Fungal Infections in the Neonatal Intensive Care Unit

KIRTIKUMAR UPADHYAY AND MIHAI PUIA-DUMITRESCU

KEY POINTS

- Fungal infections account for approximately 12% of neonatal late-onset sepsis, with a mortality rate of approximately 32%, and the most important risk factor remains the gestational age at birth.
- When a lumbar puncture is performed, 10% to 50% of candidemic infants have associated meningitis and a significant percentage of extremely low birth weight (ELBW, BW<1000 g) infants with *Candida* meningitis have negative blood cultures.
- *Candida* species isolated from a blood culture should be considered as an infection, not a contaminant.
- Rapid institution of parenteral amphotericin B deoxycholate is the therapy of choice for systemic fungal infection; if there is also meningitis, 5-flucytosine or fluconazole should be added.
- Central venous catheters should be removed within 24 hours after the identification of yeasts in the blood culture, if possible.
- The finding that prophylactic fluconazole reduces the incidence of invasive neonatal fungal infections should be interpreted with caution; nevertheless, recent guidelines recommend fluconazole prophylaxis in ELBW infants in nurseries with high rates (>10%) of invasive candidiasis.

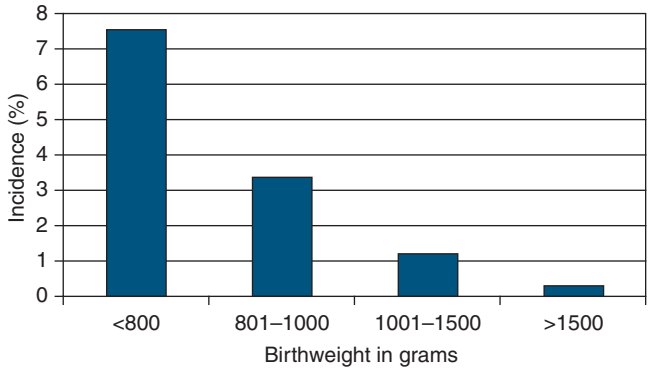
Epidemiology

Invasive fungal infection accounts for approximately 10% of healthcare associated infections in very low birth weight infants[1] and occurs in approximately 1% to 2% of all infants admitted to US neonatal intensive care units (NICUs).[2] The incidence rises dramatically with decreasing gestational age and birth weight. Fungal infections are associated with high mortality and morbidity, including poor neurodevelopmental outcomes in extremely low and very low birth weight infants.[3] Among the fungi, *Candida* species (spp.) are the dominant pathogens. There are over 200 identified species of *Candida*,[4] but fewer than 12 appear to cause disease in neonates. These infections are evenly distributed among *C. albicans* and non–*C. albicans* spp. (*C. parapsilosis, C. orthopsilosis/C. metapsilosis, C. glabrata, C. guilliermondii, C. krusei*, and *C. lusitaniae*). *Candida* spp. are the third most common pathogen in neonatal nosocomial bloodstream infections and carry a fatality rate more than sevenfold greater than that of *Staphylococcus epidermidis*, the most common pathogen found in the NICU.[5,6] In late-onset sepsis, fungi account for approximately 12% of cases, with a mortality rate of 32%.[7] Other fungi encountered include *Aspergillus (fumigatus* and *flavus)* and *Malassezia (furfur* and *pachydermatis)*. The yeast *Cryptococcus neoformans* and the fungi *Histoplasma capsulatum, Blastomyces dermatitidis*, and *Coccidioides immitis* are rarely seen in the NICU.

Pathophysiology

The most important risk factor for fungal infection is gestational age. In a survey of 2847 infants from six different nurseries, the incidence of candidemia in infants weighing less than 800 g (7.55%) was 25 times that of the infants weighing more than 1500 g (Fig. 36.1).[8] This latter group acquires bloodborne candidal infection in association with congenital anomalies, especially those of the gastrointestinal tract.[9] Candidemia carries a mortality rate exceeding 25% in most studies.[10,11]

Colonization with ubiquitous fungal spp. occurs in at least 25% of very low birth weight (VLBW) infants,[12] and both the amount of *Candida* in the gastrointestinal tract[13] and colonization at sites such as endotracheal tubes[14] have been correlated with increased risk of invasive disease caused by *Candida* spp. Prospective studies correlating colonization by other fungal genera (e.g., *Aspergillus, Malassezia*) with risk of invasive disease have not been done.



• **Fig. 36.1** Incidence of Candidemia related to birthweight in grams. (Data from Saiman L, Ludington E, Pfaller M, et al. Risk factors for candidemia in neonatal intensive care unit patients. The National Epidemiology of Mycosis Survey study group. *Pediatr Infect Dis J*. 2000;19:319–324.)

Apart from colonization and gestational age, other host factors that contribute to the susceptibility of the NICU neonate to fungal infection include a 5-minute Apgar score of less than five and an age-dependent immunocompromised state ascribable to reduced numbers of T cells, impaired phagocyte number and function, and reduced levels of complement.[15–18] Other factors thought to increase the risk of fungal infections include length of NICU stay greater than 1 week, indwelling central venous catheters (CVCs), abdominal surgery, parenteral nutrition, intralipids, H_2 blockers, endotracheal intubation, and prolonged use of broad-spectrum antimicrobials, especially third-generation cephalosporins.[6,8,19] Some studies have identified associations with systemic steroids and catecholamine infusions and with topical petrolatum.[5,20,21]

A number of variables appear to not be associated with candidal colonization, including use of antibiotics in the mother, premature rupture of the membranes, the infant's gender, use of antimicrobial agents other than third-generation cephalosporins in the infant, surgical procedures, or frequency of intubation.[6] Although approximately 5% of NICU staff carry *C. albicans* on their hands and 19% carry *C. parapsilosis*, there is no correlation with site-specific rates of neonate colonization.[6]

This chapter will place its major emphasis on infections caused by *Candida* spp. and will also discuss infections caused by other fungi, as well as the approach to diagnosis, treatment, and management of infants with fungal infection.

Infections Caused by *Candida* Species

Congenital Candidiasis

Congenital candidiasis typically presents within the first 24 hours of life in both full-term and premature neonates. The infection manifests as a deeply erythematous skin rash in the setting of pronounced neutrophilia, with white blood cell counts often rising to 50,000 mm^3 or more. *Candida* funisitis (discussed later in the chapter) can be an infrequent accompaniment. In the full-term neonate, there are usually no invasive consequences, and desquamation typically ensues within 2 to 3 days. In contrast, the condition is life-threatening in the premature neonate[22,23] and is distinguished by a pustular rash, hazy infiltrates reminiscent of respiratory distress syndrome on chest radiograph, and frequently positive blood cultures. The premature neonate is thought to acquire the organism from inhalation of infected amniotic fluid.

The diagnosis of congenital candidiasis in both premature and full-term neonates requires visualization of the organism on Gram stain from a bullous lesion or an opened pustule. On rare occasions, placental culture can yield the diagnosis. Treatment for the full-term neonate requires only the full-body application of topical antifungal creams containing either nystatin or azoles such as miconazole or clotrimazole. In the premature neonate, the initiation of parenteral amphotericin B deoxycholate at a dose of 1 to 1.5 mg/kg is mandatory (this dose may be reduced to 1.0 mg/kg), but respiratory involvement typically heralds death despite antifungal therapy. (Except where noted, all dosages come from *Nelson's Pediatric Antimicrobial Therapy*, 2017 edition, AAP Press.)

Local Infections With *Candida* Species

Diaper Dermatitis

This entity presents as an erythematous, erosive dermatitis of the perineal region, typically with pustular "satellite lesions" beyond the borders of the rash. Predisposing factors include systemic antibiotics, glucosuria, and wet diapers. Care must be taken to differentiate this tractable condition from invasive fungal dermatitis (discussed later in the chapter). Candida diaper dermatitis responds well to topical antifungal ointments.

Funisitis

Infection of the umbilical cord with *Candida* spp., while rare, is an indicator of chorioamnionitis and carries a poor prognosis, especially in the premature neonate.[24]

Urinary Tract Infection

Isolation of *Candida* spp. from a catheterized specimen or via suprapubic bladder aspiration, as opposed to a bagged sample, is a reliable indicator of infection. However, asymptomatic colonization of urinary catheters, stents, or nephrostomy tubes can be difficult to distinguish from true infection.[25]

The presence of candiduria in the NICU neonate is associated with renal candidiasis—the latter manifested by cortical abscesses or fungal mycelia in the collecting system ("fungus balls")—nearly half the time and may be a cause of frank obstruction.[26] Thus, in contrast to older children or adults, the finding of candiduria in a neonate should prompt blood cultures and renal imaging, at the very least. If blood cultures are positive, a full evaluation for disseminated candidiasis should be undertaken (discussed later in the chapter).

Because of the high prevalence of associated upper urinary tract disease, imaging of the kidneys by ultrasonography should be performed upon isolation of *Candida* spp. from a catheterized urine specimen or from a suprapubic bladder aspiration. Approximately half of patients who eventually develop upper tract manifestations will display them on the first ultrasound.[26] Therefore, follow-up imaging is recommended both to ensure the clearance of fungal mycelia, if present, and to monitor for later development of this complication. Unfortunately, no standard interval for monitoring has been proposed. However, in the infant who remains persistently funguric or candiduric, a single negative ultrasound should not be considered definitive.

Removal of a colonized urinary catheter may suffice for treatment in a patient without pyuria or systemic symptoms. Disease confined to the lower tract is best addressed with azoles (e.g., fluconazole, 4 to 6 mg/kg/day). Upper tract disease requires parenteral amphotericin B in systemic doses (1 mg/kg/day). Liposomal amphotericin B may not be an acceptable alternative. The particles in at least one liposomal preparation (Abelcet) appear to be too large to penetrate the adult kidney, and treatment failures with Abelcet in premature newborn with persistent candiduria have been reported.[27] Therefore, amphotericin B deoxycholate appears to be the best alternative.[27]

Peritonitis

Candida peritonitis typically develops as a consequence of bowel perforation or, rarely, as a complication of peritoneal dialysis. In the former situation, multiple organisms such as gram-negative rods and enterococci may also be involved, and the neonate is at risk for sepsis with any one of them.[28] Peritonitis associated with a peritoneal dialysis catheter usually occurs as an isolated process, and the outcome is much better.

