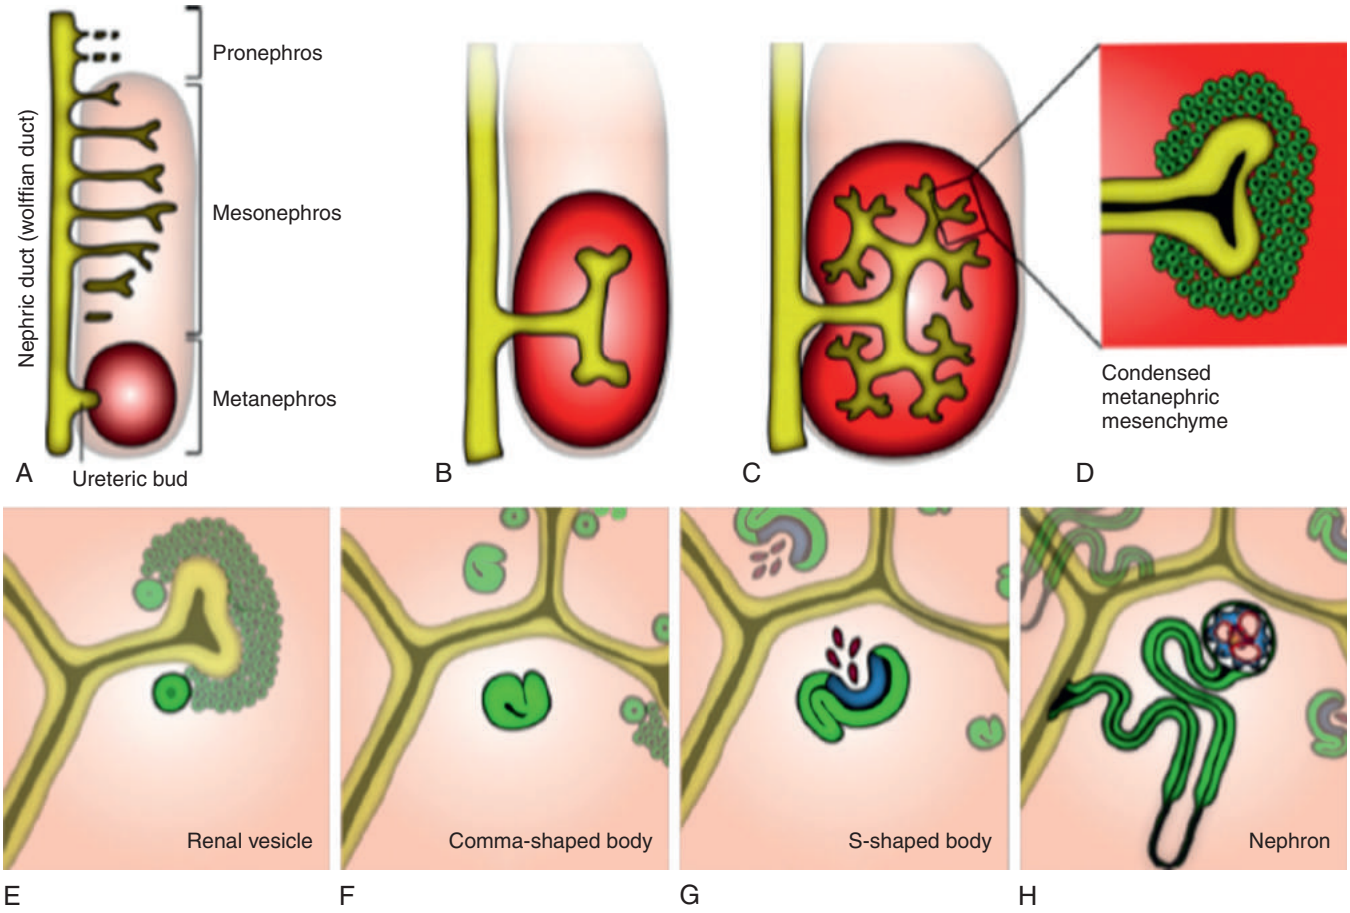
Once the ureteral bud has been stimulated to extend out to the developing metanephric mesenchyme, it begins to branch, forming the ureteric tree, which occurs only at the tips of ureteric tips with RET–GDNF reciprocal signaling, which upregulates RET–Wnt11, further upregulating GDNF secretion. This ureteral signal to release RET is localized to the cap mesenchyme. With continued proliferation, elongation, patterning, and segmentation, the specific functioning regions of the nephron form the recognizable adult nephron (glomerulus, proximal tubule, loop of Henle, distal tubule), which all connect back to the collecting duct (Fig. 74.3).

Once the ureteral bud epithelium invades the metanephric mesenchyme at the cap mesenchyme region, this mesenchyme condenses around the ureteral bud tips under the influence of

The formation of a connection between the forming nephron and the lumen of the adjacent ureteric epithelium occurs at the late RV stage and is shown here at the CSB stage. *BMP7*, Bone morphogenetic protein 7; *GDNF*, glial cell–derived neurotropic factor. (From Little MH. Improving our resolution of kidney morphogenesis across time and space. *Curr Opin Genet Dev*. 2015;32:135–143.)

Wnt genes.[10] The renal vesicle is the first epithelial structure that will ultimately become the future nephron and is activated by the developing ureteral bud. The next phase is the development of the comma-shaped bodies as the first condensation of the renal vesicle metanephric mesenchyme. Formation of the cleft in the comma-shaped bodies denotes the development of the S-shaped bodies, which ultimately initiate renal nephron development (Fig. 74.4). The S-shaped bodies are derived from the cap mesenchyme and become the glomerular tuft once endothelial cells infiltrate this area of the developing nephron. The



• **Fig. 74.4** Nephron Development. (A) In mammals, the kidney develops from the metanephric mesenchyme on invasion of the ureteric bud from the nephric duct. (B, C) The ureteric bud starts branching within the growing metanephric mesenchyme. (D) The mesenchyme condenses around the ureteric bud tips, forming the Six2-positive cap mesenchyme. (E) Renal vesicles form from the condensed cap mesenchyme. (F) A cleft develops in the comma-shaped bodies. (G) Podocyte progenitors start to attract angioblasts in the S-shaped body. (H) The developing nephron connects with the collecting duct. (From Schell C, Wanner N, Huber TB. Glomerular development—shaping the multi-cellular filtration unit. *Semin Cell Dev Biol*. 2014;36:39–49.)

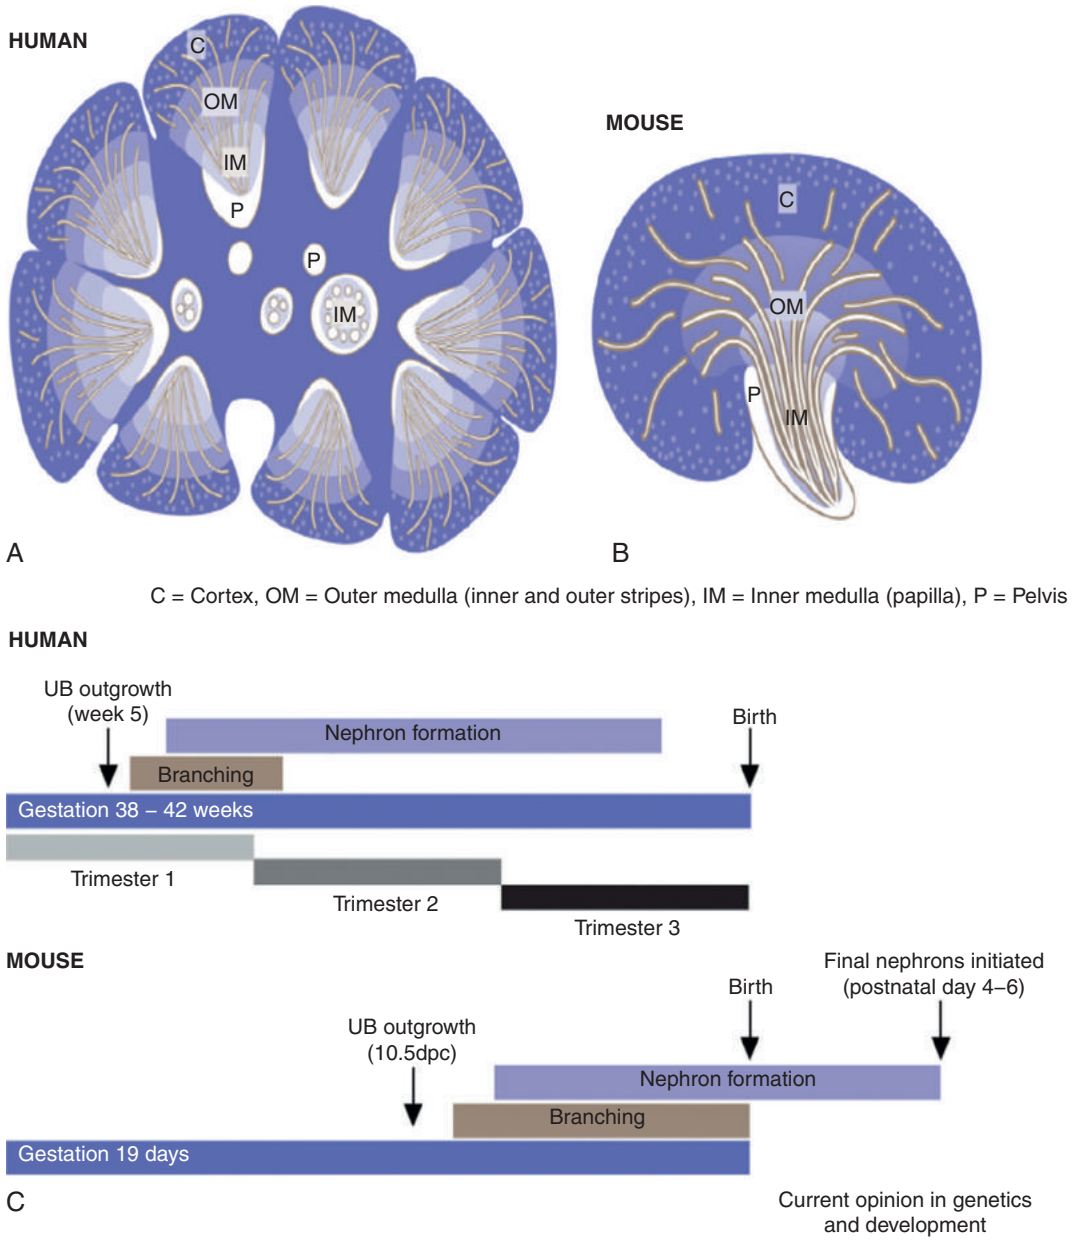
axis of the developing nephron is determined by the S-shaped body after it fuses to the ureteral tip. The proximal end of the S-shaped body will be the glomerulus, while the distal end will fuse to the ureteral bud branching system as the collecting duct. The S-shaped phase of development is when the nephrogenic and vasculogenic processes connect because of secretion of VEGF from the podocytes in the S-shaped body and attract migrating vascular endothelial cells to the S-shaped body cleft (Fig. 74.5).[11]

With time and continued development, the ureteral tip and cap mesenchyme decrease in size. Ureteric branching ceases in the human at around week 14 to 15 of gestation. The human kidney is multipapillate, with about 8 to 15 lobes, each having about 15 generations of collecting duct branching. The extensive patterning and segmentation that occur in nephron development are driven by anchor genes that have absolute specificity for each cell compartment where they are located in the developing embryo. The kidney alone has more than 15 distinct anatomic compartments. To date, 37 anchor genes have been defined for only six sub-compartments in the kidney. The actions of these genes are not yet well known, but the anchor genes may be responsible for initiating differentiation of the various compartments of the nephron by releasing promoters and tissue factors to the local mesenchyme to initiate formation of the functioning renal unit.[12]

Human nephron development is compared with mouse development to extrapolate similar or speculated steps in development that may be the same (see Fig. 74.5). The human nephron complement may differ between individuals, particularly with lower total nephron number with variability in number based on prematurity, extreme prematurity (<28 weeks gestation), low birth weight (<2500 g), and other gestation events such as in utero exposure to maternal factors (preeclampsia, other hypertension, smoking, malnutrition, diabetes, and other maternal conditions).[3]

Glomerular Development

Glomerular formation occurs in stages and is dependent on specific cell type signaling within the glomerular capillary. Malformation of any component of glomerular development may result in decreased nephron filtration ability, typically characterized by proteinuria.



• **Fig. 74.5** Comparative timeline of kidney development between human and mouse. The human (A) and mouse (B) kidney illustrating the anatomic differences. The human kidney consists of 8–15 lobes, each with a branching ureteric tree and inner medulla (*IM*; papilla), while the mouse kidney is unipapillate. (C) Comparative developmental timeline of human and mouse nephrogenesis identifying the duration of gestation, timing of initial ureteral bud (*UB*) outgrowth, period of ureteric branching, and period of nephron formation. Note the prolonged period of nephron formation in the human after the end of branching in comparison with the mouse. Note also that the final nephron formation in the mouse occurs in the immediate postnatal period. *C*, Cortex; *dpc*, date post conception; *OM*, outer medulla, *P*, pelvis. (From Little MH. Improving our resolution of kidney morphogenesis across time and space. *Curr Opin Genet Dev*. 2015;32:135–143.)

Development of the glomerulus is intricately linked with the development of the renal tubule. Glomerular formation begins at the S-shaped body stage of nephron development. Glomerular endothelial progenitors are found adjacent to the nephron-developing podocytes at the cleft of the S-shaped structure during the early stage of nephron development. An initial capillary loop will ultimately mature into six to eight capillary loops representing the mature glomerular capillary tuft. Migration of glomerular endothelia progenitors is likely due to VEGF secretion by the local podocytes. The amount of VEGF released by the podocytes controls capillary development through proangiogenic and antiangiogenic signaling.[7] It is critical that these podocyte foot processes connect tightly or the filtrate from the afferent arteriole will allow leakage of larger molecules such as protein and larger solutes,

causing loss of important proteins, fluid, and solutes that should be returned to the systemic vasculature. These foot processes are integral to the glomerular filtration barrier.

Vasculogenesis starts during the S-shaped body stage of glomerular development when expression of several VEGFs from the glomerular podocytes occurs, inducing migration of endothelial cells to the cleft of the S-shaped body. VEGF-A secretion by the podocytes of the S-shaped body causes fenestration of the podocytes near the glomerular basement membrane in close proximity to the glomerular endothelial cells, possibly allowing limited transmission of fluid from the vascular tuft into the glomerulus, but the function and mechanism of these fenestrations are not well understood.

WT1 is a zinc finger transcription factor, with four different isoforms isolated to date. It is thought to be a transcription factor that binds to DNA as well as messenger RNA as either a repressor or an activator in different organs during fetal development. Studies in mice showed that WT1 is important for genitourinary development. In humans, WAGR syndrome (Wilms' tumor, aniridia, genitourinary abnormalities, and mental retardation) is caused by interstitial deletion of the 11p13 locus, where the *WT1* and *PAX6* genes are located. Similarly, *WT1* mutations are thought to contribute to the abnormalities seen in Denys-Drash syndrome (mesangial sclerosis, Wilms' tumor, and gonadal dysgenesis). Studies of WT1 absence or mutations have been done extensively in mice, showing that WT1 is essential for podocyte development and possibly for podocyte maintenance. Further study in humans is needed to better understand WT1 interactions in normal genitourinary development as well as what aberration of WT1 expression does in disease states.

Ureteral Growth and Development

The ureters are muscular tubes conveying urine from each renal pelvis to the urinary bladder. The upper ureter, leaving the kidney at the renal pelvis, is a thin-walled, funnel-shaped tube that thickens as it passes through the abdomen and enters the bladder obliquely to terminate at the bladder trigone. There are two tissue components to the ureter: the specialized endothelial-lined lumen and the outer mesenchymal coat consisting of the lamina propria, multilayered smooth muscle, and the outer tunica adventitia. This outer tunica adventitia also contains ascending and descending blood vessels, nerves, and lymphatics. The ureter does not passively allow the urine to drain from the kidney to the bladder but directs the urine to the bladder with unidirectional peristaltic contractions propelling the urine to the bladder. The peristaltic waves, triggered by pacemaker cells, cause depolarizing contractions in the smooth muscle cells located in the ureteropelvic junction.

Abnormalities in the smooth muscle function, particularly in the ureteropelvic or ureterovesical junctions, prevent efficient drainage of urine from the renal pelvis to the bladder and can cause either urinary efflux or urinary reflux. Obstruction at either the upper ureter or the lower ureter, with dilation of the ureter (hydroureter) or renal pelvis (hydronephrosis), can cause damage to the renal parenchyma, with marked decrease or even absence of function if obstruction is severe. These conditions comprise a large subset of congenital anomalies of the kidney and urinary tract, and are frequent manifestations of underlying genetic defects. Diagnosis of such defects is now frequently made before birth with prenatal ultrasound imaging.[13]

The ureters arise from the nephric duct, as do the metanephric kidneys. The ureteral bud evaginates from the nephric duct and becomes the ducting system in the kidneys ending as the collecting duets through extensive branching and elongation, and the stalk portion of the ureteral bud becomes the epithelial portion of the ureter. In the human, starting on embryonic day E12.5, the distal end of the stalk separates from the nephric duct to integrate into the urinary bladder and separate from the genital tube structures. Urine production starts around E16.5, by which time the epithelium around the ureteral stalk differentiates into urothelium. The development of the smooth muscle layer starts around E13.5 to E15.5.

The development of the ureter depends on ureteral bud development and on GDNF binding to RET, which activates the formation of the endothelium from the tissue near the nephric duct. If the GDNF signaling is anterior or posterior to the normal placement of the ureteral bud, the ureters may develop ectopically in the bladder or urethra.[13] The primordial ureters that arose from the nephric duct will differentiate into the vas deferens in the male, while they degenerate in the female.

To remain patent, the ureter must translocate from the nephric duct into the developing bladder wall in the cloaca. The first step occurs when the nephric duct fuses to the cloaca. This may occur from mutual signaling between the nephric duct to the cloaca. The precise mechanisms on this translocation are poorly understood. In the second step, the distal part of the ureter is incorporated into the bladder wall, where it undergoes apoptosis until the ureter is placed in its final position on the bladder trigone. If there is aberrant distal ureteral maturation, the ureter will end blindly inside or outside the bladder as a ureterocele or an ectopically located ureter in the bladder, urethra, or other ectopic location along the genitourinary tract following the path of the involuting nephric duct. These ureters are hydronephrotic.

Further formation of the proximal, mid, and distal parts of the ureter depends on the local epithelia and mesenchyme tissue in the region of that portion of the developing ureter. The mesenchyme near the distal ureteral stalk will elongate, while the same mesenchyme transplanted to the proximal ureteral region will branch and induce nephrogenic aggregates that will lead to nephron-like structures. The signaling molecule for distal ureteral development through mesenchymal specialization is likely bone morphogenetic protein 4 (BMP4). Absence of or a decrease in the level of BMP4 leads to ectopic budding of the nephric duct and the distal ureteral stalk. In the human, by E12, experiments on explant metanephric cell cultures have shown that the ureteral mesenchyme is radially arrayed with connective tissue and smooth muscle cells that depend on the adjacent epithelium to develop as the distal ureter. Signaling by sonic hedgehog (Shh) expressed by the ureteral epithelium at E11.5 to E18.5 also stimulates development of the ureter by increasing mesenchymal growth of the ureter. BMP4 appears to stimulate Shh to help differentiate the smooth muscle cells into the developing ureter (Fig. 74.6).

At E16.5, terminally differentiated smooth muscle cells with abundant contractile filaments are located all along the developing ureter. The ureteral smooth muscle differentiation occurs from the distal ureter near the ureterovesical junction and ascends to the upper ureter to the ureteropelvic junction.[14] These muscle fibers are tightly packed and interconnected with gap junctions, causing smooth muscle contractions to be propagated in proximal to distal waves. The waves are coordinated and are preceded by spontaneous electrical activity in the renal pelvis. This is independent of nerve function or stimulation.[13] The smooth muscle cells in this region show spontaneous oscillations of a membrane potential

that spreads to the other smooth muscle cells and generates the wave down the ureter to the distal part of the ureter.

The urothelium itself is highly specialized stratified epithelium, which is the inner lining of the urinary drainage system from the renal pelvis to the proximal part of the urethra. Molecular signals from the ureteral epithelial cells requires close interaction with the ureteral mesenchymal cells that ultimately allow the primitive ureteral epithelial cells to mature into multilayer urothelial cells that are impermeable to urine through uroplakin proteins in urothelial plaques in the final mature urothelial layer.[14] The derivation of

the epithelium in the bladder is endoderm in nature, while the ureteral epithelium is mesodermal in origin.

Renin–Angiotensin System Interaction for Programming Fetal Development

The RAS is a systemic hormonal process mediating sodium reabsorption, vasoconstriction, aldosterone production, and vasopressin secretion. Angiotensinogen is produced by the liver and activated by renin (from the kidney) to form angiotensin I. Angiotensin I is cleaved by angiotensin-converting enzyme (ACE) to create angiotensin II, which is the most biologically active peptide. Angiotensin II acts on the angiotensin type 1 (AT1) and angiotensin type 2 (AT2) receptors.

Beyond the circulating RAS, there is also a local RAS in many other organs which acts as an autocrine or a paracrine agent.[15] The RAS plays a critical role in the growth, development, and functioning of many organs, including the kidney and the placenta. During renal angiogenesis, angiotensin II, acting on AT1 receptors, mediates renal tubular growth and branching. AT2 receptors in the fetal kidney act as a growth mediator to prevent uncontrolled renal tubule growth through apoptosis. The uteroplacental circulation local aids RAS-assisted placental angiogenesis and modulates placental cytokine, growth factor, and vasoactive substance production, which will all affect fetal growth and development. Angiotensin II–stimulated AT1 receptor activity promotes trophoblast invasion, angiogenesis, growth, and branching of the placenta, and also regulates vasoconstriction in the uterine spiral arteries. AT1 receptors have also been found in the chorionic villi, regulating function of fetal blood flow within the placenta.

Studies have shown that sex hormones differentially regulate the RAS pathway: testosterone increases the expression of renin and AT1 receptor with upregulation of the vasopressor arm, and estrogens increase the upregulation of the vasodepressor arm (ACE2 and AT2 receptor).[15] The renal RAS and the placental RAS may be differentially expressed in male and female tissues, may respond differently to adverse stimuli, and may result in differences between adult males and females.

Prenatal exposure of the fetus to excessive glucocorticoids may have adverse effects. Glucocorticoids are potent regulators of fetal growth and development. Short course use during pregnancy for women at risk for preterm birth has improved neonatal survival but repeated doses has been associated with adverse fetal growth. There has also been increased evidence that antenatal glucocorticoid treatments have long-term adverse metabolic, cardiovascular and renal consequences including reduced GFR and increased insulin resistance in young adults who had prenatal glucocorticoid exposure.[4]

Renal Ascent

Renal ascent from the sacral region to the final renal position near the first lumbar vertebra has been thought to be due to the straightening of the body due to lumbosacral vertebral growth and decreased flexion of the lumbar spine. The changing vascular supply to the kidneys during ascent has been thought to be due to segmental vessels attaching to the migrating kidney that arise and disappear until the final most superior vessel that attaches to the kidney becomes the renal artery.

Renal ascent has also been associated with a change in orientation of the renal hilum from a ventral orientation to a 90-degree rotation, to a medially orientated renal hilum.

Recent studies have brought these theories into question. In recent studies, the final renal artery did not appear until after the kidney migrated to the first lumbar area and the segmental vessels disappeared as the kidney was migrating.[16]

Studies on human 5- to 7-week gestation embryos found that the developing metanephros, composed of several oval shaped pelvises, was surrounded by a belt of mesenchymal tissue, with the superior pole of the kidney adjacent to this belt of tissue. This band extended superiorly to developing adrenal cortex and is composed of densely developing nerve twigs connecting to major splanchnic nerves and is thought to be the origins of the celiac ganglia.

In the embryos studied, the kidneys were long and extended along the lengths of second or third to the fifth lumbar vertebrae and always adjacent to the umbilical artery. The mesonephros was also identified on the specimens caudal to the metanephros. The dense band connecting the adrenal cortex, the likely celiac ganglia, and the metanephros formed a solid band and allowed ascent of all the organ structures at the same time regardless of the change in curvature of the developing lumbosacral vertebrae. The researchers found that the kidney had reached its final first lumbar location while there was still ventral spinal curvature. They speculated that the migration of the kidney depended on renal growth itself and not on spinal growth and body straightening. Once the kidney reached its final location, the dense band connecting the adrenal cortex and developing celiac ganglia dissipated, and the kidney was then separated from the developing adrenal gland and celiac ganglia by an investing adipose capsule (Fig. 74.7).

They also found that the ladder of arteries thought to allow blood flow to the developing kidney were attached to the mesonephros and not adjacent to the migrating metanephros. This suggests that the proximity of the metanephros to the umbilical artery may be the source of blood flow to the developing kidney until it reaches its final vascular supply in the developing renal artery.

As nephrogenesis continues to occur in the metanephros after it reaches its final position, the glomerulus may not need direct blood flow while the kidney is ascending to the first lumbar region (Fig. 74.8).

Fetal Programing of Renal Function and the Perinatal Environmental Factor's Influence

Development of Renal Function and Adult Renal Disease

Genetic and environmental factors are important determinants of the development and function of the major organ systems of the body. It is becoming more and more evident that prenatal programing can affect subsequent organ function and some adult diseases.

Preterm birth (gestational age <37 weeks) has become more prevalent over the past few decades with incidence of prematurity up to 14% of live births worldwide. Over 95% of those born prematurely, including extreme premature infants (gestation <28 weeks), have survived to adulthood (>18 years).[3]

Although most of these preterm patients have low risks for early mortality, there are increased risks of chronic diseases involving

the cardiovascular, renal, endocrinologic, metabolic, respiratory, and neurodevelopmental systems. These chronic conditions may be responsible for moderately increased mortality risks (30% to 50%) from early to mid-adulthood when compared to patients born at or close to term.[3] Preterm birth increases the likelihood of the infant being born before nephrogenesis can be completed. Nephrogenesis is most active during the third trimester of pregnancy where more than 60% of the functioning nephrons are formed.[3] Interrupting this process will cause a lower lifelong complement of nephrons increasing the likelihood that the patient will develop chronic kidney disease (CKD) and hypertension later in life. Although the nephrons continue to form after premature birth, nephrogenesis ceases with premature birth.

Males and females are similarly and equally affected by this risk of chronic kidney disease. Low birth weight infants (<2500 g) have also been found to have an increased risk of developing CKD regardless of gestational age. Extremely premature infants and small for gestational age (SGA) infants additionally are at higher risk for cardiovascular and renal diseases.[2,4]

The risk of intrauterine growth restriction (IUGR) and low birth weight (LBW) is twice as high in African Americans as in white populations. Risk factors for IUGR and LBW are consistently found more often in certain populations. Fetuses have a higher risk of IUGR and LBW when associated with maternal hypertension, maternal smoking, inadequate maternal weight gain or malnutrition, shorter maternal height, poor prenatal care, advanced maternal age, and lower socioeconomic status. Congenital anomalies, maternal obesity (BMI ≥30) and preeclampsia has also been found to have a higher risk of CKD in prematurely born infants.

Low birth weight and premature birth is associated with nephron deficit in infants. Nephrogenesis is completed around 34 to 36 weeks' gestation, with 60% of the nephrons being formed in the third trimester, especially between 28 and 34 gestational weeks. Brenner hypothesized, because of the lower overall nephron number in these infants, that each nephron available has to increase its filtration rate to meet the body's excretory demands and, in order to meet necessary renal sodium excretion, there must

be a commensurate increased blood pressure increasing likelihood of eventual development of essential hypertension.[4]

Human studies have found an inverse relationship between LBW and higher blood pressures in infancy through adulthood. Although not all children with LBW have hypertension, the blood pressure measurements in LBW infants, children, and young adults tend to be higher than those of normal birthweight individuals. High birthweight (>4000 g) has also been associated with adverse renal outcomes in later life. It is uncertain in humans if there is any relationship with abnormal nephron number. LBW infants also have an increased adult risk of coronary heart disease, insulin sensitivity, and hypertension. Females have approximately 12% fewer glomeruli then males, although, generally, the risks for CKD due to prematurity affect males and females equally. There are some conflicting data as to specific gender risk for CKD after premature birth. A Swedish study found prematurely born women were more likely to develop CKD than similarly prematurely born men, while another study found a 1.3-fold increased risk for CKD in premature males as compared to premature females.[2]

Additionally, IUGR is associated with about 30% to 35% nephron deficit, and these infants may develop secondary glomerular hypertension and nonnephrotic focal segmental glomerulosclerosis (FSGS).[4]

The numbers of nephrons are determined before birth, but the kidney can increase filtration capacity by hypertrophy of the glomerulus. Mean glomerular volumes correlate inversely with glomerular numbers but directly with current body size. Hypertensive individuals have a 133% higher mean glomerular volume, but a 46.6% reduction in glomerular numbers, compared with nonhypertensive controls.

Perinatal programing controls nephrogenesis from early fetal development until 34 to 36 weeks' gestation, at which time the full nephron development is complete. If an infant is born before 36 weeks' gestation, nephrogenesis is still ongoing, but the number of nephrons produced may be reduced because of intrauterine stress or prenatal/perinatal stressors on development. Although most of the risk for CKD is in infants born with extreme prematurity (<28 weeks) and premature birth (<37 weeks), there still is a significantly increased risk of CKD in infants born at early term (37 to 38 weeks). This increased risk appeared to be due to the direct effects of preterm birth and not due to shared genetic or environmental factors when co-siblings of prematurely born infants were also studied for CKD risk.[2]

Premature infants have their in utero environment abruptly terminated before full fetal development with immature organ development and need to adapt to extrauterine function and the stressful environment of an early birth. Early postnatal life has a different physiology from the in utero conditions that the fetus is accustomed to experiencing, and the premature infant is generally exposed to intensive care management, including various drug exposures, suboptimal nutrition, and possible life support measures.

Short course antenatal glucocorticoids are used frequently in women at risk for preterm birth to help with fetal lung maturation and to reduce neonatal morbidity and mortality seen with preterm birth. Although there may some benefits with repeated doses, there is a decreased GFR and increased insulin resistance in young adults born prematurely who were exposed to even one short course of prenatal glucocorticoids.[4]

Initial suboptimal nutrition is common in premature infants who have lost their in utero nutrition prior to normal development of feeding and the gastrointestinal organs where many premature infants have feeding issues and may suffer from extrauterine growth restriction (EUGR). EUGR was found to effect early postnatal growth with associated poor outcomes early in life and had adverse long-term cardiovascular and renal outcomes. To prevent EUGR, neonatal intensive care units have shifted to increased protein and energy formulas for infants postdischarge to help with catch-up growth. Catch-up growth may manifest as asymmetric overgrowth and rapid weight gain up to 3 months after hospital discharge and has been associated with high fat deposition and altered insulin sensitivity.

These high protein formulas may have adverse short- and long-term effects on renal and cardiac function due to the increased protein load exposure in the premature heart and kidneys.

These high protein formulas are both seen as problems of EUGR in premature infants who are relatively calorie and protein deficient without the rich in utero nutrition source, and then have later adverse effects from high protein diets with subsequent cardiac, metabolic, and renal damage, while used trying to overcome EUGR.

A randomized control trial that breastfed premature infants had lower blood pressure and better insulin sensitivity as adolescents than those premature infants who were formula fed. Further study is needed to better determine if there are any long-term adverse effects of high protein formula feeds as these premature infants become adults.[4]

Adverse environmental prenatal conditions such as malnutrition of the mother through low protein intake during intrauterine and neonatal life may have an adverse effect on renal function. Vitamin A has been found to determine fetal renal programming in rats through modulation of nephron number and vascular supply to the developing kidney. Vitamin A and other retinoids help regulate cell proliferation, differentiation, immune function, and apoptosis. Low circulating levels of vitamin A are common in women who are smokers, abuse alcohol, or have poor perinatal nutrition, which may cause low or absent vitamin A levels in the developing fetus and is associated with IUGR in infants.

Maternal intake of nephrotoxic drugs during pregnancy has also been associated with neonatal development of acute renal failure, especially in preterm or LBW infants. It is postulated that maternal exposure to non-steroidal anti-inflammatory drugs (NSAIDs) may cause hypoperfusion of the kidneys and fetal nephrotoxicity from vasomotor nephropathy due to decreased levels of prostaglandin E_2. There appears to be less damage to the newborn kidney with NSAID exposure, suggesting that the risk of damage is highest during nephrogenesis itself. Other fetoplacental factors causing a decrease in the necessary nutrients by restricting their transfer include maternal smoking, hypertension, poor nutrition, and socioeconomic factors affecting nutrition.

Perinatal obstructive uropathy may cause reduced nephron numbers in affected infants. The diminution of nephrons with obstruction may be due to mechanical stretching of the tubules, which in turn activates ion channels that increase intracellular calcium levels and, subsequently, cellular apoptosis. In animal models with unilateral ureteral obstruction, the major damage seen after relief of the obstruction was tubular apoptosis and atrophy, causing subsequent impaired growth of the previously obstructed kidney, reduced glomerular numbers, and decreased GFR. The uninvolved kidney showed compensatory growth, but both kidneys showed glomerular sclerosis, tubular atrophy, macrophage infiltration, and interstitial fibrosis. Urinary obstruction in adults does not appear to cause reduction in the nephron number as

is seen in congenital or perinatal obstruction. There may be an increased vulnerability of the nephrons to damage at this early phase of renal development with obstruction occurring during or just after completion of nephrogenesis. High-grade vesicoureteral reflux diagnosed shortly after birth may also be associated with poor renal outcome. Early postnatal diagnosis and treatment does not improve the renal outcomes in this group of patients.

Although low nephron number is associated with renal disease and hypertension, not all renal programing models show this; some studies have found associated hypotension. Some ethnic groups, for example, African Americans, with decreased nephron numbers have not exhibited associated hypertension. Some other as yet undetermined factors may be required to induce hypertension and renal disease. Some factors that may or may not have an association with low nephron number and hypertension/renal disease may include individual genetics, including the sex of the individual, with less hypertension generally seen in premenopausal females with decreased nephron numbers. Sex differences in arterial pressure may be due to sex hormones, as well as sex chromosomal complement. Female fetuses also appear in some studies to be less vulnerable to adverse in utero environmental factors than male fetuses.

New research into the mechanisms affecting organ system development due to premature birth and neonatal and perinatal conditions is focusing on epigenetics.

Epigenetics look at gene modifications due to environmental factors causing changes in gene expression while not changing the genetic code itself. There is increasing evidence that early epigenetic imprinting tracks early gene interaction with the environment and converts that imprinting into changes in gene expression allowing cellular differentiation based on which genes are activated and which are not. Arrested or altered development due to premature birth and delivery, where different postnatal stimuli due to stress, extra-uterine nutrition and toxicant exposures, changes gene regulation and may cause lifelong effects. Early studies are targeting epigenetic modifications of the angiogenic capacity of preterm infant progenitor cells and are the basis of studies into epigenetic expression in different organ systems, like the renal and cardiovascular systems. These studies show epigenetic alterations of DNA methylation, histone modifications, and non-coding RNAs affecting changes in gene expression in development and changes seen due to premature birth. Antenatal glucocorticoid exposure has been shown in animal models to alter gene methylation and elevate blood pressure, leading to concern about similar epigenetic manifestations in fetuses exposed to steroids before birth.[4]

Although fetal renal programming may put the LBW, IUGR, and individuals with in utero environmental exposure to renal damaging factors at risk of hypertension and poor renal function as an adult, there appears to be a significant ability of the kidney to compensate for these prenatal insults to normal renal development. Controlling secondary risk factors, such a diet and stress in the adult, may possibly reduce the adverse outcomes of hypertension and renal insufficiency that may arise from abnormal renal development.

Conclusion

Renal organogenesis is a complex process that is not yet fully understood but has complementary interactions stimulated by anchor genes, activator molecules, growth factors, and hormone effects. Epigenetic factors in the maternal-placental-fetal environmental interface are being further studied with implications in adverse adult health outcomes. Recent studies on adults who were born prematurely or were LBW infants show that they have a high subjective quality of life similar to age-matched full term or normal birth weight adults. Current survival of over 50% of premature birth adults without major comorbidities reflects well on advancements in early treatment interventions and in the resilience of this patient group in trying to maintain as good health as possible.

Chronic Kidney Disease

LAUREL WILLIG AND BRADLEY A. WARADY

KEY POINTS

- Kidney development continues until 34 weeks' gestation. Neonatal intensive care unit graduates, especially those with a history of acute kidney injury (AKI), premature infants, and those with intrauterine growth retardation, are at risk for long-term chronic kidney disease (CKD).
- Clinical sequelae of CKD include anemia, acidosis, electrolyte abnormality, growth restriction, renal osteodystrophy, fluid overload, hypertension, and uremia. Attention to these complications is critical to optimizing long-term outcomes.
- Long-term survival of neonates with end-stage kidney disease (ESKD) appears to be approaching that of older infants and young children, but they continue to have higher morbidity and mortality due to infectious and cardiovascular complications.

Chronic Kidney Disease

Neonatal chronic kidney disease (CKD) is diagnosed when sustained derangements of glomerular filtration or tubular function occur with minimal to no resolution over time. According to guidelines published by the Kidney Disease Outcomes Quality Initiative (KDOQI), CKD is present if there is evidence of kidney damage for more than 3 months, as defined by structural or functional abnormalities, with or without decreased glomerular filtration rate (GFR), or a GFR less than 60 mL/min/1.73 m^2 for more than 3 months in children older than 2 years with or without kidney damage.[1] These guidelines do not apply to infants less than 2 years of age as a result of ongoing maturation of the kidney and improvement in GFR over the first 2 years of life. In turn, the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines from 2012 recommend that for the classification of CKD in neonates and infants, available normative values and conventionally accepted equations should be used to classify neonatal CKD into one of three categories: normal (GFR <1 standard deviation [SD] below the mean); moderately reduced (GFR >1 SD to ≤2 SD below the mean), or severely reduced (GFR >2 SD below the mean).[2]

Currently, none of the commonly used pediatric GFR estimating equations is validated for neonates with CKD. Studies in healthy neonates suggest that equations incorporating the use of cystatin C, renal mass, and body surface area may provide a more accurate assessment of GFR.[3] Whereas a new equation, the so-called U25 equation, utilizes age and sex-specific constants to improve the estimation of measured GFR in children with CKD, this equation has not been studied in neonates.[4]

Epidemiology

There is little information on the incidence and prevalence of CKD in neonates and infants due to the lack of a uniform definition. In one small study, the estimated incidence of CKD was 1: 10,000 live births with a male-to-female ratio of 2.8:1, skewed primarily due to lower urinary tract obstruction as a leading cause of CKD.[5–7]

Most epidemiologic reports focus on the development of end-stage kidney disease (ESKD) in this age group. These studies demonstrate a varying regional incidence of ESKD, and the worldwide incidence is unknown. The European Registry for Children on Renal Replacement Therapy collects data from countries across Europe and recently reported the incidence rate of ESKD in children aged 0 to 4 years to be around 5.2 per million children.[8] Within the International Pediatric Peritoneal Dialysis Network (IPPN) registry, this same age group (0 to 4 years) accounts for approximately 35% of all pediatric patients on peritoneal dialysis.[9] The adjusted incidence rate of ESKD in the less than 1 year age group, as reported by the United States Renal Data System (USRDS), was 23.2 cases per million US population in 2018.[10] Studies show that wealthier countries, those that spend more on health care, and countries where patients pay less out of pocket expenses have higher rates of kidney replacement therapy (KRT) initiation. Thus, much of the variability is likely explained by socioeconomic factors and less by genetic susceptibility to kidney disease.[8]

Pathophysiology

Congenital Causes of Neonatal CKD

Congenital Anomalies of the Kidney and Urinary Tract

Congenital anomalies of the kidney and urinary tract (CAKUT) are the leading cause of birth defects in neonates and infants, with an incidence of 0.4 per 1000 births.[11] They account for approximately 50% to 60% of all cases of ESKD in those children less than 1 year of age.[10,12,13] Posterior urethral valves/obstructive uropathy cause 21% of cases, and renal hypo/dysplasia is responsible for an additional 28% of these cases.[14] Historically, the etiology of CAKUT was considered sporadic, polygenic, or non-heritable. However, several genes are associated with CAKUT development, primarily in an autosomal dominant pattern.[15] Additionally, many pediatric patients with CKD have copy number variations.[16] Many

of these kidney anomalies occur in the setting of co-existing extrarenal manifestations, and those cases often tend to have a higher rate of associated morbidity and mortality.

Polycystic Kidney Disease and Ciliopathies

Cilia are complex, flagella-like organelles found in most mammalian cell types, which have a wide variety of functions. Due to their wide distribution amongst cell types and their diverse functions, mutations in ciliary proteins lead to a variety of pleiotropic clinical manifestations. Mutations in ciliary proteins cause many different kidney diseases, including polycystic kidney disease (PKD), nephronophthisis, and Bardet-Biedl syndrome. The most common renal ciliopathy is autosomal dominant PKD (ADPKD). It affects about 1 in 1000 people, and most cases are caused by mutations in PKD1 and PKD2. While most cases do not present until later childhood or adulthood, severe cases may present in utero and mimic autosomal recessive PKD (ARPKD).[17] ARPKD, caused primarily by PKHD1, is much less common, affecting about 1 in 10,000 to 1 in 40,000 births. It presents in utero or in the neonatal period with large echogenic kidneys. The severity of kidney disease in ARPKD varies from ESKD at birth to slowly progressive CKD, with most children progressing to kidney failure by 20 years of age. Approximately 30% of patients presenting in the neonatal period die primarily from pulmonary hypoplasia.[18] Other ciliopathies such as Bardet-Biedl and Joubert syndrome often present with extrarenal manifestations. Other causes of neonatal CKD include prune belly syndrome, HNF1B disease, congenital nephrotic syndrome, and neurogenic bladder from spinal cord defects.

Acquired Causes of Neonatal Chronic Kidney Disease

Prematurity and Low Birth Weight

Preterm neonates are at high risk for the development of CKD for three reasons: (1) they have a smaller complement of nephrons at birth as a result of disruption of nephrogenesis, which typically continues to 36 weeks; (2) increased risk of acute kidney injury (AKI) due to medications and comorbidities often associated with premature birth; (3) prenatal kidney disease leads to an increased risk of premature delivery either as a result of direct complications such as oligohydramnios, or the presence of extrarenal comorbidities found in syndromic prenatal kidney disease. In a small German study, 53% of children with CKD were premature, a figure significantly higher than the rate experienced by the total infant population of Germany.[19] A publication from the Chronic Kidney Disease in Children (CKiD) cohort also revealed a high prevalence of children with CKD; the lifetime risk for CKD was increased in those neonates who had an abnormal birth history as defined by low birth weight (17%), small for GA (14%), or prematurity defined as GA less than 36 weeks (12%).[20] In a study of more severe CKD, 35% of affected patients were born prematurely, and approximately 50% had a comorbidity, such as cardiopulmonary and/or neurologic involvement.[5]

A systematic review and meta-analysis in 2009 concluded that low birth weight babies (≤5.5 lb) were 70% more likely to develop CKD later in life compared with individuals with normal birth weight.[21] More recent studies show that the incidence of CKD in preterm infants (<37 weeks' gestation) by mid-adulthood is 9.24/100,000 person-years (py), 5.90/100,000 py for those born at 37 to 38 weeks, and 4.64/100,000 py for those born full term. Low birth weight in the setting of prematurity independently increases the risk for CKD.[22]

Decreased nephron number either due to deranged nephron development and/or scarring leads to an increased risk for CKD regardless of etiology and likely underlies much of the increased risk conferred by premature birth. Total GFR is determined by the filtration rate of single nephrons and the number of nephrons present. When the number of nephrons is diminished, single nephron GFR increases as the kidney works to compensate for the low nephron numbers. This compensatory hypertrophy causes glomeruli to function under increased intracapillary hydraulic pressure, which, over time, causes damage to capillary walls. This abnormal process leads to progressive glomerulosclerosis, proteinuria, hypertension, and CKD.[23] The hyperfiltration hypothesis has been applied and confirmed in autopsy data of hypertensive patients [24,25] and has been written about at length with reference to infants with intrauterine growth restriction.[21,26–28] Nephrogenesis continues through 34 weeks' gestation. Premature infants (even those born appropriate for GA) are therefore born with low nephron numbers compared with term infants. Using computer-assisted morphometry, Rodriguez et al. showed that premature infants who survived to at least 36 weeks' postconception had nephron numbers similar to premature infants with short survival, suggesting that the extrauterine environment does not support normal neoglomerulogenesis. In addition, preterm infants with AKI had fewer nephrons than similar infants without AKI.[29]

Acute Kidney Injury

The epidemiology, etiology, and treatment of AKI in neonates are discussed separately in this textbook. Briefly, recent studies show that thirty percent of all neonates in neonatal intensive care units develop AKI.[30] In small studies looking at the risk for CKD development in those who experienced AKI in intensive care units, 10% of all children developed CKD, while 16.6% of neonates had CKD, suggesting that AKI is more likely to lead to CKD in neonates.[30]

In addition to the loss of nephron number and hyperfiltration injury, as discussed above, tubular and vascular endothelial cellular damage occurs with prolonged kidney hypoperfusion in ischemic AKI. Animal models suggest that although tubular recovery occurs, damage to the vascular endothelial cells remains and can lead to interstitial fibrosis and progressive kidney dysfunction.[31] To further delineate the pathophysiology and extent of AKI-related CKD and to provide guidelines for long-term follow-up, further studies such as those being conducted through the Neonatal Kidney Collaborative are imperative.[32] Given the high rate of AKI and subsequent CKD within this population, future studies of interventions (such as ACE inhibition) to decrease the rate of CKD progression should be explored.

Renal Cortical and Medullary Necrosis

Renal cortical and medullary necrosis is uncommon in newborns. When it occurs, it is usually encountered in critically ill newborns as a manifestation of perinatal and postnatal stress leading to end-organ injury. Risk factors associated with renal cortical and medullary necrosis include congenital heart disease, perinatal anoxia, placenta abruption, twin–twin or twin–maternal transfusions, sepsis, infectious myocarditis, vascular malformations, dehydration, prematurity, respiratory distress syndrome, bleeding diathesis, cardiac catheterization, and use of intravenous contrast agents.[33,34] Subsequent medication administration, blood loss, and ischemia can interfere with compensatory mechanisms to maintain kidney

perfusion and can lead to acute tubular necrosis that, depending on the severity of the insult, may then lead to vascular injury and microthrombi formation with subsequent renal cortical and medullary necrosis.

The clinical and laboratory manifestations of renal cortical and medullary necrosis include hematuria, oliguria, rising serum creatinine and BUN, thrombocytopenia, and kidney enlargement, which are nondiagnostic and are associated with many other common neonatal kidney abnormalities. Initially, renal ultrasound results are typically normal but may ultimately show small kidneys that are hyperechoic for age and have a loss of corticomedullary differentiation. A radionucleotide renal scan shows decreased to no perfusion, with delayed or no function.[35] Infants with cortical necrosis may have partial recovery or no recovery at all. Typically, these infants require KRT, short-term or long-term, and even those who recover enough kidney function to be managed without dialysis early on are at risk for the late development of ESKD. Other acquired causes, such as renal vein and renal artery thrombosis, are discussed in the chapter on acute kidney injury.

Clinical Sequelae of Neonatal Chronic Kidney Disease/End-Stage Kidney Disease

Anemia

Anemia is defined as a Hgb concentration less than the 5th percentile of normal for age and sex.[36] The normative values used to define anemia in children older than 1 year are taken from the third National Health and Nutrition Examination Survey[37] database, whereas the norms for infants younger than 1 year are derived from other reference sources (Table 78.1).[38] More recently, Kidney Disease: Improving Global Outcomes (KDIGO) defined anemia as Hgb less than 11.0 g/dL in children 0.5 to 5 years with CKD.[39]

Anemia is a frequent complication of CKD in infants and children, and the prevalence of anemia increases with worsening stages of CKD, with up to 93% of pediatric patients with CKD stage 5 having anemia or receiving treatment for anemia. Anemia may lead to decreased tissue oxygen delivery, increased cardiac output, cardiac enlargement, ventricular hypertrophy, congestive heart failure, and impaired immune responsiveness.[40–42] Anemia is associated with faster CKD progression,[43] increased risk of hospitalization due to cardiovascular disease in hemodialysis patients,[44] and has a negative impact on health-related quality of life.[45]

The pathophysiology of anemia in infants and young children with CKD is primarily the result of a decrease in the kidney production of erythropoietin, iron deficiency, or both.[46] Other potential contributing factors include a shortened red blood cell life span, secondary hyperparathyroidism, hypothyroidism, folate and vitamin B_{12} deficiency, chronic inflammation, and hemoglobinopathies. In the early stages of CKD, iron deficiency tends to be common.[47] The cause of absolute iron deficiency is multifactorial and can be related to poor intake, gastrointestinal blood loss, and repeated phlebotomies for laboratory tests.

Erythropoietin deficiency becomes more prevalent in the later stages of CKD. Children with CKD may be particularly prone to factors that contribute to relative erythropoietin resistance, including hyperparathyroidism, aluminum toxicity, and hemolysis.[48] The decreased erythropoietin production from the kidney leads to anemia through increased apoptosis of red blood cell precursors in the bone marrow, often accompanied by iron deficiency related to the factors listed above, as well as increased production and decreased excretion of hepcidin.[49,50]

The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines recommend checking Hgb in all patients with CKD at least annually. In those children found to be anemic, the initial work-up should include red blood cell indices, reticulocyte count, white blood cell count with differential, platelet count, and iron parameters (serum iron, total iron binding capacity, and serum ferritin). These guidelines also recommend targeting a Hgb level between 11.0 and 12.0 g/dL.[39] Iron and erythropoiesis-stimulating agents (ESAs) such as recombinant erythropoietin-alfa (EPO), darbepoetin, an analogue of erythropoietin with a longer half-life, and methoxy polyethylene glycol-epoetin beta (continuous erythropoietin receptor activator, CERA) are the key elements of anemia management in CKD.[51]

Iron therapy typically consists of the provision of oral elemental iron in doses ranging from 2 to 3 mg/kg/day up to 6 mg/kg/day in two to three divided doses.[52] In hemodialysis (HD) patients, intravenous iron administration is often recommended because of inadequate iron absorption after oral administration coupled with increased losses of blood and iron during HD treatments. Levels of serum ferritin greater than 100 ng/mL and transferrin saturation values greater than 20% are believed to reflect adequate iron stores in patients with CKD.[52]

All ESAs have equal efficacy and a similar safety profile[53,54], and both epoetin and darbepoetin have been studied in premature infants.[55] When treated with an ESA, infants and young children require larger doses than older children and adults, despite having a higher capacity for hematopoiesis. This difference is thought to be related to additional nonhematopoietic erythropoietin binding sites, which are thought to be important for the inhibition of apoptosis. Also, EPO needs tend to increase at times of rapid growth, such as in infancy.[49] Children receiving HD typically require more EPO than patients receiving PD as a result of the blood loss that routinely occurs with HD.

TABLE 78.1 Hemoglobin Levels in Children Between Birth and 24 Months of Age

Age	Mean Hb (g/dL)	−2 SD*
Term (cord blood)	16.5	13.5
1–3 days	18.5	14.5
1 week	17.5	13.5
2 weeks	16.5	12.5
1 month	14.0	10.0
2 months	11.5	9.0
3–6 months	11.5	9.5
6–24 months	12.0	10.5

*Values 2 SDs below the mean are equivalent to less than the 2.5th percentile.
Data taken from normal reference values.

Malnutrition and Growth Failure

The origin of malnutrition in children with CKD is multifactorial; nausea and vomiting, delayed gastric emptying, gastroesophageal reflux, and protein energy wasting (PEW) all contribute. Seventy-five percent of patients exhibit GI complaints.[56] The International Society of Renal Nutrition and Management (ISRNM) defines PEW as reduced body mass index, reduced muscle mass, short stature, and specific biochemical evidence. Modified PEW scores that incorporate these parameters are associated with an increased risk for hospitalization, disease progression, and neurocognitive complications in pediatric patients.[57–59] Studies show that each week of stagnant weight leads to compounding weight percentile loss.[60] While being underweight is associated with higher mortality in children on PD, so too does being overweight. Almost 20% of pediatric patients initiating PD have been found to be overweight and being overweight in infancy was associated with higher mortality rates in patients receiving peritoneal dialysis.[61]

Children with CKD often experience some degree of growth failure, which may occur in children with mild-moderate CKD (CKD stage 3).[62] According to data collected by the USRDS, greater than 50% of all infants with ESKD had short stature, defined as height below the 3rd percentile for age.[10] Growth failure associated with CKD is especially concerning during infancy, and delayed growth is regularly present at the time of dialysis initiation.[12,42] Young children on dialysis have often failed to grow normally, despite meeting 100% of the recommended daily allowance of caloric and protein intake.[63,64]

Growth and nutritional outcomes of infants with ESKD have improved over time, likely because of advances in medical, nutritional, and surgical therapies.[65–67] In particular, multiple reports have described improved longitudinal growth and sustained catch-up growth in infants with CKD in whom recombinant growth hormone (rhGH) treatment was initiated in the first year of life. To that end, guidelines support the use of rhGH in infants greater than 6 months old and with CKD who have a height velocity less than the 25th percentile for more than 3 months, despite addressing all of the potentially modifiable risk factors (e.g., nutrition, acidosis, bone abnormalities).[68] Similar results have, on occasion, also been obtained with intensive nutritional regimens.[69–71] Finally, growth outcomes regularly improve after kidney transplantation in young patients.[72,73]

Nutritional Assessment

Frequent monitoring of the patient is mandatory in view of the importance of nutritional status to the outcome of the infant and young child with CKD. Collaboration with a pediatric renal dietician is beneficial to assist in the nutritional evaluation and treatment strategy.[74] An age-related schema for parameters and frequency of nutritional assessment have been published by the Pediatric Renal Nutrition Task Force (Table 78.2).[75]

Neonates with CKD are also at nutritional risk and may need more frequent monitoring if they are preterm or are characterized by any of the following: low birth weight (<2500 g), a birthweight *z* score less than −2 SD for GA, polyuria, or associated renal salt wasting. Nutritional intervention is indicated in children with CKD when there are findings of an impaired ability to ingest or tolerate oral feedings, a BMI less than the 5th percentile of height-for-age, an acute weight loss of 10% or more, or a length/height ratio more than 2 SDs below the mean.

Nutritional Management

Both spontaneous energy and protein intake decrease as CKD progresses. Energy intake is the principal determinant of growth during infancy. Energy requirements should, in turn, be 100% of the estimated energy requirement for chronologic age.[60,76,77] Similarly, targeted protein intake should be 100% of the suggested daily intake (SDI) (Table 78.3). The SDI includes the average recommended amount of a nutrient from all the available published values ± 2 SDs.[78] There is no evidence that strict dietary protein restriction has any nephroprotective effect,[79] and aggressive restriction has been noted to compromise the growth of infants with CKD.[80] Because moderate dietary protein restriction reduces the accumulation of nitrogenous waste products, decreases acid load, and helps to lower dietary phosphorus intake (which helps preclude bone-mineral and cardiovascular complications), it is

TABLE 78.2 Recommended Parameters and Frequency of Nutritional Assessments for Children With Chronic Kidney Disease Stages 3–5 and 5d

	AGE <1 YEAR (FREQUENCY IN WEEKS)		AGE 1–3 YEARS (FREQUENCY IN MONTHS)

appropriate to gradually lower protein intake toward 100% of the SDI as CKD progresses toward the need for dialysis.[60]

Supplemental nutritional support with tube feedings (e.g., nasogastric, gastrostomy, gastrojejunostomy) is indicated when the voluntary intake by the infant fails to meet energy requirements and the child is failing to grow as expected. Tube-fed infants must continue to have some oral stimulation and oral intake to mitigate the chance of persistent oral aversion.[76] In patients receiving either peritoneal or hemodialysis, the dietary protein requirements are increased to account for dialysis-related protein losses.

Fluid and Electrolyte Derangements

CKD leads to derangements in several solutes, vitamins, and minerals. In CKD, nutritional issues arise related to fluid balance, sodium handling, and potassium intake (Table 78.4). In turn, understanding the daily recommended intake (DRI) for sodium and potassium (Table 78.5) and consideration of the type of kidney disease is key. Nonglomerular disease secondary to posterior urethral valves or renal dysplasia often leads to polyuria and substantial urinary losses of water and salt. In contrast, diseases such as ARPKD lead to oligoanuria and water and salt

TABLE 78.5 Dietary Reference Intake for Sodium, Chloride, and Potassium in Healthy Children

	SODIUM (mg/day)		CHLORIDE (mg/day)		POTASSIUM (mg/day)

retention. All forms of kidney disease in infancy may result in hyperkalemia through decreased filtration and/or aldosterone resistance. Management of these nutritional complications often involves changes to the amount and composition of formula or breastmilk and sometimes the need for additional medications (see Table 78.4).

Metabolic acidosis is a common manifestation of CKD in children and an important negative influence on growth. Metabolic acidosis leads to changes in bone composition and decreases in 1,25-$(OH)_2$D synthesis, in addition to endogenous growth hormone and rhGH resistance.[86] Based on the experience of successfully enhancing the growth of infants and children with isolated renal tubular acidosis with alkali therapy,[87] it is recommended that children with CKD be treated to achieve a serum bicarbonate level of at least 22 mmol/L.[76] A publication from the CKiD study revealed that a serum bicarbonate level of less than 18 mmol/L was a risk factor for poor growth.[88] In other studies, decreased serum bicarbonate was associated with faster progression of kidney disease and development of secondary hyperparathyroidism, while a resolution of acidosis was associated with decreased CKD progression.[89,90]

Chronic Kidney Disease Mineral and Bone Disorder

Infants with CKD often develop alterations in bone and mineral metabolism leading to CKD mineral and bone disorder (CKD-MBD) which contributes to poor growth and short stature. Renal osteodystrophy refers specifically to bony changes that are characterized by abnormalities of bone turnover and mineralization. CKD-MBD is broader and includes systemic dysregulation of bone and mineral metabolism, including the development of extra-skeletal calcifications. Although limited studies have focused specifically on CKD-MBD in those with CKD during infancy, investigations in pediatric patients on dialysis have revealed that greater than 60% had some dysregulation of bone turnover and 48% had decreased bone mineralization.[91] Secondary hyperparathyroidism occurs in 30% to 45% of patients with CKD stage 2 to 4 and in 50% to 60% of pediatric dialysis patients.[67]

While a complete understanding of the pathophysiology of CKD-MBD remains to be elucidated, the complex interplay of phosphate, calcium, parathyroid hormone (PTH), vitamin D 1,25-dihydroxy vitamin D3 (1,25D), and fibroblast growth factor-23 (FGF23) has a significant role. Worsening CKD leads to increases in phosphate retention which stimulates FGF23 and PTH and decreases 1,25 vitamin D. The decreased 1,25 vitamin D leads to further increases in PTH and lower calcium absorption.[92] In turn, management of CKD-MBD requires optimization of calcium and phosphorus balance and attention to age-appropriate serum phosphorus levels.

Recently, the Pediatric Renal Nutrition Taskforce published guidelines for the management of calcium and phosphorus in children with CKD. Infants should receive the SDI for phosphorus and should receive no more than two times the SDI for calcium. Calcium-containing phosphate binders contribute to the SDI for calcium. When hyperphosphatemia or hyperparathyroidism exists, phosphorus intake must be restricted. If phosphorus remains elevated, phosphate binders taken with food should be initiated. To lessen the risk for vascular calcification, one must not exceed twice the SDI for calcium between dietary intake and binder intake if calcium-containing binders are used. Sevelamer, a non-calcium-containing phosphate binder, should be considered in this setting.[78]

Patients with secondary hyperparathyroidism, despite adequate calcium intake, phosphorus restriction, and the use of phosphorus binders, are typically also treated with vitamin D analogs such as calcitriol, if inactive (nutritional) vitamin D levels are normal. These medications may cause hypercalcemia and hyperphosphatemia, and should this occur, medications such as cinacalcet, a calcimimetic, may be used to lower PTH. This medication may induce hypocalcemia, and thus frequent monitoring of phosphorus, calcium, and PTH should be initiated if using activated vitamin D or calcimimetics.[92] Infants with advanced CKD and secondary hyperparathyroidism may experience improvement in the management of CKD-MBD after the initiation of KRT.[63,65]

Management

Kidney Replacement Therapy

ESKD is an uncommon disorder in children less than 4 years of age, with an incidence of 5.2 to 10.3 per million age-related population.[8] Neonatal ESKD is even less common, with an incidence of approximately 0.32 per 100,000 live births.[7] A large international registry study of neonates on KRT showed that neonates made up between 6.8% and 18.3% of all infants less than 2 years of age on dialysis. Although kidney transplantation is the nearly universal goal for children who develop ESKD, data from the most recent North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) annual report revealed that 80% of children under 2 years old who received a kidney transplant also received chronic dialysis before transplantation.[73]

Peritoneal Dialysis

Peritoneal dialysis (PD) is the preferred chronic dialysis modality for infants with ESKD. A publication from NAPRTCS showed that greater than 90% of patients 0- to 1-year-old who received chronic dialysis received PD at dialysis initiation.[14,93] The mechanics of chronic PD (CPD) are similar to those discussed for acute

PD in the chapter on AKI. While the CPD prescription initially mirrors that of acute PD, the fill volume is subsequently titrated upwards during CPD to a goal of 600 to 800 mL/m^2 body surface area in infants (<2 years) during each exchange; the duration of the dwell is adjusted to reach predefined adequacy metrics in terms of solute and fluid removal.[94]

The complications of PD are similar in acute and chronic PD. The single most serious complication is peritonitis, which occurs more frequently in infants than in older children.[93,95,96] The recent USRDS report showed that infection requiring hospitalization had an incidence of 0.99 per person-year in those less than 1 year of age, and rates of admission for infection have increased over time in those less than 1 year.[10] G-tube placement following PD catheter insertion and nephrectomy at the time of PD catheter placement both increase the risk of peritonitis and mandate the use of prophylactic antibiotic therapy prior to those procedures.[96] Whereas gram-positive organisms account for many infections, gram-negative episodes of peritonitis are common in infants and young children.[97] Empiric therapy for peritonitis should, in turn, always provide coverage for gram-positive and gram-negative organisms.[98] Other CPD-related complications that occur most frequently during infancy include anterior ischemic optic neuropathy and sudden blindness secondary to hypovolemia, excessive loss of sodium and protein across the peritoneal membrane, and hernia formation.[66,99,100]

Hemodialysis

The use of HD during infancy is most often dictated by the presence of a medical condition (e.g., omphalocele, gastroschisis, diaphragmatic hernia, bladder exstrophy) that compromises the ability to use the peritoneal membrane as a dialyzing membrane. Additional reasons for the use of HD are often related to metabolic conditions that accompany kidney failure.[101] The HD procedure during infancy is complicated due to the infant's small size and the associated challenges related to vascular access and safe fluid removal, and limited clinical experience has revealed a high incidence of patient morbidity.[63,102,103] Recent studies of complications in infants on chronic HD reveal improvements in central venous catheter longevity but continued high rates of hypertension, psychomotor retardation, and hospitalization.[104–106]

Transplantation

The topic of kidney transplantation in patients who develop ESKD as neonates or young infants is complicated, and a lengthy discussion is beyond the scope of this chapter. In short, transplantation is a viable alternative for these young patients, and it is their best hope for long-term survival. In a review of NAPRTCS data, 20% of 0- to 1-year-olds and 24% of 2- to 5-year-olds with ESKD received a preemptive (e.g., no prior dialysis) transplant. The overall transplant rates and graft survival rates for some of the largest and most recent studies of outcomes in neonates or young children with ESKD are listed in Table 78.6.

Infants with HD and PD have shown similar mortality and transplantation rates.[101] Graft survival in patients who developed ESKD as neonates or infants (31 days to 1 year) has improved,[14] and the rates of graft survival for the two groups are similar. These improvements in transplant rates and graft survival likely contribute to the improved overall survival of these patients and likely will improve further as outcomes with respect to other comorbidities, such as cardiovascular disease and growth, also improve.

What is often most important for the neonatologist is recognition of the need to develop a collaborative strategy with members of the pediatric nephrology, surgery, and urology teams for the management of congenital structural abnormalities of the urinary tract that are present in the patient with severe CKD/ESKD, the majority of whom will ultimately require dialysis and transplantation.[107]

Outcomes

Neurocognitive Impairment

Impairment of normal kidney function in infancy, a crucial time of neural development, raises concerns regarding the neurodevelopmental outcomes in children with CKD/ESKD. Advanced CKD has been linked to poor neurocognitive function in the areas of attention, memory, and inhibitory control.[108,109] Small studies examining the effect of ESKD during infancy on neurocognitive development have suggested that there may be minor delays in intellectual and metacognitive function but that most children without other comorbidities do not experience significant developmental delay.[110] Other comorbidities of CKD (e.g., anemia, iron deficiency, hypertension, cerebral vascular accidents, adverse effects of therapy) have been implicated in the neurodevelopmental impairments seen in many patients, and these comorbidities may explain the association between the duration of CKD and impaired executive function.[110–113] Genetic syndromes involving the central nervous system may also influence neurocognitive outcomes for these patients.[114] A recent meta-analysis of 34 studies that examined the effects of CKD on neurocognitive ability in children and adolescents showed that severity of disease and duration of disease did lead to deficits in many aspects of neurocognition, but that age of onset did not contribute to these deficits.[115]

Hospitalization

The majority of neonates and infants with CKD or ESKD will require frequent hospitalization throughout childhood. For those infants in the first year of life who must initiate dialysis, the incidence of hospitalization in days per person-year is as follows: 13.1 for nonsurgical reasons; 8.5 for surgical reasons unrelated to catheter revision; and 1.9 for catheter revisions based on data derived from the USRDS. This rate of hospitalization was higher compared to all other age groups.[10] In one study from outside the US of 18 children requiring chronic HD by 2 years of age, the median hospitalization rate per patient was 8.2 admissions per year, with the duration of hospitalization ranging from 63 to 399 days.[63] Another study divided 698 children requiring chronic dialysis within the first 2 years of life into those initiating dialysis by 1 month of age and those initiating dialysis between 1 month and 24 months of age. Approximately 80% of children in both groups required hospitalization at some point in the 13-year follow-up period. Among children ever hospitalized, those initiating dialysis as neonates were hospitalized more frequently than those children who initiated dialysis later (mean number of hospitalizations 54 vs. 39; $P < .001$). In addition, the average duration of the hospital stays was longer in the younger children.[7]

Survival

The long-term survival of neonates with ESKD appears to be approaching that of older infants and young children. In several recent studies examining medium-term survival of neonates, infants,

or young children who started dialysis, the overall 3- to 5-year survival rates ranged from 70% to 90% (see Table 78.6).[7,12–14,101,116] Neonates who received chronic dialysis had only slightly lower survival rates compared with older infants and children.[7,13,14] The main reasons for death included infection and cardiovascular disease. Concomitant neurologic disease and other comorbidities were associated with increased mortality.[5,12] Studies that examined multiple time periods have shown improved survival for neonates and infants in more recent years.[7,13,14] Although the recent large studies suggest a good medium-term survival and support the recommendation for KRT in these complex patients, more long-term data are clearly needed to be able to provide parents and families with the best possible prognostic information and to enhance patient therapies and outcomes.

Ethics of Initiating or Withdrawing Kidney Replacement Therapy

Using the conceptual framework for medical decision-making that classifies anticipated therapy and outcomes as clearly beneficial, clearly futile, or of uncertain benefit, KRT for neonates and very young infants has long been considered of uncertain benefit due to unclear long-term outcomes. In turn, medical providers have often deferred to family members with regard to decisions about dialysis initiation and withdrawal in young patients. However, as dialysis is more routinely offered to neonates and infants with ESKD and more published data on improved medium and long-term outcomes have become available, consideration has

been given to classifying this therapy as clearly beneficial.[117] This improvement in outcomes has raised the question of whether dialysis therapy should be refused or withheld in infants, especially for those without other comorbidities.[118] Nevertheless, few studies have directly examined the changing attitudes of medical providers on this issue.

Geary and colleagues initially conducted an international survey on the attitudes of pediatric nephrologists regarding the management of ESKD during infancy nearly two decades ago.[111] More than 200 physicians from eight countries replied to a series of questions pertaining to the provision of KRT to neonates younger than 1 month of age versus those 1 to 12 months old. At that time, 93% of respondents stated that they would offer dialysis to some patients less than 1 month of age, 41% would offer it to all patients less than 1 month of age, and 50% believed it was usually ethical for families to withhold KRT. In a follow-up study conducted by the same group using an almost identical survey 10 years later, 98% of pediatric nephrologists responded that they would offer dialysis to some patients less than 1 month of age, although only 30% of pediatric nephrologists would offer it to all neonates. Additionally, there was a 25% increase compared with the earlier survey results in those who thought it was the parent's right to "usually" refuse KRT in neonates.[119] In both studies, physicians responded that they more routinely provided dialysis to infants in the 1-month to 12-month age group and thought it was less acceptable for families to refuse dialysis initiation for children of this age.[111,119] The factors that most often influenced the decision to initiate or withhold KRT were the presence of coexistent serious medical disorders and the anticipation of significant morbidity for the child.[111,119] Evidence for this age-related variation in philosophy and practice has been seen in other surveys as well.[120]

Factors to consider when making the decision regarding initiation or withdrawal of KRT during infancy include underlying comorbidities, quality of life concerns, allocation of resources, legal issues, and, most importantly, the opinions of the hospital team and the parents. Palliative care involvement early in cases of neonatal CKD/ESKD facilitates medical decision-making for families and improves care coordination while attempting to mitigate suffering for the patient and family and helping frame quality-of-life discussions.[121] Future research into the ethical issues surrounding infant dialysis should focus on separating isolated kidney failure from kidney failure in the setting of comorbid conditions, the cost financially, socially, and emotionally, and the informed consent process around the initiation of chronic dialysis.[117] The role of hospital ethics committees in the process remains extremely variable. In the end, clinicians and parents often struggle bravely to reach a compassionate decision with as much agreement as possible. Principles of practice that may provide valuable assistance in this process have been published.[122]

Glomerulonephropathies and Disorders of Tubular Function

ELIZABETH YU AND KARYN YONEKAWA

KEY POINTS

- Nephrotic syndrome (NS) comprises persistent heavy proteinuria, hypoalbuminemia, edema, and hyperlipidemia.
- Genetic abnormalities of structural or regulatory proteins within the glomerular basement membrane and/or podocyte lead to primary congenital NS (CNS).
- Treatment of CNS does not involve immunosuppression and is aimed at minimizing symptoms and preventing serious complications.
- Infections causing secondary NS include human immunodeficiency virus, syphilis, toxoplasmosis, hepatitis B, malaria, rubella, and cytomegalovirus.
- Renal tubular acidosis (RTA) causes a non-anion gap metabolic acidosis. It is important to evaluate for other sources of bicarbonate (HCO_3^-) loss before initiating a work-up for RTA and to note that immature tubular function in premature infants may cause a self-limited moderate metabolic acidosis in the first 2 weeks of life.
- Inherited renal tubulopathies are rare and can be distinguished from each other in part by differences in serum potassium levels, presence of metabolic acidosis or alkalosis, presence of hypertension, and urine findings.
- Fanconi syndrome is a condition of diffuse proximal tubule dysfunction resulting in polyuria and wasting of HCO_3^-, amino acids, uric acid, phosphate, glucose, and low-molecular-weight proteins. Fanconi syndrome may be due to an isolated defect or can be a part of a broader genetic syndrome.
- Primary nephrogenic diabetes insipidus may present during pregnancy as polyhydramnios. In the newborn period, treatment should focus on maintaining adequate fluid balance.

Glomerulonephropathies

Generally, glomerulonephropathies are considered when nephrotic syndrome (NS)—the constellation of persistent heavy proteinuria, hypoalbuminemia, edema, and hyperlipidemia—is present. Greater than 40 mg/m^2 body surface area per hour of protein excretion on a 24-hour urine collection is consistent with nephrotic range proteinuria. Alternately, an untimed "spot" urine protein-to-creatinine ratio can be used when a 24-hour urine collection is impractical. In this setting, nephrotic range proteinuria is defined as a ratio of ≥2 mg protein/mg creatinine.[1]

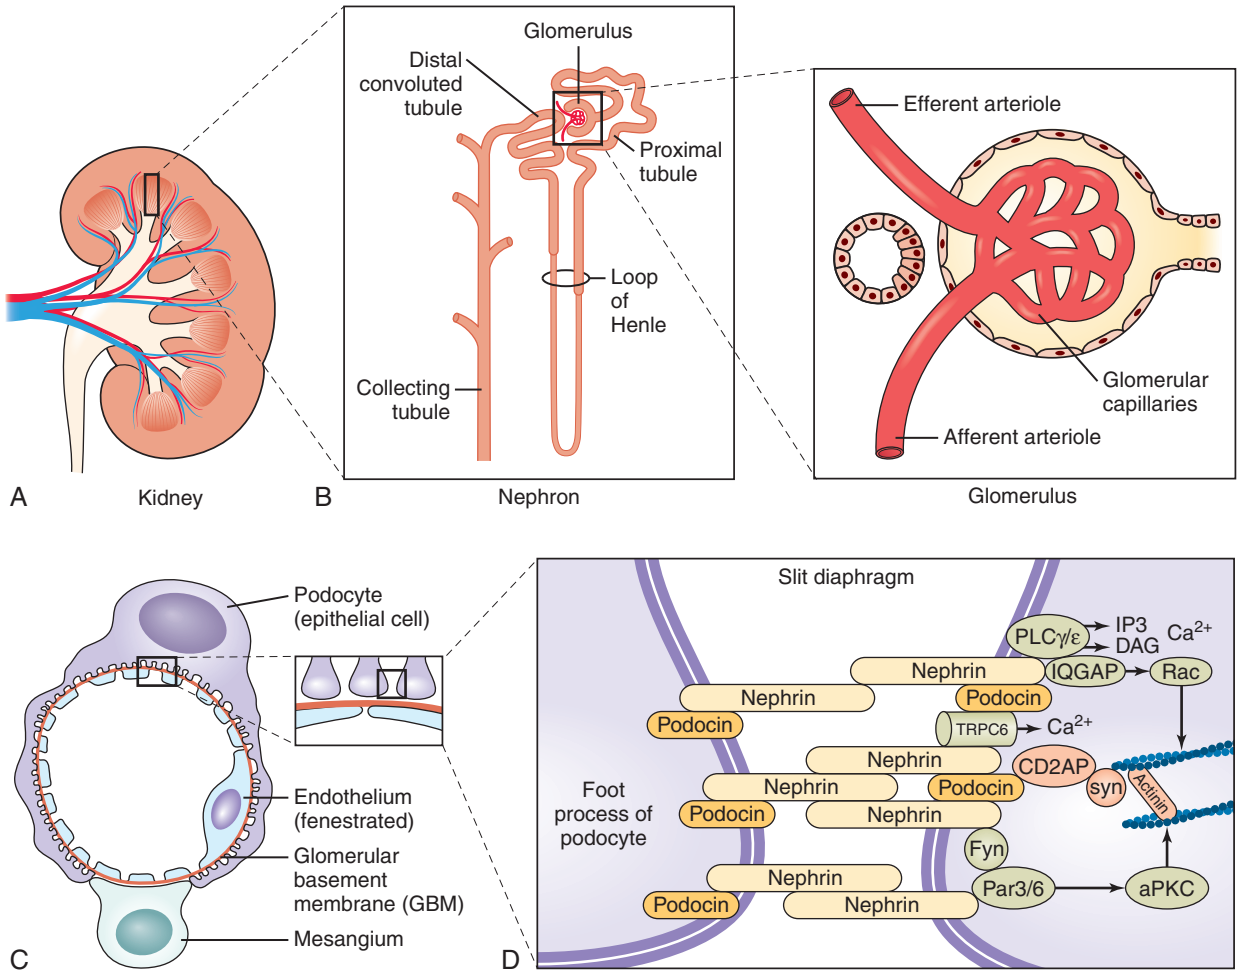
Congenital Nephrotic Syndrome

Congenital nephrotic syndrome (CNS) is defined as NS onset within the first 3 months of life. Infantile NS refers to NS onset within the first year of life. Both congenital and infantile NS can be divided into primary and secondary causes, with primary being the most common. Genetic abnormalities of structural or regulatory proteins within the glomerular basement membrane and/or podocyte lead to primary CNS.[2] Podocytes are cells with extensive foot processes that wrap around the capillaries of the glomerulus to prevent loss of proteins from the capillary into the urinary space. They are anchored in place by many proteins that make up the slit diaphragm, located between podocytes (Fig. 79.1). When there are abnormalities of the podocyte or slit diaphragm proteins, large molecules (such as proteins) may leak into the urinary space leading to proteinuria. Secondary CNS can be a presentation of congenital or perinatal infections or related to underlying metabolic disease.[3] Diagnosis may be made prenatally when a positive family history is present or because of an elevated amniotic fluid alpha fetoprotein indicating fetal proteinuria. In infants, clinical concerns (e.g., edema, failure to thrive, developmental delay) or NS complications, such as thromboembolism or infection, may lead to work-up and diagnosis.[4] Genetic screening identifies the genetic abnormality in greater than 85% of CNS patients.[5] Renal biopsy is not generally recommended due to success and availability of genetic screening, and because biopsy findings are commonly nonspecific. The most common light microscopy findings are mesangial hypercellularity and sclerosis, dilated proximal tubules, microcystic changes, or focal segmental glomerular sclerosis (FSGS), but these are not pathognomonic. Electron microscopy demonstrates diffuse foot process effacement.[3,6–8] Although most children with CNS require kidney transplant at a young age, there are case reports of CNS with spontaneous resolution or delayed progression, likely related to mild genetic mutations.[9]

Primary Congenital Nephrotic Syndromes

Finnish-Type Congenital Nephrotic Syndrome (MIM #256300)

Mutations in the nephrin protein encoding gene *NPHS1* are the most common cause of autosomal recessive (AR) CNS. It



• **Fig. 79.1** (A) The kidney contains approximately one million nephrons. (B) The nephron is composed of a glomerulus, proximal tubule, loop of Henle, distal tubule, and collecting duct. (C) The glomerular filtration barrier is composed of fenestrated endothelial cells, a basement membrane, and epithelial cells (podocytes). (D) Podocytes have structures called foot processes. The area between the foot processes is called the slit diaphragm. Proteins such as nephrin and podocin are essential for proper functioning of the slit diaphragm and filtration barrier. *actinin*, α-Actinin-4; *aPKC*, atypical protein kinase C; *CD2AP*, CD2 adaptor protein; *DAG*, diacylglycerol; *IP3*, inositol 1,4,5 triphosphate; *IQGAP*, IQ motif containing GTPase activating protein 1; *PLC*, phospholipase C; *syn*, synaptopodin; *TRPC6*, transient receptor potential-like channel 6. (Adapted from Chiang CK, Inagi R. Glomerular diseases: genetic causes and future therapeutics. *Nat Rev Nephrol*. 2010;6:539–554.)

is referred to as CNS of the Finnish type (CNF), owing to an incidence of approximately 1 in 8000 live births in the Finnish population.[3] Nephrin is an essential component of the podocyte slit diaphragm.[6] The classic presentation includes placental enlargement, premature delivery, and proteinuria.[3] Patients may have microscopic hematuria in addition to massive proteinuria, and typically present at birth or within the first 3 months of life.[6] Cardiac abnormalities, such as pulmonary stenosis or patent ductus arteriosus, have been reported in patients with *NPHS1* mutations, although severity and frequency are not well defined.[10] Renal ultrasound images demonstrate large echogenic kidneys with poor corticomedullary differentiation. These imaging findings are similar among all forms of congenital and infantile NS.[3]

Congenital Nephrotic Syndrome Type 2 (MIM #600995)

Podocin protein mutations in the *NPHS2* gene lead to the second most common form of AR CNS.[2,11] This is the most common gene implicated in CNS in central European populations.[12] Podocin is essential for targeting nephrin to the slit diaphragm of the podocyte, and protein absence leads to early onset, severe NS.[3] Clinical presentation is often slightly later than for *NPHS1* mutations, with NS commonly presenting between 4 months and 1 year of age.[13] Additionally, progression to end-stage kidney disease (ESKD) is thought to occur more gradually, with a mean time of 6.6 years from diagnosis to development of ESKD.[12] Ultrasound findings are similar to other forms of congenital and infantile NS.

Wilms Tumor Suppressor Gene Mutation Syndromes (MIM #194072, 136680, 194080)

Mutations of the Wilms tumor suppressor gene (*WT1*) may result in isolated diffuse mesangial sclerosis or be part of a syndrome associated with CNS such as Wilms tumor, aniridia, genitourinary abnormalities, and intellectual disabilities (WAGR), Frasier,

or Denys-Drash syndrome. On average, ESKD occurs at 3 years of age but can occur in infancy, and disease severity is partially dependent on mutation type. Patients with *WT1* mutations are at risk for Wilms tumors and gonadoblastomas and should be screened for these malignancies. Patients should also be screened with karyotype testing and, possibly, further genitourinary imaging, as they may have ambiguous genitalia or other genitourinary tract anomalies such as cryptorchidism in males or uterine abnormalities in females.[8]

Pierson Syndrome (MIM #609049)

Pierson syndrome is an AR disorder caused by mutations in *LAMB2*, which codes for the beta 2 chain of laminin, a basement membrane protein integral to the glomerular and ocular basement membranes, retina, and neuromuscular junctions.[14] Children with Pierson syndrome classically present with NS and ophthalmic findings (often microcoria) and neurodevelopmental abnormalities such as hypotonia. Age of presentation varies depending on the mutation type, but many present within the first 3 months of life.

Other Primary Causes of Congenital Nephrotic Syndrome (MIM #251300, 161200)

Galloway-Mowat syndrome is a rare AR condition in patients with NS and central nervous system anomalies, primarily microcephaly, with a genetic defect in the *WDR73*, or *OSGEP*, *TP53RK*, *TPRKB*, and *LAGE3* genes.[15,16] Case studies of other conditions such as nail–patella syndrome (an autosomal dominant [AD] condition associated with *LMX1B* mutations) may present with renal involvement, nail dysplasia, glaucoma, and bony anomalies classically identified by the presence of iliac horns. Though significant proteinuria may be present, this is not typically a presentation of NS.[17]

Management of Primary Congenital Nephrotic Syndromes

Primary CNS does not respond to the immunosuppressive treatments used for idiopathic NS. Given the abnormal or absent functional proteins in the basement membrane or slit diaphragm, this group of diseases is generally treated with symptomatic management targeted at minimizing protein loss. Definitive treatment is kidney transplant, but supportive therapies are used until the child is of appropriate size. The basic principles of management include maintenance of intravascular volume, minimization of proteinuria, adequate nutritional support, and maintaining electrolyte balance.

Albumin infusions are sometimes given to replace protein loss and restore intravascular volume. Diuretics are used in combination with intravenous albumin infusions to avoid severe edema. Treatment frequency varies based on patient characteristics. Medications to decrease the glomerular filtration rate by modulating renal blood flow can be used in an attempt to limit protein loss. Angiotensin-converting enzyme (ACE) inhibitors and nonsteroidal anti-inflammatory drugs (NSAIDs) can be used for this purpose either alone or in combination.[18,19] If medical management is insufficient to maintain stable serum albumin concentrations and prevent severe edema, then unilateral or bilateral nephrectomy would be indicated.

Neonates with CNS are at risk for many serious complications and should be monitored vigilantly. This is in part due to nonspecific urinary protein loss (e.g., immunoglobulins, coagulation proteins), which leads to the higher incidence of sepsis, thrombosis, and failure to thrive seen in this population. Serious bacterial infections are among the leading causes of death in infants with CNS.[5] Management with intravenous immunoglobulins (IVIGs) is not routinely recommended due to rapid loss into the urine.[20] However, IVIG supplementation may be helpful in conjunction with antibiotics during severe bacterial infections.[5]

Neonates with CNS will experience failure to thrive without nutritional supplementation, which often requires tube feedings. In general, fluid intake is limited by use of concentrated formulas. Recommended diet consists of high caloric (i.e., 130 kcal/kg/day) and protein intake (i.e., 4 g/kg/day), with low sodium intake (<0.5 to 2 g/day depending on age), along with the guidance of a renal dietician as part of the multidisciplinary team.[1,5] Commonly, hypothyroidism is found due to thyroid binding protein loss in the urine and is treated with levothyroxine.[5]

Approximately 10% of children with CNS will experience thrombotic complications due to urinary loss of antithrombin III and protein S, as well as increased thrombocytosis and plasma levels of factors V and VIII.[21] No standard guidelines exist regarding when nephrotic children should receive anticoagulation. However, hypercoagulability is of particular concern in children requiring central venous access, and this subgroup should be placed on antithrombotic therapy.[5]

Complications less often reported include anemia and copper deficiency. Smaller studies report refractory anemia related to transferrin and transcobalamin loss.[22] Ceruloplasmin loss leading to copper deficiency and subsequent neutropenia and refractory anemia has been reported.[23]

Most children progress to need kidney replacement therapy. At present, patients with CNS who receive a kidney transplant are expected to do as well as children with ESKD due to other etiologies.[3] A small percentage of patients, particularly with CNF, have a return of proteinuria after transplantation due to antibody formation against the previously absent nephrin protein.[24]

Secondary Causes of Congenital Nephrotic Syndrome

Although primary forms of CNS are most common, clinicians should consider secondary causes in children with negative genetic testing or clinical findings that point to other etiologies. For example, children with signs of metabolic disease in addition to their proteinuria should be evaluated for mitochondrial cytopathies. Those with nipple inversion and other dysmorphisms should be evaluated for congenital disorders of glycosylation.[25] Congenital and perinatal infections may cause CNS, a finding more common in developing countries. Implicated infections include human immunodeficiency virus, syphilis, toxoplasmosis, hepatitis B, malaria, rubella, and cytomegalovirus. Infection-related NS may respond with appropriate antimicrobial treatment, depending on the degree of glomerular damage.

Other Glomerular Diseases

Neonatal glomerulonephritis (GN) is uncommon and primarily described in case reports. GN is defined by proteinuria and hematuria accompanied by varying degrees of acute kidney injury, oliguria, and hypertension. Rarely, maternal antibody transfer can lead to membranous nephropathy in a neonate because of

absence of maternal neutral endopeptidase and subsequent antibody production following exposure to fetal neutral endopeptidase. The infant may experience transient glomerulopathy or may develop chronic kidney disease.[26] Additionally, nephritis may be the result of transfer of maternal antibodies related to systemic lupus erythematosus to the infant.[4]

Renal Tubular Disorders

The renal tubule regulates and modifies the glomerular filtrate to avoid excess salt and water loss in the urine. Defects along the tubule lead to varying pathology. The proximal tubule is in charge of bulk water and electrolyte reabsorption. The distal nephron delicately regulates the final urinary product with close regulation of acid-base balance and water reabsorption. In neonates, genetic causes of tubular dysfunction predominate; however, medications and other secondary causes of tubular dysfunction can occur. Adequate evaluation of renal tubular disorders in neonates can be complicated by the use of intravenous fluids, parenteral nutrition, or electrolyte supplementation, as these modify serum and urine studies. In addition, the renal tubules of premature infants have high urinary sodium excretion that improves over the first month of life.[27] This immature tubular function may cause self-limited moderate metabolic acidosis within the first few weeks of life.[28]

Renal Tubular Acidosis

Renal tubular acidosis (RTA) is suspected in children with a nonanion gap, hyperchloremic metabolic acidosis. There are four types of RTA (Table 79.1). Type 1 RTA is due to a distal nephron defect, type 2 is due to a proximal tubule defect, type 3 is a mix of type 1 and type 2 defects, and type 4 is due to hypoaldosteronism or aldosterone resistance.

Children with RTA present with failure to thrive, emesis, and polyuria. It is important to evaluate for other sources of bicarbonate (HCO_3^-) loss, such as diarrhea, as this should be addressed before pursuing a work-up for RTA. Baseline testing of serum electrolytes, blood gases, and a urine sample should be obtained while the child is acidotic. Evaluation of the serum anion gap (AG) is helpful to determine if a high AG acidosis or a normal AG acidosis is present. The AG is calculated by subtracting the serum anions from the serum cations.

$$AG = Na^+ - (Cl^- + HCO_3^-)$$

Normal values vary by institution, based on instrumentation and methodology. A high AG usually indicates increased unmeasured anions, whereas a normal AG acidosis is usually due to increased serum chloride. RTA is associated with a normal AG acidosis.

TABLE 79.1 Characteristics of Renal Tubular Acidosis Types

	Inheritance	Acid/Base	Potassium	Other Findings
Proximal Tubule				
Proximal RTA (type 2 RTA)	AD or AR or acquired	Metabolic acidosis	N or ↓	
Fanconi syndrome (diffuse proximal RTA)	Inheritance depends on underlying disease or acquired	Metabolic acidosis	N or ↓	Aminoaciduria Phosphaturia Glycosuria Uric aciduria Low-molecular-weight proteinuria
Loop of Henle				
Bartter syndrome	AR	Metabolic alkalosis	↓	Hypercalciuria Hypochloremia
Distal Tubule				
Distal RTA (type 1 RTA)	AD or AR or acquired	Metabolic acidosis	N or ↓	Hypercalciuria Nephrocalcinosis Urinary pH >5.5
Pseudohypoaldosteronism type 1	AD or AR	Metabolic acidosis	↑	Hyponatremia Elevated serum renin and aldosterone
Pseudohypoaldosteronism type 2	AD	Metabolic acidosis	↑	Hypertension Elevated serum aldosterone-to-renin ratio
Gitelman syndrome	AR	Metabolic alkalosis	↓	Older age Hypocalciuria Hypomagnesemia
Liddle syndrome	AD	Metabolic alkalosis	↓	Hypertension Low serum renin and aldosterone

AD, Autosomal dominant; *AR*, autosomal recessive; *N*, normal; *RTA*, renal tubular acidosis.

Urinary studies may help differentiate between the types of RTA. Normal renal response to metabolic acidosis will involve lowering urine pH and eliminating urinary ammonium (NH_4^+). The urinary anion gap ($U_{Na+} + U_{K+} - U_{Cl}^-$) is an approximate indirect measure of NH_4^+ concentration as NH_4^+ cannot be measured directly.[29] The urinary anion gap becomes negative with high urinary NH_4^+ and Cl^- excretion.[30] With low NH_4^+ concentration in the urine ($U_{Na+} + U_{K+} > U_{Cl-}$), the urinary anion gap becomes inappropriately positive. (Of note, in the setting of volume depletion and low urine sodium [≤25 mmol/L], the urine anion gap is also positive as the kidney reabsorbs chloride and has limited ammonia excretion.)[29,31,32] This volume depletion setting may mimic the serum and urine anion gap findings of RTA. Urinary osmolar gap ($U_{Osm} - 2U_{Na+} + 2U_{K+} + (U_{urea\ (mg/dL)}/2.8) + U_{glucose\ (mg/dL)}/18$) also helps determine if adequate NH_4^+ excretion is present. An elevated urinary osmolar gap (>100 mOsm/kg) suggests high NH_4^+ excretion.[30,33]

Distal Renal Tubular Acidosis (Type 1 RTA)

Distal RTA (type 1) is caused by an inability of the collecting duct to excrete adequate hydrogen (H^+) ions. Inherited distal RTA typically presents early in life with hyperchloremic metabolic acidosis, failure to thrive, hypercalciuria, and nephrocalcinosis that is usually seen on ultrasound within the first month of life.[29] Patients may be hypokalemic due to decreased distal hydrogen ion secretion and subsequent increased distal potassium excretion to maintain electroneutrality within the urinary filtrate. Specific AR mutations in the H^+ adenosine triphosphatase have been associated with sensorineural hearing loss as well as distal RTA.[34] Individuals with distal RTA typically have an inappropriately high urinary pH, generally greater than 5.5. The urine anion gap is usually positive, and the urine osmolar gap is low, representing inadequate NH_4^+ excretion. Treatment is with alkali supplementation.

Isolated Proximal Renal Tubular Acidosis (Type 2 RTA)

Proximal RTA (type 2) is not often seen in isolation and usually accompanies more diffuse proximal tubular dysfunction like Fanconi syndrome. The proximal tubule generally reabsorbs 80% of filtered HCO_3^-; therefore, defects lead to massive bicarbonaturia and subsequent acidosis. Serum potassium may be normal or decreased, due to impaired proximal potassium reabsorption in the setting of metabolic acidosis.

While inherited isolated proximal RTA is rare, it can be associated with ocular abnormalities and neurologic findings (i.e., intellectual disability, familial migraine).[29] Age of presentation is variable. Proximal RTA can be distinguished from distal RTA by the absence of hypercalciuria and absence of nephrocalcinosis. In proximal RTA, the urinary pH is often inappropriately high (>5.5) due to bicarbonaturia; however, once the serum HCO_3^- drops, less HCO_3^- will be filtered at the glomerulus, and urinary pH will also drop (<5.5). Treatment is with alkali replacement to correct the metabolic acidosis. Large doses of HCO_3^- supplementation are often needed to maintain balance. As this therapy can often worsen hypokalemia, potassium supplementation is also needed.

Hyperkalemic Tubulopathies (Type 4 RTA)

Hypoaldosteronism

Clinical hypoaldosteronism may be due to either a deficiency in aldosterone production or an inability of the renal tubules to respond to aldosterone (pseudohypoaldosteronism). Aldosterone deficiency can be primary in cases of congenital adrenal insufficiency or secondary due to drugs or infection, and is outside the scope of this chapter.

Pseudohypoaldosteronism Type 1

Pseudohypoaldosteronism type 1 (PHA1) can be AR (MIM #264350) or AD (MIM #177735). AR PHA1 involves a loss-of-function mutation in any one of the three genes (SCNN1A, SCNN1B, and SCNN1G) encoding the epithelial sodium channel (ENaC). This affects all mineralocorticoid targets and can present in infancy with volume depletion, hyponatremia, hyperkalemia, and acidosis. Because of mineralocorticoid resistance, patients have symptoms and laboratory results consistent with hypoaldosteronism, but with elevated renin and aldosterone levels. AD PHA1 is caused by a mutation in the mineralocorticoid receptor gene (NR3C2), and is milder in presentation, renal limited, and clinically may improve later in life.[35] Management requires treatment with Na^+ supplementation and K^+ restriction.

Pseudohypoaldosteronism Type 2 (MIM #145260, 614491, 614492, 614495, 614496)

Pseudohypoaldosteronism type 2 (PHA2), also known as Gordon hyperkalemia-hypertension syndrome, is an AD condition caused by a mutation in the WNK1, WNK4, KLHL3, or CUL3 gene. Patients traditionally present at an older age with normal kidney function, hyperkalemia, hypertension, and mild metabolic acidosis. Hypertension is due to volume overload through mutations in the distal convoluted tubule that increase Na^+ and Cl^- reabsorption. Although renin levels are depressed, aldosterone is not suppressed and, therefore, the aldosterone-to-renin ratio is elevated, which can help in the diagnosis. Low-dose diuretics are the mainstay of therapy, and patients are usually highly responsive to thiazides.[36]

Fanconi Syndrome

Fanconi syndrome is a condition of diffuse proximal tubule dysfunction. Children with Fanconi syndrome have polyuria and wasting of HCO_3^-, amino acids, uric acid, phosphate, glucose, and low-molecular-weight proteins. Fanconi syndrome may be an isolated defect or part of a broader genetic syndrome. In addition to the genetic syndromes described below, many medications can lead to proximal tubular dysfunction. Common offending medications include tenofovir, ifosfamide, carbonic anhydrase inhibitors, and aminoglycosides.

Tyrosinemia (MIM #276700) and classic galactosemia (MIM #230400) can both cause Fanconi syndrome. Both diseases are part of the uniform newborn screening panel performed in the United States, therefore often diagnosed early in life. Tyrosinemia is an AR disorder where toxic metabolites of tyrosine accumulate in the liver and kidney. Early therapy with nitisinone to reduce the production of toxic metabolites can improve renal proximal tubular dysfunction.[37] Classic galactosemia is also AR and presents early in life with emesis, lethargy, hepatomegaly, sepsis, and failure to thrive. Cataracts may also be present in infancy. Proximal tubular dysfunction can accompany galactosemia and exacerbate the clinical picture, although early dietary modification can prevent worsening of disease.[38]

Hereditary fructose intolerance (MIM #229600) is another genetic cause of Fanconi syndrome. Fructose intolerance does not usually present until fructose or sucrose is introduced to the infant's diet. Infants present with emesis and hypoglycemia. On subsequent evaluation the infant may be found to have proximal

tubular dysfunction due to deficient aldolase B within the kidney. Early dietary modification can prevent renal complications.[39]

Lowe syndrome (MIM #309000), also known as the oculocerebrorenal syndrome, is a rare X-linked syndrome that can cause Fanconi syndrome. Congenital cataracts and hypotonia are often detected at birth, with proximal tubulopathy and failure to thrive developing over subsequent weeks to months. Many patients develop chronic kidney disease and subsequent end-stage kidney disease in the second decade of life.[40]

Dent disease (MIM #300009) is another rare X-linked recessive proximal tubulopathy. It is characterized by hypercalciuria and recurrent nephrolithiasis. Urinary phosphate losses can lead to rickets and significant bone abnormalities in infancy.[41]

Fanconi syndrome is also a defining feature of Fanconi-Bickel syndrome (MIM #227810), which is characterized by hepatic and renal dysfunction caused by GLUT2 mutations.[42] This generally presents after a few months of life but can be seen in early infancy.

Nephropathic Cystinosis (MIM #219800)

Cystinosis is the most common cause of primary proximal tubular dysfunction in children. It is an AR lysosomal storage disease caused by a mutation in the *CTNS* gene leading to defects in the transporter cystinosin. This protein is responsible for cystine transport through the lysosome, and malfunction causes systemic cystine accumulation. The renal manifestations are due to cystine accumulation within the proximal tubular cells and present early in life, often leading to diagnosis.[43] Additional clinical features include corneal deposits, hepatomegaly, insulin-dependent diabetes mellitus, weakness, infertility, and hypogonadism. Corneal deposits initially cause light sensitivity and later lead to significant visual impairment.

Cystinosis diagnosis is made by measuring leukocyte cystine levels, detecting corneal deposits, or genetic testing. Genetic testing can also be done prenatally by chorionic villi sampling.[44] Discovery of cysteamine in 1976, now the mainstay of treatment, was a breakthrough in the treatment of patients with cystinosis.[45] Cysteamine decreases cystine concentration within cells, and, although cysteamine therapy cannot reverse renal tubular dysfunction, it can help preserve glomerular filtration rate, delaying the onset of ESKD.[46] Measurement of leukocyte cystine concentration is used to monitor efficacy of therapy. Compliance with treatment is difficult, as the medication has many side effects such as gastrointestinal upset, bad breath, body odor, and skin lesions at high doses. Compliance may be difficult due to need for dosing every 6 hours, although newer delayed release formulations may be easier, given as they are dosed twice daily. Cysteamine eye drops are used to limit corneal deposits, and these require hourly dosing.

Hypokalemic Tubulopathies

Bartter Syndrome (MIM #601678, 241200, 607364, 613090, 602522, 601198)

Bartter syndrome is caused by AR mutations in the thick ascending limb (TAL) of the loop of Henle. There are many known types of Bartter syndrome. Mutations in the genes *SLC12A1, KCNJ1, CLCNKB, CLCNKA, BSND*, and *CASR* have been found. Bartter syndrome is extremely rare, with a prevalence of 1 in 1,000,000 based on adult studies.[47] Bartter syndrome often comes to clinical attention based on poor growth and development, typically at a young age. In Bartter syndrome, impairment of sodium chloride reabsorption in the TAL involving the Na-K-2Cl cotransporter leads to decreased urinary concentrating ability, polyuria, volume depletion, and renin and aldosterone system activation. The secondary aldosterone activation increases Na^+ reabsorption and K^+ and H^+ ion excretion. This physiology can be thought of as analogous to the effect seen with loop diuretics.

Laboratory evaluation will demonstrate hypokalemia, metabolic alkalosis, hypochloremia, and hypercalciuria. Serum magnesium is often normal. Nephrocalcinosis may develop in infancy because of high urinary calcium. Sometimes, differentiation of Bartter syndrome from electrolyte abnormalities related to volume depletion can be difficult. Urinary Cl^- measurement can be very useful, as this should be low (<35 mEq/L) in patients with volume depletion.[48] Bartter syndrome patients uniquely have elevated urinary Cl^- in the presence of hypochloremia.

Bartter syndrome type IV is uniquely associated with sensorineural hearing loss, as the barttin protein is present in the kidney and the inner ear.[49] Genetic testing can confirm the diagnosis and specific mutation type; however, the diagnosis is primarily made clinically. Types I, II, and IV may be detected prenatally as part of the work-up for polyhydramnios. Amniotic fluid alpha fetoprotein should be low in cases of suspected Bartter syndrome.[50]

Early fluid management with adequate volume and electrolyte repletion is necessary to allow appropriate growth.[51] The TAL defect leads to an upregulation of prostaglandin-E_2; therefore, NSAIDs can help counteract this problem and limit fluid and electrolyte losses. Spironolactone and amiloride may also be used to limit distal potassium loss and minimize the need for large-dose potassium supplements.

A more recently described mutation is melanoma-associated antigen D2 (*MAGE-D2*) on the X chromosome and has been associated with a severe but transient form of neonatal Bartter syndrome. This mutation has also been associated with perinatal death.[52] These patients have an earlier, more severe presentation with polyhydramnios around the 20th week of gestation. Because of massive polyhydramnios, infants are often born premature. In the small group of infants studied, polyuria resolved at a median of 4.5 weeks after birth.[52]

Gitelman Syndrome (MIM #263800)

Gitelman syndrome is AR with defects found in the *SLC12A3* gene, which codes for the sodium chloride cotransporter in the distal convoluted tubule. Gitelman syndrome presents with hypokalemia and metabolic alkalosis similar to Bartter syndrome. However, in contrast to Bartter syndrome, it typically presents later in life and with hypomagnesemia and hypocalciuria. This condition can be thought of as analogous to the laboratory findings seen in patients being treated with a thiazide diuretic. Patients commonly present with muscle weakness, paresthesia, paralysis, or tetany. Diagnosis is primarily made based on serum and urine electrolyte measurements and can be confirmed with genetic testing. Treatment involves NSAIDs and drugs that block distal potassium–sodium exchange, combined with potassium and magnesium supplementation.[53]

Liddle Syndrome (MIM #177200, 618114, 618126)

Liddle syndrome is an AD condition where children are hypertensive due to a mutation in the *SCNN1B, SCNN1G*, or *SCNN1A* gene, each encoding a subunit of the ENaC. A mutation in this channel, which is responsible for distal sodium reabsorption, is a gain of function mutation and leads to excess sodium and subsequent water reabsorption. Consequently, Liddle syndrome

is associated with low renin and aldosterone levels, and, classically, hypokalemia and metabolic alkalosis accompany this disease. Therapy of choice is triamterene or amiloride as they directly inhibit ENaC channels.[36] Low sodium diet is also beneficial in minimizing the effects of ENaC activation.

Other Tubulopathies

Nephrogenic Diabetes Insipidus (MIM #304800, 125800)

In children, nephrogenic diabetes insipidus (NDI) is more often primary than secondary. Arginine vasopressin receptor type 2 (*AVPR2*) mutations are inherited in an X-linked recessive pattern and are the most common genetic defect, accounting for 90% of primary NDI.[54] Typically, arginine vasopressin is released from the pituitary in response to volume depletion, and signals to increase water reabsorption. *AVPR2* encodes for arginine vasopressin receptor-2, the receptor for arginine vasopressin on the basolateral surface of collecting duct cells. Receptor activation leads to translocation of aquaporin channels to the apical surface of the nephron for water reabsorption. Mutations in *AVPR2* result in arginine vasopressin resistance because of an inability to appropriately interact with circulating vasopressin.[55] Defects in the aquaporin channel are inherited in an AR pattern and are much less common.[54]

Children with genetic forms of NDI present at a young age with polyuria, failure to thrive, and hypernatremic volume depletion. Infants and small children that do not have the ability to increase their own water intake based on thirst responses are at greatest risk of complications, particularly at times of illness. Long-term complications include developmental delay, growth failure, and chronic kidney disease, all thought to be secondary to repeated volume and Na^+ depletion and rapid fluid shifts. Prenatal polyhydramnios may be appreciated during pregnancy.

Imaging often demonstrates a dilated urinary system because of the high volumes of urine. Elevated arginine vasopressin hormone levels in the setting of hypernatremic volume depletion and polyuria can help differentiate central diabetes insipidus from NDI, as can a desmopressin challenge. Definitive diagnosis is made through genetic testing.

Treatment of NDI in the newborn period focuses on providing adequate fluids. Decreasing the osmolality of the infant's formula helps maintain balance as these children have a limited ability to excrete osmotic loads. Breastfed infants often present later than formula-fed infants due to the lower osmotic and salt loads of breastmilk versus cow's milk based formulas (higher osmolality also necessitating increased urine volume).[54] Thiazide diuretics and nonsteroidal prostaglandin-synthetase inhibitors aid in management. Thiazide diuretics block sodium chloride reabsorption in the distal tubule leading to mild volume depletion, stimulating upregulation of proximal tubular sodium, and water reabsorption to overcome some of the massive water loss in the distal nephron. Nonsteroidal prostaglandin-synthetase inhibitors increase urinary concentrating ability, and are particularly effective when combined with a thiazide diuretic.[56] Gastrointestinal upset may limit usage, however.[57] Recently, sildenafil has been presented as a possible treatment to reduce proteinuria in therapy-resistant patients.[58] These current therapies are primarily aimed at symptomatic relief, but new research is investigating protein folding and increased protein expression to better target the cause of disease.[54]

Urinary Tract Infections and Vesicoureteral Reflux

KATHY HUEN, PETER (ZHAN TAO) WANG, AND ELIAS WEHBI

KEY POINTS

- The presentation of urinary tract infections (UTIs) in neonates differs from that seen in older children.
- The type and route of infection also differ in neonates, when compared with older children.
- An appropriate urine sample for diagnosis is needed, but treatment should not be delayed.
- A febrile neonate in whom a UTI is suspected should be evaluated for sepsis, including blood and possible spinal fluid cultures.
- The risk factors for UTIs in neonates are uncircumcised males, white race, high-grade vesicoureteral reflux (VUR), a maternal history of UTI, bladder bowel dysfunction, instrumentation of the urinary tract, and the existence of congenital anomalies of the kidney and urinary tract.
- After a documented neonatal UTI, a radiologic work-up is warranted to detect anatomic anomalies.
- VUR is diagnosed in 20% of neonates with a proven UTI.
- Voiding cystourethrogram is the gold standard for the diagnosis of VUR and should be performed on high-risk neonates.
- Treatment of VUR should be tailored to each patient's individual risk of UTI recurrence, with the goals of preventing future UTIs and renal scar formation.

Urinary Tract Infection

Epidemiology

Neonates, by virtue of their immature immune system, are at a higher risk for urinary tract infections (UTIs).[1] In the United States, the prevalence of UTI within the first 30 days of life is estimated at 0.1% to 1%,[2–4] while in developing countries, it is as high as 1.8%.[5,6] UTI is the second most common bacterial infection in children after otitis media.[7]

In febrile children less than 2 months of age without an obvious source of infection, the prevalence of UTI is 5% to 20%.[8–10] There is a male predominance in the neonatal period, with males comprising 70% to 90% of all cases of neonatal UTI before the age of 6 months,[11–13] irrespective of their degree of prematurity.[14] Hispanics and whites are more likely to be diagnosed with a UTI than children of African descent.[15,16]

Pathophysiology

The natural pathophysiology of UTI is dependent on the migration of uropathogenic bacteria through the fecal–perineal–urethral route with subsequent entry into the bladder.[17,18] Iatrogenic instrumentation and hematogenous seeding are alternative modes of entry into the urinary system. Once in the bladder, these uropathogens may ascend into the ureter and kidney in a retrograde manner. The effectiveness of this process is determined by both pathogen and host factors.

Host factors in the neonate often relate to anatomy and involve urogenital malformations such as posterior urethral valves, vesicoureteral reflux (VUR), phimosis, ureteropelvic junction obstruction, and neurogenic bladder dysfunction secondary to spinal dysraphism. These conditions ultimately disturb the washout effect of antegrade urinary flow that would normally clear the uropathogens.[19] Additional host factors include the neonatal immune function and the antimicrobial properties of urine, such as low pH.[20]

Uropathogens have a number of virulence factors that are used to overcome the defense of the host. *Escherichia coli* serotypes with P-fimbriae are commonly isolated in infected urine.[21] These are adhesion proteins at the tip of the bacterium's attachment structures that enhance binding to receptors on the host urothelium.[22–24] These increase the bacteria's ability to ascend the urinary tract, even in the absence of VUR.[25]

Epidemiologic studies have shown that 76% to 94% of pyelonephritic strains of *E. coli* are P-fimbriated, compared with 19% to 23% of strains causing cystitis and 14% to 18% of strains isolated from patients with asymptomatic bacteriuria.[26,27] In one study, P-fimbriated *E. coli* was isolated in only 36% of girls with VUR and recurrent pyelonephritis, as compared with 71% of girls with pyelonephritis without VUR.[28]

However, in the presence of VUR, P-fimbriated *E. coli* is not necessary for infection of the upper urinary tract. Other virulence factors from uropathogenic *E. coli* include the release of alpha hemolysin and cytotoxic necrotizing factor-1,[29–31] as well as the ability to form a protective glycosylated polysaccharide capsule.[32]

Clinical Presentation

The signs and symptoms of UTI in newborns differ from those of older children. The familiar symptoms of dysuria, frequency, urgency, malodorous urine, incontinence, suprapubic pain, and hematuria are often absent or not recognized. The clinician must retain a high index of suspicion for the diagnosis of a UTI in a neonate. In full-term infants the most common presentation is a fever of greater than 38.5°C followed by poor feeding, tachypnea, and lethargy.[13,33] In contrast, premature infants commonly present

with apnea, hypoxia, tachypnea, and fevers with a temperature greater than 39°C.[34] Other nonspecific signs and symptoms, such as abdominal distention, diarrhea, vomiting, and failure to thrive, have also been described in infants with UTIs.[35]

Neonatal jaundice, especially with an onset after 8 days of life, has been associated with neonatal UTIs.[34,36] Mutlu et al. found that the incidence of UTI in children with hyperbilirubinemia was 18%.[37] This is an important association, as Xinias et al. showed that approximately 50% of neonates with UTI-induced jaundice had renal cortical changes on dimercaptosuccinic acid (DMSA) scan.[38]

Bacteriology

Neonatal UTIs are commonly caused by gram-negative rods, with *E. coli* (40% to 72%) and *Klebsiella* species (7% to 40%) responsible for over 80% of cases.[39,40] Enterococcus, a gram-positive coccus, is the third most common organism, with an incidence of 10% to 16%.[3,35]

It is hypothesized that the incompletely developed neonatal immune system not only increases the newborn's risk of infection but also makes the newborn susceptible to additional organisms compared to older children.[41] In neonates with UTIs, group B streptococci have been found to be more common than in older children.[42] Additionally, other gram-positive bacteria, such as coagulase-negative staphylococci, have been associated with UTIs in premature infants, although this remains controversial.[43] Candida, as a causative agent for UTIs, has a reported incidence of 25% to 42% in premature children admitted to the neonatal intensive care unit.[44,45]

Risk Factors

The important risk factors for UTIs in neonates are prematurity, uncircumcised males, white race, high-grade VUR, a maternal history of UTI, instrumentation of the urinary tract, and the existence of congenital anomalies of the kidney and urinary tract.[46,47]

The decreased risk for UTI in circumcised males is supported by two metaanalyses.[10,48] In febrile neonates, the incidence of UTI in uncircumcised males is 20% to 21% compared with 2% in circumcised males and 5% to 8% for females.[10,49] This phenomenon is supported by studies showing a higher concentration of uropathogenic bacteria in the periurethral region of uncircumcised males.[50] Laway et al. prospectively studied the effects of circumcision on the colonization of the periurethral area of 124 children.[51] The authors found that the periurethral region was devoid of *E. coli*, *Llebsiella, Proteus, Pseudomonas*, and *Enterococci* after the children underwent circumcision, whereas these uropathogenic bacteria were present in 68% preoperatively.

In its 2012 Policy Statement on circumcision (current version at the time of this writing), the American Academy of Pediatrics (AAP) states that the health benefits of male newborn circumcision outweigh the risks of the procedure.[52] Benefits include significant reductions in the risk of UTIs in the first year, as outlined above, and reductions in the risk of heterosexual acquisition of human immunodeficiency virus, and the transmission of other sexually transmitted infections. Despite the risk reduction, however, the AAP suggests that the health benefits are not great enough to recommend routine circumcision for all male newborns. Instead, the AAP recommends that clinicians routinely inform parents of the health benefits and risks of circumcision in an unbiased and accurate manner and that the parents should decide whether circumcision is in the best interests of their child.[52]

A maternal history of UTI is a risk factor for neonatal UTI. Milas et al. studied 1200 newborns for a 6-month period and showed that neonates with UTIs were more likely to have mothers that were diagnosed with a UTI during the pregnancy (22.2% vs. 5.2%, $P < .001$).[34] This was further supported by a cross-sectional study by Khalesi et al. who demonstrated a 5.9-fold increased risk for neonatal UTI in newborns where there was a history of maternal UTIs.[53]

The overall reported incidence of genitourinary abnormalities in neonates is 5%.[3] VUR is a common renal abnormality predisposing neonates to UTIs and pyelonephritis. Cleper et al. retrospectively studied 64 neonates with UTIs and found the incidence of VUR to be 20.3%, of which 31% represented high-grade VUR.[54] However, other studies have reported rates between 20% and 50%.[55,56] In male neonates with UTI, the most common anomaly was VUR.[57] In neonates with UTI the incidence of VUR increases to 30% to 50%.[3,58] Although other anatomic abnormalities, such as posterior urethral valves, congenital urethral strictures, ureteroceles, ureteropelvic junction obstruction, and neurologic bladder dysfunction, increase the risk of UTIs, these are less common than VUR. An obstructive pathology represents less than 1% to 2% of the abnormalities found in neonates with UTIs.[59] A detailed discussion on VUR can be found in this chapter under the subheading "Vesicoureteral Reflux."

A calculator was recently developed to help clinicians estimate the probability of UTI in febrile infants at the bedside (https://uticalc.pitt.edu).[60] Although not specific to neonates, it is based on five risk factors that include age under 12 months, white race, female sex (or uncircumcised boy), maximum temperature of 39°C, and the absence of another source for fever. The calculator was validated in a cohort of 2000 children and was found to reduce unnecessary testing, to decrease missed UTIs, and to reduce treatment delays.

Evaluation

The diagnosis of UTI in neonates differs from older children. An initial assessment should involve a detailed history including birth and family history and findings on prenatal imaging, if performed. The focused physical examination should include vital signs, general appearance, as well as abdominal and genital examination. In girls, special attention should be paid to the presence of labial adhesions or intravaginal foreign bodies.[61] In boys, special attention should be paid to the presence of phimosis or meatal stenosis, and testicular examination for signs of epididymoorchitis.[62]

In febrile newborns with a UTI, 20% to 30% have associated bacteremia.[33,63,64] For this reason, a comprehensive work-up for sepsis should be performed in all febrile neonates.

Urine Sample

In children age 2 to 24 months, a UTI is defined as pyuria on urinalysis and a urine culture with >50,000 colony forming units/mL (CFU/mL) of a single organism.[65] Neonates void frequently, which can lead to lower colony counts on urine culture. Therefore, 10,000 CFU/mL is sometimes used as a cutoff for the diagnosis of neonatal UTI.[4,66]

The easiest method of obtaining a specimen from neonates is with a bag applied to the perineum. However, this carries a high contamination rate with a false-positive urine culture rate of 75%, and its only validity is to rule out a UTI in the event of a negative culture.[67] As always, the culture result must be correlated to a urinalysis, looking for signs of inflammation.

A superior method in neonates is urethral catheterization. This yields a sensitivity of 95% and a specificity of 99% for urine culture.[68,69] An even more accurate, although more invasive, method is suprapubic aspiration, with a contamination rate of 1%.[70] This may be a more appropriate option for boys with tight phimosis and girls with labial adhesions.[71] Topical anesthetics such as Eutectic Mixture of Local Anesthetic may be used to reduce pain associated with suprapubic aspiration in children.[72]

Dipstick urinalysis is an inexpensive and rapid screening tool and tests for urine nitrites and leukocyte esterase. Nitrites in the urine imply the presence of nitrate reductase, which is common among gram-negative uropathogens. Positive detection of leukocyte esterase, which is released by white blood cells (WBCs), is a surrogate for pyuria. In a retrospective study of 13,030 febrile infants, the sensitivity and specificity of a dipstick urinalysis were 91.7% and 90.4%, respectively. This was comparable with microscopic urinalyses obtained from the same sample population.[73]

Microscopic analysis completes the simple dipstick analysis by quantifying the WBCs, red blood cells, and presence of bacteria. Pyuria is the presence of five or more WBCs per high power field (HPF) in a centrifuged sample or greater than 10 WBC/HPF in a noncentrifuged sample if a counting chamber is used,[74] although these definitions may be less reliable in neonates.[75]

Renal Imaging

Renal imaging after UTI is driven primarily by a need to rule out underlying renal or urinary tract abnormality, or for the assessment of renal injury. The 2011 American Academy of Pediatrics clinical practice guideline, reaffirmed in 2016, recommends when to obtain renal bladder ultrasound (RBUS) and VCUG following febrile UTI for children aged 2 to 24 months. However, there is no consensus about when to obtain imaging in neonates.[65,76] Traditionally, routine imaging with ultrasonography, VCUGs, and 99Tc-DMSA renal scans were all recommended for neonates with a febrile UTI.[77] Yet, in the past two decades there has been a shift towards more selective usage of DMSA scans and VCUGs, due to concern for ionizing radiation exposure to neonates and their invasive nature relative to RBUS.

Renal Bladder Ultrasound

In the acute UTI phase, RBUS is the first-line imaging tool for the investigation of a neonate with a UTI. It is safe, noninvasive, inexpensive, and readily available, and should be routinely performed to evaluate for urinary tract anomalies. These include obstruction, renal structural anomalies, nephrolithiasis or calcification, and perinephric abscesses or abdominal masses.[46] In the authors' practice, a deferred RBUS after the UTI resolves should also be obtained for more accurate interpretation of anatomy, without the potential for false positive findings associated with tissue edema or endotoxin-induced dilation.

RBUS is a less sensitive imaging modality for the diagnosis of VUR.[78] In a retrospective review of 197 neonates, Wallace et al. found that the sensitivity of RBUS for VUR in infants younger than 2 months of age who were diagnosed with UTI was only 33% for grade I-V VUR, but improved to 86% when limited to grade IV–V.[79] Furthermore, a Cochrane meta-analysis of 42 studies looked at the accuracy of RBUS and/or DMSA in detecting VUR.[80] The authors found that RBUS lacked accuracy to detect either VUR or high-grade VUR, with summary sensitivity estimates ranging from 0.44 to 0.59 and summary specificity estimates ranging from 0.78 to 0.79. Thus, RBUS cannot replace VCUG in detecting VUR, nor can it serve to rule in or rule out VUR or high-grade VUR.

Voiding Cystourethrography

Voiding cystourethrography (VCUG) has the unique ability to provide detailed information about both the anatomical and functional status of the urinary tract. During the procedure, a nonballoon urinary catheter is placed using sterile technique for retrograde filling of the bladder with contrast dye. During cyclic filling, multiple spot images are obtained in the anteroposterior, oblique, and lateral positions, as well as urethral images during voiding. The AAP Sections on Radiology and Urology initiated a consensus standardized VCUG protocol in 2016 to improve the quality of VCUGs performed and to standardize the reporting of findings.[81]

The arguments for routine VCUG in neonates with a febrile UTI revolve around the higher incidence of VUR in this population, which requires aggressive and timely management.[54,57] The discussion against the routine use of VCUG is based on evidence that renal scarring is more common with grades IV and V VUR,[64] while the majority of VUR detected on routine VCUG is grade I–III.[82] AAP guidelines from 2011, reaffirmed in 2016, recommend that infants with initial febrile UTI undergo a RBUS, but state that a VCUG should not be routinely carried out unless indicated by the presence of abnormal sonographic findings (i.e., hydronephrosis, scarring) or atypical/complex clinical circumstances. The guidelines also suggest that additional work-up be considered if a child experiences recurrent febrile UTIs.[65,76] Given the lack of sensitivity and specificity of RBUS to detect VUR,[80] RBUS and VCUG are frequently considered complementary studies. They each impart important, but different, information. In line with this debate, the AAP Section on Urology expressed strong opposition to the AAP guidelines with respect to the omission of VCUG in the evaluation of infants with febrile UTI.[83] Failure to effectively screen children with a febrile UTI for VUR might place young children with VUR at untoward risk of both recurrent UTIs and potential renal injury.[84] It is the authors' opinion that the decision to perform a VCUG in a neonate should be individualized to the patient, with a thorough discussion with the parents regarding the risks, benefits, and alternatives to the imaging modality. A VCUG should be performed in high-risk neonates such as those with UTIs caused by bacteria other than *E. coli*, those with renal bladder ultrasound abnormalities, and uncircumcised males. If a decision is made to perform a VCUG, one should consider performing it 2 to 4 weeks after the infection to ensure that the infection is appropriately treated before instrumentation, although early VCUG may also be appropriate.[54]

Contrast-Enhanced Voiding Urosonography

Contrast-enhanced voiding urosonography (ceVUS) has emerged in the past decades as a replacement for the diagnosis and follow-up of VUR. It is a dynamic, real-time imaging technique that involves injection of an ultrasonic detectable microsphere-based

contrast intravesically via a urinary catheter.[85] CeVUS was first introduced in the 1990s as a means of diagnosing VUR without exposure to ionizing radiation inherent in VCUGs.[86] The current second-generation commercial ultrasound contrast agent, which has improved stability compared to the first generation, was developed in 2001.[87] However, owing to regulatory restrictions in the United States, the intravesical use of commercial contrast agents continues to be much more common in Europe than in the United States.[88] In a 2009 survey of pediatric urologists who belonged to the American Academy Pediatric Section of Urology, 98% indicated a preference for the use of VCUG for evaluating VUR despite awareness of the risks of radiation exposure in the pediatric population.[89]

Similar to a VCUG, ceVUS allows both morphologic and functional evaluation of the urinary tract. A 2018 literature review reported on aggregate findings of 45 comparative studies that assessed the diagnostic accuracy of ceVUS in the detection and evaluation of VUR, using VCUG as the standard reference.[90] The diagnostic accuracy of ceVUS in diagnosing VUR among children is comparable to VCUG, specifically for high-grade VUR and in younger children. Among studies using the second-generation contrast, the median sensitivity was 86.26 (interquartile range [IQR] 81.13 to 97), and the median specificity was 90.99 (IQR 84 to 98). No serious adverse events were reported in any of the studies.[90] However, one must account for the technical expertise and operator dependence required for the procedure. In a prospective study of 39 patients, Velasquez et al. noted a technical learning curve related to poor contrast mixing and the need to titrate the contrast agent, but noted that over a short period of time, a center previously naïve to ceVUS can quickly demonstrate concordance between ceVUS and VCUG.[91]

99Tc-Dimercaptosuccinic Acid Renal Scan

The DMSA renal scan is performed by injecting radiolabeled DMSA through an intravenous catheter. DMSA uptake by the kidneys is visualized with a gamma camera approximately 2 hours later, enabling the radiologist to evaluate uptake of DMSA by different regions of the kidney.[80] The debate surrounding the routine use of a DMSA scan is twofold; first, whether it predicts VUR and second, if it should be performed at all in neonates.

A Cochrane meta-analysis of 42 studies looked at the accuracy of RBUS and/or DMSA in detecting VUR.[80] The summary sensitivity and specificity estimates for DMSA to detect all grades of VUR were 0.75 (95% CI 0.67 to 0.81) and 0.48 (95% CI 0.48 to 0.57), respectively. Thus, DMSA cannot replace VCUG in the detection of VUR or high-grade VUR.

DMSA scan is the current gold standard for assessment of renal parenchymal injury in children with a history of febrile UTI.[46] It is more sensitive for renal scarring than RBUS, which misses a substantial proportion of such cases. If a DMSA scan is to be performed, a delayed one at 4 to 6 months after UTI resolution allows the acute inflammatory reaction to subside, at which point any persistent cortical defects can be assumed to represent permanent renal scarring.[92]

The decision for a DMSA scan should be shared with the parents, taking into account the risk for renal scarring based on the ultrasound findings and grade of VUR (i.e., abnormal renal parenchyma or VUR grade ≥III). Demonstration of renal scarring increases the risk for further renal deterioration,[93] and may influence surgical decision-making in patients with surgically correctable conditions such as VUR.

Management

For a febrile neonate, a septic work-up should be performed, including complete blood count, blood culture, urinalysis, urine culture and lumbar puncture. UTIs in the newborn are considered complicated and are associated with higher incidences of bacteremia (16% to 31%).[58,94] As such, empiric therapy with broad-spectrum antibiotics should be initiated without delay, after blood, urine, and cerebrospinal fluid (CSF) cultures are obtained. The goal of early treatment is to prevent sequelae such as urosepsis and renal scarring.

Local antibiotic resistance patterns and maternal antibiotics history should be used to determine choice of antimicrobial medication for empiric therapy.[95,96] The antibiotic should then be changed to one with less broad activity, according to the bacterium's antibiotic sensitivities.[97]

Parenteral ampicillin and gentamicin are the recommended empiric antibiotic regimen for neonates. Doses are dependent on the weight and age of the infant.[98] An alternative regimen described by the European Association of Urology includes ampicillin with ceftazidime.[99] In a retrospective review of 103 infants aged 0 to 60 days hospitalized with UTIs in a single institution in the United States, empiric antibiotics demonstrated organism susceptibility in 87.6% of cases.[100] Ampicillin and gentamicin were identified as the most common empiric antibiotic combination, with the combination of ampicillin and cefotaxime being the second most common.[100]

In young neonates, parenteral therapy should be continued for 7 to 14 days, followed by oral therapy for a total of 14 to 21 days.[99] For older and more mature neonates with negative blood and CSF cultures, parenteral antibiotics should be continued for 3 to 4 days, followed by oral therapy for a total of 7 to 14 days.[98] Routine follow-up urinalysis and culture after the resolution of UTI symptoms are not necessary unless clinically indicated.[101]

Neonatal candidiasis, which includes candiduria and/or candidemia, occurs predominantly in the neonatal intensive care unit. It is associated with significant mortality and neurodevelopmental impairment in extremely-low-birth-weight (ELBW) infants who weigh under 1000 g.[102] Recent studies have highlighted the significance of candiduria in the absence of candidemia in this specific population.[45,103] In a multicenter prospective observational cohort of ELBW infants in neonatal intensive care units, mortality was similar in those from whom Candida was isolated from only the blood (28%) or only from the urine (26%).[45] The authors suggest that Candida isolated from any normally sterile body fluid, including urine by suprapubic aspiration or in/out catheterization, should be treated as evidence of systemic disease. The clinical data are consistent with animal model studies, in which Candida injected into the blood of rodents was first isolated from urine.[104] When small amounts of Candida were injected, blood cultures were often negative while urine cultures were more frequently positive. For EBLW neonates, and neonates in the neonatal intensive care unit, candiduria should prompt a consultation with a pediatric infectious disease specialist for further work-up (blood cultures, lumbar puncture, abdominal ultrasound) for disseminated Candida infection and warrants treatment.[102] Treatment of neonatal candidiasis typically involves either amphotericin B deoxycholate or fluconazole.[102] For healthy term neonates, there are no specific guidelines from the Infectious Diseases Society of America, possibly in light of the rarity of candiduria in the healthy neonate.

Antibiotic Resistance

In the United States, the incidence of ampicillin- and gentamicin-resistant *E. coli* in the neonatal population reaches upwards of 75% and 17%, respectively.[105,106]

Vesicoureteral Reflux

Epidemiology

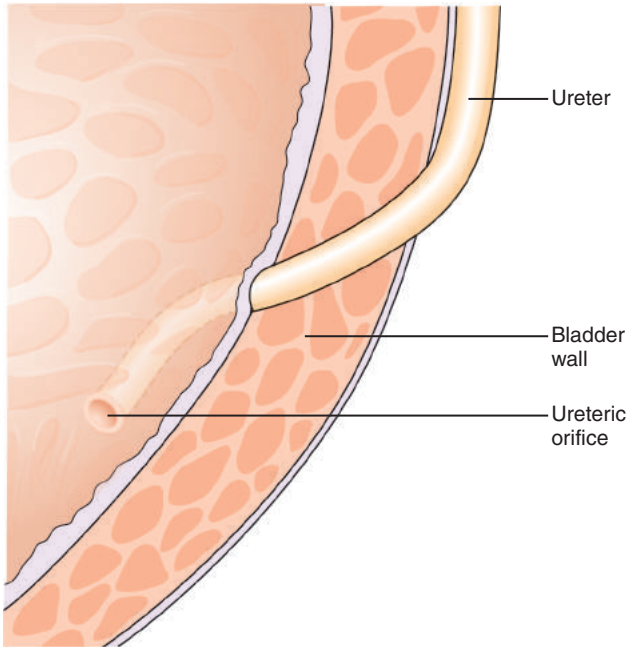
VUR is defined as the retrograde flow of urine from the bladder to the upper urinary tract. VUR is associated with approximately 20% of neonatal UTIs.[3,54] *Klebsiella pneumoniae* has a higher incidence in neonates with VUR presenting with a UTI compared with those without VUR.[54]

Pathophysiology

Primary VUR is thought to result from the abnormal structure and function of the ureterovesical junction, whereas secondary VUR is acquired as a result of increased intravesical pressure. Normally, the ureters enter the bladder obliquely, where a certain length of the ureter courses intramurally and submucosally. This creates a flap-valve mechanism where the distal ureter is compressed as the bladder fills with urine, thus normally preventing urine backflow. (Fig. 80.1 demonstrates this relationship.)

The lateral displacement of the ureteric orifice in the bladder in patients with VUR is thought to occur from an abnormal ureteric bud origin along the mesonephric duct, where the extent of lateral displacement correlates with the degree of associated renal dysplasia.[107]

The International Reflux Study grading system is universally accepted and used when grading reflux.[108,109] The grade of VUR is strongly associated with outcomes such as spontaneous resolution, recurrence of UTI, and renal scarring.[110] (Fig. 80.2 describes the appearance of each grade along with an example of each on VCUG.)



• **Fig. 80.1** Normal Course of the Ureter in the Bladder. Notice how the ureter courses through the bladder wall (intramural portion) and under the mucosa (submucosal portion) to expel urine into the bladder through the ureteric orifice.

Management

Surgical intervention is rarely required in the neonatal period, excluding obstructive abnormalities. If surgery is required, it is reserved for infants with high-grade VUR associated with recurrent breakthrough UTIs and renal scarring. A comprehensive discussion regarding the surgical management of VUR after the neonatal period is beyond the scope of this chapter.

Overall, the management of VUR diagnosed in the neonate after a UTI after the initial evaluation includes close follow-up with renal bladder ultrasounds and selective use of continuous antibiotic prophylaxis (CAP).

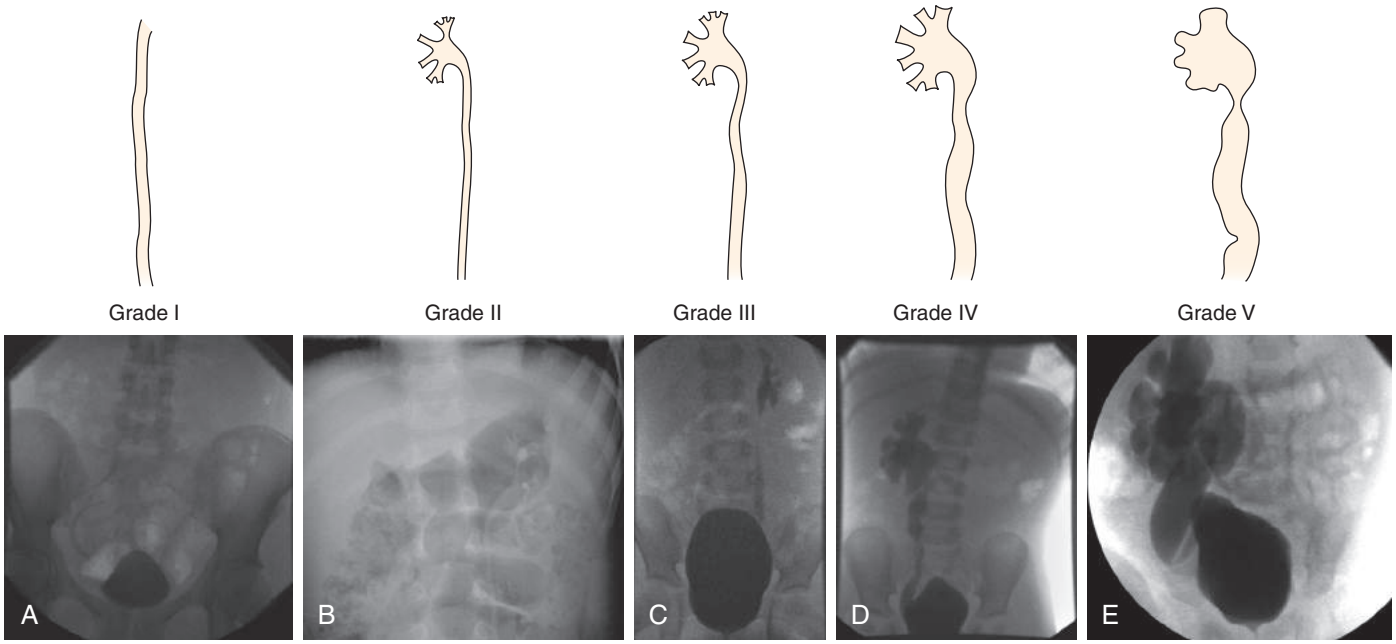
Continuous Antibiotic Prophylaxis

The basis for CAP stems from studies in the 1970s showing that the use of long-term antibiotics reduces the risk of repeat positive urine cultures, in comparison with no prophylaxis.[111,112] In the past decade, a number of randomized controlled trials (RCTs) have been conducted to elucidate the role of CAP in preventing UTI recurrences and renal scars. However, evidence for the efficacy of CAP in the neonatal population is lacking. The following discussion is based on study populations older than 1 month of age. Table 80.1 summarizes these RCTs and their findings.

There have been variations in results, attributed to significant differences in study designs, including patient inclusion and exclusion criteria.[113] In 2014, the findings of the Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) trial were published, showing CAP reducing risk of UTI recurrence by 50%.[114] The findings of a similarly double-blinded, placebo-controlled trial from the Prevention of Recurrent Urinary Tract Infection in Children with VUR and Normal Renal Tracts (PRIVENT) Investigators showed a more modest effect but with CAP similarly providing benefit, with the number needed to treat to prevent an infection being 14.[115] Other studies fail to show a significant difference in UTI recurrence rate and renal scar formation between those treated with CAP, surveillance, or ureteral reimplantation.[116–121] In systematic reviews and metaanalyses, researchers have also reported mixed results, with some suggesting that CAP is effective,[122] while an updated Cochrane review in 2019 concluded that although CAP may reduce the risk of repeat symptomatic UTI in children with recurrent infections, the benefit may be small.[123]

The 2014 RIVUR trial is the largest randomized, placebo-controlled, double-blind, multicenter study to date investigating the efficacy of trimethoprim-sulfamethoxazole as the CAP agent compared with placebo in young children with VUR.[114,124] This trial, sponsored by the National Institute of Diabetes and Digestive and Kidney Diseases, showed a significantly lower rate of UTI recurrence in children receiving CAP compared with placebo (12.8% vs. 25.4%, $P < .001$). As aforementioned, CAP reduced the risk of UTI recurrence by 50% (hazard ratio 0.50, 95% confidence interval 0.34 to 0.74).[114]

Nevertheless, the results and implications of the RIVUR trial have been widely debated. Critique of the trial includes the homogeneity of the study population. Females and those with VUR grades I–III comprised 91.9% and 91.7% of the study population, respectively.[113] The authors acknowledge that a benefit from



• **Fig. 80.2** International Reflux Study Grading With Voiding Cystourethrogram Examples. (A) In grade I, urine refluxes only into the ureter without reaching the renal pelvis or calyces (notice that it only appears upon voiding in this voiding cystourethrogram example). (B) In grade II, urine refluxes into the ureter, renal pelvis, and calyces, without any dilatation of the collecting system (notice the sharp contours of the fornices). (C) In grade III, urine refluxes into a mildly dilated and tortuous ureter, the renal pelvis, and calyces, with mild blunting of the fornices (notice how the forniceal contours are less sharp). (D) In grade IV, urine refluxes into a moderately dilated and tortuous ureter, the renal pelvis, and calyces, with complete obliteration of forniceal angles but maintenance of papillary impressions. (E) In grade V, urine refluxes into a grossly dilated and tortuous ureter, the renal pelvis, and calyces, with blown fornices where papillary impressions are no longer visible.

CAP was demonstrated; however, the number needed to treat (NNT) of 8 translates to a total of 5840 doses of antibiotic to prevent one UTI recurrence.[113] The AAP practice guidelines were recently reaffirmed by the AAP, which suggests that the results of the RIVUR trial may not be clinically significant.[76] Wang et al. conducted a reanalysis of the RIVUR trial by stratifying children with VUR into low- and high-risk categories.[125] Low-risk patients included circumcised males and females with grade I–III VUR and had no bladder bowel dysfunction (BBD). High risk patients included the following: (1) uncircumcised males with grade I–III VUR with or without BBD, (2) females with grade I–III VUR with BBD, or (3) females and males with grade IV–V VUR with or without BBD. The reanalysis demonstrated that high risk children benefit more, with a NNT of 5 compared to 18 in low-risk children.[125] These findings support a selective, risk-based approach for CAP management.

Antibiotic Resistance on Continuous Antibiotic Prophylaxis

Children being treated with prolonged administration of antibiotics have been found to have an increased risk of resistance.[46] A recent metaanalysis of six RCTs investigating antibiotic prophylaxis for children with VUR included data on microbial resistance.[126] A total of 1299 patients with VUR were included in the final analysis, contributing 224 first recurrent UTIs. Of first recurrent UTIs, 86% were *E. coli*, which was not statistically significant between control (86%) and prophylaxis (85%) groups ($P = .74$). Patients being treated with prophylaxis were more likely to have a multidrug-resistant (33% vs. 6%, $P < .001$) result on their first recurrent UTI, and they were subsequently more likely to receive a broad-spectrum antibiotic (68% vs. 49%, $P = .004$).

Neonatal Continuous Antibiotic Prophylaxis

In cases of febrile UTI and VUR, the American Urological Association (AUA) recommends CAP in children under 1 year of age, in contrast to its recommendations for older children, where a more selective approach is taken.[127] In addition to the AUA recommendations, the recommendations of the European Association of Urology and European Society of Paediatric Urology both include younger age as a particular consideration for prophylaxis, due to the nonspecific clinical presentation for UTI, the difficulty in getting urine specimens, the higher possibility of a need for hospitalization for intravenous antibiotics administration, and an increased risk of septicemia.[99]

The decision to start CAP should be made on an individual and selective basis, based on risk for UTI recurrence, in consultation with parents. The use of a clinical calculator (iReflux) developed by Hidas et al. for determining a child's individualized risk for UTI recurrence may help in this decision.[128] However, it is the authors' opinion that in children with high-grade VUR (grades III–V), especially in uncircumcised males, CAP should be initiated (Table 80.2). Unlike in older children, ampicillin, amoxicillin, and cephalexin are the commonly used antibiotics for CAP in neonates with VUR.[129] Trimethoprim-sulfamethoxazole should be avoided because of the immaturity of the newborn liver and kidneys, which cause slower metabolism and excretion. The prophylactic dose of antimicrobials is one-fourth to one-half of the therapeutic dose for acute infection.[129]

TABLE 80.1 Randomized Controlled Trials Evaluating the Effect of Continuous Antibiotic Prophylaxis on Urinary Tract Infection Recurrence Rates and Renal Scar Formation

Authors	Publication Date	PATIENTS INCLUDED: Age	PATIENTS INCLUDED: VUR Status (Grade)	Randomization	Rate of UTI Recurrence	Renal Scar Formation
Jodal et al.	2006	<11 years	III–IV	CAP vs. ureteral reimplantation	CAP = reimplantation Febrile CAP > girls > boys	CAP = reimplantation
Garin et al.	2006	3 months –18 years	0–III	CAP vs. surveillance	CAP = surveillance	CAP = surveillance
Roussey-Kesler et al.	2007	1 month –3 years	I–III	CAP vs. surveillance	CAP = surveillance (except boys with grade III reflux: CAP < surveillance)	
Montini et al.	2008	2 months –7 years	0–3	CAP vs. surveillance	CAP = surveillance Grade III = independent predictor febrile recurrence	CAP = surveillance
Pennesi et al.	2009	<30 months	II–IV	CAP vs. surveillance	CAP = surveillance	CAP = surveillance
Craig et al. (PRIVENT Investigators)	2009	<18 years	0–IV (60% 0–II)	CAP vs. placebo	CAP < placebo ARR 6% NNT 14	CAP = placebo
Brandstrom et al.	2011	1–2 years	III–IV	CAP vs. endoscopy vs. surveillance	CAP < surveillance girls Endoscopic < surveillance girls, not boys	CAP < surveillance girls
RIVUR Trial Investigators	2014	<6 years, 8% boys	I–IV (92% I–III)	CAP vs. placebo	CAP < placebo ARR 12% NNT 8 CAP > placebo resistance	CAP = placebo
Hari et al.	2015	<12 years	I-IV	CAP vs. placebo	CAP > placebo	CAP = placebo

= signifies that these treatments were shown to be equivalent; > signifies that the first listed treatment yields more of the outcome than the second one; < signifies that the first listed treatment yields less of the outcome than the second one.
ARR, Absolute risk reduction; *CAP*, continuous antibiotic prophylaxis; *NNT*, number needed to treat; *RIVUR*, randomized intervention for children with vesicoureteral reflux; *UTI*, urinary tract infection; *VUR*, vesicoureteral reflux.

TABLE 80.2 Risk of Breakthrough Urinary Tract Infection Stratification Groups

Risk Category	Defining Risk Factors	% Found in Population	% 2-Year Risk of Breakthrough UTI	Treatment Suggested
Low	VUR grade I–III in female without BBD Circumcised male	67.0	8.6	Surveillance
Intermediate	VUR grade I–III female with BBD Uncircumcised male VUR grade IV–V female presented as prenatal hydronephrosis	27.0	27.0	CAP
High	VUR grade IV–V female presented as UTI	6.0	62.0	CAP and endoscopic or surgical correction

BBD, Bladder bowel dysfunction; *CAP*, continuous antibiotic prophylaxis; *UTI*, urinary tract infection; *VUR*, vesicoureteral reflux.

Systemic Hypertension

JOSEPH T. FLYNN JR.

KEY POINTS

- There are numerous influences on normal blood pressure (BP) in neonates, including gestational age, birthweight, and maternal factors such as preeclampsia.
- As in older children, identification of hypertension (HTN) in the neonate is dependent on proper BP measurement technique.
- While the differential diagnosis of systemic HTN in the neonate is broad, common causes include catheter-related thromboembolic phenomena, chronic lung disease, kidney disease, and iatrogenic causes. A focused diagnostic evaluation should lead to correct identification of the underlying cause in most neonates.
- Therapy for HTN in the neonate is largely empiric because of a lack of data on outcomes of elevated BP in neonates and exclusion of neonates from clinical trials of antihypertensive medications.

Advances in the ability to care for premature infants have led to an increased awareness of systemic hypertension in the neonatal intensive care unit (NICU). However, there is also uncertainty regarding normative blood pressure (BP) in neonates and the best therapeutic approach to elevated BPs, mostly because of a lack of rigorous evidence. This chapter will review the many factors that influence BP in the neonate, present what we know about normal neonatal BP, and then discuss differential diagnosis of hypertension (HTN), the optimal diagnostic evaluation, and antihypertensive therapy.

Factors that Influence Neonatal Blood Pressure

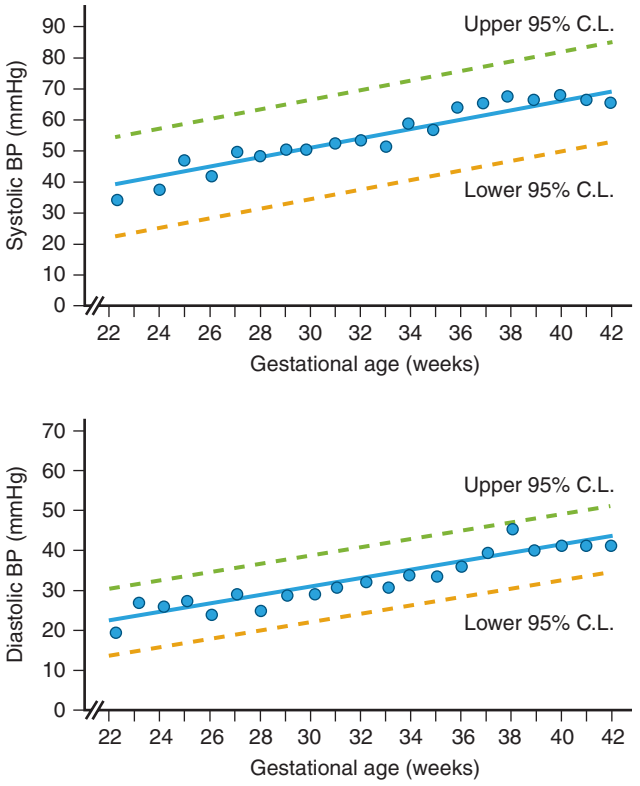
Many studies have examined the factors that influence BP patterns in normal and premature infants. In a study of BP in over 600 infants of various birthweights (BWs) and gestational ages (GAs) admitted to 14 Philadelphia-area NICUs, Zubrow et al.[1] made a series of observations. First, they found that BP at birth is closely correlated with GA (Fig. 81.1) and BW (Fig. 81.2). Then after delivery, there is a predictable increase in BP over the first 5 days of life that is independent of these factors. Thereafter, BP continues to rise gradually, with the most important determining factor being postmenstrual (postconceptual) age (Fig. 81.3). A more recent study of stable NICU infants showed a similar pattern, with BPs in each GA category of premature infants increasing at a faster rate during the first week of life, with subsequent slowing[2]; the rate of rise was more rapid in preterm infants than in term infants (Fig. 81.4). The rate of change in BP has also been shown to be slower in infants born small for GA compared to those born appropriate for GA.[3]

Several maternal factors have emerged that also may have important influences on neonatal BP, including antenatally administered medications and maternal health conditions. Regarding antenatal steroids, while an initial case series suggested that antenatal glucocorticoid exposure led to increased BP in the first week of life,[4] a later randomized controlled trial of corticosteroids versus placebo showed no difference in infant BPs between groups.[5] Inadvertent exposure to agents affecting the renin-angiotensin-aldosterone system (RAAS) during pregnancy is well-known to result in neonatal hypotension, particularly when the exposure occurs in the third trimester.[6] There is some suggestion in the literature that chorioamnionitis and HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome may also be associated with lower infant BPs. On the other hand, maternal preeclampsia appears to be associated with higher offspring BP during the first month of life.[7] Higher infant BPs have been correlated with maternal body mass index greater than 30 kg/m^2 and low socioeconomic status in a study of Nigerian infants[8] and in an Australian study of premature infants born to mothers with diabetes or neonates with abnormal uteroplacental perfusion as evidenced by placental pathology.[9] While these factors may not have caused hypotension or HTN per se, it is clear that many prenatal and postnatal processes combine to influence BP in the newborn period.

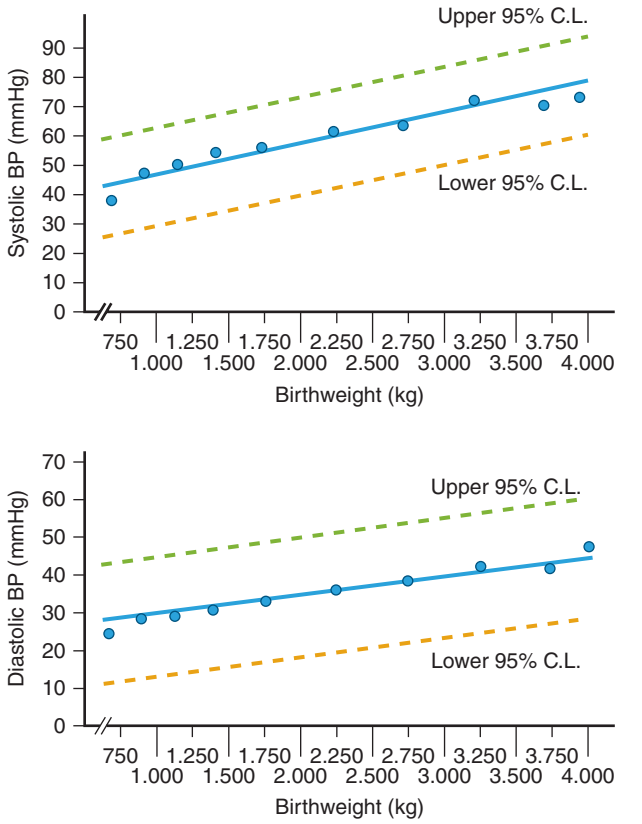
Definition of Hypertension

While the definition of HTN in an older infant or child is clear, it is more difficult to define HTN in newborns and preterm infants given the changes in BP that normally occur in the first few weeks of life discussed earlier.[10] Dionne et al. have summarized available BP data on preterm neonates and have published a table of BPs that is helpful in categorizing an infant's BP as normal or elevated (Table 81.1). Their data were recently endorsed in the 2017 American Academy of Pediatrics (AAP) Clinical Practice Guideline (CPG) on childhood hypertension as the most appropriate reference values for neonates up to 44 weeks post-menstrual age.[11] Sadly, there is a definite gap in knowledge regarding normal BP over the subsequent 12 months of life; the only available data are from the 1987 Second Task Force Report,[12] but they do not correlate well with the revised normative childhood BP data in the 2017 AAP CPG.

For relatively stable infants still in the NICU, a pattern of elevated readings using the data of Dionne et al.,[10] particularly if >99th percentile, should be sufficient to make the diagnosis of



• **Fig. 81.1** Correlation between gestational age and neonatal blood pressure (BP). C.L., Confidence limit. (From Zubrow AB, Hulman S, Kushner H, et al. Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. *J Perinatol*. 1995;15:470–479.)



• **Fig. 81.2** Correlation between birthweight and neonatal blood pressure (BP). C.L., Confidence limit. (From Zubrow AB, Hulman S, Kushner H, et al. Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. *J Perinatol*. 1995;15:470–479.)

HTN. If the infant is critically ill and continuous BP monitoring reveals sustained BP elevation over several hours, then HTN should be diagnosed, and appropriate investigation and intervention should be initiated. For older infants and NICU graduates who are being followed up as outpatients, at least three elevated readings should be documented over 1 to 2 weeks before a diagnosis of HTN is made.[12]

Epidemiology

Although one recent series found that 28% of very low birth weight (VLBW) infants had at least one elevated BP reading documented during their NICU stay, the actual incidence of HTN in neonates is very low, ranging from 0.2% in healthy newborns to between 0.7% and 2.5% in high-risk newborns.[11] However, in a recent publication from the Assessment of Worldwide Acute Kidney Injury Epidemiology in Neonates (AWAKEN) study, while the proportion of diagnosed HTN was 1.8% in infants admitted to the NICU, they found that another 3.7% had undiagnosed HTN.[13] This was estimated based upon BP values from a literature review conducted by the AWAKEN investigators themselves, as opposed to the values recommended by the AAP CPG, again highlighting the need for more robust normative data for neonatal BP.

Certain categories of infants are at significantly higher risk, however. For example, HTN is relatively common in patients with a history of umbilical artery (UA) catheterization (3%) and those with bronchopulmonary dysplasia (BPD) (as high as 43%). In one series it was also associated with patent ductus arteriosus and intraventricular hemorrhage. On the other hand, HTN is so uncommon in otherwise healthy term infants that routine BP determination is not even recommended.

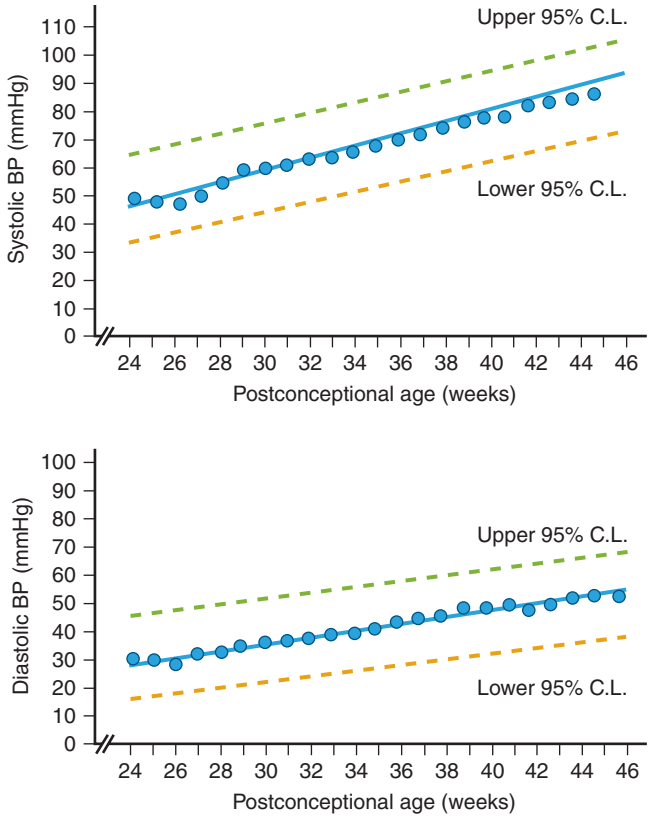
Fewer data are available on the incidence of sustained HTN in NICU graduates. In their classic study, Sheftel et al.[14] performed BP measurement in infants followed up in a neonatal follow-up clinic and found that 8.9% were hypertensive according to criteria used at that time. A later report by some of the same authors demonstrated an incidence of 2.6%.[15] Secondary causes such as those discussed later were found in most cases. More recently, an incidence of elevated BP of 2.9% was seen in a cohort of infants from the neonatology follow-up clinic at the University of Iowa Children's Hospital;[16] elevated BP was associated with the cytochrome P450 genotype (*CYP2D6*) in that cohort. Given these data, it is recommended that BP screening be incorporated into the long-term follow-up of NICU graduates.

Pathophysiology

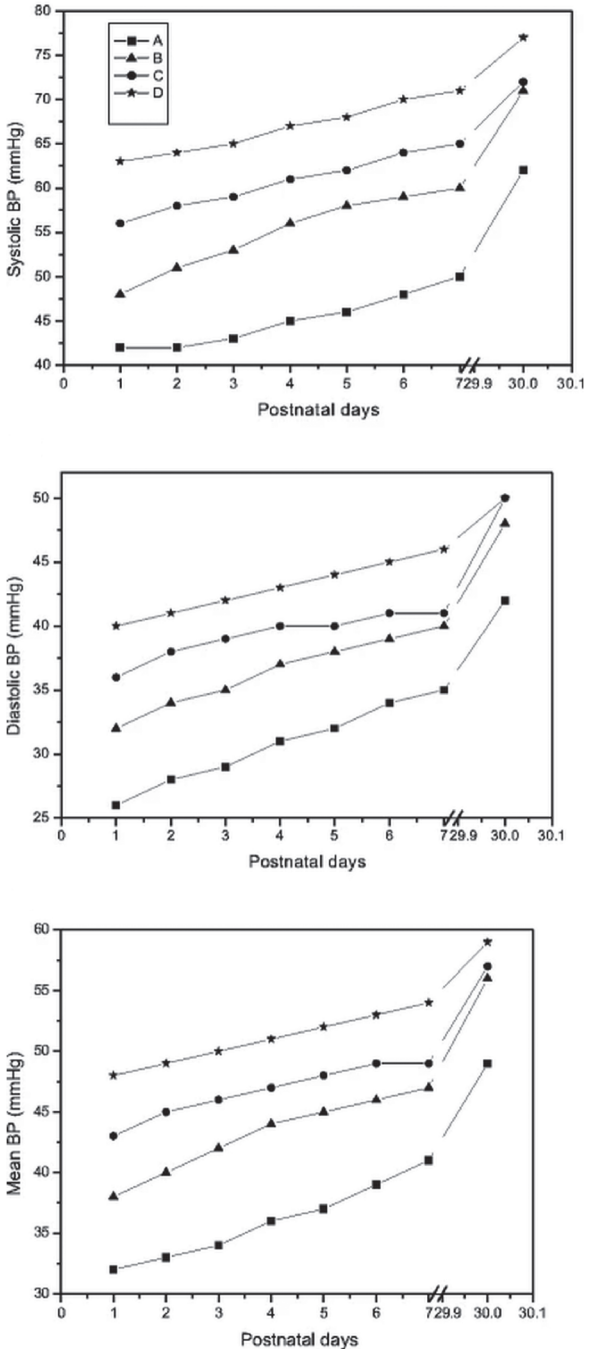
While the differential diagnosis of HTN in the neonate or older infant is extensive (Box 81.1), the most important categories of causes of neonatal HTN include renovascular HTN, BPD, and congenital and acquired kidney disease.

Renovascular Causes

The most common cause of neonatal renovascular HTN is aortic or renal thromboembolism related to UA catheterization.



• **Fig. 81.3** Correlation between postmenstrual (postconceptual) age and neonatal blood pressure (BP). C.L., Confidence limit. (From Zubrow AB, Hulman S, Kushner H, et al. Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. *J Perinatol*. 1995;15:470–479.)



• **Fig. 81.4** Increase in systolic (A), diastolic (B), and mean blood pressure (C) during the first month of life in groups of infants classified by estimated gestational age: A (≤28 weeks), B (29 to 32 weeks), C (33 to 36 weeks), and D (≥37 weeks). (From Pejovic B, Peco-Antic A, Marinkovic-Eric J. Blood pressure in non-critically ill preterm and full-term neonates. *Pediatr Nephrol*. 2007;22:249–257.)

HTN may develop either while the catheter is in place or long after its removal and may be associated with a history of elevated serum creatinine or gross hematuria. Associated signs may include acute kidney injury (AKI) in patients with bilateral involvement, hematuria, and loss of femoral pulses and blood flow to the lower extremities in patients with extensive aortic thrombosis.

Studies using ultrasound report an incidence of UA-related thromboembolism ranging from 14% to 35%, whereas studies using angiography document incidences up to 64%. Autopsy studies have shown an incidence of UA-related thromboembolism between 9% and 28%, although major clinical symptoms of UA-related thromboembolism occur in just 1% to 3% of infants.[17] Trauma at the time of insertion of an UA catheter caused by endothelial injury is postulated to be the cause of aortic thrombus formation, with clot embolization to the kidneys, causing localized areas of infarction and increased renin release.

Although several studies that have examined the duration of line placement and line position ("low" vs. "high") as factors involved in thrombus formation, the data have not been conclusive. The Cochrane Neonatal Group has attempted to resolve this controversy.[18] It analyzed 11 randomized clinical trials and one study using alternate assignments to compare the incidence of morbidity and mortality for high versus low UAC catheter tip placement. The placement of a catheter tip was defined as 'high' when it was in the descending aorta above the diaphragm and 'low' when it was placed in the descending aorta above the bifurcation but below the renal arteries. The reviewers concluded that high catheter position causes fewer clinically obvious ischemic complications. With regard to HTN, however, it was concluded that it seems to appear with equal frequency among infants with high or low catheter placement.[18]

Congenital vascular anomalies responsible for neonatal renovascular HTN include stenosis or hypoplasia of the renal artery and segmental intimal hyperplasia. These conditions may involve the aorta and the renal arteries. Unilateral renal artery stenosis

• BOX 81.1 Differential Diagnosis of Hypertension in the Neonate

Renovascular
- Thromboembolism
- Renal artery stenosis
- Midaortic coarctation
- Renal venous thrombosis
- Compression of renal artery
- Idiopathic arterial calcification
- Congenital rubella syndrome

Kidney Parenchymal Disease
- Congenital/chronic
  - Polycystic kidney disease
  - Multicystic dysplastic kidney
  - Tuberous sclerosis
  - Ureteropelvic junction obstruction
  - Kidney hypodysplasia
  - Congenital nephrotic syndrome
  - Renal tubular dysgenesis
- Acquired/acute
  - Acute tubular necrosis
  - Cortical necrosis
  - Interstitial nephritis
  - Hemolytic–uremic syndrome
  - Obstruction (stones, tumors)

Pulmonary
- Bronchopulmonary dysplasia
- Pneumothorax

Cardiac
- Thoracic aortic coarctation

Endocrine
- Congenital adrenal hyperplasia
- Hyperaldosteronism
- Hyperthyroidism
- Pseudohypoaldosteronism type II

Medication Related
- Infant
  - Dexamethasone
  - Adrenergic agents
  - Vitamin D intoxication
  - Theophylline
  - Caffeine
  - Pancuronium
  - Phenylephrine

- Neuroblastoma
- Pheochromocytoma

Neurologic
- Pain
- Intracranial hypertension
- Seizures
- Familial dysautonomia
- Subdural hematoma

Miscellaneous
- Total parenteral nutrition
- Closure of abdominal wall defect
- Adrenal hemorrhage
- Hypercalcemia
- Traction
- Extracorporeal membrane oxygenation
- Birth asphyxia
- Fluid overload

may cause a reversible syndrome characterized by hypokalemic alkalosis, hyponatremia, and increased echogenicity of the contralateral kidney.[19]

HTN may rarely result from calcium infiltration of the arterial wall. Generalized arterial calcification of infancy types 1 and 2 (GACI1, Online Mendelian Inheritance in Man [OMIN] catalog #208000; GACI2, OMIM # 614473) are rare disorders characterized by calcium deposits in all layers of the arteries, including the aorta and the coronary arteries, and in the heart valves. Even though these are caused by different genetic mutations (ENPP1 in GACI1 and the ABCC6 gene in GACI2,[20] the disorders are phenotypically similar. HTN is severe and typically fails to respond to standard antihypertensive medication or even to nephrectomy; biphosphonates, calcium antagonists, or prostaglandin infusion may be successful, although reported mortality rates are high.

Other causes of renovascular HTN include neonatal renal arterial embolism in the absence of UA catheterization, intramural hematoma of the renal artery, renal venous thrombosis, and external compression of the renal artery by a hydronephrotic kidney, adrenal hemorrhage, and urinoma. Finally, a neonate with HTN as a result of an aneurysm of the abdominal aorta has

been reported[21]; this fortunately rare condition may present with intractable congestive heart failure.

Bronchopulmonary Dysplasia

Many infants with BPD develop HTN. This phenomenon was first described in the mid-1980s by Abman.[22] In a study of 65 infants discharged from a NICU, the incidence of HTN in infants with BPD was 43%, versus 4.5% in infants without BPD. The investigators were unable to identify a clear cause of HTN but postulated that hypoxemia might be involved. More than half of the infants with BPD who developed HTN did not display it until after discharge from the NICU, further highlighting the need for measurement of BP in all NICU "graduates," and particularly in those with chronic lung disease.

The findings of Abman et al., have been reproduced by other investigators, including Alagappan and Malloy,[23] who found that HTN was twice as common in VLBW infants with BPD compared with all VLBW infants. Because all of the hypertensive infants required supplemental oxygen and aminophylline, development of HTN appeared to be correlated with the severity of pulmonary disease. Anderson et al.[24] have demonstrated that the more severe the BPD (defined as a greater need for diuretics and bronchodilators), the higher the likelihood of the development of increased BP. BPD was also noted as a common diagnosis in a case series from Houston, Texas,[25] and infants from the Iowa cohort mentioned previously[16] were more likely to have elevated BP if they required ongoing oxygen therapy after NICU discharge. These observations reinforce the impression that infants with severe BPD are clearly at increased risk and need close monitoring for the development of HTN.

Congenital and Acquired Kidney Disease

HTN is a common complication of congenital kidney anomalies, including hypoplastic and dysplastic kidneys, and obstructive lesions causing hydronephrosis. It is well known that both autosomal dominant polycystic kidney disease and autosomal recessive polycystic kidney disease (ARPKD) may present in the newborn period with severe nephromegaly and HTN.[26,27] With ARPKD, the median age of onset of HTN has been reported to be 16 days; most affected infants will be discovered to be hypertensive during the first year of life. The most severely affected infants with ARPKD are at risk of development of congestive heart failure from severe, malignant HTN.

Although much less common than in polycystic kidney disease, HTN has also been reported in infants with multicystic dysplastic kidneys.[28,29] This is somewhat paradoxical, as such kidneys are usually thought to be nonfunctioning. The case has been made that HTN in such patients is the result of another coexisting abnormality such as parenchymal scarring.[30] Another possible explanation is increased renin production by macrophages within the dysplastic kidney.[31]

Kidney obstruction may be accompanied by HTN, even when there is no compression of the renal vasculature. This has been seen, for example, in infants with congenital ureteropelvic junction obstruction and sometimes may persist following surgical correction of the obstruction. HTN has also been described in infants with congenital primary megaureter. Ureteral obstruction by other intraabdominal masses may also be accompanied by HTN. The mechanism of HTN in such instances is unclear, although activation of the RAAS may be involved.

HTN as a result of acquired kidney disease occurs less commonly in the NICU than that as a result of congenital abnormalities. However, AKI from nephrotoxic or hypoxic acute tubular necrosis, interstitial nephritis, or cortical necrosis may be accompanied by significant HTN, usually as a result of fluid and sodium overload or activation of the RAAS. Atypical hemolytic–uremic syndrome, which has been described in both term and preterm infants,[32] is usually also accompanied by HTN. Such HTN may be extremely difficult to control, requiring treatment with multiple agents.

Genetic Causes

Genetic forms of HTN that may present in the neonatal period fall into two broad categories: HTN resulting from a single-gene disorder and HTN occurring as one feature of a malformation syndrome. Single-gene disorders causing HTN with reported cases in the neonatal period include Liddle syndrome, glucocorticoid-remediable aldosteronism, and pseudohypoaldosteronism type II (Gordon syndrome). A summary of the major features of these disorders is presented in Table 81.2; for a detailed discussion of monogenic HTN, the reader should consult other references.[33–35]

Malformation syndromes that may cause HTN include Williams syndrome (renal artery stenosis), Turner syndrome (aortic coarctation), neurofibromatosis (renal artery stenosis, coarctation), and Cockayne syndrome. Usually, the HTN in these syndromes presents beyond the neonatal period, but infantile presentations with HTN have been described.

Miscellaneous Causes

Coarctation of the Aorta

Coarctation of the thoracic aorta has been reported in numerous case series of neonatal HTN. Although usually detected in the newborn period based on decreased pulses and lower BPs in the lower extremities compared with the upper extremities, the similarity of upper and lower extremity BP readings in early infancy means that echocardiography is needed for definitive diagnosis.[36] Coarctation repair early in infancy seems to lead to an improved long-term outcome compared with delayed repair; however, recurrence of hypertension later in life is common.[37]

Endocrine Disorders

Endocrine disorders, particularly congenital adrenal hyperplasia, hyperaldosteronism, and hyperthyroidism, constitute easily recognizable clinical entities that have been reported to cause HTN in neonates. Several adrenal disturbances can induce HTN directly; they should be differentiated from Liddle syndrome. Hyperthyroidism is associated with systolic HTN and sustained tachycardia and, sometimes, with episodes of supraventricular tachycardia. An interesting link between phthalate exposure and neonatal HTN reportedly mediated by activation of the mineralocorticoid receptor has recently been reported in a large single-center case series.[38] This association has yet to be confirmed by other investigators.

Tumors

Tumors, including neuroblastoma, Wilms tumor, and mesoblastic nephroma, may present in the neonatal period and may produce HTN, either because of compression of the renal vessels or ureters

TABLE 81.2 Major Features of Monogenic Forms of Hypertension

	OMIM Catalog #	Inheritance Pattern	Age	Potassium Level	Renin Level	Aldosterone Level	Genetic Defect	Therapy
Apparent mineralocorticoid excess	218030	AR	I, C, A	Decreased or normal	Decreased	Decreased	Loss of function in 11-β-HSD2 gene	Spironolactone, eplerenone
Glucocorticoid remediable aldosteronism	103900	AD	I, C	Decreased or normal	Decreased	Decreased or normal	Chimeric gene; fusion of aldosterone synthase and 11-β-hydroxylase genes	Amiloride, triamterene, glucocorticoids
Congenital adrenal hyperplasia	202010	AR	I	Decreased or normal	Decreased	Decreased	Loss of function in 11-β-hydroxylase or 17α-hydroxylase gene	Spironolactone, eplerenone
Liddle syndrome	177200, 618114, 618126	AD	C, A	Decreased or normal	Decreased	Decreased	Gain of function in ENaC gene	Amiloride, triamterene
Pseudohypoaldosteronism type II (Gordon syndrome)	145260, 614492, 614495, 614496	AD, AR	A, C	Increased or normal	Decreased	Increased or normal	Gain of function in WNK1 gene; loss of function in WNK4 gene	Thiazide

A, Adulthood; *AD*, autosomal dominant; *AR*, autosomal recessive; *C*, childhood; *ENaC*, epithelial sodium channel; *11-β-HSD2*, 11-β-hydroxysteroid dehydrogenase2; *I*, infancy; *OMIM*, Online Mendelian Inheritance in Man; *WNK*, WNK lysine-deficient protein kinase.

or because of production of vasoactive substances such as renin or catecholamines. Neurologic causes of HTN include intracranial HTN, drug withdrawal, seizures, pain, and familial dysautonomia. Seizures are common complications of severe HTN; in turn, BP may increase transiently during seizure episodes. Appropriate pain relief should be given before and after surgical procedures.

Iatrogenic Causes

Iatrogenic causes of neonatal HTN are common and usually obvious but are important to consider. If the infant is hypervolemic secondary to excessive administration of sodium or fluids, intake should be restricted, and a diuretic should be administered. It is imperative to eliminate hidden sources of sodium, such as isotonic saline used to flush an arterial line and sodium-containing medications (e.g., antibiotics). If HTN is induced by a medication, one may consider withholding it, decreasing the dose, or using an infusion instead of repeated injections. As noted earlier, dexamethasone is a relatively common cause of BP elevation[39,40]; if this occurs, a decision must be made regarding the possible benefits of continued steroid treatment versus the risks of HTN. HTN induced by pancuronium is probably related to catecholamine release; BP may normalize after substitution of vecuronium for pancuronium.

Extracorporeal Membrane Oxygenation

HTN develops in 11% to 92% of neonates receiving extracorporeal membrane oxygenation[41,42] and may result in serious complications, including intracranial hemorrhage and increased mortality. Despite extensive investigation, the exact pathogenesis of this form of HTN remains poorly understood. Fluid overload, altered kidney sodium and water handling, and altered baroreceptor function have all been proposed as causative factors. Nicardipine infusions are commonly used to treat this form of HTN.[43]

Postsurgical

Finally, HTN may develop after surgery, specifically following repair of various abdominal wall defects. Including omphalocele and gastroschisis.[44] HTN appearing after primary closure for bladder exstrophy may be related to traction for skeletal immobilization.[45]

Evaluation

The first step in the evaluation is to make sure the BP is being measured correctly; this is discussed in detail in the next section. After that, it is important to determine whether the infant is persistently hypertensive or if the BP rises only during periods of agitation, pain, crying, feeding, or performance of procedures. Only in infants with correctly measured BP and persistent BP elevation should the "diagnosis" of HTN be considered and diagnostic work-up be initiated.

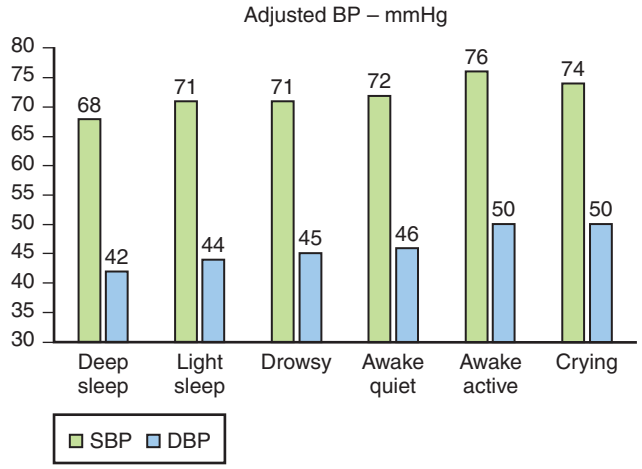
Blood Pressure Measurement

Many aspects of BP measurement in neonates are addressed in a recent systematic review of the literature[46]; therefore, only a few key points will be covered here. While direct measurement of BP via an indwelling arterial catheter is the most accurate method of BP measurement in neonates, the most commonly

used method in most NICUs, especially in stable infants, is the oscillometric technique, which directly measures mean arterial pressure (MAP) based on the oscillations of the arterial wall as the cuff is deflated. Although the readings obtained by oscillometric devices may differ between 1 and 5 mmHg compared with directly measured BP, these devices are usually sufficiently accurate for routine clinical use.[47] Oscillometric devices are clearly useful for measuring BP in infants without indwelling arterial catheters (especially those who require frequently repeated BP measurement) and in infants who have been discharged from the nursery.

Selection of a proper sized cuff is crucial for correct indirect BP measurement. The cuff bladder length should encircle 80% to 100% of the arm circumference; a cuff bladder with a width-to-length ratio of 0.45 to 0.55 is recommended.[46] A full range of "neonatal" cuff sizes will need to be available for outpatient follow-up of NICU graduates. If BP is measured in the calf, it is important to use a wide enough cuff; cuffs designed for use in the upper arm may be too narrow to use on the calf, resulting in a falsely high BP reading.