Spontaneous intestinal perforation associated with *Candida* peritonitis with or without sepsis has been described within 7 to 10 days of birth in neonates weighing less than 1000 g, typically in the absence of necrotizing enterocolitis.[29–32] Hallmarks include

bluish discoloration of the abdomen and a gasless pattern on abdominal film. A substantial proportion of these neonates will have systemic candidiasis, although *S. epidermidis* can also be seen. In a small study of seven patients,[32] deficiency of the muscularis propria was found in six.

Diagnosis of Candida peritonitis requires visualization of the organism on a Gram stain of sterilely obtained peritoneal fluid or culture of the organism from the same source. Isolation of *Candida* spp. from the peritoneal fluid should always prompt a search for bowel perforation, either by radiology or by surgical exploration, depending upon the clinical circumstances.

Treatment of *Candida* peritonitis caused by necrotizing enterocolitis or bowel perforation requires surgical evaluation, supportive therapy, and directed treatment of all contaminating microorganisms in the peritoneal fluid and the bloodstream. The typical regimen should address enterococci, gram-negative rods, and anaerobes together with systemic antifungal therapy, with the most likely choice being amphotericin B. *Candida* spp. isolated from peritoneal dialysate can be treated with removal of the catheter and a short course (7 to 10 days) of amphotericin B therapy in a dose of 0.3 to 0.5 mg/kg/day. In cases of *Candida* peritonitis associated with a peritoneal dialysis catheter, the catheter can typically be reinserted within 24 to 48 hours, once the Gram stain is free of yeast cells.

Systemic Infection

Candidemia Associated With Central Venous Catheters

The association between prematurity and bloodborne candidal infections has been recognized for 35 years.[33,34] Over this same period of time, the incidence of candidemia has escalated from 25 per 10,000 NICU admissions to 123 cases per 10,000 NICU admissions.[8,35] The median time of onset is approximately 30 days of age.[33] In a large multicenter study, colonization of the gastrointestinal tract preceded candidemia in 43% of cases.[8]

A variety of nonspecific clinical findings may be associated with this presentation of candidal disease, including respiratory decompensation, feeding intolerance, temperature instability, or mild thrombocytopenia. It is unclear whether the latter manifestation relates more to the use of heparin in intravenous (IV) and peripheral catheters or to the presence of *Candida* spp. in the bloodstream.

Any *Candida* spp. isolated from a blood culture should be regarded as an infection and should prompt an immediate search for evidence of dissemination, which occurs in approximately 10% of premature newborns with candidemia.[36,37] A thorough evaluation includes ophthalmologic examination and ultrasonography of the heart, venous system, and abdomen. When lumbar puncture is performed, 10% to 50% of candidemic neonates may have associated meningitis;[3,38] in one prospective study, nearly 50% of ELBW infants with *Candida* meningitis (13/27) had negative blood cultures.[3]

Numerous studies have shown that CVCs should be removed within 24 hours of identification of yeasts in the blood culture;[39] in particular, removal of the CVCs within 3 days is associated with a significantly shorter median duration of candidemia (3 days vs. 6 days) and a reduced mortality rate (0% vs. 39%). In at least one study of candidemia, delayed removal of CVCs was associated with neurodevelopmental impairment at 18 to 22 months.[3] Many experts recommend routine echocardiograms for patients with catheter-associated candidemia, to look for thrombi before removal of the catheter. However, even with the prompt removal of the catheter and institution of appropriate antifungal therapy, a substantial proportion of infants may exhibit prolonged candidemia lasting 1 to 3 weeks.[10]

Disseminated Candidiasis

Disseminated candidiasis is a dreaded complication of candidemia, and mortality rates from disseminated candidiasis approach 30%. As in other forms of candidiasis, *C. albicans* is the leading pathogen. Organ involvement is most common in the vascular tree at catheter sites (15%), followed by the kidneys (8%).[36,37] Eye involvement occurs in approximately 6% of infants. Thrombi within the vascular bed may be particularly difficult to eradicate with antifungal therapy; infants with right atrial thrombi may benefit from atriotomy.[40] Other sites less frequently involved include the liver, spleen, and skeletal system. In infection of the bones and joints in premature newborns, *Candida* spp. are typically the second most likely pathogen, preceded by *S. aureus*.[41]

Antifungal Therapy for Systemic Infection

As is true of most medications used in the NICU, dosing recommendations for antifungal therapies have not undergone rigorous testing in this patient population. With that caveat in mind, practice guidelines for this difficult clinical problem are suggested (Table 36.1). There are four widely used classes of drugs in the treatment of invasive fungal infections in children and infants, including the polyenes, pyrimidine analogues, azoles, and echinocandins.[42] Fluconazole and Amphotericin B are the most commonly used antifungals in the neonatal period.[43] Amphotericin B is the "gold standard" antifungal agent for treatment of systemic neonatal fungal infection. amphotericin B binds to ergosterol in the membrane of fungi, facilitating membrane leakage. Rapid institution of parenteral amphotericin B deoxycholate in doses of 1 mg/kg/day, given by IV infusion over 2 to 6 hours, is the therapy of choice for systemic infection, including catheter-associated candidemia and disseminated candidiasis. Liposomal amphotericin B in a single dose of 5 mg/kg/day as an IV infusion over 2 hours[44,45] is an equivalent choice for initial therapy, but clinicians should be aware that some lipid formulations (e.g., Abelcet) have decreased renal penetration and are therefore not appropriate choices in disseminated candidiasis with renal infection.

Azoles are fungistatic agents that interfere with ergosterol synthesis by inhibiting C-14 alpha demethylase, a cytochrome P450 enzyme. Some experts recommend this class of antifungals as initial therapy for *C. albicans* infection because of their fungistatic effects; others use them primarily to complete a course of antifungal therapy after clearance of the infecting organisms. Fluconazole, the most frequently used antifungal in neonates, requires an IV loading dose of 25 mg/kg on day 1, with subsequent IV doses of 12 mg/kg/day for the remainder of therapy. Azoles such as itraconazole and posaconazole are preferable to fluconazole for *Aspergillus* and zygomycetes. However, *Aspergillus* and zygomycetes are extremely rare in the NICU; therefore, no studies have been done to recommend neonatal dosing guidelines.

In the 2016 Infectious Diseases Society of America candidiasis guidelines, echinocandins are the primary drugs of choice for invasive candidiasis.[46] Caspofungin, an echinocandin, has also been used in dosages of 25 mg/m^2/day to treat invasive candidal disease in the newborn in several case reports. Caspofungin and other echinocandins such as micafungin (10 mg/kg/day) or anidulafungin

TABLE 36.1 Summary of Antifungals in Infants

Drug	Neonatal	FDA Approved in Children	FDA Indication
Polyenes			
Amphotericin B deoxycholate	1 to 1.5 IV mg/kg/day	No	Potentially life-threatening fungal infections: aspergillosis, cryptococcosis (torulosis), North American blastomycosis, systemic candidiasis, coccidioidomycosis, histoplasmosis, zygomycosis including mucormycosis due to susceptible species of the genera *Absidia, Mucor*, and *Rhizopus*, and infections due to related susceptible species of *Conidiobolus* and *Basidiobolus*, and sporotrichosis
Liposomal amphotericin B	3 to 7 IV mg/kg/day	1 mo to 16 yr	Empirical therapy for presumed fungal infection in febrile, neutropenic patients; treatment of *Cryptococcus* meningitis in HIV-infected patients; treatment of patients with *Aspergillus* species, *Candida* species, and/or *Cryptococcus* species infections refractory to amphotericin B deoxycholate, or in patients where renal impairment or unacceptable toxicity precludes the use of amphotericin B deoxycholate; treatment of visceral leishmaniasis
Amphotericin B lipid complex	5 mg/kg/day	<16 yr	Invasive fungal infections in patients who are refractory to or intolerant of conventional amphotericin B therapy
Pyrimidine analogues			
Flucytosine	General dosing: 75 mg/kg/day PO divided q6h to q8h Candidal meningitis: 75 to 100 mg/kg/day PO divided q6h to q8h in combination with amphotericin B	No	Serious infections caused by susceptible strains of *Candida* and/or *Cryptococcus* Use with extreme caution in renally impaired patients and monitor closely for hematologic, renal and hepatic toxicity
Azoles			
Fluconazole	Treatment of systemic infection Postnatal age < 8 days Loading dose: 12 to 25 mg/kg IV Maintenance: 12 mg/kg IV/PO q48h Postnatal age > 8 days Loading dose: 12 to 25 mg/kg IV Maintenance: 12 mg/kg IV/PO q24h Candidiasis prophylaxis < 30 weeks' gestation Postnatal age < 7 days 3–6 mg/kg IV twice weekly Postnatal age > 7 to 42 days 3 mg/kg IV q24h or 6 mg/kg IV q72h Postnatal age > 42 days 6 mg/kg IV q48h Candidiasis prophylaxis 30 to 40 weeks' gestation 6 mg/kg IV q48h	>6 mo	Oropharyngeal candidiasis, esophageal candidiasis, systemic candidiasis, cryptococcal meningitis and prophylaxis of invasive candidiasis in immunocompromised children

Continued

TABLE 36.1 Summary of Antifungals in Infants—cont'd

Drug	Neonatal	FDA Approved in Children	FDA Indication
Echinocandins			
Caspofungin	Preterm neonates and infants < 3 mo 25 mg/m² IV q24h Infants >3 mo Initial: 70 mg/m² IV once Maintenance: 50 mg/m² IV q24	>3 mo	Empirical therapy for presumed fungal infections in febrile, neutropenic patients; treatment of candidemia and the following *Candida* infections: intraabdominal abscesses, peritonitis, and pleural space infections; treatment of esophageal candidiasis; treatment of invasive aspergillosis in patients who are refractory to or intolerant of other therapies
Micafungin	Neonates 10 mg/kg IV q24h Infants and children 2 to 4 mg/kg IV q24h	>4 mo	Candidemia, acute disseminated candidiasis, Candida peritonitis and abscesses; treatment of patients with esophageal candidiasis; prophylaxis for patients undergoing hematopoietic stem cell transplantation
Anidulafungin	Initial: 3 mg/kg once followed by 1.5 mg/kg q24h	No	Candidemia and other forms of *Candida* infections (in intraabdominal abscess and peritonitis), esophageal candidiasis

(1.5 mg/kg/day) interrupt biosynthesis of β-(1,3)-D-glucan, an integral part of the fungal cell wall. However, identification of infecting spp. has important implications for choice of therapy. Although amphotericin B formulations, the azoles, and the echinocandins are all appropriate for infections caused by *C. albicans*, non–*C. albicans* spp. such as *C. glabrata, C. guilliermondii*, and *C. krusei* may have decreased susceptibility to fluconazole and can be variably sensitive to the echinocandins.[47–49] *C. lusitaniae* is usually resistant to amphotericin B formulations.

Some experts recommend institution of empiric antifungal therapy in acutely thrombocytopenic neonates of less than 25 weeks' gestation, especially if there is a recent exposure to third-generation cephalosporins.[50] Dosage adjustment for renal dysfunction is necessary only if serum creatinine increases significantly during therapy. Amphotericin B has poor cerebrospinal fluid penetration; in neonates with accompanying meningitis, fluconazole may also be added to amphotericin B. The use of 5-flucytosine in doses of approximately 25 mg/kg per dose (range 12.5 to 37.5 mg/kg) given orally every 6 hours in patients with normal renal function is no longer routinely recommended because of bone marrow suppression or hepatotoxicity when serum concentrations rise above 40 to 60 µg/mL.

With prompt removal of an offending CVC and no evidence of dissemination, the duration of therapy for catheter-associated candidemia is typically 10 to 14 days after the blood culture becomes negative.[51] Disseminated candidiasis, including *Candida* meningitis, requires at least three or more weeks of parenteral therapy; the course is typically completed when all foci have been eradicated. Most infectious disease experts will use fungicidal doses of parenteral amphotericin B or a liposomal preparation for the entire course.

Antifungal Prophylaxis

Appropriate use of antifungals in infants is important for both treatment and prevention of infection. Fluconazole prophylaxis for the prevention of invasive candidiasis is effective and safe in randomized control trials in premature infants.[52] Five randomized controlled trials comparing IV fluconazole (3 mg/kg/day) with placebo or no treatment in VLBW or ELBW infants for 4 to 6 weeks[53–57] met criteria for analysis in Cochrane reviews.[58] Some authors[53,56] reported significantly lower incidences of invasive fungal infection, while there was no difference in treated versus untreated infants in the studies of others.[54,55,57] The only study to evaluate neurologic outcomes found no difference in neurologic impairment at 16 months.[53] Fluconazole prophylaxis was not associated with a significant difference in the risk of death before discharge in any of the five studies or in a metaanalysis.[58] No study documented clinically significant adverse effects of fluconazole or the emergence of fluconazole resistance. In a recent multicenter, randomized, placebo-controlled trial of fluconazole prophylaxis, the MIC of colonizing *Candida* isolates increased in the fluconazole group, with most isolates remaining in the susceptible range.[59]

One study from a single center compared nonrandomized fluconazole prophylaxis from 2002 to 2006 with an untreated, retrospective cohort from 2000 to 2001 and reported that invasive candidiasis decreased from 0.6% to 0.3%, although the proportion of invasive disease caused by non–*C. albicans* spp. increased from 26% to 41% after the introduction of fluconazole prophylaxis.[60] Interestingly, fluconazole prophylaxis in this study was extended to several infants with birthweights greater than 1000 g, if risk factors were present (e.g., maternal human immunodeficiency virus infection, intestinal abnormalities).

The finding that prophylactic fluconazole reduces the incidence of invasive fungal infection must be interpreted "with caution"[58,61] as:

1. The incidence of invasive fungal infection in the placebo groups in these[53,56,57] studies was significantly higher (13% to 16%) than in other large cohort studies of VLBW or ELBW infants in the United States (6% to 7%) or the United Kingdom (1% to 2%).

2. Fluconazole prophylaxis may have impaired the microbiologic isolation of some fungal spp. and led to underdiagnosis of infection in the treatment group.
3. Six years after the introduction of fluconazole prophylaxis, one study reported that non–*C. albicans* spp. with relatively reduced susceptibility to the azoles were the most common causes of invasive fungal infection.[57] This study did not detect a significant effect of fluconazole prophylaxis in reducing invasive candidal disease.

Current guidelines from the Infectious Diseases Society of America[46] recommend IV or oral fluconazole, 3 to 6 mg/kg twice weekly for 6 weeks in ELBW infants in nurseries with high rates (>10%) of invasive candidiasis. Oral nystatin, 100,000 units three times daily for 6 weeks, is an alternative in neonates less than 1500 g where issues with availability or resistance to fluconazole militate against its use.

Infections Ascribable to Other Fungi

Invasive Fungal Dermatitis

Invasive fungal dermatitis typically presents in the infant weighing less than 1000 g who displays macerated or bruised lesions that are contaminated with fungal species. In one report, three of seven confirmed cases of invasive fungal dermatitis had *C. albicans*. *C. parapsilosis, C. tropicalis, Trichosporon beigelii, Curvularia*, or *Aspergillus niger*, and *fumigatus* were cultured from the remainder.[62] Among cases considered "probable," seven of eight had *C. albicans*. Systemic complications, including fungemia, meningitis, or infection of the urinary tract, occurred in four of seven confirmed cases and seven of eight probable cases. More cases than controls had postnatal steroids and prolonged hyperglycemia. Disseminated infection occurred in 69%, all ascribable to *Candida* spp.

The diagnosis of invasive fungal dermatitis requires a skin biopsy demonstrating fungal invasion beyond the stratum corneum or a positive potassium hydroxide preparation of skin scrapings; growth of the identical organism from an otherwise sterile site is confirmatory (e.g., blood, cerebrospinal fluid, or urine obtained via sterile technique). Treatment requires systemic doses of amphotericin B in the range of 0.7 to 1.0 mg/kg/day; in those infants who do not develop systemic infection, oral therapy with fluconazole or topical antifungal creams may suffice. Oral therapy is not advisable for pathogens like *Aspergillus*, and repeated skin biopsies may be necessary to define duration of therapy.

Line Infections Caused by Lipophilic Organisms

The spp. *M. furfur* and *M. pachydermatis* are lipophilic organisms commonly carried on the skin, even in patients without tinea versicolor.[63] Cutaneous colonization can infect hyperalimentation fluids or parenteral lipid formulations. Infants with lipophilic organisms infections typically present with mild but nonspecific signs: respiratory decompensation, glucose intolerance, or thrombocytopenia.[64,65] Diagnosis requires isolation of the organism from blood by growth on fungal medium overlaid with olive oil, since *Malassezia* spp. will not grow in the absence of lipids and may take up to 2 weeks to grow.[66] Removal of the intravascular catheter usually suffices for therapy, although some experts recommend the addition of amphotericin B in doses of 0.5 mg/kg/day for 7 days.

Miscellaneous Fungal Infections

Aspergillus Species

Although rarely seen in neonates, systemic infection with *Aspergillus* suggests severe immunocompromise, such as in DiGeorge syndrome or myeloperoxidase deficiency.[67,68] Invasive aspergillosis most commonly presents as pulmonary or disseminated disease in neonates, but can also present in the CNS and GI tract.[69,70] Disseminated *Aspergillus* disease has occurred in premature newborns without additional immunologic abnormalities.[71] The diagnosis of invasive aspergillosis requires isolation of the fungus from a normally sterile tissue site or visualization by Gomori-methenamine silver stain on biopsy of infected tissue. Of note, a commercially available enzyme-linked immunosorbent assay for diagnosis of aspergillosis on serum specimens had an 83% rate of false positives in premature newborns.[72] PCR assays for *Aspergillus* spp. have been developed and may aid in the diagnosis, but have low sensitivity and specificity (80% for both) and are not available at all centers.[73] Treatment requires systemic amphotericin B in doses of 1 mg/kg/day. Fungistatic therapies such as the triazoles are not recommended for aspergillosis.

Trichosporon beigelii

In a cluster of five neonatal cases of infection caused by *T. beigelii*, a yeast found ubiquitously in soil, no common source was identified.[74] Two of three premature neonates infected with this organism died. Resistance to achievable concentrations of amphotericin B complicates therapy.

Healthcare-Associated Infections

LAKSHMI SRINIVASAN

KEY POINTS

- Healthcare-associated infections (HAIs) are important preventable causes of morbidity and death in neonates.
- Central line–associated bloodstream infections cause the bulk of HAIs in the neonatal intensive care unit; other HAIs include ventilator-associated pneumonias, urinary tract infections, surgical site infections, and nosocomial viral infections.
- Several modifiable risk factors have been identified for these conditions. Preventive strategies must focus on basic hand hygiene and infection control measures, along with specific measures for the infection.
- Quality improvement collaboratives have achieved great strides in infection reduction by developing improved surveillance and benchmarking strategies and implementation of bundles of preventive measures.
- However, some high-risk infants continue to experience infections; additional customized strategies may be needed to enhance infection prevention in these high-risk patients.

Healthcare-associated infections (HAIs) are infections acquired by patients during hospitalization. For decades, HAIs were considered an unavoidable problem in the neonatal intensive care unit (NICU). Several factors converge to create a high risk of infection in the NICU patient: immature innate and adaptive immune defenses, the need for life-sustaining invasive interventions, broad-spectrum antibiotic exposure, colonization with potentially pathogenic microorganisms, and prolonged hospital stays.[1–3] The improved survival of very low birthweight (VLBW) infants and their attendant need for invasive technologies during the NICU course magnify the impact of this problem. HAIs have been shown to impact neonatal outcomes, including short-term and long-term morbidities, hospital length of stay, healthcare costs, and death significantly and independently.[4–13]

Continuous surveillance and monitoring of HAI rates and pathogens are necessary to establish reference points in each nursery and facilitate early identification of epidemics. Clinicians can prevent HAIs by consistently and reliably following best practices for infection prevention and minimizing invasive procedures to the extent possible. Quality improvement strategies, education of staff on bundles of preventive care, standardization of practice, and hospital programs such as antimicrobial stewardship are essential to preventing harm. Many centers have used these strategies to reduce the burden of HAIs with great success.[14–20] In this chapter we will review the definitions, epidemiology, and adverse outcomes related to HAIs, as well as current concepts and evidence surrounding strategies for prevention of HAIs in NICUs.