BP increases when an infant is awake, in the knee–chest position, with crying, pain, and during physical examination and procedures, or during feeding. A recent study from Japan of BP in 3148 newborns demonstrated the effects on BP of various states of activity (Fig. 81.5).[48] Even pacifier use during sleep has been shown to increase BP.[49] Because of these factors, it is important to follow a standard approach for BP measurement in neonates; the protocol described by Nwankwo et al.[46,50] is appropriate. The protocol involved BP measurements at least one and one-half hours following their last feeding or medical intervention, or just before feeding. An appropriately sized cuff (sizes 2 to 4) was applied to the right upper arm. The infant was then left undisturbed for at least 15 minutes or until the infant was sleeping or in a quiet awake state prior to BP measurement.[50] Measurements in NICU graduates should be obtained only when the infant is asleep or calm.[51]



• **Fig. 81.5** Effect of infant state on blood pressure (BP). *DBP*, Diastolic blood pressure; *SBP*, systolic blood pressure. (From Satoh M, Inoue R, Tada H, et al. Reference values and associated factors for Japanese newborns' blood pressure and pulse rate: the babies' and their parents' longitudinal observation in Suzuki Memorial Hospital on intrauterine period (BOSHI) study. *J Hypertens*. 2016;34:1578–1585.)

History and Physical Examination

In most neonates suspected of having HTN, a relatively focused history can be obtained, paying attention to determining whether there were any relevant prenatal exposures and to the particulars of the infant's clinical course and any concurrent medical conditions/complications of prematurity. The procedures that the infant has undergone (e.g., umbilical catheter placement) should be reviewed, and the current medication list should be scrutinized. Easily identifiable causes of HTN such as fluid overload or medication-induced HTN should be able to be identified at this stage, and appropriate countermeasures should be taken to correct the problem.

The physical examination should similarly focus on identifying obvious problems that may be causing the high BP. While four-extremity BP readings are commonly recommended as a screen for aortic coarctation, this may not be sufficient, as arm and calf BP readings may be similar in neonates.[36] The general appearance of the infant should be assessed, with particular attention paid to the presence of dysmorphic features. Careful cardiac and abdominal examinations should be performed, as specific findings (heart murmur, unilateral flank mass, ambiguous genitalia, etc.) can help direct subsequent diagnostic testing.

Laboratory Testing and Imaging

If no iatrogenic or other obvious correctable cause of HTN has been found, laboratory testing and diagnostic imaging will be needed, beginning with a urinalysis and screening chemistry tests (Table 81.3). If there is any suspicion of urinary tract infection, urine obtained by suprapubic aspiration or bladder catheterization should be sent for bacterial and fungal culture. Ultrasonography of the kidneys, adrenal glands, aorta, and bladder, with a flow study (i.e., Doppler ultrasonography) of the aorta and the renal arteries and renal veins, is usually appropriate. A chest radiograph may be useful if one has not been obtained recently. An echocardiogram will be needed to confirm the diagnosis of aortic coarctation. Nuclear renal scans, angiography, magnetic resonance imaging, or computed tomography are generally less useful in neonates because of immature kidney function and/or size considerations but may be indicated in specific patients.

Plasma renin activity (PRA) measurement is often included as part of the laboratory evaluation of neonatal hypertension. The PRA is most helpful if it is extremely low—in such cases, a single-gene disorder affecting kidney sodium transport should be suspected (see the preceding discussion on monogenic HTN). Elevated PRA is less helpful, as it may be secondary to the administration of diuretics or adrenergic medications or may be secondary to severe respiratory disease; mild elevations of PRA may be seen in normal infants given the role of renin in kidney development.

Other blood studies listed in Table 81.3 should be reserved for selected infants when there is a suggestion from the history, physical examination, and/or screening studies that a specific secondary cause of HTN may be present. Usually, it is best to obtain the assistance of the appropriate subspecialist (nephrologist, endocrinologist, oncologist, etc.) before such studies are ordered.

Management

As already mentioned, treatment of neonatal HTN should begin with correction of any iatrogenic causes such as fluid overload or medications that increase BP. After that, a decision needs to be

TABLE 81.3 Diagnostic Studies

Generally Useful	Useful in Selected Infants
Urinalysis (with or without culture)	Thyroid studies
Complete blood count and platelet count	Aldosterone
Electrolytes	Cortisol
Blood urea nitrogen, creatinine	Urine vanillylmandelic acid/homovanillic acid
Calcium	Plasma catecholamines/metanephrines
Plasma renin	Echocardiogram
Chest x-ray	Abdominal/pelvic ultrasonography
Renal ultrasonography with Doppler measurement	Voiding cystourethrogram
	Renal angiography
	Nuclear scan (DTPA/MAG-3)

DTPA, Diethylenetriaminepentaacetic acid; *MAG-3*, mercaptoacetyltriglycine.

made as to whether antihypertensive medications are indicated. Clearly, infants with severe, symptomatic HTN should receive immediate treatment. However, in those with less severe HTN, particularly those in whom the high BP does not appear to be causing any immediate problem, the necessity of initiating treatment with antihypertensive medications is often unclear. We do not know whether HTN in such infants has any impact on long-term outcomes, and we certainly do not know at what BP target-organ effects begin to appear. Furthermore, no clinical trials of antihypertensive medications have ever been conducted in neonates, so there are no data on efficacy or safety in this population. Thus, a great deal of individual judgment must be brought to bear in deciding to treat HTN in the NICU.

Critically ill infants with acute onset of severe HTN should generally be treated with an intravenous agent administered by continuous infusion, as this will allow the greatest control of the rate and magnitude of the BP reduction. These infants should have their BP lowered by no more than 25% of the planned reduction in the first 8 hours to prevent cerebral ischemia.[52] On the other hand, relatively well infants with mild HTN may be treated with oral antihypertensive agents. Recommended doses for intravenous and oral antihypertensive drugs in neonates can be found in Table 81.4.

The choice of oral antihypertensive medication to use in hypertensive neonates is somewhat controversial. Available data indicate that hypertensive infants are treated with a wide variety of classes of antihypertensive agents.[41] Whereas angiotensin-converting enzyme (ACE) inhibitors are considered the drugs of choice for adults and children with HTN secondary to kidney disease, and although there is a long history of their use in neonatal HTN, many neonatologists and pediatric nephrologists have serious concerns about the potential major side effects, such as excessive hypotension, AKI,[53] and CNS ischemia. There may also be adverse effects on the completion of kidney development in premature neonates.[54] Other medications, such as a β-blocker or, in the case of a hypertensive crisis, a potent vasodilator, should be tried first. The advantage of a β-blocker such as propranolol is that it reduces the secretion of renin and the release of norepinephrine; however, it may also cause bronchoconstriction, making its use problematic in some infants.

Of the available vasodilators, the calcium channel blockers isradipine and amlodipine have found widespread use in neonates.[10] Older vasodilating agents such as hydralazine and minoxidil may also be useful in selected infants or when the newer agents are not available. Clonidine is yet another potential choice. All oral antihypertensive medications excepting propranolol and amlodipine need to be compounded into suspensions by the hospital pharmacy.

Of the many intravenous antihypertensive agents available, nicardipine has emerged as the most useful for management of severe neonatal HTN, including HTN in neonates who are on ECMO.[43,55,56] It can be precisely titrated to the desired antihypertensive effect, and its use may be continued for prolonged periods without loss of antihypertensive efficacy. A possible issue is the need to infuse nicardipine through a central line. Alternative agents that may be given by continuous infusion include esmolol, hydralazine, labetalol, and sodium nitroprusside. Esmolol and labetalol may be contraindicated in infants with lung disease, and nitroprusside can be used only for limited periods (usually <72 hours) because of the accumulation of thiocyanate.

Intravenous antihypertensives that can be administered by intermittent bolus injection include hydralazine and labetalol. The intravenous ACE inhibitor enalaprilat has been reported to be effective in cases of severe neonatal HTN in one small case series[57]; however, our anecdotal experience suggests that this agent may cause sudden, oliguric AKI similar to that reported for orally administered enalapril.[58] Given this, we do not recommend use of enalaprilat in neonates.

Surgery is indicated for treatment of neonatal HTN in a limited set of circumstances.[59] In particular, HTN caused by urologic causes such as ureteropelvic junction obstruction or aortic coarctation is best approached surgically. On the other hand, most infants with renal artery stenosis will need to be treated medically until they have grown sufficiently to undergo definitive repair of the vascular abnormalities, although case reports of successful intervention in infancy have been published.[60] Infants with HTN secondary to Wilms tumor or neuroblastoma will require surgical tumor removal, possibly following chemotherapy. A case has also been made by some authors for prophylactic removal of multicystic dysplastic kidneys because of the risk of development of HTN,[61] although this is controversial.

Outcomes

The prognosis of neonatal HTN depends on the cause, timing of the diagnosis, presence of complications, and response to therapy. Patients with severe HTN and neurologic, cardiovascular, or AKI requiring kidney replacement therapy have a high mortality rate. Although data are limited, the long-term prognosis for newborns with HTN related to thromboembolism or BPD appears to be good, often with progressive resolution of the HTN within 6 to 12 months of age.[62,63] On the other hand, patients with parenchymal kidney disease, especially those with persistently impaired kidney function following NICU discharge, are likely to have persistent HTN throughout childhood. Infants who undergo repair of aortic coarctation are at long-term risk of persistent or recurrent HTN later in childhood and require continued follow-up.[37]

TABLE 81.4 Recommended Dosing of Selected Antihypertensive Agents in Neonates

Class	Drug	Route	Dose	Interval	Comments
ACE inhibitors	Captopril	Oral	<3 months: 0.01–0.5 mg/kg/dose Maximum 2 mg/kg/day >3 months: 0.15–0.3 mg/kg/dose Maximum 6 mg/kg/day	TID	1. First dose may cause rapid drop in BP, especially if receiving diuretics 2. Monitor serum creatinine and K^+ levels
	Enalapril	Oral	0.08–0.6 mg/kg/day	BID	
	Lisinopril	Oral	0.07–0.6 mg/kg/day	QD	
α and β antagonists	Labetalol	Oral	0.5–1.0 mg/kg/dose up to 10 mg/kg/day	BID–TID	Heart failure, BPD relative contraindications
		IV IV	0.20–1.0 mg/kg/dose (bolus) 0.25–3.0 mg/kg/h	Q4h–Q6 hInfusion	
	Carvedilol	Oral	0.1 mg/kg/dose up to 0.5 mg/kg/dose	BID	May be useful in heart failure
β antagonists	Esmolol	IV	100–500 μg/kg/min	Infusion	Very short acting—constant infusion necessary
	Propranolol	Oral	0.5–1.0 mg/kg/dose Maximum 8–10 mg/kg/day	TID	Monitor heart rate; avoid in BPD
Calcium channel blockers	Amlodipine	Oral	0.05–0.3 mg/kg/dose up to 0.6 mg/kg/day	QD	All may cause mild reflex tachycardia
	Isradipine	Oral	0.05–0.15 mg/kg/dose up to 0.8 mg/kg/day	QID	
	Nicardipine	IV	0.5–4 μg/kg/min	Infusion	Useful for management of severe neonatal HTN, including HTN in neonates who are on ECMO
Central α agonist	Clonidine	Oral	5–10 μg/kg/day up to 25 μg/kg/day	TID	May cause mild sedation
Diuretics	Chlorothiazide	Oral	5–15 mg/kg/dose	BID	Monitor electrolyte levels
	Hydrochlorothiazide	Oral	1–3 mg/kg/dose	QD–BID	
	Spironolactone	Oral	0.5–1.5 mg/kg/dose	BID	
Vasodilators	Hydralazine	Oral	0.25–1.0 mg/kg/dose up to 7.5 mg/kg/day	TID–QID	Tachycardia and fluid retention are common side effects
		IV	0.15–0.6 mg/kg/dose	Q4h	
	Minoxidil	Oral	0.1–0.2 mg/kg/dose	BID–TID	Tachycardia and fluid retention are common side effects; prolonged use causes hypertrichosis
	Sodium nitroprusside	IV	0.5–10 μg/kg/min	Infusion	Thiocyanate toxicity can occur with prolonged (>72 h) use or in renal failure

Use of any of these medications in neonates should be considered off-label.
ACE, Angiotensin-converting enzyme; *BID*, twice daily; *BP*, blood pressure; *BPD*, bronchopulmonary dysplasia; *IV*, intravenous; *K^+*, potassium; *QD*, once daily; *Q4h*, every 4 hours; *Q6h* every 6 hours; *QID*, four times daily; *TID*, three times daily.

82 Developmental Endocrinology

SARA A. DIVALL AND LINA MERJANEH

KEY POINTS

- Developmental disorders of endocrine organs often manifest themselves in the neonatal period.
- The fetal adrenal gland produces large amounts of androgens to be used by the placenta for estrogen biosynthesis.
- Neonatal hypopituitarism may be due to a number of specific gene mutations with or without defects in other cranial structures.
- The thyroid emerges from the pharyngeal floor and then migrates caudally to its final destination in the anterior neck. Abnormalities in thyroid descent result in ectopic thyroid, thyroglossal duct, or cysts.
- Pancreatic β-cell differentiation and proliferation are dependent on insulin-like growth factor 2.
- The placenta actively transports maternal calcium, phosphorus, and magnesium to maintain the high fetal serum levels necessary for the developing skeleton.

Like the development of other fetal organ systems, the development of the endocrine system involves the integration of complex genetic, cellular, and hormonal cues as well as the coordinated action of transcription factors, signaling molecules, and epigenetic regulation. Additionally, endocrine communication is necessary for vital maternal-placental-fetal interaction because endocrine signals are the tools that cells and organs use to communicate. In this chapter, we will first review basic concepts of hormonal systems and then discuss the unique hormonal milieu of the placenta that allows maternal-fetal communication and fetal growth. The development of each of the classic endocrine organs will then be discussed. Finally, the developmental origins of the adult disease hypothesis will be examined.

Endocrine Systems

A few key concepts of cell communication will be presented here to help build a foundation of knowledge to understand hormonal abnormalities in neonates.

In the process of communication, cells emit signals that act locally or distally. If a cell emits signals that are received by the cell itself, this is termed *autocrine regulation*. If a cell emits signals that are received by neighboring cells, this is termed *paracrine regulation*. Finally, if the cell signal travels through the bloodstream to distant cells and organs, this is termed *endocrine regulation*.

A feature of endocrine systems is that the hormonal signals are present in the bloodstream at very low concentrations, and even small changes in hormone concentration can elicit a robust response from receiving cells. The released endocrine hormones can be either water-soluble peptide hormones that must bind to receptors on the extracellular surface of the cell or fat-soluble steroid-like molecules that can pass through the cell membrane directly into the cell's nucleus to bind its receptor to regulate gene transcription. On binding to their specific cell membrane receptor, peptide hormones activate downstream signaling transduction pathways in the cell to induce biological responses. These responses can be immediate; for instance, thyroid-stimulating hormone (TSH), when bound to the TSH receptor on thyroid follicular cells, cause iodine transport into the cell to increase. It can also induce relatively delayed cell responses, such as an increase in gene transcription of enzymes involved in thyroglobulin production. In contrast, steroid-like molecules, such as cortisol, when bound to their respective receptors, induce a biological response by causing an increase in the transcription of various genes. These induce longer-term, broader changes in the target cell function by modulating which genes the cells express and, thus, the proteins they produce.

Many hormonal systems exhibit a hierarchy of hormone signals that allow strict regulation of system function. The hypothalamic-pituitary-end gland system is an example of this multitier hormonal system. In this system, a hormone released by the upstream hypothalamus travels through the portal circulation of the pituitary and binds to the corresponding receptor on the dedicated pituitary cell. Once bound, this receptor induces the cell to synthesize and release the corresponding pituitary hormone. This hormone then travels through the systemic circulation to the endocrine gland to bind to the hormone's dedicated receptor on the target gland. The binding of the hormone to its receptor induces the target organ to release its dedicated end hormone. This hormone then travels through the bloodstream to multiple organs to affect cell function. End hormones use negative feedback to regulate their own production. That is, the hypothalamus and pituitary sense the end hormone concentration, adjusting the release of the upstream regulatory hormone cascade to fine-tune end hormone production. Negative feedback is a unique and consistent property of hormonal systems and is useful in interpreting the adequate response of a hormonal cascade to perturbation in the system.

Endocrine Organ Development and Perinatal Transition

Early in fetal development, fetal hormonal gland development is driven by fetal genotype. However, later in fetal development, the hormonal responsiveness of target tissues is dependent not only on fetal genotype but also on the complex fetal hormonal milieu, which comprises fetal, maternal, and placental hormones. Placental hormones may be influenced by maternal and fetal genotype, as well as maternal prepregnancy and pregnancy health and nutrition. Thus the fetal hormonal environment is dependent on a complex interplay between fetal and maternal factors.

In evaluating hormonal disorders in newborns, one needs to consider both maternal and fetal factors and keep the following principles in mind. First, human fetal endocrine organ development begins predominantly independently of maternal hormones. This independence is possible because the placenta is a barrier to many (but not all) maternal hormones, including steroids, peptides, and glycoproteins. Second, although endocrine organ development may be normal, perturbations in the maternal hormonal milieu may still affect fetal development for the rare hormone that crosses the placenta. An example is disorders of thyroid hormone production. Maternal-fetal transfer of thyroxine (T_4) may result in 25% to 50% of neonatal plasma levels of T_4.[1] This transfer allows children with athyrosis to have good neurodevelopmental outcomes if treatment is initiated within 2 weeks of birth, as the maternal thyroid hormone crossed the placenta and allowed normal fetal neurodevelopment and growth. In contrast, children born to mothers with untreated or undertreated hypothyroidism during pregnancy have poor neurodevelopmental outcomes because of the hypothyroxinemia early in gestation before T_4 production by the fetal thyroid.[2] Third, alterations in transplacental substrate transfer can modify the late development of the fetal and, thus, neonatal hormonal pathways and feedback mechanisms. This can be seen in neonates born from pregnancies with uncontrolled diabetes, in which the transplacental passage of glucose induces robust insulin release and subsequent β-cell hypertrophy in the still-developing pancreas. This leads to transient neonatal hyperinsulinemic hypoglycemia due to the abrupt fall in glucose supply at birth. This is also seen in the placental transfer of hormonal agents or maternal antibodies that affect neonatal endocrine gland function. Examples include the transplacental crossing of maternal TSH antibodies causing neonatal hyperthyroidism. Fourth, when interpreting research on endocrine developmental biology from animal fetal physiology models and gene manipulation studies, one must consider similarities and differences between animal and human fetuses and newborns. The maturational state at birth differs widely among species. For many species, including rodents and some large animals, the maturational state of the newborn is relatively immature (altricial). Organ systems in humans, in contrast, are relatively more developed at birth (precocial). This is especially true in neuroendocrine and most endocrine systems. Thus a study of hormonal physiology in nonhuman species may yield insights, but they may not be immediately applicable to human newborns.

The Maternal-Placental-Fetal Unit

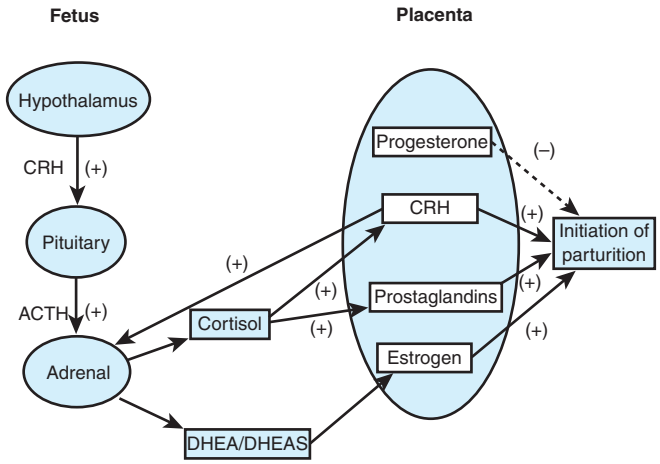
During pregnancy, the mother, fetus, and placenta function in concert as a steroidogenic unit for estrogen and progesterone production. Most steroidogenic activity is exerted in the fetal zone (FZ) of the human fetal adrenal (HFA) gland, where large amounts of adrenal androgens are produced to be used by the placenta for estrogen biosynthesis. Estrogen promotes placental trophoblast differentiation into syncytiotrophoblast and upregulates key enzymes in progesterone biosynthesis.[3]

Cortisol may act as a "two-edged sword" for the fetus; it promotes the maturation of fetal organs necessary for extrauterine life, but it can also adversely influence fetal growth and postnatal development. Therefore, cortisol production in the fetoplacental unit is strictly regulated to protect the fetus from hypercortisolism effects. Fetal access to maternal glucocorticoid is restricted, and a maternal-fetal gradient is maintained by the enzyme 11β-hydroxysteroid dehydrogenase type 2, which converts cortisol to inactive cortisone. Maternal cortisol levels are usually 5 to 10 times higher than fetal cortisol levels. Fetal protection is also achieved through other mechanisms in the HFA by regulation of 3β-hydroxysteroid dehydrogenase/$\Delta^{4,5}$ isomerase type 2, the key steroidogenic enzyme for cortisol biosynthesis, and in fetal membranes by control of 11β-hydroxysteroid dehydrogenase type 1 activity, which converts inactive cortisone to cortisol.[3] A single course of glucocorticoids is accepted as standard therapy for pregnant women at risk of preterm delivery to accelerate fetal lung maturation and reduce morbidity and mortality in preterm infants.[4] However, multiple courses of prenatal glucocorticoids (more than 2) may be associated with decreased weight, length, and head circumference at birth and are currently not recommended because of concerns for maternal and fetal harm.[5]

Placental corticotropin-releasing hormone (CRH) is one of the key determinants of the timing of parturition. Near term, CRH levels increase and directly stimulate the HFA by increasing its responsiveness to adrenocorticotropic hormone (ACTH) and secretion of cortisol and dehydroepiandrosterone (DHEA) and its sulfonated form, precursors of placental estrogen. Cortisol, in turn, stimulates placental CRH production, forming a positive feedback loop and generating more cortisol and estrogen near term. Estrogen upregulates contraction-associated proteins and transforms the myometrium into a contractile state, preparing for successful uterine contractions and parturition. Cortisol also promotes the maturation of fetal organs (e.g., the lung) and stimulates the production of prostaglandins necessary for parturition. Increased levels of estrogen, cortisol, and CRH, together with functional progesterone withdrawal, are thought to contribute to the initiation of parturition (Fig. 82.1).[6,7]

From this perspective, one would expect that the lower cortisol levels seen in preterm infants may have adverse consequences. This is not confirmed. Some studies showed no adverse effects related to low cortisol levels in preterm infants,[8] while others correlated low cortisol levels to increased severity of illness, hypotension, mortality, and development of bronchopulmonary dysplasia.[9] Selective hydrocortisone supplementation could be beneficial for survival in very preterm infants but with possible increased risks of spontaneous gastrointestinal perforation and late-onset sepsis.[10]

Umbilical plasma estradiol and progesterone levels are quite high and fall approximately 100-fold during the first day after birth. The consequences of estradiol and progesterone withdrawal earlier in premature infants remain largely unknown. Pilot studies of estradiol and progesterone supplementation in extremely low-birth-weight infants have shown trends toward increased bone mineralization and a decrease in the incidence of chronic lung disease.[11,12] Adequately powered clinical trials are needed to determine the benefits and risks of hormonal replacement in preterm infants.

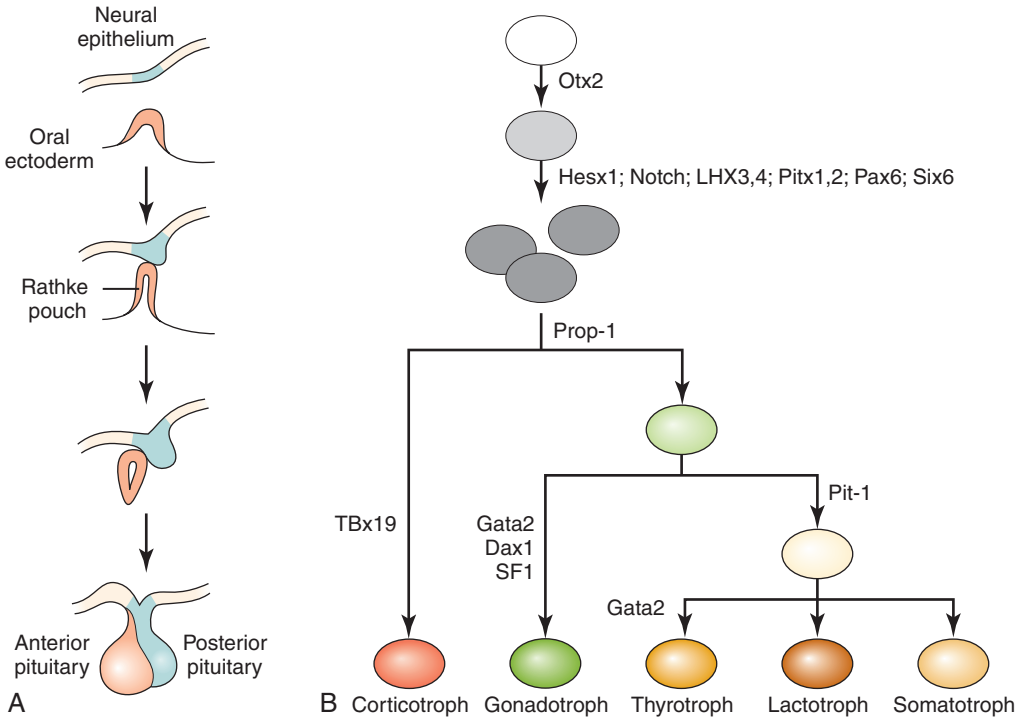


• **Fig. 82.1** Endocrine Cascades in the Fetoplacental Unit That Lead to Initiation of Parturition. Near term, the production of placental corticotropin-releasing hormone *(CRH)* increases and stimulates fetal adrenal glands to produce dehydroepiandrosterone *(DHEA)*/dehydroepiandrosterone sulfate *(DHEAS)* and cortisol. Increased cortisol production stimulates production of placental CRH through a positive feedback loop. DHEA/DHEAS is converted by the placenta to estrogen, promoting the initiation of parturition through the upregulation of contraction-associated proteins. Cortisol and CRH also stimulate the production of prostaglandins necessary for contractions. When "functional withdrawal" of progesterone occurs, coupled with these changes, parturition is initiated. *ACTH*, Adrenocorticotropic hormone.

Hypothalamic and Pituitary Development

The anterior and posterior pituitary glands have different embryonic origins. The anterior lobe arises from the oral ectoderm, and the posterior pituitary arises from the infundibulum of the developing central nervous system. A section of the oral ectoderm thickens very early in development, forming an invagination termed a *Rathke pouch*. As the Rathke pouch invaginates further, the adjacent neural ectoderm evaginates to form the infundibulum (Fig. 82.2A). With further evagination, the Rathke pouch and the infundibulum directly contact each other. This close contact is essential for subsequent anterior and posterior pituitary development. The Rathke pouch later "pinches off" from the remaining oral ectoderm to form the anterior pituitary gland. In humans, this occurs by 5 to 6 weeks of gestation.

The hypothalamus comprises a diverse collection of neurons that regulate pituitary hormone release, thirst, body temperature, blood pressure, and serum osmolality. Although the location of the diverse neurons within the hypothalamus is well delineated, the development of these neuron populations within the hypothalamus has yet to be elucidated. The complexity of the anatomy and neuronal cell types makes it difficult to elucidate the developmental cascade of events. Nevertheless, it is known that the hypothalamic nuclei, which contain the individual neuron types, are fully developed with projections to the median eminence (with subsequent release of hormones into the pituitary portal circulation) by 15 to 18 weeks' gestation.[13]



• **Fig. 82.2** Pituitary Gland Development. (A) Simplified schematic of anterior pituitary development from oral ectoderm via evagination into the Rathke pouch, with subsequent pinching from tissue to separate from oral ectoderm and eventually form the anterior pituitary. (B) The transcription factor cascade is implicated in pituitary development and cell differentiation. *Dax1*, Dosage-sensitive sex reversal, adrenal hypoplasia congenital, X-chromosome factor; *Gata2*, GATA binding protein; *Hesx1*, homeobox1; *LHX3,4*, LIM homebox3,4; *Pax6*, paired box 6; *Pitx1,2*, paired-like homeodomain 1, 2; *Prop-1*, prophet of Pit-1; *Otx2*, orthodenticle homeobox 2; *SF1*, steroidogenic factor 1; *Six6*, sine oculis-related homeobox 6; *TBx19*, T-box 19.

In contrast, knowledge regarding differentiation of the anterior pituitary is well delineated. Differentiation of Rathke pouch cell progenitors into the pituitary cell types (corticotrophs, gonadotrophs, lactotrophs, thyrotrophs, and somatotrophs) is tightly regulated by a cascading series of transcription factors (see Fig. 82.2B). Knowledge of the series of events comes from knockout studies in mice as well as genetic studies in humans with congenital hypopituitarism. The pituitary cell types arise in a temporally and spatially specific pattern as directed by the transcription factors, occurring between week 7 and week 16 of human gestation. If one transcription factor of the developmental series malfunctions or is expressed out of series, as is seen in clinical syndromes of hypopituitarism (Table 82.1), then a very typical pattern of pituitary hormone deficiency is manifest.[14]

Each mature pituitary cell type synthesizes and secretes a corresponding hormone that is regulated by a hypothalamic peptide: corticotrophs secrete ACTH in response to CRH; gonadotrophs secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in response to gonadotropin-releasing hormone (GnRH); lactotrophs secrete prolactin in response to dopamine; thyrotrophs secrete thyrotropin (TSH) in response to thyrotropin-releasing hormone (TRH; and somatotrophs secrete growth hormone in response to growth hormone-releasing hormone and somatostatin.

The mature pituitary cell types contain secretory granules by 10 to 12 weeks' gestation, and the hormones can be measured by 12 to 17 weeks' gestation.[13] The pituitary portal circulation is mature by 12 to 17 weeks, and thus regulation of pituitary hormone release by the corresponding hypothalamic peptide may be operational by that time. However, the negative feedback mechanisms that finely tune hypothalamic-pituitary-end hormone release may not be fully mature until later in gestation. At birth, the negative feedback mechanisms are fully mature, which is crucial in the diagnostic evaluation of infants with suspected pituitary hormone disorders.

The neurohypophysis (posterior pituitary), formed by the evagination of the neuroectoderm, is fully developed by 10 to 12 weeks of gestation and contains granules of arginine vasopressin (AVP) and oxytocin.[15] The neurohypophysis comprises the axonal terminals of hypothalamic neurons whose cell bodies are in the mature paraventricular nuclei and supraoptic nuclei. These neurons generate AVP or oxytocin separately and are thus regulated by separate factors. AVP-releasing neurons integrate signals from plasma osmolality sensors and baroreceptors in the carotid sinus and aortic arch to release AVP and thus regulate serum osmolality and systemic blood pressure. AVP acts on the renal collecting duct via V_2 receptors to induce water reabsorption. AVP also acts on V_{1A} receptors on endothelial cells to increase

TABLE 82.1 Genes Important in Pituitary Development and Implicated in Human Disease

Gene	Involved Pituitary Cell Types	Extrapituitary Phenotype	Radiology Findings	Mode of Inheritance
HESX1	Somatotrophs, thyrotrophs, gonadotrophs, posterior pituitary cells	Septo-optic dysplasia/optic nerve hypoplasia Midline forebrain abnormalities	Pituitary hypoplasia EPP	AD or AR
LHX3	Somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, corticotrophs (variable)	Rigid cervical spine with limited neck rotation	Pituitary hypoplasia	AR
LHX4	Somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, corticotrophs	Abnormality of skull base Cerebellar abnormalities	Pituitary hypoplasia EPP	AD
GPR161	Somatotrophs, thyrotrophs	None	Pituitary hypoplasia EPP	AR
GLI2	Somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, corticotrophs	Polydactyly Cleft lip/palate	Pituitary hypoplasia EPP	AD variable penetrance
PROP1	Somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, corticotrophs (later in life)	May have normal puberty (variable gonadotroph function)	Pituitary hypoplasia	AR
POU1F1 (PIT1)	Somatotrophs, lactotrophs, thyrotrophs,		Pituitary hypoplasia	AD/AR
OTX2	Somatotrophs, thyrotrophs, gonadotrophs	Microphthalmia or anophthalmia	Pituitary hypoplasia EPP	Unknown
SOX2	Somatotrophs, gonadotrophs	Microphthalmia or anophthalmia Sensorineural defects Esophageal atresia	Pituitary hypoplasia	De novo
SOX3	Somatotrophs, lactotrophs, thyrotrophs, gonadotrophs, corticotrophs	Duplication of Xq26–27 in affected males	Pituitary hypoplasia EPP Abnormal corpus callosum	X-linked recessive

AD, Autosomal dominant; *AR*, autosomal recessive; *EPP*, ectopic posterior pituitary.

arterial and venous constriction and thus increase blood pressure. Serum osmolality is tightly controlled between 280 and 295 milliOsmoles (mOsm)/kg water in adults. With even a slight increase in serum osmolality, AVP release increases exponentially to induce renal water reabsorption to a maximum urine osmolality of 800 to 1200 mOsm/kg water (maximum urine osmolality depends on the osmolality of the upstream kidney medulla). In neonates, however, the urine-concentrating ability of the kidney is impaired to a maximum of 300 mOsm/kg water because of the relative immaturity of the renal tubules rather than lack of AVP release; AVP is present in the fetus and neonate, and V_2 receptors are functional.[16]

Diseases of Hypothalamic or Pituitary Maldevelopment

Given the overlapping developmental windows of important cranial midline structures, a diagnosis of congenital hypopituitarism in a neonate should be considered if there are intracranial or extracranial midline defects. For instance, hypopituitarism has been reported in children with cleft lip or palate or central incisors. Hypopituitarism and diabetes insipidus can be encountered in neonates with holoprosencephaly. Children who have intracranial abnormalities along the spectrum of optic nerve hypoplasia, with or without septo-optic dysplasia, commonly have congenital hypopituitarism.

Neonates with congenital hypopituitarism because of a mutation in a gene important in pituitary differentiation may or may not have obvious defects in midline structures (see Table 82.1).[14] In the absence of these clinical signs, hypopituitarism may be suspected in neonates with micropenis and normal testicular descent (caused by growth hormone with or without gonadotropin deficiency), prolonged hypoglycemia (caused by combined growth hormone and cortisol deficiency), or rarely, cholestatic giant cell hepatitis (caused by combined growth hormone, thyroid hormone, and cortisol deficiency). As fetal growth is independent of growth hormones, children with congenital hypopituitarism are of normal size and weight at birth. If a newborn screen uses T_4 levels as the screen for congenital hypothyroidism, then low T_4 levels may be a diagnostic clue; if a newborn screen measures thyrotropin (also known as thyroid-stimulating hormone, TSH) to screen a newborn for congenital hypothyroidism, the central hypothyroidism of hypopituitarism will not be detected. After 2 months of life, a clue to optic nerve hypoplasia may be a disconjugate gaze. If diabetes insipidus is diagnosed, then full evaluation of the remaining pituitary hormones is mandatory.

Adrenal Gland Development

Cells of the adrenal cortex arise from the intermediate mesoderm and can be recognized at the upper pole of the mesonephros by 3 to 4 weeks' gestation. Cells of the adrenal medulla are derived from the ectoderm, and they infiltrate the adrenal cortex cells at 7 to 8 weeks' gestation. Encapsulation of the adrenal gland occurs at 9 weeks' gestation, resulting in the formation of a distinct organ above the developing kidneys. The cortical and medullary cells proliferate rapidly and sort into a central medulla and surrounding cortex.[3]

The HFA cortex acquires two distinct zones: the inner FZ and the outer definitive zone (DZ). DZ cells are in an undifferentiated proliferative state, whereas FZ cells are differentiated, steroidogenic cells. Current data suggest that the HFA cortex is a dynamic organ in which cells proliferate in the periphery (i.e., the DZ) and migrate centripetally, differentiating to form the inner FZ that is unique to primate gestation.[3] There is a third zone between the DZ and FZ, named the *transitional zone* (TZ). Cells in this zone show intermediate characteristics and can produce cortisol, analogous to the zona fasciculata cells of the adult adrenal cortex. By the 30th week of gestation, the HFA cortex manifests a rudimentary form of the adult adrenal cortex; the DZ and TZ begin to resemble the zona glomerulosa and the zona fasciculata, respectively. The third definitive cortical layer, the zona reticularis, is absent at birth and starts developing at 3 years of age to form an extragonadal source of sex steroids. The cells of the inner FZ are the primary site for steroidogenesis during gestation, producing an abundant amount of adrenal androgens, which are the substrates for placental estrogen production.

The weight of the adrenal gland increases 10-fold from the 8th to 10th week of gestation, and the gland continues to grow rapidly thereafter until term. By 30 weeks, it achieves a relative size 10 to 20 times that of the adult adrenal gland. A further doubling in weight occurs after that. Soon after birth, the HFA undergoes rapid involution with rapid disappearance of the FZ and a decrease in androgen secretion. As a consequence, the total weight of the glands decreases by approximately 50%. Remodeling of the postnatal adrenal gland involves a combination of FZ regression and the development of the zona glomerulosa and zona fasciculata. During the first year, the fetal cortex regresses, and adrenal mass diminishes to 2 to 3 g.

The early stages of adrenal development are regulated by several transcription factors, mainly steroidogenic factor 1 (SF1) and DAX1 (aka NR0B1; dosage-sensitive sex reversal, adrenal hypoplasia congenital, X-chromosome factor). SF1-knockout mice manifest adrenal and gonadal agenesis and gonadotropin deficiency.[17] Inactivating DAX1 mutations are associated with adrenal hypoplasia and gonadotropin deficiency in mice and humans.[18]

ACTH secreted by the fetal pituitary is the primary regulator of the development and function of the HFA. Other ACTH-independent regulators include local peptide growth factors and placenta-derived factors, such as CRH and estrogens. The steroidogenic activity in the HFA is characterized by early transient cortisol biosynthesis.[19] The hypothalamic-pituitary-adrenal axis is sensitive to glucocorticoid-mediated feedback at this time. Therefore 46 XX females with steroidogenic defects (such as congenital adrenal hyperplasia) who lack cortisol will have an elevated ACTH level that stimulates overproduction of androgens, resulting in virilization of the female genitalia. Cortisol production is suppressed thereafter until late gestation (because of the lack of 3β-hydroxysteroid dehydrogenase type 2 expression). Near term, the fetal cortisol production rate increases and is similar to that in adults per unit of body weight. During most of gestation, there is extensive production of DHEA and its sulfate, precursors of placental estrogen. This begins at around 8 to 10 weeks' gestation and increases significantly during the second and third trimesters. Aldosterone synthesis in the HFA may be suppressed during midgestation because of the probable lack of *CYP11B2* expression but likely becomes active by the term because 80% of aldosterone in human fetal blood at term appears to originate from the HFA.

The adrenal medulla functions as a classic endocrine (ductless) gland that secretes hormones directly into the bloodstream. It also participates in sympathetic control via preganglionic sympathetic nerve fibers. Pheochromocytoblasts give rise to the medullary pheochromocytes, which are epinephrine- and

norepinephrine-secreting homologues of sympathetic postganglionic cells. By 3 months' gestation, adrenal pheochromocytes secrete epinephrine and norepinephrine into the medullary sinusoids and then into the systemic circulation.[20] The hypothalamic-pituitary-medullary adrenal axis becomes sufficiently functional by midgestation so that fetal stress responses can be independent of the mother's.[21] This fetal catecholamine stress response contrasts with the fetal cortisol output capacity, which is minimally present before midgestation.

Thyroid Gland Development

The thyroid is the first endocrine gland to develop in the embryo. It is derived from contributions of two anlagen: a midline thickening of the pharyngeal floor (median anlage) that gives rise to the T_4-producing follicular cells and paired caudal extensions of the fourth pharyngobranchial pouches (lateral anlagen) that act as the precursor to the parafollicular calcitonin-secreting cells (C cells). The thyroid begins its development by 24 days' gestation when the median anlage forms the thyroid diverticulum that extends from the floor of the buccal cavity to the fourth branchial arch. At 24 to 32 days, the median anlage becomes a bilobed structure. By 50 days, the median and lateral anlagen have fused, and the buccal stalk has ruptured. During this period, the thyroid gland migrates caudally from the pharyngeal floor to the developing hyoid bone and laryngeal cartilage. It reaches its final location in the anterior neck below the thyroid cartilage. During its descent, the thyroid gland retains an attachment to the pharynx by a narrow epithelial stalk known as the *thyroglossal duct* that disappears by 7 weeks of gestation. Abnormalities in thyroid descent result in ectopic thyroid, persistent thyroglossal duct, or cysts. The genes involved in thyroid gland development include *HEX*, *TTF1*, *FOXE1*, *NKX2-5*, *PAX8, GLIS3*, and *TUBB1*.[22–24] Defects in these genes can result in various abnormalities in thyroid gland development and congenital hypothyroidism.

By 10 to 11 weeks, clusters of endodermal epithelial cells form single layers around lumens, the thyroid follicles, in which colloid begins to appear. At 4 weeks, the fetal gland can synthesize thyroglobulin; 6 to 8 weeks later, the thyroid synthesizes thyroid hormones mediated by the incorporation of iodine. This early growth and development appear to be independent of TSH, as secretion of TSH cannot be shown before 10 to 12 weeks. Because of the maturation of the hypothalamic-pituitary-thyroid axis, TSH levels increase rapidly thereafter. Similarly, total T_4 and free T_4 levels increase significantly in the second and third trimesters. The fetal pituitary-thyroid feedback mechanism appears to be fully responsive by 18 to 20 weeks. Hypothyroidism will result in elevated fetal TSH production, whereas hyperthyroidism caused by maternal Graves disease (due to transplacental passage of maternal thyroid-stimulating autoantibodies) will cause suppressed TSH production.

Thyroid hormones T_4 and triiodothyronine are essential for the development and maintenance of normal fetal physiologic processes, especially those of the central nervous system, where thyroid hormones assist in brain maturation throughout gestation.[25] Thyroid hormones regulate genes involved in myelination and neuronal/glial cell differentiation.[26] Delivery of thyroid hormones to the fetal brain is a complex process requiring, at different times, expression of brain thyroid hormone receptors, placental thyroid hormone, and iodide transport, a feedback system that involves the hypothalamic-pituitary-thyroid (HPT) axis, and thyroid hormone metabolism by liver and brain deiodinase enzymes (deiodinase type 2 and deiodinase type 3), which ensure basal levels are sustained.[27]

The fetus is dependent on maternal contribution as the primary source of thyroid hormone during pregnancy, especially during the first trimester.[1] This dependence decreases as the fetal T_4 production increases and the HPT axis matures. At birth, maternal T_4 comprises 30% to 50% of T_4 measured in cord blood. In congenital hypothyroidism due to thyroid agenesis (athyreosis), maternal T_4 lessens the impact on fetal neurologic development. Early neonatal diagnosis and T_4 treatment permit normalized growth and development. In contrast, when the mother is hypothyroid throughout pregnancy, the developmental consequences are more severe.[2] Additionally, substances that negatively affect fetal thyroid development, including thyroid autoantibodies and antithyroid medications, can also cross the placenta if present in the mother. Maternal TSH receptor antibodies (TRAbs) can be stimulating or inhibiting, cross the placenta, bind to thyroid follicular cells, and alter fetal thyroid hormone production, leading to transient neonatal hyperthyroidism or hypothyroidism, respectively.[28]

Prematurity can result in low thyroid hormone levels, and the severity correlates inversely with gestational age because of the immaturity of the HPT system. Fifty percent of preterm infants born before 28 weeks' gestation will have transient hypothyroxinemia of prematurity identified by low T_4 and normal TSH levels that do not require treatment. Very low-birth-weight infants are at higher risk of developing primary hypothyroidism and can have a delayed TSH level rise. Thyroid hormone treatment is indicated in these infants, although hypothyroxinemia of prematurity is commonly a temporary problem.

Reproductive Axis Development

Like other hypothalamic-pituitary-end gland systems, early gonadal development is completely separate from neuroendocrine development and thus will be discussed separately. GnRH neurons, the hypothalamic neurons that induce gonadotrophs to synthesize and secrete LH and FSH, are unique among hypothalamic neurons in that they arise outside the neuroectoderm in the olfactory pit. This occurs at week 6 after conception. The GnRH neuron begins to synthesize and secrete GnRH shortly thereafter. The neurons then migrate via the forebrain, arriving at the hypothalamus by week 9.[29] The location, number of GnRH neurons, and projection to the median eminence are similar to those in adult animals. Migration is supported by the signaling protein products of the genes *ANOS1* (anosmin 1), *PROK1* (prokineticin 1), and *FGF8* (fibroblast growth factor 8), as well as receptor encoding genes such as *FGFR1*, *PROKR2*, and *CHD7*.[30]

Before gestational week 6, the male and female genital duct systems coexist with an indifferent (bipotential) gonad. The specifics of sex-specific gonadal differentiation and associated disorders are discussed elsewhere in this textbook. In brief, the presence or absence of the Y chromosome, and thus the gene *SRY*, is the determining factor directing the development of the bipotential gonad into either testes or ovaries. *SRY* is expressed by week 6 of gestation. *SRY* directs the expression of many genes that direct the differentiation of the bipotential gonad into the Leydig (testosterone-producing) cells of the testes and the Sertoli cells.[31] *SRY* also induces the expression of the gene *SF1*. *SF1*, in turn, acts to induce the expression of the anti-müllerian

hormone, which induces regression of the female (müllerian) duct structures. Müllerian structures include the fallopian tubes, uterus, and upper third of the vagina. In the presence of two normal X chromosomes, ovarian differentiation commences, although less is known about ovarian development. Formation of the bipotential gonad into testes or ovaries is completed by 8 weeks of gestation, while differentiation of the genital duct systems into the male or female internal reproductive organs is complete by week 9 of gestation.[31]

External development of male or female structures is determined by the presence or absence of testosterone (and thus the *SRY* gene). Further conversion of testosterone to dihydrotestosterone (DHT) is necessary for the normal development of the penis and prostate gland. In the absence of DHT, the lower two-thirds of the vagina and the labia minora and majora develop. Placental human chorionic gonadotropin directs testosterone secretion by the ever-expanding Leydig cell population after week 14 of gestation. The testosterone directs the formation of the external genitalia. LH and FSH reach peak levels at midgestation, about 20 to 24 weeks. The testes and ovaries are responsive to LH and FSH by week 20, and some primary follicles are seen in the ovaries. However, placental estrogen predominates, so estrogen secretion by the fetal ovary is thought to be minimal. LH-directed testosterone synthesis is required for normal testicular descent from the abdomen into the scrotal sac in late gestation, as well as for further lengthening the penis in late gestation. By the last half of the third trimester, placental estrogen production provides negative feedback to the axis to cause LH and FSH levels to decrease.[31]

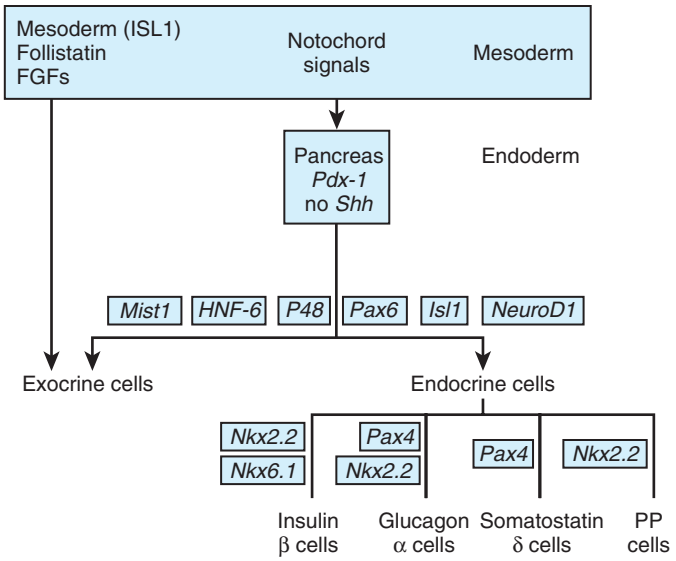
Development of the Endocrine Pancreas

The pancreas is derived from two buds, dorsal and ventral, that arise from the distal foregut endoderm. It contains a distinctive combination of cell lineages. The exocrine tissue comprises acinar cells that secrete digestive fluid and a duct system by which the fluid drains into the intestine. The endocrine part is arranged as discrete islets of Langerhans, which contain distinct cell types secreting different hormones into the circulation (α cells, glucagon; β cells, insulin; δ cells, somatostatin; ε cells, ghrelin; and γ cells, pancreatic polypeptide).[32]

Human pancreas formation is first evident at 26 days' gestation, and it begins with the dorsal bud formation, followed by the appearance of two ventral buds at 30 days. The left ventral bud gradually regresses, whereas the right ventral bud migrates posteriorly and fuses with the dorsal bud on gut rotation at 6 to 7 weeks' gestation. Failure of the left ventral bud to regress could lead to annular pancreas. The dorsal pancreas gives rise to most of the pancreas, including the upper part of the head, the isthmus, the body, and the tail of the pancreas. The right ventral bud gives rise to the inferior part of the head.[33]

Starting from day 45 to day 47 of gestation, the pancreatic epithelium undergoes active growth and branching morphogenesis to give rise to endocrine and acinar cells under the influence of locally acting signals and activation of lineage-specific transcription factors. During this process, the pancreatic epithelium is embedded in the loose mesenchyme and is surrounded by dense peripancreatic mesenchyme. At approximately 7 to 8 weeks, the epithelium begins to ramify and form a lobular pattern.[33]

The first endocrine cells that appear are insulin-expressing cells at 7.5 weeks, and they remain the most prevalent endocrine cell type during the first trimester.[34] This is followed by the appearance of glucagon- and somatostatin-expressing cells at week 8 and pancreatic polypeptide-expressing and ghrelin-expressing cells at week 9. Ongoing β-cell proliferation and differentiation are dependent on insulin-like growth factor type 2 (*IGF2*) expression. Islet formation begins by week 12. Islet volume increases from about 4% to 13% of total pancreatic tissue by term.[33] Targeted gene deletion studies in mice have demonstrated critical roles for several transcription factors in pancreatic endocrine development (Fig. 82.3).



• **Fig. 82.3** Molecular Control of Cell Fate Choices in the Pancreas. *Pax6* and *Isl1* are expressed early, and their disruption leads to the reduction or absence of endocrine differentiation, which suggests that they could be expressed in endocrine progenitors able to give rise to all cell types. In *Isl1*-mutant mice, *Pax6* is not expressed, which suggests *Pax6* is downstream of *Isl1*. Although *Pax4*, *NeuroD1*, *Nkx2.2*, and *NKx6.1* are expressed as early as *Pax6* and *Isl1*, they affect the differentiation of only a subset of lineages. *Pax4* is required for glucagon-producing and somatostatin-producing cell differentiation. *Nxk2.2* is expressed in all islet cells, except somatostatin-producing cells, and its inactivation leads to the absence of the cell types where it is expressed. *Nkx6.1* is itself required for insulin cell differentiation. Although *Mist1* and *Onecut1* (also known as *Hnf6*) are expressed in endocrine cell lineages, their function has not yet been assessed by inactivation experiments. *FGFs*, Fibroblast growth factors; *PP*, pancreatic peptide. (From Grapin-Botton A, Melton DA. Endoderm development: from patterning to organogenesis. Trends Genet. 2000;16:124–130.)

Neonatal insulin kinetics and end-organ sensitivity to insulin appear to be established during the third trimester in preparation for extrauterine fuel metabolism. The maternal environment and fetal genome appear to influence the number and/or function of pancreatic β cells in early life, with lifelong implications for postnatal diabetes.[35] In contrast, insulin gene-knockout mice and human newborns with pancreatic agenesis both experience severe intrauterine growth restriction (IUGR), demonstrating insulin's role in mitogenesis and growth.

Development of Parathyroid Glands and Fetal Mineral Homeostasis

The parathyroid glands arise from the third and fourth pharyngeal pouches. The third pouches develop into the inferior parathyroid glands, and the fourth pouches develop into the superior

glands. Fetal parathyroid glands produce low amounts of parathyroid hormone (PTH) throughout gestation that can be detected by 10 weeks. It is unclear if they also make PTH-related protein (PTHrP), which is mainly produced in the placenta. Other hormones involved in mineral homeostasis include calcitonin, which is detectable in fetal thyroidal C cells as early as 14 weeks. As early as the second half of gestation, the fetal renal tubules can synthesize the active form of vitamin D, 1,25-dihydroxyvitamin D (calcitriol), but the fetal levels remain low.

Mineral and bone metabolism is regulated differently in utero compared with the adult. The placenta meets the fetal mineral need by actively transporting calcium, phosphorus, and magnesium from the maternal circulation to maintain higher fetal concentrations compared with maternal levels. These high levels are necessary for the developing skeleton to accrete a normal amount of mineral by term. A human fetus typically accumulates approximately 30 g of calcium by term, with 80% of that mineral content obtained in the third trimester.

PTH and PTHrP are critical for fetal bone development, regulation of serum minerals, and placental mineral transfer, while calcitriol and calcitonin are not required. PTH and calcitriol circulate at low concentrations in fetal circulation. PTH is suppressed by the high fetal serum calcium level. Low calcitriol concentration is caused by low PTH concentration, high calcium concentration, and rapid clearance.[36]

After birth, there is a loss of active transport of minerals through the placenta, and the neonate has to rely on an enteral intake of minerals. The calcium levels fall after birth, reaching a nadir at 24 to 48 hours, and gradually rise to adult values over several days, likely due to a fall in PTHrP levels and hyporesponsiveness of parathyroid glands. As PTH and calcitriol levels increase postnatally, calcium levels rise with maturation in the function of the kidneys and intestines. However, there may be a significant delay in intestinal maturation in preterm infants, along with an increased demand for mineral accretion, which predisposes them to osteopenia of prematurity.

Hormonal Regulation of Fetal Growth

Hormones that play an important role in postnatal growth, such as thyroid hormones, growth hormone, and gonadal steroids, play a very limited role in fetal growth. As such, neonates with these hormonal disorders are generally born with normal weight and size. Fetal growth is driven by nutritionally dependent growth factors such as insulin or other growth factor systems such as IGF1 and IGF2.

Insulin

Insulin is an important fetal growth factor, as evident by the hyperinsulinemia and macrosomia experienced by infants born to women with uncontrolled diabetes mellitus. In contrast, infants with pituitary agenesis and corresponding lack of insulin are small at birth, with minimal muscle bulk and adipose tissue.[37]

Insulin-Like Growth Factor 1

The importance of IGF-1 in fetal growth is derived from studies of humans and mice with *IGF1* or IGF-1 receptor (*IGF1R*) mutations. Humans with mutations in these genes have IUGR, microcephaly, hypoglycemia, and severe developmental delay.[38] Mice null for the *IGF1* gene or the *IGF1R* gene are 60% of normal weight and die shortly after birth because of impaired lung maturation.

Insulin-Like Growth Factor 2

The importance of IGF-2 to fetal somatic and organ growth is manifest in the phenotypes of Beckwith-Wiedemann syndrome (BWS) and Russell-Silver syndrome (RSS). The *IGF2* gene is normally imprinted such that only the paternal allele is active. In BWS, either there is loss of imprinting, such that the maternal allele is also active, or there are two copies of the active paternal allele (uniparental disomy). Infants with BWS have *IGF2* overexpression and have resultant fetal and postnatal overgrowth. This overgrowth manifests as macrosomia, enlarged tongue, β-cell hypertrophy with hyperinsulinemic hypoglycemia, and an increased risk of certain childhood cancers. In contrast, RSS may be due to duplication of the maternal allele or silencing of the paternal allele via imprinting. Infants with RSS have IUGR with postnatal growth retardation, with adult height four standard deviations below the mean.[38] Other clues to the diagnosis of RSS include hemihypertrophy, clinodactyly, triangular facies, and normal head circumference.

Placental Factors

Human placental lactogen is a major regulator of maternal glucose, amino acid, and lipid metabolism during pregnancy, allowing mobilization of these fuel sources for use by the fetus.[39] Alterations in maternal nutrition induced by starvation or disease also affect fetal growth. Uterine vasoconstriction or vascular insufficiency of the placenta is also associated with poor fetal growth and neonatal IUGR. Vascular compromise of the placenta may be due to maternal hypertension, drug exposure, infection, or placental abruption.

Developmental Origin of Health and Disease

The developmental origin of the health and disease hypothesis is the theory that the perinatal environment (conception to infancy into toddlerhood) directly influences the development of metabolic and cardiovascular disease during adulthood. This hypothesis, also termed the *Barker hypothesis*, was first proposed in the 1990s by David Barker, attempting to account for higher rates of heart disease in more impoverished areas of Britain.[40] Using longitudinal data, he found that London boroughs with historically high neonatal mortality had the highest rates of adult cardiovascular disease, and low birth weight was associated with an increased risk of death from coronary heart disease. Many studies since Barker's original studies have replicated his results in men and women in Europe, North America, South America, and India. In addition to heart disease, low birth weight has been associated with an increased risk of type 2 diabetes, cerebrovascular disease, hypertension, dyslipidemia, altered puberty, and obesity in adulthood.

The association of low birth weight with the metabolic disease led to the proposal that a nutrient supply perceived as limited by the fetus yields a fetal/neonatal "thrifty phenotype" that would allow survival in a nutrient-limited extrauterine environment.[41] The "programming" for an extrauterine life of limited nutrients proves maladaptive in the abundant postnatal nutrition environment. As a corollary to low birth weight, epidemiologic studies find that excess maternal weight during pregnancy or excessive

weight gain in early infancy (whether experienced by low-birth-weight or normal-weight neonates) is also associated with an increased risk of metabolic diseases later in life. At the highest risk of metabolic disease as adults are individuals with low birth weight and excessive weight gain in infancy and childhood.

Other in utero exposures that have been associated with the development of adult disease include increased risk of obesity and mental disorders in offspring of pregnancies complicated by maternal depression, increased risk of metabolic disorders in offspring of mothers with hyperandrogenemia, and increased risk of hypertension in offspring of pregnancies complicated by preeclampsia.[42] A number of mechanisms have been proposed to program later disease by environmental influences. These include epigenetic regulation of gene expression, oxidative stress of tissues resulting in damage to DNA, lipids, and proteins, and direct hormonal effects on development. Epigenetic changes that affect gene expression include DNA methylation, histone modification, chromatin packing, and micro-ribonucleic acid expression. These changes are malleable or permanent and can accumulate over time to influence gene expression in the short term or long term.[42]

Disorders of Calcium and Phosphorus Metabolism

KELSEY B. EITEL, ILDIKO H. KOVES, KATHRYN D. NESS, AND PARISA SALEHI

KEY POINTS

- Neonatal hypocalcemia may be asymptomatic or present with signs of increased neuromuscular excitability, including focal or generalized seizures.
- Neonatal hypocalcemia is classified by the timing of onset, with early and late hypocalcemia having different causes and approaches to evaluation.
- Neonatal hypercalcemia may be asymptomatic if there are only mild elevations in calcium level or may lead to severe symptoms such as failure to thrive, polyuria, lethargy, and seizures.
- The causes of hypercalcemia can differ but are due to the dysregulation of calcium regulatory systems.
- Metabolic bone disease of prematurity is caused by deficiencies in dietary phosphate and calcium, early withdrawal of placental estradiol and progesterone, lack of mobility, and therapy with medications that can increase urinary calcium excretion and contribute to serum mineral imbalance and osteopenia.
- Osteopenia in preterm infants usually appears between 6 and 12 weeks of age, and fractures may be seen. The incidence and severity increase with decreasing gestational age and birthweight and are more common in preterm infants having a complicated medical course and delayed nutrition.

Homeostatic Control of Calcium and Magnesium

Calcium plays two important physiologic roles. Calcium salts in bone provide structural integrity. Calcium ions present in the cytosol and extracellular fluid (ECF) are essential for the maintenance and control of many biological processes, including cell-cell communication, cell aggregation and division, coagulation, neuromuscular excitability, membrane integrity, and permeability, enzyme activity, and secretion. This functional diversity is made possible by the maintenance of a large electrochemical gradient between the ECF ionized calcium (Ca^{2+}) concentration, which is in the 1-mmol/L range, and the resting intracellular (cytosolic) Ca^{2+} concentration, which is about 0.1 µmol/L.

Significant alterations in serum calcium concentration frequently occur in the neonatal period. It is important to evaluate these potential derangements in light of normal dynamic changes that occur during the perinatal transition. After the first 2 to 3 days, normal total serum calcium concentrations vary only slightly with age and a range between 8.8 and 10.6 mg/dL (2.2 to 2.6 mmol/L), with an ionized serum calcium concentration of 4 to 5.6 mg/dL (1 to 1.4 mmol/L). The metric measurement unit conversion factors are 0.2595 and 0.2495, respectively, as used everywhere other than the United States.

Approximately 55% to 60% of the total plasma calcium is diffusible (or ultrafilterable), the remainder being protein bound. Most diffusible calcium is ionized, but about 5% of total circulating calcium is complexed to plasma anions, such as phosphates, citrate, and bicarbonate. Ca^{2+} is the only biologically available fraction of ECF calcium. It is subject to precise metabolic control based on the integrated regulation of calcium fluxes with respect to the intestine, kidneys, and bone. The precise regulation of circulating Ca^{2+} is controlled by calcium itself, through a calcium receptor and several hormones, the most important of which are parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D ($1,25(OH)_2D$).[1–3]

Hypoalbuminemia leads to a decline in total serum calcium, but proportionate increases in the ionized fraction usually maintain serum Ca^{2+} concentration within the normal range. Acute alkalosis (e.g., hyperventilation or bicarbonate infusion) or rapid administration of citrate-buffered blood (e.g., during exchange transfusion, initiation of extracorporeal membrane oxygenation [ECMO], cardioplegia, or organ transplant) may acutely lower serum Ca^{2+} concentration by increasing albumin binding or citrate chelation. These conditions can produce transient clinical manifestations of hypocalcemia but do not lower the total serum calcium concentration.[4] In general, for routine clinical purposes, measurement of total serum calcium concentration often suffices, and the correction formula in the setting of hypoalbuminemia for total serum calcium concentration measured as mg/dL is:

$$\text{Corrected Ca Level} = [0.8 \times (\text{Normal Albumin Level} - \text{Patient's Albumin Level})] + \text{Serum Ca Level}$$

Large amounts of calcium exchange occur in the kidney, bone, and intestine. Although the intestine has considerable calcium absorptive capacity, renal tubular calcium reabsorption usually exceeds intestinal absorption by at least 40-fold. Most of the tubular Ca^{2+} load is reabsorbed in the proximal tubule and thick

ascending limb of the loop of Henle via paracellular, passive flux (coupled with sodium reabsorption) driven by the existing electrochemical gradient. A transcellular pathway in the distal nephron tightly regulates the rest of urinary Ca^{2+} reabsorption. Calcitropic hormones regulate the distal Ca^{2+}-selective, Na^+-independent channels. More than 98% of total body calcium is deposited in the skeleton as hydroxyapatite ($Ca_5[OH][PO_4]_3$); the ECF and soft tissues contain the remainder. A small fraction of skeletal calcium freely exchanges with the ECF and serves as an important buffer of circulating calcium. Consequently, decreased skeletal calcium is a hallmark of most metabolic bone diseases (MBDs).

Magnesium homeostasis is largely mediated through the kidneys. Approximately 80% of total plasma magnesium is filtered through the glomerulus and is reabsorbed mainly in cortical segments of the thick ascending limb of the loop of Henle. Once the maximal tubular reabsorption is exceeded, filtered magnesium is excreted into the urine. Hormones regulate magnesium reabsorption by changing the transepithelial voltage and paracellular permeability of tubular cells. Magnesium is required to maintain normal PTH secretory responses.

Homeostatic Control of Phosphorus

Blood inorganic phosphate concentration varies with age. It is highest during infancy and gradually declines to adulthood. Approximately 10% of plasma inorganic phosphate is noncovalently bound to protein, whereas 90% circulates as ions or as complexes with sodium, calcium, or magnesium. About 80% to 85% of total body phosphorus contributes to mechanical support as part of the hydroxyapatite lattice of bone. The remainder is distributed in the ECF, largely as inorganic ions or complexes, and in soft tissues as phosphate esters. Intracellular phosphate esters and phosphorylated intermediates regulate cell metabolism and gene expression (via phosphorylase, kinase, and phosphatase activities) and generate and transfer cellular energy (i.e., via adenosine triphosphate). Cytosolic and ECF phosphorus levels (approximately 0.1 and 0.2 mmol/L, equivalent to 0.31 and 0.62 mg/dL, respectively) are less stringently regulated than are levels of Ca^{2+} and magnesium (Mg^{2+}).

Dietary phosphate is generally absorbed in proportion to its content in food. Although phosphorus and calcium can be absorbed along the entire length of the small intestine, most phosphate absorption occurs in the jejunum and ileum. In contrast, most calcium absorption occurs in the duodenum. The renal proximal tubule is the principal regulatory site for phosphorus homeostasis.[5] Renal regulation is accomplished primarily by variation of the threshold for phosphate reabsorption (the tubular maximum for inorganic phosphate [TmP]/glomerular filtration rate [GFR]). Hormones (PTH, PTH-related protein [PTHrP], growth hormone) and dietary phosphate reset this theoretical threshold by regulating apical tubular Na^+-TmP cotransporters.[6] Essentially, TmP/GFR is the "setpoint" that defines the fasting serum phosphorus concentration. At lower serum phosphorus levels, most filtered phosphorus is reabsorbed; at higher levels, most filtered phosphorus is excreted. To assess TmP/GFR, a fasting urine specimen is obtained to measure phosphorus and creatinine, along with the simultaneous determination of serum phosphorus and creatinine. A nomogram has been constructed so that TmP/GFR can easily be derived from these values.[7]

The higher serum phosphate levels in infants (e.g., 4.5 to 9.3 mg/dL) compared with those in adults (3.0 to 4.5 mg/dL) reflect infants' greater tubular phosphate resorption. This adaptation permits avid tubular phosphate conservation despite high ambient serum phosphate levels. For this reason, neonatal disorders of chronic hypophosphatemia and/or phosphorus depletion usually result from an inadequate dietary supply (as in preterm infants) or intrinsic (e.g., familial hypophosphatemic rickets) or extrinsic (e.g., hyperparathyroidism) alterations in TmP/GFR. Similarly, chronic hyperphosphatemia usually implies either intrinsic (e.g., renal insufficiency) or extrinsic (e.g., hypoparathyroidism) abnormalities in TmP/GFR.

Parathyroid-Renal Hormonal Axis

In mammals, calcium and phosphate homeostasis is controlled by a parathyroid-renal hormonal axis involving PTH and $1,25(OH)_2D$. The influence of these two hormones on bone deposition, mobilization of minerals, and regulation of intestinal and renal absorption is depicted in Fig. 83.1. Deficiency or excess of either hormone causes hypocalcemia or hypercalcemia, respectively.

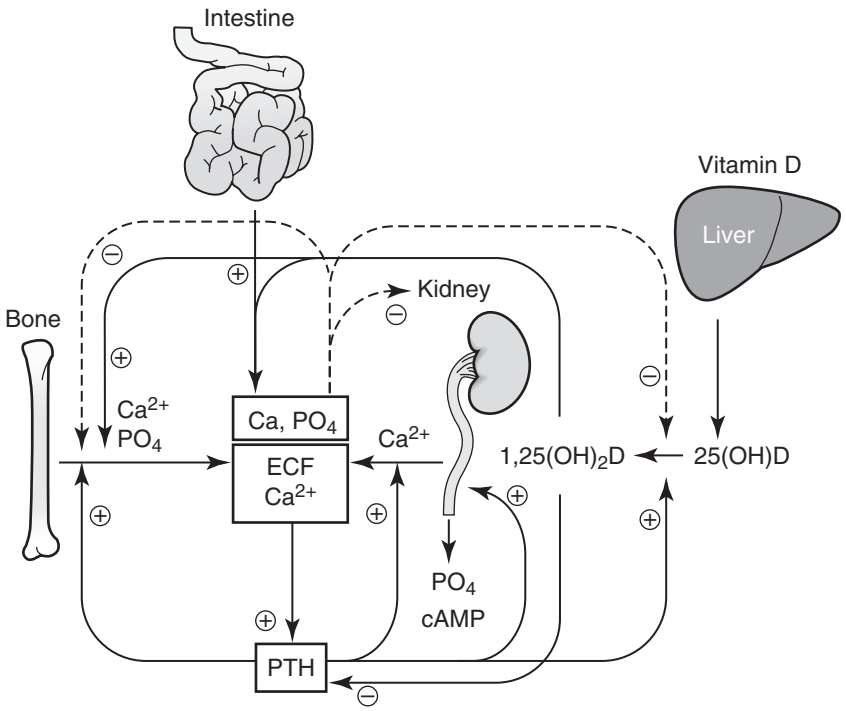
Parathyroid Hormones

PTH mobilizes calcium and phosphorus from bone, stimulates calcium reabsorption in kidneys, inhibits phosphorus reabsorption by reducing TmP/GFR, and stimulates the renal synthesis of $1,25(OH)_2D$, which participates with PTH in calcium reabsorption in kidneys, increases the efficiency of intestinal absorption of calcium and phosphorus, and mobilizes calcium from bones. Therefore PTH secretion causes the serum calcium concentration to rise and the serum phosphorus concentration to be maintained or decline.

PTH is a 9500-Da, single-chain polypeptide. It is synthesized by the four parathyroid glands embedded within the thyroid gland poles, which are derived from the embryonic third and fourth pharyngeal pouches. The messenger ribonucleic acid (mRNA) for PTH (preproPTH) encodes the 84 amino acids of the mature peptide, an amino-terminal (N-terminal) "pre" sequence of 25 amino acids, and a basic "pro" hexapeptide, which is clipped intracellularly. After secretion, the intact PTH molecule, PTH (1 to 84), is further metabolized and rapidly cleared from the circulation, with a half-life of less than 4 minutes. The N-terminal region of the PTH molecule, PTH (1 to 34), binds the PTH receptor and shows full biological activity, whereas the carboxyl terminal (C terminal) has specific, albeit poorly understood, activities in osteoclasts and osteoclastic precursors.

Secretion of PTH fragments by the parathyroid glands and prolonged clearance of the C-terminal PTH metabolites add considerable immunoheterogeneity to circulating PTH. The numerous inconsistencies found in reports on PTH pathophysiology until the late 1980s are due to the use of earlier generation "C-terminal" and "midmolecule" PTH assays. In contrast, current two-site "intact PTH" assays are sufficiently sensitive and specific to detect physiologic levels of biologically active PTH (1 to 84) and to distinguish hypoparathyroid from euparathyroid states. The normal circulating levels of intact PTH range from approximately 10 to 60 picogram (pg)/mL; the maximally stimulated (hypocalcemic) and maximally suppressed (hypercalcemic) levels for normal parathyroid function are about 100 to 150 pg/mL and 2 to 5 pg/mL, respectively.

Parathyroid cells are exquisitely responsive to changes in ambient Ca^{2+} concentration. PTH secretion may be described as an inverse sigmoid hysteretic relationship between serum PTH and



• **Fig. 83.1** Hormonal Regulation of Calcium and Phosphate by Parathyroid Hormone (PTH) and 1,25-Dihydroxyvitamin D (1,25[OH]$_2$D). Decreased Ca^{2+} concentration stimulates PTH and 1,25(OH)$_2$D secretion. Renal, gastrointestinal, and skeletal mechanisms increase Ca^{2+} concentration, inhibiting PTH secretion and closing the negative feedback loop. *cAMP*, Cyclic adenosine monophosphate; *ECF*, extracellular fluid. (From Brown EM, MacLeod RJ. Extracellular calcium sensing and extracellular calcium signaling. *Physiol Rev*. 2001;81:239–297.)

Ca^{2+} with a parathyroid cell setpoint (the Ca^{2+} concentration at which PTH secretion is half maximal) of 1.2 to 1.25 mmol/L. The parathyroid "calcistat" detects perturbations of blood Ca^{2+} concentration as small as 0.025 to 0.05 mmol/L and promptly adjusts PTH secretion. The molecular mechanism that enables specific cells (e.g., parathyroid cells, thyroidal C cells, renal tubular cells, osteoblasts) to sense these minute changes in ECF Ca^{2+} concentration involves a member of the family C of G protein–coupled receptors, Ca^{2+}-sensing receptor (CaSR). ECF Ca^{2+} (and, at lower affinity, Mg^{2+}) binds the CaSR, activates several intracellular effector pathways, and ultimately leads to oppositely directed changes in PTH secretion, and altered renal cation handling CaSR activation inhibits renal cellular Ca^{2+} absorption induced by PTH, as well as passive paracellular Ca^{2+} transport. As described later, loss-of-function (or inactivating) mutations in the *CaSR* gene are responsible for neonatal hyperparathyroidism and familial hypocalciuric hypercalcemia (FHH). In contrast, gain-of-function *CaSR* mutations result in autosomal dominant neonatal hypocalcemia.[8]

PTHrP is a second member of the PTH family, first identified as the cause of humoral hypercalcemia of malignancy. The amino acid sequences of PTHrP and PTH are homologous at the N terminal, and 8 of the first 13 amino acids are identical. Beyond this region, the sequences have little in common. PTHrP is a multifunctional molecule, like neuropeptides such as proopiomelanocortin (the precursor of corticotropin, endorphins, and melanocyte-simulating hormones). The three PTHrP isoforms (139, 141, and 173 amino acids) give rise to several secreted peptide fragments. PTHrP is widely expressed, especially in fetal tissues, and has important local functions in morphogenesis and differentiation. The normal circulating levels of PTHrP are considerably lower than the levels of PTH, and it is doubtful that PTHrP has a major role in calcium homeostasis. Two important exceptions are in the fetus and the lactating woman, for whom PTHrP appears to be an important calcitropic hormone.[9]

The actions of PTH on its two major target organs, kidney, and bone, are mediated through the type 1 PTH/PTHrP receptor (PTHR1),[10] a G protein–coupled receptor belonging to a receptor subfamily that includes receptors for calcitonin, secretin, and corticotropin-releasing hormone. This versatile receptor mediates the actions of its two physiologic ligands in multiple tissues and signals through several second-messenger pathways. The best-characterized effector of PTH action is cyclic adenosine monophosphate (cAMP).

Vitamin D

A main biological function of 1,25(OH)$_2$D is to increase intestinal absorption of calcium and phosphorus. During low calcium intake, increased PTH levels stimulate the renal conversion of 25-hydroxyvitamin D (25[OH]D) to 1,25(OH)$_2$D, which in turn stimulates osteoclast differentiation and bone resorption. Most of the identified biological actions of 1,25(OH)$_2$D are mediated via binding to vitamin D receptor (VDR), a member of the intracellular receptor superfamily. VDR interacts with specific response elements in promoters of vitamin D–responsive genes.

Vitamin D is a secosteroid synthesized in the skin or absorbed from the diet.[11,12] Exposure to sunlight (290 to 320 nm) cleaves the B ring of 7-dehydrocholesterol, or provitamin D, the immediate precursor of cholesterol, to form a sterol, previtamin D.

Previtamin D in the skin undergoes isomerization to the biologically inert vitamin D. Vitamin D enters the circulation bound to vitamin D–binding protein and is transported to the liver, where a mitochondrial cytochrome P450 vitamin D 25-hydroxylase produces 25(OH)D. 25(OH)D (provitamin D) is the major circulating vitamin D metabolite. Because the activity of hepatic 25-hydroxylase is not tightly regulated, the measurement of serum 25(OH)D is a useful assessment of vitamin D stores. In renal proximal tubule cells, mitochondrial 25(OH)D 1α-hydroxylase metabolizes 25(OH)D to the biologically active hormone, $1,25(OH)_2D$. The normal circulating level of 25(OH)D is approximately 10 to 50 ng/mL. The normal circulating concentration of $1,25(OH)_2D$ ranges from 30 to 75 pg/mL, or about 1/1000 that of 25(OH)D.

Serum 25(OH)D levels are increased by sunlight exposure and by vitamin D ingestion and are decreased in vitamin D deficiency and in hepatobiliary disorders. Circulating $1,25(OH)_2D$ levels are increased by hyperparathyroidism and phosphate depletion and are reduced in hypoparathyroidism. $1,25(OH)_2D$ is biologically inactivated through a series of reactions beginning with 24-hydroxylation. $1,25(OH)_2D$ induces the 24-hydroxylase in vitamin D target cells. Hypocalcemia, by increasing PTH levels, suppresses this enzyme. 24-Hydroxylase metabolizes 25(OH)D as well as $1,25(OH)_2D$. In vitamin D–sufficient states, the kidney preferentially 24-hydroxylates the prohormone, 25(OH)D, to 24,25-dihydroxyvitamin D ($24,25[OH]_2D$). In contrast, when vitamin D action is required, 25(OH)D 1α-hydroxylase is preferentially activated for $1,25(OH)_2D$ synthesis.

The parathyroid-renal (PTH–$1,25[OH]_2D$) axis, reminiscent of the hypothalamic-pituitary-adrenal axis, is the principal means for systemic response to a sustained or major hypocalcemic challenge. In this long-loop feedback system, $1,25(OH)_2D$-mediated calcium absorption provides the ultimate feedback on PTH secretion. PTH secreted in response to hypocalcemia is the principal regulator of renal production of $1,25(OH)_2D$, which, in turn, feeds back to suppress PTH gene expression (see Fig. 83.1). Hypocalcemia directly stimulates PTH mRNA transcription. PTH regulates minute-to-minute perturbations of ECF Ca^{2+} concentration. Maximal adjustments of intestinal calcium absorption via the PTH-$1,25(OH)_2D$ axis require 1 to 2 days to become fully operative, so $1,25(OH)_2D$ effects come into play only when hypocalcemic stress persists.

Calcitonin

Calcitonin, a peptide hormone synthesized by thyroid parafollicular C cells (also known as *clear cells*), has an antihypercalcemic effect (i.e., opposite that of PTH). Human calcitonin is a 32-amino-acid chain with a 1,7-disulfide bridge and a C-terminal prolinamide. Alternative splicing of several transcripts from the calcitonin gene produces several polypeptide products, some of which have uncertain calcitropic importance. The primary stimulus for calcitonin secretion is a rise in circulating calcium concentration. Calcitonin lowers serum calcium and phosphorus concentrations mainly by inhibiting bone resorption and increasing calcium excretion in the kidneys (Table 83.1).

Glucocorticoids lower serum calcium concentration by inhibiting osteoclast formation and activity but use for a long time causes osteoporosis by decreasing bone formation and increasing bone resorption. They also decrease intestinal absorption and increase renal excretion of calcium and phosphorus. Because of these mechanisms, glucocorticoids depress hypercalcemia in vitamin D intoxication and subcutaneous fat necrosis (SFN).

Growth hormone increases calcium excretion in the kidney and intestinal absorption. Insulin-like growth factor 1, generated by growth hormone action, stimulates protein synthesis in bone. Insulin increases bone formation, with observed bone loss in patients with uncontrolled diabetes mellitus.

Thyroid hormone excess has been described to be associated with hypercalcemia, hypercalciuria, and osteoporosis. The mechanism of these findings is not entirely clear.

Currently, there is no compelling evidence that the calcitonin-like calcium-lowering hormones are critical regulators of calcium homeostasis in nonpregnant adult humans, perhaps because the low prevailing rate of bone turnover blunts the impact of the antiresorptive actions. However, calcitonin may have important calcitropic functions in pregnant and lactating women and in the fetus and neonate, and in other mammals, particularly rodents, whose bones are constantly growing. In human newborns, the parafollicular C-cell population and serum calcitonin concentrations are much greater than in adults.

Perinatal Mineral Metabolism

During human pregnancy, approximately 30 g of calcium and more than 16 g of phosphorus are transferred transplacentally from the maternal circulation to the growing fetus during the third trimester, when fetal calcium accretion is approximately 140 to 150 mg/kg/day. In humans, a doubling of maternal intestinal calcium absorption and a net increase of calcium accretion into bone compensate for the formidable demand on maternal calcium.[13] A mid-molecule PTHrP hormone[14] expressed principally by the placenta regulates this transplacental calcium pump. TRPV6, a member of the transient receptor potential channel superfamily,

TABLE 83.1 Other Hormones

	Serum Calcium Concentration	Intestinal Calcium Absorption	Renal Calcium Excretion	Bone Effects
Glucocorticoids	Increase	Decrease	Increase	
Growth hormone		Increase		
Insulin-like growth factor 1				Protein synthesis in bone
Insulin				Bone loss
Thyroid hormone excess	Increase		Increase	Osteoporosis

may be the primary calcium channel at the trophoblast apical membrane. Calcium flux across the placenta in *Trpv6*-null mice is reduced by approximately 40%.[15]

Pregnancy

Pregnancy constitutes a unique hormonal milieu that promotes a state of "physiologic absorptive hypercalciuria."[16] Maternal total serum calcium concentration declines slightly during pregnancy, reaches a nadir in the middle of the third trimester, and then increases slightly toward term. The maternal serum phosphorus and magnesium profiles are similar to that of calcium. Maternal serum 25(OH)D concentration varies seasonally and with vitamin D intake, but the vitamin D transport protein concentration increases during pregnancy. Serum $1,25(OH)_2D$ concentrations increase early in pregnancy and continue to rise throughout gestation.[17] The calculated concentration of free $1,25(OH)_2D$ also rises. For many years it was believed that PTH levels also increased steadily throughout pregnancy. However, the use of newer immunometric "sandwich" assays indicates that PTH concentration declines during pregnancy.[17–19] PTHrP levels, in contrast, may be higher in pregnant than in nonpregnant women.[20] The role of circulating calcitonin in pregnancy is uncertain.

$1,25(OH)_2D$ drives enhanced maternal intestinal mineral absorption (reviewed in Kovacs, 2008). After parturition, $1,25(OH)_2D$ concentrations and calcium absorption rates[21] decrease to prepregnancy levels. The interplay of calcitropic and progestational hormones in pregnancy protects the maternal skeleton from demineralization. In contrast, during the relatively low estrogen state of lactation, calcium is mobilized from bone stores, possibly under the influence of PTHrP.[22]

Fetal plasma PTH concentration is low, and calcitonin and PTHrP levels are relatively high. Even these low circulating PTH levels may be functionally important in fetal calcium and magnesium metabolism. There is also a close correlation between maternal and fetal serum 25(OH)D levels, consistent with the transplacental transfer of this metabolite. Hypocalcemia is commonly found in infants born to women with low circulating 25(OH)D levels resulting from poor dietary intake of vitamin D and lack of sunlight exposure. Fetal plasma $1,25(OH)_2D$ concentration is also relatively low, despite robust renal 25(OH)D 1α-hydroxylase activity, whereas the concentrations of $24,25(OH)_2D$ are high. The major function of the fetal kidneys in calcium homeostasis may be the production of $1,25(OH)_2D$ rather than renal tubular regulation of calcium excretion. The high circulating concentrations of calcitonin may support this stimulated fetal 25(OH)D 1α-hydroxylase activity. In contrast, the relatively low circulating fetal $1,25(OH)_2D$ concentrations are a consequence of enhanced placental clearance.[23] Constitutively activated placental 24-hydroxylase activity[24] also preferentially hydroxylates maternally derived 25(OH)D to $24,25(OH)_2D$. This placental capacity to metabolize 25(OH)D and $1,25(OH)_2D$ accounts for the enhanced clearance of fetal $1,25(OH)_2D$, limits access of placenta-synthesized $1,25(OH)_2D$ to the fetal and maternal circulations, and, in effect, partitions the maternal and fetal vitamin D pools.

The Neonate

Placental transfer of calcium ceases abruptly at birth. In healthy term newborns, total calcium concentration and Ca^{2+} concentration decline from nearly 11 mg/dL and 6 mg/dL, respectively, in umbilical cord blood to serum levels of 8 to 9 mg/dL and 5 mg/dL, respectively, by 24 to 48 hours. The nadir of Ca^{2+} concentration may range from 4.4 to 5.4 mg/dL. Concomitant rises in the concentrations of PTH and $1,25(OH)_2D$ stabilize serum calcium concentration as the newborn adapts to extrauterine mineral homeostasis and dietary calcium intake. In preterm infants, calcium absorption from the intestine is nonsaturable and may be vitamin D independent.[25] Serum calcitonin levels increase sharply during the first day and remain elevated compared with those in adults. In the mother, prolactin helps stimulate PTHrP expression in lactating breast tissue. PTHrP is secreted into milk at concentrations 10,000-fold higher than in serum. It is possible that the abundant milk PTHrP content ingested by the neonate is important for mineral regulation. By 2 weeks of life, serum calcium concentration rises to the mean values observed in older children and adults.

During the first week of life, urinary phosphate excretion is significantly higher in preterm newborns than in term newborns but then approximates that of term newborns, possibly owing to accelerated postnatal renal maturation. Calcium excretion is low during the first week when the newborn must compensate for the postpartum fall in serum calcium concentration. After the first several days, calcium excretion increases with a magnitude inversely proportional to gestation. The high urinary calcium-to-creatinine ratio (UCa/Cr) of young infants then steadily declines with age.[26] However, in preterm breastfed infants who are more than 2 weeks old, the UCa/Cr can exceed 2.0.[27] These changes may reflect the relative phosphate deficiency in many preterm infants, which results in an adaptively low urinary phosphate excretion, decreased bone mineralization, and, consequently, relatively high urinary calcium excretion.

Neonatal Hypocalcemia

The definition of hypocalcemia depends on gestational age and birthweight. A precise definition of hypocalcemia, like hypoglycemia, in preterm infants is particularly difficult to formulate. Neonatal hypocalcemia has been defined as a serum calcium level below 8 mg/dL (2 mmol/L) or Ca^{2+} level less than 4.4 mg/dL (1.10 mmol/L) in term infants and preterm infants weighing >1500 g. Hypocalcemia in very low birthweight (VLBW) infants has been defined as a serum calcium level below 7 mg/dL (1.75 mmol/L) or Ca^{2+} level less than 4 mg/dL (1 mmol/L).[28] Under conditions of normal acid-base status and normal serum albumin concentration, total serum calcium and Ca^{2+} levels are linearly correlated, so total serum calcium measurements remain useful as a screening test. However, because Ca^{2+} is the physiologically active fraction in sick infants, it may be preferable to assay Ca^{2+} directly in freshly obtained blood samples. The causes of neonatal hypocalcemia are classified by the timing of onset. Early hypocalcemia occurs in the first 2 to 3 days of life. "Early" and "late" occurring hypocalcemias (Box 83.1) have different causes, usually occur in different clinical settings, and should prompt different approaches to evaluation and management.

Clinical Presentation

Most infants with hypocalcemia are asymptomatic. Hypocalcemic signs in neonates are variable and may not correlate with the magnitude of the decline in calcium level. Calcium ions couple excitation and contraction in skeletal and cardiac muscle, so increased neuromuscular excitability (tetany) is a cardinal feature of hypocalcemia. Such infants are jittery and hyperactive and frequently exhibit muscle jerks and twitches induced by environmental noise

• BOX 83.1 Causes of Neonatal Hypocalcemia

- Early-Onset Hypocalcemia (<48 h of Age)
  - Prematurity
  - Perinatal distress/asphyxia
  - Infants of diabetic mothers
  - Intrauterine growth restriction
- Late-Onset Hypocalcemia (First Week of Life)
  - High phosphate load with or without hypoparathyroidism or vitamin D deficiency
- Neonatal Hypoparathyroid Syndromes
  - Parathyroid agenesis
  - DiGeorge syndrome (22q11.2 deletions)
  - Familial isolated hypoparathyroidism
    - *PTH* mutations
- Autosomal Dominant Hypocalcemic Hypocalciuria
  - Activating mutations of Ca^{2+}-sensing receptor
- Neonatal Hypoparathyroidism Secondary to Maternal Hyperparathyroidism
- Autoimmune Polyglandular Syndrome Type 1 (Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dystrophy)
- Hypoparathyroidism Associated With Skeletal Dysplasias
  - Kenny-Caffey syndrome
  - Hypoparathyroidism-retardation-dysmorphism (Sanjad-Sakati) syndrome
  - Osteogenesis imperfecta type II
- Parathyroid Hormone Resistance (Transient Neonatal Pseudohypoparathyroidism)
- Hypomagnesemia With or Without Distal Renal Tubular Acidosis
  - Primary hypomagnesemia
  - Renal tubular acidosis type 1
- Abnormal Vitamin D (1,25-Dihydroxyvitamin D) Production or Action ("Hypocalcemic Rickets")
  - Vitamin D deficiency (secondary to maternal vitamin D deficiency)
  - Acquired or inherited disorders of vitamin D metabolism
  - Resistance to the actions of vitamin D
- Hyperphosphatemia
  - Excessive dietary phosphate
  - Phosphate-containing enemas
  - Rhabdomyolysis-induced acute renal failure
  - Hyperphosphatemic renal insufficiency
- "Hungry Bones Syndrome" (Mineralization Outpacing Osteoclastic Bone Resorption)
- Other Causes
  - Metabolic or respiratory alkalosis
  - Phototherapy
  - Long-chain 3-hydroxyacyl-coenzyme A dehydrogenase deficiency
  - Pancreatitis
  - Sepsis, septic shock
  - Rotavirus gastroenteritis
  - Osteopetrosis and other skeletal dysplasias
  - Pseudohypocalcemia (hypoalbuminemia)
  - Medications
    - Bicarbonate
    - Rapid transfusion or plasmapheresis with citrated blood
    - Furosemide induced
    - Lipid infusions

or other stimuli. Generalized or focal clonic seizures may occur. Other signs of neonatal tetany include poor feeding, hypotonia, apnea, tachycardia, tachypnea, high-pitched cry, and irritability.[29] Occasionally, respiratory or gastrointestinal rather than neurologic signs predominate. Rare presentations include inspiratory stridor caused by laryngospasm, wheezing caused by bronchospasm, or vomiting possibly resulting from pylorospasm, which may cause hematemesis or melena. At times the gastrointestinal signs are severe enough to mimic those of intestinal obstruction.[30] Carpopedal spasm and the Chvostek sign are not as reliably elicited in hypocalcemic newborns as in older children or adults. Hypocalcemia characteristically causes prolongation of the QT interval in the electrocardiogram.[31]

Early Neonatal Hypocalcemia

Hypocalcemia occurring during the first 3 days of life, usually between 24 and 48 hours postpartum, is termed *early neonatal hypocalcemia*. It is an exaggeration of the normal decline in circulating calcium concentration. Early neonatal hypocalcemia is typically encountered in any of four circumstances: prematurity, severe perinatal stress or asphyxia, maternal diabetes, or significant intrauterine growth restriction (IUGR). In addition, phototherapy, maternal hyperparathyroidism, maternal anticonvulsant use, and iatrogenic causes (e.g., transfusion with citrated blood, furosemide use) have also been implicated with early neonatal hypocalcemia.

In preterm infants, there is a steeper and more rapid postnatal decline in serum calcium concentration. The magnitude of the depression is inversely proportional to gestational age. Approximately one-third of premature infants and most VLBW infants have low total serum calcium levels (<7.0 mg/dL) during the first 2 days after birth.[32] However, the fall in Ca^{2+} concentration is not proportional to the fall in total calcium concentration. The ratio of ionized to total calcium in these newborns is higher than at term. This "sparing" of Ca^{2+} may be related to the lower serum protein concentration and pH in prematurity. Multiple factors contribute to the fall in total serum calcium concentration, including low milk intake, impaired response to PTH, and hypoalbuminemia, which does not lower the Ca^{2+} concentration. The sparing effect on Ca^{2+} concentration explains the frequent absence of hypocalcemic signs in preterm infants.

The neonatal parathyroid glands, regardless of the degree of prematurity, can mount an appropriate PTH response to hypocalcemia. Hypocalcemia in extremely preterm newborns[33] or infants undergoing cardiac bypass[34] stimulates increases in serum PTH at least as great as those seen in adults during citrate-induced hypocalcemia.[35] PTH resistance plays an uncertain role in early neonatal hypocalcemia. A several-day delay in the phosphaturic and renal cAMP responses to PTH has inconsistently been reported, suggesting that there might be a maturational delay in renal responses to PTH. Calcitonin usually peaks in 12 to 24 hours of life. Preterm infants' exaggerated rise in calcitonin may also promote hypocalcemia.[36]

Early neonatal hypocalcemia with hyperphosphatemia is frequently observed in severely stressed or asphyxiated infants. Possible mechanisms include increased phosphate load caused by tissue catabolism, renal insufficiency, and acidosis. There is an exaggerated serum calcitonin response and decreased PTH secretion. Low serum Ca^{2+} and elevated serum magnesium levels have been correlated with the severity of hypoxic–ischemic encephalopathy and poor outcome.[37]

Hypocalcemia occurs in at least 20% to 50% of infants of diabetic mothers (IDMs).[38] IDMs show an exaggerated postnatal drop in circulating calcium levels compared with gestational-age controls that typically occur between 24 and 72 hours after birth and are often associated with hyperphosphatemia. The course is usually similar to early neonatal hypocalcemia in preterm infants, although hypocalcemia sometimes persists for several additional days. The greater bone mass and relative undermineralization typical of macrosomic IDMs may increase the neonatal demand for

calcium, producing a deeper and prolonged decline in postnatal serum calcium levels. In addition, magnesium deficiency leads to decreased PTH production and action.[33,39] Maternal glycosuria is associated with urinary magnesium losses, which may lead to significant maternal magnesium deficiency followed by fetal magnesium deficiency.

Neonatal hypocalcemia in IDMs has been associated with the severity and duration of maternal diabetes and inadequate glycemic control. Not surprisingly, preterm IDMs who have sustained IUGR and asphyxia as a result of uteroplacental insufficiency invariably become quite hypocalcemic. Improved metabolic control for pregnant diabetic women can markedly diminish the occurrence and severity of early neonatal hypocalcemia.[40] Healthy IDMs who can start milk feedings on the first day do not require serum calcium monitoring unless suspicious signs (e.g., jitteriness, stridor) are noted.

Hypocalcemia occurs with increased frequency in infants with IUGR. The mechanism is thought to involve a decreased transfer of calcium across the placenta due to uteroplacental insufficiency.

Late Neonatal Hypocalcemia

Late neonatal hypocalcemia develops after 3 to 5 days of life and typically occurs at the end of the first week. It occurs more frequently in term than in preterm infants and is not usually associated with maternal diabetes, birth trauma, or asphyxia. Historically, late-onset hypocalcemia is associated with ingestion of cow's milk or formula with a high phosphate load.[41] The high phosphate level increases calcium deposition in bone and antagonizes PTH secretion and action, leading to hypocalcemia.[42] However, the widespread use of high phosphorus formula in the United States and elsewhere contrasts with the rarity of this condition, which suggests that infants who develop phosphate-induced late neonatal hypocalcemia may have an otherwise undetected renal phosphate excretion problem.

The hyperphosphatemia may also result from varying combinations of immature renal tubular phosphate excretion, transiently low levels of circulating PTH, hypomagnesemia, and inadequate maternal vitamin D intake. A relatively high dietary phosphate load coupled with a low GFR leads to an increase in serum phosphate levels and a reciprocal decline in serum calcium levels. The physiologic response to hypocalcemia is an increase in PTH secretion, leading to increased urinary phosphate excretion and tubular calcium resorption. Serum calcium levels frequently increase when these infants are placed on a low-phosphate formula and supplemental calcium. After several days to weeks, serum PTH usually increases, and the infants then can tolerate more dietary phosphate. The pathogenesis of this "transient hypoparathyroidism" in late neonatal hypocalcemia is not readily apparent. Some of these infants show a persistent or recurrent inability to mount an adequate PTH response to a hypocalcemic challenge, indicating partial hypoparathyroidism.

In other infants, maternal vitamin D deficiency can cause late (or occasionally "early") neonatal hypocalcemia. This possibility is checked by measuring maternal and neonatal serum 25(OH)D levels. Maternal vitamin D deficiency is implicated by the increased incidence of late neonatal hypocalcemia in winter due to inadequate sunlight. The high prevalence of enamel hypoplasia of incisor teeth reported in affected infants indicates that the mineralization defect begins during the third trimester of pregnancy.

Hypocalcemia and hyperphosphatemia after the first 3 to 5 days should always prompt a thorough investigation for the underlying causes (see Box 83.1). Hypocalcemia in this setting usually implies primary or secondary dysregulation of (1) the parathyroid-renal (PTH–-,25[OH]$_2$D) axis, (2) hypomagnesemia, or (3) renal insufficiency. The primary hormonal and end-organ disturbances that cause neonatal hypocalcemic syndromes are described later. As a cautionary note, observations of generally favorable neurologic outcomes in newborns with hypocalcemic or hypomagnesemic seizures may be valid for those with a nutritional cause but are less relevant to patients with associated medical conditions. In this group, the neurologic prognosis may be more closely related to the causative disorder.[43]

Hypocalcemia Caused by Hypoparathyroid Syndromes

The biochemical hallmarks of hypoparathyroidism are hypocalcemia and hyperphosphatemia in the presence of normal renal function. Serum PTH concentrations are inappropriately low or undetectable. Cytogenetic and molecular genetic diagnosis permits the characterization of several types of congenital hypoparathyroidism. Isolated hypoparathyroidism is usually sporadic but may show X-linked, autosomal recessive, or autosomal dominant inheritance.

Congenital hypoparathyroidism is a common feature of DiGeorge syndrome (DGS) in addition to CHARGE (Coloboma, Heart defects, Atresia choanae, Retarded growth and development, Genital hypoplasia, and Ear anomalies/deafness) syndrome. DGS arises from a failure of migration of neural crest cells into the third and fourth pharyngeal pouches. Fully expressed DGS comprises hypoparathyroid hypocalcemia, thymic hypoplasia with defects in T-cell immunity, conotruncal cardiac defects, palatal insufficiency, dysmorphic facial features, and neurobehavioral and psychiatric features. DGS, velocardiofacial (Shprintzen) syndrome, and conotruncal face anomaly (Takao) syndrome commonly result from contiguous gene deletions in the same chromosomal region.

Most patients having a clinical diagnosis of DGS share a common 1.5- to 3-Mb deletion (monosomy or partial monosomy) of chromosome region 22q11.2, but there is molecular heterogeneity and rearrangement within this region.[44] The size of the deletion does not correlate with the clinical phenotype. Haploinsufficiency of the TBX1 (T-box 1) transcription factor gene may be responsible for most features. Studies showed patients with point mutations in the gene encoding TBX1 manifested all major phenotypes of DGS.[45] Fluorescence in situ hybridization (FISH) using 22q11 probes had a higher detection rate than high-resolution G-band karyotyping. However, the most sensitive (and preferred) laboratory assay is array-comparative genomic hybridization. In addition, rarer identification of other cytogenetic abnormalities suggests that several distinct molecular defects can lead to disturbed cranial neural crest cell migration and DGS phenotypes.[46]

DGS affects an estimated 1 in 4000 live births. It occurs sporadically or is transmitted as a variably penetrant autosomal dominant trait. Sporadic loss in the DGS chromosomal region is more common than parental transmission. In members of the same family, DGS may be associated with different phenotypic features. It often manifests itself in the first week of life with hypocalcemic tetany or seizures. Craniofacial features include microretrognathia, mandibular hypoplasia, submucous cleft palate, low-set and abnormal pinnae, telecanthus with short palpebral fissures, short philtrum, and a relatively small mouth. The presence of cardiac outflow tract or aortic arch abnormalities (especially pulmonary atresia/tetralogy of Fallot, type B interrupted aortic arch, truncus

arteriosus, anomalies of aortic arch laterality, or abnormal branching of the brachiocephalic vessels) should prompt genetic investigation even in the absence of other DGS features. Parents of an infant with DGS should be screened for carrier status. These neonates require close anticipatory monitoring for the onset of hypocalcemia.

A normal serum PTH level obtained when an infant is relatively normocalcemic does not exclude the diagnosis of DGS. The absence of a thymic shadow on chest radiograph is not a reliable indicator. Infants with DGS may show resolution of hypoparathyroidism by early childhood, although PTH reserves may remain inadequate for defense against hypocalcemic stresses.

Hypoparathyroidism is a prominent feature of several rare skeletal dysplasias. Kenny-Caffey syndrome is a rare osteosclerotic bony dysplasia associated with hypocalcemia and ocular abnormalities. Autosomal recessive and autosomal dominant inheritance patterns have been described, in addition to an association with CATCH 22 microdeletions.[47] Features include IUGR, transient neonatal hypoparathyroidism, short stature, macrocephaly, delayed fontanel closure, dysmorphic facies, and cortical thickening of tubular bones.[47] The autosomal dominant form of Kenny-Caffey syndrome is clinically distinguished by the absence of developmental delay and is caused by a heterozygous mutation of the FAM111A gene.[48] The recessive form of Kenny-Caffey syndrome is the same disorder as hypoparathyroidism-retardation-dysmorphism (HRD) syndrome, also known as *Sanjad-Sakati syndrome*. HRD syndrome is an extremely rare disorder characterized by congenital hypoparathyroidism, growth retardation, characteristic facies (deep-set eyes, depressed nasal bridge, beaked nose, long philtrum, thin upper lip, large and floppy earlobes), small hands and feet, skeletal defects, and developmental delay.[49] The loci for HRD syndrome is on chromosome 1q42–q43 with mutations in the gene encoding tubulin-specific chaperone E *(TBCE)*.[50] Parathyroid hemorrhage ("parathyroid apoplexy") is a common event in osteogenesis imperfecta (OI) type II and may contribute to early death.[51]

Several mitochondrial syndromes are also associated with hypoparathyroidism. Pearson Marrow-Pancreas syndrome is characterized by pancreatic dysfunction, sideroblastic anemia, neutropenia, and thrombocytopenia and presents as an infant.[52] Kearns-Sayre syndrome is marked by encephalomyopathy, ophthalmoplegia, retinitis pigmentosa, and heart block and presents in childhood.[53]

Barakat syndrome, also known as hypoparathyroidism, sensorineural deafness, and renal dysplasia syndrome (HDR), has an autosomal dominant inheritance. The locus for HDR syndrome is on chromosome 10p14–15 with mutations in the GATA3 gene.[54] The GATA3 protein is a transcription factor expressed in the development of the parathyroid gland, thymus, kidney, inner ear, and central nervous system. There is a wide phenotypic variability with hypoparathyroidism being asymptomatic, resolving after infancy, or severe and permanent into adulthood. Renal involvement is the least penetrant finding, with 60% of patients having renal disease and only 9% developing end-stage renal disease.[55]

The parathyroid glands are an infrequent target for autoimmunity, the exception being autoimmune polyglandular syndrome type 1 (APS 1), also known as *autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy*.[56] APS 1 is a rare autosomal recessive disorder characterized by hypoparathyroidism, adrenal insufficiency, and chronic mucocutaneous candidiasis.[57] It results from the inheritance of mutations in an autoimmune regulator gene (AIRE). Candidiasis is usually the initial clinical manifestation, most often occurring in patients less than 5 years of age. Hypoparathyroidism occurs next, usually in patients younger than 10 years. Hypoparathyroidism most often precedes the development of hypoadrenocorticism. Affected persons often eventually develop chronic hepatitis, malabsorption, juvenile-onset pernicious anemia, alopecia, and primary hypogonadism.

There are several forms of isolated congenital hypoparathyroidism caused by isolated parathyroid aplasia or defects in PTH synthesis or secretion. Affected infants have subnormal or undetectable serum PTH levels but do not have congenital anomalies or developmental defects, DGS locus deletions, candidiasis or autoimmune polyglandular failure, or antiendocrine antibodies. Two mutations affecting embryologic development have been identified as etiologies of isolated parathyroid aplasia. The most common cause is a loss of function mutation in the GCM2 gene located at chromosome 6p23–24, which encodes an essential transcription factor.[58] These mutations can be autosomal recessive or autosomal dominant. X-linked recessive inheritance is caused by the SOX3 gene.[59]

The PTH gene is located on chromosome 11p15.3–p15.1 and produces the preproPTH protein, which undergoes two cleavages to become a biologically active PTH molecule. There have been several autosomal dominant and autosomal recessive mutations described in the PTH gene.[60]

Impaired PTH secretion has been attributed to gain-of-function mutations in *CaSR* and *GNA11* genes, resulting in autosomal dominant hypocalcemia type 1 (ADH1) and type 2 (ADH2), respectively. The *CaSR* gene is located on chromosome band 3q13.3–q21, and it encodes a cell-surface protein that is expressed in the PTH-producing chief cells of the parathyroid glands and kidney tubules. Activation of the gene increases the sensitivity of the calcium-sensing receptor to extracellular Ca^{2+}, which suppresses the secretion of PTH and renal calcium reabsorption from the cortical thick ascending limb.[61] The parathyroid and renal calcistat is reset downward, so hypocalcemia does not elicit normal compensatory PTH secretion or renal calcium reabsorption. Familial activating mutations in the GNA11 gene occur at chromosome 19p13, which encodes the alpha subunit of the G protein (Gα11) that couples to the CaSR receptor and activates intracellular signaling pathways to produce PTH.[62] A similar mechanism of increased sensitivity of Gα11 to extracellular Ca^{2+} resulting in decreased PTH secretion has been proposed. ADH2 is distinguished by short stature and lack of hypercalciuria compared with ADH1. Most patients with ADH are asymptomatic. Children, in particular, may become symptomatic with seizures and neuromuscular irritability during periods of stress such as febrile illness. Serum calcium level is usually in the range of 6 to 8 mg/dL (1.5 to 2.0 mmol/L), with normal or only slightly low serum PTH concentrations. Because both familial and de novo *CaSR* mutations producing CaSR hyperfunction have been described,[63] mutational analysis of the *CaSR* gene should be considered in the work-up of isolated hypoparathyroidism in infants, especially when hypocalcemia manifests itself with inappropriately normal urinary calcium excretion (relative hypercalciuria). Hypercalciuria and nephrocalcinosis can develop even when serum calcium concentration remains below the normal range. Therefore it is important to distinguish hypocalcemia due to an activating mutation of *CaSR* gene from isolated hypoparathyroidism because ADH1 patients can develop nephrocalcinosis and

renal impairment during treatment with calcium and vitamin D. For this reason, these patients require close monitoring of urinary calcium excretion for adjustment of therapy with $1,25(OH)_2D$ analogues.

Pseudohypoparathyroidism refers to a heterogeneous group of disorders that are usually inherited as an autosomal dominant trait characterized by hypocalcemia, hyperphosphatemia, and increased serum PTH concentrations due to PTH hormone resistance of peripheral tissues. Deletion of the PTH/PTHrP receptor is embryologically or perinatally lethal. Loss of one allele for *GNAS1*, which encodes $G_s\alpha$, the G protein α subunit required for receptor-stimulated cAMP generation, produces pseudohypoparathyroidism type 1A (PHP1A).[64] In patients with PHP1A, there is the characteristic phenotype of Albright hereditary osteodystrophy (AHO) (short stature, obesity, round face, brachymetacarpalism, and subcutaneous calcifications), and it is associated with multihormone resistance (e.g., thyroid-stimulating hormone, gonadotropins, and growth hormone). Isolated PTH resistance in the absence of a somatic phenotype is called *pseudohypoparathyroidism type 1B*. This disorder is an imprinting defect in which both *GNAS1* alleles have an unmethylated (paternal) pattern.[65] Although most patients who eventually receive a diagnosis of PTH resistance syndrome are usually not hypocalcemic during the first month of life, transient neonatal pseudohypoparathyroidism has occasionally been reported.[66] Individuals with pseudopseudohypoparathyroidism have the clinical phenotype of AHO but normal serum calcium, phosphorus, and PTH levels. Pseudohypoparathyroidism type 2 is characterized by hypocalcemia, hyperphosphatemia, and increased serum PTH level. However, individuals usually lack physical features associated with AHO.[67]

Neonatal Hypocalcemia Associated With Maternal Hyperparathyroidism

Hypocalcemia is commonly observed in newborns of hyperparathyroid mothers.[68] In maternal hyperparathyroidism the increased maternal serum calcium concentration facilitates transplacental calcium transport, producing fetal hypercalcemia greater than the moderate elevations of serum calcium concentration normally observed in the third trimester. As a result, fetal PTH secretion is suppressed.[69] The suppressed parathyroids are unable to maintain normal serum calcium levels postpartum. The reason for the hypomagnesemia observed in some infants born to hyperparathyroid mothers is uncertain. However, this derangement may be due to (1) maternal magnesium depletion as a complication of hyperparathyroidism, (2) transient neonatal hypoparathyroidism, or (3) hyperphosphatemia, which may result from transient hypoparathyroidism or high dietary phosphate intake, or both. These newborns may show increased neuromuscular irritability during the first 3 weeks of life but, occasionally, do so much later as limited PTH reserve and latent hypoparathyroidism emerge under stress or with time. The serum calcium levels usually range from 5.0 to 7.5 mg/dL, and the serum phosphate levels are often greater than 8.0 mg/dL. Hypocalcemic signs may be exacerbated by high-phosphate diets or maternal vitamin D deficiency. In some instances, signs of hypocalcemia can be quite severe and may be resistant to several weeks of calcium replacement therapy.

Maternal serum calcium and phosphorus should be assayed whenever this diagnosis is suspected. Hypocalcemic tetany occurring in the infant may lead to a diagnosis of hyperparathyroidism in an asymptomatic mother. Maternal serum calcium values in the upper normal range may be falsely reassuring if the samples were obtained during pregnancy, a time when serum calcium levels normally decline.

Hypomagnesemia causes hypocalcemia by interfering with the parathyroid cell CaSR-mediated release of PTH and by blunting end-organ PTH response. Hypomagnesemia with secondary hypocalcemia (HOMG1) can present in the first weeks of life as persistent hypocalcemia, tetany, and seizures uncontrolled by anticonvulsants or calcium therapy. Delay in establishing the diagnosis may lead to permanent neurologic impairment. This rare autosomal recessive disorder results from defective intestinal magnesium absorption and renal magnesium leak. Hypocalcemia is a secondary consequence of parathyroid failure and PTH resistance as a result of severe magnesium deficiency. HOMG1 is caused by mutations in the *TRPM6* gene, a member of the transient receptor potential channel gene family expressed in intestinal epithelia and renal tubules.[70] Treatment includes immediate administration of magnesium, usually intravenously, followed by high-dose oral magnesium.

Several forms of primary renal hypomagnesemia have been described, including autosomal recessive familial hypomagnesemia with hypercalciuria and nephrocalcinosis caused by mutations in the paracellin 1 gene on chromosome 3q27[71] and a genetically heterogeneous autosomal dominant isolated renal magnesium wasting. The initial symptoms may include recurrent urinary tract infections, polyuria and polydipsia, moderate metabolic acidosis with an inappropriately high urine pH, muscle weakness, persistent tetany, failure to thrive, sensorineural hearing loss, and distal tubular acidosis. All patients exhibit hypercalciuria and nephrocalcinosis, and 50% of cases usually require renal replacement therapy in the second decade of life. The distal acidification defect is probably secondary to a medullary interstitial nephropathy. The serum magnesium level is frequently less than 0.8 mg/dL (normal range 1.6 to 2.8 mg/dL). High-dose enteral magnesium administration leads to increases in serum PTH and calcium levels and renal phosphate clearance. Kidney transplant normalizes serum magnesium and urinary calcium.

Transient hypomagnesemia in newborns often occurs in association with hypocalcemia. Less commonly, the serum calcium level may be normal. In transient hypomagnesemia, the decrease in serum magnesium level typically is less severe (0.8 to 1.4 mg/dL) than in magnesium transport defects. In many infants with transient hypomagnesemia, the serum magnesium level increases spontaneously as the serum calcium level normalizes following the administration of calcium supplements. However, in other cases, hypocalcemia responds poorly to calcium therapy, but when magnesium salts are given, serum calcium and magnesium levels both rise.

Secondary hypomagnesemia from renal magnesium wasting can result from drug administration (e.g., loop diuretics, aminoglycosides, amphotericin B) or urinary tract obstruction. It also may occur during the diuretic phase of acute renal failure. This disorder may be mistaken for neonatal hypoparathyroidism because of tetany and hypocalcemia or Bartter syndrome (hypokalemic alkalosis with hypercalciuria) because of secondary potassium wasting. An index of suspicion should be raised whenever hypomagnesemia occurs in one of these situations. The finding of low serum magnesium levels with inappropriately high urinary magnesium excretion confirms a diagnosis of renal magnesium wasting. Hypokalemia is a common laboratory feature of magnesium depletion. Attempts to replace the potassium deficit with potassium alone are usually unsuccessful unless magnesium is given concurrently.

Distal renal tubular acidosis type 1 (RTA1) is characterized by hypocalcemia, hypercalciuria, various degrees of hypomagnesemia, hyperchloremia, low serum bicarbonate level, and a fixed urinary specific gravity and urinary pH (about 5.0). The mineral excretion defect leads to nephrocalcinosis and MBD. RTA1 sometimes manifests itself during early infancy, when hypocalcemia may precede the renal tubular acidosis.

Hypocalcemia Resulting From Vitamin D Disorders

Vitamin D increases the intestinal absorption of calcium. In older children and adults, disorders of vitamin D intake or metabolism rarely present as isolated hypocalcemia. Instead, most patients with abnormalities in either production or action of $1,25(OH)_2D$ have rickets or osteomalacia. In sharp contrast, young infants may exhibit hypocalcemic tetany before rachitic features become conspicuous. Abnormalities in vitamin D metabolism can be divided into three broad categories: vitamin D deficiency, acquired or inherited disorders of vitamin D metabolism, and resistance to vitamin D actions.

Maternal vitamin D deficiency is the major risk factor for neonatal vitamin D deficiency manifesting itself as hypocalcemia. Maternal vitamin D deficiency is becoming less common in countries where dairy products and other foods are supplemented with vitamin D. It is still a common and serious health problem of women of reproductive age and their infants in developing countries. Female immigrants from the Middle East or South Asia who wear traditional concealing dress, have inadequate dietary vitamin D intake, or are dark-skinned are at particularly high risk, especially during pregnancy.[72,73] Breastfed infants of lactovegetarian mothers are also susceptible to early-onset hypocalcemic rickets. Nutritional rickets in newborns can be prevented by daily supplementation of 400 international units (IU) for infants and 400 IU daily for mothers during pregnancy and lactation or 1000 IU daily if supplementation is begun in the third trimester.

Intestinal absorption of fat-soluble vitamin D requires a functioning exocrine pancreas, biliary tract, and bowel mucosa. Consequently, pregnant women with malabsorption syndromes are likely to be vitamin D deficient.

Anticonvulsant therapy (e.g., with phenobarbital or diphenylhydantoin) during pregnancy, which increases hepatic catabolism of 25(OH)D, can also induce maternal and fetal vitamin D deficiency. Pregnant women who take anticonvulsants should receive vitamin D supplementation (800 to 1000 IU/day).

Phosphate-Induced Hypocalcemia

Phosphate directly precipitates calcium in bone or soft tissues by inhibiting bone resorption and blocking the renal synthesis of $1,25(OH)_2D$. Conditions leading to phosphate-induced neonatal hypocalcemia include excessive phosphate intake, rhabdomyolysis-induced acute renal failure, and hyperphosphatemic renal insufficiency. Phosphate-containing enemas can produce significant phosphate absorption.[74] Their use is hazardous and contraindicated for infants. Chronic renal failure is the primary cause of secondary hyperparathyroidism. Patients with mineral metabolism disorders commonly have low serum calcium levels, hyperphosphatemia, and calcitriol deficiency. In uremic conditions, however, the parathyroid glands become hyperplastic. In recent years, fibroblast growth factor 23 (FGF23) has been identified.[75] FGF23 is a bone-derived hormone that regulates systemic phosphate hemostasis and vitamin D metabolism. FGF23 inhibits renal tubular reabsorption of phosphate independently of PTH.[76]

Other Causes of Neonatal Hypocalcemia

It is important to recognize that hypocalcemia may occur whenever skeletal mineralization significantly outpaces the rate of osteoclastic bone resorption. Examples of this type of hypocalcemia occur with overzealous vitamin D replacement in infants with rickets or hypoparathyroidism.[77] Pancreatitis can cause hypocalcemia and tetany through the action of pancreatic lipase on retroperitoneal and omental fat to release free fatty acids (FFAs). FFAs avidly chelate calcium and remove it from the ECF. Pancreatitis may also result in the release of pancreatic calcium-lowering factors.[78,79] Hypocalcemia is commonly seen in critically ill patients with sepsis. It is believed to be due to parathyroid gland suppression, failure to activate vitamin D, and calcium chelation.[80] Neonatal or infantile hypocalcemia and hypocalcemic seizures may accompany long-chain 3-hydroxyacyl-coenzyme A dehydrogenase deficiency and severe cases of rotavirus gastroenteritis.[81] Hypocalcemic jitteriness or seizures can be the presenting sign of infantile osteopetrosis, likely due to the failure of osteoclasts to resorb immature bone.[82] Prompt recognition permits early referral for bone marrow or hematopoietic stem cell transplantation.

Several common therapeutic interventions can induce hypocalcemia. Bicarbonate therapy, as well as any form of metabolic or respiratory alkalinization, decreases both Ca^{2+} levels and bone turnover. Rapid blood transfusion or plasmapheresis can promote calcium complexes with the infused citrate, decreasing Ca^{2+} levels. Hypocalcemia after initiation of ECMO is related to the composition of the circuit-priming solution and to acute citrate loading and may lead to hemodynamic instability.[83] Large doses of ethylenediaminetetraacetic acid (EDTA)-containing contrast dyes have also been reported to cause hypocalcemia.[84] Furosemide therapy for hypercalcemia promotes calciuresis and nephrolithiasis. Phototherapy for hyperbilirubinemia may be associated with mild hypocalcemia. This effect has been attributed to decreased melatonin secretion, which potentiates glucocorticoid actions on bone metabolism. Lipid infusions may elevate serum levels of FFAs, which form insoluble complexes with calcium. Most of these effects are transient, and cessation of therapy is followed by a return to normal serum calcium levels. The major exception is aggressive furosemide therapy, which, when prolonged, may lead to bone demineralization and renal dysfunction.

Management of Hypocalcemia

The decision to treat hypocalcemia in an infant depends on the severity of the hypocalcemia and the presence of clinical signs and symptoms. The morbidity associated with calcium treatment must be weighed against the potential benefits. Hypocalcemic preterm infants with no symptoms and are not ill from any other cause probably do not need specific treatment. Early neonatal hypocalcemia should resolve by day 3. Some clinicians begin treatment in preterm newborns once serum calcium levels have dropped to 6.0 to 6.5 mg/dL or after Ca^{2+} concentration has decreased to 2.5 to 3.0 mg/dL. Some advocate initiation of prophylactic calcium infusions (or calcium-containing parenteral nutrition) for all extremely low birthweight (ELBW) infants within the first 24 hours. There is no role for prophylaxis or treatment with pharmacologic doses of vitamin D. For newborns who exhibit cardiovascular compromise (e.g., severe respiratory distress, pulmonary hypertension, asphyxia, sepsis) or who require cardiotoxic drugs or blood pressure support, monitoring of blood Ca^{2+} concentration is particularly helpful, to prevent the onset of significant hypocalcemia.

The mainstay of treatment for neonatal hypocalcemia is intravenous (IV) administration of calcium salts. Calcium gluconate is

preferred over calcium chloride (which, in sufficient doses, produces hyperchloremic acidosis) or calcium lactate. A 10% solution of calcium gluconate contains 9.4 mg elemental calcium per mL. A constant infusion of approximately 45 to 75 mg/kg/day of elemental calcium usually produces a sustained increase in serum calcium level (7 to 8 mg/dL). Bolus infusions are hazardous and only transiently effective.

The risks associated with calcium infusions are minimized by attention to detail. Rapid IV infusion of calcium can cause a sudden elevation in serum calcium level, leading to bradyarrhythmias. Bolus infusion of calcium should be reserved for the treatment of hypocalcemic tetany and seizures. Extravasation of calcium solutions into subcutaneous tissues may cause necrosis and subcutaneous calcification. Therefore meticulous care of peripheral IV catheter sites is particularly important when calcium-containing solutions are infused. Inadvertent intrahepatic infusion of calcium through an umbilical vein catheter due to failure to reach the inferior vena cava can cause hepatic necrosis. Rapid intra-aortic infusion via an umbilical artery can cause arterial spasm and, at least experimentally, intestinal necrosis.

Hypocalcemic Crisis

Acute hypocalcemia constitutes an emergency that requires prompt attention. For emergency treatment of a hypocalcemic crisis with seizures or tetany, 100 to 200 mg/kg calcium gluconate should be given within 5 to 10 minutes. The dose can be repeated in 10 minutes if no response occurs. Calcium should not be administered rapidly intravenously because hypercalcemia may adversely affect cardiac conduction; monitoring the electrocardiogram QT interval is useful in guiding therapy. Alternatively, 20 mg/kg calcium chloride can be given. If necessary, IV calcium therapy may be repeated 3 or 4 times in 24 hours to help control acute symptoms. After short-term treatment, maintenance calcium gluconate should be added to IV fluid. Careful observation of the infant and infusion site is essential, and the infusion should be discontinued if there is bradycardia or when the desired clinical result is obtained. Serum calcium must be frequently monitored during infusion, and calcium should not be mixed with fluids containing phosphate or bicarbonate to avoid precipitation.[85]

Nonemergency Treatment

After acute symptoms have been controlled, calcium therapy should be continued as needed to maintain a serum calcium concentration above 7.0 mg/dL. In part, the level of serum calcium to be achieved depends on serum total protein, particularly albumin. In hypoalbuminemic infants, lower levels of total serum calcium are normally present. The dose varies with age. In preterm and sick infants for whom oral intake is limited, 45 to 75 mg/kg elemental calcium gluconate may be infused with IV fluids in a 24-hour period. For older infants and children, a starting dose of 20 mg/kg elemental calcium gluconate every 24 hours should be provided. The lower dose range is preferred whenever there is hyperphosphatemia. If oral feedings are tolerated, a dose range of 50- to 150-mg/kg/day of elemental calcium gluconate in four to six divided doses should be given. Alternatively, calcium glubionate (Neo-Calglucon) may be given in a dosage of 30 to 50 mg/kg divided into feedings. Orally administered calcium gluconate is better tolerated by young infants because the high sugar content and osmolality of calcium glubionate may cause gastrointestinal irritation or diarrhea. IV or oral calcium supplements should be continued until the serum calcium level stabilizes.

Dietary factors and hypoparathyroidism are important in the pathogenesis of late neonatal hypocalcemia. Therefore therapy is often directed at reducing the phosphate load and increasing the calcium-to-phosphorus ratio of feedings to 4:1. This can be accomplished by using low-phosphorus feedings such as human milk or Similac PM 60/40 (Abbott Nutrition) in conjunction with calcium supplements. These interventions inhibit intestinal absorption of phosphorus. Phosphate binders are not generally necessary. Serum calcium and phosphorus levels should be monitored at least once to twice weekly, and the use of calcium supplements should be discontinued in a stepwise fashion after several weeks.

Magnesium Administration

When hypomagnesemia contributes to hypocalcemia, administration of magnesium salts is indicated. Magnesium may be given intramuscularly as a 50% magnesium sulfate solution (50% $MgSO_4 \cdot 7H_2O$ contains 4 mEq/mL magnesium). The suggested intramuscular or IV dose of 50% magnesium sulfate is 25 to 50 mg/kg. IV infusions should be administered slowly using electrocardiographic monitoring to detect rhythm disturbances, which may include prolonged atrioventricular conduction time and sinoatrial or atrioventricular block. The magnesium dose may be repeated every 12 to 24 hours, depending on the clinical and serum magnesium response. Many infants with transient hypomagnesemia will respond sufficiently to one or two magnesium injections. Infants with primary hypomagnesemia have permanent magnesium wasting. The low serum magnesium levels may require lifelong treatment with magnesium supplements.

Vitamin D Treatment

Infants with normal intestinal absorption who develop late hypocalcemia with vitamin D–deficiency rickets usually respond within 4 weeks to 1000 to 2000 IU/day oral vitamin D. These infants should receive at least 40 mg/kg/day of elemental calcium to prevent hypocalcemia because the unmineralized osteoid may avidly incorporate calcium once vitamin D is provided ("hungry bones" syndrome). PTH-dependent renal production of $1,25(OH)_2D$ is deficient in all hypoparathyroid states, renal failure, or vitamin D–dependent rickets. Vitamin D metabolites that do not require renal 1α-hydroxylation should be administered. Calcitriol ($1,25[OH]_2D$) is indicated, usually starting with 0.25 to 1 μg daily to twice a day. The dose may be adjusted at 2- to 4-week intervals. Most patients with hypoparathyroidism require lifelong calcium and vitamin D supplementation. The goals of therapy are to relieve symptoms and maintain the serum calcium level in the low normal range (e.g., 8.0 to 8.5 mg/dL [2.0 to 2.1 mmol/L]) to prevent hypercalciuria and nephrocalcinosis.[86] Assessment of urinary calcium excretion by urinary calcium-to-creatinine ratio should be performed within 2 weeks of initiation of therapy. The urinary calcium measurement reflects the effect of therapy and monitors the risk of nephrocalcinosis. The ratio of 0.2 mg/mg or greater usually defines hypercalciuria in older children, but the age-dependent 95th percentile can be as high as 0.7 mg/mg for infants.[87] Periodic renal sonograms are also recommended to detect nephrocalcinosis.

It is essential that patients with hypocalcemia be aware that their calcium level should be monitored more frequently during intercurrent illnesses that may affect calcium absorption to prevent the development of hypocalcemia or severe hypercalcemia.

Recombinant Parathyroid Hormone Analogue

Studies have suggested subcutaneous injections of recombinant PTH can be an alternative therapy for hypoparathyroidism. However, such treatment poses a number of challenges, particularly fluctuations in calcium levels. Further studies are needed to assess the long-term effects.[88]

Neonatal Hypercalcemia

Hypercalcemia is usually defined as total serum calcium concentration greater than 11.0 mg/dL and Ca^{2+} concentration greater than 5.0 mg/dL. Hypercalcemia in neonates may be asymptomatic if there are only mild elevations in calcium levels, but as calcium levels start to rise above 12.0 mg/dL, then symptoms may start to manifest themselves. These may include poor weight gain, poor feeding, weakness, constipation, and polyuria. As calcium levels increase (>14 mg/dL), more severe symptoms may present, such as vomiting, respiratory distress, apnea, hypotonia, lethargy, and seizures. The polyuria seen in hypercalcemic states is due to impairment in the kidney's concentration ability, leading to a state of nephrogenic diabetes insipidus.[89] This may be partly due to inhibition of sodium chloride reabsorption in the loop of Henle, which impairs the osmotic gradient needed for concentration, as well as decreased antidiuretic hormone–mediated water permeability in the collecting tubules.[90] Usually, there are no physical examination findings associated with hypercalcemia unless findings are associated with genetic syndrome dysmorphisms or SFN. Hypertension can be seen, most likely due to the effects of hypercalcemia on vasoconstriction as well as possible effects on catecholamine.[91] Shortened QT interval may also be seen on electrocardiogram.[92] When hypercalcemia is chronic, calcifications can be seen in multiple tissues and organs, including the kidney, skin, subcutaneous tissue, heart (valves, arteries, muscle), lung, brain, and gastric mucosa. Nephrocalcinosis, nephrolithiasis, and osteitis fibrosa cystica (loss of bone mass and replacement with fibrous tissue with formation of cystic lesions due to increased osteoclastic resorption) may also be seen in chronic, untreated hypercalcemia. In infants, the most clinically apparent manifestation of chronic hypercalcemia is poor growth and failure to thrive.

Neonatal hypercalcemia is associated with several clinical entities (Box 83.2). Normally calcium concentrations are tightly regulated by interplays between PTH, CaSR, calcitonin, and vitamin D analytes affecting intestinal and renal calcium absorption. Hypercalcemia may occur when there is a disruption in this system and can be due to multiple causes, which can be categorized on the basis of abnormalities of PTH, CaSR, intake, or other causes.

Neonatal Hyperparathyroid Syndromes Associated With CaSR Mutations

Inactivating mutations of CaSR can lead to a spectrum of hypercalcemic diseases from severe neonatal hyperparathyroidism (NSHPT) to mild presentations as seen in FHH. These mutations cause a shift in the dose-response curve for calcium to the right, so there is a higher setpoint for the CaSR, leading to higher serum calcium levels and an elevated or inappropriately normal PTH level. Urinary calcium-to-creatinine clearance ratios will usually be less than 0.01 (gray zone between 0.011 and 0.019), and there will often be a family history of hypercalcemia, although de novo mutations can be present. FHH is usually due to a heterozygous mutation, while NSHPT is due to a homozygous mutation; however, there have been cases of mild homozygous mutations leading to an FHH presentation and severe heterozygous mutation presenting more like NSHPT.[93–95]

FHH is an autosomal dominant disorder characterized by mild hypercalcemia, low renal excretion of calcium leading to hypocalciuria, and normal or mildly elevated PTH. Usually, FHH is asymptomatic with normal phosphorus, magnesium, vitamin D levels, and bone density. The presentation can be masked if there is concomitant vitamin D deficiency.[96] There are three types of FHH. FHH type 1 is the most common form and accounts for 65% of cases. It is due to a loss of function mutation of the *CaSR* gene on chromosome 3q21.1. Mutations lead to insensitivity of the receptor to serum calcium levels, causing a release of PTH from the parathyroid glands at higher serum calcium levels. This leads to hypercalcemia, hypocalciuria and high normal to elevated magnesium levels. More than 200 CaSR mutations have been reported.[94] FHH type 2 and type 3 account for the rest of the cases. FHH type 2 accounts for about 10% of FHH cases and is characterized by high-normal PTH and mildly elevated magnesium levels and is due to loss of function mutation of *GNA11* on chromosome 19p13.3. *GNA11* encodes the $G\alpha_{11}$ proteins, which are involved in CaSR signaling.[95,97] The mutation results in decreased CaSR-induced signal transduction and increased secretion of PTH.[94,98] FHH type 3 presents with elevated PTH, decreased phosphate, and osteomalacia. It is due to a loss of function mutation for *AP2S1* on chromosome 19q13.3, which affects the Arg15 residue.[94,99] *AP2S1* encodes for the adaptor-related protein complex 2, which is involved in the endocytosis of CaSR. Mutations result in decreased expression of CaSR at the cell membrane. FHH type 3 may have a more severe presentation with higher calcium levels. Mutations in *AP2S1* account for 20% of cases of FHH without *CaSR* mutations.[94] FHH generally does not require treatment unless there is evidence of symptoms or

• BOX 83.2 Causes of Neonatal Hypercalcemia

- Hyperparathyroidism
  - *CaSR* mutations
    - Neonatal severe hyperparathyroidism
    - Familial hypocalciuric hypercalcemia
  - Maternal hypocalcemia
  - Mucolipidosis type II
- Iatrogenic
  - Hypophosphatemia
  - Vitamin D intoxication
  - Calcium supplement excess
  - Hypervitaminosis A
  - Extracorporeal life support
- Hypercalcemia Associated With Skeletal Dysplasias
  - Infantile hypophosphatasia
  - Jansen metaphyseal chondrodysplasia (activating mutations of parathyroid hormone/parathyroid hormone–related protein receptor)
- Other Causes
  - Williams syndrome
  - Idiopathic infantile hypercalcemia
  - Subcutaneous fat necrosis
  - Blue diaper syndrome
  - Tumor-associated hypercalcemia (parathyroid hormone–related protein secretion)
  - Congenital lactase deficiency
  - Congenital sucrase-isomaltase deficiency
  - Immobilization

complications due to hypercalcemia. Parathyroid glands can be normal or hyperplastic, and surgical resection is usually not helpful. Therefore genetic testing can be very useful for both management and genetic counseling as parents who are carriers of *CaSR* mutations can have a child with NSHPT.

NSHPT is a rare autosomal recessive disorder resulting in a life-threatening disorder associated with elevated PTH, elevated serum calcium, elevated magnesium, and relatively low urinary excretion of calcium, although some may have hypercalciuria. It is diagnosed within the first 6 months of life, but severe forms will present as a critically ill newborn with symptoms of poor feeding, dehydration, lethargy, and respiratory distress. Respiratory distress can be due to hypotonia, rib cage deformities, and multiple fractures.[95] Elevated PTH may lead to bony changes, including demineralization, fractures, and rickets. Homozygous mutations of *CASR* usually lead to a more severe presentation and are inherited from parents who have FHH. Heterozygous gene mutations may have lower calcium levels and may be inherited from one parent or occur from a de novo mutation.[93,100] Typically, these patients have large, hyperplastic parathyroid glands that need to be surgically removed. However, prior to surgery, hypercalcemia needs to be medically managed. This includes the use of sodium-containing fluids and diuretics to induce sodium diuresis and therefore urine calcium excretion. Medications such as bisphosphonates and calcimimetics can decrease serum calcium as well. Pamidronate 0.5 to 1 mg/kg and cinacalcet 0.4 to 2 mg/kg/day have been used successfully in reported cases to decrease serum calcium levels as patients await total parathyroidectomy.[93,99]

Neonatal Hyperparathyroidism Not Associated With CaSR Mutations

Other forms of inherited hyperparathyroidism include those seen in syndromes such as multiple endocrine neoplasia (MEN) 1, MEN 2A, and hyperparathyroidism-jaw tumor syndrome, which typically present with hyperparathyroidism later in life.[94] Autosomal dominant forms of familial hypercalcemia have been associated with mutations in the following tumor suppressor genes: MEN1, HRPT2 (CDC73), CDKN1B, APC, SFRPs, GSK3β, RASSF1A, HIC1, RIZ1, WT1. Mutations of proto-oncogenes associated with autosomal dominant forms of familial hypercalcemia include CCND1/PRAD1, RET in MEN2, ZFX, CTNNB1, and EZH2.95.

Secondary neonatal hyperparathyroidism may also be seen as a consequence of maternal calcium-PTH abnormalities. Maternal hypocalcemia during pregnancy will lead to decreased placental transport of calcium, fetal hypocalcemia, and subsequent hyperplasia of the parathyroid glands. This condition is transient and normally resolves within the first few weeks of life. Hypercalcemia and hypophosphatemia are not seen universally in these cases, but bony changes secondary to elevated PTH are common.[101] Another condition that may lead to secondary hyperparathyroidism is mucolipidosis type II. These cases present with elevated PTH, normal calcium, bony changes and resolve with vitamin D and calcium supplementation. The etiology is hypothesized to be secondary to diminished transplacental calcium transport as this condition is associated with abnormalities of the placenta.[102]

A syndrome that has features of hyperparathyroidism but has low levels of PTH is Jansen metaphyseal chondrodysplasia. In this condition, mutations of PTHR1 lead to constitutive, ligand-independent activation of the receptor, causing hypercalcemia despite low serum PTH levels. These patients will also have irregularities of the metaphysis and rachitic changes seen on x-ray. Other distinguishing features include short-limbed dwarfism with postnatal growth failure, hypertelorism, and mandibular hypoplasia.[103,104]

Williams Syndrome and Idiopathic Infantile Hypercalcemia

Williams syndrome (WS) (or Williams-Beuren syndrome) is a genetic disorder due to the deletion of the Williams-Beuren syndrome critical region (WBSCR) of chromosome band 7q11.23, which includes the elastin gene *(ELN)*. The deletion can be detected by FISH or deletion/duplication testing. It is usually due to a de novo mutation but can be transmitted in an autosomal dominant fashion. It is characterized by distinctive facial features (broad forehead, stellate iris, short nose, broad nasal tip, malar flattening, long philtrum, wide mouth, small jaw, large earlobes), mild intellectual disability, a social personality, short stature, cardiovascular disease (elastin arteriopathy, peripheral pulmonary stenosis, supravalvular aortic stenosis, hypertension), hypotonia, joint hyperextensibility, and endocrine abnormalities (hypercalcemia, hypothyroidism, early puberty). In infancy, inguinal or umbilical hernias, hypotonia, poor feeding, failure to thrive, developmental delays, and rectal prolapse may also be present.[105]

About 30% of patients have hypercalciuria, and 15% to 45% have idiopathic hypercalcemia. The hypercalcemia is noted during infancy and typically resolves by 2 to 4 years of life, although rarely it can persist into adulthood. The cause of hypercalcemia is not well understood, but it is thought that there is increased gut absorption of calcium.[106] PTH level is normal or low, and there is no consistent pattern in vitamin D metabolism to explain the abnormality. Hypercalciuria is relatively common, and nephrocalcinosis has been reported.[107] Therefore early screening for hypercalcemia and hypercalciuria is warranted in infancy. The severity of the calcium abnormalities can range from mild to severe and can lead to dehydration, irritability, vomiting, constipation, and muscle cramps.[106] If hypercalcemia is present, the work-up should include serum blood urea nitrogen, creatinine, 25(OH)D, $1,25(OH)_2D$, PTH levels, and urine calcium/creatinine ratio. If hypercalciuria is present, renal ultrasounds will need to be monitored to evaluate for nephrocalcinosis. Treatment consists of limiting calcium and vitamin D intake and increasing fluid intake until the condition resolves.[106] More severe cases have also been treated with short courses of calcitonin, glucocorticoids, and pamidronate.[105,108]

A similar calcium profile seen in WS has been described in certain infants classified as idiopathic infantile hypercalcemia (IIH). These infants may present with failure to thrive, dehydration, and nephrocalcinosis with a biochemical profile of hypercalcemia, hypercalciuria, and suppressed PTH. Abnormal renal calcium deposition leads to a higher risk for nephrolithiasis and nephrocalcinosis.[109] They do not have the same clinical features or gene deletion as WS and can be differentiated from WS through genetic testing. In IIH, hypercalcemia can resolve in the first few years of life, although it may persist into adulthood, and treatment is similar to that of children with WS.[109,110] The cause of the hypercalcemia was a mystery for many years; however, mutations in two genes have been identified as causative, leading to differentiation into two forms of IIH.[109] IIH type 1 is inherited in an autosomal recessive manner and is due to mutations of *CYP24A1*, which encodes for the enzyme 25-hydroxyvitamin D 24-hydroxylase. This enzyme plays an important role in the metabolism and deactivation of $1,25(OH)_2D$. Mutations of the CYP24A1 gene can result in hypercalcemia in infants due

to decreased degradation of calcitriol ($1,25(OH)_2D$), leading to increased intestinal absorption of calcium and downregulation of PTH. Biochemically, this leads to hypercalcemia, hypercalciuria, suppressed PTH, increased intestinal calcium absorption, and elevated $1,25(OH)_2D$. An elevated 25-OHD/$24,25(OH)_2D$ ratio can also be seen.[95,109,111,112] Vitamin D supplementation leads to exaggerated increases of $1,25(OH)_2D$ levels and subsequent hypercalcemia. Therefore treatment is a limitation of vitamin D and calcium intake. If symptomatic hypercalcemia persists despite this intervention, then treatment with bisphosphonates, ketoconazole/fluconazole, or rifampin may be considered.[109] IIH type 2 is due to loss of function mutations of *SLC34A1*, which codes for the NaPi-IIa cotransporter. The condition has a similar biochemical profile to IIH type 1 but has a wasting of phosphate in the urine, leading to suppression of FGF23 and inappropriate synthesis of $1,25(OH)_2D$. The combination of hypercalcemia, hypercalciuria, and hyperphosphaturia leads to the development of kidney stones. Treatment for IIH type 2 includes phosphate supplementation to restore serum phosphate levels and normalize vitamin D and calcium metabolism. Molecular testing should be done for all patients suspected to have IIH.[109]

Neonatal Hypercalcemia Associated With Subcutaneous Fat Necrosis

SFN is a panniculitis that develops in term or postterm infants. Lesions are erythematous to violaceous, indurated subcutaneous nodules and plaques which appear in the first few days of life (mean 4 days) and are typically found on the back, head, and arms. The lesions may initially be painful and resolve within the first few months of life. Biopsy of the nodules shows granulomatous necrosis in the subcutis with crystal-like structures in adipocytes and giant cells. Risk factors for the development of SFN include birth trauma, asphyxia, meconium aspiration, infections, and cutaneous trauma. Maternal risk factors may include gestational diabetes, preeclampsia, cocaine or calcium blocker use during pregnancy, and high risk of thrombosis.[113] SFN has also been recognized as a complication of neuroprotective cooling with lesions occurring in areas in contact with the cooling blanket.[114]

Complications of SFN include mild to severe hypercalcemia, dyslipidemia, hypoglycemia, thrombocytopenia, anemia, and eosinophilia. Although usually asymptomatic, when symptoms are present, they are usually related to hypercalcemia (irritability, vomiting, polyuria, poor weight gain, hypotonia, hypertension, seizures, nephrocalcinosis, renal dysfunction).[115] Hypercalcemia may occur 1 to 2 months after delivery. Therefore infants with SFN should have calcium levels monitored regularly. In the majority of cases with hypercalcemia, the hypercalcemia presented less than 28 days after the appearance of skin lesions, although a minority can have hypercalcemia prior to the appearance of the lesions and >70 days after the lesions. The majority of patients have resolution of the hypercalcemia within the first 3 months of life, although some can persist longer.[115] Some of the hypercalcemia may be asymptomatic despite high levels of calcium.[113,116] Hypercalciuria is often present, and nephrocalcinosis may persist into early childhood but does not seem to result in adverse renal outcomes.[116] The etiology of hypercalcemia is not well understood, but there are a few theories. One thought is that there is uncontrolled production of $1,25(OH)_2D$ by activated macrophages that infiltrate the necrotic fat. This leads to increased intestinal absorption of calcium in the gut. Another is that elevated PTH and prostaglandin E increases bone resorption. Others hypothesize that calcium is mobilized from the resolving lesions, and another theory is that there is decreased calcium clearance by the kidneys due to early renal injury.[104,115,116] Body cooling may contribute to the presentation due to crystallization during hypothermia from the higher ratio of saturated to unsaturated fat in the skin of neonates.[115] It is recommended that infants with SFN lesions be screened for hypercalcemia at diagnosis of the lesions and again at 30, 45, and 60 days following resolution of the lesions or if a child develops symptoms of hypercalcemia.[115] Treatment includes hydration, furosemide, and a low-calcium/low vitamin D diet. However, SFN is also highly responsive to glucocorticoids. Severe, refractory cases have also been treated with bisphosphonates.[116]

Hypercalcemia Due to Iatrogenic Causes

Neonatal hypercalcemia may also be due to increased intake of calcium or vitamin D or decreased intake of phosphorus. Hypercalcemia due to phosphate depletion is most often seen in VLBW infants fed unsupplemented human milk, which is low in phosphorus, or given parenteral nutrition with inadequate phosphate. There is a high consumption of phosphorus by cells in growing newborns. If inadequate phosphorus is given, then phosphorus will be released through bone resorption, which in turn also releases calcium. This may also be associated with high alkaline phosphatase (ALP) levels. Low phosphorus will also stimulate increased renal production of $1,25(OH)_2D$ and increased calcium absorption through the gut.[117,118] The condition is preventable by anticipatory monitoring of serum calcium and phosphorus levels in high-risk infants.[119]

Excessive supplementation with vitamin D may cause neonatal hypercalcemia. The excess vitamin D may be from improperly made formula, ingestion of cow milk fortified with vitamin D, or overdose of vitamin D supplements. Infants respond to discontinuation of vitamin D supplements. These occurrences have prompted vitamin reformulation of preterm nutritional products. Laboratory studies in hypervitaminosis D typically show elevated 25(OH)D but not $1,25(OH)_2D$ and suppressed serum PTH.

Hypervitaminosis A due to renal failure or ingestion of a large amount of vitamin A has been associated with hypercalcemia. It is hypothesized that vitamin A inhibits osteoblasts and stimulates osteoclasts, leading to increased bone turnover.[120,121]

Hypercalcemia has also been reported in neonates undergoing extracorporeal life support (ECLS). The mechanism is not well understood. High PTH has been reported but does not seem to correlate well with the calcium and vitamin D levels. Hypercalcemia was associated with higher mortality and a longer duration of ECLS.[122,123]

Other Causes of Neonatal Hypercalcemia

Tumor-associated hypercalcemia in neonates is extremely rare. Congenital mesoblastic nephromas have been associated with hypercalcemia in infancy and may be due to tumor secretion of PTHrP.[124] Metabolic disorders, congenital lactase deficiency, and congenital sucrase-isomaltase deficiency are associated with hypercalcemia. They will also have symptoms of persistent diarrhea and failure to thrive. The hypercalcemia may be due to increased ileal absorption of calcium as well as effects of metabolic acidosis on the release of calcium from bone.[125,126] Immobility can also cause hypercalcemia due to increased bone turnover.[127]

Blue diaper syndrome is a rare familial disease in which hypercalcemia and nephrocalcinosis are associated with a defect in the intestinal transport of tryptophan.[128] Bacterial degradation of tryptophan in the intestine leads to excessive indole production, which is converted to indican in the liver. Oxidative conjugation of indican

in the urine forms the water-insoluble dye indigo blue (indigotin), with a consequent peculiar bluish discoloration of the diaper. The clinical course is characterized by failure to thrive, recurrent unexplained fever, infections, marked irritability, and constipation.

Hypophosphatasia is a rare autosomal recessive condition caused by loss of function mutations in the tissue nonspecific ALP gene *TNSALP*. Laboratory tests will show very low ALP levels. Depending on the age at diagnosis, six clinical forms are currently recognized: perinatal (lethal), perinatal benign, infantile, childhood, adult, and odontohypophosphatasia. Prominent features of the early-onset, severe forms are respiratory complications, increased intracranial pressure, widespread undermineralization, rickets, and hypercalcemia.[129] Recently developed enzyme replacement therapy with Asfotase Alfa has improved symptoms and prognosis for this condition.[130]

Treatment of Hypercalcemia

Treatment will depend on the cause and severity of hypercalcemia. If the hypercalcemia is mild to moderate, then restriction of calcium and vitamin D may be sufficient. In more severe cases, further steps must be taken. Part of the treatment is rehydration. Hydration with normal saline is recommended to help induce sodium diuresis and increase urine calcium excretion. Once adequate rehydration with adequate urine output has been established, a loop diuretic such as furosemide (1 mg/kg intravenously at 6- to 8-hour intervals) may be added as it inhibits calcium reabsorption. Hydrocortisone reduces calcium absorption in the intestine and can be given as 1 mg/kg every 6 hours. Calcitonin decreases skeletal reabsorption and inhibits renal reabsorption of calcium. Subcutaneous or intramuscular doses of 3 to 6 μg/kg every 6 hours can be given, but it is only effective for a few days as tachyphylaxis will occur. Bisphosphonates such as pamidronate have been used successfully in a number of conditions resulting in hypercalemia. These agents inhibit osteoclasts and bone resorption. Pamidronate doses of 0.5 to 2 mg/kg have been reported. A third-generation bisphosphonate, zolendronic acid, has also been used to treat hypercalcemia. This has been shown to decrease hypercalcemia more significantly, faster, and for longer duration than pamidronate. It should be used with caution in those with kidney disease. Neonatal dosing is 0.0125 mg/kg to 0.025 mg/kg every 3 months. Cinacalcet is a calcimimetic that works to make the CaSR more sensitive. It has been used in cases of CaSR mutations.

Neonatal Disorders of Serum Magnesium

Neonatal hypermagnesemia is usually due to maternal magnesium sulfate administration or postnatal excess administration of magnesium-containing products, including magnesium in neonatal parenteral nutrition solutions that exceeds magnesium clearance, use of magnesium hydroxide–containing antacids (e.g., milk of magnesia), or medication errors resulting in overadministration of magnesium. Magnesium inhibits acetylcholine release at neuromuscular junctions; therefore elevated levels will lead to symptoms of low tone in mild cases to paralysis in severe cases. The hypermagnesemic newborn may exhibit central nervous system depression (lethargy, hypotonia, poor suck ability), hyporeflexia, and hypotension in mild to moderate cases. Severe cases may result in muscle paralysis, hypoventilation, respiratory depression, coma, arrhythmias, complete heart block, and asystolic arrest. As hypermagnesemia decreases myocardial electrical conduction, cardiac features may include prolonged PR, QRS, and QT intervals, intraventricular conduction defects, bradycardia, and peaked T waves. Because of effects on increased bowel motility, increased fluid secretion and electrolyte abnormalities may be seen; however, delayed passage of meconium has also been reported.[131] In addition, hypocalcemia caused by inhibition of PTH by high levels of magnesium may also be seen. Treatment is mostly supportive as eventually the magnesium will be cleared by the kidney. Any administration of magnesium (oral or IV) should be discontinued. Regular monitoring for cardiac, respiratory, and electrolyte abnormalities should be done, and any abnormalities should be treated accordingly. Feedings should be deferred until normalization of bowel function occurs. Calcium infusions may be helpful in severe, symptomatic cases as calcium is an antagonist of magnesium. Hemodialysis may be considered in life-threatening situations in anuric patients.[132]

Metabolic Bone Disease in Newborns and Infants

MBD is characterized by the reduction in the mineral content and protein matrix of bone, frequently presenting with rachitic changes. MBD is especially common in premature infants and has been referred to as *osteopenia* and *rickets of prematurity*. The forms of MBD manifesting themselves in infants and children are listed in Box 83.3.

The following are terms commonly used in describing MBD:

- *Osteopenia* is generally defined as diminished bone mineral density secondary to a reduction in the thickness of bone cortex and trabeculae.

• BOX 83.3 Forms of Metabolic Bone Disease Manifesting Themselves in Newborns and Infants

Phosphate Deficiency
- Osteopathy of prematurity
- X-linked hypophosphatemic rickets
- Fanconi syndrome
- Antacid-induced osteopathy (aluminum hydroxide)
- Tumor (including hemangioma)-associated rickets

Calcium Deficiency
- Osteopathy of prematurity
- Inadequate intake of dietary calcium after weaning
- Inadequate calcium in total parenteral nutrition solution

Vitamin D Deficiency
- Maternal vitamin D deficiency (congenital rickets)
- Inadequate intake of dietary vitamin D
- Lack of adequate sunlight exposure and dietary inadequacy

Vitamin D Malabsorption
- Hepatic disease (steatorrhea)
- Short bowel syndrome
- Pancreatic insufficiency

Vitamin D Metabolic Defects
- Vitamin D 25-hydroxylation defect
- 1α-Hydroxylase deficiency
- Renal insufficiency (renal osteodystrophy)
- Anticonvulsants (increased 25(OH)D metabolism)

Vitamin D Receptor Defects
- Hereditary vitamin D resistance

Genetic/Syndromic Causes
- Osteogenesis imperfecta
- Hypophosphatasia
- Osteopetrosis

- *Osteoporosis* is defined in pediatrics as a reduction in bone mineral density with clinically significant fractures.[133] Unlike in rickets and osteomalacia, in which mineralization defects predominate, the primary abnormality in osteoporosis is either a decrease in matrix formation or an increase in matrix and mineral resorption.
- *Rickets* results from undermineralization of the bone matrix, or osteoid, in growing bone at the growth plate (physis). *Osteomalacia* is the undermineralization of established trabecular and cortical bone. Growing children can have rickets and osteomalacia concurrently; however, osteomalacia occurs after the growth plates have fused. In infancy, the most rapidly growing bones are the skull, upper limbs, and ribs. Therefore early development of rickets leads to craniotabes, characterized by softening of the skull with the "ping-pong ball" sign; widened cranial sutures; frontal bossing; swollen epiphyses of wrists; costochondral beading manifesting itself as a "rachitic rosary"; and Harrison sulcus, which is caused by diaphragmatic depression of the lower thorax on inspiration. Manifestations of muscle weakness may include dilated cardiomyopathy and ventricular dysfunction, which may respond to vitamin D therapy.[134,135] Radiographic features in rickets result from an expansion of the cartilaginous growth plate and delayed mineralization. They include lucency and widening of the gap between metaphysis and epiphysis, known as the *zone of provisional calcification*, as well as irregularity, cupping, or fraying of the metaphyseal margin. Serum phosphorus or calcium level or both are characteristically depressed, and serum ALP level is elevated. An exception is in the hyperphosphatemia of renal osteodystrophy.

Metabolic Bone Disease of Prematurity

MBD of prematurity is caused chiefly by deficiencies in dietary phosphate and calcium. Eighty percent of bone mineralization in the fetus occurs during the third trimester,[136,137] when fetal calcium and phosphorus requirements are 100 to 130 mg/kg/day and 60 to 75 mg/kg/day, respectively.

Preterm infants miss this critical period of in utero bone development and need fortified breastmilk or fortified formulas as standard infant formulas do not meet the needs for bone mineralization of preterm infants. Nevertheless, despite this improved nutritional practice, 10% to 20% of infants with birthweight <1000 g have radiographic evidence of rickets.[138] Intestinal immaturity of pre-term infants can limit the absorption of calcium and phosphorus from the diet. Many of these infants require prolonged parenteral nutrition, which may be limited in calcium and phosphate content.[139,140]

Additional, nonnutritional risk factors for MBD in ill preterm infants include the early withdrawal of placental estradiol and progesterone, lack of mobility, necrotizing enterocolitis, and therapy with a variety of medications, including dexamethasone, loop diuretics, and methylxanthines (Box 83.4), which can increase urinary calcium excretion and contribute to serum mineral imbalance, nephrocalcinosis, and osteopenia.[140] Glucocorticoids decrease bone formation by inhibiting osteoblast growth and increasing cell death of osteoblasts and osteocytes and, at least over several months, increasing osteoclastogenesis and bone resorption. Copper deficiency is a rare contributor to osteopenia in low birthweight preterm infants.[141]

• BOX 83.4 Medications Associated With Metabolic Bone Disease in Preterm Infants

Glucocorticoids
Furosemide/loop diuretics
Methylxanthines
Anticonvulsants: phenytoin and phenobarbital
Antacids: proton pump inhibitors and H_2 blockers
Anticoagulants
Cyclosporine

In preterm infants, osteopenia with or without rachitic changes at the cartilage-shaft junction usually appears between 6 and 16 weeks of age. Fractures of the ribs and long bones are reported in 10% of preterm infants, frequently presenting with pain on handling.[142] The incidence and severity increase with decreasing gestational age and birthweight, and they are more common in preterm infants with a complicated medical course and delayed nutrition. In VLBW babies, postnatal bone mineralization significantly lags behind the expected intrauterine bone mineralization rate. Gestational age and birthweight are the strongest risk factors for MBD.

Clinical Presentation

The clinical findings in VLBW infants with severe osteopathy, as in older, term infants with rickets, include a widened anterior fontanel, craniotabes, bony expansion of wrists, costochondral beading, and rib or long-bone fractures. Rib undermineralization, softening, and fractures can lead to respiratory distress (especially tachypnea), atelectasis, or pneumonia. Long-term effects of osteopathy of prematurity may include reduced height[143] and bone mineral density in adulthood,[144] although other studies have shown more contradictory results.

Pathophysiology

Phosphate depletion and osteopathy occur in rapidly growing preterm infants fed unsupplemented human milk, which has low phosphate content. Characteristically, these infants develop hypophosphatemia, hypophosphaturia, hypercalcemia, and hypercalciuria. Serum PTH level may be low or normal, 25(OH)D level is normal, and $1,25(OH)_2D$ level is elevated. The hypophosphatemia stimulates the production of $1,25(OH)_2D$, which in turn increases intestinal calcium absorption. However, in the presence of hypophosphatemia, only limited amounts of calcium can be deposited in bone, leading to hypercalcemia and hypercalciuria. The hypercalcemia inhibits PTH secretion.

MBD of prematurity does not respond to vitamin D therapy unless vitamin D deficiency also is present. Vitamin D supplementation without prior correction of the underlying dietary phosphate deficiency may aggravate hypercalcemia and hypercalciuria by enhancing intestinal calcium absorption. The bone disease in these infants responds to increased dietary phosphate, accomplished by the addition of a human milk supplement designed for preterm infants or by the switching to a preterm milk formula; both diets provide additional calcium and phosphorus. The recommendations for enteral nutrition for VLBW infants for phosphate and calcium range from 75 to 140 mg/kg/day and from 150 to 220 mg/kg/day, respectively.[138] The addition of 10 to 20 mg/kg/day of elemental phosphorus may also be required to replete deficient serum phosphorus levels. However, because phosphate

repletion promotes bone mineralization, serum calcium levels may fall to subnormal levels ("hungry bones" syndrome) unless supplemental calcium (e.g., 20 to 60 mg/kg/day elemental calcium) also is provided. The recommended intakes of calcium and phosphorus[145] have benefits of improved bone growth, less severe dolichocephaly, and avoidance of fractures. For infants with a history of osteopathy of prematurity, it is important that after hospital discharge, a mineral-enriched diet and serial laboratory monitoring be maintained for several weeks to months.

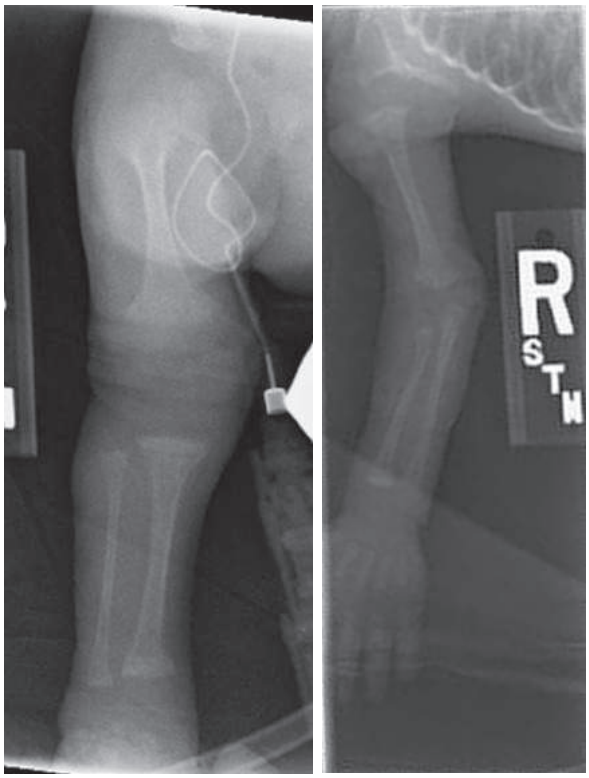
Most often, neither hyperparathyroidism nor vitamin D deficiency is present in phosphate-deficient osteopathy of prematurity. In contrast, the pathogenesis of calcium-deficiency rickets and vitamin D deficiency is similar in that hypocalcemia causes hyperparathyroidism. The elevated PTH level increases bone resorption and enhances renal $1,25(OH)_2D$ synthesis, increasing intestinal calcium and phosphorus absorption. Individual preterm babies may have predominant phosphate depletion, but mixed phosphate and calcium deficiency is more common; isolated calcium deficiency is rare. In dual-mineral deficiency, laboratory tests may show low, normal, or slightly elevated serum calcium levels and low to low-normal phosphorus levels. In cases of severe or complicated bone disease, serum 25(OH)D is a useful screen for evaluation of the sufficiency of vitamin D stores; levels less than 6 ng/mL indicate *severe* vitamin D deficiency, and levels of at least 20 ng/mL are required for sufficiency.[146]

For evaluation of bone mineral status in preterm neonates, measurement of cortical bone thickness and visual inspection of the proximal part of the humerus on a chest radiograph are a common screen for bone disease. Additional images may be required to fully assess the neonate for MBD (Fig. 83.2). However, the appearance of "osteopenia" may not be appreciated on plain film until a 20% to 40% decrease in mineralization is reached.[147] For that reason, assessment of bone mineral content by dual x-ray absorptiometry (DXA) may be used for its accuracy, reproducibility, and low radiation exposure. Normative data remain somewhat limited in preterm and former preterm infants, decreasing DXA's utility.[138] Longitudinal quantitative ultrasound measurement of the speed of sound in long bones, combined with measurement of serum bone markers, is a promising assessment tool[148] although not one commonly used clinically at this time. The use of quantitative computed tomography to assess true volumetric bone density is limited by its significantly higher radiation exposure and lack of normative data in infants.

Evaluation

Serum ALP, a marker of osteoblastic bone formation, is frequently used to monitor skeletal metabolism in preterm infants. However, the magnitude of elevations in ALP concentrations is not a good predictor of the extent of bone mineral deficits. As elevations of ALP concentrations and clinical MBD are rare in the first 4 weeks of life, the American Academy of Pediatrics Committee on Nutrition recommends ALP and serum phosphorus concentrations be measured at 4 to 6 weeks after birth in VLBW infants and biweekly thereafter. The ALP concentration usually peaks at 400 to 800 IU/L and then decreases in VLBW infants who do not develop MBD.[138]

The use of PTH has been suggested as an early marker of MBD in preterm infants.[149] Moreira et al. reported that a PTH level greater than 180 mg/dL at 3 weeks' chronologic age should alert clinicians to the possibility of MBD. Serial urinary biomarkers of bone metabolism (e.g., pyridinoline, deoxypyridinoline) have not yet been shown to be useful in predicting severe osteopathy because the levels are related to bone volume and normative data for growing preterm infants are lacking.



• **Fig. 83.2** The long bones in this 6-week-old ex-26-week infant demonstrate severe generalized osteopenia. The zones of provisional calcification are frayed and very irregular. The metaphyses are irregular, showing cupping and fraying, particularly prominent at the knees and distal part of the femurs.

Vitamin D–Deficiency Rickets

Vitamin D–deficiency rickets most often occurs in exclusively breastfed infants who also have little exposure to sunlight and are dark skinned. Unfortified human milk has a vitamin D activity ranging from 5 to 80 IU/L,[150–152] which may be insufficient for maintaining normal 25(OH)D levels in infants. Historically, a marked rise in the prevalence of nutritional rickets has accompanied industrialization and urban crowding. Clinical rickets often manifests itself at 3 months of age or later, but onset in early infancy is not uncommon. In developed countries, nutritional rickets has never been eradicated, and there is a resurgence of vitamin D deficiency in North America and Europe.[153] Maternal vitamin D deficiency during pregnancy and lactation puts the newborn at high risk. The deleterious effects of vitamin D deficiency in the mother may impact the musculoskeletal health of the offspring into adolescence.[154]

The 2008 American Academy of Pediatrics statement on prevention of rickets and vitamin D deficiency[155] doubles the previous American Academy of Pediatrics vitamin D intake recommendation. These guidelines state that breastfed and partially breastfed infants should receive supplementation with 400 IU vitamin D per day beginning in the first few days of life. All infant formulas available in the United States must contain

at least 400 IU/L vitamin D. Consequently, the guidelines also state all nonbreastfed infants who are ingesting less than 1 L of formula per day should receive a vitamin D supplement of 400 IU/day. In 2013 the American Academy of Pediatrics Committee on Nutrition recommended that VLBW infants receive 200 to 400 IU vitamin D per day. This can be increased to 400 IU/day when the weight exceeds 1500 to 2000 g, and the infant is tolerating full enteral nutrition.[138] European guidelines suggest higher intakes of vitamin D of 800 to 1000 IU/day may be used for VLBW infants.[156]

Higher doses of vitamin D may be necessary for infants with fat malabsorption or those taking anticonvulsant medications. Vitamin D status should be assessed using 25(OH)D and PTH concentrations and measures of bone mineral status.[155] Stoss therapy, which occasionally is used to treat rickets, consists of a single large oral or intramuscular dose (150,000 to 300,000 IU) of vitamin D.[157]

Nutritional rickets worldwide is due to degrees of vitamin D deficiency and calcium deficiency. Although vitamin D deficiency is thought to be the most common cause of nutritional rickets worldwide, calcium deficiency is the major cause of rickets in developing countries where dairy product consumption is low and is also recognized in other parts of the world.[158,159] In tropical populations, rickets may occur later than at higher latitudes, between 1 and 2 years of age, after weaning, and with the introduction of a low-calcium diet. One study showed, for example, that in Turkey, most rachitic children had vitamin D deficiency, whereas in Egypt, they mainly had calcium insufficiency combined with vitamin D deficiency.[160] It is likely that relative deficiencies of calcium and vitamin D interact with genetic (e.g., VDR genotypes) and/or environmental factors to stimulate the development of rickets. An international consensus statement provides guidelines for the prevention, diagnosis, and treatment of nutritional rickets due to both calcium and vitamin D deficiency.[158]

Congenital rickets, defined as biochemical and radiographic signs of rickets within the first 4 weeks of life, should always prompt an investigation for maternal vitamin D deficiency. Mothers of babies with congenital rickets typically have not taken supplemental vitamin D and are thus at risk for osteomalacia, severe vitamin D deficiency, and hypocalcemia.[158]

Renal Osteodystrophy

Because normal renal function is essential for physiologic mineral and bone metabolism, renal insufficiency induces hyperphosphatemia and bone disease. Renal osteodystrophy can be predominantly high or low bone turnover, or the two types may alternate during the clinical course in an individual infant.[161] High bone turnover or osteitis fibrosa is a manifestation of secondary hyperparathyroidism. Parathyroid hyperfunction often occurs early in the course of renal failure. Contributing factors include phosphate retention, impaired renal $1,25(OH)_2D$ synthesis, hypocalcemia, parathyroid gland hyperplasia, and skeletal resistance to PTH actions. Low-turnover osteodystrophy (adynamic bone or osteomalacia) results from a suppressed bone formation and is a major concern in the treatment of dialyzed infants.

A principal goal of therapy is to lower serum phosphate levels to prevent hypocalcemia and severe hyperparathyroidism.[162] Phosphate restriction is accomplished by the feeding of breast milk or Similac PM 60/40. Oral phosphate binders such as calcium carbonate or sevelamer may be needed to reduce the intestinal absorption of phosphate. Hypocalcemia and metabolic acidosis should be treated with appropriate supplements. If serum $1,25(OH)_2D$ level is low, $1,25(OH)_2D$ therapy will increase intestinal calcium absorption, transcriptionally suppress PTH gene expression, and decrease parathyroid hyperplasia. Serum calcium, phosphorus, and PTH levels, as well as linear growth and bone radiographs, should be serially monitored.[163] Management of severe renal osteodystrophy in neonates is particularly complicated by increased phosphate requirements for growth. Calcium supplementation and use of potent vitamin D metabolites may also produce an "oversuppression" of PTH, contributing to adynamic bone disease. As with any complex disorder, effective clinical management requires close monitoring and an integrated team approach.

Inherited Metabolic Bone Disease in Infancy

Several forms of inherited MBD or rickets have been described that can present in newborns and infants. Vitamin D–dependent rickets, type 1A (VDDR-1A), is the most prevalent form of hereditary vitamin D resistant rickets. It is caused by an autosomal recessive loss of function mutation in the gene encoding 25(OH)D 1α-hydroxylase *(CYP27B1)*[164] and is associated with the defective conversion of 25(OH)D to $1,25(OH)_2D$. Muscle weakness with severe hypocalcemia and secondary hyperparathyroidism appear shortly after birth, and rickets presents within the first year of life. Intrauterine development is not impacted as normal maternal calcium and $1,25(OH)_2D$ levels provide a sufficient calcium supply. Patients with this condition tend to have undetectable $1,25(OH)_2D$ levels. Treatment with 1α-hydroxylated vitamin D analogs induces remission.

Vitamin D–dependent rickets, type 1B (VDDR-1B) is a rare disorder with a milder phenotype than VDDR-1A. It is caused by a recessive loss of function mutation in the CYPR1 gene encoding 25-hydroxylase. This presents later in childhood (between 2 and 7 years of age) with rickets and low $25\text{-}(OH)D_3$ despite normal vitamin D intake.[164] Preparations containing $25\text{-}(OH)D_3$ (calcidiol and calcifediol) are considered the therapeutic option of choice for VDDR-1B.

Hereditary resistance to vitamin D, formerly known as *vitamin D–dependent rickets type 2*, is caused by mutations in the VDR gene. This mutation leads to end-organ resistance to $1,25(OH)_2D$. Affected infants show early-onset rickets, hypocalcemia, elevated serum $1,25(OH)_2D$ levels, secondary hyperparathyroidism, and alopecia. Depending on the genotype, there is a variable response to supraphysiologic doses of $1,25(OH)_2D$ analogues and calcium.[165]

X-linked dominant hypophosphatemia (XLH), also known as *familial hypophosphatemic rickets*, is a disorder of phosphate homeostasis.[166] Its prevalence is 1 in 20,000. XLH is characterized by hypophosphatemia, rickets, and poor linear growth and is associated with an FGF23 mediated low tubular maximum reabsorption of phosphate (TmP) and renal tubular phosphate leak. Defective regulation of vitamin D metabolism results in inappropriately normal $1,25(OH)_2D$ concentrations in the face of hypophosphatemia. XLH is caused by mutations in the phosphate-regulating endopeptidase homolog, X-linked gene *(PHEX)*. Standard treatment consists of supplemental phosphate and calcitriol, with the goal of normalizing the ALP level, keeping the PTH level normal, maximizing linear growth, and reducing rachitic changes. More recently, burosumab, a fully human monoclonal antibody against

FGF23, has been approved for management of XLH in patients ages 6 months and older.[167]

There is a similar condition of autosomal dominant hypophosphatemic rickets caused by an activating mutation in the FGF23 gene *(FGF23)* on chromosome band 12p13. Treatment is similar to that for XLH with phosphate and calcitriol. Autosomal recessive hypophosphatemic rickets type 1 and autosomal recessive hypophosphatemic rickets type 2 are caused, respectively, by mutations in the dentin matrix acidic phosphoprotein 1 gene *(DMP1)* and the ectonucleotide pyrophosphatase/phosphodiesterase 1 gene *(ENPP1)*, which interfere with bone mineralization and renal phosphate handling.[166]

OI is a heterogeneous group of disorders that cause various degrees of bone fragility and skeletal deformity.[168] OI was originally identified as an autosomal dominantly inherited abnormality of type I collagen due to mutations of *COL1A1* and *COL1A2*. Four primary types were initially described. However, in the past several years, several other types have been identified, most of which have an autosomal recessive inheritance. The most severe forms present with fractures at or shortly after birth. The affected babies may also have deformities of long bones, osteopenia of the skull, and early death due to respiratory deficiency. Administration of a bisphosphonate such as pamidronate may help reduce bone fractures and bone pain.

Hypophosphatasia is characterized by defective bone mineralization secondary to deficiency of the tissue-nonspecific isoenzyme of ALP. It is caused by a mutation of the *ALPL* gene on chromosome band 1p36. Perinatal lethal, infantile, childhood, and adult-onset forms have all been described, with the most severe forms being the perinatal and infantile forms. Clinical manifestations in infants include osteomalacia and rickets with respiratory insufficiency due to progressive chest deformity. Hypercalcemia and hyperphosphatemia can be seen in severely affected infants. Enzyme replacement with recombinant ALP can improve survival, skeletal findings, and pulmonary and overall physical function in infants with the perinatal and infantile forms of hypophosphatasia.[169]

Neonatal bone fragility with increased bone density rather than osteopenia can occur in infantile osteopetrosis, a rare autosomal recessive disorder of osteoclast formation. Children may present with failure to thrive, skull abnormalities including frontal bossing, rachitic changes, hypocalcemia, and delayed dentition. This condition is usually fatal within the first 10 years of life unless treated with hematopoietic stem cell transplantation.[170]

Disorders of the Adrenal Gland

PATRICIA Y. FECHNER

KEY POINTS

- Infants born with ambiguous genitalia or nonpalpable testes need to be evaluated for congenital adrenal hyperplasia as it can be life threatening.
- Adrenal steroid levels vary with gestational age.
- Adrenal insufficiency should be treated with hydrocortisone to avoid adrenal crisis. High doses of hydrocortisone contain mineralocorticoid activity.

The Adrenal Gland

Embryology

Normal adrenal function is critically important for maintenance of intrauterine homeostasis, promotion of organ maturation, and adaptation to extrauterine life. The dual embryologic origin of the human adrenal gland results in an outer adrenal cortex and an inner adrenal medulla; each part secretes different vital hormones critical to fetal development. Embryologically, the adrenal cortex develops from the coelomic mesoderm of the urogenital ridge, whereas the medulla arises from neural crest tissue in the adjacent sympathetic ganglion at celiac plexus level. During the fifth week of fetal development, mesothelial cells from the posterior abdominal wall between the root of the bowel mesentery and developing mesonephros proliferate and form the primitive adrenal cortex. In the sixth week, a second wave of mesothelial cells surrounds the primitive cortex and later forms the adult or definitive cortex. By 8 weeks of gestation, the cortical mass separates from the rest of mesothelial tissue and becomes surrounded by connective tissue.[1] This separation divides adrenocortical and gonadal primordium.[2] Chromaffin cells, which originate from neural crest, migrate toward the adrenal cortex around this time and gradually invade the medial aspect of the cortical tissue along its central vein to gain central position, forming the adrenal medulla. Fig. 84.1 summarizes the embryologic origin of the adrenal gland.[3] By 8 to 9 weeks of gestation, the adrenal gland is encapsulated and contains an outer "definitive" zone where glucocorticoids and mineralocorticoids are synthesized and a larger inner "fetal" zone where dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) are produced and then subsequently converted to estriol by the placenta.

Postnatally, the fetal or primitive zone of the adrenal gland rapidly involutes to disappear by approximately 6 months of age.[4] Zonation of the cortex, zona glomerulosa, and fasciculata is present at birth, but full differentiation into three separate zones occurs much later at approximately 3 years of age when zona reticularis development takes place.[5] Fig. 84.2 depicts these changes in the adrenal gland from 9 weeks of gestation through childhood.

Morphology

The adrenal glands are bilateral structures located above the kidneys in the retroperitoneum area. At birth, the adrenals are approximately one-third the size of neonatal kidneys, weighing 8 to 9 g, and are 10- to 20-fold larger than the adult glands relative to body weight (0.4% vs. 0.01%).[6] In the third trimester and the first 3 months after birth, the glands predominantly consist of cortex, where active production of glucocorticoids, steroid precursors, estrogens, and progesterone takes place. Ultrasonographically, the neonatal adrenal gland characteristically has a thin reflective core surrounded by a thick transonic zone. The gland subsequently decreases in size as the active fetal cortex regresses to reach approximately 8% of the kidney size in adulthood.[5]

Histologically, the fetal adrenal cortex consists of a small outer definitive zone, which appears to produce few adrenal steroid hormones until late gestation, and a larger inner fetal zone that produces adrenal steroid hormones throughout gestation. In addition, there is a transitional zone where cortisol production takes place toward the end of fetal development.[2] At birth, the large fetal zone of the fetal adrenal involutes and disappears by 6 months of age. Concurrently, the definitive zone together with the transitional zone develops into the fully differentiated zona glomerulosa and fasciculata by the age of 3 years. The zona reticularis begins to develop only after 4 years of age and may not be fully differentiated before the age of 15 years. In an adult adrenal gland, these three distinctive zones lie adjacent to one another. The zona glomerulosa is located immediately below the capsule, the zona fasciculata is in the middle, and the zona reticularis is the innermost zone next to the medulla.