Defining Neonatal Healthcare-Associated Infection

The Centers for Disease Control and Prevention (CDC) surveillance definition states that an HAI is an illness associated with a pathogen or its toxins that is not present or incubating at the time of admission.[21] Although this definition appears straightforward, additional special considerations exist for neonates. Infections that manifest themselves early in the first week of life are typically related to perinatal risk factors and vertical transmission from the mother. HAIs occur later and are more often related to patient colonization and environmental risk factors. Although most sources define HAIs in neonates as infections occurring after 3 days of postnatal life,[2,22] there is no specific age that clearly distinguishes maternally transmitted infections from HAIs.[22] There may be substantial temporal overlap between HAIs. The CDC National Healthcare Safety Network (NHSN) currently defines HAIs in neonates as those infections initially identified on day 3 or later (or 7 days and later for group B streptococcus infections) and thus may include some infections that may have been acquired perinatally but manifest clinically beyond 3 days of life.[21] Neonatal HAI rates may be slightly overestimated during the first few weeks of life. Definitions of central line–associated bloodstream infection (CLABSI), ventilator-associated pneumonia (VAP), pediatric ventilator-associated event (pedVAE), and catheter-associated urinary tract infection (UTI) are given in Box 37.1.[23]

Diagnosing Neonatal Healthcare-Associated Infection

Diagnosis of Central Line–Associated Bloodstream Infection

Although coagulase-negative staphylococci (CoNS) are common skin commensals, they are also the most common cause of CLABSIs in the NICU. Differentiating contamination from true infections with CoNS is one of the greatest challenges surrounding neonatal CLABSI definitions. The CDC introduced a change to its definition in 2008, namely, the requirement for two blood cultures positive for skin commensals to fulfill the definition of a CLABSI.[21] However, the Vermont Oxford Network (VON), the National Institute for Child Health and Human Development (NICHD), and Children's Hospital Neonatal Consortium (CHNC) include infants with only one culture positive for CoNS

• BOX 37.1 Definitions of Healthcare-Acquired Infections for Patients Younger Than 12 Months*

Nosocomial Bloodstream Infections

Laboratory-confirmed bloodstream infection (LCBI). Must meet one of the following definitions:

- Patient has a recognized bacterial or fungal pathogen (not included on the NHSN common commensal list), identified from one or more blood specimens obtained by a culture *AND* organism(s) identified in blood is not related to an infection at another site
- Patient has at least one sign or symptom (fever >38.0°C, hypothermia <36.0°C, apnea, or bradycardia) *AND* organism(s) identified in blood is not related to an infection at another site *AND* the same NHSN common commensal is identified by a culture from two or more blood specimens collected on separate occasions. Common commensal organisms include, but are not limited to, diphtheroids (*Corynebacterium* spp. not *C. diphtheria*), *Bacillus* spp. (not *B. anthracis*), *Propionibacterium* spp., coagulase-negative staphylococci (including *S. epidermidis*), viridans group streptococci, *Aerococcus* spp., *Micrococcus* spp., and *Rhodococcus* spp.

Central Line–Associated Bloodstream Infection

- LCBI (as defined above) *AND*
- Central line or umbilical catheter in place for more than 2 days *AND*
- Central line in place on day of or day before CLABSI diagnosis

Pneumonia

- Imaging evidence: Two or more serial chest radiographs with new/progressive and persistent infiltrate, cavitation, consolidation, or pneumatoceles for patients with underlying pulmonary or cardiac disease (respiratory distress syndrome, bronchopulmonary dysplasia, pulmonary edema) *or* one chest radiograph with the aforementioned abnormalities for patients without underlying pulmonary or cardiac disease *AND*
- Worsening gas exchange *AND*
- At least three of the following: (1) temperature instability, (2) white blood cell count less than 4000/μL or greater than 15,000/μL with 10% or more bands, (3) new-onset purulent sputum, change in character of sputum, increased respiratory secretions, or increased suctioning requirements, (4) physical examination findings consistent with increased work of breathing or apnea, (5) wheezing, rales, or rhonchi, (6) cough, (7) bradycardia (<100 bpm), or tachycardia (>170 bpm)

Ventilator-Associated Pneumonia

- Pneumonia (as defined above) *AND*
- Patient on ventilator for more than 2 days *AND*
- Ventilator in place on day of or day before VAP diagnosis

Pediatric Ventilator-Associated Events

- Patient has a baseline period of stability or improvement on the ventilator, defined by ≥2 calendar days of stable or decreasing daily minimum FiO_2 or MAP values
- After a period of stability or improvement on the ventilator, the patient has at least one of the following indicators of worsening oxygenation: (1) Increase in daily minimum FiO_2 of ≥0.25 (25 points) over the daily minimum FiO_2 of the first day in the baseline period, sustained for ≥2 calendar days. (2) Increase in daily minimum MAP values of ≥4 cmH_2O over the daily minimum MAP of the first day in the baseline period, sustained for ≥2 calendar days

Urinary Tract Infection

Symptomatic Urinary Tract Infection (SUTI)

- At least one of the following symptoms: (1) fever (temperature >38.0°C), (2) hypothermia (temperature <36.0°C), (3) apnea, (4) bradycardia, (5) lethargy, (6) vomiting, or (7) suprapubic tenderness *AND*
- Urine culture with no more than two species identified, at least one of which is present at more than 10^5 CFU/mL

Asymptomatic Bacteremic Urinary Tract Infection (ABUTI)

- Urine culture with no more than two species identified, at least one of which is present at more than 10^5 CFU/mL *AND*
- Bacteria identified in blood (culture-based or nonculture-based microbiologic method) that matches at least one of the bacteria present at more than 10^5 CFU/mL in urine

Catheter–Associated Urinary Tract Infection:

- Urinary tract infection (as defined above, either SUTI or ABUTI) *AND*
- Indwelling urinary catheter for more than 2 days *AND*
- Urinary catheter in place on day of or day before urinary tract infection diagnosis

Surgical Site Infection

Superficial Incisional SSI

- Occurs within 30 days after the NHSN operative procedure *AND*
- Involves only skin and subcutaneous tissue of the incision *AND*
- At least one of: (1) purulent drainage from the superficial incision. (2) organism(s) identified from an aseptically obtained specimen from the superficial incision or subcutaneous tissue. (3) superficial incision deliberately opened and microbiologic testing of the superficial incision or subcutaneous tissue is not performed *and* at least one of: localized pain or tenderness; localized swelling; erythema; or heat. (4) diagnosis of a superficial incisional SSI by a physician or physician designee

Deep Incisional SSI

- Occurs within 30 or 90 days after the NHSN operative procedure *AND*
- Involves deep soft tissues of the incision (e.g., fascial and muscle layers) *AND*
- At least one of: (1) purulent drainage from the deep incision; (2) a deep incision that spontaneously dehisces, or is deliberately opened or aspirated *and* at least one of the following: fever (>38°C); localized pain or tenderness; (3) abscess or other evidence of infection involving the deep incision detected on gross anatomical or histopathologic exam, or imaging test.

Organ/Space SSI

- Occurs within 30 or 90 days after the NHSN operative procedure *AND*
- Involves any part of the body deeper than the fascial/muscle layers that is opened or manipulated during the operative procedure *AND*
- At least one of: (1) purulent drainage from a drain that is placed into the organ/space; (2) organism(s) identified from fluid or tissue in the organ/space by microbiologic testing; (3) abscess or other evidence of infection involving the organ/space that is detected on gross anatomic or histopathologic exam, or imaging test evidence suggestive of infection; *AND*
- Meets at least one criterion for a specific organ/space infection (e.g., osteomyelitis, myocarditis, intraabdominal infection etc. as defined by NHSN module)

*Centers for Disease Control and Prevention National Healthcare Safety Network; modified from CDC NHSN modules for LCBI, CLABSI, VAP, pedVAE SSI.

bpm, Beats per minute; *CFU*, colony-forming unit; *SSI*, surgical site infection.

in the presence of clinical signs of infection.[1] Furthermore, there is considerable clinical practice variation regarding whether single or multiple cultures (from phlebotomy and/or central line) are drawn, which could impact rates of CoNS diagnosis.[24] Refinements of CLABSI definitions (relating to the timing of infection following hospital admission, line placement, etc.) may impact the number of CLABSIs reported.[25,26]

Another area of uncertainty surrounds source attribution. For example, some CLABSIs in infants with underlying gastrointestinal (GI) conditions may result from translocation caused by

mucosal barrier injury. However, studies to date have not fully borne out this hypothesis.[27] Studies have demonstrated that International Classification of Diseases, Ninth Revision (ICD-9) coding of hospital administrative data has low concordance with NHSN definitions of CLABSI.[28,29] Although these studies were not limited to neonatal data, the findings reflect limitations of the NHSN definitions in certain situations where clinicians may diagnose secondary etiologies for the infection, but infections remain attributed to the central line per NHSN criteria.

Diagnosis of Ventilator-Associated Pneumonia

Prior to 2013, VAP definitions were used by NHSN for surveillance of ventilator-associated events (VAEs). These definitions, including the NHSN definitions, are problematic to apply in neonates because overlap of signs and symptoms and radiographic findings with underlying respiratory conditions posed significant challenges to the diagnosis of VAP.[1,30–35] Identifying a suitable source of pathogens is an additional cause of variability. Because of these challenges with defining VAP accurately in the neonatal population, in 2014 the NHSN discontinued surveillance of VAP in the NICU. However, many NICUs and collaboratives continue surveillance and internal benchmarking of this condition.

The CDC organized a working group in 2012 to consider whether the VAE surveillance approach used in adults could also be applied to neonatal and pediatric inpatient populations. Following the publication of a study on pediatric VAE, the CDC created a pedVAE definition. PedVAEs are identified by objective criteria defining deterioration in respiratory status after a period of stability or improvement on the ventilator. However, this approach has limitations because many pedVAE are not due to infectious etiologies but rather due to progression of underlying respiratory or cardiac disease.[31]

Diagnosis of Urinary Tract Infection

Clinicians often use less stringent microbiologic criteria (ranging from 100 to 10,000 colony-forming units [CFUs] of bacteria per milliliter in urine) for neonatal UTI diagnosis compared with CDC definitions.[36–38] CoNS may be isolated in urine samples, raising the question similar to bloodstream infections of whether they represent contamination or true infection.[38,39]

Healthcare-Associated Infection Surveillance and Data Sources

Sources of data on neonatal HAIs in the United States include the CDC, NHSN, VON, NICHD, NRN, and the CHNC.[1] Reporting overall incidence rates may be misleading because of wide variations in case mix and device utilization rates. In 2005, the CDC NHSN system developed monitors device-associated HAI rates by using an approach that accounts for variability in device use and length of hospital stay.[40–42] These data are also stratified by birthweight categories and expressed as incidence density per 100 or 1000 patient or device days, which facilitates risk adjustment based on birthweight and the duration of exposure to the risk factor. Another approach to surveillance is the use of the standardized infection ratio (SIR), which is a summary measure used to track HAIs at a national, state, or local level over time. The SIR is calculated by measuring observed HAIs over predicted HAIs (derived using data from a baseline period) and adjusts for facility and/or patient-level factors that contribute to HAI risk within each facility.