Adrenal Functions

A cascade of adrenal steroidogenesis in the adult is shown in Fig. 84.3. Three major pathways of mineralocorticoid, glucocorticoid, and androgen synthesis take place mainly in the glomerulosa, fasciculata, and reticularis zones of the cortex, respectively. Aldosterone is the main mineralocorticoid regulating sodium and fluid volume homeostasis. Aldosterone is under the control of the rennin–angiotensin system and blood potassium concentrations.[7] The principal glucocorticoid in humans is cortisol and has a wide range of roles in regulating body functions, from carbohydrate metabolism, immune system, and acute and chronic stress

Philadelphia: Elsevier; 2016: 489–555.)

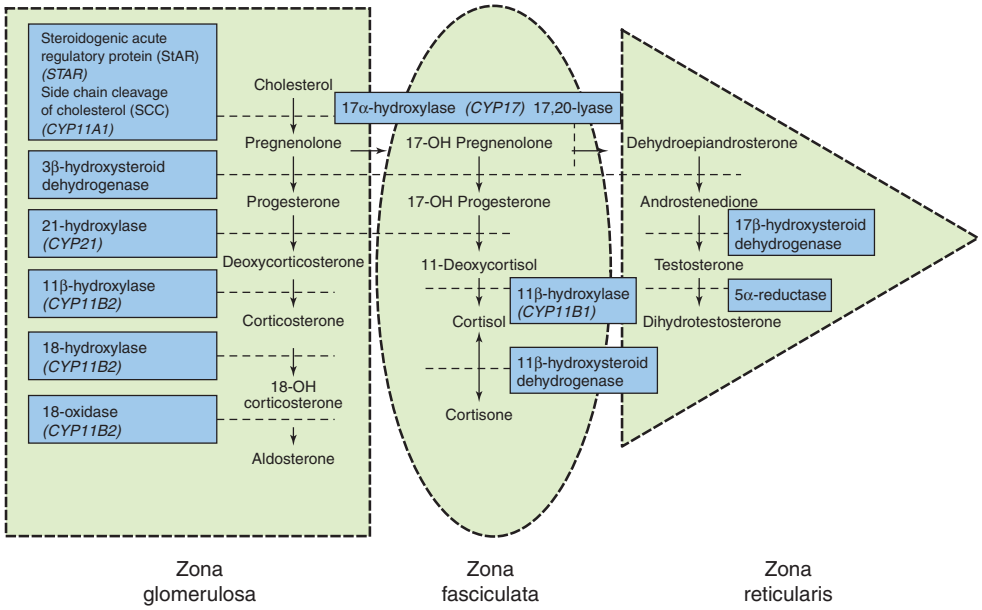
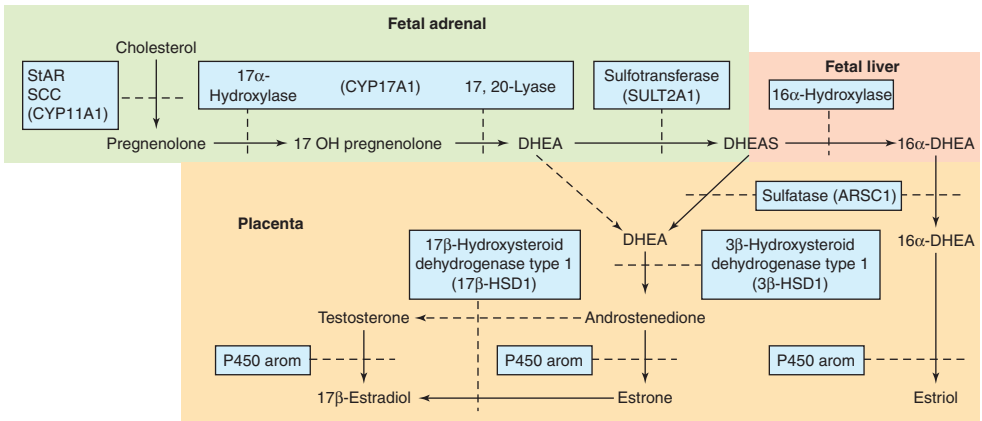
response to musculoskeletal metabolism. Cortisol production is regulated through a negative feedback loop involving hypothalamic corticotropin-releasing hormone (CRH) and pituitary adrenocorticotropic hormone (ACTH).[8] Adrenal androgens have an age-specific secretion profile with an increase at adrenarche, which occurs 2 years before the time of puberty, and then a gradual decrease with aging until andropause.[9] The regulatory mechanism behind normal adrenal androgen production is largely unknown but involves ACTH to some extent.[10]

In the fetal adrenal gland, steroidogenic enzymes are found as early as 7 weeks' gestation.[10,11] At 8 weeks' gestation, the fetal adrenal gland produces cortisol under ACTH control. A transient expression of 3β-hydroxysteroid dehydrogenase type 2 (3β-HSD2) during this critical time from 7 to 12 weeks' gestation allows the fetal adrenal gland to produce cortisol. Activation of 3-HSD2 serves principally to prevent virilization of the female genital anlage that would otherwise result from overwhelming amounts of DHEAS and its downstream androgen metabolites. It is believed that a transient peak of cortisol during this time suppresses the fetal hypothalamic–pituitary–adrenal (HPA) axis, keeping DHEAS production at a low level.[11,12] By the end of the first trimester, cortisol secretion from the fetal adrenal gland begins to wane as a result of a decrease in 3β-HSD2 expression, thus decreasing HPA axis suppression with resultant increased DHEAS secretion. During the second and third trimesters, the fetal adrenal gland secretes abundant amounts of DHEA and its sulfated derivative DHEAS, earning the term *androgen factory*.[4] The rate of steroid secretion by the fetal adrenal glands may be fivefold that of the adult adrenal glands at rest.[13] The placenta can also convert DHEAS back to DHEA by a sulfatase enzyme (i.e., arylsulfatase). These adrenal steroids serve as precursors for 17,20 lyase activity of the P450C17 enzyme for androgen production and subsequent estrogen production (Fig. 84.4). In addition, DHEAS is oxidized in the fetal liver to a 16α-hydroxylated derivative, which



• **Fig. 84.3** Steroidogenesis of the Adult Adrenal Gland. Each of the three biosynthetic pathways takes place in different zones: aldosterone biosynthesis in the zona glomerulosa, cortisol biosynthesis in the zona fasciculata, and androgen production in the zona reticularis. The enzymes that catalyze the reactions are indicated in *boxes*.



• **Fig. 84.4** Steroidogenesis of the Fetal Adrenal Gland and Fetoplacental Unit. Predominant dehydroepiandrosterone and dehydroepiandrosterone sulfate production occurs after 12 weeks' gestation. *DHEA*, Dehydroepiandrosterone; *DHEAS*, dehydroepiandrosterone sulfate; *SCC*, side chain cleavage of cholesterol; *StAR*, steroidogenic acute regulatory protein.

is converted by the placenta to estriol by the same set of enzymes as in estradiol synthesis.

The physiology of human pregnancy involves a continuous supply of relatively increased amount of estrogens. In near-term human pregnancy, the rate of estrogen production increases strikingly, reaching concentrations 1000-fold greater than that of nonpregnant women.[13] During early gestation, the estradiol required to maintain pregnancy is provided by the corpus luteum of the maternal ovary. But after 8 weeks' gestation, the fetoplacental unit synthesizes most of the estradiol required to maintain pregnancy.[14]

DHEAS is the main steroid secreted by the fetal adrenal cortex from mid-gestation onward. The activity of 3β-HSD2 controls fetal cortisol synthesis. By the end of pregnancy, fetal cortisol is required in preparation for parturition (i.e., lung maturation or surfactant production) and could have a role in triggering parturition, as shown in other species.[15] Maternal cortisol cannot normally reach the fetus because it is oxidized to cortisone, an inactive steroid, by placental 11β-hydroxysteroid dehydrogenase type 2.[16] When pregnancy approaches term, 3β-HSD2 expression increases again and remains high, allowing increased cortisol secretion. In a child, 3β-HSD2 secretion is high in the adrenal gland until adrenarche, when 3β-HSD2 activity decreases again to allow an increase in DHEA[17] and its downstream androgen metabolite secretion, which gives rise to the development of pubic and axillary hair.

Control of Glucocorticoid and Mineralocorticoid Production

Two distinct regulatory circuits control adrenal glucocorticoid and mineralocorticoid secretion. The HPA axis determines the set point for circulating glucocorticoid (cortisol) concentration. The neuropeptide CRH (or factor) and arginine vasopressin (AVP) are synthesized in the hypothalamic paraventricular nucleus and released into the hypophysial portal circulation at the median eminence in response to stress[18] and, beginning at approximately 6 months of age, to circadian cues.[19] These neuropeptides stimulate the release of ACTH from the anterior pituitary corticotrophs. CRH is the primary stimulator of ACTH, while AVP amplifies the effect of CRH. ACTH released into the systemic circulation augments adrenocortical secretion of cortisol and DHEA by acting on the ACTH receptor,[20] a member of the melanocortin receptor family. The ACTH receptor is present on steroidogenic cells of the fetal zone and transitional zone of the fetal adrenal as well as the adult adrenal cortex. The resulting increase in plasma cortisol concentration limits further the release of hypothalamic neuropeptides and ACTH by negative feedback through glucocorticoid receptors at the central nervous system and pituitary sites. As a corollary, if glucocorticoid production is impaired by intrinsic adrenal dysfunction, then neuropeptide CRH and ACTH release are augmented.

The components of the HPA axis are present early in human development.[2] As detailed earlier, the fetal adrenal gland begins to develop at 4 weeks' gestation, when initial evagination of the pituitary primordium occurs.[21] ACTH-producing pituitary cells can be detected at 7 weeks' gestation, and an intact hypophysial portal vascular system is present by 12 weeks' gestation.[22,23] Nerve terminals containing CRH can be detected in the hypothalamus by approximately 16 weeks' gestation. Virilization caused by increased production of adrenal androgens in females with congenital adrenal hyperplasia (CAH) occurs before 12 weeks' gestation; therefore, ACTH-producing corticotrophs must undergo cortisol-mediated feedback modulation at the initial stages of hypothalamic–pituitary development.[12]

Mineralocorticoid (aldosterone) release by the zona glomerulosa of the adrenal cortex is determined by the renin-angiotensin system with acute modulation to a lower extent by ACTH as well.[24] Decreases in vascular volume result in increased secretion of renin by the renal juxtaglomerular apparatus. Renin, a proteolytic enzyme, cleaves angiotensinogen to angiotensin I, a biologically inactive decapeptide. Angiotensin I is then cleaved and activated by angiotensin-converting enzyme in the lung and other peripheral sites to angiotensin II. Angiotensin II and its metabolite angiotensin III possess vasopressor and potent aldosterone secretory activity. Although angiotensin II receptors are present on cells of the definitive zone at 16 weeks' gestation, significant aldosterone production by the fetal adrenal gland does not occur until the third trimester of pregnancy.[2]

Molecular Basis of Adrenal Development

Several transcription factors are critically important for normal adrenal development. Two related transcription factors have emerged as key regulators of adrenal development: the nuclear receptor DAX-1 (dosage-sensitive sex reversal-adrenal hypoplasia congenita [AHC] critical region on the X chromosome gene-1, encoded by *NROB1*/*AHC*) and steroidogenic factor-1 (SF-1, encoded by *NR5A1*, also known as AD4BP). Sf-1 (*Nr5a1*) knockout mice lack adrenal glands and gonads, and subsequent identification of *NR5A1* mutations in humans with adrenal insufficiency confirms the essential role of SF-1 in development.[25] *Nr5a*1 expression is found in the early urogenital ridge of the mouse in cells that give rise to both the bipotential gonad and adrenal cortex. Expression of *Nr5a1* remains high throughout embryogenesis, the postnatal period, and adult life.[25]

DAX-1 is an orphan nuclear receptor that colocalizes with SF-1 in the cells of adrenal glands, gonads, gonadotropes, and ventral–medial lateral nucleus of the hypothalamus. Deletion of *NROB1* results in AHC. Although the exact role of DAX-1 in adrenal development is not known, it has been shown to interact with SF-1.[26] Normally, DAX-1 recruits the nuclear corepressor N-CoR to SF-1 and represses SF-1.[27] Similarly, the Wilms tumor suppressor gene (*WT1*) protein has been shown to interact with SF-1. *WT1* encodes 24 different protein isoforms that act as transcription factors. *Wt1* is detected in the urogenital ridge of the mouse embryo but is not detected in adult or fetal adrenals. Mutations in *Wt1* have resulted in abnormal development of the adrenal in the mouse but have not been clearly correlated with abnormal human adrenal development.[28] *WT1* has been found though to be expressed in the fetal adrenal gland.[29]

Assessing Adrenal Function in the Newborn

The adrenal cortex plays a major role in the newborn postnatal adaptation, and significant evolution of adrenal steroid production occurs over the first days and months of life. During interpretation of the newborn adrenal steroidogenic function, special attention must be paid to age-related changes in adrenal steroid intermediates, circulating cortisol, and aldosterone concentrations that reflect ongoing adrenal maturation.[30–32] For example, until at least 1 month postnatally, a large proportion of cortisol and its metabolites is excreted as sulfate esters. This sulfation may serve to

inactivate a number of circulating cortisol metabolites during fetal and neonatal life.[33]

Immediately after birth the third trimester fetal zone that once was the predominant component of the adrenal cortex in the fetus and preferentially produced DHEA and DHEAS starts to reduce in size. This rapid loss of the fetal zone during this period results in a dramatic fall of the circulating DHEA concentration over the first week to 1 month postnatally. The variable pattern of decline in the ensuing weeks probably reflects variation in remodeling of the fetal zone and emergence of the zona fasciculata of the definitive zone, the latter being a feature of an adult cortex. In addition to diminished 3β-HSD2 activity, preterm infants have sustained elevations in 17-hydroxyprogesterone and the 17-hydroxyprogesterone-to-cortisol ratio, suggesting a reduction in 21-hydroxylase activity.[34,35] Because blood-spot 17-hydroxyprogesterone concentration is used for newborn screening of CAH in many states,[36] many preterm infants initially have an abnormal test result. Subsequent follow-up testing is then required to determine whether CAH is present. Plasma aldosterone concentrations tend to be higher in preterm infants than in term infants, both of which in turn are higher than in older children and adults.[37,38]

Cortisol has a critical role in maintaining homeostasis in response to stress. Relative adrenal insufficiency occurs when the HPA axis produces less than adequate cortisol for the degree of illness or stress. Immaturity of the adrenal gland and the HPA axis of the premature newborn infant suggest a rationale for why preterm infants are at increased risk of cortisol insufficiency.[39] Clinicians are commonly faced with critically ill infants who have cardiovascular insufficiency with hypotension, a condition that has been associated with adverse consequences. The question often arises as to whether these manifestations reflect underlying glucocorticoid insufficiency. There is increasing evidence that *relative* adrenal insufficiency may be a cause of hemodynamic instability and hypotension in the critically ill newborn, but there is definitely a paucity of data in this population.

Random plasma cortisol measurement is often inadequate to answer this question because the majority of critically ill newborns have low cortisol and ACTH values without the expected increase in response to critical illness. Infants also do not exhibit diurnal variation of ACTH and cortisol until 6 months of age. Thus, obtaining two or more samples of cortisol may be informative. Response to exogenous ACTH (cosyntropin) is usually normal, suggesting that the inadequate response to critical illness in these newborns does not result from adrenal dysfunction but arises from some other components of the HPA axis.[40] Interestingly, in extremely low birthweight infants (500 to 999 g) low cortisol concentrations were not predictive of adverse short-term mortality and morbidity. In contrast, high basal cortisol levels were associated with severe intraventricular hemorrhage, and extremely elevated values were associated with morbidity and death.[41]

Data associating treatment of adrenal insufficiency with outcomes in the term newborn are limited, and there have been no studies on outcomes beyond the immediate neonatal period. Nonetheless, no adverse events have been attributed to glucocorticoid treatment based on a relatively small number of study subjects. Currently there is insufficient evidence to support the routine use of glucocorticoids in critically ill newborns. On encountering an infant with vasopressor-resistant hypotension accompanied by signs of cardiac hypofunction, the clinician must consider the risk-to-benefit ratio before arriving at the appropriate management. Therapeutic trials with hydrocortisone at the dose of 1 mg/kg of body weight have been suggested[39] and can be discontinued if there is no clinical improvement or if the pretreatment cortisol level is later observed to be greater than 15 μg/dL. A meta-analysis of the use of hydrocortisone for hypotension and vasopressor dependence in preterm infants showed improvement in blood pressure and less need for vasopressor, but the clinical benefit is unknown, and long-term effects of hydrocortisone use are not known.[42] Special attention should be paid to the premature newborn concurrently receiving indomethacin because the combination of hydrocortisone and indomethacin is associated with spontaneous gastrointestinal perforation.[43]

Primary Adrenal Disorders

Steroidogenic Defects Caused by Adrenal Enzyme Deficiency

CAH refers to a family of inherited adrenal gland disorders in which defects occur in one of the enzymatic steps required to synthesize cortisol from cholesterol; therefore, impaired cortisol synthesis is the cornerstone shared by all forms of CAH. The pathway of steroidogenesis in the adrenal cortex is illustrated in Fig. 84.3. Five forms of CAH with autosomal recessive mode of inheritance are summarized in this section.

Disorders That Lead to Virilization in Females

21-Hydroxylase Deficiency

Epidemiology

21-Hydroxylase deficiency (21-OHD) is responsible for 90% to 95% of all CAH cases. Newborn screening has demonstrated an overall incidence of 1:15,000 live births for the classic form of 21-OHD.[44–46] The incidence of classic CAH in either homogeneous or heterogeneous general populations is as high as 1 case per 7500 live births.[47]

Pathophysiology

In 21-hydroxylase deficiency (21-OHD), the conversion of 17-hydroxyprogesterone (17-OHP), the main substrate of the 21-hydroxylase enzyme, to 11-deoxycortisol in the pathway of cortisol synthesis is impaired, and precursors are shunted through the androgen pathway. The enzyme defect also impairs the conversion of progesterone to aldosterone, causing abnormal salt loss.[48,49] There are two forms of classic 21-OHD: (1) simple virilizing and (2) salt-wasting. The forms are distinguished by the adrenal gland's ability to produce adequate aldosterone. In both forms, severe 21-OHD results in elevated levels of adrenal androgens that cause ambiguous genitalia in the genetic female fetus.

Diagnosis of 21-OHD is made by the detection of extremely high concentrations of 17-OHP. In some cases, a stimulated 17-OHP level is checked after performing an ACTH stimulation test. Table 84.1 lists steroid levels at baseline and following 250 mcg of ACTH given as an intravenous (IV) bolus in infants at various ages. Cosyntropin (synthetic ACTH) IV or IM is dosed at 15 mcg/kg up to 125 mcg in children less than 2 years and at 250 mcg for children greater than 2 years. Samples should be drawn at baseline and 60 minutes. The diagnosis is confirmed by molecular genetic analysis of the *CYP21A2* gene.

Hormonally and clinically defined forms of 21-OHD CAH are associated with distinct genotypes characterized by varying enzyme activity demonstrated by in vitro expression studies.

TABLE 84.1 Adrenal Steroid Levels in Response to Adrenocorticotropic Hormone for Various Ages

Steroid		Premature 26–28 Weeks' Gestation	Premature 34–36 Weeks' Gestation	1–6 Months	<1 Year
Androstenedione ng/dL	Baseline	92–892	90–837	6–78	6–78
	Stimulated	145–1248	183–1367	21–114	21–139
	Change	40–718	13–1084	9–76	10–75
Cortisol mcg/dL	Baseline	1–11	3–34	3–22	3–23
	Stimulated	6–52	16–76	27–50	32–60
	Change	4–41	6–44	19–41	17–40
Deoxycorticosterone ng/dL	Baseline	20–105	28–78	7–48	7–57
	Stimulated	44–320	28–95	40–158	20–157
	Change	17–215	1–67	13–144	26–110
11-Deoxycortisol ng/dL	Baseline	110–1376	70–455	10–200	10–200
	Stimulated	206–2504	81–645	101–392	80–390
	Change	15–1128	40–190	5–366	5–350
17-OH progesterone ng/dL	Baseline	124–841	186–472	13–173	11–173
	Stimulated	285–1310	334–1725	85–250	85–466
	Change	50–596	18–1253	52–193	50–275

Data was obtained by extraction, chromatography, and RIA (radioimmunoassay) method and may not be applicable to other methods. These values should be treated as approximate and not exact cutoffs. In the preterm infants, testing was done on postnatal days 2 to 4. Adapted with permission from Nakamoto JM, Mason PW (eds). *The Quest Diagnostics Manual. Endocrinology.* 5th ed. Madison, NJ: Quest Diagnostics Incorporated; 2012.

The gene encoding 21-hydroxylase is a microsomal cytochrome P450, family 21, subfamily A, polypeptide 21 (*CYP21A2*) located on the short arm of chromosome 6 within the human leukocyte antigen complex.[50,51] *CYP21A2* and its homolog pseudogene *CYP21A1P* alternate with two genes, *C4B* and *C4A*, which encode two isoforms of the fourth component of the serum complement system.[52] More than 100 mutations have been described to date. These mutations include point mutations, small deletions, small insertions, and complex rearrangements of the gene.[53] The most common mutations appear to be the result of two types of meiotic recombination between *CYP21A2* and *CYP21A1P*: (1) misalignment and unequal crossing over, resulting in large-scale DNA deletions, and (2) apparent gene conversion events that result in the transfer to *CYP21A2* of smaller-scale deleterious mutations present in *CYP21A1P*. It is not always possible to accurately predict the phenotype on the basis of the genotype; such predictions have been shown to be 79% to 88% accurate[54–56] with some non-concordance. Studies have demonstrated that there is often a divergence in phenotypes within mutation-identical groups; the reason for this requires further investigation.[57,58]

Clinical Presentation

Females with simple virilizing CAH can be diagnosed at birth because of the apparent genital ambiguity.[59] For newborn males, however, differentiation of the external genitalia is not affected because the main source of testosterone is the testes and not the adrenal gland. Postnatally, genitalia may continue to virilize because of an excess of adrenal androgens, and pseudo-precocious puberty can occur. In affected females, signs of hyperandrogenism include facial, axillary, and pubic hair; adult body odor; temporal balding; severe acne; irregular menses; and reduced fertility. Poor control of adrenal androgens in males has been associated with small testes, infertility, and short stature. Infertility occurs because the excess androgens are aromatized peripherally to estrogens, which suppress pituitary gonadotropins and function of the gonads, and due to the development of testicular adrenal rest tumors. The high estrogens also advance bone age. The high levels of androgens can also accelerate growth in early childhood, producing an unusually tall and muscular child. Thus, untreated patients with 21-OHD CAH are tall as children but short as adults. The salt-wasting phenotype, which occurs in approximately 75% of CAH cases,[60] is biochemically distinct from the simple virilizing form because of a deficiency of aldosterone, the salt-retaining hormone.[48,61] Resulting hyponatremia, hyperkalemia, high plasma renin activity, and fluid volume depletion that occur at days 5 to 15 of life are potentially fatal.

Management

Hormone replacement therapy with corticosteroids is used to correct the deficiency in cortisol secretion, which will in turn suppress ACTH overproduction and subsequent stimulation of the androgen pathway.[8] Hormone replacement prevents further virilization, allowing normal growth and onset of puberty. The initial dose of hydrocortisone required is usually 15 to 20 mg/m^2 per day divided into three doses per day[62,63] but may be even higher in the newborn. The dose can then be decreased to 10 to 15 mg/m^2 per day after there has been initial suppression of the ACTH–adrenal axis. It is important that the appropriate balance be maintained to avoid hypercortisolism, which can result in Cushing syndrome and suppression of linear growth. Attempts to suppress 17-OHP

levels to normal will inevitably result in iatrogenic Cushing syndrome. Hormonal control can be difficult to achieve in some cases, and adrenalectomy in the past had been offered as an extreme alternative therapeutic option in select patients.[64,65] Patients with salt-losing CAH have elevated plasma renin activity and require mineralocorticoid replacement with 0.05 to 0.4 mg/day of 9α-fludrocortisone. Neonates have mineralocorticoid resistance as evidenced by higher levels of aldosterone present in normal infants and thus the required dose of 9α-fludrocortisone is higher in infants than in adults. In infancy, most patients also require an oral salt supplement as in other forms of primary adrenal insufficiency. There is no parenteral formulation for mineralocorticoid. Therefore, if 9α-fludrocortisone cannot be given orally, hydrocortisone at higher doses can be given IV along with sodium chloride. A dose of 20 mg of hydrocortisone will provide the equivalent of 0.1 mg 9α-fludrocortisone.

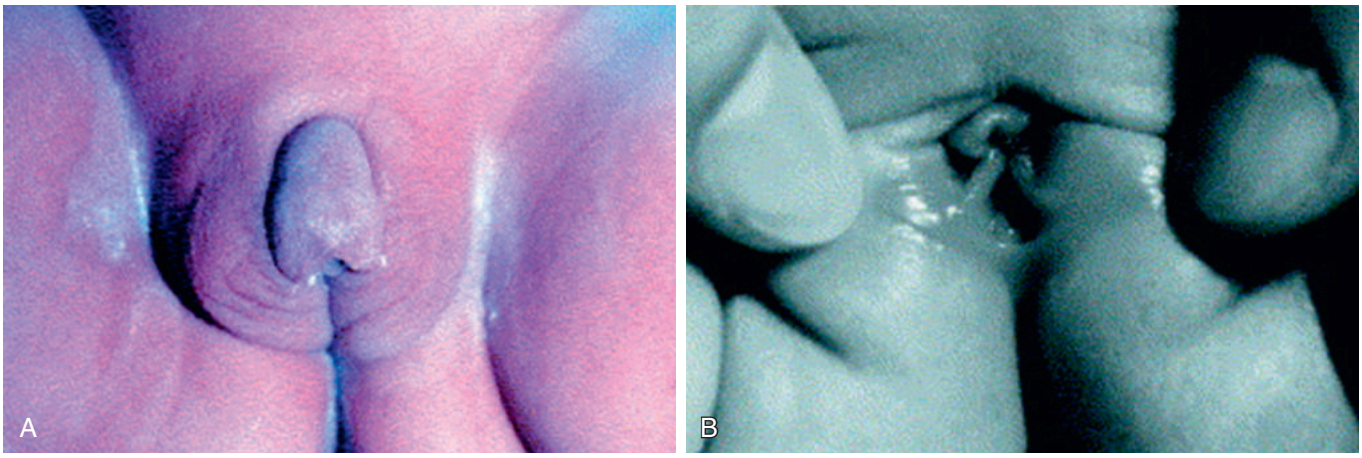
With the advent of newborn screening, infants are diagnosed with CAH prior to a salt-wasting crisis, and thus it is not possible to distinguish the infant with the 75% chance of having salt-wasting CAH without genetic testing. Because females with classic 21-OHD CAH are born with ambiguous genitalia caused by the production of excess androgens in utero, corrective surgery is contemplated. However, before surgical restoration is considered as a form of treatment in patients with ambiguous genitalia, consultation with the patient's parents, psychologist, pediatric endocrinologist, and pediatric urologist is essential.

Prevention of prenatal virilization in affected females is possible with a prenatal diagnosis and treatment program. The disease can be diagnosed prenatally through molecular genetic analysis of fetal DNA. Prenatal treatment by dexamethasone administration to the pregnant mother carrying an at-risk fetus before 6 weeks post conception is effective in reducing virilization in the genetic female, making postnatal female restorative surgery less likely to be necessary and thereby avoiding potential impairment of sexual function (Fig. 84.5). At 7 to 10 weeks, cell-free DNA testing may allow for discontinuation of the dexamethasone if an XY fetus is identified or, if using massive parallel sequencing (MPS) of cell-free fetal DNA, an XX fetus is found to not have CAH.[66] However, the technique of MPS for CAH is not readily available as routine care. Dexamethasone may also be discontinued after diagnosis is made by fetal DNA analysis obtained from chorionic villus sampling at 10 to 12 weeks' gestation in unaffected female or male fetuses.[67] Some believe there are accurate, compelling data from the largest human studies[68–70] indicating the benefit of prenatal treatment and that it is safe in the short term for both the fetus and the mother. Some preliminary data from long-term studies also support these results,[71] although other long-term follow-up studies are still under way. In contrast, studies from Sweden found that children without CAH treated prenatally with dexamethasone had decreased verbal working memory and decreased self-perception of scholastic ability. Those with CAH had decreased verbal processing speed that normalized though when adjusted for intelligence quotient.[72,73] A more recent review found that there is a negative effect on executive function and on social behavior.[74] Long-term cardiovascular, renal, and metabolic risk have yet to be determined. Thus, the ethics of prenatal dexamethasone therapy remains controversial because of unknown long-term outcomes and because seven fetuses were treated unnecessarily to prevent virilization in one fetus. Dexamethasone therapy also incurs maternal risk. Consequently, all endocrine societies consider prenatal dexamethasone therapy for 21-OHD to be experimental and that it should only be performed in a research environment with long-term outcome studies, as the risk for long-term effect is not known.[75]

11β-Hydroxylase Deficiency

Epidemiology

Classic 11β-OHD CAH occurs in approximately 1 in 100,000 births in the general white population.[76] Many cases have been reported in Israel, where the incidence was estimated to be 1 in 5000 to 1 in 7000 births with a gene frequency of 1 in 71 to 1 in 83. A subsequent study showed that 11β-OHD CAH occurred in a lower frequency, yet it remains more common in this population than in others.[77] This unexpected clustering of cases was traced to Jewish families of North African origin, particularly from Morocco and Tunisia.[78] In Turkey, 11β-OHD accounts for 13.5% of the CAH cases.[79]



• **Fig. 84.5** Two Sisters with Congenital Adrenal Hyperplasia. (A) Female infant with congenital adrenal hyperplasia. There is enlargement of the clitoris with fusion and rugation of labial scrotal folds. (B) Sister of the female infant in (A) who also has congenital adrenal hyperplasia but whose mother received dexamethasone therapy prenatally to prevent virilization of external genitalia. (From Forest MG, Morel Y, David M. Prenatal treatment of congenital adrenal hyperplasia. *Trends Endocrinol Metab*. 1998;9:284–289.)

Pathophysiology

The 11β-hydroxylase deficiency (11β-OHD) form of CAH represents 5% to 8% of all cases in the general population.[80] Deficiency of this enzyme results in an accumulation of 11-deoxysteroid precursors, which are shunted into the androgen pathway. Excess adrenal androgen secretion results in ambiguous genitalia in the affected female fetus. Hypertension in patients with this disorder is commonly attributed to deoxycorticosterone (DOC)-induced sodium retention.[81] The hallmark serum abnormality in patients with 11β-OHD is normal or suppressed renin, because hypokalemia is not uniformly present in all cases. Infants may also present with hyponatremia due to the physiologic newborn resistance to mineralocorticoids. 17-OHP may also be elevated due to the high 11-deoxycortisol levels and be detected by the newborn screen for 21-OHD CAH. Diagnosis is made by the determination of extremely high basal and stimulated levels of DOC and 11-deoxycortisol after performing an ACTH stimulation test. The diagnosis can be confirmed by molecular genetic analysis of the CYP11B1 gene.

Two 11β-hydroxylase genes have been identified within the human adrenal cortex, each encoding for a different enzyme with distinct enzymatic ability. The two genes *CYP11B1* and *CYP11B2* are located 30 to 40 kilobases apart on chromosome 8q.[82,83] Although gene conversions occur between *CYP11B1* and *CYP11B2*,[84,85] the majority of the mutations found in *CYP11B1* are random point mutations,[76,86–88] unlike what occurs in 21-OHD CAH. By 2003, approximately 41 mutations in *CYP11B1* from individuals of diverse ethnic backgrounds had been identified.[53] There are now over 100 mutations found in CYP11B1.[89,90]

Clinical Presentation

Hypertension occurs in approximately two-thirds of patients with 11β-OHD and distinguishes 11β-OHD from the more common 21-OHD in cases of virilizing CAH.[81,87] However, hypertension correlates variably with the presence of hypokalemia or with the extent of virilization.[87] Patients can present with or without hypokalemic alkalosis. Hypertension is usually not identified until later in childhood or in adolescence, although its appearance in early childhood has been documented. A patient was positively identified by the newborn screening program aiming for 21-OHD CAH.[91]

Management

Like 21-OHD CAH, glucocorticoid therapy is the most effective means of regaining hormonal control in patients with 11β-OHD. Corticosteroids at the same dose range as for 21-OHD CAH provide feedback inhibition of ACTH, reduce stimulation of the androgen pathway, and allow normal growth and the onset of puberty. Treatment with corticosteroids also contributes to the reduction of DOC and thus controls hypertension. Through careful clinical monitoring, doses can be continuously adjusted to match patients' needs while avoiding suppression of linear growth caused by overdosing. In addition to hormonal therapy, reduced salt intake is often used to reduce fluid volume and hypertension. Maintaining fluid balance in children is often difficult, however, and poses an ongoing challenge to treatment. Affected females suffer from genital ambiguity and may require genital restorative surgery. To prevent prenatal virilization, a similar experimental protocol to 21-OHD CAH for prenatal diagnosis and treatment can be performed.[92]

Disorders That Lead to Males With Undervirilization

17α-Hydroxylase/17,20-Lyase Deficiency

Epidemiology

17α-hydroxylase/17,20-lyase deficiency has an estimated frequency in most countries of approximately 1 case per 50,000 newborns and accounts for approximately 1% of all cases of CAH worldwide.[93] However, 17-hydroxylase (CYP17) deficiency is the second most common cause of CAH in Brazil.[94,95] This frequency is the result of two founder effects in areas with high coefficients of consanguinity such that two mutations account for more than 80% of cases in that country.[94]

Pathophysiology

17α-hydroxylase/17,20-lyase deficiency involves an enzyme that catalyzes more than one reaction—namely both the 17α-hydroxylation and 17,20-lyase reactions—with both reactions commonly being impaired in the disorder. Affected individuals cannot produce cortisol but synthesize large amounts of corticosterone (a weak glucocorticoid that mitigates the adrenal insufficiency) and deoxycorticosteroid, which causes hypertension and hypokalemia. Deficiency of 17,20-lyase impairs the ability to synthesize androgens and estrogens and causes male 46,XY differences of sex development (DSD) at birth and results in failure to virilize at puberty. Affected females have primary amenorrhea and clinical hypogonadism.[93,96]

Since the cloning of the gene,[97] over 100 different mutations have been described in *CYP17*.[98,99] Founder effects probably explain the high incidence of the disease in other patient populations in the Netherlands and Japan.[94] Severity of disease tends to be milder with mutations that retain partial catalytic activity, but the nature of the variability in hypertension and hypokalemia is unclear.

Clinical Presentation

The typical features of complete deficiency include hypertension and hypokalemia, which occur due to increased ACTH stimulation of the mineralocorticoid pathway, absent adrenarche and puberty in genetic females, and undervirilization in genetic males. Nevertheless, there is considerable variability in the clinical and biochemical features, including a few mutations that cause isolated 17,20-lyase deficiency.[96] The age of onset of hypertension and the severity of hypokalemia are highly variable, even among individuals with the same mutations.[94]

Management

Adequate glucocorticoid administration suppresses ACTH and the excessive mineralocorticoid secretion and generally normalizes the blood pressure. Adult females and undervirilized males reared as females require estrogen therapy. Abdominal testes should be relocated or removed because of the risk of malignancy. Adult genetic males reared as males need surgical correction of the external genitalia and androgen replacement.

3β-Hydroxysteroid Dehydrogenase Type 2 Deficiency

Epidemiology

The exact frequency of this rare disorder remains unknown.

Pathophysiology

3β-Hydroxysteroid dehydrogenase converts 3β-hydroxy $^{5}\Delta$ steroids (pregnenolone, 17-hydroxypregnenolone, and DHEA) to 3-keto $^{4}\Delta$ steroids (progesterone, 17-OHP, and androstenedione) and is essential for the biosynthesis of mineralocorticoids, glucocorticoids, and sex steroids.[100] Two forms of the 3β-hydroxysteroid dehydrogenase enzyme have been described in humans: type 1 enzyme expressed in placenta and skin and type 2 expressed in adrenal glands and gonads. The type 1 and 2 genes are closely linked on chromosomal region 1p13.1. The two forms are closely related in structure and substrate specificity, although the type 1 isoenzyme has higher substrate affinity and a fivefold greater enzymatic activity than type 2.[101] The type 1 isoenzyme can lead to elevated 17-OHP and androstenedione levels in addition to the expected elevated levels of pregnenolone, 17-hydroxypregnenolone, and DHEA.

3β-Hydroxysteroid dehydrogenase type 2 deficiency has an autosomal recessive inheritance. *HSD3B2* is the gene responsible for 3β-HSD2 deficiency CAH. There are approximately 40 mutations in the *HSD3B2* gene already described.[53] Mutations that lead to the abolition of 3β-HSD2 activity lead to the salt-wasting form.[102–105] Mutations that reduce but do not abolish type II activity lead to CAH with mild or no salt loss, which in males is associated with 46,XY DSD as a result of the reduction in androgen synthesis.[104] Mild mutations were also associated with hyperandrogenic symptoms of premature pubic hair development and hirsutism.[106,107]

Clinical Presentation

3β-HSD2 isoenzyme is essential for the formation of progesterone, the precursor for aldosterone; 17-OHP, the precursor for cortisol in the adrenal cortex; androstenedione; testosterone; and estrogen. Simultaneous 3β-HSD2 deficiency in both gonads and adrenal glands results in incomplete virilization of the external genitalia in males. Male patients with 3β-HSD2 deficiency present with ambiguous external genitalia, characterized by micropenis, perineal hypospadias, bifid scrotum, and blind vaginal pouch[108] with or without salt loss.[100] Gynecomastia is common at pubertal stage in affected males. In females, virilization of external genitalia occurs as a result of the androgen effect from the peripheral conversion of circulating $^{5}\Delta$ precursors to active $^{4}\Delta$ steroids; therefore, genital ambiguity can result in both sexes. Newborns can present with adrenal insufficiency due to deficiency of glucocorticoids, mineralocorticoids, and sex steroids. Later clinical presentations also include salt-wasting crises, premature pubic hair development, hirsutism, and menstrual disorders.[104]

Management

Like other forms of CAH, corticosteroid is the mainstay therapy. Salt-wasting phenotypes seen in some patients can be managed the same way as the salt-wasting form of 21-OHD CAH. Male patients with 3β-HSD2 deficiency have ambiguous external genitalia. Although most males are raised as males and retain the male social sex at puberty, gender identity is an important management issue. In one Brazilian family, two cousins with 46,XY DSD caused by 3β-HSD2 deficiency were reared as females; one of them had bilateral orchiectomy in childhood and retained the female social sex; the other retained their testes during childhood and changed to male social sex at puberty.[109]

Male patients may require testosterone replacement therapy during puberty and adulthood. The aim of the surgical treatment after consultation with a DSD team in this condition is to allow development of adequate external genitalia. Only skilled surgeons with specific training in the surgery of DSD should perform these procedures.[110]

Lipoid Congenital Adrenal Hyperplasia

Lipoid CAH is a severe form of congenital adrenal insufficiency. Affected patients exhibit glucocorticoid and mineralocorticoid deficiencies early in life, and males exhibit undervirilization. The reduced synthesis of steroids in patients with lipoid CAH results from an inability to transfer cholesterol to the inner mitochondrial membrane where the cholesterol side-chain cleavage complex is located.[111] It is characterized by lipid droplet accumulation in the cytoplasm of the adrenocortical cells. Most cases of lipoid CAH are caused by autosomal recessive mutations in the gene encoding steroidogenic acute regulatory protein (StAR). The *StAR* locus is in the 8p11.2 region and encodes a protein with an essential role in cholesterol transfer from the outer to the inner mitochondrial membrane, thus providing the substrate for steroid hormone biosynthesis.[112] Once in the mitochondria, cholesterol is converted to pregnenolone by the cytochrome P450 side-chain cleavage (CYP11A1) enzyme, and then steroid biosynthesis is initiated. Karyotypic 46,XY persons are phenotypically female because of Leydig cell destruction and impaired testosterone production. Sertoli cell function is intact so that anti-müllerian hormone is secreted, and thus müllerian ducts regress, leading to absence of the uterus and fallopian tubes. The ovary in XX subjects is initially spared damage because steroidogenesis is delayed until the time of puberty, after which stimulation of steroidogenesis by the tropic hormones (i.e., luteinizing and follicle-stimulating hormones) causes progressive damage to the ovary.[113] *StAR* mutations have been described most frequently in Japanese and Palestinian populations, in part because certain mutations occur repeatedly, probably reflecting a founder effect.[112,114] Although less common than mutations in *StAR*, mutations in *CYP11A1* can also cause a clinical phenotype similar to those with mutations in the *StAR* gene, but the adrenal gland does not have the adrenal hyperplasia seen in lipoid CAH.[115–117]

Cytochrome P450 Oxidoreductase (POR) Deficiency

Cytochrome P450 oxidoreductase (POR) deficiency is an autosomal recessive disorder of steroidogenesis involving P450c17, P450c21, and P450-aro with a phenotypic spectrum ranging from cortisol deficiency at the milder end to classic Antley–Bixler syndrome (ABS) at the severe end. The phenotype of cortisol deficiency can range from clinically insignificant to life threatening.[118] Manifestations of POR deficiency can include ambiguous genitalia in males and females, primary amenorrhea and enlarged cystic ovaries in females, poor masculinization during puberty in males, and maternal virilization and low estriol levels during pregnancy with an affected fetus carrying certain POR mutations. Manifestations of ABS include craniosynostosis, hydrocephalus, distinctive facies, choanal stenosis or atresia, low-set, dysplastic ears with stenotic external auditory canals, skeletal anomalies (radiohumeral synostosis, neonatal fractures, congenital bowing of the long bones, joint contractures, arachnodactyly, clubfeet), renal anomalies (ectopic kidneys, duplication of kidneys, renal hypoplasia, horseshoe kidney, hydronephrosis), and reduction of cognitive function and developmental delay. The skeletal differences have been hypothesized to be due to decreased activity

of CYP26B1, a POR-dependent enzyme that degrades retinoic acid.[119] In moderate POR deficiency, craniofacial and skeletal anomalies are less severe than in ABS.[120] Infants with ABS with normal steroidogenesis and without ambiguous genitalia have a mutation in the fibroblast growth factor receptor 2 and not in the *POR* gene.[121] As more and more patients are identified with POR deficiency, this newly discovered form of CAH may not be as rare as formerly thought.

Familial Glucocorticoid Deficiency

Familial glucocorticoid deficiency (FGD) is an autosomal recessive disorder resulting from defects in the action of ACTH to stimulate glucocorticoid synthesis in the adrenal leading to ACTH resistance. It is also known as "isolated glucocorticoid deficiency" or "hereditary unresponsiveness to ACTH." The majority of patients with FGD have episodes of hypoglycemia in the neonatal period. These episodes will often respond quickly to more frequent feeding regimens. In a few cases, excessive skin pigmentation is recognized at this early stage. Biochemically, patients with FGD have low or undetectable cortisol levels and—because of the failure of the negative feedback loop to the pituitary and hypothalamus—grossly elevated ACTH levels are found. Mineralocorticoid deficiency usually is not a presentation; therefore, aldosterone levels, plasma renin measurements, and serum electrolytes are normal. A clinical feature sometimes observed in patients with FGD is tall stature that is identified later in life.[122] Approximately half of all cases result from mutations in the ACTH receptor (*MC2R*, melanocortin 2 receptor) FGD type 1 or from mutations in the melanocortin 2 receptor accessory protein (*MRAP*), FGD type 2.[123] About 10% of FGD is due to mutations in *nicotinamide nucleotide transhydrogenase (NNT)*.[124–126] Other etiologies include MCM4, *TXNRD2*,[127] *GPX1* and *PRDS3*.[124] Milder mutations in *StAR* and CYP11A1 may also present with FGD. Other genetic causes of this potentially lethal disorder remain to be discovered in about one-third of the cases.

Triple A Syndrome

Triple A or Allgrove syndrome is a similar disorder to FGD with additional features of alacrima and achalasia. Alacrima (reduced or absent tear production) is the first symptom, followed by achalasia (difficult for food and liquid to pass through the esophagus) and then adrenal insufficiency. Presenting in the first decade of life, it is frequently associated with progressive neurologic dysfunction, polyneuropathy, deafness, mental retardation, and hyperkeratosis of palms and soles.[128] Some of these families have a defect in the alacrima–achalasia–adrenal insufficiency neurologic disorder (*AAAS*) gene encoding a protein named ALADIN.[129] ALADIN participates in the nuclear translocation of the ferritin heavy chain protein. Mutations in *AAAS* prevent ferritin heavy chain protein from entering into the nucleus, which is necessary to prevent oxidative damage of the nucleus.[130] ALADIN belongs to a WD-repeat family of regulatory proteins that shares a common motif made up of highly conserved repeating units usually ending with tryptophan-aspartate (WD).[131]

Neonatal Adrenoleukodystrophy

Neonatal adrenoleukodystrophy (NALD) is a fatal rare autosomal recessive disease of impaired peroxisome biogenesis. NALD belongs to a class of disorders involving peroxisomal biogenesis that includes Zellweger syndrome and infantile Refsum disease. NALD is the only one of the three diseases that often involves adrenal insufficiency. Mutations in seven different peroxisome biogenesis factor genes have been shown to cause NALD.[132] Mutations in peroxisome biogenesis factor 1 (*PEX1*) are the most common cause of NALD.[133] As in X-linked adrenoleukodystrophy (X-ALD), patients with NALD accumulate very long chain fatty acids and develop degenerative changes of the white matter of the nervous system and adrenal atrophy. Infants with NALD characteristically demonstrate dolichocephaly, prominent and high forehead, esotropia, epicanthic folds, broad nasal bridge, high-arched palate, low-set ears, and anteverted nostrils. Affected patients usually die in early childhood.[134] X-ALD is a recessively inherited X-linked defect of the adrenoleukodystrophy protein (ALDP).[135] It is encoded by the *ABCD1* gene on Xq28. It is also a peroxisomal defect that usually results in adrenal insufficiency and central nervous system deterioration. X-ALD can present in early childhood, and at birth there is already elevation of very long chain fatty acids. Because early diagnosis can improve outcome through the use of hematopoietic stem cell transplantation or gene therapy, some state newborn screening programs have added X-ALD to their newborn screening panel. X-ALD can also manifest later in adulthood.[136]

Defective Cholesterol Metabolism: Smith–Lemli–Opitz Syndrome

The clinical picture of adrenal insufficiency and 46,XY gonadal dysgenesis may be caused by a deficiency of 7-dehydrocholesterol C-7 reductase enzyme that catalyzes the final step in cholesterol biosynthesis leading to primary adrenal insufficiency. The syndrome results from mutations in the sterol Δ-7-reductase gene (*DHCR7*) located at 11q12-q13. Smith–Lemli–Opitz (SLO) syndrome can manifest with typical facial appearance, mental retardation, microcephaly, proximally placed thumbs, congenital cardiac abnormalities, syndactyly of the second and third toes, incomplete development of the male genitalia, and photosensitivity. The biochemical abnormalities of SLO syndrome include low cholesterol and high 7-dehydrocholesterol.[137] Thus, it is important to consider the diagnosis as an elevated 7-dehydroxycholesterol level will confirm the diagnosis.

The birth prevalence of SLO syndrome is estimated to be approximately 1:20,000 to 1:40,000 live births.[137] Among persons of northern or central European ancestry, it has been estimated to range from 1:10,000 to 1:60,000.[138] SLO syndrome is less common in those of Asian or African ancestry. As it is an autosomal recessive disorder, the recurrence risk is 25%.

In utero, the primary defect in fetal adrenal glands results in a combination of low maternal estriol levels, undervirilization of the male fetus, and large adrenal glands in the fetus with SLO syndrome. Preliminary studies suggested that cholesterol supplementation may be of benefit to patients with SLO syndrome.[139]

Unfortunately, replacement of cholesterol has not been as beneficial as once hoped. Cholesterol does not cross the blood–brain barrier and has not been shown to reduce developmental delay.[140] A more recent placebo-controlled trial using simvastatin found that the medication crossed the blood–brain barrier and was relatively safe. There was improvement in serum dehydrocholesterol-to-total-sterol ratio and improvement of irritability symptoms.[141]

Adrenal Insufficiency Associated With Other Syndromic Disorders

Lysosomal Storage Disorders

Complete deficiency of lysosomal esterase can also result in adrenal insufficiency in Wolman disease, a rare autosomal recessive disease with an incidence of 1 in 350,000 infants. Wolman disease usually is fatal in the first year of life. Affected infants exhibit mild mental retardation, hepatosplenomegaly, vomiting, diarrhea, growth failure, and adrenal calcifications. Calcifications that delineate the outline of both adrenals are pathognomonic of this condition.[142]

Mitochondrial Disorders

Adrenal insufficiency can result from mitochondrial disorders, characterized by chronic lactic acidosis, myopathy, cataracts, and nerve deafness.[143,144] Cases with the Kearns–Sayre syndrome form of mitochondrial myopathy and deafness, with large-scale deletions in mitochondrial DNA, are often associated with endocrine dysfunction, particularly short stature, hypogonadism, diabetes, hypoparathyroidism, hypothyroidism, and adrenal insufficiency.[145,146]

IMAGe Syndrome

Three patients with AHC and additional findings that represent a new syndrome known as IMAGe (i.e., intrauterine growth retardation, metaphyseal dysplasia, AHC, and genital anomalies) have been reported. Genital abnormality was described as bilateral cryptorchidism, small penis, and hypogonadotropic hypogonadism. The patients also had hypercalciuria with or without hypercalcemia, resulting in abnormal calcium deposits in vital organs.[147] As of 2016, 28 individuals in 16 families have been reported.[148] Mutations in the proliferating cell nuclear antigen (PCNA)-binding domain of the maternally expressed cyclin-dependent kinase inhibitor (*CDKN1C*) gene on the short arm of chromosome 11, which results in the loss of PCNA binding, have been identified as the etiology of IMAGe syndrome. These mutations serve as a gain of function mutation.[149] *CDKN1C* is a tumor suppressor gene, and it encodes an inhibitor of cell cycle progression. Beckwith–Wiedemann syndrome, an overgrowth syndrome, also has mutations in the *CDKN1C* gene but at a different location, resulting in a loss of function.

MIRAGE Syndrome

MIRAGE syndrome (myelodysplasia, infections, restricted growth, adrenal hypoplasia genital anomalies and enteropathy) is due to heterozygous changes in the *SAMD9* gene. Individuals affected have a poor prognosis.

Adrenal Hypoplasia Congenita

Adrenal hypoplasia congenita (AHC), a familial condition in which the adrenal cortex has arrested development, occurs in approximately 1 in 12,500 births.[150,151] The disorder can manifest as four clinical forms of primary adrenal insufficiency: (1) a sporadic form associated with pituitary hypoplasia; (2) an autosomal recessive form with a distinct miniature adult adrenal morphology characterized by small glands with a permanent cortical zone but a diminished fetal zone (the genetic basis of the recessive form of AHC is unknown); (3) an X-linked cytomegalic form associated with hypogonadotropic hypogonadism; and (4) an X-linked form associated with glycerol kinase deficiency and Duchenne muscular dystrophy.[152,153] Mutations in the *NROB1* gene encoding DAX-1 are responsible for both X-linked forms.

The X-linked or cytomegalic form of AHC is characterized by the absence or near absence of the permanent or adult zone of the adrenal cortex and by structural disorganization of the fetal cortex with abnormally large cells. It differs from the autosomal recessive miniature adult form of AHC in which the adrenal cortex has the normal adult structure but is small. X-linked AHC results in severe primary adrenal insufficiency involving glucocorticoids and mineralocorticoids and failure to respond to elevated levels of ACTH with usual age at onset in the neonatal period or during infancy. However, in some patients, age of onset is later—up to several years of age and presumably caused by residual functional cortex.[154,155] The secretion of other pituitary hormones is not impaired. Hypogonadotropic hypogonadism can manifest with cryptorchidism or delayed puberty.[156] Whereas presentation of adrenal insufficiency can occur from birth, there is great variability of presentations. Isolated adrenal insufficiency in infancy, isolated adrenal insufficiency later in life, isolated hypogonadotropic hypogonadism, adrenal insufficiency and hypogonadotropic hypogonadism, delayed-onset adrenal insufficiency from 2 to 9 years of age with incomplete hypogonadotropic hypogonadism, and delayed puberty in females all may result.[153] The phenotypic variation does not correlate well with genotype. Treatment includes both glucocorticoid and mineralocorticoid replacement.

Adrenal Hypoplasia as Part of Contiguous Gene Deletion Syndrome

An X-linked form of adrenal insufficiency associated with glycerol kinase deficiency is characterized by psychomotor retardation, muscular dystrophy, characteristic facies with hypertelorism, alternating strabismus, and drooping mouth. Additional phenotypic features can include testicular abnormalities (anorchia or cryptorchidism), short stature, and osteoporosis. Time of presentation can vary from birth through childhood. Nearly all patients reported were male. The genetic locus was mapped to Xp21.3-21.2, and variants of contiguous gene deletion syndrome (glycerol kinase deficiency, Duchenne muscular dystrophy, ornithine transcarbamylase deficiency, and mental retardation) can be seen.

Abnormalities of Development: DAX-1 and Steroidogenic Factor-1 Deficiency

The nuclear receptors DAX-1 and SF-1[157] have an important role in adrenal development and function, and mutations in the genes that encode these transcription factors have been found in patients with adrenal hypoplasia. Both SF-1 and DAX-1 belong to the family of nuclear hormone receptors. DAX-1 protein is expressed in the developing urogenital ridge, ovary, testis, all zones of the fetal adrenal cortex, hypothalamus, and anterior pituitary gland—sites in which it colocalizes with SF-1.[158,159] SF-1 is essential for the development of the adrenal cortex, gonads, and ventromedial nucleus of the hypothalamus because it interacts with the promoter of the NROB1 gene, anti-müllerian hormone gene, and the genes for the α-subunits of the pituitary glycoprotein hormones.[160] Furthermore, SF-1 is a transcription factor that regulates gene expression of the CYP steroid hydroxylases (21-hydroxylase, the aldosterone synthase isoenzyme of steroid

11β-hydroxylase, CYP11A), 3β-hydroxysteroid dehydrogenase, aromatase, and StAR in the adrenal gland; therefore, it is essential for development of the adrenal cortex.

In one large study of this relatively rare disease, *NROB1* mutations were found in 58% of 46,XY phenotypic boys referred with adrenal hypoplasia and in all boys with hypogonadotropic hypogonadism and a family history suggestive of adrenal failure in males. *NR5A1* (SF-1) mutations causing adrenal failure were found in only two patients with 46,XY gonadal dysgenesis. No *NROB1* or *NR5A1* mutations were identified in the adult-onset group.[161]

Human mutations in *NR5A1* are even less common and have been described in a few patients with primary adrenal failure. Two individuals with a 46,XY genotype, female phenotype, and müllerian structures harbored missense mutations that affected DNA binding,[162,163] whereas a 46,XX girl with an *NR5A1* mutation had primary adrenal failure and apparently normal ovarian development.[164] In addition, it is now emerging that heterozygous nonsense or frameshift mutations associated with haploinsufficiency of *NR5A1* can cause 46,XY gonadal dysgenesis in patients with normal adrenal function.[165–167] Therefore, it is possible that a range of different endocrine phenotypes are associated with mutations in different domains of *NR5A1*.

Adrenal Hemorrhage

Adrenal hemorrhage is not uncommon at birth. Birth asphyxia and sepsis are the most common causes. The incidence in the neonate is reported to be 1.7 cases per 1000 autopsied infants and as many as 3% of infants screened by abdominal ultrasound examination. The etiology of neonatal adrenal hemorrhage is largely unknown, but it has been associated with birth trauma related to difficult deliveries, sepsis, coagulopathies, traumatic shock, and ischemic disorders. Infants with minimal hemorrhage may be asymptomatic and be discovered incidentally to have adrenal calcifications, indicating an earlier hemorrhage. Adrenal insufficiency can manifest in neonates with larger hemorrhages. Major adrenal hemorrhage can manifest as an abdominal mass, anemia from blood loss, or jaundice from reabsorption of the hematoma. Hemorrhage can also lead to adrenal insufficiency, which can manifest as neonatal hypoglycemia, hypotension, hypothermia, apnea, or shock. Because of the location of the right adrenal gland between the liver and spine, it is the one most often affected by hemorrhage.[168]

In meningococcal septicemias, hemorrhage into the adrenal glands can complicate the clinical picture, leading to circulatory collapse. This disorder is called Waterhouse–Friderichsen syndrome.[169] Other infections in the neonate that have been associated with adrenal hemorrhage include herpes virus, *Pseudomonas aeruginosa, Bacteroides* spp., herpes simplex virus type 6, and echovirus types 11 and 6.[170–174] Septic shock in newborns, especially in those who are small for their age, can result in adrenal hemorrhage with rhabdomyolysis and renal insufficiency.[153]

Secondary and Tertiary Adrenal Insufficiency

Iatrogenic Adrenal Insufficiency

Secondary and tertiary forms of adrenal insufficiency result from defects in pituitary corticotroph and hypothalamic function, respectively. Supraphysiologic doses of glucocorticoids are often used for the treatment of bronchopulmonary dysplasia. With prolonged use of supraphysiologic doses of glucocorticoids, these neonates are at risk for iatrogenic suppression of corticotroph ACTH release, with secondary adrenocortical atrophy and adrenal insufficiency.[175] Evidently, even a single course of prenatal betamethasone treatment induces a suppression of stress reactivity in healthy newborns.[176] Once administration of glucocorticoids is discontinued the duration of recovery of corticotroph function from adrenal suppression is highly variable. Some reports suggest evidence of suppression of the HPA axis evident for more than 1 year.[177] Even in preterm infants, the HPA axis behaves in a similar manner as in adult subjects, and the pituitary function recovers earlier than that of the hypothalamus and the adrenals.[178]

Developmental Adrenal Insufficiency

Secondary or tertiary adrenal insufficiency in the neonate often is a consequence of abnormalities in development of the hypothalamus and pituitary. Examples include de Morsier syndrome (septooptic dysplasia; Morsier[179]), hydrencephaly or anencephaly, and pituitary hypoplasia or aplasia. If these infants have concomitant diabetes insipidus, they have an increased risk of sudden death during childhood.[180,181] Patients with developmental abnormalities of the pituitary or hypothalamus often have deficiencies of other hormones. ACTH deficiency can be part of a multiple pituitary hormone deficiency syndrome caused by abnormal expression of *HESX1*, *LHX4*, *SOX3*, or *PROP1*, which encode transcription factors.[182] Isolated ACTH insufficiency is a rare condition that can be caused by mutations in *TPIT*, a T-box factor that controls transcription of the proopiomelanocortin gene in corticotrophs only, thereby resulting in an adrenal-only phenotype.[183] However, approximately 50% of patients do not carry mutations in *TPIT*, suggesting that other unknown factors exist.[184–186] Septooptic dysplasia can be caused by mutations in *HESX1* and *SOX2*.[180,181] Signs of hypopituitarism in a neonate include hypoglycemia, prolonged jaundice, shock, and microphallus in males. Trauma to the hypothalamus, pituitary, or hypophysial portal circulation from significant head injury, cerebrovascular accident, Sheehan syndrome, or hydrocephalus may be a cause of central adrenal insufficiency. Historical factors associated with increased risk for central adrenal insufficiency include maternal drug use and traumatic delivery.

There have been rare case reports of families with inherited abnormalities of neuropeptides involved in HPA axis regulation. Adrenal insufficiency, pigmentary abnormalities, and obesity have been described in families with a defect in proopiomelanocortin (POMC).[187] One kindred has been reported with Arnold–Chiari type I malformation and suspected *CRH* deficiency. The mutation in this kindred is linked to the *CRH* locus; however, a specific mutation in the *CRH* gene has not yet been defined.[188] Mutations in *TPIT*, which encodes a highly restricted transcription factor involved in the expression of the *POMC* gene, have been found in eight individuals with autosomal recessive congenital isolated ACTH deficiency.[189]

Management

Cortisol replacement for patients with secondary or tertiary adrenal insufficiency is the same as described for patients with primary adrenal insufficiency. To minimize growth suppression, these children can be treated with doses of hydrocortisone that are slightly less than physiologic replacement doses. Furthermore, because

mineralocorticoid production is under the control of the renin-angiotensin system, patients with secondary or tertiary adrenal insufficiency do not require mineralocorticoid replacement. However, these infants require evaluation for deficiencies of other pituitary hormones.

Adrenal Crisis in the Neonate

Adrenal crisis is a potentially life-threatening disorder that can manifest with a salt-losing crisis or profound hypoglycemia in a neonate or infant. Adrenal crisis requires immediate resuscitation and appropriate steroid replacement. Determining the exact cause of this condition can be challenging once the child has started treatment, but defining a precise etiology has important implications for long-term management, for identifying associated features, and for appropriate counseling regarding inheritance and the risks of other family members being affected.[161] Detailed questioning about family history that could reveal any insight into possible adrenal disease is important.

Initial Management

In a suspected adrenal crisis, blood for determination of electrolytes, aldosterone, plasma renin activity, cortisol, and ACTH should be drawn and treatment started before the results are obtained. Fluid resuscitation with normal saline containing 5% or 10% dextrose should be given to restore cardiovascular stability. Plasma sodium should be monitored closely, as rapid correction of hyponatremia with sodium repletion of more than 0.5 to 1 milliequivalent (mEq)/L per hour increases the risk of central pontine myelinolysis. The sodium deficit may be calculated by subtracting the infant's sodium from a customarily normal sodium of 140 mEq/L and then multiplying this value by 0.6 × weight (in kg). The rate of replacement should occur over an initial rate such that the sodium increase does not exceed 0.5 mEq/L per hour. Hydrocortisone IV should be given initially at 50-100 mg/m^2 and then continued at 50-100 mg/m^2 per day, divided every 6 to 8 hours, until the infant's condition is stable.

Maintenance Therapy

Corticosteroid and mineralocorticoid replacement therapies should suppress the excessive secretion of CRH, ACTH, and resting renin levels. The normal daily cortisol production rate is 6 to 7 mg/m^2 per day in children and adolescents.[190,191] This rate translates to approximately 10 to 12 mg/m^2 per day of oral hydrocortisone to allow for step-down losses from absorption, hepatic processing, and metabolic bioavailability. Because the bioavailability of oral steroids varies from person to person,[192] infants should be monitored closely for signs of either inadequate cortisol replacement or cortisol excess.[193] Although adults and older children may be able to take hydrocortisone twice daily, most infants should be dosed three times daily to avoid hypoglycemia associated with low cortisol on a twice-daily regimen.[194,195] Hydrocortisone is the preferred steroid for treatment of infants because it has fewer growth-suppressive effects than synthetic steroids.[196–198] The United States Food and Drug Administration withdrew oral hydrocortisone suspension from the market because of poor absorption and undertreatment of children.[153] The smallest tablet for hydrocortisone is 5 mg, and it can be cut into quarters for a dose of 1.25 mg. A new formulation for lower doses of hydrocortisone—0.5 mg, 1 mg, and 2 mg—was recently FDA approved. This medication though can only be given orally and not via nasal or gastric tubes.

In primary adrenal insufficiency, aldosterone production is usually decreased. Physiologic doses of hydrocortisone do not provide enough mineralocorticoid activity to prevent salt wasting[48]; therefore, these infants often require 0.05 to 0.4 mg/day of fludrocortisone acetate (Florinef, 9α-fluorocortisol) and added salt. Because after the first month of life aldosterone production does not vary, the dose of fludrocortisone does not increase with growth and aging.[30,199] Infants with mineralocorticoid deficiency require 1 to 2 g of sodium chloride (1 g contains 17 mEq of sodium) added to their diet because formula and breast milk are low in sodium content (approximately 8 mEq/L).[200]

Stress Replacement

The normal response to surgery, trauma, or critical illness is to increase plasma ACTH and cortisol levels.[201] The secretion rate of cortisol has been found to be proportional to the degree of stress and ranges from 60 to 167 mg/day in adults after surgery.[202,203] Based on data from adults, it is recommended that infants with adrenal insufficiency receive 30 to 100 mg/m^2 per day of hydrocortisone, divided every 6 to 8 hours, when stressed. In patients at risk for adrenal crisis, stress doses of hydrocortisone should be given with the onset of fever and gastrointestinal or other significant illness and continued for 24 hours after the symptoms resolve.[204] Usually, this treatment translates to the routine steroid dose being tripled and administered over three divided daily doses. If oral steroids are not tolerated, an intramuscular or IV dose should be given. For surgery, infants should be given 30 to 100 mg/m^2 of IV hydrocortisone on call to the operating room before the administration of anesthesia. Alternatively, the 30 to 100 mg/m^2 of hydrocortisone can be given continuously during the surgery in the IV fluids. Stress dosing of hydrocortisone (30 to 100 mg/m^2 per day divided every 6 to 8 hours) should be continued postoperatively for the next 24 to 48 hours. It is unnecessary to give mineralocorticoids over such periods if the patient begins the operative period in adequate salt balance. Sodium, potassium, and glucose levels as well as blood pressure should be monitored.

The patients and their families should have instructions for such instances. Every patient should wear a medical identification (e.g., MedicAlert) bracelet or necklace and carry the emergency medical information card that is supplied with it. Both should indicate the diagnosis, the daily medications and doses, and the physician to call in the event of an emergency.

Differences in Sex Development

MARGARETT SHNORHAVORIAN AND PATRICIA Y. FECHNER

KEY POINTS

- Differences in sex development (DSD) are due to a variety of etiologies, requiring expertise of the pediatric endocrinologist, pediatric urologist, geneticist, and child psychologist, as well as the adolescent gynecologist, cytogeneticist, radiologist, and ethicist in some cases, to aid in the diagnosis, treatment, and optimization of long-term outcomes.
- Understanding normal sex development in males and females is critical to determining the cause of DSD.
- Genetic testing has advanced our understanding of the origins of sex development, and specific testing may be driven by results of hormonal testing. In other situations, the differential diagnosis for a given condition such as complete gonadal dysgenesis is so large that the use of a DSD panel is necessary. Knowing the genetic diagnosis provides closure for families and identifies other risks associated with the diagnosis, such as recurrence, renal disease, or tumor risk. A genetic diagnosis may also predict outcome at puberty.

For parents of a newborn with genitalia that are not clearly male or female, the ambiguity is a distressing matter that needs to be addressed with sensitivity and some urgency. There are four general classifications that can cause differences in sex development (DSD): (1) androgenization of the 46,XX individual, (2) incomplete androgenization of the 46,XY individual, (3) sex gonadal differentiation and chromosomal disorders, and (4) syndromes associated with incomplete genital development (Box 85.1). The first category, 46,XX DSD, comprises the majority of definable cases of ambiguous genitalia, whereas in the second category, 46,XY DSD, a genetic diagnosis is seen in less than 50% of cases.

This chapter presents an overview of the pathophysiology of DSD, including a discussion of the practical aspects of diagnosis and management. An overview of the traditional surgical methods used in the treatment of infants with DSD, including the risks and benefits of these procedures, is included at the end of the chapter.

General Considerations in the Approach to the Newborn With Ambiguous Genitalia

The medical evaluation of a newborn with ambiguous genitalia is necessarily time consuming. Open and honest discussions with the parents are invaluable in allaying anxiety and establishing a trusting relationship. Full disclosure of available information is essential in this regard.

Care must be taken to avoid premature sex assignment for the infant. Proper evaluation of the infant with ambiguous genitalia requires a multidisciplinary team that should include the primary care physician, neonatologist, pediatric endocrinologist, psychologist, pediatric urologist, pediatric geneticist, and pediatric radiologist.[1] Psychological assessment and support of the family are essential in the newborn period, along with long-term psychological follow-up evaluation.[2–4] Decisions regarding the sex of rearing should be made collaboratively between the multidisciplinary team and the parents, with the recognition that cultural and psychosocial factors play a role.[5,6]

In the past, sex assignment was based largely on clitoral-phallic size, relative ease of surgical reconstruction, or the potential for fertility. This approach has come under criticism as dissatisfaction with sex assignment based on these criteria has been reported in several case studies.[7–10] The importance of prenatal androgen imprinting has been implicated as an important variable in some of these cases.[8] Studies in 46,XY males with incomplete androgenization indicate that a small phallus can be associated with a satisfying adult sex life.[11] Other studies have found that gender role tends to increasingly correspond with assigned sex as individuals with DSD proceed into adulthood[12]; therefore, female sex assignment might not be necessarily warranted for 46,XY males with partially incomplete androgenization.

The degree of genital androgenization is one determinant of sex assignment in the infant with ambiguous genitalia; however, other factors such as chromosome complement and etiology of the DSD also play an important role. Parents need to understand that only a sex of rearing is being assigned. It will be up to the individual to choose their gender identity. The formation of a healthy gender identity seems to involve a complex interplay between psychobiologic and environmental factors.[2,13–16] Today with the increased awareness of gender dysphoria, these individuals will have an easier time confirming their own gender identity, even if it is different from the chosen sex of rearing.

Embryology of Sex Determination and Differentiation

Normal and abnormal sex determination and differentiation constitute superb examples of how an understanding of embryology is critical to the approach and management of a group of complex and intriguing clinical disorders. Development of the testis and ovary is unique compared with the development of other organs in that they both derive from the same bipotential gonad. The establishment of a testis or an ovary depends on which pathway is taken based on the genetic background. In the past, the ovarian

• BOX 85.1 Differential Diagnosis for Ambiguous Genitalia

46,XX Androgenized Female

- Congenital adrenal hyperplasia
  - 21-Hydroxylase deficiency
  - 11-Hydroxylase deficiency
  - 3β-Hydroxysteroid dehydrogenase deficiency
  - P450 oxidoreductase deficiency
- Aromatase deficiency (fetal and maternal virilization)
- Virilizing maternal conditions
- Ovotesticular disorder of sex development
- Adrenal/ovarian tumors/luteoma of pregnancy
- Maternal ingestion of progestins, androgens

46,XY Underandrogenized Male

- Androgen insensitivity
  - Complete
  - Partial
- 5α-Reductase type 2 deficiency
- Testosterone biosynthetic defects
  - Steroidogenic acute regulatory (StAR) deficiency
  - P450 side chain cleavage enzyme deficiency
  - 17α-Hydroxylase/17,20-lyase deficiency
  - P450 oxidoreductase deficiency
  - 3β-Hydroxysteroid dehydrogenase deficiency
  - 17β-Hydroxysteroid hydrogenase type 3 deficiency
- Leydig cell hypoplasia
- Idiopathic, undetermined
- Drug ingestion: progestins, spironolactone, cimetidine, phenytoin
- Persistent müllerian duct syndrome

Gonadal Differentiation and Chromosomal Disorders

- 46,XY gonadal dysgenesis
  - Complete (Swyer syndrome)
  - Partial
  - Mixed (45,X/46,XY)
- Ovotesticular disorder of sex development
  - 46,XX, 46,XY, 45X/46XY, 46,XX/46,XY

Syndromes Associated With Ambiguous Genitalia

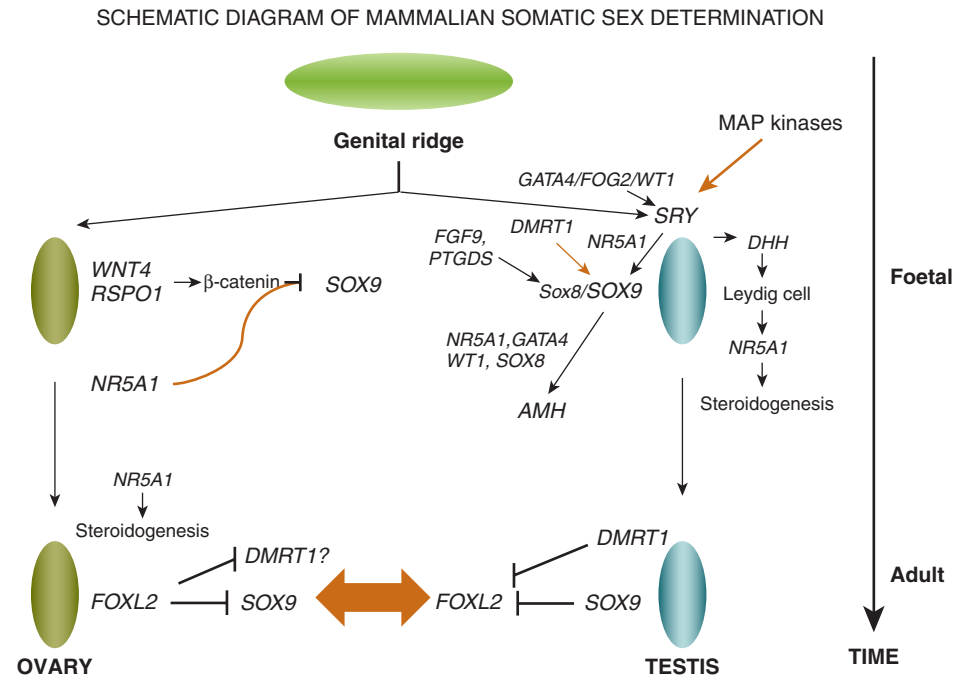
- Gonadal dysgenesis
  - 45,X/46,XY mixed gonadal dysgenesis (Turner syndrome features)
  - Campomelic dysplasia
- Renal degenerative diseases and gonadal dysgenesis
  - Denys-Drash syndrome
  - Frasier syndrome
  - WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation) syndrome
- Smith-Lemli-Opitz syndrome (7-dehydrocholesterol reductase deficiency)
- Robinow syndrome

pathway was thought to be the default pathway. However, from studies of individuals with DSD, it is now known that ovarian development is an active process, and certain genes must be present for the ovary to develop.

Sex determination and differentiation are sequential processes that can be divided into three stages,[17] with the sequence as follows: chromosomal sex is determined at fertilization and dictates the differentiation of the bipotential gonad, which in turn dictates the phenotypic sex, or the differentiation of the internal ductal system and external genitalia on the basis of which hormones are produced by the gonad.[5]

Chromosomal sex is determined at the moment of conception by the sex chromosome complement of the fertilizing sperm. If this sperm carries an X chromosome, a 46,XX (normal female) complement results. If the sex chromosome is Y, a 46,XY (normal male) genotype results. The *SRY* (*s*ex-determining *r*egion of the *Y* chromosome) gene is necessary but not sufficient for testicular differentiation. Other autosomal and X chromosomal genes are also necessary for male sex development. *SRY* is, however, the only gene on the Y chromosome involved in testicular determination and differentiation. SRY, through a number of steps, instructs the medullary region of the bipotential gonad to develop into Sertoli cells and later into testicular cords and seminiferous tubules. SRY continues to be expressed at low levels in Sertoli cells until adulthood.

In addition to X chromosomal genes, autosomal genes influence sex differentiation insofar as mutations of these genes result in disorders of sex differentiation. Some of these genes include *WT1* (*W*ilms *t*umor gene *1*), associated with Denys-Drash syndrome and WAGR (*W*ilms tumor, *a*niridia, *g*enitourinary abnormalities, mental *r*etardation) syndrome; *NR5A1* (*n*uclear *r*eceptor subfamily *5*, group *A*, member *1*), which encodes steroidogenic factor 1; and *SOX9*, which has been associated with campomelic dysplasia and testicular dysgenesis in 75% of XY individuals.[18] *SOX 9* expression is upregulated by SRY. The *DMRT1* and *DMRT3* genes on chromosome arm 9p, when deleted, are associated with female development in an XY individual. More recently, a de novo missense mutation in *DMRT1* was identified in a female with 46,XY karyotype, providing evidence that *DMRT1* is the critical gene for testicular differentiation.[19] The *FOXL2* gene is expressed in fetal and adult ovarian follicular cells and is critical to ovarian development, fertility, and maintenance of the ovary. It is also expressed in eyelids, with mutations leading to blepharophimosis–ptosis–epicanthus inversus syndrome, and is located within the homologous region in the human at 3q23.[20] The *DAX1* gene is located on Xp22 and appears to be necessary for correct testis determination and, in the mouse at least, necessary for the upregulation of *Sox9* expression.[21] When the *DAX1* gene is duplicated, 46,XY individuals develop gonadal dysgenesis with a female phenotype.[22] The *WNT4* gene is critical for normal ovarian and female sexual development. A mutation in *WNT4* leads to müllerian duct regression and virilization in a 46,XX female,[23] whereas duplication of the locus containing *WNT4* leads to overexpression of DAX1 and thus a 46,XY female phenotype.[24] The desert hedgehog gene (*DHH*) is a member of a family of signaling genes with an important role in regulating morphogenesis. The follistatin gene (*Fst*) and the bone morphogenetic protein 2 gene (*Bmp2*) appear to be important for ovary organogenesis in mice.[25,26] Mutations in *Gata4* or *Fog2* can cause sex reversal in mice.[27–29] In humans, GATA4 is a transcription factor necessary for genital ridge formation, testicular and ovarian differentiation, and male and female fertility. GATA4 interacts with multiple genes, such as *SRY*, *SOX9*, and *AMH*, as well as others involved in hormonal synthesis. GATA4 acts synergistically with NR5A1 to activate the *AMH* promoter, and a mutation in *GATA4* led to the lack of this synergy with NR5A1 as well as inability for FOG2 to bind to GATA4, resulting in familial 46,XY DSD and congenital heart defects.[30] FOG2 modifies GATA4 activity by binding to GATA4's zinc finger.[31] Missense mutations in *FOG2* have been identified in two individuals with 46,XY gonadal dysgenesis.[32] The pathways to testicular and ovarian development are illustrated in Fig. 85.1.



• **Fig. 85.1** Testicular and Ovarian Development Pathways. In the XY gonad, *SRY* expression is initiated by WT1/GATA4/FOG2, which leads to the upregulation of *SOX9* expression via synergy with NR5A1. Once SOX9 levels reach a critical threshold, SOX9 autoregulates its own expression. In the XX gonad, the supporting cell precursors accumulate β-catenin in response to RSPO1/WNT4 signaling, which either directly or indirectly represses *SOX9* expression. NRA51 is also critical for steroidogenesis. *AMH*, Antimüllerian hormone; *DHH*, desert hedgehog; *DMRT1*, doublesex and mab-3 related transcription factor 1; *FGF9*, fibroblast growth factor 9; *FOG2*, aka ZFPM2 (zinc finger protein, FOG family member 2); *FOXL2*, forkhead box L2; *GATA4*, GATA binding protein 4; *MAP*, mitogen-activated protein; *MAP kinase*, mitogen-activated protein kinase; *NR5A1*, nuclear receptor subfamily 5 group A member 1; *PTGDS*, prostaglandin D2 synthase; *RSPO1*, R-spondin 1; *SOX8*, SRY-box 8; *SOX9*, SRY-box 9; *SRY*, sex determining region Y-chromosome; *WNT4*, wingless-related integration site 4; *WT1*, Wilms tumor 1. (Reproduced with permission from Bashamboo A, McElreavey K. Mechanism of sex determination in humans: insights from disorders of sex development. Sex Dev. 2016;10:313–325.)

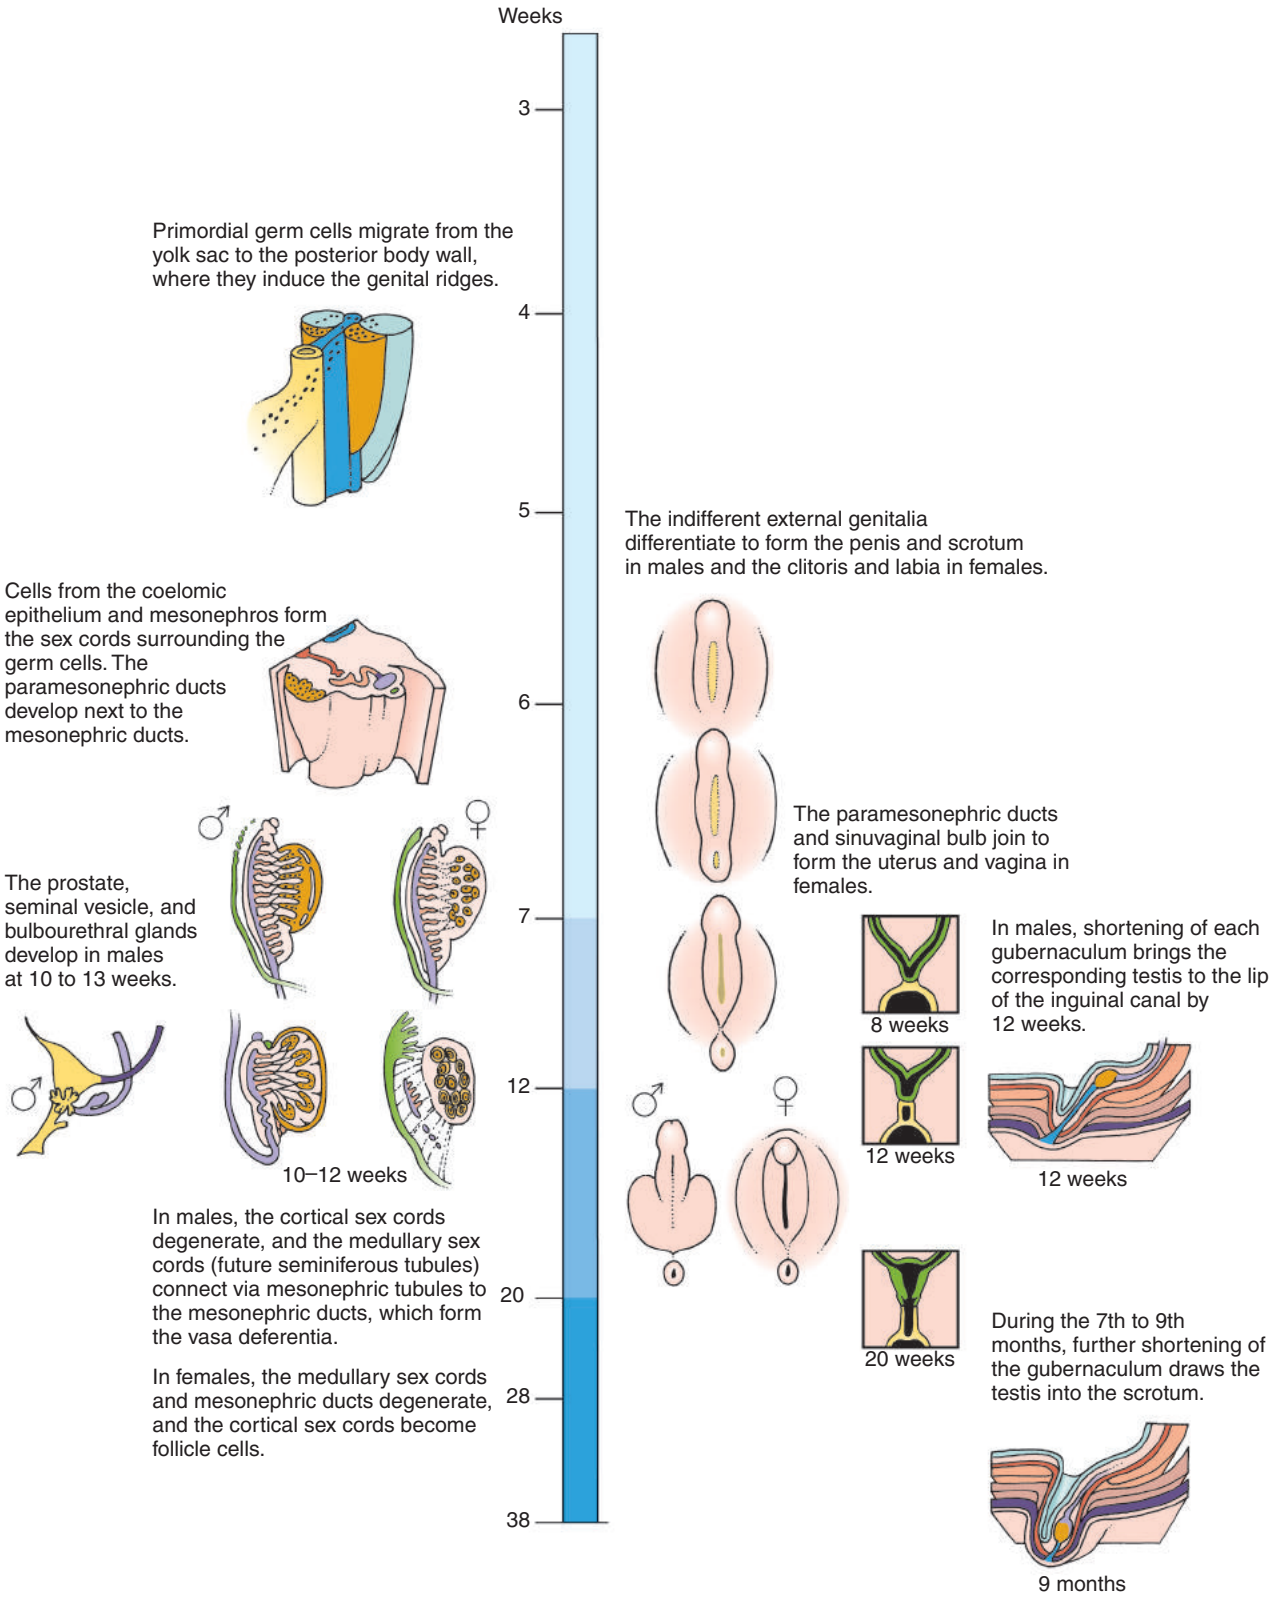
The gonad develops from both somatic and germ cells. The somatic cells are located at the ventral region of the mesonephros and arise from the mesonephric cells and the coelomic epithelium. Somatic cells become the Sertoli cells of the testis and the granulosa cells of the ovary. The germ cells migrate from a more inferior position on the yolk sac to the genital ridge, just medial to the mesonephros on each side (Fig. 85.2, upper left). This migration occurs between 4- and 6-weeks' gestation. Once the germ cells reach the gonadal ridge, they become surrounded by the somatic cells, which appear to regulate germ cell differentiation.

Gonadal sex is established by 7 weeks' gestation. At this stage the fetus contains two parallel internal ductal systems—wolffian and müllerian—and undifferentiated external genital primordia. The wolffian, or mesonephric, duct is a tubular structure that connects the capillary network of the mesonephros to the urogenital sinus. Evagination of the coelomic epithelium leads to formation of a second tubular structure adjacent to the mesonephric duct—the paramesonephric, or müllerian, duct. The distal ends of these two ducts are joined. That portion of the urogenital sinus distal to the termination of these ducts contributes to external genital development, whereas the proximal portion develops into the bladder, trigone, and posterior urethra.

Phenotypic sexual differentiation is predicated on establishing gonadal sex. If an ovary develops, the wolffian ducts involute because of a lack of local testosterone exposure, and only the terminal portion persists as a Gartner duct. In the absence of antimüllerian hormone (AMH), a glycoprotein secreted by the fetal Sertoli cells, the müllerian ducts develop into the proximal portion of the vagina, uterus, and fallopian tubes (see Fig. 85.2). The unfused cephalic portions of the müllerian ducts form the fallopian tubes, whereas the caudal ends fuse to form the ureterovaginal canal (see Fig. 85.2). The union of the fused caudal ends of the müllerian ducts and urogenital sinus forms the vagina. Thus, the proximal two-thirds of the vagina is of müllerian duct origin, and the distal third is of urogenital sinus origin. There is no fusion of the labioscrotal folds and no increase in clitoral–phallic structure in the absence of elevated levels of circulating androgens.

Male phenotypic differentiation is the result of the elaboration of two distinct testicular hormones: testosterone and AMH. These factors are produced and secreted by the 8-week stage of development, and they are essential for normal male differentiation. Involution of the müllerian ducts is caused by AMH. The remnants of the müllerian ducts persist caudally as the prostatic utricle and cephalically as the appendix testis. AMH exerts its action unilaterally and locally (exocrine secretion) rather than bilaterally via the systemic circulation.

Immediately after müllerian duct regression, the wolffian ducts develop under the local influence of testosterone secreted by the



• **Fig. 85.2** Embryologic timeline for gonadal development and development of internal and external genitalia. (From Larsen WJ. Human Embryology. New York, NY: Churchill Livingstone; 1993:237.)

fetal Leydig cells. The Leydig cells, like the Sertoli cells, differentiate from the mesenchymal cells within the gonadal ridges; this occurs at 9 to 10 weeks' gestation. Under the influence of testosterone, the wolffian ducts evolve into the epididymis, vas deferens, and seminal vesicles (see Fig. 85.2). The mesonephric tubules develop into the ductuli efferentes, which will provide continuity between the seminiferous tubules and rete testis to the vas deferens. This process occurs as a direct action of local testosterone on

the ductal structures. Elevated serum testosterone levels such as seen in congenital adrenal hyperplasia due to 21-hydroxylase deficiency in females do not cause wolffian duct stabilization.

Androgenization of the male external genitalia, fusion of labioscrotal folds, and movement of the urethral opening, starts at approximately 8 weeks' gestation (see Fig. 85.2). Androgenization relies on the ability of the tissues involved to convert testosterone into a more potent androgen: dihydrotestosterone (DHT). The target cells possess the enzyme 5α-reductase type 2, which is necessary for this conversion. In addition, an intact androgen receptor is necessary for the androgenization of the male external genitalia. By 12 to 14 weeks' gestation, formation of the male external genitalia is nearly complete. Androgen exposure after this time results in further phallic enlargement. Initially, testes are stimulated to make testosterone by maternal HCG during the first trimester but by 16 to 20 weeks' gestation, the fetus' own luteinizing hormone (LH) is driving testosterone production.

Testicular descent occurs in two stages. The initial transabdominal descent occurs at 8 to 15 weeks and depends on insulin-like 3 (INSL3) and its G protein–coupled receptor (GREAT) which are secreted by the testes. Other testicular factors likely also play a role, as most dysgenetic gonads are intraabdominal. Descent into the inguinoscrotal region occurs at 25 to 35 weeks and is androgen dependent.

Clinical Assessment of Differences of Sex Development

History

A detailed family history is important in the evaluation of ambiguous genitalia. Information on early neonatal deaths, consanguinity, or urogenital anomalies should be obtained. A family history of female infertility, amenorrhea, or müllerian duct abnormalities can be suggestive of a DSD. In one study of androgen insensitivity disorders that are X-linked, a positive family history of a sex differentiation disorder was often overlooked.[33]

The presence of maternal androgenization is suggestive of a variety of disorders that can affect the androgenization of the fetus. Features of maternal androgenization include hirsutism, severe acne, deepening of the voice, and clitoromegaly.

The ingestion of any recreational drugs, alcohol, or medications by the mother during pregnancy should be noted. Particular attention to medications with androgenic or progestational activity is indicated. Medications that affect fetal genital development include cimetidine, spironolactone, hydantoin, and progestational agents.[5] Maternal retention of progesterone-secreting intrauterine devices at the time of conception have also been associated with androgenization of a female fetus.[34] Progestational agents are used in assisted reproductive technology to support the pregnancy in the first trimester; therefore, asking if the pregnancy was conceived spontaneously or through the use of assisted reproductive technology is important.

Physical Examination

There is significant overlap of the genital anatomy among the various sex differentiation disorders. The physical examination, however, can provide the first clues to the underlying disorder. In addition, the physical examination will provide important information about the degree of androgenization of the external genitalia and the presence or absence of palpable gonads. Prader stage (Fig. 85.3A) is used to describe the androgenization of female external genitalia. The external masculinization score (see Fig. 85.3B) is used to describe the incomplete androgenization of male external genitalia.[35] The physical examination will also inform the examiner as to when the DSD occurred in fetal life.

Clitoris

Significant clitoral enlargement deserves careful evaluation. A point to keep in mind is that premature infants have relatively underdeveloped labia majora, so the clitoris may appear enlarged. A truly enlarged clitoris can be distinguished from a large clitoral hood by the presence of palpable corporal or erectile tissue.

Penis (Phallus)

Measurements of the phallic stretch length and middle shaft diameter are important in determining the degree of virilization. The phallus should be stretched and measured from the pubic ramus to the tip of the glans. Gestational age–corrected phallic stretch lengths are shown in Fig. 85.4. The presence of a chordee structure on the ventral surface of the phallus can impair measurement of the true phallic length (Fig. 85.5).[36] Chordee is the result of residual urethral tissue that continues to tether the phallus to the perineum. Measurement of the middle shaft diameter is particularly useful in this circumstance. For term male infants, a normal middle shaft diameter is approximately 1 cm.[36]

An isolated microphallus warrants careful evaluation for the presence of hypopituitarism (gonadotropin, ACTH, TSH, or growth hormone deficiency), particularly in the presence of hypoglycemia or unexplained jaundice. Microphallus and undescended testes may occasionally be the presenting phenotype for a DSD.

Labioscrotal Folds

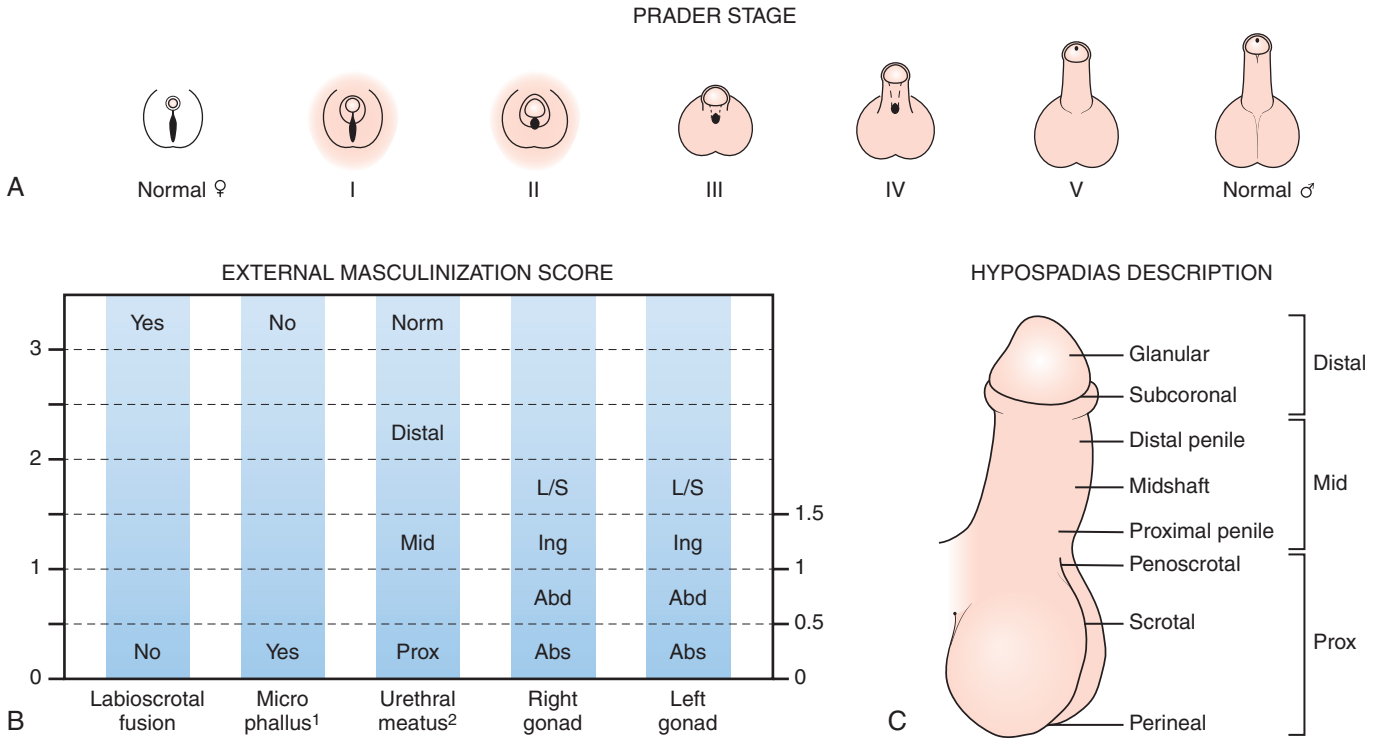
In neonates with ambiguous genitalia, assessment of the degree of fusion of the labioscrotal folds should be performed. When the infant is exposed to androgens during embryogenesis, fusion of the labioscrotal folds progresses from a posterior to an anterior direction. The spectrum of labial fusion can range from mild posterior fusion to complete labial fusion (Fig. 85.6). Fusion of the labioscrotal folds occurs in the first trimester. The examiner should note whether the folds are rugated or hyperpigmented. Is the phallus positioned in the normal superior position relative to the scrotum, or is there a shawl scrotum (penoscrotal transposition)? Is the scrotum fused normally in the midline, or is the scrotum bifid (see Fig. 85.5)?

Gonads

Careful examination for the presence of gonads should be performed in all infants with ambiguous genitalia. The presence of bilateral gonads in the labial folds is highly suggestive of a genetic male with incomplete androgenization (see Fig. 85.5). A unilaterally palpable gonad is often seen in infants with mixed gonad dysgenesis or ovotesticular DSD (Fig. 85.7), although other disorders such as androgen insensitivity can manifest themselves similarly. When cryptorchidism and hypospadias occur simultaneously, there is a greater than 25% chance of a DSD.[37,38]

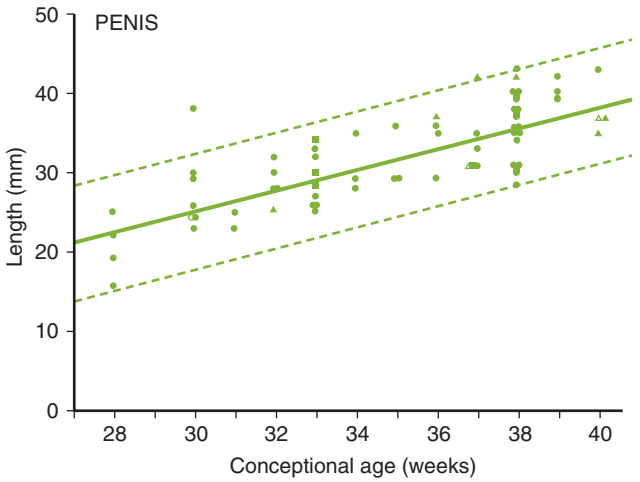
Hypospadias or Urogenital Sinus

The severity of hypospadias can differ, with the condition ranging from mild glanular hypospadias to penoscrotal hypospadias (see Fig. 85.3C), although most disorders of sexual differentiation manifest themselves with severe penoscrotal or scrotal hypospadias

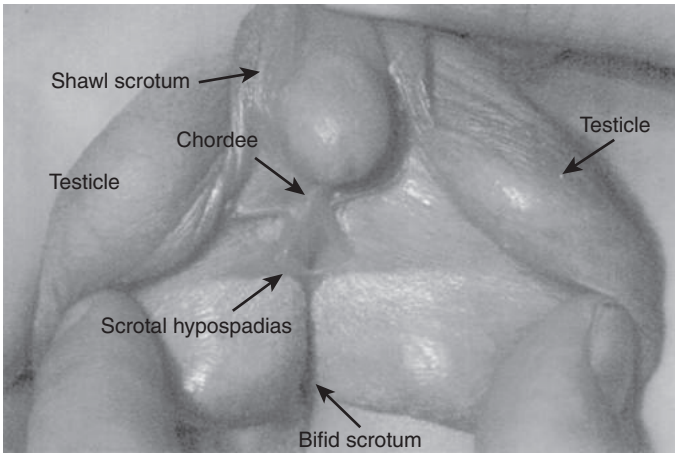


[1]Microphallus is a phallic length below the male reference range.
[2]The location of the urethral meatus is based on the location described in C.

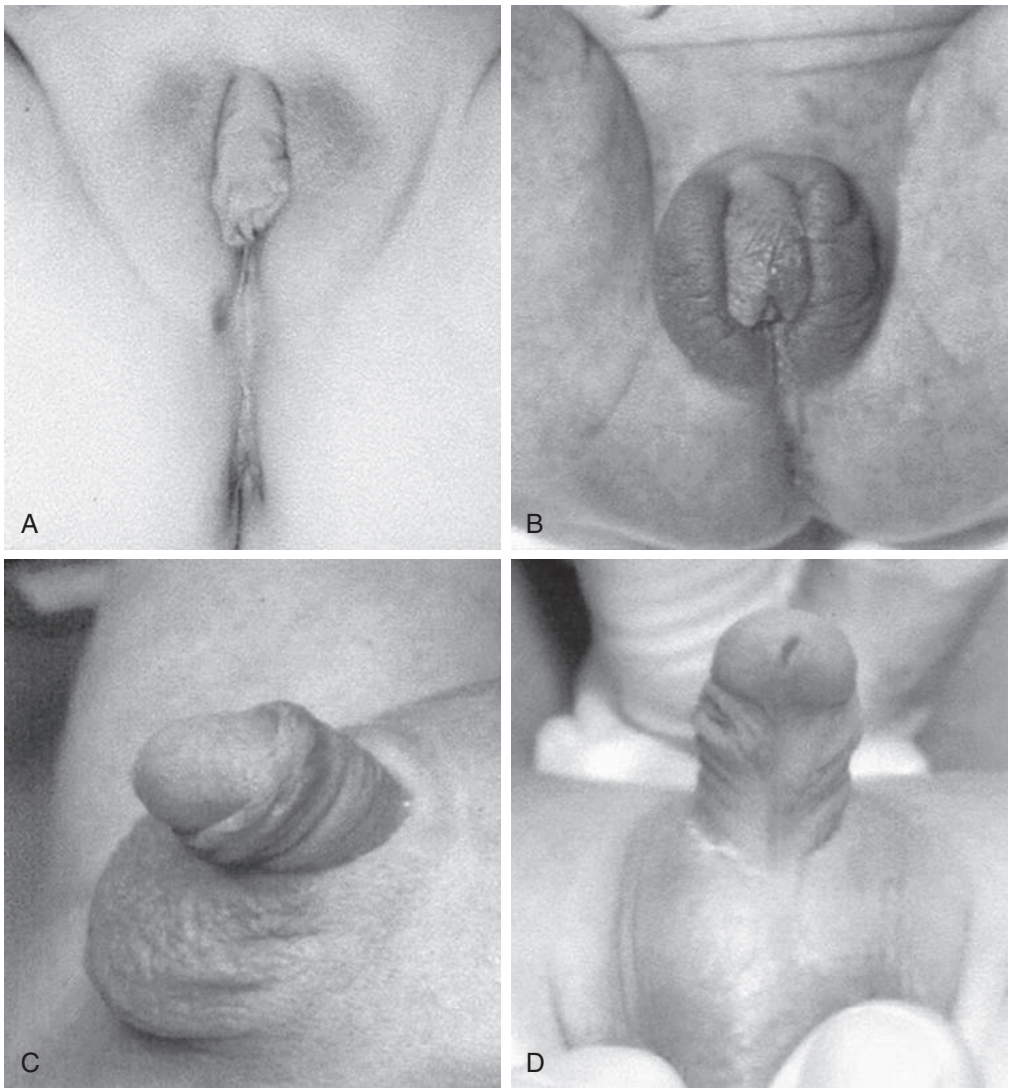
• **Fig. 85.3** (A) The stages of virilization of the female with congenital adrenal hyperplasia as developed by Prader. Stage I indicates mild clitoromegaly only; stage V indicates complete masculinization. (B) External masculinization score. A score of 0 to 3 is given for four aspects of male external genitalia. The sum of the four values is the external masculinization score. A normal male has a value of 12. (C) Hypospadias description. *Abd*, Abdomen; *Abs*, absent; *Ing*, inguinal; *L/S*, labioscrotal; *norm*, normal; *prox*, proximal. (A, from Migeon CJ, Berkovitz G, Brown T. Sexual differentiation and ambiguity. In: Kappy MS, Blizzard RM, Migeon CJ, eds. Wilkens' Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence. 4th ed. Springfield, IL: Charles C. Thomas; 1994:573. B–C, from Ahmed SF, Achermann JC, Arlt W, et al; Society for Endocrinology UK guidance on the initial evaluation of an infant or an adolescent with a suspected disorder of sex development (Revised 2015). Clin Endocrinol. 2016;84(5):771–788.)



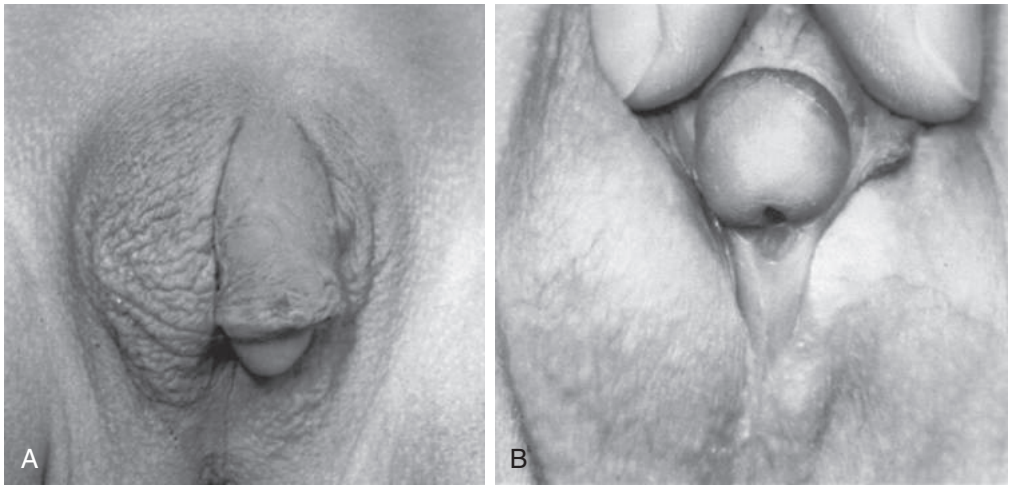
• **Fig. 85.4** Penis stretch length in 63 normal premature and full-term male infants *(circles)*, showing lines of mean ± two standard deviations. Superimposed are data for two small-for-gestational-age infants *(open triangles)*, seven large-for-gestational-age infants *(closed triangles)*, and twins *(squares)*. (Reproduced with permission from Feldman KW, Smith DW. Fetal phallic growth and penile standards for newborn male infants. J Pediatr. 1975;86:395–398.)



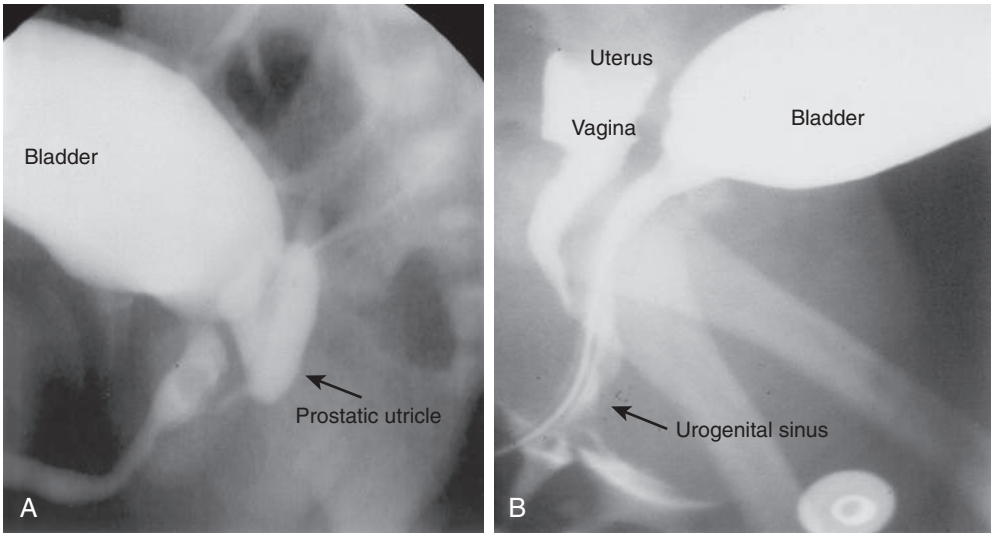
• **Fig. 85.5** Undervirilized male demonstrating bifid scrotum, scrotal hypospadias, chordee, and bilateral descended testes.



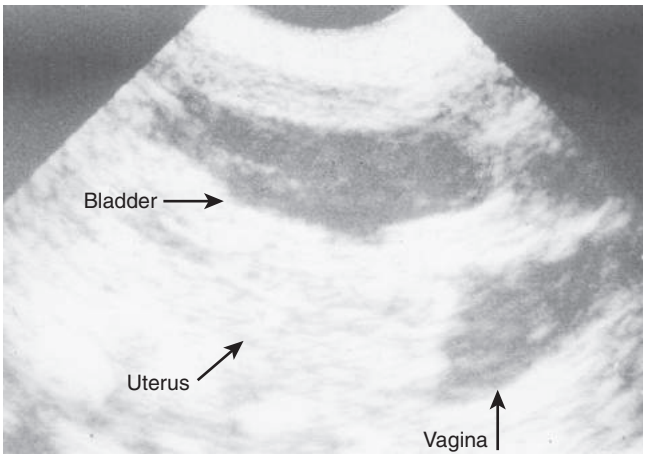
• **Fig. 85.6** Virilization of external genitalia in 46,XX congenital adrenal hyperplasia (21-hydroxylase deficiency). (A) There is a mild to moderate degree of virilization, with primarily clitoral hypertrophy and significant fusion of the labia. (B) Virilization is moderate, with clitoromegaly, labial fusion, and rugation of labial folds. (C, D) Complete masculinization is evident.



• **Fig. 85.7** Asymmetric external genitals with left unilateral descended testis (A), penoscrotal hypospadias, and chordee (B). Asymmetric external genital development or gonadal descent would be characteristic of mixed gonadal dysgenesis or ovotesticular disorder of sexual development.



• **Fig. 85.8** Genitourethrograms. (A) Genitogram from a 46,XY infant with microphallus and undescended testes with a clearly delineated prostatic utricle. (B) Genitogram from a 46,XX infant with congenital adrenal hyperplasia and severe masculinization of external genitals. The confluence of the vagina with the urogenital sinus is of intermediate severity.

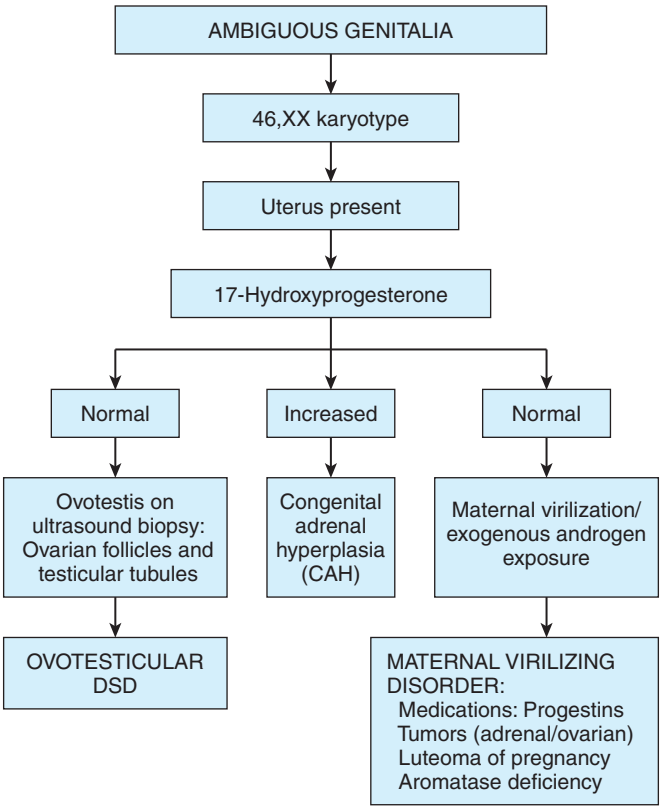


• **Fig. 85.9** Ultrasound image from a 46,XX infant with ambiguous genitalia. Note the presence of a well-developed uterus with an endometrial stripe.

(see Fig. 85.5). Examination for the presence of separate urethral and vaginal openings versus a single perineal opening (urogenital sinus) conveys important anatomic information. The vagina may be blind ending or completely formed. A urogenital sinus results from failure of the urologic and genital tracts to differentiate completely. In females exposed to androgens, the level at which the vagina enters the sinus (low-level versus high-level vaginal entry) has important implications for determining the ease of subsequent surgical exteriorization of the vagina (Fig. 85.8). In addition, when the urethra enters a urogenital sinus, there is potential for urinary stasis and therefore urinary tract infections. Excessive pigmentation of the genitals or signs of dehydration should alert the examiner to the possibility of congenital adrenal hyperplasia (CAH).

Dysmorphic Features

Dysmorphic features suggestive of Turner syndrome indicate the possibility of gonadal dysgenesis or mixed gonadal dysgenesis. Such abnormalities or multiple congenital anomalies could indicate any of a variety of syndromes associated with ambiguous genitalia (see Box 85.1).

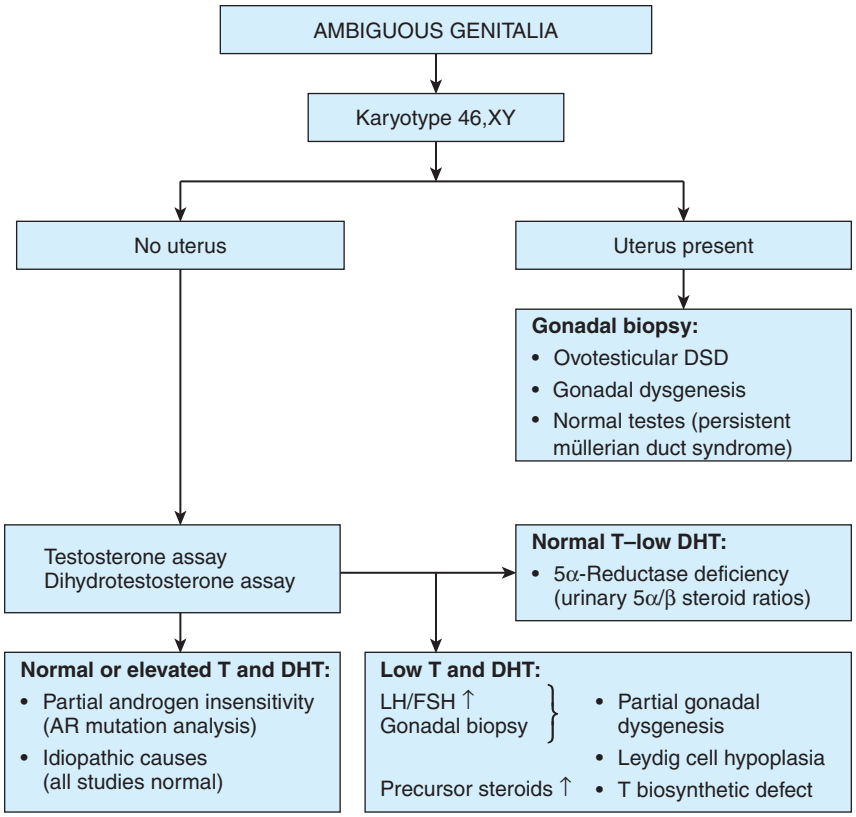


• **Fig. 85.10** Algorithm for evaluation of the 46,XX infant with ambiguous genitalia. The presence of a uterus would be determined radiographically by ultrasound examination, genitourethrogram, or magnetic resonance imaging.

Radiologic Investigations

Pelvic Ultrasonography

Pelvic ultrasonography reveals vital information in the evaluation of DSDs. The presence or absence of a uterus is a critically important determinant in the initial evaluation (Figs. 85.9–85.11). The newborn period is a time when the uterus,



• **Fig. 85.11** Algorithm for evaluation of the infant with ambiguous genitalia and 46,XY karyotype. The presence or absence of a uterus would be determined by radiographic imaging, including ultrasound examination, genitourethrogram, or magnetic resonance imaging, as appropriate. Testosterone *(T)* and dihydrotestosterone *(DHT)* levels ideally should be obtained between 2 weeks and 3 months during the mini-puberty. *AR*, Androgen receptor; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

ovaries, and adrenal glands are optimally visualized.[39] The presence of a well-developed uterus will direct the differential diagnosis toward a condition leading to androgenization of a genetic female's external genitalia, 46,XY ovotesticular DSD, 46,XY complete gonadal dysgenesis, or persistent müllerian duct syndrome (PMDS); however, only a rudimentary uterus may be seen in 46,XY gonadal dysgenesis or ovotesticular DSD. Importantly, the inability to identify a uterus on ultrasound is not conclusive for lack of a uterus. Ultrasonography for testes location has sensitivity and specificity of 45% and 78%[40] and is not recommended per current American Urologic Association (AUA) guidelines.[41] Ultrasound examination can determine whether the adrenal glands appear enlarged, as in CAH; however, normal adrenal size does not rule out CAH.

Genitourethrogram

A genitourethrogram is a fluoroscopically-guided genital dye study that can provide important information on the urethra and internal genital ducts.[39] An experienced radiologist should perform this study. It is important to ensure that all perineal orifices are examined. The main features to be noted are the presence or absence of a vagina (or prostatic utricle) and the relationship between the vagina and the urethra (see Fig. 85.8). Demonstration of the level at which the vagina opens into the urogenital sinus and its relationship to the external sphincter has important surgical implications. Recognition of male or female urethral configurations may also be possible during genitourethrography.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has been used to assess the internal genitalia of a limited number of infants and children with genital differentiation disorders. The strength of MRI lies in its ability to image large areas in multiple planes and characterize soft tissues. Detailed information about müllerian and wolffian structures and the position of the gonads can be obtained; however, thin sections (3 to 5 mm) are required for an adequate study. Streak gonads remain difficult to visualize. MRI has the capability to differentiate between an enlarged clitoris and a penis, because the bulbospongiosus muscle and transverse perineal muscle are absent or poorly visualized in the virilized female.[39] MRI is a promising modality for the evaluation of ambiguous genitalia as it offers greater sensitivity and specificity than other studies, but it is more expensive, and anesthesia may be required.

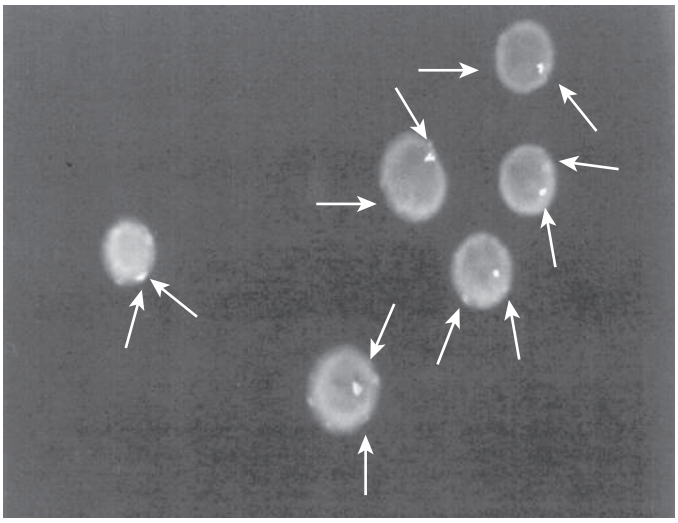
Laboratory Investigations

Endocrine and genetic laboratory studies are germane in the evaluation of ambiguous genitalia in the newborn. Day 1 of life is an ideal time to obtain serum testosterone and dihydrotestosterone (DHT) levels by liquid chromatography—tandem mass spectrometry (LC–MS/MS), as testosterone levels fall rapidly in the first several days of life.[42] It is important to use LC–MS/MS assays as other assays measure interfering substances that will falsely elevate the testosterone level.[43] Chromosomal studies should optimally be performed on day 1, as a preliminary karyotype can be available

by 24 to 48 hours with use of the fetal nucleated red blood cells. Fluorescence in situ hybridization (FISH) for *SRY* should also be performed. On day 2 or day 3 of life, determinations of serum 17-hydroxyprogesterone (17-OHP), 17-hydroxypregnenolone, 11-deoxycortisol, dehydroepiandrosterone (DHEA), androstenedione, and plasma renin activity are performed if CAH is suspected. Some clinicians perform an adrenocorticotropic hormone (ACTH) stimulation test at this time to more clearly demonstrate a block in steroid biosynthesis. However, if the ACTH level is already elevated, then additional information from an ACTH stimulation test will not be gained. Results of these studies should be sent immediately to the appropriate reference laboratory for analysis. Alerting the reference laboratory to the urgent nature of the studies performed will facilitate rapid processing. 17-OHP levels are physiologically elevated on the first day of life, and screening for CAH should preferably not be done at this time. Serum gonadotropins are often suppressed in the immediate newborn period, so they should be measured after 1 week of life. LH and follicle-stimulating hormone (FSH) levels are helpful in assessing newborns for androgen insensitivity syndrome (AIS), gonadal dysgenesis, and LH receptor abnormalities. Repeated LH, FSH, testosterone, and DHT testing should be done between 2 and 8 weeks of life in the evaluation of incomplete androgenization in males. This period coincides with the physiologic testosterone surge (mini-puberty) seen in healthy male infants.[42] AMH and inhibin B levels can be obtained at any time. When CAH is suggested, it is important to check sodium and potassium levels daily to prevent a salt-wasting crisis. An elevated renin level with a lower sodium level is concerning for impending salt wasting crisis, and therapy with hydrocortisone, fludrocortisone and sodium chloride should be initiated.

A human chorionic gonadotropin (hCG) test has been used in the past in the evaluation of suspected incomplete masculinization of the genetic male. However, if LH level is elevated, then hCG testing is not useful as it will not provide any additional information. HCG, as does LH, binds the LH receptor and stimulates the testes to synthesize sex steroids. A testosterone response greater than 200 ng/dL rules out a testosterone biosynthetic defect and is considered a normal response to hCG (a value less than 200 ng/dL may be normal in some assays as the assays have become more specific for testosterone). A normal testosterone-to-DHT ratio of less than 8:1 argues against 5α-reductase type 2 deficiency, with the caveat that the testosterone level must be high enough to adequately test the enzyme function. The gold standard for 5α-reductase type 2 deficiency is genetic testing, as the testosterone-to-DHT ratio can be misleading. In addition, the hCG test can result in phallic enlargement if there is a good testosterone response. An increase in phallic length of 0.25 to 0.75 cm in six 46,XY males with idiopathic microphallus was reported within 5 days of beginning injections.[44] A bolus of 1500 international units (IU) hCG was given intramuscularly on 3 consecutive days, with steroids and phallic length measured on the fifth day. Growth of the phallus in response to hCG suggests that the phallus will further virilize at puberty, although no longitudinal study has documented this assumption. An alternative is to give testosterone to see if there is increase in the phallus and to look at T:DHT. This bypasses the testes from producing testosterone at a nonphysiologic age, which could have negative effect on the testes.[45]

FISH can rapidly determine the sex chromosome complement of the newborn by use of X chromosome- and Y chromosome-specific centromeric probes (Fig. 85.12).[46] In addition, this method allows the detection of low levels of chromosomal mosaicism, because hundreds of cells can be analyzed rapidly. FISH is also useful in identifying an *SRY* gene translocated to an X chromosome.[47] FISH analysis for determination of sex chromosome constitution has been shown to be highly reliable, although this method has not been used extensively in the evaluation of ambiguous genitalia of the newborn. FISH will only determine the presence of the X and Y centromere and SRY if requested. It will not identify large deletions or insertions of the sex chromosomes. Therefore, results should be interpreted with some degree of caution until confirmation by karyotypic analysis is available. If there is concern for additional congenital anomalies, then a single nucleotide polymorphism (SNP) chromosome microarray may be helpful to look for microdeletions and microduplications, as well as sex chromosome complement, but the turnaround time may be longer.



• **Fig. 85.12** Fluorescence in situ hybridization technique demonstrating the sex chromosome constitution of peripheral blood leukocytes. *Arrows* point to sex chromosomes in each cell.

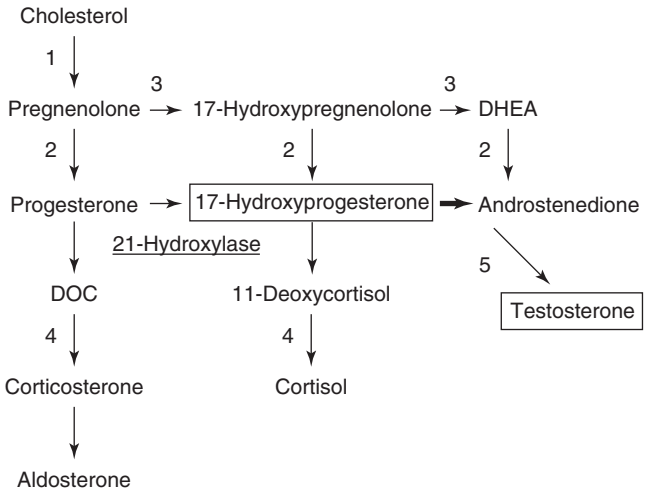
In a small percentage of ambiguous genitalia cases, laparoscopy with gonadal biopsy is necessary to confirm the diagnosis of ovotesticular DSD, gonadal dysgenesis, or Leydig cell aplasia. Obtaining a karyotype from gonadal tissue may be helpful when sex chromosome mosaicism or chimerism is suggested.

46,XX Differences in Sex Development

Androgenization of the Female

Androgenization of an XX neonate is most commonly caused by CAH, although other virilizing conditions can be involved (see Fig. 85.10). CAH encompasses a group of disorders of adrenal steroid hormone biosynthesis, of which more than 90% to 95% are due to 21-hydroxylase deficiency (OHD) (Fig. 85.13).[48]

Occasionally, the presence of excess androgens of maternal origin can result in androgenization of the female fetus.[5] A unique cause of both maternal and fetal masculinization is placental aromatase deficiency.[49] The degree of androgenization of the external genitalia of 46,XX fetuses is dependent on the timing and magnitude of androgen exposure of the fetus. Exposure of the female fetus to high androgen levels before 12 weeks' gestation results in fusion of the labial folds, with formation of a urogenital sinus.



• **Fig. 85.13** Steroid biosynthetic pathway demonstrating the defect in 21-hydroxylase deficiency *(solid bars)* and accumulated precursor 17-hydroxyprogesterone. Note the increased shunting into androgen-producing pathways. Steroidogenic enzymes are indicated as follows: (*1*) steroidogenic acute regulatory protein and side chain cleavage, (*2*) 3β-hydroxysteroid dehydrogenase, (*3*) 17α-hydroxylase/17,20-lyase, (*4*) 11β-hydroxylase, and (*5*) 17β-hydroxysteroid dehydrogenase. *DHEA*, Dehydroxyepiandrosterone; *DOC*, deoxycorticosterone.

In severely androgenized cases the external genitalia may appear completely male (see Fig. 85.6C and D). High-level androgen exposure after 12 weeks' gestation will result in mainly clitoral hypertrophy but with separate labial folds (see Fig. 85.6A). 46,XX testicular DSD occurs when the *SRY* gene is translocated from the Y chromosome to an X chromosome. Most patients with *SRY*-positive 46,XX testicular DSD have normal male external genitalia, but occasionally the genitalia are ambiguous.[47,50,51]

Congenital Adrenal Hyperplasia

21-OHD is the most common cause of ambiguous genitalia in the newborn female.[48] 21-OHD has a population frequency of approximately 1 in 15,000, and the disorder is inherited in an autosomal recessive fashion. Males and females are equally affected; however, in classic cases, females have androgenization of their external genitalia at birth, resulting in the clinical presentation of ambiguous genitalia.

Deficiency of 21-hydroxylase results in excess accumulation of the substrate 17-hydroxyprogesterone (17-OHP), which is shunted into the androgen synthesizing pathway and results in excess levels of androstenedione (see Fig. 85.13). Androstenedione is then converted peripherally to testosterone or DHT using the backdoor pathway.[52] The excess production of androgens results in androgenization of the external genitalia of the female fetus, whereas a male infant with 21-OHD is phenotypically normal. The degree of androgenization in the female is variable and can range from mild enlargement of the clitoris to complete fusion of the labioscrotal folds and urethral opening at the tip of the phallus (see Fig. 85.6). The degree of androgenization can be classified by Prader stages, ranging from I to V (see Fig. 85.3A). Stage I represents mild enlargement of the clitoris only. Stage V represents complete androgenization of the external genitalia, with intermediate stages designating lesser degrees of involvement. The internal genitalia (ovaries, uterus, and fallopian tubes) of the females with androgenization of external genitalia are normal, however, and wolffian duct–derived structures are absent, as there was no local exposure to testosterone (see Chapter 84 for more details).

The diagnosis of 21-OHD should be suspected in all newborns with ambiguous genitalia (or clitoral hypertrophy) and absent gonads in the labial or scrotal folds. A serum 17-OHP level obtained after the first day of life will often be diagnostic. 17-OHP levels are usually 50-fold to 100-fold above the normal range in classic cases, with typical random levels of 10,000 ng/dL or higher.[48] In some cases of 21-OHD, ACTH stimulation testing may be necessary to establish the diagnosis. If the ACTH level is already significantly elevated, however, an ACTH stimulation test will not provide additional information.

The levels of androstenedione, testosterone, 11-deoxycortisol, electrolytes, and plasma renin activity should also be determined. Plasma renin activity is a sensitive indicator of the intravascular volume status of the infant. Impaired sodium–potassium and sodium–hydrogen exchange owing to aldosterone deficiency in the distal tubule of the kidney results in hyponatremic dehydration, hyperkalemia, and metabolic acidosis.

Assessment for the less common forms of CAH resulting in ambiguous genitalia in an XX infant—11β-hydroxylase deficiency (11β-OHD), 3β-hydroxysteroid dehydrogenase (3β-HSD) deficiency, and P450 oxidoreductase deficiency—includes measurement of 11-deoxycortisol, deoxycorticosterone (DOC), DHEA and 17-hydroxypregnenolone in addition to the usual measurements of 17 OHP, androstenedione, cortisol and testosterone when evaluating for CAH. An elevated ACTH level may also be useful. Infants, though, who are stressed will have elevated ACTH and cortisol levels. Use of a comprehensive steroid panel from a reliable reference laboratory will limit the amount of blood required to 3 to 5 mL.

11β-OHD accounts for approximately 5% of CAH cases worldwide, and this disorder will also result in androgenization of the female fetus (see Fig. 85.13). However, the presence of volume overload and hypertension distinguishes 11β-OHD from 21-OHD.[48] Presumably, the hypertension in 11β-OHD is caused by the excess mineralocorticoid activity of the DOC metabolite. Typically, 11-deoxycortisol level is elevated and plasma renin activity is suppressed in this disorder. However, hypertension may not present in the young infant, and thus absence of hypertension does not exclude 11β-OHD.

3β-HSD deficiency may result in ambiguous genitalia in the newborn period (see Fig. 85.13). Unlike 21-hydroxylase, this enzyme is present in the gonads as well as the adrenal glands, and deficiency of 3β-HSD can result in mild androgenization of the female infant and incomplete androgenization of the male infant. This enzyme deficiency also results in excess production of the steroid DHEA, which can be converted to more potent androgens peripherally. The female infant with this disorder can have clitoromegaly, although such children are often phenotypically normal. 3β-HSD is needed for testosterone biosynthesis, leading to inadequate androgenization of the male fetus. A marked increase in the ratios of 17-hydroxypregnenolone to 17-OHP and of DHEA to androstenedione is diagnostic in mutation-positive forms of this disorder.[53]

P450 Oxidoreductase Deficiency

P450 is necessary for the function of 17,20 lyase, 21 hydroxylase, and aromatase. In POR deficiency, the hormonal picture is

quite mixed with partially deficient 17,20 lyase deficiency with or without 21 hydroxylase and aromatase deficiency. Sequencing of the *POR* gene may be necessary to determine the diagnosis. Depending on the specific mutation in *POR*, there may or may not be maternal virilization during the pregnancy. Maternal estriol levels may be low. XX infants may have ambiguous genitalia as well as skeletal defects associated with the Antley-Bixler syndrome.[54]

Sex assignment for 46,XX infants with 21-OHD has traditionally been female.[48,55–58] Gender identity of 46,XX adults with CAH is typically female, with various degrees of gender expression.[8,13,59] Prenatal androgenization affects gender-related behavior, but not gender identity, in girls with CAH aged 5 to 12 years.[60] Cases of gender identity disorder have been reported in treated females with CAH,[2] and cases of gender reassignment from female to male have been reported.[14] Individuals with undiagnosed 46,XX CAH who are profoundly virilized have functioned successfully as males[61–63] which has prompted some to suggest male sex assignment in profoundly virilized 46,XX infants. However, female sex assignment is likely to prevail in current practice until evidence is obtained to indicate otherwise.[64,65] 46,XX females with CAH are infertile.

In addition to medical therapies for CAH, efforts to normalize the appearance of the external genitalia may be pursued. It should be kept in mind that hypertrophy of the clitoris will gradually lessen after medical therapy is instituted; however, complete normalization in the more virilized cases is not likely to occur. In severe cases of clitoral enlargement, clitoral recession surgery is a treatment option, although suboptimal cosmetic results have been reported in long-term outcome studies. Atrophy or loss of the clitoris or excessive regrowth of clitoral tissue has been described in examinations of adolescent and adult patients who underwent genital surgery in early childhood.[66,67] If CAH is not well controlled with hormonal suppression of the adrenal gland, there will be clitoral enlargement in response to the elevated testosterone levels. The risk of surgery needs to be balanced against the potential detrimental effects of masculinized genitalia on the development of a poor body image[14] and of social stigmatization by family or community members.[68] Nerve-sparing ventral clitoroplasty in virilized females has been shown to preserve dorsal nerves for better sensitivity after surgery.[69]

Surgical restoration of the vagina in CAH is performed to exteriorize the vagina and to enlarge the vaginal opening so that successful intercourse can occur later in life. There is considerable debate about when to perform vaginal exteriorization surgery. A number of studies have demonstrated the development of vaginal stenosis when vaginoplasties are performed in the prepubertal period.[66,67,70] The authors advocate delaying vaginoplasty until puberty or later, when manual dilation can be undertaken by the patient, and estrogenization of the vaginal mucosa can help to prevent stricture formation. Others recommend that vaginoplasties be undertaken early in life, because the procedure is technically easier in the first several years of life, and the emotional trauma of a major surgery in adolescence is avoided.[55,71] Reports of long-term outcome of genitoplasty by patient advocate groups such as the Accord Alliance and others have called for a general moratorium on all nonessential genital surgery in infancy until affected individuals are old enough to express their wishes and give consent.[63] Problems with loss of sexual sensation and pleasure have been reported in adult patients because of genital surgery in early life.

Increased Levels of Maternal Androgens and Progestins

Androgenization of the female fetus has been reported in pregnant mothers taking various progestational agents to prevent miscarriage. These agents include norethindrone, ethisterone, and medroxyprogesterone. Danazol, which has been used in the treatment of endometriosis, has also been associated with fetal masculinization.[5] A recent report identified retained progesterone secreting intrauterine devices during the first trimester also resulted in androgenization of the XX fetus's external genitalia with labial fusion.[34]

Androgenization of the female fetus because of maternal virilizing ovarian or adrenal tumors or luteomas of pregnancy has been reported. In such cases, virilization beyond the time of birth does not occur, and the prognosis is good.[5]

Placental Aromatase Deficiency

Placental aromatase deficiency has been associated with androgenization of the female fetus. Aromatase is a cytochrome P450 enzyme responsible for the conversion of testosterone to estradiol and of androstenedione to estrone. Autosomal recessive inheritance of aromatase deficiency causes androgenization of the female external genitalia because of a failure to metabolize the large amounts of androstenedione and testosterone produced by the placenta. Placental aromatase deficiency will also cause significant virilization of the mother. The affected female infant will have androgenization of external genitalia with normal müllerian structures. The levels of gonadotropins are elevated in infancy, and ovarian cysts may develop. At puberty, females have hypergonadotropic hypogonadism with failure to feminize and progressive virilization. Plasma androstenedione and testosterone levels are elevated, whereas estrone and estradiol levels are low. Postpubertal individuals have delayed bone maturation, tall stature, and osteopenia.[49]

46,XX Ovotesticular and 46,XX Testicular Disorders of Sex Development

46,XX ovotesticular DSD is defined as the presence of both testicular tissue with distinct seminiferous tubules and ovarian tissue containing mature graafian follicles in a single individual with a 46,XX karyotype. Both testicular and ovarian elements may be found in the same gonad, or one testis and one ovary may be found in the same individual. In most cases, the karyotype is 46,XX; 46,XX/46,XY chimerism and 46,XY karyotypes can also be found. Clinically the external genitalia are often ambiguous, but also predominantly male or female phenotypes have been described.[5,72] In ambiguous cases, a relatively marked degree of virilization can be found. Almost all have some degree of hypospadias and incomplete labioscrotal fold fusion. The labioscrotal folds are asymmetric, with an appearance of a hemiscrotum on one side and labium majus on the other being seen in 10 of 22 cases.[72] At least one gonad is usually palpable. Palpation of a polarized gonad should also lead the clinician to suggest the diagnosis of ovotesticular DSD. A vagina and a uterus are present in most patients, and a genitourethrogram may provide further elucidation. Internal duct development is consistent with the associated gonad, although müllerian ducts predominate with an ovotestis. In one study, 11 of 12 individuals with 46,XX ovotesticular DSD

examined before 6 months of age had baseline testosterone levels greater than 40 ng/dL; normal levels for females of this age would be less than 15 ng/dL.[72] Breast development is common during puberty, and menses can occur in up to 50% of individuals. Virilization can also occur at puberty.

Sex assignment depends on the degree of androgenization, the capacity of testicular tissue to secrete testosterone, and the presence or absence of a uterus and fallopian tubes. In general, in less androgenized individuals with a 46,XX karyotype, a female sex assignment may be favored because there is the possibility of fertility with oocyte development in the ovarian tissue but virilization will occur from testosterone production by the testes at puberty. If the infant is raised male, there will be lack of spermatogenesis as the genes for spermatogenesis are on the Y chromosome and the testes will be small due to lack of spermatogenesis. Gynecomastia often occurs at puberty. Removal of ductal or gonadal structures not consonant with the sex of rearing is controversial as gender identity is not known in infancy. As in all cases of DSD, gender identity and behavior issues, along with general psychological well-being, should be evaluated longitudinally.

The formation of a testis or an ovary from the bipotential gonad is controlled by increased expression or repression of key pro-testis, anti-testis and pro-ovarian genes. Disruption of the expression pattern can result in a different gonad developing despite the gonads chromosomal complement. The p.Arg92Trp and p.Arg92Gln variants of the *NR5A1* gene has been found to cause ovotesticular DSD in almost 10% of the ovotesticular cases through loss of the repression of the testicular pathway in an XX individual.[73,74] The p.Arg92Trp variant has decreased ability to upregulate the expression of the anti-testis gene, DAX1, leading to decreased repression of SOX9 expression which leads to testis formation rather than ovarian formation. The p.Arg92Gln change has been associated with adrenal insufficiency with or without ovotesticular DSD.[75] *NR2F2*, encoding *COUP-TF2*, has also been associated with ovotesticular/testicular DSD and cardiac defects. Two children also had blepharophimosis-ptosis-epicanthus inversus syndrome.[76] Bashamboo et al.[76] propose that COUP-TF2 is a "pro-ovary" and "anti-testis" factor in the XX gonad. Homozygous mutations in *RSPO1*, encoding R-spondin1 which is a pro-ovarian gene can lead to ovotesticular/testicular DSD associated with hearing impairment and eye and skin abnormalities.[77]

In contrast to 46,XX ovotesticular DSD, 46,XX testicular DSD presents 90% of the time with normal male external genitalia and 10% with hypospadias. 46,XX testicular DSD and 46,XX ovotesticular DSD may be part of a continuum as there are families with different members having 46,XX testicular or 46,XX ovotesticular DSD. In the past, 46,XX testicular DSD was not often diagnosed until puberty, when a male may be noted to have small testes and/or gynecomastia, or later as an adult when he presented with infertility due to absence of the Y chromosomal genes for spermatogenesis. Unlike Klinefelter syndrome, individuals with 46,XX testicular DSD are not tall as they lack the Y chromosome and three copies of the *SHOX* gene which those with Klinefelter syndrome have. With the increased use of prenatal cell-free DNA testing, the diagnosis of 46,XX testicular DSD may be made at birth when there is discordance between genotype XX and phenotype male. Approximately 80% of the time, there is translocation of the SRY gene from the Y chromosome to the X chromosome during the obligate crossover of the Xp and Yp terminal ends during male meiosis.[50] In those who lack SRY, mutations have been found in *NR5A1* and *NR2F2*[73,76] which further support the idea that XX ovotesticular DSD and XX testicular DSD are part of a continuum. Duplications of the *SOX9* locus or three copies of SOX9 result in overexpression of SOX9 and leads to the development of XX testicular DSD.[78] Over expression of SOX3[79] on the X chromosome or SOX10[80] from chromosome 22q13 may be the etiology for 46,XX ovotesticular or 46,XX testicular DSD. Loss of function changes in *RSP01*, a pro-ovarian gene, have also been seen in 46,XX testicular DSD.[81] WNT4, which upregulates *DAX1* expression, is another pro-ovarian gene. Autosomal recessive changes in WNT4, leading to decreased function, can also lead to 46,XX ovotesticular/testicular DSD associated with IUGR, oligohydramnion, renal agenesis, adrenal hypoplasia, and lung and cardiac anomalies or SERKAL syndrome.[82]

Disorders of Ovarian Development

Heterozygous mutations in *WNT4* in 46,XX individuals have been associated with Mayer-Rokitansky-Kuster-Hauser syndrome and androgen excess.[83] Disorders of the ovary are usually not identified until the girl fails to enter puberty as the ovary is quiescent until puberty. Most often, primary ovarian failure is due to sex chromosome aneuploidy, 45,X, which is discussed later. Blepharophimosis, ptosis, epicanthus inversus syndrome is associated with premature ovarian insufficiency due to mutations in *FOXL2*.[20]

46,XY Differences in Sex Development

Disorders of Testosterone Biosynthesis and Action

Incomplete androgenization refers to absence of or incomplete androgenization of the external and internal genitalia in a person with a 46,XY karyotype and normal testes. Disorders leading to incomplete androgenization of the male include androgen receptor defects, testosterone biosynthetic defects, 5α-reductase deficiency, Leydig cell hypoplasia, and effects of maternal medications (see Fig. 85.11).

In 25% to 50% of underandrogenized males, a specific cause cannot be found.[84–86] Other factors such as medications and placental insufficiency may potentially interfere with genital androgenization. Placental insufficiency may be related to genital underdevelopment through the presumed mechanism of inadequate hCG production. Placental hCG is required for early fetal testosterone production and, therefore, early fetal genital development.

Medications such as cimetidine, spironolactone, phenytoin (Dilantin), phenobarbital, medroxyprogesterone, and cyproterone acetate have been associated with altered androgen action or metabolism. Their use during pregnancy may be detrimental to male genital development.[5,55] Furthermore, various xenobiotics can bind the androgen receptor; therefore, there has been speculation regarding the role of environmental factors in abnormal sex differentiation.[87,88]

Androgen Receptor Defects (Androgen Insensitivity)

Disorders of the androgen receptor are the most common definable cause of incomplete masculinization of the genetic male.[89] Disorders of the androgen receptor can be divided into complete

androgen insensitivity syndrome (CAIS) and partial androgen insensitivity (PAIS) syndrome. The gene for the androgen receptor (*AR*) is located on the X chromosome, and more than 800 germline mutations have been found.[90] Information regarding the *AR* mutations can be found in the McGill Androgen Receptor Gene Mutation Database (http://www.androgendb.mcgill.ca). Mutations have been found throughout the *AR* gene, with most mutations occurring in the DNA- or steroid-binding domains. Despite extensive characterization of the molecular genetics of *AR* mutations, no genotype–phenotype correlation has been found.[89]

The sex-differentiating actions of testosterone and DHT are mediated by the androgen receptor. DHT is important in the differentiation of the male external genitalia and prostate, whereas testosterone is important in the differentiation of internal wolffian ducts to epididymis, vas deferens, and seminal vesicles.

Complete Androgen Insensitivity

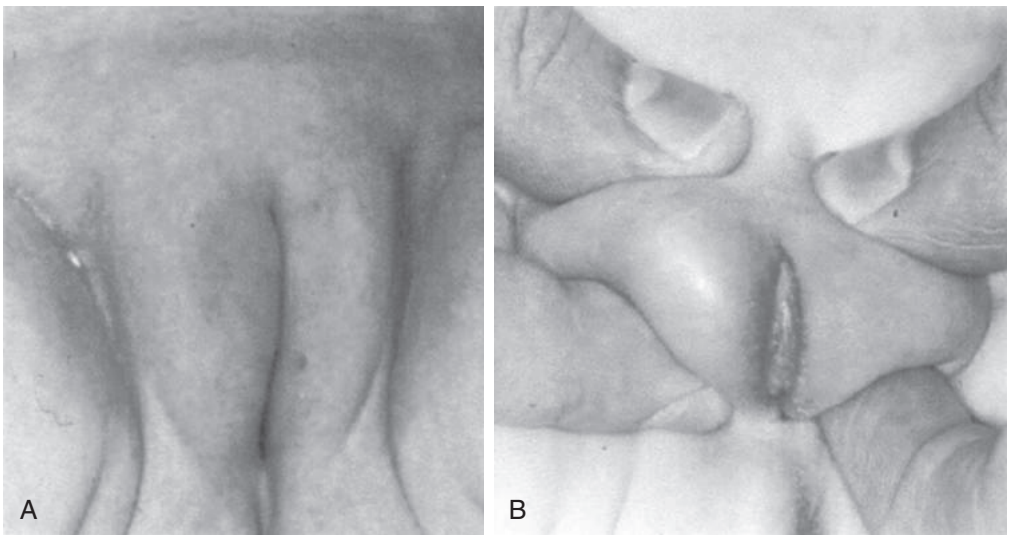
CAIS in a 46,XY is due to a mutation of the androgen receptor which is located on the long arm of chromosome X. CAIS is characterized by phenotypically normal female external genitalia in a 46,XY neonate (Fig. 85.14). Affected girls may have an inguinal hernia before puberty or primary amenorrhea with lack of pubic hair after puberty onset. With the increased use of noninvasive cell free DNA testing, many female infants are diagnosed at birth due to discordance between the cell free DNA which revealed an XY complement, and the female phenotype. Robust breast development occurs at puberty due to peripheral aromatization of testosterone to estrogen. There is usually scant or absent pubic and axillary hair, with some vulvar hair. The vagina is short and blind ending, and müllerian structures (cervix, uterus, fallopian tubes) are absent because of testicular production of AMH. There are only vestigial or no wolffian duct–derived internal structures. The testes are located in the abdomen, inguinal canal or in the labia majora. Even though there is testosterone production at puberty, in the newborn there is absence of testosterone production during the mini puberty.[91] There is no spermatogenesis due to the absence of the androgen receptor function. Gender identity and role behaviors are typically female. Removal of the testes is controversial because of low risk of development of germ cell tumors in childhood and during puberty,[92] and there is no consensus on the timing of orchidectomy.[93]

Partial Androgen Insensitivity

PAIS, also due to mutations in the androgen receptor, is characterized by various degrees of ambiguity of the external genitalia. The term *Reifenstein syndrome* was formerly used to describe partial androgen insensitivity with intermediate degrees of androgenization. Affected infants have a small phallus and a ventral chordee that tethers the phallus to the perineum. There is often a penoscrotal hypospadias and a bifid scrotum, which may or may not contain gonads (see Fig. 85.5). Cryptorchidism is a common finding. Müllerian structures are absent, and the wolffian duct–derived structures are absent or poorly developed. A genitourethrogram may demonstrate a urogenital sinus.

The diagnosis of partial androgen insensitivity is complex. A family history of ambiguous genitalia in male relatives on the maternal side is suggestive of this diagnosis since it is X-linked. However, Viner[33] reported a family history in only 25% of patients with PAIS. 5α-Reductase deficiency and testosterone biosynthetic defects should be ruled out by appropriate steroid and/or genetic analysis. This can be accomplished by measurement of intermediates in testosterone biosynthesis, especially androstenedione, to exclude 17β-hydroxysteroid dehydrogenase (17β-HSD) type 3 deficiency and by measurement of the ratio of testosterone to DHT to exclude 5α-reductase deficiency. Abnormal testosterone-to-DHT ratios can be seen in PAIS[94]; this could be caused by poor development of tissues, which express 5α-reductase type 2 in PAIS.[95] Genetic testing of the androgen receptor is the gold standard, and with the availability of DSD panels, sequencing in parallel rather than series is now possible.

Androgen levels in male newborns are highest at birth and then decline rapidly during the first week. A second testosterone surge occurs between 15 and 60 days of life,[42] which is often referred to as *mini puberty*. Androgen and LH levels should be obtained at these peak production times. Abnormally elevated levels of LH, testosterone, or both in the first several months of life are suggestive of partial androgen insensitivity. A report of five neonatal cases of PAIS showed testosterone values in the high-normal range



• **Fig. 85.14** (A) Appearance of external genitalia of a 46,XY infant with complete androgen insensitivity syndrome. (B) Note presence of bilateral palpable gonads.

on days 2 to 7 of life (mean 107 ± 27 ng/dL) and on day 30 (mean 411 ± 154 ng/dL.[91] LH levels were elevated in comparison with those of historic controls (mean LH level on days 7 to 15 of life was 5.2 IU/L ± 4.0 ng/dL; on day 30 of life the mean level was 8.7 IU/L ± 2.5 ng/dL). Testosterone response to hCG and LH response to gonadotropin-releasing hormone were exaggerated.[91]

The androgen receptor binding assay used to be considered standard for defining this disorder. However, normal ligand binding does not rule out androgen insensitivity, because there may be mutations in domains of the androgen receptor not involved in ligand binding. Direct sequencing of the androgen receptor for mutation analysis is commercially available (GeneTest) and can detect up to 95% of mutations associated with CAIS and PAIS. Androgen receptor mutations, however, are not always found in cases of possible partial androgen insensitivity, and it is speculated that defects in androgen receptor–interacting proteins may be involved[96] or, more commonly, the child may have another disorder. There have also been cases of postzygotic mutations of the androgen receptor resulting in mosaicism in the individual with PAIS.[97] In the past, individuals were often labeled as having PAIS when instead they had another disorder such as 17β-HSD deficiency type 3. This misdiagnosis has serious implications as at puberty this individual will virilize as other 17β-HSD isoenzymes convert androstenedione to testosterone.

Determining the sex of rearing in partial androgen insensitivity is a difficult task, and multiple factors must be considered. If there is a significant degree of virilization (Prader stages IV and V (see Fig. 85.3A), then male sex assignment is made.[8,63] If masculinization is severely limited (Prader stages I and II), then female sex assignment is often recommended. In intermediate forms (Prader stage III), responsiveness to exogenous testosterone may be of help in the decision-making process.[5,98] However, adult males with a small phallus have reported satisfactory sex lives.[11] These cases deemphasize the importance of phallic size in male sex assignment. Slijper[2] reported the absence of serious gender identity disorder in five undervirilized 46,XY males, although these boys were "more fearful and bothered about the smallness of their penises." These studies indicate the importance of a nurturing, supportive environment for a successful long-term outcome for these children. A recent review of the literature revealed gender identity dysphoria in 12% of females and 25% of males with PAIS which was not statistically significant.[99] More comprehensive long-term outcome studies of partial androgen insensitivity are needed.

5α-Reductase Type 2 Deficiency

5α-Reductase type 2 deficiency is an autosomal recessive disorder that results in an inability to convert testosterone to DHT. DHT is required for the development of the male external genitalia.

At birth, 46,XY infants with 5α-reductase type 2 deficiency can have a wide range of phenotype. Some have a very small phallus that appears to be a normal or slightly enlarged clitoris. However, more significant virilization of the phallus may occur, and the affected infant will then be identified as a male with hypospadias. There is usually severe penoscrotal hypospadias and a bifid scrotum. The testes are usually in the inguinal canals or labial folds. Approximately half of these patients have a penoscrotal urethra with a separate blind-ending vagina; a smaller percentage have a single urogenital sinus opening on the perineum.[95] A more recent study identified isolated microphallus (36%), microphallus with hypospadias (56%), and female external genitalia with clitoromegaly (9%) as the presenting phenotype.[100] Another study, of 55 patients with genetically confirmed 5α-reductase type 2 deficiency, found the following phenotypes: clitoromegaly (49.1%), microphallus with hypospadias (32.7%), female external genitalia (7.35%), and isolated microphallus (3.6%).[101] With the advent of genetic testing, the phenotypic range for 5α-reductase type 2 deficiency is much broader than originally described. In neonates with 5α-reductase type 2 deficiency, müllerian structures are absent, and wolffian duct–derived structures (vas deferens, epididymis, seminal vesicles) which are responsive to testosterone are well developed. The prostate is poorly developed because it requires exposure to DHT.

At the time of puberty, individuals with this disorder will characteristically virilize. The phallus will typically increase to a length of 4 to 8 cm.[56] In affected individuals who were raised as females, a change to the male gender role after puberty is commonly seen.[95,102] Unlike in partial androgen insensitivity, gynecomastia does not occur in the pubertal period.

In the past, 5α-reductase type 2 deficiency was most often diagnosed in the postpubertal period, although diagnosis in the newborn period has been reported.[103,104] The disorder is suggested by assessment of the ratio of testosterone to DHT in blood.[105] The normal testosterone-to-DHT ratio in the newborn period is 4:1, whereas the ratio in infants and children with this disorder is often greater than 14:1. An hCG stimulation test is usually needed to obtain a more definitive diagnosis in the prepubertal period but there is concern for damage to the testis when using hCG in a nonphysiologic time.[45] A positive response to hCG rules out Leydig cell aplasia or a testosterone biosynthetic defect. Measurement of normal androstenedione levels will rule out the testosterone biosynthetic defect—deficiency of 17β-HSD type 3. This enzyme is responsible for the conversion of androstenedione to testosterone in the testes, and the level of androstenedione is elevated compared with that of testosterone when 17β-HSD deficiency is present. The clinical presentation of 17β-HSD deficiency in infancy can be similar to that of 5α-reductase deficiency or PAIS. Giving exogeneous testosterone can provide a T:DHT ratio.

In addition, abnormal ratios of 5β-urinary steroids to 5α-urinary steroids can establish a definitive diagnosis of 5α-reductase type 2 deficiency,[103] but it can be challenging to perform the test. Distinguishing 5α-reductase deficiency from partial androgen insensitivity is important because androgen insensitivity can cause a secondary DHT deficiency owing to the incomplete development of tissues that express 5α-reductase activity.[95] Measurement of urinary 5β-glucocorticoids and 5α-glucocorticoids will help to make this distinction, because only 5α-reductase deficiency will also affect glucocorticoid metabolism. Finally, analysis for mutations in the *SRD5A2* gene is diagnostic, and is the gold standard. This gene test is readily available commercially as a separate test or as part of a DSD panel.

Sex assignment in cases of 5α-reductase deficiency is a complicated issue, but long-term outcome information is available. As in androgen insensitivity disorders, sex assignment is often significantly influenced by the degree of androgenization at birth, and because infants with this disorder are usually markedly undervirilized, female sex assignment has been advocated.[5,56] However, if the disorder is diagnosed early, topical DHT treatment, which is not available in the United States, has been shown to enlarge the phallus.[104] In addition, the natural history of the disorder is for masculinization of the phallus to occur at puberty. Testicular histopathologic analysis in males with this disorder has shown that, unlike in isolated bilateral cryptorchidism, their testes display type

Ad (i.e., dark) spermatogonia and a normal germ cell count. These patients are largely infertile because of defective transformation of spermatogonia into spermatocytes.[106] However, there have been case reports of men fathering children.[107,108] 46,XX females with 5α-reductase deficiency do not have a known phenotype.

There are frequent reports of reversal from female to male gender behavior after puberty.[109,110] The accumulated evidence supports male sex assignment in this disorder,[102] although female sex assignment is likely in the newborn period if the diagnosis is overlooked or if the infant with 5α-reductase deficiency has no androgenization. With the use of gonadotropin-releasing hormone (GnRH) analogs, male puberty can be suppressed and estrogen can be given to promote female secondary sexual characteristics in an individual who was raised female and has female gender identity.[111] Close follow-up with endocrinology and behavioral health is important as the child goes through puberty.

Testosterone Biosynthetic Defects

Six enzymes are necessary for the synthesis of testosterone. A defect at any step will result in inadequate testosterone synthesis (see Fig. 85.13). Defects in the first four enzymes of the testosterone synthesis pathway (cholesterol side chain cleavage enzyme, steroidogenic acute regulatory [StAR] protein, 17,20-lyase enzyme and P450 oxidoreductase) will also affect adrenal steroid production, resulting in both an underandrogenized male and CAH. POR deficiency leads to an underandrogenized male and CAH due to decreased 17,20 lyase activity. Because testosterone production is impaired in these disorders, wolffian duct structures are likely to be underdeveloped, whereas müllerian structures are absent because of normal testicular AMH production. These enzyme deficiencies are rare; therefore, these disorders are discussed only briefly here (see also Chapter 84 for more details).

StAR Deficiency or Congenital Lipoid Adrenal Hyperplasia

Lipid accumulation in both the adrenal glands and the gonads is characteristic of this disorder pathologically—hence the name *congenital lipoid adrenal hyperplasia*. Because all adrenal and gonadal steroid synthesis is affected by this disorder, infants are likely to exhibit complete adrenal insufficiency, characterized by vomiting, weight loss, and hypotension. The phenotype is likely to be female, although there is clinical variability. In an early report of 35 cases in the medical literature, only 11 patients survived beyond infancy.[57] Today, more cases are recognized early and, with glucocorticoid and fludrocortisone replacement, these infants have excellent survival rates.

Endocrine findings include elevation of ACTH level and plasma renin activity but low or immeasurable levels of all steroid hormones. The main consideration in the differential diagnosis is another form of CAH due to mutations in *CYP11A1*. In vitro studies performed on either adrenal or testicular tissue demonstrated an inability to convert cholesterol to pregnenolone in these patients. A defect in the first step of adrenal and gonadal steroid biosynthesis mediated by the cytochrome P450 side-chain cleavage enzyme was suspected. However, subsequent molecular studies demonstrated mutations in the steroidogenic acute regulatory protein (StAR).[5] StAR acts to promote sterol translocation to the cytochrome P450 side-chain cleavage enzyme in mitochondria (see Fig. 85.13).

The presence of markedly enlarged lipid-laden adrenals on ultrasound, computed tomography, or MRI studies is highly suggestive of the disorder. Successful treatment requires replacement of both glucocorticoids and mineralocorticoids. All individuals with this diagnosis have been raised as females.[5]

This disorder is due to "two hits."[112] The initial hit is the inability to make steroids, and the second hit is the destruction of the steroidogenic cell due to the high level of lipid content. The infant may not initially present with salt-losing crisis due to the initial sparing of the cells in the definitive zona, which are relatively inactive in utero. Females may have some pubertal development because the ovary is also quiescent until puberty, which spares initially the ovarian follicular cells. Eventually, though, they too are damaged, and the female develops hypergonadotropic hypogonadism. Nonclassical forms of this autosomal recessive disorder, which can present as isolated glucocorticoid deficiency have also been identified.[113]

Side Chain Cleavage Cytochrome P450

The side chain cleavage enzyme, encoded by CYP11A1, converts cholesterol to pregnenolone. Deficiencies of the side chain cleavage enzyme leads to adrenal insufficiency with a range in external genitalia phenotype from absence of androgenization in the male to hypospadias or normal male external genitalia.[114,115]

17α-Hydroxylase/17,20-Lyase Deficiency

A single enzyme encoded on the cytochrome P450c17gene (*CYP17A1*) mediates the 17-hydroxylation of pregnenolone and progesterone and the conversion of 17-hydroxypregnenolone and 17-OHP to DHEA and androstenedione. Specific mutations can cause partial loss of 17α-hydroxylase/17,20-lyase activity or dissociation between the 17α-hydroxylase and 17,20-lyase function.[116] Clinical disorders of this enzyme affect primarily either the hydroxylation or the lyase reaction, although there have been reports of combined 17α-hydroxylase and 17,20-lyase deficiency.[117]

Cases of primarily 17α-hydroxylase deficiency should be considered in underandrogenized males or females with low renin hypertension and hypokalemic alkalosis. The hypertension is presumably due to elevated levels of DOC and corticosterone (see Fig. 85.13). Although cortisol synthesis is blocked, the overproduction of DOC and corticosterone is protective against adrenal insufficiency.

Most cases are diagnosed in the pubertal period because the 46,XY phenotype is largely female. This disorder is treated with glucocorticoid, which suppresses ACTH overproduction and subsequently suppresses DOC and corticosterone overproduction if there is hypertension.[5] Sex steroid replacement is needed at puberty.

17,20-Lyase deficiency results in various degrees of undervirilization of the 46,XY infant. The phenotype ranges from complete female external genitalia to ambiguous genitalia to a mildly undervirilized male. 46,XX females will fail to enter puberty. The levels of gonadotropins will be elevated, and there will be impaired formation of DHEA and androstenedione (see Fig. 85.13). DOC and corticosterone levels are normal in this form of the disorder. ACTH stimulation tests may be helpful to reveal the steroid biosynthetic block more fully. Gene testing for *CYP17A1* is available as a single gene or as part of a DSD panel.

POR Deficiency

Phenotype of POR deficiency is similar to 17,20 lyase deficiency with or without Antley-Bixler syndrome. (See section in 46,XX Differences in Sex Development as well as Chapter 84 for more details.)

3β-Hydroxysteroid Dehydrogenase Deficiency 2

3β-HSD deficiency type 2 was first reported by Bongiovanni.[118] 3β-HSD is an important enzyme required for the conversion of Δ^5-steroids to Δ^4-steroids in the adrenal glands and gonads (see Fig. 85.13). There is marked heterogeneity in clinical presentation, and both sexes are affected.[57] With severe deficiency of 3β-HSD, salt-losing crisis can occur. Male infants may have ambiguous or completely feminine external genitalia, whereas female infants may be mildly androgenized. Severely underaandrogenized males may have normal mineralocorticoid activity; fully androgenized males may display salt loss.

Diagnosis of this disorder in the newborn period can be difficult because of relatively high levels of Δ^5-steroids physiologically. The diagnosis is based on the elevated ratio of 17-hydroxypregnenolone to 17 OHP and of DHEA to androstenedione in the basal and stimulated states.[53]

17β-Hydroxysteroid Dehydrogenase Type 3 Deficiency (17-Ketosteroid Reductase Deficiency)

The final step in testosterone biosynthesis involves the conversion of androstenedione to testosterone by the enzyme 17β-HSD type 3 in the testis. Mutations that impair the function of 17β-HSD are the cause of this relatively rare autosomal recessive disorder.[110]

The clinical presentation externally is that of a female at birth with perhaps a mild degree of clitoral enlargement. Therefore, these infants are typically raised as females unless the diagnosis is made at birth. At puberty, there is progressive androgenization, with enlargement of the phallus to 4 to 6 cm, and labial enlargement and rugation. By late puberty, the testes are found at the lower ring of the inguinal canal. They are of normal size and consistency. Internal wolffian duct–derived structures are found. In addition, a male body habitus develops, with deepening of the voice and appearance of male body hair, including a mustache and beard.[56]

In the past, patients received a diagnosis at puberty or as adults. Now with the advent of genetic testing, this diagnosis is made more frequently in infancy. Endocrine studies reveal markedly elevated androstenedione levels, whereas testosterone levels are in the low-normal range.[119] Plasma LH levels are consistently high. In infancy or childhood, the presence of inguinal hernias may bring the child to medical attention. Androstenedione levels in the prepubertal patient may be normal.

Sex of rearing is often influenced by the cultural context. In societies in which a high priority is given to the male, sex reassignment at puberty has been successful.[57] Mendonca observed changes in gender role (female to male) in 3 of 10 affected individuals.[119] Despite androgenization in some affected individuals, the female gender role was maintained. Suppression of virilization using a GnRH analog and replacement of estrogen has been used in 46,XY females with 1717β-HSD who identify as female at the time of puberty.[111]

Leydig Cell Hypoplasia

Failure of the testes to produce testosterone in response to hCG and LH is characteristic of this disorder. Histologic examination of the testes reveals absent or low numbers of Leydig cells, normal-appearing Sertoli cells, and seminiferous tubules with spermatogenic arrest.[5] LH receptor mutations have been described in this disorder.[120] Phenotypically in the 46,XY infant, the external genitalia range from those of a normal female to those of a male with microphallus. Müllerian-derived structures are absent in all patients, whereas wolffian structures may be present. LH and FSH levels are elevated in postpubertal patients, and LH levels decrease after testosterone administration. In less severe forms of the disorder, testosterone therapy augments phallic growth. In severe forms of testicular unresponsiveness to hCG/LH, sex assignment has been female. The gonads are removed, and estrogen replacement therapy is instituted at the time of expected puberty.[5] Females with LH receptor changes may present with elevated LH and amenorrhea.

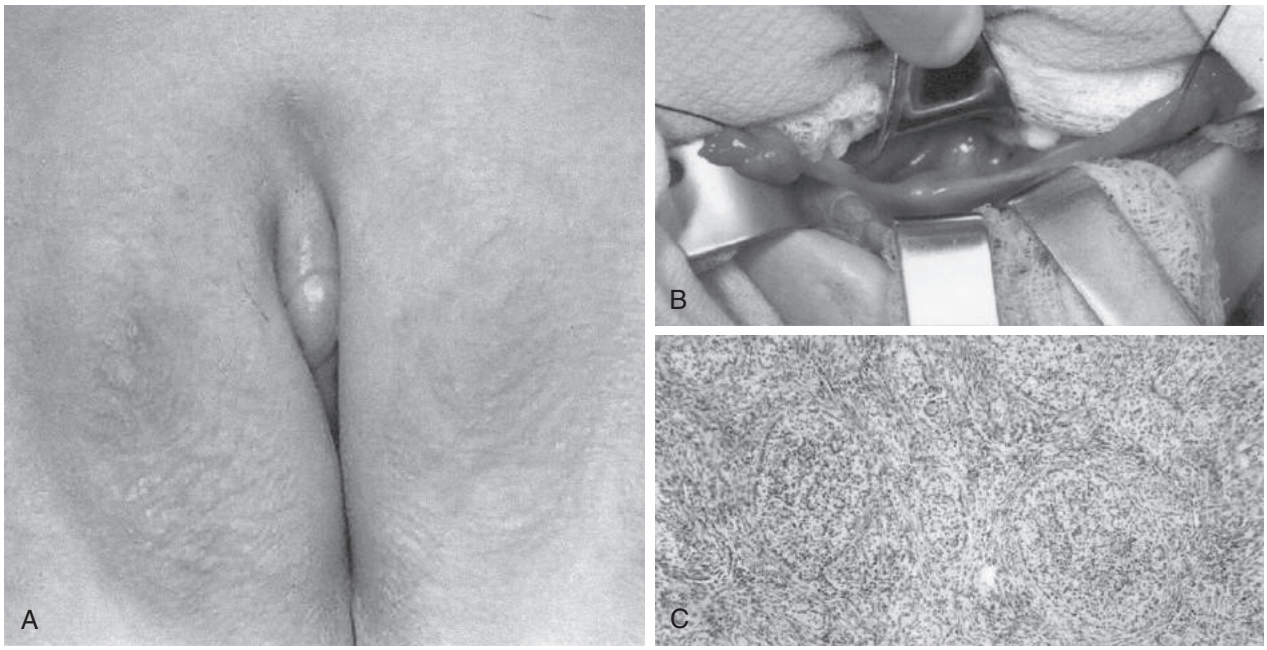
Persistent Müllerian Duct Syndrome

Diagnosis of PMDS is often made in otherwise phenotypically normal 46,XY males at the time of surgery for an inguinal hernia or orchidopexy. In the case of hernia repair, a fallopian tube and uterus are often found along with a partially descended testis. In other cases, testes, uterus, and fallopian tubes are found in the pelvis. Inheritance of PMDS is autosomal recessive, although the female phenotype is completely normal. The disorder has been found to be due to a mutation in AMH or in the AMH receptor in 85% of cases and unknown causes in 15% of cases.[121] Therapy involves orchidopexy and partial hysterectomy, with care taken to avoid injuring the vas deferens, which is embedded in the uterine wall.

Gonadal Differentiation and Chromosomal Disorders

46,XY Complete Gonadal Dysgenesis

46,XY complete gonadal dysgenesis was first described by Swyer in 1955.[5] The phenotype of the external genitalia is female, with normal development of müllerian-derived internal structures in a 46,XY individual. The gonads do not develop into testes but rather formed streak gonads. Streak gonads are completely nonfunctional; they did not produce AMH or testosterone. Therefore, müllerian structures do not regress, and wolffian structures are poorly developed or absent (Fig. 85.15). Most affected individuals are seen in the teenage years with lack of pubertal development. Serum gonadotropin levels are elevated. Mutations in the *SRY* gene account for only a small proportion of these cases.[57] Fig. 85.1 depicts other genes that when mutated can lead to complete gonadal dysgenesis. Familial cases have been reported. There has been a report of a 46,XY mother who developed as a normal woman and gave birth to a 46,XY daughter with complete gonadal dysgenesis in a family with multiple disorders of sexual development, suggesting an unidentified sex-determining gene.[122] In up to 30% of affected individuals, gonadoblastomas will develop in the streak gonad; therefore, removal of the streak gonad is recommended at the time of diagnosis (see Fig. 85.15).[56,123,124] Females with gonadoblastoma may present with breast development as



• **Fig. 85.15** (A) Appearance of external genitalia in an infant with 46,XY complete gonadal dysgenesis. (B) Uterus and fallopian tubes were found at surgery, along with a gonadoblastoma, at 1 year of age. (C) Micrograph of tumor cells.

the gonadoblastoma produces estrogen. Estrogen replacement therapy will provide appropriate feminization, and the subsequent addition of progesterone will lead to menses. Women with complete gonadal dysgenesis can successfully carry a pregnancy using donor oocytes and appropriate hormonal supplementation.

46,XY Partial Gonadal Dysgenesis

Patients with 46,XY partial gonadal dysgenesis will typically be seen in the newborn period for evaluation of ambiguous genitalia.[125] The extent of androgenization of the external genitalia depends on the extent of testicular differentiation. Gonadal tissue is usually intraabdominal, but testes can be found in the scrotum. Testosterone response to hCG is variable but usually low. In most cases, there is a mix of müllerian and wolffian structures. The presence of müllerian structures on genitourethrogram or ultrasound examination increases the index of suspicion for this disorder. The diagnosis is confirmed by gonadal biopsy. Some affected children are found to have one dysgenetic gonad on one side and a streak gonad on the other; others have bilateral dysgenetic gonads. Dysgenetic gonads are histologically defined by poorly formed and disorganized seminiferous tubules surrounded by wavy ovarian stroma. In many cases, the dysgenetic gonads resemble ovotestes, except that primordial ovarian follicles are lacking.[125]

Single Genes Important in Normal Testicular Development

SRY

SRY is the only gene on the Y chromosome necessary for normal male sex development. Mutations in the highly conserved HMG DNA binding domain account for about 15% of the cases of complete gonadal dysgenesis. Mutations have also been identified in the non-HMG domain. There is variable penetrance in that a few cases have been described in which the father and unaffected brother carry the same mutation in SRY as the female with complete gonadal dysgenesis.[126]

NR5A1

NR5A1 encodes steroidogenic factor 1 (SF1) a master regulator which controls the expression of *SRY, SOX9, AMH, AMHR, LHCGR, STaR, CYP11A1, CYP17A1*, and gonadotropins. Consequently, the range of phenotype in 46,XY infants with changes in *NR5A1* goes from complete gonadal dysgenesis to male infertility. Ovotesticular DSD can be present as well as adrenal insufficiency. Bashamboo et al. demonstrated how the p.Arg92Trp mutation acts as a switch between male and female gonadal development.[73]

SOX8

SOX8 located on chromosome 16p.13.3 shares the same HMG motif with *SRY*. Heterozygous missense mutations have been shown to cause 46,XY complete gonadal dysgenesis.[127]

NROB1

NROB1 located on the X chromosome at Xp21.2 encodes DAX1 which is an orphan nuclear receptor. Duplication of NROB1 leads to 46,XY complete gonadal dysgenesis.[22,128] Loss of function changes in NROB1 leads to adrenal hypoplasia congenita in XY individuals.[128] In addition, there can be unilateral or bilateral cryptorchidism and, at puberty, hypogonadotropic hypogonadism.

MAMLD1

MAMLDI is also located on the X chromosome and is expressed in the Leydig cells of the developing testis. Heterozygous mutations were initially found in boys with isolated severe hypospadias.[129] Changes in MAMLD1 have also been seen in other 46,XY DSD which have hypospadias as a feature,[130] but changes in other DSD genes may also be necessary.[131]

MAP3K1

Map3K1 is expressed in early testis cords and Sertoli cells in mice. Mutations in MAP3K1 have been seen in a range of phenotype from complete gonadal dysgenesis to isolated hypospadias to micropenis associated with cryptorchidism. It is inherited in an autosomal dominant fashion.[132]

GATA4

Heterozygous changes in GATA4 have been associated with congenital heart disease and disorders of sex development in 46,XY individuals.[133]

DMRT1 and DMRT2

DMRT1 and *DMRT2* are on 9p24.3, a region long associated with 46,XY gonadal dysgenesis. Haploinsufficiency of *DMRT1* has been found in gonadal dysgenesis.[134] The range of phenotype associated with 9p24.3 deletion, though, includes gonadal dysgenesis, ovotestis, hypospadias, penoscrotal transposition, and cryptorchidism.[135]

Testicular Regression Syndrome

Testicular regression syndrome refers to the spectrum of disorders affecting individuals with 46,XY karyotype who demonstrate evidence of prior testicular function, followed by usually symmetric gonadal regression.[136] Loss of testicular function between weeks 8 and 10 of gestation would result in ambiguous genitalia and variable internal genitalia. Loss of testicular function after 12 to 14 weeks' gestation would result in normal male genital differentiation with a small phallus. When the male external and internal ducts are completely normal, the term *vanishing testis syndrome* is used by some authors. Presumably the testes were lost during the second half of pregnancy. Testicular torsion or loss of blood supply has been invoked as a possible explanation in this syndrome.[137] Another potential etiology is anomalous vascular development.[138]

FSH levels are elevated in infancy, and an exaggerated response to gonadotropin-releasing hormone in the prepubertal period is typically seen.[5] AMH levels in infancy and childhood are very low in anorchia and intermediately low with abnormal testes.[64]

46,XY Ovotesticular Disorder

Ovotestes, or an ovary on one side and a testis on the contralateral side, can also develop in individuals with 46,XY karyotype. While not as commonly seen as in individuals with a 46,XX karyotype, the diagnosis should be considered when ambiguous genitalia are noted, especially if müllerian structures are present. Changes in the *NR5A1* gene have also been associated with XY ovotesticular DSD. In this case, the p.Arg92Trp mutant NR5A1 protein has decreased ability to upregulate the *SOX9* gene leading to decreased SOX9 formation and, therefore, decreased Sertoli cell and testis formation.[73] The ovotestis and testis in a 46,XY ovotesticular disorder have spermatogenesis, unlike the 46,XX ovotesticular DSD.

Syndromes Associated With Ambiguous Genitalia

Denys-Drash Syndrome

Denys-Drash syndrome is a rare syndrome consisting of the classic triad of XY ambiguous genitalia, congenital nephrotic syndrome leading to end-stage renal failure, and Wilms tumor. The external genitalia of 46,XY individuals are either ambiguous or female. Gonadal development encompasses a spectrum from streak gonads to dysgenetic testes. Nephropathy and proteinuria are noted at an early age, and renal biopsy will demonstrate mesangial sclerosis. More than 90% of cases will have a mutation in the *WT1* gene, which is a critical gene for the development of the normal genital tract. *WT1* is also associated with WAGR (Wilms tumor, aniridia, genitourinary anomalies, retardation) syndrome. Large deletions of chromosome band 11p13 that encompass the *WT1* gene are responsible for this disorder. Frasier syndrome also involves the *WT1* gene. Frasier syndrome manifests itself in 46,XY females with gonadal dysgenesis and progressive glomerulopathy. The risk of gonadal malignancy in Frasier syndrome is reported as 60% and in Denys-Drash with a Y chromosome as 40%.[123]

Campomelic Dysplasia

Campomelic dysplasia is a rare autosomal dominant disorder associated with often lethal skeletal dysplasia, in which 75% of affected 46,XY males have dysgenetic testes associated with undervirilization.[18] Manifestations of this disorder include bowing of the femora and tibiae, hypoplastic scapulae, 11 rib pairs, pelvic malformations, bilateral clubfoot, cleft palate, macrocephaly, micrognathia, hypertelorism, and a variety of cardiac and renal defects. The disorder is caused by heterozygous mutations in the *SOX9* gene.[139] Most patients with campomelic dysplasia die of respiratory distress in the neonatal period.

Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome is an autosomal recessive disorder with an estimated frequency of 1 in 20,000 to 1 in 40,000. The disorder is caused by deficiency of 7-dehydrocholesterol reductase[57] enzyme which catalyzes the final step in cholesterol biosynthesis leading to elevated serum 7-dehydrocholesterol level that is pathognomonic for Smith-Lemli-Opitz syndrome. Cholesterol levels are not always low. Growth failure, severe developmental delay and multiple congenital anomalies (microcephaly, ptosis, anteverted nostrils, micrognathia, cleft palate, cardiac defects extra axial polydactyly, syndactyly of second and third toes) characterize this syndrome.[140] Males can present with genital anomalies ranging from severe hypospadia and micropenis to complete absence of external virilization of genitalia due to inability to synthesize cholesterol, the precursor for testosterone. Adrenal insufficiency has also been reported in this condition as cholesterol is also a precursor for cortisol and aldosterone.

Treatment with cholesterol has been used in Smith-Lemli-Opitz syndrome to try to improve growth and neurodevelopmental status. Unfortunately, cholesterol replacement has not been as beneficial as once hoped as it does not cross the blood-brain barrier and has not been shown to reduce developmental delay.[141] A more recent placebo-controlled trial using simvastatin (non–FDA-approved indication) found that the medication crossed the blood–brain barrier and was relatively safe. There was improvement in serum dehydrocholesterol-to-total sterol ratio and improvement of irritability symptoms.[142]

Robinow Syndrome

Robinow syndrome is an autosomal dominant disorder characterized by a flat facial profile, short forearms, and hypoplastic genitals.[140] Sporadic cases have been reported. Microphallus

may be severe in males, although normal virilization at the time of puberty has been reported.[140] Undescended testes have been reported in 65% of affected boys. Females have characteristic hypoplastic labia and clitoris. Other features include small size at birth, macrocephaly, frontal bossing, hypertelorism, prominent eyes, small, upturned nose, micrognathia, and posteriorly rotated ears. Short forearms are seen in 100% of described cases. Other skeletal abnormalities include thoracic hemivertebrae, fusion or absence of ribs, and scoliosis. The abnormal facial features become less pronounced as the child grows, and cognitive performance has been normal in most affected individuals.

Other Disorders of Genital Differentiation

Hypospadias

Hypospadias is one of the most common anomalies of male genital development, with an estimated incidence of 4 to 8 cases per 1000 male births.[5] Hypospadias can be classified as glanular, subcoronal, distal penile, midshaft, proximal penile, penoscrotal, scrotal, and perineal (see Fig. 85.3C). Glanular and subcoronal hypospadias account for more than 50% of hypospadias. Typically, the more severe forms of hypospadias have been associated with DSD, although the phenotypic spectrum of DSD is wide. In a study of 33 patients with severe (scrotal or penoscrotal) hypospadias, 12 were found to have a DSD, which included Denys-Drash syndrome (in 3 of the 12), partial androgen insensitivity (in 2), ovotesticular DSD (in 2), chromosomal abnormality (in 1), AMH abnormality (in 1), gonadal dysgenesis (in 1), 5α-reductase deficiency (in 1), and 46,XX *SRY*-positive karyotype (in 1).[38] The testes were undescended in 11 of the 12 patients. Aarskog[143] found an approximately 15% prevalence of DSD in association with hypospadias, in addition to a significant role for maternal progestins. Intrauterine growth retardation and prematurity also have a higher association with hypospadias and undescended testes thought to be due to placental insufficiency, with lower hCG levels leading to decreased androgen production early in the pregnancy.[144] Other factors associated with hypospadias include maternal hypertension, preeclampsia, maternal vegetarian diet, assisted reproductive techniques, multiple births, pollution, and endocrine disruptors.[145] Genetic factors also play a role, and mutations in MAMLD1, NR5A1, and AR have been found in a few cases.[130] In addition, studies of families with multiple males having hypospadias have identified other genes such as AKR1C2, AKR1C3, and AKR1C4 as having possible involvement in the development of hypospadias.[146]

Severe cases of hypospadias require a thorough evaluation, including karyotype and evaluation of testosterone biosynthesis, along with examination of the genitourinary tract, particularly if accompanied by undescended testes.

Cryptorchidism

Cryptorchidism is one of the most common genital differences at birth. The testes descend into the scrotum in two phases. The transabdominal descent occurs in the first trimester with the testes at the internal inguinal ring at 22 to 25 weeks gestational age. The second phase of descent, the inguinoscrotal phase, occurs between 25 and 30 weeks and is androgen dependent.[147] Consequently, the prevalence of cryptorchidism is higher in premature male infants (15% to 30%) compared to term male infants (1% to 3%).[148] In premature infants with cryptorchidism, if testicular descent into the scrotum does not occur by 6 months corrected age, it is unlikely to occur spontaneously. Orchiopexy is usually done after 6 months of age and prior to 12 to 18 months to decrease risk of infertility, testicular malignancy, and torsion.[41] Male newborns with bilateral, nonpalpable testes need further evaluation to exclude a 46,XX female with congenital adrenal hyperplasia. The male infant should also be evaluated for pituitary dysfunction (ACTH, TSH, and growth hormone deficiency) which could be associated with hypogonadotropic hypogonadism. Evaluation for a DSD should also occur. If the cryptorchidism is unilateral with hypospadias or micropenis or other penile abnormalities, an evaluation for a DSD should also occur.[41]

Sex Chromosome Disorders of Sex Development

Klinefelter Syndrome

Klinefelter syndrome, 47,XXY, has a prenatal cytogenetic incidence of 1 in 667. The prevalence of newborns with 47,XXY in Denmark based on a public health registry over a 53-year span was 57 per 100,000 males, yet only 38% of males with Klinefelter syndrome received a diagnosis of Klinefelter syndrome.[149] Individuals identified by prenatal diagnosis may not have as many features of Klinefelter syndrome as those ascertained postnatally because of concern for Klinefelter syndrome. Most infants have normal male phenotype. Boys with Klinefelter syndrome often come to medical attention when they are noted to have smaller testes, delayed or absent puberty, tall stature, and gynecomastia. The testes have decreased testosterone production and spermatogenesis due to progressive testicular failure. Males may have decreased language and executive function.[150] Guidelines for the care of males with Klinefelter syndrome have been developed.[151]

Turner Syndrome

Turner syndrome is a condition in which a female has complete or partial loss of one of her sex chromosomes. Mosaicism may be present with an XX or XY cell line. Turner syndrome has a prevalence of 1 in 1700 newborn females.[149] There is a high level of fetal loss as demonstrated by Gravholt, who identified a prevalence of Turner syndrome of 392/100,000 by chorionic villus sampling, of 176/100,000 by amniocentesis, and 32/100,000 by newborn karyotype.[152] With the increase in use of cell free DNA, a noninvasive prenatal testing (NIPT) screening test, there is increased recognition of possible Turner syndrome at birth. However, cell free DNA was not developed to diagnose Turner syndrome and thus the predictive value may be only 23-36%.[153] In the absence of prenatal genetic testing, the timing of diagnosis is dependent on physical features. Prenatally, an infant may be suspected as having Turner syndrome due to cystic hygroma, increased nuchal translucency, or coarctation of the aorta. Confirmation by a postnatal karyotype with 30 cells to exclude mosaicism is necessary. The presence of a Y cell line increases the risk for gonadal tumor, and gonadectomy needs to be considered. At birth, an infant may be suspected of having Turner syndrome when she presents with webbing of her neck or pedal edema or congenital heart disease.

Guidelines for the health maintenance of girls with Turner syndrome were updated in 2017.[154] At the time of diagnosis, all infants should have a cardiovascular evaluation by a cardiologist, including a cardiac echo. Girls with Turner syndrome are at

increased risk for bicuspid aortic valve, coarctation of the aorta and anomalous pulmonary veins. They should also have a renal ultrasound to look for a horseshoe kidney. They will need a formal audiologic evaluation as well as an ophthalmologic exam at 1 year due to increased risk of strabismus. They should also be screened for hip dysplasia. Long-term follow up with a pediatric endocrinologist is recommended for evaluation of short stature, ovarian function due to premature ovarian failure which can occur prior to birth, and yearly thyroid function tests. Girls with Turner syndrome have normal intelligence but may have decreased visual-spatial skills, information processing and math skills.[155] They may also have decreased social skills.[156]

Mixed Gonadal Dysgenesis

Mixed gonadal dysgenesis refers to asymmetric gonadal dysgenesis with ambiguous genitalia (see Fig. 85.7) and a mosaic karyotype with an XY cell line. The most common karyotype is 45,X/46,XY. There is a wide spectrum of phenotypes, ranging from a female with clitoral enlargement to a male with hypospadias. Asymmetric external and internal genital development has been classically described in this syndrome.[57] Considerable phallic development was reported in most patients in one study, and there was often penoscrotal hypospadias.[157] The phenotypic features of Turner syndrome are described in a significant percentage of patients, although these features may not be readily apparent in the newborn period. An incompletely formed uterus is found in almost all patients. Fallopian tubes are always found on the side of the streak gonad and often on the side with the dysgenetic gonad. Wolffian structures may be developed on the side with the dysgenetic gonad.

A genitourethrogram is likely to demonstrate internal müllerian structures that can be confirmed at laparoscopy. Demonstration of abnormal gonadal histopathologic features will confirm the diagnosis. Mixed gonadal dysgenesis shares many features with partial gonadal dysgenesis, and some authors view these disorders as representing a continuum of gonadal dysgenesis.[125] Histologic analysis will also differentiate this disorder from ovotesticular DSD. Although the characteristic karyotype is 45,X/46,XY, this genotype has been associated with normal male differentiation in most cases diagnosed by prenatal amniocentesis.[158] While these males may have normal external genitalia, they may also have short stature and cardiac features associated with Turner syndrome. While there are no formal recommendations for screening, many follow the guidelines developed for females with 45,X/46,XX Turner syndrome.[154]

Some authors advocate female sex assignment in mixed gonadal dysgenesis because surgical repair of the vagina is usually easy and a uterus or hemiuterus is present. In addition, the dysgenetic gonad is at risk of development of a tumor and should be removed, particularly if the gonad cannot be brought down into the scrotum.[57] However, sex assignment is likely to be guided by the degree of androgenization with the more virilized cases being assigned as males. The capacity for near-normal androgen production in this disorder has been described.[157] In all cases the streak gonads should be removed because of the risk of malignancy.

46,XX/46,XY Chimerism

Chimerism is the result of the fusion of two different zygotes. In cases where the zygotes have the same sex chromosomes, chimerism may not be recognized. However, if the zygotes have different sex chromosomes, then the infant may be identified by the presence of ambiguous genitalia. The gonad will develop into an ovary, testis, or ovotestis depending on the genetic complement of the cells in the gonad. Internal and external genitalia will reflect the type of gonad and the amount of testosterone produced by the gonad. Ovotesticular DSD is often seen in 46,XX/46,XY chimerism. There can also be isolated chimerism in the blood, 46,XX/46,XY hematologic chimerism, due to twin-twin transfusion.[41,159] This may only be identified if a chromosomal analysis of the blood was done as the gonad and genitalia are consistent with the donor karyotype. Chimerism is not mosaicism, which arises with a mitotic error in a single zygote.

Surgical Management of Disorders of Sexual Differentiation

Surgery for DSD conditions has been recently criticized. The criticism has focused not only on the timing of surgery but also on whether reconstructive surgery should be done at all. Some authorities have advised that surgery be postponed until the affected person is of an age to make his or her own decision regarding the advisability of surgical correction.[63] Others have found that delay in surgery may be associated with problematic outcomes.[8,14,68] It is imperative that these divergent viewpoints be discussed with the parents of an infant with a DSD condition.

The need for surgical intervention in DSD should be assessed on a case-by-case basis. The parents need to be informed about the risks and benefits of surgery. Surgery on the external genitalia should perhaps be reserved for individuals with significant discord between the sex of rearing and the appearance of the external genitalia.

The infant with a DSD and the family will have to cope with difficult psychosocial challenges throughout life. Physicians caring for these patients should ensure the integration of well-trained mental health professionals into the longitudinal care of these complex infants and children. These issues must be kept in mind in any decision regarding surgery for management of DSD. Current surgical techniques that are available for correction of ambiguous genitalia and DSD are presented here.

Feminizing Genitoplasty

Feminizing genitoplasty is one of the more common procedures done for correction of ambiguous genitalia. Feminizing genitoplasty is indicated in the genetic female who is externally virilized, most commonly as the result of CAH. The degree of virilization can be highly variable (see Fig. 85.6) and will have a significant influence on the type of procedure done, especially the vaginoplasty portion of the operation. Restorative surgery in this group of patients has three components: clitoral recession, vaginoplasty, and labial reconstruction. The timing of surgical correction also has undergone some changes over the years. The current thinking is that once a decision is made to proceed with genital reconstruction, performance of this type of surgery at a younger age will have distinct advantages, including easier mobilization of the urogenital sinus and a more benign postoperative course.

Clitoral Reduction

Attempts at managing the enlarged clitoris in genetic females with clitoral hypertrophy started with total clitorectomy.

Young[160] originally advocated this procedure. Later, Lattimer[161] suggested a recession rather than a resection of the clitoris, and he hoped to be able to preserve the arousal function of the clitoris. This led to cases in which painful clitoral erections occurred later in life; therefore, further modification was needed. Spence and Allen[162] advocated the preservation of the glans with reduction in the size of the clitoris. Since then, several reports have examined preservation of the neurovascular bundle using a clitoral reduction and recession type of approach. Kogan et al.[163] and Snyder et al.[164] separately described a similar approach in which the erectile tissue of the clitoris is removed, but preservation of the neurovascular bundle and the glands is afforded to preserve the neurologic and arousal functions of the clitoris. If the glans is unusually large, then a reduction of the glans size may be indicated as well.

Vaginoplasty

Reconstruction of the vagina in cases of virilization in females requires an understanding of the anatomy. One may consider the anatomic abnormality an embryologic arrest of maturation with a persistence of an early embryologic stage. The anatomic issue that is important to the surgical management of the common urogenital sinus is the site of confluence of the genital tract and urethra. This site varies considerably but is somewhat predictable from the appearance of the degree of external virilization. Children with severe degrees of external virilization are more likely to have a higher confluence of the urethral and vaginal channels, leading to a longer urogenital sinus or a more masculinized urogenital sinus. In the classic article on urogenital sinus abnormalities, Hendren and Crawford[165] described the variable anatomy that can be seen in these children and noted that the operative procedures needed to be tailored toward the location of the confluence of the urinary and genital tracts. One may describe the confluence anatomically as it relates to the external sphincter, with confluences distal to the external sphincter being considered *low* and those proximal to the external sphincter being referred to as *high*. One also may describe the variable anatomy according to the length of the urethra from the bladder neck to the point of confluence. If that length of urethra were long, then one would consider this a low confluence. Conversely, if the length of the urethra were short and, therefore, close to the bladder neck, then a high confluence would be present (see Fig. 85.8B).

The low confluence cases can generally be repaired either by a cutback procedure on the fused labioscrotal folds or by a flap vaginoplasty. A cutback procedure would be indicated in cases with a minor degree of fusion of the labioscrotal folds. The middle to high vaginal confluence, however, generally requires either a pull-through vaginoplasty or a total urogenital mobilization to bring the vagina down to the perineum.

Flap Vaginoplasty

Flap vaginoplasty should be used for a low confluence of the urogenital sinus. The procedure entails mobilization of a perineum-based flap with its apex at the meatus of the urogenital sinus. Dissection then proceeds along the posterior wall of the urogenital sinus until the vaginal opening is identified. The perineum-based flap is then inserted into the posterior wall of the vagina, thereby exteriorizing the vagina to the perineum.

Total Urethral Mobilization

Total urogenital mobilization can be used for the high urogenital sinus, which has been advocated by Peña[166] and subsequently substantiated by a report from Rink et al.[167] This approach has been shown to have a superior cosmetic result, compared with that obtained with a flap vaginoplasty, for a middle to high confluence. In addition, there has been a reduced incidence of urethral vaginal fistula and vaginal stenosis. The mobilization occurs in a plane both anterior to the urogenital sinus and up to the bladder neck under the pubic symphysis and posteriorly along the urogenital sinus, and then along the posterior wall of the vagina.

Pull-Through Vaginoplasty

Pull-through vaginoplasty is reserved for use in severely masculinized genetic females, whose surgical treatment continues to present a major challenge. Initially, the approach was a combined perineal and abdominal approach with complete mobilization of the vagina and uterus and separation of the vagina from the urethra at the confluence. The abdominal mobilization will then allow the vagina to be brought down to the perineum. A modification of this approach was described by Passerini-Glazel[168] in which the more distal urogenital sinus tissue was used to provide an anterior vaginal wall flap, which will then connect to the true vagina and allow a complete perineal approach to the procedure.

Vaginal Reconstruction

Vaginal reconstruction has a role in certain DSD or structural abnormalities of the genital urinary tract. The DSD in which vaginal reconstruction may be indicated are 46,XX vaginal agenesis, 46,XY male karyotype with severely inadequate virilization or CAIS, and structural urogenital defects such as cloacal exstrophy or persistent cloaca or after a pelvic exenteration for malignancy. A variety of tissues and techniques are used for vaginal reconstruction: buccal tissue, skin grafting, progressive perineal indentation, and split-thickness or fold thickness tissue grafts with expanders, myocutaneous flaps, and bowel segment. The critical point in creating a vagina is to maintain an adequate perineal opening, an adequate-length tunnel, and good fixation to pelvic structures. This area is highly controversial in terms of the best management. Overall, the most popular tissue for vaginal plate replacement has been the split-thickness skin graft as described by McIndoe.[169] The major disadvantage of this technique is the need for long-term dilatation to maintain patency and to avoid vaginal stenosis. Recently, buccal mucosa grafts have been used rather than skin grafts for vaginal replacement as an alternative to the McIndoe graft.

The use of bowel segments for vaginal replacement was first described by Baldwin.[170] Because of an extraordinarily high mortality rate associated with this approach, earlier attempts using this technique were abandoned. Since then, this approach has been adopted by many groups and has been shown to be highly successful, with minimal complication rates. Early on, intestinal mucus production can be a problem, but this lessens over time, and mucus may act as a natural lubricant. Minimal perineal scarring is associated with this approach as well, and it can be done at a very young age.[171] Because of the risks and complications with any surgical approach, vaginal dilation has been recommended, when feasible, as first-line therapy for patients with vaginal agenesis who are candidates for a nonsurgical approach.

Gonadectomy

Gonadectomy prior to the age of consent is considered in DSD when the assigned sex is different from the gonadal sex, mostly in the 46,XY DSD and 45,X/46,XY DSD, and when there is a risk of tumor related to the testicular tissue. This is most commonly seen in complete gonadal dysgenesis (46,XY karyotype) in which dysgenetic gonads are high risk for gonadoblastoma at a young age in a female with a Y chromosome. An example is shown in Fig. 85.15, in which a 1-year-old infant with complete XY gonadal dysgenesis was found to have a gonadoblastoma on gonadectomy. Other syndromes in which gonadal malignancy is a concern include mixed gonadal dysgenesis and the presence of a dysplastic testis in an XY male.

Conservative management of the gonads in CAIS until puberty is recommended since tumors in these gonads do not develop until puberty and the risk is less than 1%. Alternatives to gonadectomy include bringing the gonads down (orchiopexy), monitoring with clinical examinations, imaging studies, and biopsies, although there are limited data regarding safe and effective long-term surveillance. The importance of shared decision making is critical for these adolescent girls. In DSD where there is a risk of virilization at puberty, hormonal suppression with sex hormone replacement congruent with gender identity is an alternative to surgical management until the patient is able to consent.[111]

Removal of Müllerian Remnants

Removal of müllerian remnants in male-assigned patients is not recommended unless they are associated with symptoms such as dysuria, urinary tract infections, pain, bleeding, herniation, and stone formation. Removal of the müllerian remnant can be performed laparoscopically. In most cases, müllerian remnants are asymptomatic, and cancers have rarely been reported.[121,172]

Disorders of the Thyroid Gland

GRACE KIM, DEBIKA NANDI-MUNSHI, AND CAROLINA CECILIA DI BLASI

KEY POINTS

- Appropriate thyroid hormone function is essential for normal neurodevelopment in infancy and childhood. Hypothyroidism in the first year of life can result in significant deleterious effects on growth and neurologic injury.
- Delays in treating congenital hypothyroidism (CH) is the most common preventable cause of intellectual disability.
- Neonatal screening can provide early diagnosis and can prevent delays in treatment. Newborn screening methods differ and may miss rare forms of congenital hypothyroidism.
- In preterm newborns, thyroid hormone levels may fall because of the immaturity of the thyroid gland, but these changes may be exacerbated by complications of prematurity.
- Thyroid metabolism can be affected by exogenous sources of iodine, dopamine infusions, blood transfusion, and glucocorticoid treatment.
- The clinical manifestations of Graves disease in the newborn include irritability, flushing, diarrhea, vomiting, tachycardia, hypertension, poor weight gain, thyroid enlargement, and exophthalmos.

Regulation of Thyroid Function

The hypothalamic-pituitary-thyroid (HPT) axis functions as a typical feedback loop (Fig. 86.1). Triiodothyronine (T_3) levels in the pituitary gland direct the secretion of thyroid-stimulating hormone (TSH). Also, an inverse relationship exists between thyroid hormone formation and iodide level in the thyroid. Subsequently, the rate of hormone production is not affected by rapidly changing levels of iodide, and the reservoir of thyroid hormone balances against quick changes in hormone synthesis.

TSH, produced in the anterior pituitary, is the chief player in thyroid gland function and morphology. TSH provides negative feedback by decreasing the synthesis of thyrotropin-releasing hormone (TRH) from the hypothalamus, as well as blocking the action of TRH that stimulates TSH release.[1] Release of TSH fuels uptake of iodide by the thyroid gland and accelerates many steps in thyroid hormone synthesis. It also drives the growth and vascularization of the thyroid gland itself. Both T_3 and thyroxine (T_4) provide negative feedback to TSH secretion, while TRH determines the setpoint. Given the logarithmic relationship between free T_4 (fT_4) and TSH, TSH levels are a sensitive indicator of thyroid hormone status.

Thyroid Hormone Synthesis

Synthesis of thyroid hormone is initiated by the entry of iodide molecules into the follicular cell of the thyroid gland via the sodium–iodide transporter; these are then transported into the colloid. Once they are in the thyroid gland, oxidization of iodide occurs, after which it is quickly associated with thyroglobulin (TG). Organification of the iodide forms tyrosine residues, which are then coupled to form the two active thyroid hormones: T_4 and T_3. This complexed TG, which resides in the colloid of the thyroid gland, serves as the reservoir for the production of T_3 and T_4. Thyroid hormones are then moved via endocytosis into the follicular cell. This vesicle fuses with lysosomes, after which T_4 and T_3 are disassociated from TG via hydrolysis and eventually released into the bloodstream. Residual monoiodothyronine (MIT) and diiodothyronine (DIT) are deiodinated and enter the synthesis cycle again along with iodide (I^-) and tyrosine. Important steps in thyroid hormone synthesis are summarized in Fig. 86.2.

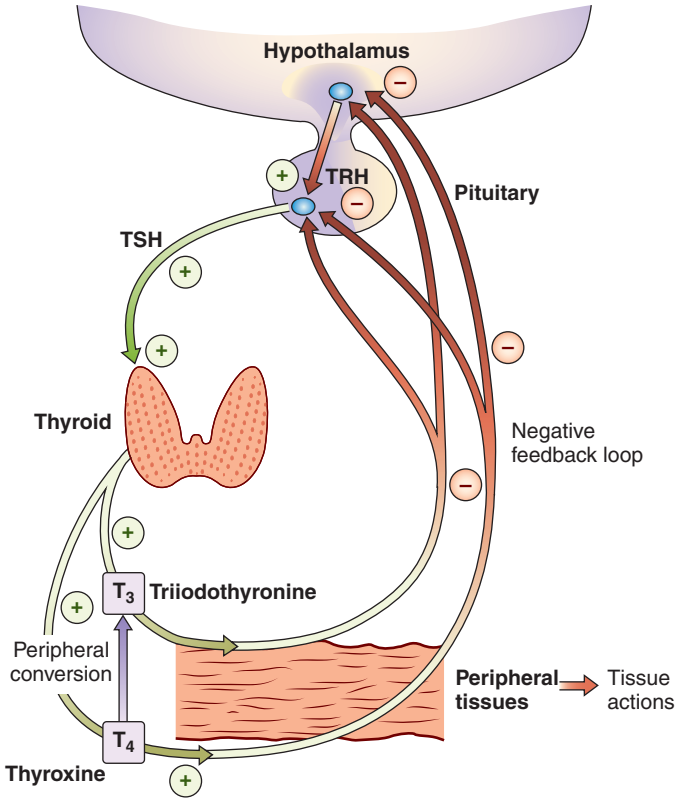
Serum Protein Binding and Transport

In the circulation, T_3 and T_4 are transported by attachment to binding proteins that include T_4-binding globulin (TBG), transthyretin (TTR; formerly termed T_4-binding prealbumin [TBPA]), and albumin. These binding transport proteins are produced in the liver. Production of these proteins increases through the latter half of gestation and is stimulated by estrogen. Free thyroid hormone levels appear to remain constant despite increasing total hormone concentrations because of an increase in binding protein production.

The serum concentration of T_4 is vastly greater than that of T_3 by a factor of 50 to 100. The primary transport protein (~75% of T_3 and T_4) is TBG. The remaining 25% of thyroid hormone is equally distributed between TBPA and albumin. The fT_4 concentration more precisely reflects the metabolic status in comparison with total T_4 or T_3. This is because only an unbound hormone can enter cells to exert its action.[2]

Embryogenesis of Hypothalamic-Pituitary-Thyroid Axis

The thyroid gland is the first endocrine organ to develop in the fetus. The development of the thyroid gland and the HPT axis occurs in two phases. The first phase is characterized by the embryogenesis of the structures involved, and the second phase is characterized by the maturation of the HPT axis, which is described later.[3] By about 3 weeks of gestation, the rudimentary beginnings of the hypothalamus have developed. Subsequently, anlagen from the floor of the forebrain and the Rathke pouch

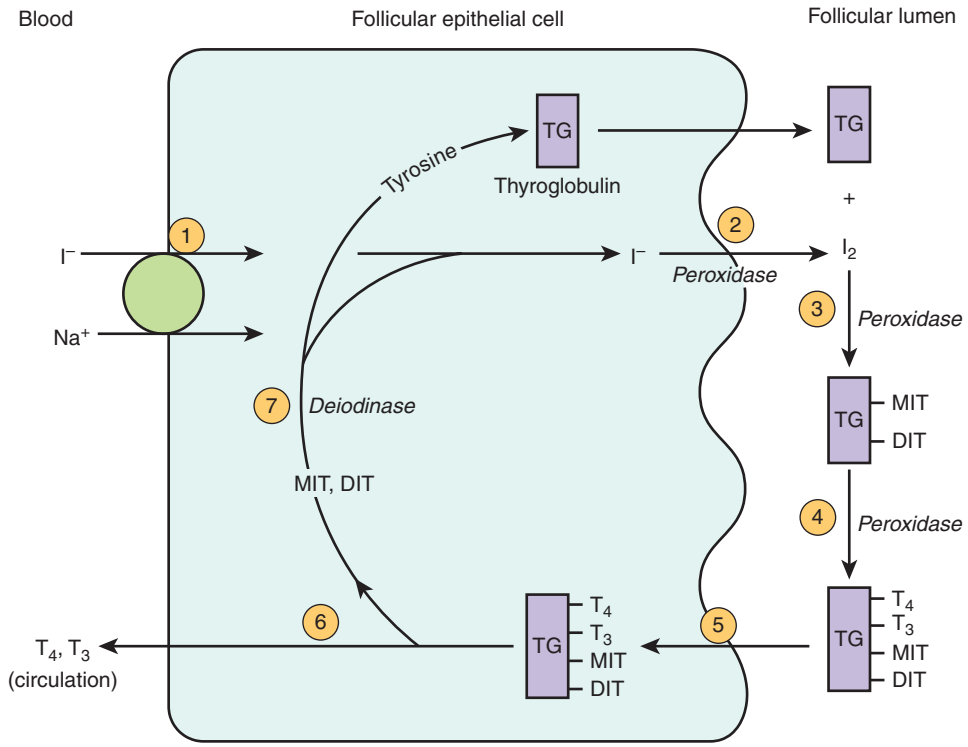


• **Fig. 86.1** The Hypothalamic–Pituitary–Thyroid Axis. Thyroid stimulating hormone *(TSH)* is secreted in response to TSH-releasing hormone *(TRH)* and stimulates secretion of thyroxine *(T_4)* and triiodothyronine *(T_3)* from the thyroid. T_3 and T_4 have actions in peripheral tissues and exert negative feedback on the hypothalamus and the pituitary.

converge to form the pituitary gland. By 14 to 15 weeks of gestation, this embryologic structure has become the mature pituitary gland.[4] Detection of TSH has been observed as early as 10 to 12 weeks of gestation.[5]

A programmed sequence of transcription and homeobox factors (e.g., thyroid transcription factors-1 and -2 [TTF-1 or TiTF-1, now designated as NKX2 homeobox 1 -NKX2.1-; and TTF-2, now Forkhead box E1 -FOXE1-] and paired box gene 8 [PAX8]) directs thyroid embryogenesis. Thyroid gland development begins with convergence of three structures: the median anlage from the floor of the pharyngeal pouch (caudal end of the foregut) and two lateral anlagen from the fourth pharyngobranchial pouch. The median anlage is visible by day 22 after conception. The lateral anlagen develop into a pair of ultimobranchial bodies from which the calcitonin-producing parafollicular C cells arise. Between day 32 and day 48 after conception, this primordial thyroid structure breaks off from the pharyngeal pouch and completes its migration to the pretracheal region. Little is known about the molecular factors involved in this migration; however, FOXE-1 has been implicated in cases of thyroid ectopy.[6]

By 4 weeks after thyroid descent is complete, functional and structural changes are mature, and the thyroid can produce thyroid hormone. Follicles fill with colloid. By 12 weeks of gestation, the thyroid gland is able to take up iodide, synthesize TBG, and produce hydrogen peroxide (H_2O_2) at the apical membrane—all steps required for thyroid hormone production. T_4 has been detected in human fetal blood as early as 11 to 12 weeks of gestation.[7] This accrual of the ability to produce thyroid hormone coincides with the maturation of the hypothalamus and pituitary gland with the production of TRH and TSH.



• **Fig. 86.2** Steps involved in the synthesis of thyroid hormones: (1) iodide transport; (2) oxidation of I^- to I_2; (3) organification of I_2 into monoiodothyronine *(MIT)* and diiodothyronine *(DIT)*; (4) coupling reaction of MIT and DIT to form triiodothyronine *(T_3)* and thyroxine *(T_4)*; (5) endocytosis of thyroglobulin *(TG)*; (6) hydrolysis of T_4 and T_3, T_4, and T_3 enter circulation; and (7) deiodination of residual MIT and DIT, recycling of I^- and tyrosine.

Fetal–Placental–Maternal Thyroid Interaction

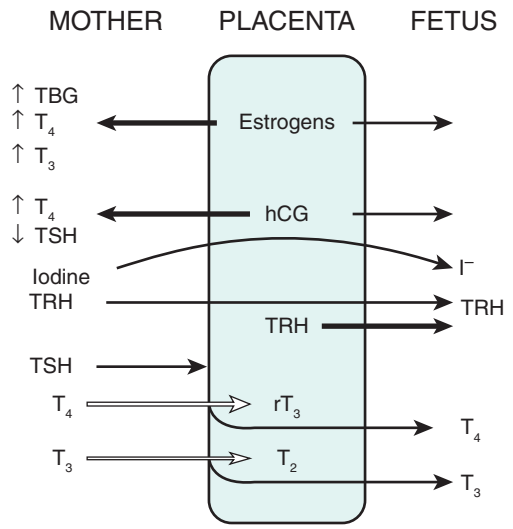
The placenta is of utmost importance in fetal thyroid physiology as it regulates the passage of maternal thyroid hormone to the fetus (Fig. 86.3). Thyroid hormone is paramount for normal neurodevelopment. Maternal-to-fetal transfer of T_4 is essential, especially in the first trimester when the fetal thyroid axis has yet to mature. With the landmark study by Vulsma et al.,[8] it was shown that T_4 does cross the placenta, contradicting previous concepts—placental transfer of T_4 in athyreotic fetuses resulted in levels that were 25% to 50% of those of normal term newborns. There are mixed reports on the effect of hypothyroidism in the mother on the neonate. In case series of women with severe hypothyroidism diagnosed during pregnancy and treated to normalize levels during the third trimester, the offspring were noted to have normal intellectual outcomes.[9,10] Additionally, similar developmental outcomes were seen in offspring of both T_4-treated versus placebo-treated women with low T_4 levels.[11,12] Multiple clinical studies have shown the deleterious effects of inadequate maternal thyroid hormone levels.[13–15]

TSH does not cross the placenta; however, TRH does. During pregnancy, maternal thyroid axis changes result in increased fT_4 levels early and maintenance of higher levels until birth (Fig. 86.4). This is a result of human chorionic gonadotropin produced by the placenta, which is homologous to TSH with some TSH-like activity.[16]

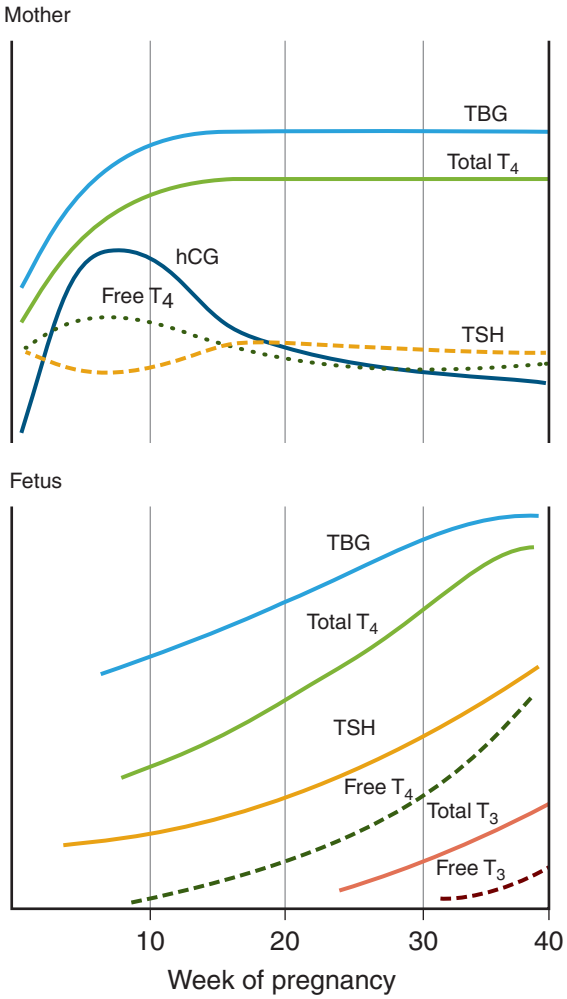
Although most of the transfer of the maternal thyroid hormone is dependent on maternal thyroid hormone concentrations, plasma membrane thyroid hormone transporters and metabolism via deiodinases (DIs) also play a role. Thyroid hormone transporters are found in the apical and basolateral membrane of the placenta. Several transporters have been discovered in the placenta (monocarboxylate transporters, L-type amino acid transporters, and organic anion–transporting polypeptides).[17] The placenta also has both type 2 and type 3 DI, which is involved in the metabolism of thyroid hormone in this milieu. The activity level of type 3 DI is 200 times higher than that of type 2 DI. T_3 is thought not to cross the placenta; however, this is not clear.[18]

Iodide is taken up by the thyroid gland for thyroid hormone synthesis. There is free passage of iodides between the mother and the fetus. Large-quantity ingestion of iodine will decrease the synthesis of T_4 transiently. This decreased synthesis is due to decreased uptake via the sodium–iodide symporter. Typically, there is an escape from this phenomenon in about 48 hours. However, cases of goiter and hypothyroidism have been reported with excessive iodine intake.[19] An adequate amount of iodine, around 250 µg/day, is still recommended for pregnant women according to the American Thyroid Association.[20]

Miscellaneous other compounds can cross the placenta, affecting fetal thyroid function. TSH receptor-blocking antibodies (TRBAbs), also known as TSH Binding Inhibitory Immunoglobulins, have been implicated in cases of transient neonatal hypothyroidism.[21] In mothers with a history of Graves disease,



• **Fig. 86.3** The Placental Role in Thyroid Metabolism. The placenta produces estrogens and human chorionic gonadotropin *(hCG)*, which increase maternal thyroxine *(T_4)*-binding globulin *(TBG)* levels and stimulate maternal thyroid hormone production, respectively. Both activities tend to increase maternal T_4 and triiodothyronine *(T_3)* concentrations and inhibit maternal thyroid-stimulating hormone *(TSH)* secretion. Iodide and TSH-releasing hormone *(TRH)* readily cross the placenta. In addition, the placenta synthesizes TRH. The placenta is impermeable to TSH and only partially permeable to T_4 and T_3. *rT_3*, Reverse triiodothyronine.



• **Fig. 86.4** Relative changes in maternal and fetal thyroid function during pregnancy. The effects of pregnancy on the mother include a marked and early increase in hepatic production of thyroxine *(T_4)*-binding globulin *(TBG)* and placental production of human chorionic gonadotropin *(hCG)*. The increase in serum TBG level, in turn, increases serum T_4 concentrations; hCG has thyroid-stimulating hormone *(TSH)*-like activity and stimulates T_4 secretion. The transient hCG induces increase in serum T_4 and inhibits maternal secretion of TSH.

thyroid-stimulating immunoglobulin (TSI) can lead to thyrotoxicosis in the neonate.[22] Antithyroid medications ingested by the mother can result in fetal goiter with or without hypothyroidism.[23]

Thyroid System Maturation

The fetal thyroid gland can synthesize and secrete thyroid hormone after 12 weeks of gestation. As the pregnancy continues, the levels of fT_4 and T_4 continue to rise in step with the gestational age of the fetus. T_3 levels, however, remain low until about 30 weeks of gestation, after which they increase slowly until birth. This delayed rise in T_3 levels is due to low rates of conversion of T_4 to T_3 by type 1 DI and high activity of type 3 DI metabolizing T_3 to diiodothyronine (DIT).[4] With an increased amount of type 1 DI produced by the liver after 30 weeks, there is increased conversion of T_4 to T_3 in the liver and decreased metabolism of T_3 by placental type 3 DI, resulting in the steady rise until delivery. TSH has also been detected at 12 weeks of gestation, with subsequent increases in its level in parallel with increases in fT_4 level.[24] The level of reverse T_3 (rT_3) is relatively high early in the third trimester because of placental type 3 DI activity converting T_4 to rT_3 and T_3 to DIT (Fig. 86.5).

Fetal Thyroid Hormone Metabolism

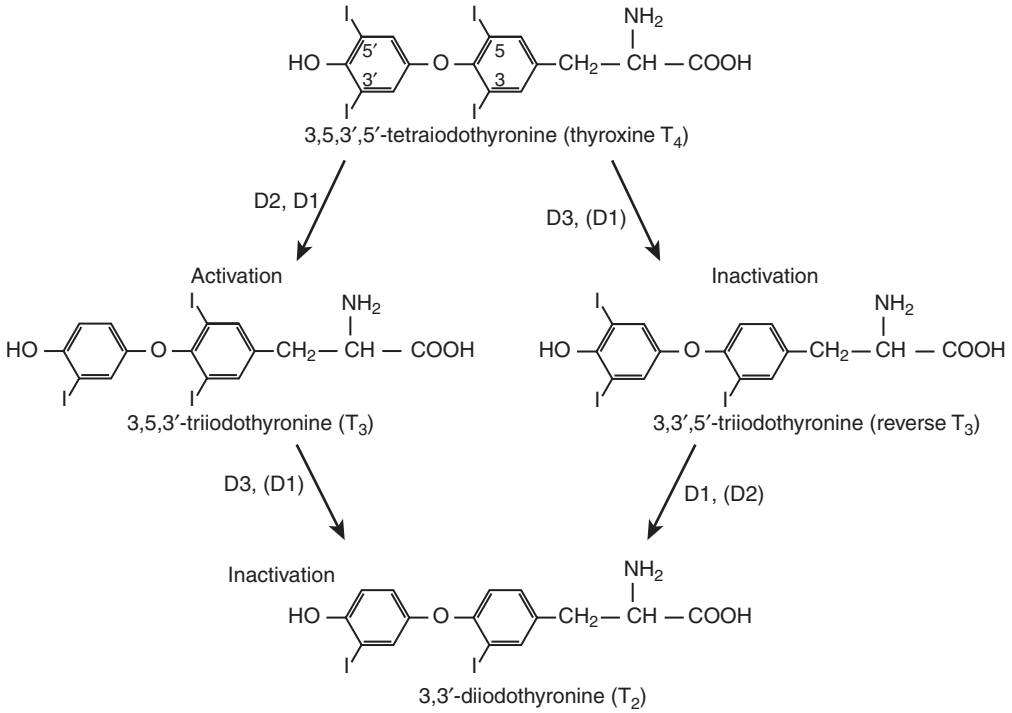
The thyroid gland is the body's only source of T_4. Conversion of T_4 to T_3 peripherally contributes to most of the circulating T_3. This conversion is accomplished by a group of three DIs, types 1, 2, and 3 (see Fig. 86.5). T_3, with its greater affinity for the thyroid hormone receptor, is the active form of thyroid hormone. T_3 is derived from the deiodination of the outer ring of T_4. Conversely, deiodination of T_4 at the inner ring produces the inactive rT_3.[25]

Type 2 and type 3 DIs are selective in their action, performing deiodination on only the outer ring and inner ring, respectively. Type 1 DI is nonselective, with deiodination at the outer ring converting T_4 to T_3 and deiodination at the inner ring producing rT_3 from T_4. Type 1 DI is produced in the liver, kidney, and thyroid. Type 1 DI is inhibited by propylthiouracil and rT_3 and stimulated by thyroid hormone. Type 2 DI is primarily found in the brain, pituitary, placenta, skeletal muscle, heart, thyroid, and brown adipose tissue, and is not sensitive to propylthiouracil and is inhibited by thyroid hormone. It converts T_4 to T_3. Type 3 DI is found primarily in fetal tissues, including the placenta, brain, and skin. Type 3 DI converts T_4 to rT_3 and T_3 to DIT.[26]

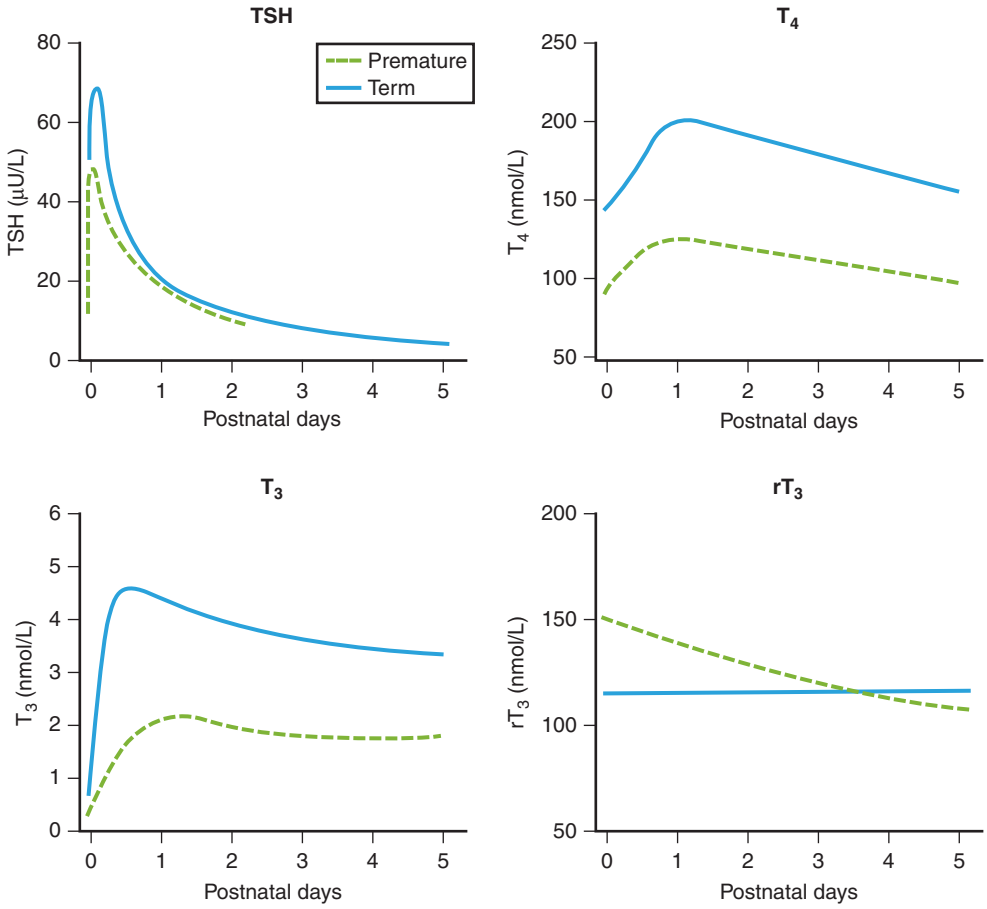
During pregnancy, fetal DI levels vary with time and are reflective of thyroid hormone concentrations. Type 1 DI in hepatic tissues remains quiescent until late in gestation, resulting in a late rise of fetal T_3 levels. Type 3 DI activity is responsible for high rT_3 levels in the fetus. The interplay of these enzymes is critical to normal brain development. Given that both type 1 and type 2 DI are sensitive to thyroid hormone levels, a hypothyroid fetus will have increasing type 2 DI activity in the brain and decreasing type 1 hepatic activity, resulting in more T_4 in the brain, at which point it is converted to T_3 by type 2 DI.[27]

Extrauterine Thyroid Adaptation

At birth, fT_4 levels in the newborn are slightly below that of the maternal concentration, and the T_3 level is relatively low in umbilical cord blood. Also, at this time, partly in response to cold and stress, there is a TSH surge that peaks at about 2 to 4 hours of life and then returns to its initial value within about 48 hours (Fig. 86.6). T_3 and T_4 levels also rise within a few hours of birth and reach their peak by 24 hours. TSH, as well as extrathyroidal conversion of T_3 to T_4 by type 1 and type 2 DIs, contributes to this surge of thyroid hormone.[28] During the next 4 to 5 weeks of life, T_4 and T_3 levels progressively decrease to levels just above the normal range of children. By 1 month of age, the TSH level has



• **Fig. 86.5** Enzymatic conversion of iodothyronines. *D1*, Type 1 deiodinase; *D2*, type 2 deiodinase; *D3*, type 3 deiodinase.



• **Fig. 86.6** Postnatal thyroid-stimulating hormone *(TSH)*, thyroxine *(T_4)*, triiodothyronine *(T_3)*, and reverse T_3 *(rT_3)* secretion in the term and premature infant in the first week of life. (Adapted from www.thyroid-manager.org, the free online thyroid textbook. In: Brown R, Larsen PR, De Groot LJ, eds. *Thyroid Gland Development and Disease in Infants and Children*. South Dartmouth, MA: Endocrine Education, Inc; 2009.)

declined to about 5 mU/L[29] and declines further to a near-adult range of 0.5 to 4 mU/L by the second month.[30]

Infants born prematurely appear to have an attenuated TSH surge. This is due to an immature HPT axis. T_3 and T_4 levels also have a blunted rise in comparison with the levels in term newborns. The TSH level can peak at about 40 mU/L by 30 minutes.[31] Many factors need to be taken into account when one is assessing thyroid function in preterm infants. As many preterm newborns have other complications, such as respiratory distress syndrome or nutritional problems, serum T_4, and especially T_3, concentration may fall to low levels as a result of the immaturity of the thyroid gland, as well as reduced TBG production. Illness also causes suppression of the hypothalamic-pituitary-thyroid axis, impairs the conversion of T_4 to T_3, and increases type 3 DI activity.[28]

Congenital Hypothyroidism

Epidemiology

Congenital hypothyroidism (CH) is defined as variable dysfunction of the hypothalamic-pituitary-thyroid axis present at birth, resulting in insufficient thyroid hormone production and thyroid hormone deficiency. CH is caused by abnormal development or function of the thyroid gland, pituitary, hypothalamus, or thyroid hormone function. The overall incidence is 1 in 2500 to 1 in 3000 newborns.[32,33] Higher incidence rates have been reported in certain populations. The prevalence rates of CH can differ with sex, ethnicity, and birthweight. Twice as many female as male infants are affected. Compared with whites, the prevalence of CH is higher in Asians and Hispanics and lower in Blacks. A study noted an increased risk of CH in macrosomic (>4500 g) and low birthweight (<2000 g) infants.[32] There is an increased risk in infants with Down syndrome. The reported incidence of central CH is 1 in 80,000 to 1 in 100,000.

Pathophysiology

In most cases, CH is permanent and results from an abnormality in thyroid gland development (dysgenesis or agenesis) or a defect in thyroid hormonogenesis. Less commonly, the altered thyroid function is transient, attributable to transplacental passage of maternal medication, maternal blocking antibodies, or iodine deficiency or excess. In rare cases, CH may result from a pituitary or hypothalamic abnormality. Potential causes are listed in Table 86.1. Regardless of the duration of the thyroid dysfunction, immediate treatment with levothyroxine (LT_4) in the newborn period is needed to prevent cognitive or neurodevelopmental decline. The developing fetal brain is protected in utero by an adequate source of T_3, supplied by local deiodination of maternal T_4 in the fetal brain.

TABLE 86.1 Thyroid Disorders and Their Approximate Incidence in the Neonatal Period

Disorder	Incidence
Thyroid Dysgenesis	1 in 2500 to 1 in 4000
Agenesis	
Hypogenesis	
Ectopia	
Thyroid Dyshormonogenesis	1 in 30,000
TSH receptor defect	
Iodide-trapping defect

TABLE 86.2 Clinical Signs and Symptoms of Congenital Hypothyroidism in Infancy

Age/Manifestation	Frequency (%)
0–7 Days	
Prolonged jaundice >3 days	73
Birthweight >4 kg	40
Poor feeding	40
Transient hypothermia	38
Large posterior fontanel (>5 mm)	32
1–4 Weeks	
Failure to gain weight	45
Constipation	35
Hypoactivity	33
1–3 Months	
Failure to thrive	90
Umbilical hernia	49
Macroglossia	43
Myxedema	40
Hoarse cry	30

Clinical Presentation

The diagnosis of hypothyroidism should be considered in any infant with prolonged jaundice, transient hypothermia, an enlarged (greater than 5 mm) posterior fontanel, failure to feed properly, or respiratory distress with feeding.[34] Approximately one-third of maternal T_4 crosses to the fetus at term. With a half-life of 6 days, the maternal T_4 will be metabolized and excreted by 3 to 4 weeks of age.[35] The classic signs evolve during the first few weeks after birth. Fetal growth is normal; however, there is a delay in bone maturation and a rapid reduction in growth rate after birth[36] with progressively worsening myxedema in subcutaneous tissues and tongue. The thickened tongue becomes protuberant, and increasing difficulty in nursing and handling salivary secretions is noted. The cry is hoarse because of myxedema of the vocal cords. Additional signs and symptoms include marked muscular hypotonia; constipation; thick, dry, cold skin; long, abundant, and coarse hair; abdominal distention; umbilical hernia; hyporeflexia; bradycardia; hypotension with narrow pulse pressure; anemia; and widely patent cranial sutures. Goiter can be present. The typical facies are characterized by a depressed nasal bridge, a relatively narrow forehead, and puffy eyelids.[37] The cardiac silhouette may be enlarged, and the electrocardiogram shows low voltage and a prolonged conduction time. Some of the signs and symptoms are present by 6 to 12 weeks postnatally, especially lethargy, constipation, and umbilical hernia. The characteristic facies and growth retardation become increasingly obvious during the first several months of life.

Nonspecific symptoms and signs associated with hypothyroidism are listed in Table 86.2. Because clinical manifestations of hypothyroidism may not appear until weeks after birth, even in athyreotic infants, newborn screening has enabled pediatricians to identify newborns with low thyroid hormone production and to initiate therapy within the first 2 weeks of life before the development of signs and symptoms.

Evaluation

Screening for Neonatal Hypothyroidism

Newborn screening programs for CH avoid delay in its diagnosis because signs and symptoms of CH may not manifest for several weeks.

Newborn screening programs are designed to detect abnormal thyroid hormone levels in newborn blood samples collected on filter paper. Some programs measure TSH primarily with T_4 levels as a backup, some measure T_4 primarily with TSH as a backup, and some measure both TSH and T_4 primarily. Screening programs have been established in industrialized countries. Despite the benefits of neonatal screening, 70% of infants worldwide are born in areas that do not have access to neonatal screening.[38]

Both screening methods—primary TSH/backup T_4 method and primary T_4/backup TSH method—appear to be capable of detecting almost all infants with primary CH. However, the combined TSH plus T_4 approach is the ideal screening approach.

Primary CH is associated with a low serum T_4 and fT_4 concentration and a high TSH concentration in umbilical cord blood or neonatal blood samples. It is estimated that 5% to 8% of affected infants can escape detection by newborn screening because of a delayed elevation in serum TSH concentration or because of errors in sample collection or laboratory routine. In addition, infants with TSH deficiency who have normal TSH levels are not detected because most newborn screening programs report only those infants with elevated TSH levels. Infants with central hypothyroidism may have normal or low TSH. Normal TSH would be inappropriate in the setting of low thyroid hormone levels. Newborn screens that use elevated TSH to detect congenital hypothyroidism will miss diagnosing these infants. Infants with signs or symptoms suggestive of thyroid dysfunction (see Table 86.2) should be investigated regardless of previous screening results. Determination of serum fT_4, T_4, and TSH values is necessary for any infant with suspicious clinical or laboratory findings.

Accurate screening results depend on good-quality blood samples. Blood samples should be collected on approved filter paper forms, dried at room temperature, and not subject to excessive heat. Capillary blood samples are placed in the circular areas to fill and saturate them and applied to one side only. Filter paper should not be handled or placed on wet surfaces.[39]

Every infant should be tested before discharge from the nursery, optimally by 2 to 4 days of age. The practice of early hospital discharge (before 48 hours of age) has led to an increased frequency of false-positive results because of the normal physiologic TSH surge that occurs after birth. Infants screened before 48 hours of age require the newborn screen to be rechecked by the primary care physician at 2 weeks of life.

Some infants may have a false-negative neonatal screening result or have a high risk of mild CH not detected by newborn screen. These infants include premature, low-birth weight, and sick babies. These babies might not be able to generate an adequate TSH response in the first weeks of life. As a result, in TSH-based neonatal screening programs, their results may be false negative.[40,41] Maturation and recovery of the HPT axis with an increase in TSH occurs between 2 and 6 weeks of life. Screening programs have revised recommendations for this group of infants. In preterm newborns, the TSH surge, T_4, and T_3 are lower than those in term neonates. The immaturity of the HPT axis in extremely premature infants is characterized by markedly blunted TSH surge, T_4 decrease, and lower and shorter T_3 increase within the first 24 hours of life.

Transient hypothyroxinemia of the preterm neonate is a frequent finding aggravated by general illness; it is due to an immature HPT axis function. LT_4 therapy of preterm hypothyroxinemia remains controversial. Down syndrome is associated with a 14 to 21 times higher than expected incidence of CH and highly prevalent mild TSH elevation, especially in the first months to years of life.[42,43] In patients with Down syndrome, it is recommended to measure TSH at the end of the neonatal period.[38]

Endocrine testing is recommended in all neonates with a familial history of CH or signs/symptoms of CH, such as micropenis with undescended testes, hypoglycemia, prolonged jaundice, or unexplained failure to thrive.[38]

All neonates with CH should be examined carefully for dysmorphic features suggestive of syndromic CH and congenital malformations, particularly cardiac.[38] The Bamforth-Lazarus syndrome is characterized by thyroid dysgenesis, cleft palate, spiky hair with or without bilateral choanal atresia, or bifid epiglottis (biallelic mutation in the FOXE1 gene). Brain-lung-thyroid syndrome is characterized by CH, respiratory distress syndrome, and benign hereditary chorea (due to NKX2-1 haploinsufficiency). Alagille syndrome is associated with thyroid in situ, bile duct hypoplasia, and cardiac malformations. William-Beuren and DiGeorge syndromes have a high prevalence of thyroid hypoplasia. Kabuki and Johanson-Blizzard syndrome is associated with subclinical hypothyroidism. Pendred syndrome can be seen with or without goiter and sensorineural hearing loss (SLC26A4 gene).

Thyroid Function Tests

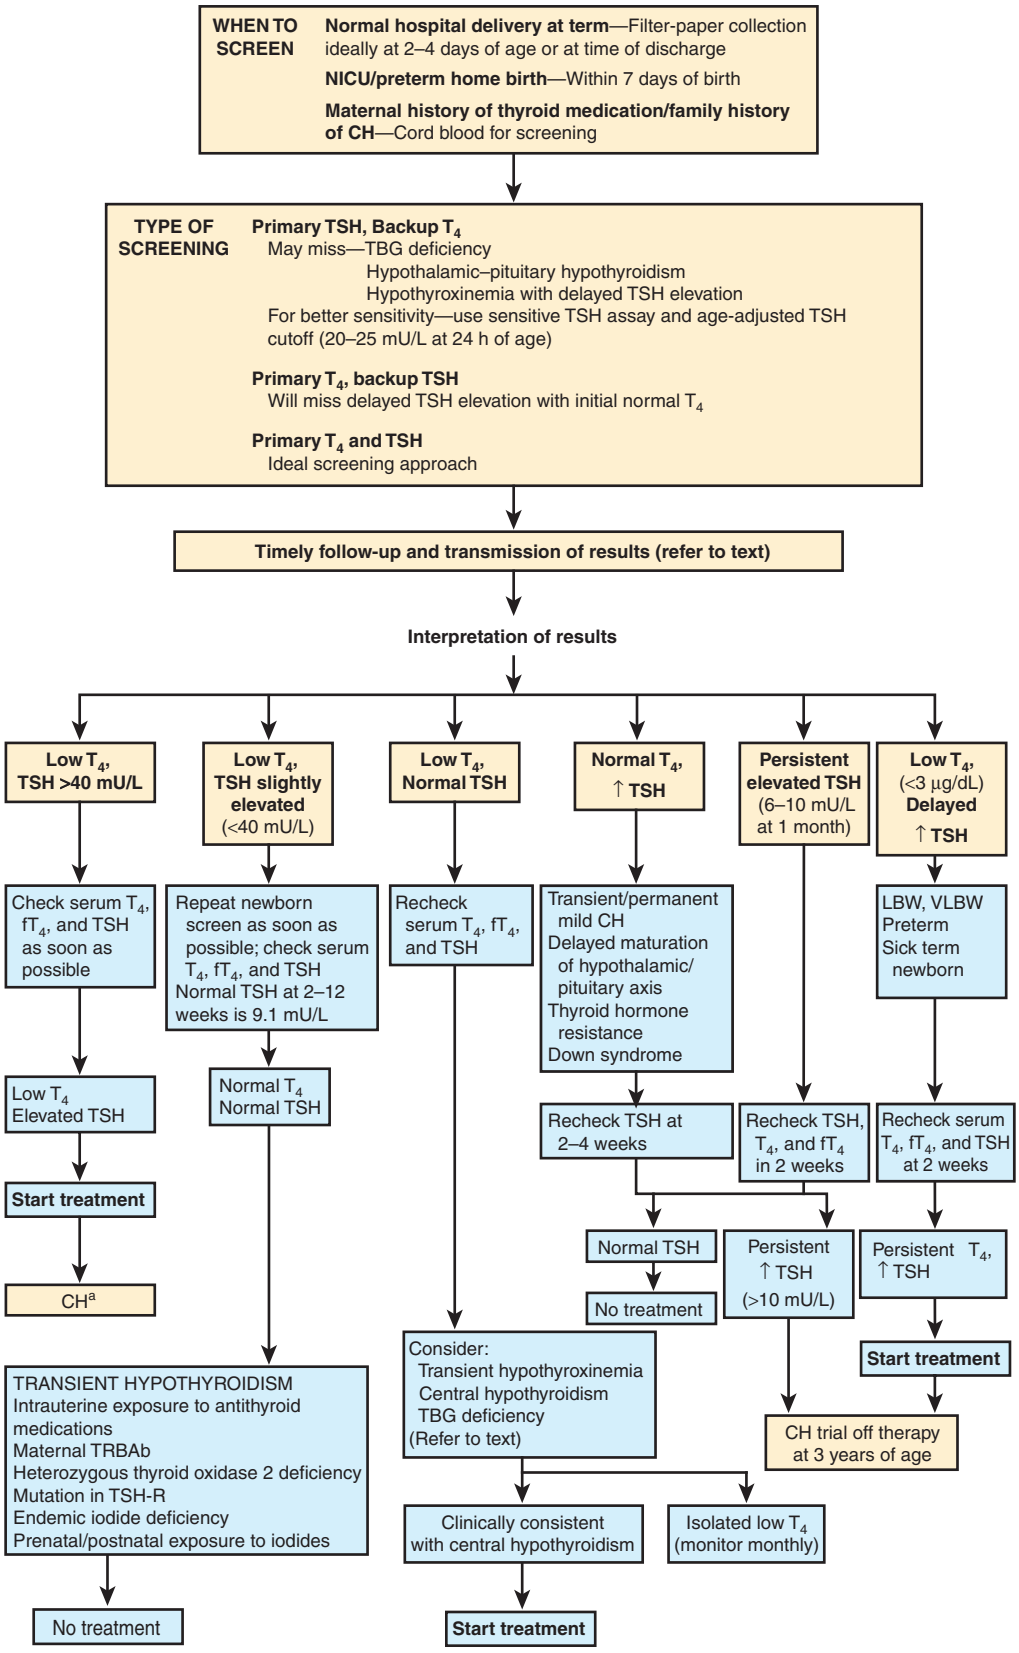
When the diagnosis of CH is suspected, confirmatory thyroid function tests should be performed. It is advisable to assess fT_4 and TSH.[38] Elevated serum TSH value is the most sensitive and specific test to confirm the diagnosis of primary hypothyroidism. Typical laboratory findings for primary hypothyroidism include elevated TSH levels, with T_4 and fT_4 values in the low or low-normal range. A low or undetectable TG concentration[44] with TSH level elevation confirms a dysgenetic or absent thyroid gland,[45] whereas a high TG concentration with TSH level elevation suggests an organification defect.[46] In central hypothyroidism, TSH level is usually normal, T_4 level is low normal, and fT_4 level is in the lowest third of normal.[47]

Interpreting Thyroid Function Tests

When interpreting thyroid function tests, it is critically important to consider the day of life on which the samples were drawn. The recommended period for newborn screening of thyroid function is at 24 hours of life. If screening is done at less than 24 hours of life, it must be redone, regardless of the results. After 24 hours of life, a TSH value greater than 40 μU/L is highly suggestive of hypothyroidism, but confirmatory testing is required. A TSH value above the normal limit for the hours of life and gestational age but below 40 mU/L is indeterminate. Therefore, repeated testing is necessary, and the primary care physician should obtain a second screen (Fig. 86.7). The practice of early hospital discharge (less than 48 hours of age) has led to a higher rate of indeterminate results.

Eight to 10% of infants with CH have TSH values between 20 and 40 mU/L. One in 12 to 1 in 24 hypothyroid infants (1 in 50,000 to 1 in 100,000 newborns) will have a screening TSH level of less than 20 mU/L, with a delayed postnatal increase to hypothyroid levels.[48] Therefore, any infant with suspicious screening or sampling results requires confirmatory testing with measurement of serum fT_4, T_4, and TSH concentrations.[39]

The biochemical profile of hypothalamic–pituitary hypothyroidism comprises low serum T_4 concentration with a normal TSH value. A similar biochemical profile characterizes TBG deficiency (1 in 5000). However, the two states can be differentiated by further assessment of TBG and fT_4 levels. A low serum TBG concentration and a normal fT_4 level identify patients with TBG deficiency. In contrast, a low or low-normal fT_4 level and a normal TBG level identify a patient with hypothalamic-pituitary hypothyroidism. An infant with a low fT_4 concentration needs to be carefully examined for evidence of hypothyroidism, and other tests of pituitary function should be conducted. TRH stimulation testing can be used to differentiate between primary and central hypothyroidism. TRH, however, is not available in the United States. A subnormal TSH response to TRH or a normal but delayed and prolonged TSH response to TRH indicates central hypothyroidism.[47] TSH deficiency may be isolated or associated with other pituitary hormone deficiencies. Frequently it is not possible to



• **Fig. 86.7** Algorithm for evaluating congenital hypothyroidism *(CH)* on the basis of newborn screening results. *fT_4*, Free thyroxine; *LBW*, low birthweight; *NICU*, neonatal intensive care unit; *T_4*, thyroxine; *TBG*, thyroxine-binding globulin; *TRBAb*, thyroid-stimulating hormone receptor–blocking antibody; *TSH*, thyroid-stimulating hormone; *TSH-R*, thyroid-stimulating hormone receptor; *VLBW*, very low birthweight. discriminate between secondary and tertiary hypothyroidism, so the most useful diagnostic term is central hypothyroidism. The presence of midline facial abnormalities, hypoglycemia (growth hormone and/or adrenocorticotropic hormone deficiencies), microphallus (gonadotropin and growth hormone deficiencies), nystagmus or blindness, or polyuria (antidiuretic hormone deficiency) should suggest the possibility of a hypothalamic abnormality. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can manifest itself as CH. Mutations in HESX1 have been described in septo-optic dysplasia. Alternatively, multiple pituitary hormone deficiencies suggest a genetic defect in the cascade leading to fetal pituitary formation, such as in PROP1, LHX3, LHX4, and POU1F1.

Isolated TRH deficiency may cause low-normal T_4 and low-normal TSH levels. Mutations have been identified in the TRH gene, TRH receptor gene, and the gene encoding the β subunit of TSH. Newborns who are born before term, of low birthweight (<2500 g) or very low birthweight (<1500 g), and ill are found among those with this set of laboratory values. In neonates, inhibition of TSH causing low T_4 concentration can result from dopamine infusions or high-dose glucocorticoids.[39]

A strategy of second newborn screening should be considered for the following conditions: preterm neonates; low birthweight or very low birthweight neonates; ill newborns admitted to the neonatal intensive care unit; specimen collection within the first 24 hours of life; and multiple births.

TABLE 86.3 Genes and Thyroid Development

Gene	Thyroid Phenotype	Other Features
TTF-2/ FOXE-1	Athyreosis	Cleft palate, choanal atresia, kinky hair, bifid epiglottis
TTF-1/ NKX2.1	Athyreosis to normal gland	Respiratory distress syndrome, developmental delays/hypotonia, ataxia/ choreoathetosis
PAX-8	Athyreosis to normal gland	Cysts within thyroid remnants, kidney and urinary tract malformations
GLIS3	Athyreosis to normal gland	Congenital glaucoma, deafness, liver/kidney and pancreatic abnormalities
TSHR	Athyreosis to normal gland	None
NKX2.5	Athyreosis, ectopy	Cardiac defects

Specific Causes of Hypothyroidism

Thyroid Dysgenesis

Eighty-five percent of cases of permanent CH are associated with abnormal development of the thyroid gland, which includes agenesis, ectopy, or hypoplasia of the gland. Thyroid ectopy accounts for approximately two-thirds of cases worldwide.[24] There is female predominance associated with ectopic glands. Ectopic locations of the thyroid gland include lingual, neck, and substernal locations. Most cases are sporadic; however, more recent studies show evidence of genetic factors involved in the pathogenesis.

A unique combination of transcription factors controls the embryonal development of the thyroid gland. Mutations in the genes encoding these transcription factors can lead to varying degrees of abnormalities, from athyreosis to normal glands. Other clinical features can be associated, as noted in Table 86.3. Thyroid ectopy, the most common form of thyroid dysgenesis, remains unexplained.

Mutation in NKX2.5, which encodes a transcription factor involved in heart morphogenesis, has also been reported to be associated with thyroid dysgenesis.[49]

Extrathyroidal abnormalities occur at a higher frequency in children with CH. The most frequent malformations associated with thyroid dysgenesis are cardiac, largely septation defects.[50] Other relatively common malformations include anomalies of the gastrointestinal tract, nervous system, and eyes.[51–53]

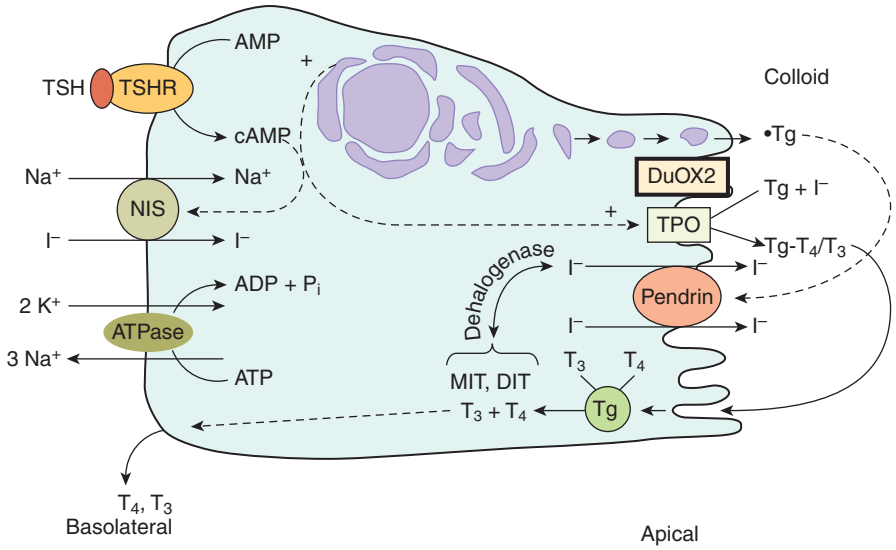
The biochemical picture can differ depending on the amount of thyroid tissue remaining. The presence of residual thyroid tissue is evident by detectable TG levels and normal or near-normal T_3 levels with low T_4 and elevated TSH values. The presence of residual thyroid tissue can be confirmed with a thyroid scan.

Thyroid Dyshormonogenesis

The remaining 10% to 15% of cases of CH involve defects in the synthesis of thyroid hormone. Hereditary defects in virtually all of the steps of thyroid hormone synthesis, secretion, and action have been described (Fig. 86.8). These patients often have normally located and normal-sized thyroid glands. Thyroid enlargement, however, can present at birth or even before, but more commonly, goiter develops later in life. The inheritance pattern is autosomal recessive.[54]

Defects associated with the trapping of iodide or in the oxidation or organification of iodide can result in dyshormonogenesis. These mutations include:

1. Sodium–iodine symporter defect. The gene encoding the sodium–iodine symporter is SLC5A5 on chromosome 19. Hypothyroidism presents most frequently in the neonatal or infantile period. Patients have a goiter on physical examination or ultrasound imaging, contrasting with limited or absent uptake on scintigraphy.
2. Thyroid peroxidase (TPO) defect. TPO is the enzyme responsible for iodide oxidation, organification, and iodothyrosine coupling. Mutations in the thyroid peroxidase gene are the most common cause of thyroid dyshormonogenesis. The enzyme is located at the apical membrane of the follicular cell. The clinical presentation is permanent goitrous, CH, high uptake on thyroid scintigraphy, and a high serum TG level.
3. Defects in H_2O_2 generation. Dual oxidase 1 and dual oxidase 2 are enzymes that generate H_2O_2 at the apical membrane.
4. TG defect. TG is an iodinated glycoprotein. The TG gene is located on chromosome 8. TG serves as the matrix for the synthesis of T_4 and T_3 and the storage of thyroid hormone and iodine. It is the essential substrate for organification and the major protein component of the colloid in the follicular lumen. Goiter and hypothyroidism manifest themselves at birth or before, and patients have low or undetectable TG levels.
5. Pendred syndrome is an autosomal recessive disorder associated with a partial defect in iodine organification, goiter, and sensorineural deafness. It is caused by mutations in the SLC26A4 gene on chromosome 7, which encodes the chloride-iodide



• **Fig. 86.8** A thyroid follicular cell, indicating areas of possible defects in thyroid hormone synthesis (e.g., thyroid dyshormonogenesis). *ADP*, Adenosine diphosphate; *AMP*, adenosine monophosphate; *cAMP*, cyclic AMP; *ATPase*, adenosine triphosphatase; *DIT*, diiodothyronine; *DuOX2*, dual oxidase 2; *K*$^+$, potassium ion; *MIT*, monoiodothyronine; *Na*$^+$, sodium ion; *NIS*, sodium–iodide symporter; P_i, inorganic phosphate; T_3, triiodothyronine; T_4, thyroxine; *Tg*, thyroglobulin; *TPO*, thyroid peroxidase; *TSH*, thyroid-stimulating hormone; *TSHR*, thyroid-stimulating hormone receptor. (Modified from Van Vliet G, Deladoey J. Disorders of the thyroid in the newborn and infant. In: Sperling MA, ed. *Pediatric Endocrinology*. 4th ed. Philadelphia; Elsevier; 2014.)

transporter pendrin. The gene is expressed in the cochlea, thyroid, and kidney. Pendrin functions to maintain the endocochlear potential and is involved in the apical efflux of iodide in the thyroid follicular cells.[55] The thyroid phenotype is usually mild and is seldom identified by neonatal TSH screening. Goiter development and hypothyroidism are variable and depend on nutritional iodine intake.

6. Dehalogenase defects. MIT and DIT, the main iodinated byproducts of thyroid hormonogenesis, are deiodinated in the thyroid cell by dehalogenase. In this way, iodine is conserved within the thyroid gland for another cycle of synthesis of thyroid hormone.[54] Patients with iodothyrosine dehalogenation defects have goiter and CH. The diagnostic hallmark is the presence of MIT and DIT in large amounts in the urine.

When available, genetic testing should be performed using new techniques, such as comparative genomic hybridization (CGH) array, next-generation sequencing (NGS) of gene panels (targeted NGS), or whole exome sequencing (WES).

Antenatal diagnosis, evaluation of fetal thyroid function, and management of fetal hypothyroidism is recommended in cases of goiter discovered during systematic ultrasound examination of the fetus. For the evaluation of fetal thyroid volume, an ultrasound scan is recommended at 20 to 22 gestational weeks to detect fetal thyroid hypertrophy and potential thyroid dysfunction in the fetus. Goiter or an absent thyroid tissue can be documented by this technique. If a large fetal goiter is detected, prenatal care should be provided in a specialized center. Cordocentesis, rather than amniocentesis, is recommended to obtain blood for fetal thyroid function. Norms have been established as a function of gestational age. The test should be carried out only if prenatal intervention is considered. In most cases, fetal thyroid function can be inferred from context and ultrasound criteria, and fetal blood sampling is rarely required. Fetal treatment is recommended by intra-amniotic T_4 injections in a euthyroid pregnant woman with a large fetal goiter associated with hydramnios and/or tracheal occlusion. In a hypothyroid pregnant woman, treating the mother, rather than the fetus, with T_4 is recommended.[38]

Central Hypothyroidism

Congenital central hypothyroidism is uncommon, and isolated TRH/TRH receptor/TSH β subunit deficiency is exceedingly rare. In the United States, the combined incidence of secondary and tertiary hypothyroidism is about 1 in 80,000 to 1 in 100,000 births. Studies in the Netherlands suggest a higher incidence of 1 in 21,000.[56,57] Congenital central hypothyroidism is often associated with mutations in the gene that encode transcription factors involved with pituitary development, including Pit-1, LHX3, LHX4, POU1F1, and HESX1, and can be associated with other hormone deficiencies.

Midline facial, cranial, or intracranial defects should suggest the possibility of hypopituitarism, including altered functioning of the HPT axis. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can be manifested as secondary or (more commonly) tertiary hypothyroidism. Clinical symptoms of hypopituitarism, such as neonatal hypoglycemia (from growth hormone and/or adrenocorticotropic hormone deficiencies), polyuria (from antidiuretic hormone deficiency), or a small phallus or undescended testicles (from gonadotropin deficiency), whether or not accompanied by the presence of blindness, congenital nystagmus, or midline defects of the brain, should alert the physician to suspect septo-optic dysplasia. Prolonged jaundice with unconjugated hyperbilirubinemia in CH and conjugated hyperbilirubinemia in adrenocorticotropic hormone or cortisol deficiency, can also be seen.

The consequences of central hypothyroidism are as neurologically devastating as those of primary hypothyroidism and therefore also require prompt treatment.[56] However, many newborn

screening programs that use elevated TSH values to recognize thyroid dysfunction are inadequate in identifying newborns with central hypothyroidism.

Central hypothyroidism may be acquired during difficult delivery from traumatic brain injury; however, the fT_4 level may not become abnormal until 2 weeks of age.

The biochemical picture comprises normal or low TSH levels with low or low-normal T_4 levels and low fT_4 levels. Other laboratory evidence includes an abnormal TSH surge of less than 50% and a subnormal TSH response to a TRH stimulation test. Attention to other clinical features such as hypoglycemia, microphallus, and midline facial defects can lead to earlier identification of central hypothyroidism. Other causes of this FT_4–TSH combination are nonthyroidal illness, premature birth (with a correlation between severity and GA/birthweight), and certain forms of reduced sensitivity to thyroid hormone.[58]

In neonates with central CH, it is recommended to start LT_4 treatment only after evidence of intact adrenal function.[38]

Down Syndrome

The association of thyroid abnormalities in individuals with Down syndrome has been well known for several decades, with early case reports of hypothyroidism in trisomy 21 dating back to the 1960s.[59,60] Examination of fetal thyroid glands showed small thyroid follicles and that TSH concentration was consistently in the highest percentiles. This may suggest that the cause of thyroid problems in Down syndrome may be thyroidal in nature.[61]

CH is seen commonly in Down syndrome, with prevalence estimates ranging from 28 to 35 times higher than in the general population.[62] Hypoplasia of the thyroid gland appears to be the most typical occurrence, whereas thyroid agenesis, dysgenesis, and ectopic thyroid are rare causes of CH.[63] When the diagnosis of CH is clear with hyperthyrotropinemia and low T_4 level, treatment should be initiated and guidelines followed as for neonates without Down syndrome. What is more difficult to determine is the natural history and benefit of treatment in those with subclinical hypothyroidism. In one study, Claret et al.[64] found that subclinical hypothyroidism resolved in 73.6% of young children with Down syndrome. The remission rate was higher in those without positive thyroid autoantibodies and without an enlarged thyroid gland. Evidence to support treatment of subclinical hypothyroidism includes improved growth[65,66] and better cognitive and developmental outcomes.[67] Also, there is little in the way of adverse effects of LT_4 treatment when thyroid function is being normalized. However, proponents of not treating subclinical hypothyroidism cite studies such as that of Claret et al. in which a large majority of those with subclinical hypothyroidism progress back to normal thyroid function. Hyperthyroidism is exceedingly rare in the newborn period, with onset most common in the adolescent years. Prevalence estimates for hyperthyroidism in the Down syndrome population range from 0% to 3%.[68]

Consumptive Hypothyroidism

In infants with hepatic hemangiomas and in adults with hemangioendothelioma and malignant fibrous tumors, consumptive hypothyroidism may occur.[69–71] During infancy, hemangiomas occur at a high frequency. Rapid growth during first year of life can be observed followed by involution and gradual regression by adolescence. The first year of life is a critical time for development.[69] There is a concern for neurological damage in infants with hemangiomas when associated consumptive hypothyroidism occurs and goes untreated.[69] Other presentations of consumptive hypothyroidism have been reported as cases of cutaneous hemangiomas[72] and gastric gastrointestinal stroma tumors.[73]

Hypothyroidism in hemangiomas involves increased expression of type III iodothyronine monodeiodinase (MDI III), which accelerates the rate of inactivation of thyroid hormone.[69,74] Type III MDI catalyzes the conversion of T_4 to rT_3 and T_3 to T2. Reverse T_3 and diiodothyronine are inactive metabolites. Type III MDI is particularly expressed in the placenta, uterine endometrium, and neurons of the central nervous system.[75] Due to the high rate of thyroid hormone degradation, hypothyroidism can be refractory to thyroid hormone treatment.[69] Thus, infants with consumptive hypothyroidism may require very high doses of levothyroxine and liothyronine to reduce serum thyrotropin concentrations to normal.[69] The presenting thyroid function tests in consumptive hypothyroidism show low T_3 and T_4, elevated TSH, and elevated serum rT_3. With regression of the hemangioma, the thyroid hormone levels normalize.[69] Some cases have been treated with propranolol therapy alone,[76] liothyronine alone,[77] and a combination of propranolol, levothyroxine, and liothyronine.[78]

Transient Primary Hypothyroidism

Transient CH is associated with excess maternal iodine ingestion or deficiency (pregnant women should ingest 250 μg iodine per day), maternal ingestion of antithyroid drugs, maternal TRBAbs, heterozygous mutations of DUOXA2, and large congenital hepatic hemangiomas (increased type 3 DI activity).[35]

Hypothyroidism in the newborn period can be transient in 10% of cases.[39] Studies in the Netherlands reported an incidence of 1 in 12,000.[57] The newborn screen is initially abnormal, with a low T_4 level and a slightly elevated TSH level. However, repeated laboratory evaluation may demonstrate normalization of thyroid function test results, indicating a transient state of thyroid dysfunction. Because normalization may not occur for several months, thyroid hormone therapy should be initiated to protect the infant's brain development if the TSH level remains elevated at 2 weeks of life. Therapy should be continued until age 3 years when the child should be reevaluated. If the child with no permanent CH and a gland in situ requires LT_4 dose less than 3 μg/kg/day at the age of 6 months, then reevaluation can be done at that time. Transient hypothyroidism is more common in preterm infants.

Transplacental passage of maternal TRBAbs (also known as TSH-binding inhibitory immunoglobulins) is estimated to cause transient thyroid dysfunction in 2% of newborns with CH.[79] This transient thyroid dysfunction is often difficult to differentiate from permanent forms of hypothyroidism in the newborn period. These babies should be treated but will not require lifelong treatment.

Although many women with autoimmune disease are receiving thyroid replacement therapy, some may be clinically euthyroid and thus are not on medications. Some of these women have hyperthyroidism or a history of Graves disease. Therefore, diagnosis of thyroid dysfunction may be delayed until the postpartum period.[79]

Maternal autoimmune thyroid disease may be associated with the production of TRBAbs, a type of immunoglobulin G. TRBAbs, like other immunoglobulins G, do not cross the placenta until after 16 weeks of gestation. TRBAbs can cross the placenta and block TSH receptors in the neonatal thyroid. Therefore, the TRBAbs do not affect thyroid embryogenesis, and infants do not develop permanent abnormalities in thyroid function.[80] The severity and duration of the hypothyroid state in these newborns correlate with the initial titer of the blocking antibody and the duration of its presence in the infant's blood.[79] Subsequent

offspring remain at risk because the antibodies can persist for up to 7 years in maternal sera.[79]

The biochemical profile in transient CH shows low T_4 levels with elevated TSH levels that subsequently normalize. A thyroid scan is not helpful because the TRBAbs are sufficiently potent to block TSH-induced uptake, which can be misleading and suggestive of thyroid agenesis. The distinguishing feature is the presence of TRBAbs in newborn and maternal sera. While routine screening for TRBAbs is not currently indicated, this diagnosis should be suspected in any infant with CH born to a woman who has a history of autoimmune disease or if her previous offspring had thyroid disease.[79]

The Wolff–Chaikoff effect, which is an autoregulatory phenomenon whereby a large amount of ingested iodine acutely inhibits thyroid hormone synthesis within the follicular cells irrespective of the serum level of thyroid-stimulating hormone (TSH), matures at the end of the third trimester. Therefore premature neonates cannot protect themselves from iodine overdose. Thus, the use of iodine-containing disinfectants is contraindicated in preterm babies, as it can cause transient neonatal hypo- or hyperthyroidism.[81]

Euthyroid Sick Syndrome

In acutely ill patients, thyroid function changes take place. It is hypothesized that alterations in thyroid hormone occur as an adaptive response to decreased basal metabolic rates in severely ill patients. The syndrome has been observed in sick infants and children.[82] These patients may have acute or chronic nonthyroidal illnesses. There is a decrease in T_3 activation in the periphery. The consistent finding is an abnormally low serum T_3 level, an increase in the rT_3 level, and a reduction in TSH secretion. Normal TSH secretion can also be observed during mild or moderate illnesses. However, the TSH is inappropriately low in the context of low serum T_3 levels.[75] T_4 may be low or normal and FT_4 may be normal, depending on the metabolic clearance rate of T_4.

In preterm infants, T_4, FT_4, and T_3 levels are naturally lower than those in term infants, and rT_3 is high.[83] Therefore, thyroid tests in a preterm infant may be hard to interpret, especially when infants are sick from nonthyroidal diseases. The most common neonates with euthyroid sick syndrome are preterm infants with respiratory distress syndrome.[83,84] In the pediatric population, nonthyroidal illnesses associated with this syndrome include severe gastroenteritis, acute leukemia, anorexia nervosa, renal disease, burns, and surgical stress.

Euthyroid sick syndrome is found in patients with metabolic stress (e.g., diabetic ketoacidosis), in pediatric patients who underwent cardiac surgery, and in pediatric patients with cancer.[85] There is a sharp rise in rT_3 and a less dramatic fall in T_3 by 2 hours after cardiac surgery. Reverse T_3 returns to normal before T_3. The changes in thyroid function tests are a continuum.[75] There is an inverse relationship between the severity of illness and the T_3 level. In euthyroid sick syndrome, abnormal thyroid function gradually reverts to normal function as the patient's primary illness improves.[37] During recovery, TSH may be transiently elevated (up to 15 mU/L). Treatment with thyroid hormone is not indicated in these patients.

Transient Hypothyroxinemia of Prematurity

In preterm infants, postnatal thyroid hormone concentrations may differ from those in term infants. The thyroid hormone concentrations vary based on the degree of prematurity. There are multiple etiologies such as loss of maternal transfer of T_4[86]; immaturity of hypothalamic-pituitary-thyroid axis[87] and peripheral metabolism of iodothyronines,[88] iodine deficiency,[89] nonthyroidal illness;[83] and decreased TBG concentrations secondary to undernutrition or hepatic dysfunction.[90] Thyroid metabolism can be affected by other factors: exogenous sources of iodine, dopamine infusions, blood transfusion, and glucocorticoid treatment.

In preterm infants, hypothalamic-pituitary-thyroid immaturity is characterized by a limited neonatal TSH surge, decline in T_4 in the first week of life, limited TSH response to hypothyroxinemia, and a prolonged TSH response to TRH. Impairment of T_4 to T_3 and increases in D3 activity may also influence thyroid function tests.[31] Only in the third trimester does hypothalamic TRH begin to increase markedly.[31,91]

In transient hypothyroxinemia in premature infants (before 30 to 32 weeks' gestation), thyroid function tests show low T_4 and FT_4 levels with normal or low TSH levels. Thyroid hormone replacement has not been consistently effective in improving neurologic outcomes or reducing morbidity.[92,93] Research efforts continue to investigate this question. At the current time, therapy is only recommended when low T_4 is accompanied by TSH elevation.[83,92] Abnormalities in thyroid levels in preterm infants can be difficult to interpret when the infants are ill from nonthyroidal diseases. Preterm infants at risk should be monitored by serial determinations of FT_4 and TSH. T_4 treatment should be initiated if the illness state is expected to be persistent and TSH remains elevated for a month or longer. A dosage of 4 to 5 μg/kg of oral levothyroxine was suggested in earlier dosage studies.[94,95]

Low Triiodothyronine Syndrome in Premature Infants

Changes in thyroid function tests during neonatal adaptation are qualitatively similar to those in term infants but occur at lower concentrations in premature infants. The neonatal surge and T_4 and T_3 peak responses diminish with decreasing gestational age.[31] Premature infants have increased susceptibility to neonatal morbidity, including birth trauma, acidosis, hypoxia, hypoglycemia, hypocalcemia, and infection, all superimposed on feeding disorders and relative malnutrition. All of these factors tend to inhibit peripheral T_4 to T_3 conversion. This action leads to the characteristically low T_3 state seen in premature infants. Serum T_3 values may remain low in these infants for 1 to 2 months. Other features of the low T_3 syndrome in premature infants are variable but usually include elevated serum rT_3 levels and normal or low total serum T_4 concentrations. Free T_4 levels usually are in the range of healthy premature infants or matched gestation age and weight.[31] TSH values are low in these infants. Treatment with thyroid hormone is not warranted.[92,93]

Iodine Deficiency

Severe iodine deficiency is associated with cretinism. Iodine deficiency is a rare cause of transient hypothyroidism in North America but may occur in dieting women who are not eating bread or using salt. Many countries have initiated salt iodination.

Iodine is a critical component of thyroid hormone synthesis; therefore, even mild to moderate forms of iodine deficiency can result in an adverse outcome for the fetus. Although the mother with iodine deficiency may be clinically euthyroid with normal T_3 levels, maternal T_4 concentration is low in iodine deficiency. An increase in type 2 DI activity is detected in the fetus in response to iodine deficiency. Because normal development of the fetal neocortex is dependent on maternal T_4, which is the primary source of cerebral T_3, low levels of maternal T_4 place the infants at risk of neurologic cretinism. The fetus can experience several neurologic

manifestations, such as deafness, motor deficits (spasticity, trunk rigidity, flexion dystonia, muscle wasting), and mental retardation. Therefore, it is imperative for the pregnant mother to receive an adequate supply of iodine early in pregnancy to avoid brain damage in the fetus.[96,97] Vitamin supplements that contain at least 250 µg iodine should be used daily.[20]

Preterm infants are at increased risk of iodine deficiency. The premature separation from the maternal supply of iodine and thyroid hormone prevents the preterm infant from accumulating adequate amounts of intrathyroidal hormone. Therefore, the infant is unable to keep up with postnatal thyroid hormone demands. The biochemical profile of iodine deficiency in the newborn comprises low T_4 and elevated TSH levels. Iodine deficiency can lead to a transient state of thyroid dysfunction. An infant is sensitive to maternal iodine nutrition during fetal development.

The thyroid is also protected against iodide excess that might otherwise lead to hyperthyroidism. The sources of excess iodide are pharmaceutical: amiodarone, povidone–iodine, and radiographic dyes. The quantity of iodine organified to TG displays a biphasic response to increasing doses of iodide, at first increasing and then decreasing. The decreasing yield is termed the *Wolff-Chaikoff effect*. The inhibition of iodothyronine formation is reduced over time, the escape phenomenon. This does not occur in the third-trimester fetus, so long-term high iodine intake must be avoided because it will cause fetal hypothyroidism.

Disorders of Thyroid Hormone Carrier Protein

Thyroid hormone in the circulation travels bound to transport proteins (TBG, TBPA, and albumin). As discussed previously, these carrier proteins are produced by the liver. The gene for TBG, the primary transport protein, is located on the long arm of the X chromosome; thus, TBG defects are inherited in an X-linked manner. Given that TBG is the major transport protein, TBG deficiency causes significant thyroid changes in total thyroid hormone concentration. But given that free concentrations remain normal, these individuals are euthyroid. Treatment is not required. Primary T_4 newborn screening methods may be misleading, and confirmation with fT_4 levels is necessary before initiation of treatment.

Thyroxine-Binding Globulin Deficiency

The prevalence of thyroxine-binding globulin (TBG) deficiency varies from 1 in 2500 to 1 in 12,000 newborns.[75,98,99] The frequency in males is much higher, 1 in 2400 to 1 in 2800 males, because it is an X-linked trait.[99] The transmission of this trait is usually from affected males to female offspring.[75] TBG deficiency has no clinical importance but leads to abnormal laboratory tests.

Congenital central hypothyroidism can be detected on newborn screen programs that utilize T_4-reflex thyroid-stimulating hormone (TSH) test method. Congenital central hypothyroidism must be distinguished from TBG deficiency. The diagnosis of congenital central hypothyroidism is made with low serum free T_4 and can be supported by the presence of other pituitary hormone deficiencies. Serum TBG levels play an essential role in the diagnosis of TBG deficiency but do not play a role in the diagnosis of congenital central hypothyroidism.[100]

Serum TBG levels are very low in affected males and are approximately half of normal in carrier females. In about half of the families with this trait, the TBG level shown by radioimmunoassay is very low. In the other half, the defect is partial; serum T_4 levels vary similarly. Affected persons are euthyroid, with normal serum TSH responses to exogenous TRH. Treatment is not indicated.[98]

As many as 26 different mutations have been reported in the TBG gene. These mutations have included a single amino acid substitution or deletion, leading to abnormal post-translational processing.[75] Two novel mutations in the TBG gene identified most recently include a T insertion at the beginning of intron 1 between nucleotides 2 and 3 and a T deletion in exon 1 leading to a truncated protein. Both mutations fail to produce a functional TBG molecule.[101] In partial TBG deficiency, the defects are associated with altered TBG binding of T_4.[75]

Females tend to have partial TBG deficiency, whereas males generally have complete TBG deficiency. A partial deficiency comprises reduced TBG levels and normal TSH and FT_4 with T_4 values at the lower limit of normal. A complete deficiency comprises undetectable TBG levels with normal TSH, normal FT_4, and low levels of T_4. Another useful laboratory tool is T3RU, which is elevated with TBG deficiency.[102] However, this is an indirect measure of TBG levels.

Treatment of Hypothyroidism

Treatment with levothyroxine should begin if the FT_4 is low and the TSH is elevated or if the TSH is greater than 20 mU/L, even if FT_4 is normal. Treatment with levothyroxine should also begin if the TSH greater than 6 mU/L beyond 21 days of age. Treatment of hypothyroidism relies on replacement with exogenous thyroid hormone. LT_4 is the drug of choice because of its uniform potency and reliable absorption.[38] Appropriate doses of synthetic T_4 produce normal serum levels of T_3 via peripheral conversion. The best guide to the adequacy of therapy is the periodic measurement of circulating levels of T_4, fT_4, and TSH. Treatment with LT_4 should be started as soon as possible and no later than the first 2 weeks of life. History and physical examination are important in the follow-up evaluation, but mild hypothyroidism or hyperthyroidism cannot always be excluded on clinical grounds.

The usual starting dosage of thyroid hormone for hypothyroid infants is 10 to 15 µg/kg/day, which approximates to 100 µg/m^2/day. Infants with severe disease, as defined by a very low T_4/fT_4 concentration, should be treated with the highest initial dose. Those with mild to moderate hypothyroidism should be treated with a lower dose. If intravenous treatment is necessary, the dose should be no more than 80% of the oral dose. The aim of treatment is to keep the T_4 level in the upper half of the normal range, approximately 10 to 16 µg/dL, or the fT_4 level in the 1.4 to 2.3 ng/dL range with the TSH level on the lower half of the normal range (0.5 to 2.0 mU/L) during the first 3 years of life. Recent studies have reported neurodevelopmental benefits of quick normalization of T_4 and fT_4 levels within three days of initiation of thyroid hormone therapy with high-dose treatment. Thyroid hormone requirements, however, quickly drop after 2 weeks, and therefore close monitoring of growth and development along with thyroid function tests is necessary.[103,104] The treatment of each patient must be individualized. The adequate dosage of thyroid hormone in the first year usually ranges between 25 and 50 µg daily.

Current recommendations favor the administration of levothyroxine in tablet form. The tablet is crushed and given orally in a small amount of liquid. Liquid formulations should be used only if they are pharmaceutically produced and licensed. The U.S. Food and Drug Administration approved a liquid levothyroxine formulation (Tirosint-SOL) in 2017. There is limited published data on the use of liquid levothyroxine for congenital hypothyroidism. Some theoretical advantages of liquid formulations include the ability to deliver more precisely individualized

doses for infants, unaltered absorption when administered with milk, and better patient satisfaction over tablets. However, two European studies found overtreatment based on TSH suppression in infants with congenital hypothyroidism treated with liquid levothyroxine compared to tablet form, despite equivalent weight-based dosing.[105] LT_4 suspensions prepared by individual pharmacists may lead to an unreliable dosage.[39] Care should be taken to avoid concomitant administration of soy, fiber, calcium, or iron. The thyroid hormone–pituitary feedback setpoint is altered in rare infants with CH, and in such infants, serum TSH concentration remains elevated in the face of a normal or even elevated serum T_4 level.[106]

Infants with presumably transient hypothyroidism resulting from maternal goitrogenic drugs need not be treated unless the low serum T_4 and elevated TSH levels persist beyond 2 weeks of age. Infants with TRBAb-induced hypothyroidism may require treatment for as long as 6 months.

When infants with severe myxedema associated with fluid retention are being treated, potential complications should be kept in mind. Cardiac insufficiency caused by overtaxing of the myxedematous heart, through too rapid a mobilization of the myxedema fluid into the circulation, is well known in the adult. This complication in older children and adults is prevented by administering a small dose of thyroid hormone at first, followed by a gradual increase of the dose. However, infants generally tolerate a rapid restoration to the euthyroid state better than adults, and a prompt restoration of T_4 concentration to a normal value is important for the recovery of brain development and maturation. Nevertheless, excessive thyroid hormone therapy must be avoided, and the dose must be adjusted judiciously if there is evidence of severe myxedema, particularly of the heart.

After initiation of therapy with LT_4, the growth rate should accelerate. Any growth deficit is commonly restored within a few months. Bone age is a sensitive index of thyroid deficiency; however, radiographs are not routinely obtained in the newborn period. Overtreatment can induce tachycardia, excessive nervousness, disturbed sleep patterns, and other problems suggesting thyrotoxicosis. Excessive thyroid hormone administered over a long period can produce premature synostosis of cranial sutures and advancement of bone age.

During the first few years of life, patients should be monitored frequently: the first follow-up examination should occur 2 weeks after the start of LT_4 treatment. Subsequent evaluations should occur at least every 1 to 2 months during the first 6 months of life, every 3 months between 6 months and 3 years, and then twice a year until growth is completed (Box 86.1).[35] Evaluations should occur at more frequent intervals when adherence is questioned, abnormal values are obtained, or the dose of medication has been changed. Clinical observation should be supplemented with monitoring of the growth curve and T_4, fT_4, and TSH levels. Because poor adherence and nonadherence have major sequelae, the initial and ongoing counseling of parents is of great importance.

Patients with permanent CH (e.g., dysgenesis, dyshormonogenesis) require lifetime substitution therapy. After age 3 years, if there is uncertainty about whether the disease is permanent or transient or if the dose of LT_4 has not required an increase, discontinuation of LT_4 therapy for 4 to 6 weeks with close monitoring of the TSH level should distinguish transient from permanent CH. Recent reports indicate that treatment of CH is discontinued within 3 years in more than one-third of children with CH. This is inconsistent with current guidelines; however, it remains unknown how many of the children in whom treatment was discontinued prematurely experience adverse effects or require continued treatment.

• BOX 86.1 Management of Congenital Hypothyroidism

Initial Work-Up

Detailed history and physical examination
- Referral to pediatric endocrinologist
- Recheck serum TSH and FT_4 levels
- Thyroid ultrasonography and/or thyroid scan (see text for recommendations)

Medications

LT_4: 10–15 μg/kg by mouth once daily

Monitoring

Recheck serum FT_4 (or total T_4) and TSH
- Two to 4 weeks after initial treatment has begun
- Every 1–2 months in the first 6 months
- Every 3 months between 6 months and 3 years of age
- Every 6–12 months from 3 years of age to end of growth
- Four weeks after a change in LT_4 dosage

Goal of Therapy

Normalize TSH and maintain T_4 and FT_4 in the upper half of the reference range

FT_4, Free thyroxine; *LT_4*, levothyroxine; *T_4*, thyroxine; *TSH*, thyroid-stimulating hormone.

Neonatal Hyperthyroidism

Epidemiology and Pathophysiology

The overall incidence of neonatal hyperthyroidism is low. It occurs more commonly in pregnancies complicated by Graves disease. Of the offspring born to women with Graves disease, 1% are affected with hyperthyroidism.[107] The thyroid dysfunction in the fetus and newborn is associated with the transplacental passage of TSH receptor-stimulating antibodies/thyroid-stimulating immunoglobulins (TSA/TSI). The mother may have active or inactive Graves disease. The hyperthyroidism is not related to the transfer of maternal thyroid hormone. The antibodies stimulate the fetal and neonatal thyroid gland. It is generally a transient state that clinically resolves by 4 months of age with the clearance of maternal antibodies from the infant's circulation.[108] Rarely, neonatal hyperthyroidism is caused by mutations in the TSH receptor or its mediators. These causes include activating mutations of the stimulatory G protein, as in McCune-Albright syndrome, or an activating mutation of the TSH receptor.[109,110]

In pregnancies complicated by maternal Graves disease, the fetal levels of TSA approximate those of the mother at 30 weeks' gestation. Therefore, fetal thyrotoxicosis generally manifests in the third trimester with fetal tachycardia, fetal goiter, and intrauterine growth retardation. Fetuses of mothers with TSA levels greater than 250% of the upper limit are at increased risk for thyrotoxicosis. Therefore, these fetuses need to be monitored more closely.[111,112]

Clinical Presentation

The clinical manifestations of Graves disease in the newborn include irritability, flushing, diarrhea, vomiting, tachycardia,

hypertension, poor weight gain, thyroid enlargement, and exophthalmos. Thrombocytopenia, hepatosplenomegaly, jaundice, and hyperviscosity syndrome also have been reported. If thyrotoxicity is severe and treatment is inadequate, arrhythmias, congestive heart failure, and death may occur. In some infants, the onset of symptoms and signs may be delayed as long as 8 to 14 days. Late onset of neonatal disease can occur for at least two reasons: (1) postnatal depletion of transplacentally acquired blocking doses of maternal antithyroid drugs and the abrupt increase in conversion of T4 to active T3 shortly after birth in the newborn, and (2) presence of maternal TRBAb, which can block the effect of TSA for several weeks.[111]

Evaluation

The diagnosis of neonatal hyperthyroidism is confirmed by high levels of T4, free T4, and T3 in postnatal blood. Cord blood values may be normal or near normal, whereas levels at 2 to 5 days may be markedly increased; the serum TSH is suppressed below normal levels. Neonatal Graves disease resolves spontaneously as maternal TSA in the newborn is degraded. The usual clinical course of neonatal Graves disease is 3 to 12 weeks.

Management

Fetal thyrotoxicosis is treated by administering antithyroid agents to the mother. Propylthiouracil (PTU) is recommended during pregnancy because it is associated with a lower rate of fetal malformations than methimazole. PTU crosses the placenta to inhibit the fetal production of excess thyroid hormone.[113] Since the concentration of drugs in breast milk is very low, hyperthyroid mothers on antithyroid drugs may breastfeed their infants. Medical treatment of hyperthyroidism in the newborn period depends on the severity of the illness. These medications include iodide or antithyroid agents. Antithyroid agents inhibit thyroid hormone synthesis. Iodide rapidly inhibits hormone release.

Lugol's solution (5% iodine and 10% potassium iodide, containing 126 mg/mL of iodine) is given in a dose of 1 drop (8 mg of iodine) three times daily. Antithyroid agents such as methimazole are administered in doses of 0.25 to 1 mg/kg/day, divided, at 8-hour intervals. PTU is no longer recommended for use in children because of increasing rates of PTU-induced liver failure.[114] Propranolol can be given in a dose of 2 mg/kg/day to decrease β-adrenergic symptoms and inhibit deiodination of T4 to T3. A therapeutic response should be observed within 24 to 36 hours. If a satisfactory response is not observed, the dose of antithyroid drug and iodide can be increased by 50%.

More severe cases may require corticosteroids. Steroids suppress the deiodination of T4 to T3. Digoxin treatment can be used in the case that cardiac failure is present. If hyperthyroidism persists (as in cases with a strong family history of Graves disease, an activating mutation of the stimulatory G protein, or an activating mutation of the TSH receptor), ablative therapy such as thyroidectomy must be performed.[109]

The treatment goal is to achieve a euthyroid state while avoiding hypothyroidism in the infant. Frequent monitoring to adjust methimazole doses is indicated. Another method to treat hyperthyroidism using antithyroid medication is to completely block the synthesis of thyroid hormone while replacing thyroid hormone.

Specific Causes of Hyperthyroidism

Familial Dysalbuminemic Hyperthyroxinemia

Familial dysalbuminemic hyperthyroxinemia (FDH) is characterized by almost a 60-fold increase in the affinity of albumin for T_4 but not for T_3. Mutations in ALB (albumin) gene are inherited in an autosomal dominant manner.[75] The biochemical profile demonstrates increased serum T_4 concentrations but normal FT_4, total serum T_3, and TSH levels. Although the binding of T_4 to albumin is increased, T_3 is less avidly bound, accounting for the preferential increase in serum T_4 concentration. Patients with this disorder are euthyroid with normal thyroid hormone production rates.[115]

The diagnosis of FDH is confirmed by protein electrophoresis of serum containing labeled T_4. The fraction of t4 label associated with TBG, thyroid hormone binding by human serum prealbumin (TBPA), or albumin is measured. The albumin-bound T_4 can be calculated and related to normal values. Measurement of TBG and TBPA concentrations is useful. Euthyroid individuals with FDH have often falsely elevated serum free thyroxine (fT_4) concentrations determined by different automated immunoassays. Refetoff et al. measured serum fT_4 in families with FDH through three methods: (1) direct dialysis coupled with tandem mass spectrometry, (2) direct immunometric assay, and (3) free thyroxine index. The free thyroxine index method greatly reduced the discordance of fT_4 results relative to thyrotropin in FDH.[116] Antithyroid therapy is not necessary for FDH.[117]

Thyroxine-Binding Globulin Excess

The prevalence of TBG excess is estimated to be in 1 in 15,000 to 1 in 25,000 individuals. TBG excess is inherited as an X-linked trait.[98] Persons with increased levels of TBG have increased total serum T_4 concentrations with normal TSH and FT_4 levels. Serum T_3 is modestly increased. These individuals are euthyroid. In these persons, TBG production rates and serum levels are correlated, suggesting that the mechanism for high TBG is increased production, presumably by the liver. TBG levels are increased four- to fivefold in affected persons. Carrier females have intermediate serum TBG values.[75]

Neonatal Hypoglycemia and Hyperglycemia

DAVID WERNY, ALYSSA HUANG, JESSICA TENNEY, AND CATHERINE PIHOKER

KEY POINTS

- Neonatal hypoglycemia requires diagnostic consideration and urgent management to prevent recurrent hypoglycemia and avoid neurologic injury.
- Neonatal metabolism in the first days of life reflects a transition from the passive glucose consumption of the fetus to the active regulation of glucose of the neonate.
- Diagnosing the cause of hypoglycemia requires an evaluation of the hormonal and metabolic response to hypoglycemia.
- Patients with hyperinsulinemic hypoglycemia should be assessed for diazoxide-responsiveness, and non-responsive patients should have an evaluation to determine if the process is due to focal or diffuse disease.
- Diabetes diagnosed before 6 months of age is very likely to have a genetic cause.
- Patients with neonatal diabetes due to pathogenic variants in the K_{ATP} channel can be treated with oral sulfonylurea in place of insulin therapy.

Introduction

Glucose is the primary metabolic fuel for the neonatal brain. Maintenance of normal glucose levels in the serum and across the blood-brain barrier is essential for normal neurologic function and development. Hypoglycemia in the neonate, therefore, requires thoughtful diagnostic evaluation and urgent treatment to prevent injury to the central nervous system (CNS). The mechanisms underlying neonatal hypoglycemia are best understood as inadequate hormonal and metabolic responses to hypoglycemia, occurring in the context of the necessary shift from fetal to neonatal glucose metabolism in the first days of life. These pathways and pathologies are the focus of the initial portion of this chapter.

In the latter portion of this chapter, we focus on hyperglycemia in neonates. Hyperglycemia most commonly occurs in the context of a physiologic stressor such as sepsis with cortisol and catecholamine release. Intravenous glucose infusion and exogenous glucocorticoid administration can also cause hyperglycemia. Rarely genetic causes of hyperglycemia result in transient neonatal diabetes mellitus (TNDM) or permanent neonatal diabetes mellitus (PNDM).

Neonatal Hypoglycemia

Fetal to Neonatal Transition and Energy Metabolism

Fetal glucose supply is dependent on maternal plasma levels and its diffusion across the placenta. There is no evidence for the existence of fetal gluconeogenesis or a robust ability to adjust rapidly to maternal hypoglycemia.[1–3] Once the placental link is interrupted, and glucose is no longer delivered continuously via the umbilical vein, the neonate must maintain normoglycemia and adequate cerebral glucose delivery despite minimal and sporadic enteral carbohydrate intake during the first 24 to 72 hours of life. Glucose homeostasis is accomplished in a manner generally similar to older children who are fasted: via secretion of the counter-regulatory hormones—namely cortisol, glucagon, growth hormone, and catecholamines—and their actions at target tissues, in combination with the suppression of insulin secretion. In concert, these hormonal changes regulate four different metabolic systems: glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (Fig. 87.1). The result is to facilitate normoglycemia until carbohydrate intake and absorption occur on a more regular basis.

In response to decreased delivery of glucose in the first few hours of life, glucagon and catecholamine levels rapidly increase, and insulin falls. This combination shifts metabolic activity from anabolism to catabolism and induces enzymes necessary for glycogenolysis (glycogen phosphorylase) and gluconeogenesis (pyruvate carboxylase and phosphoenolpyruvate carboxykinase [PEPCK]).[3–5] Glycogenolysis plays the largest role in meeting glucose needs during the first 24 hours (approximately 50%) and causes a depletion of glycogen stores from 50 mg/g of the liver at birth to <10 mg/g of the liver by 24 hours of life.[2] Gluconeogenesis develops somewhat more slowly and is not fully active until 8 to 12 hours of life, providing only 20% to 30% of glucose needs in the first 24 hours.[4,6]

Gluconeogenesis and lipolysis contribute to plasma glucose levels after 8 to 12 hours of life, with their role increasing as glycogen stores are depleted. Lipolysis produces glycerol, which can enter the gluconeogenic pathways, and free fatty acids can be oxidized directly by some organs, including the heart, kidney, and

skeletal muscle, but long-chain fatty acids cannot cross the blood-brain barrier.[7] Importantly, partial oxidation of fatty acids in the liver via ketogenesis produces ketones such as beta-hydroxybutyrate (BOHB) and acetoacetate, which the brain can metabolize. However, ketogenesis is impaired in the first 8 to 12 hours of life, coincident with the known transitional hypoglycemia of infancy discussed later.[8,9] The importance of gluconeogenesis, lipolysis, and fatty acid metabolism is highlighted in breastfed infants as the macronutrient profile of colostrum favors protein and fatty acids, compared to the relative carbohydrate predominance of mature human milk.[10]

Glucagon continues to rise gradually over the first few days of life, concurrent with the known, gradual increase and stabilization of glucose levels that normally occurs in infants by 48 to 72 hours of life.[11,12]

The brain is the most metabolically active organ in the neonate, and its demand for glucose is proportional to brain weight.[13,14] Glucose uptake and oxidation in the brain occurs via insulin-independent facilitated diffusion through glucose transporter (GLUT) channels and is dependent on arterial blood glucose concentration. An in vivo study using rats (which are believed to have GLUT channels with similar kinetics to humans) showed that the consumption of glucose in the brain outpaces its replacement via diffusion at an arterial concentration of 36 mg/dL.[15] At this point, cerebral blood flow increases markedly to prevent severe CNS glucose depletion and neurologic sequelae. The relatively large size of the neonatal brain and its high metabolic demand are associated with a two- to threefold higher (per weight) hepatic glucose production compared to adults. Conditions that interfere with hepatic glucose production, therefore, place the infant at risk for

hypoglycemia, some of which are discussed briefly in this chapter, and others are discussed in Chapter 29.

In total, the combined counter-regulatory response and insulin suppression are similar to the starvation response that occurs in older children with two exceptions: (1) the additional complication that maternal factors and immaturity of the counter-regulatory response can interfere with glucose homeostasis in the neonatal period; and (2) the decrease in insulin production and release of glycogen stores is less robust than in older children. These latter factors may explain the "transitional hypoglycemia" seen in normal infants during the first 24 hours of life.

Transitional Neonatal Hypoglycemia

Plasma glucose values in the first hours of life are frequently lower than accepted thresholds for normoglycemia in older children, a phenomenon known as "transitional neonatal hypoglycemia." Serial measurements of glucose in the first days of life in healthy, term appropriate for gestational age (AGA) infants demonstrate average values in the 50s to low 60s (mg/dL).[12,16] If normal is defined as within two standard deviations from the mean, the lower limit of normal may be as low as the high 30s to low 40s in the first few hours of life.[16,17] In support of this, Lubchenco and Bard showed that if feeding is delayed 3 to 6 hours from birth, approximately 10% of healthy, term AGA infants will have glucose <30 mg/dL.[12]

A recent review of the data available on transitional hypoglycemia shows that it is characterized by relative hyperinsulinism as indicated by hypoketosis and preserved glycogen release in response to glucagon.[8,9] An additional factor may be the time required for the enzymatic machinery of gluconeogenesis and glycogenolysis to become active in response to the rise in glucagon and catecholamine secretion after birth.

It is unknown whether the decline in glucose values or the relative hyperinsulinism seen with transitional hypoglycemia serves an adaptive function. The important diagnostic distinction is that this phase of hypoglycemia is transient. Just 2 of the 374 infants (0.5%) in the Lubchenco and Bard cohort had glucose <50 mg/dL prior to feeding on day 3 or 4 of life.

Signs and Symptoms of Hypoglycemia

Neonates with hypoglycemia may have no detectable symptoms and may only be identified incidentally upon measurement of blood glucose levels or in the monitoring of a high-risk infant. When symptoms occur, they may be seen in a progression due to initial counterregulatory hormone responses (such as adrenergic hormones as well as cortisol and growth hormone), which result in symptoms due primarily to the autonomic system (autonomic, or "neurogenic" symptoms and signs). When deficient glucose supply to the brain occurs, neurological dysfunction is detectable and may be considered the symptoms of "neuroglycopenia" (Box 87.1). However, these may be subtle and difficult to recognize clinically and may also be accompanied by other nonspecific symptoms such as apnea, cyanosis, temperature instability (especially hypothermia), and bradycardia.

It is difficult to define a consistent threshold in the neonate below which hypoglycemia produces the above symptoms, especially neuroglycopenia. One often-quoted study of 17 children showed changes in auditory evoked potentials below a whole blood glucose concentration of 47 mg/dL (2.6 mmol/L) but only included four neonates with hypoglycemia (aged 1 to 3 days).[18] In those four neonates, three had no clinical signs at the time of the abnormal recorded evoked potentials, and one was reported to be drowsy. The challenge of defining a true threshold is underscored in these four infants, given that one of these was asymptomatic with normally evoked potentials at a whole blood glucose level of 1.9 mmol/L (34 mg/dL) on day 1 of life, while another infant was symptomatic at 2.5 mmol/L (45 mg/dL).

Blood Glucose Monitoring

While symptomatic, prolonged hypoglycemia in neonates is a risk factor for cerebral injury and poorer neurodevelopmental outcomes, the lower limit of normoglycemia in asymptomatic infants has been difficult to elucidate.[19,20] This is complicated by the pattern of transitional hypoglycemia mentioned above, during which plasma glucose values may drop to levels considered very low for older children. Maternal and neonatal conditions with a high risk for hypoglycemia are well-known, and it is a commonplace for newborn nurseries to have screening protocols for these infants (Box 87.2). Such protocols commonly result in the treatment of asymptomatic infants based on point-of-care (POC) glucose values, with the limited evidence available to define the optimal threshold that minimizes overtreatment while still preventing neuroglycopenia and neurologic damage.

Multiple definitions of the ideal asymptomatic treatment threshold with regard to long-term neurologic outcomes have been proposed: 47 mg/dL,[21] 45 mg/dL,[22] 40 mg/dL,[23] and 30 mg/dL.[24] It is unlikely that a single threshold exists, as the point at

• BOX 87.1 Signs of Neonatal Hypoglycemia

Autonomic	Neuroglycopenic
Sweating	Hypotonia
Pallor	Lethargy
Tachycardia	Coma
Tachypnea	Seizure
Tremor	Weak suck
"Jittery"	Abnormal cry (weak, high pitched)

• BOX 87.2 Maternal and Neonatal Conditions That Increase the Risk of Neonatal Hypoglycemia

Maternal Conditions

Diabetes (gestational or pre-gestational)
Administration of drugs (β sympathomimetics [e.g., terbutaline, oral hypoglycemic agents])
Intrapartum dextrose infusion
Hypertension/preeclampsia

Neonatal Conditions

Prematurity
Intrauterine growth restriction
Hypoxia-ischemia
Large/small for gestational age
Sepsis
Hypothermia
Polycythemia
Presence of syndromic features (microphallus, midline defects, Beckwith-Wiedemann syndrome)

which neurologic injury occurs is likely patient and situation-dependent and related to the availability of ketones and other substrates to the brain.

Recently, a prospective investigation into an appropriate glucose treatment threshold for infants was performed with a cohort of 404 infants of gestational age at least 35 weeks who were at risk for hypoglycemia (infant of mother with diabetes, birth <37 weeks gestational age, and birth weight <10th or >90th percentile).[25] Infants also wore blinded continuous glucose monitoring (CGM) systems to allow the investigators to evaluate for outcomes related to subclinical hypoglycemia missed on the intermittent POC checks. Infants were treated to maintain a blood glucose concentration of at least 47 mg/dL for at least the first 48 hours of life. Neurodevelopmental outcomes were then assessed at 2 years of age using the Bayley Scales of Infant Development III and tests of executive and visual function. The authors found no association between hypoglycemic episodes and neurosensory impairment and concluded that neonatal hypoglycemia was not associated with the adverse neurologic outcomes when treatment was aimed at maintaining a blood concentration of 47 mg/dL in these high-risk infants. A follow-up study with the same cohort of patients aimed to assess higher cognitive function at age 4.5 years. While once again, no neurosensory impairment was seen on follow-up testing, an increased risk of poor executive and visual motor performance was seen. Additionally, the risk was highest in those with severe or recurrent hypoglycemia.[26]

Recent Pediatric Endocrine Society (PES) guidelines make glucose threshold recommendations for infants that are at risk for hypoglycemia and without a known risk for permanent hypoglycemic disorders such as hyperinsulinism, hypopituitarism, or an inborn error of metabolism. According to the PES, such infants should have a treatment threshold of 50 mg/dL in the first 48 hours. Based on evidence that suggests average glucose values in normal infants older than 48 hours of age are no different than those of older children, the authors suggest that these infants should demonstrate an ability to maintain glucose >60 mg/dL during a 6 to 8 hours fast prior to discharge.[27] The PES guidelines are designed to have high sensitivity to detect infants with a pathologic cause of persistent hypoglycemia and to detect these infants before they are discharged from the hospital. The American Academy of Pediatrics (AAP) issued guidelines in 2011 with a focus on the first 24 hours of life, acknowledging that transitional glucose levels in the first few hours of life can be as low as 30 mg/dL.[28] The AAP guidelines recommend a target prefeed glucose of 40 mg/dL in the first 4 hours of life and 45 mg/dL from 4 to 24 hours of life. The differences between the two guidelines reflect the uncertainty regarding the significance of asymptomatic glucose levels <50 mg/dL in the first 48 hours of life, as well as the different weighting of the risks and benefits of continued screening and longer hospital stays in the context of the clinical reality that most term infants in the United States are discharged home between 24 and 48 hours of life.

For diagnostic workup of hypoglycemia after 48 hours of age, we recommend a glucose threshold of 50 mg/dL for collection of a "critical sample" to assess for the counterregulatory hormone response, insulin level, acidosis, and the presence of important metabolic substrates such as BOHB, lactate, serum amino acids, and free fatty acids (Box 87.3). Most importantly, a plasma glucose level should be obtained simultaneously to allow for accurate interpretation of the critical sample, as the POC test result may be artificially low. It's important that the plasma glucose sample reach the lab quickly because glucose in the plasma sample is lost through glycolysis at a rate of 5% to 7%/h.[29] Higher rates of loss can occur with increased ambient temperature and in blood samples with high white blood cell counts.

• BOX 87.3 Components of Critical Sample and Diagnostic Criteria for Hyperinsulinism Based on Critical Sample at Time of Hypoglycemia

Critical Sample

- Serum glucose
- Basic metabolic panel and venous blood gas
- Insulin
- C-peptide
- Growth hormone
- Cortisol
- Free fatty acid
- Beta-hydroxybutyrate
- Lactate
- IGFBP-1
- Ammonia*
- Acyl carnitine profile*
- Serum amino acids*
- Pyruvate*
- Urine organic acid*

*Not necessary to collect at time of hypoglycemia.

Diagnostic Criteria for Hyperinsulinism

- Insulin >2 uIU/mL)
- β-hydroxybutyrate of <1.8 mmol/L
- FFA <1.7 mmol/L
- Glucagon stimulation test rise of ≥30 mg/dL
- IGF-BP1 ≤110 ng/mL

Normoinsulinemic Hypoglycemia

Insulin's role in maintaining normoglycemia is paramount. Insulin simultaneously lowers serum glucose concentration via glucose uptake through insulin-sensitive glucose transporters and represses the effects of counterregulatory hormones, whose primary function during hypoglycemia is to increase serum glucose values. It is therefore relevant to divide a discussion of the causes of hypoglycemia into those that are associated with appropriate suppression of insulin during hypoglycemia (normoinsulinemic hypoglycemia) and those that have inappropriate, elevated insulin levels at the time of hypoglycemia (hyperinsulinemic hypoglycemia) (Box 87.4).

Hypoglycemia in Premature and Small for Gestational Age Infants

Infants born premature or small for gestational age (SGA) are at high risk for transient hypoglycemia due to immaturity of the metabolic pathways described above, exacerbated by inadequate stores of glycogen and triglycerides. The doubling of average fetal weight from 1700 g at 32 weeks to 3400 g at birth is largely due to the accrual of hepatic glycogen and adipose tissue fat stores, which then serve as an important reserve of substrates for energy metabolism in the first days of life. Hypoglycemia can also be caused by delayed maturation of enzymes necessary for gluconeogenesis. Premature infants can have markedly reduced glucose-6-phosphatase activity relative to term infants that may persist for months after birth.[30] There is also a lack of glucose rise after administration of gluconeogenic precursors, which suggests the impaired activity

• BOX 87.4 Causes of Neonatal Hypoglycemia

Hyperinsulinemic

Transient:
- Infants of diabetic mothers
- Intrapartum dextrose infusion to mother
- Stress in peripartum/postnatal period: trauma, asphyxia, hypothermia
- Small for gestational age infants

Permanent:
- K_{ATP} channel defects
- Glutamate dehydrogenase (GLUD1)-activating mutation
- Short-chain 3-hydroxyacyl-coenzyme A dehydrogenase (HADH or SCHAD) mutation
- Glucokinase (GCK) activating mutation
- HNF1A and HNF4A pathogenic variants
- Uncoupling protein-2 (UCP2) pathogenic variants
- Hexokinase-1 (HK1) pathogenic variants
- Beckwith-Wiedemann syndrome (BWS)
- Postfundoplication (dumping syndrome)
- Hyperinsulinism in congenital disorders of glycosylation
- β-cell adenoma—MEN1

Normoinsulinemic

Transient:
- Developmental immaturity in adaptation to fasting: prematurity, SGA
- Increased metabolic expenditure: sepsis, erythroblastosis fetalis, polycythemia
- Maternal conditions: toxemia, administration of tocolytics (β sympathomimetics)

Permanent:
- Hypopituitarism
- Primary adrenal insufficiency
- Inborn errors of metabolism
  - Glycogen storage disease
  - Disorders of gluconeogenesis
  - Defects in fatty acid catabolism and ketogenesis
  - Organic acidurias
  - Galactosemia
  - Hereditary fructose intolerance

of the enzymes of gluconeogenesis.[31] For these reasons, SGA and premature infants should be screened for asymptomatic hypoglycemia and supported with IV dextrose or nasogastric feeding until their hypoglycemia resolves. It is important to note that hypoglycemia in these infants may be multifactorial, as hyperinsulinism may be a contributing factor as well (discussed later).

Counterregulatory Hormone Deficiency

Hypopituitarism

Deficiencies of cortisol, growth hormone (GH), or their combined deficiency in the neonatal period can cause hypoglycemia. Often these two deficiencies occur together in the context of hypopituitarism with adrenocorticotropic hormone (ACTH) hormone and GH deficiency. Infants with congenital hypopituitarism often have other signs of midline malformations such as a midline cleft palate, nystagmus (observed in optic-nerve hypoplasia; of note, however, is that nystagmus is usually not apparent until age 6 weeks, so it is not a distinguishing sign in the neonatal period), seizures (holoprosencephaly), direct hyperbilirubinemia (thyroid hormone deficiency), or micropenis and undescended testes in a male (gonadotropin deficiency). Brain MRI may reveal the underlying cause of hypopituitarism, which may range from severe midline malformations such as alobar holoprosencephaly to more subtle abnormalities such as an isolated ectopic posterior pituitary bright spot or a hypoplastic pituitary gland.

Biochemical evaluation of hypopituitarism requires careful consideration in the first months to a year of life. Conventional stimulation tests used to diagnose GH deficiency in older children have been used in infants, but normal responses are not well established. The stimulation test believed to be safest for use in infants is the glucagon stimulation test, which causes a rapid rise, then rapid fall in glucose, placing the infant at risk for hypoglycemia. Therefore, this testing should only be done under close monitoring, preferably in an ICU setting.[32] As an alternative, taking into account normal physiological processes in the perinatal period, there is evidence that a single random GH measurement in the first week of life can adequately diagnose GH deficiency.[33] Using a post-hoc defined threshold of 7 mcg/L, Binder et al. demonstrated a sensitivity and specificity of 100% and 98%, respectively, for the diagnosis of GH deficiency in the first week of life using a single random GH measurement.[33]

Similarly, optimal testing to diagnose adrenal insufficiency in the neonatal period is a matter of debate. Glucagon stimulation testing can be used to simultaneously assess for GH and ACTH deficiency but carries the risk of hypoglycemia mentioned above. The conventional ACTH stimulation test using Cortrosyn has been used in infants. However, the appropriate dose of 125 mcg, 1 mcg, or 15 mcg/kg has not been well established, and endocrinologist preference varies. Importantly, infants with ACTH deficiency will not develop classical salt-wasting with hyponatremia and hypokalemia due to intact aldosterone production and secretion, which is regulated not by the pituitary but by the renin-angiotensin system. Hyponatremia may occur but is less severe relative to primary adrenal insufficiency and is likely due to reduced free water clearance, for which both cortisol and thyroid hormone play a role.

An important consideration in patients with hypopituitarism is that thyroid hormone should not be replaced until adrenal insufficiency has been either treated or ruled out, as thyroid hormone replacement can precipitate an adrenal crisis if done in the context of untreated adrenal insufficiency.

Isolated Adrenocorticotropic Hormone Deficiency

Isolated ACTH deficiency is very rare and is associated with pathogenic variants in the genes responsible for the production and/or modification of the proopiomelanocortin (POMC) precursor polypeptide. The *TBX19* gene regulates transcription of the *POMC/ACTH* gene in corticotrophs, and deficiency has been associated with adrenal insufficiency in infants.[32] A low estriol level on the prenatal triple-marker screen may be a predictor of TBX19 pathogenic variant and ACTH deficiency in general.[33] Allelic pathogenic variants of the *POMC* gene itself affect all POMC peptides, including α-melanocyte-stimulating hormone (α-MSH), resulting in red hair and fair skin, in addition to ACTH deficiency, with severe obesity developing within the first few months of life.[34] Pathogenic variants in prohormone convertase 1/3 (PCSK1) result in impaired cleavage of ACTH from POMC, as well as several gut hormones. Deficiency results in severe congenital diarrhea and failure to thrive, and a high risk of ACTH deficiency as well as panhypopituitarism, including central diabetes insipidus.[35]

Primary Adrenal Insufficiency

Congenital Adrenal Hyperplasia

Cortisol deficiency in infants is most commonly due to pathology of the adrenal gland (primary adrenal insufficiency) caused by congenital adrenal hyperplasia (CAH). The most common form of CAH, 21-hydroxylase deficiency (incidence 1/10,000 to 1/15,000 annually), results in ambiguous, virilized genitalia in an XX infant driven by overproduction of adrenal androgens synthesized from precursors upstream of the enzyme block. However, in an XY infant, the presentation of CAH due to 21-hydroxylase is more subtle and may present only with hyperpigmentation of the skin, particularly of the scrotum. The classic presentation of hyponatremia, hyperkalemia and severe dehydration due to the cortisol and aldosterone deficiency of primary adrenal insufficiency often do not develop until 7 to 10 days of life, so their absence in a newborn with hypoglycemia does not rule out CAH. Newborn screening for the 21-hydroxylase deficiency form of CAH is now widespread in the U.S., and thus a diagnosis is often suspected early due to elevated 17-hydroxyprogesterone (17-OHP) levels on newborn bloodspot samples. Where hypoglycemia occurs in an infant, especially with any of the features mentioned above of salt wasting or ambiguous genitalia, confirmation of a normal 17OHP should be sought. Treatment is with hydrocortisone and fludrocortisone for glucocorticoid and mineralocorticoid replacement, respectively, along with sodium chloride supplementation due to the low salt content of breastmilk and most formulas.

More rare forms of CAH include 11-beta hydroxylase deficiency (1/100,000 or 1/5000 in Jews of Moroccan ancestry),[34] and the very rare 3-beta hydroxysteroid dehydrogenase (HSD) deficiency. Similar to 21-hydroxylase pathogenic variants, 46 XX infants with 11-beta hydroxylase deficiency resulting in hypoglycemia will have ambiguous genitalia. They may also have hypertension due to excessive production of deoxycorticosterone, a potent mineralocorticoid located upstream of the 11-beta hydroxylase enzyme block. 3-beta HSD deficiency results in undervirilized male genitalia due to deficient testosterone synthesis but may be associated with virilized female genitalia due to elevated DHEA levels. Lipoid CAH is associated with pathogenic variants in the *STAR* gene, which result in loss of function in the steroidogenic acute regulatory protein (StAR), which impairs the transfer of cholesterol into the mitochondria.[35] This disrupts the necessary first step of steroid synthesis, the conversion of cholesterol to pregnenolone. These patients have cortisol deficiency, almost always have aldosterone deficiency, and XY infants can have phenotypically female external genitalia due to impaired androgen synthesis.[36,37]

X-linked Adrenal Hypoplasia Congenita

DAX-1 (dosage-sensitive sex reversal adrenal hypoplasia congenital region of the X-chromosome; also known as NROB1) is a transcription factor located on the short arm of the X-chromosome (Xp21). It is expressed in adrenal, hypothalamic, pituitary, and hypothalamic tissues, but its gene targets are largely unknown.[38] Pathogenic variants in DAX-1 result in underdevelopment or agenesis of the adrenal gland with the potential to cause severe adrenal insufficiency in infancy, otherwise known as adrenal hypoplasia congenita (AHC). Males are classically present in the first weeks of life with vomiting, severe dehydration leading to vascular collapse, and often with hyperpigmentation. Some patients are more mildly affected and present later in childhood with milder adrenal insufficiency. Patients later develop hypogonadotropic hypogonadism, manifesting as delayed pubertal development without elevation of gonadotropins. However, DAX-1 appears to have a direct role in gonadal development, as there is also a component of primary hypogonadism.[39,40] Further implicating its role in gonadal development is the finding that *DAX1* is the likely critical gene for a duplication within Xp21 that causes sex-reversal with female external genitalia and variable presence of Mullerian structures in 46 XY individuals.[41–43] AHC is also seen as a part of Xp21 contiguous gene deletion syndrome, which occurs due to the deletion of DAX1 and nearby genes encoding glycerol kinase (GK) and dystrophin (DMD). Affected patients have severe developmental delay and develop Duchenne's muscular dystrophy in addition to the primary adrenal insufficiency secondary to AHC.

IMAGe Syndrome

IMAGe syndrome (intrauterine growth restriction, metaphyseal dysplasia, congenital adrenal hypoplasia, and genital anomalies) was first described in 1999 in 3 boys who presented with severe adrenal insufficiency shortly after birth.[44] The affected infants also had skeletal abnormalities, micropenis, and hypogonadotropic hypogonadism. Linkage analysis and sequencing in a 5-generation family identified a likely causative variant in the gene encoding cyclin-dependent kinase inhibitor 1C (CDKN1C) located on chromosome 11p15 within an imprinted cluster of genes.[45] Affected patients in the pedigree had maternally transmitted pathogenic variants, suggesting that imprinting silences the paternal allele of CDKN1C. CDKN1C is believed to have a role in inhibiting cell cycle progression, and gain-of-function variants in CDKN1C are established as causative of IMAGe syndrome. Interestingly, pathogenic variants in CDKN1C have also been associated with Beckwith-Wiedemann Syndrome (BWS) as well as Russel-Silver syndrome, demonstrating the importance of this gene in regulating growth.[46]

Adrenocorticotropic Hormone Resistance

Resistance to ACTH at the level of the adrenal gland causes a rare form of primary adrenal insufficiency with retained aldosterone secretion. ACTH is elevated, and cortisol is low. Hyperpigmentation due to excessive production of α-MSH and stimulation of the melanocortin 1 receptor can be present at birth or develop over time. Almost 50% of cases are due to autosomal recessively inherited pathogenic variants in the melanocortin 2 receptor (MC2R, or ACTH receptor) and melanocortin 2 receptor accessory protein (MRAP) genes.[37] Autosomal recessive pathogenic variants in nicotinamide nucleotide transhydrogenase (NNT) caused ACTH resistance in three consanguineous families, presumably due to increased oxidative stress in the adrenal zona fasiculata.[37]

Adrenal Hemorrhage

Adrenal hemorrhage is a rare occurrence in neonates and rarely results in adrenal insufficiency even when it is confirmed radiographically, likely because adrenal hemorrhage occurs bilaterally in only 5% to 10% of cases.[47] Maternal diabetes, high birth weight, fetal acidemia, and birth asphyxia are associated with higher rates of adrenal hemorrhage. Additionally, neonatal adrenal glands are larger than adult adrenal glands, increasing the risk of hemorrhage.[48]

Inborn Errors of Metabolism

The neonatal inborn errors of metabolism are covered extensively in Chapter 29, and the key pathways of metabolism are outlined

in Fig. 87.1. Hypoglycemia resulting from these conditions often requires fasting for at least 4 to 6 hours, and therefore they are less likely to present with hypoglycemia in infancy. However, a few conditions can impact early fasting adaptation and, therefore, can present with hypoglycemia in the neonatal period.

Glycogen Storage Diseases

Many glycogen storage diseases (GSDs) become clinically apparent later in childhood. However, GSD type 1 can present in neonates as it is associated with hypoglycemia after fasting for just 2 to 2.5 hours. GSD 1 results from impaired function of glucose-6-phosphatase, the enzyme responsible for the final step of glycogenolysis and gluconeogenesis in which glucose is produced from glucose-6-phosphate (see Fig. 87.1). Patients have hepatomegaly due to accumulation of fat, and untreated infants typically present with elevated serum lactate, lipids, triglycerides, and uric acid. Administering glucagon 2 to 4 hours after a carbohydrate meal is helpful diagnostically as it causes a rise in lactate but no rise in glucose. Treatment is with frequent feeding as well as more slowly absorbed carbohydrates, such as uncooked cornstarch, to help prolong fasting tolerance.

Defects of Fatty Acid Catabolism and Ketogenesis

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common disorder of fatty acid oxidation (1/17,000). Newborn screening for MCAD deficiency is widespread, and infants are often detected based on screening. Defects arise from autosomal recessively inherited pathogenic variants in the *ACADM* gene, and MCAD is responsible for the initial dehydrogenation of acyl-CoAs with a chain length between 4 and 12 carbon atoms. Patients with MCAD present with metabolic decompensation after periods of fasting or with illness, and acylcarnitine profile can show elevations in chain lengths of C6 to C10, with elevations of C8 (octanoylcarnitine) being the most prominent. Hypoglycemia is often a late finding, but lethargy, coma, and severe neurologic injury can occur due to the additional lack of ketone bodies available to the brain. Children typically present between the ages of 3 months and 3 years (average 18 months), but the presentation can occur in the first few weeks of life.[49] Uric acid, ammonia, and liver function tests are often abnormally elevated as well in the context of hepatic steatosis.

Galactosemia

Galactosemia occurs due to pathogenic variants in one of three genes necessary to metabolize galactose to glucose: galactose 1-phosphate uridyl transferase (GALT), galactokinase (GALK), and uridine diphosphate (UDP) galactose 4-epimerase (GALE). Hypoglycemia can be a clinical presentation of galactosemia, often associated with other classic features such as hepatomegaly, jaundice, failure to thrive, cataracts, and *Escherichia coli* sepsis.[50,51]

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is due to pathogenic variants in the gene for aldolase B (*ALDOB*), responsible for metabolizing fructose-1-phosphate into substrates for gluconeogenesis. Vomiting, abdominal pain, acidosis, and hypoglycemia result after fructose or sucrose ingestion begins in infancy.[52] The accumulation of fructose-1-phosphate leads to liver and kidney dysfunction, the extent of which is proportional to the degree of fructose consumption. Hypoglycemia at least partially results from impaired gluconeogenesis and glycogenolysis in the liver, resulting in impaired response to glucagon.[53] Acute treatment is with IV dextrose, and further organ injury can be prevented by avoidance of dietary fructose and high-fructose corn syrup.

Hyperinsulinemic Hypoglycemia

The next section will focus on infants with hypoglycemia due to excessive insulin production. Hyperinsulinism may be caused by transient or permanent disorders of insulin secretion, and single-gene defects predominate in the permanent forms of hyperinsulinism (Table 87.1). A key management distinction among infants with hyperinsulinism is whether they can be managed with diazoxide and, if not, whether they have a focal or diffuse abnormality of pancreatic insulin regulation. Prior to discussing the causes and management of hyperinsulinism, it is important to consider the physiology of insulin secretion from the pancreatic β-cell.

Mechanism of Insulin Secretion

Depolarization of the pancreatic β-cell leads to insulin secretion, and the most important regulator of membrane polarization in the pancreatic beta cell is the ATP-sensitive potassium channel (K_{ATP} channel) (Fig. 87.2). The K_{ATP} channel is an octameric complex of two different subunits: (1) four inward-rectifying potassium channel subunits (Kir6.2 encoded by the *KCNJ11* gene), and (2) four regulatory sulfonylurea receptor subunits that surround the channel and help regulate the open or closed conformation of the channel (SUR1 encoded by the *ABCC8* gene). The channel is sensitive to the metabolic and energy state of the cell, as manifested by the ATP/ADP ratio in the cellular cytoplasm. Glucose enters the beta cell via an insulin-independent glucose channel (GLUT2 encoded by the *SLCA2A* gene). If glucose concentration is sufficiently high, it is phosphorylated by galactokinase to glucose-6-phosphate, the first step of glycolysis and, therefore, the entry point for glucose in the metabolic pathways that produce ATP (see Fig. 87.1). The increased ATP/ADP ratio causes closure of the K_{ATP} channel, resulting in membrane depolarization. In response to depolarization, voltage-gated calcium channels open, and the increase in intracellular calcium causes the fusion of the insulin-containing vesicles with the cellular membrane and subsequent release of insulin extracellularly.

The essential role that the K_{ATP} channel plays in regulating insulin secretion is evidenced by the large number of pathogenic variants in either KCNJ11 and ABCC8 that cause either congenital hyperinsulinism (decreasing channel presence in the membrane or favoring the closed conformation) or neonatal diabetes (favoring the open channel conformation), both of which are discussed later in this chapter.

Diagnosis of Hyperinsulinism

Estimates of the incidence of congenital hyperinsulinism vary widely depending on the study population but may be as high as 1 in 2500 in regions with high rates of consanguinity.[54] While hyperinsulinism is a common cause of neonatal hypoglycemia; the clinical features may be difficult to recognize and even missed until detection in later life or adulthood. However, infants with hyperinsulinism may have recognizable features of fetal hyperinsulinemia, such as overgrowth and hypertrophic cardiomyopathy. The hypoglycemia is usually present early but can be initially difficult to distinguish from the transient neonatal hypoglycemia seen in the first few hours of life. Alternatively, hypoglycemia may be immediately apparent as more severe and recalcitrant to early

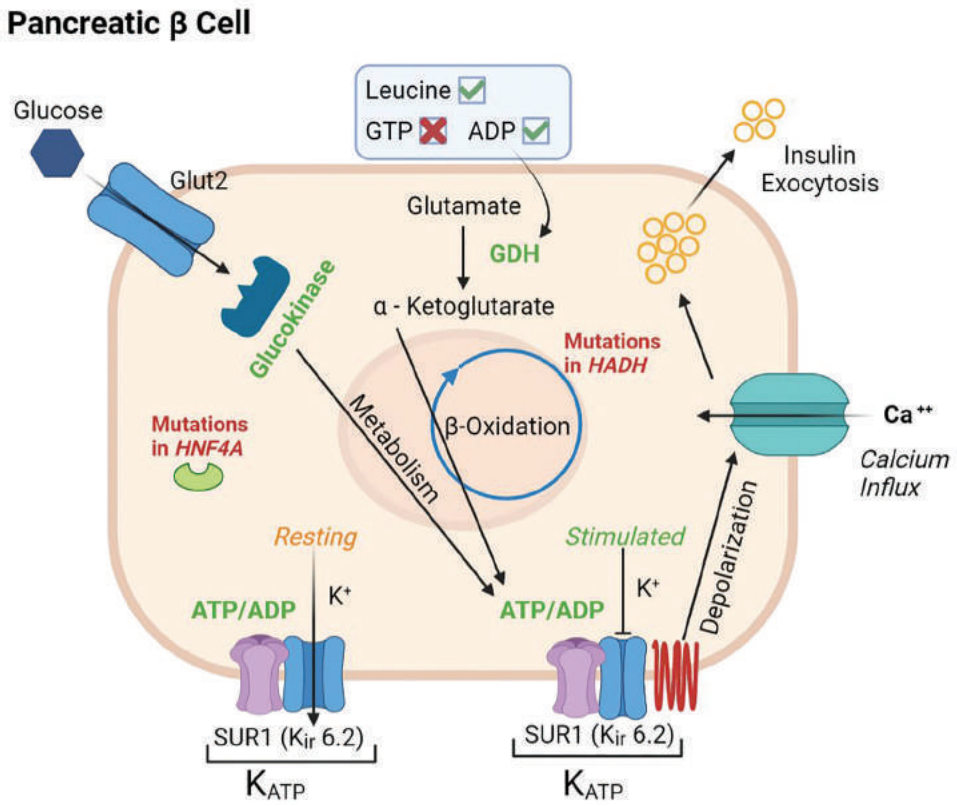
TABLE 87.1 Genetic Causes of Hyperinsulinemic Hypoglycemia

Inheritance	Molecular Defect	Chromosome	Histology	Clinical Features	Treatment
Sporadic	Paternally inherited ABCC8/KCNJ11 mutation with somatic loss of heterozygosity	11p15	Focal	Macrosomia, moderate to severe hypoglycemia in first few days to weeks of life	Poor response to diazoxide, local resection for focal and near-total pancreatectomy for diffuse form
AR	ABCC8/KCNJ11 (inactivating)	11p15	Diffuse	Macrosomia, onset in first few days to weeks of life, family history or consanguinity may be present	Near-total pancreatectomy
AD	ABCC8/KCNJ11 (dominant-negative, inactivating)	11p15	Diffuse	Milder symptoms, may manifest in late infancy	Usually responsive to diazoxide (Pinney, 2008)
AD	GLUD1 (activating)	10q23	Diffuse	Modest hyperinsulinemia and hyperammonemia, onset usually >6 months	Diazoxide, restriction of leucine in diet
AD	GCK (activating)	7p13	Diffuse	Modest hyperinsulinemia, onset usually >6 months	May respond to diazoxide
AR	HADH	4q25	Diffuse	Variable clinical presentation, abnormal acylcarnitine profile	Diazoxide
AD	HNF4α or HNF1α	20q13 and 12q24	Diffuse	Possible Fanconi tubulopathy; may have family history of MODY	Diazoxide
AD	UCP-2	11q13	Diffuse		Diazoxide
AD	HK1	10q22	Diffuse	Variable severity and penetrance	Diazoxide
AR	PGM1	1q31		Congenital disorder of glycosylation; bifid uvula, hepatopathy, hypogonadotropic hypogonadism, poor growth, myopathy, dilated cardiomyopathy[81]	Galactose supplementation may benefit

feeding. Confirming the diagnosis requires an index of suspicion on the part of the clinician, and a search for historical and physical examination findings such as macrosomia and, potentially, signs suggestive of an underlying syndrome known to be associated with hyperinsulinism such as Beckwith-Wiedemann syndrome, Kabuki syndrome, or Turner syndrome. In a state of excess glucose consumption, the normal physiologic rates of glucose supply are insufficient to maintain euglycemia, and thus a supraphysiologic glucose infusion rate (especially if >10 mg/kg/min) in the hypoglycemic infant strongly suggests hyperinsulinism. Where hypoglycemia is recognized and confirmed, the confirmatory diagnosis of hyperinsulinism hinges on the critical detection of inappropriate hyperinsulinemia, including measurable insulin, and the metabolic markers of persistent insulin effect, including suppressed free fatty acid (FFA) mobilization, hypoketosis (low beta-hydroxybutyrate, or BOHB) and an exaggerated glycemic response to glucagon (see Box 87.4).[54,55]

A 2016 retrospective review of infants with hypoglycemia showed that some children with hyperinsulinism do not have detectable insulin at the time of hypoglycemia; of 28 subjects with congenital hyperinsulinism, only 23 had detectable insulin (median value 6.7 uIU/mL). However, in those where ketosis was measured, none had β-hydroxybutyrate levels >1.8 mmol/L.[56] Importantly, bedside β-hydroxybutyrate levels show a good correlation with laboratory values, suggesting clinical utility in making a rapid diagnosis of hyperinsulinism. Similarly, infants without hyperinsulinism have FFA levels on average three times higher than in hypoglycemia due to hyperinsulinism. While previous data suggested an FFA cutoff of 0.5 mmol/L, recent data suggest that this cutoff misses many with true hyperinsulinism and that an FFA cutoff of <1.7 mmol/L provides sensitivity to >85%. Other biochemical data that are consistent with hyperinsulinism but may not yield results in as timely a manner as is ideal for rapid clinical confirmation, include C-peptide levels ≥0.5 ng/mL and IGF-BP1 (an insulin-like growth factor binding protein that is suppressed by insulin) levels ≤110 ng/mL.

Biochemical findings may be challenging to coordinate and collect in the setting of acute hypoglycemia. Therefore, a diagnostic challenge using a provocative fast performed under controlled conditions may be required.[57] This should include the frequent sampling of plasma glucose, insulin, β-hydroxybutyrate, and FFAs. At a point where the glucose falls below 2.8 mmol/L (50 mg/dL), the test can conclude with a glucagon challenge to see the glycemic response to an IV or IM dose of glucagon (1 mg), followed by a collection of glucose levels every 10 minutes for 40 minutes. A rise of ≥30 mg/dL in plasma glucose is considered consistent with hyperinsulinism. This test has high specificity, and while some patients with subsequently confirmed hyperinsulinism in the abovementioned study did not achieve a rise in glucose ≥30 mg/dL, its sensitivity is greater than relying solely on the detection of serum insulin levels at the time of hypoglycemia. While the subsequent detection of urine ketones may provide adjunctive data, ketonuria does not exclude hyperinsulinism, and accurate diagnostic results are more likely to be achieved in a



• **Fig. 87.2** Mechanisms of Insulin Secretion by the β-Cell of Pancreas. Glucose transported into the β cell by the insulin-dependent glucose transporter, GLUT 2, undergoes phosphorylation by glucokinase and subsequent metabolism, resulting in an increase in the intracellular ATP:ADP ratio. The increase in the ATP:ADP ratio closes the K_{ATP} channel and initiates the cascade of events characterized by increase in intracellular potassium concentration, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (GDH) and by increasing the oxidation of glutamate, thereby increasing the ATP:ADP ratio and closure of the KATP channel. Pathogenic variants in the *HADH* gene, which codes for the mitochondrial enzyme L-3-hydroxyacyl-coenzyme A dehydrogenase that catalyzes the penultimate step in the fatty acid β-oxidation pathway, are also associated with CHI. Pathogenic variants in HNF4α cause multiple defects in glucose-stimulated insulin secretion. ×, inhibition; √, and stimulation. (Modified from Sperling MA, Menon RK. Differential diagnosis and management of neonatal hypoglycemia, *Pediatr Clin North Am*. 2004;51:703–723.)

timely fashion at the bedside by blood sampling.[58] These authors thus do not recommend routine reliance on urinary ketosis as a replacement for the above protocol.

Hypoglycemia in Infants of Diabetic Mothers

Transient hyperinsulinemic hypoglycemia is often associated with pregnancies affected by diabetes, including both gestational diabetes as well as permanent maternal diabetes. Infants are typically macrosomic; despite high energy stores in the form of glycogen and fat reserves secondary to fetal hyperinsulinemia, hypoglycemia may persist for several days after disconnection from the high maternal glucose supply. Hypoglycemia in infants of diabetic mothers typically resolves within the first days to the week of life. Studies show that the severity of neonatal hypoglycemia in this setting is impacted by late pregnancy maternal glycemia, with avoidance of maternal hyperglycemia reducing the severity of fetal hyperinsulinemic hypoglycemia.[59,60] Neonates may require high rates of dextrose administration and/or frequent feedings, similar to patients with permanent congenital hyperinsulinism, but may successfully be weaned off high delivered substrate support judiciously over the first week or two of life.

Perinatal Stress and Transient Hyperinsulinism

While the well-described transitional hypoglycemia in normal newborns typically resolves within the first hours to the first day of life, in stressed infants, a persistent form of hypoglycemia may be seen.[61] The mechanism, similar to transitional hypoglycemia in healthy newborns, appears to be related to persistent hyperinsulinism, as ketogenesis and lipolysis remain suppressed. While somewhat unclear, it has been postulated that a lower glucose threshold for insulin secretion persists, given that insulin is a key fetal growth factor, and thus, its persistent secretion may confer a protective effect on the small or stressed neonate.[54] This may be seen in the context of perinatal asphyxia, pre-eclampsia, or SGA and may require interventions with early frequent feeding, medical therapy (including diazoxide directed at the hyperinsulinemia), or continuous feeds to avoid the complications of hypoglycemia.[27,62,63] For SGA infants with hyperinsulinemic hypoglycemia, diazoxide

treatment is often required for as long as 6 months and has been reported to last as long as 22 months.[64]

Genetic Causes of Hyperinsulinemic Hypoglycemia

Pathogenic Variants in the K_{ATP} Channel Genes KCNJ11 and ABCC8

Pathogenic variants in the KCNJ11 and ABCC8 genes located on chromosome 11p15.1 are the most common cause of permanent hyperinsulinism, accounting for about 40% to 50% of cases in neonates, the majority of which affect ABCC8.[65,66] Most commonly, this is due to pathogenic variants that prevent channel formation, trafficking to the cell membrane, or insensitivity to the cellular ATP/ADP ratio. In the absence of a functional K_{ATP} channel the β-cell is permanently depolarized, leading to insulin secretion. Because diazoxide activity requires a functional channel present in the cell membrane, patients with KCNJ11 or ABCC8 pathogenic variants typically do not respond to diazoxide therapy. However, some autosomal dominant mutations in KCNJ11 and ABCC8 are responsive to diazoxide.[67]

The mechanism of inheritance of the pathogenic variant affecting K_{ATP} channel function correlates strongly with the extent of pancreatic involvement. Patients with autosomal recessively inherited (biallelic) pathogenic variants will have diffuse involvement of the pancreas, whereas patients with one paternally inherited pathogenic variant will have a focal disease. The focal lesion arises from a somatic loss of the maternal allele in a sub-population of pancreatic cells, leading to focal unopposed expression of the mutated paternal allele, as well as unbalanced expression of imprinted genes that contribute to cellular hyperplasia.[66,68] Rarely, dominant-negative single allele pathogenic variants can result in diffuse disease. As described later in this section, the extent of pancreatic involvement directly impacts treatment. Patients with the focal histological subtype can be cured by targeted surgical resection, whereas those with the diffuse disease may require near-total pancreatectomy for definitive therapy.

Activating Variant of the Glutamate Dehydrogenase 1 Gene: Hyperinsulinemia-Hyperammonemia Syndrome

After pathogenic variants in KCNJ11 and ABCC8, pathogenic variants in glutamate dehydrogenase 1 (*GLUD1*) are the second most common cause of genetic hyperinsulinism. Glutamate dehydrogenase is an enzyme thought to localize to the mitochondrial matrix protein that converts GDP to GTP, which in turn regulates amino acid and ammonia metabolism. Autosomal dominant gain-of-function pathogenic variants increases the GTP/GDP ratio in the beta cell, leading to the closure of the K_{ATP} channel and subsequent depolarization and insulin secretion. Presentation is typically between 4 and 12 months of age, but infants can present in the first few days of life with hypoglycemia.[69] Leucine is an allosteric activator of GDH, causing hypoglycemia to worsen 30 to 90 minutes after a protein-rich meal. In addition to hyperinsulinemic hypoglycemia, patients also have elevated serum ammonia levels (hyperinsulinemia-hyperammonemia syndrome), although this is believed to have no clinical consequence and does not require therapy.[2] The hypoglycemia is diazoxide-responsive, and carbohydrate-loading is encouraged prior to protein-rich meals to prevent hypoglycemia. Patients may also develop generalized seizures, including absence epilepsy.[70]

L-3-Hydroxyacyl-Coenzyme A Dehydrogenase Gene Pathogenic Variants

L-3-hydroxyacyl-coenzyme A dehydrogenase (SCHAD; encoded by the *HADH* gene) is a mitochondrial enzyme responsible for the β-oxidation of fatty acids. Patients with autosomal recessive pathogenic variants can have a presentation similar to those with hyperinsulinemia-hyperammonemia syndrome.[71] This is due to HADH's additional role as a direct inhibitor of GDH activity via protein-protein interaction.[72] These patients share the same hypoglycemic sensitivity to protein-loading as patients with hyperinsulinemia-hyperammonemia; however, they do not have hyperammonemia and do not have an increased risk for a seizure disorder. Affected patients can be identified by the presence of elevated serum 3-hydroxybutyryl-carnitine and elevated urine 3-hydroxyglutaric acid.[73]

Glucokinase Pathogenic Variants

Glucokinase (GCK) catalyzes the reaction of glucose to glucose-6-phosphate and serves as the "glucose sensor" of the pancreatic beta cell. Dominant, activating pathogenic variants lower the glucose threshold for insulin secretion, causing hypoglycemia. Activating *GCK* pathogenic variants are usually de novo and not inherited from either parent; therefore family history is typically negative. Affected infants can be large for gestational age and have severe hypoglycemia in the neonatal period, but there is a wide spectrum of severity of presentation and hypoglycemia. Diazoxide therapy is effective in some cases, but pancreatectomy is required for some patients.[74]

Hepatocyte Nuclear Factor-4-Alpha and Hepatocyte Nuclear Factor-1-Alpha Pathogenic Variants

HNF4A (hepatocyte nuclear factor-4-alpha) and HNF1A (hepatocyte nuclear factor-1-alpha) are transcription factors expressed in hepatocytes, beta cells, intestinal epithelial cells, and renal tubular cells and are traditionally associated with mature onset diabetes of youth (MODY) type 1 and 3, respectively. Transcriptional regulation targets of HNF4A and HNF1A include each other, glucose transporter 2 (GLUT2), and possibly Kir6.2, but the exact cause of hyperinsulinism in infants is unclear.[75] Interestingly, some patients with neonatal hyperinsulinism due to HNF4A and HNF1A develop diabetes years later in adolescence or young adulthood, consistent with MODY 1 and 3.[76] Diazoxide is an effective therapy for patients with hypoglycemia secondary to HNF4A and HNF1A pathogenic variants. HNF4A hyperinsulinism has also been described in combination with renal Fanconi tubulopathy and hepatomegaly due to increased glycogen stores.[75]

Beckwith-Wiedemann Syndrome

Patients with BWS have characteristic features, including macrosomia, macroglossia, hemihypertrophy, ear pits, umbilical hernia, and a high risk for embryonal tumors. BWS results from epigenetic or genomic abnormalities in the imprinted 11p15.5 region or heterozygous maternally inherited pathogenic variants at CDKN1C. The majority (85%) of patients with BWS do not have a family history of the disorder. Children conceived by assisted reproductive technologies may be at increased risk for BWS and other imprinted disorders. Up to 50% of patients have hyperinsulinemic hypoglycemia with a wide spectrum of severity, most of which resolves in the first few days of life.[77,78] The cause of hyperinsulinism in BWS is variable and may depend on the patient's specific genetic abnormality, which rarely includes

pathogenic variants in either KCNJ11 or ABCC8.[78] Patients with BWS may respond to diazoxide; however, some patients require partial pancreatectomy.

Other Genetic Causes of Hyperinsulinism

Pathogenic variants in uncoupling protein 2 (UCP2) have been shown in a few individuals who presented with diazoxide-sensitive hyperinsulinemic hypoglycemia in infancy.[79] UCP2 has subsequently been shown to regulate mitochondrial, and cellular oxidation and decreased UCP2 activity is thought to increase the oxidation of glucose, thereby increasing the intracellular ATP/ADP ratio and increasing insulin secretion. There are some conflicting data regarding the role of UCP2 in hyperinsulinism, with a large-scale sequencing study not supporting the role of UCP2 in causing hyperinsulinism. However, in another study of a large cohort of diazoxide-responsive patients, 5 out of 211 were found to have one of 4 UCP pathogenic variants. The mechanism of hypoglycemia in patients with UCP2 pathogenic variants appears to be due to an exaggerated insulin response to glucose rather than persistent hyperinsulinism. With the cooperation of a 4-generation pedigree of autosomal dominantly inherited congenital hyperinsulinism, investigators identified a new single gene cause of hyperinsulinism: hexokinase 1 (HK1).[80] Family members were varyingly affected, but all who were treated with diazoxide responded well.

Autosomal recessive pathogenic variants in phosphoglucomutase 1 (PGM1) cause a syndrome of abnormal protein N-glycosylation associated with multifactorial hypoglycemia.[81] Patients demonstrate defects in glycogen breakdown as well as postprandial hyperinsulinemia, both of which have been associated with hypoglycemia in infancy.[54] Other congenital disorders of glycosylation have been associated with hyperinsulinism, including CDG1a (phosphomannomutase 2 deficiency) and CDG1b (mannosephosphate isomerase deficiency).[82]

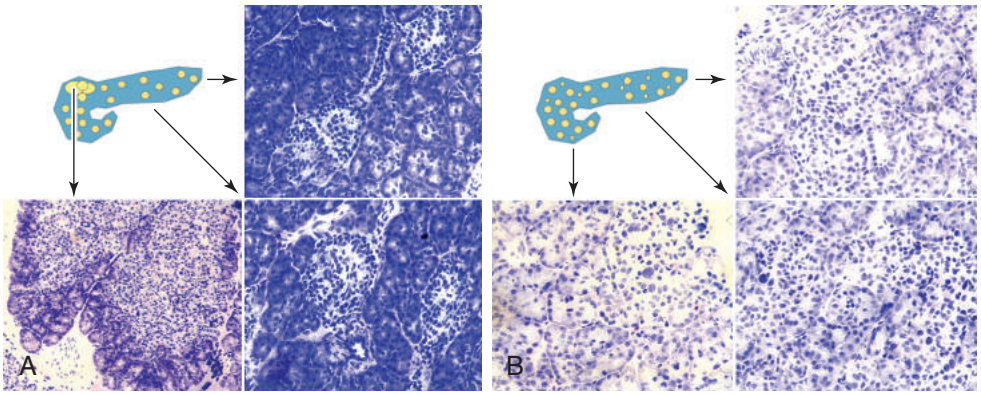
Recently an infant was diagnosed with a combination of congenital hyperinsulinism and hypopituitarism. A variant of uncertain significance (VUS) identified in the *FOXA2* gene was thought to possibly be causative.[83] FOXA2 regulates the expression of ABCC8, KCNJ11, and HADH, as well as several regulators of pituitary gland development, such as SHH, Gli2, and *NKX2-2*. The patient responded to diazoxide, suggesting that at least partial function of Sur1 and Kir6.2 was present.

Postfundoplication Hypoglycemia

Neonates undergoing fundoplication for gastric reflux or other reasons are at risk for postprandial hypoglycemia related to dumping syndrome. Often this hypoglycemia goes undetected—prompting the need for better surveillance, including the use of continuous glucose monitoring.[84] Approximately 25% of neonates develop dumping syndrome after fundoplasty, most of which is identified in the first postoperative week.[85,86] Hypoglycemia occurs 1 to 3 hours after a meal due to an exaggerated insulin response to early postmeal hyperglycemia, which is often detectable as well. Treatment is with gradual gastric feeds, and sometimes continuous feeds are required. Uncooked cornstarch, pectin, octreotide, and acarbose have been attempted with varying degrees of success.[85] More recently, GLP-1 levels were found to be high in children with dumping syndrome, which led to GLP-1 receptor antagonists being studied as a potential treatment for postprandial hypoglycemia from dumping syndrome.[85,87]

Differentiation Between Focal Adenomatous and Diffuse Pancreatic Hyperplasia

Patients with hyperinsulinism who are not responsive to diazoxide therapy should receive specialized imaging to evaluate for a focal pancreatic lesion that can be cured surgically. Positron emission tomography (PET) imaging with 18F-fluoro-L-DOPA exploits the fact that pancreatic β-cells take up the radiolabeled L-DOPA (Fig. 87.3). Simultaneous PET and MRI, therefore, provide visualization of the hyperactive β-cells within the pancreas and allows the differentiation of focal and generalized hyperactivity



• **Fig. 87.3** (A) Frozen sections obtained from three pancreatic sites during surgery for a focal form of hyperinsulinism in the head. Specimens taken from the tail and body show islets of Langerhans at rest with little cytoplasm, leading to crowded nuclei, whereas the focal form aspect from the head is that of multilobular involvement with local signs of β-cell hyperactivity: abundant cytoplasm and large, abnormal nuclei (toluidine blue stain; original magnifications ×200 and ×100). (B) Frozen sections obtained from three pancreatic sites during surgery for diffuse form of hyperinsulinism. On each biopsy, there is one islet showing hyperfunctional signs with abundant cytoplasm and irregular nuclei more than four times the size of the acinar nuclei nearby taken as internal control. The disease involves the whole pancreas and, in consequence, can be called diffuse, which does not mean that all islets are involved in the same manner (toluidine blue stain; original magnification ×200). (From Delonlay P, Simon A, Galmiche-Rolland L, et al. Neonatal hyperinsulinism: clinicopathologic correlation. *Hum Pathol*. 2007;38:387–399.)

(see Fig. 87.3). This distinction is critical as it is far preferable to perform a curative focal resection rather than a "near-total" pancreatectomy which has a more variable outcome ranging from continued hyperinsulinism to diabetes.[88]

In all, approximately half of patients requiring surgery will have a focal lesion.[65] Such imaging is often successful in identifying the appropriate surgical management in those patients with hyperinsulinism refractory to medical management.[89]

Management of Hyperinsulinemic Hypoglycemia

The goal of treatment is to minimize hypoglycemia frequency and duration to prevent impaired neurologic development. First-line treatment is with diazoxide, which opens the beta-cell ATP-dependent potassium channel, limiting depolarization and thereby decreasing insulin secretion. Common side effects of diazoxide include hypertrichosis and fluid retention, sometimes requiring diuretic use.

Pulmonary hypertension has also been described in a small number of patients receiving diazoxide.[90] A retrospective cohort study was able to estimate the risk for pulmonary hypertension to be 7% (13 out of 177 patients), the majority of which were symptomatic.[91] The onset of pulmonary hypertension was most commonly within 2 weeks of starting therapy but could occur at any time while on treatment with diazoxide. Pulmonary hypertension resolved in 10 out of the 13 patients identified but persisted for as long as 12 months after discontinuation of diazoxide. Risk factors for the development of pulmonary hypertension included the presence of congenital heart disease and higher volumes of fluid given prior to the start of diazoxide. The authors proposed a best practice guideline that recommends obtaining an echocardiogram prior to starting diazoxide and 1 to 2 weeks following initiation of therapy.

As mentioned above, not all hyperinsulinism patients will respond to diazoxide (particularly those with K_{ATP} channel pathogenic variants), and second-line therapies include subcutaneous octreotide and glucagon infusion (Table 87.2). Octreotide is known to result in tachyphylaxis, causing diminishing efficacy of the medication. There is also a possible association with necrotizing enterocolitis, which requires special consideration in the neonatal population.[92,93] Lanreotide, a long-acting form of somatostatin administered as a once a month injection, has been successful in treating hyperinsulinism as well.[92,93] Glucagon infusion is effective but not sustainable as a long-term treatment strategy due to the need either for IV infusion or continuous delivery via a subcutaneous catheter. Continuous subcutaneous delivery systems have been described, but they are limited by crystallization of the glucagon and obstruction of the tubing.[94] Sirolimus, a known cause of transplant-related diabetes, has also been used experimentally with some success.[95]

Nutritional factors should also be considered by increasing the carbohydrate content of feeds or by altering the length and frequency of feeding breaks. Continuous dextrose (D20W) delivered enterally is sometimes required to maintain normoglycemia overnight.[96] Families should be taught how to use a glucometer and to be vigilant for signs and symptoms of hypoglycemia. Parental education on the administration of glucagon is necessary prior to discharge.

Patients that require pancreatectomy have a high risk for future development of insulin-dependent diabetes and neurobehavioral problems.[88] Lord et al. recently reported the outcomes for 121 children with congenital hyperinsulinism treated with pancreatectomy, finding that 36% developed diabetes during long-term follow-up, and 20% of these patients developed diabetes in the immediate postoperative period. The risk of diabetes was associated with the percentage of pancreatectomy: 93% of those with diabetes had a 95% pancreatectomy or greater, while those without diabetes had a median 65% pancreatectomy. Also, 48% had neurobehavioral concerns, including 21% of patients with psychiatric or behavioral concerns, 18% with speech delay, and 16% with a learning disability, using parent-reported questionnaires. Quantitative measures of adaptive behavior were abnormal in 27% of patients. The finding that these neurodevelopmental outcomes were similar for the focal and diffuse groups suggests that a shared exposure to recurrent hypoglycemia in the neonatal period may be causative.

Neonatal Hyperglycemia

Insulin is a critical mediator of fetal growth, and therefore infants with hyperglycemia due to persistent insulin deficiency are almost universally born small for gestational age and have a history of intrauterine growth restriction. It is thought that the autoimmune process leading to beta-cell destruction takes at least 6 months to manifest itself, and therefore autoimmune-mediated Type 1 Diabetes does not occur earlier than 6 months of age, with the notable exception of IPEX-related diabetes.[97] Persistent hyperglycemia that meets the criteria for diabetes (>125 mg/dL fasting or >200 mg/dL) in an infant <6 months of age suggests a

TABLE 87.2 Drugs Used in the Management of Neonatal Hyperinsulinism

Drug	Dose/Route	Mechanism of Action	Adverse Effects
Diazoxide	5-15 mg/kg/day in three divided doses orally	Binds to SUR1 subunit, opens K_{ATP} channel	Fluid retention, hypertrichosis, rarely eosinophilia, leukopenia, hypotension
Chlorothiazide (in conjunction with diazoxide to decrease fluid retention)	10-20 mg/kg/day in two divided doses orally	Synergistic response to diazoxide	Hyponatremia, hypokalemia
Octreotide	5–25 μg/kg/day 6–8 hourly SC injection or IV infusion	Inhibits insulin secretion by binding to somatostatin receptors and inducing hyperpolarization of β-cells, direct inhibition of voltage-dependent calcium channels	Anorexia, nausea, abdominal pain, diarrhea, tachyphylaxis Risk of NEC in young infants, thus lower doses are recommended
Glucagon	1–20 μg/kg/h, SC or IV infusion	Increases glycogenolysis and gluconeogenesis	Nausea, vomiting, paradoxical insulin secretion at high dose

monogenic cause strongly, and genetic testing is positive in at least 80% of cases.[98] About 50% of infants with diabetes in the first few months of life will have a resolution by 1 to 2 years of age (transient neonatal diabetes, or TNDM), but a significant portion of these patients will have relapse of diabetes later in childhood or adolescence.[99,100] Family history of early adulthood onset diabetes mellitus, perhaps reported as or assumed initially to be T1DM or T2DM, or MODY, can suggest an inherited abnormality of insulin secretion, but positive family history is not present in 70% of molecularly confirmed cases.[98] Elucidation of the specific genetic etiology has immediate implications for treatment, as those with pathogenic variants in the KCNJ11 or ABCC8 components of the K_{ATP} channel are best treated with oral sulfonylurea rather than insulin.

Transient Stress-Related Hyperglycemia

Most commonly, neonatal hyperglycemia is transient and caused by physiologic stress such as sepsis or other acute illness, particularly in infants receiving continuous intravenous dextrose infusions (Box 87.5).[101] Cortisol and catecholamines secreted during acute illness increase gluconeogenesis, glycogen breakdown, and insulin resistance, all of which increase plasma glucose concentration. The hyperglycemia will improve as the neonate's overall clinical status improves and as glucose infusion rates are minimized to the lowest necessary amount. Insulin infusions may be necessary to control hyperglycemia in the short term.

Neonatal Diabetes Mellitus

Neonatal diabetes mellitus (NDM) is a genetically heterogeneous disease with over 20 known genetic subtypes. Different types of NDM vary widely in their prognosis, from mild self-resolving hyperglycemia to permanent forms associated with severe neurodevelopmental features. Some types of NDM respond to sulfonylureas, while others do not. Thus, early referral for genetic testing should be made as soon as a clinical diagnosis of NDM is made. It is important to recognize that the absence of a family history does not exclude a genetic cause, as most NDM-causing pathogenic variants arise spontaneously.[98]

Transient Neonatal diabetes Mellitus due to Chromosome 6q24 Anomalies

The majority (70%) of patients with transient neonatal diabetes mellitus (TNDM) have an abnormality of the imprinted region of chromosome 6q24. Within this imprinted region are two genes, PLAGL1 and HYMAI, that share a promoter. This promoter is differentially methylated depending on the parent of allelic origin. In the normal situation, only the paternally inherited allele is expressed, while the maternally inherited allele is methylated and not expressed. Situations that lead to a relative increase in the expression of PLAGL1 and HYMAI cause TNDM. These include paternal uniparental disomy, duplication of the 6q24 on the paternal allele, hypomethylation of the maternal allele producing inappropriate PLAGL1 and HYMAI expression from the maternal allele, or multilocus imprinting disturbance (MLID) caused by biallelic pathogenic variants in ZFP57. The mechanism by which overexpression of PLAGL1 and HYMAI leads to TNDM is not fully understood. A second, nonimprinted promoter also controls PLAGL1 expression, which has led to the hypothesis that the postnatal remission of TNDM is due to a switch over to this nonimprinted promoter postnatally. This form of TNDM resolves at a median age of 3 months, but about half of patients will have a return of diabetes during adolescence. Management is with subcutaneous insulin therapy until remission. Associated clinical features include intrauterine growth retardation (IUGR), macroglossia (44%), and umbilical hernia (21%), while other reported findings have included facial dysmorphism (18%), cardiac and renal anomalies (9%), and hand anomalies (8%).[102,103]

Interestingly, reports have shown that a subset of patients with TNDM due to 6q24 abnormalities develops hyperinsulinemic hypoglycemia after the resolution of neonatal diabetes.[104] These patients have reportedly responded to diazoxide therapy and, at follow-up, have still required treatment with diazoxide 1 to 4 years later.