NHSN tracks HAIs in more than 17,000 medical facilities and shares the data with the facilities, the CDC, other partners, and quality improvement organizations to help guide efforts at infection prevention. Outside of the United States, the International Nosocomial Infection Control Consortium runs a surveillance network for HAIs, using CDC NHSN definitions, in more than 1000 hospitals around the world, and provides aggregate data on HAI from several countries.[43]

Epidemiology of Healthcare-Associated Infection

Healthcare-Associated Infection in the Newborn Nursery

Accurate rates of HAI in the "well-baby" nursery is difficult to ascertain because there is no systematic reporting or surveillance network for this location; however, the incidence appears to be low. Some researchers estimate rates of less than 1 per 100 patients discharged.[22] Typical risk factors for acquiring an HAI are uncommon in this population. Discharge from the hospital within 48 hours of birth, "baby-friendly" hospital policies, and rooming-in practices have helped to further decrease the risk of exposure in modern mother-baby units. However, early discharge may also limit surveillance efforts and documented rates of HAI, as patients may be discharged home before they become symptomatic from HAIs.[44]

HAIs in the well-baby nursery are commonly superficial, involving the skin, mouth, or eyes, and include omphalitis, pustules, abscesses, and bullous impetigo.[44] Community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) has been implicated in outbreaks of skin and soft tissue infections (SSTIs) and pneumonia in newborn nurseries.[45–49] Legionella outbreaks have been reported in term neonates, because of nosocomial contamination from water sources (water births, humidifiers).[50,51] Nursery epidemics of other bacterial enteropathogens and viral enteropathogens have been reported but occur infrequently in the United States in the current era.[44,52,53]

Healthcare-Associated Infection in the Neonatal Intensive Care Unit

Most neonatal HAIs occur in term and preterm infants hospitalized in NICUs. Comparison of surveillance data between institutions needs to be carefully performed with attention to differences in patient demographics, device utilization rates, and use of neonate-specific definitions for HAI.

Data from the NICHD NRN in 2002 demonstrated that 21% of VLBW infants who survived beyond 3 days postnatally had at least one episode of late-onset sepsis.[2] There was significant variability among participating centers, with rates ranging from 10.6% to 31.7% at individual sites.[2] In another study, 19% of VLBW infants had HAIs, with the highest rates in infants with the lowest birthweights.[54] A point prevalence survey conducted by 29 level II to level IV nurseries participating in the Pediatric Prevention Network revealed a prevalence of 11.4% for HAI.[55] Data from the NICHD NRN showed that the rates of late-onset sepsis declined from 2005 to 2012 among VLBW infants of all gestational ages: the rates for infants born at 24 weeks' gestation

declined from 54% to 40% (adjusted relative risk [RR] 0.94, 95% confidence interval [CI] 0.93 to 0.95), for infants born at 26 weeks' gestation the rates declined from 37% to 27% (adjusted RR 0.93, 95% CI 0.92 to 0.94), and for infants born at 28 weeks' gestation the rates declined from 20% to 8% (adjusted RR 0.91, 95% CI 0.90 to 0.92).[14,56]

CLABSIs constitute most HAIs in the NICU.[40,55] CLABSIs contribute to 25% to 60% of HAIs in the neonatal population.[57] The remaining cases involve the respiratory tract, eye, ear, nose, throat, GI tract, or urinary tract or may be surgical site infections (SSIs). VAPs are difficult to diagnose in the NICU but can contribute to morbidity, especially in patients with evolving lung disease.[32] Although the use of indwelling urinary catheters is low in the NICU compared with other intensive care units, UTIs in the NICU are still a problem. Surveillance data for meningitis are limited. There are widespread differences in clinical practice regarding the inclusion of a lumbar puncture with cerebrospinal fluid analysis in the evaluation for possible neonatal sepsis. Although early-onset meningitis is rare, studies suggest that late-onset meningitis may be underdiagnosed in VLBW infants.[58,59] Neonates may experience SSI, most frequently with abdominal, cardiac, or neurosurgical procedures.

Rates of device-associated infections in NICUs in the United States are presented in Table 37.1. HAI rates remained constant

TABLE 37.1 Healthcare-Associated Infection Rates in the United States and Internationally

CLABSI Rates for Level III NICUs in the United States, 2013 (CDC NHSN)

in the 1990s[40,60] but decreased in the later years of the first decade of this century, likely because of the impact of collaborative quality improvement efforts.[3,16,17,19,57,61,62] The most recent epoch has demonstrated a plateauing of CLABSI rates.[63] The impact of the COVID-19 pandemic on HAI rates in neonatal populations needs to be more thoroughly elucidated, but overall data demonstrate significant increases in the national SIRs for CLABSI, CAUTI, VAE, and MRSA bacteremia in 2020.[64]

Although catheter-associated UTIs are not very frequent in the NICU, non–catheter-associated UTIs remain a common cause of infections and need for antibiotic treatment in the NICU.[65] VAP rates also decreased from 1.6 to 0.6 per 1000 ventilator days from 2007 to 2012.[57] SSIs occur in about 5.6% of neonates who undergo surgical procedures.[66]

The International Nosocomial Infection Control Consortium published surveillance data from 2012 to 2017 from NICUs in Africa, Asia, Europe, and Latin America.[67] Rates of CLABSI and VAP were generally higher than the corresponding CDC NHSN rates in the United States (see Table 37.1).[43] Recent advances in resources, technology, and regulations in healthcare in many countries have led to reductions in infection rates, which are reflected in the reductions in NICU CLABSI and VAP rates seen in the later years of surveillance (see Table 37.1).[43]

Risk Factors for Development of Healthcare-Associated Infection

Minimizing exposure to known modifiable risk factors for infection is important to reduce the rate of HAIs in the nursery. Many HAIs previously thought to be not preventable can in fact be substantially decreased in frequency with appropriate interventions.

The risk of developing an HAI is inversely related to gestational age and birthweight.[2,40,57,68–70] Infants with birthweights less than 1000 g experience twice the rate of nosocomial bloodstream infections compared with infants with birthweights greater than 1000 g.[2,40,54,69,71] Overall, VLBW infants are more vulnerable to infection because of the immaturity of their immune response, severity of illness, and their greater need for invasive devices.[44,72]

The use of any type of invasive device increases the risk of infection. The most common invasive devices used in the nursery are intravascular catheters, mechanical ventilators, ventriculoperitoneal shunts, and urinary catheters. In general, risk rises as the duration of exposure to invasive devices lengthens. Compared with adult patients, neonates are at higher risk of CLABSI and at lower risk of VAP and UTI.[62,73] These patterns correlate with the frequency with which these invasive devices are used in the neonatal population.

Histamine-blocking agents, proton pump inhibitors, and postnatally administered corticosteroids are the medications most associated with an increased risk of HAIs among newborns.[74–76] It is hypothesized that the reduced gastric pH associated with the use of histamine-blocking agents promotes bacterial overgrowth and invasion of pathogenic bacteria.[77] With greater understanding of the adverse neurodevelopmental consequences of prolonged ventilator need and consequent bronchopulmonary dysplasia (BPD), there has been an increase in use of lower-dose steroids after the first 2 weeks postnatally, especially in infants at high risk of developing BPD.[78–83] However, steroid use has been associated with an increased risk of infection in VLBW infants,[84,85] and therefore neonatologists need to include this concern in any risk-benefit analysis of the use of steroids in their patients.

Nursery design and staffing influence the risk of infection. Overcrowding and larger workloads decrease compliance with hand washing and raise the risk of HAI.[86–91] Inadequate numbers of staff and the use of temporary or inexperienced staff members both adversely affect the rate of infection. Studies have shown a relationship between nurse-to-patient ratio and colonization of patients with MRSA and CLABSI rates.[86,91] Furthermore, strategic nursery design and improvement in nursing staffing correlate with lower rates of HAIs.[92] However, there continue to be nurse staffing challenges, as exemplified by a VON study that identified rates of understaffing and infections in NICUs across the United

States.[90] NICU design may also impact infection rates. Several NICUs are transitioning to single-patient room design to reduce infection risk among other reasons. The evidence surrounding the effectiveness of single patient rooms in reducing infection risk for neonates is mixed.[93–95] Many of these HAI risk factors hold true globally. Nosocomial infection rates are much higher in lower-income countries than middle-income and higher-income countries (see Table 37.1), likely reflecting a combination of personnel and resource limitations, overcrowding, lack of infection control regulatory and auditing mechanisms, hospital accreditation, and healthcare workers inexperienced in infection prevention standard practices.[43]

Risk Factors for Central Line–Associated Bloodstream Infection

CDC NHSN data demonstrate that VLBW infants have a twofold increased risk of developing CLABSI compared with normal-weight infants.[57] Infants with an underlying GI condition such as necrotizing enterocolitis, gastroschisis, or omphalocele may be predisposed to mucosal barrier injury and at heightened risk of CLABSI. In a multicenter cohort study in 14 NICUs, 40% of infants who developed CLABSIs had underlying GI conditions associated with loss of mucosal integrity or impaired gut motility or both.[27] However, the proportion caused by "enteric pathogens" was not different in the overall group, except for infants with intestinal failure who developed multiple CLABSIs; this latter group experienced higher rates of infections with enteric pathogens.[27] A study from the NICHD NRN also demonstrated that VLBW infants with intestinal failure were at increased risk of recurrent bloodstream infections; however, gram-positive organisms were the most frequent pathogens.[96]