Transient Neonatal Diabetes Mellitus due to K_{ATP} Pathogenic Variants

About 25% of patients with TNDM have normal methylation at 6q24. Most of these 6q24 normal TNDM patients have heterozygous activating pathogenic variants in either KCNJ11 or ABCC8, the two components of the K_{ATP} channel, as described previously. Activating pathogenic variants in these same genes can also cause PNDM; see below. Although some studies have suggested that TNDM-causing pathogenic variants are functionally less severe than PNDM-causing pathogenic variants, some pathogenic variants in KCNJ11 have been reported in both PNDM and TNDM patients, so an absolute genotype-phenotype correlation may not exist.[105,106] Compared with 6q24-associated TNDM, infants with K_{ATP}-associated TNDM have higher birth weight, later diagnosis, later remission, and earlier relapse of hyperglycemia.[107] No significant clinical differences have been noted between KCNJ11 and ABCC8-related TNDM, both of which respond favorably to sulfonylureas.

Additional Genetic Causes of Transient Neonatal Diabetes Mellitus

Several different biallelic pathogenic variants within the promoter of the insulin gene (*INS*) have been reported in TNDM patients.[108] Pathogenic variants within the promoter of the *INS* gene can also cause PNDM. Genotype-phenotype correlations are limited as several of these variants have been reported in both TNDM and PNDM. For example, the INS promoter variant(c.-331C>G) has been reported to cause TNDM in some individuals and PNDM in others, even within the same family. The reason for this variability is unknown.

• BOX 87.5 Differential Diagnoses of Neonatal Hyperglycemia

Common Causes

Excessive intravenous glucose infusion
Impaired glucose homeostasis in preterm/sick/SGA infants
Sepsis
Stress
Corticosteroids

Rare Causes

Transient neonatal diabetes
Permanent neonatal diabetes

Homozygous pathogenic variants in the gene *SLC2A2*, encoding the GLUT2 transporter, which transports glucose into the beta cell, have been reported in 4 unrelated patients with TNDM; parents were first cousins in 3 of these patients.[107,109] Three of the patients presented with apparently isolated diabetes, but eventually, all four demonstrated findings associated with Fanconi-Bickel syndrome (FBS). Biallelic pathogenic variants in *SLC2A2* are known to cause FBS, whose features include renal Fanconi syndrome, poor growth, hepatomegaly, and impaired utilization of glucose and galactose.[110] However, over 95% of patients with biallelic *SLC2A2* pathogenic variants present with symptoms of FBS without evidence of neonatal diabetes, but the reason for this variable expressivity is unknown.

Nonsyndromic Causes of Permanent Neonatal Diabetes Mellitus

Infants with neonatal diabetes without evidence of remission in the first year or two of life are classified as having PNDM. The most common cause of PNDM is heterozygous, activating pathogenic variants in the potassium channel subunit genes KCNJ11 and ABCC8 (more commonly KCNJ11), accounting for almost half of all patients with PNDM.[111,112] These pathogenic variants decrease the potassium channel's sensitivity to the cellular ATP concentration, keeping the channel inappropriately open and inhibiting insulin secretion. 20% of individuals with PNDM due to KCNJ11 pathogenic variants will also have *d*evelopmental delay, *e*pilepsy, and *n*eonatal *d*iabetes (DEND) syndrome.[113] There are clear genotype-phenotype correlations within the *KCNJ11* gene, with some pathogenic variants being associated with DEND syndrome and others with only PNDM. Patients with PNDM due to pathogenic variants in KCNJ11 and ABCC8 typically respond well to sulfonylureas.[114] Interestingly, some neurologic features of DEND have also been reported to respond to sulfonylureas, highlighting the importance of the potassium channel in neuronal cells.[115]

Pathogenic variants within the INS are also a common cause of PNDM, found in approximately 10% of patients with PNDM. *INS* gene pathogenic variants can be homozygous (more common among offspring of consanguineous relationships) or heterozygous, but in both cases, the pathogenic variants lead to inadequate production of insulin protein.[98,108,116]

Rarer genetic causes of nonsyndromic PNDM include biallelic inactivating pathogenic variants in glucokinase (GCK), and the transcription factor PDX1.[117,118] GCK serves as the "glucose sensor" of the beta cell, converting glucose into glucose 6-phosphate. PDX1 is a transcription factor necessary for the formation of the pancreas in utero. Heterozygous pathogenic variants in GCK are a relatively common cause of MODY, accounting for 20% to 50% of MODY patients. Therefore, GCK should be strongly considered in patients with PNDM who have a positive family history of MODY, mild fasting hyperglycemia, or gestational diabetes in a nonobese mother. Some patients with homozygous pathogenic variants of PDX1 have pancreatic agenesis, producing exocrine insufficiency in addition to PNDM, while in others, a pancreatic exocrine function is intact.[118]

Syndromic Causes of Neonatal Diabetes Mellitus

In addition to the genes described above, there are multiple other known genetic causes of NDM, which are typically considered "syndromic" because they are often associated with other non-endocrine features. Although some syndromic forms of NDM present with other features (e.g., congenital heart defects), diabetes is often the initial presentation, making early genetic diagnosis helpful as it can guide management and necessary screening. For example, patients with biallelic pathogenic variants in *EIF2AK3* have Wolcott-Rallison syndrome, which usually presents with neonatal diabetes, while other features (skeletal dysplasia, developmental delays, and liver dysfunction) may not manifest until later. A quarter of NDM patients whose parents are consanguineous have Wolcott-Rallison syndrome, making it the most common cause of PNDM among this group of patients. The remaining syndromic causes of neonatal diabetes are listed in Table 87.3. Because of the considerable number of genetic causes of neonatal diabetes, sequencing multiple genes in parallel is typically the most efficient diagnostic approach.

TABLE 87.3 Syndromic Causes of Neonatal Diabetes

Gene	Syndrome	Reference
EIF2AK3	Wolcott-Rallison syndrome	122,123
FOXP3	IPEX syndrome: severe diarrhea, type 1 DM, dermatitis, X-linked	124,125
GATA4	Neonatal and childhood onset DM, may have pancreatic hypoplasia, cardiac malformations, and neurocognitive defects	126
GATA6	Pancreatic agenesis, ± congenital heart defects	127
GLIS3	NDM with congenital hypothyroidism	128,129
HNF1B	Renal cysts and diabetes (RCAD), neonatal diabetes (NDM)	130
IER3IP1	NDM with microcephaly, lissencephaly, and epileptic encephalopathy	131,132
MNX1	NDM with neurologic features, Currarino syndrome (sacral agenesis, imperforate anus)	133,134
NEUROD1	NDM with cerebellar hypoplasia, sensorineural hearing loss, visual impairment	135
NEUROG3	NDM with congenital malabsorptive diarrhea	136,137
NKX2-2	NDM with developmental delays, hypotonia, short stature and hearing loss	134
PTF1A	NDM with pancreatic and cerebellar agenesis	138
RFX6	NDM with pancreatic hypoplasia, intestinal atresia, gall bladder hypoplasia (Mitchell-Riley syndrome)	139,140
SLC19A2	NDM with deafness and thiamine-responsive megaloblastic anemia (Rogers syndrome)	141
SLC2A2	NDM with renal dysfunction (Fanconi Bickel syndrome)	142
WFS1	Wolfram syndrome, DIDMOAD, low frequency sensorineural hearing loss, optic atrophy	143
PAX6	Neonatal diabetes with brain malformations, microcephaly, and microphthalmia	144
LRBA	Common variable immunodeficiency with autoimmunity	145

Management of Neonatal Hyperglycemia

Management of hyperglycemia in the neonatal period is dictated by the clinical scenario and the results of genetic testing. Transient hyperglycemia is best managed by treating the underlying cause (e.g., sepsis). In addition to close monitoring of glucose, exogenous glucose administration can be decreased to approximately 3 mg/kg/min. If necessary, insulin treatment can commence, starting with a low-dose insulin infusion (e.g., 0.03 units/kg/h).

Treatment of neonatal diabetes requires insulin, at least until a genetic diagnosis is made. For those with a genetic aberration at 6q24, insulin requirements usually drop quite quickly, and treatment is often discontinued by 12 weeks of age.[119] Hyperglycemia may recur with intercurrent illness and then recurs in over half of children, generally at the time of puberty.

Infants with an identified pathogenic variant in *KCNJ11* or *ABCC8* can be treated with sulfonylureas. Generally, it is best to gradually decrease insulin dosing as sulfonylurea treatment is initiated. Sulfonylurea dosing tends to be higher than typically used in adults. While over 90% of those with a *KCNJ11* or *ABCC8* pathogenic variant can successfully transition from insulin to sulfonylurea and maintain near normal glycemic control, the factors associated with sulfonylurea failure are the specific genetic variant and longer duration of diabetes.[120] Treatment with sulfonylureas is not only effective in achieving euglycemia but also has led to improvements in neurological status for patients with DEND syndrome; this appears to be secondary to improved cerebellar perfusion.[121]

Acknowledgments

We would like to thank the authors of the 9th edition of this chapter—Vandana Jain, Ming Chen, and Ram K. Menon—whose work was the starting point for our chapter.

88 Craniofacial Conditions

G. KYLE FULTON, MATTHEW S. BLESSING, AND KELLY N. EVANS

KEY POINTS

- Craniofacial malformations can impact swallowing, breathing, hearing, vision, speech, and development and for some neonates can result in life-threatening airway compromise.
- Early recognition and assessment of craniofacial conditions that include appropriate diagnostic studies, identification of associated health concerns, and family education can have a positive impact on the care and outcome of affected newborns.
- Timely referral to or consultation with a multidisciplinary craniofacial team in a newborn with a craniofacial condition is an important step in the provision of coordinated medical and surgical management. Key members of the craniofacial team are shown in Box 88.1. A list of teams accredited by the American Cleft Palate-Craniofacial Association (ACPA) can be found on the ACPA website: https://acpa-cpf.org/acpa-family-services/find-a-team/.

The neonatal care provider is often the first point of contact for a child born with a craniofacial malformation. Abnormalities of the face and head can be distressing to a new parent, who is immediately wondering, "Is my child going to look, feel, and develop normally?" Having a basic understanding of the relationship between craniofacial abnormalities and feeding, breathing, hearing, vision, speech, and overall development will help care providers to begin to counsel a family. Airway compromise is well described in multiple craniofacial syndromes, and early identification can be lifesaving. Prompt recognition of a constellation of anomalies pointing toward a syndrome or diagnosis will result in better-targeted evaluations and therapies for that patient. Tables 88.1 and 88.2 contain a concise presentation of potential intensive care unit (ICU) issues that may be encountered with craniofacial malformations and syndromes. This chapter highlights the most relevant craniofacial conditions that neonatal care providers will encounter. We describe here the diagnosis, etiology, phenotype, and potential ICU issues as well as basic management and screening recommendations to help guide neonatal practitioners in caring for an infant with craniofacial malformations.

Micrognathia/Robin Sequence

Diagnosis and Etiology

The triad of micrognathia, glossoptosis, and airway obstruction is known as *Robin sequence* (RS) or *Pierre Robin sequence*. Cleft palate is a common feature of RS, although not obligatory to the diagnosis. Approximately one-quarter of infants with cleft palate (CP) were found to have RS in a population-based, case-control study.[1] RS is an etiologically and phenotypically heterogeneous disorder. In a large cohort study of 191 children with RS, 38% had isolated RS, 9% had a chromosome anomaly, 29% had a Mendelian disorder, and 24% had no detectable cause. Twenty-two Mendelian disorders were diagnosed, of which Stickler syndrome was the most frequent.[2] The tremendous heterogeneity and lack of uniformly accepted diagnostic criteria for, or definitions of, RS make it challenging to know the true prevalence. In a review of 42 international studies, the estimated birth prevalence for RS ranged between 1:3900 and 1:122,400 (0.8 to 32.0 per 100,000), with a mean prevalence of 1:24,500.[3]

Phenotype

While there is great variation in severity, RS is characterized by the following phenotypic features: micrognathia, glossoptosis, and resultant base of tongue-level upper airway obstruction (Fig. 88.1A, B).[4] Cleft palate is a common additional feature, occurring in approximately 90%.[5] A wide, U-shaped cleft is classic in RS and should prompt the provider to evaluate for any signs of micrognathia or airway obstruction, while the narrow, V-shaped cleft palate is more typical in infants without RS. Micrognathia, or a small and symmetrically receded mandible, is a subjective diagnosis, although assessing the maxillomandibular discrepancy (distance between the maxillary and mandibular alveolar ridges in the midline) can help with recognition. Glossoptosis is dynamic and defined as displacement of the tongue base into the oropharynx and hypopharynx. Tongue size varies across the spectrum of RS, and the severity of glossoptosis does not always correlate with the degree of micrognathia. Intraoral examination of the infant with glossoptosis may reveal a posteriorly positioned tongue, occasionally pulled up into a palatal cleft. Upper airway obstruction (often presenting with stertor, increased effort, or obstructive apnea) in infants with RS can be associated with feeding difficulties and challenges gaining weight. Clinical judgment can be made about whether the patient represents "isolated RS," "RS plus (RS with other anomalies)" or a syndromic form of RS.

Intensive Care Unit Concerns

Upper airway obstruction in RS is a result of tongue displacement toward the posterior pharyngeal wall or up into the cleft. The tongue can act as a ball valve, leading to inspiratory obstruction.

TABLE 88.1 Craniofacial Syndromes Commonly Associated With Cleft Lip and/or Cleft Palate

Syndrome	Phenotype	ICU Issues	OMIM
Robin sequence[a]	Micrognathia, glossoptosis with upper airway obstruction, cleft palate	Airway obstruction, feeding difficulties	261800
Stickler syndrome[a]	Cleft palate, micrognathia, glossoptosis (Robin sequence), high myopia, risk of retinal detachment and blindness, midface hypoplasia, hearing impairment, arthropathy, pectus, short fourth and fifth metacarpals	Airway obstruction, feeding difficulties	180300, 604841, 184840, 614134, 614284, 609508
22q11.2 deletion syndrome (velocardiofacial syndrome, DiGeorge syndrome)[a]	Cleft palate and submucous cleft palate, small mouth, myopathic facies, retrognathia, prominent nose with squared-off nasal tip, hypoplastic nasal alae, short stature, slender tapering digits	Cardiac anomalies, airway obstruction, feeding difficulties, aspiration	192430, 188400, 611867
Opitz oculogenitolaryngeal syndrome (Opitz BBB/G syndrome)[a]	Hypertelorism, telecanthus, cleft lip and/or palate, dysphagia, esophageal dysmotility, laryngotracheoesophageal cleft (aspiration), hypospadias, bifid scrotum, cryptorchidism, agenesis of the corpus callosum, congenital heart disease, intellectual disability	Laryngotracheoesophageal clefting (stridor, feeding difficulties, choking, aspiration)	145410, 300000
Pallister–Hall syndrome[a]	Cleft palate, flat nasal bridge, short nose, multiple buccal frenula, microglossia, micrognathia, malformed ears, hypothalamic hamartoblastoma, hypopituitarism, postaxial polydactyly with short arms, imperforate anus, genitourinary anomalies, intrauterine growth restriction	Laryngotracheoesophageal clefting (stridor, feeding difficulties, choking, aspiration), panhypopituitarism	146510
IRF6-related disorders (including Van der Woude and popliteal pterygium syndrome)	Cleft lip with or without cleft palate, cleft palate only, lower lip pits or cysts, ankyloglossia; popliteal pterygium syndrome will also have popliteal pterygia, bifid scrotum, cryptorchidism, finger and/or toe syndactyly, abnormalities of the skin around the nails, syngnathia and ankyloblepharon	Not anticipated	119300, 119500
CHARGE syndrome[a]	Coloboma of the eye, heart malformations, choanal atresia, growth retardation, genital anomalies, ear abnormalities and/or deafness, facial palsy, cleft palate, dysphagia	Airway obstruction, bilateral choanal atresia, cardiac anomalies, feeding difficulties, aspiration	214800
Smith–Lemli–Opitz syndrome[a]	Cleft palate, micrognathia, short nose, ptosis, high square forehead, microcephaly, hypospadias, cryptorchidism, ventricular septal defect, tetralogy of Fallot, hypotonia, intellectual disability, postaxial polydactyly, 2–3 toe syndactyly, defect in cholesterol biosynthesis	Cardiac anomalies, airway hypotonia, and airway obstruction	270400
Ectrodactyly, ectodermal dysplasia, and clefting syndrome	Cleft lip and/or palate, split-hand/split-foot, ectodermal dysplasia (sparse hair, dysplastic nails, hypohidrosis, hypodontia), genitourinary anomalies	Not anticipated	129900, 604292, 129400
Ankyloblepharon, ectodermal dysplasia, and clefting syndrome	Cleft lip with or without cleft palate, cleft palate only, intraoral alveolar bands, maxillary hypoplasia, ankyloblepharon (eyelid fusion), ectodermal dysplasia (sparse hair, dysplastic nails, hypohidrosis, anodontia)	Not anticipated	106260
Orofaciodigital syndrome	Median cleft of upper lip, cleft palate, accessory oral frenula, lobulated tongue with hamartomas, broad nasal root, small nostrils, syndactyly, brachydactyly, postaxial polydactyly, polycystic renal disease, agenesis of the corpus callosum	Not anticipated	311200
Kabuki syndrome[a]	Cleft palate, arched eyebrow, long palpebral fissures, eversion of lateral third of lower eyelid, brachydactyly, short fifth metacarpal, cardiac anomalies, postnatal growth deficiency/dwarfism, intellectual disability	Cardiac anomalies	147920, 300867
Fryns syndrome[a]	Cleft lip with or without cleft palate, micrognathia, coarse facies, diaphragmatic hernia, distal limb hypoplasia, malformations of the cardiovascular, gastrointestinal, genitourinary, and central nervous systems	Congenital diaphragmatic hernia, pulmonary hypoplasia; cardiac anomalies	229850
Miller syndrome (postaxial acrofacial dysostosis)[a]	Cleft palate (more than cleft lip), malar and mandibular hypoplasia, downslanting palpebral fissures, lower eyelid coloboma, microtia/atresia, conductive hearing loss, postaxial limb deficiency, absent fifth digit	Airway obstruction	263750

Continued

TABLE 88.1 Craniofacial Syndromes Commonly Associated With Cleft Lip and/or Cleft Palate—cont'd

Syndrome	Phenotype	ICU Issues	OMIM
Treacher Collins syndrome (mandibulofacial dysostosis)[a]	Cleft palate, malar and mandibular hypoplasia, downslanting palpebral fissures, lower eyelid coloboma (missing medial lower eyelid lashes), microtia/atresia, conductive hearing loss	Airway obstruction	154500, 613717, 613715, 248390, 618939
Aarskog syndrome (faciodigitogenital syndrome)	Hypertelorism, widow's peak, ptosis, downslanting palpebral fissures, strabismus, maxillary hypoplasia, broad nasal bridge with anteverted nostrils, occasional cleft lip and/or palate, floppy ears, brachydactyly, clinodactyly, joint laxity, shawl scrotum	Not anticipated	100050, 305400
Wolf–Hirschhorn syndrome (4p deletion syndrome)[a]	Cleft lip and palate, coloboma, hypertelorism, growth deficiency, microcephaly, intellectual disability, cardiac septal defects	Congenital diaphragmatic hernia, cardiac anomalies, seizures, airway hypotonia/obstruction	194190
Amnion rupture sequence[a]	Cleft lip and palate, oblique facial clefts, focal areas of scalp aplasia, constriction bands with terminal limb amputations and syndactylies, occasional anencephaly, encephalocele, and ectopia cordis	Encephalocele, oropharyngeal/ airway deformation	217100

TABLE 88.2 Craniosynostosis Syndromes and Potential Airway Compromise

Syndrome	Key Features	Tracheal Abnormalities	Midface Hypoplasia	OMIM
Apert syndrome[a]	Craniosynostosis (coronal > lambdoid > sagittal), acrobrachycephaly (steep, wide forehead and flat occiput), proptosis, hypertelorism, exotropia, trapezoid-shaped mouth, prognathism, invariable symmetric syndactyly of hands and feet, variable elbow fusion, cognitive impairment, narrow palate with lateral palatal swellings, widely patent sagittal suture connecting anterior and posterior fontanels	Tracheoesophageal fistula, tracheal cartilaginous sleeve less common	Significant maxillary hypoplasia, obstructive sleep apnea syndrome	101200
Crouzon syndrome[a]	Craniosynostosis (coronal > lambdoid > sagittal), brachycephaly, prognathism, exophthalmos, papilledema, hypermetropia, divergent strabismus, atresia of auditory canals, Chiari type 1 malformation and hydrocephalus	Solid cartilaginous trachea or tracheal cartilaginous sleeve	Significant maxillary hypoplasia, obstructive sleep apnea syndrome	123500, 612247
Pfeiffer syndrome types I, II, and III[a]	Craniosynostosis (coronal > sagittal > lambdoid), brachycephaly, hypertelorism, proptosis, broad first digits with radial deviation, variable syndactyly and elbow fusion, cloverleaf skull	Solid cartilaginous trachea or tracheal cartilaginous sleeve	Significant maxillary hypoplasia, obstructive sleep apnea syndrome	101600
Muenke syndrome	Unilateral or bilateral coronal craniosynostosis, brachydactyly, downslanting palpebral fissures, thimble-like middle phalanges, coned epiphysis, carpal and tarsal fusions, sensorineural hearing loss, Klippel-Feil anomaly		Mild maxillary hypoplasia, no airway compromise anticipated	602849
Saethre-Chotzen syndrome[a]	Unilateral or bilateral coronal craniosynostosis, acrocephaly, brachycephaly, low frontal hairline, hypertelorism, facial asymmetry, ptosis, characteristic ear (small pinna with a prominent crus), fifth finger clinodactyly, partial 2–3 syndactyly of the fingers, duplicated halluces		Maxillary hypoplasia	101400
Carpenter syndrome	Craniosynostosis (coronal > lambdoid > sagittal), hypertelorism, proptosis, brachycephaly, brachydactyly, preaxial polysyndactyly, intellectual disability		Maxillary hypoplasia	201000
Jackson–Weiss syndrome	Craniosynostosis (coronal), acrocephaly, hypertelorism, proptosis, midface hypoplasia, radiographic abnormalities of the foot including fusion of the tarsal and metatarsal bones, 2–3 syndactyly, broad short first metatarsals and broad proximal phalanges		Maxillary hypoplasia	123150

• **Fig. 88.1** (A) Infant with Robin sequence and significant micrognathia. (B) U-shaped cleft palate. (C) Infant with Robin sequence and a nasopharyngeal tube in place.

The principal physiologic sequelae of RS are the inability to effectively feed and breathe due to airway obstruction. In the immediate neonatal period, patients with RS may have increased inspiratory work of breathing, cyanosis, and apnea. Rising CO_2 levels may be a signal of worsening airway obstruction and often precedes hypoxemia in the neonate with RS.[6] Obstruction is more common in the supine position and can be exacerbated during feeding and in sleep or in any state where there is loss of pharyngeal tone. Chronic obstruction can lead to failure to thrive, carbon dioxide retention, pulmonary hypertension, and eventually right-sided heart failure (cor pulmonale). Airway exposure is often compromised in the infant with RS, which impacts the ability to safely intubate the neonate with RS.[7]

Airway obstruction is the main cause of feeding and growth issues in infants with RS. Feeding problems can also be related to abnormal coordination, primary swallowing dysfunction, pharyngeal hypotonia, and suction mechanics are complicated by the presence of a cleft palate. Increased energy expenditures because of the increased work of breathing may lead to failure to thrive if the infant is not receiving adequate caloric intake. Gastroesophageal reflux is common in infants with RS, as it is in other infants who have increased work of breathing, and may contribute to episodes of distress and aspiration or apnea.

Management

First and foremost, the airway must be addressed. Placement of a nasopharyngeal (NP) airway or endotracheal tube may be required in an emergency, and it is important to realize that severe, life-threatening airway obstruction can present in the delivery room. RS features are not commonly noted before birth; however, if microgathia or maternal polyhydramnios is a prenatal concern, there should be heightened suspicion for worse airway obstruction. Although uncommon, a prenatal diagnosis of micrognathia allows the involvement of neonatologists and otolaryngologists before and during delivery.

• Box 88.1 Key Members of a Multidisciplinary Craniofacial Team

These are the core members of the craniofacial team that follow a neonate through early adulthood. Each team has slightly different core and ancillary members, and frequently includes other specialists guided by patient-specific needs.

Typical Core Disciplines

- Audiology
- Dentistry
- Feeding and Nutrition Specialist
- Genetics
- Neurosurgery
- Nursing
- Oral Surgery
- Orthodontics
- Otolaryngology
- Pediatrics
- Plastics and Craniofacial Surgery
- Social Services
- Speech and Language Pathology

Other ancillary but important disciplines that are frequently consulted depending on specific patient needs: Child Life, Cardiology, Gastroenterology, Neurodevelopmental Medicine, Ophthalmology, Psychology, Pulmonology, and Sleep Medicine

Key members of the craniofacial team are shown in Box 88.1. Treatment protocols differ across institutions,[8] and an example of the initial evaluation and clinical team discussion for the neonate with tongue-based airway obstruction is provided in Box 88.2. While the threshold for intervention and the management options differ substantially, most neonates with RS can be treated nonsurgically. A number of therapeutic maneuvers can be used to stabilize

• Box 88.2 Evaluation and Decision Making for Neonates With Tongue-Based Airway Obstruction

Initial Evaluation in the Neonatal ICU

- Physical examination (supine vs. prone): attention to craniofacial features, respiratory status, cardiac and limb differences
- Evaluation for presence of glossoptosis, stertor, obstructive apnea, and work of breathing
- Capillary blood gas and total CO_2 level
- Oxygen saturation monitoring
- Growth parameters
- Dysmorphology evaluation
- Craniofacial and otolaryngology consultations
- Consider genetics evaluation if there are multiple anomalies or a concerning family history (micrognathia, cleft palate, childhood hearing loss/myopia/joint problems)
- Consider airway endoscopy (guided by airway severity and response to interventions)
- Consider airway imaging (guided by airway severity and response to interventions)

Multidisciplinary Team Treatment Discussions May Address

- Does the patient need escalation in care to treat airway obstruction?
- Have appropriate subspecialty consults and evaluations been obtained? (Varies by institution, but can include specialists with expertise in neonatal intensive care, craniofacial and pediatric care, airway evaluations, airway surgery, jaw surgery, parent/family support)
- Should the patient undergo CT imaging to assess the craniofacial bony anatomy, level(s) of airway obstruction, and candidacy for MDO (if so, when and how to proceed safely)?
- Has the distal part of the airway been evaluated to look for other levels of airway obstruction?
- Does the patient need a tracheostomy tube, or is he/she a candidate for mandibular distraction?
- What is the family and social context?
- What will the disposition be once airway has been stabilized?

CT, Computed tomography; *ICU*, intensive care unit; *MDO*, mandibular distraction osteogenesis.

the upper airway in RS, ranging from positioning to surgery. Placing the baby in the prone or lateral decubitus position can improve airway patency to some degree, and has the potential to decrease work of breathing.[9] When prone positioning fails to stabilize the airway, alternative approaches include the use of an NP airway, intraoral device such as the Tubingen palatal plate (TPP) or orthodontic airway plate (OAP), noninvasive positive pressure, treatment with tongue–lip adhesion (TLA), and mandibular advancement through distraction osteogenesis. An NP airway provides a temporary way to bypass the infant's airway obstruction (see Fig. 88.1C). An endotracheal tube can be modified so that it can be passed through the nares into the hypopharynx above the epiglottis, bypassing the obstruction at the base of the tongue.[10] The NP airway can be both diagnostic of isolated base of tongue level airway obstruction, and therapeutic, and in some institutions, the infant is discharged home with an NP airway in place.[11] Infants are monitored with oximetry, and parents are taught NP airway suctioning and replacement. The TPP or OAP is a newer therapy in the United States but well established in Europe. This intraoral device can bring the tongue forward to improve airway patency in neonates and infants, allow for full oral feeding, and safe discharge home. Airway compromise and stability are assessed by physical examination, CO_2 levels, oxygenation, overnight sleep studies, and growth, monitored over time.[12,13] While trending oxygen and CO_2 levels is considered the minimum assessments for RS,[14] some centers recommend sleep studies routinely to aid in decision making and to assess the success of interventions.[15] Improved infant normative sleep data, access to quality sleep studies, and understanding long-term outcomes will impact approaches to neonates at risk for early obstructive sleep apnea.

The infant's clinical status, a perceived need for long-term respiratory support, and failure of less invasive interventions will determine whether invasive surgery is recommended.[16] Tracheotomy is considered a gold standard to bypass severe tongue-based airway obstruction, and the preferred option for infants who are not candidates for less invasive treatments, for example, those with multilevel airway obstruction and those who need longer-term mechanical ventilation. However, other surgical interventions may avoid a tracheostomy tube.

Children with isolated airway obstruction at the base of the tongue without other medical comorbidities may be considered for mandibular distraction osteogenesis (MDO).[17,18] The surgery consists of surgical osteotomy and placement of a distraction device to slowly increase mandibular length and bring the base of the tongue forward, thereby increasing the airway space. This procedure will not achieve respiratory stabilization in patients with concomitant airway anomalies, lung disease, central apnea, or the need for positive pressure ventilation. In some institutions, TLA may be a temporizing measure to reduce base of tongue-level obstruction while allowing for mandibular growth.[19]

Airway endoscopy helps to delineate the level of obstruction, and computed tomography (CT) of the facial skeleton provides optimal understanding of jaw anatomy and tooth bud position before MDO. For many infants with RS needing an ICU, the patterns of obstruction are more complex. In addition to glossoptosis, other mechanisms may contribute to airway obstruction in individuals with RS, such as pharyngeal hypotonia and/or compromised airway clearance in the infant with a concomitant neurological disorder. Recognition of other causes of respiratory compromise, for example, poor secretion handling, laryngotracheomalacia, or ventilatory muscle weakness, affects treatment decisions. Children with RS associated with syndromes, skeletal dysplasia, or neurologic conditions may have multiple causes of respiratory compromise such that a tracheostomy may be the best approach to alleviate respiratory compromise. Thus infants with RS who have airway obstruction unresponsive to positional techniques for whom surgical options are being considered should have a comprehensive airway evaluation as well as a diagnostic evaluation for an underlying syndrome or associated malformations that might impact respiratory status and response to therapies. The multidisciplinary approach and considerations of all therapeutic options and potential outcomes should be considered for the neonate with RS requiring airway escalation.

Nutrition can be maintained with a fortified breast milk or formula given by side-lying feeding using a cleft feeder, or via a feeding tube; placement of a surgical gastrostomy tube is more common among infants with a syndromic form of RS.[20] Oral feeding can and should be introduced when the airway is stable, and consultation with a feeding therapist is crucial. As tone and tongue position improve, and growth ensues, swallow coordination and safe feeding can also improve. A formal swallow evaluation may be helpful for the infant with persistent feeding challenges. Close observation for symptoms of gastroesophageal reflux with proactive treatment to prevent reflux and aspiration should also be considered.

Genetics consultation is recommended, as identification of an associated syndrome will have implications for treatment decisions and additional screening.

Screening and Surveillance

Syndrome diagnoses may become more apparent over time, and reassessments investigating a unifying diagnosis should be continued as the child with RS grows.[21] Associated anomalies can impact respiratory function, including skeletal dysplasias. CNS anomalies and hypotonia will impact care needs and prognosis. Congenital heart defects are present in up to 25% of babies with RS who die in early infancy.[22] It has been reported that a portion of individuals with RS experience developmental delay, cognitive impairment, and poorer school achievement.[23] Overall morbidity and mortality are higher in syndromic RS, RS plus, and RS with associated neurological anomalies compared with isolated RS.[24] Diagnostic work-up should include investigation of common associated anomalies and syndromes.[25,26] Specific genetic and syndrome diagnosis will guide surveillance protocols, but for all infants and children with RS, we recommend:

- An eye exam in the first 6 months of life to evaluate for ocular features of Stickler syndrome
- Hearing assessment annually, more frequently if hearing loss is detected
- Close monitoring of development and referral to early intervention services for developmental assessment, monitoring, and support
- Monitoring for obstructive sleep apnea, with a low threshold for a sleep study referral
- Monitoring dental eruption, occlusion and facial growth over time; most children will benefit from orthodontic management, and some will be candidates for mandibular or bimaxillary advancement surgery in adolescence

• **Fig. 88.2** Infant with Stickler syndrome, showing a flat face, depressed nasal bridge, and epicanthal folds. This infant also has Robin sequence and required tracheostomy.

Stickler Syndrome

The most common syndrome associated with RS is Stickler syndrome (SS). Approximately one-third of individuals with RS will have Stickler syndrome.[21] Stickler syndrome is most commonly an autosomal dominant (with variable expressivity) connective tissue disorder with ophthalmic, orofacial, auditory, and articular manifestations.[27] SS may present with a wide range of findings, including RS, cleft palate without RS, hearing loss, or early onset osteoarthritis. Ocular forms of SS can present with congenital high myopia, cataracts, and risk for retinal detachment. Midface hypoplasia in SS can produce a flat and occasionally concave facial profile, and other facial features can include a depressed nasal bridge, short nose, anteverted nares, micrognathia, telecanthus, and epicanthal folds (Fig. 88.2). Hearing loss can be sensorineural with increasing prevalence with age (most common) with or without conductive hearing loss. Skeletal features associated with some forms of SS include early-onset arthritis, joint hypermobility, scoliosis, and kyphosis.[24,28]

The diagnosis of Stickler syndrome should be considered in any neonate with RS or a cleft palate, especially when associated with myopia or hearing loss. Spondyloepiphyseal dysplasia is not usually apparent in the newborn period. Mutations affecting multiple collagen genes have been associated with Stickler syndrome, and clinical molecular testing by sequence analysis is sensitive and available. More than 90% of individuals with Stickler syndrome are found to have a mutation in either *COL2A1* or *COL11A1*.[27] The diagnosis should also be considered in any newborn with a family history of RS or SS features.

In addition to appropriate management of feeding, breathing, and growth (as described for RS), management of Stickler syndrome includes active detection of the ocular features of the syndrome, as the associated risk of retinal detachment and blindness are preventable. An initial ophthalmologic evaluation is recommended for all children with RS aged between 6 and 12 months or at the time of a definitive molecular diagnosis of Stickler syndrome and then routine surveillance thereafter.

Orofacial Clefts

Orofacial clefts of the primary and secondary palate are among the most common congenital anomalies. Classified as either cleft lip with or without cleft palate (CL±P) or cleft palate only (CPO), these two phenotypes are thought to be distinct in origin. On an average day in the United States, 17 infants are born with an orofacial cleft,[29] and prevalence varies by phenotype (Table 88.3).

TABLE 88.3 Orofacial Clefting Prevalence and Relative Risk for Recurrence

Phenotype	Prevalence[29]	Babies Affected per Year in the United States[29]	Relative Risk for Recurrence for Offspring (%)[40]	Relative Risk for Recurrence for a Subsequent Sibling (%)[40]
Cleft lip with cleft palate	1 in every 1563 births	2518	4.1	4.6
Cleft lip without cleft palate	1 in every 2807 births	1402	3.5	2.2
Cleft palate	1 in every 1687 births	2333	4.2	3.3

Diagnosis and Etiology

Cleft lip and palate is the most common type of orofacial clefting, followed by cleft lip, then CPO. Less prevalent are atypical clefts (macrostomia or lateral cleft, Tessier or oblique, and midline clefts). Unilateral CL±P is more common than bilateral involvement.[1] A bifid uvula can be a normal variant, found in 2% to 4% of births, but can also be a sign of an associated submucous cleft palate, which can have the same functional impact as an overt CP.[30]

The causes of most orofacial clefts are unknown and are nonsyndromic (isolated) in 70% to 75% of infants with CL±P and approximately 55% of those with CPO.[31,32] Neonates with orofacial clefting who are born prematurely or have low birth weight may have a higher incidence of associated congenital malformations.[33] Racial and ethnic variation in the prevalence of clefts has been described. In the US, rates are closest to those of the area from which the population originated[34] with the highest prevalence of CL±P found in Native Americans, followed by whites and Hispanics, and the lowest overall prevalence of CL±P demonstrated in African Americans.[35] The cause of nonsyndromic clefts is complex and multifactorial, likely resulting from an interaction between environmental and genetic factors. Known environmental risk factors include maternal tobacco and alcohol use, anticonvulsant treatment, and nutritional status.[34,36] There is some evidence showing a protective association with preconception folate supplementation in preventing nonsyndromic orofacial clefts.[37–39] Although many candidate genes have been described, in the absence of a family history of cleft or lip pits, routine clinical genetic testing for a child with isolated CL±P is not recommended. Recurrence risk information for the parents of a child with CL±P or for the affected individual depends upon either the specific syndrome/genetic diagnosis or the empiric risks for those with nonsyndromic clefts. Recurrence risk for nonsyndromic clefts differs based on the cleft phenotype and the number of affected individuals in a family (see Table 88.3).[40]

Anatomy

Embryologic development of the primary palate begins early in gestation, and the upper lip and primary palate have usually fused by the seventh week of gestation. A failure of fusion of the medial and lateral nasal processes with the maxillary process produces CL±P. Clefts can affect the primary palate (lip, alveolus, or anterior portion of the hard palate that extends to the incisive foramen) and secondary palate (posterior hard palate and soft palate). Clefts of the primary and secondary palate can be unilateral or bilateral and complete or incomplete. A complete cleft of the primary palate leaves no residual tissue between the alar base and the lip, whereas an incomplete cleft does not extend through the floor of the nose (Fig. 88.3A–C, F). A submucous cleft palate is a defect in the musculature of the palate with intact overlying mucosa.

Phenotype

The cleft of the primary and secondary palate affects facial shape and growth (see Fig. 88.3A–C). Children with cleft palate (CP) are at increased risk of eustachian tube dysfunction, recurrent otitis media, acquired hearing loss, as well as speech issues in childhood. Feeding difficulties, nasal regurgitation of feeds, and difficulty gaining weight may also occur in infants with a CP (submucous and overt clefts of the palate). Associated dental findings include hypodontia and natal teeth.

Lateral facial clefting or macrostomia is pathogenically distinct from isolated CL±P and is often associated with syndromes, including craniofacial microsomia and Treacher Collins syndrome. Amniotic rupture sequence can be associated with oblique facial clefts and may be associated with underlying central nervous system (CNS) malformations and transverse limb anomalies.

A true median cleft of the upper lip is the rarest type of facial cleft (see Fig. 88.3D). Midline clefts can be associated with other congenital defects as can be seen in orofaciodigital syndrome and frontonasal dysplasia, and CNS malformations are common in

• **Fig. 88.3** (A) Infant with a unilateral incomplete cleft lip. (B, C) Infant with bilateral complete cleft lip and palate. (D) Infant with midline cleft and hypertelorism. He also has a frontonasal encephalocele. (E) Infant with premaxillary agenesis and holoprosencephaly. (F) Infant with Van der Woude syndrome with unilateral complete cleft lip and a lip pit (*arrow*).

children with midline clefts. Some midline clefts are not true clefts but represent hypoplasia or agenesis of the primary palate or premaxillary agenesis, which can be associated with holoprosencephaly (HPE) sequence (see Fig. 88.3E). Infants with HPE often have a depressed nasal tip and a short columella and appear hypoteloric (compared with FND or frontonasal encephalocele, where a midline cleft may be present, but the infant has a broad nasal tip, wide columella and hypertelorism).

Orofacial clefts are rarely associated with clefting of airway structures, such as cleft larynx or extension of clefting into the trachea. Opitz G/BBB syndrome is a multiple congenital anomaly syndrome characterized by facial anomalies (100% are hypertelorics and 50% have CL±P), genitourinary abnormalities (90% have hypospadias), and laryngotracheoesophageal (LTE) defects (present in 70%).[41] Autosomal dominant and X-linked recessive forms of Opitz G/BBB syndrome are recognized. Pallister–Hall syndrome (PHS) is characterized by a constellation of findings that include hypothalamic hamartoma (resulting in seizures and pituitary dysfunction), polydactyly, airway clefting, and other anomalies (genitourinary, renal, pulmonary, and imperforate anus). Bifid epiglottis is the most common airway manifestation in PHS, although LTE clefts have been reported. LTE defects may range from LTE dysmotility in mild forms to laryngeal or tracheoesophageal clefts in more severe forms.

Syndromes Associated With Cleft Lip and/or Palate

It is estimated that there are more than 400 syndromes associated with orofacial clefts.[22] Associated malformations occur in about 30% of children with CL±P.[42] In considering a diagnosis of a syndrome, one should categorize the type of cleft (CL±P, U-shaped or V-shaped cleft palate, or more atypical orofacial cleft) and look for any other malformations. Table 88.1 describes the syndromes most commonly associated with clefting, their key features, and potential ICU issues. A referral to a clinical geneticist is recommended when an underlying diagnosis is suspected.

Intensive Care Unit Concerns

Most infants with CL±P do not require ICU care. Thus an infant with an apparently isolated cleft who develops significant respiratory or electrolyte abnormalities requiring ICU care should be considered syndromic until proven otherwise. In these infants, a genetics consultation should be pursued.

The newborn with a midline cleft or premaxillary agenesis is at risk of serious underlying CNS anomalies, including HPE. In the presence of HPE, the detection of associated medical issues is essential. Endocrine abnormalities can arise because the midline malformation affects the development of the hypothalamus and the pituitary gland. Clinical manifestations include growth hormone deficiency, adrenal hypoplasia, hypogonadism, diabetes insipidus, and thyroid deficiency. Neurologic manifestations warrant close attention, including seizures, hypotonia, spasticity, autonomic dysfunction, and developmental delays.

With an LTE cleft, there is communication between the airway and the esophagus, allowing tracheal aspiration of oral contents, including saliva and feeds. Clefting of the larynx may result in stridor, a hoarse cry, respiratory distress, swallowing dysfunction, feeding difficulties, regurgitation, aspiration, hypoxia, recurrent pneumonias, and eventually severe respiratory compromise if unrecognized. An infant boy with hypertelorism, hypospadias, orofacial clefting, and symptoms of airway obstruction or aspiration should be evaluated for Opitz syndrome. Infants with PHS may also have respiratory distress due to airway clefting, as well as other potentially life-threatening clinical manifestations such as seizures and severe panhypopituitarism. Genetic evaluation and consideration of molecular testing for Opitz syndrome and PHS can be coordinated through a geneticist.

Management

The specifics of management of orofacial clefting are center-specific. Because of the potential impact of the orofacial cleft on breathing, eating, hearing, speech, facial growth, and dental health, it is recommended that infants and children with clefts be referred to a multidisciplinary care team for long-term management. Infants cared for with a multidisciplinary cleft or craniofacial team have better long-term functional and aesthetic outcomes.[42] The nearest cleft team may be found through the American Cleft Palate-Craniofacial Association (ACPA) team listings. Overviews of recommended team care for patients with cleft lip/palate can be accessed electronically.[43,44]

On the initial assessment, the provider should assess the cleft and examine the infant for dysmorphic features and other anomalies. Hearing should be evaluated by evoked otoacoustic emissions or by brainstem auditory evoked response if the newborn does not pass the initial hearing screen.[45] Although this finding is often attributed to middle ear effusion because of the high prevalence of middle ear disease in children with CP, the incidences of sensorineural hearing loss, conductive hearing loss, and mixed hearing loss are higher in children with clefts.[46] A neonate with a complete cleft lip should be evaluated by a craniofacial or cleft team in the first 2 weeks of life, and some centers offer taping or presurgical molding (such as nasoalveolar molding) that can be initiated in early infancy. Many mothers will be able to breastfeed an infant born with an isolated cleft lip. Breastfeeding a baby with CP (with or without cleft lip) will prove extremely challenging because the open palate will not generate the negative pressure needed for sucking. Thus the mother of infants with CP with or without cleft lip should be encouraged to provide expressed breast milk with the use of a specialized cleft feeder. Lactation counselor support should be offered to all mothers to discuss feeding at the breast or pumping to provide expressed breast milk to the infant. A variety of cleft nipples/bottles exist to allow oral feeding (http://www.cleftline.org/who-we-are/what-we-do/feeding-your-baby/). There are assisted milk delivery systems such as the Medela special needs feeder (formerly known as the Haberman) and the Mead Johnson squeeze bottle. There are also infant-driven systems, such as the Dr. Brown's specialty feeding system (with valve and varied nipple sizes allowing flow variation) and the Pigeon system. Infants with CP tend to swallow more air during feedings and should feed in an upright position, as gravity will help prevent nasal regurgitation. If the child is still having difficulty feeding safely or efficiently, a feeding therapist should be consulted. If a feeding specialist is not available, a lactation counselor or the nearest ACPA Cleft/Craniofacial team's nurse coordinator can be an additional helpful resource for feeding support.

Adequate weight gain is important for overall health, development, and readiness for the surgical procedures that occur in the first year of life. Newborns with clefts are considered nutritionally high risk, but a child with an isolated orofacial cleft should be expected to follow typical growth charts. Infants with suboptimal weight gain may require additional nutrition support from a

dietitian to help determine caloric needs and to closely monitor growth.

Surgical timelines and approach differ between teams but often span from infancy into early adulthood. In general, surgery to repair the cleft lip and associated nasal deformity occurs within the first 6 months of life. Palatoplasty typically occurs between 9 and 12 months of age with the primary goal to normalize palate muscle function to facilitate normal speech development.

Newborns with orofacial clefting should have a follow-up with their primary care pediatrician and be evaluated by a cleft/craniofacial specialist as soon as possible after discharge from the birth and NICU hospitalization, ideally within 1 week from discharge.

Screening and Surveillance

Routine screening laboratory and imaging studies are not typically recommended in the neonate with an isolated cleft. For children with syndromes, surveillance is guided by syndrome-specific protocols, with some special considerations noted here:

- Although rare, airway or laryngeal clefts can cause respiratory distress, coughing, choking, stridor, recurrent croup, and recurrent aspiration. Recommended evaluations include a clinical swallow evaluation, videofluoroscopy, functional endoscopic evaluation of swallow, and the gold standard for diagnosis is microlaryngoscopy and bronchoscopy. Given the risk of gastrointestinal manifestations such as gastroesophageal reflux, dysmotility, and aspiration, anti-reflux precautions should be initiated in infants with suspected or confirmed LTE defects. Early diagnosis and proper repair of the laryngeal cleft are essential to prevent injury to the lungs. Significant LTE defects will need to be managed surgically,[47] and tracheostomy may be necessary initially to ensure airway stability and safety.
- In the presence of a midline cleft, it is important to evaluate the neonate for underlying CNS malformations such as HPE. In any child with a midline cleft or facial features consistent with premaxillary agenesis/hypoplasia, CNS imaging (CT or MRI) is recommended. Consultation with a geneticist or genetic counselor may provide insight into the genetics, molecular testing options, and recurrence risk of HPE. Treatment of HPE is supportive and based on symptoms. The outcome depends on the severity of HPE and the associated medical and neurologic manifestations.

22q11.2 Deletion Syndrome

Diagnosis and Etiology

22q11.2 deletion syndrome (22q11.2DS) is the most common microdeletion syndrome, with an estimated prevalence of 1 in 4000 births, in which affected individuals are missing a region (typically 3 Mb, encompassing approximately 40 genes) on one copy of chromosome 22.[48,49] 22q11.2DS is associated with more than 180 clinical features, and phenotypic variation is a hallmark of this genetic condition.[49] In some cases, this condition is diagnosed prenatally. Testing may occur as part of the evaluation for fetuses with congenital heart disease or because of a parental history of 22q11.2DS. The clinical indications for genetic testing for this condition in neonates include congenital heart malformations (particularly conotruncal anomalies), hypocalcemia, dysphagia, CP, other palatal dysfunction (e.g., submucous CP, velopharyngeal insufficiency with intact palate), and immunodeficiency identified on newborn screening or by noting thymic hypo-/aplasia, such as during heart surgery.[50] Overt CP is less common than submucous CP and velopharyngeal insufficiency; genetic testing is more definitively indicated for CP when other features associated with 22q11.2DS are also observed.

Phenotype

22q11.2DS commonly presents with multiorgan system involvement, including cardiac and palatal abnormalities, immune differences, endocrine and gastrointestinal problems, developmental delay, and later-onset conditions across the life span, including variable cognitive deficits and psychiatric illness.

Several craniofacial features have been observed in individuals with 22q11.2DS; however, many of these are subtle and may not be apparent in the newborn period. Common features identified include small ears with overfolded helices, a long face, tubular conformation of the nose, nasal alar hypoplasia, and hooded eyelids.[50] In neonates, some of the most indicative findings include dysphagia and/or nasal regurgitation (including in the absence of an overt CP, due to palatal dysfunction), congenital heart disease, and hypocalcemia.

Intensive Care Unit Concerns

About two thirds of patients with 22q11.2DS have congenital heart disease, sometimes severe, which often leads to prolonged neonatal hospital stays. If a seizure occurs in the neonatal period, especially in the setting of known congenital heart disease, 22q11.2DS and hypocalcemia should be strongly suspected. Hypocalcemia is most common in the newborn period and is triggered by physiologic stressors (e.g., peripartum period, surgery, infection). Importantly, hypocalcemia and neonatal seizures caused by it have been linked with worse intellectual outcomes for patients.[51] Feeding challenges can be due to cleft palate, palatal dysfunction, and dysphagia. Rarely, severe immunodeficiency can be present, increasing the risk for serious infections. It can be identified on newborn screening for T-cell receptor excision circles (TRECs).[52] About one-third of patients with 22q11.2DS have structural urinary tract abnormalities. Cervical spine anomalies can occur; routine screening in infancy is not recommended, but neonates should be monitored for symptoms of cord compression and cervical spine instability.[48] In addition, infants with 22q11.2DS often have airway obstruction, most commonly due to tracheomalacia, subglottic stenosis, laryngomalacia, glottic web, and bronchomalacia; this is most commonly observed in patients who also have congenital heart disease.[53]

Management

Chest x-ray, EKG, echocardiogram, and cardiology consultation should be pursued in suspected and confirmed cases of this condition, and 22q11.2 deletion testing should be considered in cases of confirmed congenital heart disease.[54] Calcium and parathyroid levels should be checked, as the neonatal period is the most common time for hypoparathyroidism to present itself.[48,51] A complete blood count, screening for leukopenia and thrombocytopenia, and flow cytometry for T and B cells should be obtained. An immunologist should be consulted if any concern arises for abnormalities in these studies, newborn screening, or clinical suspicion of hypo- or athymia. Renal ultrasonography should be obtained for all suspected and confirmed cases.[48] Newborns should have a palatal examination to evaluate for overt or submucous CP, as

well as a diagnostic hearing test. Infants with evidence of dysphagia, regardless of the presence/absence of CP, benefit from an evaluation by a feeding therapist to determine if a swallow study is needed and/or if other feeding interventions, such as the introduction of a specialized cleft feeder, would be helpful. Families of infants diagnosed with 22q11.2DS should receive genetic counseling. Ophthalmology evaluation is warranted for all confirmed diagnoses, as well. Thyroid function should be assessed with newborn screening.

Screening and Surveillance

Long term, children with 22q11.2DS benefit from a multi-disciplinary team, often including pediatrics, cardiology, immunology, behavioral health, psychiatry, feeding therapy, speech, social work, nursing, audiology, and endocrinology. In addition, other subspecialties may need to be involved, depending on which chronic issues are present, such as constipation, urologic abnormalities, cervical spine instability, and scoliosis. Some children's hospitals and academic health centers include dedicated 22q11.2DS clinics. Many infants and toddlers with 22q11.2DS have persistent dysphagia and swallowing problems, and it is not uncommon for them to depend on supplemental tube feedings for months or years. As they get older, medical issues often stabilize, and the focus shifts to understanding and supporting learning differences, behavioral health, and mental health. Older children and young adults are at an increased risk for psychiatric disorders, including depression, anxiety, ADHD, and schizophrenia.

Craniosynostosis

Diagnosis and Etiology

Craniosynostosis refers to the premature fusion of one or more cranial sutures (metopic, sagittal, right or left coronal, right or left lambdoid) that normally separate the bony plates of the cranium. The birth prevalence of all craniosynostoses has been estimated at 1 in 2500 live births, with shifting epidemiology and a more recent study estimating an increase of prevalence to 1 in 1400 live births.[55,56]

Typically, patent sutures allow the calvaria to expand as the brain grows, producing a normal head shape and size. If one or more sutures fuse prematurely, this typically happens prenatally, and there is restricted growth perpendicular to the fused sutures and compensatory growth in the patent sutures, producing a progressively abnormal head shape.[57] Physical exam by an experienced craniofacial provider can be sufficient for the diagnosis, and a CT scan is typically needed to confirm the extent of synostosis and for surgical planning. Plain skull radiographs in neonates are unreliable and not helpful.[58] Craniosynostosis is a heterogeneous disorder with health consequences that range from an abnormal head shape and increased intracranial pressure (ICP) to secondary visual and intellectual impairments.

The causes of craniosynostosis are heterogeneous, with monogenic, chromosomal, polygenic, and environmental/teratogenic factors all playing key roles. A genetic diagnosis can currently be identified in 25% of individuals with craniosynostosis. Nonsyndromic single suture craniosynostosis accounts for 65% of patients.[59] Syndromic craniosynostosis may involve single or multiple fused sutures, additional anomalies (such as limb, cardiac, CNS, and tracheal malformations), and developmental delay. Multiple suture involvement is usually considered hereditary even when it does not fit a classic pattern of anomalies. Advances in high-throughput DNA sequencing have led to the identification of causative variants and genetic pathways in these relatively common congenital anomalies.[60,61] Our understanding of the genetic causes of craniosynostosis is increasing, and for the growing proportion of syndromic forms, identification of the primary genetic cause is possible with the use of clinically available genetic tests.

Single Suture Synostosis

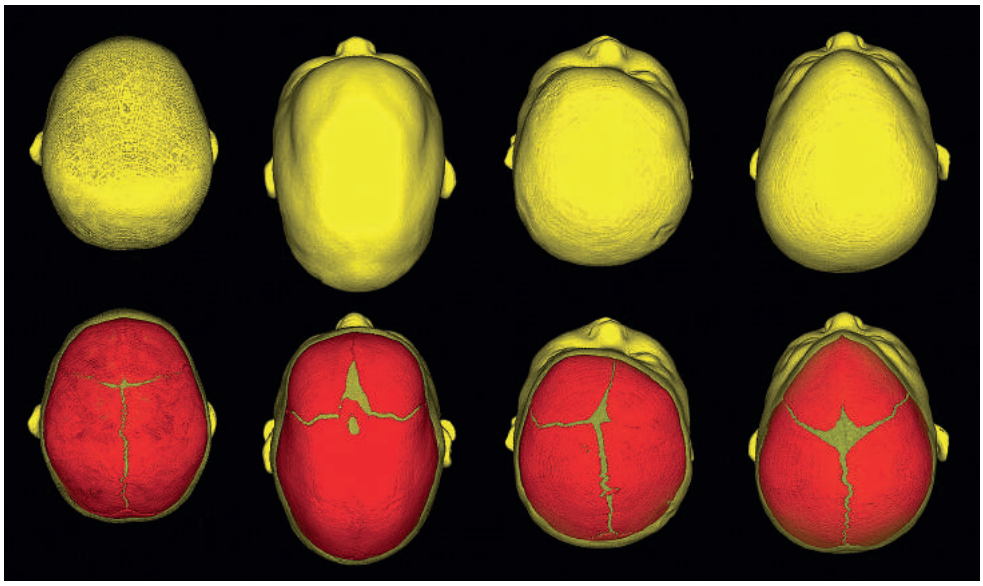
There is a concern that children with untreated single suture synostosis are at risk for elevated ICP, local brain injury, and later developmental delays. For this reason, early recognition and referral are thought to be key to devising optimal treatment plans to protect the developing brain.[62]

Sagittal synostosis is the most common single suture synostosis (approximately 60%).[63] Known risk factors include male sex, intrauterine head constraint, twin gestation, maternal thyroid hormone dysregulation, and maternal smoking. Uncommon but reported associated anomalies include congenital heart defects and genitourinary tract malformations. Syndromes with synostosis involving only the sagittal suture are rare. Premature union of the sagittal suture hinders normal calvarial expansion, leading to scaphocephaly, an elongated, narrow calvarium, decreased biparietal width, frontal bossing, and occipital elongation (Fig. 88.4). Premature fusion of the suture before birth leads to abnormal head shape in the newborn period. A breech-positioned neonate can have dolichocephaly that may mimic sagittal synostosis. However, in sagittal synostosis, frontal bossing and biparietal narrowing progress, whereas the head shape in a breech-positioned infant will begin to normalize in the first months of life.

Metopic synostosis has become increasingly common, representing approximately 20% to 30% of single suture synostosis. Risk factors include male sex, twin gestation, and in-utero exposure to valproate.[64] Syndromes, associated anomalies, and chromosomal abnormalities occur in approximately one-quarter of individuals with metopic synostosis.[65,66] Premature fusion of the metopic suture results in a triangular head shape, or trigonocephaly, and additional features including a midline forehead ridge, frontotemporal narrowing, pterion constriction, hypotelorism, and an increased biparietal diameter (see Fig. 88.4). Isolated metopic ridging is common in infancy, does not distort forehead shape, and is not associated with metopic synostosis.

Coronal synostosis represents about 10% to 20% of single suture synostosis and presents with anterior plagiocephaly. Recognizable skull differences in unicoronal craniosynostosis include a flat supraorbital rim and orbit that appears higher on the affected side, with a frontal bulge on the contralateral side (see Fig. 88.4). In addition to orbital and frontal asymmetry, the nose often twists away from the coronal fusion. Genetic syndromes are more frequently seen in individuals with coronal synostosis, including Saethre-Chotzen syndrome, Muenke syndrome, and craniofrontonasal dysplasia. All families of children with coronal synostosis should be offered genetic consultation and/or genetic testing to include *FGFR2, FGFR3, TWIST1*, *TCF12*, and *EFNB1* on the basis of clinical examination.

Lambdoid synostosis (1% to 3% of single suture craniosynostosis) is the least common form of single suture synostosis. It is characterized by flattening of the ipsilateral occiput, posterior–inferior displacement of the ear, bulge of the mastoid process on the fused side, a skull base tilted downward on the affected side, and may exhibit facial scoliosis or asymmetry. This head shape is



• **Fig. 88.4** Head shapes in single suture synostosis. *From left to right:* normal head shape, sagittal synostosis, right coronal synostosis, and metopic synostosis.

often confused with positional deformational plagiocephaly, but skull base tilt and vertical ear displacement should not be present in positional plagiocephaly.

Multiple Suture Synostosis

Multiple suture (or *multisuture*) *synostosis* describes patients who have two or more fused sutures. Although children with multisuture synostosis are more likely to have a known syndromic form of craniosynostosis such as Apert, Crouzon, Pfeiffer, or Muenke syndromes, some have chromosome aberrations or patterns of craniosynostosis with associated anomalies not previously described. With 20 known hereditary forms of craniosynostosis, genetic consultation and counseling are of critical importance in the management of these conditions.[60,61,67] Discussed in this section are select major syndromes with craniosynostosis that may have medical issues in the newborn period. See Table 88.2 for a description of key phenotypic features and potential airway compromise.

Apert syndrome was initially described as acrocephaly with four-limb syndactyly. The symmetric hand and foot involvement with syndactyly and symphalangism is an important clue to the diagnosis (Fig. 88.5). Inheritance is autosomal dominant and Apert is associated with advanced paternal age. Neurocognitive outcomes vary, but a moderate to severe degree of cognitive impairment is most common. Multiple mutations in *FGFR2* causing Apert syndrome have been identified.[68]

Crouzon syndrome is an autosomal dominant condition that demonstrates wide phenotypic variability. Shallow orbits with proptosis are an important diagnostic finding, although this feature may be subtler in the newborn (Fig. 88.6). Significant abnormalities involving the CNS include the frequent presence of a Chiari type 1 malformation, with progressive hydrocephalus and risk for intracranial hypertension. Compared with Apert syndrome, Crouzon syndrome is associated with more extensive suture involvement, smaller cranial volume, and more severe intracranial constraint; however, cognitive development is usually normal. Like Apert syndrome, Crouzon syndrome is caused by mutations in *FGFR2*. A less common form of Crouzon syndrome with acanthosis nigricans skin findings developing in the first 2 years of life is caused by a transmembrane mutation in *FGFR3*.

Pfeiffer syndrome is a hereditary craniosynostosis that shares significant overlap, both phenotypically and genetically, with Crouzon syndrome. It is an autosomal dominant disorder with craniosynostosis accompanied by proptosis, broad and deviated thumbs, and large first toes (Fig. 88.7). Mutations in *FGFR1* and *FGFR2* cause Pfeiffer syndrome. Type 1 Pfeiffer syndrome involves mild manifestations including brachycephaly, midface hypoplasia, and digital malformations. Type 2 consists of cloverleaf skull, extreme proptosis, digital malformations, elbow ankylosis, developmental delay, and neurologic complications. Type 3 is similar to type 2 but without a cloverleaf skull. CNS and spine anomalies are common in Pfeiffer syndrome.[69]

Muenke syndrome is an autosomal dominant syndrome caused by a single P250R mutation in the *FGFR3* gene. Like Apert syndrome, Muenke syndrome is associated with advanced paternal age. Individuals with Muenke syndrome may have coronal craniosynostosis (unilateral or bilateral), macrocephaly, variable degrees of proptosis, a high prevalence of sensorineural hearing loss, and do not typically have significant midface hypoplasia (Fig. 88.8).

Saethre-Chotzen syndrome is caused by a mutation in the *TWIST1* gene on chromosome 7. The inheritance is autosomal dominant, and many children with Saethre-Chotzen syndrome will have an affected parent. In addition to craniosynostosis, affected individuals commonly have a low frontal hairline, ptosis, 2 to 3 syndactyly of the fingers, cervical spine anomalies, and duplicated halluces. Although learning difficulties may be noted, cognitive impairment is not typical of Saethre-Chotzen syndrome caused by intragenic mutations. Children with deletions rather than point mutations often demonstrate significant developmental delays.

ERF-related craniosynostosis is a recently recognized syndromic form of craniosynostosis caused by variants in the *ERF* gene.[70] The multisutural involvement varies, including pansynostosis and a pattern involving the sagittal and lambdoid sutures (Mercedes-Benz pattern), and can be postnatal in onset with insidious and progressive effects on head shape and unsuspected

• **Fig. 88.6** (A) Infant with Crouzon syndrome with acro brachycephaly. (B) Proptosis and midface retrusion are seen in the lateral view.

• **Fig. 88.7** (A, B) Infant with Pfeiffer syndrome, brachycephaly, a high forehead, midface hypoplasia, proptosis, and ocular hypertelorism. (C) An older child with Pfeiffer syndrome and the typical broad thumbs with radial deviation.

• **Fig. 88.8** (A, B) Infant with Muenke syndrome, acrobrachycephaly due to bicoronal synostosis, and absence of proptosis. (C) Sibling of the infant in (A, B) also with Muenke syndrome; note the downslanting palpebral fissures.

intracranial hypertension. Facial features include hypertelorism, mild exorbitism, and malar hypoplasia. Chiari malformation and developmental concerns are common.

Cloverleaf skull can result from any form of multisuture craniosynostosis. The skull forms a trilobular appearance, as the cerebrum bulges through the sagittal and squamosal sutures, because of craniosynostosis affecting the coronal, metopic, and lambdoid sutures. Cloverleaf skull is most commonly associated with a syndrome, and it is estimated that up to 20% of cases represent Pfeiffer syndrome.

Intensive Care Unit Concerns

The most significant concerns for the newborn with craniosynostosis are airway compromise due to upper airway obstruction and intracranial hypertension.

Midface hypoplasia and tracheal anomalies that may be present in syndromic craniosynostosis can lead to significant airway compromise (see Table 88.2). With midface hypoplasia, there is decreased nasal and oropharyngeal space because of a small maxilla, narrowing at the level of the posterior choanae, and posterior displacement of bony and soft tissue structures, leading to breathing problems, obstructive sleep apnea, asphyxia, and even death (Fig. 88.9). Obstructive sleep apnea is common in Apert, Pfeiffer, and Crouzon syndromes.

Cartilaginous tracheal abnormalities can be present in multisuture craniosynostosis syndromes. Vertically fused tracheal cartilage (also referred to as tracheal cartilaginous sleeve, solid cartilaginous trachea, and stovepipe trachea) in Crouzon and Pfeiffer syndromes may produce a rigid trachea resulting in upper airway stenosis, inability to clear secretions, and increased risk of injury because of decreased distensibility. Characteristic tracheal cartilaginous rings are fused to form a continuous sleeve of cartilage, which may extend from below the subglottis to the carina or bronchus; rarely, the cartilaginous sleeve can begin more proximally, at the level of the cricoid cartilage. Infants with congenital tracheal anomalies may have stridor, increased work of breathing, and distress, particularly with respiratory illnesses.

Neurologic abnormalities such as hydrocephalus and increased ICP may arise, especially in multisuture craniosynostosis. Increased ICP due to constraint of the growing brain within a restricted calvarium is usually chronic, causing symptomatic intracranial hypertension when brain growth is rapid during the first 2 years of life. ICP issues in the neonate are not usually life threatening, given the open fontanel and compensatory splaying of normal sutures or erosion of the calvarium, but brain injury and encephalomalacia may result if cranial expansion is not performed.

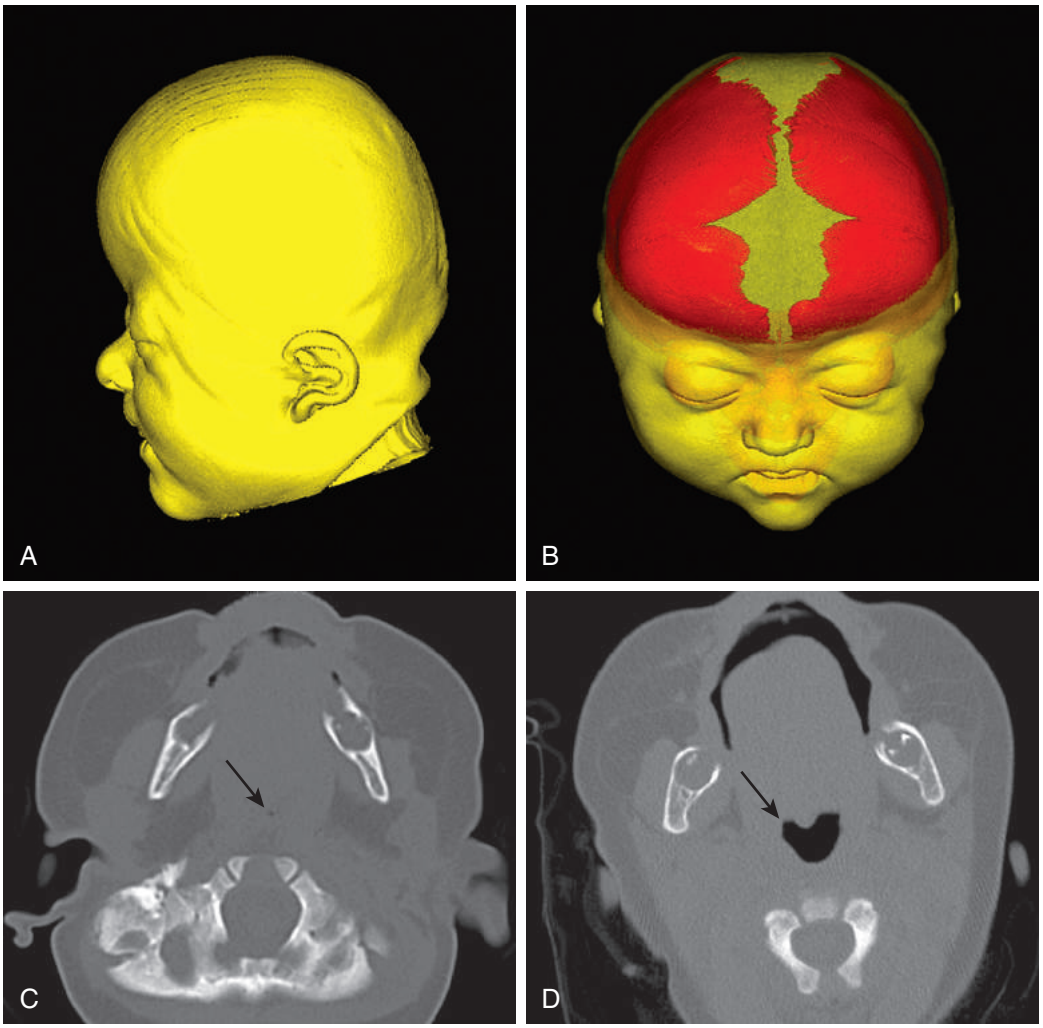
Hydrocephalus, which is more common in Crouzon and Pfeiffer syndromes compared with other multisuture synostosis syndromes, can occur as a result of obstruction of cerebrospinal fluid at the basal cistern, aqueductal stenosis, or impeded venous flow or when there is an associated Chiari malformation. Hydrocephalus is extremely common in cloverleaf skull. Individuals with multisuture craniosynostosis (particularly Apert syndrome) more commonly have nonprogressive distortion ventriculomegaly or compensated hydrocephalus, which does not require shunting.[71] Abnormalities of the corpus callosum and septum pellucidum have been described in Apert syndrome, and neuroimaging and genetic advances will illustrate links between brain architecture, phenotype, and genotype.[72] Seizures presenting in multisuture craniosynostosis syndromes are more commonly due to encephalopathy rather than increased ICP.

Chiari malformation is frequently diagnosed in syndromic craniosynostosis. Cerebellar tonsillar herniation, especially in the setting of cord compression, can affect control of breathing and lead to central sleep apnea, ranging from mild to profound. Treatment of airway obstruction can unmask central apnea and continued monitoring for apnea over time is necessary in syndromic craniosynostosis.

Management

The evaluation of the patient with craniosynostosis includes recognizing and confirming the type of suture fusion, clinical syndrome identification, evaluation for associated anomalies, and preparedness for surgical repair.

A detailed physical examination should be performed as part of the initial evaluation, looking for any other anomalies, with specific attention to cleft palate, limb defects, heart defects, and ear anomalies. The assessment of cranial and face shape, the fontanelles, presence of sutural ridging, skull base symmetry, and ear position is important. Proptosis and exorbitism due to shallow orbits are important to recognize as exposure keratopathy is the major etiology of corneal pathology encountered in multisuture craniosynostosis, and ophthalmology involvement early can be vision sparing. If proptosis is present, as can occur in Apert, Crouzon, and Pfeiffer syndromes, ocular lubricants help to prevent exposure keratopathy. Although rare, severe proptosis can lead to globe luxation and may need surgical intervention such as tarsorrhaphy, in addition to eye surface lubrication,



• **Fig. 88.9** (A, B) Three-dimensional reconstruction of a child with Apert syndrome with significant midface hypoplasia, leading to upper airway obstruction. Also notable is acrobrachycephaly due to bicoronal synostosis and the typical pattern of sagittal suture patency. (D) CT scan of a newborn illustrating a normal airway (*arrow*).

to preserve eye health. During the neonatal period and as a child grows, an ophthalmologist with experience in craniosynostosis is recommended.[73]

CT with three-dimensional reconstruction will ultimately confirm the diagnosis of craniosynostosis, delineate the degree of suture involvement, and help with preoperative planning. Although the specific timing of the surgical treatment may differ between teams, it is generally accepted that individuals with synostosis should undergo cranial surgery in the first year of life. Cranioplasty involves the release of fused sutures and repositioning and reconstruction of the calvaria to expand the skull to prevent increased ICP and progressive abnormal craniofacial development. Several techniques, including endoscopic strip craniectomy, calvarial distraction, and traditional cranioplasty, are currently used. Consultation with a craniofacial team should be initiated when craniosynostosis is suspected, as the timing of some surgical interventions are performed in the first few days or weeks of life. A comprehensive guideline has been recently updated by Mathijssen in 2021.[74]

Attention to facial shape, especially the degree of maxillary hypoplasia, is important in determining the risk of airway compromise due to midface hypoplasia. If concerning airway symptoms are present, such as snoring, stridor, or apnea, consultation with a sleep specialist and polysomnography may help to quantify the presence and severity of early obstructive sleep apnea, and identify perhaps more subtle central apnea and the need for positive pressure ventilation. Awareness of potential airway compromise and proactive airway management are crucial in many craniosynostosis syndromes. Temporizing measures to bypass airway obstruction include placement of nasal stents, endotracheal intubation, and tracheotomy. Specific airway management in syndromic craniosynostosis will depend on the level and severity of obstruction. Consultation with an otolaryngologist and airway endoscopy to identify the types and degree of airway narrowing is essential in infants with multisuture craniosynostosis and airway obstruction. Particular attention to the presence of tracheal malformations, such as vertically fused tracheal cartilage, is crucial in craniosynostosis syndrome as early recognition of tracheal malformations

can be lifesaving.[75] With the increased awareness of this condition, the diagnosis of tracheal malformations is increasingly made on direct laryngoscopy/bronchoscopy or with MRI, and ultrasound is an emerging tool.[76] Infants with tracheal anomalies benefit from skilled complex airway management that may include airway surgery or even tracheotomy with custom airways to achieve airway patency and prevent mortality in infancy.[77] Serious caution must be exercised in the placement and care of tracheostomies in patients with tracheal cartilaginous sleeves because of unique airway shape, abnormal tissue healing, and granulation tissue formation. Midface advancement surgery may be necessary for some children who have nasal level airway obstruction, swallowing, feeding, and dental malocclusion. This is usually performed later in childhood.

The family and prenatal history, including documentation of affected family members, teratogen exposure, maternal thyroid disease, and in utero constraint (oligohydramnios, twins, fetal movement), and the birth history should be ascertained, specifically looking for risk factors.

For all individuals with craniosynostosis, we recommend the early involvement of a craniofacial team including members specializing in pediatrics, genetics, neurosurgery, ophthalmology, oral surgery, orthodontics, otolaryngology, nursing, nutrition, plastic surgery, and social work.[78] Prenatal involvement of craniofacial and airway specialists is especially critical for planning the safe delivery and post-partum care when multisuture craniosynostosis is anticipated.

Screening and Surveillance

Many genetic causes of craniosynostosis require screening for additional health characteristics as well as complications. Accurate and prompt diagnosis requires a combination of careful clinical evaluation and correctly targeted diagnostic testing, proceeding to exome/whole genome sequencing if necessary.[59] The role of the geneticist in understanding the causes of single suture craniosynostosis is evolving. The families of children with multisuture synostosis with the presence or absence of associated syndrome should be offered appropriate genetic consultation, molecular testing, genetic counseling, and surveillance monitoring guided by the unique genotype.[79] Below are some important considerations:

- CNS: In all children with craniosynostosis, and particularly in those with multisuture involvement, it is important to monitor for any signs or symptoms of increased ICP. Evaluation for hydrocephalus should be a part of the initial assessment of all children with multisuture craniosynostosis. Ventriculomegaly may be identified by the initial diagnostic head CT, and follow-up imaging should be pursued if any acceleration in OFC or bulging fontanelle is noted. MRI of the brain may be helpful in defining any associated CNS anomalies, and screening for Chiari malformation is recommended for children with multisuture craniosynostosis, or craniosynostosis with Chiari symptoms.
- Spine: In coronal synostosis and syndromes including Apert, Crouzon, Pfeiffer, and Saethre-Chotzen, associated vertebral anomalies, including fusions and instability, may be present, detected on spine radiographs, and more accurately visualized with CT C-spine imaging that can be coordinated with CT head imaging in the young infant.
- Eyes: Early ophthalmology consultation and ongoing surveillance are valuable in the management of proptosis, monitoring for optic neuropathy, vision and eye alignment given the high risk for strabismus.
- Hearing: Conductive and mixed hearing loss, most commonly due to middle ear disease, ossicular abnormalities, and external auditory canal stenosis or atresia, can be present in syndromic craniosynostosis. Early amplification (for example with a bone conduction sound processor on a soft band in the setting of canal atresia) may be indicated to support communication. Sensorineural hearing loss has been described in Saethre–Chotzen syndrome and Muenke syndrome. Timely hearing screening is recommended for all children with craniosynostosis, and continued monitoring for progressive hearing loss is indicated for children with coronal and multisuture craniosynostosis.
- Development: Developmental monitoring and referral to early intervention services is recommended for all infants with single and multi-suture craniosynostosis, especially those with craniosynostosis syndromes. Although school-age children with repaired single suture craniosynostosis have been found to have evidence of mild developmental delays, the pathogenesis and direct relationship to synostosis have not been determined.[80]
- Sleep: Monitoring for sleep apnea in infants and children with multisuture craniosynostosis and syndromes is recommended, with a low threshold for referral for a sleep study.
- Heart: In Apert syndrome, a cardiac and genitourinary evaluation is recommended.
- GI: Low threshold to obtain imaging to rule out malrotation in the infant with emesis and multisuture craniosynostosis, given the association with intestinal abnormalities.[81]
- Limbs: If any limb abnormalities are seen, as in Apert, Jackson–Weiss, Pfeiffer, and Saethre–Chotzen syndromes, radiographs with orthopedic or hand specialist consultation should be obtained.

Disorders of the First and Second Branchial Arches

Craniofacial Microsomia

Craniofacial microsomia (CFM), a congenital malformation in which there is asymmetric deficiency in skeletal and soft tissue on one or both sides of the face, is the most frequently encountered form of facial asymmetry. CFM affects approximately 1 in 3000 to 1 in 5600 births.[82,83]

Diagnosis and Etiology

Individuals with features of CFM have been classified under a variety of different diagnoses (hemifacial microsomia, oculoauriculovertebral spectrum, facioauriculovertebral syndrome, first and second branchial arch syndrome, otomandibular dysostosis, Goldenhar syndrome, lateral facial dysplasia) attesting to the phenotypic variability. There are no accepted diagnostic criteria, but the presence of ipsilateral mandibular and ear defects is most common. Infants with CFM are often born small for their gestational age, and the perinatal history may include polyhydramnios due to fetal swallowing dysfunction. Various causes, both environmental and heritable, have been studied, and for most, the cause is thought to be multifactorial. Most often CFM is a sporadic condition with a recurrence risk of approximately 2% for future pregnancies unless there is a known family history of microtia or CFM.[84]

Phenotype

CFM is primarily a condition of the first or second branchial arches, resulting in the underdevelopment of the ear, temporomandibular joint, mandibular ramus and body, and mastication muscles. Asymmetric bilateral facial involvement is common (Fig. 88.10A). The affected external ear can be underdeveloped and small (microtia) or malformed, may be lower in position compared with the ear on the contralateral side (see Fig. 88.10B), can present with no external ear (anotia), and may be accompanied by preauricular tags. Hearing loss may result from maldevelopment of the ossicular chain and a stenotic or atretic external auditory canal and can affect one or both sides. Second branchial arch defects can involve the facial nerve and muscles of facial expression, which can be difficult to appreciate in a newborn.

A common classification system for CFM is the OMENS system, which characterizes the degree of involvement of facial structures: *o*rbital distortion, *m*andibular hypoplasia, *e*ar anomaly, *n*erve involvement, and *s*oft tissue deficiency.[85,86] Isolated microtia may represent a forme fruste of CFM. Other craniofacial features include external auditory canal stenosis or atresia, unilateral macrostomia (transverse facial cleft leading to lateral displacement of the oral commissure and the most common form of orofacial clefting in CFM), cleft lip and/or palate, temporomandibular joint ankylosis, ankyloglossia, preauricular or facial pits (most common in the distribution of the facial nerve), midface hypoplasia and malocclusion, epibulbar lipodermoids (see Fig. 88.10C), microphthalmia, eyelid and ocular colobomas, facial nerve palsy or paresis, and other cranial nerve palsies. There can be extreme variability of phenotypic expression, and the severity of mandible, ear, and facial involvement varies from mild to more impacted (see Fig. 88.10D). Goldenhar syndrome has historically been described as a subgroup variant of CFM characterized by vertebral anomalies and epibulbar dermoids in addition to the ear and jaw findings. Extracraniofacial anomalies are common in CFM, with one large study describing a prevalence of 47%, and higher among those with bilateral CFM or more severe bony and soft tissue involvement. Extracraniofacial anomalies can include vertebral (28%; scoliosis, block vertebrae, hemivertebrae), cardiac (21%; septal defects, valve anomalies, tetralogy of Fallot), CNS (11%; hydrocephalus, ventriculomegaly, intracranial cyst), urogenital tract (11%; renal aplasia, undescended testicle, hydronephrosis), GI tract (9%; inguinal hernia, imperforate anus, esophageal atresia), and respiratory tract (3%; laryngomalacia).[87]

In CFM, deficient growth of the hypoplastic mandible and the compensatory growth of the contralateral maxilla and zygoma contribute to facial asymmetry that progresses with growth. Conversely, facial and skull asymmetry caused by deformation (intrauterine or postnatally with plagiocephaly and torticollis) will improve with time, repositioning, and treatment of torticollis.

Branchial Arch Malformation Syndromes

While multiple syndromes can be associated with malformations of the first and second branchial arches, presented in this chapter are two syndromes with particular relevance to the neonatologist.

Moebius Syndrome

Moebius syndrome is a rare congenital condition affecting approximately 2000 people worldwide.[88] The sixth and seventh cranial nerves are universally affected. Sixth nerve palsy leads to an inability to abduct the eyes beyond the midline. This is usually bilateral but may be unilateral or asymmetric. Paralysis of facial muscles results from the seventh nerve palsy. While newborns may have a "masklike facies," the presentation is challenging to recognize in the newborn period.[89] Feeding difficulties may result from problems with swallowing and sucking, aspiration, and palatal weakness related to more widespread cranial nerve involvement. Both abnormalities of cranial nerve nuclei and neural connection issues are hypothesized to cause Moebius syndrome. Many associated features have been described, and hypotonia is common, also impacting swallowing and breathing in infancy.[90] Associations with chest wall abnormalities, including the absence of the pectoralis muscle, suggest a pathogenic relationship with the Poland anomaly. Exposure conjunctivitis and keratopathy can occur in children with facial paralysis and lagophthalmos and should be prevented with ocular lubricants. Limb defects occur in more than half of children with Moebius syndrome, most commonly talipes deformity; however, transverse limb anomalies are also seen. Individuals with hypoglossia-hypodactylia or Hanhart syndrome can have severe limb deformities, ankyloglossia, and temporomandibular joint ankylosis, in addition to Moebius syndrome–like features and micrognathia. As a consequence, they are at risk of significant swallowing dysfunction and airway compromise.[91]

Treacher Collins Syndrome

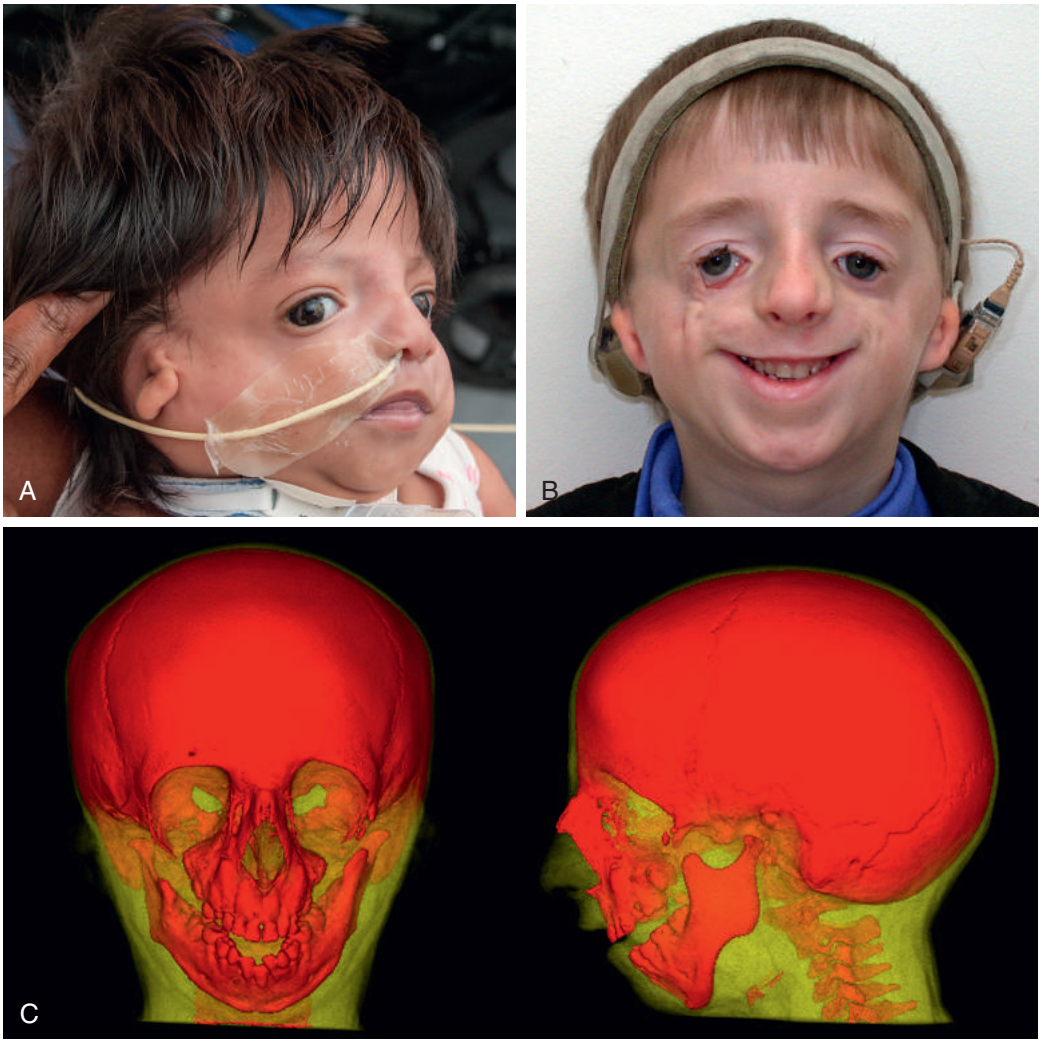
Treacher Collins syndrome (TCS) is a disorder of craniofacial development that affects approximately 1 in 50,000 live births.[92] As in CFM, the tissues affected in TCS arise from the first and second branchial arches. The major clinical features of TCS include hypoplasia of facial bones (mandible and zygoma), microtia,

• **Fig. 88.10** (A, B) Infant with craniofacial microsomia, mandibular asymmetry, and left-sided microtia. (C) Child with an epibulbar lipodermoid and craniofacial microsomia. (D) Infant with more severe mandible hypoplasia, airway obstruction, and an associated tracheostomy tube.

external auditory canal atresia, bilateral conductive hearing loss, downward sloping palpebral fissures, and lower eyelid colobomas, as well as risk of exposure keratitis (Fig. 88.11A, B).[93] Cleft palate may occur and hearing loss is present in up to 50% of individuals with TCS.[94] In severe cases, the zygomatic arch may be absent. Extracraniofacial features are rare in TCS, and limb anomalies can distinguish other forms of mandibulofacial dysostoses from TCS: for example, Miller syndrome with craniofacial features similar to TCS plus postaxial limb anomalies affecting the fifth digital ray of all four limbs, and Nagar syndrome with craniofacial features similar to TCS plus preaxial limb anomalies, hypoplastic/absent thumbs and or radii. Mutations in one of four genes (*TCOF1, POLR1B, POLR1C, POLR1D)* are causative of TCS and mutations in the *TCOF1* gene account for 71% to 93% of affected individuals. The diagnosis of TCS is usually made clinically and can be confirmed with genetic testing.[95] In newborns with TCS, airway management may be required to address narrowing of the airway or extreme shortening of the mandible (see Fig. 88.11C). When compared with that in CFM, the mandibular hypoplasia in TCS is usually bilateral and symmetric, leading to an even higher risk of upper airway obstruction. In addition to glossoptosis and mandible involvement similar to RS, choanal stenosis or atresia can be present in neonates with TCS predisposing to multilevel airway involvement not effectively resolved with neonatal mandible advancement.[96,97] Among infants with TCS and significant airway compromise, there is an increased need for tracheostomy, and risk of death in the neonatal period.

Intensive Care Unit Concerns

Mandibular hypoplasia in CFM can lead to upper airway obstruction that may be obvious on physical examination, presenting with stertor or stridor and increased work of breathing, or may be more subtle, with noisy breathing occurring with sleep or feeding. Bilateral severe mandibular and maxillary involvement in TCS leads to airway obstruction at the level of the nasopharynx and base of the tongue and substantial respiratory compromise. As multilevel airway obstruction is common in TCS, airway endoscopy to help target treatment options should be pursued for any neonate with TCS or CFM and signs of airway obstruction.



• **Fig. 88.11** (A) Infant with Treacher Collins syndrome (TCS), microtia, severe mandibular and zygomatic hypoplasia, and airway obstruction requiring tracheostomy. (B) An older child with TCS, downslanting palpebral fissures, eyelid colobomas, and bilateral microtia wearing a hearing augmentation device. (C) Three-dimensional reconstruction of TCS. Note the severe mandibular hypoplasia, which may lead to significant airway compromise. Also notable are zygoma hypoplasia and orbital defects seen in TCS.

Infants with CFM may have feeding difficulties that may be related to macrostomia affecting lip seal; among infants with CFM and TCS, swallow coordination issues and dysphagia are attributed to both palate dysfunction and more commonly hypoglossal dysfunction and muscular and bony underdevelopment. Infants with Moebius syndrome may have cranial nerve palsies that affect swallow and oral coordination and are consequently at high risk of aspiration. Close monitoring and support of feeding, swallowing, and growth is recommended in all of the branchial arch conditions.

Management

In newborns with suspected CFM, an evaluation for associated anomalies should be undertaken. All children with external ear anomalies or any evidence of first or second branchial arch abnormalities should undergo diagnostic hearing testing in the newborn period, with follow-up audiometry in the first year of life. If there is any hearing loss, ongoing monitoring of hearing is routine. It is also important to monitor ear health and eustachian tube function in the patent/hearing ear. CT imaging to assess middle and inner ear anatomy is not recommended in the neonatal period. Consultation to discuss ear reconstruction and atresia repair typically occur by 4 years of age, although consultation for hearing amplification should occur as soon as possible in infants with hearing loss, and infants diagnosed with hearing loss should receive intervention services as soon as possible, but no later than 6 months of age (https://www.cdc.gov/ncbddd/hearingloss/treatment.html). Additionally, aural habilitation support is helpful.

Mild airway obstruction in CFM and TCS may be reduced with prone positioning. However, infants with severe unilateral or bilateral mandibular hypoplasia or multilevel airway obstruction may have significant airway compromise and require tracheostomy placement. In cases with airway compromise or signs of obstructive sleep apnea, early referral to a craniofacial center to determine optimal and safe airway management should be pursued.[98] The timing of surgery to address mandibular underdevelopment is typically in later childhood and depends on the degree of mandibular hypoplasia, mandibular growth, occlusion, and airway involvement.[99] For children with severe hypoplasia of the mandible, bone grafting may be necessary for jaw reconstruction before mandible distraction. Oral feeding should be introduced when the airway is stable. Given the risk of feeding difficulty and aspiration in infants with malformations of the first and second branchial arches, early consultations with a dietitian and a feeding therapist are helpful.

Screening and Surveillance for Craniofacial Microsomia

- Diagnostic hearing test in infancy and regular assessments of hearing guided by initial audiologic assessment and hearing loss risk
- CT to assess middle and inner ear anatomy and guide atresia repair options at 4 years of age.
- Renal ultrasound in infancy to evaluate for structural malformations
- Cardiac examination (echocardiogram) in infancy if any clinical concerns or murmur
- Ophthalmology consultation to manage epibulbar lipodermoids, colobomas (if present), and prevent exposure keratopathy
- Cervical spine screening radiographs to identify vertebral anomalies (defects in segmentation). If the newborn has no symptoms of cervical spine abnormality, screening four-view cervical spine radiographs can be deferred until the child is 2 to 3 years old, when vertebrae are more reliably imaged. Appropriate cervical spine imaging is recommended in children undergoing surgery before 2 years of age and children with head tilt or signs of vertebral anomalies.
- Spine monitoring for progressive scoliosis
- Monitoring for obstructive sleep apnea, with a low threshold for referral for a sleep study
- Dental and occlusal monitoring through childhood

CHARGE Syndrome

Diagnosis and Etiology

The term *CHARGE* (*c*oloboma, *h*eart defect, *a*tresia choanae, growth *r*etardation, *g*enital hypoplasia, *e*ar anomalies/deafness) was first coined by Pagon, given the observation that the associated malformations occurred more frequently together than one would expect on the basis of chance.[100] Over time, the facial features and associated malformations were better characterized as a syndrome, with mutations in at least one major gene described.

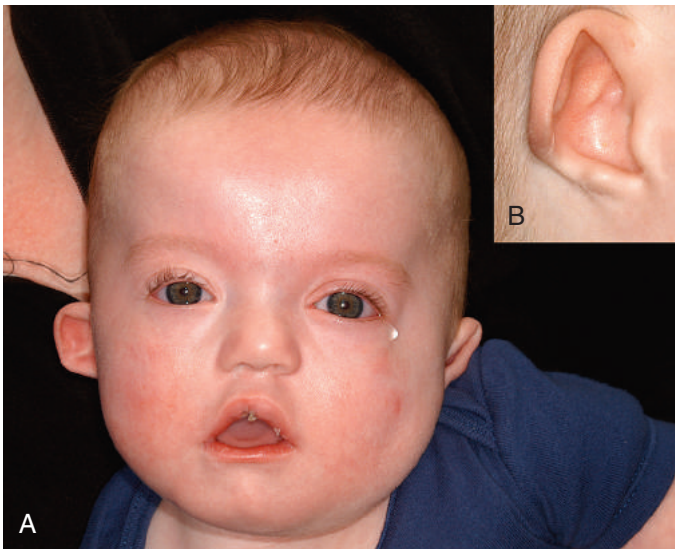
This multiple malformation condition has a prevalence of approximately 1 in 10,000 births.[101] Mutations in the *CHD7* gene account for most cases, but CHARGE syndrome remains a clinical diagnosis, with some individuals meeting the classic criteria without a *CHD7* abnormality.[102] Molecular testing for mutations in the *CHD7* gene is especially useful in atypical cases where the diagnosis is being considered but can also be performed to confirm the diagnosis and assist in counseling for the parents and the patient. For children in whom *CHD7* gene testing results are normal, further genetic testing is warranted.[103]

The clinical diagnosis of CHARGE syndrome is summarized in Table 88.4. Additional findings include renal, spinal, hand, neck, and shoulder anomalies.[101,103] With improving diagnostics, the

TABLE 88.4 Clinical Diagnosis of CHARGE Syndrome

Major Criteria	Minor Criteria
Coloboma (80%–90%)	Cardiovascular malformations (conotruncal and aortic arch most common)
Choanal atresia/stenosis (50%–60%)	Genital hypoplasia
Cranial nerve dysfunction (especially I, VII, VIII, IX, X) (40%–90%)	Cleft lip and/or palate
Characteristic CHARGE ear findings (inner, middle, outer) (90%–100%)	Tracheoesophageal fistula
	Distinctive CHARGE facies
	Growth deficiency
	Developmental delay

CHARGE syndrome strongly suspected if all major criteria or 3 major and 3 minor criteria are present.



• **Fig. 88.12** (A) Child with CHARGE syndrome with (B) classic ear malformation—hypoplastic lobes, cupped and low set.

phenotype is expanding, and gastrointestinal problems, immunodeficiency, and neuromuscular problems are also described.[103] Polyhydramnios is commonly present prenatally, secondary to upper airway obstruction and/or swallowing dysfunction.

Phenotype

Distinctive ear anomalies (hypoplastic lobes, cupped/lop, low-set, and posteriorly rotated) occur in most cases (Fig. 88.12). Facial features include a square face with malar flattening, broad forehead, facial asymmetry, pinched nostrils, full nasal tip, and long philtrum. Ocular colobomas can range from iris involvement to anophthalmia. A minority of cases have cleft lip and/or palate. A heart murmur may indicate congenital heart disease. Limited neck range of motion may indicate cervical spine anomalies. In the neonatal period, breathing and feeding difficulties are often the most prominent features, as the characteristic facial and ear features may not be as pronounced.

Intensive Care Unit Concerns

The most important potential postnatal emergency in CHARGE syndrome is bilateral posterior choanal atresia.[104] Neonates with bilateral choanal atresia will have breathing difficulty and cyanosis within the first hour of life. Crying relieves the cyanosis by allowing the obligate nose breather to take in air through the mouth; feeding exacerbates respiratory distress. Left untreated, asphyxiation and death can occur. Symptoms of bilateral choanal stenosis or unilateral atresia may not present until after the newborn period with chronic rhinorrhea and nasal airway obstruction exacerbated by respiratory infections. Feeding difficulties and sialorrhea are significant causes of morbidity. These issues, and secondary growth problems, are common in early infancy and may be attributed to swallowing dysfunction, pharyngeal incoordination, gastroesophageal reflux, and aspiration. Cranial nerve palsies (specifically of V, IX, and X) may contribute to swallowing dysfunction, and tracheoesophageal fistula (TEF), if present, contributes to aspiration risk.

Swallowing dysfunction and gastroesophageal reflux can cause descending and ascending aspiration and lower respiratory tract disease, leading to chronic respiratory distress. Infants with CHARGE may also have micrognathia and glossoptosis, putting them at risk of airway obstruction at the level of the pharynx/hypopharynx. Infants with CHARGE syndrome may require multiple surgical procedures during the first year of life and are at increased risk of postoperative airway events.[104,105]

Cyanotic heart disease may present in the immediate newborn period because of tetralogy of Fallot, outflow tract anomalies, and interrupted aortic arch. There should be a very low threshold to obtain an echocardiogram and involve cardiology in a neonate with possible CHARGE syndrome.

Although it is well described that infants with CHARGE syndrome who survive the newborn period are more likely to survive childhood, the risk of death in infancy remains. Bilateral choanal atresia, TEF, cyanotic heart disease, atrioventricular septal defects, CNS malformations, and ventriculomegaly have all been associated with reduced life expectancy in individuals with CHARGE syndrome.[104,106] A study of 77 individuals with CHARGE syndrome found mortality to be 13%; the ages at the time of death range from less than 1 week old to 9 years old.[106]

Management

Many children with CHARGE syndrome will require intensive medical management and undergo multiple surgical interventions in infancy and early childhood. Early management targets airway stabilization and circulatory support. Neonates suspected to have CHARGE syndrome require immediate evaluation of their airway and cardiac structure and function. An oral airway should be placed if bilateral choanal atresia is suspected. Once the airway has been secured, a confirmatory CT scan of the nasal passages can be obtained; a CT of the temporal bones should be included and may reveal the characteristic inner ear findings of CHARGE syndrome (Mondini malformation of the cochlea and/or absent or hypoplastic semicircular canals). If the oral airway does not allow adequate air entry, endotracheal intubation may be required. In consultation with a pediatric otolaryngologist, trans-nasal stents may be placed to keep the nasal passages patent in choanal stenosis (and postoperatively after choanal atresia repair). Given the significant risk of cyanotic heart defects, an echocardiogram should be obtained as soon as feasible. If heart surgery is needed, documentation of the presence/absence/removal of the thymus should be reported.

Infants with confirmed or suspected CHARGE syndrome should have audiologic and ophthalmologic evaluations in the neonatal period and should be referred to early intervention services. While there is no consensus on immune screening in CHARGE, given the emerging data and implications, a full blood count with a lymphocyte differential and calcium level (because of the connection between immunodeficiency and abnormalities of the parathyroid glands observed in CHARGE syndrome, not unlike 22q11.2DS) should be considered in the neonatal period in CHARGE syndrome.[107] Consultation with an immunologist should occur for the individual with CHARGE syndrome and recurrent infections.[108] Underdevelopment of the genitals and genitourinary anomalies may be present. If there is a concern for hypogonadism, the pituitary-gonadal axis can be evaluated in infancy and will help determine the option for sex steroid therapy. Screening renal ultrasonography should also be performed in all suspected cases.[109]

Consultations with a feeding specialist and a dietitian are recommended in the newborn period. If the clinical bedside feeding evaluation or video fluoroscopic swallow study are concerning for swallowing dysfunction or aspiration, supplemental tube feeding should be initiated. With prolonged feeding issues, gastrostomy tube feeding is often necessary. Infants with severe gastroesophageal reflux and/or aspiration risk may benefit from post-pyloric feeding with a nasoduodenal or more secure gastrojejunal feeding tube.

Screening and Surveillance

CHARGE syndrome has potential impacts on nearly all body systems, and it is difficult to summarize them here. Trider et al. (2017) provides an exceptional summary of health supervision for these patients. Some important highlights include:

- Gonadotropins screening at 3 months of age
- Screening for lymphopenia and hypocalcemia due to overlap in phenotype with 22q11.2 deletion syndrome
- Referral to deaf-blind resources
- Assessment for potential cochlear implants
- Treatment of GI motility issues
- Holistic neurodevelopmental and early intervention services.

Macroglossia/Beckwith-Wiedemann Syndrome

Diagnosis and Etiology

Beckwith-Wiedemann syndrome (BWS) has been estimated to affect 1 in 10,340 live births.[110] The genetics of BWS is complex and variable. Most cases are sporadic and may result from chromosomal rearrangement, mutations, or epigenetic effects (DNA methylation changes) affecting imprinted genes on chromosome band 11p15.5. Approximately 80% of individuals with features of BWS are found to have an 11p15.5 abnormality by clinically available testing.[111] An international group of experts has developed consensus criteria for classical BWS, which require a score ≥4 in Table 88.5 for clinical diagnosis.[112] As children with BWS are at risk of neoplasms in early childhood, recognition and diagnosis of BWS are consequential. Infants conceived by in vitro fertilization may be at higher risk of BWS.[113] Although genetic testing can provide confirmation of diagnosis in 80% of individuals, clinical suspicion alone should initiate medical management and tumor surveillance studies. At this time, initiation of screening studies and consultation with genetics are recommended.[112]

Phenotype

Most clinical features outlined in Table 88.5 can present in the neonatal period. Macroglossia (Fig. 88.13) is the most frequent and most obvious manifestation of BWS, present 85% to 95% of the time.[112] It is defined as a tongue that protrudes beyond the alveoli at rest.[114] Other craniofacial features include capillary nevus flammeus, large fontanelle, mandibular prognathism, prominent eyes, infraorbital creases, anterior earlobe linear creases, and posterior helical pits. Additional findings in BWS include renal and cardiac defects; cleft palate is also described, albeit less often.[115] The risk of embryonal tumors (Wilms tumor, hepatoblastoma, neuroblastoma, rhabdomyosarcoma) in childhood is estimated to be 7.5%, of which 95% present in the first 8 years of life.[112]

Some features suggestive of BWS may present prenatally, including polyhydramnios (due to swallowing dysfunction), preeclampsia, fetal macrosomia, and a large placenta. Prematurity is also associated with BWS.[112]

Intensive Care Unit Concerns

Hypoglycemia due to hyperinsulinemia occurs in 30% to 60% of neonates with BWS, usually within the first days of life.[116] Polycythemia can occur and is a potential marker of a congenital Wilms tumor.[117]

Upper airway obstructive symptoms typically present in later infancy, although they may present in the newborn period if macroglossia is severe. The enlarged tongue can occlude the upper airway, leading to respiratory distress, apnea, and hypoxia. Macroglossia can also contribute to feeding issues, dysphagia, and aspiration.

Mortality among infants with BWS has been reported to be as high as 21% and is related to complications of prematurity and macroglossia.[111] Congenital heart disease is present in 13% to 20% of neonates with BWS and can include cardiomegaly, cardiomyopathy, patent ductus arteriosus, patent foramen ovale, atrial and ventricular septal defects, long QT syndrome, and more severe defects.[112]

Management

Neonatal hypoglycemia should be managed according to standard protocols. If it persists or is refractory to therapy, additional biochemical testing and consultation with an endocrinologist are helpful to guide treatment.[116,118] In severe cases, subtotal pancreatectomy may be a treatment option.[112,116] If present, polycythemia may need to be treated and could have implications for

TABLE 88.5 Clinical Diagnosis of Beckwith-Wiedemann Syndrome

Cardinal Features (2 Points Each)	Suggestive Features (1 Point Each)
Macroglossia	Birth weight >2 standard deviations above mean
Omphalocele	Facial nevus simplex
Lateralized overgrowth	Polyhydramnios and/or placentomegaly
Multifocal and/or bilateral Wilms tumor or nephroblastomatosis	Ear creases and/or pits
Hyperinsulinism beyond 1 week of age and needing escalated treatment	Neonatal hypoglycemia lasting <1 week
Pathology features: adrenal cortex cytomegaly, placental mesenchymal dysplasia, pancreatic adenomatosis	Neuroblastoma, rhabdomyosarcoma, unilateral Wilms tumor, hepatoblastoma, adrenocortical carcinoma, pheochromocytoma
	Nephro- and/or hepatomegaly
	Umbilical hernia and/or diastasis recti

A score of ≥4 meets criteria for BWS. A score of ≥2 warrants geneticist involvement to evaluate for possible BWS.

• **Fig. 88.13** (A) Premature newborn with Beckwith-Wiedemann syndrome, macroglossia, and rectus diastasis. (B) Same child at 6 months of age. Macroglossia has increased, and he now has a tracheostomy.

anesthesia. Neonates with an omphalocele may require surgery in the first few days of life.

There is no definitive approach to the management of macroglossia, and even confirmation of its presence can be challenging. Otolaryngology involvement and endoscopic airway assessment to assess the degree of airway narrowing due to base of tongue airway obstruction should be considered in symptomatic infants. Polysomnography can quantify the severity of airway obstruction and complement airway endoscopy to guide airway management. If endotracheal intubation is needed, it is important to exercise caution, because macroglossia can affect airway exposure. If macroglossia results in significant airway obstruction or prolonged intubation, tracheostomy may be needed as a temporizing measure. After infancy, progressive tongue growth will slow, and as jaw growth accelerates, airway compromise may decrease. Some children may benefit from a surgical reduction of the tongue,[119] which is usually performed between 2 and 4 years of age but may be offered as early as 3 to 6 months at some centers. Whenever possible, surgical intervention should be pursued at a multidisciplinary center with an experienced surgical team.[112,116]

Referrals to an infant feeding specialist and dietitian are recommended if macroglossia or associated airway obstruction result in feeding difficulties. Oral feeding should not be attempted if upper airway obstruction is significant, and some infants may require surgical placement of a gastrostomy tube for long-term nutritional support.

It is important to perform a thorough cardiac evaluation, including an electrocardiogram and echocardiogram if any cardiac abnormalities are suspected.

Neurodevelopment is typically normal but can be impacted by prematurity, hypoglycemia, and unbalanced chromosomal translocations. Other overgrowth syndromes, such as Sotos, Costello, and Simpson-Golabi-Behmel syndromes, are more commonly linked with developmental delay. Trisomy 21 also can present with macroglossia. A thorough evaluation of neurodevelopment is important for neonates with features of BWS.

Surveillance for tumors begins in the neonate with BWS or at the time of diagnosis. Abdominal ultrasonography to assess for organomegaly, tumors, and renal abnormalities should be considered when BWS is suspected clinically. Genetic consultation must be pursued as soon as the diagnosis is suspected.

Screening and Surveillance

Referral to a craniofacial team may be helpful in the management of airway obstruction in BWS, including evaluation for macroglossia and facial hemihypertrophy and later orthodontic and orthognathic surgical management to address developing compensatory prognathia and malocclusion. Ongoing follow-up with a geneticist and genetic counselor are essential, as the underlying genetic causes of BWS have differing cancer risk profiles and this can guide specific strategies for ongoing screening, treatments, and therapies. Some large children's hospitals or academic centers may have a dedicated multidisciplinary BWS clinic or program.

- Until the specific underlying genotype is identified, an abdominal ultrasound should be performed every 3 months to screen for embryonal tumors. The underlying genetics are complex and influence surveillance, and there are currently differing regional surveillance guidelines.[112,120] The geneticist involved can guide tumor surveillance based on the genotype identified.
- Abdominal ultrasounds can also monitor for the increased risk of hypercalciuria, nephrolithiasis, renal cysts, pelviectasis (which might indicate vesicoureteral reflux), and nephromegaly.
- At a minimum, ultrasound evaluation of the kidneys and bladder should be done at diagnosis and transition to adult care in patients who do not warrant more regular abdominal ultrasounds.[112]

- Ongoing cardiac surveillance will vary depending on the cardiac anomaly identified at the time of diagnosis.
- Monitoring for obstructive sleep apnea in infancy and early childhood, with a low threshold for referral for a sleep study
- Monitoring dental eruption, occlusion, and facial growth. Most children with macroglossia and mandible overgrowth benefit from orthodontic management, and some will be candidates for jaw surgery in adolescence
- Primary care providers should monitor children with BWS for leg-length discrepancy annually and refer them to an orthopedic surgeon if it is confirmed.[112]

Other Notable Craniofacial Conditions

Frontonasal Dysplasia, Hypertelorism, Encephalocele

Diagnosis and Etiology

Frontonasal dysplasia (FND; also known as *frontonasal malformation, median cleft face syndrome*, and *frontal nasal syndrome*) is a malformation resulting from abnormal morphogenesis of the frontonasal process. The development of the facial midline is abnormal, leading to ocular hypertelorism and associated craniofacial features. Most cases of FND are sporadic.

Phenotype

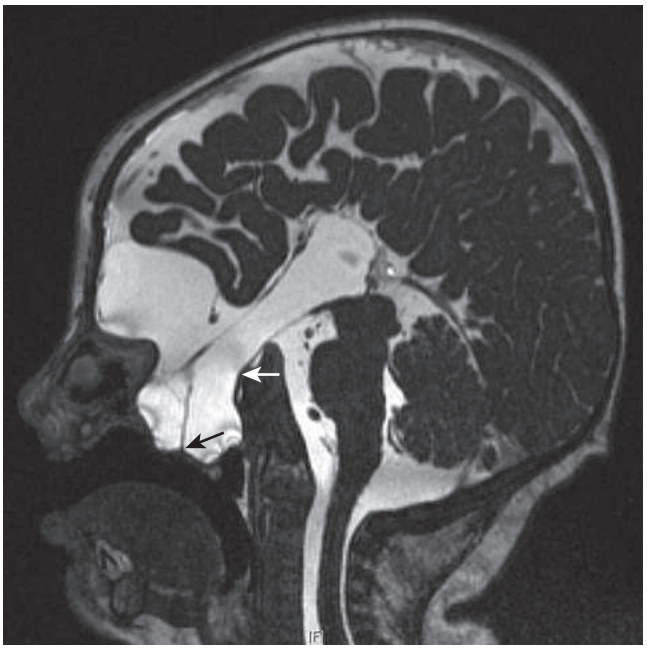
FND has been defined clinically as containing two or more of the following craniofacial features[121]:

- Ocular hypertelorism (interpupillary distance >4.5 cm in a term neonate)
- Broadening of the nasal root
- Midline facial cleft affecting the nose, lip, or palate
- Unilateral or bilateral clefting of the alae nasi
- Hypoplastic nasal tip
- Anterior cranium bifidum
- V-shaped frontal hairline

FND is a diverse and genetically heterogeneous condition found in isolation without other concerns, or can be associated with a pattern of other malformations,[122] or as a spectrum of syndromes with known genetic changes[123] such as craniofrontonasal syndrome.[124]

In addition to hypertelorism, eye anomalies, including epibulbar dermoids, colobomas, ptosis, nystagmus, or cataracts, may be present in FND and are associated with a more severe phenotype and an increased incidence of CNS abnormalities. Associated CNS manifestations include encephalocele or meningocele (most commonly frontonasal location), agenesis of the corpus callosum, and abnormal neuronal migration. When FND is associated with CNS anomalies, there is an increased association with cognitive impairment.[122]

Craniofrontonasal syndrome is an X-linked condition in a subset of patients with frontonasal malformations who also present with coronal craniosynostosis and variable skeletal and ectodermal defects. Similar to FND, facial features include hypertelorism, frontal bossing, broad nasal bridge, and a bifid nasal tip. Children with CFNS often have significant facial asymmetry due to unicoronal synostosis. In this X-linked condition, females are more severely affected (and typically have hypertelorism and grooved nails), and mutations are detected in the *EFNB1* gene. Affected individuals usually have normal intelligence.[124]



• **Fig. 88.14** MRI of an infant with frontonasal dysplasia and a midline cleft lip. The scan reveals a moderate-sized meningocele extending into the posterior nasopharynx. The *white arrow* points to midbrain meningocele coming through the cribriform plate; the *black arrow* points to the intraoral meningocele.

Intensive Care Unit Concerns

Intracranial abnormalities associated with FND may put the infant at risk of CNS manifestations such as hydrocephalus or seizures. If the pituitary gland is involved or deficient, as can be seen with HPE sequence, there can be serious endocrine abnormalities (as discussed in Orofacial Clefts). Also, frontonasal encephalocele may contribute to upper airway compromise at the level of the nasopharynx (Fig. 88.14).

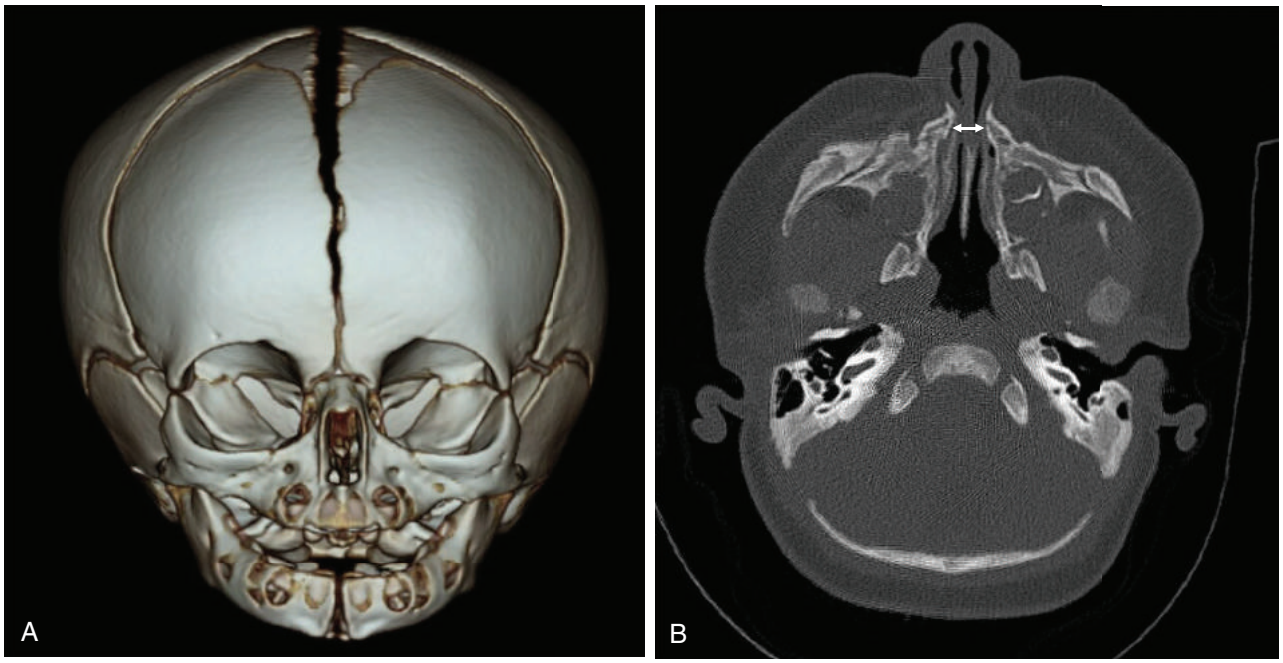
Management

In any infant with hypertelorism or features that raise suspicion for FND, awareness of potential underlying malformations is critical, and cranial imaging by CT scan or MRI should be considered. Instrumentation of the nose and mouth, including placement of a nasogastric tube or suction catheter, should be avoided or used with caution until the CNS anatomy has been delineated. Because infants with FND have a high incidence of frontonasal encephalocele or meningocele, placement of these catheters could lead to brain injury. If an infant with FND needs urgent or emergent endotracheal intubation, intraoral structures should be examined carefully to prevent injury to potential herniating CNS structures. Management of seizures or any electrolyte derangements should be managed as per the neonatal ICU standard protocol. Consultation with a craniofacial team, including ophthalmology, can clarify the work-up and management (including potential surgical interventions) for individuals with FND.

Congenital Nasal Pyriform Aperture Stenosis

Diagnosis and Etiology

Congenital nasal pyriform aperture stenosis (CNPAS) is a rare but notable cause of nasal obstruction in the neonate. The pyriform aperture (PA) is the pear-shaped maxillary nasal inlet and is



• **Fig. 88.15** (A) 3D reconstruction of CT scan with congenital nasal pyriform aperture stenosis (CNPAS). (B) CT scan axial slice with arrow showing CNPAS measuring 4mm.

the narrowest portion of the nasal airway (Fig. 88.15). CNPAS is caused by a bony overgrowth of the maxilla at the pyriform aperture during embryogenesis. Any decrease in the cross-sectional area leads to a significant increase in nasal airway resistance. The true prevalence of CNPAS is unknown due to varying degrees of clinical presentation and stenosis but has been estimated at 1 in 25,000 births.[125] First described in the medical literature in 1989, case reports and publications have more than doubled in recent years.

Age and symptoms at presentation often depend on the degree of narrowing. CNPAS may not be diagnosed immediately due to its rare occurrence and nonspecific presentation as other types of nasal obstruction, most frequently mistaken as neonatal rhinitis or choanal atresia or stenosis. Most infants have symptoms shortly after birth or in the first few weeks of life. Presentation can be mild with intermittent noisy breathing, constant congestion, and stertor, and for some infants, nasal airway obstruction presents with difficulties feeding, cyanosis with feeds, or failure to thrive. More severe obstruction may present with obstructive apneas and occasionally, infants may have life-threatening respiratory distress.

When suspected clinically, the diagnosis of CNPAS is confirmed with nasal endoscopy and imaging. Respiratory distress or cyanosis with feeding, constant congestion that improves with crying, or difficulty/inability to pass a 5 to 6 French catheter or NG through the PA should prompt further investigation into nasal airway obstruction. Anterior rhinoscopy will reveal a narrow anterior nasal valve passage, typically effecting both nares. Otolaryngology may have difficulty passing a flexible fiberoptic scope through the PA to visualize the rest of the nasal cavity.

A definitive diagnosis is made by measuring the width of the PA at the level of the inferior meatus on axial cuts of a maxillofacial computed tomography scan. In a term infant, the PA averages 16.9 mm (depending on the study); with CNPAS being defined as a PA that measures less than 11 mm in a term neonate.[126]

Phenotype

Physical exam findings in the infant with CNPAS can include microcephaly, midface hypoplasia, absent maxillary labial frenulum, and prominent central incisor; with the last two findings being relatively unique to CNPAS.[127] CNPAS can occur as an isolated condition or in combination with other midline defects, most commonly a solitary median maxillary central incisor (60%). It is considered a microform of the holoprosencephaly spectrum and can have CNS anomalies: pituitary anomalies, corpus callosum abnormalities, Arnold-Chiari I malformation, optic nerve hypoplasia, olfactory bulb agenesis, hydrocephalus, and a shallow sella turcica. Up to 40% of patients manifest endocrine dysfunction due to agenesis or hypoplasia of the hypothalamus and anterior or posterior pituitary gland.[128]

CNPAS has been associated with multiple chromosomal abnormalities and syndromes in the literature including Apert and Crouzon syndromes; tuberous sclerosis; craniosynostosis; RHYNS; VACTERL; deletion of Xp22.2, 22q11,[128] 18p, 13q, 5q[129]; and ring 18.[125]

Intensive Care Unit Concerns

Most infants with CNPAS are admitted to the NICU for respiratory distress or cyanosis with feeding. Use of an oral airway, supplemental oxygen, or CPAP are common initial first steps to stabilize the airway in the neonate with CNPAS and respiratory distress.

A complete metabolic panel can assess an infant's glucose, electrolytes, and bilirubin levels. Hypoglycemia and conjugated hyperbilirubinemia are highly predictive of pituitary dysfunction.[130] For any infant suspected or confirmed to have CNPAS, an endocrinology consult and evaluation is recommended to monitor for a disorder of the hypothalamic-pituitary axis that can include diabetes insipidus, adrenal insufficiency, hypothyroidism, growth hormone deficiency, and hypogonadism. Early diagnosis and appropriate hormonal replacement are crucial as morbidity

and mortality are risks among the cohort of neonates that have respiratory distress and may need surgery.[130] Recurrent hypoglycemic seizures, electrolyte imbalance, and subsequent cardiac arrest have been reported in infants with CNPAS.[131]

Nutrition can be supported with supplemental nasogastric or orogastric feeds, and continued oral trials are appropriate as respiratory status allows. Working with a feeding therapist is key to developing a safe feeding plan, including pacing, preventing overexertion, and providing a positive feeding experience for the neonate.

Management and Screening

Once diagnosed, treatment of CNPAS can be conservative or surgical, depending on the degree of obstruction and severity of associated symptoms. Initial medical management consists of saline irrigation, intranasal steroids, and topical decongestants with the timing of medications optimized for feeds. Conservative management should be attempted for up to 2 weeks before considering surgery.[129]

During this time, it is paramount to evaluate the neonate for endocrine dysfunction, electrolyte abnormalities, CNS anomalies, or any other associated issues. Brain MRI is recommended for all infants with CNPAS. An ectopic posterior pituitary, anterior pituitary aplasia/hypoplasia, and a pituitary stalk abnormality (in descending order of specificity) on MRI is highly suggestive of pituitary dysfunction, and a structurally normal pituitary does not rule out pituitary dysfunction. Endocrine follow-up through at least 1 year of life is recommended for all infants with CNPAS, and low or plateaued linear growth at 1 year is a predictor of long-term pituitary dysfunction.[130] Given the rarity of CNPAS and potential concomitant clinical abnormalities and syndromes that would affect management, genetic consultation is warranted.

Failure of medical management is determined by persistence of symptoms: stertor, wheezing, increased work of breathing, inability to wean from respiratory or airway support, sleep apnea, inability to feed, or failure to thrive.[125] In these cases, before performing surgery, an alternative procedure has emerged using dilation of the anterior nasal opening. This technique uses a balloon or dilators to provide slight concentric pressure on the bone/cartilage tissue that has natural plasticity due to the presence of circulating maternal estrogens.[132]

Ultimately, surgical intervention may be needed for infants with persistent symptoms. The mean PA width in neonates needing surgical intervention varied from 4.8 mm to 6.6 mm.[133] The most common technique is a sublabial approach where the excessive bony growth around the PA is removed to widen the bony nasal entry. It is considered sufficient to open each side so that at least a 3.5-mm endotracheal tube can be passed without difficulty. Postoperatively, nasal stents are generally left in place for 2 to 4 weeks; however, there is no standardization of technique or timeline for stent usage. Some otolaryngologists may recommend topical or parenteral steroids after surgery. Newer techniques are emerging using endoscopic repairs or using silicon splints along the nasal septum. As with any nasal surgery, postoperative nasal irrigation with saline solution is important to clean the nasal passages and maintain the patency of a stent or other surgically placed foreign body.[125] Infants who have surgical treatment are found to have good long-term success, with few needing subsequent nasal airway surgery.[133]

Prenatal Screening for Fetal Face Anomalies

The American College of Obstetricians and Gynecologists recommend routine surveillance of pregnancy with an ultrasound at 18 to 22 weeks' gestation and have included essential elements to a standardized examination of fetal anatomy that now includes visualization of the upper lip.[134] Most studies estimating the incidence of prenatal recognition and diagnosis of orofacial clefting focus on this anatomic examination. Adequate evaluation of the facial structures with ultrasonography can be achieved by 16 to 17 weeks' gestation. However, the accuracy of this evaluation is impacted by multiple factors such as fetal size, position, limb positioning, and movement; maternal factors such as maternal abdominal scars and maternal body habitus; and other factors including oligohydramnios, type or technology of ultrasound machine, and experience of the ultrasonographer.[134,135] Ideally, many facial features can be visualized with routine two-dimensional ultrasonography at 18 weeks' gestation with standard 3-plane facial views: orbital size and position, eye size (including microphthalmia and anophthalmia), shape of nose, nasal hypoplasia, length of the philtrum, clefts of the upper lip, frontal bossing, retrognathia, micrognathia, macroglossia, and soft tissue abnormalities.[136]

Cleft lip with or without cleft palate can be detected by prenatal ultrasonography, whereas cleft palate only (CPO) without lip and alveolar involvement may be obscured by the tongue, thus making a prenatal diagnosis of CPO more difficult using traditional 2D ultrasound. A systematic review evaluating the diagnostic accuracy of orofacial clefts detected by second-trimester anatomy scans showed that with 2D ultrasound, detection of CL±P was 9% to 100%, and only 0% to 22% in cases of CPO. Using 3D and 4D ultrasounds, detection was 86% to 90% for CL±P and 0% to 89% of cases of CPO.[137] Advances in ultrasound technology and techniques allow ultrasonographers to provide a more detailed, comprehensive, and systematic evaluation of fetal anatomy and should improve detection rates of all craniofacial conditions.[138]

Among high-risk pregnancies, fetal MRI has higher accuracy in confirming and diagnosing anomalies of the head, face, and neck[135,139] and extracraniofacial anomalies otherwise not detected on ultrasound.[140] Some centers have started using fetal MRI to predict the need for immediate neonate airway intervention due to airway compromise caused by glossoptosis in Robin sequence,[141] micrognathia, or craniofacial masses.[142] When fetal airway compromise is anticipated based on prenatal imaging with polyhydramnios, severe micrognathia, mass induced in utero neck extension, neck vessel compression,[142] tracheal compression/deviation, or a solid neck mass,[143] delivery may be coordinated at a tertiary care center with obstetric, neonatology, pediatric otolaryngology, and pediatric anesthesia cooperation to perform an ex utero intrapartum treatment (EXIT) procedure. EXIT procedure allows controlled treatment of fetal airway obstruction while maternal-fetal circulation is maintained as a bridge to a secure airway, resection of obstructing lesion, or onto ECMO for severe cardiac anomalies or congenital diaphragmatic hernias.[142]

Improvement in fetal imaging modalities has shifted the diagnosis of craniofacial anomalies from detection at birth to prenatal diagnosis, and this facilitates parental counseling and planning of delivery and postnatal treatment.[135] Prenatal counseling with a craniofacial team has been shown to decrease negative parental perceptions of orofacial clefting[144] and reduce rates of postpartum

depression.[145] Families who meet members of an experienced craniofacial team before delivery have the opportunity to build trust with their baby's providers, to know what to expect after their child's birth, and to be armed with knowledge, tools, and partners to help their child receive the best care possible.

Acknowledgment

Common Neonatal Orthopedic Conditions

KATHERINE M. SCHROEDER, MARYSE L. BOUCHARD, AND KLANE K. WHITE

KEY POINTS

- Developmental dysplasia of the hip represents a spectrum of diseases. All infants should be screened by physical examination; selective imaging based on risk factors is recommended.
- Most cases of congenital muscular torticollis resolve spontaneously. Physical therapy and surgery are reserved for recalcitrant cases.
- A variety of foot deformities are common and can be encountered in the neonate. Stretching, casting, or surgery may be required for resolution.
- Torsional and angular deformities of the lower extremities must be differentiated from physiologic variants. Asymmetry and rapid progression are the hallmarks of pathologic variants.
- Congenital vertebral anomalies result from failures of formation or segmentation of spinal elements. Spinal deformities such as scoliosis or kyphosis may ensue.
- Although orthopedic afflictions of the newborn are generally not life threatening, they do have the potential to significantly impair functional performance, even when diagnosed and treated early. This chapter discusses the most commonly encountered of these orthopedic problems.

Developmental Dysplasia of the Hip

The term *developmental dysplasia of the hip* (DDH) encompasses a spectrum of diseases from acetabular dysplasia to hips that are located but unstable (femoral head can be moved in and out of the confines of the acetabulum), to frankly dislocated hips in which there is a complete loss of contact between the femoral head and acetabulum. Although geographic and racial variations have been reported, DDH occurs in 11.5 of 1000 infants, with frank dislocations occurring in 1 to 2 per 1000.[1] Studies have suggested that breech positioning, family history of DDH, limited hip abduction, talipes, female sex, swaddling, large birth size, and first-born infants have all been associated with a higher probability of finding DDH.[2] The left hip alone is affected in 60% of infants, the right hip alone is affected in 20% of infants, and both hips are affected in 20% of infants.[3]

With regards to dislocated hips, they can be divided into two groups: syndromic and typical. *Syndromic* dislocations are most frequently associated with neuromuscular conditions such as myelodysplasia and arthrogryposis or with syndromes such as Larsen syndrome. Syndromic dislocations probably occur between week 12 and week 18 of gestation.[1] *Typical* dislocations occur in otherwise healthy infants in the third-trimester prenatal period or postnatally.

Congruent reduction and stability of the femoral head are necessary for normal growth and development of the hip joint. The natural history of untreated DDH is controversial as newborn hip instability may resolve or progress to painless dislocation. In cases that progress to subluxation, individuals have significantly increased risk of developing precocious arthritis with moderate to severe hip pain as young adults.[4,5] This pain can be debilitating and the reconstruction difficult. Early detection and treatment of DDH are thus important in avoiding the devastating sequelae of a late diagnosis.

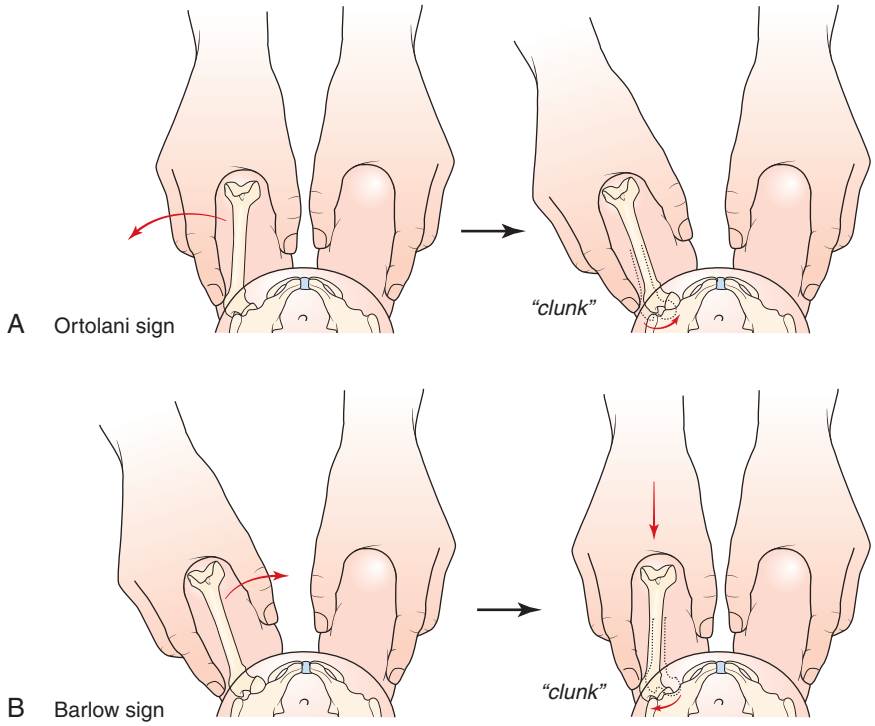
While the physical exam of an infant hip is paramount to the diagnosis of DDH, there are no pathognomonic signs of a dislocated hip. The physical examination requires patience on the part of the examiner and may be facilitated by having the baby feed from a bottle or swaddling the arms. Communication between providers is encouraged if the practitioner examining the newborn in the hospital is different from the 2-week follow-up examiner. The presence of asymmetric hip abduction is suggestive of a unilateral dislocation. Limitation of hip abduction in babies older than 12 weeks is the most reliable examination finding suggestive of DDH. Hip abduction of 75 degrees should be possible in most newborns. The Galeazzi sign is elicited with the baby placed supine on an examining table so that the pelvis is level, with the hips and knees flexed to 90 degrees. With the baby's hips in neutral abduction, the examiner determines if the knees are at the same height. If one femur appears shorter than the other, the hip may be dislocated posteriorly (Fig. 89.1). Each of these signs, individually or in combination, may serve to increase the index of suspicion of the examiner and lower the threshold for further diagnostic studies or referral to a pediatric orthopedist. A unilateral dislocated hip may result in asymmetric thigh folds; however, extra thigh folds are a normal variant and do not necessarily indicate hip dislocation. *It is important to note that in an infant with bilateral hip dislocations, the Galeazzi sign will be negative and the hip abduction symmetric.*

There are two common methods of assessing hip stability in the newborn (Fig. 89.2). The Ortolani test aims to reduce a dislocated hip. This is performed on one leg at a time, with the infant supine on the examining table. The index and middle fingers of the examiner are placed along the greater trochanter, while the thumb is placed on the medial aspect of the thigh. The pelvis is stabilized

by the placing of the thumb and ring or long finger of the opposite hand on top of both anterior iliac crests simultaneously. The hip is flexed to 90 degrees and gently abducted while the leg is lifted with the hip in neutral external/internal rotation. A palpable clunk is felt as the dislocated femoral head reduces into the acetabulum. This finding is reported as the Ortolani sign (positive result on the Ortolani test). The Barlow test is an attempt to dislocate or sublux-ate a located but unstable hip. The thigh is held, and the pelvis stabilized in the same manner as for the Ortolani test. With the hip in neutral external/internal rotation and at 90 degrees of flexion, the leg is then gently adducted with a mild posteriorly directed pressure applied to the knee. A palpable clunk or sensation of posterior movement constitutes a positive result (i.e., the Barlow sign). High-pitched clicks are frequently elicited with hip range of motion. These sounds are most frequently attributed to snapping of the iliotibial band over the greater trochanter and are not associated with dysplasia.[6] With progressive soft tissue contractures and loss of ligamentous laxity, both the Ortolani test and the Barlow test become unreliable after approximately 3 months of age.

• **Fig. 89.1** Presence of Galeazzi Sign.

Imaging of the immature hip can be a valuable adjunct to the physical examination. An anteroposterior (AP) radiograph of the pelvis can be difficult to interpret before the age of 4 to 5 months as the femoral head is composed entirely of cartilage until the secondary center of ossification appears. Before the appearance of the secondary center, ultrasound examination is the method of choice for visualizing the cartilaginous femoral head and acetabulum. Static ultrasound images allow visualization of acetabular and femoral head anatomy, while the complementary dynamic images give information on the stability of the hip joint.[7,8] The primary limitation of hip ultrasonography is that the results are dependent on the experience and skill of the operator, especially when performed within the first 3 weeks after birth.[9] For these reasons, ultrasonography is recommended as an adjunct to clinical evaluation rather than as an independent screening tool.[1] Studies conducted before 6 weeks after birth may be useful for confirming equivocal physical examination findings and for monitoring treatment of hips with known dislocations. Clinicians must be aware, however, that ultrasound images in this age group often reveal minor degrees of dysplasia (physiologic immaturity) that usually resolve spontaneously and may lead to overtreatment of physiologic hip variations. Ultrasonography is the technique of choice for assessment of infants at high risk of DDH after 4 to 6 weeks of age and again is useful in following up the results of



• **Fig. 89.2** Assessing Hip Stability. (A) Ortolani-positive hips are those where the dislocated hip can be relocated. (B) Barlow-positive hips are reduced but can be dislocated.

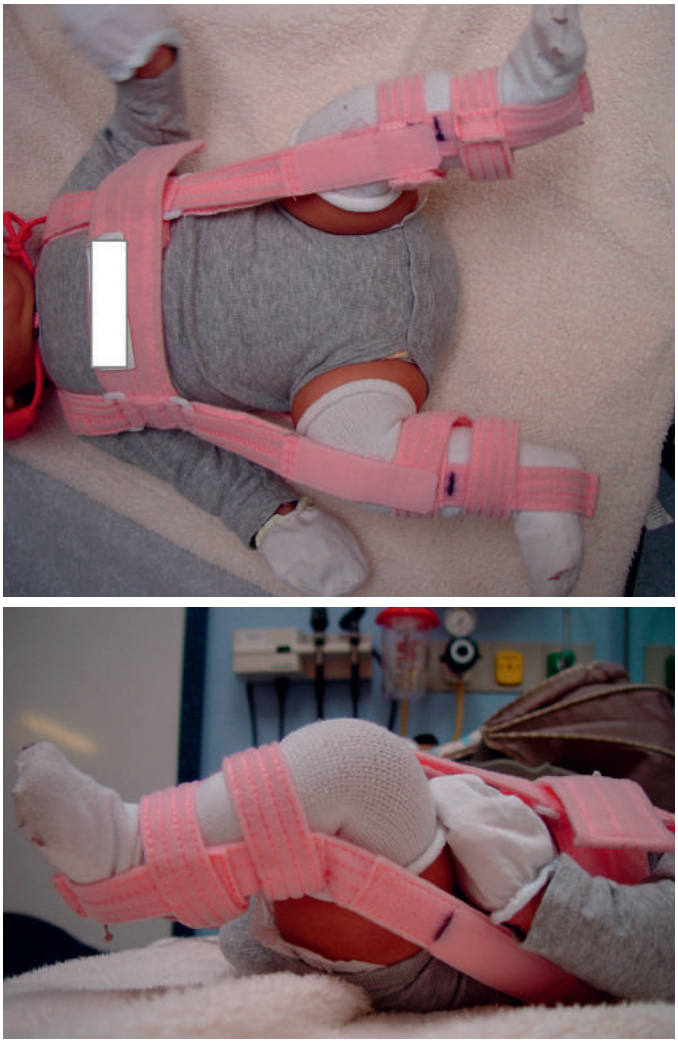
intervention. After 6 months of age, the gold standard remains the AP radiograph of the pelvis.

All newborns should be screened for DDH by a properly trained healthcare provider by physical examination. Risk factors for DDH should be determined by the treating physician. A Cochrane review found that neither universal nor targeted ultrasound screening strategies have been demonstrated to improve clinical outcomes, including the incidence of late-diagnosed DDH and need for surgery.[10] Adding further confusion to the debate over the approaches to optimal DDH screening procedure is a report by the US Preventive Services Task Force, which found "insufficient evidence" to recommend *any* routine DDH screening, including physical examination.[11] This recommendation was based on the lack of clear evidence for the efficacy of infant screening to reduce the incidence of late-presenting DDH. In response to these findings, the American Academy of Orthopedic Surgeons (endorsed by the American Academy of Pediatrics, the Pediatric Society of North America, and the Society for Pediatric Radiology) has published a revised clinical practice guideline to aid in the early diagnosis of and initiation of appropriate intervention for DDH.[12] These recommendations are summarized as follows:

1. Universal ultrasound screening. Moderate evidence supports not performing universal ultrasound screening of newborn infants.
2. Evaluation of infants with risk factors for DDH. Moderate evidence supports performing an imaging study before 6 months of age in infants with one or more of the following risk factors: breech presentation, family history, or history of clinical instability.
3. Imaging of the unstable hip. Limited evidence supports that the practitioner might obtain an ultrasound image in infants younger than 6 weeks of age with positive instability examination findings to guide the decision to initiate brace treatment.
4. Imaging of the infant hip. Limited evidence supports the use of an AP radiograph of the pelvis instead of an ultrasound image to assess DDH in infants beginning at 4 months of age.
5. Surveillance after normal findings from an infant hip examination. Limited evidence supports that a practitioner reexamine infants previously screened as having normal hip examination findings on subsequent visits before 6 months of age.
6. Stable hip with ultrasound imaging abnormalities. Limited evidence supports observation without a brace for infants with a clinically stable hip with morphologic ultrasound imaging abnormalities.
7. Treatment of clinical instability. Limited evidence supports either immediate or delayed (2 to 9 weeks) brace treatment for hips with positive instability examination findings.
8. Type of brace for the unstable hip. Limited evidence supports use of the von Rosen splint over Pavlik, Craig, or Frejka splints for initial treatment of an unstable hip.
9. Monitoring of patients during brace treatment. Limited evidence supports that the practitioner perform serial physical examinations and periodic imaging assessments (ultrasound or radiograph depending on age) during management for unstable infant hips.

If there are no risk factors, then serial examinations are recommended according to a standard periodicity schedule until the child is 6 months old. If during these periodic visits physical findings raise suspicion of DDH, or if a parental concern suggests hip disease, confirmation is recommended by an expert physical examination, by referral to a pediatric orthopedist (or other practitioner with expertise in medical and surgical management of newborn hip disease), or by age-appropriate imaging. When a positive Ortolani or Barlow test is present at birth and persists beyond the usual age of spontaneous resolution (2 to 9 weeks), the infant should be referred to an orthopedist for management. However, if the positive Ortolani or Barlow test disappears, then age-appropriate imaging (ultrasonography at 6 weeks or radiograph by 6 months) is warranted. If the infant has positive risk factors, such as breech positioning at birth or a family history but stable hip examination findings, then age-appropriate imaging is recommended (ultrasonography at 6 weeks or radiograph at 6 months).

Treatment of DDH is dependent on the age at presentation. Although previously recommended, double diapering is not an accepted form of treatment in DDH. For children aged 0 to 6 months, a reducible hip is treated in a Pavlik harness or another appropriate orthosis. The Pavlik harness is a dynamic orthosis that allows the infant to actively move the hips through a sphere of motion that encourages deepening and stabilization of the acetabulum (Fig. 89.3). The harness is applied as soon as possible after the diagnosis of DDH is made. The length of treatment is dependent on the age at presentation and severity of dysplasia. Progress



• **Fig. 89.3** The Pavlik Harness. Lightweight orthotic, useful in treatment of neonatal developmental dysplasia of the hip (DDH). The device holds the hip in flexion and abduction, promoting optimal positioning of the femoral head in the acetabulum. Excessive flexion and abduction should be avoided.

is judged by serial physical examinations and ultrasonography. In the case of a frankly dislocated hip, treatment is abandoned if the hip is not reduced within 4 weeks of harness application. The success of Pavlik harness treatment is variable and correlates with the severity of the hip dysplasia. Treatment is successful in nearly 100% of stable hips, greater than 90% of dislocatable (Barlow-positive) hips, 61% to 93% of dislocated but reducible (Ortolani-positive) hips, and only 40% of irreducible dislocations.[13–17]

For a persistently irreducible dislocation, or a child that presents late with a dislocated hip (after 6 months of age), either closed or open reduction of the hip under general anesthesia, with subsequent spica casting, is often required.[18]

Foot Deformities

Congenital deformities of the foot are relatively common but often overlooked in newborns. Consequently, the true incidence of the milder, self-limited deformities is unknown. For identification purposes, congenital foot abnormalities can be divided into those that result in the toes pointing upward (calcaneovalgus, congenital vertical talus), those that result in the toes pointing inward (metatarsus adductus, clubfoot), and those with too many toes or toes stuck together (polydactyly, syndactyly).

Calcaneovalgus is thought to be a postural deformity secondary to intrauterine positioning in which the dorsum of the foot is, or can be, directly opposed to the anterior aspect of the leg (Fig. 89.4). Plantar flexion of the foot is often limited from contracture of the anterior ankle and lateral soft tissues. The estimated incidence of calcaneovalgus is 0.4 to 1 per 1000 live births.[19,20] It appears to be more common in girls and after breech deliveries.[20] There may be an increased association with hip dysplasia, so a thorough hip examination is warranted, as outlined in Developmental Dysplasia of the Hip.[21] Complete resolution with gentle stretching exercises conducted by the parents can be achieved, although generally occurs spontaneously by 3 to 6 months of age. In the more severe calcaneovalgus feet where the ankle cannot be plantar flexed past the neutral position, serial casting to facilitate correction is often required. Calcaneovalgus may be seen in conjunction with external rotation of the tibia and posteromedial bowing of the tibia. A deformity that fails to resolve mandates referral to a pediatric orthopedist.

Calcaneovalgus should be differentiated from congenital vertical talus (CVT), a rarer condition that is frequently associated with neuromuscular conditions and syndromes such as arthrogryposis and spina bifida.[22] In CVT the hindfoot is fixed in equinus (plantar flexion), giving the sole of the foot a characteristic "rocker bottom" appearance because of dorsal dislocation of the midfoot though the talonavicular joint (Fig. 89.5). Treatment during infancy consists of serial casting to stretch dorsal soft tissues and reduce the midfoot, followed by limited surgical release if needed, pinning of the talonavicular joint, and Achilles tenotomy.[23] Most children require surgery between 6 and 12 months of age, and best outcomes are achieved when surgery is performed before age 2 years.[24] When casting fails to reduce the midfoot, more extensive surgical releases are required.

The two common neonatal foot deformities resulting in medial deviation of the toes are metatarsus adductus and talipes equinovarus (clubfoot). Metatarsus adductus is present at birth but frequently diagnosed later during the first year of life. It has been estimated to occur in 1 in 100 births[25] and is thought to result from intrauterine crowding.

Characteristic features include a concave medial border of the foot with a curved lateral border, a "bean-shaped" sole of the foot, a higher-than-normal-appearing arch, and a neutral heel (Fig. 89.6).[26] Metatarsus adductus can be classified into cases that undergo passive correction and those that do not. Feet which passively correct are best left alone and will improve spontaneously. Feet in which passive correction is not possible (the curved lateral border cannot be straightened) should be treated with manipulation and serial casting by age 6 to 9 months. The corrections can then be maintained with reverse or straight last shoes if necessary. Operative treatment should be considered only in children older than 3 years who have a rigid deformity and have failed to respond to a casting program.[27]

• **Fig. 89.4** Calcaneovalgus Foot. (From *Pediatric Pes Planus JAAOS* Oct. 2015, Bouchard M, Mosca VS. Flatfoot deformity in children and adolescents: surgical indications and management. *J Am Acad Orthop Surg*. 2014;22:623–632.)

• **Fig. 89.5** Congenital Vertical Talus. (From *Pediatric Pes Planus JAAOS* Oct. 2015, Bouchard M, Mosca VS. Flatfoot deformity in children and adolescents: surgical indications and management. *J Am Acad Orthop Surg*. 2014;22:623–632.)

The term *clubfoot* describes a foot with hindfoot equinus, heel varus, and adduction and supination of the forefoot (Fig. 89.7). Clubfoot deformities range from mild to severe and occur in 1 in 1000 to 2 in 1000 live births.[28] A risk factor for clubfoot is early amniocentesis (11 to 13 weeks' gestation), which is hypothesized to cause decreased fetal movement during a critical phase of foot development.[29] Although the cause of clubfoot remains unproven, there appears to be dysplasia of all osseous, muscular, tendinous, cartilaginous, skin, and neurovascular tissues distal to the knee in the affected limb.

The mild, "postural" clubfoot appears to represent a packaging problem due to intrauterine positioning. This deformity is passively correctible, demonstrates minimal or no calf atrophy, and resolves spontaneously or responds quickly to a stretching and casting regimen. At the opposite end of the spectrum is the arthrogrypotic or neuromuscular clubfoot that demonstrates severe rigidity. Between these two extremes lies the classic, idiopathic clubfoot deformity. Idiopathic clubfeet demonstrate a deep, single medial skin crease, curved lateral border with a high arch, and rigid varus and equinus of the heel with a deep, single, posterior skin crease.[30] This gives the foot its "down and in" position and toes pointing to the midline. In unilateral cases the affected limb has a smaller foot and calf circumference (see Fig. 89.7).

• **Fig. 89.6** The Appearance of the Foot with Metatarsus Adductus. (Courtesy Dr. Vincent S. Mosca, Seattle Children's Hospital, Seattle.)

• **Fig. 89.7** The Appearance of an Untreated Newborn Clubfoot. (Courtesy Dr. Vincent S. Mosca, Seattle Children's Hospital, Seattle.)

All clubfoot deformities should be referred to a pediatric orthopedist for treatment. Initial treatment for all cases of congenital clubfoot is nonoperative. Untreated clubfoot has a poor natural history, with development of early degenerative changes in the foot joints. Historically, clubfeet were treated with early and extensive surgical correction. The long-term results, however, are poor, with high recurrence rates.[27] Consequently, this approach was abandoned, and surgeons began advocating nonoperative methods of clubfoot correction.[31–33] Although many forms of nonoperative clubfoot treatment exist, the Ponseti method of cast correction has achieved preeminence in this regard. Studies show excellent mid-term to long-term results with decreased stiffness.[34]

The Ponseti method uses a specific set of manipulations and serial corrective long-leg casts, followed by a prolonged period of bracing. Treatment is ideally commenced within the first few weeks after birth, but successful treatment is commonly achieved when treatment is initiated up to 1 year of age.[35] We prefer to initiate treatment 1 to 2 weeks after discharge from the hospital to allow parental adjustment for the new infant at home. Every 5 to 7 days, manipulation of the foot is performed with passive stretching, and the correction is maintained with a new long-leg cast, with an average of four to five casts in the idiopathic clubfoot.[23] This is followed by percutaneous Achilles tenotomy in most patients and a further 3 weeks of casting. Children are then placed into a foot abduction orthosis full-time for a period of 3 months and then part-time, while sleeping, until approximately age 4 years.

The "French functional method" has also been successfully duplicated in at least one US hospital with good results.[28,36] This method necessitates daily manipulations by a trained physical therapist for 8 weeks, with the addition of continuous passive motion during the first 4 weeks. This is followed by strapping and continued bracing.

The Ponseti and the French "nonoperative" methods both frequently use Achilles tenotomy and, at times, tendon transfers to attain the ultimate desired result. Recurrences of deformity are common (16% to 37%), requiring further casting. A smaller percentage of patients (8% to 16%) require surgical release of the hindfoot to various degrees.[36,37]

Torticollis

Congenital muscular torticollis (CMT) manifests itself at birth or soon, thereafter, and is the most frequent cause of wryneck. However, other conditions, some more serious, may cause torticollis.

1. Bony anomalies of the vertebra and skull (e.g., Klippel-Feil syndrome, hemivertebrae, basilar invagination, craniosynostosis)[38–40]
2. Abnormalities of the central nervous system (e.g., syringomyelia, tumors)[41]
3. Chiari malformations[42]
4. Ocular abnormalities[43]
5. Pharyngeal abscess
6. Gastroesophageal reflux (e.g., Sandifer syndrome).[44]

Patients with CMT can be divided into those who demonstrate a sternocleidomastoid muscle (SCM) "pseudotumor," those with tightness or fibrosis of the SCM without pseudotumor (termed *muscular torticollis*), and those with all the characteristic features of congenital torticollis without evidence of contracture or fibrosis of muscle (termed *postural torticollis*).[45]

CMT has been estimated to occur in 0.3% to 2.0% of live births.[45] It is usually discovered between 6 and 8 weeks after birth. Infants present with a cock robin appearance, with the head tilted toward and the chin rotated away from the affected SCM. 20-30% of patients will have a palpable pseudotumor present in the middle to inferior aspect of the affected SCM, which spontaneously regresses with time, leaving a fibrous band.[46] More than half will have facial asymmetry or plagiocephaly. The left and right SCMs are affected in equal proportions. CMT probably results from ischemia within the SCM, leading to fibrosis.[47] The cause of the ischemia is unknown, but intrauterine crowding may play a role, in as much as some authors have reported an association of torticollis with other deformations, such as DDH and metatarsus adductus.[48,49]

Excellent results with a manual stretching program can be attained in children first seen before 1 year of age.[48,50] Initially, the parents are instructed in the technique of stretching the contracted SCM by rotating the infant's chin toward the affected SCM while simultaneously tilting the head away from it. This is completed 10 times each session and held for a count of 10 and done at least 10 times per day. Unfortunately, adherence may be an issue. If the child fails to improve substantially within 3 to 4 weeks, a physical therapist is enlisted to see the child two or three times weekly to supervise the program and reinforce the home therapy. Additionally, parents are instructed to configure the infant's crib and toys in such a manner as to encourage active rotation toward the involved side.

Surgery is not warranted in any child younger than 1 year or in any child who has not completed a minimum of 6 months of therapy.[45,48] In a prospective study of 821 children with muscular torticollis, only 8% of patients with a history of a pseudotumor, and 3% of those without, required surgical intervention following a well-structured stretching program.[45] Because of the difficulty of monitoring exercise programs, because parental adherence is always in question, and because surgical intervention is infrequent, it is possible that in many patients the resolution is spontaneous. No patients with postural torticollis require surgery. Risk factors for surgery include late initial presentation, presence of a pseudotumor, and rotation deficit of greater than 15 degrees.

The timing of surgical intervention remains controversial. In patients with significant plagiocephaly and facial asymmetry, surgery should be considered just before 2 years of age to maximize the chance for complete remodeling. For those with either no or mild facial asymmetry, good to excellent results can be expected with surgery up to 6 years of age.[51] Acceptable results are reported as late as 12 years of age, but the ability to remodel facial asymmetry appears diminished.[52] More recent literature suggests good surgical outcomes in neglected CMT even after 15 years of age.[53] Surgery entails bipolar release or lengthening of the SCM through cosmetically pleasing incisions.[54] The use of a molded helmet to promote facial and skull remodeling is common. Prospective studies that establish the effectiveness of helmets are lacking, and in at least one study was found to be possibly detrimental.[55]

A less frequent cause of congenital torticollis is osseous fusion between bones in the cervical spine. These fusions may be between the skull and C1 and/or C2 or in the lower cervical spine. They result from failure of the bones to properly segment during embryogenesis. These abnormalities, in combination with a low posterior hairline and a short, webbed neck with limited range of motion and head tilt, constitute the triad referred to as Klippel-Feil syndrome (KFS).[56] These congenital bone fusions can range from involvement of two segments to involvement of the entire cervical spine. Colloquially, KFS has come to refer to any congenital malformation in the cervical spine with or without other elements of the triad. Most cases of KFS do not have a genetic etiology, however additional forms of KFS include autosomal recessive KFS2 caused by mutation in the MEOX1 gene, autosomal dominant KFS3 caused by mutation in the GDF3 gene, and autosomal recessive KFS4 caused by mutation in the MYO18B gene.

In infants and young children, the neck may remain quite flexible despite the bone abnormalities. In a newborn with torticollis who does not improve with passive stretching exercises, radiologic evaluation is mandatory. Cervical spine radiographs are not recommended in all patients initially presenting with neonatal torticollis, as these radiographs are quite difficult to interpret in this age group because of the predominance of cartilage in the bones of the neck. Furthermore, many neonates would be subjected to unnecessary ionizing radiation.

The natural history of KFS in most cases is quite favorable, requiring nothing more than periodic observation. In patients with severe involvement, however, the consequences of this disorder can include early spondylosis with the development of pain or stenosis, the development of progressive torticollis and scoliosis, and the occurrence of neurologic compromise and sudden death secondary to even minimal trauma.[46] Despite these potentially devastating sequelae, the greatest advantage of early detection of KFS is in being alerted to commonly associated disorders, including congenital heart disease (14% to 29%), renal anomalies (25% to 35%), scoliosis (60%), audiologic anomalies (80%), including deafness (15% to 35%), synkinesis (15% to 20%), and less commonly, posterior fossa desmoid tumors.[46,57] The recognition of a Klippel-Feil anomaly should prompt a thorough evaluation for these associations. Treatment of KFS most often involves periodic observation with activity modification. In the face of progression of deformity or severe deformity, surgical intervention may be warranted.

Sandifer syndrome (gastroesophageal reflux) can also cause a torticollis. With this syndrome the torticollis is intermittent and may change direction, and there is no tightness of the SCM, with normal findings on radiographs.[44]

Hemiatlas, or the failure of formation of a portion of the first cervical vertebra, is also a rare cause of torticollis.[39] In an infant the neck may be quite flexible and the torticollis passively correctable. An open-mouth (odontoid view) cervical spine radiograph reveals this deformity. If the torticollis is progressive or severe, gradual correction of the deformity with a halo vest followed by posterior occiput to cervical spine fusion is necessary. Other potential causes of torticollis in the neonate include central nervous system tumors and syringomyelia. If radiographs appear normal, a thorough neurologic examination and referral to a neurologist are recommended.

Torsional and Angular Deformities of the Lower Extremities

Torsional and angular deformities of the legs constitute the most frequent nontraumatic reason for referral to a children's orthopedist. Torsional deformities of the lower extremities rarely come to the attention of the physician before the child reaches walking age. Neonates often demonstrate bowing of the legs, or genu varum, but are rarely concerning to parents prior to walking age. Internal tibial torsion imparts an appearance of bowing to the tibia,[58] which is often concerning to both the parent and the physician. The true

incidence of genu varum is unknown, but in our experience, it is extremely common. Both genu varum and internal tibial torsion are nearly universal in neonates. Both should spontaneously resolve between 2 and 3 years of age, with a small minority of affected children manifesting a pathologic condition.

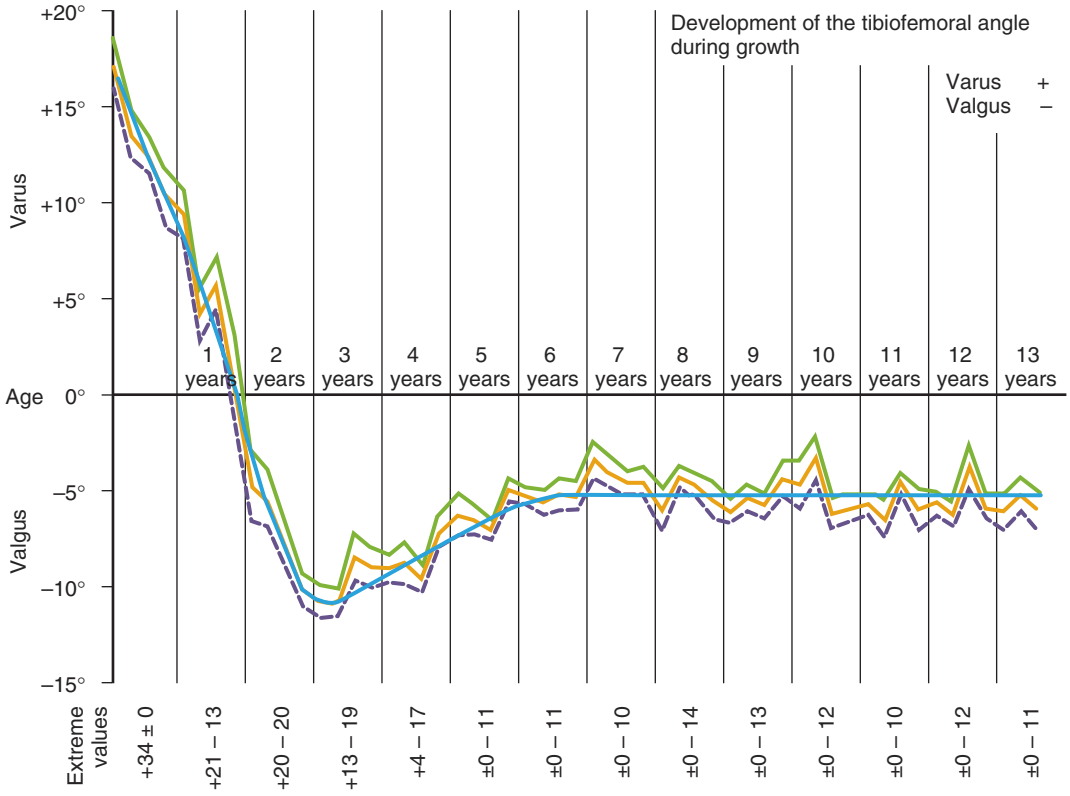
Genu varum is physiologic up to the age of 2 years. In 1975, Salenius and Vankka[59] documented the tibiofemoral angles both clinically and radiographically in 979 children based on 1408 examinations between birth and 16 years of age. They noted that newborns demonstrate a mean varus alignment of 15 degrees, which increases and becomes maximal at 6 months of age and then decreases to neutral at approximately 18 months. The maximum valgus (knock knees) of 12 degrees is then achieved by 3 to 4 years. By age 7 years, normal adult valgus alignment is achieved (Fig. 89.8). Natural history studies have demonstrated that physiologic genu varum is a self-limited process, and even with an angulation greater than 30 degrees has been shown to undergo correction spontaneously with growth.[60] Management of physiologic genu varum and tibial torsion consists of serial observation, parental reassurance and education. Treatment with an orthosis is not recommended.

Physical examination should include evaluation of the torsional profile,[61] which includes measurements of internal and external rotation of the hips, the thigh–foot angle, and the patient's foot progression angle when walking. Measurement of the thigh–foot angle is performed with the child in the prone position comparing the axes of the sole of the foot with the thigh and is an indicator of tibial torsion.

It is important to note whether onset of the varus of the lower extremities is gradual or abrupt, and if the deformity can be localized to the distal part of the femur, the proximal part of the tibia, or the midportion of the tibia. Radiographs are indicated only with asymmetric deformities, with short stature, persistent varus past 2 years of age, or in infants with progressive deformities. The examiner should also look for evidence of rhizomelic shortening and genu varum, which may herald a diagnosis of achondroplasia or other skeletal dysplasia.

Considerations in the differential diagnosis of genu varum include focal fibrocartilage dysplasia, skeletal dysplasias, posttraumatic physeal growth arrests, osteogenesis imperfecta (OI), and metabolic bone disease such as vitamin D–resistant rickets, renal osteodystrophy, and tibia vara (infantile Blount disease). Blount disease is bilateral in 80% of affected children and does not occur before walking age. Most clinicians agree that this diagnosis cannot be made before 2 years of age.

Tibial bowing can also occur in the sagittal plane. There are two major types of bowing distinguished by the direction of the apex of the bow. Posteromedial bowing has been previously described in conjunction with calcaneovalgus foot position in the neonate. Its cause is unknown, but numerous hypotheses have been proffered, including intrauterine fracture with malunion and in utero malpositioning with subsequent growth retardation and soft tissue contractures.[62] The deformity is unilateral and evident at birth. Other features include shortening of the tibia and a smaller calf circumference and smaller foot relative to the contralateral side. Frequently there is a skin dimple at the apex of the deformity. Radiographic examination of the entire extremity from hip to ankle should be performed. Radiographs demonstrate the degree of bowing and in some cases thickening and sclerosis of the diaphyseal cortices on the compression side of the deformity with obliteration of the intramedullary canal. There is no increased fracture risk associated with the deformity.



• **Fig. 89.8** Development of the Tibiofemoral Angle During Growth. (Data from Salenius P, Vankka E. The development of the tibiofemoral angle in children. J Bone Joint Surg Am. 1975;57:259–261.)

Posteromedial bowing tends to resolve with growth, such that much of the deformity resolves by 2 years of age, with continued gradual correction beyond that. The shortening of the tibia and fibula persists, however, and progressively worsens during growth. Leg length inequality at skeletal maturity averages 4.1 cm.[63] Early referral to and serial follow-up assessments by a pediatric orthopedist are necessary to appropriately time epiphysiodesis surgery of the normal longer leg to allow equal leg lengths at skeletal maturity.

The second and more serious type of tibial bowing is anterolateral. It is usually identified at the newborn examination. It is unilateral and can be associated with congenital pseudoarthrosis of the tibia. Although its cause is unknown, congenital pseudoarthrosis of the tibia is associated with neurofibromatosis type 1 (NF1) in 40% to 80% of cases.[62,64,65] It is arguably the most challenging congenital malformation to treat in orthopedics. It is estimated to occur in 1 in 140,000 live births.[66] Cutaneous signs of NF1 may be evident. Early referred to pediatric orthopedics and genetics are recommended.

If fracture has occurred, motion at the pseudoarthrosis site will be apparent. The foot may be normal or slightly small. The ankle may be in slight valgus to compensate for the bowing. The natural history of congenital pseudoarthrosis of the tibia is that of fracture with nonunion and repeated surgical attempts at obtaining union. In the perambulatory child, a total-contact (clamshell) ankle–foot orthosis should be fabricated and worn full-time except for bathing, to diminish the chance of fracture. Bracing is continued until skeletal maturity is attained. Although definite proof that long-term bracing affects the natural history of this condition is lacking, most orthopedists consider that bracing is warranted. Many treatment options exist once a documented pseudoarthrosis occurs. Long-term immobilization, external fixation, internal fixation, bone transport, bone grafting, microvascular bone transfer, and electric stimulation have been attempted.[66] High failure rates are commonly reported. Amputation has been advocated as a salvage procedure after failed attempts at union and typically has good outcomes.[67,68] Herring et al.[68] reported that children who underwent Syme amputation had better psychologic and orthopedic functioning than those children who underwent numerous corrective surgical procedures. A more recent cross-union technique has been described with the goal of producing a synostosis between the tibia and fibula and has shown excellent union rates.[69]

Tibial bowing in the anteromedial direction rarely occurs and is typically seen in children with fibular hemimelia, a condition with multiple lower limb anomalies. In addition to a deficient or absent fibula, there is a strong association with absent lateral rays of the foot, a bowed tibia, knee deformities, a short femur, hip dysplasia, and leg length discrepancy. Orthopedic referral is indicated.

Tibial bowing may also be confused with a congenital knee dislocation. This is a rare condition, noted at birth, with a reported incidence of 0.017 per 1000.[70] The cause is unknown but most likely related to contracture of the quadriceps muscle. Congenital knee dislocations can be associated with clubfoot, arthrogryposis, myelodysplasia, and Larsen syndrome, with ipsilateral hip dysplasia occurring in 70% to 100% of cases.[71] The knee can be hyperextended so severely that the foot might even reach the child's face, and the knee cannot be flexed. Nonsurgical treatment, consisting of manipulation and serial casting, should be started promptly after radiographic diagnosis. Surgery is reserved for children who do not respond to nonsurgical treatment and is best performed at the age of approximately 6 months (Fig. 89.9).[72]

Congenital Vertebral Malformations

Congenital vertebral malformations occur in 0.5 in 1000 to 1 in 1000 live births. Although a minority of cases may be due to genetic inheritance, there are no established gene defects that solely account for these disorders. The syndromes associated with them include Klippel-Feil syndrome (KFS), Goldenhar syndrome, VATER (VACTERL) sequence, and spondylocostal dysostosis. Likewise, many congenital vertebral malformations occur in isolation and may be due to intrauterine exposures such as maternal hyperglycemia, exposure to carbon monoxide, or exposure to antiepileptic drugs. The ultimate concern with congenital vertebral anomalies is their potential to result in significant spinal deformity; namely, scoliosis or kyphosis, or a combination of the two. Many, however, remain asymptomatic throughout life.

Defects can be attributed to a failure of formation, a failure of segmentation, or both.[73] Failures of formation result from asymmetric vertebral body formation and ensuing development of a hemivertebra. Hemivertebrae can be incomplete, with partial retention of the affected side, or complete. When partial retention of the pedicle occurs, a wedge vertebra develops. Complete hemivertebra can be further categorized. Radiographically, the presence of open disk spaces signifies the presence of growth plates and therefore growth potential. Unsegmented hemivertebrae, in which the segment is fused to one vertebra or both adjacent vertebrae, have less growth potential and therefore less deformity potential. Fully segmented hemivertebrae retain full growth potential from both the cranial end and the caudal end and consequently demonstrate a much greater propensity to result in significant deformity. Failures of segmentation are characterized by bony fusions (bars) between adjacent vertebrae. Bilateral bars result in "block vertebrae" that, because of their symmetry, have minimal potential for deformity.

The propensity to result in a clinically significant deformity depends on the location of the defect, the type of defect, and the age of the patient.[74] Curves at the lumbosacral and cervicothoracic junctions may result in more clinically apparent deformities. Prediction of progression is largely driven by the presence of unbalanced defects.[73] In order of severity, the risk of progression in congenital spinal deformities is associated with the following

• **Fig. 89.9** Congenital Knee Dislocation.

defects: unilateral bar with contralateral hemivertebra, unilateral bar, hemivertebra, wedge vertebra, and block vertebra (Fig. 89.10). Additionally, the presence of multiple anomalies at multiple levels (e.g., multiple hemivertebra) can result in additional risk of progression when they are on the ipsilateral side or, conversely, may result in balanced growth when they are on contralateral sides of the spine.

All patients with known congenital spinal deformities should be evaluated for associated cardiac and renal anomalies. Cardiac anomalies are found in approximately 15% of these children and are usually evident on physical examination. Routine screening with an echocardiogram is not recommended unless clinical findings are suggestive.[75] Renal anomalies, on the other hand, are often clinically silent and have been reported in up to 37% of children with known congenital spinal anomalies.[76] Thus, routine sonography of the urinary tract system is recommended for all children with congenital spinal malformations.

Occult intraspinal anomalies are found in up to 30% of children with congenital spinal malformations. These include Chiari malformations, syringomyelia, tethered cord, reduced spinal cord diameter, and diastematomyelia. Associated physical examination findings are those consistent with occult dysraphism, such as dimpling of the skin, pigmentation changes, or the presence of hairy patches or skin tags in the lower back or intergluteal cleft. Changes to the lower extremities such as atrophy, foot deformities, and asymmetric or pathologic reflexes are also suggestive of intraspinal defects.

Infants with congenital spine anomalies should initially be evaluated with dedicated plain radiographs of the whole spine. Coned-down views of affected parts of the spine may offer additional information about the anatomy of interest. Rib anomalies should be noted, because they are commonly associated with thoracic spine malformations and may have significant long-term implications with regard to restrictive lung disease.[77] The position of the scapula should also be evaluated, because Sprengel deformity is found in up to 50% of children with congenital cervical spine anomalies.[38] The use of magnetic resonance imaging (MRI) is reserved for those children preparing to undergo surgical intervention or those with clinical evidence of neurologic abnormality.[74] Cutaneous anomalies of the lumbar spine in the newborn may be evaluated by ultrasonography. This is a particularly effective method for determining the level of the conus medullaris and thus the presence of tethered cord. Computed tomography is typically not indicated in the newborn owing to concerns of unneeded radiation exposure, but if done for other reasons, it can give additional detail on spinal anatomy.

Obstetric Trauma

Birth trauma can be divided into two categories: fractures and neurologic injuries. Birth fractures most commonly involve the clavicle, with clavicular fractures occurring in 2 to 3 per 1000 births.[78] Birth fractures may also occur in the proximal part of the humerus[79,80] the femur (0.13 per 1000 births),[81] and even the thoracic spine. It is important to note that clavicular fracture can be seen in combination with a proximal humeral physeal separation or in combination with a brachial plexus injury. Reported risk factors for upper extremity birth fractures include:

1. Large size of the baby
2. Limited experience of the obstetrician
3. Midforceps delivery[78,82]

Risk factors for femoral fracture include:

1. Twin gestation
2. Breech presentation
3. Prematurity
4. Osteoporosis[81]

Nadas et al. have reported an association of long-bone fractures with cesarean delivery, breech delivery with assistance, and low birth weight.[83]

The natural history of isolated birth fractures to the extremities is that of uneventful rapid healing without untoward sequelae. Clavicle fractures may be difficult to diagnose, because the neonate may be asymptomatic. Newborns with either a clavicle fracture or a proximal humeral physeal separation often have pseudoparalysis of the upper extremity. Considerations in the differential diagnosis include an obstetric brachial plexus palsy and hematogenous metaphyseal osteomyelitis of the humerus with septic glenohumeral arthritis. Pain with direct palpation of the clavicle may be present with obvious deformity. Pain with motion of the shoulder joint and with palpation of the proximal part of the humerus may be caused by either fracture or infection. Elicitation of neonatal reflexes such as the Moro reflex and asymmetric tonic neck reflex (ATNR) may be helpful in evaluating active upper extremity muscle function.[84] Radiographs should be obtained. Ultrasound evaluation of the proximal part of the humerus may be helpful because the proximal humeral epiphysis is entirely cartilaginous at birth and thus radiolucent. Ultrasound examination can detect proximal physeal separation, metaphyseal osteomyelitis, and septic shoulder arthritis.[79,80]

Asymptomatic birth fractures of the clavicle and humerus in neonates may be observed. The fracture will unite in short order, with remodeling of bone occurring with growth. Symptomatic fractures in which the child exhibits pseudoparalysis of the upper

• **Fig. 89.10** Types of Congenital Spinal Anomaly and Risk of Progression. (From McMaster MJ, Ohtsuka K. The natural history of congenital scoliosis. A study of two hundred and fifty-one patients. *J Bone Joint Surg Am*. 1982;64:1128–1147.)

extremity should be treated with 7 to 10 days of immobilization in a soft dressing or until symptoms subside. Femoral birth fractures can be treated with a soft Pavlik harness with good results.[81] This device provides a simple means of immobilization that is accepted well by new parents. Excellent outcomes with no residual deformities or limb length inequalities can be expected.