Intravascular devices commonly used in the neonatal population are peripheral intravenous catheters (PIVCs), umbilical catheters, peripherally inserted central catheters (PICCs), surgically placed central venous catheters (CVCs), and percutaneous arterial catheters. Regardless of the type of device used, the rate of CLABSI appears to be related to the number of days the catheter is in place.[2,40,70,97] Table 37.2 summarizes evidence regarding several of the interventions associated with increased CLABSI risk.[98] A 2015 Cochrane review of trials comparing PICCs with PIVCs found that use of a PICC line decreases the risk of complications associated with PIVCs, without increasing the rate of infection.[99] For central lines, theoretically the risk should be lower for tunneled catheters, because the Dacron cuff proximal to the exit site of a surgically placed catheter can inhibit the migration of organisms into the catheter track.[100] Adult data suggest that tunneled catheters have lower infection rates than nontunneled catheters; however, studies of neonates with tunneled lines show rates of infection comparable with or worse than the reported rates of PICC line infections in other NICU populations.[101,102] Data regarding umbilical catheters is mixed, with some studies showing higher risk,[103] whereas others found similar or lower risk than PICC lines.[97,104–108] Studies on the relationship between catheter dwell time and CLABSI rates show conflicting findings, with some studies demonstrating no association.[97,107] However, several

TABLE 37.2 Studies Identifying Interventions With Increased Risk of Bloodstream Infections

Intervention	Adjusted Risk for Each Intervention[a]			
Mechanical ventilation	6.8 (5.9–7.8)[b]	1.7 (1.4–2.1)[g]	4.2 (1.4–12.4)[d]	
Central line	6.1 (5.0–7.4)[b]	9.3 (5.9–14.8)[h]		
Central line >7 days	6.2 (5.0–7.6)[b]	3.5 (1.3–9.2)[i]

others have suggested that increasing risk of CLABSI is associated with increased dwell time of PICC and umbilical catheters.[103,108] A large retrospective review of more than 13,000 infants found that although dwell time did not affect CLABSI risk for PICCs, it did impact CLABSI risk with tunneled catheters, with increased CLABSI risk beyond week 7 from placement.[109]

Exposure to parenteral nutrition has been shown to be associated with increased risk of bloodstream infections, which may in part be mediated by increased use of central lines for delivery of parenteral nutrition.[110,111] A meta-analysis identified parenteral nutrition and lipid infusions as independent predictors of neonatal bloodstream infections.[76] Lipid emulsions may decrease the flow rate through the intravenous (IV) catheter, potentiate growth and proliferation of some microorganisms, and interfere with host defense mechanisms by impairing the function of neutrophils and reticuloendothelial cells.[112–114] Use of lipid emulsions was independently associated with the development of CoNS bacteremia.[114] Administration of such emulsions has also been linked to a higher risk of HAI with *Candida* and *Malassezia* spp. in neonates.[115–117]

Risk Factors for Ventilator-Associated Pneumonia

CDC NHSN data indicate that VLBW infants have a 3.5-fold increased risk of VAP compared with normal-weight infants.[57] VAPs are more common in infants with underlying cardiopulmonary disease such as BPD, as well as infants who have experienced previous thoracoabdominal surgery.

Prolonged duration of mechanical ventilation is the primary risk factor for development of hospital-acquired pneumonia. Endotracheal tubes circumvent normal airway protective and clearance mechanisms and become coated with biofilms of bacteria, which have the potential to enter the lower airways and cause infections.[30] Contamination of respiratory equipment, especially with gram-negative organisms that thrive in moist environments, such as *Acinetobacter, Pseudomonas*, and *Flavobacterium* species (spp.), frequently leads to colonization of the respiratory tract.[118] Aspiration of gastric and oropharyngeal secretions around uncuffed endotracheal tubes could be a mechanism for VAP.[30,119,120] Closed-system suctioning devices may decrease the risk of environmental contamination during suctioning; however, there is a theoretical risk that they could reintroduce pathogens suctioned from the secretions from major airways into smaller lower airways. Although there is a paucity of NICU evidence on the subject, adult studies have demonstrated higher colonization rates but lower VAP rates with closed suctioning systems.[121–126] Supine positioning and dependent position of the endotracheal tube in relation to the ventilator circuit may increase the risk of VAP by increasing the risk of aspiration.[127–129] Data on nasal continuous positive airway pressure suggest that its lack of disruption of normal airway protective mechanisms compared with endotracheal tubes may be responsible for lower rates of nosocomial pneumonia; however, the association of nasal continuous positive airway pressure with greater rates of gram-negative sepsis needs further elucidation.[74,130]

Risk Factors for Urinary Tract Infection

UTIs are more prevalent in ex-preterm infants; neonatal males are at higher risk than neonatal females, as are infants with underlying renal anomalies.[39,65]

Healthcare-Associated Infection: Distribution by Pathogen

The predominant pathogens responsible for nosocomial bloodstream infections have changed over time. Goldmann[44] proposed that these trends are explained by changes in the neonatal intensive care patient population and advancing technology. *S. aureus* was the most common nosocomial pathogen in the 1950s and 1960s. By 1970, gram-negative organisms emerged as the predominant pathogens; globally, these organisms are the most important pathogens responsible for HAIs in the nursery.[131] In the United States, CoNS was the most common nosocomial pathogen in the 1990s and early years of the first decade of this century.[2,40] Among the cohort of VLBW infants born between 2002 and 2008 with late-onset infections, the NICHD reported that in singleton infants, gram-positive organisms were responsible for 77% of cases, gram-negative organisms were responsible for 16%, and fungi were responsible for 8% of cases.[132] These findings were similar to studies from the previous decade.[2,133] A study comparing pathogens causing late-onset sepsis in extremely preterm infants from two eras—2000 to 2005 and 2006 to 2011—also demonstrated that pathogens remained similar across epochs, except for a decline in fungal infections (Table 37.3).[14] However, reports from at least one center after the introduction of standardized central line insertion and maintenance bundles and checklists noted declines in CoNS as a causative pathogen.[134]

Microbial Resistance

Antimicrobial resistance is increasing across NICUs.[135,136] Drug-resistant gram-negative pathogens are associated with the highest attributable mortality rates.[137–139] Cantey and Milstone[98] identified a marked increase in the number of NICU publications associated with MRSA, vancomycin-resistant enterococcus (VRE), extended-spectrum β-lactamase (ESBL), and carbapenemase-producing bacteria (CPB) between 1993 and 2013. NHSN data show that MRSA infection rates tripled in NICUs between 1995 and 2004 and more recently demonstrate that NICU infants continue to experience a considerable proportion of infections caused by resistant pathogens.[140,141] Resistant bacteria have been implicated in more than 15% of NICU outbreaks worldwide.[135] Colonization with resistant bacteria has been associated with approximately a 33% infection risk with the same pathogen.[75,142,143] Many NICUs have adopted periodic surveillance strategies to detect resistant bacteria such as MRSA or VRE.[144]

Gram-Positive Bacteria

Coagulase-Negative Staphylococci

CoNS (e.g., *S. epidermidis, S. capitis, S. hominis, S. warneri*, and *S. haemolyticus*) are commonly thought of as skin commensals but are also the most common endemic nosocomial pathogen in neonates.[2,54,72,132,133] Most CoNS infections are bloodstream infections, with a reported incidence of 51% to 78% among VLBW infants.[2,14,68,72,132,145] CoNS are lower-virulence pathogens, with low mortality rates.[134,146] Known risk factors for CoNS infection are low birthweight, lower gestational age, use of CVCs, prolonged parenteral nutrition, use of IV lipid emulsions, postnatal administration of corticosteroids, and prolonged hospital stay.[44,54,110,114] CoNS produce a capsular polysaccharide adhesin—poly(*N*-succinyl glucosamine)—which forms a "biofilm," enhancing its ability to

CoNS, Coagulase negative staphylococci.
Data from Greenberg RG, Kandefer S, Do BT, et al. Eunice Kennedy Shriver National Institute of Child Health and Human Development Neonatal Research Network. Late-onset sepsis in extremely premature infants: 2000–2011. *Pediatr Infect Dis J.* 2017;36(8):774–779.
Data from all studies have been adjusted for gestational age.

adhere to intravascular devices.[147] Although some studies suggest that prophylactic use of vancomycin or vancomycin locks reduces the risk of CoNS catheter-related infections, this practice is not recommended because of the serious risk of encouraging antibiotic-resistant organisms, especially VRE and vancomycin-resistant *S. aureus* (VRSA).[148]

Staphylococcus aureus

S. aureus has caused epidemics of infections in well-baby nurseries and in NICUs and causes up to 10% of CLABSIs.[45–47,49,149–151] The skin, nares, and umbilicus are the most common sites of colonization. MRSA rates differ greatly between institutions but can account for 50% to 55% of staphylococcal infections.[141,149,152] MRSA colonization increases the risk of MRSA infection.[153] Consequently, when one is covering for a possible *S. aureus* infection, it is critical to select an antibiotic that is effective against methicillin-resistant strains. Attributable mortality due to *S. aureus* HAI is between 5% and 18%, with rates as high as 25% in VLBW infants, irrespective of whether the strain is methicillin resistant or not.[149,152,154] *S. aureus* HAI has been found to be associated with increased rates of adverse neurodevelopmental outcomes.[154]

Enterococcus

Enterococci *(Enterococcus faecalis, Enterococcus faecium)* are responsible for both endemic and epidemic HAIs in the NICU and are responsible for approximately 3% of NICU bloodstream infections.[2,132] Prematurity, use of CVCs, prolonged hospital stay, and prior antibiotic use are recognized risk factors for colonization with these organisms.[155] The GI tract is often the primary source of infection; however, the pathogens are typically spread via the hands of healthcare workers or through environmental contamination. The widespread use of antibiotics has led to the emergence of VRE.[156] There are published guidelines to prevent the spread of VRE, which include periodic surveillance, hand washing, isolation, barrier precautions, and cohorting of infected patients.[157,158]

Group B Streptococcus

Group B streptococcus remains an important cause of early-onset and late-onset infection in neonates, but neither has a clear role as an HAI. CDC NHSN guidelines have modified exclusion criteria such that group B streptococcus identified from blood, within the first 6 days of life, will not be reported as a CLABSI.