The presence of multiple long-bone and rib fractures at birth may herald the presence of osteogenesis imperfecta (OI). Prenatal diagnosis is commonly made by ultrasonographic screening, as early as 13 to 14 weeks' gestation, based on deformity.[85] OI is typically classified by the Sillence classification, with type II and type III being the most common types identified in the perinatal period.[86] Type II OI is generally considered to be lethal in the neonatal period, whereas most children with type III OI survive into adulthood with considerable short stature and fracture-related morbidity. Thus, prompt genetic consultation is critical to establish a diagnosis and prognosis for an affected child. A diagnosis of Bruck syndrome should be considered when clinical and radiographic findings of OI are coupled with joint contractures.[87] Infants with type III OI often require substantial respiratory support and pain management because of rib fractures, with respiratory failure being identified as the most common cause of death in the neonatal period. Treatment of long fractures is primarily to support pain management and can be achieved by custom splints or merely soft supports, such as pillows or blankets. Patients with multiple fractures at birth who are expected to survive the neonatal period should be considered for bisphosphonate treatment.[88]

Brachial plexus injuries represent the second category of birth trauma afflicting newborns. The mechanism of injury is a separation of the head from the shoulder by lateral bending of the neck with simultaneous shoulder depression during vaginal delivery resulting in a stretching or avulsion of the brachial plexus. These injuries occur in 1 per 1000 to 4 per 1000 live births.[89,90] Risk factors include maternal diabetes, large birthweight, prolonged labor, forceps delivery, and shoulder dystocia during a vertex delivery.[91] They are rarely seen in cesarean deliveries. Brachial plexus palsies are associated with clavicle and humerus fractures, as well as torticollis.[91] Risk factors for brachial plexus injury include:

1. maternal diabetes
2. large birthweight
3. prolonged labor
4. forceps delivery
5. shoulder dystocia during vertex delivery

The brachial plexus receives contributions from the anterior spinal nerve roots of C5 through T1, which combine and divide to form the peripheral nerves that supply the motor innervation to the upper extremity. Three major injuries are encountered. The most frequent injury is to the upper trunk that involves the C5 and C6 nerve roots primarily and results in Erb palsy. Affected infants lack external rotation and abduction of the shoulder. Hand function is preserved. The next most frequently occurring injury is a global plexus palsy involving the C5 through T1 nerve roots. This results in flaccid paralysis of the involved upper extremity, including the hand. An isolated lower plexus injury involving the C8 and T1 nerve roots, termed Klumpke palsy, is the least common and may be a manifestation of a recovered global plexus injury.[92]

Physical examination has proved to be the most reliable method of assessing the level and severity of the neural injury and thereby predicting the potential for spontaneous recovery.[92,93] Myelography, computed tomographic myelography, magnetic resonance imaging, and electrodiagnostic studies have not proved useful in predicting recovery.[92] Active shoulder, elbow, wrist, and finger motion need to be assessed.[91] Frequently, such assessment can be facilitated by elicitation of the primitive reflexes that are transiently present in normal newborns. The hand grasp reflex is normal in all newborns and disappears between 2 and 4 months. The examiner's little finger is placed on the ulnar aspect of the infant's palm, and the infant's fingers reflexively flex and grasp the examiner's finger. The Moro reflex begins to fade at 3 months of age. It is elicited by the examiner holding the newborn's hands while raising the baby off the table and then suddenly releasing them. In response, the newborn extends the spine, abducts and extends all four limbs and digits, and then subsequently adducts and flexes the limbs and digits. Last, the ATNR, or fencing reflex, can be elicited in a normal newborn until the age of 4 months. With the infant lying supine on an examining table, the head is rotated to one side by the examiner. The infant should respond by extending the elbow on the side toward which the face is looking and by flexing the opposite elbow. In newborns with a brachial plexus injury, some of these reflexes will be abnormal because of lack of motor control. For instance, the newborn with Erb palsy will, most notably, not be able to actively flex at the elbow during the ATNR or the Moro reflex. The presence or absence of Horner syndrome (contracted pupil, drooping eyelid, and decreased sweating on the affected side) must also be noted.

Affected infants need repeated serial examinations until 6 months of age. Return of biceps function by 3 months is the most important indicator of brachial plexus recovery.[94] When biceps recovery is combined with the return of shoulder abduction, wrist extension, and finger extension, there is a 95% chance of normal function.[94] When biceps function recovers later than 3 months, it is rare for the child to have complete recovery of normal function.[95] A total plexus palsy or the presence of Horner syndrome also heralds a poor prognosis.[92,94]

The initial treatment of obstetric brachial plexus injury is aimed at avoiding contractures of the shoulder, elbow, forearm, and hand with occupational or physical therapy during the observation-for-recovery phase. Fortunately, as few as 1 in 10 infants with brachial plexus palsies at birth will require surgical intervention.[91] With the decision for surgery being based on muscle function recovery, prompt referral to a specialist is recommended to initiate monthly neurologic examinations.

Brachial plexus exploration with subsequent reconstruction is indicated for infants with total plexus involvement, Horner syndrome, and no return of biceps function at 3 months and for infants with a C5 to C6 (Erb) plexopathy and no return of biceps function at 3 to 6 months.[92] Surgery is undertaken between 3 and 6 months of age. Using this algorithm prospectively,[95] operated on six infants at 6 months and found that their results were better than those for the 15 patients with biceps recovery at 5 months but worse than those for the 11 patients with biceps recovery at 4 months. Despite treatment as outlined, some children will have residual deficits. Secondary reconstruction, for chronic brachial plexopathy resulting in a dysfunctional shoulder, can be achieved with a tendon transfer of the latissimus dorsi and teres major to the rotator cuff or by derotational osteotomy of the humerus. These procedures and others designed to correct limitations in hand and forearm function are undertaken after the true scope of the disability has been assessed. Some infants with no biceps recovery by 3 months will eventually achieve adequate biceps and shoulder function without surgery.[96] The optimal timing of

surgical intervention remains controversial. Surgical exploration after 18 months is of little benefit.

Neonatal Osteomyelitis and Septic Arthritis

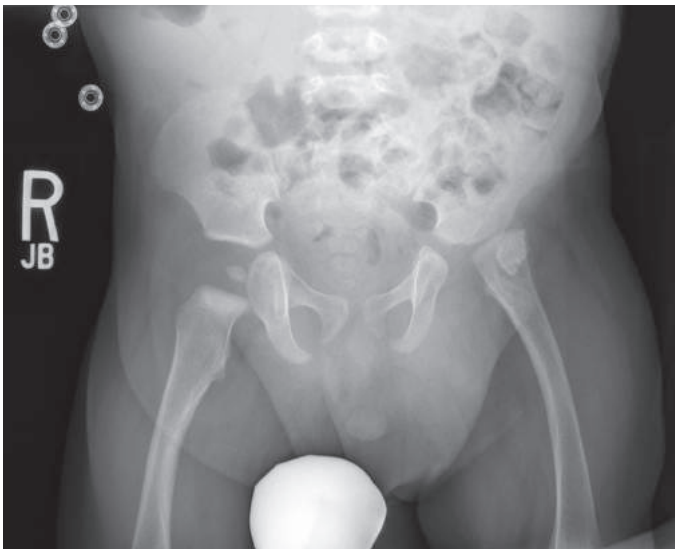
Osteomyelitis is a bacterial infection of bone, and septic arthritis is a pyogenic infection of a joint. Incidence rates of 0.12 per 1000 live births and 0.67 per 1000 neonatal intensive care unit admissions[97] have been reported for septic arthritis. The mortality rate is reported to be 7.3%.[98] The hip, knee, and shoulder joints are involved most frequently. Neonates are particularly susceptible to osteomyelitis and septic arthritis because of an immature immune response, resulting in vulnerability to organisms that are not ordinarily virulent in infants and children, and because of delays in expressing the classic physical findings associated with these conditions.[99]

Two subgroups of neonates are affected: premature neonates requiring prolonged hospitalization and otherwise healthy newborns in whom presentation occurs within 2 to 4 weeks after delivery.[99] Most cases of neonatal osteomyelitis and septic arthritis result from hematogenous spread, but some occur from direct inoculation during percutaneous arterial blood sampling (especially if obtained from the femoral artery). Acute hematogenous osteomyelitis (AHO) and septic arthritis in hospitalized neonates usually occur in premature infants with multiple peripheral and central vascular catheters.[100] These infections are frequently caused by *Staphylococcus aureus* or gram-negative organisms.[101,102] Up to 40% of these patients may demonstrate multiple areas of involvement and these patients can be systemically ill.[103,104]

This presentation contrasts with that of the typical out-of-hospital newborn with AHO and septic arthritis, in whom 2 to 4 weeks after birth, swelling, pseudo paralysis (lack of active movement of affected limb) and tenderness of the extremity present, but the infant otherwise feeds well and is not systemically ill.[99] *S. aureus* and group B streptococcus are the most common organisms encountered in this latter population. Because of the immature immune response, neonates frequently do not demonstrate fever, leukocytosis, or elevation in erythrocyte sedimentation rate (ESR).[105] However, C-reactive protein (CRP) is a reliable indicator of AHO and septic arthritis, with a negative predictive value of 95%.[100] Blood culture findings are positive in only 50% of patients; cultures of synovial aspirates identify an organism in only 30% of cases.[106]

Prompt diagnosis is imperative, both to decrease the risk of systemic infection and sepsis but also decrease the chances of long term local musculoskeletal issue such as avascular necrosis of the hip. Imaging studies are useful in diagnosing neonatal osteomyelitis and septic arthritis. Plain radiographs are usually the first study performed although they do not always yield a diagnosis in early infections. Bone changes on plan radiographs are not present for 1 week after the onset of symptoms.[107,108] Ultrasound examination is the first line radiologic method for evaluating the neonate with suspected AHO and/or septic arthritis, as it detects joint effusions and subperiosteal and soft tissue fluid collections and can guide aspiration. If an infection is still suspected despite negative findings after radiographic and ultrasound examination, MRI is warranted. MRI provides accurate regional information on both the soft tissues and bones and is highly sensitive in identifying early infections[109] but requires sedation in infants.

In neonates, before the appearance of the secondary ossification center, the epiphysis receives blood directly from metaphyseal blood vessels. When the infection occurs in these metaphyseal veins causing osteomyelitis, it can traverse the growth plate into the epiphysis, cause abscess formation, and rupture into the joint.[110] Thus, septic arthritis is a sequela of adjacent osteomyelitis in up to 76% of neonates.[103,111] The hip and shoulder are two of the more common sites of neonatal septic arthritis as they have intra-articular metaphysis, allowing a more direct subperiosteal route of decompression for pus into the joint. Because of this unique ability to spread from the metaphysis through the growth plate into the joint, early detection and treatment are necessary to avoid permanent damage to each of these structures. Infection can result in destruction of the growth plate and articular cartilage in short order, resulting in growth disturbances and precocious arthritis. When an area of involvement is suspected, aspiration should be undertaken,[99] which can confirm the diagnosis and provide fluid for culture to better direct antibiotic treatment. Osteomyelitis without a pus collection in bone or soft tissue can typically be managed with antibiotic therapy; septic arthritis and subperiosteal and bone abscesses should always be drained surgically in the operating room (Fig. 89.11).



• **Fig. 89.11** Unrecognized neonatal hip sepsis can result in complete dissolution of the femoral head as demonstrated in this child's left hip radiograph.

Skeletal Dysplasias and Heritable Connective Tissue Disorders

GEORGE E. TILLER AND GARY A. BELLUS

KEY POINTS

- Many skeletal dysplasias, as well as many connective tissue disorders, look similar in the newborn period, especially in premature infants. Arriving at the most accurate diagnosis possible is essential to proper medical decision-making and counseling the family. Utilizing all resources available (medical consultants, texts, online resources, and molecular diagnostics) contributes to this process.
- With respect to molecular diagnostics, (1) it is not essential in all cases, especially where diagnoses can be made clinically by physical examination and/or radiographs, (2) particular mutations within a gene do not always determine prognosis, with notable exceptions (i.e., *FGFR3*, *COL1A1*), (3) diagnostic molecular testing is commercially available in all disorders for which a gene has been identified, and prenatal diagnosis is available if the particular gene mutation has been previously identified in an affected individual, and (4) medical geneticists and genetic counselors, as well as genetics laboratory directors, can aid in choosing the best approach to a molecular diagnosis (which may take several weeks to complete), so as to accommodate disorders exhibiting genetic heterogeneity.
- As in all cases, the family should be kept updated on the current clinical status, what is known, what remains unknown, and the timeline for receiving additional diagnostic and prognostic input.

Skeletal dysplasias, or osteochondrodysplasias, are disorders of the development and growth of cartilage and bone. Connective tissue disorders involve abnormalities of the cells' supporting and connecting components in the extracellular matrix. In a Boston series of greater than 100,000 deliveries monitored postnatally for 15 years, the incidence of skeletal dysplasias was 2.14 in 10,000.[1] With the growing use and accuracy of ultrasonography in prenatal care, a greater number of osteochondrodysplasias and connective tissue disorders are diagnosed prenatally.

The most recent classification of skeletal dysplasias into 42 groups is based on radiologic, clinical, and/or molecular criteria.[2] This chapter focuses on several of the more "common" skeletal dysplasias (Tables 90.1 and 90.2 for an expanded list) and connective tissue disorders (Table 90.3) that manifest themselves prenatally or perinatally, but the discussion is not exhaustive. The osteochondrodysplasias have been reviewed extensively elsewhere.[3,4]

There are many different connective tissue molecules, including collagens (more than 24 types), elastin, fibrillin (two types), and microfibril-associated glycoproteins. These molecules are components of tissues such as bone, cartilage, skin, vascular media, tendon, ligament, and basement membrane in many organs. The heritable disorders of connective tissue are varied, may be very dissimilar clinically, and may manifest themselves in utero or at any age postnatally. Those that may manifest themselves at birth include the early-onset (neonatal) form of Marfan syndrome, congenital contractural arachnodactyly (CCA; Beals syndrome), cutis laxa, some forms of Ehlers–Danlos syndrome (EDS), and Menkes disease.

Clinical Spectra of Disorders With Common Molecular or Cellular Bases

The number of clinically distinguishable skeletal dysplasias and connective tissue disorders is extensive. With advances in molecular knowledge, several different dysplasias have been recognized to have mutations in the same genes. In some of these disorders, clinical similarities noted previously suggested a common cause. One such clinical spectrum includes achondroplasia, hypochondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), and thanatophoric dysplasia, all of which are caused by mutations in the fibroblast growth factor receptor 3 gene, *FGFR3*.[5–8] Another spectrum of disorders includes Stickler syndrome, Kniest dysplasia, some forms of spondyloepimetaphyseal dysplasia, spondyloepiphyseal dysplasia congenita (SEDC), hypochondrogenesis, achondrogenesis type II, and recessive multiple epiphyseal dysplasia, all of which are caused by mutations in the gene encoding collagen type II, *COL2A1*.[9] With other disorders, the common cause is not as obvious clinically: diastrophic dysplasia, atelosteogenesis type II, and achondrogenesis type IB are all caused by mutations in the *SLC26A2* gene.[10–12] The obverse is also evident, wherein a specific clinical entity (e.g., multiple epiphyseal dysplasia) may be caused by a mutation in one of several genes—a concept known as *genetic heterogeneity*.

Genetic heterogeneity can sometimes be explained when (a) the functions of a group of genes are similar, (b) they share a common cellular pathway, or (c) they all impact a common subcellular process. This is the case for ciliopathies, which are disorders affecting the primary cilia of cells. Cilia are microtubule-based organelles that provide a cellular "antenna" for receptors involved in chemosensory, mechanosensory, and osmoregulatory signaling. The short rib thoracic dysplasias are ciliopathies that disproportionately affect the development of the fetal skeleton (see Table 90.1).[13]

TABLE 90.1 Lethal Skeletal Dysplasias Manifesting Themselves Prenatally or Perinatally

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance and Genes
Achondrogenesis type IB (OMIM 600972)	Soft cranium; short, round chest; very short limbs	Round face; polyhydramnios	Poorly ossified calvarium; short ribs with fractures and beading; nonossified vertebrae; short broad femurs with metaphyseal spikes, short broad tibiae, and fibulae	AR; *SLC26A2*
Achondrogenesis type II, hypochondrogenesis (OMIM 200610)	Large head, flat face, cleft palate; short trunk; very short limbs (micromelia)	Fetal hydrops; distended abdomen	Lack of vertebral mineralization; short limbs (all segments); enlarged cranium with normal ossification	AD; *COL2A1*
Atelosteogenesis type II (OMIM 256050)	Narrow chest, short limbs, joint dislocations, equinovarus deformities, gap between first and second digits	Cleft palate, laryngeal stenosis; patent foramen ovale	Occasional coronal and sagittal vertebral clefts; short ribs; short "dumbbell" humeri and femurs, small fibulae; large second and third metacarpals; small round midphalanges	AR; *SLC26A2*
Campomelic dysplasia (OMIM 114290)	Large cranium; small face, flat nasal bridge, cleft soft palate; small, narrow chest; angulated thighs and legs; dimples on legs	Polyhydramnios, congenital cardiac abnormalities; female external genitalia in XY males	Large dolichocephalic calvarium with shallow orbits; short and wavy ribs, often 11 pairs; hypoplastic scapula; small, flat vertebrae; tall, narrow pelvis; relatively long, thin limbs with bent femurs and short tibiae	AD (most are new mutations); *SOX9*
Chondrodysplasia punctata, rhizomelic type 1 (OMIM 215100)	Flat face; very flat nasal bridge and tip; proximal shortening of limbs	Cataracts; joint contractures; ichthyosiform erythroderma	Wide coronal vertebral clefts; short humeri and femurs; stippled epiphyses of long bones, pelvis, and periarticular areas; trapezoid ilia	AR; *PEX7*
Short rib thoracic dysplasias ± polydactyly (including asphyxiating thoracic dystrophy [a.k.a. Jeune] and Ellis-van Creveld syndromes) (OMIM 613091, 611263, 225500, others)	Variable chest narrowing, variable limb shortening; severe cases: round flat face, hydropic appearance, micrognathia, very narrow chest, very short limbs ± postaxial polydactyly	Usually lethal pulmonary insufficiency; variable cardiac, renal, and/or anal malformations	Very short, horizontal ribs; flat, wide intervertebral disk spaces; small pelvis; short limbs with lateral and medial metaphyseal spurs	AR; *DYNC2H1*, *IFT80*, *IFT140*, *IFT172*, *WDR19*, *WDR34*, *TTC21B*, *EVC*, and >12 others
Thanatophoric dysplasia (OMIM 187600)	Large cranium, proptosis, flat nasal bridge, narrow chest, very short limbs (all segments)	Polyhydramnios, hydrocephalus, brain anomalies, congenital cardiac abnormalities	Large calvarium, small foramen magnum, cloverleaf skull (type 2); short, splayed, cupped ribs; very flat U-shaped vertebrae; short, flat pelvis; short, bowed limbs; metaphyseal flare with spike	AD (most are new mutations); *FGFR3*

AD, Autosomal dominant; *AR*, autosomal recessive; *OMIM*, Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim).

Approach to Diagnosis

An early and precise diagnosis is important for prognosis, optimal immediate-term and long-term management, accurate genetic counseling about recurrence risk, and identification of other possibly affected family members or disease carriers. An example is the group of disorders with punctate calcifications ("stippling") in epiphyses, called *chondrodysplasia punctata*. There are several types, with three possible modes of inheritance: autosomal recessive, X-linked recessive, and X-linked dominant (see Table 90.1). As in any uncommon genetic condition, multiple components may be required to arrive at the correct diagnosis: a complete physical examination, three-generation family history, radiologic studies, and biochemical and/or molecular tests.

Most skeletal dysplasias cause short stature, which can be proportionate or disproportionate. The disproportion may be evident as a short-limbed or short-trunk form of dwarfism. If the limbs are affected, there may be segmental shortening of the upper arms

TABLE 90.2 Nonlethal Skeletal Dysplasias Manifesting Themselves Prenatally or Perinatally

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance and Gene
Achondroplasia (OMIM 100800)	Large cranium; frontal bossing, flat nasal bridge, short neck; slightly narrow chest; proximal limb shortening (rhizomelia), short trident hands; brachydactyly; joint laxity	Hypotonia: delayed motor milestones; spinal stenosis causing spinal compression; small foramen magnum may cause hydrocephalus and/or apnea	Large calvarium, small foramen magnum; diminished lumbosacral interpedicular space, short pedicles; short ribs with anterior cupping; short humeri and femurs; relatively long fibulas; metaphyseal flare; small squared iliac wings	AD (most are new mutations); *FGFR3*
Chondrodysplasia punctata, X-linked recessive (OMIM 302950)	Distal phalangeal hypoplasia; severe hypoplasia of the nose; short stature	Cataracts; hearing loss; congenital ichthyosis; anosmia, and hypogonadism (in contiguous gene deletion patients)	Distal phalangeal hypoplasia; stippled epiphyses of long bones; paravertebral stippling	XLR; *ARSE*
Chondrodysplasia punctata, X-linked dominant (Conradi–Hünermann syndrome) (OMIM 302960)	Asymmetric rhizomesomelia	Congenital cataracts; ichthyosis; patchy alopecia	Stippled epiphyses of long bones; paravertebral stippling; tracheal calcifications	XLD; *EBP*
Diastrophic dysplasia (OMIM 222600)	Cleft palate; micrognathia; normal chest at birth; very short limbs; thumbs proximally placed and adducted (hitchhiker's thumb); equinovarus; limited joint movement	Cystic masses in auricles (cauliflower ears) during infancy; deafness caused by lack or fusion of ossicles; narrow external auditory canal	Premature ossification of rib cartilage; narrow L1–L5 interpedicular spaces; scoliosis; short limbs; short ulnae and fibulae (mesomelia); broad flared metaphyses; ovoid first metacarpals; variable symphalangism of proximal interphalangeal joints	AR; *SLC26A2*
Kniest syndrome (OMIM 156550)	Large cranium; flat face with large eyes, flat nasal bridge, cleft palate; proximal limb shortening, enlarged joints, flexion contractures	Infancy: tracheomalacia childhood: myopia and retinal detachment, hearing loss, delayed motor development	Frontal and maxillary hypoplasia, shallow orbits; slightly short ribs; flat vertebrae with coronal clefts; irregular acetabular roof; short limbs with dumbbell metaphyses; lateral bowing of femurs and tibiae	AD; *COL2A1*
Spondyloepiphyseal dysplasia congenita (OMIM 183900)	Flat face, cleft palate, short limbs	Infancy: tracheomalacia childhood: myopia and retinal detachment, hearing loss	Frontal and maxillary hypoplasia, flat vertebrae, small pelvis with irregular acetabular roof, short limbs; normal hands and feet	AD; *COL2A1*

AD, Autosomal dominant; *AR*, autosomal recessive; *XLD*, X-linked dominant; *XLR*, X-linked recessive; *OMIM*, Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim).

and thighs (rhizomelia), forearms and legs (mesomelia), and/or hands and feet (acromelia). Most skeletal dysplasias that manifest themselves at birth involve short limbs. Accurate measurements of length (on a firm surface) and head and chest circumferences should be plotted on standard growth curves, with measurement of arm span and calculation of upper body/lower body segment ratios to objectively assess disproportion.

Other skeletal characteristics can give important clues for specific disorders:

- Children with achondroplasia and thanatophoric dysplasia have large heads (macrocephaly). Cloverleaf skull deformity is present in some forms of thanatophoric dysplasia.
- A relatively long, narrow chest is seen in asphyxiating thoracic dystrophy and other short rib thoracic dystrophies.
- In achondroplasia, the hand is short, and the fingers form a trident configuration. In diastrophic dysplasia, there are distinctive "hitchhiker" thumbs.
- Clubfeet may occur in diastrophic dysplasia, Kniest dysplasia, spondyloepiphyseal dysplasias, and osteogenesis imperfecta (OI) type II.
- Postaxial (and occasionally preaxial) polydactyly may be present in some of the short-rib thoracic dysplasias.
- Multiple joint dislocations can manifest themselves at birth in Larsen syndrome, EDS type VII, atelosteogenesis, and Desbuquois syndrome.

The presence of extraskeletal abnormalities may provide additional clues to diagnosis, as follows:

- Cleft palate may occur in campomelic, Kniest, spondyloepiphyseal, short-rib polydactyly (Majewski), atelosteogenesis types I and II, hypochondrogenesis, and diastrophic dysplasia.
- Congenital cataracts are frequent in some forms of chondrodysplasia punctata.
- Congenital cardiac defects occur in some short-rib thoracic dysplasias, such as Ellis-van Creveld syndrome.

Clinical and Molecular Evaluation

Radiographs of the entire skeleton, including the skull, thorax (with rib technique), long bones, hands, feet, pelvis, and lateral spine, are essential for accurate diagnosis. Atlases dedicated

TABLE 90.3 Heritable Connective Tissue Disorders Manifesting Themselves Perinatally or in Childhood

Connective Tissue Disorders	Inheritance	Genes	Key Clinical Features
Marfan syndrome (OMIM 154700)	AD; congenital Marfan syndrome, usually sporadic	*FBN1*	Aortic dilation, joint laxity, arachnodactyly, ectopia lentis, dural ectasia

to skeletal dysplasias are essential for this purpose,[4,14] even for the experienced radiologist or neonatologist. Ultrasound images of the brain, heart, and kidneys may be helpful if anomalies in those organs are suspected. Detailed family history and measurements of family members may be helpful; disorders in more mildly affected members may have gone undiagnosed. Molecular investigations may be necessary to arrive at the proper diagnosis; given their complexity, such analyses should be considered after consultation with a clinical geneticist. The advent of "next-generation" DNA sequencing has led to more widespread availability of multigene diagnostic panels, which can be used when the diagnosis cannot be determined solely by clinical and radiographic means (see the Genetic Testing Registry at https://www.ncbi.nlm.nih.gov/gtr/). Rapid whole exome sequencing may also be employed in the newborn period when an accurate diagnosis is critical to clinical decision-making. The molecular definition is also helpful in the cases of autosomal recessive and X-linked disorders, as this information may be useful for counseling with respect to recurrence risk and prenatal diagnosis in subsequent pregnancies.

If the infant or fetus dies with the disorder undiagnosed, cord blood for DNA as well as specimens of cartilage and skin fibroblasts can be obtained for histochemical tests, biochemical assays, and/or molecular analyses; these can be used to make or confirm diagnoses and permit accurate future prenatal diagnosis. Even if the molecular or enzymatic basis of the condition is not understood at the time, the tissue may be useful in the future. If photographs and skeletal radiographs were not obtained before death, they should be obtained after death. Additional information for diagnosing challenging cases may be obtained from the International Skeletal Dysplasia Registry at the University of California, Los Angeles (https://www.uclahealth.org/departments/ortho/isdr/about-isdr).

Disorders of Bone Fragility

Osteogenesis Imperfecta Types II and III

OI is characterized by increased bone fragility. There are classically four major clinical types; of these, types II and III are the most severe and manifest prenatally and perinatally.[15] However, fractures at birth can also occur in the mildest form, OI type I. Further heterogeneity in OI has recently been described, especially in severe autosomal recessive forms.

Presentation

OI type II (perinatal lethal type) is estimated to affect 1 in 20,000 to 1 in 60,000 infants. Affected infants may be born prematurely, with low birth weight and disproportionately short stature. The limbs are short and bowed with extra circular skin creases; the hips are abducted and flexed. The head is soft and boggy, and minimal calvarial bone can be felt. The sclerae are dark blue, and the chest is narrow. The infant cries with handling because there may be many fractures at different stages of healing. Sixty percent of affected babies are stillborn or die during the first day of life, and 80% die by 1 month. With the growing use of ultrasonography, affected fetuses may be detected in the second trimester because of short and bowed or angulated limbs and narrow thoraces (Fig. 90.1).

OI type III (progressive deforming type) can manifest itself prenatally, perinatally, or during the first 2 two years after birth. Prenatal and perinatal clinical features resemble those in OI type II but are less severe (Fig. 90.2), and perinatal death is not uncommon. The highest prevalence of fractures in OI, up to 200 in a lifetime, occurs in type III. Extremely short stature, with an adult height of 92 to 108 cm, can result from microfractures in growth plates. The head may be large because the calvarium is soft with a large anterior fontanel. The sclerae may be blue initially but are white by puberty. The head assumes a triangular shape, with a bossed, broad forehead and a tapered, pointed chin. Later in childhood, dentinogenesis imperfecta and hearing loss may develop. Severe kyphoscoliosis may occur, leading to cardiopulmonary compromise, which is the major cause of early death.

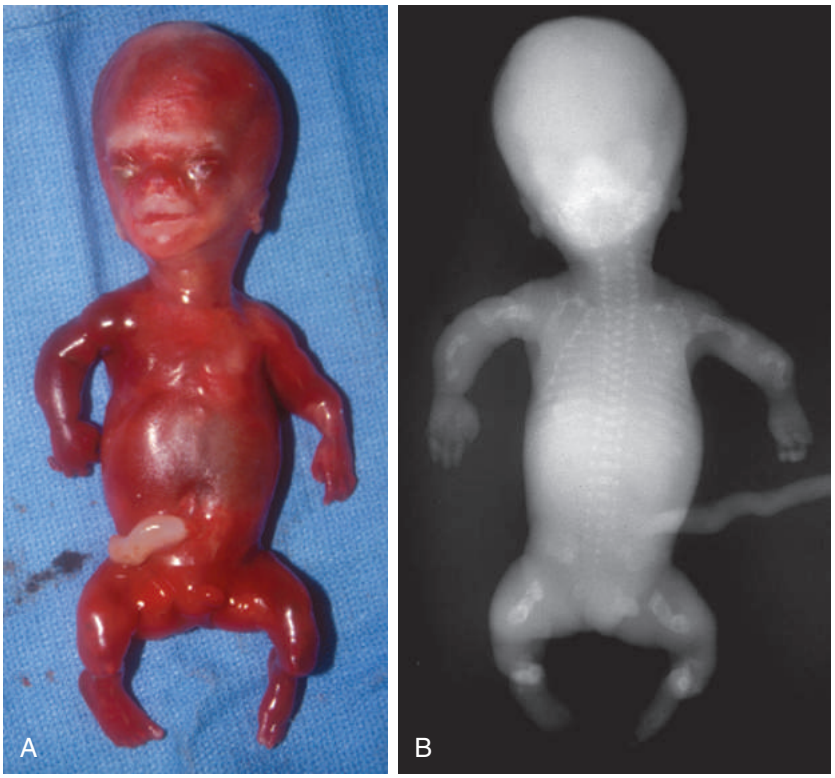
Radiographic Features

Radiographs show the femurs in OI type II to be short, broad, and "telescoped" or "crumpled." The tibiae are short and bowed or angulated, and the fibulae may be thin (see Fig. 90.1B). There is minimal to no calvarial mineralization. The acetabular and iliac wings may be somewhat flattened. The ribs are short, wavy, and thin or broad, with "beading" from callus formation at fetal fracture sites.

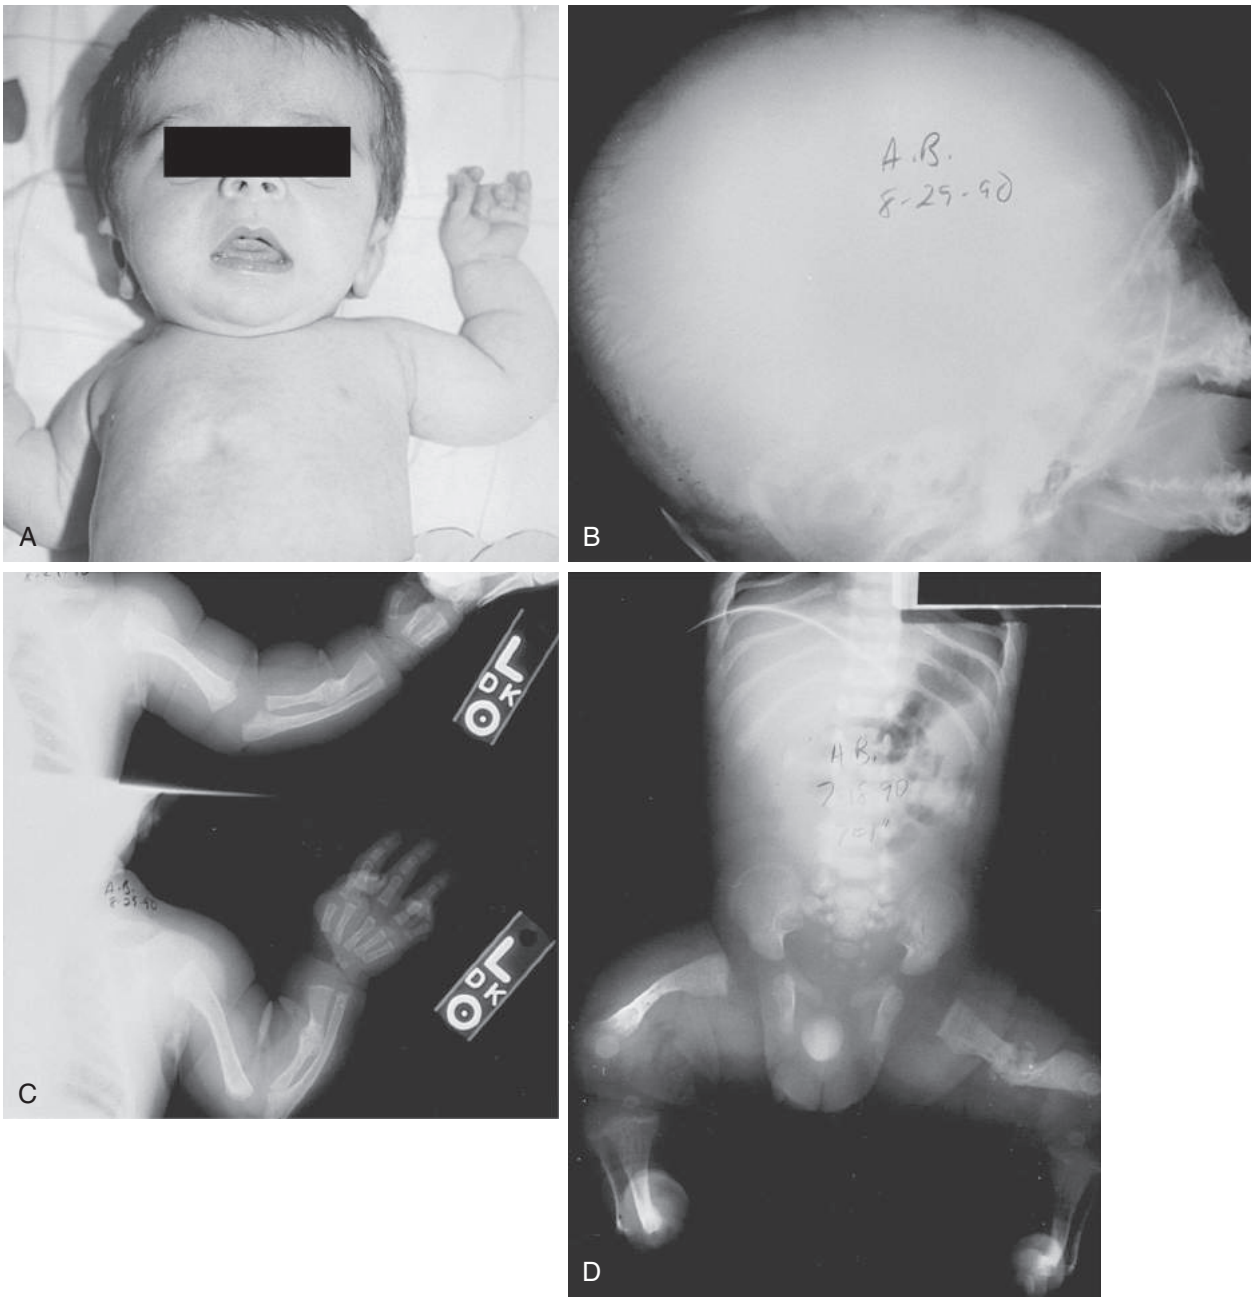
In OI type III, the femurs are short and deformed but not crumpled as in OI type II (see Fig. 90.2B–D). The other long bones are thinner than usual, with healing fractures incurred in utero, bowing, and deformations. The calvarium is undermineralized with a large anterior fontanel, and there are many Wormian bones (small islands of bone in the suture spaces; see Fig. 90.2D). The ribs are thin and gracile.

Etiology

OI is most commonly caused by mutations in one of the two genes encoding collagen type I (*COL1A1* and *COL1A2*), the predominant protein building block of bone. More clinically severe forms of OI are the result of qualitatively abnormal collagen synthesis rather than decreased production,[15] as well as the result of numerous recessive types affecting noncollagen proteins.[16]



• **Fig. 90.1** Osteogenesis Imperfecta Type II. (A) A 20-week fetus. The limbs are angulated and deformed from multiple fractures. (B) Radiograph of a fetus (20 weeks' gestation) showing an absence of ossification in the calvarium, short telescoped or crumpled humeri and femurs, and short and wavy ribs with fractures.



• **Fig. 90.2** Osteogenesis Imperfecta Type III. (A) Neonate with a normal face, short neck, and slightly short limbs. (B) Radiograph showing that the calvarium is undermineralized with Wormian bones. (C) Radiograph showing the upper limbs, which have bowed humeri and callus in the ulnae. (D) Radiograph showing lower limbs with moderately short, thick femurs and angulated tibiae and fibulae. (Courtesy of Paige Kaplan, Children's Hospital, Philadelphia.)

Inheritance

A fetus or infant with OI type II or III is usually the result of a spontaneous dominant-acting gene mutation, but there is a small risk of recurrence (approximately 6%) in subsequent siblings because of possible parental somatic or gonadal mosaicism. The parent is usually asymptomatic but may have minimal manifestations, such as short stature. Prenatal diagnosis is available if the particular gene mutation has been identified in the affected individual. Most cases of OI are inherited as autosomal dominant traits, although rare recessive forms have been shown to be caused by mutations in genes encoding, for example, cartilage-associated protein (*CRTAP*), prolyl 3-hydroxylase (*P3H1*), and cyclophilin B (*PPIB*).[16]

Differential Diagnosis

Other lethal skeletal dysplasias may have abnormalities similar to those in OI type II and may be difficult to distinguish by prenatal ultrasonography; however, in experienced hands, they can be differentiated on the basis of several ultrasound findings.[17] Krakow et al.[18] published a retrospective analysis of 1500 prenatally diagnosed cases of skeletal dysplasias. The three most common

prenatal-onset skeletal dysplasias were OI type II, thanatophoric dysplasia, and achondrogenesis type II, which together accounted for almost 40% of all cases. Postnatal radiographs clearly reveal distinctive differences among thanatophoric dysplasia, campomelic dysplasia, achondrogenesis, and perinatal hypophosphatasia, among other disorders.

Management

If the diagnosis of OI is made prenatally, cesarean delivery has *not* been shown to decrease the fracture rate or increase the survival rate of severely affected fetuses.[19] Those severely affected with OI type II are not expected to survive the neonatal period. In OI type III, the neonate needs careful handling to minimize pain and prevent further fractures. Analgesia alleviates pain. Consideration can be given to treatment with bisphosphonates (with the use of intravenously administered pamidronate), which increase bone density, reduce the frequency of fractures and pain, possibly prevent short stature and deformations, and permit ambulation.[16] It is prudent to treat only severely affected children in whom the clinical benefits outweigh potential long-term effects.

Handling an Infant With Osteogenesis Imperfecta

When the diapers of an infant with OI are being changed, a hand should be placed behind the infant's buttocks with the forearm supporting the legs. Similarly, when the infant is lifted, the buttocks, head, and neck must be supported. The infant can be laid on a pillow to be carried. To transport the infant, an infant seat that reclines as much as possible and allows easy placement or removal should be used. The seat can be padded with egg crating or 1-inch foam. A layer of foam can be placed between the seat's harnesses and the child for extra protection. The car seat must always be placed in the back seat. Sling carriers and "umbrella" strollers should not be used for infants with OI because they do not give sufficient leg, head, and neck support.

Perinatal Hypophosphatasia

Presentation

Perinatal hypophosphatasia is a lethal condition characterized by short, deformed limbs, a soft skull, blue sclerae, and undermineralization of the entire skeleton, such that many bones cannot be visualized and may seem absent in radiographs. In the skull, only the base can be visualized radiologically. There may be rachitic changes and fractures. Seizures that are responsive to pyridoxine may occur. There is polyhydramnios during pregnancy, and death can occur in utero. The disorder affects approximately 1 in 100,000 live births, and neonatal death is common.[20,21]

Radiographic Features

The radiographic features of perinatal hypophosphatasia include polyhydramnios (prenatal); underossification, especially of the calvarium and long bones (with marked variability); small thoracic cavity; short, bowed limbs; spurs in the middle portion of the forearms and lower legs; and dense vertebral bodies.

Etiology

Mutations in the *ALPL* gene are responsible for deficiency of the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP), thus causing perinatal hypophosphatasia. The serum alkaline phosphatase value is low. Serum values of inorganic pyrophosphate and pyridoxal 5′-phosphate (putative natural substrates for TNSALP) may be elevated, and urinary phosphoethanolamine level is elevated.[20]

TNSALP acts on multiple substrates: the essential function of TNSALP is in osteoblastic bone matrix mineralization. TNSALP hydrolyzes inorganic pyrophosphate to phosphate, which is thought to be critical in promoting osteoblastic mineralization. If TNSALP is deficient, there is an extracellular accumulation of inorganic pyrophosphate, which inhibits hydroxyapatite crystal formation and mineralization of the skeleton. TNSALP is also needed for the delivery of pyridoxal 5′-phosphate into cells, where it is a cofactor (vitamin B_6).

Inheritance

Perinatal hypophosphatasia is inherited as an autosomal recessive trait, with a 25% recurrence risk in future pregnancies. Prenatal diagnosis is optimized with the use of ultrasonography, an assay of TNSALP activity in amniocytes, DNA mutation analysis if the previously affected infant's mutations were identified, or a combination of these methods.

Differential Diagnosis

Differential diagnoses include OI type II and achondrogenesis.

Management

Until very recently, treatment was primarily supportive and directed toward minimizing pain and discomfort. Clinical trials with a bone-targeted human recombinant enzyme replacement therapy have been shown to be effective in nonlethal cases.[22]

FGFR3 Spectrum

Achondroplasia

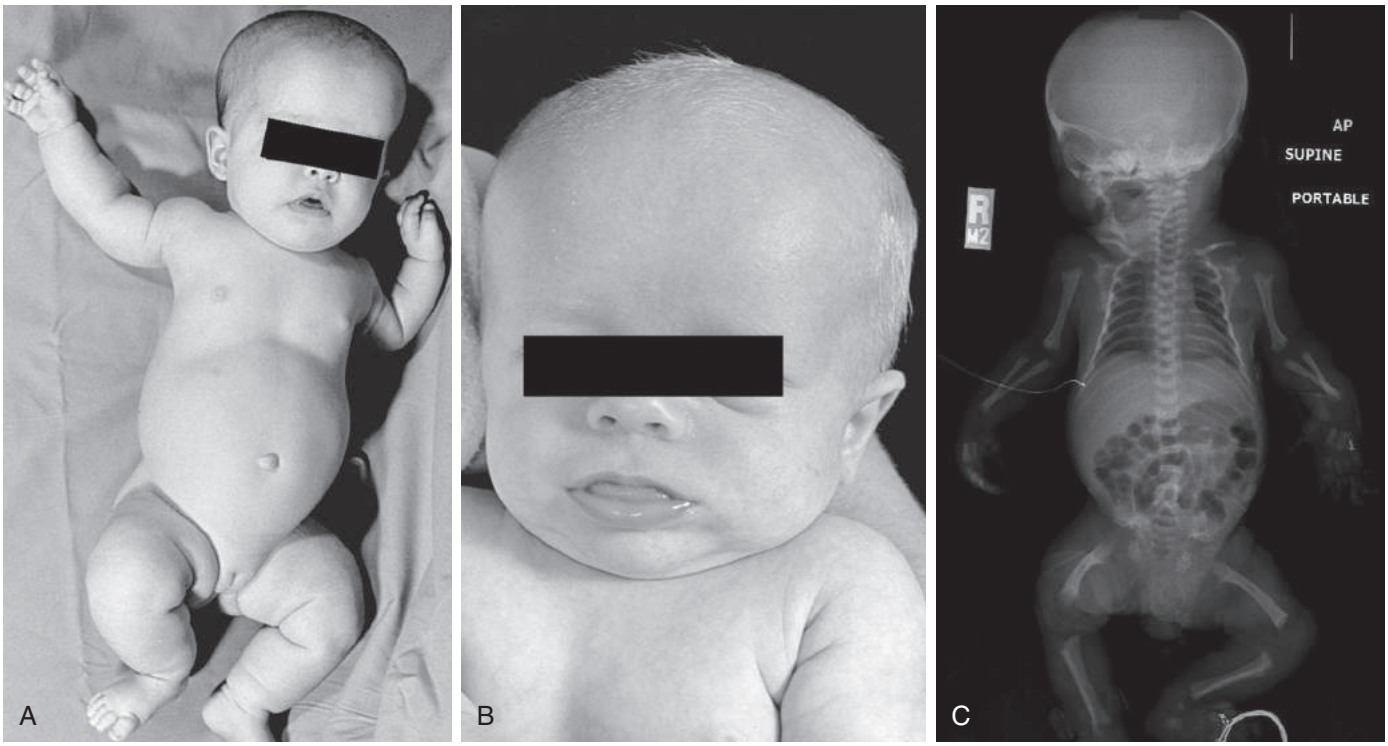
Presentation

Achondroplasia is the most common of the nonlethal chondrodysplasias; it affects 1 in 25,000 live births. It is characterized by short stature with short limbs, particularly rhizomelic (proximal) and acromelic (hands) shortening with trident hand configuration, large head with frontal prominence ("bossing"), flat nasal bridge and midface, long narrow trunk, joint laxity, and development of thoracolumbar kyphosis ("gibbus") in infancy (Fig. 90.3).[5]

The foramen magnum and cervical spinal canal may be narrow and can cause compression of the spinal cord. Standards have been published for foramen magnum size in achondroplasia.[23] Compression of the lower brainstem and cervical spinal cord can lead to hypotonia, central apnea, retardation, quadriparesis, and (rarely) sudden death.[24]

Radiographic Features

The calvarium is large with a relatively small foramen magnum and a short base. The lateral cerebral ventricles may be large, but hydrocephalus is not a common complication. The proximal long bones (humeri and femurs) are short, including the femoral neck. Fibulae are longer than tibiae. There is metaphyseal flaring. The hand is short with a trident configuration of the fingers, with short proximal and middle phalanges. Vertebrae are small and cuboid with short pedicles, and there may be anterior beaking of the first or second lumbar vertebrae; there is a lack of widening of the interpedicular distance in the lumbar vertebrae. The pelvis has squared iliac wings ("elephant ear" appearance), a narrow greater sciatic



• **Fig. 90.3** Achondroplasia. (A) Infant with achondroplasia who has macrocephaly and proximal limb shortening (rhizomelia). (B) Infant with achondroplasia who exhibits frontal bossing and flat nasal bridge. (C) Neonatal radiograph of achondroplasia illustrating a large skull, a somewhat narrow chest, short vertebral bodies with a lack of lumbar interpediculate flare, and rhizomelia. (B courtesy Charles I. Scott, Nemours/Alfred I. du Pont Hospital for Children, Wilmington, DE.)

notch, and flat acetabular roofs (see Fig. 90.3C). Compression of the cervical cord, if present, can be ascertained with magnetic resonance imaging with cerebrospinal fluid flow studies in flexion and extension.

Etiology

The cause of achondroplasia is a mutation of the *FGFR3* gene, which encodes fibroblast growth factor receptor 3, a membrane-spanning tyrosine kinase receptor. More than 99% of individuals with achondroplasia have a common recurrent mutation in the transmembrane domain of the *FGFR3* gene, in which arginine is substituted for glycine (Gly380Arg). The same gene is mutated at different sites in hypochondroplasia, thanatophoric dysplasia, SADDAN, Muenke craniosynostosis, and Crouzon craniosynostosis syndrome with acanthosis nigricans.[5] Histopathologic examination demonstrates a defect in the organization and maturation of the cartilage growth plates of long bones because of differing degrees of constitutive activation of the receptor.

Inheritance

The inheritance pattern in achondroplasia is autosomal dominant. Approximately 80% of cases are sporadic occurrences in a family, representing new mutations. Cases may be associated with advanced paternal age, and molecular studies have confirmed that new mutations are of paternal origin.[25] Rare recurrences due to gonadal mosaicism in a parent have been reported. Affected individuals are fertile, and achondroplasia is transmitted as a fully penetrant autosomal dominant trait, meaning that each person who inherits the mutant gene will manifest the condition.

Differential Diagnosis

Differential diagnoses include SADDAN[5,8] and hypochondroplasia.[6]

Management

The infant with achondroplasia is often hypotonic; together with the large head, the hypotonia leads to delayed motor milestones. Development of thoracolumbar kyphosis may be exacerbated by unsupported sitting before truncal muscle strength is adequate; therefore, infants should not be carried in flexed positions (including soft sling carriers and umbrella strollers). Rear-facing car safety seats should always be used. Physical therapy in the first year of life may strengthen core musculature at a faster rate. Most infants lose their kyphosis and develop the typical exaggerated lumbar lordosis when they begin walking.

Hydrocephalus may occasionally develop during the first 2 years, so the head circumference and body length should be carefully measured and plotted on standard achondroplasia growth charts.[26] Routine imaging of the skull and brain is not recommended; however, the development of hyperreflexia, hypotonia, or apnea may herald the development of clinically significant cord compression in infancy or early childhood and requires prompt evaluation. Surgical decompression at the foramen magnum or the upper cervical spine may prevent neurologic damage, although most patients usually gain motor milestones late but spontaneously because the foraminal diameter expands faster than the cord.

The upper airway in individuals with achondroplasia is small, often leading to obstructive apnea, snoring, and chronic serous otitis media beyond infancy. Treatment may consist of tonsillectomy, adenoidectomy, and placement of myringotomy tubes. Parents

should be counseled about the clinical and hereditary aspects of the disorder and given a copy of the guidelines for health supervision of children and adults with achondroplasia issued by the American Academy of Pediatrics.[26]

Drugs designed to impede the overexpression of the FGFR3/tyrosine kinase pathway are currently in clinical trials and thus far look promising.[27] However, trials as yet have not included newborns and infants.

Thanatophoric Dysplasia

Presentation

Thanatophoric dysplasia is one of the most common lethal dysplasias, occurring once in 45,000 births.[7] It is characterized by extremely short limbs, long narrow trunk, large head with a bulging forehead, prominent eyes, flat nasal bridge, wide fontanel, and occasionally cloverleaf skull deformity (Fig. 90.4). It is differentiated into types I and II based on radiologic features and mutation specificity. Death typically occurs in the neonatal period from respiratory insufficiency, although rare survivors have been reported with multiple chronic problems. Polyhydramnios is common during pregnancy.

Radiographic Features

Femurs are short, flared at the metaphyses with a medial spike, and are bowed (type I) or straight (type II); other long bones are also short and bowed (see Fig. 90.4). The calvarium is large with a short base and small foramen magnum; the cloverleaf skull is sometimes present in type I thanatophoric dysplasia and is severe in type II. Vertebrae are strikingly flat (platyspondyly) with a U shape or an H shape in anteroposterior projection and uniform interpediculate narrowing. Ribs are short, cupped, and splayed anteriorly.[4,14]

Etiology

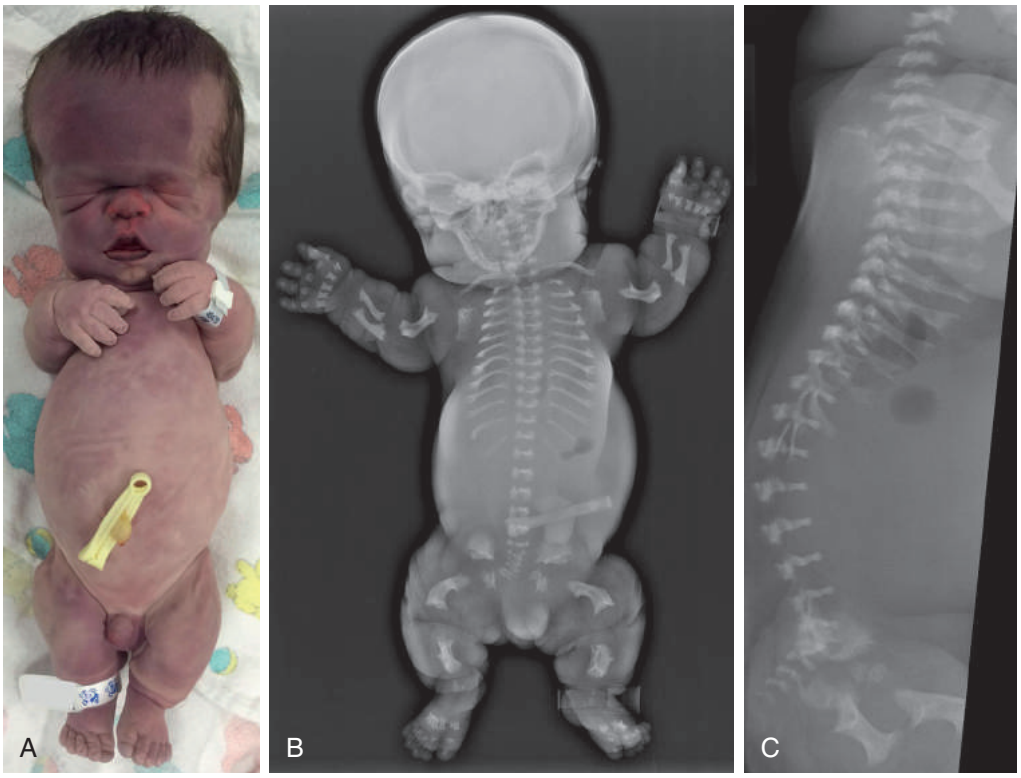
Thanatophoric dysplasia represents the severe end of the *FGFR3* spectrum. In thanatophoric dysplasia type I, the most common mutation is a substitution of cysteine for arginine at position 248 (Arg248Cys) in the receptor's extracellular domain, but other mutations have been described throughout the gene. In all studied cases of thanatophoric dysplasia type II, there is a substitution of glutamate for lysine at position 650 (Lys650Glu).[7] These mutations have been shown to constitutively activate FGFR3 to a greater extent than the common mutation seen in achondroplasia, thus resulting in a more severe phenotype.

Inheritance

All cases of thanatophoric dysplasia, as with most cases of achondroplasia and hypochondroplasia, occur sporadically and result from new autosomal dominant-acting mutations. Nevertheless, there may be a small risk of recurrence in siblings of an infant with sporadic thanatophoric dysplasia, possibly due to gonadal mosaicism. Prenatal diagnosis is available if the particular gene mutation has been previously identified in an affected individual.

Differential Diagnosis

Differential diagnoses include OI types II and III, achondroplasia (severe), achondrogenesis, and hypochondrogenesis.



• **Fig. 90.4** Thanatophoric Dysplasia. (A) Stillborn with thanatophoric dysplasia with a large head with frontal bossing, narrow chest, short limbs, and short fingers (brachydactyly). (B) Radiograph of stillborn with thanatophoric dysplasia demonstrating large cranium, narrow chest, with short ribs, shortening of all long bones (micromelia) with bowing, flattened vertebral bodies (platyspondyly), and normal bone density. (C) Lateral spine radiograph of stillborn with thanatophoric dysplasia demonstrating remarkable platyspondyly.

Management

If the condition is suspected prenatally and diagnosed by molecular means (mutation analysis following amniocentesis), the parents should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographically confirmed, management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.

COL2A1 Spectrum

Spondyloepiphyseal Dysplasia Congenita

Presentation

SEDC manifests itself with shortened neck, trunk, and limbs, normal-sized hands and feet, flat facial profile, and occasional cleft palate and clubfoot (Fig. 90.5).[28] The name *spondyloepiphyseal dysplasia congenita* (SEDC) is derived from the spinal (*spondylo*) and growth plate (*epiphyseal*) involvement. *Congenita* indicates that the condition is evident at birth.

Radiographic Features

Radiographic features include ovoid or pear-shaped vertebral bodies in infancy, with platyspondyly more evident at a later age; odontoid hypoplasia evident in early childhood; midface hypoplasia; retrognathia; mild rhizomelia and mesomelia (see Fig. 90.5B–D); absent ossification of the os pubis; apparent decreased bone age caused by epiphyseal involvement; and development of coxa vara, variable kyphosis, and scoliosis in childhood.[15]

Etiology

SEDC is caused by mutations in the gene for collagen type II (*COL2A1*), the predominant protein building block of cartilage. Mutations in *COL2A1* are also responsible for Kniest dysplasia, some forms of spondyloepimetaphyseal dysplasia and Stickler syndrome, and the perinatal lethal disorders achondrogenesis type II and hypochondrogenesis.[9,28]

Inheritance

SEDC is inherited in an autosomal dominant pattern. Offspring of affected individuals are at 50% risk of inheriting the disorder. The recurrence risk for unaffected parents is approximately 6%, considering the possibility of parental gonadal mosaicism.

Differential Diagnosis

Differential diagnoses include a mild form of hypochondrogenesis (in neonates), as well as Morquio syndrome (in early childhood).

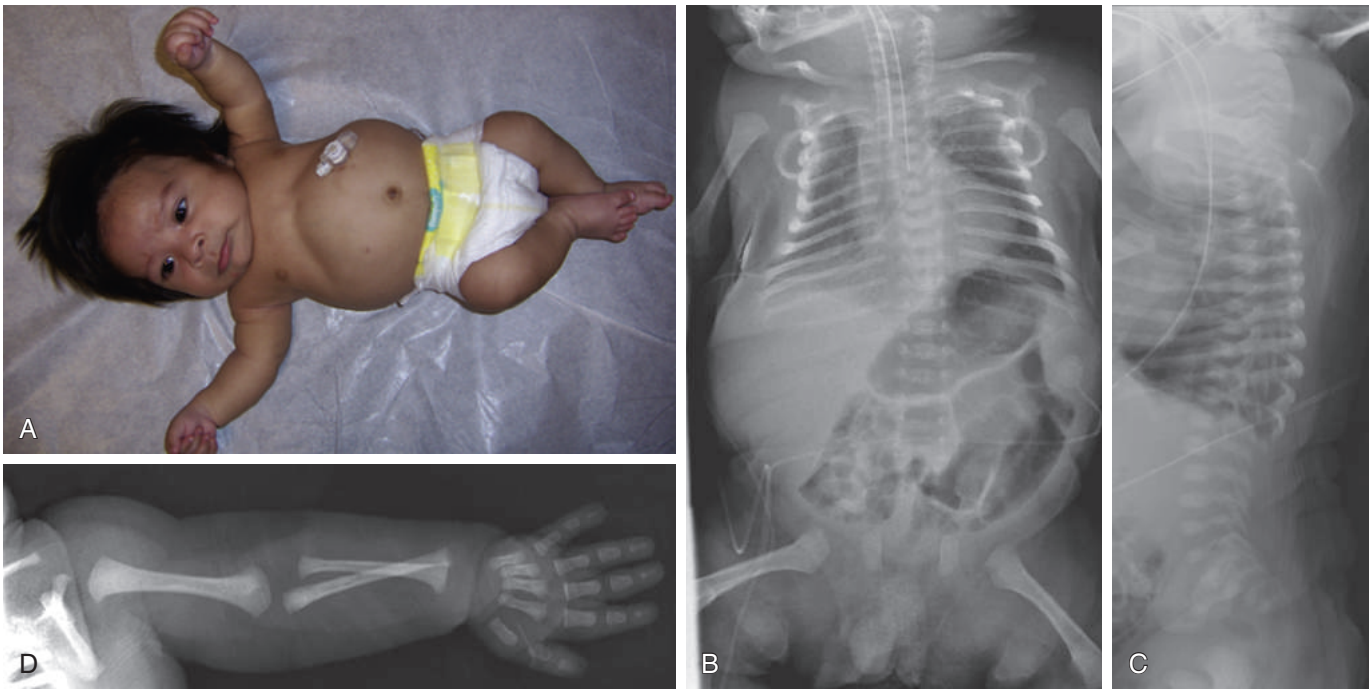
Management

Neonates may require intubation because of upper airway compromise. Care must be given when the cervical spine is manipulated (as in endotracheal intubation) because of odontoid hypoplasia. C1 and C2 fusion may be required in early childhood to stabilize the cervical spine. Annual hearing screens are recommended during childhood. Regular ophthalmologic evaluation (semiannually before school age) is essential to detect the early development of retinal detachment and to manage myopia. Osteoarthritis is a common feature in early adulthood, often requiring hip arthroplasty.

Achondrogenesis Type II–Hypochondrogenesis

Presentation

The severe end of the *COL2A1* spectrum manifests itself with fetal hydrops and maternal polyhydramnios, severely shortened trunk and limbs, and fetal or neonatal death caused by pulmonary hypoplasia.



• **Fig. 90.5** Spondyloepiphyseal Dysplasia Congenita. (A) A 2-month-old infant with a short neck, trunk, and limbs. Note the flat facial profile and normal size of the hands and feet. (B) Anteroposterior radiograph revealing platyspondyly and short chest. (C) Lateral radiograph revealing platyspondyly. (D) Upper limb radiograph revealing rhizomelia, mesomelia, and a normal-sized hand.

Radiographic Features

Radiographic features include prenatal polyhydramnios, a large calvarium with normal ossification, midface hypoplasia, retrognathia, platyspondyly with underossification of the vertebral bodies (achondrogenesis type II), short chest with a protuberant abdomen, marked shortening of all tubular bones (Fig. 90.6), and small iliac wings.

Etiology

Achondrogenesis type II–hypochondrogenesis is caused by mutations in the gene for collagen type II (*COL2A1*), the predominant protein building block of cartilage.[9,28]

Inheritance

All cases of achondrogenesis type II–hypochondrogenesis are caused by spontaneous dominant-acting mutations in *COL2A1*. The recurrence risk has been reported to be as high as 6% because of parental gonadal mosaicism.[29] Prenatal diagnosis is available if the particular gene mutation has been previously identified in an affected individual.

Differential Diagnosis

Differential diagnoses include achondrogenesis type I and OI types II and III.

Management

If the condition is diagnosed prenatally, the couple should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographic confirmation is obtained, management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.

SLC26A2 Spectrum

Diastrophic Dysplasia

Presentation

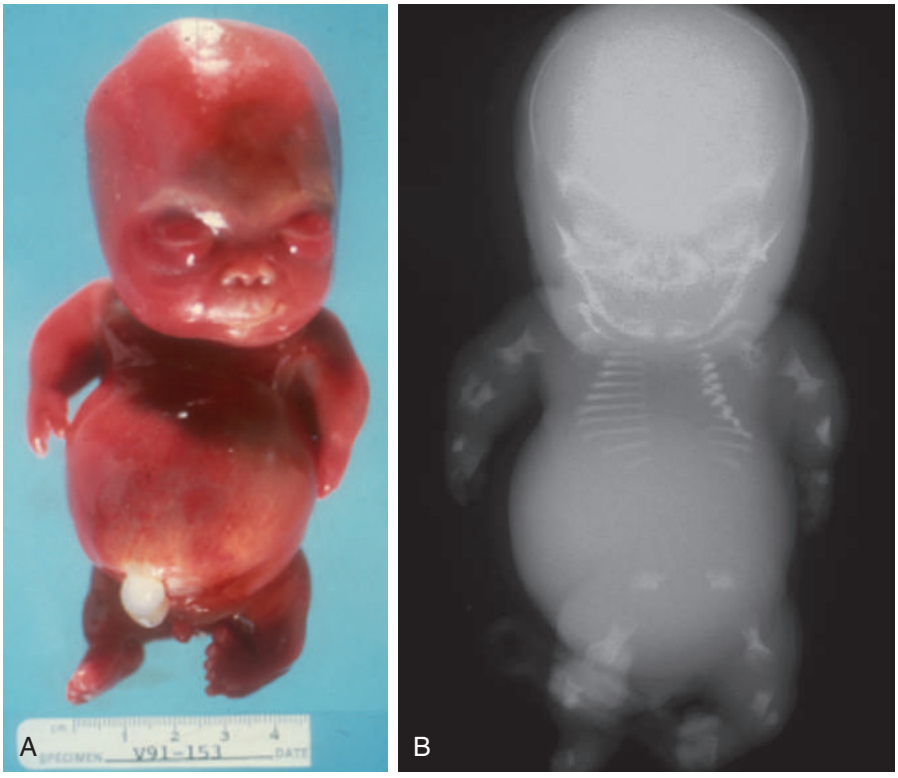
Newborns with diastrophic dysplasia exhibit limb shortening, hitchhiker thumbs, spinal deformities (especially cervical kyphosis), and contractures of the large joints (Fig. 90.7). Clubfoot and ulnar deviation of the fingers may also be present. Cystic ear swelling, with subsequent inflammation and calcification, may develop in infancy. On occasion, the disease can be lethal at birth, but most individuals survive the neonatal period.[10]

Radiographic Features

The most characteristic clinical and radiographic feature is the proximally placed hitchhiker thumb, with ulnar deviation of the fingers. Cervical kyphosis is a frequent finding. Long bones are moderately shortened and thick, with mild metaphyseal flaring, rounding of the distal part of the femur, and bowing of the radius and tibia. Severe talipes equinovarus may be present. Iliac wings are hypoplastic, with flat acetabular roofs. The chest can be narrow, bell-shaped, or both. Narrowing (lack of flare) of the interpedicular distance in the lumbar spine is reminiscent of achondroplasia.

Etiology

Diastrophic dysplasia is caused by mutations in the *SLC26A2* gene (formerly referred to as the diastrophic dysplasia sulfate transporter gene, *DTDST*), which also cause the lethal disorders achondrogenesis type IB and atelosteogenesis type II, as well as a rare recessive form of multiple epiphyseal dysplasia. The gene product is a sulfate–chloride exchanger of the cell membrane[10]; this affects



• **Fig. 90.6** Achondrogenesis Type II. (A) A 20-week fetus with a small chest and short limbs. (B) Radiograph demonstrating poor ossification of vertebral bodies and short limbs.

• **Fig. 90.7** Diastrophic Dysplasia. (A) Infant with prominent eyes, small chin, slightly narrow chest, proximally placed angulated thumbs and short limbs. (B) Neonate profile showing small chin, swollen ears, and short neck. Note the proximally placed angulated thumb. (C) View of the neonate's hand showing the proximally placed angulated thumb and mild syndactyly. (Courtesy of Paige Kaplan, Children's Hospital, Philadelphia.)

the incorporation of sulfate into proteoglycans (mucopolysaccharides), especially chondroitin sulfate B–containing proteoglycans, which are prevalent in the cartilage extracellular matrix.

Inheritance

Diastrophic dysplasia is inherited in an autosomal recessive pattern. Siblings of affected individuals are at 25% risk of inheriting an abnormal allele from both carrier parents.

Differential Diagnosis

Differential diagnoses include atelosteogenesis type II (part of the *SLC26A2* spectrum),[11] spondyloepiphyseal dysplasia, and arthrogryposis.

Management

Mechanical ventilation may be required because of the small chest circumference and a floppy airway. Maintenance of joint mobility and proper positioning through physical therapy is essential. Serial casting and/or surgical correction of clubfeet may be required. Cervical kyphosis can impede endotracheal intubation and can result in cord compression but may resolve spontaneously during infancy. The preferred treatment of auricular cysts is an application of a compression mold rather than incision and drainage.[30]

Achondrogenesis Type IB

Presentation

Achondrogenesis type IB is characterized by short stature, extremely short limbs, a relatively large head with a round face, short nose, small mouth, soft skull, and a very short neck.[12] Polyhydramnios during pregnancy, premature delivery, and hydrops are common. The affected infant is stillborn or dies within hours of birth.

Radiographic Features

The long bones are extremely short, with square, globular, or triangular shapes and medial spikes in the metaphyses of the femurs (Fig. 90.8). The calvarium and vertebrae are poorly ossified (type IB), and the ribs are short.

Etiology

Achondrogenesis type IB is caused by mutations in the *SLC26A2* gene (see Diastrophic Dysplasia earlier).

Inheritance

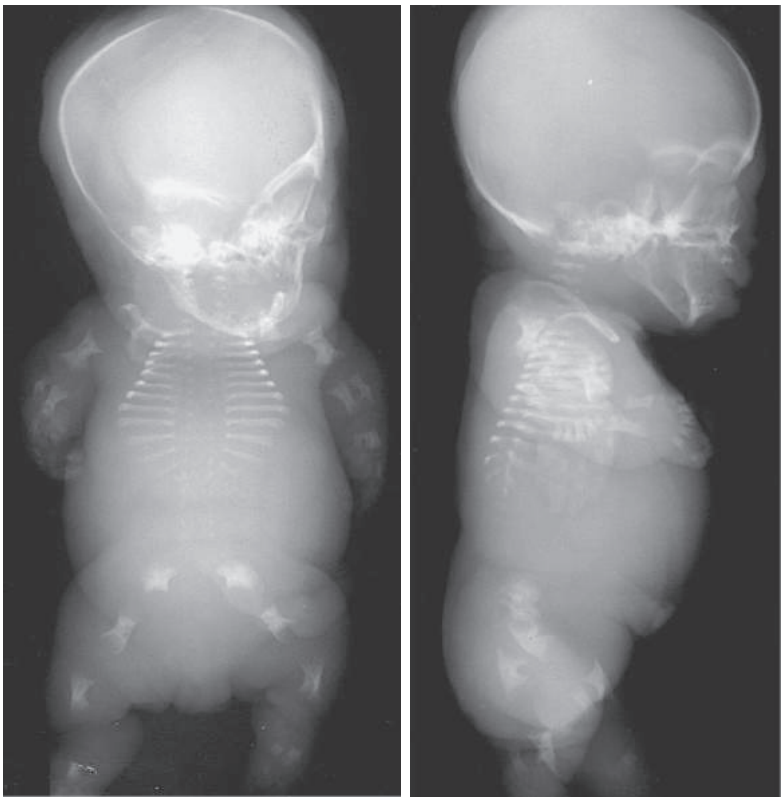
Achondrogenesis type IB is inherited in an autosomal recessive pattern. Siblings of affected individuals are at 25% risk of inheriting an abnormal allele from both carrier parents.

Differential Diagnosis

Differential diagnoses include atelosteogenesis type II (part of the *SLC26A2* spectrum), achondrogenesis type II, and hypochondrogenesis.

Management

If the condition is diagnosed prenatally, the couple should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographic confirmation is obtained, management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.



• **Fig. 90.8** Achondrogenesis Type IB. Cervical, thoracic, and lumbar vertebral bodies are not ossified, the sacrum is not ossified, the ribs are short, and the limbs are extremely short with medial femoral metaphyseal spikes. (Courtesy Elaine Zackai, Children's Hospital, Philadelphia.)

Other Skeletal Dysplasias

Campomelic Dysplasia

Presentation

Campomelic dysplasia is characterized by short stature (birth length of 35 to 49 cm), large narrow (dolichocephalic) skull, large anterior fontanel, high forehead, flat face, widely spaced eyes with short palpebral fissures, low-set ears, cleft soft palate, micrognathia, relatively long and slender thighs, and upper arms, somewhat shortened bowed legs with dimples in the midshaft (in most cases), narrow chest, and kyphoscoliosis (Fig. 90.9). Sex reversal or varying degrees of ambiguous genitalia affects 75% of chromosomal (46, XY) males. The absence of the olfactory bulbs and tracts, as well as cardiac and renal malformations, may occur. Death, usually in infancy, results from pulmonary hypoplasia, tracheomalacia, or cervical spinal instability. Rare survivors are usually globally developmentally delayed. A few more mildly affected people without bowed limbs have been reported.[31]

Radiographic Features

The most characteristic finding is midshaft angulation (campomelia) of the femurs, although it is not a constant finding. Other features include hypoplastic, undermineralized cervical vertebrae and thoracic pedicles; narrow iliac wings with dislocated hips; brachydactyly; clubfeet; anterior bowing of tibiae; bell-shaped chest with thin, wavy ribs (with only 11 pairs); and scapular hypoplasia (see Fig. 90.9C).

Etiology

Campomelic dysplasia is caused by mutations in or near the sex-determining region Y–box 9 gene, *SOX9*.[31] *SOX9* is homologous to the *SRY* gene and encodes a transcription factor involved in both bone formation and testis development.

Inheritance

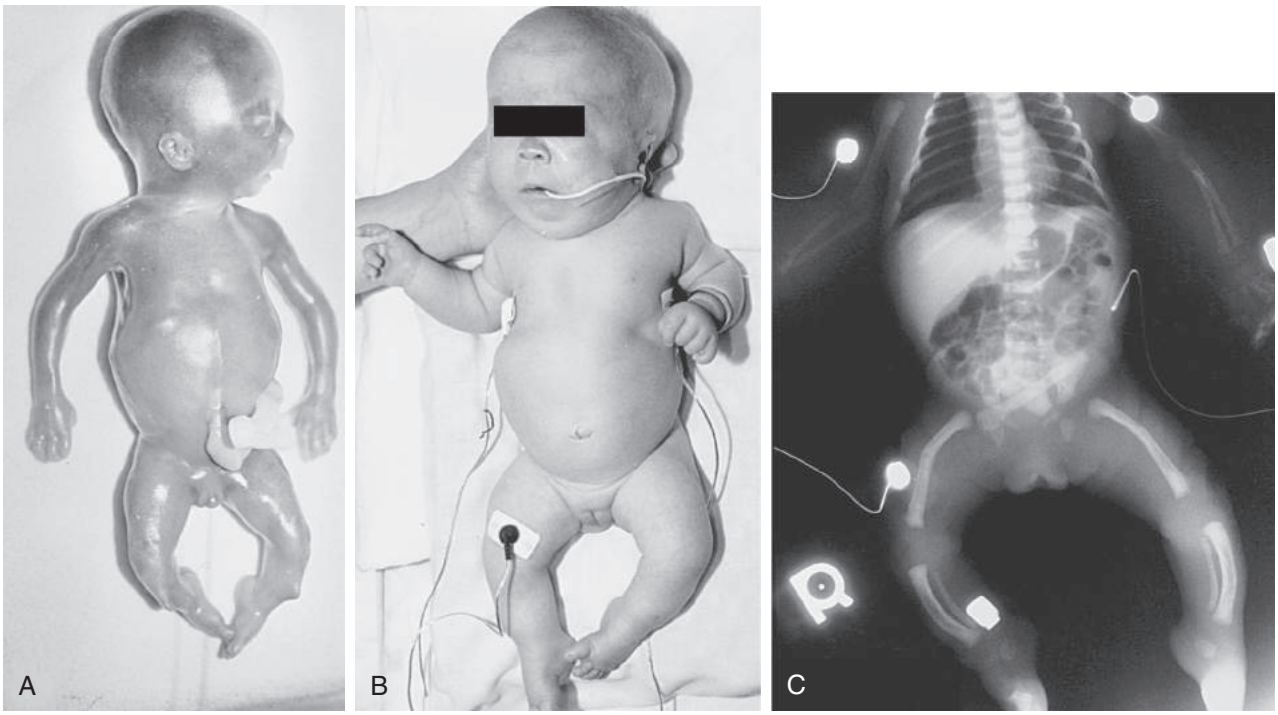
Campomelic dysplasia is due to spontaneous dominant-acting SOX9 mutations. Most cases are new sporadic occurrences in a family; recurrence caused by gonadal mosaicism has been reported.[31]

Differential Diagnosis

Differential diagnoses include OI types II and III, diastrophic dysplasia, kyphomelic dysplasia, thanatophoric dysplasia, and SEDC (severe).

Management

Survival beyond the newborn period is rare; therefore, support is primarily directed toward comfort measures. In survivors, care must be given to the cervical spine, which may be unstable. Chromosomal studies to determine sex and pelvic ultrasonography to examine internal genitalia may be performed. For survivors, cleft palate may be repaired in those able to feed orally, and clubfeet may require casting or surgical correction.



• **Fig. 90.9** Campomelic Dysplasia. (A) A 22-week-old 46, XY female fetus with normal head, long philtrum, micrognathia, low-set ears, mild narrowing of the chest, proximally placed thumbs, and bowed or angulated lower limbs resembling those of osteogenesis imperfecta type II but less shortened. The external genitalia is female. (B) Neonate with the long-limb form of the disorder who has a relatively large head, micrognathia, a narrow chest, and bowing of the lower limbs with characteristic dimpling of the lower leg. (C) Radiograph showing the narrow chest, the relatively long, thin limb bones with bowing of the femurs and tibiae, and a long, narrow pelvis. (Courtesy of Paige Kaplan, Children's Hospital, Philadelphia.)

Heritable Connective Tissue Disorders

Genetic disorders of connective tissue represent a large group of pleiotropic diseases that may involve the musculoskeletal, cardiovascular, and pulmonary systems as well as the eyes and skin. These diseases are caused by pathogenic variants in genes that function in extracellular matrix assembly and/or homeostasis and may result in serious clinical consequences.[32,33] Several of these disorders present in the newborn period with dramatic joint hypermobility and/or abnormal skin findings (see Table 90.3). Diagnosis of many of these conditions can be established by prenatal or neonatal testing via multigene NGS panels[34] or whole exome sequencing.

Early-Onset/Rapidly Progressive (Congenital; Neonatal, Infantile) Marfan Syndrome

Presentation

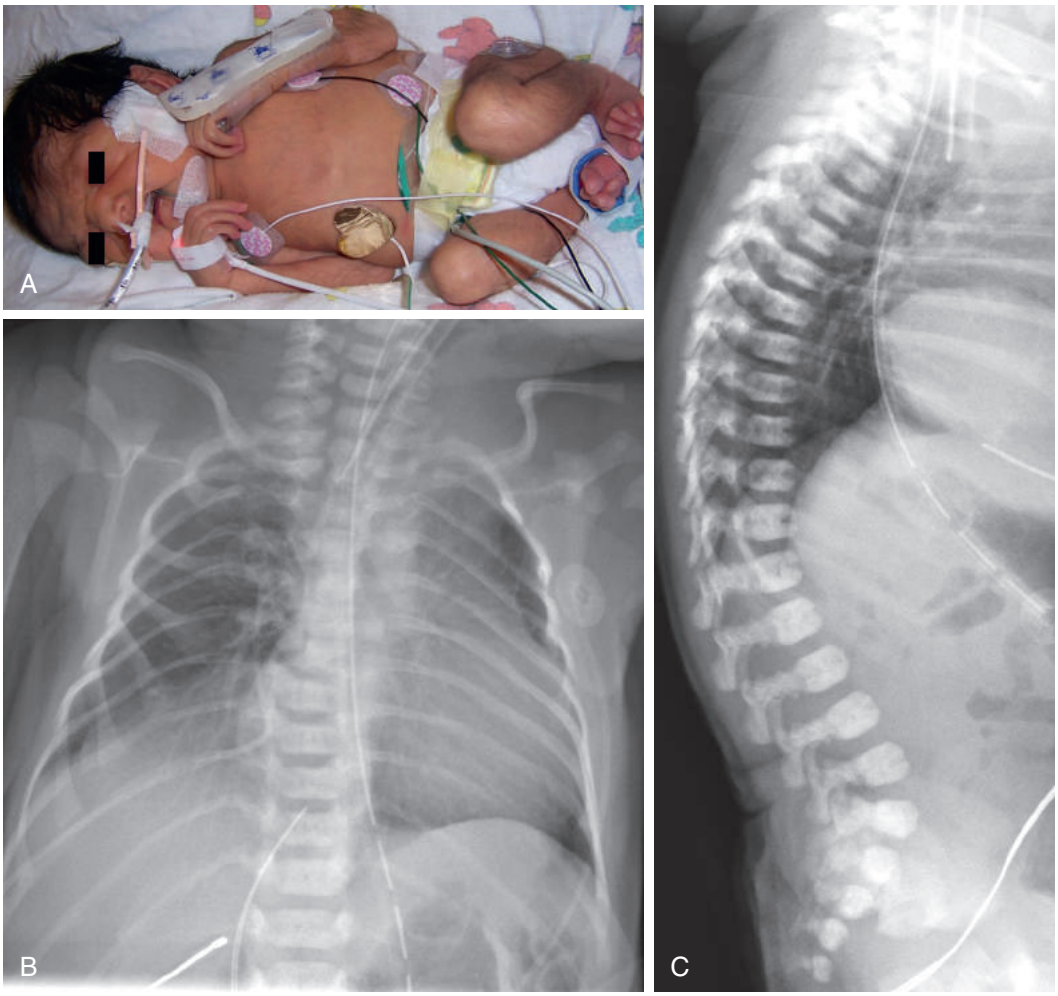
Infants with early-onset/rapidly progressive Marfan syndrome have a long, thin body and can have an aged appearance because of a lack of subcutaneous tissue and wrinkled, sagging skin (Fig. 90.10).[35] The craniofacial features include dolichocephaly (narrow head), deep-set eyes with large or small corneas (and occasionally cataracts), high nasal bridge, high palate, small pointed chin with a horizontal skin crease, and large, simple or crumpled ears. The fingers and toes are long and thin (arachnodactyly). Some joints are hyperextensible, and others have flexion contractures causing clubfoot, dislocated hips, or adducted thumbs. Infants tend to exhibit hypotonia with low muscle mass. Lenses are usually not subluxated at birth. The most important cause of morbidity and mortality is severe cardiovascular disease, which affects almost every neonate with congenital Marfan syndrome (cMS)—namely, mitral and tricuspid valve prolapse and insufficiency, as well as aortic root dilation. The ascending aorta may be dilated and tortuous. Many infants die of congestive heart failure in the first year of life. Survivors have chronic hypotonia and contractures, are unable to walk, and require many surgical procedures.

Radiographic Features

Radiographic features include pectus deformity, spontaneous pneumothorax, dural ectasia, aortic root dilation, and mitral valve prolapse. Many of these features may not be present in the newborn period.

Etiology

Congenital Marfan syndrome is caused by mutations in the gene encoding fibrillin 1 (*FBN1*).[36] Fibrillin is a glycoprotein associated with microfibrils, which form linear bundles in the matrices of many tissues, such as aorta, periosteum, perichondrium, cartilage, tendons, muscle, pleura, and meninges. There are two regions in *FBN1* in which many mutations cause cMS to occur; these lie among exons 24 to 27 and exons 31 to 32.[36] Molecular analysis does not yield mutations in all cases.



• **Fig. 90.10** Congenital Marfan Syndrome. (A) Neonate with furrowed brow and lax facial skin, thin, simple ears, small chin, short neck with redundant skin (not shown), multiple joint flexion contractures, and striking arachnodactyly of fingers and toes. The neonate also had megalocornea, pectus carinatum, mitral valve prolapse, aortic root dilation, and an *FBN1* gene missense mutation. (B) Chest radiograph revealing thin ribs and serpentine clavicles. (C) Lateral spine radiograph demonstrating exaggerated thoracic kyphosis.

Inheritance

Marfan syndrome is an autosomal dominant disorder. In most neonates with cMS, an occurrence is sporadic within a family.[35] However, there is one well-documented neonate with cMS whose father had classic Marfan syndrome except for average height.[37] There are also reports of familial cMS due to parental gonadal mosaicism.[38]

Differential Diagnosis

Differential diagnoses include CCA, autosomal recessive cutis laxa, and Loeys–Dietz syndrome.

Management

Patients require annual ophthalmologic and cardiac evaluation throughout childhood. The use of cardioselective beta-blockers, such as atenolol, is often implemented at the first signs of aortic root dilation. The angiotensin II antagonist losartan has also shown promise in this regard and may be used in combination with beta-blockers.[39,40] Children should be screened for the development of scoliosis.

Congenital Arachnodactyly (Beals Syndrome; Distal Arthrogryposis Type 9)

Presentation

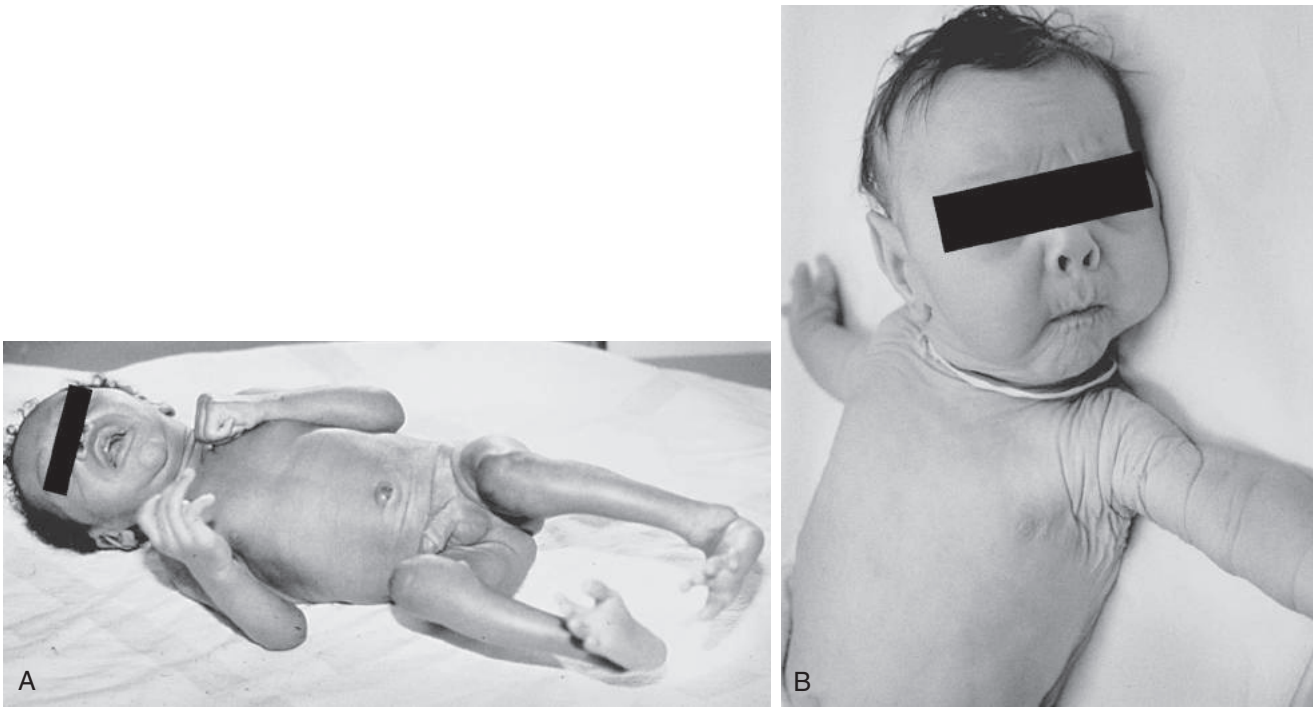
CCA (Beals syndrome; distal arthrogryposis type 9) is characterized by a thin, wasted appearance with minimal muscle and fat mass (similar to neonatal Marfan syndrome). Distinctive features include arachnodactyly with contractures of the large and small joints (Fig. 90.11A), as well as crumpled, overfolded helices of the external ear. Cardiovascular involvement is usually limited to mitral valve prolapse, but aortic root dilation may occasionally develop.[41]

Radiographic Features

Features are nonspecific and include elongated proximal phalanges; contractures of digits, ankles, knees, and hips; thin, gracile tubular bones; and gradual development of kyphoscoliosis.

Etiology

CCA is caused by dominant-acting mutations in the gene encoding fibrillin 2 (*FBN2*).



• **Fig. 90.11** (A) Congenital contractural arachnodactyly (Beals syndrome). This infant has a long, thin trunk and limbs, contractures of the joints, and crumpled ears. (B) Infant with cutis laxa. (Courtesy Montreal Children's Hospital.)

Inheritance

CCA is inherited in an autosomal dominant manner, with most patients representing the result of spontaneous mutations. Offspring of affected individuals are at 50% risk of inheriting the condition. Gonadal mosaicism has been described in CCA.[42]

Differential Diagnosis

Differential diagnoses include cMS, Stickler syndrome, homocystinuria, and distal arthrogryposis.

Management

Proper nutrition is essential to ensure adequate weight gain. Joint contractures respond to physical therapy, but occasionally surgical release may be required. Surveillance for the development of spinal curvature and aortic root dilation, although rare, is essential throughout childhood.[41]

Ehlers–Danlos Syndromes

Presentation

The EDSs are a clinically and genetically heterogeneous group of connective tissue disorders that are characterized by various degrees of joint and skin hypermobility, excessive bruising, abnormal wound healing, and fragility of tissues.[32,43] The types that are more likely to present in the newborn period include the classical type (formerly type I), the kyphoscoliotic type (formerly type VI), the dermatosparaxis type (formerly type VIIc), and the arthrochalasis type (formerly types VIIa and VIIb). The classical type often presents with premature delivery of an affected fetus as a result of rupture of the fragile amniotic membranes. The infant may be floppy and in the breech position, and there may be joint laxity and joint instability.[44] Among the rarer types of EDS, the kyphoscoliotic type often presents with severe hypotonia and scoliosis with a risk of subsequent ocular involvement.[45] In the arthrochalasis type, the major involvement is of the ligaments and joint capsules. Large and small joints are hypermobile and dislocated; severe congenital dislocation of hips occurs. The findings in the dermatosparaxis type include soft, fragile, and redundant skin with some joint hypermobility.

In vascular (formerly type IV) EDS, the greatest danger is to the pregnant affected woman, for whom there is a high risk of uterine and arterial rupture.[46] Although there is a 50% risk that the fetus will be affected, the problems of blood loss and prematurity are more important in the newborn period than the disorder itself.

Radiographic Features

Radiographic features are dependent on the particular type of EDS. Congenital hip dislocation may be evident on plain films. Hydronephrosis, bladder diverticula, and spontaneous pneumothorax may occur occasionally. Aortic dilation and arterial aneurysms may be evident by echocardiography and other imaging modalities but occur only in patients of school age or older.

Etiology

Mutations in two of the genes for collagen type V (*COL5A1* and *COL5A2*) are demonstrable in some cases of classical EDS.[44] The vascular type is caused by mutations in the gene for collagen type III (*COL3A1*). The arthrochalasis type is caused by mutations in either of the collagen type I genes (*COL1A1* or *COL1A2*), which result in loss of the N-proteinase cleavage site of the protein. The kyphoscoliotic type is caused by mutations in the gene for a procollagen cross-linking enzyme (*PLOD1*). The dermatosparaxis type is caused by mutations in a gene for a procollagen proteinase (*ADAMTS2*).

Inheritance

Most types of EDSs are inherited as autosomal dominant traits. Each child of an affected person has a 50% chance of inheriting and manifesting the disorder, although there can be marked intrafamilial variability.[44] The kyphoscoliotic and dermatosparaxis types of EDSs are inherited in an autosomal recessive manner.

Differential Diagnosis

Differential diagnoses include cMS, CCA (distal arthrogryposis type 9), Larsen syndrome, and other rare variant forms of EDS.[32,33]

Management

Trauma should be avoided because of skin fragility. The effective closure of surgical wounds is challenging in some types because of a tendency for dehiscence.

Cutis Laxa

Presentation

Cutis laxa is a group of genetically heterogeneous disorders that primarily affect the assembly and homeostasis of elastic fibers. As such, the presentation can be highly varied. Infantile forms may exhibit loose, furrowed skin, a large anterior fontanel, hypotonia, hernias, and congenital hip dislocation (see Fig. 90.11B).[33,47]

Radiographic Features

Radiographic features are, in part, dependent on the genetic form of the disorder. Nonspecific features include a large anterior fontanel, congenital hip dislocation, and hernias. The X-linked form may exhibit occipital horns of the skull. Arterial tortuosity, aortic root dilation, and cortical and cerebellar anomalies may be seen in some forms, as well as the gastrointestinal tract and urinary tract diverticula.

Etiology

The relatively mild, autosomal dominant form of cutis laxa is caused by mutations in the elastin gene (*ELN*). The X-linked recessive form (occipital horn syndrome) is caused by mutations in the *ATP7A* gene (allelic with Menkes syndrome). Autosomal recessive forms may be caused by mutations in the fibulin 4 gene (*FBLN4*), the fibulin 5 gene (*FBLN5*), or the gene that encodes the A2 subunit of vacuolar H^+-ATPase (*ATP6V0A2*). Biochemical clues as to the cause in a particular patient may include decreased serum copper and ceruloplasmin levels (X-linked form), or an abnormal serum sialotransferrin isoelectric focusing pattern in cases caused by *ATP6V0A2* mutations.

Inheritance

Because cutis laxa is genetically heterogeneous, the modes of inheritance include autosomal dominant, autosomal recessive, and X-linked recessive. The latter two modes are usually responsible for forms with a neonatal and infantile presentation.

Differential Diagnosis

Differential diagnoses include EDS, Menkes syndrome, generodermia osteodysplastica, and de Barsy syndrome.

Management

Serious childhood complications include developmental delay, pulmonary emphysema, aortic root dilation, and arterial tortuosity. Annual ophthalmologic and cardiac examinations are essential, and referral to special education programs may be indicated.

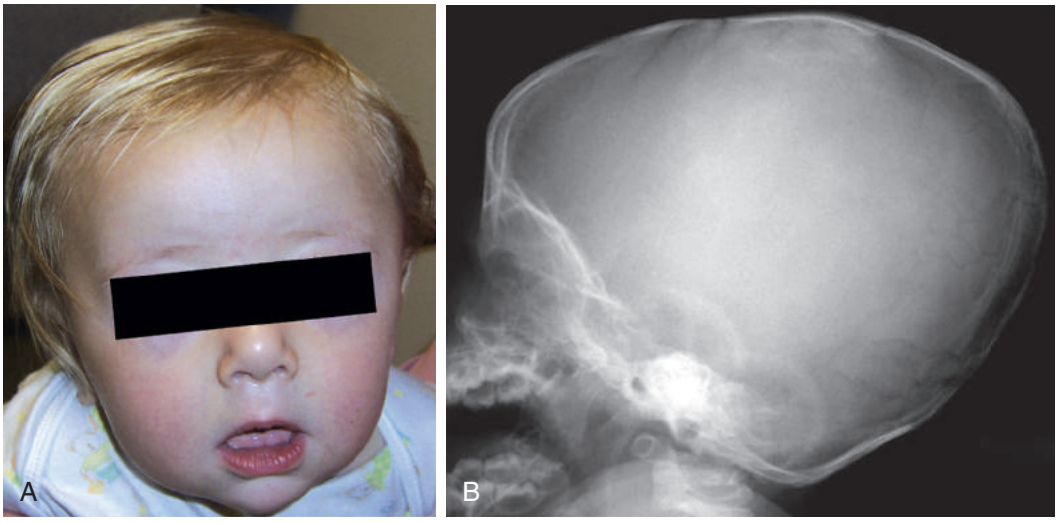
Menkes Syndrome

Presentation

Menkes syndrome often appears in the newborn period with nonspecific neurologic manifestations. Typically, developmental delay is evident in the first 2 to 3 months of life, with failure to thrive, seizures, and severe ocular manifestations. Changes in the appearance of the hair include hypopigmentation, brittleness, patchy alopecia, and twisted shafts seen by light microscopy (i.e., pili torti; Fig. 90.12A). Early death is common and may occur in infancy. Serum copper and ceruloplasmin concentrations are low, and the plasma dopamine-to-norepinephrine ratio may be elevated.[48]

Radiographic Features

Features may evolve during infancy and may include bladder diverticula (seen on bladder ultrasonography and voiding cystourethrogram), tortuous vessels (on echocardiogram or magnetic resonance



• **Fig. 90.12** Menkes Syndrome. (A) Note the blonde hair and fair complexion in this 11-month-old Hispanic boy. (B) Note multiple Wormian bones near the occiput.

imaging with contrast agent), gastric polyps (on upper gastrointestinal [GI] contrast study), metaphyseal spurring, osteopenia, and Wormian bones on plain radiographs (see Fig. 90.12B).[14]

Etiology

Menkes syndrome is caused by mutations in the gene encoding a copper-transporting adenosine triphosphatase (*ATP7A*). This enzyme participates in the final processing of several copper-dependent enzymes, including dopamine β-hydroxylase, tyrosinase, lysyl oxidase, superoxide dismutase, and cytochrome *c* oxidase. As a result, several physiologic processes and cellular functions are impaired, including collagen cross-linking, pigment production, and neurotransmission.[48]

Inheritance

Menkes syndrome is an X-linked recessive disorder, and therefore only males are affected. Female carriers may exhibit pili torti in some hair shafts because of lyonization.[48] Sons born to carrier females have a 50% risk of manifesting the disease.

Differential Diagnosis

Differential diagnoses include cutis laxa (the occipital horn form is allelic), EDS, neonatal cMS, biotinidase deficiency, mitochondrial myopathies, nutritional copper deficiency, and some organic acidurias.

Management

Early diagnosis allows copper supplementation therapy, but this is not effective in all patients.[49] Patients should be monitored for the development of seizures, as well as a propensity for bone fragility, poor wound healing, and vascular fragility leading to excessive bleeding, hemorrhagic strokes, and subdural hematomas. Bladder diverticula may result in urinary retention and urinary tract infections and should be surgically corrected. Patients are at risk of moderate to severe developmental delay, and they should be referred to infant stimulation and early intervention programs.

Family Support and Education

Many of the conditions described in this chapter are rare, and parents (and sometimes medical staff) are unfamiliar with or bewildered by such conditions. Providing appropriate educational materials is of utmost importance for making important medical decisions and preparing for the future. Support groups such as the Little People of America (http://www.lpaonline.org) and the Osteogenesis Imperfecta Foundation (http://www.oif.org) are helpful in this regard, as the medical content is reviewed and updated by experts in the field. In addition, individual entries in GeneReviews (https://www.ncbi.nlm.nih.gov/books/NBK1116/) frequently include links to support groups as well as to educational pieces written in lay languages, such as the NIH Genetics Home Reference (https://ghr.nlm.nih.gov/condition).

ROBERT SIDBURY

KEY POINTS

- Healthy full-term infant skin is well developed and serves as an effective barrier. Premature infants, especially those of very low birth weight, have an ineffective barrier that increases the risk of invasive infection, dehydration, cutaneous injury, and toxic absorption.
- Birthmarks may have neurologic implications that require magnetic resonance imaging. In some cases, newborns and very young infants can be imaged using a "feed and wrap" technique without sedation. Awareness of this window of opportunity may help avoid unnecessary general anesthesia.
- Early application of emollients in certain infants can improve barrier function, decrease risk of infection, and potentially prevent atopic outcomes.
- Blaschko lines are patterns formed by the migration of skin cells during embryogenesis. They are distinct from dermatomes. Cutaneous findings in this distribution are a clue to an underlying mutational event.

The skin serves several critical roles, including as a primary barrier against infection, thermoregulation, and electrolyte homeostasis. Disruption as a result of genetic mutation, injury, or prematurity can be life-threatening. This chapter details the stages of human skin development, the potential challenges of prematurity, and an approach to important clinical presentations.

Cutaneous morphogenesis is complex and incompletely understood. Advances have come from traditional murine model work but also in "reverse" by identifying mutations causing disorders that manifest with developmental defects (e.g., aplasia cutis congenita).[1] Human skin develops from apposed tissue of both mesodermal and ectodermal origin. From the mesoderm arise fibroblasts, vascular cells, adipocytes, and immune-presenting Langerhans cells, which ultimately reside in the epidermis. Ectoderm-derived tissue includes keratinocytes and neural crest-derived melanocytes. The assembly of the epidermis, dermoepidermal junction (DEJ), dermis, and fat, along with epidermal appendages and immigrant cells, is a complex dynamic with the potential for clinically significant disruption at every step. Table 91.1 enumerates these critical stages. The clinician can use this ontogeny to guide assessment: Any newborn with evident cutaneous pathology should prompt additional scrutiny of the hair, nails, teeth (natal teeth can suggest specific disorders), and the central nervous system.

Epidermis

The epidermis derives entirely from ectoderm. A single-layered epithelium spans the embryo from gastrulation. Subsequent development proceeds in discrete stages: embryonic (5 to 8 weeks) and embryonic/fetal transition (9 to 10 weeks) and then to the early (11 to 14 weeks), mid (15 to 20 weeks), and late (20 weeks–birth) fetal periods.[2] Differentiation and formation of appendages occur predominantly during the second trimester. It is during the late fetal stage that the skin first becomes functional. The stratum corneum, or outer epidermis, has been likened to "bricks and mortar."[3] Epidermal keratinization begins first on the head, face, and palms. Anucleate corneocytes flatten and form "bricks," while a mixture of cells, adhesion proteins, and lipids form the semipermeable mortar. One such protein, filament aggregating protein, or filaggrin, has recently been linked to atopy. Patients with filaggrin mutations are at greater risk for eczema, asthma, and allergies.[4] Decreased ability to retain moisture with resulting fissures in the stratum corneum may promote epicutaneous allergen exposure and sensitization. Emerging evidence suggests that early aggressive application of thick emollients to at-risk infants decreases their chance of developing atopic dermatitis.[5]

Dermoepidermal Junction

The DEJ is the interface between basal layer keratinocytes of the epidermis and the dermis and helps the skin resist shearing forces. The critical elements of the DEJ form by 8 to 10 weeks' gestation. The DEJ is composed of hemidesmosomes, anchoring filaments, anchoring fibrils, and type VII collagen, which combine to tether the dermis to the epidermis (Fig. 91.1). Epidermolysis bullosa (EB) is an inherited disorder of cutaneous fragility that results from defective proteins in this complex. The type of EB depends on the affected protein, and outcomes can vary widely.

Dermis and Subcutis

The dermis is derived from diverse tissue types. Embryonic mesenchymal cells capable of becoming multiple cell types are enmeshed in a hyaluronic matrix called a *cellular dermis*. At 8 weeks' estimated gestational age (EGA), the dermis is

TABLE 91.1 Milestones in Fetal Skin Embryogenesis

Milestone	Gestational Week
Expression of epidermal keratins	6
Development of specialized cells, including melanocytes, Langerhans	8
Formation of dermoepidermal junction	8–10
Beginning of nail development	10
Beginning of hair development	12
Palmoplantar sweat gland formation	10–12
Formation of fat in subcutis	15
Sweat gland formation in rest of body	24–26

Adapted from Holbrook KA, Odland GF. The fine structure of developing human epidermis: light, scanning, and transmission electron microscopy of the periderm. *J Invest Dermatol.* 1975;65:16–38.

distinguishable from underlying tissue. By 15 weeks, collagen fibers accumulate, and by 22 to 24 weeks, elastin fibers are first detectable by electron microscopy.[2] Immature dermis will not scar when traumatized (e.g., with a fetal skin biopsy), whereas the increasing tensile strength that accompanies maturation also connotes potential to scar; this occurs at roughly the end of the second trimester. Blood vessel plexi are discernible by 12 weeks' EGA but do not fully mature until after birth. Vasculogenesis, the formation of endothelial cells and then vessels from angioblasts, is completed by 20 weeks' gestation; angiogenesis follows as existing vessels give rise to new ones. Sprouting angiogenesis may add new vessels to tissue previously lacking vascularity; this involves spouts of endothelial cells growing toward an angiogenic stimulus, such as vascular endothelial growth factor or basic fibroblast growth factor. Intussusceptive angiogenesis is characterized by a splitting process whereby the vessel wall invades the lumen, causing the vessel to divide in two. This type of angiogenesis occurs only in areas of preexisting vascularity. Both types of angiogenesis can occur in virtually all tissues and organs.[6] Neural networks develop toward the end of the first trimester and follow a vascular pattern. Adipose tissue develops beneath the dermis, starting in the second trimester.[7]

Goltz syndrome (focal dermal hypoplasia) is an X-linked dominant disorder caused by mutations in *PORCN*. Ninety percent of affected individuals are female and manifest with striking linear atrophic plaques with distinctive fat herniation due to dermal atrophy.

Appendages

Hair, nail, sweat gland, and apocrine gland development relies on coordinated dermal–epidermal interaction that commences around 10 weeks' gestation. Hair follicle formation, which directs overlying epidermal basal cells to aggregate in the form of a placode, is initiated in the dermis. Hair follicles differentiate during the second trimester, and hair canals are formed by 20 weeks' EGA when scalp hairs are just visible. Hairs cycle between growth (anagen), resting (catagen), and shedding (telogen). The first shedding cycle occurs around 28 weeks' gestation, after which they reenter the anagen phase. The final shedding phase generally occurs postnatally, at the occiput, leading to occipital alopecia that often is misattributed to pressure or friction.

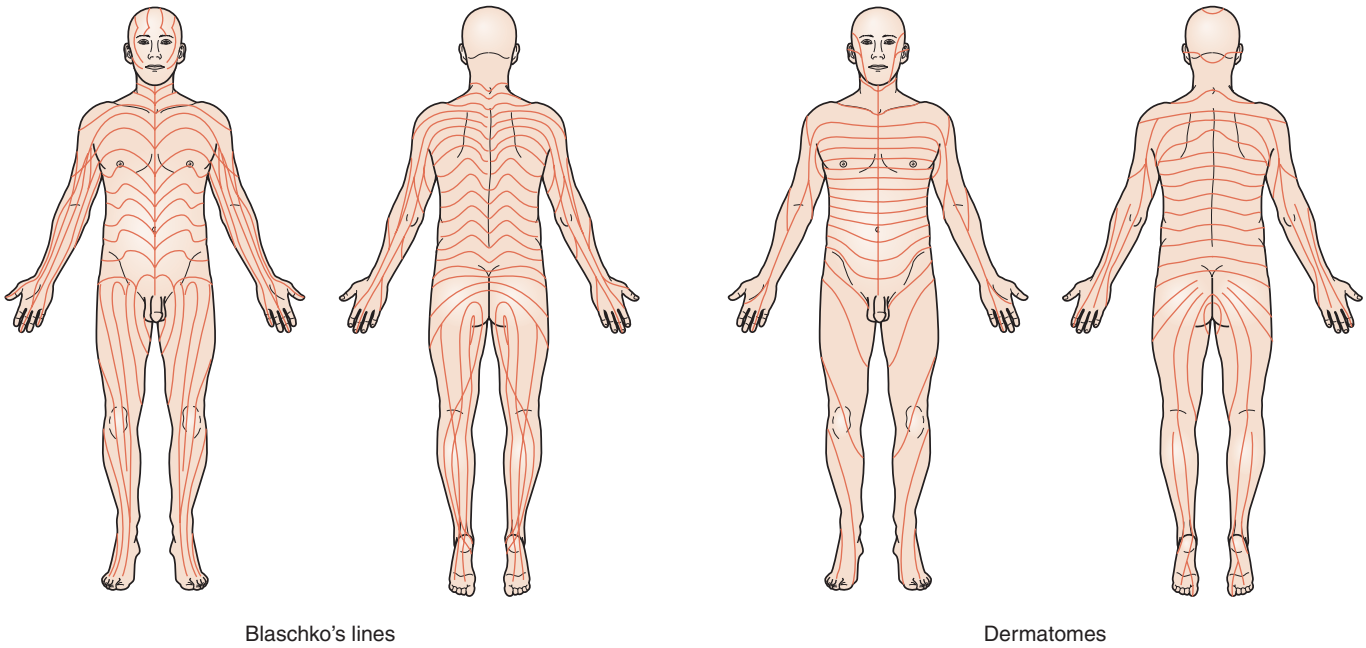
Nails begin development at 8 weeks' EGA, slightly earlier than the hair follicles. A keratinized nail has completely covered the nail plate by 5 months' EGA. Hair and nail keratins have greater structural integrity than those in the epidermis.

Sebaceous glands develop contemporaneously with hair follicles. At 13 to 16 weeks' EGA, characteristic sebaceous gland bulges can be seen with hair follicles, just above the insertion of the arrector pili muscle. Maternal hormones induce sebaceous gland production of sebum during the late second and third trimesters. Sebum and shed corneocytes form vernix, which progressively coats the fetus in a cephalocaudal orientation. Fetal lung maturity parallels sebaceous gland activity, and increased physiologic concentrations of surfactant emulsifies surface vernix.

Palmoplantar eccrine sweat glands begin to develop at 55 to 65 days' gestation and are fully developed by the second trimester. Interfollicular sweat glands and apocrine glands do not form until the middle of the second trimester. Ectodermal dysplasias are a heterogeneous group of disorders with striking abnormalities in skin appendages. Hydrotic ectodermal dysplasia, or Clouston syndrome, is due to mutations in *GJB6* (connexin 30), which directs formation of gap junctions found notably in adnexal structures.

Specialized Skin Cells

Melanocytes, Langerhans cells, and Merkel cells comprise the primary epidermal immigrant cells. Melanocytes derive from the neural crest and migrate along Blaschko lines to populate the entire fetal epidermis. Melanocytes are first identifiable at 50 days' EGA and are fully present at birth, but melanogenesis continues such that skin is not fully pigmented at birth and will darken in the first months. Blaschko lines are distinct from



• **Fig. 91.2** Blaschko's lines or developmental lines of epidermal migration.

dermatomes, and clinical abnormalities in this distribution can be helpful diagnostically (Fig. 91.2). Incontinentia pigmenti, an X-linked dominantly inherited gene dermatosis due to mutations in *NEMO*, presents with a series of cutaneous findings over time, first vesicles and then a warty hyperkeratotic phase, followed by dyspigmentation all along Blaschko lines. Knowledge of this pattern can help discriminate from fundamentally different processes, such as herpes zoster, which would present with vesicles in a dermatomal distribution.

Langerhans cells first appear at 40 days' gestation and serve as antigen-presenting cells. Merkel cells appear at 8 weeks' gestation and serve a mechanoreceptor function.

Epidermal Stem Cells

The skin must constantly repair and renew itself. There are several different types of stem cells within the skin, including basal keratinocytes, hair follicles, and melanocytes. Basal keratinocytes can be grown in sheets and used for therapeutic barrier purposes in burn patients and those with chronic wounds (e.g., in EB). Such grafts are useful but do not contain appendages such as hair follicles or sweat glands. Improved understanding of the interaction among various cutaneous stem cells, their microenvironments, and their pluripotential is driving advances in stem cell technology.[8]

Impact of Prematurity

The stratum corneum reaches functional maturity around 33 weeks' EGA. The combination of a developmentally and functionally incompetent barrier, absence or diminished vernix caseosa, large body-surface-area-to-mass ratio, and an immature immune system places premature infants, in particular those born at less than 33 weeks' gestation, at significant risk for invasive infection and skin injury. A unique consideration in premature infants is the risk of percutaneous toxicity. Topical medications, cleansers, and even emollients (e.g., lactic acid) can lead to dangerous systemic levels in premature infants. A particularly seductive risk is that of cutaneous anesthesia when used for small invasive procedures. Minimizing pain is important, but careful attention to safe limits of topical anesthetic is vital.[9] Table 91.2 compares premature and term infant skin. Table 91.3 summarizes important potential cutaneous absorption risks.

TABLE 91.2 The Impact of Prematurity on Skin Physiology

	Premature	Term
Skin thickness	0.9 mm	1.2 mm
Epidermal thickness	20 μ	40 μ
Epidermal covering	No vernix before 28 weeks	Vernix
TEWL	High (at 26 weeks TEWL = 45 g/m per h)	Low (TEWL = 5 g/m per h)
Acid mantle	Incomplete	Complete
Percutaneous absorption	Very high	Normal

TEWL, Transepidermal water loss.

Care of Preterm Skin

Advances in the understanding of newborn physiology, coupled with technological developments, have contributed to the increased survival of extremely low birth weight (ELBW) infants. The care of such infants poses unique issues across organ systems,

TABLE 91.3 Reported Hazards of Percutaneous Absorption in the Newborn

Compound	Reference	Product	Toxicity
Aniline	Rutter (1987)	Dye used as a laundry marker	Methemoglobinemia,* death
Mercury	Dinehart et al. (1988)	Diaper rinses, teething powders	Rash, hypotonia
Pentachlorophenol	West et al. (1981)	Laundry disinfectant	Tachycardia, sweating, hepatomegaly, metabolic acidosis, death
Hexachlorophene	—	Topical antiseptic (pHisoHex)	Vacuolar encephalopathy, death
Resorcinol	West et al. (1981)	Topical antiseptic	Methemoglobinemia*
Boric acid	Goldbloom and Goldbloom (1953)	Baby powder	Vomiting, diarrhea, erythroderma, seizures, death
Lindane	Rutter (1987) and West et al. (1981)	Scabicide	Neurotoxicity
Salicylic acid	Abidel-Magid and El Awad Ahmed (1994) and West et al. (1981)	Keratolytic emollient	Metabolic acidosis, salicylism
Isopropyl alcohol (underocclusion)	Rutter (1987)	Topical antiseptic	Cutaneous hemorrhagic necrosis
Silver sulfadiazine	Payne et al. (1992)	Topical antibiotic (Silvadene)	Kernicterus (sulfa component), argyria (silver component)
Povidone–iodine	Rutter (1987) and West et al. (1981)	Topical antiseptic (Betadine)	Hypothyroidism, goiter
Neomycin	Rutter (1987)	Topical antibiotic	Neural deafness
Corticosteroids	Rutter (1987) and West et al. (1981)	Topical antiinflammatory (Lotrisone)	Skin atrophy, adrenal suppression
Benzocaine	Gelman et al. (1996)	Mucosal anesthetic (teething products)	Methemoglobinemia*
Prilocaine	Frayling et al. (1990) and Reynolds (1996)	Epidermal anesthetic (EMLA)	Methemoglobinemia*

*Heritable glucose-6-phosphate deficiencies are associated with an increased susceptibility to methemoglobinemia, as is coadministration of several drugs such as sulfonamides, acetaminophen, nitroprusside, phenobarbital, and phenytoin.
EMLA, Eutectic mixture lidocaine anesthetic.

and the skin is no exception. The most immediate issue is thermoregulation. The skin barrier in ELBW infants is ineffective, predisposing them toward dehydration and electrolyte imbalance. At delivery, maintenance of body temperature is critical; gentle drying and the use of alternate heat sources, such as a humidified incubator, will limit evaporative water loss. Barrier immaturity also puts EBLW infants at risk for skin injury from pedestrian exposures such as adhesives or cleaners like alcohol or iodine. Frequent repositioning and appropriate bedding are necessary to avoid pressure necrosis. Specialized dressings, such as those that may be used for infants with mechanobullous diseases like epidermolysis bullosa, can protect vulnerable sites (e.g., umbilical catheter, endotracheal tubes). Examples of such dressings include DuoDerm (ConvaTech, Bridgewater, New Jersey, United States) Mepilex (Molnlycke, Gothenburg, Sweden), and Vigilon (Bard Medical, Covington, Georgia, United States).

Early use of emollients has yielded conflicting results. Proposed benefits include decreased transepidermal water loss, decreased skin fragility, and lower risk of infection. However, a randomized trial demonstrated a higher rate of nosocomial infection in infants using prophylactic emollients compared with a control cohort.[10] Accordingly, the use of prophylactic emollients is not broadly recommended but may be beneficial for some infants at greater risk for skin breakdown.

General Care of Newborn Skin

Conversely, application of cream-based emollients in infants older than 29 weeks' EGA has been shown to enhance skin barrier development.[11] In infants at high risk for atopic dermatitis, early application of an emollient decreased the incidence of that disorder at 6 months of age by 50%,[5] although a more recent randomized trial did not validate these findings.[12] Sunflower seed oil application reduced the incidence of nosocomial infections by 41% when applied to infants less than 33 weeks' EGA in a study from Bangladesh.[13] Oils such as safflower, sesame, coconut, and apricot contain fatty acids that may have antiinflammatory and antibacterial properties. Olive oil can promote *Pityrosporum* growth, so it may not be the optimal choice.[14] Box 91.1 details general principles of neonatal skin care.

• BOX 91.1 Proposed Guidelines for Basic Skin Care in the Newborn

Use adhesives sparingly
- Place protective dressing (e.g., DuoDerm or Tegaderm) at sites of frequent taping (endotracheal tube and nasogastric tube placement)
- Use nonadhesive electrodes, and change them only when they become nonfunctional

Limit bathing
- Defer initial cleansing until body temperature has stabilized
- Avoid cleansing agents for the first 2 weeks
- Use warm water and moistened cotton pledgets in a humid environment
- Surface cleansing is required no more than twice per week
- If antimicrobial skin preparation is required, use short-contact chlorhexidine (except on the face)

Be aware of the composition and quantity of all topically applied agents
- These agents include antimicrobial cleansers, diaper wipes, adhesive removers, and perineal products

Dispense from single-use containers, if possible

Ensure adequate intake of protein, essential fatty acids, zinc, biotin, and vitamins A, D, and B
- Erosive periorificial dermatitis is a sign of nutritional deficiency

Apply a simple cream or ointment emollient every 8 hours

Guard against excessive thermal and ultraviolet exposure
- Use thermally controlled water for bathing
- Avoid surface monitors with metal contacts
- Use Plexiglas shielding over daylight fluorescent phototherapy

Protect sites of cutaneous injury with the appropriate occlusive dressing
- Use a film dressing on nonexudative sites
- Use a hydrogel dressing on exudative wounds
- Maintain appropriate hydration at the skin-dressing interface
- Remove necrotic debris with each dressing change

Bathing newborns has myriad potential hygienic, social, and cultural benefits but can potentially be detrimental to newborn skin. The timing of vernix removal varies considerably. Vernix is a complex mixture of water, protein, and lipids. It is hydrophobic and hydrating and contains lysozyme and lactoferrin, which are antimicrobial. Delayed bathing of newborns beyond 6 hours after birth is recommended by the World Health Organization in high-risk settings. The pH of the skin surface of term and preterm infants is more alkaline (6.5 to 7.5) but declines in the first week to values comparable to adult skin (4.0 to 5.5). The establishment of this "acid mantle" is important for many reasons and can be interrupted or delayed by the use of alkaline or irritating soaps. Gentle cleansers, neutral in pH and lacking fragrances and excessive preservatives or abrasives, can be used safely. Caregivers should practice good hand hygiene, preferably with chlorhexidine, for bacterial decontamination, although 10% povidone–iodine is advantageous for *Candida* species. Chlorhexidine may provide the most effective agent for umbilical stump care to prevent omphalitis and sepsis. Chlorhexidine 0.5% is superior to povidone–iodine in reducing peripheral catheter colonization in neonates.[7]

Morphologic Approach to Skin Pathology

Any skin examination should begin by attempting to identify a primary morphology. This helps limit a differential diagnosis and avoid the diagnostic confusion that can arise from secondary findings such as erosions and ulcerations (Table 91.4). Newborns present most commonly with benign, transient skin findings. These and other common neonatal presentations are detailed in subsequent chapters. There are several distinctive presentations that are important for pediatricians and neonatologists to recognize.

TABLE 91.4 Morphologic Approach to Diagnosis

Morphology	Description	Example
Macule/patch	Flat, no epidermal change	Capillary malformation
Papule/plaque	Raised, discrete edge, epidermal change	Superficial hemangioma
Nodule/tumor	Raised, sloping border, no epidermal change	Dermoid cyst
Vesicle/bulla	Clear, fluid filled	Epidermolysis bullosa
Pustule	Turbid, fluid filled	Candidiasis
Wheal	Edematous, red plaque	Neonatal onset multi-inflammatory disease

• Fig. 91.3 A newborn with taut skin representing a collodion membrane.

Collodion Membrane

Collodion membrane (CM) is a congenital cutaneous phenotype that has both immediate and longer term implications.[15] Clinically, a "collodion baby" presents with a tight "plastic wrap–"like encasement on the skin (Fig. 91.3). This taut skin can lead to eversion of the lips (eclabium) and eyelids (ectropion) as well as dysregulation of cutaneous homeostasis, mandating careful monitoring of fluids, electrolytes, and thermoregulation. Affected infants should be kept in the neonatal intensive care unit in a controlled environment as the membrane spontaneously sheds over the first weeks after birth. The majority of CM infants will ultimately have some form of chronic skin disorder, most commonly autosomal recessive congenital ichthyosis; however, other disorders, including Gaucher disease and ectodermal dysplasia, can present as CM. Rarely, CM infants may go on to have normal skin (lamellar exfoliation of the newborn). Diagnosis may be facilitated by skin biopsy and/or genetic testing, but evolution of the skin examination over time may also point toward the ultimate diagnosis noninvasively.

• BOX 91.2 Differential Diagnosis of Cutaneous Vesicles, Bullae, and Erosions in the Neonate

Infectious Vesiculopustular Dermatoses

Herpes simplex virus infection
Varicella infection
Cytomegalovirus
Candida infection
Scabies
Aspergillus infection
Bacterial infection
- Group B streptococcus
- Group A streptococcus
- *Haemophilus influenzae* type B

- *Pseudomonas*

Noninfectious Transient Conditions With Vesicles and Erosions

Erythema toxicum neonatorum
Transient neonatal pustular melanosis
Miliaria
Neonatal acne
Eosinophilic pustular folliculitis
Acropustulosis of infancy
Sucking blister
Trauma

Nontransient Bullous Dermatoses

Epidermolysis bullosa
Incontinentia pigmenti
Epidermolytic hyperkeratosis
Hyper-IgE syndrome
Herpes gestationis
Pemphigus vulgaris
Langerhans cell histiocytosis
Mastocytosis

From Avram MM, Gobel V, Sepehr A. Case records of the Massachusetts General Hospital. Case 30-2007. A newborn girl with skin lesions. *N Engl J Med.* 2007;357:1327–1325.

Vesicopustular and Bullous Eruptions

An infant born with widespread vesicles, pustules, bulla, or erosions presents a daunting differential diagnosis (Box 91.2), including infectious, inflammatory, metabolic, and genetic disorders.[16] Treatable infectious etiologies, such as herpes simplex virus (HSV), varicella, *Staphylococcus aureus*, and *Candida* infections should be first ruled out by careful history and cultures. Subsequent consideration may be given to other dermatoses, including mastocytosis and histiocytosis. Transient benign dermatoses that present with a vesicopustular morphology, such as erythema toxicum (Fig. 91.4) or transient neonatal pustular melanosis (TNPM), should be considered and may be identified by simple laboratory studies (e.g., eosinophils on a smear of erythema toxicum vs. neutrophils on a smear from TNPM). Widespread blistering and erosion, in particular at friction-prone areas, such as the hands and feet, raise the uniquely important specter of EB (Fig. 91.5). EB is an inherited disorder of cutaneous fragility, and early awareness can avoid unnecessary iatrogenic exacerbation because of inappropriate handling, adhesives, leads, or monitors.[17] It is impossible to determine EB subtype from clinical examination alone. Relatively mild blistering at birth can occur in infants with severe subtypes, so providers should be cautioned against trying to predict the eventual phenotype on the basis of initial presentation.

• Fig. 91.4 Small eosinophil-rich pustules on an inflamed base consistent with erythema toxicum.

• Fig. 91.5 Blistering on the foot of a newborn with epidermolysis bullosa.

Blueberry Muffin Babies

A so-called "blueberry muffin baby" presents with distinctive red–purple macules, papules, and plaques that have historically prompted consideration of congenital infections denoted by the acronym TORCH: *T*oxoplasmosis, *O*ther, *R*ubella, *C*ytomegalovirus and *H*SV. These entities should be ruled out by history; evaluation; appropriate cultures; and supportive findings, such as dysmorphology. Several noninfectious conditions should be added to the clinical differential. Histiocytosis, neuroblastoma, leukemia cutis, transient myeloproliferative disorder, mastocytosis, and multifocal vascular lesions can all mimic blueberry muffin lesions.[18] A skin biopsy may be necessary to discriminate and appropriately triage such infants.

Erythroderma

Erythroderma is defined as diffuse erythema with or without associated findings, like scaling. Newborns have extremely reactive skin, so it may take time to discern normal physiologic change, including cutis marmorata, from actual pathology. Diffuse erythema can herald many underlying conditions, and appropriate assessment must be comprehensive, not unlike the approach to a newborn with vesicles and pustules. Although infectious causes of erythroderma are less common, all treatable triggers should be eliminated. More commonly, erythroderma in a newborn may herald genetic or inflammatory conditions, such as ichthyosis, psoriasis, or seborrheic dermatitis. Metabolic disorders, primary immunodeficiency, and autoinflammatory syndromes must also be considered. Timely assessment is essential, even when infectious etiologies have been ruled out, because timely intervention can mitigate morbidity in some disorders (e.g., Menkes disease).[19]

Birthmarks With Neurologic Implications

Large congenital melanocytic nevi may be associated with neurocutaneous melanosis (NCM) (Fig. 91.6). The risk of NCM is increased if the nevus is located on the scalp, or anywhere in the midline, or if infants have multiple (>20) satellite nevi. Magnetic resonance imaging (MRI) with and without contrast is necessary to rule out NCM. Early infancy may offer a unique opportunity to obtain an unsedated (feed-and-wrap) MRI, potentially avoiding general anesthesia later.[20]

Cutaneous stigmata, including pigmented or vascular lesions, excessive hair, or abnormal dimpling/clefting in the midline sacrum, can all herald underlying occult spinal dysraphism(OSD). Two or more such lesions, dimples more than 5 mm at the base or farther than 2.5 cm from the anus, all increase the risk of OSD.[21] Ultrasound, before complete vertebral ossification, can permit assessment of the brain and spine; however, the false-negative rate is high.

Facial vascular anomalies, such as capillary malformations, may herald underlying ipsilateral angiomatosis and glaucoma (Sturge-Weber syndrome). An MRI with contrast may show leptomeningeal malformation that can predispose toward seizures and developmental delay. Computed tomography may show "tram-track calcifications" in the temporal and occipital cortex, although these may not be present initially.

• **Fig. 91.6** Giant melanocytic nevus on the back.

• **Fig. 91.7** Large segmental infantile hemangioma in the setting of PHACE syndrome.

Segmental infantile hemangiomas, also typically on the face, can be associated with posterior fossa abnormalities such as Dandy–Walker malformation and cerebral artery dysmorphology, which predispose toward stroke, aortic coarctation, and ocular abnormalities (PHACE syndrome)[22] (Fig. 91.7). An MRI with angiography looking for distinctively tortuous, dysmorphic cerebral vessels can be diagnostic. As noted earlier, the potential for unsedated feed-and-wrap imaging may exist.

Congenital and Hereditary Disorders of the Skin

CHERYL BAYART AND HEATHER A. BRANDLING-BENNETT

KEY POINTS

- Genodermatoses are a broad spectrum of heritable disorders that affect the skin and may or may not affect other organ systems.
- Many, but not all, genodermatoses present with cutaneous and sometimes systemic findings in the neonatal period.
- Classification and nomenclature of these disorders is evolving as we learn more about the genetic basis and pathogenesis of these conditions.
- Newborns with signs of genetic skin disease often require multidisciplinary care.

Heritable disorders of the skin, also known as *genodermatoses*, encompass a diverse array of conditions that can affect the color, texture, and structural integrity of the epidermis, epidermal appendages, and connective tissue. Some of these diseases affect only the skin, but many are associated with other organ system anomalies. Knowledge of the molecular genetic basis of the genodermatoses is rapidly evolving, with the hope that this will lead to novel and more efficacious therapies. Table 92.1 provides a list of resources and support groups for patients with genodermatoses and their families.

Genetic mosaicism refers to an organism composed of two or more genetically distinct populations of cells. Mosaicism affecting the skin can lead to unique cutaneous patterns. One example of this is Blaschko lines, which refers to a linear and whorled pattern with midline demarcation, thought to represent migration of embryonic cells (Fig. 92.1; Lombillo and Sybert, 2005). Blaschko lines are different from dermatomes, skin tension lines, or lines of lymphatic drainage. There are various heritable skin disorders that present with skin lesions that follow Blaschko lines, including pigmentary disorders, incontinentia pigmenti (IP), and Goltz syndrome, which will be discussed in this chapter.

Ichthyoses

The ichthyoses, also referred to as *disorders of keratinization or cornification*, are a group of skin disorders that are characterized by scaly skin and/or hyperkeratosis (thickened stratum corneum). Historically they have been classified by their clinical and sometimes histologic features, but nosology is evolving as the molecular basis of these disorders is being discovered. More than 50 genes have been reported to result is various types of ichthyoses.[1] In 2009 an international consensus conference was held to revise the nomenclature and classification of inherited ichthyoses, which were subdivided into two principal groups: nonsyndromic and syndromic forms, summarized in Tables 92.2 and 92.3, respectively, with exceedingly rare or minor variants that are beyond the scope of this chapter.[2,3] The most striking neonatal presentations are discussed in more detail.

Collodion Baby

The term *collodion baby* refers to a neonate born encased in shiny, thickened skin that resembles parchment or plastic wrap (Fig. 92.2). The taut skin leads to various distorting features such as ectropion (eversion of eyelids), eclabium (eversion of lips), flattening or hypoplasia of the nose and ears, and pseudocontractures of the digits. These infants have an ineffective cutaneous barrier against transepidermal water loss and invasion of pathogenic organisms and are at risk of multiple complications, including temperature instability, dehydration, electrolyte instability, infections, poor sucking, failure to thrive, keratitis, ear canal obstruction, percutaneous toxicity from topical medications, pneumonia from aspiration of squamous material in amniotic fluid, and distal limb or digital ischemia.[4]

These neonates need diligent supportive care in a humidified incubator with close monitoring of temperature, fluid and electrolyte balance, and caloric intake. Surveillance for signs of cutaneous or systemic infection is important, but prophylactic antibiotics or antifungals are not recommended. Skin care is somewhat controversial, but many advocate application of a bland petroleum-based or water-in-oil emollient at least every 6 to 8 hours. Caution is advised with use of topical medications or keratolytics because of increased percutaneous absorption and risk of toxicity. If there are erosions or fissures, bathing with normal saline may be more comfortable than with plain water. Ophthalmology and otolaryngology consultations should be considered for eye and ear involvement.[4]

Collodion baby refers not to a specific disease but rather to an initial phenotype seen in several forms of ichthyosis

TABLE 92.2 Most Common Nonsyndromic Inherited Ichthyoses

Disorder	Newborn Cutaneous Features	Extracutaneous Features
Common Ichthyoses		
Ichthyosis vulgaris	Onset usually after 2–6 months of age	Association with atopy
Recessive X-linked ichthyosis	May have mild scaling and/or erythroderma or mild collodion membrane	Cryptorchidism (5%–20%); corneal opacities (~50%); prolonged labor; contiguous gene syndromes
Autosomal Recessive Congenital Ichthyosis, Major Subtypes		
Lamellar Ichthyosis	Collodion membrane; ectropion; eclabium	With or without short stature
Congenital ichthyosiform erythroderma	Mild scaling and erythroderma or mild collodion membrane	With or without short stature; failure to thrive
Harlequin ichthyosis	Severe collodion membrane with armor-like scales; ectropion; eclabium; contractures	Contractures; failure to thrive; short stature
Keratinopathic Ichthyosis, Major Subtype		
Epidermolytic ichthyosis	Erythroderma, bullae, or erosions, mild scaling	With or without growth failure

(Table 92.4). Ichthyosis prematurity syndrome, Netherton syndrome (NS), and Sjögren–Larsson syndrome must also be considered in the differential diagnosis. The collodion membrane is typically shed in 3 to 4 weeks, and the eventual phenotype depends on the underlying genetic mutation. More than half of collodion babies have autosomal recessive congenital ichthyosis (ARCI), discussed in more detail below. About 10% have almost normal skin after the collodion membrane sheds, which has been referred to as *self-healing collodion baby*. It is difficult to predict the long-term prognosis during the neonatal period. The diagnostic work-up should include a detailed family history and consideration of microscopic examination of scalp and eyebrow hair to look for tiger-tail banding seen on polarized microscopy in trichothiodystrophy (TTD). The role of skin biopsy before the collodion membrane has shed is controversial, and the underlying diagnosis may become evident with time, which will help determine appropriate genetic testing or the need for biochemical or metabolic assays.

TABLE 92.3 Most Common Syndromic Inherited Ichthyoses

Disorder	Newborn Cutaneous Features	Extracutaneous Features
Prominent Hair Abnormalities		
Netherton syndrome	Erythroderma, scaling	Atopic diathesis with elevated IgE concentration and eosinophilia; failure to thrive
Ichthyosis–hypotrichosis–sclerosing cholangitis syndrome[a]	Mild scaling; jaundice	Sclerosing cholangitis or congenital paucity of bile ducts
Trichothiodystrophy[b]	Collodion membrane or erythroderma and scaling	Developmental delay; short stature; cataracts; facial dysmorphism; bone abnormalities; gonadal abnormalities; recurrent infections
Ichthyosis follicularis–atrichia–photophobia	Mild collodion membrane; congenital atrichia (alopecia)	Severe photophobia (vascularizing keratitis); developmental delay; short stature; atopic diathesis; other
Prominent Neurologic Abnormalities		
Sjögren–Larsson syndrome	Scaling accentuated on scalp and neck, with or without erythema	Spastic paraplegia; mental retardation; ocular findings (retinal glistening white dots)
Mental retardation–enteropathy–deafness–neuropathy–ichthyosis–keratoderma syndrome	EKV-like features, may present at birth or within the first few weeks of life	Congenital sensorineural deafness; peripheral neuropathy; developmental and growth delay; chronic diarrhea
Refsum disease	Usually normal	Tetrad of retinitis pigmentosa, peripheral neuropathy, cerebellar ataxia, and elevated protein levels in the cerebrospinal fluid; anosmia; progressive deafness; other
Prominent Skeletal Abnormalities		
Conradi-Hünermann-Happle syndrome (CDPX2)	Severe scaly erythroderma or collodion membrane	Chondrodysplasia punctata with asymmetric skeletal hypoplasia; cataracts; short stature
Congenital hemidysplasia–ichthyosiform erythroderma or nevus-limb defects[c]	Persistent cutaneous findings may present at birth or within the first few months	Ipsilateral skeletal hypoplasia (x-ray may show punctate epiphyseal dysplasia); with or without renal, cardiac, or CNS anomalies
Fatal Disease Course		
Gaucher syndrome type 2	Mild collodion membrane or CIE-like features	Hydrops fetalis; progressive neurologic deterioration; hepatosplenomegaly
Multiple sulfatase deficiency	RXLI-like (may have mild scaling and/or erythroderma or mild collodion membrane) or presents later	Metachromatic leukodystrophy and mucopolysaccharidosis with progressive neurologic deterioration
Cerebral dysgenesis-neuropathy-ichthyosis-keratoderma	Normal at birth, presents between 5 and 11 months of age	Sensorineural deafness; cerebral dysgenesis; neuropathy; microcephaly; neurogenic muscle atrophy; optic nerve atrophy; cachexia
Arthrogryposis–renal dysfunction–cholestasis syndrome	Scaling within a few days of birth or mild collodion membrane	Arthrogryposis; intrahepatic bile duct hypoplasia with cholestasis; renal tubular degeneration with metabolic acidosis; cerebral malformation; abnormal platelets
Other Abnormalities		
Keratitis–ichthyosis–deafness syndrome	Erythematous, thickened skin; with or without congenital alopecia	Congenital sensorineural deafness; progressive keratitis with photophobia
Neutral lipid storage disease with ichthyosis[c]	Mild collodion membrane or CIE-like or EKV-like features	Vacuolated granulocytes (Jordan anomaly); hepatosplenomegaly; myopathy; cataracts; hearing loss; developmental delay
Ichthyosis prematurity syndrome	Thick, desquamating scale (vernix caseosa-like) with accentuation on scalp and eyebrows	Polyhydramnios with opaque amniotic fluid (from shedding epidermis); respiratory distress at birth; asthma; eosinophilia

[a]Also known as neonatal ichthyosis sclerosing cholangitis syndrome.
[b]Also known as ichthyosis–brittle hair–impaired intelligence–decreased fertility–short stature syndrome; there are forms of trichothiodystrophy not associated with congenital ichthyosis.
[c]Also known as Chanarin-Dorfman syndrome.
CDPX2, Chondrodysplasia punctate (X-linked dominant) type 2; *CIE*, congenital ichthyosiform erythroderma; *CNS*, central nervous system; *EKV*, erythrokeratodermia variabilis; *HPV*, human papillomavirus; *RXLI*, recessive X-linked ichthyosis.

• **Fig. 92.3** Three-week-old male with generalized large scales characteristic of lamellar ichthyosis after shedding of collodion membrane.

TABLE 92.4 Disorders That May Present as a Collodion Baby

Nonsyndromic ichthyoses	Autosomal recessive congenital ichthyosis: lamellar ichthyosis and congenital ichthyosiform erythroderma phenotypes
	Ichthyosis vulgaris
	X-linked recessive ichthyosis epidermolytic ichthyosis
	Bathing suit ichthyosis
	Self-healing collodion baby
	Keratosis linearis with ichthyosis congenital and sclerosing
	Loricrin keratoderma
Syndromic ichthyoses	Ichthyosis follicularis–atrichia–photophobia syndrome
	Neutral lipid storage disease with ichthyosis
	Trichothiodystrophy with ichthyosis
	Conradi-Hünermann-Happle syndrome
	Keratitis-ichthyosis-deafness syndrome
	Loricrin keratoderma
	Arthrogryposis-renal dysfunction-cholestasis syndrome
Metabolic diseases	Holocarboxylase synthetase deficiency
	Gaucher disease type 2
Other diseases	Hypohidrotic ectodermal dysplasia
	Congenital hypothyroidism
	Koraxitrachitic syndrome
	Palmoplantar keratoderma with anogenital leukokeratosis

Autosomal Recessive Congenital Ichthyosis: Harlequin Ichthyosis, Lamellar Ichthyosis, and Nonbullous Congenital Ichthyosiform Erythroderma

ARCI encompasses a spectrum of nonsyndromic autosomal recessive ichthyoses that includes phenotypes ranging from lamellar ichthyosis (LI) to nonbullous congenital ichthyosiform erythroderma (CIE) to harlequin ichthyosis (HI). ARCI is caused by mutations in more than a dozen different genes.[5]

• **Fig. 92.4** Newborn with harlequin ichthyosis born with thick, fissured, platelike scales, severe ectropion and eclabium, and hypoplastic nose and ears.

The classic LI phenotype is characterized by coarse, yellow to brown-black, platelike scales (Fig. 92.3) with varying degrees of underlying erythema, ectropion, and eclabium. Many patients with LI are born with a full or partial collodion membrane, discussed earlier. The classic CIE phenotype is characterized by more prominent erythroderma and finer, white scales that may not be apparent until the collodion membrane sheds. Neonates with CIE often have a less severe collodion membrane or may be born without a membrane.[2] The principles of neonatal management for these phenotypes are the same as those discussed earlier for a collodion baby.

HI is the most severe clinical phenotype of ichthyosis in a newborn and is rarely diagnosed by prenatal ultrasound. These neonates are born with an "armor" of thick, fissured, platelike scales (Fig. 92.4). They have severe ectropion and eclabium and flattened, hypoplastic nose and ears. Constricting bands lead to contractures and digital ischemia. They are at high risk of the complications discussed earlier for collodion babies but have a higher rate of infant mortality. Historically, almost 50% of babies with HI have died in the neonatal period, more than half in the

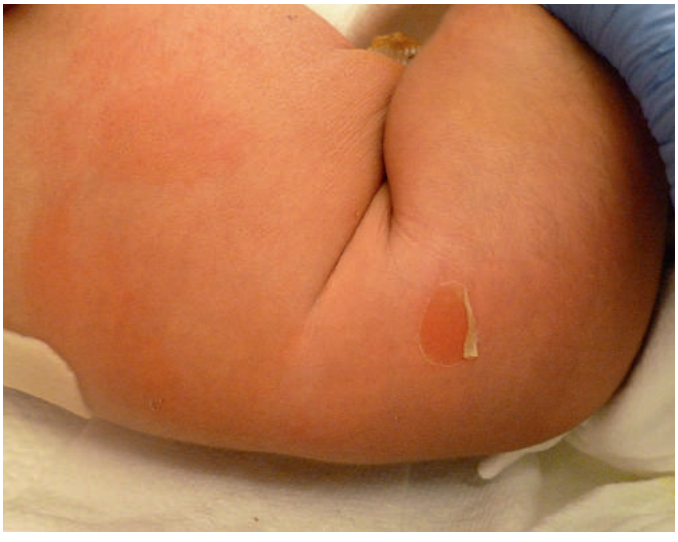
first 3 days of life. The cause of death is most commonly attributed to sepsis and/or respiratory failure.[6] Intensive, multidisciplinary, supportive care is critical for neonates with HI, with detailed recommendations for neonatal care available.[7] Early initiation of therapy with a systemically acting retinoid (such as isotretinoin, 0.5 to 1 mg/kg per day, or acitretin, 0.5 mg/kg per day) before day of life 7 may improve the survival rate. Patients who survive infancy have a lifelong ichthyosis that resembles CIE.

Epidermolytic Ichthyosis

The term *keratinopathic ichthyoses* encompass ichthyoses that are a result of keratin mutations, most of which are autosomal dominant. Epidermolytic ichthyosis (EI), previously referred to as *epidermolytic hyperkeratosis* or *bullous CIE*, is the most common and presents with generalized erythroderma and bullae. The term *epidermolytic hyperkeratosis* describes the histopathologic or ultrastructural features seen on skin biopsy characterized by marked hyperkeratosis (thickened stratum corneum) with clumping and lysis (disintegration) of the epidermal cells above the basal layer.[8] Newborns with EI typically present with widespread erythema and superficial blistering, as a result of the fragility of the epidermis from abnormal keratin production (Fig. 92.5). These neonates may receive a misdiagnosis of epidermolysis bullosa (EB) or staphylococcal scalded skin syndrome. Subtle skin thickening over the elbows, knees, palms, or soles may be diagnostic clues. During the first few months of life, the phenotype gradually evolves into more pronounced skin thickening with verruciform, ridged scales, accentuated in areas of friction, including flexural and intertriginous areas. Malodorous bacterial colonization is common.

Treatment of neonates with EI requires supportive care with attention to gentle handling to minimize blister formation, including use of nonadherent dressings. They are at risk of temperature instability, dehydration, and electrolyte instability and should be closely monitored for bacterial infections.

EI is caused by autosomal dominant mutations in *KRT1* or *KRT10*, either inherited or caused by a spontaneous mutation. It is also possible that the parent of a child with EI may have a congenital epidermolytic epidermal nevus caused by a somatic mosaic keratin mutation in *KRT1* or *KRT10*. Gonadal involvement of the keratin mutation, more common in those with widespread epidermal nevi, results in an offspring affected by generalized EI.[9]



• **Fig. 92.5** Newborn with epidermolytic ichthyosis who exhibited widespread erythema and superficial blisters.

Diagnosis of Ichthyoses

Cutaneous and extracutaneous clinical features are critical in narrowing down the differential diagnosis for a neonate born with scaly or hyperkeratotic skin and can sometimes be sufficient for diagnosis. Family history may be helpful, particularly for ichthyoses with a dominant inheritance pattern.[3] The gold standard for diagnosis is genetic mutation analysis.

Histopathologic findings from a skin biopsy in many patients with ichthyosis are nonspecific, with a few exceptions. EI has characteristic histologic findings of "epidermolytic hyperkeratosis" discussed earlier. Biopsy specimens from an individual with ichthyosis vulgaris, NS, TTD, Refsum syndrome, or Conradi-Hünermann-Happle syndrome (chondrodysplasia punctate X-linked dominant type 2) may show reduced or absent stratum granulosum. Histopathology of loricrin keratoderma is notable for parakeratosis and hypergranulosis.[2] Special immunohistochemical stains or ultrastructural analysis by electron microscopy may be considered in certain cases.

Examination of hair shafts can be helpful for diagnosing NS and TTD. Trichorrhexis invaginata ("bamboo hair" or "ball-and-socket" deformity) is characteristic of NS but is not usually present until after 1 year of age and even then is invariably present. The hair of patients with TTD may show trichoschisis (clean transverse fracture) or trichorrhexis nodosa (nodes from longitudinal splitting of fibers) on light microscopy and characteristic tiger-tail banding on polarized microscopy from low sulfur content.

Further work-up for syndromic ichthyoses is typically based on extracutaneous findings.

Prognosis and Treatment of Ichthyoses

Distinguishing the type of ichthyosis is crucial for offering prognostic information to the family, as prognosis is highly variable. Neonatal care for severe phenotypes, including collodion baby, LI, HI, and EI, was discussed earlier. For all types of ichthyosis, skin care typically involves application of bland emollients to hydrate the stratum corneum.[3] Emollients with keratolytics such as urea, salicylic acid, α-hydroxy acids, and propylene glycol are usually avoided in infancy because of risk of toxicity from absorption. Oral retinoids are primarily considered for patients with HI or rarely in those with severe collodion membrane with delayed shedding.

Epidermolysis Bullosa

Epidermolysis bullosa (EB) encompasses a group of mechanobullous disorders characterized by skin fragility and blister formation. The clinical spectrum is broad, but in the neonatal period most patients have vesicles, bullae, or erosions. Most forms of EB are caused by genetic mutations that result in absent or reduced levels of adhesion proteins normally present at the interface of the epidermis and dermis, which is called the *basement membrane zone* (BMZ). As a result, the epidermis separates from the dermis with less friction or force than usual, resulting in blister formation. In some EB subtypes, the epithelia of the external eye, ear, nose, upper airway, and gastrointestinal and genitourinary tracts are involved. The nature of the mutated protein and the severity of the mutation typically determine the phenotype: whether blistering is

localized or generalized and the extent of extracutaneous involvement. As a general rule, less severe forms of EB tend to be more common and autosomal dominantly inherited, whereas more severe forms are rarer with autosomal recessive inheritance.[10,11]

Classification of Epidermolysis Bullosa

EB classification and nomenclature have evolved over many years and were most recently updated at a 2013 international consensus meeting,[12] although additional subtypes and genes have been identified since.[13] EB is classified into three major types: EB simplex, junctional EB, dystrophic EB, and Kindler syndrome. EB type is determined by the level of the skin at which mechanical fragility and blister formation occur. EB simplex is the most superficial form, with the level of skin cleavage occurring in the epidermis, usually in basal keratinocytes. In junctional EB, blisters form deeper, within the midportion (lamina lucida) of the skin's BMZ. Skin cleavage in dystrophic EB occurs just below the BMZ in the most superficial layer of the dermis (the sublamina densa). In Kindler syndrome, which is very rare, fragility and blister formation are seen at multiple depths within the skin. EB is further subdivided into more than 39 subtypes on the basis of clinical presentation, ultrastructural features, immunohistochemical findings, and the presence of specific genetic mutations.[12] Only the more common or more notable subtypes are discussed in this chapter (Tables 92.5–92.7).

TABLE 92.5 Subtypes of Epidermolysis Bullosa Simplex

Subtype and Previous Eponym	Clinical Features
EBS, generalized severe (EBS, Dowling–Meara)	*Presentation*: birth *Bullae*: herpetiform, generalized *Mucosal involvement*: present or absent *Nails*: dystrophic *Prognosis*: progressive PPK, blistering abates with age
EBS, generalized intermediate (EBS, Koebner)	*Presentation*: birth to early infancy *Bullae*: pressure points *Mucosal involvement*: during infancy *Extracutaneous*: cardiomyopathy (KLHL24) *Nails*: may be lost, but regrow *Prognosis*: abates with age
EBS, localized (EBS, Weber–Cockayne)	*Presentation*: early childhood *Bullae*: acral *Mucosal involvement*: mild to none *Extracutaneous*: nephropathy (CD151) *Prognosis*: abates with age
EBS, intermediate with muscular dystrophy	*Presentation*: newborn–neonatal period *Mucosal involvement*: present *Extracutaneous*: congenital or delayed-onset muscular dystrophy; tooth enamel hypoplasia Prognosis: early death
EBS, severe with pyloric atresia	*Presentation*: birth *Bullae*: generalized *Extracutaneous*: pyloric atresia, GU anomalies *Prognosis*: neonatal death

EBS, Epidermolysis bullosa simplex; *GU*, genitourinary; *PPK*, palmoplantar keratoderma.

TABLE 92.6 Subtypes of Junctional Epidermolysis Bullosa

Subtype and Previous Eponym	Clinical Features
JEB, generalized severe (JEB, Herlitz)	*Presentation*: birth *Bullae*: widespread with nonhealing granulation tissue *Nails*: dystrophic or absent *Extracutaneous*: airway (25%), GI tract, GU systems, eyes, teeth *Prognosis*: death by 2 years of age because of sepsis, failure to thrive, or airway compromise
JEB, generalized intermediate (JEB, non-Herlitz)	*Presentation*: birth *Nails, hair, teeth*: commonly involved *Prognosis*: neonatal death to normal life span
JEB with pyloric atresia	*Presentation*: birth *Bullae*: severe, generalized *Extracutaneous*: pyloric atresia, GU anomalies *Prognosis*: neonatal death

GI, Gastrointestinal; *GU*, genitourinary; *JEB*, junctional epidermolysis bullosa.

TABLE 92.7 Dystrophic Epidermolysis Bullosa

Subtype and Previous Eponym	Clinical Features
RDEB, generalized severe (RDEB, Hallopeau-Siemens)	*Presentation*: birth *Blistering*: widespread, involving skin and mucosa *Nails*: dystrophic or absent *Extracutaneous*: ocular, GI tract, GU system, kidneys, heart *Sequelae*: mutilating scarring, pseudosyndactyly of digits, aggressive SCC *Prognosis*: poor, death most commonly caused by metastatic SCC
RDEB, generalized intermediate (RDEB, non-Hallopeau-Siemens)	*Presentation*: birth *Blistering*: widespread but less severe involvement of skin and mucosa *Nails*: dystrophic or absent *Extracutaneous*: variable to absent *Sequelae*: variable pseudosyndactyly, SCC *Prognosis*: lifelong blistering, risk of early death
DDEB, generalized (DDEB, Cockayne-Touraine, and Pasini)	*Presentation*: birth *Blistering*: most pronounced on hands, feet, knees, and elbows *Nails*: dystrophic or absent *Extracutaneous*: variable GI tract involvement *Prognosis*: lifelong blistering but normal life span
Bullous dermolysis of the newborn	*Presentation*: birth *Blistering*: generalized or localized; spontaneous or induced by trauma *Prognosis*: spontaneous resolution in first year of life

DDEB, Dominant dystrophic epidermolysis bullosa; *GI* gastrointestinal; *GU*, genitourinary; *RDEB*, recessive dystrophic epidermolysis bullosa; *SCC*, squamous cell carcinoma.

Epidermolysis Bullosa Simplex

EB simplex most commonly results from genetic mutations affecting keratins 5 and 14 in the basal layer of the epidermis (see Table 92.5). Blisters typically heal without scarring. Most patients with EB simplex have autosomal dominantly inherited forms and a normal life span. However, some of the recessive forms, including those associated with muscular dystrophy and pyloric atresia, carry a poor prognosis and are associated with early death.[11] Patients with generalized subtypes of EB simplex (intermediate and severe types) present with blistering in the newborn period. Severe generalized EB simplex is characterized by extensive blistering in herpetiform (herpes-like) or arcuate clusters. Mucosal involvement may be seen, nail dystrophy is common, and progressive palmoplantar keratoderma is characteristic. In the intermediate subtype of generalized EB simplex, bullae are most common over pressure points such as the elbows, knees, legs, feet, and hands and may be widespread following the trauma of birth. Mucosal involvement may occur during the newborn period but reduces with age. Nails may be lost but regrow. Localized EB simplex is the most common form of EB. Patients with localized EB simplex are usually asymptomatic during the newborn period, with onset of acral blisters in early childhood.

Junctional Epidermolysis Bullosa

Junctional EB is caused by gene mutations that affect expression of proteins integral to the lamina lucida of the BMZ. All known subtypes of junctional EB are autosomal recessive, and clinical severity is highly variable (see Table 92.6). Tooth enamel hypoplasia is characteristic. Generalized severe junctional EB, previously known as *Herlitz subtype*, is the most severe form and carries the highest risk of early death of all forms of EB.[14] Patients present at birth with widespread mucosal and skin blistering, most pronounced over pressure points (Fig. 92.6). Nails are dystrophic or absent. Exuberant granulation tissue often develops periorally and on the upper back. Airway involvement is typical, and the eyes and gastrointestinal and genitourinary systems are also commonly affected. Prognosis is extremely poor. Most patients die during the first 2 years of life secondary to failure to thrive, sepsis, or respiratory failure.[11] The presentation of the generalized intermediate subtype of junctional EB is variable and less severe than that of the generalized form. Localized subtypes are also seen.

Dystrophic Epidermolysis Bullosa

The dystrophic subtypes of EB are all caused by mutations affecting the expression of collagen VII, which forms the anchoring fibrils, critical for adhesion of the basement membrane to the upper dermis. Blistering occurs just below the BMZ, resulting in significant scarring and milia formation (Fig. 92.7). Dystrophic EB can be categorized into autosomal dominant and recessive variants. In general, recessively inherited forms are associated with absence of collagen VII and are more severe than dominant forms, in which collagen VII expression is decreased or abnormal (see Table 92.7).

The generalized severe recessive variant is the most severe subtype of dystrophic EB. Patients present at birth with generalized blistering of the skin and mucosa. Involvement of multiple organ systems, including the eyes, gastrointestinal tract, kidneys, genitourinary tract, and the heart, can be seen. Scarring of the hands and feet can lead to functionally limiting pseudosyndactyly and bone deformation. Anemia and failure to thrive are characteristic.[15] Aggressive squamous cell carcinomas arising in chronic wounds are the most common cause of death in patients with recessive dystrophic EB and develop as early as the teenage years.[14]

In patients with dominantly inherited forms of dystrophic EB, blistering is typically induced by trauma and limited to the hands, feet, elbows, and knees. Scarring and milia formation occur but do not typically cause functional impairment. Nail dystrophy or loss is common and may be the only manifestation of disease. Life expectancy is usually normal.[11] There is a subtype of dystrophic EB called *bullous dermolysis of the newborn* where skin fragility is usually transient and spontaneously resolves within the first year of life.[16] These patients are often born with absent skin (aplasia cutis), especially on the lower extremities (Fig. 92.8).

Diagnosis of Epidermolysis Bullosa

The differential diagnosis for skin blisters or erosions in the neonate is broad but should include EB. Traumatic and infectious causes of blistering should be ruled out. A thorough history, including family history of blistering disorders, should be obtained. Physical examination findings are an unreliable indicator of EB type during the neonatal period, and discussion of long-term prognosis should be deferred until the subtype of EB is determined through testing.[13]

• **Fig. 92.6** Newborn with junctional epidermolysis bullosa who exhibited bullae in the diaper area and other areas of friction.

• **Fig. 92.7** Four-month-old with dystrophic epidermolysis bullosa characterized by bullae, erosions, and milia.

• **Fig. 92.8** Bullous dermolysis of the newborn with absent skin on legs and feet.

Diagnosis of EB type is not straightforward and has traditionally entailed specialized examination of a skin biopsy specimen, which remains essential in many cases. As the accuracy of genetic testing has increased and the cost decreased, current standard of care also includes mutational analysis of DNA obtained from peripheral blood.[17] A list of laboratories that provide testing for EB can be found at http://www.ncbi.nlm.nih.gov/gtr/tests/. In families with a known history of EB, methods of prenatal or preimplantation diagnosis can be considered.

Skin biopsy in a patient with suspected or known EB should be performed at the junction of a fresh blister and normal skin. Ideally, a blister is induced by the rubbing of a pencil eraser against the skin until erythema develops. The level of blister formation (i.e., intraepidermal, lamina lucida, or superficial dermis) can be determined by transmission electron microscopy (TEM) or immunofluorescence antigen mapping (IFM) of newly induced blisters. TEM allows detailed visualization of the epidermal–dermal junction to determine whether blister formation occurs superficial to, within, or deep to the BMZ. IFM uses monoclonal antibodies directed against proteins in the BMZ to help determine the level of split and in some cases will show decreased or absent expression of certain proteins mutated in EB. For optimal accuracy, both should be performed by a laboratory experienced in performing these studies on patients with EB.[17] It is important to note that EB type cannot be determined through routine light microscopy of hematoxylin- and eosin-stained sections.

Management of Epidermolysis Bullosa

Novel and highly effective treatments for EB, including gene replacement therapy and injection of genetically corrected fibroblasts, have shown success in a very small number of patients. The status of ongoing trials can be found at https://clinicaltrials.gov/.[18] For the time being, supportive measures remain the mainstay of therapy. A multidisciplinary approach is important, involving specialists in fields such as dermatology, surgery, gastroenterology, otolaryngology, dentistry, hematology/oncology, wound care, pain management, occupational and physical therapy, nutrition, and psychology.[15,19] EB patients who die in infancy and early childhood most often succumb to sepsis, followed by failure to thrive or respiratory failure. Those with severe subtypes of junctional EB are at markedly higher risk of early death,[14] and in some patients it may be appropriate to emphasize comfort measures over aggressive treatments that prolong life.[20]

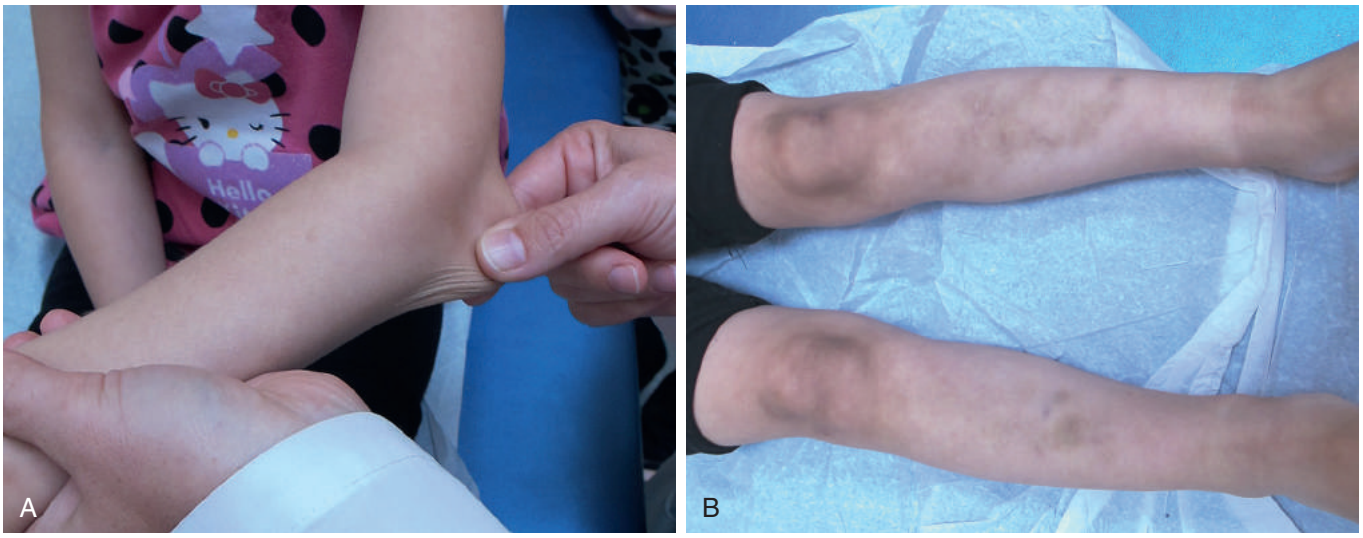
In the neonatal period, prevention of new blisters and prevention of infection are of the utmost importance. Gentle handling and avoiding of frictional trauma should be emphasized. Infants should be rolled or moved with a sheet when possible to avoid friction. When lifting is necessary, one hand should gently support the head and neck, with the other under the buttocks. Ambient temperature should be cool, and routine use of incubators should be avoided, as heat may increase skin fragility. Bedding should be soft, and silicone dressings or padding should be applied to bony prominences and inside diapers. Intact bullae should be gently ruptured and drained with a sterile needle, leaving the roof intact as a biologic dressing. Wounds should be covered with nonadhesive dressings, and these should be changed daily or every other day. Tape and adhesives should never be applied to the skin. Nonadhesive wound dressings can be placed under pulse oximeter probes and electrocardiogram leads. Prevention of infection often involves use of chlorhexidine, dilute bleach, and/or dilute vinegar baths. Topical antibiotics should be used sparingly to avoid resistance. Pain control is essential.[19]

Aggressive nutritional support is essential, especially in patients with feeding difficulties caused by significant mucosal involvement, or pyloric atresia, or those with increased fluid and energy requirements because of widespread blisterings.[19] Soft nipples used for feeding infants with cleft palates should be used in those with oral involvement. EB patients are prone to cutaneous infection, most commonly with *Staphylococcus*, which may disseminate. Indwelling catheters and overuse of topical antibiotics such as mupirocin should be avoided when possible.[10] Tracheostomy may be indicated in patients with airway involvement.[15,20] Surgical repair of pyloric atresia enhances survival in affected patients, particularly those with relatively mild skin involvement.[15] Patients with severe disease should also be monitored for iron-deficiency anemia.

Ehlers–Danlos Syndrome

The Ehlers-Danlos syndromes (EDS) are a heterogeneous group of inherited connective tissue disorders characterized by with variable manifestations of cutaneous hyperextensibility, joint hypermobility, and tissue fragility. The 1997 Villefranche Nosology described six types of EDS. The most recent consensus classification from 2017 describes 13 distinct clinical subtypes with diverse genetic etiology.[21] Premature rupture of membranes is more common in infants with EDS or in pregnancies of affected mothers and may be the presenting sign of the condition.

Classical EDS (cEDS) is the most common subtype and is usually caused by autosomal dominant mutations in the COL5A1 gene, which codes for type V collagen. The skin of affected patients is soft, velvety, doughy and hyperextensible. Importantly, it readily recoils to the normal position after being stretched (in contrast to cutis laxa, discussed later) (Fig. 92.9A). The skin is also fragile with a tendency to form widened, atrophic scars often referred to as *fish-mouth* or *cigarette-paper scars*. Vessel fragility leads to easy bruising (Fig. 92.9B). Hematomas can become fibrotic and may result in soft subcutaneous nodules referred to as *pseudotumors* or hard calcified nodules referred to as *spheroids*. cEDS is also characterized by joint hypermobility and resulting complications.[22] Patients with the autosomal recessive cardiac-valvular form of



• **Fig. 92.9** Three-year-old girl with classic Ehlers-Danlos syndrome characterized by hyperextensible skin (A) and easy bruising (B).

EDS (cvEDS) present with similar skin findings but are also at high risk for severe progressive cardiac-valvular dysfunction.

Vascular EDS (vEDS) is caused by autosomal dominant mutations in the COL3A1 and COL1A1 genes, which code for type III and type I collagen respectively. vEDS carries risk of life-threatening arterial or organ rupture. Cutaneous findings include thin, translucent skin and extensive bruising but not skin hyperextensibility. Patients with more rare and severe forms of EDS may come to attention at birth with multiple anomalies, including severe joint hypermobility resulting in multiple dislocations and subluxations (arthrochalasia EDS), congenital hypotonia with kyphoscoliosis (kyphoscoliotic EDS), ocular abnormalities (brittle cornea syndrome), hypotonia with short stature and bowing of limbs (spondylodysplastic EDS), and congenital contractures (musculocontractural and myopathic EDS).

Dermatosparaxis EDS is a very rare but severe autosomal recessive phenotype which is notable for extremely fragile, lax skin, which may present with tears at birth or with minimal trauma, as well as severe bruisability with risk of subcutaneous hematomas and hemorrhage.[21] It is important to note that infants with EDS have not been shown to be of increased risk for fractures, including those with hypermobile EDS, which does not have a clear genetic basis. This finding should raise suspicion for child abuse in a nonambulatory patient.[23]

Cutis Laxa

The skin of patients with cutis laxa is characterized by loose, redundant, hypoelastic skin that does not recoil after stretching (in contrast with the skin in EDS patients which does recoil and does not form redundant folds). Cutis laxa can be congenital (inherited) or acquired. Mutations in at least 13 different genes which code for proteins involved in dermal elastic fiber production have been reported to cause variants of cutis laxa. The autosomal dominant form is caused by mutations in the *ELN* gene, which encodes elastin. Clinical presentation is highly variable. Cutaneous findings and dysmorphic facial features may be evident at birth. Elastic fibers in extracutaneous sites are often affected, which may result in life-threatening complications, including arterial tortuosity and aneurysms, genitourinary and gastrointestinal diverticulae.[24]

The X-linked form of cutis laxa, once classified as a type of EDS, is also referred to as *occipital horn syndrome*. This disorder is caused by mutations in the *ATP7A* gene leading to impaired copper metabolism and is allelic with Menkes disease. Cutaneous manifestations of these allelic conditions may include soft, doughy skin and hypopigmented, fragile, kinky hair (pili torti).

Ectodermal Dysplasias

The ectodermal dysplasias comprise a heterogeneous group of more than 200 inherited conditions affecting development and/or homeostasis of two or more ectodermal derivatives, including at least one of the following appendages: hair, teeth, nails, and certain glands.[25] Other structures derived from embryonic ectoderm include the central and peripheral nervous systems, mucosal epithelium mammary glands, external ear, melanocytes, and multiple ocular structures. The most recent consensus classification system developed in 2017 groups these conditions based on genotype, molecular pathway and phenotype.[25] Most implicated genes function in one of the following molecular pathways essential to ectodermal development: nuclear factor kappa-B (*NFκB*), *WNT*, and *TP63*.

Characteristic dysmorphic features and hypotrichosis are often the earliest recognized signs of ectodermal dysplasia. Temperature dysregulation is a common complication of hypohidrosis (reduced sweating) and may lead to recurrent fevers of unknown origin. The clinical features of the ectodermal dysplasias are diverse. The most common or notable forms are discussed below and summarized in Table 92.8.

Management of ectodermal dysplasias hinges on establishing the diagnosis, referral to appropriate specialists on the basis of symptoms and known associations, and supportive measures. Early involvement of a geneticist is important, and ideally molecular confirmation of the diagnosis is obtained. For children with hypohidrotic forms of ectodermal dysplasia, avoidance of overheating is paramount. Eye drops and nasal irrigation should be used to lubricate the ocular and respiratory mucosa. Dental assessment should be performed early in life as intervention may be initiated before age 2 years.[26]

TABLE 92.8 Notable Ectodermal Dysplasias[25]

Syndrome	Clinical Features
Hypohidrotic ectodermal dysplasias	Mostly males Hypohidrosis Hypotrichosis Hypodontia Periorbital hyperpigmentation and dermatitis Craniofacial dysmorphology Dry skin
Incontinentia pigmenti	Mostly females Short stature Staged skin involvement Cataracts, microphthalmia Hypodontia Breast aplasia Nail dystrophy Abnormal hair
Ectodermal dysplasia and immunodeficiency 1 (EDAID1)	Mostly males Hypotrichosis Hypohidrosis Immunodeficiency, recurrent infection
Focal dermal hypoplasia (Goltz syndrome)	Mostly females Short stature Facial asymmetry Skin atrophy Narrow auditory canals, hearing loss Hypodontia, oral papillomas Syndactyly Sparse hair
Rapp-Hodgkin syndrome	Short stature Maxillary hypoplasia, cleft lip/palate, hypodontia Hearing loss
Ankyloblepharon-ectodermal defects-cleft lip/palate–clefting (AEC, Hay–Wells syndrome)	Scalp erosions, hypotrichosis Conductive heating loss Maxillary hypoplasia, cleft lip/palate, hypodontia Ankyloblepharon, lacrimal duct atresia
Ectrodactyly, ectodermal dysplasia, and cleft lip/palate syndrome 3 (EEC3)	Blepharophimosis Cleft lip/palate, hypodontia, microdontia Syndactyly, dystrophic nails Hypotrichosis
Clouston syndrome	Nails: dystrophic Hair: normal at birth; becomes sparse, brittle Teeth prone to caries Ocular abnormalities Hyperkeratosis of palms, soles, knees, elbows, knuckles French-Canadian families

Hypohidrotic Ectodermal Dysplasia

HED is the most common type of ectodermal dysplasia and most often results from an X-linked recessive mutation of the ectodysplasin A gene (*EDA*). The classic triad of associated clinical features is hypohidrosis, alopecia, and hypodontia (reduced number of teeth). In X-linked HED, males are hemizygous for the *EDA* mutation and generally display the complete triad, as well as a propensity for respiratory disorders. Most are identified within the first 2 years of life. Females are typically heterozygous for the *EDA* mutation. Their presentation may be subtle and diagnosis delayed.

Infants with X-linked HED may exhibit failure to thrive, nasal congestion, decreased saliva production, and gastroesophageal reflux. Eczema usually presents during the first year of life. Males are more likely to suffer from respiratory problems, including chronic, malodorous nasal congestion, wheezing, and recurrent sinusitis.[27]

Ectodermal Dysplasia and Immunodeficiency 1 (EDAID1) is most commonly caused by mutations in the IKBKG gene on chromosome band Xq28. Affected males present similarly to those with HED, but also with immunodeficiency and multiple infections. Female carriers of more severe mutations in this same gene have IP, as discussed later.

Ankyloblepharon-Ectodermal Defects-Cleft Lip/Palate (AEC, also known as Hay-Wells syndrome) is of particular importance to the neonatologist, as the congenital scalp erosions seen in affected patients can raise concern for neonatal infection or epidermolysis bullosa (discussed above).

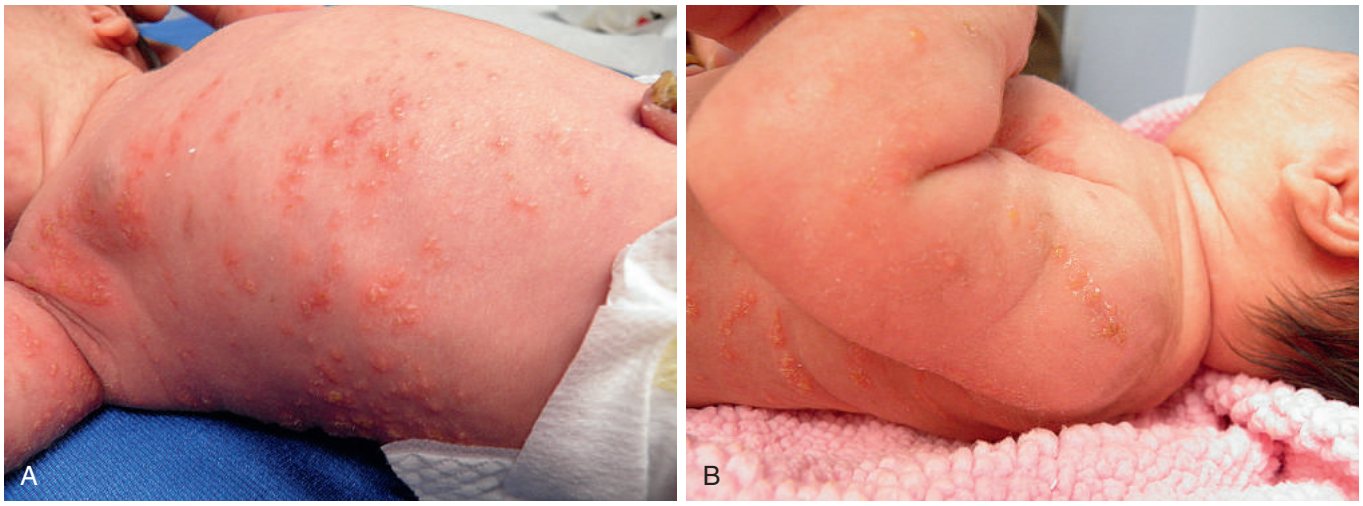
Incontinentia Pigmenti

Incontinentia pigmenti (IP), also referred to as *Bloch-Sulzberger syndrome*, is an X-linked ectodermal dysplasia that variably affects the skin, hair, nails, teeth, eyes, and central nervous system (CNS). The disorder is caused by mutations in the *IKBKG* gene, also called *NEMO* (which encodes nuclear factor κB essential modulator), localized to chromosome band Xq28. The vast majority of patients with IP are female, suggesting causative mutations in *IKBKG* are lethal in males, but there are rare reports of affected males with Klinefelter syndrome (XXY genotype), somatic mosaicism, or hypomorphic alleles.[28,29] Females with a missense mutation in *IKBKG* may have a son with X-linked ectodermal dysplasia with immunodeficiency, discussed above. Females with IP are functionally mosaic because of random X chromosome inactivation early in embryologic development (lyonization), which explains the variability in clinical phenotype. Cutaneous lesions of IP demonstrate mosaicism and typically follow Blaschko lines.

Cutaneous Findings

Almost all patients with IP will exhibit cutaneous features at birth or within the first few weeks of life. Four classic stages of skin lesions have been described, but not all patients will exhibit each stage, and there can be overlapping of stages. Stage 1 is characterized by erythema and vesiculobullous or pustular lesions in a linear and whorled pattern following Blaschko lines (Fig. 92.10). This stage can last from weeks to months and then resolves spontaneously but can recur even years later, often precipitated by infection. The distribution along Blaschko lines can help distinguish cutaneous lesions of IP from herpes or bacterial infection.

In stage 2 there are linear, hyperkeratotic, verrucous papules and plaques that may or may not have evolved from previous vesiculobullous lesions. The verrucous stage is usually distributed on the extremities and is most pronounced on the hands or feet.



• **Fig. 92.10** Newborn with incontinentia pigmenti who exhibited extensive vesiculobullous lesions on the trunk (A) and extremities (B), some following Blaschko lines.

These lesions often resolve by about 6 months of age but rarely persist or recur.

Stage 3 is characterized by linear and whorled brown to slate-gray hyperpigmentation along Blaschko lines and typically involves both the trunk and extremities or just the trunk. The distribution does not usually correspond to prior inflammatory or verrucous lesions. This stage begins within the first few weeks to months of life and may last for years, often resolving spontaneously by adolescence or adulthood.

Less than half of patients exhibit stage 4, with atrophic, hypopigmented, or hypovascular streaks lacking adnexa (hair follicles or sweat glands). These are often located on the posterior lower extremities and may be subtle and thus underreported. The atrophic lesions are persistent and may be the only cutaneous finding in adulthood.[30] Patients with IP may also have abnormal hair and nails.

Extracutaneous Findings

Ocular abnormalities (both retinal and nonretinal) are one of the most common and manifestations and the most important to identify early. Retinal vasculopathy leading to retinal ischemia and subsequent detachment is an important cause of blindness. Vasculopathy can be detected within the first days of life, and blindness prevented with laser therapy. CNS involvement typically presents within the first year of life may include seizures, motor impairment, or learning difficulties and intellectual disability. Brain MRI and EEG are recommended.[31] Dental anomalies are common and may affect both deciduous and permanent teeth. Mammary gland, and skeletal abnormalities as well as pulmonary hypertension have been reported.

Diagnosis

Major criteria for the diagnosis of IP include characteristic skin findings and mutation in the *IKBKG* gene (as well as dental anomalies). Minor diagnostic criteria include eosinophilia, hair, nail, or mammary abnormalities, peripheral neovascularization of the retina and characteristic skin histology.[31] A biopsy of cutaneous lesions in stage 1 will reveal characteristic infiltration of the epidermis by eosinophils with intraepidermal vesicles and dyskeratosis. Stage 1 may also be associated with a striking peripheral leukocytosis and eosinophilia. These findings can help differentiate vesiculobullous or pustular lesions of IP from infectious causes (such as herpes, varicella, or bullous impetigo), Langerhans cell histiocytosis, EB, autoimmune bullous diseases, bullous mastocytosis, or child abuse. Histopathology of stage 2 lesions shows papillomatosis, hyperkeratosis, and dyskeratosis; however, these same findings can be seen in epidermal nevi. Skin biopsy findings from stage 3 or stage 4 lesions are nonspecific.

Prognosis and Treatment

The cutaneous findings in IP, other than stage 4 atrophic or hypopigmented lesions, resolve spontaneously. Vesiculobullous lesions may require dressings or wound care, with monitoring for superinfection. All patients with suspected IP should have a thorough ophthalmology evaluation as soon as possible after birth. Careful neurologic examination is essential, and neuroimaging and electroencephalographic studies should be performed in patients with signs of CNS involvement. Dental evaluations should begin by age 2 years.[30]

Focal Dermal Hypoplasia (Goltz Syndrome)

Focal dermal hypoplasia (FDH), also known as *Goltz syndrome*, is a rare ectodermal dysplasia with skin, skeletal, ocular, and other manifestations caused by mutations in the *PORCN* gene. Like IP, FDH is an X-linked dominant disorder and predominantly affects females (90%), who are functional mosaics, as mutations are often lethal in males. Cutaneous lesions are usually present at birth, including linear streaks of dermal hypoplasia associated with telangiectasias or pigmentary changes that follow Blaschko lines, yellow to red-brown nodules or outpouching caused by herniation of fat through hypoplastic dermis, and ulcers caused by congenital absence of skin (aplasia cutis). Erythematous papillomas affecting the skin or mucosa may appear later. Nail hypoplasia or ridging, alopecia, and dental abnormalities are common. Skeletal manifestations include craniofacial findings and limb malformations such as ectrodactyly or syndactyly. X-ray of long bones reveals longitudinal striations of the metaphyses

(osteopathia striata). A number of developmental abnormalities of the eye have been associated with FDH. Other developmental anomalies, including congenital diaphragmatic hernia, have been described. Most individuals have normal development, but developmental delay has been reported. Treatment of affected individuals requires a multidisciplinary approach.[32,33]

Disorders With Generalized Hypopigmentation

Oculocutaneous albinism (OCA) is characterized by generalized hypopigmentation of the skin, hair, and eyes, with additional ocular abnormalities. OCAs are classified into "classic" nonsyndromic types and syndromic forms with additional systemic manifestations. There are eight identified forms of nonsyndromic OCA, each associated with a specific gene mutation.[34] The implicated gene mutations affect proteins integral to melanin production or distribution. Severity of pigment loss and ocular manifestations differ depending on the OCA type and mutation severity. For example, the most severe type of OCA, OCA type 1A, is caused by a nonsense mutation in the tyrosinase gene, resulting in complete absence of melanin production. OCA type 1B is caused by a missense mutation in the same gene, allowing various amounts of melanin production. OCA types 1 to 4 account for most cases, and their pathogenesis and clinical features are summarized in Table 92.9.[35]

Hermansky-Pudlak, Chédiak-Higashi, and Griscelli syndromes are syndromic forms of OCA. The Hermansky-Pudlak syndromes are most commonly observed in families of Puerto Rican descent. In addition to OCA, patients have abnormal platelet function and are prone to bleeding. The intestines, lungs, kidneys, and heart may also be affected. Patients with Chédiak-Higashi syndrome have impaired phagocytosis and are prone to pyogenic infections. Griscelli syndrome is associated with neurologic or immunologic abnormalities. Patients with metabolic disease may also present with generalized hypopigmentation. For example, those with Menkes disease are unable to metabolize copper and therefore lack this essential cofactor for tyrosinase activity and melanin production.[36]

Diagnosis of Oculocutaneous Albinism

In patients with severe forms of OCA the diagnosis is often clinically apparent during the neonatal period. However, presentation may be subtle in patients with some melanin production, such as those with OCA types 2 and 3 born to darker-skinned parents. Comparison of skin, hair, and eye color with that of other family members may be helpful. Genetic testing performed at specialized centers currently identifies causative mutations in approximately 80% of OCA patients.[36]

Treatment of Oculocutaneous Albinism

Treatment of OCA is geared toward addressing visual impairment and preventing sun-induced carcinogenesis. Early referral to and regular monitoring by an ophthalmologist is critical. Vigilant sun avoidance and protection, with use of sunscreen, UV-protective clothing, and eyewear, is essential. Sunscreens with physical blockers—namely, zinc oxide and titanium dioxide—are generally considered to be safest in infants and children. Clinical trials of

TABLE 92.9 Congenital Disorders With Generalized Loss of Skin Pigmentation[35,36,49]

Syndrome	Clinical Features
OCA types 1A and 1B	Most common OCA type in white Europeans Complete loss of (OCA type 1A) or significantly reduced (OCA type 1B) pigmentation: white or very light skin and hair Ocular: pink irides at birth become blue gray in adulthood, reduced visual acuity, strabismus, photophobia, nystagmus, misrouting of the optic nerves at the chiasm, foveal hypoplasia
OCA type 2 (brown OCA)	Most common OCA type in equatorial Africans Minimal to moderate skin pigmentation Hair white, golden, or red Irides translucent blue to light brown Ocular: similar to OCA type 1
OCA type 3 (rufous OCA)	Most common OCA type in southern Africans Skin red, freckled, or hypopigmented Reddish hair Light eyes Ocular: nystagmus, strabismus, positive red reflex Can be subtle: comparison with parents can aid in diagnosis
OCA type 4	Most common in Japanese descent Light skin and hair Translucent irides Ocular: mild nystagmus and photophobia, decreased visual acuity, absent macula
Hermansky-Pudlak syndrome	OCA, similar to OCA type 1 Abnormal platelets Easy bruising and bleeding Pulmonary fibrosis Cardiomyopathy Intestinal inflammation and hemorrhage Renal failure Most common in Puerto Rican descent
Chédiak-Higashi syndrome	Variable skin hypopigmentation Ocular: similar to OCA type 3 Gingivitis Hepatosplenomegaly Recurrent pyogenic infections Progressive neurologic decline
Griscelli syndrome	Partial albinism, with hypopigmented skin, silver-gray hair Visual problems Neurologic impairment Immunodeficiency, hemophagocytic syndrome
Menkes disease	"Doughy" inelastic, hypopigmented skin Hairs short, sparse, twisted (pili torti) Microcephaly, brachycephaly, pudgy cheeks Small stature Neurodegeneration: hypotonia, seizures, hypothermia Failure to thrive Impaired vision

AD, Autosomal dominant; *AR*, autosomal recessive; *OCA*, oculocutaneous albinism; *XLR*, X-linked recessive.

medications designed to enhance melanin production in patients with albinism and related disorders are currently under way.[35]

Disorders With Localized Hypopigmentation

Piebaldism

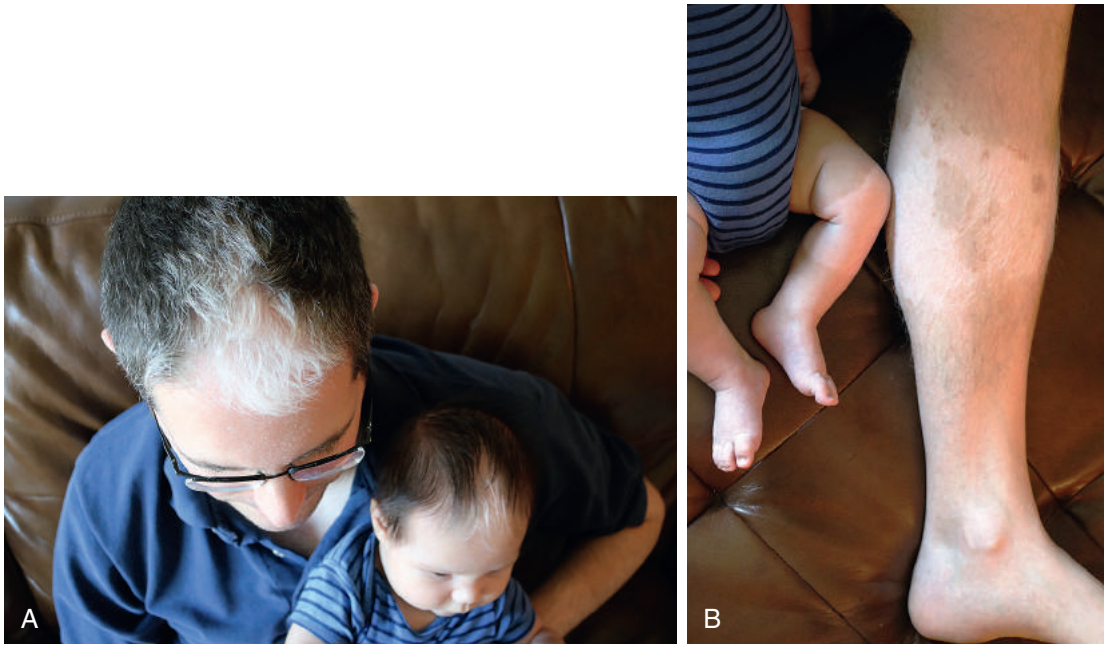
Piebaldism is an autosomal dominant disorder characterized by circumscribed areas of leukoderma (absence of skin pigment). The anterior hairline is affected in 80% to 90% of cases, resulting in a white forelock (poliosis circumscripta) (Fig. 92.11A). This is frequently the sole manifestation.[37] Well-demarcated depigmented patches with islands of normal pigmentation and hyperpigmentation are typically present at birth and remain stable through adulthood (Fig. 92.11B), although a few cases of spontaneous repigmentation have been reported.[38] Characteristically, the ventral body is more affected, particularly the central forehead, anterior trunk, arms, and legs. The dorsal midline, hands, feet, and periorificial regions are typically spared. Diagnosis is clinical and can be confirmed with molecular analysis of the *KIT* gene. Skin biopsy of depigmented areas is not necessary but when performed reveals absent or markedly reduced numbers of melanocytes. In the neonatal period, management of piebaldism hinges on vigilant photoprotection of amelanotic skin. Camouflaging makeup may be used for cosmetic purposes. Surgical and laser treatments are evolving and may be considered later in life.

The differential diagnosis for an infant with localized loss of skin or hair pigmentation includes disorders with systemic complications such as Waardenburg syndrome and tuberous sclerosis (Table 92.10) as well as nonsyndromic pigmentary anomalies. *Hypomelanosis of Ito* is a historical term used to describe linear and whorled hypopigmentation along Blaschko lines that may be an isolated cutaneous finding or associated with extracutaneous abnormalities, including neurologic or musculoskeletal conditions. Hypomelanosis of Ito is no longer considered a distinct entity but rather encompasses a group of disorders associated

TABLE 92.10 Syndromes With Congenital Localized Loss of Skin Pigmentation[37,49]

Syndrome	Clinical Features
Piebaldism	White forelock (poliosis circumscripta) Depigmented macules and patches (leukoderma) Heterochromic irides Rare: Hirschsprung disease, deafness
Waardenburg syndrome	White forelock Early graying (by age 35 years) Heterochromic, bichromic, or bright blue irises Depigmented macules or patches Congenital sensorineural deafness Bony anomalies Facies: dystopia canthorum, synophrys, broad nasal root, nose hypoplasia, smooth or shortened philtrum Hirschsprung disease (type 4)
Tuberous sclerosis	Hypomelanotic ash leaf spots, "confetti-like" hypomelanotic macules Facial angiofibromas Collagenomas/shagreen patches Forehead fibrous plaques Periungual fibromas Neurologic: cortical tubers, subependymal nodules or astrocytomas, developmental delay, seizures, infantile spasms, behavioral disorders Other: retinal achromic patch or hamartomas, renal angiomyolipomas or cysts, cardiac rhabdomyomas, lymphangioleiomyomatosis, etc.
Pigmentary mosaicism	Hypopigmented patches, whorls, or streaks along Blaschko lines Associated with various neurologic, ocular, dental, or musculoskeletal abnormalities or isolated cutaneous finding

AD, Autosomal dominant.



• **Fig. 92.11** Father and son with piebaldism manifesting itself as white forelock (A) and well-demarcated depigmented patches with islands of normal pigmentation and hyperpigmentation (B).

with various mosaic defects, and many prefer the term *pigmentary mosaicism* to describe the associated cutaneous findings. Other terms have been used to describe congenital hypopigmentation or depigmentation, including *patterned dyspigmentation, segmental pigmentation disorder*, and *nevus depigmentosus*. Congenital vitiligo has also been rarely reported. In any patient born with localized hypopigmentation or depigmentation, a thorough history, family history, and physical examination should be conducted, with further work-up directed by any abnormalities found.[39,40]

Porphyrias

The porphyrias are a group of disorders caused by mutations in enzymes involved in heme biosynthesis that result in accumulation of porphyrin or porphyrin precursors. Most porphyrias are autosomal dominant, but some are autosomal recessive, X-linked, or have more complex inheritance patterns. Cutaneous manifestations are due to the photosensitizing effects of porphyrins. Phototoxicity can be immediate with burning pain, erythema, and edema and/or delayed with blisters, dyspigmentation, and scarring. Traditionally, the porphyrias have been classified on the basis of the organ in which porphyrins or porphyrin precursors accumulate as erythropoietic (accumulation in bone marrow erythroid cells), hepatic (accumulation in liver), or mixed (i.e., hepatoerythropoietic porphyria). The porphyrias may be also categorized on the basis of primary symptoms, with "acute porphyrias" predominated by neurovisceral attacks and "cutaneous porphyrias" predominated by skin photosensitivity.[41]

The erythropoietic porphyrias (congenital erythropoietic porphyria [CEP], erythropoietic protoporphyria [EPP], X-linked EPP [XLP]) and hepatoerythropoietic porphyria (HEP) can present in early infancy with severe photosensitivity and are reviewed in the following sections. Box 92.1 lists disorders that can present with photosensitivity in infancy. Phototherapy-induced eruptions because of transient porphyrinemia may be seen in neonates with hemolytic disease of the newborn.[42,43]

The hepatic porphyrias are categorized by neurovisceral attacks, with variable cutaneous photosensitivity, and usually present later in childhood or adulthood. Exceptions include homozygous variants of hereditary coproporphyria, variegate porphyria, acute intermittent porphyria, and aminolevulinic acid dehydratase porphyria, which are exceedingly rare but can present in infancy.

Congenital Erythropoietic Porphyria

CEP, previously known as *Günther disease*, is an autosomal recessive erythropoietic cutaneous porphyria caused by mutations in the gene *UROS* encoding uroporphyrinogen III synthase. The disease is characterized by severe photosensitivity and hemolytic anemia with splenomegaly. CEP may present in utero as nonimmune hydrops fetalis. Severe photosensitivity usually begins in infancy and can sometimes present in the neonatal period with blistering after phototherapy for hyperbilirubinemia. Scarring, hyperpigmentation, hypertrichosis, and disfigurement develop in photoexposed areas over time (Fig. 92.12). There are variable ocular manifestations. Urine may be faint pink to dark red from accumulation of uroporphyrin. The teeth also develop a reddish-brown color (erythrodontia). Teeth, urine, and stool may fluoresce under Wood lamp examination.

The diagnosis of CEP can be made on the basis of elevated uroporphyrin and coproporphyrin levels in erythrocytes, urine, and stool and can be confirmed by measurement of uroporphyrinogen III synthase activity or gene mutation analysis. Historically, CEP has been managed primarily with photoprotection and long-term erythrocyte cell transfusions. More recently, CEP has been cured with hematopoietic stem cell transplant, but there are significant risks of transplant complications, and novel therapeutics are being studied.[44]

Erythropoietic Protoporphyria and X-Linked Erythropoietic Protoporphyria

EPP is the most common form of porphyria in childhood and is caused by autosomal recessive mutations in the gene *FECH* encoding ferrochelatase. XLP, also referred to as *X-linked dominant protoporphyria*, is an X-linked form that results from mutations in the *ALAS2* gene, the product of which catalyzes the first committed step of heme biosynthesis. XLP has a phenotype very similar to that of EPP but with higher concentrations of erythrocyte protoporphyrin and a higher incidence of liver disease.[45]

Clinical manifestations of EPP include immediate painful photosensitivity to sunlight and sometimes fluorescent lighting. In infancy, this may manifest itself as episodes of crying within minutes of UV exposure, and older children may complain of stinging or a burning sensation in exposed areas. Prolonged exposure may

lead to erythema, edema, and petechiae and vary rarely vesicles or bullae. Long-term UV exposure results in shallow atrophic scars and thickened, leathery skin around the mouth (pseudorhagades) and overlying knuckles.

Hepatic involvement can range from mild liver dysfunction to rare liver failure. Cholelithiasis may cause severe abdominal pain. Anemia is usually mild or absent. Diagnosis of EPP and XLP can be made on the basis of elevated erythrocyte protoporphyrin concentration, and red blood cells will fluoresce under Wood lamp examination. Increased stool protoporphyrin concentration may also be detected. The diagnosis is confirmed by genetic testing. Management in infancy includes sun avoidance and protection, with symptomatic treatment of photosensitivity reactions. Patients should be monitored for liver disease and microcytic anemia.[46] Afamelanotide is a targeted treatment option for adults with EPP.[47]

Hepatoerythropoietic Porphyria

HEP is an exceedingly rare disorder caused by homozygous or compound heterozygous mutations in the gene encoding uroporphyrinogen decarboxylase. Heterozygous mutations or sporadic mutations in the same gene result in porphyria cutanea tarda, the most common porphyria in adults. HEP usually presents with severe bullous photosensitivity before age 2 years, with subsequent hypertrichosis and scarring, resembling CEP. The diagnosis can be made on the basis of highly elevated erythrocyte zinc protoporphyrin concentration, along with elevated urine and stool porphyrin concentrations, and can be confirmed by genetic testing.[48]

Infections of the Skin

MARKUS D. BOOS AND ROBERT SIDBURY

KEY POINTS

- Owing to their cutaneous, immunologic, and renal immaturity, newborns (especially premature neonates) are at increased risk of skin infection.
- As a group of potentially life-threatening but often treatable diseases, infections must always be considered in a newborn with skin lesions.
- Prompt diagnosis and initiation of therapy are crucial to prevent devastating long-term sequelae, particularly in instances of disseminated disease.
- *Staphylococcus aureus*, *Streptococcus* species, *Candida albicans*, and herpes simplex virus are the most common causes of skin infection in the neonate.

Staphylococcus aureus Infections

Staphylococcus aureus is ubiquitous and harbored as a commensal organism in about one-third of the population, with a predilection for the nares (especially in children), perineum, and other moist cutaneous surfaces.[1] It is more likely to be present early if the child is born via cesarean delivery rather than vaginally, reflecting colonization via the bacterial microbiota of adult skin.[2] However, by 1 week of age, most newborns will exhibit nasopharyngeal or umbilical colonization by *S. aureus*.

Invasive infection of infants by *S. aureus* remains a healthcare challenge. A retrospective study of staphylococcal infections in 348 neonatal intensive care units (NICUs) demonstrated that the incidence of invasive *S. aureus* infection (defined as a positive culture result from blood, cerebrospinal fluid (CSF), sterile fluid, or an abscess) was 44.8 per 10,000 infants. Most of these infections were caused by methicillin-sensitive strains.[3] Cutaneous signs of invasive *S. aureus* infection are mediated by local or circulating bacterial toxins; *S. aureus* is therefore responsible for skin lesions of protean morphology.[4]

Impetigo

Impetigo is a group of superficial skin infections caused by *S. aureus*, group A streptococcus (GAS), or both. Neonatal bullous impetigo is caused by *S. aureus* and can occur in nursery-based, epidemic patterns, often attributed to nasal carriage of *S. aureus*.

Clinical Findings

Impetigo is one of the most common neonatal skin infections. Bullous impetigo manifests itself as flaccid vesicles/bullae or pustules on an erythematous base, most often seen in the diaper area, periumbilically, or in skin folds (Fig. 93.1). Ruptured lesions leave behind a moist red base with a characteristic collarette of scale.[5,6] Lesions of bullous impetigo are usually not closely grouped, which distinguishes this infection from herpes simplex virus (HSV) infection. Aggressive cases of *S. aureus* bullous impetigo may also present as widespread desquamation in a degloving pattern.[7]

In contrast, nonbullous impetigo is characterized by thin-walled vesicles or pustules, often at sites of broken skin on the extremities or face. These lesions rapidly burst and assume their characteristic appearance of variably pruritic, eroded red patches with a superimposed honey-colored crust. In both forms of impetigo, affected areas heal without scarring.

Etiology

S. aureus is the exclusive cause of bullous impetigo and the primary cause of nonbullous impetigo. GAS may also be associated with the nonbullous form. Bullous impetigo is mediated by local production of exfoliative toxin A (ETA) or B (ETB); these toxins cleave the desmosomal protein desmoglein 1 in the superficial layers of the epidermis. This loss of adhesion between keratinocytes results in characteristic flaccid blisters.

Diagnosis

Diagnosis is supported by the presence of gram-positive cocci in clusters on Gram stain of a swab from a pustule, vesicle, or crusted plaque of impetigo. Confirmation is made by bacterial culture taken from blood, skin, and soft tissues.

Treatment

Bullous impetigo is benign if treated early, although extensive local proliferation with exotoxin production or dissemination can be life threatening. Treatment should be instituted promptly and isolation maintained until lesions have ceased to spread, no longer have associated crusting, and have begun to reepithelialize. Infants should be closely monitored, and a high index of suspicion should be maintained for evidence of systemic disease. Infants with periumbilical lesions are at risk of bacterial omphalitis. Extremely limited infections may be treated with topical mupirocin, but this form of therapy should be used with caution in neonates. More extensive lesions require a systemically (most recommend parenterally) administered penicillinase-resistant antibiotic for 7 to 10 days. Antibiotic choice should ultimately be guided by sensitivities of cultured organisms, especially with the rising incidence of

• **Fig. 93.1** Bullous Impetigo. Widespread superficial erosion with characteristic collarettes of scale in a periumbilical distribution.

methicillin-resistant strains. In those cases, clindamycin, vancomycin, or linezolid would be considered.

Importantly, *S. aureus* outbreaks in nurseries continue to be documented, and it has been suggested that these epidemics may be underreported.[4,8,9] These outbreaks may present as multiple cases of staphylococcal scalded skin syndrome (SSSS), pustulosis, bullous impetigo, abscesses, or other varied presentations of staphylococcal infection.[8] Factors that have been proposed to increase the likelihood of staphylococcal outbreaks include crowded nurseries, poor adherence to hand washing by medical staff, inadequate umbilical cord care, nursery staff carriage of the organism, and lack of isolation early in the course of an outbreak. As such, universal hand-washing protocols, a reduction in overcrowding, increased nurse-to-patient ratio, and staff monitoring for carriage have all been proposed to mitigate the risk of nursery outbreaks. Aggressive monitoring of patients via active surveillance cultures and subsequent treatment of *S. aureus*–colonized neonates with topical mupirocin therapy and chlorhexidine baths have also been successful in limiting staphylococcal infections.[10]

Staphylococcal Scalded Skin Syndrome

In contrast to the localized effects of the exfoliative toxins that mediate bullous impetigo, SSSS is a generalized manifestation of circulating toxin produced by *S. aureus*. Early diagnosis and treatment of SSSS can be lifesaving.

Clinical Findings

SSSS is most common in full-term infants and young children, although cases of affected premature infants have also been reported.[11,12] Affected infants demonstrate abrupt onset of temperature instability, lethargy, and irritability, with subsequent generalized skin tenderness and erythema. Initial erythema tends to occur on the face but subsequently becomes more marked in intertriginous areas (Fig. 93.2).[13] Facial swelling, conjunctivitis, and significant periorificial crusting is common; crusting accompanied by radial fissuring about the mouth gives afflicted children a characteristic appearance. Notably, mucosal surfaces are spared in SSSS. Following these initial signs and symptoms, focal or widespread flaccid bullae may develop within hours to days with subsequent desquamation. This is easily elicited by light stroking of intact skin (Nikolsky sign). Following desquamation, affected areas appear as painful shiny denuded patches. At this stage, diffuse skin involvement may cause problems with thermoregulation, fluid and electrolyte balance, and superinfection.[4]

SSSS must be distinguished from toxic epidermal necrolysis (TEN), a life-threatening condition involving full-thickness epidermal necrosis, most commonly secondary to medication administration.[14] A distinguishing feature of these two conditions is the presence of mucosal blistering and hemorrhagic crusting in TEN.

Etiology

The signs and symptoms of SSSS are the result of circulating exfoliative toxins produced from an often subclinical focus of *S. aureus* infection. Infants are thought to be more at risk of developing SSSS because of immunologic and renal immaturity, which allows excess accumulation of exfoliative toxin within the circulation. Specifically, significantly lower anti-exfoliative toxin antibodies have been noted in patients with SSSS compared with healthy controls.[15] In contrast to bullous impetigo, which is more commonly associated with ETA, SSSS is more frequently caused by ETB. Additionally, while *S. aureus* is identifiable in the blisters of bullous impetigo, in SSSS, *S. aureus* is present at a primary distant site such as the nose, mouth, conjunctiva, umbilicus, or circumcision site. Fresh skin lesions are therefore sterile and blister fluid is culture negative.

Diagnosis

If the diagnosis is in question, a skin biopsy sample prepared for frozen section can be examined emergently. The presence of an

intraepidermal rather than a full-thickness blister with separation at the dermal-epidermal junction distinguishes SSSS from TEN, allowing rapid initiation of appropriate therapy. If the clinical impression is strong, swabs from potential niduses of infection (nasopharynx, conjunctiva, umbilicus, etc.) may identify the primary focus. Gram staining may be performed emergently, while bacterial culture will confirm the diagnosis. Bullous lesions do not contain organisms. Blood culture specimens should be obtained because sepsis, although uncommon, may occur.

Treatment

Empiric therapy with a cephalosporin- or penicillinase-resistant penicillin, such as oxacillin, is the treatment of choice for SSSS; additional coverage to include methicillin-resistant *S. aureus* (MRSA) should be considered in areas with higher prevalence of MRSA and patients with severe systemic disease.[16] Clindamycin may also be considered as a first-line agent for treatment of SSSS because of its superior cutaneous penetration, as well as its ability to inhibit bacterial toxin production. However, reports assessing antibiotic resistance in SSSS have shown that there are certain geographic areas in which clindamycin-resistant strains predominate.[16] As such, empiric treatment with both oxacillin and clindamycin may be useful until antibiotic sensitivities return.[17] In cases of widespread disease, fluid and nutritional support and maintenance of normal body temperature may be required. Close monitoring for secondary superinfection (particularly with gram-negative organisms) is also warranted. Approximately 2 to 3 days after initiation of therapy, denuded areas become dry and desquamation ensues. Crusted, flaky areas may be treated with normal saline compresses. Application of a bland ointment emollient may promote skin healing and resolution. Additional treatment of family members may be considered in instances of recurrent staphylococcal skin infections. As in bullous impetigo, the intraepidermal cleavage plane is superficial and therefore does not result in scarring in the absence of secondary infection or other complications.

Streptococcus Species Infections

Cutaneous streptococcal infections occur in the newborn but are less common than staphylococcal infections. Nevertheless, outbreaks of GAS in nurseries have been reported[18,19] following introduction of the organism via maternal carriers or nursery personnel. Omphalitis is a common manifestation, although cellulitis, pustular eruptions, and paronychia may also be seen. GAS dissemination may occur and often presents as respiratory distress, a toxic shock-like syndrome, lethargy, abdominal distension, and poor oral intake.[20] However, certain classic signs of invasive disease, such as fever, may not be present, particularly in neonates less than 5 days old. Meningitis is more commonly seen in affected individuals 5 days of age or older. Since sepsis and meningitis can result, infected infants should be identified and treated promptly with strict isolation. Disinfection of the umbilical stump reservoir and penicillin prophylaxis for carriers and exposed infants have been the most effective measures in preventing spread. Active GAS infections respond readily to penicillin.

Group B streptococcus (GBS) is one of the most frequently encountered pathogens in the newborn nursery and remains a primary cause of neonatal sepsis. Early-onset disease (during the first week of life), probably acquired during labor and delivery, most commonly becomes manifest as septicemia with respiratory distress and shock. Late-onset disease (7 days to 3 months) is acquired after birth and more commonly associated with meningitis and adverse neurodevelopmental outcomes.[21]

Skin infections caused by GBS are uncommon but have been documented. The most common skin manifestation of GBS is cellulitis, often of the face and neck.[22,23] This so-called GBS cellulitis-adenitis syndrome typically occurs from 1 to 11 weeks of age and is characterized by progressive erythema and swelling. Extracutaneous symptoms include fever, irritability, and poor oral intake. Erosions, abscesses, and necrotizing fasciitis have also been noted with GBS. A diagnosis of GBS can be made via blood culture, which is often positive; CSF cultures are also recommended. Penicillin G or ampicillin is effective as first-line therapy.

Omphalitis

Omphalitis is a bacterial infection of the umbilical stump that presents around day 3 of life. It is commonly caused by *S. aureus*, *Staphylococcus epidermidis*, *Streptococcus* species (spp.), *Escherichia coli*, *Clostridium difficile*, *Klebsiella*, and *Pseudomonas*; these pathogenic bacteria may be contracted from the birth canal or other nonsterile exposures, including the hands of individuals assisting in delivery.[24] Outbreaks in nurseries have been described and are often attributable to staphylococcal or streptococcal infections. Risk factors for the development of omphalitis include unplanned home birth, septic delivery, prematurity, low birth weight, umbilical cord catheterization, prolonged rupture of membranes, and perinatal maternal infection.[25]

Clinical Findings

Omphalitis is characterized by edema, erythema, and tenderness around the umbilicus. Purulent, malodorous discharge may be present. Infection can evolve to cellulitis or lymphangitis or extend deeper into the subcutis or along the abdominal wall, leading to systemic signs of infection or necrotizing fasciitis. Other potential complications include sepsis, peritonitis, bowel ischemia, abscesses, and hepatic vein thrombosis.[24]

Diagnosis

Gram stain and bacterial culture from moist umbilical stump fluid can be performed, but because this area can be contaminated easily, clinical correlation is needed. Infection must be differentiated from embryonic duct remnants.

Treatment

Systemically acting ampicillin and gentamicin can be used empirically to treat both gram-positive and gram-negative organisms until culture and sensitivities are obtained. Intravenous antibiotics can be switched to enteral antibiotics once the skin improves clinically. Appropriate umbilical cord care is an important component of preventing omphalitis. Typically, dry cord care (keeping the cord clean and open to air or covered with a clean cloth) is recommended for neonates born in the hospital and/or in high-resource countries. In contrast, application of topical chlorhexidine is recommended for children born outside of the hospital setting, in areas with high neonatal mortality rates, or in situations where hygiene is poor and infection rates are increased.[24]

Candida Species Infections

Candida albicans is a yeast species that typically exists with humans as a commensal organism. Colonization of the gastrointestinal,

respiratory, and cutaneous surfaces occurs rapidly after birth and is thought to occur primarily via the maternal genitourinary tract, although skin contact may contribute. Nevertheless, decreased host immunity, altered surface microbiota, and epidermal immaturity all contribute to *Candida* pathogenesis and invasive disease.[26,27] Development of active infection may occur in utero, during delivery, or postnatally.

Localized *Candida* Infection (Primary Cutaneous)

Oral Candidiasis (Thrush)

Oropharyngeal candidiasis is characterized by adherent white patches on a normal or erythematous base, most typically on the buccal mucosa or the tongue. These patches are characteristically recalcitrant to physical removal and may be asymptomatic or cause discomfort, resulting in decreased oral intake.[28] Although the peak incidence of *C. albicans* colonization of the oropharynx is estimated to occur at 4 weeks of age,[29] most infants affected do not subsequently develop oral thrush. In a study of 650 infants in a NICU in India, however, approximately 3% developed symptomatic oral candidiasis at a mean age of 10.5 days, with birth asphyxia noted to be the only significant risk factor for this occurrence.[30] A more recent prospective study evaluating oral lesions of Turkish children in an outpatient setting found a 13.6% incidence of oral candidiasis in neonates less than 1 month of age.[31] Notably, thrush is more common in neonates born to mothers with symptomatic *Candida* vulvovaginitis rather than those who are simply colonized. However, there does not appear to be an association between the mode of delivery (vaginal vs. cesarean section) and the development of oral thrush in the first year of life.[32]

Candida *Diaper Dermatitis*

Candida diaper dermatitis is exceedingly common. Cutaneous candidiasis is characterized by widespread, confluent erythema with scalloped edges and characteristic involvement of moist, intertriginous areas. Peripheral white scale and satellite papules or pustules may be evident.[28] Alternatively, candidiasis may present as multiple pink papules with overlying scale that merge into broader plaques. In addition to the diaper area, intertriginous sites, including the neck folds and axillae, may also be infected with *Candida*, as may the nails.

Diagnosis of Localized Cutaneous Candida *Infection*

Presumptive diagnosis can be made by physical examination and history, but microscopic examination of scrapings suspended in 10% potassium hydroxide for yeast and pseudohyphae is useful. The diagnosis may be confirmed by identification of the organism in culture.

Treatment

Nystatin is a polyene antifungal with activity against *Candida* but not dermatophytes. Oral lesions usually respond promptly to a course of nystatin suspension: 100,000 to 200,000 units, administered by mouth four times daily for 7 to 14 days. In refractory cases, an increased dosage of nystatin or systemic therapy may be instituted.[33] Orally or intravenously administered fluconazole has also been used for the treatment of recalcitrant oral thrush or in infants at high risk of dissemination. Nevertheless, its higher relative cost makes it a less suitable first-line treatment.

Localized cutaneous candidiasis in an otherwise healthy infant is most easily treated with topical agents, including nystatin, an imidazole antifungal (e.g., miconazole, ketoconazole), or ciclopirox olamine.[34] A recent study examining the efficacy of a 7-day course of 0.25% miconazole nitrate ointment in the treatment of diaper candidiasis showed a clinical cure rate of approximately 50%; cure rates for recurrent episodes were even higher and did not result in antifungal resistance.[35] Importantly, if a breastfeeding mother is also affected, treatment of the mother with nystatin cream or orally administered fluconazole may be indicated. Gentian (crystal) violet is an antiseptic dye effective against *Candida* species. In a 0.5% or 1% aqueous solution, it has proven to be a safe and effective treatment for thrush but is less commonly used because of side effects, including transient purple staining of the skin and mucosal ulceration. Carcinogenicity in mice has been reported.

Congenital (Intrauterine) Candidiasis

Congenital candidiasis refers to widespread candidiasis (rarely with extracutaneous involvement) that results from ascending intrauterine infection where *Candida* spp. cross the fetal membrane and infect surfaces that contact amniotic fluid. Congenital candidiasis occurs within 6 days after birth, although it is most commonly evident on the first day of life.

Clinical Findings

Lesions of congenital candidiasis may at times be seen on the placenta and fetal membranes, including characteristic miliary granulomas of the umbilical cord.[33] These umbilical cord lesions are discrete yellow-white flat-topped papules measuring 0.5 to 4 mm in diameter. Congenital cutaneous candidiasis (CCC) in affected infants is characterized by erythematous macules, papules, and vesicopustules with intense background erythema, often in various stages of development. The back, extensor extremities, and intertriginous areas are most commonly affected, while the face, oral mucosa, and diaper area are comparatively spared. Palmar and plantar pustules, paronychia, and nail involvement characterized by onychomadesis (nail shedding) and yellow hyperkeratotic bands (Fig. 93.3) help distinguish this condition from more common, benign neonatal dermatoses.[36] In rare instances, nail changes are the sole manifestation of CCC,

• **Fig. 93.3** Onychodystrophy Secondary to Congenital Candidiasis. Note the yellow, hyperkeratotic bands characteristic of the condition.

and a high index of suspicion must be maintained to make the correct diagnosis.[37] A scald-like erythema reminiscent of disseminated neonatal candidiasis (see later) has also been reported in full-term infants but is more characteristic of CCC presenting in premature neonates with a birth weight below 1000 g.[36,38] Skin lesions usually resolve with desquamation within 1 to 2 weeks, and nail changes improve spontaneously with time. The prognosis is good in full-term infants, but that of affected low-birth-weight infants is guarded.[34]

Diagnosis

The differential diagnosis of vesicopustular eruptions in neonates is broad, and includes CCC (Box 93.1). Rapid bedside diagnosis can be made via a potassium hydroxide preparation that reveals budding yeasts and pseudohyphae. Positive results on cultures from an intact pustule or skin scrapings, as well as evidence of fungal elements present in the stratum corneum on histologic analysis of skin biopsy tissue, are also diagnostic. Cultures of skin, blood, urine, and CSF are usually negative but should always be considered when CCC is included in the clinical differential diagnosis; they are required when systemic disease is clinically suspected, as well as in all preterm infants.

Treatment

In well full-term infants with an uncomplicated course, active nonintervention with close monitoring may be sufficient as CCC resolves spontaneously within 1 to 2 weeks.[38] Alternatively, topical antifungals may be considered. In at-risk neonates, particularly low birth weight or preterm infants, empiric systemic treatment should be initiated while awaiting culture results. Recommended treatment of CCC includes systemic amphotericin or fluconazole for 14 or more days, which has been shown to prevent dissemination and mortality secondary to *Candida* spp.[39] Other risk factors that may warrant systemic treatment of at-risk neonates include antibiotic or corticosteroid therapy, indwelling catheters, and parenteral nutrition. Clinical findings, including respiratory distress, widespread burn-like dermatitis, or other signs or symptoms of systemic infection, also warrant more aggressive therapy.

Disseminated/Invasive Candidiasis

In contrast to congenital candidiasis, invasive candidiasis (IC) is a disseminated form of neonatal candidiasis characterized by *Candida* infection in otherwise sterile body fluid, such as blood, urine, or CSF. It is more commonly seen in premature, very low birth weight (VLBW) infants, and is typically acquired via the vaginal canal or handling in the nursery, although congenital onset may also occur. In contrast to congenital candidiasis, invasive neonatal candidiasis usually presents after the first week of life. While IC is uncommon in infants weighing more than 2500 g, its incidence increases to 5% to 10% in neonates weighing less than 1000 g. The most common causes of IC are *C. albicans* and *C. parapsilosis* species.[40]

The risk factors for systemic infection include VLBW (< 1500 g), indwelling catheters, endotracheal tubes, broad-spectrum antibiotic therapy (most specifically with third-generation cephalosporins), steroid administration, and parenteral nutrition with intravenous lipid emulsions.[41] Infection rates differ across medical centers owing to differences in the aforementioned modifiable risk factors. Mortality is estimated at approximately 20% to 30% across all affected neonates, with even greater rates of accompanying morbidity in survivors.[41,42]

Clinical Findings

Skin manifestations include erosive, burn-like dermatitis followed by desquamation, scaly and erythematous patches, papules, pustules, and abscesses (Fig. 93.4). Intertriginous accentuation and involvement of the oral mucosa is often appreciated.[38] Reports of perioral or diffuse hyperpigmentation in the context of disseminated *Candida* spp. infections have also been reported.[43] Systemic involvement occurs via hematogenous spread from gastrointestinal and cutaneous reservoirs, most frequently involving the kidney, central nervous system (CNS), and eyes. The spleen, liver, heart, bones, and joints may also be affected. Respiratory distress, temperature instability, apnea, bradycardia, abdominal distension, and hypotension are suggestive of IC and should prompt a thorough evaluation. Supportive laboratory features may include an elevated white blood cell count and thrombocytopenia, as well as persistent hyperglycemia and glycosuria.[40]

Diagnosis

The differential diagnosis of IC with cutaneous involvement is similar to that for CCC and includes neonatal vesiculopustular eruptions that range from benign, self-limited cutaneous processes to rapidly progressive, life-threatening diseases (see Box 93.1). Early and correct diagnosis is essential. Organisms from skin are usually demonstrable on potassium hydroxide or calcofluor white preparations and cultures of scrapings from involved skin.

• BOX 93.1 Causes of Vesicopustular Eruptions in the Newborn

- Transient neonatal pustular melanosis
- Erythema toxicum neonatorum
- Staphylococcal impetigo
- Congenital candidiasis
- Herpes virus infections
- *Listeria*
- Syphilis
- Langerhans cell histiocytosis

• Fig. 93.4 Congenital Candidiasis. "Sunburn-like" erythema with accompanying superficial desquamation on the back of a neonate.

The diagnosis of disseminated candidiasis can be expedited by a positive touch preparation of a punch biopsy specimen of skin. Using this technique, the practitioner firmly imprints the dermal side of the specimen on a microscope slide and then assesses it for yeast after potassium hydroxide preparation or Gram staining. Histologic examination of specimens from the placenta and umbilical cord prepared with the appropriate stains may also be supportive if fungal elements are demonstrated.

Disseminated disease can be difficult to diagnose, as culture of the organism from blood or CSF is estimated to have a sensitivity of 50% or less, and fungal antigen detection systems appear to have low sensitivity (and have also not been tested in neonates).[40,42] Although urine culture often leads to false-positive results, such findings are strongly associated with systemic disease in infants at risk and should be interpreted in the clinical context. In addition to blood, urine, and CSF cultures, ophthalmologic examination, chest x-ray for pulmonary involvement, echocardiogram, and head and abdominal ultrasonography should be considered.

Prognosis and Treatment

Systemic infection with *C. albicans* in premature infants is a serious infection with high morbidity and mortality. Sequelae of IC include neurodevelopmental impairment, deafness, retinopathy of prematurity, chronic lung disease, and renal failure.[40,44] Minimizing the aforementioned risk factors for IC and instituting meticulous hand hygiene are considered effective means of prevention. Probiotic supplementation has also been posited to provide protection against IC.[45] Empiric first-line treatment should be initiated while diagnostic results are awaited in patients for whom suspicion of IC is high, as this results in improved clinical outcomes. Among the various antifungals used to treat IC, fluconazole and amphotericin B are the agents of choice (including liposomal amphotericin B if urinary tract involvement is excluded).[42,46] Echinocandins such as caspofungin are less favored but may also be considered, although they are inappropriate for cases with ophthalmologic involvement as they are unable to penetrate the vitreous. Fluconazole prophylaxis has been recommended for neonates weighing less than 1000 g cared for in NICUs with high rates of IC (≥ 15%). However, a randomized controlled trial evaluating the effects of fluconazole prophylaxis in patients weighing less than 750 g in NICUs with lower rates of IC (including most of those in the United States and European Union) showed no reduction in the rates of IC or death, suggesting that universal administration of fluconazole prophylaxis in this population may not be appropriate.[47] Therapy is recommended for 21 days after microbiologic clearance as documented by culture and imaging.

Primary Cutaneous Aspergillosis

Primary cutaneous aspergillosis (PCA) is an increasingly common cutaneous infection in neonates, particularly the premature. This increased incidence is due in part to improved survival of extremely premature infants, as well as increased exposure to fungal spores made airborne by construction in and around hospitals.[48] PCA is thought to occur primarily via traumatic insult, with subsequent inoculation through intravenous line placement or use of adhesive tape, elastic dressings, armboards, cyanoacrylate adhesives or contaminated gauze.[49] Contributing factors also include an immature skin barrier and immune system, frequent use of systemic corticosteroids in NICU patients, and administration of broad-spectrum antibiotics.[50,51]

• **Fig. 93.5** Primary Cutaneous Aspergillosis. Erythematous plaques and broad pustules, many with dusky centers, on the back of a premature neonate.

Clinical Findings

PCA typically presents as an erythematous papule, patch, or plaque that with time can become pustular and may eventuate in cutaneous ulceration with crusting and, at times, purpura (Fig. 93.5). The differential diagnosis for PCA includes other deep fungal infections, as well as cutaneous *Pseudomonas* infection or inflammatory conditions, including cutaneous polyarteritis nodosa or pyoderma gangrenosum.[50]

Diagnosis and Treatment

A diagnosis of PCA is made via skin biopsy for histologic analysis and tissue culture. Systemic involvement must also be excluded, particularly when lesions are multifocal. Specific evaluation, including blood culture, chest x-ray, echocardiogram, funduscopic examination, lumbar puncture, and abdominal ultrasonography, should be considered when one is evaluating a patient with known or suspected PCA.

The treatment of choice for PCA is amphotericin B, with consideration of use of its liposomal formulation. Voriconazole may be used as an alternative. For single lesions, surgical debridement should be considered to prevent systemic dissemination.[50,51]

Tinea Capitis and Tinea Corporis

Although uncommon in neonates, dermatophytoses, such as tinea corporis (involving the body) and tinea capitis (involving the scalp), are important infections to recognize as they can be clinically mistaken for more serious disorders. Most commonly caused by superficial invasion of the epidermis by *Trichophyton* and *Microsporum* species, dermatophytoses are thought to occur in infants in part because of epidermal and immune immaturity. Other predisposing factors in hospitalized infants (particularly in the NICU setting) include moist, humid environments, administration of broad-spectrum antibiotics, and frequent application of tapes and instrumentation.[52]

• **Fig. 93.6** Tinea Corporis. Annular erythema with central clearing on the forehead of an infant. Note the presence of erythematous papules and superficial scale on the periphery of the lesion.

Clinical Findings

Clinically, neonatal tinea capitis presents with a variable combination of alopecia, erythema, and scale. An annular morphology may be appreciated, and lymphadenopathy may also be present. It may or may not be accompanied by tinea corporis (dermatophytosis of the body), which classically appears as an annular patch or thin plaque with central clearing and peripheral erythema and scale (Fig. 93.6).[53] Other more atypical presentations reported include pustules, nodules, and vesicles.[54] As such, the differential diagnosis for neonatal tinea includes neonatal lupus, Langerhans cell histiocytosis, impetigo, HSV infection, and benign diagnoses, including seborrheic dermatitis.

Diagnosis and Treatment

Consideration of dermatophyte infection in the neonate is important as recognition of this infection can prevent costly unnecessary procedures and evaluations to exclude more serious diagnoses, including neonatal lupus. Potassium hydroxide preparations are a useful bedside diagnostic tool to quickly diagnose tinea corporis or tinea capitis, while dermatophyte culture and skin biopsy may also be considered in more atypical presentations.

Treatment consists of either topical or oral antifungal therapy. Topical therapy two or three times daily with agents, including azole antifungals or terbinafine, can help clear even scalp infections in neonates and is an appropriate first treatment choice as the risk of systemic absorption and potential side effects is low.

For more information regarding the diagnosis, prevention, and management of fungal infections in neonates, see Chapter 36, Fungal Infections in the NICU.

Herpes Simplex Virus Infection

HSV exists as two viral types: HSV-1 and HSV-2. Historically, HSV-2 was associated with genital eruptions, while HSV-1 was associated with orolabial infections, although the incidence of HSV-1-associated genital herpes appears to be increasing.[55] Neonatal infection can be associated with either serotype. Despite a high prevalence of HSV infections in adults, neonatal herpes is relatively uncommon. Nevertheless, early recognition and prompt initiation of therapy for neonatal herpes are critical as the consequences of delaying therapy can be devastating. While approximately 5% of cases of HSV infection in the neonatal period are due to in utero exposure, with another 10% occurring after birth, most occur in the perinatal period.

Clinical Findings

Neonatal HSV infection is classified on the basis of the extent of involvement: skin, eye, and/or mouth (SEM) disease without visceral or CNS involvement; CNS disease; or disseminated disease. Infection typically presents within the first week to two weeks after birth, with a slightly later onset of CNS disease at approximately 16 to 17 days. Neonatal HSV infection may present with temperature instability, lethargy, irritability, or poor oral intake or a sepsis-like syndrome that may include new-onset seizures, pneumonia, and disseminated intravascular coagulation. Approximately 60% to 80% of afflicted neonates exhibit characteristic skin lesions or develop them during the course of the disease. Nevertheless, there remains a significant proportion of patients who never develop skin vesicles throughout their disease course.[55,56]

Approximately 45% of infected infants exhibit SEM disease, often presenting at about day 10 to 12 of life.[57] Characteristic cutaneous lesions begin as erythema that quickly evolves into isolated or grouped vesicles on an erythematous base. Continued evolution may result in pustules, crusts, or erosions. Vesiculation typically occurs at sites of trauma, including the presenting part and sites of fetal electrode placement.[58] Conjunctivitis is relatively common in SEM disease, although oral involvement remains rare. With early institution of therapy, infants with SEM disease have an excellent prognosis, with low rates of morbidity and a mortality rate of zero. Nevertheless, if infection is left untreated, it will progress to disseminated or CNS disease in three-quarters of all cases.[58] Additionally, infants with SEM disease and three or more recurrences of cutaneous vesicles in the first 6 months of life appear to be at greater risk of neurologic impairment.[59]

In contrast, approximately 30% of infected infants have CNS disease, with an increased associated mortality and risk of neurodevelopmental abnormalities. Up to 70% of infants with CNS disease will have cutaneous involvement during the course of their infection.[57] Prematurity and the presence of seizures at onset of therapy appear to portend a worse prognosis in infants with CNS disease, even with therapy (acyclovir era). The remaining 25% of infants have evidence of disseminated disease (sepsis, liver failure, encephalitis, disseminated intravascular coagulation, respiratory distress). Forty percent of patients in this group do not manifest any cutaneous findings.[60] The prognosis of disseminated disease is worse than for other forms of neonatal HSV infection; treatment with high-dose acyclovir has improved outcomes compared with historical measures, but mortality associated with disseminated disease is still estimated at approximately 30%. Almost 20% of survivors have neurodevelopmental delays.

Infants infected in utero (congenital HSV infection) have a distinct clinical presentation (Fig. 93.7). Skin lesions are almost always present at birth and include widespread erosions and bullae, scars, hyperpigmentation, hypopigmentation, and aplasia cutis. Other frequent findings include microcephaly, hydranencephaly, intracranial calcification, chorioretinitis, optic atrophy, and microphthalmia.[55,58]

Etiology

Most cases of neonatal herpes simplex are the result of vertical transmission in the perinatal period. Most cases of neonatal HSV infection in developed countries are secondary to HSV-1 infection, reflecting the increased prevalence of HSV-1 associated with genital herpes. The usual route of infection is via intrapartum contact with genital mucosa during a phase of active viral shedding, which may be symptomatic or asymptomatic. Nevertheless, physicians should also be aware of uncommon means of HSV transmission associated with certain ethnic or religious groups. For instance, postnatal transmission of HSV has been reported in ultra-Orthodox Jewish populations in which orogenital suctioning of blood is performed following ritual circumcision.[61]

Epidemiology

In developed countries, the incidence of neonatal HSV infection ranges from 1.6 to 33 per 100,000 live births.[60] When compared with the risk of genital herpes reactivation, the risk of neonatal herpes is greater with maternal first episode primary or first episode nonprimary infection (the latter category reflects acquisition of an HSV serotype in individuals with preexisting protective antibodies versus the other serotype).[62] Unfortunately, it has been estimated that up to 80% of mothers who transmit HSV to their infants have no known history of genital herpes.[55] Vaginal delivery, prolonged rupture of membranes, maternal infection with HSV-1, and use of instrumentation during delivery (i.e., fetal scalp electrodes) are additional risk factors for acquisition of HSV in the neonate.

Diagnosis

A high index of suspicion is required, particularly in cases without cutaneous manifestations. When characteristic herpetic lesions are present, the differential diagnosis includes other causes of vesicopustular eruptions (see Box 93.1). A Tzanck smear test or direct fluorescent antibody detection using skin scrapings from the base of a fresh vesicle is a relatively rapid means of detecting cutaneous HSV infection, but the diagnostic yield of both is variable, largely influenced by the age, quality, and handling of the specimen. Viral culture and polymerase chain reaction (PCR) for HSV DNA are the preferred methods for diagnosing neonatal HSV infection; the sensitivity of PCR in identifying HSV DNA in CSF samples is 75% to 100%.[60] Obtaining specimens from the CSF, oropharynx, anus, conjunctivae, and nasopharynx is recommended; evaluation of peripheral blood via PCR is also useful in establishing a diagnosis of neonatal herpes, although it does not assist in identifying the extent of disease. Notably, HSV serologic tests are not a useful diagnostic adjunct. If they are elevated, serum alanine aminotransferase levels may indicate disseminated disease.

Treatment

Strategies to decrease the risk of vertical transmission of HSV include cesarean delivery, maternal prophylactic antiviral therapy, and limiting use of invasive monitoring techniques in mothers shedding HSV at the time of delivery.[62] Specifically, birth via cesarean delivery for women with active lesions or prodromal symptoms has been shown to reduce the risk of neonatal HSV infection.[63] Maternal suppressive therapy with acyclovir is known to reduce the frequency of both genital lesions near term and cesarean delivery, but whether this reduces acquisition of HSV by the neonate remains unclear.

Early treatment with antiviral agents is critical to decrease the risk of serious complications and death. All cases of presumptive neonatal HSV infection should be treated with intravenous acyclovir therapy, with a recommended dosage of 60 mg/kg/day administered every 8 hours at 20 mg/kg/dose.[64] A notable side effect of this therapy, however, is transient neutropenia that warrants ongoing monitoring. Nephrotoxicity has also been documented in patients treated with acyclovir, although this appears less common in patients with normal renal function whose fluid status is closely monitored. Treatment is recommended for 14 days for SEM disease and 21 days for disseminated and CNS disease. In cases of CNS involvement, repeated evaluation of CSF for HSV infection via PCR should be performed at the conclusion of therapy, and, if the findings are positive, it should be continued until PCR evaluations return negative.[57]

For more information on diagnosing and managing viral infections in neonates, please refer to Chapter 34.

Common Newborn Dermatoses

KATE KHORSAND AND ROBERT SIDBURY

KEY POINTS

- Papulopustular lesions on the palms and/or soles in the first month of life likely represent a self-limited inflammatory process such as eosinophilic pustular folliculitis or infantile acropustulosis—but scabies should be ruled out.
- Neonatal acne (a.k.a. *cephalic pustulosis*) is typically multifactorial and self-limited. Treatment is not necessary, but topical agents aimed at reduction of the commensal yeast *Malassezia* can be beneficial.
- Evidence suggests that early use of emollients in infants at risk of developing atopic dermatitis may prevent later disease.
- Subcutaneous fat necrosis of the newborn is generally benign and self-limited but when extensive can cause hypercalcemia.

This chapter describes a group of cutaneous disorders commonly found in neonates. Most of these disorders are benign and are either self-limited or treated with ease. Recognition of these common neonatal dermatoses is important so as to distinguish them from more serious conditions, sparing patients unnecessary work-up and treatment. Each section includes common clinical features and presentation, notes on establishing the diagnosis (with a short differential diagnosis), the cause if known, and a brief discussion of basic treatment and prognosis.

Erythema Toxicum Neonatorum

Clinical Findings

Erythema toxicum neonatorum (ETN) is a benign inflammatory condition affecting newborns. Estimates of incidence range from 7% to 41%, and it is seen more commonly in white newborns with a higher birth weight and greater gestational age.[1] The condition presents in the first 1 to 3 days after birth as irregularly shaped erythematous macules that can develop overlying vesicles or pustules (Fig. 94.1). ETN most commonly affects the trunk but can involve the face and extremities as well. The palms and soles are typically spared. Affected infants are otherwise healthy. The lesions persist for 1 to 2 weeks and then spontaneously resolve without sequelae.

Diagnosis

The diagnosis is often clinical but can be further supported by the scraping of a pustule, smearing the contents onto a slide, and staining with Wright or Giemsa stain.[2] This will reveal a large number of eosinophils. The differential diagnosis of ETN includes other benign entities such as transient neonatal pustular melanosis, miliaria, infantile acropustulosis, and eosinophilic pustular folliculitis. Additionally, infections such as folliculitis, candidiasis, impetigo, and herpes should be considered and ruled out. If a biopsy sample is obtained, histopathologic features include intraepidermal vesicles filled with eosinophils and a mixed intradermal inflammatory infiltrate localizing around the superficial pilosebaceous follicle.

Etiology

The cause of ETN remains unclear. Studies have shown the presence of inflammatory mediators, as well as increased eosinophil and macrophage activity[3,4] in affected skin compared with unaffected skin. This has led to the theory that ETN could represent a cutaneous immunologic response to microbial colonization of the hair follicles after birth.[4]

Treatment and Prognosis

No treatment is required for this benign condition. It is usually asymptomatic. Parents can be reassured and informed that the condition will spontaneously resolve in a matter of weeks. Prolonged courses or recurrence is rare.

Transient Neonatal Pustular Melanosis

Clinical Findings

Transient neonatal pustular melanosis is a benign, self-limited condition that presents at birth in affected infants. It is more common in African-American infants.[5] There are three clinical phases of transient neonatal pustular melanosis. At birth, the neonate has very fragile and superficial 2- to 10-mm pustules located most commonly on the forehead, under the chin, on the lower back, and on the shins. These pustules are often wiped off during the initial cleaning after birth. Next, a fine collarette of scale is noted around the resolving pustule. Last, hyperpigmented brown macules develop at the site of the previous pustules (Fig. 94.2).[2] The first two phases usually last 1 to 2 weeks, but hyperpigmentation can persist for several months.[6]

Diagnosis

Diagnosis is clinical, but it can be supported by a scraping from the pustule, with Wright staining of the contents. This will reveal a predominance of neutrophils. The differential diagnosis

• **Fig. 94.1** Erythema Toxicum Neonatorum. Pinpoint pustules overlying ill-defined erythema on the trunk and extremity of a healthy newborn consistent with erythema toxicum neonatorum.

• **Fig. 94.2** Transient Neonatal Pustular Melanosis. Intact discrete pustules on non-inflamed base, some ruptured, with residual hyperpigmentation.

includes ETN, and these conditions can overlap. Additional considerations include miliaria, acropustulosis of infancy, and infectious diseases such as candidiasis, impetigo, and herpes, which should be ruled out.

Etiology

The underlying cause of transient neonatal pustular melanosis is unknown. Studies linking it with ETN suggest a similar cause.

Treatment and Prognosis

No treatment is required for this benign and self-limited condition. Parents should be informed that while the initial skin findings resolve quickly, the residual hyperpigmentation may take months to completely resolve.

Eosinophilic Pustular Folliculitis

Clinical Findings

Eosinophilic pustular folliculitis (EPF) is a vesiculopustular eruption that can occur in several distinct settings. The infantile form

• **Fig. 94.3** Eosinophilic Pustular Folliculitis. Grouped folliculocentric eosinophil-rich erythematous papules and pustules on the chest.

is relatively rare and presents with pruritic follicular lesions typically on the extremities or scalp, although truncal involvement is described (Fig. 94.3). Crops of lesions will occur discretely, not in an annular array as in adults, and persist for days to weeks before resolving without sequelae. EPF tends to present somewhat later than erythema toxicum but has been described on the first day after birth.[7]

Diagnosis

Diagnosis is clinical, and persistence past several weeks generally distinguishes EPF from erythema toxicum, although peripheral eosinophilia may be supportive. Histologic examination demonstrates an eosinophilic follicular infiltrate.

Etiology

The cause is unknown.

Treatment and Prognosis

Treatment is symptomatic and can include emollients, topical corticosteroids, and antihistamines. Topical indomethacin therapy has been used in refractory cases.[8]

Acropustulosis of Infancy

Clinical Findings

Acropustulosis of infancy is a relatively uncommon pruritic, vesiculopustular rash that occurs on the hands and feet with spread to the wrists and calves. First described in 1979, this rash is closely related to preceding infections and infestations, with scabies preceding approximately 50% of cases.[9,10] The eruption is most common in African-American, Hispanic, and Asian children and presents at less than 1 year of age. Crops of intensely pruritic vesicles and pustules appear on the hands and feet, persist for around 2 weeks, and then resolve (Fig. 94.4). Frequent recurrences are the

• **Fig. 94.4** Infantile Acropustulosis. Discrete, grouped erythematous papules and pustules on the sole of the foot.

norm, with each eruption decreasing in intensity until eventual complete resolution around 2 to 3 years of age.

Diagnosis

Diagnosis is primarily clinical, and a history of preceding scabies can be quite helpful in making the diagnosis. If a biopsy sample is obtained, it shows necrolysis of the keratinocytes with intraepidermal pustules filled with neutrophils and eosinophils.[11] The differential diagnosis includes scabies (concurrent infestation must be ruled out and treated if present), pustular psoriasis, coxsackievirus infection, eosinophilic folliculitis, and less likely, an allergic contact dermatitis.

Etiology

The cause of acropustulosis is unknown, but the condition is known to frequently follow prior scabies infestation or coxsackievirus infection.

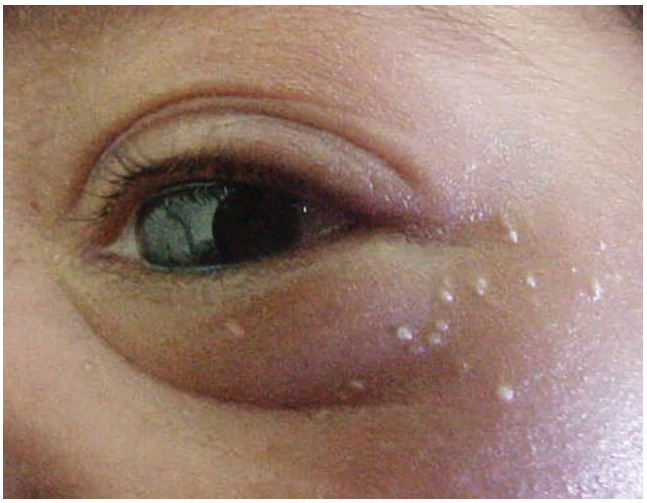
Treatment and Prognosis

The recurrent episodes of acropustulosis of infancy will eventually resolve around 2 to 3 years of age, but episodes can be managed. Ruling out scabies and treating it if it is present should be a first step.[12] Topical treatment with mid-potency to high-potency corticosteroids is effective for discrete episodes but will not help to prevent relapses.[10] Historically, acropustulosis of infancy was treated with orally administered dapsone, but this is no longer frequently used because of the risk of hemolysis and methemoglobinemia in patients with glucose 6-phosphate dehydrogenase deficiency.

Milia

Clinical Findings

Milia are an extremely common benign entity, seen at birth in 40% to 50% of newborns. They are more common with longer gestations and in infants born to multigravidas.[13] Milia (singular, *milium*) are tiny, white monomorphic papules with a smooth surface. They can number from several to dozens. They are an entity distinct from miliaria, which is discussed next. Milia can be present anywhere on the body but occur most commonly on the face, predominantly on the forehead, cheeks, and chin (Fig. 94.5).



• **Fig. 94.5** Milia. Numerous, discrete, pinpoint monomorphic white papules around the eye.

Diagnosis

A useful diagnostic tool is expression of the milia contents, which will resemble a tiny, white pearl. This is the keratinocyte debris that forms the interior of the cyst. The differential diagnosis includes sebaceous hyperplasia, which would also present on the face but tend to be more yellow, and miliaria, which presents primarily on the body and in greater numbers with distinct clinical variants.

Etiology

Milia are tiny inclusion cysts that form in the epidermis. The epidermal tissue invaginates, often around a vellus hair, and forms a cyst with a wall of keratin-producing cells.

Treatment and Prognosis

Treatment of milia is not required. They tend to resolve spontaneously over several months. Of note, the presence of multiple large or persistent milia can rarely be associated with syndromes such as epidermolysis bullosa or orofaciodigital syndrome.

Miliaria

Clinical Findings

Miliaria is a benign rash due to obstruction of the eccrine duct occurring in the first 1 to 2 weeks of life, with rapid resolution within days. There are multiple variants depending on the location of the eccrine duct obstruction, with differing clinical presentations. Miliaria crystallina occurs when eccrine ducts within or below the stratum corneum are obstructed and causes small clear

• **Fig. 94.6** Miliaria Crystallina. Numerous, discrete, easily ruptured superficial vesicles. (From Antaya RJ, Robinson DM. Blisters and pustules in the newborn. *Pediatr Ann*. 2010;39:635-645.).

• **Fig. 94.7** Epstein's Pearls. Discrete, opaque yellow keratin-rich papulonodules along the alveolar ridge of the mouth.

vesicles that can be easily wiped away (Fig. 94.6). Miliaria rubra is caused by obstruction of the eccrine duct at the level of the epidermis and is thought to be related to overheating. This causes erythematous papules or papulopustules primarily on the head, neck, face, and trunk. Dermal inflammation contributes to the clinical presentation. Miliaria profunda is caused by occlusion of the eccrine duct at or below the dermal-epidermal junction and causes a mildly inflammatory papular eruption that is rare in newborns.

Diagnosis

The diagnosis of miliaria is made clinically, although scraping of a vesicle or pustule with subsequent Wright staining will reveal few to no cells in miliaria crystallina and lymphocytes in miliaria rubra. The differential diagnosis includes ETN, transient neonatal pustulosis, milia, eosinophilic folliculitis, and infectious entities. Recurrent episodes of pustular miliaria rubra could be a sign of the rare and potentially fatal condition type I pseudohypoaldosteronism, which is an inherited disorder of mineralocorticoid resistance leading to a salt-wasting crisis.

Etiology

Miliaria is caused by obstruction of the eccrine duct, possibly by sweat accumulation. Neonates can have incompletely canalized eccrine ducts, predisposing them to developing obstruction and subsequent miliaria.[14]

Treatment and Prognosis

No treatment is required for this benign condition, which will self-resolve. Prevention of overheating can reduce the incidence of miliaria rubra.

Epstein Pearls and Bohn Nodules

Clinical Findings

Epstein pearls and Bohn nodules are very common and benign cysts that form in the mouths of neonates. They present as single or clustered 1- to 2-mm smooth white to yellow papules. Epstein pearls are more often seen in infants born to multigravidas, after longer gestations, and with higher birth weights.[15] Bohn nodules are often mistaken for natal teeth, prompting referral.

Diagnosis

Epstein pearls are found on the palate, typically at the midline of the junction between the hard and soft palate. Bohn nodules are found on the alveolar ridge, most commonly in the maxillary region (Fig. 94.7). They are distinguishable from neonatal teeth in their location in addition to their appearance; neonatal teeth are usually located in the region of the lower incisors. Radiographic examination would distinguish between these diagnoses.[15]

Etiology

Both Epstein pearls and Bohn nodules are inclusion cysts. They are thought to originate from remnants of odontogenic epithelium or to potentially be remnants of salivary glands.[16]

Treatment and Prognosis

Spontaneous resolution will occur with time, typically within the first several weeks to months after birth. No treatment is required.

Sebaceous Hyperplasia

Clinical Findings

Sebaceous hyperplasia is a common finding, seen in approximately half of newborns,[17] and is typically most noticeable surrounding the nose and upper lip (Fig. 94.8). It presents as regular, smooth white to yellow papules that can be grouped around follicles.

Diagnosis

The differential diagnosis includes milia and neonatal acne (neonatal cephalic pustulosis).

• **Fig. 94.8** Sebaceous Hyperplasia. Pinpoint yellow macules and papules along the sebaceous triangle on the nose.

Etiology

Sebaceous hyperplasia in newborns is thought to occur secondary to maternal androgens, which stimulate the sebaceous glands in utero.[4,17]

Treatment and Prognosis

No treatment is required, and the findings will spontaneously resolve in the first few weeks of life.

Neonatal Cephalic Pustulosis (Neonatal Acne)

Clinical Findings

Neonatal cephalic pustulosis, which is also known by the more common term of *neonatal acne*, consists of erythematous papules and pustules on the cheeks, chin, and forehead of infants (Fig. 94.9). It occurs within the first 30 days after birth and can last up to several months. Comedones are absent. It is an entity distinct from infantile acne, which occurs at 3 to 6 months of age and can last for years.

Diagnosis

Diagnosis is made primarily on the clinical appearance, although Wright stain of a smear will reveal neutrophil predominance. The differential diagnosis includes miliaria, milia, ETN, or rarely, severe infectious processes such as candidiasis or folliculitis.

Etiology

The cause of neonatal cephalic pustulosis is debated but is thought to be related to skin colonization with *Malassezia* species. *Malassezia* colonization begins at birth and increases during the first few weeks after birth from approximately 5% of newborns colonized during the first week to 30% colonized by the second to fourth week.[18] This increased *Malassezia* colonization is thought to trigger an inflammatory reaction that some believe becomes neonatal cephalic pustulosis.[2,19] However, others suggest that the degree of skin colonization by *Malassezia* does not differ between affected and unaffected infants and that there is no correlation between the severity of disease and *Malassezia* isolation.[18] If, and why, *Malassezia* colonization causes an inflammatory reaction in some neonates but not in others is undetermined.

• **Fig. 94.9** Neonatal Cephalic Pustulosis (Neonatal Acne). Small monomorphic papules and pustules on the head and neck of a newborn consistent with neonatal cephalic pustulosis or neonatal acne. (From Sidbury R, Paller AS. The diagnosis and management of acne. *Pediatr Ann*. 2000;29:17–24.)

Treatment and Prognosis

No treatment is required for this benign self-limited condition. However, the lesions can take months to resolve. Topical treatment with imidazole antifungals, such as clotrimazole, econazole, or ketoconazole, may be effective at shortening the duration of the eruption.

Seborrheic Dermatitis

Clinical Findings

In newborns, seborrheic dermatitis (SD) is an extremely common finding and presents as irregular salmon pink patches with waxy scaling on the scalp, forehead, and nasolabial folds (Fig. 94.10). It can also involve the diaper area. Appearing around 2 to 4 weeks of age, this condition usually resolves or abates by 1 year of age. Severe cases can become secondarily infected. A strong association between atopic dermatitis (AD) and infantile SD has been postulated, suggesting that infantile SD may precede the development of AD or that these conditions may be on the same spectrum of disease.[20]

• **Fig. 94.10** Seborrheic Dermatitis. Waxy yellow loosely adherent scaly plaques on an erythematous base on the forehead and scalp.

Diagnosis

Diagnosis is clinical, and the differential diagnosis includes AD, psoriasis, Langerhans cell histiocytosis, or another superficial fungal infection. AD may overlap with SD, as discussed previously, and psoriasis does not typically present this early. Langerhans cell histiocytosis is a more serious, but fortunately rare, condition.

Etiology

In adults, SD is related to *Malassezia* overgrowth, but it is unclear if this is the pathogenesis behind the disorder in infants, although that has been suggested by several historical studies.[21,22]

Treatment and Prognosis

This condition often resolves spontaneously or abates by 1 year of age. Both topical antifungals and topical steroids have been used to treat this condition. Ketoconazole was shown to be equally as efficacious at treating SD as steroid creams such as hydrocortisone,[23] and therefore this could be a viable treatment option. Treatment of the scalp with olive oil should be avoided, as this medium can encourage yeast growth.[24]

Atopic Dermatitis

Clinical Findings

AD is an extensive topic, spanning all ages of childhood into adulthood. This section will focus on infantile AD, as there are multiple informational sources for this common and important condition as it pertains to later childhood. AD, commonly known as *eczema*, is a chronic, relapsing condition defined by distinctive cutaneous manifestations and associations with additional atopic conditions such as asthma and allergic rhinitis. It is extremely common, affecting 15% to 20% of the population, particularly in developed countries. In more than half of cases, the onset of AD is in infancy.[25] In infants the most common areas of involvement include the cheeks (often seen concurrently with an irritant dermatitis secondary to saliva), neck, flexural folds, wrists, ankles,

• **Fig. 94.11** Atopic Dermatitis. Ill defined erythematous papules coalescing into plaques on the cheeks with characteristic nipple inflammation.

and notably the nipples (Fig. 94.11). In infantile eczema, involvement of the extensor surfaces (skin on the opposite side of a joint) and trunk is seen more commonly than flexural involvement. Erythema, scaling, lichenification, and excoriation are common clinical findings. Itching is the predominant symptom. The diaper area and nasal tip are notably spared. Superinfection can be common. There is significant overlap with SD, as discussed previously. As infants age, the "typical" presentation of AD often evolves with prominent involvement of the antecubital and popliteal fossae with associated diffusely dry skin.

Diagnosis

Diagnosis is made clinically, and biopsy is rarely performed. The differential diagnosis of AD is broad and includes common entities such as SD, contact dermatitis, and irritant dermatitis. More rarely, severe AD can be associated with recurrent infections of various forms in multiple rare immunologic disorders, including Wiskott-Aldrich syndrome, chronic granulomatous disease, hyper-immunoglobulin E (IgE) syndrome, and severe combined immunodeficiency. Severe recalcitrant eczema with other unusual infections should raise awareness of these serious conditions particularly in the setting of failure to thrive. If lesions appear superinfected with crusting, bacterial culture should be performed.

Etiology

The exact cause of AD remains elusive. At its core, AD appears to be a condition of defective skin barrier function and immune alteration. In AD, there is a prominence of the T-helper2–T-cell subsets, which produce interleukin-4 and promote production of IgE, eosinophilia, mast cell proliferation, and release of histamine. Loss of filaggrin mutations has been linked to individuals with early-onset and persistent AD.[26,27] Filaggrin acts in the top layer of the skin and maintains skin barrier function. When the skin's barrier function is impaired, it is increasingly susceptible to exogenous triggers. Nearly all patients with AD carry *Staphylococcus aureus* on their skin, and staphylococcal exotoxins can act as superantigens that stimulate T-cell responses.[28] The impact of food and food allergy, a common question from parents, is only relevant in a minority of patients. Food allergies are more common in atopic individuals, and in some cases of AD recalcitrant to treatment, food allergies may play a role in the persistence of the disease. A Cochrane review stated that maternal dietary antigen avoidance during pregnancy had no impact on the development of AD in

the first 18 months of life and could increase the risk of preterm birth or decreased birth weight.[29] Breastfeeding during the first 4 months of life has been shown to reduce the incidence and severity of AD in high-risk infants,[30] although prolonged breastfeeding has not impacted its incidence.[31]

Treatment and Prognosis

There is no cure for eczema; therefore, the goal of treatment is to manage signs and symptoms and reduce recurrences. Spontaneous resolution often occurs as children age. Maintenance therapies include gentle bathing techniques such as limiting a gentle soap to soiled areas and avoidance of long, hot bathing. Diligent moisturization at least twice daily and always after bathing with a thick, bland emollient is important to restore cutaneous moisturization and maintain barrier function. Treatment of active rash with appropriate strength topical corticosteroids, rarely stronger than class 6 or 7 (e.g., hydrocortisone 2.5% or 1%, respectively) is first-line treatment for symptomatic AD refractory to emollients and good skin care. Second-line agents include topical calcineurin inhibitors such as tacrolimus or pimecrolimus, but these agents are not approved for use in children younger than 2 years. Adjunctive topical or systemic antibiotics address concurrent skin infection when present, and dilute bleach baths may be preventive.[32] Treating inflammation as described earlier is the best way to reduce itch, but when there is sleep disruption, a sedating antihistamine such as diphenhydramine or hydroxyzine may help, if it is age appropriate.

Diaper Dermatitis

Clinical Findings

Diaper dermatitis (DD) is likely the most common skin condition of infants. The vast majority of affected infants are otherwise healthy, but occasionally DD can suggest an underlying systemic disorder. DD is primarily an irritant process, occurring when the skin in contact with the diaper becomes inflamed because of friction and contact with urine, feces, cleansing materials, and other irritants. The clinical presentation includes erythema, with mild scaling of the gluteal crease, buttocks, and convex surfaces of the pubic area and perianal rim (Fig. 94.12). There is often relative sparing of the skinfolds, which are protected from direct contact with the diaper. Erosions or plaques can be present in more severe cases, and discrete ulcerations are seen in a severe form of DD known as *Jacquet dermatitis*. This distinctive noduloerosive presentation is seen more frequently in association with cloth diaper use.

Diagnosis

DD is a clinical diagnosis, and as such, histopathology is usually not helpful. Other infectious and noninfectious causes of rashes in the diaper area should be excluded. Infectious causes of diaper rashes include congenital syphilis and infections caused by *Candida* or other fungi, *Streptococcus*, *Staphylococcus* (including staphylococcal scalded skin syndrome), herpes simplex virus, and human immunodeficiency virus. These infectious diaper area eruptions are usually clinically distinct. *Candida* infections present with bright red, relatively well-demarcated patches and plaques with satellite lesions in the groin region and perianal rim.

• **Fig. 94.12** Irritant Contact Dermatitis. Ill-defined confluent erythematous plaques symmetrically along the convexity of the buttocks.

Staphylococcal infection presents most commonly in the diaper area as bullous impetigo with scattered bullae and vesicles. Streptococcal infections present as a brightly erythematous perianal patch. Skin findings caused by infections are often found in areas additional to the diaper region. Other considerations include infantile SD, allergic contact dermatitis, nutritional deficiencies (such as acrodermatitis enteropathica in zinc deficiency), Langerhans cell histiocytosis, and rare metabolic disorders. Similar findings will often be identified in other nondiapered skin areas, which can be a distinguishing feature.

Etiology

DD is exceedingly common, with most infants experiencing one or more episodes. Multiple factors contribute, including occlusion friction, and maceration. When the barrier has been compromised by these factors, chemical or biologic irritants in urine and feces continue to drive the dermatitis. Further irritants such as soaps, diaper wipes, and numerous topical products perpetuate the problem.

Treatment and Prognosis

Prevention of DD starts with maintenance of skin barrier function and prevention of irritation. The use of disposable diapers, particularly the superabsorbent variety, has been shown to be better at preventing DD than the use of cloth diapers.[33] Avoiding prolonged skin contact with soiled diapers is an important aspect of basic infant care. Potential irritants or sensitizers should be identified and removed. Commercial diaper wipes are a common culprit. Barrier pastes such as zinc oxide ointment and zinc paste as well as petroleum jelly are bland skin protectants. Thick layers of these protective agents should be applied, and with diaper changes, only a partial layer should be removed to protect the underlying skin. Mineral oil provides a way to remove zinc preparations without rubbing the skin excessively. In the absence of *Candida* infection, a low-potency topical steroid can be helpful. If *Candida* infection is suspected, an anti-*Candida* agent can be added. Daily bathing is acceptable, but harsh soaps and scrubbing should be avoided. DD is self-limited and episodic.

Harlequin Color Change

Clinical Findings

Harlequin color change is a rare but benign event. It was first reported in 1952. It represents an abrupt deep vascular red color change to one side of the body, with contralateral blanching and sharp midline demarcation (Fig. 94.13). It can involve the entire body or can be more localized to a single body area. It occurs most commonly in the newborn and is more often seen in premature infants.

Diagnosis

Diagnosis is by clinical appearance. Rapid resolution is the norm.

Etiology

Harlequin color change is thought to be due to the immaturity of the hypothalamic control center in newborns, which causes asymmetric control of the sympathetic peripheral vascular tone, resulting in skin color change with a sharp midline demarcation.

Treatment and Prognosis

No treatment is required for this entity. It is benign and rapidly resolves on its own. Recognition and education are important, as harlequin color change is a surprising and alarming occurrence for parents. Harlequin color change is unrelated to harlequin ichthyosis.

Subcutaneous Fat Necrosis

Clinical Findings

Subcutaneous fat necrosis is a relatively uncommon condition affecting full-term infants within the first several weeks after birth. It presents as single or multiple, poorly demarcated, tender nodules and plaques that are firm and have an underlying dusky reddish-purple hue (Fig. 94.14). The lesions are located in areas with fat pads, including the buttocks, thighs, arms, face, and shoulders. Calcification of the lesions can occur and can be associated with hypercalcemia.

• **Fig. 94.13** Harlequin Color Change. Unilateral macular erythema along the trunk.

Diagnosis

Skin biopsy will reveal subcutaneous granulomatous infiltration with multinucleated giant cells and damaged lipocytes containing characteristic needle-shaped clefts. Soft tissue necrosis and inflammation may cause local production of vitamin D, leading to hypercalcemia. Differential diagnosis includes sclerema neonatorum, which is a rare life-threatening panniculitis characterized by diffuse, progressive skin hardening.

Etiology

Subcutaneous fat necrosis is thought to be caused by some form of intrauterine or perinatal trauma. It has been associated with maternal cocaine use, hypothermia, meconium aspiration, and perinatal asphyxia.[34]

Treatment and Prognosis

This condition is often self-limited, but care must be taken to monitor calcium levels because of the risk of severe hypercalcemia and to assess the newborn for evidence of renal injury because of nephrocalcinosis.[35] Appropriate immediate treatment should be instituted if there is evidence of either of these complications. Resolution of subcutaneous fat necrosis occurs over a period of weeks to months. Bisphosphonates have been suggested for use in subcutaneous fat necrosis, but appropriate controlled clinical trials are still lacking.

Cutis Marmorata

Clinical Findings

Cutis marmorata is a common finding, particularly in premature infants. It presents with a netlike violaceous reticular blanching pattern affecting the extremities more than the trunk (Fig. 94.15). It is exaggerated with cooling and resolves with warming.

Diagnosis

Diagnosis is made by clinical observation. Findings should resolve with warming, and the condition itself should resolve by

• **Fig. 94.14** Subcutaneous Fat Necrosis. Brawny, indurated, erythematous plaque on the back of an otherwise healthy infant with associated hypercalcemia.

• **Fig. 94.15** Cutis Marmorata. Reticulate violaceous erythematous patches on the upper extremity.

approximately 1 month of age. Persistent cutis marmorata past 1 month of age can be associated with genetic abnormalities such as Down syndrome, trisomy 18, and Cornelia de Lange syndrome. Cutis marmorata that persists after warming, and is localized and asymmetric, could represent cutis marmorata telangiectatica congenita, a distinctive vascular anomaly that can be associated with limb atrophy. Another diagnostic possibility is livedo reticularis, which presents with a clear vascular pattern that can be related to underlying vascular inflammation/vasculitis; however, this condition is quite rare in infants.

Etiology

Cutis marmorata occurs because of transient shifts in skin blood flow.

Treatment and Prognosis

Warming should resolve the cutaneous findings. If cutis marmorata is unresponsive to warming or persists past several months of age, further work-up for underlying causes may be required.

Dermal Melanocytosis

Clinical Findings

Dermal melanocytosis (DM), previously known as *Mongolian spots*, is an exceedingly common congenital cutaneous finding in children of African-American, Asian, and Hispanic descent. It presents as well-demarcated, deep blue to gray pigmented macules and patches that are most commonly seen on the buttocks and low back (Fig. 94.16). DM is usually an isolated finding and is not typically associated with tissue malformations or systemic disorders. There are very rare case reports of DM associated with inborn errors of metabolism (e.g., GM1 gangliosidosis) and other potential associations with a vascular nevus called *phakomatosis pigmentovascularis*, which is a form of twin spotting that occurs when two genetically distinct patches involve nearby or corresponding body areas.[36]

Diagnosis

Diagnosis is by clinical appearance. The differential diagnosis includes postinflammatory hyperpigmentation, nevus of Ito, vascular malformation, and child abuse. Bruising concerning for child abuse is suggested when the color of the lesion changes over time from blue green to brown, and if the lesion is tender to palpation. Biopsy of DM is rarely performed but would show increased numbers of dermal melanocytes.

• **Fig. 94.16** Dermal Melanocytosis. Gunmetal gray macules and patches on the back of a healthy infant consistent with dermal melanocytosis (a.k.a. *Mongolian spots*).

Etiology

DM is caused by an excessive number of dermal melanocytes. The bluish-gray coloration is due to the Tyndall effect (light reflection off the dermal-based melanocytes).

Treatment and Prognosis

No treatment is required for this benign and self-limited condition. DM tends to fade over time, with studies showing that 42% of cases disappear by 1 year of age.[37] Features that portend persistence past 1 year of age are multiple dark and/or large patches and presence in locations other than the sacrum. Most of these lesions fade by several years of age. Laser treatment of the lesions is not recommended. Because of possible confusion with bruising as mentioned earlier, it may be prudent to document DM when it is first encountered.

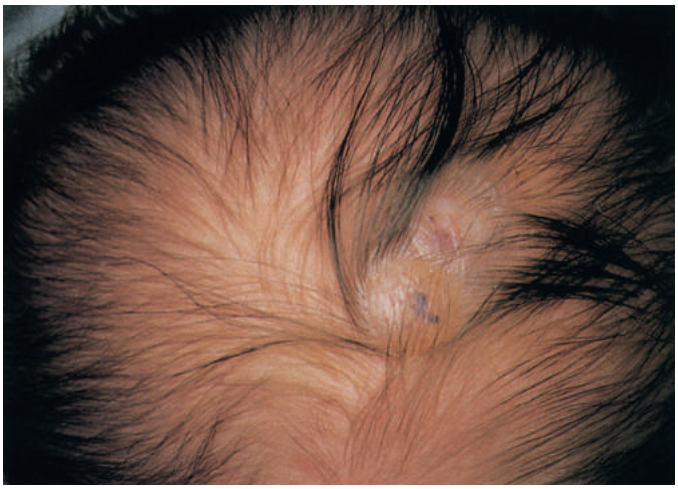
Aplasia Cutis Congenita

Clinical Findings

Aplasia cutis congenita (ACC) is a rare congenital skin defect that is localized and is most often seen on the scalp as an isolated lesion.[38] It presents with a localized loss of skin of variable thickness and is rarely associated with underlying skeletal abnormalities. Findings can include an open ulceration or a healed atrophic scar (Fig. 94.17). The clinical finding of a "hair collar sign" that presents as a ring of darker, longer hair surrounding the lesion represents an increased risk of an underlying neurodevelopmental abnormality.

Diagnosis

Diagnosis is clinical. Imaging of the central nervous system should be performed if a hair collar sign is present. Variants of ACC include focal dermal hypoplasia, or Goltz syndrome. Scalp ulcerations can be seen in infectious processes such as herpes simplex virus infection or can be due to perinatal trauma such as scalp



• **Fig. 94.17** Aplasia Cutis Congenita. Atrophic alopecia plaques at the vertex scalp.

electrode placement. Extensive ACC may be associated with limb hypoplasia (e.g., Adams-Oliver syndrome) or a variant of epidermolysis bullosa (e.g., congenital localized absence of skin, aka *Bart syndrome*).

Etiology

There are numerous theories regarding the cause of ACC. These include primarily intrauterine events such as intrauterine trauma, vascular abnormalities, intrauterine infection, and maternal medications.[39] No firm cause has been elucidated to date.

Treatment and Prognosis

The lesions of ACC will heal without intervention, but scarring will be present. Identification and management of the rare underlying neurodevelopmental abnormality are important aspects of care for these patients. In especially large lesions, surgical intervention may be required to close the defect. Scar revision can be performed later in life if desired.

Vascular Anomalies and Other Cutaneous Congenital Defects

DEEPTI GUPTA AND ROBERT SIDBURY

KEY POINTS

- Infantile hemangiomas (IHs) are the most common soft tissue tumor of infancy, with a reported incidence of 4% to 5% in mature newborns and up to 23% in extremely preterm infants.
- There is often parental concern regarding the risk of hemorrhage in IHs, but serious bleeding rarely occurs, and there is not a risk of coagulopathy or Kasabach-Merritt phenomenon.
- Propranolol is a nonselective beta blocker that was serendipitously discovered to effectively treat IHs.
- Port-wine stains can occur in isolation but also can be related to an underlying genetic disorder, of which *Sturge–Weber syndrome* is the most common. Laser therapy can yield remarkable improvement for many port-wine stains, minimizing the emotional pain that accompanies facial disfigurement.
- Localized areas of hypopigmentation on the skin of the newborn may be isolated phenomena, or they may be markers of extracutaneous abnormalities.
- Congenital melanocytic nevi are hamartomas derived from neural crest cells that form in utero and are often classified by the largest diameter of their adult projected size. The risk of melanoma in small and intermediate-sized nevi is low, but for large and giant congenital melanocytic nevi, the risk of melanoma is higher, ranging from 4.5% to 10%.

The spectrum of congenital cutaneous defects can be organized by the type of tissue or cell of origin or on the basis of their location within the skin. This chapter presents information on the most common and clinically significant vascular anomalies and other congenital cutaneous defects.

Vascular Anomalies

There has been long-standing confusion regarding the nomenclature and pathogenesis surrounding cutaneous vascular anomalies, which has led to delays in diagnosis and improper treatment and management. Terms such as *cavernous hemangioma* were used to describe both vascular tumors and vascular malformations, and terms such as *hemangioma* have been used indiscriminately to encompass various vascular tumors of differing behavior, prognosis, morphology, and treatment. A classification system for vascular anomalies was originally proposed by[1] and was most recently updated in 2015[2] by the International Society for the Study of Vascular Anomalies to allow more precise diagnosis, categorization, and management. Vascular anomalies can be largely divided into two groups—vascular tumors and vascular malformations—with a smaller third group of provisionally unclassified vascular anomalies (Table 95.1). Vascular tumors demonstrate cellular hyperplasia, while vascular malformations comprise a single malformed and dysplastic vessel or a combination of such vessels.[3,4] Vascular tumors can be further subdivided into benign, locally aggressive, and malignant tumors. Vascular malformations are subdivided into categories based on the predominant type of anomalous channel, arising either from a single abnormal channel type or a mixed malformation comprising a combination of capillary, venous, lymphatic, or arterial vessel involvement. Simple and combined vascular malformations can be further divided according to their flow characteristics. Vascular malformations can also be classified by their association with other clinical features or associated syndromes (Table 95.2). A complete list of the various vascular tumors and malformations is given in Table 95.1, with highlighting of the most common vascular anomalies described within the text.

Vascular Tumors

Infantile Hemangiomas

Infantile hemangiomas (IHs) are the most common soft tissue tumor of infancy. They have a reported incidence of 4% to 5%[5–7] in mature newborns, and incidence rates of up to 23% have been reported in preterm infants weighing less than 1000 g.[8] Infantile hemangiomas have a female (2.3 to 2.9 times higher) and white predominance.[9] The most significant risk factor for the development of IHs is low birth weight, with the risk increasing by 40% for every 500-g decrease in birth weight.[10] Additional risk factors include prematurity, multiple gestation, preeclampsia, placental abnormalities, advanced maternal age, and in vitro fertilization.[6,7]

Clinical Features

IHs have a characteristic and unique growth pattern that is similar in both full-term and premature infants. At birth, IHs are either absent or barely evident. Within the first few weeks after birth, a precursor lesion is present, which can appear as either a pale area of vasoconstriction or a telangiectatic red macule or a "bruise-like" area (Fig. 95.1). There is a short latency period of 1 to 3 weeks before initiation of a rapid proliferation phase in most hemangiomas. This rapid growth phase occurs within the first 3 months after birth, with most of the growth occurring between 5 and 8 weeks of

TABLE 95.1 Classification of Vascular Anomalies

Vascular Tumors	Vascular Malformations

Benign
• Infantile hemangioma/Hemangioma of infancy
• Congenital hemangioma
  • Rapidly involuting (RICH)[a]
  • Noninvoluting (NICH)
  • Partially involuting (PICH)
• Tufted angioma[a,b]
• Spindle-cell hemangioma
• Epithelioid hemangioma
• Pyogenic granuloma (aka lobular capillary hemangioma)
Others
• Hobnail hemangioma
• Microvenular hemangioma
• Anastomosing hemangioma
• Glomeruloid hemangioma
• Papillary hemangioma
• Intravascular papillary endothelial hyperplasia
• Cutaneous epithelioid angiomatous nodule
• Acquired elastotic hemangioma
• Littoral cell hemangioma of the spleen
Related lesions
• Eccrine angiomatous hamartoma
• Reactive angioendotheliomatosis
• Bacillary angiomatosis
Locally aggressive or borderline vascular tumors
• Kaposiform hemangioendothelioma[a,b]
• Retiform hemangioendothelioma
• Papillary intralymphatic angioendothelioma (PILA), Dabska tumor
• Composite hemangioendothelioma
• Pseudomyogenic hemangioendothelioma
• Polymorphous hemangioendothelioma
• Hemangioendothelioma not otherwise specified
• Kaposi sarcoma
• Others
Locally aggressive
• Kaposiform hemangioendothelioma (with or without Kasabach-Merritt phenomenon)[a,b]
• Retiform hemangioendothelioma
• Papillary intralymphatic angioendothelioma
• Kaposi sarcoma
Malignant vascular tumors
• Angiosarcoma
• Epithelioid hemangioendothelioma
• Others
	Simple
	• Capillary malformation
	• Venous malformation
	• Lymphatic malformation
	• Arteriovenous malformations
	• Arteriovenous fistula
	Mixed/combined malformation
	• Capillary-venous malformation
	• Capillary-lymphatic malformation
	• Capillary-arteriovenous malformation
	• Lymphatic-venous malformation
	• Capillary-lymphatic-venous malformation
	• Capillary-lymphatic-arteriovenous malformation
	• Capillary-venous-arteriovenous malformation
	• Capillary-lymphatic-venous-arteriovenous malformation

[a]May be associated with thrombocytopenia or consumptive coagulopathy.
[b]Expert consensus is that these lesions lie along a spectrum, rather than being distinct entities.
ISSVA Classification of Vascular Anomalies ©2018 International Society for the Study of Vascular Anomalies Available at https://www.issva.org/UserFiles/file/ISSVA-Classification-2018.pdf Accessed October 2022.

age.[11] It is important to note that up to 80% of IHs have completed their growth by 3 months of age. Their growth is also limited to increasing volume within a predefined area rather than exhibiting a true radial growth phase, which is seen more characteristically in other neoplasms.[12] After a more rapid growth phase, IHs can continue to grow more slowly up until 9 to 12 months of age. There is then an observed phase of relative stabilization followed by spontaneous regression. Regression of a hemangioma occurs slowly over many years, with approximately 90% regression noted by 4 years of age.[13] Clinical signs of regression include dulling of the bright red color to a more purple color and a central gray-white discoloration that spreads centrifugally. If the white discoloration occurs in infants younger than 3 months, it can sometimes be a marker of impending ulceration. Regression does not indicate complete resolution and normalization of the underlying skin in all cases. There can be remaining telangiectasias, anatomical distortion most notable in facial lesions, and permanent textural changes characterized by residual fibrofatty tissue and skin laxity because of loss of elastic

TABLE 95.2 Syndromes Associated With Vascular Malformations

Vascular Malformation Type	Associated Syndrome	Clinical Features	Other Features
Capillary malformation/ port-wine stain	Sturge-Weber syndrome	• Facial port-wine stain (often involving forehead or V1 distribution) • Ipsilateral eye abnormalities (choroidal vascular anomalies, increased ocular pressure, buphthalmos, glaucoma) • Leptomeningeal and brain abnormalities	Mutations in *GNAQ* in syndromic and nonsyndromic port-wine stains identified
	Nova syndrome	• Capillary malformation of the glabella • Neurologic malformations (Dandy–Walker malformation, hydrocephalus, cerebellar agenesis, mega cisterna magna)	
	Phakomatosis pigmentovascularis	Combination of cutaneous vascular and pigmentary abnormalities Classification into five subtypes: 1. Capillary malformation, epidermal nevus 2. Capillary malformation, dermal melanosis, with or without nevus anemicus 3. Capillary malformation, nevus spilus, with or without nevus anemicus 4. Capillary malformation, dermal melanosis, nevus spilus, with or without nevus anemicus 5. Cutis marmorata telangiectasia congenita, dermal melanosis	Phakomatosis pigmentovascularis has been associated with other vascular anomaly syndromes, including Sturge–Weber syndrome and Klippel-Trenaunay syndrome
	Beckwith–Wiedemann syndrome	• Prominent nevus simplex/capillary malformation of the philtrum and glabella • Hemihypertrophy • Visceromegaly • Macroglossia • Omphalocele	Intelligence is often not impaired. Overgrowth syndrome, therefore increased risk of Wilms tumor—screening is recommended.
	Macrocephaly–capillary malformation syndrome/ megalencephaly–capillary malformation–polymicrogyria syndrome	• Macrocephaly • Capillary malformation most prominent of the central face (philtrum and glabella) but can occur anywhere • Overgrowth of the body and brain (megalencephaly, hemihypertrophy) • Brain malformations (polymicrogyria, hydrocephalus) • Digital abnormalities (syndactyly, polydactyly) • Joint laxity	Overgrowth syndrome, therefore increased risk of Wilms tumor—screening is recommended. *AKT3, PIK3CA, PIK3R2* mutations detected. Developmental delay and seizures often occur.
Venous malformations	Blue rubber bleb nevus syndrome (Bean syndrome)	Multifocal venous malformations of the skin, mucosa, and gastrointestinal tract. Present as small black-blue papules and skin-colored nodules. Involvement of the palms and soles is common. Gastrointestinal bleeding is common.	Gastrointestinal bleeding is common and is a unique feature of blue rubber bleb nevus syndrome. Bleeding can result in chronic anemia and can require transfusions.
	Glomuvenous malformation syndrome	Small to large segmental venous malformations with cobblestoned appearance and bluish-purple color. Often painful to palpation.	Autosomal dominant inheritance or sporadic, mutations in glomulin gene (*GLMN*)
	Familial venous malformation cutaneous and mucosal	Small venous malformations mainly involving skin and mucosa but can also involve gastrointestinal tract, brain, and skeletal muscle. Usually asymptomatic.	Autosomal dominant inheritance. Often associated with *Tie2* mutation.
	Maffucci syndrome	• Venous malformation like skin nodules, rare presentation in infancy • Enchondromas, benign cartilage-forming tumors within the medullary cavity of the bone leading to bony distortion, fragility, and shortening of the affected limb. Hands and feet are involved 90% of the time.	Malignant transformation of the enchondromas can occur over time. Somatic mosaic mutations in *IDH1* and *IDH2* have been identified in cases.
	Cutis marmorata telangiectatica congenita	• Capillary malformation, reticulated, can have focal areas of atrophy and ulceration (see Fig. 95.34) • Limb asymmetry of affected limb	Other reported abnormalities: glaucoma and other ocular anomalies, cardiac defects, syndactyly, brain and spinal cord abnormalities
Lymphatic malformation	Gorham syndrome	• Multiple lymphatic malformations present in the bone, skin, and soft tissue • Progressive destruction of the bone associated with lymphatic malformation	

Continued

TABLE 95.2 Syndromes Associated With Vascular Malformations—cont'd

Vascular Malformation Type	Associated Syndrome	Clinical Features	Other Features
Arteriovenous malformation	Capillary malformation–arteriovenous malformation syndrome	• Multiple capillary malformations, congenital and acquired • Arteriovenous malformations of the central nervous system and soft tissues	Autosomal dominant Mutation in *RASA1*
	Cobb syndrome	• Spinal arteriovenous malformation • Vascular malformation of the skin (extremities or trunk)	
	Hereditary hemorrhagic telangiectasia	• Telangiectasias of the skin and mucosa • Epistaxis • Arteriovenous malformation of the lungs, brain, and liver	Autosomal dominant Infants with hereditary hemorrhagic telangiectasia can present with intracranial hemorrhage in the neonatal period
Vascular malformation and overgrowth syndromes	Beckwith-Wiedemann syndrome	• Prominent nevus simplex/capillary malformation of the philtrum and glabella • Hemihypertrophy • Visceromegaly • Macroglossia • Omphalocele	Intelligence is often not impaired. Overgrowth syndrome, therefore increased risk of Wilms tumor—screening is recommended.
	Macrocephaly–capillary malformation syndrome/ megalencephaly–capillary malformation–polymicrogyria syndrome	• Macrocephaly • Capillary malformation most prominent of the central face (philtrum and glabella) but can occur anywhere • Overgrowth of the body and brain (megalencephaly, hemihypertrophy) • Brain malformations (polymicrogyria, hydrocephalus) • Digital abnormalities (syndactyly, polydactyly) • Joint laxity	Overgrowth syndrome, therefore increased risk of Wilms tumor—screening is recommended. *AKT3, PIK3CA*, and *PIK3R2* mutations detected. Developmental delay and seizures often occur.
	Klippel-Trenaunay syndrome	• Combined slow-flow vascular malformation (capillary malformation, capillary malformation–venous malformation, capillary malformation–lymphatic malformation–venous malformation) in a characteristic geographic morphology • Venous varicosities • Overgrowth or undergrowth of the affected limb • Leg length discrepancy	At risk of coagulopathy, pulmonary embolism, contractures
	Parkes Weber syndrome	• Fast-flow vascular malformation (arteriovenous malformation) and arteriovenous shunts • Vascular stain • Overgrowth of the affected limb • Leg length discrepancy	Can occur as part of capillary malformation–arteriovenous malformation syndrome due to *RASA1* mutation, therefore family history should be obtained
	CLOVES syndrome	• Combined vascular malformation (capillary malformation, capillary malformation–lymphatic malformation–venous malformation, lymphatic malformation, arteriovenous malformation) • Epidermal nevus • Lipomas/truncal lipomatosis • Skeletal anomalies/scoliosis • Sandal gap deformity of toes	*PIK3CA* mutation. Risk of Wilms tumor.
	Proteus syndrome	• Slow-flow vascular malformation (capillary malformation, capillary malformation–lymphatic malformation–venous malformation, lymphatic malformation) • Connective tissue nevi	Growth is progressive
	PTEN hamartoma tumor syndrome (Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome)	• Vascular malformation (arteriovenous malformation, lymphatic malformation) • Epidermal nevus • Collagenomas • Lipomatosis	Segmental overgrowth. At risk of internal malignancies such as breast, thyroid, and endometrial cancers. Syndrome has characteristics of penile lentigines, developmental delay, and macrocephaly.

• **Fig. 95.1** A hemangioma precursor sign presenting as a pale vasoconstrictive halo surrounding two faint erythematous macules on the lumbosacral region of an infant.

• **Fig. 95.2** Infantile hemangioma with minimal or absent growth. A 4-month-old male with a reticulated vascular patch on the lower back.

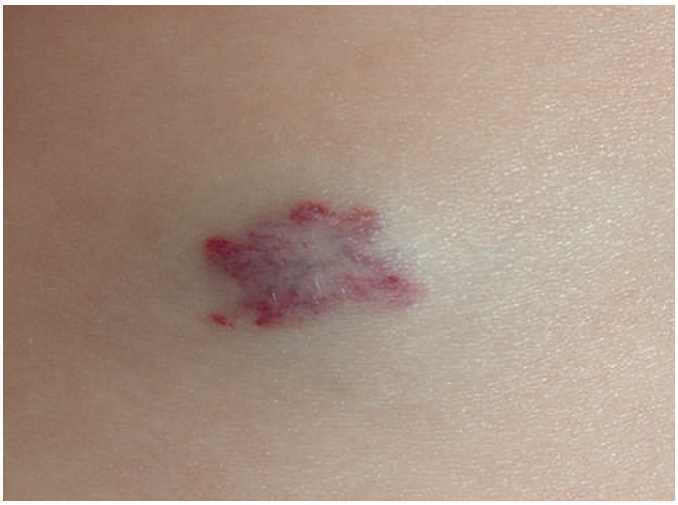
fibers causing fine wrinkling of tissue. Permanent scarring can also result from hemangiomas that were previously ulcerated.

While proliferation is often a key characteristic of IHs, it should not be considered an absolute defining feature. There is a unique subset of IHs known as *abortive hemangiomas* or *infantile hemangiomas with minimal or absent growth* in which the proliferation phase is absent (Fig. 95.2).[14] These hemangiomas present preferentially on the lower extremities and sometimes can be confused with capillary malformations (CMs). Although they lack the proliferation phase, they do spontaneously regress.

The clinical appearance of an infantile hemangioma is dictated by the depth of involvement, which can also lend itself to differences in the timing of growth. Superficial hemangiomas (Fig. 95.3) are located in the upper dermis and present as elevated bright-red, well-demarcated papules or plaques, which are sometimes in lay language referred to as *strawberry hemangiomas*. In their early proliferation phase, small bright-red papules can be seen arising from fine telangiectatic vessels, which can be a distinguishing feature between IHs and CMs that have a similar appearance in early

• **Fig. 95.3** Infantile hemangioma, superficial type, located on the upper arm of an infant.

• **Fig. 95.4** Infantile hemangioma, deep type, located on the lower back of an infant.



• **Fig. 95.5** Infantile hemangioma, mixed type, with both superficial and deep components.

infancy. Deep infantile hemangiomas (Fig. 95.4) are confined to the deep dermis and subcutis and present as bluish, dome-shaped tumors or nodules, with ill-defined borders. They can present in isolation or more commonly as a mixed infantile hemangioma (Fig. 95.5) with both superficial and deep components. The deep

component of IHs often has a distinct growth pattern in which they tend to appear later, around 2 to 3 months of age, and grow for a longer period, sometimes even over years, as compared with their superficial counterparts.[12,15] Hemangiomas are further characterized by their shape, pattern, and extent of involvement—whether focal or segmental. Focal hemangiomas seem to grow from a single point, whereas segmental hemangiomas are thought to arise from an embryonic developmental unit or placode and comprise a pattern on the skin correlating with these developmental units. Segmental hemangiomas are at risk of associated anomalies and syndromes. Large facial or scalp hemangiomas should be evaluated for the possibility of PHACE (*p*osterior fossa abnormalities, infantile *h*emangioma, *a*rterial abnormalities, *c*oarctation of the aorta, *e*ye abnormalities) syndrome, which can also have associated midline defects such as supraumbilical raphe and sternal cleft abnormalities and therefore are sometimes referred to as *PHACES*. Perineal hemangiomas or segmental hemangiomas in the lumbosacral area should be evaluated for the possibility of underlying spinal and genitourinary abnormalities with possible LUMBAR (*l*ower body hemangioma, *u*rogenital abnormalities, *u*lceration, *m*yelopathy, *b*ony deformities, *a*norectal malformations, and *r*enal abnormalities) syndrome, also known as *SACRAL* (*s*pinal dysraphism, *a*nogenital abnormalities, *c*utaneous, *r*enal and urologic abnormalities, associated with *a*ngioma of the *l*umbosacral localization) or *PELVIS* (*p*erineal hemangioma, *e*xternal genitalia malformations, *l*ipomyelomeningocele, *v*esicorenal abnormalities, *i*mperforate anus, and *s*kin tag) syndrome. Segmental hemangiomas, like deep IHs, can sometimes have a prolonged growth phase, which in rare cases may last for years.

There is often parental concern regarding the risk of hemorrhage in IHs, and parents should be reassured that serious bleeding rarely occurs. Coagulopathy and risk of Kasabach-Merritt phenomenon (KMP) was originally thought to be associated with large infantile hemangioma, but it has been shown that KMP does not occur with IHs and is seen only with other vascular tumors, such as tufted angiomas and kaposiform hemangioendotheliomas.[16]

Pathogenesis

IHs form as a result of dysregulation of both vasculogenesis and angiogenesis. There are many proposed theories as to the trigger that initiates this dysregulation, without any one unifying cause, but it is likely that hypoxia plays an important role. There is strong evidence in support of IHs being derived from endothelial stem and progenitor cells.[17] Isolation of $CD133^+$ endothelial progenitor cells from infantile hemangioma tissue and injection of these progenitor cells into nude mice lead to formation of tumors with the unique immunohistochemical and growth characteristics of IHs.[17] The endothelial cells that were isolated from IHs were also found to be clonal in nature, suggesting that these tumors were caused by a somatic mutation in one or more genes regulating endothelial cell proliferation.[18] The endothelial cells in infantile hemangioma express a unique phenotype of cell surface markers with positive staining for glucose transporter 1 (GLUT1), merosin, and antigen Lewis Y, which is also expressed by placental endothelial cells, but are not present in any other tumor or vascular malformation.[19] Histologically, IHs have increased cellularity and form small sinusoidal vascular channels. It has been suggested that IHs may result from ectopic placental tissue given the similarity in their endothelial cell profiles and the fact that the placenta and IHs share a similar life cycle.[20] Further evidence suggestive of this link relates to the increased risk of development of IHs in low birth weight infants—particularly those whose mothers had preeclampsia or placenta previa, both of which are associated with placental hypoxia. Hypoxia likely plays a large role in the development of IHs and is thought to be an important triggering signal for their development,[21,22] with in utero hypoxia as a risk factor for localized hemangiomas and regional hypoxia from arterial abnormalities as a risk factor for segmental hemangiomas. It is likely that this hypoxic stress acts as a triggering signal and leads to overexpression of vascular endothelial growth factor via the hypoxia-inducible factor α pathway, which then leads to proliferation of $CD133^+$ endothelial progenitor cells that are present in fetal tissue and causes them to differentiate into immature endothelial cells, along with pericytes, dendritic cells, and mesenchymal cells with adipogenetic potential. The adipogenetic potential may play a role during regression—when blood vessels are replaced with fibrofatty tissue. During the involution phase, endothelial cells are also noted to express caspases, which are known markers of apoptosis.

Diagnosis

In most cases, a hemangioma can be diagnosed by its clinical appearance and characteristic pattern of evolution. A lesion that deviates from this typical picture presents a diagnostic dilemma. Doppler ultrasound examination can be easily performed and may be helpful in distinguishing between an infantile hemangioma and low-flow malformation or nonvascular tumor. Other imaging modalities—magnetic resonance imaging (MRI) or angiography—may be indicated for large or obstructive lesions (e.g., ocular, upper airway) to help define the extent of involvement or associated abnormalities (e.g., PHACE or LUMBAR syndrome).[9,23] Skin biopsy is diagnostic for nonvascular tumors, which can mimic vascular birthmarks (e.g., pilomatricoma, juvenile xanthogranuloma [JXG], Langerhans cell histiocytosis, infantile myofibromatosis, rhabdomyosarcoma). IHs can also be differentiated from other vascular tumors by staining with GLUT1, an immunohistochemical marker that is highly selective and specific for IHs. GLUT1 is also expressed at the blood–brain barrier and in placental tissue but has not been found in any other vascular tumors, including congenital hemangiomas. Its discovery has helped in making the correct diagnosis of these vascular tumors, especially in cases with atypical presentations.[20] It should be noted that congenital hemangiomas (NICH, RICH, PICH) are Glut-1 negative.

Complications

While the majority of IHs are uncomplicated and spontaneously regress without any need for intervention, in approximately 10% to 15% of cases, complications can arise requiring treatment.

• **Fig. 95.6** Painful ulcerated infantile hemangioma on the neck.

• **Fig. 95.7** Nasal tip infantile hemangioma with both superficial and deep components. Nasal tip hemangiomas are at high risk of causing disfigurement.

Local Complications

Ulceration. Ulceration is the most common complication observed in IHs and can be seen in up to 30% of cases (Fig. 95.6).[24] It can cause significant pain and discomfort and permanent scarring in the area of ulceration. Ulceration has been described to be more likely to occur during two points during the life cycle of the hemangioma: either just before the rapid proliferation phase, which can be the presenting sign of the hemangioma, or at the end of the growth phase (usually around 4 months of age). The exact mechanism causing ulceration is unknown but is thought to be related to tissue hypoxia, with the tumor outgrowing its blood supply.[25] Ulceration is more commonly seen in large hemangiomas, those with segmental distribution, and those with mixed morphology with both superficial and deep components.[25–27] Areas of friction or those exposed to moisture for a long time, such as the lower lip, neck, intertriginous areas, and anogenital and diaper region, are at high risk of ulceration. Nearly one-third of all ulcerated hemangiomas are found in the diaper region.[28] Various treatment modalities have been shown to be effective in treating ulcerated hemangiomas, but all ulcerated hemangiomas benefit from local wound care, and combination therapy is more effective than monotherapy.[29] Treatment options included topically administered brimonidine, 0.2% or timolol, 0.5%, topical antibiotics with mupirocin or metronidazole, pulsed dye laser treatment, and systemic therapy with propranolol. Topical analgesics can also be useful to minimize pain and discomfort.[30]

Disfigurement. In addition to the transient disfigurement (hemangiomas located on the central face), large hemangiomas, and those with a significant superficial component, can predispose the affected child to permanent scarring. IHs involving the nasal tip are at risk of a bulbous nasal tip or a "Cyrano" deformity (Fig. 95.7). This is caused by splaying of the alar cartilage during the proliferative growth phase. Early intervention with initiation of propranolol therapy can preserve the contour of the nose.[31] If a persistent deformity develops, surgical debulking may be needed. Similarly, IHs located on the lip are at risk of deformity and disruption of the natural contours of the lips, in addition to being at high risk of ulceration and permanent scarring (Fig. 95.8).[32] Large hemangiomas of the central chest or hemangiomas involving the breast tissue in females can also be quite disfiguring, leading to permanent breast hypoplasia in some cases (Fig. 95.9).[33]

• **Fig. 95.8** Partial segmental infantile hemangioma of the lip and nose with ulceration of the lip.

Disfigurement alone, regardless of threat to function, is a reasonable indication for medical therapy in certain cases, and should be considered. Regression of hemangiomas does not always ensure complete normalization of the underlying skin and therefore can lead to lifelong psychosocial and emotional sequelae experienced by both the family and the patient.[34]

Functional Complications

Periocular Hemangiomas. Hemangiomas located on the lid or around the orbit are at risk of causing visual impairment and can lead to amblyopia in severe cases. Amblyopia can be caused by direct pressure on the globe, causing astigmatism or myopia, or because of the size of the hemangioma there can be visual axis obstruction or strabismus.[35] Larger and segmental hemangiomas in the periorbital area pose the greatest risk of ocular

complications. Deep retrobulbar IHs may present with proptosis and can also cause strabismus and visual acuity changes. Deep and mixed infant hemangiomas can also cause tear duct obstruction and exposure keratopathy. Aggressive and early initiation of treatment along with evaluation by a pediatric ophthalmologist can help prevent some of these complications.[36,37] Further imaging, such as MRI, may be needed to assess the extent of the hemangioma or the presence of a deeper component.

Auricular Hemangiomas. With infantile hemangiomas of the ear there is high risk of physical deformity of the ear, cartilage destruction, ulceration, potential infection when ulceration is present, and potential hearing alterations. Segmental hemangiomas in this region have a higher rate of complications, and with them there can also be a risk of sensorineural and conductive hearing loss.

Potential Life-Threatening Complications

Airway Hemangiomas. Airway obstruction by an infantile hemangioma is a life-threatening complication that requires immediate evaluation and treatment. Airway hemangiomas can occur with or without the presence of cutaneous IHs. The highest risk occurs with hemangiomas located in a "beard distribution" specifically involving the left or right preauricular areas, chin, lower lip, and anterior part of the neck.[38] Involvement with IHs at four or more of these sites is associated with a 63% risk of a symptomatic airway hemangioma. A greater number of lesions in the beard distribution leads to a higher risk of airway involvement. Segmental hemangiomas involving facial segment 3 have a 29% risk of airway involvement. Clinically, airway hemangiomas present most commonly between 6 and 12 weeks of age with biphasic stridor or a hoarse, croup-like cry. The subglottis is the most common site of involvement, but the oral cavity, oropharynx, hypopharynx, larynx, and upper trachea can also be involved. Referral to a pediatric otolaryngologist is important for evaluation of the airway, and systemic treatment should be started immediately.[39] Treatment of airway hemangiomas may require a combination of multiple medical and surgical treatments depending on the extent of involvement, which may include propranolol, oral and intralesional corticosteroids, vincristine, interferon alpha, surgical excision, and laser therapy.

Hepatic Hemangiomas. The presence of an IH in the liver can lead to potential serious complications such as congestive heart failure and consumptive hypothyroidism. Individuals with five or more cutaneous IHs (Fig. 95.10) of any size and in any location should be screened for the possibility of hepatic IH.[40] This study showed that in patients with five or more cutaneous hemangiomas, 16% of them had evidence of a hepatic hemangioma versus none in the group with fewer than five cutaneous hemangiomas. Individuals with large or segmental IHs do not seem to be at greater risk of hepatic IHs.[41,42]

Parotid Hemangiomas. Parotid hemangiomas can be isolated to the parotid gland or can be present as part of a segmental IH in the maxillary distribution of facial segment 3. Parotid hemangiomas have a unique pattern of growth as they can have a longer proliferative growth phase than typical IHs. This can lead to longer treatment courses.[15] They have also been associated with functional complications relating to deformity of adjacent structures such as the ear and lip and conductive hearing loss caused by narrowing of the external auditory canal. Life-threatening complications can also arise, including an association with subglottic hemangiomas and, less commonly, congestive heart failure and consumptive hypothyroidism.[43,44]

Treatment

Most IHs are uncomplicated and spontaneously regress, but there is a subset of approximately 10% to 15% of IHs that result in complications requiring treatment.[27,45] Treatment is indicated in cases complicated by disfigurement or risk of disfigurement, ulceration, or functional compromise. There are various treatment modalities, including topical or systemic medications, surgery, or laser therapy, that are chosen on the basis of various factors, including the stage of growth, location, potential complications, and associated conditions. The various treatment modalities are outlined in the following sections. In general, pharmacologic treatment is the first-line treatment, with surgical and laser therapies being considered as adjunctive or second-line treatment following medical interventions.

Active Nonintervention. For most lesions the initial treatment of choice is "active nonintervention." This is reserved for hemangiomas that are not at risk of causing disfigurement, ulceration, or causing any functional impairment. These often tend to be small focal hemangiomas in nonfacial locations. Anticipatory guidance should be discussed with the family in regard to the natural course of IHs: the initial period of rapid growth in the first few months of life and the slow rate of involution over many years.

• **Fig. 95.9** Infantile hemangioma of the breast involving the nipple and areola.

• **Fig. 95.10** Diffuse hemangiomatosis presenting with multifocal infantile hemangiomas on the skin and in the liver.

Demonstration of before-and-after photographs of growing and involuted hemangiomas in other children can help demonstrate the natural course and diminish parental concern. There is also a common concern of risk of significant hemorrhage. This is rare in IHs. Minor episodes of bleeding can result from trauma and, like any superficial wound, respond to short-term compression.

Although the large majority of IHs do not require treatment and spontaneously regress, the disfigurement associated with the residua of IHs should not be underestimated, and treatment should be considered on the basis of the location and size of the infantile hemangioma. Up to 40% of hemangiomas leave permanent skin changes that can be disfiguring.[46] Psychological and social problems may result from facial or other visible deformities. A small study found that patients with untreated involuted facial hemangiomas had higher levels of social anxiety and decreased social initiative as compared with children with treated facial IHs.[47] Therefore, early intervention should be considered for lesions with a higher potential for complications.

Topical Therapies. Topically administered timolol maleate is a nonselective β-adrenergic receptor blocker that was first reported to be used in IHs in 2010 and has been shown to be most effective for superficial and thin hemangiomas.[48] It is approved for use in pediatric glaucoma, but its use topically on the surface of the IHs is off-label. The preferred formulation is timolol gel forming solution, 0.5%. In general, timolol is well tolerated, without significant systemic side effects. However, a recent prospective study showed systemic absorption with use of one drop twice a day—although the concentrations detected were below 0.2 ng/mL, which is below the level at which systemic effects may begin to be seen.[49] Caution should be used in preterm infants with postmenstrual age less than 44 weeks and low birth weight infants weighing less than 2500 g at the time of initiation of treatment, as there have been a few case reports of symptomatic bradycardia in this group.[50] However, in these reported cases, the doses of timolol being used exceeded 0.2 ng/mL, and the treatment areas had variable or increased absorption (e.g., thin-skinned areas such as eyelids, mucosal surfaces, and ulcerated sites). Absorption within mucosal sites and ulcerated hemangiomas is variable, and therefore caution should be used, but there have been reports of use in these areas without any adverse side effects.[51] A recent randomized controlled trial showed that timolol, though well tolerated, did not differ from placebo at 24 weeks in terms of complete or nearly complete hemangioma resolution.[52]

Systemic Therapies

Propranolol. Propranolol is a nonselective β-adrenergic receptor blocker that in 2008 was discovered by chance to treat IHs.[53,54] It had been used at higher doses in children with cardiac disease for many decades previously. In 2014, Hemangeol (propranolol hydrochloride, Pierre Fabre, Parsippany, New Jersey, United States) was approved by the U.S. Food and Drug Administration as the only approved systemic treatment for IHs, and propranolol become first-line systemic treatment for IHs. The dosages for IHs range from 1 to 4 mg/kg per day in divided doses (two or three times daily), with a 98% response rate at a mean dosage of 2.1 mg/kg per day.[55] There have now been three randomized controlled trials[53,56,57] examining the efficacy of propranolol for IHs, with the largest trial showing the highest efficacy at dosages of 3 mg/kg per day for a 6-month course.[53] Despite this, most practitioners use maintenance dosages of 2 mg/kg per day because dosing regimens of more than 2 mg/kg per day did not show a significant increase in effect but did show an increase in the rate of adverse events.[58] The most common adverse side effects of the medication reported are gastrointestinal disturbance, sleep disturbance, and acrocyanosis. These side effects were overall mild and reversible. Serious adverse effects such as symptomatic hypotension, hypoglycemia, bradycardia, and bronchospasm occurred infrequently and, in a randomized control trial, were reported at a similar frequency in the placebo group.[53] Once the medication is discontinued, rebound growth can occur, but this was more likely if the hemangioma was treated for less than 9 months versus a course of 12 to 15 months.[59]

Corticosteroids. Oral corticosteroids were the first-line treatment before the discovery of propranolol. Prednisone or prednisolone dosages of 2 to 5 mg/kg per day were used, with the most optimal effects reported at a dosage of around 3 mg/kg per day.[9,27] Within 1 to 2 weeks, 30% of hemangiomas would show a dramatic response, but 40% would respond equivocally. Many side effects were noted in these patients, most notably cushingoid appearance, gastroesophageal reflux, insomnia, irritability, transient growth retardation, hyperglycemia, and, rarely, adrenal insufficiency, hypertension, and osteoporosis. Studies comparing propranolol with oral corticosteroids showed that clinical response to propranolol was more rapid and effective, with need for fewer surgical interventions, and that, overall, propranolol was better tolerated.[60] Corticosteroids as a monotherapy are no longer used for IHs but rather are now reserved for complex and refractory cases and can be used in conjunction with propranolol or other therapies.[61]

Intralesional corticosteroid injections may be used in small, localized hemangiomas in cosmetically sensitive areas with high rates of morbidity such as the lip, nasal tip, and eyelid.[62,63] This can be used as a therapy adjuvant to other topical or systemic treatments. Complications include cutaneous atrophy, skin necrosis, and, for intralesional periocular injections, ophthalmic artery occlusion and blindness. Thus, periocular intralesional steroid injection should be performed only by experienced pediatric ophthalmologists.

Other Therapies. Historically, interferon alpha and vincristine were used with variable effect for treatment of IHs. These therapies have potential adverse effects and are now reserved only for refractory lesions.[64–66] Orally administered sirolimus, a mammalian target of rapamycin (mTOR) inhibitor, has now been considered in a few such cases.[67]

Surgical Therapies

Laser Therapy. Pulsed dye laser treatment has been used in various settings with IHs. There have been some controversial data regarding its use as a monotherapy for uncomplicated hemangiomas, and it seems to be more efficacious when used in conjunction with propranolol or timolol.[68] It has also been used to heal ulcerations[69] and to decrease residual erythema and telangiectasias in an involuting hemangioma. However, a randomized prospective controlled trial of 121 infants found that pulsed dye laser treatment in uncomplicated hemangiomas is no better than watchful waiting.[70] Pulsed dye laser treatment cannot prevent the preprogrammed growth pattern of hemangiomas and has a limited role during the proliferative phase. One risk of laser use during the proliferative phase can be ulceration. In contrast, it can be useful during involution, if there is residual redness or telangiectasias, which may be resolved faster than with the natural course of involution but has no effect on fibrofatty residuum.

Surgical Excision. Surgical excision can be done in cases of medically refractory hemangiomas that are symptomatic and proliferating, in an emergency situation where there is life-threatening functional compromise, or in situations with recurrent profuse bleeding. It may also be beneficial in situations where there is a large disfiguring pedunculated lesion that will leave behind significant fibrofatty residual or scar.

Wound Care. Ulceration is a therapeutic challenge, but all ulcers benefit from local wound care and potential occlusive dressings. The type of dressing chosen depends on the amount

of exudate and on the location of ulceration. For sites that are difficult to dress, for example the diaper area, frequent and liberal application of petrolatum jelly is effective. Various dressing materials, including petrolatum-impregnated gauze and seaweed-derived alginate dressings, are often recommended. Off-label use of becaplermin gel, a recombinant human platelet-derived growth factor, has reportedly shown dramatic healing in a small case series. The product now carries a warning from the Food and Drug Administration, which must be taken into consideration before its use.[71,72] Agents for pain control should be considered, including topical anesthetics (being mindful of the percentage of body surface area covered) and oral analgesics such as acetaminophen or ibuprofen. A high index of suspicion should be maintained for secondary infection, with appropriate use of topical or oral antibiotics as needed. If conservative therapy is unsuccessful, pulsed dye laser treatment may relieve pain and speed reepithelialization.[26,73,74] The ulcers will heal but will inevitably leave scars.

Work-Up and Associations. A complete list of associations and the work-up needed for specific hemangiomas on the basis of their size and location is given in Table 95.3. Here we will highlight a few other special circumstances.

Visceral Involvement/Hepatic Hemangiomas. Diffuse neonatal hemangiomatosis (see Fig. 95.10) manifests itself as widely scattered, small superficial hemangiomas. Infants with this pattern of cutaneous involvement may have lesions limited to the skin, known as *benign neonatal hemangiomatosis*. However, associated hemangiomatosis of the liver, gastrointestinal tract, lungs, and/or central nervous system (CNS) can be complicated by visceral hemorrhage, hepatomegaly, high-output cardiac failure, or unexplained anemia or thrombocytopenia, with a significant mortality rate.[75] Congestive heart failure can also occur with a large, isolated hepatic hemangioma.[27]

Segmental Hemangiomas

PHACE Syndrome. PHACE syndrome is characterized by a large (>5 cm) segmental hemangioma of the face, scalp, or neck with associated anomalies and developmental defects.[76] The acronym PHACE is used to describe the constellation of anomalies related to this syndrome: posterior fossa malformations, hemangioma, arterial anomalies, cardiac anomalies/coarctation of the aorta, and eye abnormalities. Midline defects such as sternal cleft and supraumbilical raphe can also be seen, and therefore sometimes this disorder is referred to as *PHACES*. The diagnostic criteria for PHACE syndrome were formalized by a consensus panel, and clinical features were grouped into major criteria. Definitive diagnosis of PHACE syndrome requires a facial segmental IH or an IH larger than 5 cm on the face or scalp in addition to one major or two minor criteria.[77] This was revised in 2016 to also include a segmental hemangioma of the neck, upper trunk, or trunk and proximal upper extremity plus two major criteria.[78] The exact incidence of PHACE syndrome is unknown, but it may be more common than Sturge-Weber syndrome (SWS).[79] There is a striking female predominance in PHACE syndrome, with a female-to-male ratio of 9:1. A prospective study for PHACE syndrome found that 31% of infants with facial IHs with a surface area of 22 cm^2 or greater met the PHACE diagnostic criteria, which is based on expert consensus, and approximately 90% of affected infants had more than one extracutaneous finding.[80] Children with frontotemporal and frontonasal IHs (known as segments 1 and 4) have a higher correlation with structural cerebral and cerebrovascular anomalies. Those with mandibular (segment 3) or beard distribution lesions are at higher risk of cardiac abnormalities and IHs in the airway.[81] The maxillary face (segment 2) appears to be a lower-risk segment for association with PHACE syndrome. The most common and potentially devastating sequelae of PHACE

TABLE 95.3 Indications for Work-Up of Extracutaneous Anomalies Associated With Infantile Hemangiomas

Clinical Presentation of Hemangioma	Association	Evaluation
Large facial hemangioma/segmental facial hemangioma >5 cm	PHACE syndrome	MRI/MRA of the brain and neck, echocardiogram, ophthalmology evaluation
Multifocal hemangiomas ≥5 cm	Extracutaneous hemangiomas, especially hepatic hemangiomas	Abdominal ultrasound examination with Doppler imaging
Periocular hemangioma	Ocular complications	Ophthalmology evaluation
Parotid hemangioma	Consumptive hypothyroidism, congestive heart failure, airway hemangioma	
Lumbosacral hemangioma >2.5 cm	LUMBAR syndrome	MRI of lumbar spine and pelvis, neurosurgical evaluation
Large lower trunk or lower extremity hemangioma	PELVIS syndrome	MRI of lumbar spine and pelvis, neurosurgical evaluation, urologic evaluation
Beard distribution hemangiomas	Evaluation for respiratory distress	Otolaryngology evaluation and MRI of the neck
Breast hemangioma/large segmental chest hemangioma	Breast hypoplasia	Consider systemic treatment
Midline hemangiomas (with other cutaneous markers)	Spinal dysraphism	Spinal ultrasound examination at <3 months of age, MRI of the spine
Segmental proximal upper extremity hemangioma with extension onto the chest	PHACE syndrome or cardiac abnormality	Echocardiogram

MRA, Magnetic resonance angiography; *MRI*, magnetic resonance imaging.

syndrome are neurologic, including structural brain anomalies and abnormalities of cerebral vasculature. Progressive stenoses and occlusions of cerebral arteries can also be seen. Both moyamoya-like vasculopathy and arterial ischemic strokes have been reported.[82,83] Other comorbidities have recently been reported in patients with PHACE syndrome, including headaches, endocrine abnormalities, hearing abnormalities, speech delay, dysphagia, and dental anomalies.[78]

Because of the associated anomalies, patients suspected of having PHACE syndrome require the following:

- Echocardiogram to assess the patient for coarctation of the aorta or other structural cardiac abnormalities with possible cardiac MRI/magnetic resonance angiography (MRA) if the echocardiogram is abnormal
- MRI with contrast medium and MRA of the head and neck evaluating the patient for cerebrovascular and structural anomalies
- Ophthalmology examination of the retina
- Complete physical examination with particular focus on ventral midline defects
- Additional studies as indicated on the basis of signs and symptoms

Lumbar/Sacral/Pelvis Syndrome. Similarly to PHACE syndrome, large hemangiomas of the lower body may be associated with underlying structural abnormalities. Sacral and lumbar hemangiomas may reveal spinal dysraphism, including tethered spinal cord, lipomyelomeningocele, imperforate anus, renal anomalies, or abnormal external genitalia.[84–87] Many acronyms have been coined, all describing a similar entity of a segmental hemangioma in the lumbosacral or perineal region with associated regional abnormalities. These include LUMBAR, SACRAL, and PELVIS.[88–90]

Exact diagnostic criteria have not yet been defined, but IHs in the lumbosacral or perineal area that are large, midline, segmental, or present with other cutaneous markers (i.e., lipoma, gluteal cleft deviation, skin tag, aplasia cutis) should be screened for underlying abnormalities. One prospective study noted that 35% of patients with lumbosacral hemangiomas larger than 2.5 cm had evidence of spinal dysraphism on MRI.[91] Segmental hemangiomas in the lumbosacral region typically present with minimal or absent growth and persist as a patch with coarse telangiectasias, which can lead to delays in diagnosis. These are also at high risk of ulceration.

Congenital Hemangiomas. Congenital hemangiomas are an uncommon and distinct type of vascular proliferation that are fully formed at birth. They do not undergo the characteristic proliferative growth pattern in postnatal life as seen with IHs, but rather their proliferative phase occurs in utero. They are also GLUT1 negative, unlike IHs. Congenital hemangiomas can be divided into three major subtypes of rapidly involuting congenital hemangiomas (RICHs), noninvoluting congenital hemangiomas (NICH), and partially involuting congenital hemangiomas (PICHs) on the basis of their clinical progression. Congenital hemangiomas are usually solitary in nature and are more common on the extremities and head and neck.[92]

Rapidly Involuting Congenital Hemangiomas. RICHs can present clinically in three distinct ways: (1) a raised violaceous tumor with prominent peripheral vasculature, (2) a raised tumor with coarse overlying telangiectasias with a peripheral halo of vasoconstriction or pallor, or (3) a pink-purple tumor with deep infiltrative nodules. There can sometimes be overlying hypertrichosis.[93] Rapid involution often begins in the first few weeks of life and is completed by 14 months of age. After involution there may be some residual atrophy, telangiectasias, persistent and prominent vessels, or milia present. There is a rare subtype of RICH where complete involution occurs in utero called *RICH fetal involution type*. Complications of RICHs are that they can undergo ulceration and bleeding shortly after birth, which can be painful and leave a permanent scar in the area of ulceration. There have also been reports of transient coagulopathy with thrombocytopenia occurring. The decrease in platelet count is brief and not progressive as seen in KMP. The presence of this phenomenon can lead to misdiagnosis of RICH with tumors associated with KMP, such as tufted angiomas and kaposiform hemangioendothelioma, and, therefore, biopsy may be required to confirm the diagnosis.

Noninvoluting Congenital Hemangiomas. NICHs (Fig. 95.11) present as vascular patches, plaques, or nodules with blue or pink-purple color with overlying coarse telangiectasias and peripheral rim of pallor and vasoconstriction.[94] They persist over time and grow proportionally with the child, without spontaneous regression. Some can become more protuberant or develop an increase in draining veins over time. Symptoms may develop during pregnancy or puberty, most notably that of pain.[94]

Partially Involuting Congenital Hemangiomas. There is a small subset of congenital hemangiomas that begin a phase of involution that lasts until 12 to 30 months of age, at which time the involution halts.[95] The residual vascular lesion then persists lifelong morphologically, resembling a NICH. There have been no reported complications in patients with PICH. The existence of PICH suggests that all congenital hemangiomas may exist along a spectrum.

Kaposiform Hemangioendotheliomas and Tufted Angiomas. Kaposiform hemangioendotheliomas (KHEs) and tufted angiomas are rare vascular tumors with locally aggressive and benign growth potential, respectively. They are thought to exist along a spectrum and are associated with life-threatening KMP. KMP is a profound and life-threatening thrombocytopenia that results from intralesional platelet trapping with a consumptive coagulopathy evidenced by elevation of D-dimer levels, reduction in fibrinogen levels, and prolongation of prothrombin time and partial thromboplastin time. The severity of the coagulopathy is variable.

Tufted angiomas (Fig. 95.12) typically present in infancy or early childhood as a solitary dusky erythematous indurated vascular plaque with overlying hypertrichosis, hyperpigmentation, and/or telangiectasias.[96,97] Tufted angiomas tend to not be as aggressive and do not have as deep an infiltration as their counterpart kaposiform hemangioma. Spontaneous regression has been reported in some congenital cases or cases with earlier onset.[98]

• **Fig. 95.11** Noninvoluting congenital hemangioma presenting as an unchanged vascular plaque in a 1-year-old. There are coarse telangiectasias with a blue background and surrounding vasoconstrictive halo.

KHE presents as a solitary ill-defined red-purple plaque during infancy or early childhood. It can extend to involve the viscera, chest wall, and retroperitoneum and may present without cutaneous findings. KHE is more commonly seen in neonates and infants, as compared with older children, and may be associated with an increased risk of KMP.[99] Treatment can be either medical or surgical. A recent randomized controlled trial showed that sirolimus plus prednisolone was superior to sirolimus monotherapy for KHE complicated by Kasabach-Merritt phenomenon.[100]

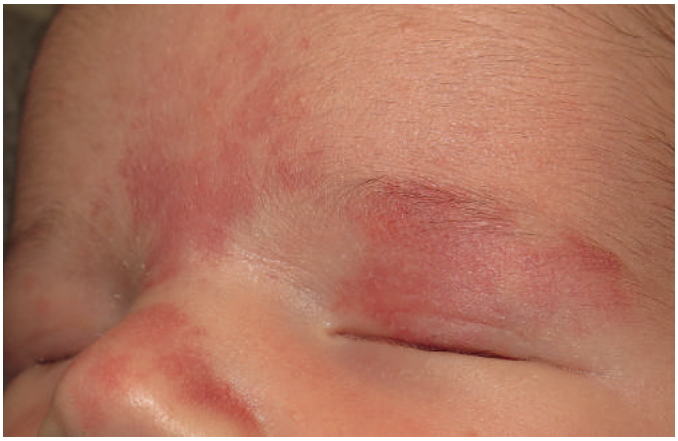
Pyogenic Granulomas. Pyogenic granulomas, also known as *lobular capillary hemangiomas* because of their histologic appearance, are benign acquired vascular tumors that are commonly seen in infants and children (Fig. 95.13).[101] They have also been seen to develop within an existing port-wine stain. They present clinically as a rapidly growing solitary, red papule that can sometimes be exophytic or pedunculated in nature. They often present with a crusted or eroded surface because of their friable nature. They do not spontaneous involute, and treatment is often pursued because of recurrent episodes of bleeding and their friability. Treatment options include simple curettage or shave excision with electrocautery of the base, which is most definitive and curative. Other treatment options include topical therapies, such as topically administered timolol therapy, a beta blocker, imiquimod therapy, or pulsed dye laser treatment, which have variable success with prolonged treatment courses. Recurrence is possible.

Vascular Malformations

Nevus Simplex

Nevus simplex, also known as a *salmon patch* or *fading capillary stain* and colloquially referred to as *angel's kiss* when it occurs on the forehead or eyelids and as *stork bite* when it occurs on the nape of the neck, is a very common capillary malformation that almost always spontaneously fades by 1 to 2 years of age (Fig. 95.14), although some malformations persist, most notably those at the nape of the neck (Fig. 95.15). It typically presents as a bilateral and symmetric faint pink patch with a feathery border and a midline predilection and most commonly occurs on the central forehead, glabella, upper eyelids, nose, upper lip, nape of the neck, posterior occiput, and the lower back. Nevus simplex located at the midline in the lumbosacral area is usually a benign finding in isolation and not associated with underlying spinal dysraphism, but if there are any other cutaneous findings in this area (i.e., lipoma, hypertrichosis, faun tail, aplasia cutis) or abnormalities noted (i.e., gluteal cleft deformity), then further work-up is

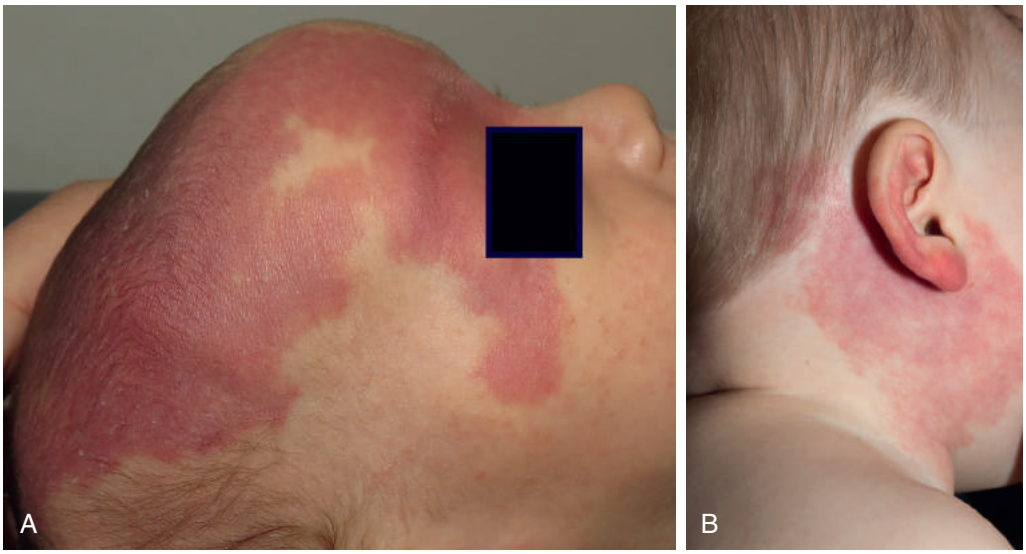
• **Fig. 95.12** Tufted angioma without Kasabach–Merritt phenomenon on the foot of a 4-month-old child. This was confirmed by biopsy.



• **Fig. 95.14** Nevus simplex on the glabella, nose, and eyelids of a newborn presenting as faint pink patches with feathery borders.

• **Fig. 95.13** Pyogenic granuloma on the cheek of an 8-month-old infant presenting as a bright-red glistening papule.

• **Fig. 95.15** Nevus simplex on the posterior occiput. Nevus simplex in this location can often persist.



• **Fig. 95.16** (A) Port-wine stain of the periocular area, forehead, and scalp. (B) Port-wine stain involving the posterior auricular scalp, neck, cheek, and ear.

warranted. Prominent and persistent nevus simplex can be associated with underlying syndromes such as Beckwith–Wiedemann syndrome, macrocephaly–capillary malformation syndrome, and Nova syndrome (see Table 95.2).[102]

Capillary Malformation (Port-Wine Stain)

The terms *capillary malformation* and *port-wine stain* are used synonymously in the literature and refer to collections of malformed and ectatic dermal capillaries that persist over time (Fig. 95.16). They are present at birth and occur in 0.3% of neonates. They present as fairly well-demarcated red or pink patches that are often asymmetric, occur anywhere on the body, and may or may not be associated with localized overgrowth. They grow proportionally to the individual's somatic growth and over time can gradually darken from pink red to a darker red and deep purple. They also tend to thicken over time, developing a papulonodular surface change and can develop localized soft tissue or even bony hypertrophy. Nodular vascular growths called *pyogenic granulomas* (see earlier) can also develop within the existing port-wine stain and may require therapeutic intervention.

Port-wine stains can occur in isolation but also can be related to an underlying genetic disorder (see Table 95.2). Of these syndromes, SWS is the most common. SWS is a sporadic neurocutaneous syndrome characterized by facial capillary malformation most commonly involving the upper face and forehead, leptomeningeal vascular malformation that can lead to seizures, hemiparesis, developmental delay, malformations of the choroid, and ophthalmologic abnormalities, most commonly glaucoma. SWS occurs in less than 30% of infants with facial port-wine stains. The risk is increased in infants with more extensive CMs of the face, notably those that have hemifacial or median forehead patterns of involvement, previously thought to be located in the V1 trigeminal region. Patterns associated with SWS are now thought to correlate with patterns of mosaicism[103] rather than trigeminal nerve distribution. A recent study demonstrated that those children with smaller forehead capillary malformations (less than half of the "hemi-forehead") were at very low risk for brain involvement. This can help neonatal care providers in risk assessment.[104]

The degree of CNS involvement is variable in SWS, ranging from subclinical lesions to intractable seizures and intellectual impairment. Patients can still be at risk of glaucoma without SWS when the port-wine stain involves the forehead or upper or lower eyelid, V1 or V2 trigeminal pattern; therefore, complete ophthalmologic examination is indicated for affected infants. Both SWS and isolated CMs have been found to be due to an activating somatic mosaic mutation in the *GNAQ* gene.[105] In SWS, this mutation is also found in affected brain tissue, which is not seen in patients with isolated CMs. It is hypothesized that earlier timing of the mutation can lead to more extensive neurocutaneous involvement.

Treatment of an uncomplicated CM is aimed at minimizing disfigurement. With time these lesions can thicken and develop irregular surface changes, often with friable nodules. Most of the published data on laser treatment of port-wine stains in children come from studies using a pulsed dye laser.[106] Children require an average of 4 to 10 pulsed dye laser treatments for maximal lightening. The best results have been seen in children younger than 4 years, with studies recommending earlier onset of therapy to achieve the best results. Some studies describe use of laser treatment in patients as young as 4 weeks. In younger age groups, 20% can expect 95% clearing.[107] Pulsed dye laser therapy is less effective for facial port-wine stains that are close to the midline or those on the extremities.[108,109] Laser therapy can yield remarkable improvement for many port-wine stains, minimizing the emotional pain that accompanies facial disfigurement. Unfortunately, none of the currently available lasers is capable of permanently erasing port-wine stains in most patients. There are also reports of darkening of port-wine stains many years after effective lightening.[110] Laser treatment with the 1064-nm neodymium-doped yttrium aluminum garnet (Nd:YAG) laser and the 755-nm alexandrite laser has also been described to penetrate deeper vessels in more refractory port-wine stains on the basis of the theory that the longer wavelength of the second laser may be able to better target deeper vessels.[111] Recently, the use of topically administered rapamycin (an mTOR inhibitor) in conjunction with pulsed dye laser treatment has been used for refractory port-wine stains, with the hypothesized mechanism being decreased angiogenesis after laser therapy.[112]

Venous Malformations

Venous malformations are slow-flow vascular malformations composed of ill-defined venous channels with abnormal vessel walls that lack smooth muscle cells. They are often evident at birth, and present as soft, blue-purple tumors or plaques with tortuous vessels that increase in size with exertion or when in a dependent position (Fig. 95.17). Over time, they may become symptomatic and larger with increased dilation of vessels. They may affect the skin, mucous membranes, subcutaneous tissue, muscles, and joints, and can involve visceral organs. Most cases are sporadic, but familial cases have also been reported. Localized intravascular coagulation can occur within the venous malformation (VM) that leads to either formation of thrombi, which form into calcifications called *phleboliths*, which can be quite painful, or bleeding.[113] Glomuvenous malformations are a distinct subset of VMs that present more superficially as blue–purple, cobblestoned plaques and nodules commonly located on the extremities. Glomus cells distinctly line the malformed veins. Familial cases caused by mutations of the glomulin gene (*GLMN*) are more common than sporadic cases.

Lymphatic Malformations

Lymphatic malformations (LMs) are slow-flow vascular malformations. They can be classified as microcystic when individual malformed channels are smaller than 1 cm and macrocystic (i.e., cystic hygroma) when individual channels are larger than 1 cm, combined, or rarely generalized. LMs are most often seen in the head and neck region and can cause life-threatening airway compromise in neonates. They can occur as an isolated finding or can be seen in association with underlying syndromes (see Table 95.2). Some isolated LMs and those related to overgrowth syndromes are caused by a mutation in the gene encoding phosphatidylinositol 4,5-bisphosphate 3-kinase, catalytic subunit alpha (*PIK3CA*).[114] Therefore, in some cases, rapamycin (the mTOR inhibitor also used for refractory port-wine stain) has been used as a medical therapeutic option. Other possible therapeutic interventions include surgical excision for localized lesions, sclerotherapy, and laser treatment with a pulsed dye laser and a long-pulse Nd:YAG laser for superficial lesions (Fig. 95.18), but many lymphatic malformations, particularly cervicofacial lesions, require a multidisciplinary approach.[115]

Arteriovenous Malformations

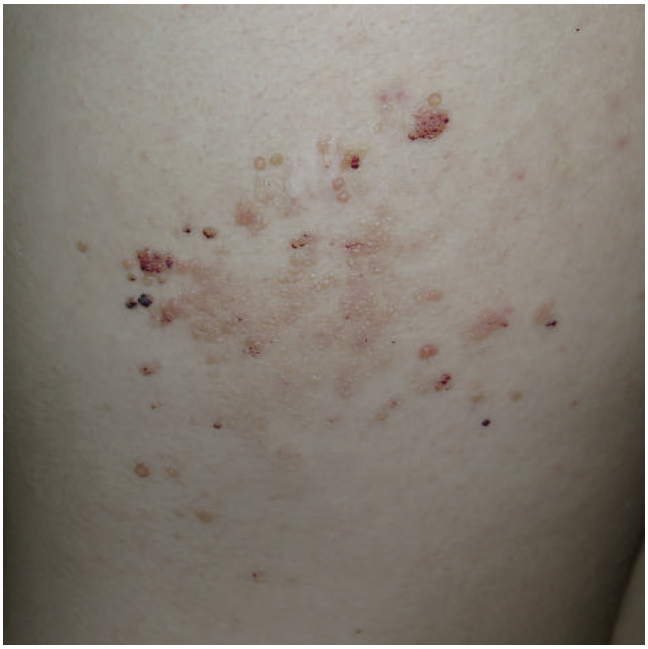
Arteriovenous malformations (AVMs) are fast-flow vascular malformations that are characterized by direct shunting of blood between the arteries and veins with bypassing of the capillaries. AVMs may present as a capillary malformation on the skin with pulsatility and significant warmth. The formation of vascular blebs that can easily bleed may also be seen. They can present within the skin but also viscerally anywhere in the body. The head and neck region, including the brain, are common locations. AVMs can occur in isolation or in association with various genetic syndromes (see Table 95.2). Recently, mutations in *RASA1*, associated with familial forms of AVMs, have been found in individuals with an AVM of an extremity (Parkes Weber syndrome) and in individuals with CM-AVM syndrome, where individuals present with multiple cutaneous CMs, many with a "thumb print"–like quality and potential AVMs in the brain and/or spine.

These lesions do not resolve spontaneously and are more likely to become larger and more symptomatic over time. Complications are related to the flow rate and extent of the lesion. Localized thrombosis and phlebitis occur in low-flow lesions; high-flow lesions can cause significant bleeding, destructive interosseous changes (Fig. 95.19), and high-output cardiac failure. Many centers now have collaborative multidisciplinary groups to help manage the most complicated vascular malformations and vascular tumors, which typically require treatment by physicians in many specialties.

Lymphedema

Lymphedema is a term used to describe diffuse soft tissue swelling characterized by firm, pitting edema. Lymphedema can occur in the setting of anomalous lymphatic drainage. Congenital variants have been reported. Females are affected more frequently than males. The lower limbs are the most commonly affected sites, but other sites may also be involved, and, rarely, chylothorax or ascites may be present. *Milroy disease* is an autosomal dominant

• **Fig. 95.17** A venous malformation on the sole of the foot.



• **Fig. 95.18** A superficial lymphatic malformation on the back presenting with characteristic hemorrhagic papules and vesicles.

condition that manifests itself with progressive lymphedema of the lower extremities. Lymphedema of the extremities also occurs in *Turner (XO) syndrome*. Disorders associated with lymphedema are listed in Table 95.4.

• **Fig. 95.19** Arteriovenous malformation of the hand causing distortion and contracture of the hand.

TABLE 95.4 Hereditary Lymphedema Syndromes (Primary Lymphedema)

Syndrome	Clinical Features	Genetics
Nonne-Milroy disease (primary congenital lymphedema)	Congenital lymphedema of the lower limbs Associated with enlarged veins of the leg, hydrocele and recurrent cellulitis	Mutation in *VEGFR3*, autosomal dominant
Meige disease/ lymphedema–distichiasis (pubertal-onset lymphedema)	Most common type of lymphedema Can be associated with distichiasis, yellow nails, ptosis, syndactyly, cleft palate, and cardiac septal defects	Mutation in *FOXC2*, autosomal dominant
Hypotrichosis–lymphedema–telangiectasia	Lymphedema, sparse hair, and telangiectasias of the skin	Mutation in *SOX18*, autosomal dominant
Hennekam syndrome (generalized lymphatic dysplasia)	Lymphedema and multiorgan involvement (intestinal lymphangiectasia, protein-losing enteropathy), developmental delay	Mutations in *CCBE1* (some cases), autosomal recessive

Disorders of Pigmentation

Hypopigmented Lesions

Localized areas of hypopigmentation on the skin of the newborn may be isolated phenomena, or they may be markers of extracutaneous abnormalities. The degree of hypopigmentation and the distribution of the defect help distinguish among the different conditions. To properly evaluate a patient with hypopigmentation, a distinction must first be made between complete depigmentation and hypopigmentation. A depigmenting condition produces pure white lesions that are devoid of normal melanocytes. Even in fair-skinned infants the lesions can often be easily seen in ordinary daylight. This group of disorders includes tyrosinase-negative oculocutaneous albinism, piebaldism, and vitiligo, all of which are rarely seen in infancy. A hypopigmented lesion is often subtly lighter in color than the surrounding skin. Histologic examination reveals a normal number of melanocytes. In fair-skinned children these lesions may require Wood lamp illumination to become obvious. This group includes anomalies with a deficient amount of melanin or hemoglobin caused by vasoconstriction, causing pallor and decreased skin pigment. Nevus anemicus and hemangioma precursors are two examples of areas of pallor that result from diminished superficial blood flow. Here we will discuss disorders of cutaneous mosaicism presenting as patterned pigmentation on the skin.

Nevus Depigmentosus (Nevus Achromicus)

Nevus depigmentosus is an uncommon condition occurring in 0.4% of newborns.[116] It presents as a well-demarcated hypopigmented patch with irregular borders that can involve a small, isolated circular or rectangular area or a larger segmental region following the lines of Blaschko, which are embryonic lines of ectodermal cell migration (Fig. 95.20). The patches are not truly depigmented as the name suggests but actually have reduced melanin levels. Nevus depigmentosus is thought to be a form of cutaneous mosaicism and results in a postzygotic somatic mutation that leads to a population of cells with decreased melanogenesis potential. They usually present at birth or shortly thereafter and grow in proportion to the child's overall growth, thus maintaining its shape. They occur sporadically, with no familial pattern of inheritance. There have been case reports of seizures, cognitive delays, and ipsilateral extremity hypertrophy, but most affected individuals do not have any extracutaneous abnormalities.[117] Sometimes, lentigines can be seen within the hypopigmented area. These are thought to be areas within the nevus where there is resolution of the mutation and a return of pigmentation.[118]

• **Fig. 95.20** Nevus depigmentosus presenting as a well-demarcated hypopigmented patch that tends to be circular or oval.

Pigmentary Mosaicism

The term *pigmentary mosaicism* is representative of a group of heterogeneous disorders of hypopigmentation and/or hyperpigmentation that include hypomelanosis of Ito (incontinentia pigmenti achromians), linear and whorled nevoid hypermelanosis that present as unilateral or bilateral linear streaks, and whorls of cutaneous pigment change oriented along the lines of Blaschko (Fig. 95.21). They can also present in a block-like or checkerboard pattern or a phylloid or leaf-like pattern. Affected individuals may have areas that are hyperpigmented or hypopigmented, or both. The pattern may be congenital or may become apparent within the first 2 years after birth.

This condition is a form of somatic mosaicism. Various extracutaneous abnormalities (CNS, ocular, cardiac, and musculoskeletal)[119–122] have been reported in patients, but the vast majority of individuals have pigmentary changes confined only to the skin. CNS abnormalities, manifesting themselves as seizures or developmental delay, most often present by the age of 2 years.

• **Fig. 95.21** Pigmentary mosaicism presenting as a segmental block-like hypopigmented patch on the back of an infant.

Ash Leaf Macules

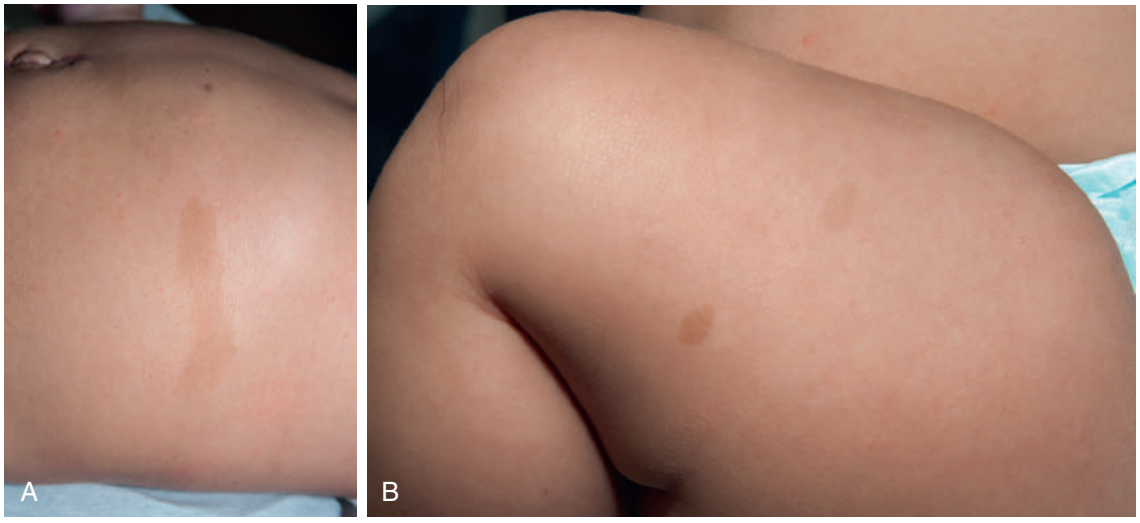
Ash leaf macules are small oval areas of hypopigmentation, named for their similarity in size and shape to a leaflet from a European mountain ash tree. They are one of the few congenital markers for infants with tuberous sclerosis. Tuberous sclerosis complex is a disorder of autosomal dominant inheritance with variable clinical manifestations characterized by the development of benign and malignant tumors in a variety of tissues, including the skin, CNS, and kidney.[123–125]

Hyperpigmented Lesions

Brown lesions usually reflect an increased number of melanocytic cells or an excess amount of melanin. Brown coloration can also be associated with a thickened epidermis. Most congenital brown lesions are isolated and benign, but it is important to recognize that some of them are syndrome associated and others may be potentially life threatening.

Café au Lait Macules

Café au lait macules (CALMs) are well-demarcated, oval or round, light brown macules or patches that differ in size, ranging from several millimeters to several centimeters in diameter (Fig. 95.22). They are commonly noted at birth or during infancy but may present in childhood as well. They cannot always be distinguished from melanocytic nevus on clinical grounds, but histologic examination is diagnostic, showing increased melanin levels within the basal keratinocytes, without melanocyte proliferation. CALMs differ within different ethnic groups, with a higher number and prevalence seen in darker-skinned individuals. The prevalence of CALMs is approximately 2.7% in the general population, 2% in white infants, and up to 12% in African-American infants. Large or segmental café au lait patches can be seen in McCune–Albright syndrome,[126–128] and multiple CALMs in the neonatal period may be an isolated finding but should alert the physician to the possibility of an associated syndrome, especially when six or more



• **Fig. 95.22** (A) Café au lait patch on the abdomen presenting as a tan brown well-demarcated patch. (B) Two café au lait spots presenting on the lateral thigh as well-demarcated tan brown macules.

are present (Box 95.1; Fig. 95.23). Six or more cafe au lait lesions measuring 0.5 cm or greater in diameter in prepubertal children and 1.5 cm or greater in diameter in post pubertal children should alert the practitioner of the possibility of neurofibromatosis type 1 (NF1). Presence of cafe au lait lesions alone do not fulfill NF1 criteria.[129]

Lentigines

Lentigines are small tan-to-dark brown macules that most commonly appear sporadically in adulthood. They may be distinguished from other pigmented lesions by histologic examination that reveals elongated rete ridges, an increased number of singly dispersed melanocytes along the basal layer, and increased melanization of the basal keratinocytes. Multiple or congenital lentigines are features of several syndromes.

• BOX 95.1 Syndromes Associated With Multiple Café au Lait Macules

Neurofibromatosis type 1 and type 2
Legions syndrome
Watson syndrome
McCune–Albright syndrome
Noonan syndrome
Noonan syndrome with multiple lentigines (LEOPARD syndrome)
Tuberous sclerosis
Bloom syndrome
Russell–Silver syndrome
Turner syndrome
Bannayan–Riley–Ruvalcaba syndrome
Ataxia–telangiectasia

• Fig. 95.23 Multiple café au lait spots presenting on an infant with neurofibromatosis type 1. The presence of six of more café au lait spots larger than 0.5 cm in diameter on an infant and larger than 1.5 cm in adolescents is suggestive of the possibility of neurofibromatosis type 1. The presence of only café au lait spots does not meet the criteria for definitive diagnosis.

Congenital Dermal Melanocytosis (Mongolian Spots)

More than 90% of African Americans, 81% of Asians, and 10% of whites[130] are born with blue-gray macule of infancy, formerly known as *Mongolian spots*. These are brown, gray, or blue macules and patches, most commonly located in the lumbosacral area, but they can occur anywhere on the body. The macules may be single or multiple and range in size from a few millimeters to several centimeters in diameter. They often fade within the first few years after birth. Extensive lesions have been mistakenly attributed to abuse. Histologically, blue-gray macule of infancy is a collection of spindle-shaped melanocytes located deep in the dermis. Malignant change has never been reported.

Nevus of Ota/Ito

Nevus of Ota is a unilateral blue or gray discoloration involving the orbital and zygomatic areas, following the ophthalmic and zygomatic branches of the trigeminal nerve, including the sclera and fundus (Fig. 95.24). It is a sporadic condition, but it occurs with the highest frequency in Asians, affecting up to 1% of individuals in Japan,[131] and has a female predominance. The discoloration is detected at birth in 60% of cases. Glaucoma is a frequent complication, occurring in 10% of individuals. A similar lesion, located in the deltotrapezius area, is called *nevus of Ito* (Fig. 95.25). Spontaneous resolution does not occur, and over time these lesions can darken, increase in size, and potentially thicken. Individuals with periorbital involvement should undergo ophthalmologic examination. A rare association with malignant melanoma and uveal melanoma has been reported. Successful treatment has been achieved with Q-switched laser devices—ruby, alexandrite, and Nd:YAG.

Melanocytic Nevi

The category of nevocellular nevi includes congenital or acquired nevomelanocytic neoplasms. Nevomelanocytes are dendritic cells of neural crest origin. Nevocellular nevi have traditionally been categorized by the histologic position of the tumor nests within

• Fig. 95.24 Nevus of Ota on the lateral right cheek of a girl presenting as a blue-gray patch of discoloration.

• **Fig. 95.25** Nevus of Ito on the left arm of a child presenting as a blue-gray patch.

the skin. *Junctional nevi* are the most superficial, located at the junction between the epidermis and dermis. These lesions appear clinically as macules. *Intradermal nevi* are located deep to the dermoepidermal junction and are usually papular. *"Blue" nevi* are a variant located in the deep dermis, made up of cells that have elongated, neural features. *Compound nevi* have both junctional and dermal nests of nevomelanocytes. Melanocytic nevi can be further subdivided by their time of onset: congenital, early onset (before the age of 2 years), and acquired.[132,133]

Congenital Melanocytic Nevi

Congenital melanocytic nevi (CMN) are hamartomas derived from neural crest cells that form in utero and are most often present at birth or within the first year (Fig. 95.26). They are classified by the largest diameter of their adult projected size. On the basis of size classification, they are categorized as small (<1.5 cm), intermediate sized (1.5 to 19.9 cm), large (20 to 40 cm), and giant (>40 cm). Delineations are based on adult data. Conversion factors have been developed to help predict ultimate size: for CMN on the head, multiply size by 1.7; CMN on the lower extremities, multiply size by 3.3; and for CMN on the trunk, upper extremities, and feet, multiply size by 2.8.[134] On the basis of these classifications, the estimated incidence of small and intermediate-sized CMN is approximately 1% to 6%, that of large CMN is approximately 1 in 20,000, and that of giant CMN is approximately 1 in 500,000.[135] Melanoma in small and intermediate-sized nevi tends to be approximately 1% lifetime risk or less, nearing the risk within the general population, with most cases occurring after puberty. In large and giant CMN, the risk of melanoma development ranges from 4.5% to 10%,[134,136–141] with 70% of melanomas diagnosed before the age of 10 years. Other malignancies have also been reported to arise from CMN. These include rhabdomyosarcoma, liposarcoma, malignant peripheral nerve sheath tumors, and other sarcomas. In addition to cutaneous malignancy, large and giant

• **Fig. 95.26** (A) Congenital melanocytic nevus with hypertrichosis, small size. (B) Large congenital melanocytic nevus involving the neck and back with multiple smaller "satellite" nevi on the arms and lower back.

CMN have been associated with the development of neurocutaneous melanosis (NCM), which is characterized by CNS proliferation of melanocytes.[142] Symptomatic NCM manifests itself with signs or symptoms of increased intracranial pressure and carries a very poor prognosis, with an increased incidence of CNS melanoma.[143,144] NCM often becomes symptomatic within the first few years after birth. MRI can aid in the diagnosis.[145] Although initial reports emphasized thickening of the leptomeninges, the most common MRI sign of NCM is the spin–lattice (T1) nuclear magnetic relaxation time in the parenchyma of the cerebellum or anterior temporal lobes (sometimes accompanied by the spin–spin [T2] relaxation time). Radiologic identification of malignant degeneration is difficult. Roughly half of asymptomatic infants and children with giant CMN have evidence of NCM on MRI.[143] The presence of asymptomatic NCM does not necessarily bode a poorer prognosis, and NCM can continue to be present and asymptomatic throughout life. The term *CMN syndrome* has now been used to broaden the scope of NCM to include more

extracutaneous manifestations associated with CMN. Patients with NCM are at risk of developing CNS melanomas, but this risk is significantly higher in individuals with symptomatic NCM. The risk of developing NCM has been correlated with the number of accompanying CMN, historically termed *satellite lesions*, with patients who have more than 20 such lesions carrying a five times greater risk of NCM. Neonatal care providers have the unique opportunity to consider a "feed and swaddle" MRI upon recognition of NCM risk, thereby potentially avoiding later exposure to general anesthesia.[146]

Conservative management of large congenital nevi by surveillance alone is complicated by the presence of features that may fit the screening ABCDE criteria (asymmetry, border irregularity, color variegate, diameter >6 mm, evolution) for a lesion that is suggestive of melanoma. Most of these nevi have an irregular surface appearance from birth and are variably thickened, hairy, verrucous, or nodular. Smaller, widely scattered satellite lesions are almost always present, but there have been no reports of melanoma in satellite lesions. Extracutaneous lesions have also been detected in several sites, including the meninges, lymph nodes, and placental villi.[147] Often these nevi have atypical histologic features as well. For children who develop malignant melanoma within a giant nevus, the prognosis is very poor. However, many of the lesions that have an alarming appearance at birth do not exhibit malignant behavior or produce widespread metastases or cause death. In fact, congenital melanoma is very rare and is associated with congenital nevi in less than 50% of reported cases.[141]

The management of CMN remains controversial, with advocates for and against prophylactic excision. Routine excision is generally not recommended and may not eliminate the risk of melanoma completely, given the presence of melanocytes deep with the fascia. Surgical removal is never an easy option. Multiple procedures are usually required, with the attendant high risks of significant morbidity, sometimes yielding results that are more disfiguring than the birthmark. Procedures performed in early childhood, such as tissue expansion[148] and partial-thickness resection,[149] may improve the aesthetic outcome but have associated stigma and pain. The efficacy of such approaches in the prevention of malignancy has never been documented, and it is unlikely to eliminate the risk of malignancy completely.

Nevus Spilus

Nevus spilus (speckled lentiginous nevus) is a hyperpigmented lesion that consists of focal proliferation of melanocytes along the basal layer of the epidermis (dark spots) within a café au lait spot in the background (Fig. 95.27). Nevus spilus is considered a distinct subtype of a congenital melanocytic nevus, with the associated risk of melanoma being lower than with traditional CMN. There are no other associated abnormalities.

Congenital Tumors of Epithelial Origin

Epidermal Nevus

Epidermal nevus may manifest itself in the newborn period as a smooth hyperpigmented patch or rough, skin-colored plaque, most often on the trunk or extremities, frequently oriented along the lines of Blaschko (Fig. 95.28). With time, epidermal nevi may enlarge, usually within the first few years after birth, and most become verrucous and hypertrophic over time. Treatment is difficult because recurrence is common after destruction or excision.

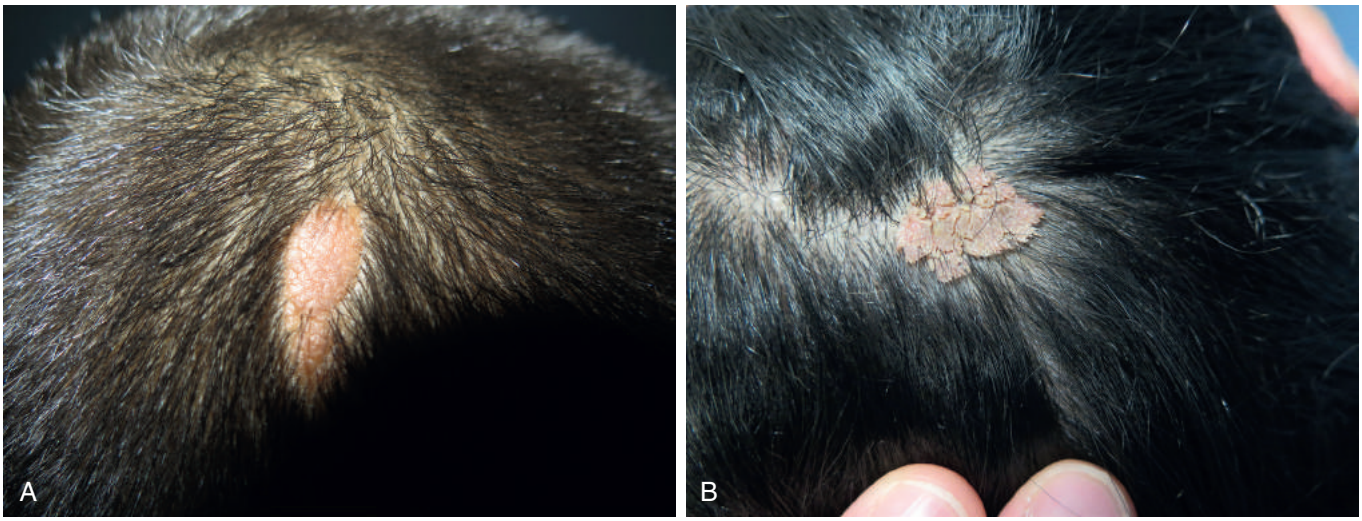
• **Fig. 95.27** Nevus spilus presenting as a tan patch with multiple darker brown macules and papules within the patch.

• **Fig. 95.28** Epidermal nevus presenting as verrucous tan brown papules coalescing in a curvilinear plaque.

Nevus Sebaceous

Nevus sebaceous presents as an alopecic tan, yellow- to salmon-colored plaque appearing most often on the scalp or face (Fig. 95.29). It may be nodular at birth and again after puberty, flattening during childhood. A variety of neoplasms, both benign and malignant, including basal cell carcinoma, develop in up to 15% of patients with sebaceous nevi. Development of neoplasms rarely occurs before puberty.

Like other mosaic disorders, epidermal and sebaceous nevi are believed to be localized manifestations of somatic genetic mutations that would be lethal if fully expressed. A subset of patients with epidermal nevi are genetic mosaics for an autosomal dominant form of ichthyosis called *epidermolytic hyperkeratosis* (or *bullous ichthyosiform erythroderma*).[150] These individuals may



• **Fig. 95.29** (A) Nevus sebaceous in an adolescent male presenting as a thickened yellow-pink alopecic plaque with wart-like changes. (B) Nevus sebaceous presenting as an alopecic plaque with verrucous or wart-like changes.

be at risk of having offspring with total body involvement. The striking appearance of epidermal nevi has inspired descriptive nomenclature. *Nevus verrucosus* is a solitary plaque. *Nevus unius lateris* is an extensive linear lesion that is unilateral, following the lines of Blaschko. Both keratinocytic and sebaceous components may occur in the same patient, the former more commonly involving the trunk and extremities and the latter more often involving the head and neck. The term *ichthyosis hystrix* refers to extensive, bilateral involvement with epidermal nevus.

Skin biopsy will rule out other conditions, distinguish between epidermal nevus and nevus sebaceous, and detect the diagnostic histologic features of epidermolytic hyperkeratosis, but is not typically performed. Small epidermal nevi do not require treatment. Nevus sebaceous carries a small risk of malignant degeneration generally later in childhood and adolescence. It may be excised at any time, depending on the size of the lesion, the benefits of surgical intervention versus the risks of anesthesia, and the preference of the patient and family, but rarely becomes symptomatic or much of an issue until after puberty. Recent studies suggest that the risk of basal cell carcinoma, the most common malignancy to arise in nevus sebaceous, is closer to 1%, much lower than was reported in the past.[151]

There is no optimal therapy for larger lesions or those that are disfiguring. Full-thickness excision, including the subcutaneous tissue, is recommended to decrease the risk of recurrence. Laser therapy has been performed with ablative lasers, and there are a few reports suggesting that the Q-switched Nd:YAG laser holds some promise as another therapeutic option. Topically applied keratolytic agents may be palliative. Genetic counseling about the risk for offspring of fully expressed disease should be considered for individuals with epidermal nevi that reveal the histologic features of epidermolytic hyperkeratosis.

Epidermal (Linear Sebaceous) Nevus Syndrome

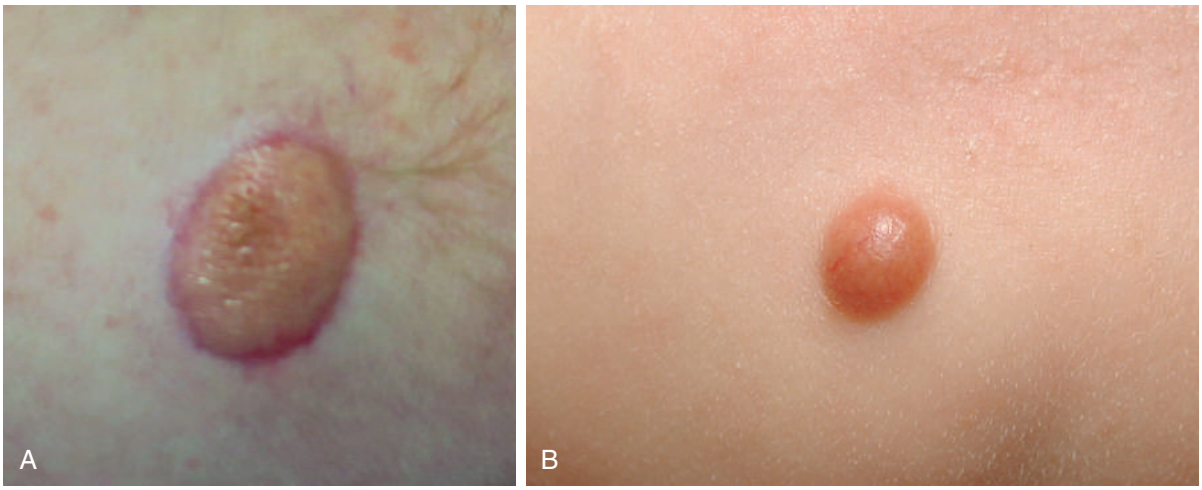
In less than 10% of affected people, epidermal nevi and sebaceous nevi (especially those involving the head) are associated with a variety of extracutaneous abnormalities, mainly ocular (in 33% of cases), neurologic (in 50%), and skeletal (in 70%), a condition referred to as *epidermal nevus syndrome*. Bone abnormalities include vertebral anomalies, kyphoscoliosis, limb shortening, and hemihypertrophy. CNS disorders include seizures, mental retardation, and hemiparesis; ocular abnormalities include eyelid/conjunctival nevus, coloboma, corneal opacity, and nystagmus. Malignancies also occur in this syndrome with a greater than expected frequency, including Wilms tumor, nephroblastoma, gastrointestinal carcinomas, and rhabdomyosarcoma.[152]

Congenital Tumors of Dermal and Subcutaneous Origin

Juvenile Xanthogranuloma

JXG is a benign, self-healing, non–Langerhans cell histiocytic tumor of infancy (Fig. 95.30). JXG is derived from dermal dendrocytes and is present in normolipemic individuals without abnormalities in their lipid metabolism.[153–155] JXG may be congenital in approximately 30% of cases, with 75% presenting within the first year of life.[156] Early on, cutaneous lesions present as erythematous papules with minimal yellow-orange color. As they mature, they become more characteristically yellow in color and may develop overlying telangiectasias. They often present on the head, neck, and trunk, and can be categorized by their size: "micronodular" (<10 mm) and "macronodular" (>10 mm) forms and rarely giant JXG, which can be up to 5 to 10 cm in size. They may present as a solitary lesion or as multiple lesions, with the solitary presentation being most common, occurring in up to 90% of patients. JXG may also be rarely localized to the eye or mucous membranes.[157] Skin biopsy is usually diagnostic, revealing characteristic foamy histiocytes and Touton giant cells within the dermis.