Gram-Negative Bacteria

Gram-negative organisms are a particularly important cause of nosocomial bloodstream infections, pneumonia, and meningitis because of the high burden and severity of disease. They are the predominant cause of infection in low- and middle-income countries.[43] *Escherichia coli* is the most common gram-negative pathogen.[132] Other gram-negative organisms responsible for HAI include *Klebsiella, Pseudomonas, Enterobacter, Acinetobacter, Serratia, Haemophilus, Citrobacter*, and *Salmonella* spp. (see Table 37.3).[132] Gram-negative infections are currently responsible for approximately 15% of infections in the NICU.[132] The GI tract is thought to serve as the reservoir for these bacteria, and prolonged antibiotic therapy may promote selection of these bacteria.[75,159] The attributable mortality is much higher for gram-negative infections than for gram-positive infections.[137–139] The occurrence of a gram-negative infection in an NICU patient has been found to be associated with a 3.5-fold higher risk of death.[2] *Pseudomonas* spp. are particularly virulent, causing death in 42% to 75% of infected neonates.[2,139,160–162]

Fungi

Fungal infections are discussed in detail in Chapter 36. Invasive fungal infection is estimated to occur in 1% to 4% of VLBW infants and up to 10% of extremely low birthweight (ELBW) infants, with the highest risk in infants weighing less than 750 g.[163–168] The rates and predominant fungal species differ considerably between centers. The smallest and most premature infants appear to be at the highest risk, particularly when they are exposed to broad-spectrum antibiotics and long courses of antibiotics. Other identified risk factors are prolonged mechanical ventilation, prolonged use of CVCs, exposure to lipid emulsions, antenatal antibiotics, and histamine H_2-receptor antagonists.[117,163,166]

Prophylactic fluconazole therapy has shown promise in reducing the rates of colonization and infection with candida, with the greatest impact seen in NICUs with high rates of candida infection.[169–176] However, a large randomized controlled trial of prophylactic fluconazole did not show reductions in mortality or the incidence of invasive fungal disease.[177] Although no study has found an increase in the incidence of fluconazole-resistant fungus, resistance remains a concern with any prophylactic strategy. Limiting prophylaxis to NICUs with high rates of invasive candidal disease and to patients at highest risk provides the greatest benefit with the least incurred risk of antifungal resistance.

Viruses

Viral organisms that commonly cause HAI in the NICU include respiratory syncytial virus (RSV), rhinovirus, metapneumovirus, influenza virus, rotavirus, and enterovirus. Isolated infections generally result from contact with infected caregivers or family members. Nursery epidemics may occur in addition to isolated individual cases. An analysis of infectious outbreaks in NICUs globally found that approximately 10% of outbreaks affecting neonates were attributed to viral causes, with the most common etiologic agents being rotavirus, RSV, enterovirus, hepatitis A virus, and adenovirus.[178] Through the COVID-19 pandemic, nosocomial transmission of SARS CoV-2 has been rarely reported in the NICU, likely due to early adoption of personal protective equipment and isolation precautions.[179] Measures to prevent and contain viral infections include standard precautions such as isolation and cohorting of affected patients, meticulous hand hygiene and use of personal protective equipment, and surveillance of patients and healthcare personnel during outbreaks. Alarmingly, mortality rates for viral outbreaks appear to be similar to those for bacterial outbreaks (7.2% vs. 6.4%).[178]

Respiratory Syncytial Virus

RSV is a fastidious organism capable of surviving on inanimate objects for prolonged periods and which can cause severe disease in neonates, particularly those who are premature or who have cardiopulmonary disease. Rapid testing to detect RSV in nasal washings facilitates efforts to cohort infected patients.[180] Guidelines from the American Academy of Pediatrics (AAP) recommend that all high-risk infants born at less than 29 weeks' gestation, or with chronic lung disease, or with hemodynamically significant congenital heart disease receive up to five doses of palivizumab (an RSV monoclonal antibody) during the RSV season but starting only at hospital discharge.[181] Although current guidelines do not list prophylactic palivizumab for prevention of nosocomial transmission of RSV, some centers choose to provide RSV prophylaxis to at-risk inpatient neonates because of sporadic occurrences of inpatient nosocomial deaths from RSV.[182–186]

Influenza

Influenza is spread primarily via airborne transmission. Hand washing and immunization of healthcare workers are the primary tools to prevent nosocomial spread.[187] Some institutions mandate yearly immunization among healthcare workers. Infection control guidelines recommend that every healthcare worker wear a mask during contact with infected patients.[187] At-risk infants should receive the influenza vaccine during the winter months once they reach the age of 6 months.[188] Parents and other close contacts of at-risk infants should also receive influenza vaccination. Oseltamivir is approved by the US Food and Drug Administration (FDA) for treatment (within the first 48 hours of symptoms) of patients older than 2 weeks infected with influenza A virus or influenza B virus; the AAP and CDC recommend its use for treatment of infected infants of any age.[188] Although safety and efficacy of oseltamivir prophylaxis have not been established in infants younger than 1 year, the CDC recommends its use for this purpose from 3 months of age onward.[188] Guidelines for minimizing risk to infants born to mothers who are actively infected have been provided by the CDC.[189] Pregnant women should receive treatment as soon as possible.[189] If tolerated, the mother should wear a mask during labor and delivery. After delivery, the newborn should be cared for away from the mother until she has received treatment for 48 hours, has become afebrile, and is able to control cough and secretions.[188] If desired, lactation should be facilitated, because the breast milk itself is not thought to be a means of viral transmission.[189]

Rotavirus

Although rare, epidemics of rotavirus diarrhea may occur in the nursery[190–193]; they are primarily caused by inadequate hand washing and cross-contamination between patients.[194] Standard and contact precautions should be followed throughout the duration of the illness. Some patients have prolonged fecal shedding of low concentrations of the virus; therefore some infection control experts recommend contact precautions for the duration of the hospitalization of such patients. Rotavirus is also an important cause of diarrhea in older infants. Live virus vaccines are now available for the prevention of rotavirus infection. Although the 2009 AAP statement recommended administration of the first dose of rotavirus vaccine at discharge from the NICU, several studies have documented the safety of pentavalent rotavirus vaccine administration during the hospital stay of preterm infants, with no concern for significant adverse events or symptomatic transmission from shedding.[195–198] Furthermore, one study noted that delaying administration of the first dose until discharge led to more than half of ELBW infants not receiving the rotavirus vaccine because they missed the window of postnatal age for vaccine administration.[199]

Enterovirus

There are numerous serotypes of enteroviruses, including polioviruses, Coxsackie viruses A and B, echovirus, and nonassigned subtypes.[200] Enterovirus infections have been described among neonates in the well-baby nursery and the NICU setting.[200–204] Both isolated cases and epidemics can occur. The clinical presentation associated with enteroviral infection is variable, ranging from asymptomatic to overwhelming multisystem organ dysfunction with poor prognosis.[201,204–207] The severity of the disease and risk of mortality are higher in perinatally acquired infections than nosocomially acquired cases, presumably related to the lack of maternal antibody present in the neonate.[201,208] Blood and cerebrospinal

fluid cultures should be obtained from any patient with clinical symptoms of disease. Polymerase chain reaction analysis is helpful in making a rapid diagnosis.[209,210] No antiviral agents are currently available to treat enteroviral infections in newborns.[209] Although commercially available intravenous immunoglobulin (IVIG) preparations have high levels of neutralizing antibodies to common enterovirus serotypes, there is no clear evidence that administration of immunoglobulin alters the process or outcome of enteroviral infection.[206,207,210,211]

Prevention of Healthcare-Associated Infection

Quality Improvement Efforts

In recent years, many NICUs and quality improvement collaboratives have described their success in decreasing the rate of CLABSI and other HAIs in the NICU.[16–20,46,212] Several guiding principles and common themes are present in these success stories. Monitoring, surveillance, and benchmarking of the HAI rates in the nursery are critical components of any prevention program. A key and powerful initial step is comparing institutional performance (or "benchmarking") to improve understanding of the performance of a NICU in comparison with peer institutions and to recognize opportunities for improvement.[213] Next, formation of "quality improvement collaboratives" helps institutions develop common sets of best practices and common definitions and attempts to minimize interhospital variation in outcomes, allowing lower-performing hospitals to learn from hospitals with lower rates of infections. Several statewide and other collaboratives have reported reductions in CLABSI rates with use of this strategy.[16–20,46,212,214,215] These significant successes have been accomplished with the development and implementation of care "bundles," incorporating a group of interventions aimed at standardizing care to minimize HAIs, education of staff on quality improvement principles, and developing a shared mental model of the preventable nature of most HAIs.

Overall Approach to Infection Control

The CDC recommends a tiered approach to infection control (Box 37.2). Standard precautions should be used with all patient contact, regardless of the underlying diagnosis or infectious status. These precautions consist of universal precautions (designed to prevent blood and body fluid contamination) and body substance precautions (designed to prevent contamination with moist substances). Transmission-based precautions are necessary when a patient is infected with a known or suspected pathogen that is associated with a high risk of contamination via airborne or droplet transmission or contact with the skin or contaminated surfaces.[216]

Guidelines for Hand Hygiene Practices

The importance of hand hygiene has been known since the 1800s, as elucidated by Labarraque and Semmelweiss.[217] Although optimal hand hygiene is the cornerstone of HAI reduction efforts, healthcare settings continue to face challenges in standardizing practices among caregivers.[218,219] Hand hygiene techniques are effective in decreasing the colonization rate of resident and transient flora and have been shown to reduce cross-contamination among patients. Direct patient contact and respiratory tract care seem to be particularly associated with contamination.[220] Organisms such as RSV, *S. aureus*, and gram-negative bacilli can survive on inanimate objects ("fomites"), so holding an infant infected with one of these organisms, changing diapers, and even touching items in the infant's environment can result in hand contamination.[44,217]

Recommendations on indications and techniques for hand hygiene were published by the CDC in 2002 and updated by the World Health Organization (WHO) in 2009 (Box 37.3).[221] These guidelines will be effective only if every healthcare provider performs hand hygiene before and after every patient contact. Reported barriers to compliance with hand hygiene recommendations include skin irritation, poor accessibility of sinks or cleansing agents, insufficient time, heavy workload, understaffing, and lack of information. Alcohol-based hand rub may increase compliance by increasing ease of accessibility.[222] Direct observation is the best method of measuring hand hygiene compliance. A common misconception is that use of gloves obviates the need for adequate hand hygiene. Leakage and contamination of gloves have been reported.[217,218] Disposable single-use gloves should be removed after each patient encounter, and hands should be washed before and after their use. The WHO has a number of excellent, publicly available educational resources to encourage appropriate hand hygiene in healthcare settings, including hand hygiene videos in many languages and tools for implementation of hand hygiene training and auditing programs.