The vast majority of infants with JXG are otherwise healthy. Giant JXG can have an alarming appearance and may be confused with other types of histiocytic tumors.[158] JXGs have two clinically significant associations. The first is ocular JXG and its associated complications. Less than 0.5% of children with skin lesions have ocular involvement, but half of children with ocular JXG have cutaneous lesions.[159] Ocular examination in individuals younger than 2 years with multiple JXGs is recommended. Ocular tumors may manifest themselves as unilateral glaucoma, uveitis, heterochromia iridis, or proptosis, and ocular JXG is the most common



• **Fig. 95.30** (A) Juvenile xanthogranuloma with characteristic tan yellow color and rim of erythema in an infant. (B) Juvenile xanthogranuloma presenting as a yellow-orange papule.

cause of hyphema in infancy.[160,161] The iris is the most frequently affected ocular tissue.[162]

The second significant association is related to reports of a rare triad of JXG, juvenile myelomonocytic leukemia (JMML), and neurofibromatosis type 1 (NF-1). The appearance of JXG usually precedes the diagnosis of leukemia or occurs concurrently at the time of diagnosis, and there are often multiple JXGs.[163,164] Routine screening for JMML is not recommended in NF-1 patients with or without JXG, but evidence of hepatosplenomegaly, lymphadenopathy, or pallor should prompt appropriate work-up.[165] Fewer than 20 patients with intracranial JXG without cutaneous manifestations have been described.[166,167]

Most cases of JXG are asymptomatic and self-limited, but ulceration and bleeding of cutaneous lesions can occur. Giant lesions have a similar prognosis.[158] Ophthalmologic evaluation is indicated for children who present in the first 2 years after birth with multiple lesions. Parents should be provided with anticipatory guidance about the ocular complications.[159] JXG typically involutes within 3 to 6 years.[168] Cutaneous lesions can leave behind residual anetoderma, mild atrophy, and/or hyperpigmentation. Recurrence has been documented after surgical excision, a therapy that is indicated only for lesions that are frequently traumatized, symptomatic, or are more disfiguring than the resultant scar would be.

• **Fig. 95.31** Solitary mastocytoma presenting as a tan brown plaque with characteristic peau d'orange (orange peel–like) surface change.

Mastocytosis

Mastocytosis comprises a group of disorders characterized by increased numbers of tissue mast cells (Fig. 95.31).[169] The skin is the most common site of involvement, but the lymphoreticular system, gastrointestinal tract, and bone marrow also may be affected. Symptoms result from the local or generalized effects of the release of histamine and other mast cell mediators. Pruritus, edema, blistering, and flushing are common. Abdominal pain, diarrhea, and vomiting are unusual. Hypotension is rare.[170] If rubbed or traumatized, skin affected by mastocytosis will develop a diagnostic wheal (Darier sign). The site may blister or become hemorrhagic in a neonate.

Urticaria pigmentosa is the name given to the most common form of mastocytosis in infants, featuring multiple, small (1 to 3 cm in diameter) papules usually located on the trunk. The disease may be congenital but usually manifests itself within the first 6 months after birth.[170] A single, localized lesion is known as a *solitary mastocytoma*. These tumors can range in size from approximately 2 to 6 cm. Diffuse cutaneous mastocytosis is an unusual condition that may manifest itself at birth with widespread blistering or diffuse thickening of the skin. Systemic mastocytosis is more commonly seen in adults and is defined by multifocal lesions in the bone marrow or other extracutaneous organs, together with signs of systemic disease. It is further subdivided into indolent systemic mastocytosis, systemic mastocytosis with an associated clonal hematologic non-mast cell lineage disease, aggressive systemic mastocytosis, and mast cell leukemia.[171]

The diagnosis may be confirmed by a skin biopsy, which reveals mast cell hyperplasia within the dermis. Aminocaproate esterase is the most specific enzyme marker for identification of mast cells. Immunohistochemical stains for tryptase and c-Kit are also sensitive and specific markers for mast cells.[172] Mutations in *KIT*, the gene encoding the receptor for stem cell factor, may

play a significant role in the biology of mast cell malignancies.[173] Plasma histamine levels are elevated in most children with mastocytosis, sometimes to remarkably high levels. Further work-up for evidence of systemic involvement should be limited to pediatric patients with extracutaneous signs and symptoms or those who require general anesthesia.[170]

Caregivers should be educated to avoid exposing infants to factors that trigger mast cell degranulation, such as friction, pressure, temperature extremes, and substances that promote mast cell degranulation (aspirin, alcohol, narcotics, amphotericin B, or iodine-containing contrast media). If general anesthesia is required, perioperative administration of histamine receptor blockers is recommended.[174]

For patients with limited skin involvement, application of potent topical corticosteroids may hasten involution of lesions. Symptomatic patients may benefit from a classic histamine H_1 receptor blocker such as hydroxyzine or cyproheptadine. An H_2 blocker, such as ranitidine, or orally administered disodium cromoglycate may be added in the presence of gastrointestinal symptoms. Hypotension requires corticosteroids in addition to H_1 and H_2 antihistamines and intensive supportive care. Solitary mastocytomas usually involute by school age. Lesions of urticaria pigmentosa typically resolve by puberty.

Connective Tissue Nevus (Connective Tissue Hamartoma)

Connective tissue nevi are hamartomas comprising dermal collagen, elastic fibers, or a combination of the two. They are benign lesions that can occur in isolation or in relation to a genetic syndrome such as tuberous sclerosis or Proteus syndrome.[128] They present as flesh-colored dermal plaques that can be subtle on examination to hypertrophic with a cobblestoned and cerebriform appearance. They are usually asymptomatic and do not often require any intervention. Diagnosis is often made clinically, but if the diagnosis is unclear, a skin biopsy can be performed.

Neurofibroma

Neurofibromas are benign tumors that are composed of neuromesenchymal tissue. They appear as brown or red-brown soft papules or papulonodules. They often present in young adulthood, but there is a variant of a plexiform neurofibroma that can present earlier in infancy and can resemble a congenital melanocytic nevus. Neurofibromas can occur as isolated tumors in an association with an underlying genetic disorder, such as NF-1. They can be surgically excised if they become symptomatic or are cosmetically disfiguring.

Developmental Anomalies of the Skin

Developmental anomalies are present at birth and represent a heterogeneous group of disorders that are caused by a disruption in the formation of vital structures within the skin. They may occur in isolation or they may be a marker of extracutaneous abnormalities and thus require further evaluation.

Midline Anomalies

Congenital midline defects are a distinct group of diagnostically and therapeutically challenging conditions. These anomalies can be markers for potential neural tube dysraphism occurring at the cranial or caudal midline. These markers include dimples, sinuses, skin tags, capillary malformation, hemangiomas, nodules, lipomas, dermoid cysts or sinus, and midline circumscribed or annular hypertrichosis that may represent a marker for an underlying CNS problem or an intracranial connection.[175,176] A midline mass in the nasal area may represent a dermoid cyst or sinus, encephalocele, or glioma.[177] Midline scalp lesions include aplasia cutis congenita, dermoid cyst or sinus, encephalocele, meningocele, and heterotopic brain tissue. The "hair collar sign" may mark ectopic neural tissue and underlying CNS malformations.[178,179] Biopsy of a midline mass should not be performed unless an imaging study, computed tomography, or MRI has been performed to help clarify the nature of the lesion and any intracranial connections, although small intracranial connections may still be missed. If the possibility of an intracranial connection exists, referral to a neurosurgeon is indicated.[176]

Markers of occult spinal dysraphism exist in the lumbosacral region and include various cutaneous midline lesions such as lipomas, skin tags, pseudotails and tails, dimples and sinuses, hypertrichosis, aplasia cutis congenital, dermoid cyst or sinus, pigmentary changes, hemangiomas, CMs, and telangiectasias. The presence of two or more stigmata indicates a higher risk of the presence of occult spinal dysraphism. Box 95.2 stratifies findings on the basis of their risk for occult spinal dysraphism.[180] There are no evidence-based guidelines for imaging recommendations for spinal dysraphism. In general, in high-risk situations, MRI is the preferred imaging modality but is limited by its cost, availability, and need for sedation. In infants up to 6 months old, high-resolution ultrasonography may be performed before the ossification of the vertebral bodies, but it has decreased sensitivity when compared with MRI and has large variability in accuracy depending on the person performing the study. If the ultrasound results are abnormal or inconclusive, MRI should be performed. It is suggested that simple dimples[181,182] and isolated low-risk lesions do not require a screening ultrasound examination.[183] On the neck, a midline pit or nodule may represent a congenital midline cervical cleft[184] or

• BOX 95.2 Risk Stratification of Markers of Occult Spinal Dysraphism

High Risk
- Two or more cutaneous stigmata
- Lipoma
- Acrochordon, pseudotail, true tail
- Aplasia cutis and congenital scars
- Dermoid cyst or dermal sinus
- Infantile hemangioma ≥2.5 cm

Intermediate Risk
- Atypical dimple >5 mm in diameter, >2.5 cm from the anal verge
- Infantile hemangioma <2.5 cm
- Hypertrichosis (faun tail or silky down)

Low Risk
- Hyperpigmentation or hypopigmentation
- Melanocytic nevi
- Simple dimple ≤5 mm in diameter, ≤2.5 cm from the anal verge
- Teratomas
- Port-wine stain (capillary malformation) or telangiectasias

Modified from Sewell MJ, Chiu YE, Drolet BA. Neural tube dysraphism: review of cutaneous markers and imaging. *Pediatr Dermatol.* 2015;32:161–170.

thyroglossal duct cyst or sinus. A bronchogenic cyst or sinus cyst presents as a nodule or pit at the suprasternal notch at birth and is due to remnant respiratory epithelium. Branchial cleft anomalies, cysts, or sinuses do not present at the midline and are located in the preauricular region and lateral neck. They are at risk of infection and therefore can be surgically removed.

Preauricular Pits and Sinuses

Preauricular pits are common congenital abnormalities that present as small depressions or dells, often 1 to 3 mm in size located adjacent to the external ear, usually at the anterior margin of the ascending limb of the helix, but have also been reported along the lateral surface of the crus of the helix and the superior posterior margin of the helix, tragus, or lobule. There may be a sinus tract connected to the pit in the skin, in which case fluid or pus may drain from the opening. Preauricular sinuses are usually asymptomatic and isolated but can be multiple and bilateral in 25% to 50% cases. The bilateral sinuses tend to be inherited in an autosomal dominant pattern. There have been associations with a few genetic syndromes as well (Box 95.3).

Preauricular sinuses are rarely associated with deafness or renal problems. Renal ultrasound screening is recommended only if there are other worrisome features present, such as the presence of dimorphic features, a family history of deafness, a maternal history of gestation diabetes, and auricular and/or renal malformations.[185] Hearing impairment occurs at a higher rate in individuals with accessory tragi, and screening is recommended if a newborn hearing screen was not performed.[186] Symptomatic sinuses that drain fluid or become infected should be cultured and treated with appropriate antibiotics. If recurrent infection occurs, surgical excision by an experienced surgeon is recommended because the sinus can extend to the periosteum with the auditory canal.[187]

Accessory Tragus

Accessory tragi, inaccurately referred to as *preauricular tags*, are relatively common congenital malformations of the external ear. They present as soft, flesh-colored pedunculated papules that can occur anywhere from the preauricular area to the angle of the mouth following the embryonic fusion line of the mandibular and maxillary branches of the first branchial arch (Fig. 95.32). They are present at birth and can be multiple and/or bilateral. In most cases they occur as an isolated developmental defect, but association with other abnormalities of the first and second branchial arch or branchial arch syndromes can occur (Box 95.4).[188] Association with deafness and renal abnormalities is controversial. The renal ultrasound and hearing screening guidelines are the same as mentioned with preauricular pits and sinuses earlier. Accessory tragi can be limited to the dermis but can also contain cartilage or can be contiguous with the external ear canal. Therefore, if surgical excision is performed, it should be done by an experienced surgeon. Suture ligation should not be done, and can result in complications.

Congenital Cartilaginous Rests of the Neck (Cervical Tabs, Wattles)

Congenital cartilaginous rests of the neck, also known as *cervical tabs* or *wattles*, are present at birth and are formed from a remnant of the branchial arch or ectopic auricular tissue (Figs. 95.33 and 95.34). They present as soft, flesh-colored papules or nodules that

VACTERL syndrome
Wolf–Hirschhorn syndrome

• Fig. 95.33 Congenital cartilaginous rests of the neck, aka *wattles*, presenting as a small flesh-colored papule on the anterior part of the neck.

• **Fig. 95.34** Cutis marmorata telangiectasia congenita.

can occur anywhere on the neck, but most commonly appear over the lower half of the sternocleidomastoid muscle. They may contain cartilage and can be multiple and bilateral. They do not have a deeper connection or sinus or tract associated with them and, therefore, do not require further imaging or treatment. Surgical excision could be considered, but largely for aesthetic purposes.

Supernumerary Digits (Rudimentary Polydactyly)

Supernumerary digits can range in their presentation from subtle small pedunculated papules to full-sized digits. They arise from the lateral surface of the normal digit and may occur on any digit, with the ulnar surface of the fifth finger being the most common site. They often contain cartilage, nerves, and nail. Therefore surgical excision with nerve dissection can be undertaken to remove these accessory digits. Ligation of the supernumerary digit without complete dissection of the nerve can result in a traumatic neuroma, skin necrosis, and infection.[189,190]

Supernumerary Nipples (Polythelia, Accessory Nipples)

Supernumerary nipples can be found anywhere along the embryologic milk lines that course from the axilla to the inner thigh. They present as brown or reddish-brown pedunculated papules and are often bilateral. In the newborn period their clinical presentation is very subtle, as a small light-brown macule. They may present with or without true extramammary tissue and mammary glands. They can be mistaken for melanocytic nevi, warts, neurofibromas, or acrochordons. Usually no further evaluation or treatment in necessary unless glandular tissue is present, in which case complete surgical excision is recommended because of enlargement at puberty causing pain and social stigma.

Median Raphe Cysts (Congenital Sinus and Cysts of Genitoperineal Raphe, Mucous Cysts of the Penile Skin, Parameatal Cysts)

Median raphe cysts present as small white to flesh-colored papules that can be found anywhere on the ventral penis, scrotum, and perineum in a midline position. They can be solitary or multiple. They are believed to result from congenital alterations in embryologic development of male genitalia and are due to incomplete closure of the urethral and/or genital folds, or result from outgrowths of the embryologic epithelium after primary closure of the folds.[191] They are asymptomatic in most cases, and there have been reports of spontaneous regression over time. If they persist, become symptomatic, or infected, simple excision with primary closure can be undertaken.[192]

96 Eye and Vision Disorders

JULIUS T. OATTS, ALEJANDRA G. DE ALBA CAMPOMANES, AND GIL BINENBAUM

KEY POINTS

- Early visual experience drives the architecture of the visual brain.
- Screening eye examinations are important in all infants, regardless of gestational age. All neonates should have an examination of the red reflex before discharge from the newborn nursery.
- The absence of visual responsiveness by 2 months of age should prompt an urgent ophthalmologic evaluation.
- Most full-term infants establish normal ocular alignment within the first 2 months.
- Nystagmus can be a manifestation of a congenital motor entity, secondary to visual pathway defects or neurologic disease. Nystagmus caused by defective vision does not develop until approximately 3 months of age.
- Successful treatment of congenital cataracts is highly dependent on early diagnosis and prompt referral.
- The successful management of retinoblastoma depends on the ability to detect the disease while it is still intraocular; disease stage correlates with delay in diagnosis.
- Neonatal care providers have both a clinical and a medicolegal responsibility to arrange timely diagnostic retinopathy of prematurity (ROP) examinations for preterm babies in the neonatal intensive care unit and to communicate to parents the vital importance of keeping outpatient ophthalmology appointments. Even a one-week delay can result in adverse outcomes.
- Improvements in neonatal care and ophthalmic surgical techniques have led to improved outcomes for infants who develop ROP.
- There are limitations to current ROP screening guidelines, and incorporation of additional factors such as postnatal weight gain can result in more precise risk stratification.
- Newer technologies for ROP screening that include telemedicine and artificial intelligence have promise but face multiple logistical barriers before being widely adopted.
- Retinal laser ablation remains the standard of care for ROP requiring treatment, but advances in our understanding of intravitreal anti-VEGF agents have led to increased use and benefits over lasers in certain cases.

The fast pace of development of the visual system in the neonatal period makes the recognition of ocular abnormalities extremely important. As early as 4 to 6 months after birth, some visual functions are permanently set and if impaired cannot be fully restored to normalcy. For example, a visually significant congenital cataract must be surgically addressed before the third month of life to avoid potentially irreversible vision loss. This urgency makes the neonatologist an invaluable player in the recognition and management of neonatal eye diseases. Screening eye examinations are important in all infants, regardless of gestational age and whether they occur in the neonatal intensive care unit (NICU), the newborn nursery, or the primary care provider's office. Healthcare professionals caring for newborns need to be familiar with indications for referral to a pediatric ophthalmologist, and in premature infants, the added risk of retinopathy of prematurity (ROP) mandates that neonatologists ensure timely diagnostic examinations by an ophthalmologist with expertise in ROP.

General Examination Techniques

The Newborn Eye Examination: Approach and Equipment

Screening eye examinations are important in all infants, regardless of gestational age. All neonates should have an examination of the red reflex before discharge from the newborn nursery.

A more thorough eye examination, although necessary, can be stressful and sometimes painful for a newborn or a young infant. ROP examinations in particular, which often necessitate the use of an eyelid speculum to retract the eyelids and scleral indentation to visualize the peripheral retina, have been associated with an increase in pain.[1] The procedure has also been associated with other adverse effects, including episodes of desaturations, bradycardia, hypertension, and prolonged crying times.[2] Swaddling, nesting, nonnutritive sucking, and oral administration of sucrose before, during, and after an examination can be very helpful in this regard,[3–5] particularly for premature babies undergoing serial ROP examinations. The most distressing aspects of the eye examination are generally the bright light of the ophthalmoscope and the insertion of the speculum. The use of a topical anesthetic, such as proparacaine hydrochloride 0.5% or tetracaine 0.5% drops, reduces the discomfort but is not always sufficient and should be supplemented with other measures, such as sucrose, pacifiers, and nesting.[6,7] In addition, NICU and office staff should be aware that the repetitive use of topical anesthetics can result in corneal ulceration and melting, so bottles should be properly disposed of and not confused with other medications, such as topical lubricants or antibiotics. The use of an indirect ophthalmoscope without a speculum may produce less pain response than that noted during examination with a speculum or with a contact fundus camera, such as the RetCam (Clarity Medical Systems, Pleasanton, California, United States).[8] Nevertheless, a speculum is often necessary to adequately visualize ocular structures and should always be used if adequate visualization of the fundus is otherwise not

possible. Assistance with comforting the baby and monitoring vital signs is important. In addition, the head and body of the infant may need to be securely held to allow both a detailed and a safe examination. Finally, a particular note should be made of the oculocardiac reflex, a dysrhythmia, typically bradycardia, resulting from direct manipulation of the eye during and immediately after the examination; monitoring by an assistant during and after the examination is therefore important. Nevertheless, it is extremely rare for a properly supported infant to be unable to tolerate a quick fundus examination, the discomfort of any observers notwithstanding. Eye examinations should not be postponed unilaterally without first discussing with the ophthalmologist the risk of ROP in each specific infant.

Pharmacologic dilation with mydriatic eye drops is commonly performed by consulting ophthalmologists, typically on all new patient evaluations and at all ROP examinations. Occasionally, a pediatrician may find it helpful to dilate the pupils to better visualize the red reflex or optic nerve head. Use of drops is better deferred if an ophthalmology consultation will be requested, because dilating the pupils may make it difficult or impossible to accurately assess the pupils, ocular alignment, intraocular pressure, and iris. Dilating eye drops include sympathomimetic drugs (e.g., phenylephrine) and anticholinergic drugs (e.g., tropicamide, cyclopentolate, and atropine). Potential side effects of these drugs include elevated blood pressure, increased heart rate, cardiac arrhythmias, feeding intolerance, slowed gastric emptying, urticaria, contact dermatitis, and seizures.[9–11] Bradycardic and apneic episodes following administration of these eye drops are pain response reactions and not a direct effect of the drugs. Cohen et al.[12] analyzed masked videotapes from before, during, and after eye drop administration and found that one-third of infants have a significant pain response to mydriatic eye drops. Supportive measures, therefore, can also be used at the time of administration of dilating eye drops. Adverse effects are potentially of greater concern in preterm infants, who are of lower weight and typically require multiple doses to achieve adequate dilation, as do many children with dark irides. Therefore it may be prudent to use reduced concentrations of mydriatics in premature infants, particularly cyclopentolate. A randomized masked trial[10] concluded that cyclopentolate 0.2% with phenylephrine 2.5% is the mydriatic of choice in preterm infants with dark irides because higher concentrations of cyclopentolate (0.5%, 1.0%) were more likely to result in increased mean blood pressure or feeding intolerance. In all children, systemic absorption of eye drops can be minimized by compression of the lacrimal sac for 1 to 2 minutes after instillation. It is also recommended to wipe all the overflow drops from the skin as local vasoconstriction and pallor of the periorbital skin are frequently observed in premature neonates in whom the epidermal permeability barrier is still incompetent.[13] These authors typically use three drops of Cyclomydril (cyclopentolate hydrochloride 0.2% and phenylephrine hydrochloride 1%) or tropicamide 1% and phenylephrine 2.5% separated by 5 minutes in each eye, 30 to 60 minutes before the examination. Multiple doses are necessary because, in premature and newborn babies, adequate pupil dilation is often difficult to obtain because of the immaturity of the dilator muscle of the pupil; the pupils of babies with dark irides, in particular, may be more difficult to dilate because of pigment binding of the mydriatic drugs, and higher concentration or more frequent administration may be required. We recommend avoiding the use of cyclopentolate 1% in children younger than 6 months.

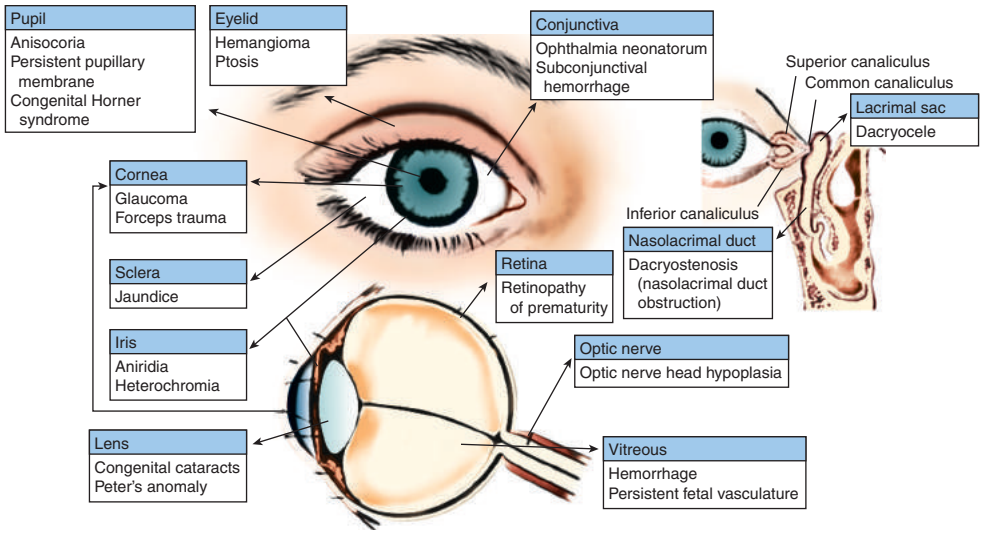
Red reflex testing with a direct ophthalmoscope (described in detail later) is a mandatory element of all newborn and well-baby physical examinations. Numerous vision-threatening and even life-threatening ocular diseases are primarily identified by the checking of red reflexes. The direct ophthalmoscope may, of course, be used to directly visualize the optic nerve head and retina, but particular considerations and limitations must be kept in mind. Pupil size must be maximal; typically this means pharmacologic dilation (see above). If mydriatics are not used, dimming ambient light will maximize pupil dilation. The examiner must be very close to the infant (a few centimeters at most). Approaching from a slightly lateral angle and following the "arrows" of branching vessels back to the nerve head will help to identify the optic disc. Most important, the field of view or "spot size" of the direct ophthalmoscope is approximately the size of the optic nerve head, which represents but a tiny fraction of the ocular fundus. Therefore it is not possible to adequately evaluate the retina for ROP or other peripheral retinal diseases with a direct ophthalmoscope; instead, an indirect ophthalmoscope is needed. This instrument requires both greater skill and a handheld lens to use but provides binocular viewing with depth perception and a much wider field of view. Pharmacologically dilated funduscopic examination with an indirect ophthalmoscope is required for ROP and other retinal diagnostic examinations, such as for retinoblastoma or retinal hemorrhage (RH) in suspected abusive head trauma (AHT).

In addition to red reflex testing, the eyes should be closely examined with proper lighting and magnification as part of a newborn general exam. The periocular and ocular structures should be approached in a systematic manner. One option is to begin with the external structures and work inward and posteriorly, looking at each eye carefully and comparing the two eyes with each other. As a guideline, any abnormality or asymmetry noted on examination should be referred to a pediatric ophthalmologist for further management. The urgency with which to seek consultation depends on the specific finding, and guidelines appear throughout this chapter. However, one should err on the side of urgency, because the neonatal period is a critical period in visual development. To adequately inspect the eyes, familiarity with normal anatomy is required. A general overview of these structures follows (Fig. 96.1).

The eyelids protect the eyes. The eyelids contain numerous glands, which produce tears to keep the ocular surface well lubricated. Blinking spreads the tears and actively pumps the tears into the lacrimal drainage system. An inability to adequately close the eyes presents a major problem and can result rapidly in surface drying, corneal epithelial breakdown, and vision- or eye-threatening complications, such as ulceration, infection, or scarring. Use of an overhead heater should be avoided for infants who have poor eyelid closure (e.g., congenital eyelid abnormalities, neurologic problems), as the ocular surface can rapidly decompensate in such cases; alternative sources of maintaining body temperature should be used, and an ophthalmology consultation should be requested to manage the ocular surface.

The nasolacrimal duct provides a means of egress for tears, which pass through the puncta, canaliculi, and lacrimal sac to the duct. The duct is blocked at birth in 5% to 20% of newborns, resulting in epiphora and discharge in an otherwise white and quiet eye; more than 90% of such blockages clear by 1 year of age.[14] Of note, congenital glaucoma can manifest itself with epiphora as well (see Corneal Clouding).

The conjunctiva is a translucent membrane that overlies the surface of the eye and the inside of the eyelids. The sclera is the white, fibrous wall of the eye. It is relatively flexible at birth and gradually toughens over the first few years of life. The cornea is continuous with the sclera, which it meets at the limbus, and is a



• **Fig. 96.1** Anatomic structures and common neonatal diseases by anatomic site.

clear dome-shaped structure in the center of the globe (eye). The iris is a donut-shaped structure posterior to the cornea. The anterior chamber of the eye lies between the cornea and the iris and is best visualized with slit lamp examination but this is often not possible in neonates and infants. The iris is an immature structure at birth. The color tends to be gray, blue, or light brown and may become darker as the pigmented layer of the iris stroma becomes more fully developed, which typically occurs by about 6 months of age. *Heterochromia* refers to differences in the color of the iris between or within eyes and can be seen in congenital Horner syndrome (with mild ptosis and a miotic pupil), as well as syndromic conditions such as Waardenburg syndrome or Hirschsprung disease. Behind the iris lies the crystalline lens. An opacity in the lens is referred to as a cataract (see Leukocoria and Abnormal Red Reflex). The uvea is composed of the iris, the ciliary body, and the choroid. The retina is a multilayered, complex, highly metabolically active structure that lines the inside surface of the globe and contains photoreceptors that receive light and generate neuronal signals that are ultimately perceived as visual images. The macula is the central, posterior retina, between the superior and inferior temporal retinal vascular arcades, and the fovea is the very central retina containing the highest concentration of photoreceptors and producing central, high-resolution vision. Visual signals are transmitted through the optic nerve, whose cell bodies lie in the most anterior retina and which is composed of approximately 1 million individual nerve fibers. The proximal end of the optic nerve is visible as a normally golden disc approximately 15 degrees nasal and just superior to the fovea. The optic nerves lead to the optic chiasm and continuing visual and pupillary pathways in the brain.

Knowledge of normal eye structures and certain growth parameters in the newborn is important because a deviation from the averages can be associated with significant disease. For example, in congenital glaucoma, the corneal diameter is increased, and the axial length (sagittal length) of the eye is a parameter that is carefully followed by the ophthalmologist, with the aid of an ultrasound examination, to determine if the intraocular pressure is adequately controlled. At birth, the eyeball is 70% of the adult size (the average axial length in a newborn is 17 mm) and reaches 95% of the adult size by age 3 years. The corneal horizontal diameter is usually 9.5 mm at birth, which is 80% of the adult diameter. Corneal diameter can be assessed by simple bedside examination.

The visual system is immature at birth. The fovea is not completely differentiated until 15 to 45 months,[15] and myelination of the optic nerve is not completed until about 1 year of age.[16] The eye continues to develop synapses in the visual cortex during the first 10 years after birth, and although visual acuity reaches normal adult ranges by 2 years of age, this period continues to be important because any abnormality can lead to amblyopia (see the definition later). Color vision improves greatly during the first 3 months after birth, and most normal 3-month-olds have at least some color vision; color visual processing mechanisms continue to mature throughout the first year of life.[17,18]

Because of the immaturity of the system at birth, qualitatively estimating the vision of a newborn is seldom attempted, and other clues to the status of visual function are more commonly used. However, clinical and laboratory techniques can be used to estimate vision in special situations. These include eliciting a nystagmus response with optokinetic targets (striped patterns), Teller cards for preferential forced looking (a test that depends on an infant's preference to look at patterns—grating of black and white stripes—rather than homogeneous fields), visual evoked potentials, and electroretinogram. Each of these techniques uses different stimuli and yields somewhat different results, but they all demonstrate a dramatic improvement in "acuity" during the first year of life. Most commonly, visual function in a newborn is assessed by the detection of light aversion, which implies light perception. A bright light is shone into each eye or even through the thin eyelids to elicit the closing or squeezing of the lids. Although visual fixation may be intermittently present soon after birth, it is not well developed until after the second month; in contrast, a blink response to light is already present at 26 weeks' postmenstrual age (PMA),[19] and head turning to a diffuse light starts around 32 weeks' PMA. A blink in response to an approaching object (visual threat response) does not develop until approximately 16 weeks' postnatal age. An infant should fix on and follow a face or object by 2 to 3 months of age. A clever technique that is based on the observation that neonates and infants will attend to the reflection of their own faces in a mirror has been described.[20] Measurement of the "mirror distance" is a simple and reliable technique to estimate visual acuity in infants that can be used as a screening test similar to the traditional "fix and follow" (see later) and is a useful additional tool for detecting impaired visual

function at this early age.[20] Generally, the absence of visual responsiveness by a developmental or corrected age of 2 months should be taken seriously and prompt an urgent ophthalmologic evaluation.

Poor vision or blindness should be suspected in any infant with absent or poor pupillary responses, paradoxical pupillary response (initial brisk constriction of the pupil when the lights are turned off),[21] and nystagmus or roving eye movements, although these are not usually present until 2 to 3 months of age. Constant poking or rubbing of the eyes can also be a sign of poor vision.

Causes of congenital blindness or poor vision include Leber congenital amaurosis (an early and severe form of retinitis pigmentosa), other retinal dystrophies (achromatopsia and congenital stationary night blindness), congenital cataract, glaucoma, aniridia, albinism, optic nerve abnormalities (hypoplasia and coloboma), chorioretinal colobomas, high refractive errors, and congenital infections. In most babies, the cause of poor vision is obvious after a complete ophthalmologic examination. Occasionally, further investigation is necessary and may include electrophysiologic testing and neuroimaging. Babies with cerebral (central or cortical) visual impairment (CVI) have normal eye examination findings, including normal pupillary responses and no nystagmus. CVI is used to describe children with visual impairment as a result of neurologic disease, which may be congenital or acquired. Perinatal causes include intrauterine infection, cerebral dysgenesis, asphyxia, hypoglycemia, intracranial hemorrhage, periventricular leukomalacia, hydrocephalus, trauma, meningitis, and encephalitis. In developed countries, CVI is the single greatest cause of visual impairment in children, and most of these children have an associated neurologic deficit (usually epilepsy or cerebral palsy), which places a major burden on children's special services in these countries.

The prevention of all causes of blindness in infants and children is considered a high priority within the World Health Organization. This is because many causes of blindness in childhood are preventable or treatable and many of the conditions associated with blindness in children are also causes of child mortality (e.g., premature birth, congenital rubella syndrome, Vitamin A deficiency). Prevention of blindness in children is therefore closely linked to child survival, in addition to decreasing the economic, emotional, and social burden of a lifetime of blindness. This, however, imposes particular challenges as children are born with an immature visual system and, for normal visual development to occur, they need clear, focused images to be transmitted to the higher visual centers in the brain. Failure of normal visual maturation (amblyopia) cannot be corrected in adult life, so there is a level of urgency in treating childhood eye diseases.[22]

Amblyopia is defined as a reduction in best-corrected vision that cannot be attributed directly to any structural abnormality of the eye or proximal visual pathway. Amblyopia is the maldevelopment of the visual centers of the brain as a result of abnormal visual experiences early in life. It includes three etiologic categories, which often overlap. Deprivational amblyopia results from obstruction at any point in the visual axis that causes the retina to perceive poor-quality, distorted, or no images. The causes of deprivational amblyopia include congenital or acquired cataracts, corneal opacity, ptosis, and vitreous hemorrhage. Strabismic amblyopia results from a child's preferring one eye over the other when the visual axes are misaligned. Refractive amblyopia is a consequence of either a significant inequality of the refractive error in each eye or very high refractive errors in both eyes. Any of these forms of amblyopia can be encountered in the first few months of postnatal life. Because amblyopia is responsible for more cases of unilaterally reduced vision in childhood than all other causes combined, and because it is highly preventable with early detection and treatment, all newborns and infants suspected of having any of these conditions should be referred promptly to an ophthalmologist.

The onset of the pupillary light reflex (constriction in response to light) occurs around 30 to 34 weeks' gestation[19] and is not fully developed until the first month after birth. The pupils should be examined for size, shape, symmetry, reactivity to light, and afferent defects.

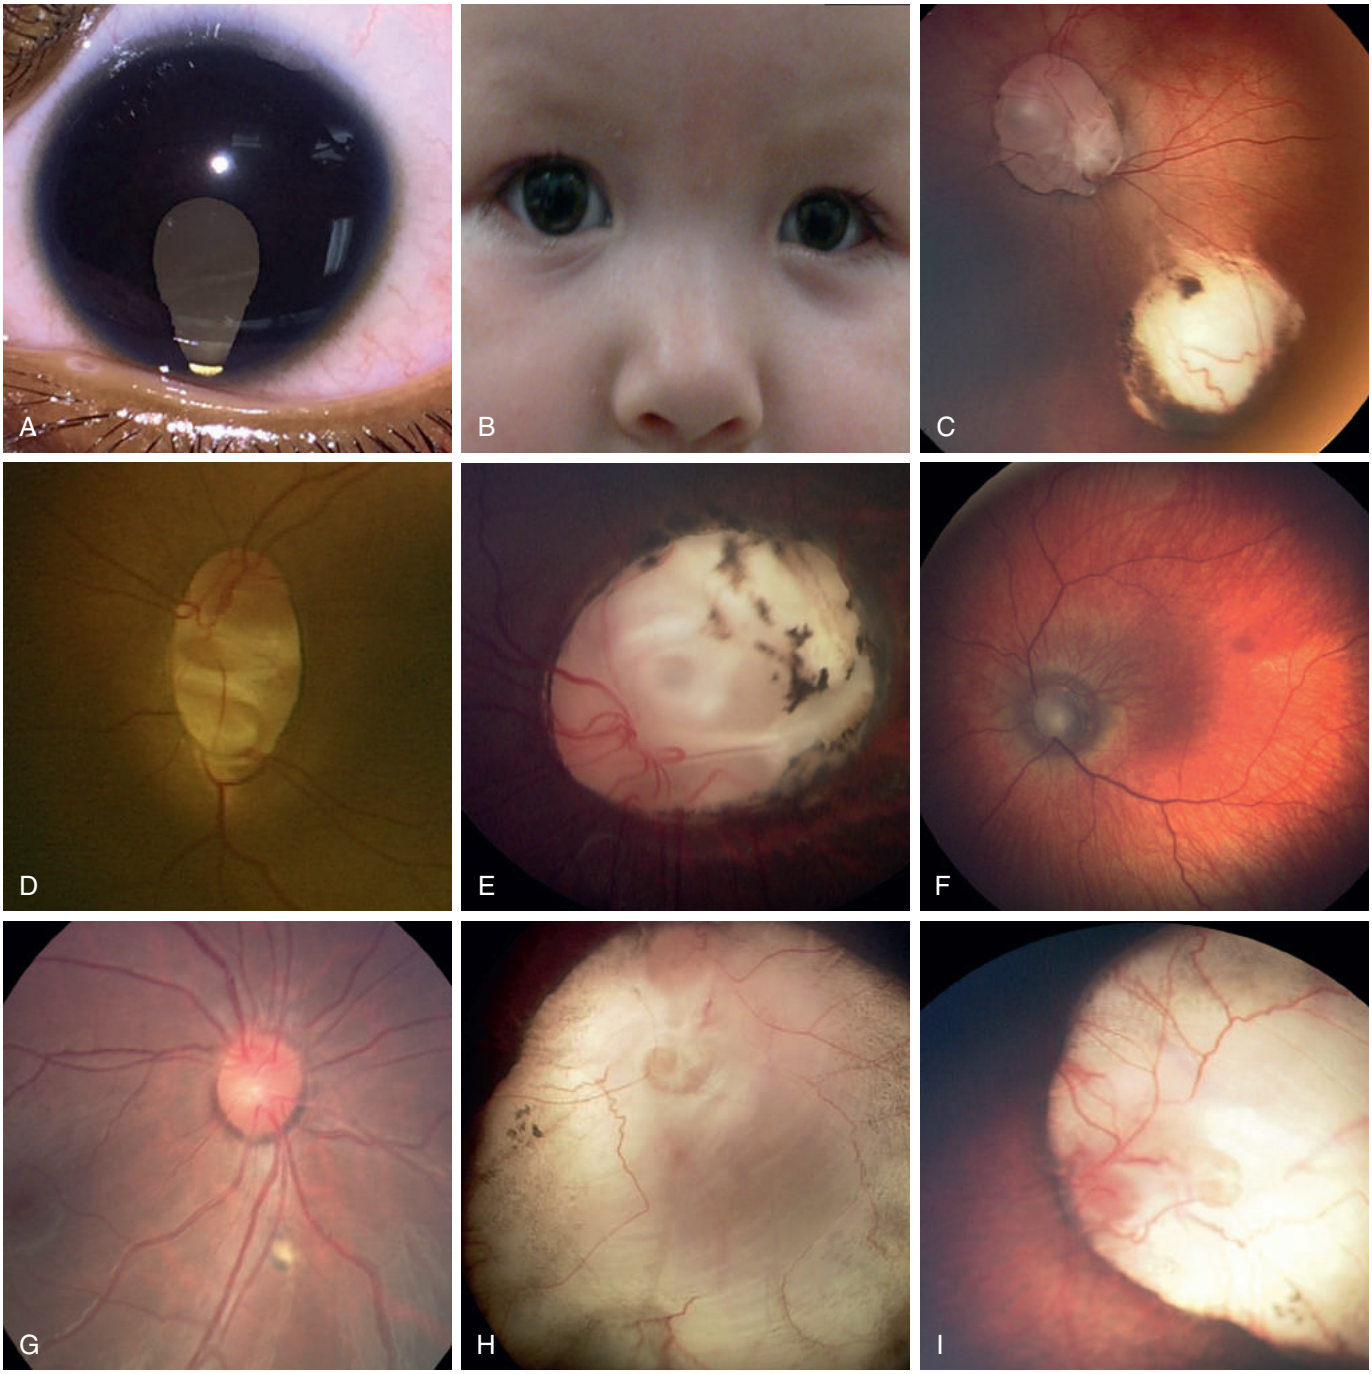
As the light passes through the pupils and is reflected through the normal clear media of the anterior and posterior segments of the eye, a characteristic red reflex is produced. The reflex is generated not from the retina, which is transparent, but from the choroidal pigmentation and vasculature. The red reflex test is vital for the early detection of vision and potentially life-threatening conditions such as cataracts, glaucoma, retinoblastoma, retinal abnormalities, systemic diseases with ocular manifestations, and high refractive errors. Red reflex assessment is an essential component of every neonatal and infant physical examination. The American Academy of Pediatrics currently recommends that all neonates have an examination of the red reflex before discharge from the neonatal nursery. In addition, the test should be performed during all subsequent routine health supervision visits.[23,24]

The red reflex test should be performed in a darkened room, projecting the largest white-light circle light of the ophthalmoscope onto both eyes of the infant—first simultaneously, from approximately 18 inches away, while looking through the aperture of the ophthalmoscope. Once the reflexes have been assessed together to allow comparison, specific abnormalities can be more closely inspected by examination of each eye separately at a nearer distance. Since neonates and infants are frequently asleep and it is difficult to open their eyes and keep them open, the red reflex test may be challenging. A useful technique to encourage a neonate to spontaneously open the eyes is the use of a primitive reflex seen in neurologically healthy children up to 6 months old: the child is supported by a hand on the thorax at approximately a 45-degree angle from the horizontal with use of the other hand to jiggle the child's bottom.[25]

It is not necessary to pharmacologically dilate the pupils, although the reflexes are easier to assess with larger pupils; indeed, the most common cause of an absent reflex is small pupils. Darkening the room or changing the light beam of the ophthalmoscope will usually overcome this problem. Although traditionally the normal reflex has been described as "red," it can often be yellow, orange, or maroon, depending on the amount of skin/eye pigmentation (i.e., light orange-yellow in lightly pigmented blue eyes or dark red in darkly pigmented brown eyes). A common cause of misdiagnosis is the inability to appreciate variations of normal due to a reference comparison to the color reflected from a blonde fundus. Darkly pigmented individuals often have a duller red reflex due to the increased amount of melanin in their fundus.[26] Therefore, the symmetry of the color, clarity, and intensity of the red reflex between the eyes is usually more useful than the qualitative assessment of each red reflex independently. A markedly diminished or dim reflex, the presence of a white reflex (leukocoria), dark spots in the reflex, or an asymmetric reflex between the eyes is an indication for immediate referral to an ophthalmologist experienced in the examination of children.[23] An exception to this rule is a transient opacity in the tear film from mucus or a foreign body that is mobile and completely disappears with blinking or manual opening and closing of the eyelids, after which the

red reflex should appear normal. Unequal or high-refractive errors (need for glasses) and strabismus may also produce abnormal or asymmetric red reflexes. An additional observation is the position of the light reflex on the corneal surface. Asymmetric positioning of this reflex can indicate misalignment of the eyes (strabismus; see later).

In addition, the shape and regularity of each pupillary aperture should be assessed to look for colobomas (Fig. 96.2A) and other congenital abnormalities (see Common Diagnostic Problems). Asymmetry of pupil size (anisocoria) can be a sign of Horner syndrome, trauma, or a congenital third nerve palsy. The tunica vasculosa lentis is a plexus of vessels that crosses the pupil, visible in preterm babies up to 34 weeks' PMA. The extent of this anterior lens capsule vascularity can be used to estimate gestational age in babies between 27 and 34 weeks' gestation.[27–29] A failure of these vessels to regress can occasionally be seen as a persistent pupillary membrane, which appears as a regular arrangement of vessels looping into the pupillary axis in front of or behind the lens.



• **Fig. 96.2** Wide spectrum in presentation of colobomas of the eye. (A) Iris coloboma, notice the difference in red reflex at the lens equator. (B) Microphthalmos with coloboma (the left eye is smaller because of a uveal coloboma). (C) Noncontiguous optic nerve and chorioretinal coloboma. (D–F) Optic nerve colobomas. (G) Small chorioretinal coloboma inferior to the optic disc. (H) Large chorioretinal coloboma involving most of the posterior pole. (I) Large chorioretinal coloboma involving the macula and optic disc.

Although the extraocular muscles are formed by 12 weeks' gestation and fetal eye movements can be detected as early as 16 weeks' gestation, the supranuclear eye movement system is not fully developed until after birth in full-term neonates. The eyes of a neonate commonly appear misaligned. It is not unusual to see the eyes shift from straight (orthotropia) to crossed inward (esotropia) to outward (exotropia). Transient deviations (neonatal ocular misalignments) occur very commonly in the first month of life in visually normal infants. At this age, it is not possible to distinguish those infants who will progress to develop pathologic strabismus from those who will develop normal binocular vision.[30] Exotropia is commonly observed in newborn nurseries and has been reported to occur in up to 33% of infants;[31] however, most exodeviations will usually resolve with the development of the fixation reflex and are rarely observed beyond 6 months of age.[32] In contrast, transient esodeviations in patients who do not go on to develop infantile esotropia do not usually persist beyond 10 weeks of age.[32,33] Most full-term infants establish normal ocular alignment within the first 8 weeks of life. In some babies the epicanthal folds of the eyelids hide the medial aspect of the sclera, creating the appearance of strabismus; however, in these cases, the visual axes are not misaligned. This common condition is referred to as *pseudostrabismus* (Fig. 96.3B) and can be confirmed by the directing of a bright light to both eyes simultaneously and observing that the reflection of the light on the corneas appears symmetric between the eyes with respect to the center of the pupil; the reflexes will appear asymmetric between the eyes if a true misalignment exists (Fig. 96.3A).

Most cases of strabismus in infants are not paralytic in origin, but congenital third, fourth, and sixth nerve palsies can occur, as well as early acquired cranial neuropathies due to trauma, infection, and other central nervous system abnormalities. When there is doubt, any apparent misalignment after 3 to 4 months of age should be considered pathologic and referred for evaluation.[23] This is especially important as, in some cases, strabismus can also be the first sign of serious ocular or systemic disorders. Premature and low birth weight infants are at increased risk of developing strabismus and other amblyogenic conditions throughout their childhood. Perinatal stroke is also associated with a high incidence of strabismus, early head turn, visual field cuts, and other vision abnormalities. Such high-risk infants as well as those with a strong family history of strabismus or amblyopia should be referred for evaluation.

It is recommended that all newborns have an ocular motility assessment.[24] In addition, since vision in young nonverbal children is mostly assessed by evaluation of the child's ability to fix on and follow an object, this test provides information on the status of the visual and extraocular muscle systems. A standard assessment strategy is to determine whether each eye can independently fixate on the object, maintain fixation on it for a short period, and then follow it as it is moved in various directions. Neonates and young infants particularly fix and follow the human face or its likeness. This assessment should be performed binocularly and then monocularly in an awake and alert child. In neonates, the following may be a jerky saccadic pursuit movement, which represents a series of hypometric saccades to localize the target. If following cannot be demonstrated, it should be verified that the motor system is intact. Range of motion and the ability to generate a saccade may be assessed by the inducement of vestibular nystagmus by rotation of the child. If poor fixation and following are noted after 3 months of age, a significant ocular or neurologic abnormality is suspected and should be referred for evaluation.[24]

• **Fig. 96.3** (A) Inward misalignment of the eyes in a premature child with infantile esotropia. (B) Pseudoesotropia or pseudostrabismus (a wide nasal bridge and prominent epicanthal folds give the appearance of esotropia; note the position of the corneal light reflex centered in the pupil of both eyes).

Common Diagnostic Problems

Leukocoria and Abnormal Red Reflex

The term *leukocoria* means "white pupil." It is often used more broadly to encompass a spectrum of opacities and abnormalities. On inspection, the pediatrician may grossly visualize a white lesion in the pupillary space or identify an abnormal red reflex. A white or abnormal reflex may also be identified in recreational photographs taken by family members.[34–36] The differential diagnosis for leukocoria includes vision- and life-threatening conditions, and leukocoria in an infant or older child requires urgent ophthalmologic evaluation. These conditions include cataract, retinoblastoma, chorioretinal or optic nerve head coloboma, retinal detachment, vitreous hemorrhage, advanced ROP, persistent fetal vasculature, Coats disease, familial exudative vitreoretinopathy, toxocariasis, and uveitis. The distribution differs widely with the population studied. In one series, 60% of 71 children who presented to a tertiary referral center with leukocoria had cataracts, 28% had retinoblastoma, and 12% had other retinal abnormalities.[37]

Cataract

A cataract is any opacification of the normally clear crystalline lens of the eye. Although congenital cataract is much less common than age-related cataract, it is among the top 3 causes of preventable childhood blindness and is responsible for approximately 10% of childhood blindness worldwide.[22] Congenital cataracts may be isolated, seen in association with another ocular

developmental abnormality, or associated with systemic diseases. The incidence of congenital cataract is approximately 2 to 4 in 10,000 live births.[22,38] Some subtypes of congenital cataracts are small and nonprogressive; dense central opacities larger than 3 mm are considered visually significant. Successful treatment of congenital cataracts may be extremely difficult, and intervention must occur very early in life; therefore early diagnosis is essential. Useful vision can be restored if the surgery is completed within the first 6 weeks after birth. Beyond this time, visual restoration becomes progressively more difficult because of irreversible deprivation amblyopia.[39,40] The appearance of nystagmus before surgery is an ominous sign of poor visual outcome and adds further urgency for surgical intervention.[41] Therefore it is essential that all newborns and young infants have screening eye examinations by a pediatrician because the visual prognosis is directly tied to timely ophthalmologic referral. Cataracts can develop or progress with time, so examination for an abnormal red reflex should be repeated at each well-child visit even if prior examination findings appeared normal.

Most patients with isolated nonsyndromic cataracts have no identifiable cause. Although teratogenic agents (e.g., rubella) may account for a proportion of cases, such insults normally give rise to other systemic malformations in addition to cataracts. Genetic mutation is likely to be the most common cause, particularly for bilateral cataracts;[42,43] it is estimated that hereditary cataracts constitute 22% of global childhood cataracts.[44] Genetic inheritance is most commonly autosomal dominant and rarely autosomal or X-linked recessive.[42,45] Multiple genes are involved in lens development; mutation screening of inherited congenital cataracts have identified nearly 200 locus and more than 100 causative genes.[38]

Marked variability can be present even within the same pedigree, and children with a family history of infantile or juvenile cataracts should be examined early by a pediatric ophthalmologist. The same is true of children with one of the numerous systemic conditions associated with cataracts: intrauterine infections (rubella, varicella); metabolic and endocrine disorders (galactosemia, neonatal hypoglycemia, diabetes mellitus, and hypoparathyroidism); fetal alcohol syndrome; chromosomal disorders (trisomy 21, Turner syndrome, trisomies 13 and 15); dermatologic diseases (congenital ichthyosis, ectodermal dysplasia); skeletal and connective tissue disorders (Smith-Lemli-Opitz, Marfan, Conradi, and Weill-Marchesani syndromes); renal disorders (Lowe, Alport, and Hallermann-Streiff-François syndromes); neurofibromatosis; and myotonic dystrophy. A selective diagnostic evaluation may be pursued in infants with cataracts, particularly bilateral cataracts, and may include TORCH titers (including syphilis); urine tests for reducing substance (galactosemia); plasma urea, electrolyte, and urinary amino acid levels (Lowe syndrome); complete blood count and ferritin, blood glucose, calcium, and phosphate levels; quantitative amino acid levels and red blood cell enzyme levels (galactokinase, galactose1-phosphate uridyltransferase); genetic consultation; chromosome analysis and next-generation sequencing and ocular examination of parents and siblings. Infants with isolated unilateral cataracts often do not have a family history and rarely have associated systemic disorders.[42]

Retinoblastoma

Retinoblastoma is the most common ocular malignancy of childhood and accounts for 3% of all childhood cancers. The average age-adjusted incidence rate of retinoblastoma in the United States and Europe is 2 to 5 per million children or 1 in 14,000 to 18,000 live births[46] but is higher in India and Africa (resulting in approximately 9000 new cases per year, of which fewer than 300 are in the United States). Seventy-five percent of patients have unilateral retinoblastoma, and 25% have bilateral retinoblastoma. The successful management of retinoblastoma depends on the ability to detect the disease while it is still intraocular; disease stage correlates with delay in diagnosis. Untreated retinoblastoma is almost uniformly fatal, and the long-term survival rate for disease diagnosed after it has spread outside the eye is less than 50%. In contrast, 5-year survival rates are greater than 90% when timely recognition and referral to centers specializing in retinoblastoma treatment occur (http://www.1rbw.org).

Two-thirds of patients receive a diagnosis before 2 years of age, and 95% receive a diagnosis before the age of 5 years.[46] The earliest age at diagnosis reported is 21 weeks' gestation by prenatal ultrasound examination.[47] Abramson et al.[48] reviewed 1831 consecutive cases of retinoblastoma. The most common presenting sign was leukocoria (54%), followed by strabismus (19%), poor vision (4%), family history with request for early examination (5%), and red eye (5%). The presenting sign was identified first by a family member or friend in 80% of cases, a pediatrician in 8% of cases, and an ophthalmologist in 10% of cases. Among patients presenting with leukocoria, the sign was first identified by a family member in 90% of cases. These findings stress the importance of routine red reflex testing for all children seen by pediatricians, beginning with newborns. Any child found to have leukocoria should be referred to an ophthalmologist for urgent evaluation.

The retinoblastoma gene, *RB1*, located on chromosomal region 13q14, was the first tumor suppressor gene to be described. Five percent of patients with bilateral disease carry a large deletion involving the 13q14 locus. In those cases, retinoblastoma is part of a more complex syndrome characterized by facial dysmorphic features (thick anteverted earlobes, high and broad forehead, prominent philtrum, and short nose), skeletal abnormalities, mental retardation, and motor impairment. Children with germline mutations are at increased risk of developing nonocular tumors. Genetic counseling of affected parents is critical to estimate the risk of transmitting the disease to their children. Regardless of the clinical presentation, it is recommended that all patients undergo genetic testing.

Persistent Hyperplastic Primary Vitreous (Persistent Fetal Vasculature)

PFV is a congenital ocular dysgenesis in which the hyaloid embryonal vasculature does not regress completely. During embryogenesis and fetal development, the "primary vitreous" contains the hyaloid vasculature system, which fills the posterior segment of the eye and comes forward to surround the lens. This system normally disappears, and a spectrum of abnormalities can be seen when these structures fail to regress, ranging from persistent pupillary strands to a vascular stalk remnant to a retrolenticular membrane and retinal disorganization or detachment. Involved eyes are typically microphthalmic, and an abnormal red reflex or leukocoria may be identifiable. Depending on the extent, surgical intervention may help to avoid recurrent hemorrhage, glaucoma, and phthisis bulbi (atrophy and degeneration of a blind eye, which can become painful), and in some cases, useful vision can be achieved.[49] Persistent hyperplastic primary vitreous (PHPV) is the most common retinoblastoma-simulating lesion, followed by Coats disease and presumed ocular toxocariasis.[50]

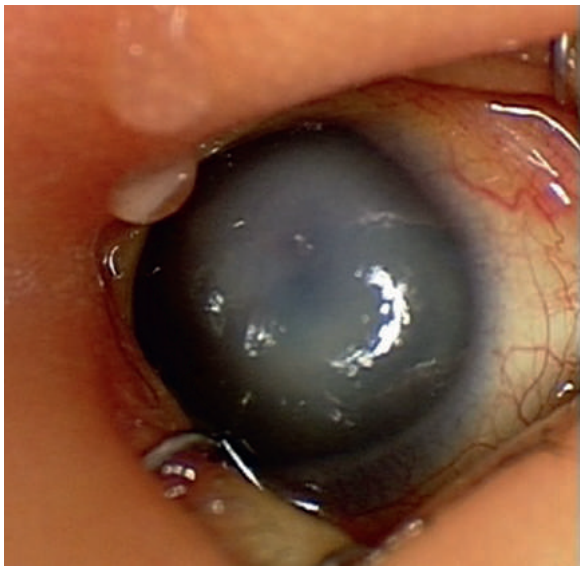
Coloboma

An ocular coloboma is a congenital anatomic defect or cleft that results from the failure of the optic fissure to close during embryogenesis.[51] The result is essentially an area of missing tissue in the eye, most commonly in the inferonasal quadrant. Depending on the population studied, its incidence ranges from 0.5 to 7.5 per 10,000 births and accounts for 3% to 11% of blind children worldwide.[51] Involved structures can include the iris, ciliary body, retina, choroid, and optic nerve (see Fig. 96.2). An iris coloboma appears as an irregular "keyhole," or "cat's-eye" pupil (see Fig. 96.2A). A chorioretinal or optic nerve head coloboma, depending on the size, will appear as an abnormal red reflex or leukocoria. The affected eye may be microphthalmic (see Fig. 96.2B). The visual prognosis depends on whether the central macula is involved, and children may have good central vision despite upper visual field defects if the macula is spared. Long term, there is a variable risk of complicating retinal detachment or choroidal neovascularization associated with retinal and optic nerve colobomas.[51] An ocular coloboma can be isolated or syndromic. There are numerous ocular abnormalities and systemic findings associated with coloboma, and more than 200 syndromes have been described. Examples include the CHARGE association, 22q11 deletion, and Treacher Collins, Walker-Warburg, and Aicardi syndromes. The systemic diagnostic testing in patients with apparently isolated bilateral or unilateral uveal coloboma should include a kidney ultrasound examination, audiometry, and spine radiographs. In addition, an echocardiogram and neuroimaging could be considered.[52,53]

Corneal Clouding

Slightly cloudy corneas can be seen in otherwise normal healthy newborns and normally clear within 1 to 2 days. Clouding is commonly seen in small for gestational age and premature infants, and it is proportional to the degree of prematurity. At 26 weeks' gestation the degree of cloudiness is significant enough to prevent the evaluation of the iris details underneath, and along with an immature hyaloid vascular system, it prevents a detailed view of the posterior segment structures (retina and optic nerve). This is an important consideration when the ophthalmologist is asked to evaluate premature infants soon after birth for an intraocular spread of systemic infections (endophthalmitis) or structural anomalies in suspected genetic diseases, etc. Slowly, as the child matures, the cornea establishes transparency and most of the time is sufficiently clear to allow retinal examinations for ROP by 30 to 32 weeks' postconceptional age.

Persistent opacification of the cornea in a newborn may be the result of congenital glaucoma, corneal dystrophies, developmental abnormalities of the cornea and or other anterior segment structures (Fig. 96.4), infection, iatrogenic trauma, or metabolic disorders. Close inspection with magnification will identify opacification in a focal, regional, or diffuse pattern, depending on the cause. The cornea is normally clear all the way to its border with the sclera (the limbus), with iris details easily visible underneath; these details will be obscured when the cornea is opacified. A large or central opacity will also result in an abnormal red reflex. When identified, congenital corneal opacification requires urgent ophthalmologic evaluation to rule out congenital glaucoma, infection—which could become eye or life threatening—or an opacification that is amenable to surgical correction during the early critical period in visual development.



• **Fig. 96.4** Cloudy cornea secondary to anterior segment dysgenesis.

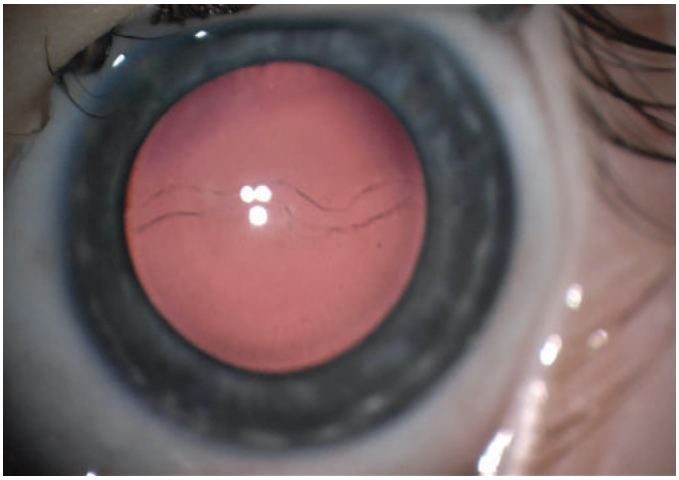
Glaucoma is an optic neuropathy usually associated with raised intraocular pressure. In contrast with adult- or juvenile-onset glaucoma, which may be successfully managed medically, congenital glaucoma is a surgical disease that requires prompt intervention, frequently in the neonatal period. Vision loss from glaucoma is typically irreversible. Key signs to identify include corneal clouding (not always), corneal and eye enlargement (buphthalmos), tearing, blepharospasm (blinking), Haab striae (tears in the Descemet membrane, seen as lines in the red reflex), and photophobia. It is worth highlighting that tearing is a sign of glaucoma, not just of a blocked tear duct. Finally, congenital glaucoma has multiple systemic associations, such as Sturge-Weber syndrome, neurofibromatosis, Lowe syndrome, congenital rubella, and Rubenstein-Taybi disease.

Sclerocornea is characterized by a cornea that is opacified and white like the sclera, with which it is developmentally continuous. Typically, these opaque areas are located at an indistinct corneoscleral limbus (border), can extend centrally, and contain superficial vascularization. It can occur in isolation or can be associated with cataracts, microphthalmos, and/or infantile glaucoma.[54] In contrast to sclerocornea, *Peters anomaly* classically has a central corneal opacity with clear cornea peripherally, absence of posterior corneal stroma, and variable attachments between the posterior corneal surface and the iris and or lens.[55] The encompassing term *anterior segment dysgenesis* is sometimes preferred to describe many of these developmental anomalies of the cornea and anterior segment that result in congenital corneal opacities and congenital glaucoma as there is significant overlap and variability in their presentation (see Fig. 96.4).

Infectious keratitis can be herpetic with characteristic epithelial dendritic ulcers and corneal stromal inflammation. *Bacterial keratitis* is less common in countries that practice routine administration of conjunctivitis prophylaxis at birth. However, a bacterial corneal ulcer can begin as a corneal abrasion (see the later discussion) and then quickly enlarge, resulting in corneal thinning or perforation, endophthalmitis, and even bacterial sepsis. Aggressive topical and sometimes systemic antibiotics are required, and any infant with a red eye and corneal opacity or abnormality should be referred for immediate ophthalmologic evaluation.

Iatrogenic trauma may result in corneal injury and may be the result of amniocentesis or forceps delivery. Injuries from the latter are characterized by linear breaks in the Descemet membrane, which are more likely to be vertical or diagonal than the horizontal breaks seen with glaucoma, and may be accompanied by other signs of trauma (Fig. 96.5).

Corneal dystrophies, such as congenital hereditary endothelial dystrophy and posterior polymorphous dystrophy, may also result in cloudy corneas. The former always manifests itself at birth, whereas the latter may or may not be present at birth.[54] Metabolic disorders, such as some mucopolysaccharidoses, may cause progressive clouding but often do so later in life and rarely during the neonatal period.



• **Fig. 96.5** Horizontal corneal endothelial breaks consistent with Haab striae in primary congenital glaucoma.

Red Eye/Eye Discharge

The most common and important causes of a red eye in neonates include infectious conjunctivitis, subconjunctival hemorrhage, foreign bodies, and vascular malformations.

The incidence of neonatal conjunctivitis (ophthalmia neonatorum) has decreased dramatically since the introduction of prophylaxis in 1881. Despite this, ophthalmia neonatorum still blinds thousands of babies annually worldwide.[56] Current prophylaxis practices vary globally, with many countries no longer considering it to be an important public health intervention, and some countries continuing with prophylaxis. Policy regarding prophylaxis should be informed by the prevalence of *Neisseria* and *Chlamydia*, their resistance profile against specific antibiotics, and access to prenatal care.[56]

The etiologic cause of conjunctivitis in the newborn can be chemical, bacterial, or viral (Table 96.1). Although infections are usually transmitted to the infant by direct contact during passage through the birth canal, organisms can ascend to the uterus, so even infants born via cesarean delivery can be infected, particularly in the setting of prolonged rupture of membranes but even with intact membranes.[57] Prophylactic agents include 1% silver nitrate, 0.5% erythromycin ointment, 1% tetracycline ointment, and 2.5% povidone-iodine with no agent shown to have superior effectiveness.[56] No prophylactic agent completely eliminates the risk of developing an infection, and a high index of suspicion

TABLE 96.1 Diagnostic Features and Management of Neonatal Conjunctivitis

Etiologic Agent	Onset	Clinical Characteristics	Diagnosis	Treatment
Chemical	24 h	Noninfectious Lid edema, watery discharge	History of exposure, self-limited in <48 h	None
Gonococcal (see Fig. 96.5)	3–4 days	Bilateral, hyperacute purulent conjunctivitis, marked lid edema, copious discharge Can perforate cornea	Cell culture and Gram stain Gram-negative intracellular diplococci	Ceftriaxone 25–50 mg/kg daily intravenously Topical irrigation Topical antibiotics useful only if corneal ulcer present
Chlamydia trachomatis (most common)	5–7 days	Mild mucopurulent nonfollicular conjunctivitis, lid edema, pseudomembrane formation Pneumonitis after 3–12 weeks	Cell culture, Giemsa stain, direct immunofluorescent assay, enzyme-linked immunoassay, PCR Basophilic intracytoplasmic inclusions in epithelial cells	Orally administered erythromycin, 12.5 mg/kg every 6 h for 2 weeks or azithromycin suspension, 20 mg/kg orally daily for 3 days
Staphylococcus, Streptococcus, and other bacteria	5–14 days	Nosocomial, mucoid discharge, conjunctival hyperemia, and chemosis	Cell cultures, Gram stain	Broad-spectrum topical antibiotic (e.g., polymyxin B–trimethoprim, one drop every 4 h for 7 days)
Herpes simplex virus	6–14 days	Unilateral or bilateral conjunctivitis (nonfollicular), serous discharge, associated lid vesicles, and, occasionally, corneal epithelial dendritic defects that stain with fluorescein with or without systemic involvement	Cell cultures, direct fluorescent antibody staining, enzyme immunoassay detection, PCR Multinucleated giant cells with intracytoplasmic inclusions	Acyclovir, 60 mg/kg/day intravenously in three divided doses for 2 weeks (3 weeks if CNS or disseminated disease) plus topical drops (1% trifluridine, 0.1% iododeoxyuridine, or 3% vidarabine)

CNS, Central nervous system; *PCR*, polymerase chain reaction.

should be maintained, in particular in those patients with risk factors (maternal infection, lack of prenatal care, or premature rupture of membranes). Gentamicin ointment should be avoided, as it is associated with periocular ulcerative dermatitis when used on the newborn eye.[58]

Despite common teaching, the timing of the onset of conjunctivitis is not a reliable diagnostic clue, because significant overlap exists among the different etiologic agents. For this reason, conjunctival cultures (in Thayer-Martin agar, blood agar, and chocolate agar) and conjunctival scraping for Gram and Giemsa staining are mandatory and should be performed without delay. It is not necessary to wait for an ophthalmology consultation to initiate laboratory investigation and treatment, because delays in treatment of gonococcal conjunctivitis can have devastating consequences. *Neisseria gonorrhoeae* can penetrate an intact corneal epithelium, rapidly leading to perforation of the globe within hours if treatment is not initiated; therefore all forms of conjunctivitis must be considered bacterial until proven otherwise. Appropriate treatment should be instituted once the results of cultures are known but should never be delayed (Fig. 96.6).

The infant with mucopurulent discharge must be distinguished from the infant who exhibits only excessive tearing (epiphora) and a relatively white eye. Congenital nasolacrimal duct obstruction is the most common cause of neonatal epiphora, although the possibility of congenital glaucoma must always be ruled out. Congenital obstruction of the nasolacrimal duct is present in about 5% to 20% of infants but usually resolves spontaneously by 12 months of age.[59] It is more common in premature infants and in patients with Down syndrome; cesarean section has been inconsistently found to be a risk factor.[59] Bilateral involvement is present in about one-third of cases. Usually, the obstruction is due to failure of the nasolacrimal duct canalization, most commonly occurring at the distal end of the nasolacrimal duct (membrane or valve of Hasner). Symptoms become manifest by 1 month of age in 80% of cases, with tearing, tear stagnation (increased tear lake), intermittent mucopurulent discharge, and crusting of the eyelashes. As a consequence of chronic obstruction, secondary infection in the lacrimal sac may occur, a condition known as *dacryocystitis*. Pressure on the lacrimal sac causes a reflux of mucopurulent material from the punctum. This tends to be a low-grade chronic infection, although occasionally it can progress to blepharoconjunctivitis and cellulitis (Fig. 96.7). The most common organism in culture-positive specimens are *Haemophilus haemolyticus* (20%) and *Haemophilus influenzae* (20%).[60] In contrast, acute dacryocystitis, more commonly seen with congenital dacryocystoceles, is a more severe infection that requires prompt intravenous antibiotics (see later). Simple nasolacrimal duct obstruction (NLDO) usually resolves spontaneously within the first year of life in more than 80% of cases; only conservative management is indicated in most cases. This consists of a digital massage downward from the lacrimal sac over the nasolacrimal duct on the side of the nose. The massage empties the sac, reducing the opportunity for bacterial growth. Topical broad-spectrum antibiotic drops or ointment, such as bacitracin zinc and polymyxin B sulfate ophthalmic ointment or drops, can be used if there is conjunctival injection and discharge. Referral to an ophthalmologist should be considered if the condition has not resolved toward the end of the first year, because probing and/or intubation of the lacrimal sac is likely necessary to relieve the obstruction, although the optimal timing of surgery remains controversial. Recent studies report an age-dependent decrease in the success rate of initial probing,[61] while others report no age-related decline in the success rate of surgical treatment for congenital NLDO in children treated up to 36 months of age.[62]

Preseptal and orbital cellulitis can also manifest with conjunctival injection, chemosis, and discharge. In addition, orbital cellulitis may cause altered ocular motility and pupillary reflexes and proptosis. Both conditions are typically unilateral and can rarely occur in the first month of life, sometimes secondary to acute dacryocystitis from an infected dacryocystocele (see Ptosis and Other Eyelid and Lacrimal Abnormalities).

• **Fig. 96.6** A 6-day-old newborn with gonococcal conjunctivitis. Note the marked lid edema and copious purulent eye discharge.

A subconjunctival hemorrhage is seen as a bright red discoloration under the conjunctiva, obscuring the white scleral background, and is common in the perinatal period. In most cases, it is caused by elevated venous pressure in the head and neck produced by compression during uterine contractions. Later in life, subconjunctival hemorrhage may be a feature of child abuse, although it can also occur spontaneously. A subconjunctival hemorrhage in isolation is completely innocuous and usually resolves in 10 to 14 days.

Motility Abnormalities and Nystagmus

Various eye motility and alignment abnormalities can be present in the first month of life. The most common form of strabismus in early infancy is infantile or essential esotropia (see Fig. 96.3A). This form of convergent strabismus is rarely actually congenital, so this term has been abandoned. It is usually present by age 3 to 4 months and is characterized by a large-angle deviation. These children tend to cross-fixate (use the left eye to view the right visual field and vice versa), simulating an abduction deficit because it is hard to get the child to follow an object to the ipsilateral field. This can easily be mistaken for bilateral sixth nerve palsy. However, sixth nerve palsies in the neonatal period are extremely rare, and an abduction movement can sometimes be elicited by the patching of one of the child's eyes to force the other eye to abduct in search of an object or by use of the doll's-eye (the eyes lag behind the turning of the head from side to side) or optokinetic nystagmus maneuvers. Infantile esotropia is a condition that is not likely to resolve spontaneously without surgical correction. Because of a high associated risk of amblyopia, prompt referral of these patients to a pediatric ophthalmologist within the first few months of life is appropriate. Even if the child's age or systemic condition is not appropriate for surgical correction, patching and other treatments should be initiated as early as possible. Ideally, surgical correction is accomplished early, by 6 to 12 months of age.

Congenital motor nystagmus (infantile nystagmus syndrome) is an involuntary, bilateral, conjugate oscillation of the eyes that develops within the first 6 months of life. Despite the name, eye movement abnormalities are rarely noticed at birth. Disorders of the anterior visual pathways resulting in blindness or severe visual deprivation very early in life can also result in nystagmus (sensory deprivation nystagmus), which can be manifest as large-amplitude "wandering" eye movements or with a smaller-amplitude, faster movement that resembles the congenital motor form. Nystagmus caused by a visual deficit does not develop until about 3 months of age. Any form of bilateral (and sometimes unilateral) visual deprivation, including cataracts, corneal abnormalities, glaucoma, optic nerve problems, and chorioretinal colobomas, can manifest themselves with nystagmus, and a prompt ophthalmic evaluation is needed to rule out these conditions, which are treatable in some cases. Other conditions such as albinism, achromatopsia (congenital absence of the retinal cones), and aniridia can also result in nystagmus, which is often very similar to motor nystagmus. Since the ocular findings in these conditions are more subtle and easily missed, an electroretinogram is usually recommended before the diagnosis is confirmed. Because of the overlap with identifiable causes, motor nystagmus should always be considered a diagnosis of exclusion, as other ocular and neurologic disorders can manifest with the same clinical characteristics. Certain specific forms of nystagmus are commonly associated with neurologic dysfunction; these include upbeat nystagmus, see-saw nystagmus, and even monocular nystagmus. However, these forms have all been associated with sensory loss, and an ophthalmologic examination is necessary even when neuroimaging studies rule out intracranial disease.

Other transient disorders of the ocular motor system include flutter-like, high-frequency, small-amplitude movements that in newborns may be self-limiting and resolve spontaneously within the first few weeks of life. This saccadic oscillation should not be confused with nystagmus. Some infants can also exhibit transient downward deviation of the eyes.[63] This disorder can be distinguished from the more serious sun-setting sign, associated with hydrocephalus, by demonstration of intact upgaze movements using vestibular–ocular responses. Neuroimaging fails to demonstrate any underlying neurologic disorder, and the deviation tends to reduce gradually over the following months. A true upgaze palsy and convergent strabismus can be seen in premature infants who sustained intraventricular hemorrhage.[64] Paroxysmal tonic upgaze of childhood is a rare and distinctive syndrome characterized by episodes of sustained conjugate upward deviation of the eyes. Symptoms normally appear in babies younger than 1 year and are characterized by an upward stare with the eyes rolled back, while the chin is held low (possibly to compensate for the abnormal eye position). The horizontal eye movements are normal, as are the rest of the neurologic examination and imaging findings. The condition tends to improve with time.[65]

Ptosis and Other Eyelid and Lacrimal Abnormalities

External inspection of the eyes and eyelids should be performed in every newborn. The eyelids are fused usually until 25 weeks' gestation, but they may rarely remain fused until 30 weeks' gestation. Eyelid colobomas are rare congenital full-thickness defects of a missing eyelid, usually involving the upper eyelid border. Eyelid colobomas may be associated with Goldenhar syndrome. The consequent lack of ocular surface coverage places the infant at high risk of corneal abrasion, ulcer, scarring, and vision loss. Such infants require urgent ophthalmology consultation and should not be placed under overhead heaters without adequate ocular protection.

Most cases of congenital ptosis are caused by an isolated developmental anomaly of the levator palpebrae muscle. Other causes include congenital third nerve palsy, Horner syndrome, blepharophimosis syndrome, and Marcus Gunn jaw-winking ptosis, which is a synkinesis between the levator palpebrae and the muscles of mastication. This type of ptosis is characterized by elevation of the lid associated with sucking or chewing.

Because form deprivation amblyopia can occur as a result of complete obstruction of the visual axis, this condition must be managed aggressively by an ophthalmologist familiar with the treatment of eyelid disorders and amblyopia. Even though this type of amblyopia is the most severe and concerning to the neonatologist, it is important to remember that even without the complete obstruction of the pupil, amblyopia can occur secondary to the blur induced by astigmatism produced by the ptotic eyelid on the cornea. If vision is not threatened, surgery may be deferred until 4 or 5 years of age, although close follow-up to detect amblyopia is necessary, and many surgeons have argued the benefits of earlier surgery.[66]

A number of eyelid tumors can be present at birth or shortly thereafter. Capillary hemangiomas are usually not present at birth and appear in the first couple of weeks of life. The lesions can have a superficial component, which is red and sometimes dimpled, resembling a strawberry, and a deeper component, which appears

as a deep, diffuse purplish mass. The hemangioma grows during the first 6 to 8 months of life and then stabilizes, regresses, and involutes over several years. These lesions are amblyogenic because they can cause mechanical ptosis, obstruct the visual axis, or cause significant astigmatism. Systemic nonselective beta-blockers (e.g., propranolol) have become first-line treatment, showing remarkable effectiveness in causing regression of these tumors.[67,68] Topically administered timolol can be effective for superficial lesions as well.[69] Other treatment options include topical, intralesional, or systemic steroids; interferon alfa; vincristine; and surgical resection.

Capillary hemangiomas should be distinguished from other capillary vascular malformations (such as port wine stains) that are present at birth and do not exhibit regression. These are sharply circumscribed lesions that are usually unilateral. In these patients, Sturge-Weber syndrome should be suspected. When the skin lesion involves the eyelid, an ophthalmologic consultation should be requested to rule out glaucoma (occurring in about 50% of patients) and vascular abnormalities of the choroid.

A dacryocystocele is formed when a proximal and a distal obstruction coexist in the lacrimal sac and the lacrimal sac becomes distended.[70] Clinically it is manifested as a bluish, nontender mass just inferior and nasal to the medial canthus (Fig. 96.8), is not uncommon, and can have potentially serious consequences in a neonate, including meningitis and septicemia. Intravenous antibiotics should be administered followed by decompression of the sac after 24 to 48 hours if the dacryocystitis shows no abatement. A dacryocystocele should be distinguished from a frontal encephalocele and can occasionally be confused with a hemangioma or a dermoid cyst.

Ocular Trauma in the Neonatal Period

Newborns may experience injuries to the eye as a result of birth, more commonly difficult births, such as those involving prolonged delivery, cephalopelvic disproportion, vacuum extraction, or forceps use. Intrauterine injuries may result from amniocentesis, with delayed discovery at birth; severe eye injuries have also

• **Fig. 96.8** (A) Bilateral dacryocystoceles. (B) Infected dacryocystocele with erythema in medial canthal area and a firm tender mass. (C, D) Dacryocystocele with progression to preseptal cellulitis. (E, F) Dacryocystitis with localized abscess before and after nasolacrimal duct probing with endonasal cyst marsupialization.

been reported to occur during antenatal fetal procedures.[71] Some common injuries will heal without long-term visual or ocular sequelae.[72] However, identification of birth-related eye trauma necessitates immediate ophthalmologic consultation to perform a complete dilated examination, identify all injuries, and assess the need for treatment.

Subconjunctival hemorrhage results from the rupture of blood vessels on the surface of the eye. It is distinguished from conjunctival injection due to an inflammatory or infectious cause by characteristically well-demarcated borders between spots of blood underneath the conjunctiva and completely white sclera directly adjacent to the blood. Subconjunctival hemorrhages will resolve spontaneously with time and do not require treatment. However, large diffuse hemorrhages can be a sign of more significant trauma underneath the hemorrhage or within the eye, and a complete eye examination, including dilated funduscopic examination, may be indicated. Recurrent subconjunctival hemorrhage could be a sign of a coagulopathy or platelet abnormality, and an appropriate work-up should be pursued in such cases.

Hyphema is the presence of red blood cells in the anterior chamber of the eye (the space between the cornea and the iris), most commonly the result of trauma, including birth trauma. It is often associated with other ocular injuries. Clot or hemorrhage of differing magnitude may be seen on close inspection, ranging from a subtle crescent of blood at the corneoscleral limbus to an eye completely filled with blood, obscuring any view of the structures underneath. The red reflex is commonly abnormal. Hyphema is a potentially vision-threatening condition and requires close management by an ophthalmologist. The immediate concern is obstruction of the aqueous fluid drainage angle structures, resulting in an acute rise in intraocular pressure (IOP) or acute glaucoma. High IOP is painful enough to cause vomiting in children and adults and may manifest as crying, irritability, grimacing, poor feeding, or emesis in an infant. If the IOP is high enough for any prolonged period, irreversible optic nerve damage can ensue, with permanent vision loss. Corneal blood staining may also occur, which takes many months to clear, and can result in amblyopia.

An open globe injury (ruptured globe) refers to a full-thickness break in the eyewall (e.g., sclera, cornea). These injuries can occur as a laceration or as a rupture, in which pressure is applied to the front of the eye, and the eye wall breaks open at its weakest points, such as the corneoscleral limbus or extraocular muscle insertion sites. Key signs include an obvious break with protrusion of intraocular contents (e.g., the iris), which typically appear brown; extensive subconjunctival hemorrhage; a flat anterior chamber (the iris and cornea have come together); hyphema; vitreous hemorrhage, which may be seen as a poor red reflex; and abnormal eye contour or intraocular foreign body on orbital imaging. An open globe is a surgical emergency.

A *corneal abrasion* is an epithelial defect on the corneal surface. Staining with fluorescein will identify areas of missing epithelium, which appear green under a blue light source and magnification. Treatment includes topical antibiotic ointment and close follow-up to ensure complete healing and to monitor the patient for the development of bacterial keratitis (see the earlier discussion of corneal clouding). In a neonate, a corneal abrasion must be taken very seriously, because complications can include the sequential development of keratitis, endophthalmitis, septicemia, and meningitis.[73]

Other injuries include RHs (see the later discussion); corneal trauma from forceps, resulting in tears of the Descemet membrane, visible as vertical or circumferential lines on red reflex examination, corneal thickening and opacification from edema, and corneal scarring; eyelid or adnexal injuries requiring surgical repair; choroidal rupture, which requires dilated fundus examination for diagnosis; and even traumatic optic neuropathy.[71]

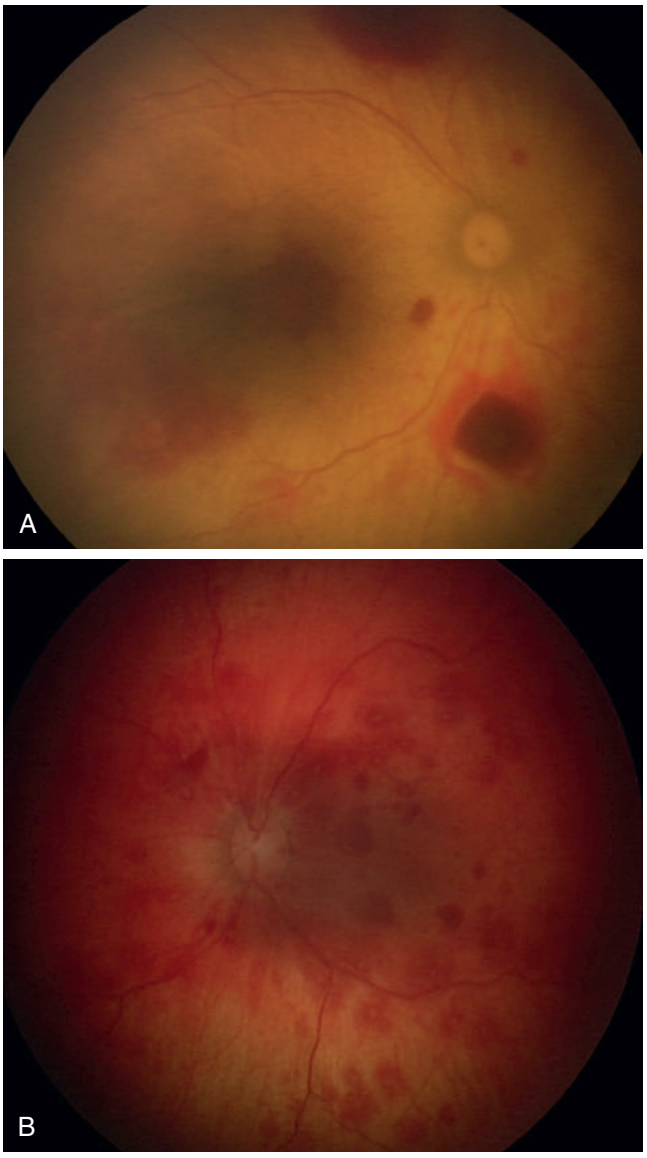
Retinal Hemorrhages and Abusive Head Injury

RH from the birth process is very common. The incidence is estimated to be between 10% and 40% of all newborns, depending on the examiner, time from birth, and the specific population studied.[74–76] The rate in infants delivered with vacuum assistance is even higher, at 75% to 78%.[74,75] The association between vacuum-assisted delivery and RH supports a role for mechanical trauma to the retinal vessels (e.g., from direct compression of the globe); however, additional factors are likely involved, because head circumference and the duration of labor are not significant factors, and RH occurs after cesarean delivery, albeit at a decreased frequency (7%).[74,76] RHs are usually identified by indirect ophthalmoscopy, although an abnormal red reflex may be noted in some severe cases.

The long-term visual consequences of birth-related hemorrhages remain unknown. Central or large hemorrhages can interfere with visual development in some cases (Fig. 96.9A), but the occurrence of significant visual deficits caused by RH is probably low. It is important to understand the characteristics that distinguish birth-related RH from those associated with AHT, as there may be considerable overlap. The great majority of birth-related RHs are intraretinal; subretinal and preretinal hemorrhages are less frequent. Such hemorrhages include superficial flame and deeper blot hemorrhages, and larger hemorrhages may frequently contain white centers, which are a completely nonspecific finding.[74–76] Although commonly located in the posterior pole of the eye, they may also extend to the mid- and far-retinal peripheries and range in number from a few to too numerous to count.[74,75] They may be bilateral, unilateral, or asymmetric.

The preceding characteristics are similar to those of the RH seen in AHT (see the later discussion), although the severity is usually greater in AHT. A key characteristic, therefore, is the time to resolution of birth-related RH. Most intraretinal hemorrhages clear within the first 2 or 3 weeks after birth, many within the first few days.[74,75] In most series, all intraretinal hemorrhages have cleared by age 4 weeks, whereas preretinal or subretinal hemorrhages may take 6 weeks or more to clear.[74] Therefore multiple intraretinal hemorrhages present past 1 month of age should be considered not related to birth. Isolated, resolving intraretinal hemorrhage or persistent preretinal or subretinal hemorrhage past 1 month of age may rarely be related to birth, but this pattern of RH would not at any age by itself be considered specific for any cause, including abuse.

Pediatric AHT is a leading cause of death in infancy. Previous names have included *shaken baby syndrome, inflicted or nonaccidental head trauma*, and *inflicted childhood neurotrauma*. AHT is characterized by intracranial hemorrhage with or without RHs and or additional injuries, including bony fractures. Affected children are less than 3 years of age, with the great majority younger than 1 year.[77,78] The mechanism of trauma is believed to be repetitive acceleration-deceleration of an infant's head, with or without blunt impact. RHs are present in 50% to 100% of victims of AHT.[77,78] The presence of any RH in an infant is highly associated with abuse, and increasing RH severity correlates with an increasing likelihood



• **Fig. 96.9** Retinal hemorrhages in neonates. (A) Birth-related hemorrhages. Note the large hemorrhage covering the central macula in this neonate with thrombocytopenia. This patient developed severe myopia and amblyopia. (B) Diffuse intraretinal hemorrhages (dot blot, flame shape, and white centered) secondary to nonaccidental head trauma.

of abuse.[78,79] In AHT, RH may range from none to a few intraretinal hemorrhages confined to the posterior pole to bilateral, "too numerous to count," intraretinal, subretinal, and preretinal hemorrhages, extending to the far periphery or ora serrata (termination of the retina).[80,81] The hemorrhages may be unilateral or markedly asymmetric. Macular retinal folds and hemorrhagic macular retinoschisis (splitting of the retinal layers) may be seen at the severe end of the spectrum. In comparison, RHs associated with accidental head trauma are typically few in number, intraretinal, and limited to the posterior pole (see Fig. 96.9).[78,82] However, more severe RH and even retinal folds may be seen with unambiguous severe accidental trauma, such as fatal motor vehicle crashes.[83]

In addition to accidental head trauma, the differential diagnosis of RH in infancy includes birth-related RH (see the earlier discussion), coagulopathy, septicemia, leukemia, anemia, and glutaric aciduria. These conditions may be recognized with the use of various diagnostic tests and are often distinguishable from the patterns of RH seen in AHT. Studies have demonstrated that prolonged chest compression with cardiopulmonary resuscitation rarely results in RH, and when present, these RHs are a few isolated posterior pole intraretinal hemorrhages. RHs associated with raised intracranial pressure are limited to small splinter hemorrhages on a swollen optic disc or superficial, flame-shaped, intraretinal hemorrhages adjacent to a swollen optic disc.[84] Vaccination injections, convulsions, and severe coughing do not cause RH.[85]

Children with AHT may present with a history of minor blunt head trauma, such as a short fall, or no trauma history at all and exhibit lethargy, seizures, increased or decreased tone, vomiting, poor feeding, breathing difficulties, or apnea.[77] Head CT identifies subdural or subarachnoid hemorrhage, sometimes with a combination of chronic and acute features, but very rarely the findings may initially be normal; brain MRI provides a better look at the soft tissue and brain parenchyma to identify features such as hypoxic-ischemic injury; plain film radiographs may reveal a skull fracture; a skeletal survey is a critical modality for identifying other bony injuries. Because the history provided is often vague or unreliable, a high index of suspicion and a low threshold for obtaining diagnostic tests and specialist consultation must be maintained.

An ophthalmologic examination should occur within 48 hours, preferably within 24 hours, because RH can begin to resolve within days.[86] A dilated fundus examination with an indirect ophthalmoscope is required to adequately visualize the retina. Ophthalmologic consultation should not be delayed because of an inability to pharmacologically dilate the pupils because of neurologic pupil examination checks; the ophthalmologist can still attempt to view a portion of the retina and return for a dilated examination later. It is very important to document the type(s), number, location(s), and laterality of all RHs, by the use of explicit descriptive terms and thorough use of diagrams.

Fundus photographs, for example, those taken with a RetCam camera, should be obtained when possible. Such photographs provide important documentation and are often easily obtained at the time of sedation administered for MRI or other tests. However, the authors stress that the presence of RH is not descriptive enough, and the extent and detailed characteristics of the hemorrhages are vitally important. Cameras may identify and characterize posterior pole RH, but they do not always provide adequate visualization of the retinal periphery and are not a substitute for an indirect examination. RHs have been reported as a result of RetCam use in a premature infant undergoing ROP screening, but not in other circumstances.[87] Notably, this 25-week-gestational-age infant was less than 34 weeks' PMA at the time of the examination and had immature retinal vasculature, without smooth muscle, elastin, or collagen layers and poor autoregulation, unlike the mature vasculature of a few-months-old infant evaluated for AHT.[87] Further, other investigators have failed to identify any RHs with the routine use of the RetCam for ROP screening.[88] Nevertheless, whenever possible an indirect ophthalmoscopic examination should be performed and documented before a contact fundus camera is used.

Visual impairment in children with AHT is thought to be due, most often, to cortical damage. However, persistent macular or vitreous hemorrhage, retinoschisis, and other scarring conditions may result in significant deprivation amblyopia, induced myopia, and anisometropic amblyopia, or photoreceptor damage limiting visual function. The overall mortality rate in AHT has been

reported to be between 13% and 36%.[89] Approximately two-thirds of the survivors have long-term neurologic deficits. A prospective study of 25 children with a mean follow-up of 5 years, found that 68% had neurologic and cognitive impairment, and half of these had severe disabilities and were totally dependent.[89]

Common Ophthalmic Manifestations of Systemic Diseases

See Tables 96.2–96.4.

TABLE 96.2 Ophthalmic Manifestations of Systemic Diseases With Neonatal Findings

Etiologic Disorder	Inheritance	Ophthalmic Manifestations
Aicardi syndrome	X-linked dominant disorder characterized by triad of callosal agenesis, infantile spasms, and chorioretinal lacunae OMIM 304050	Bilateral or unilateral, multiple, chorioretinal lacunae (most constant feature), optic disk/retinal/iris colobomas, optic nerve head hypoplasia, microphthalmos, retinal detachment[168]
Alagille syndrome (1 and 2)	Autosomal dominant disorder characterized by neonatal jaundice secondary to hepatic cholestasis OMIM 118450 and 610205	Posterior embryotoxon, optic disc drusen, and retinal pigmentary changes sometimes in associations with rod-cone dystrophy
Albinism	Heterogenous disorder of melanin metabolism associated with abnormal development of the retina and visual pathways Ocular forms: type 1 (X-linked) Oculocutaneous forms: types 1–4, Hermansky-Pudlak and Chediak-Higashi syndromes (autosomal recessive, autosomal dominant) More than 13 genes involved	Reduced vision, delayed visual maturation, nystagmus, strabismus, iris transillumination, fundus hypopigmentation, foveal hypoplasia, misrouting of optic nerve fibers, anomalous optic chiasm
CHARGE syndrome (*c*oloboma, *h*eart defect, choanal *a*tresia, *r*etarded growth, *g*enital hypoplasia, and *e*ar anomalies)	Nonrandom cluster of congenital abnormalities Mutation of *CHD7* on 8q12.1[169,170] OMIM 214800	Unilateral or bilateral uveal colobomas (retinal more frequent than iris), microphthalmos, Bell palsy
22q11.2 deletion syndrome	Contiguous gene deletion syndrome (encompasses DiGeorge syndrome, velocardiofacial syndrome, conotruncal anomaly–face syndromes) Autosomal dominant	Posterior embryotoxon, tortuous retinal vessels, eyelid hooding, strabismus, ptosis, sclerocornea[171,172]
Down syndrome	Trisomy 21 OMIM 19605	NLDO, refractive errors, nystagmus, strabismus, retinal abnormalities, keratoconus, cataracts[173]
De Morsier syndrome (septo-optic dysplasia)	Heterogeneous disorder defined by the combination of optic nerve hypoplasia, pituitary dysfunction, and midline abnormalities of the brain (absence of the corpus callosum and septum pellucidum) OMIM 182230	Optic nerve hypoplasia (unilateral or bilateral), strabismus, nystagmus, optic chiasm hypoplasia. Severe cases may have microphthalmos or anophthalmos
Galactosemia (classic)	Metabolic disorder caused by mutation in the galactose 1-phosphate uridyltransferase gene OMIM 230400	Congenital cataracts ("oil-droplet cataracts")
Goldenhar syndrome (oculoauriculovertebral dysplasia, hemifacial microsomia)	Craniofacial birth defect involving first and second branchial arch derivatives OMIM 164210	Epibulbar dermoid (unilateral or bilateral), coloboma of the upper lid, ptosis, strabismus, microphthalmos, nasolacrimal duct obstructions
Homocystinuria	Autosomal recessive metabolic disorder caused by cystathionine β-synthetase deficiency OMIM 236200	Progressive ectopia lentis (lens subluxation), pupil block glaucoma, progressive myopia, optic atrophy, retinal detachment[174]
Kabuki syndrome	Congenital mental retardation syndrome OMIM 147920	Long palpebral fissures with eversion of the lateral third of the lower eyelids, ptosis, strabismus
Möbius sequence	Sporadic disorder characterized by congenital facial weakness and abduction deficits OMIM 157900	Abnormal tearing, esotropia with limited abduction (unilateral or bilateral CN VI palsy), horizontal gaze palsy, other CN palsies (III, IV, V), ptosis
Myasthenic syndromes (congenital and neonatal myasthenia gravis)	Neuromuscular disorders. The congenital form is a nonautoimmune autosomal dominant disorder. The neonatal form is secondary to maternal antibodies	Bilateral or unilateral ptosis, any pattern of strabismus, limited ocular motility

Continued

TABLE 96.2 Ophthalmic Manifestations of Systemic Diseases With Neonatal Findings—cont'd

Etiologic Disorder	Inheritance	Ophthalmic Manifestations
Incontinentia pigmenti (Bloch-Sulzberger syndrome)	X-linked dominant disorder with characteristic skin lesions OMIM 308300	Strabismus, nystagmus, cataracts, optic atrophy, corneal abnormalities, retinovascular abnormalities (may resemble ROP), retinal detachment
PHACES syndrome (*p*osterior fossa brain malformations, *h*emangiomas of the face, *a*rterial cerebrovascular anomalies, *c*ardiovascular anomalies, *e*ye anomalies, *s*ternal defects)	Heterogeneous associations that occur in patients with large segmental cervicofacial hemangiomas OMIM 606519	Microphthalmos, Horner syndrome, retinal vascular abnormalities, optic nerve atrophy, iris hypoplasia, cataracts, sclerocornea, lens coloboma, strabismus, choroidal hemangiomas, congenital third nerve palsy, morning glory deformity, and glaucoma[175,176]
Stickler syndrome (hereditary arthro-ophthalmopathy) (1 and 2)	Autosomal dominant disorder of collagen synthesis OMIM 97300 and 604841	Congenital myopia, vitreous abnormalities, cataracts, retinal detachment
Trisomy 13	Chromosomal abnormality most consistently associated with severe ocular defects	Anophthalmos, cyclopia, microphthalmos, uveal colobomas, cataracts, corneal opacities, retinal dysplasia, intraocular cartilage
Trisomy 18	Chromosomal abnormality with frequent ocular defects	Microphthalmos, short palpebral fissures, ptosis, hypertelorism, iris coloboma, corneal opacities, cataracts
Tuberous sclerosis	Autosomal dominant multisystem disease characterized by hamartomatous growths in multiple organs OMIM 191100 and 605284	Retinal hamartomas, vitreous hemorrhage, chorioretinal punched-out lesions, papilledema, optic nerve atrophy, strabismus[177]

CN, Cranial nerve; *NLDO*, nasolacrimal duct obstruction; *OMIM*, Online Mendelian Inheritance in Man; *ROP*, retinopathy of prematurity.

TABLE 96.3 Eye Manifestations of Intrauterine and Perinatal Infections

Infection	Ophthalmic Findings		Diagnosis
Toxoplasmosis *(Toxoplasma gondii)*	Retinitis, vitritis, choroiditis and anterior uveitis; flat atrophic retinal scars	Present in 75% of newborns with toxoplasmosis, 10% have only ocular findings	Clinical ELISA Positive IgM assay result (maternal IgM does not cross the placenta)
Syphilis *(Treponema pallidum)*	Chorioretinitis (salt-and-pepper appearance or pseudoretinitis pigmentosa), anterior uveitis, glaucoma, interstitial keratitis	Bilateral interstitial keratitis is the classic ophthalmic finding; it occurs in 10% of patients but manifests itself later in childhood or adulthood	Positive VDRL and FTA-ABS test results
Rubella	Nuclear cataracts, glaucoma, uveitis, microphthalmos, retinopathy with salt-and-pepper appearance, pseudoretinitis pigmentosa	50% of children with rubella have ocular findings, bilateral 70% Severe postoperative inflammation after cataract surgery	
Cytomegalovirus infection	Retinochoroiditis, optic nerve atrophy, microphthalmos, cataracts, uveitis, strabismus[178]	Most common intrauterine viral infection in the United States Only 10% of infants show clinical features of CMV infection, with ophthalmologic abnormalities in less than 30% of these	CMV IgM, urine culture, PCR detection of CMV DNA in blood
Herpesvirus infection (HSV 1 and 2, EBV)	Vesicular skin lesions, keratoconjunctivitis, retinochoroiditis, cataracts		Cultures from conjunctival or corneal swabs

CMV, Cytomegalovirus; *EBV*, Epstein–Barr virus; *ELISA*, enzyme-linked immunosorbent assay; *FTA-ABS*, fluorescent treponemal antibody absorption; *HSV*, herpes simplex virus; *IgM*, immunoglobulin M; *PCR*, polymerase chain reaction; *VDRL*, venereal disease research laboratory.

TABLE 96.4 Eye Findings After in Utero Exposure to Teratogens

Teratogen	Ophthalmic Manifestations
Alcohol (fetal alcohol syndrome)	Short palpebral fissures, microphthalmos, epicanthal folds, optic nerve head hypoplasia, tortuosity of retinal vasculature, strabismus, cataracts[179]
Cocaine	Optic nerve abnormalities, delayed visual maturation, ROP-like fundus abnormalities,[180] prolonged eyelid edema[181]
Anticonvulsants (fetal hydantoin syndrome)	Ptosis, trichomegaly, hypertelorism, strabismus, retinal coloboma, microphthalmos, optic nerve head hypoplasia[182,183]
Methadone	Nystagmus, delayed visual development, abnormal VEPs at birth[184,185]
Warfarin and coumadin	Optic atrophy, cataracts, anterior segment dysgenesis, microphthalmos[186]
Thalidomide	Strabismus, Duane syndrome, ptosis, paradoxic gustolacrimal tearing, Möbius sequence[187]
Misoprostol	Möbius sequence[187]

ROP, Retinopathy of prematurity; *VEP*, visual evoked potential.

Role of the Neonatal Healthcare Provider

Neonatal and primary pediatric healthcare providers clearly play a central role in the ophthalmologic care of newborns and young infants. The first few weeks after birth constitute a critical period of visual development in the brain, and the opportunity and responsibility to screen the newborn for ocular disease rests in the hands of those providers, whether neonatologist, pediatrician, family physician, or nurse practitioner. A referral to a pediatric ophthalmologist should be made for any abnormality or asymmetry in an atomic structure or visual function. Some conditions require a particularly urgent referral, such as an abnormal red reflex, cloudy cornea, and ocular infection or trauma. Identification of a sight-threatening cataract or life-threatening retinoblastoma is most commonly made by an astute pediatric clinician in the NICU, nursery, or primary care office who carefully evaluates the red reflex in both eyes. In the case of neonatal conjunctivitis, diagnostic cultures and treatment should be undertaken without delay, but ophthalmology consultation is still necessary to rule out corneal or intraocular involvement. Premature infants at risk of ROP are a particularly vulnerable population. It is the neonatologist's clinical and medicolegal responsibility to arrange timely diagnostic ROP examinations in the NICU and to communicate to parents the absolute necessity of keeping ophthalmologist outpatient appointments after the infant has been discharged from the hospital. Such appointments should be scheduled before discharge. A delay in care by even 1 week could result in a disastrous visual outcome.

The neonatal healthcare and primary care pediatric teams should provide ongoing eye-related education and support. Reducing the risk of pediatric AHT is one important topic to be discussed with all parents and caregivers. Viewing of educational videos on shaken baby syndrome is mandatory in an increasing number of municipalities, and reductions in AHT incidence have been demonstrated. Pediatricians should discuss crying and parental stress at office visits during the first few months of life; the Period of PURPLE Crying educational materials (https://www.dontshake.org/purple-crying) are very useful in this regard. Pediatricians can also provide support for the families of children with visual impairment, ensuring early, anticipatory referral to state commissions for the blind and early intervention services, and ongoing encouragement for parents to maximally utilize such resources when they are available.

Rapid visual development occurs in the months following the neonatal period. Primary care eye examinations and vision assessments continue to be vital for the detection of conditions that may result in visual impairment or blindness, lead to problems with school or social performance, signal the presence of a serious systemic disease, or threaten the child's life. Children should have an eye examination at each well-child visit. Children at high risk of eye disease should be referred for examination by a pediatric ophthalmologist, including children with a history of prematurity or metabolic or genetic diseases; significant developmental delay or neurologic problems; systemic diseases associated with eye abnormalities; a family history of retinoblastoma, childhood cataracts or glaucoma, inherited retinal disorders, or blindness in childhood; and those whose parents needed glasses at a very young age.

Retinopathy of Prematurity

ROP, a disease of the developing retinal vasculature, first became a significant cause of blindness in children in the 1950s with increased survival of premature infants as a result of improved neonatal care, in particular the use of supplemental oxygen in industrialized countries. With the restriction of oxygen use in the mid-1950s, there was a reduction in the incidence of blindness from ROP, but this was associated with increased rates of death and cerebral palsy in premature babies. During the late 1960s, despite more accurate methods to monitor oxygen supplementation and improved management of perinatal complications, blindness from ROP began to reemerge because smaller and less mature babies were surviving. Surgical treatment of established disease and improved neonatal care are probably the major factors responsible for the reduction of the incidence of blinding ROP observed since the 1980s in developed high-income countries.[90] However, ROP-related blindness continues to be an important public health problem among middle-income countries, in which the capability to save small babies has developed, but oxygen use is often not controlled, and the resources to screen babies for and treat ROP are lacking.[91] From the perspective of the neonatologist, a fundamental understanding of the current classification, screening, and treatment guidelines for ROP can lead to better outcomes for premature infants.

Pathogenesis of Retinopathy of Prematurity

ROP develops as a result of incomplete retinal vascularization, resulting retinal hypoxia and pathologic neovascularization, and eventually tractional retinal detachment and blindness. With premature birth, the relative hyperoxia of the extrauterine environment and exogenous oxygen supplementation damage existing retinal blood vessels and suppresses the retinal secretion of vascular endothelial growth factor (VEGF), a hypoxia-induced vasoactive molecule responsible for normal blood vessel development in the body.[92–95] Premature birth also results in a loss of maternal insulin-like growth factor (IGF)-1, a somatic growth factor

secreted by the liver but derived primarily from maternal sources until the third trimester.[96] As retinal development progresses, relative hypoxia ensues, but VEGF-induced vessel growth is temporarily suppressed by low serum levels of IGF-1.[93] Finally, as the infant's innate production of IGF-1 rises after 30 to 33 weeks' PMA, heightened local concentrations of VEGF are activated, causing visible pathologic neovascularization.

Classification of Retinopathy of Prematurity

The International Classification of Retinopathy of Prematurity (ICROP) first was published in 1984,[97] expanded in 1987,[98] and was recently updated in a third version,[99] providing a standard nomenclature for the clinical findings and staging of ROP. As shown in Table 96.5, this classification takes into account four components of the ocular findings: anterior-posterior location of the retinopathy (zone), severity (stage), the extent of the disease at the circumference of the vascularized retina (in clock hours), and the presence or absence of "plus disease." *Plus disease* occurs along a spectrum of vascular changes with increasing dilation and tortuosity of the vessels of the posterior pole of the eye and is an important sign of disease severity and risk of imminent progression to retinal detachment. In eyes with ROP in multiple zones and stages, ROP status is determined by the highest stage and the lowest zone observed, along with noting the presence or absence of plus disease.

In ICROP, the retina is divided into three concentric "zones" centered on the optic nerve with zone I including the central retina, zone III including the far peripheral retina, and zone II inclusive of the retina between zones I and III (Fig. 96.10). The newer classification subdivides zone II into an anterior and posterior portion. The majority of retinopathy seen in the United States occurs in zone II, though generally more aggressive retinopathy may occur in zone I or posterior zone II. ROP that occurs in zone III tends to be milder. The severity of retinopathy is designated on a scale of 1 (least severe) to 5 (most severe) by "staging" the appearance of the junction between the vascular and avascular retina (Fig. 96.11). Stages 1 and 2 represent mild and moderate disease, and stage 3, characterized by fibrovascular proliferation off the retina into the vitreous indicates more serious disease. Stages 4 and 5 denote the presence of a retinal detachment. The term *plus disease*, a clinical diagnosis made based on a comparison with reference photographs used in clinical trials in the United States,[100] indicates marked tortuosity and/or dilation of the arterioles and venules in the posterior pole in at least two quadrants. *Pre-plus disease* designates the presence of abnormal vessel changes insufficiently severe

TABLE 96.5 International Classification of Retinopathy of Prematurity, Third Edition (2021)

Anterior–posterior location of vascularization	**Zone** (most posterior retinal vascularization or ROP lesion)	**Zone I:** most posterior; retinal area within a circle centered on the disc and with a radius of twice the estimated disc–foveal distance **Zone II:** ring-shaped retinal area extending nasally from the edge of zone I to the nasal ora serrata and with the same radius distance temporally, superiorly and inferiorly; **posterior zone II** is a region of 2 disc diameters peripheral to the zone I border **Zone III:** residual crescent-shaped retinal area extending beyond zone II to the ora serrata
Severity	**Stage of ROP** (most severe ROP lesion)	**Stage 0:** incomplete vascularization (no ROP) **Stage 1:** a thin, flat, sharp white line of demarcation between the vascular and avascular retina **Stage 2:** an intraretinal elevation (ridge with height and width) at the junction between vascularized and avascular retina **Stage 3:** a ridge with extraretinal neovascular extension into the vitreous (can be flat) **Stage 4:** partial retinal detachment; ***stage 4A***, does not involve the fovea; ***stage 4B***, involves the fovea **Stage 5:** total retinal detachment; ***stage 5A***, optic disc is visible by ophthalmoscope (open-funnel); ***stage 5B***, optic disc is not visible (retrolental fibrovascular tissue or closed-funnel); ***stage 5C***, 5B findings plus anterior segment abnormalities (lens displacement, shallowing of the anterior chamber, corneal opacification, etc.)
Tempo of progression and appearance of vascular abnormalities	**Aggressive ROP* (A-ROP)**	Rapid development of neovascularization and severe plus disease without progression through typical stages of ROP; atypical stage 3 (flat neovascularization), dilated vascular loops, arteriovenous shunts, ill-defined vascular-avascular junction
Extent		Number of clock hours (30° sectors) of ROP along the circumference of the vascularized retina (no longer used for treatment decisions)
Posterior pole (Zone I) vascular abnormalities	**Plus disease spectrum**	Presence of dilated and tortuous vessels in the posterior (Zone I) retina
	Pre–plus disease spectrum	Abnormal vascular dilation and tortuosity that are insufficient for diagnosis of plus disease
Late phases	**Spontaneous or after treatment**	**Regression:** disease involution and resolution with complete vascularization or incomplete with persistent avascular retina (PAR) **Reactivation:** recurrence of acute phase features (vascular dilation, tortuosity, extraretinal neovascularization, etc.) **Long-term sequelae:** late retinal detachment, retinoschisis, persistent avascular retina, lattice-like changes, retinal holes, macular abnormalities, retinal vascular changes, abnormal foveal development

*The term *aggressive posterior-ROP* is no longer used because these abnormalities are not necessarily confined to the posterior retina.
ROP, Retinopathy of prematurity.

• **Fig. 96.11** Fundus photograph showing the ridge between vascularized and avascular retina characteristic of stage 2 retinopathy of prematurity *(large arrow)*. Stage 3 retinopathy of prematurity is present (left portion of photograph, *small arrow)*.

to be designated as *plus disease*. Other signs that frequently accompany Plus disease include vitreous haze, iris vascular engorgement, and pupillary rigidity. Identification of plus disease can vary, even when performed by expert graders, who can have a tendency to systematically over-call or under-call plus disease.[101] This has led to the reframing of the diagnosis of plus disease as a spectrum of vascular change rather than a discrete classification in the most recent version of ICROP.[99] The inherently subjective nature of identifying plus disease demonstrates a need for careful consideration in using this designation in both clinical care and research.

In 2005, the designation aggressive posterior ROP (APROP) was added to ICROP. APROP was added as a separate entity based on the observation of a particularly aggressive form of ROP observed with increasing frequency in the smallest premature babies. This aggressive variant is seen more commonly in countries with developing neonatal care systems. Important hallmarks of the disease are marked posterior pole vascular abnormalities of dilation and tortuosity with what at first may appear to be mild peripheral retinopathy but on closer look is flat, subtle fine neovascularization, making this entity more difficult to recognize.[99,102]

Prevalence and Incidence of Retinopathy of Prematurity

Large natural history studies have shown that, in most cases, ROP begins at 31 to 33 weeks' PMA[100,103,104] with progression during the next 2 to 5 weeks. Spontaneous regression occurs in the majority of eyes that develop stage 1 to 3 ROP.[105,106] Blindness or severe visual impairment commonly results from progression of the retinopathy to retinal detachment or severe distortion of the posterior retina.

In the United States, ROP occurs in less than half of babies with birth weights less than 1500 g (very low birth weight [VLBW]).[104] A greater proportion of babies with birth weight less than 1000 g (extremely low birth weight, ELBW) or less than 750 g develop ROP.[100,103] As neonatal services continue to improve, a greater proportion of VLBW and ELBW babies survive, with a resultant increase in the population of babies at risk.[91] Based on a cohort of more than 7,400 neonates in the United States, the incidence of ROP was 43%, only 12.5% developed severe ROP, which was almost exclusively among those with low birth weight (less than 1251 g), and only about 6.5% met criteria for treatment.[104]

Detection of Serious Disease

Because the benefit of treatment of serious ROP has been shown in randomized clinical trials,[107–110] it is essential to identify the at-risk baby so that timely examinations can be performed to prevent blindness or at least decrease its likelihood. In the United States, the recommended guidelines for detection of serious ROP indicate that diagnostic examinations should be performed on infants with birth weights less than or equal to 1500 g or gestational age of less than or equal to 30 weeks 0 days, along with babies in the 1501- to 2000-g birth weight group thought to be at high risk by the neonatologist.[111] In Latin American countries and in urban centers of newly industrializing countries in Asia and eastern Europe, the same screening criteria do not apply, because evidence suggests that larger, older babies are also at risk in these settings, and national or regional guidelines need to be developed.[112–116]

The first examination should generally occur at 31 weeks' PMA or chronologic age of 4 weeks, whichever occurs later.[111] Examinations usually continue on an every-other-week basis unless ROP develops, at which time examination frequency may be increased depending on the severity of the disease. In general, examinations continue until ROP is observed to regress, ROP progresses to treatment severity, or vessels are observed on at least

two occasions to have progressed into zone III in the absence of prior development of ROP.

Prediction of Retinopathy of Prematurity

Following from the pathologic sequence described previously, important risk factors for ROP include the degree of prematurity (early gestational age at birth and low birth weight); hyperoxia early in the postnatal course, especially from excessive oxygen supplementation; and low postnatal serum IGF-1 level in the postnatal period up to 33 weeks' PMA.[117,118] Slow postnatal weight gain is a reliable surrogate measure for serum IGF-1 levels.[93,119,120] Numerous other factors have been associated with ROP, such as sepsis, acidosis, nutritional deficiencies, and necrotizing enterocolitis; however, many of these factors may influence serum IGF-1 levels in a common mechanistic pathway.[121,122] Newer research has suggested that the relationship between postnatal weight gain and the development of severe ROP is likely more complex than previously understood. A large study of neonates assessing postnatal weight gain found that a low weight gain rate during the 29- to 33-week postmenstrual period is consistently associated with severe ROP, but if weight gain during this period is moderate or high, subsequent rapid rises in weight gain are also associated with increased risk of developing severe ROP.[123]

Current screening guidelines focus solely on gestational age at birth and birthweight as predictors of ROP. Current guidelines have low specificity, as only 5% to 7% of infants require treatment, and very high but not 100% sensitivity for severe ROP because some infants with birth weight and gestational age above the screening thresholds develop disease severe enough to require treatment. Therefore, a third, subjective criterion, a poor postnatal course, must also be used.[122] Because slow postnatal weight gain is highly correlated with IGF-1 levels and has been shown to be a reliable predictor of subsequent ROP development,[121,124–126] multiple postnatal weight gain predictive models have been developed in an effort to improve the efficiency of ROP screening in highly developed NICU systems. These models include WINROP (Weight, Insulin-like growth factor-I, Neonatal, ROP),[127,128] ROPScore,[129] PINT-ROP,[126] the Children's Hospital of Philadelphia (CHOP) ROP model,[130] and the Colorado ROP model.[131] All of these models initially exhibited very high sensitivity for predicting severe ROP, while greatly reducing the number of infants who would have required examinations, in model development studies. However, in each case, the model was developed using too small of a cohort, resulting in overfitting and decreased sensitivity in validation studies.[122]

To address the limitations of prior models, the Postnatal Growth and Retinopathy of Prematurity (G-ROP) study group used data from 7483 infants to develop new screening criteria that led to a 30% reduction of infants requiring examinations while maintaining 100% sensitivity for detecting high-risk ROP without the need for a subjective criterion.[122] A premature infant meeting any one of the following six G-ROP criteria would receive examinations; gestational age less than 28 weeks; birth weight less than 1051 g; weight gain of less than 120 g, 180 g, or 170 g during ages 10 to 19 days, 20 to 29 days, or 30 to 39 days, respectively; or hydrocephalus. These criteria maintained 100% sensitivity in a prospective validation study of nearly 4,000 infants, and the G-ROP criteria were the first postnatal weight gain criteria to be successfully validated in this fashion.[132]

In addition to improving the specificity of ROP screening and eliminating potentially unnecessary examinations, newer risk stratification models such a G-ROP can also result in cost savings. A microsimulation model analyzing resource utilization and ROP outcomes found that instituting the more stringent screening G-ROP guidelines in the United States could result in more than 36,000 fewer examinations, with an annual cost savings of nearly $3,000,000 USD through hospital discharge.[133] Moreover, the criteria are also more sensitive than the current, conventional criteria, so the G-ROP criteria are a dominant cost-effective strategy.[133]

Based on these studies, postnatal weight gain could soon be incorporated into current screening guidelines given their high sensitivity for predicting and detecting severe ROP.[134]

Prevention of Retinopathy of Prematurity

Medical treatments designed to prevent ROP hold promise to decrease the development of serious ROP. The most obvious action is to control excessive oxygen supplementation. Strict regulation of the use of supplemental oxygen in the first few weeks of life has been recommended as a strategy to reduce the incidence of severe ROP; however, this can result in increased nonocular morbidity and mortality. In a multinational effort to determine the optimal oxygen saturation targets for premature infants, a group of harmonized randomized clinical controlled trials were conducted: the Surfactant, Positive Pressure, and Oxygenation Randomized Trial (SUPPORT) in the United States, the Canadian Oxygen Trial (COT), and the Benefits of Oxygen Saturation Targeting II (BOOST II) trial conducted in the United Kingdom, Australia, and New Zealand. In a meta-analysis of these three trials, the risk of developing severe ROP was not significantly different between the restricted oxygen group (Spo_2 targets of 85% to 89%) and the liberal oxygen group (Spo_2 targets of 91% to 95%) (risk ratio [RR] 0.72, 95% confidence interval [CI] 0.50 to 1.04); however, sensitivity analysis using a fixed-effect model (where BOOST II had a larger weight assigned) moved the estimated effect in favor of restricting oxygen use (RR 0.75, 95% CI 0.63 to 0.88). Higher rates of necrotizing enterocolitis and death before hospital discharge were, however, found in the restricted oxygen group. The study authors concluded that the level of certainty for the ROP outcome is low, and there is still significant uncertainty about the optimal target range for Spo_2.[135]

Currently, there are no other medical interventions that have been proven to prevent the development of severe ROP in VLBW infants. Interventions such as steroids given to expectant mothers immediately before preterm birth and surfactant administered to the neonate shortly after birth decrease the incidence of respiratory distress syndrome. However, these medical advances have also increased the survival rate of VLBW babies.[136] Vitamin E supplementation, dietary supplementation with omega-3 polyunsaturated fatty acids, systemic and topical beta-blockers, and intravenously administered IGF-1 and IGF-binding protein remain under investigation.[137–139]

Establishment of a Retinopathy of Prematurity Program

Robust ROP programs are essential to prevent the visual morbidity associated with failing to detect or treat severe ROP, and these programs must be tailored to each specific clinical environment. The main goals associated with establishing an ROP program are primary prevention (i.e., preventing ROP through overall care of the neonate) and secondary prevention (i.e., screening, case detection, and treatment).[140] Primary prevention, specifically with regard to supplemental oxygen administration, was discussed

earlier. The establishment of a robust screening system with the aim of secondary prevention requires a collaborative relationship between neonatologists, ophthalmologists, nurses, social workers, and discharge coordinators. An essential component is an ROP coordinator, working with the ophthalmologist and in communication with the NICU and involved staff.

Strong lines of communication improve workflows with regard to the frequency and timing of eye examinations and treatments. Maintaining a regular day and time each week for screening may improve buy-in from nursing staff who may plan to hold feedings prior to examinations. Unilateral cancellations of examinations by the neonatal team or nurse should never be made if a child is thought to be too unstable for an eye examination; rather, a conversation should occur between the neonatologist and the ophthalmologist, weighing the risks of the exam with the risks of postponing the exam in terms of the ROP risk for that specific infant at that postmenstrual age. Note that because plus disease plays a key role in most treatment decisions, and plus disease diagnosis is based upon the appearance of the more easily visualized vessels in the posterior pole of the eye, a quick, few-second look at each eye without an eyelid speculum can often be accomplished without adverse effects even in a sick infant, as a compromise partial exam, followed with another examination a week later.

An ROP coordinator can communicate with nurses to ensure that neonates are given dilating drops 30 to 60 minutes prior to their eye examination. These drops often include a combination of cyclopentolate 0.5% and phenylephrine 2.5% given 2 to 3 times 5 minutes apart; the precise agent and frequency may vary depending on provider preference and medication availability.[140] During the eye examination, pain can be addressed by administration of topical anesthetic eye drops such proparacaine and oral sucrose. Nurses can swaddle the infants and monitor oxygen saturation and heart rate. A sterile eyelid speculum and scleral depressor may be used to improve visualization of the retina. A re-usable indirect ophthalmoscope and 28 diopter indirect lens are typically used to examine the retina but should be cleaned in between patients with a disinfectant such as bleach and then rinsed well with water to avoid bleach contacting the eye and deposits on the equipment. An adenoviral outbreak involving 23 hospitalized neonates, as well as NICU staff and parents, was traced back to screening ROP examination equipment.[141] This epidemiological case study emphasized the importance of infection control measured including hand hygiene, glove use, standard and isolation precautions, and enhanced cleaning of lenses and ophthalmoscopes between examinations.[141] Given the possibility of severe health complications from adenovirus in vulnerable populations, strict hygienic standards must be prioritized.

An ROP coordinator can help not only with the logistics of inpatient examinations but also with ensuring that outpatient screening appointments are confirmed prior to discharge and kept by parents after discharge, to avoid a loss to follow-up and the risk of severe disease not being treated. A small study of follow-up for infants with or at risk for ROP found that nearly 50% did not attend timely follow-up, though the rate of follow-up was much higher when appointments were scheduled by hospital personnel prior to discharge.[142]

Coordination of this schedule among neonatal care providers, ophthalmologists, nursing staff, and parents is essential. If outpatient appointments are not kept or proper information is not conveyed with regards to the risk of blindness when the baby is transferred to another facility, potentially treatable disease may be missed, with disastrous consequences.[143] Even a week delay can be significant, as a treatment for ROP should occur within 72 hours once treatment criteria are met. From a medicolegal perspective, ROP claims represent anywhere from 0.5% to 4% of all ophthalmology-related lawsuits.[144,145] Causes for lawsuits have included inappropriately long periods between follow-up examinations, failure of outpatient referral from screening to treatment, and unsupervised resident provision of ROP care.[145] Most, if not all, of these preventable factors can be addressed through the establishment of a well-considered ROP program.

Telemedicine Screening for Retinopathy of Prematurity

Although direct examination by an ophthalmologist experienced in examining babies at risk of ROP continues to be the optimal standard of care, retinal digital imaging has emerged as a promising modality for ROP screening. The increased workload due to the increase in survival of premature infants worldwide[91] coupled with the reduced availability of ophthalmologists with sufficient ROP experience has required the development of alternative screening approaches. The published sensitivity of digital fundus imaging as a screening technique for ROP ranges from 57% to 100% (with wide 95% CIs) when compared with the reference standard (indirect ophthalmoscopy). In 2015, the American Academy of Pediatrics and the American Academy of Ophthalmology published a review of the current status of telemedicine in ROP[146] and concluded that retinal digital imaging is a reasonable alternative to but not a substitute for direct examination by an on-site ophthalmologist. However, more studies are needed to determine the overall validity of the approach.

Notwithstanding the lack of consensus, ROP telemedicine is becoming increasingly available in the United States and other countries. The Stanford University Network for Diagnosis of Retinopathy of Prematurity (SUNDROP) has reported its experience evaluating infants meeting ROP screening criteria with images taken in the NICU by trained nurses and remotely evaluated by an ophthalmologist. In this program, all infants undergo one ophthalmologist examination after discharge. In a recent report of 608 infants examined during a 6-year period, sensitivity was reported as 100%, with specificity and a negative predictive value of 99.8% and 100%, respectively.[147]

Other reports have focused on the logistics of the implementation of ROP telemedicine in various settings throughout the world. The Karnataka Internet Assisted Diagnosis of Retinopathy of Prematurity model provides ROP screening in more than 80 units in the Karnataka region of India, using technicians who obtain and grade the images at the bedside and report the need for an evaluation to an ophthalmologist, who can then give treatment if needed.[148] This model has demonstrated that ROP screening services can be provided in regions of the world with limited access, but it is still highly dependent on the availability of ophthalmologists to provide treatment and high levels of training and technical expertise. Gilbert et al.[149] have stressed the need to shift the emphasis on examination to remote imaging in low- and middle-income regions of the world where ROP remains a leading cause of childhood blindness yet the expertise, availability, and physical resources for adequate ROP screening are quite limited. In these countries, this approach has the potential to expand services dramatically as increasingly small birthweight and low gestational age infants survive worldwide. In more developed healthcare systems, the potential role of telemedicine as a stand-alone screening tool is currently undergoing intensive scrutiny, highlighting a number

of complex issues for implementation (limited number of available imaging systems, high cost of equipment, personnel training requirements, quality control issues, coordination of services, accountability, etc.) that should be resolved before a successful and safe implementation of such a screening modality.

Future directions in this domain include the use of artificial intelligence and deep learning to identify ROP. Research on these technologies has already begun with early yet encouraging results. One specific algorithm called DEEP-ROP performed well in differentiating plus disease based on wide-angle posterior pole retinal images.[150] Another deep learning system, i-ROP, was able to accurately detect a vessel severity score, which offers the potential advantage of providing objective data about ROP status based on imaging.[151] Further research and validation are required to determine the extent to which these technologies will be incorporated into ROP screening.[152]

Treatment of Retinopathy of Prematurity

Laser ablation of the peripheral avascular retina can prevent progression to blinding disease in patients with severe ROP and is currently the standard of care for treatment. The evidence of treatment effectiveness and the indications for treatment (severity level) have evolved through the last 30 years as multiple multicenter clinical trials have been conducted to evaluate different treatment modalities and preventative strategies. Landmark studies include the Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) study, the Early Treatment for Retinopathy of Prematurity (ET-ROP) study, the Supplemental Therapeutic Oxygen for Prethreshold Retinopathy of Prematurity (STOP-ROP) study, the Effects of Light Reduction on Retinopathy of Prematurity study, and the Bevacizumab Eliminates the Angiogenic Threat for Retinopathy of Prematurity (BEAT-ROP) study.

Current treatment guidelines are based on the findings of the ET-ROP study, so treatment intervention is recommended on the development of "type 1" pre-threshold ROP, which is defined as *any stage with plus disease in zone I, stage 3 without plus disease in zone I, or stage 2 or 3 with plus disease in zone II*. It is important to highlight that the number of clock hours of disease previously used in the CRYO-ROP definition of "threshold" is not considered anymore, and treatment should not be delayed until "threshold" ROP is reached.

Today, laser photocoagulation is universally preferred over cryotherapy because it causes less intra- and postoperative pain and allows direct visualization of the area during treatment. For advanced disease (i.e., retinal detachment, stages 4 and 5), studies have shown mixed results, but treatment is in general much less successful.[153–156] For eyes with total retinal detachment, a good functional visual outcome is not likely to be achieved.[154,157,158] Concerns associated with laser treatment include the risk of intubation and sedation frequently required for the procedure, the prevalence of high myopia and peripheral visual field reduction, and poor visual acuity outcomes in patients with posterior or aggressive ROP.

In the past decade, there has been increased off-label use of intravitreal anti-VEGF drugs for the treatment of ROP. The effectiveness of these drugs, since reported in multiple observational studies, was demonstrated in a multicenter randomized controlled trial,[159] BEAT-ROP, in which intraocular bevacizumab injection was shown to result in a lower retreatment rate by 54 weeks' PMA than laser photocoagulation in babies with zone I and posterior zone II type 1 ROP (6% vs. 42% in the zone I subgroup). Although the BEAT-ROP study had limitations, including a subjective outcome measure based on treatment decisions made by ophthalmologists who were unmasked to the treatment group and an unusually high re-treatment rate following laser compared to common clinical experience, the study did clearly demonstrate the short-term effectiveness of anti-VEGF. As a result, intravitreal injection of bevacizumab and other anti-VEGF agents (e.g., ranibizumab, aflibercept) is increasingly being used as a first-line treatment for eyes with zone I or posterior zone II ROP. Historically, laser photoablation has been less effective at preventing progression to retinal detachment in zone I eyes compared to zone II eyes. At the 6-year outcome of the ET-ROP study, more than 30% of lasered zone I, type 1 eyes had visual acuity of 20/200 or less, and more than 20% had a macular fold or retinal detachment.

The advantage of anti-VEGF over laser for posterior disease is due to the speed of action of each treatment modality. Both modalities work by blocking VEGF-induced pathologic neovascularization. Laser results in the destruction of the source of VEGF (hypoxic avascular retina), so it takes a week or more to begin to see the effects of laser because free VEGF remains active until it is gradually broken down in the eye. In contrast, anti-VEGF directly binds free VEGF, so that its effect is seen rapidly, usually within 12 to 24 hours. Therefore, there is a benefit to anti-VEGF when ROP is relatively more aggressive. Using early postmenstrual age as a marker of more aggressive disease, Barry et al. reported a lower rate of short-term retinal detachment with anti-VEGF versus with laser when treatment occurred before 36 weeks post-menstrual age in a non-randomized but large study.[160] Another consequence of each modality's mechanism of action is that because anti-VEGF does not destroy the source of VEGF, ROP may recur and require retreatment following anti-VEGF, the effects of which typically last 3 to 6 weeks depending on the drug. Such recurrence has been reported as late as even 2 or 3 years of age and would not have been captured in the BEAT-ROP study.[161] In contrast, when an adequate laser is performed early enough to result in full regression of ROP, recurrences generally do not subsequently occur.

With regards to long-term refractive error, The BEAT-ROP study reported that children treated with bevacizumab had a significantly lower incidence of high myopia at 2.5 years post-treatment than infants treated with laser ablation. High myopia occurred in 3.8% of zone I eyes and 1.7% of zone II eyes that received bevacizumab, compared with 36.4% of zone I eyes and 51.4% of zone II eyes that received laser treatment ($P < .001$).[162] Intravitreal injection is faster to perform and typically requires minimal sedation without intubation. There is a faster recovery to baseline respiratory status following sedation and intravitreal bevacizumab compared to infants treated with laser under general anesthesia.[160]

The long-term ocular and systemic safety of anti-VEGF agents is unknown. Retinal vascularization after anti-VEGF is not normal. Lepore et al. reported peripheral and macular vascular abnormalities detected on retinal fluorescein angiogram 9 months after ROP treatment with bevacizumab that persisted 4 years after treatment and were not present in lasered eyes.[163,164] Moreover, systemic absorption of the anti-VEGF medications after intraocular injection is significant and leads to a reduction in systemic VEGF levels, lasting at least 60 days after injection, and raises concerns about systemic anti-angiogenic consequences of these drugs. VEGF is a critical factor in neurodevelopment and vasculogenesis in other developing organ systems, including the brain, lungs, and kidneys. Long-term safety data are limited. The BEAT-ROP study was too small to evaluate short or long-term safety effects on the

development of brain and other tissues. More recently, observational reports from Canada and Taiwan described an increased risk of motor impairment in ROP patients treated with bevacizumab.[165–167] In the Canadian study, the authors attempted to control for many possible factors that could affect neurocognitive development, such as SNAP II scores, bronchopulmonary dysplasia, sepsis, intraventricular hemorrhage, gestational age, and maternal education and found that at age 18 months, bevacizumab-treated infants were two to three times more likely to display unfavorable developmental outcomes compared with those that underwent laser ablation. However, these non-randomized studies may not adequately control for other unknown confounders. Severe ROP is an independent predictor of adverse long-term neurodevelopment, and the indication for anti-VEGF treatment over laser ablation may be confounded by the severity of the disease or the underlying systemic condition of the infant (confounding by indication). Nevertheless, this early evidence increases the concern regarding the long-term safety of anti-VEGF treatment and calls for more research in this area. When treatment is required, careful consideration and a thorough discussion with the parents and neonatology team are recommended. None of the anti-VEGF drugs have been approved by the US Food and Drug Administration for the treatment of ROP, and therefore explicit consent for their off-label use must be obtained. Premature infants treated with anti-VEGF injections require close follow-up for extended periods of time, at least until complete retinal vascularization is observed or recurrence occurs. As infants get older, it becomes more challenging to obtain an adequate retinal examination, and many ophthalmologists recommend laser treatment if vascularization has not occurred by a certain postmenstrual age, typically 50 to 60 weeks. Therefore, many infants initially treated with anti-VEGF ultimately also receive laser, and parental expectations should be set accordingly.

Ear and Hearing Disorders

BETTY VOHR AND SUSAN WILEY

KEY POINTS

- Hearing loss is one of the most common congenital abnormalities, occurring in approximately 1.5 to 2 per 1000 newborns.
- Hearing loss may be present at birth or have delayed onset.
- A comprehensive work-up is indicated to identify if the etiology is related to genetic or nongenetic causes, or associated with other abnormalities.
- Early diagnosis, intervention, and access to language within the first 6 months of life provide the best opportunity for typical language development.

Normal Hearing

To understand the spectrum of permanent and transient hearing disorders that can be identified, it is necessary to understand the normal hearing pathway, which consists of transmission of sound energy from the environment via the outer ear through the middle ear, inner ear, auditory nerve, brainstem, and, finally the temporal lobe cortex, where the sound's electrical energy is interpreted as language (Table 97.1). Dysgenesis, disruption, or injury at any point in the pathway may result in a hearing loss that can have its onset in fetal life or during childhood. The auditory pathway develops embryologically very early in gestation. The inner ear develops first, at about 22 days, and is derived from the otic placodes on either side of the developing head. The middle ear and ossicles derive from the first and third pharyngeal pouches and begin to develop at about day 33. The outer ear develops from the dorsal portion of the first pharyngeal cleft. As a result, congenital hearing loss is often seen in conjunction with structural abnormalities of the head, eyes, ears, nose, and throat. In fact, the odds of having a hearing loss is significantly increased if a preauricular skin tag or pit is present.[1] Atresia or microtia of the pinna are also strongly associated with a permanent hearing loss. Table 97.2 shows the area of pathology associated with the types of hearing loss. A standard medical assessment for every newborn/child should include both a family history of hearing loss and a comprehensive physical examination for minor or major congenital abnormalities and syndromes associated with hearing loss.[2] The primary provider should be familiar with risk factors associated with hearing loss, particularly a family history of permanent hearing loss. Approximately 50% of children with permanent hearing loss, however, will not have associated stigmata. Every physical examination in childhood should include an evaluation for the presence of transient middle ear fluid. Once a child is diagnosed with a permanent hearing loss by an audiologist, additional consultation with ophthalmology, otolaryngology, genetics, and developmental behavioral specialists and a parent support group are recommended to ensure that both the hearing loss and associated diagnoses and challenges are addressed.[3]

Permanent Hearing Loss—The Challenge

Hearing loss is one of the most common congenital abnormalities, occurring in approximately 1.5 to 2 per 1000 newborns screened. Subgroups of infants with risk factors for hearing loss, especially those requiring neonatal intensive care unit (NICU) care are at increased risk of hearing loss.[4–7] Delayed identification of permanent hearing loss in infants is associated with significant delays in language development, literacy, and academic success.[8–11] Prior to newborn screening, children in the United States in the 1980s who were deaf or hard of hearing achieved reading comprehension skills at the third grade level at the time of graduation from high school (Deaf Children in America, 1986). A method of identification trialed in the 1980s was the high-risk register. Physicians would be informed by the birthing hospital of infants who were considered at high risk of hearing loss. However, approximately 50% of infants with a permanent hearing loss identified in the newborn period do not have a known risk factor for hearing loss.[12] Newborns were not routinely screened with technology for hearing loss at the time, because there was no effective physiologic method. This changed after a demonstration project[13] in Rhode Island funded by the Department of Education and Health and Human Services in 1990–1991, which demonstrated the feasibility of newborn hearing screening with a new objective physiologic technique, called oto-acoustic emissions (OAEs). This was followed in 1993 by an NIH consensus conference[14] ("NIH Consensus Statement. Early identification of hearing impairment in infants and young children") recommending universal newborn hearing screening. Data from CDC indicates that in 2018 more than 98% of newborns were screened in the United States (https://www.cdc.gov/ncbddd/hearingloss/2018-data/01-data-summary.html).

Hearing Disorders

A hearing loss is secondary to interference in the transmission of sound from the outer ear (pinna and ear canal) to the middle ear (tympanic membrane, ossicles, middle ear space and Eustachian tube opening), the inner ear (cochlea and vestibular system), the central auditory pathway (nerve pathways that transmit to the

TABLE 97.1 Anatomy of the Normal Hearing Pathway

Structure	Components	Function
Outer ear	Pinna/auricle, ear canal and the outer layer of the tympanic membrane	Sound waves travel through the air and are conducted through the ear canal to the tympanic membrane where vibrations enter the middle ear.
Middle ear	Three ossicles (malleus, incus, and stapes)	Vibrations enter the middle ear and are amplified and transmitted via the ossicles to the fluid within the cochlea (inner ear). Acoustic energy in air is converted to compression waves in fluid in the cochlea.
Inner ear	Cochlea Vestibular system	The cochlea converts sound pressure patterns into electrochemical impulses that are passed on to the auditory nerve. A part of the cochlea, the organ of Corti, consists of sensory epithelium and hair cells, which transform fluid waves to nerve signals that regulate balance.
Eighth cranial nerve Vestibulocochlear nerve contains both the auditory nerve and the vestibular nerve	Auditory nerve is also called the acoustic nerve or cochlear nerve	The auditory nerve carries auditory sensory information from the cochlea to the brainstem. The vestibular nerve transmits sensory information.
Brainstem	Superior olive, to inferior colliculus, to thalamus	Continued transmission of electrical energy on journey to temporal lobes
Temporal lobes	Superior temporal gyrus and transverse temporal gyrus (Heschl gyrus)	Sounds are processed and interpreted as language.

brainstem and cortex, and the auditory cortex (temporal lobes) where sound information is processed. There are anatomical or neural problems that can develop at any point in this pathway that may interfere with the transmission of sound energy and result in a change in the hearing threshold. There are three types of permanent hearing loss that may be present in the neonate including sensorineural hearing loss, auditory neuropathy (neural hearing loss), and permanent conductive hearing loss, in addition to transient conductive hearing loss (middle ear fluid or debris in the ear canal). Some infants may have a mixed hearing loss, which is a combination of two or more types of hearing loss. Types of permanent and transient hearing loss are shown in Table 97.2.

Degrees of hearing loss are determined using clinical audiograms, which evaluate the softest hearing level (HL) thresholds, in decibels (dB). Thresholds between –10 and +20 dB HL are considered to be in the normal range, while thresholds above 20 dB are considered diagnostic for mild (20 to 34 dB), moderate (35 to 49 dB), moderately severe (50 to 64 dB), severe (65 to 79 dB), and profound (>80 dB) hearing loss. Ear and frequency-specific behavioral response hearing testing using a visual reinforcement audiometry (VRA) protocol (conditioned response) can be accomplished beginning at approximately 5 to 6 months of age if this is consistent with the infant's development status. Behavioral testing using conditioned play audiometry can be used in children with developmental ages of 3 to 5 years. The official definition of deafness from the Individuals with Disabilities Education Act is "a hearing impairment that is so severe that the child is impaired in processing linguistic information through hearing, with or without amplification." *Hard of hearing* refers to a hearing loss where there may be enough residual hearing that an auditory device provides adequate assistance to process speech.

TABLE 97.2 Types of Hearing Loss

Type	Characteristics
Sensorineural	Pathology involving the eighth nerve, outer hair cells, and inner hair cells of the cochlea that impairs neuroconduction of sound energy to the brain stem
Permanent conductive	An anatomic obstruction of the outer (atresia) or middle ear (fusion of ossicles) that blocks transmission of sound
Neural or auditory neuropathy or auditory dyssynchrony	Pathology of the myelinated fibers of the eighth cranial nerve or the inner hair cells that impairs neuroconduction of sound energy to the brainstem. The function of the outer hair cells remains intact.
Transient conductive	Debris in the ear canal or fluid in the middle ear that blocks the passage of sound waves to the inner ear
Mixed hearing loss	A combination of sensorineural or neural hearing loss with transient or permanent conductive hearing loss

Methods for Newborn Hearing Screening

The current methods readily available for newborn screening do not independently differentiate permanent hearing loss from transient conductive hearing loss. Since the primary objective of newborn hearing screening is to identify permanent hearing loss, this limitation results in an ongoing challenge of false positive newborn screens, and at times, a delay in the diagnosis of a permanent hearing loss. There are currently two objective, non-invasive physiologic measures, OAEs, either transient or distortion product, and automated auditory brainstem response (AABR) that are available and reliable for screening newborns and young infants.[15–19]

There are important differences between the two measures as shown in Table 97.3. OAE measures a physiologic response from the cochlear outer hair cells, while AABR measurements reflect both cochlear status, as well as auditory neural function beyond the cochlea to the brainstem. Thus, the AABR response reflects

activity from a greater portion of the auditory pathway than OAE and will detect auditory neuropathy, whereas OAE screening will not. Therefore, because of the higher incidence of auditory neuropathy among NICU infants AABR is recommended for screening in the NICU.[3,20] Both methods will screen positive for sensorineural hearing loss and permanent conductive hearing loss. Permanent conductive hearing loss is caused by abnormalities of the ossicular chain or eustachian tube anatomy and is more often associated with unilateral hearing loss.[12] Relative to screen fail rates, AABR is more likely to miss borderline or mild hearing loss because of the higher threshold for a pass resulting.[21,22]

In addition, both methods screen false positive for permanent hearing loss in the presence of transient retained fluid in the ear canal or middle ear fluid with transient conductive hearing loss.[23] It is important to note that there is an increased incidence of transient middle ear fluid among high-risk infants cared for in the NICU.[24] Uncertainty also may arise with mixed hearing loss which is a combination of sensorineural or neural hearing loss in conjunction with transient conductive hearing loss. Therefore, although the methods continue to improve, limitations remain, supporting the need for ongoing surveillance in the medical home. Hearing loss missed by both methods may include mild hearing loss, hearing loss in an isolated frequency range, progressive hearing loss and late onset hearing loss.[16,25] A study[23] of a large longitudinal cohort in the United Kingdom of over 17,000 neonates born from 2013 to 2014 reported that 24% of infants who did not pass an TEOAE screen but passed an AABR screen were subsequently diagnosed with a hearing loss greater than 45 dB HL using diagnostic auditory brainstem response (ABR). Although current screen methods have limitations, tremendous headway has been made in lowering the age of diagnosis, and newborn hearing screening is recommended for all infants prior to discharge from the birthing hospital. In an effort to facilitate diagnosis of the highest risk in a timely fashion, a current recommendation is for NICU infants who do not pass their hearing screen to have a diagnostic ABR performed prior to discharge. This approach facilitates the current JCIH early hearing detection and intervention (EHDI) recommendation to screen by 1 month, diagnose by 3 months and provide intervention services by 6 months of age.[3,22]

TABLE 97.3 Comparison of Oto-Acoustic Emissions and Automated Auditory Brainstem Response Screens

	PHYSIOLOGIC SCREENING METHODS	
Characteristics	**OAE**	**AABR**
Measurement	Physiologic response of outer hair cells of cochlea	Response in cochlear and auditory neural function to brainstem
Detects sensorineural HL	Yes	Yes
Detects auditory neuropathy	No	Yes
Detects transient and permanent conductive HL	Yes	Yes
OAE threshold for fail	30–35 dB HL	
AABR threshold for fail		40–45 dB HL
Recommended for NICU screens	No	Yes
Recommended for well baby screens	Yes	Yes

AABR, Automated auditory brainstem response; *HL*, hearing level; *NICU*, neonatal intensive care unit; *OAE*, oto-acoustic emissions.

Risk Factors for Permanent Hearing Loss in Infants and Children

Although approximately 50% of infants with an identified hearing loss have a risk factor for hearing loss (Table 97.4), 50% do not. Therefore, ongoing surveillance and rescreening of all infants/toddlers is recommended with added diligence to those who pass the screen but have a risk factor. Most birthing hospitals currently report risk factors to the primary care provider. However, it may be incomplete since family history is often reported after discharge, and diagnosis of a congenital syndrome may occur postdischarge. Therefore a complete physical and comprehensive review of history of hearing loss with the family after discharge is recommended for all infants.

TABLE 97.4 Risk Factors for Permanent Hearing Loss

Family factors	1. Caregiver concern regarding hearing, speech, language, or developmental delay[30] 2. Family history of permanent childhood hearing loss[15,31,33]
Neonatal	3. Neonatal intensive care of more than 5 days or any of the following regardless of length of stay including ECMO[111] 4. In utero infections, such as CMV, herpes, rubella, syphilis, and toxoplasmosis[5,39,112]
Stigmata, syndromes, and neurodegenerative disorders	5. Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies[43] 6. Physical findings, such as white forelock, that are associated with a syndrome known to include a sensorineural hearing loss or permanent conductive hearing loss[32,43,44] 7. Syndromes associated with hearing loss or progressive or late-onset hearing loss, such as neurofibromatosis, osteopetrosis, and Usher syndrome[113]; other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson[33,44,113] 8. Neurodegenerative disorders, such as Hunter syndrome, or sensory motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome[43]
Neonatal or post-neonatal	9. Culture-positive postnatal infections associated with bacterial and viral (especially herpes viruses and varicella) meningitis[53,91]
Post-neonatal	10. Head trauma, especially basal skull/temporal bone fracture that requires hospitalization[42,114] 11. Chemotherapy[52]

Identifying risk factors among all newborns and structured monitoring for late onset or progressive hearing loss allows early recognition of children who will not be identified through robust newborn hearing screening programs. As many as 1 in 5 children who are ultimately diagnosed with hearing loss may pass their hearing screening.[26,27] It is important to perform a complete family history and risk factor query in addition to a comprehensive physical examination. Having a monitoring system for risk factors, including developmental delays within an electronic health record can provide a reminder to the medical home provider to ensure earlier recognition of childhood hearing needs.

Table 97.4 shows the list of risk factors for permanent hearing loss. Although all infants require ongoing surveillance of auditory and speech language skills, infants who pass the newborn screen and have a risk factor will benefit from enhanced surveillance. Within the 2019 Joint Committee on Infant Hearing (JCIH) position statement, monitoring for hearing status noted specific intervals by risk factor. For many risk factors, completing an audiology evaluation with an audiologist experienced in assessing children by 9 months of age is recommended. Children who have been on ECMO and those with congenital cytomegalovirus (CMV) should have a hearing evaluation by 3 months of age. For children with culture positive infections (meningitis), ototoxic medications (such as chemotherapy) and head trauma should receive a hearing assessment no later than 3 months from the event. Most importantly, any time a family or caregiver has a concern about a child's hearing or speech/language development, referral for hearing testing should be immediate. It is important to remember that passing a newborn hearing screen does not protect a child from later onset hearing loss. Surveillance is especially important since it is well documented that the rate of identified childhood deafness and hearing loss increases from approximately 1.2/1000 in newborns to 3/1000 in early school age. In a 2015 report[28] the prevalence of children confirmed as deaf or hard of hearing by school age was 3.65 per 1000.[3,15,29–52]

Family

Risk factor 1 Parent or caregiver concern of child hearing, speech, language, or developmental delay has consistently been shown to be a reliable predictor of hearing loss.[30]

Risk factor 2 A history of family members who are deaf or hard of hearing with onset in childhood,[15,31–33] has high predictive value and is associated with known genetic causes including Connexin 26 mutations. It has been shown that young parents may not be informed of a family history until after their infant is diagnosed with hearing loss. Monitoring is based on etiology with a diagnostic evaluation recommended by 9 months of age.[34–36]

Neonatal

Risk factor 3 includes infants who require care in the NICU or special care nursery for more than 5 days, which is used as an indicator of illness severity.[3] This broad category encompasses most other medical risk factors including prematurity, perinatal asphyxia, hyperbilirubinemia requiring an exchange transfusion, perinatal asphyxia, regardless of length of stay, and aminoglycosides for 5 days or more.[37,38] Use of aminoglycosides for less than 5 days is not a risk factor. It is recommended that children in these categories of risk should have a diagnostic audiology evaluation by 9 months of age.

Risk factor 3 also includes infants who have required extracorporeal membrane oxygenation (ECMO). Children who have been on ECMO should have a diagnostic audiology evaluation no later than 3 months following ECMO and every 12 months to school age. If families have concerns about hearing, testing should occur at the time of concern.

Risk factor 4 includes in utero infections such as herpes, rubella, syphilis, and toxoplasmosis, which require audiological evaluation by 9 months of age. Due to a high rate of progressive loss in infants with congenital CMV, recommendations include an audiological evaluation by 3 months of age and yearly through 3 years of age. CMV is a common cause of nongenetic unilateral or bilateral early, progressive, and delayed-onset sensorineural hearing loss.[39–41] For infants with laboratory evidence of Zika, an AABR by 1 month of age is indicated.

Risk factors 5 and 6 Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies,[42,43] and physical findings, such as cleft lip/palate, white forelock, or micro-ophthalmia can be indicators of a possible syndrome known to include a sensorineural hearing loss or permanent conductive hearing loss.

Risk factors 7 and 8 include syndromes associated with hearing loss or progressive or late-onset hearing loss, such as neurofibromatosis, osteopetrosis, and Usher syndrome;[53] other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson. There are more than 400 syndromes and genetic disorders associated with hearing loss.[31,35,45,46] Neurodegenerative disorders, such as Hunter syndrome, or sensory motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome, are strongly associated with permanent hearing loss.[53] Consultation with a geneticist is indicated for all infants diagnosed with congenital hearing loss for whom there is not a clear etiology.

Risk factors 9, 10, and 11 may occur in the neonatal period or postdischarge. Risk factor 9 includes culture-positive bacterial and viral (especially herpes viruses and varicella) postnatal infections (including meningitis) which may result in rapid onset hearing loss.[47–50] In these events, an audiological evaluation should be completed no later than 3 months from the onset of the illness. Although, widespread administration of conjugate vaccines has resulted in decreased rates of *Haemophilus influenza* type B infection, pneumonia, measles, mumps, rubella, and childhood meningitis, encephalitis viral infections especially herpes viruses and varicella remain a serious risk factor.[50] Children with cochlear implants remain at increased risk of postnatal infection.[51]

Risk factors 10 and 11. Head trauma, especially basal skull/temporal bone fractures that require hospitalization, as well as injury to the mastoid, is associated with hearing loss.[42] Chemotherapy[52] should also prompt early referrals for audiological assessment.

After Newborn Hearing Screening: Audiology Diagnostic Protocols

Since 1999, the American Academy of Pediatrics has endorsed early hearing detection and intervention (EHDI) defined as screening by 1 month, diagnosis by 3 months, and appropriate intervention services by 6 months of age. The recommended

audiology diagnostic assessment for infants who do not pass the newborn screen includes a battery of tests.[3]

1. Click-evoked ABR testing using both condensation and rarefaction single-polarity stimulus is recommended for all NICU graduates and, if there are risk indicators for neural hearing loss (auditory neuropathy), is considered the gold standard. Testing is done to quantify frequency-specific thresholds for air- and bone-conduction, and to determine the ear-specific type and degree of hearing loss.
2. OAE either distortion product or transient evoked emissions assess the integrity of the outer hair cells of the cochlea.
3. Tympanometry using a 1000-Hz probe tone is done to assess middle ear function.[24]
4. Acoustic reflexes are an important component of middle ear function. The acoustic reflex is absent in auditory neuropathy.
5. VRA is the gold standard for estimation of hearing thresholds and for confirmation of hearing level. It cannot be done until the infant reaches a developmental level of 7 to 9 months of age.
6. Clinician observation of the infant's auditory behavior may be used as a cross-check for the electrophysiologic measures. Behavioral observation alone is not adequate for determining whether hearing loss is present and is not adequate for the fitting of amplification devices.

Identification of an audiologist with skills in pediatric diagnostic assessment can be obtained from the roster of Pediatric Board–certified audiologists on the ABA website (https://www.boardofaudiology.org/) and the EHDI-PALS website (http://www.ehdipals.org/). The report from the audiologist will include the type of hearing loss, whether the loss is unilateral or bilateral, and the degree of hearing loss.

Medical Work-Up for Hearing Loss

A visit should be scheduled with the family as soon as a diagnosis of hearing loss is made by the audiologist to discuss the audiologist's report, provide information on community supports and intervention resources, and provide support for the family during a period of stress. During the visit with the family, the physician reviews the pregnancy, neonatal, and family history for hearing loss, and completes a comprehensive physical examination. The examination should focus on identifying findings which may suggest craniofacial abnormalities or a syndrome associated with hearing loss. An examination of the head, eyes, ears, nose and throat, and middle ear status are particularly important.

A thorough evaluation of middle ear status is important as the presence of fluid in the middle ear space can delay clarity regarding a child's hearing status.[27] It is not uncommon for newborns and NICU graduates to have middle ear effusion or retained amniotic fluid, which can cause transient conductive loss and a false positive screen. Persistence of middle ear fluid in the infant should be monitored and managed in the medical home as this can delay the definitive identification of a permanent hearing loss.[27] In cases of persistent middle ear fluid, myringotomy tube placement will be necessary in order to complete a valid diagnostic to rule out a concurrent permanent hearing loss. There is evidence that persistent middle ear fluid identified in the NICU is a risk factor for chronic otitis media with effusion in the first year of life.[54] Once the diagnosis of a permanent hearing loss is established it is necessary to discuss the benefits of early intervention services and amplification. The primary care physician needs to stay up to date and aware of community resources and support the family choice of early intervention program and approaches to communication development.

Multidisciplinary Care

For children identified with a permanent hearing loss, there are three medical specialties which are important for care and proactive identification of other conditions. These include an otolaryngologist with knowledge of pediatric hearing loss, a geneticist or genetic counselor, and an ophthalmologist with expertise in pediatric eye conditions.[22] The primary care provider facilitates referrals for these evaluations and can help explain to families why they are needed. The otolaryngologist conducts a comprehensive assessment to gain an understanding of etiologies of hearing loss, assesses risk for progression of hearing loss, evaluates factors which may impact an approach to management, and guides the identification of co-existing conditions,[55] and provides recommendations and information to the family, audiologist, and primary care provider. The pediatric otolaryngologist provides guidance on candidacy for amplification, assistive devices, and surgical intervention, including reconstruction, bone-anchored hearing aids, and cochlear implantation. The work-up may include genetic testing, evaluation for congenital cytomegalovirus (cCMV) infection, and imaging.

Genetics: Because of the prevalence of hereditary hearing loss, all families of children with confirmed hearing loss should be offered a genetics evaluation and counseling. This evaluation can provide families with information on etiology, prognosis, associated disorders, and recurrence in offspring. The geneticist will review a three-generation family history for specific genetic disorders or syndromes and complete genetic testing for syndromes or gene mutations for non-syndromic hearing loss such as *GJB2* (Connexin 26).[32,46,56,57] The field of genetics is rapidly evolving. While gene panels for hearing loss are commercially available, it is important for families to have accurate and up-to-date information.[58] The Hereditary Hearing Loss homepage (https://hereditaryhearingloss.org/) is a good resource for up-to-date information.

Imaging

The otolaryngologist will order radiographic imaging as appropriate. Temporal bone imaging is often indicated as part of the work-up to identify the etiology, any malformations that may need surgical intervention and appropriateness of amplification or cochlear implantation. The two modalities for imaging include high-resolution computed tomography (HRCT) and magnetic resonance imaging (MRI). These modalities have different benefits and considerations, such as visualization of bony structures (better with HRCT) and visualization of cranial nerves and soft tissue (MRI). The need for sedation and radiation exposure (HRCT) are also considerations.

Ophthalmology: It is recommended that each child with a permanent hearing loss have at least one examination by an ophthalmologist experienced in evaluating infants because of the association of hearing loss with vision impairments and the importance of vision for children with hearing loss. In some situations, an ophthalmologist may be the first to identify a finding associated with syndromic hearing loss.

Electrocardiogram: In children with profound sensorineural hearing loss without an identified etiology, it is appropriate to obtain an electrocardiogram to identify prolonged QT interval.[59]

This condition is associated with Jervell and Lange-Nielson syndrome and can result in sudden death.[59–61]

As 30% to 40% of children with confirmed hearing loss have developmental comorbidities, developmental milestones should be closely monitored and referrals initiated to developmental specialists for suspected disabilities as appropriate.

Communication Options

Early intervention providers including teachers of the deaf, the speech language pathologist and audiologist will provide information to the family on communication options consistent with the child's diagnosis. The family needs to decide on the communication mode that will work optimally for the child and family. There are five options described in Table 97.5: auditory oral communication (speech reading), auditory verbal communication, cued speech, total communication, and American Sign Language. Parents may initiate with total communication and change mode subsequently, depending on the child's progress with communication. For example, the family of a child with profound hearing loss may initially choose total communication but, after a cochlear implant at 12 months of age, may use predominantly auditory verbal or auditory oral communication.

Assistive Technologies

Hearing Aids: Infants as young as 1 month of age can be fitted with hearing aids. Hearing aids are compact and worn either in-the-ear (ITE) or behind-the-ear (BTE). Components are the microphone that picks up sounds and the amplifier. The audiologist uses computer programming to adjust the sound for an individual child's needs. If the child has different degrees of hearing loss at different frequencies, the audiologist adjusts the gain (loudness). The young growing infant needs to be seen by the audiologist approximately every 6 weeks to replace outgrown molds. Regular surveillance of hearing status is important to ensure that amplification is appropriately fitted and programmed as both progression and fluctuation of thresholds may occur.

TABLE 97.5 Characteristics of Modes of Communication

Mode	Mechanism	Language Goal
Auditory oral communication	The use of residual hearing and amplification with visual support (speech reading)	Spoken
Auditory verbal communication	Based on listening skills alone	Spoken
Cued speech	Uses visual communication and combines listening with 8 hand shapes in 4 placements near the face	Spoken
Total communication	Combines all means of communication and encourages simultaneous use of speech and sign	Spoken and sign
American Sign Language (ASL)	Visual and manual	ASL, English learned as a second language

Frequency modulated (FM) systems: FM systems were developed to enhance hearing in noisy environments. An FM system consists of a microphone and a receiver. A small radio transmitter is attached to a microphone and a small radio receiver. A parent, early intervention provider, or teacher wears the FM transmitter and microphone while the infant/child wears the FM receiver. The FM transmitter sends a low-power radio signal to the FM receiver that needs to be within 50 feet of the transmitter. The FM receiver gets the signal from the microphone and sends it to a personal hearing aid or cochlear implant. Listening to the FM signal is similar to listening to speech only inches away. Systems can be used in the home, while shopping, or at school.

Cortical Auditory Evoked Potential (CAEP): This is a relatively new assessment utilized in hearing aid fitting. CAEPs, are reported to confirm audibility of speech sounds at the cortical level.[62]

Cochlear Implants: Cochlear implants are FDA approved for children 12 months and older with severe to profound sensorineural hearing loss. As of December 2019, roughly 118,100 devices have been implanted in adults and 65,000 in children in the United States (https://www.nidcd.nih.gov/health/cochlear-implants). It is standard practice to recommend that children be adequately fit with hearing aids for 3 to 6 months before determining implant candidacy. A lack of benefit in the development of auditory skills with amplification with hearing aids needs to be demonstrated for eligibility for an implant. In 2019, the FDA expanded approval of cochlear implants to single-sided deafness (SSD) and asymmetric hearing loss. It is recognized that when children receive a cochlear implant at early ages, they have a higher likelihood of better speech and language development.[63] Early development of speech and language skills following cochlear implantation support sustained benefits in language into adolescence and beyond.[64]

Because of an increased risk for bacterial meningitis, it is recommended that physicians monitor all patients with cochlear implants.[65–67] *Streptococcus pneumoniae* is the most common pathogen causing meningitis in cochlear implant recipients.[51,68–70] All children with cochlear implants should be vaccinated according to the American Academy of Pediatrics high-risk schedule. Preferably, children under the age of 2 will have received the PCV13 at usual childhood interval. Children who have a cochlear implant should receive a Pneumovax-23 valent immunization after the age of 2 years (meningococcal cochlear implants and vaccination recommendations: information: https://www.cdc.gov/vaccines/vpd/mening/public/dis-cochlear-faq-gen.html).

Comprehensive Early Intervention

All infants diagnosed with a permanent hearing loss should be referred and enrolled in early intervention by 6 months of age to minimize to deleterious effects of communication deprivation.[71–74] The JCIH[75] recommends that states should have a single point of entry into intervention specific for children with hearing loss to ensure that, regardless of geographic location, all families who have infants or children with hearing loss receive information about a full range of options regarding amplification and technology, communication and intervention, and accessing appropriate counseling services.[3,75] The JCIH[75] published 12 best practice guidelines for EI programs that include the following:

- The provision of timely referral to EI services with providers who have knowledge and skills in early childhood deafness and hearing loss.

- Infusion within the system of partnerships with parents as well as professionals who are deaf/hard of hearing.
- Longitudinal developmental assessments for monitoring the child's development.
- Data management systems that include developmental outcomes.
- A process to monitor the fidelity of the intervention.
- Appropriate services for children with additional disabilities, those from non-English-speaking families, and those from special populations, including unilateral hearing loss and auditory neuropathy/dyssynchrony.

As the number of bilingual children with hearing loss continues to increase, the question has arisen regarding the most optimal way for early intervention providers to teach speech to bilingual children with HL. A number of investigators have reported that children with hearing loss supported in both their home language and the majority culture language compared to children with HL exposed to the majority culture language alone acquired English and their home language at similar rates.[76,77] Two studies[78,79] investigated the effects of supporting both the home language (Spanish) and the language of the majority culture (English) on language outcomes in bilingual children with HL who use CIs and HAs compared to bilingual peers who received English-only support. Bilingual children who received dual-language support outperformed peers who received English-only support as measured by Total Language and Expressive Communication language age scores of the Preschool Language Scales-4. Because of the high incidence of hearing loss among Hispanics in the US, it is likely there will be an increased need for provision of dual language Early Intervention services.[80]

In addition, a total communication approach including ASL and speech is recommended at the initiation of early intervention services to ensure access to language. An expert opinion summary proposes consideration of use of both sign and spoken language for all young children who are deaf to ensure access to language and linguistic competence. The report[81] reviews findings demonstrating that sign language development is associated with both written and spoken language development.[82,83]

Neonatal Intensive Care Unit Infants, Risk Factors, and Hearing Loss

The majority of infants cared for in an NICU have a risk factor for hearing loss. The relationship between risk factors and hearing loss in several studies of NICU infants is reviewed, and summaries

TABLE 97.6 Risk Factors and Rates of Hearing Loss Among Infants Cared for in a Neonatal Intensive Care Unit

Author	Dates of Birth	Sample	Screen Diagnostic	Rates of HL	Risk Factors
Coenraad et al., 2010[115]	2004–2009	3366 NICU infants		Screen refer 3%; diagnosed 1.7%; 17.2/1000	Dysmorphism, low 1 min Apgar, sepsis, meningitis, cerebral bleed and infarction
Schmidt et al., 2015[86]	1996–1998 at 36 centers assessed effects of brain injury, BPD and severe ROP	500–1250 g followed at 5 years	Primarily AABR and Sound Field	HL 2%	↑ Rate of HL by # morbidities None 1.3% 1 risk factor 3.6% 2 risk factors 5.4% 3 risk factors 25.0%
Van Dommelen et al., 2015[87]	1998–2012	18,564 preterms Dutch NICU	Two-stage AABR followed by diagnosis at 2–4 m	24.0–24.9 wk, 7.5% 25.0–25.9 wk, 5.2% 26.0–26.9 wk, 4.6% 27.0–27.9 wk, 2.8% 28.0–28.9 wk, 2.0% 29.0–29.9 wk, 1.6% 30.0–30.9 wk, 2.0% 31.0–31.9 wk, 1.2%	Analysis: Risk increases with decreasing gestation; small for gestation infants <27 weeks also at increased risk of HL
Kraft et al., 2014[116]	2001–2007	26,341 infants, 25,400 with completed screen	Screen not described; postdischarge, ABR, OAE, and tympanometry	Refer rate 1.3% 90 infants diagnosed including 16 with delayed onset	All JCIH risk indicators significant; however, ototoxic medications and >5 days in NICU provide small contribution; authors report congenital diaphragmatic hernia NS. Increased risk with increased number of risk factors
Goderis, 2014[117]		Review of 37 studies: 10 population, 14 longitudinal, 13 retrospective	1/3 symptomatic and 1/10 asymptomatic with HL	12.6% HL (CI: 10.2–16.5)	Delayed onset HL of 0%–50%. Calculated risk of 18% in symptomatic group, 9% in asymptomatic group

AABR, Automated auditory brainstem response; *BPD*, bronchopulmonary dysplasia; *CMV*, cytomegalovirus; *HL*, hearing level; *JCIH*, Joint Committee on Infant Hearing; *NICU*, neonatal intensive care unit; *OAE*, oto-acoustic emissions; *ROP*, retinopathy of prematurity.

are shown in Table 97.6. A study by Robertson et al.[84] included a cohort of 1279 infants weighing 1250 g and below or at 28 weeks' gestation screened with AABR followed by audiology diagnostic assessment and followed to 5 years of age. The rate of permanent hearing loss was 3.1%, rate of severe to profound was 1.9%, 28% had progressive hearing loss, and 73% had other disabilities. Risk factors included prolonged oxygen use, gastrointestinal surgery, patent ductus arteriosus ligation, and low socioeconomic status (SES).

Schmidt et al.[85] published two studies examining the effects of the major neonatal morbidities of bronchopulmonary dysplasia (BPD), major brain injury, and severe retinopathy of prematurity (ROP) on rates of hearing loss at 18 months in very low-birth-weight infants weighing less than 1250 g. Rates of hearing loss compared with not having the risk factor were 3.5% versus 1.4% for BPD, 2.9% versus 2.2% for brain injury, and 3.8% versus 2.2% for severe ROP. In the second study, children were followed to 5 years of age.[86] Overall, 2% of the 1514 infants weighing between 500 and 1250 g were described as deaf. Rates of deafness were related to the risk factors of BPD, serious brain injury, and severe ROP. In this report, the investigators identified a relationship of rate of hearing loss with an increasing number of risk factors (no risk factors: 1.3%, one: 3.6%, two: 5.4%, and three: 25%).

Van Dommelen et al.[87] reported on the relationship between gestational age and hearing loss in a large cohort of 18,564 preterm infants. The prevalence of hearing loss consistently increased with decreasing week of gestation from 1.25% at 31 weeks to 7.55% at 24 weeks. A study by Morris et al.[88] examined the effects of two protocols to provide phototherapy to very preterm infants with hyperbilirubinemia. Compared with the conservative-phototherapy group, the aggressive-phototherapy group had significant reductions in the rate of severe hearing loss, from 3% to 1%. The conclusion was that the benefit to decreased impairment may be offset by the increased mortality in the smallest infants. All of the studies indicate that there are increased rates of hearing loss among NICU infants who are the most preterm and have the highest rates of neonatal morbidities. Using a readily identifiable event (such as NICU stay longer than 5 days), allows clinicians and monitoring systems to flag and follow an individual child, thus simplifying the number of factors required to identify infants at risk of hearing loss. Among NICU cohorts described in the literature, these children have a higher prevalence rate of hearing loss than the general population, with reports as high as 7.5/1000 for preterm infants born at 24 weeks' gestation in the Netherlands (see Table 97.6). Various studies have controlled for risk factors to try to refine our understanding of individual risk. Factors which have maintained statistical significance when controlling for various other factors include dysmorphic features, low APGAR scores, sepsis, cerebral injury (bleeding/infarction),[89,90] severe asphyxia,[91,92] ventilation ≥5 days,[91] and prolonged oxygen use ECMO.[49,93]

The Brain, Language Outcomes, and Access to Language

The most important predictor of improved language outcomes is early age of identification. Age of identification reported in the 1980s and 1990s ranged from 19 months to 31–35 months of age.[94,95] Since 1997, age of identification in some reports has dropped to 2 to 4 months of age.[16,96] The National CDC EHDI data for 2013 indicate 69% of newborns who did not pass the newborn screen are diagnosed with a permanent hearing loss by 3 months of age. This rate may in part be due to incomplete reporting but indicates some parts of the country continue to struggle in achieving the EHDI 1-3-6 goal (https://www.cdc.gov/ncbddd/hearingloss/2013-data/2013_ehdi_hsfs_summary_e.pdf). Early identification remains a critical EHDI goal as earlier age is consistently associated with improved outcomes. Yoshinaga-Itano et al.[8,97] have shown that early quality intervention services in the first year of life which provide access to language (either speech or visual [ASL]) improve the language and developmental outcomes for children who are deaf or hard of hearing. The longitudinal study by Moeller[74] showed, in adjusted analyses, that enrollment in early intervention services and greater family involvement predicted higher vocabulary scores on the Peabody Picture Vocabulary test at 5 years of age among DHH children in Nebraska.[74] The 2018 CDC report indicates that 70.1% of infants with a diagnosed permanent HL are receiving EI services by 6 months of age (https://www.cdc.gov/ncbddd/hearingloss/2018-data/01-data-summary.html).

The first 3 years after birth are particularly critical for access to language since this period is a time of both rapid language and rapid brain growth. In addition, it is not the ears, but the brain where language is processed and understood. During the first 3 years, the brain grows and matures in complexity and connectivity at an incredible rate which is, in part, mediated by the infant's exposure to language. Sharma et al.[98,99] have shown that earlier implantation of a cochlear implant is also associated with more optimal development of the auditory pathway to the auditory cortex (temporal lobes). Children who are deaf and born to deaf parents have natural early exposure to visual language (ASL). However, more than 90% of children born DHH are born to hearing parents and do not have immediate access to either visual language (ASL) or auditory language (speech). Therefore, early access to language and early intervention that meets the communication needs of the family is the key. The studies of Hart and Risley[100] have shown that the amount and quality of language that all children are exposed to in the home in the first 3 years of life varies significantly, and the greater the input of child directed quality language, the more optimal the child's language and cognitive outcomes. Further evidence of the importance of language access comes from the studies of the neuronal maturation of the central auditory pathway.[98,99] In the absence of typical auditory stimulation the auditory pathway and cortex remain maximally sensitive and plastic for development for about 3.5 years in response to placement of a cochlear implant. From 3.5 to 7 years response to a cochlear implant drops to 7% to 30% and after 7 years to less than 5%. These data identify the window of opportunity and plasticity for development of the auditory pathway and speech for a child with a severe to profound HL is the first 3.5 years of life. In addition, MRI studies suggest that cross-modal reorganization of the auditory cortex occurs in DHH children without auditory stimulation, in response to visual and somatosensory stimulation. It is suggested that this modification in brain development may facilitate enhanced processing of skills in these domains for DHH.[98] Evidence of very early impact has been shown in infants who are DHH exposed to visual language who develop sign babbling at a rate that hearing infants develop verbal babbling.[101] A study by Tomblin et al.[102] of the usage characteristics of amplification identified that a combination of factors including earlier age of fitting, higher daily duration of amplification, and greater audibility of the device were all significantly associated with higher early language skills in a cohort of children with mild to severe hearing loss. Another important finding, however,

was that children fit with hearing aids after 18 months of age were able to improve their language abilities as a function of increased duration of hearing aid use. This finding again suggests that brain plasticity and the language learning system remain open to experience provided by increased access to linguistic input during the preschool years. Data from Tomblin et al.[102] also indicate that the development of language for children with a more severe HL is more challenging than children with a mild loss. Within a cohort of children divided into mild (25 to 45 dB HL), moderate (45 to 60 dB HL), and moderate to severe HL (>60 dB HL) compared to age- and SES-matched controls, children with moderate to severe HL consistently had the lowest scores at 2 to 5 years of age. For all of the HL groups, greater degree of HL was associated with lower language abilities. Additional factors that have been shown to contribute to language success in children include enhanced maternal communicative intent,[103] higher SES, higher parent education level,[100] less parental stress,[104] a more optimal home language environment,[105] and access to deaf role models.[75]

The Walker et al.[106] study clearly demonstrated the importance of wearing hearing aids among 5- to 7-year-old children with slight or mild hearing loss (≤25 dB HL). Children were divided into three groups of hearing aid use including none, part-time (2 to 8.3 hours) and full-time (>8.7 hours). Full-time users had higher Peabody receptive vocabulary scores and CELF grammar scores after adjusting for age of diagnosis, best ear speech intelligibility, and early intervention. In addition, the audibility of hearing aids has been shown to moderate school-age academic outcomes of children with all degrees of HL.[107] Finally, an important language skill is pragmatic language which forms the foundation for conversation competence. This is a particularly challenging skill for children who are deaf or hard of hearing.

In a recent report,[108] the pragmatic language of children with bilateral HL was followed longitudinally to 7 years of age. In a multivariable analysis, meeting the 1/3/6 EHDI guidelines, greater quantity of parent-child directed talk during a 25-minute recorded session at a mean age of 32.2 months, higher nonverbal intelligence, lesser degree of HL and higher maternal education were significantly associated with higher levels of pragmatic language ability at age 7. Increased parent-to-child-directed talk has also been reported in a number of studies to be associated with improved language outcomes.[109]

In summary, EHDI systems of care continue to improve access to timely screening, diagnosis, and early intervention services to ensure successful outcomes. It is expected that ongoing surveillance and facilitation of individualized coordinated care with the use of the electronic medical record, multidisciplinary partnering, implementation of both local and telemedicine services,[110] and coordination with state EHDI programs will continue to contribute to improved hearing outcomes.