Hand hygiene is extremely cost-effective. The additional hospital charges associated with a single HAI may almost equal the yearly hand hygiene budget. One study estimated the cost of a hand hygiene intervention program to be approximately $57,000 per year.[223] Assuming that 25% of the observed decrease in infections was attributable to improved hand hygiene practices, a saving of $2100 was estimated for every infection averted.

• BOX 37.2 Principles for the Prevention of Healthcare-Acquired Infection in the Neonatal Intensive Care Unit

Observe recommendations for standard precautions with all patient contact
Observe recommendations for transmission-based precautions (gowns, gloves, masks, isolation, as indicated)
Use good nursery design and engineering
Ensure appropriate cleaning and disinfection of environment of care
Appropriate nurse-to-patient ratio
Avoidance of overcrowding and excessive workload
Improve hand hygiene compliance (see Box 37.3)
Provide meticulous skin care
Encourage early and appropriate advancement of enteral feedings
Adopt care bundles targeted to prevention of each healthcare-associated infections (HAIs)
Targeted efforts may be required during outbreaks and to prevent HAIs in high-risk patients
Perform continuous monitoring and surveillance of healthcare-acquired infection rates in the neonatal intensive care unit
Provide education and feedback to nursery personnel

• BOX 37.3 Centers for Disease Control and Prevention Recommendations for Hand Hygiene

Healthcare personnel should use an alcohol-based hand rub or wash with soap and water for the following clinical indications:

- Immediately before touching a patient
- Before performing an aseptic task (e.g., placing an indwelling device) or handling invasive medical devices
- Before moving from work on a soiled body site to a clean body site on the same patient
- After touching a patient or the patient's immediate environment
- After contact with blood, body fluids, or contaminated surfaces
- Immediately after glove removal

Healthcare facilities should:

- Require healthcare personnel to perform hand hygiene in accordance with Centers for Disease Control and Prevention (CDC) recommendations
- Ensure that healthcare personnel perform hand hygiene with soap and water when hands are visibly soiled
- Ensure that supplies necessary for adherence to hand hygiene are readily accessible in all areas where patient care is being delivered

Unless hands are visibly soiled, an alcohol-based hand rub is preferred over soap and water in most clinical situations due to evidence of better compliance compared with soap and water. Hand rubs are generally less irritating to hands and, in the absence of a sink, are an effective method of cleaning hands.

Selection and handling of hand hygiene agents:

- Provide products with a low irritancy potential.
- Solicit input regarding skin tolerance, feel, and fragrance of products being considered.
- Determine known interaction between products used to clean hands, skin care products, and the types of gloves used in the institution.
- Ensure that dispensers are accessible at the point of care.
- Provide alternatives for individuals with adverse reactions to standard products.
- When alcohol-based hand rub is available in the healthcare facility, use of antimicrobial soap is not recommended.
- Soap and alcohol-based hand rub should not be used concomitantly.

Use of gloves

- The use of gloves does not replace the need for hand hygiene.
- Wear gloves when it can be reasonably anticipated that contact with blood or other potentially infectious materials, mucous membranes, or nonintact skin will occur.
- Remove gloves after caring for a patient; do not reuse them with other patients.
- Change or remove gloves during patient care if moving from a contaminated body site to either another body site within the same patient or the environment.

Other aspects

- Do not wear artificial fingernails or extenders; keep natural nails short.
- Hand hygiene promotion programs:
  - Focus specifically on factors with significant influence on behavior and not only on the type of hand hygiene product. The strategy should be multifaceted and multimodal and include education and senior executive support for implementation.
  - Educate staff about the types of patient-care activities that result in hand contamination and about the advantages and disadvantages of various methods used to clean their hands.
  - Monitor adherence to hand hygiene practices, and provide performance feedback.
  - Encourage partnerships between patients, their families, and healthcare workers.

Modified from Polin RA, Denson S, Brady MT, et al. Strategies for prevention of health care-associated infections in the NICU. *Pediatrics*. 2012;129:e1085–e1093; CDC guidance for hand hygiene (https://www.cdc.gov/handhygiene/providers/guideline.html).

Guidelines for Gloves and Gowns

Although gowning by healthcare workers is still a common practice in many countries, a meta-analysis of studies of gowning in newborn nurseries revealed that gowning by healthcare workers did not reduce rates of colonization, rates of infection, length of stay, or mortality in infants.[224] Moreover, an observational study noted that when increasing numbers of patients were placed under contact precautions, necessitating gowning and gloving, gowning actually led to a decrease in compliance with precautions.[225] However, some studies have shown that use of nonsterile gloves along with correct hand hygiene practices could reduce bloodstream infections in preterm infants compared with hand hygiene alone.[226,227]

Care of the Patient Environment

NICU design may have an impact on risk of nosocomial transmission, with emerging evidence regarding the benefits of single-occupancy rooms.[95,228,229] Airflow, ventilation, plumbing, building structure, and presence of isolation rooms are all important components of maintaining a safe environment of care. Protocols for daily cleaning of surfaces and patient equipment and periodic "deep" cleaning and disinfection are important to reduce bioburden in the immediate patient surroundings.[230] NICU visitation policies must be carefully designed based on risk of viral transmission, use of visitor screening policies, hand hygiene education to families, considerations around sibling visitation, and encouragement of influenza vaccination.[230]

Human Milk Feedings

Several studies have reported lower risks of sepsis and necrotizing enterocolitis with early enteral feeding with human milk.[231] The various mechanisms proposed for the beneficial effect of human milk feeding include its content of immunoprotective substances and prebiotics and probiotics that modulate the development of a protective infant gut microbiome.[232] Donor human milk is increasingly used as a substitute when mother's own milk is unavailable; however, the pasteurization process likely diminishes the activity of many of these immunomodulating components.[233] A Cochrane review comparing donor human milk to formula demonstrated moderate certainty evidence of lower rates of necrotizing enterocolitis (NEC) with donor breast milk but no impact on growth, neurodevelopment, or mortality.[234]

Skin Care

The skin of VLBW preterm infants is immature and an ineffective barrier to prevent transepidermal loss of water and invasion of bacteria. The stratum corneum has mechanical and chemical properties that decrease the risk of infection[235] and matures at approximately 32 weeks' gestation. In a prematurely born neonate, the maturation process is accelerated and is usually complete by 2 to 4 weeks after birth.[235] The most recent Cochrane meta-analysis found that studies of topical emollients or creams did not impact rates of invasive infections in high-income countries[236]; however, studies of topical vegetable oil emollients in low- and middle-income countries suggested a reduction in infections but no impact on mortality, with low certainty of evidence.

Topical antiseptics and bathing agents must be chosen with attention to gestational age and skin integrity.[237] Povidone-iodine

is commonly used for skin preparation prior to procedures such as umbilical line placement and lumbar punctures. For many other procedures, providers may choose between povidone and chlorhexidine for skin preparation.[238] Chlorhexidine is also widely used for daily bathing for CLABSI prevention, with some evidence of efficacy, and is also used as part of *S. aureus* decolonization efforts.[239–241] However, the FDA recommends use with care in infants younger than 2 months and premature infants due to concerns with systemic absorption. Chlorhexidine can cause irritant skin reactions and burns, especially when alcohol-based formulations are used on fragile or preterm skin.[242] There remains a lack of clear consensus across NICUs on adoption of chlorhexidine bathing and inclusion criteria for use, but its use should be considered when infection rates remain high despite high compliance with other infection prevention measures.[241,243] For preterm infants, serial bathing to decrease bacterial bioburden may be accomplished using soap and water alternatives.[237,243]

Surveillance for Resistant Pathogens and Control Measures

Units can use specific strategies to identify resistant pathogens such as MRSA and VRE and develop targeted control measures. Strategies include use of PPE, and contact isolation to limit horizontal transmission in the NICU, along with emphasis on diligent hand hygiene for family and healthcare personnel. Teams may consider routine active surveillance for MRSA, for example, to inform infection control measures and clinical management decisions. In an outbreak setting, additional active surveillance measures may be employed, along with strategies such as contact isolation and targeted decolonization when applicable.[244]

Additional Strategies in Limited Resource Settings

Use of topical antiseptics such as chlorhexidine for cord care, kangaroo mother care (skin-to-skin care), and topical emollient massage are interventions that have demonstrated some lowering of risk of sepsis and mortality in lower- and middle-income countries and could be additional considerations in these settings (Cleminson and McGuire, 2021).[230]

Prevention of Central Line–Associated Bloodstream Infection

The care and maintenance of CVCs are key to reducing CLABSIs. Most institutions currently adopt a "care bundle" of practices surrounding central line insertion and maintenance that have been shown to be effective at reducing CLABSI rates (Box 37.4).[16,18–20,46,212,213,215,245] The key elements during catheter insertion are hand hygiene, aseptic technique, skin antisepsis, and sterile dressing technique. Best practices during catheter maintenance include hand hygiene, daily review of line necessity, daily inspection of the insertion site and dressing, standardization of practices around IV tubing changes, and "scrubbing the hub (needleless connector)" of the central line to minimize contamination (see Box 37.4). In addition, NICUs have incorporated bathing strategies in patients with central lines as described earlier. Compliance with the maintenance bundle is of great importance, as NICU patients often have extended need of central lines, and most CLABSIs in NICU patients occur several days to weeks beyond insertion.[108]

Several NICUs have adopted practices targeting early removal of central lines, when infants advancing on enteral feedings demonstrate tolerance of 70% to 80% of goal volume feeds. Studies from a multicenter collaborative of Children's Hospital NICUs combined orchestrated testing with quality improvement efforts, to pinpoint individual bundle interventions that were likely to have the greatest impact on CLABSI reduction.[214] Standardized changes of IV tubing and practices around scrubbing the hub were found to be associated with the greatest benefit.[214] This is likely because contamination of the catheter hub is the most likely source of infection for neonates, and these practices directly address this risk. Specific guidelines around use of umbilical catheters have also been developed, emphasizing timely removal—not later than 14 days from placement for umbilical venous catheters and ideally not later than 5 days for umbilical arterial catheters.[219,246]

Vascular access teams of trained personnel have also been deployed in NICUs in recent years, composed of skilled personnel who ensure standardized line insertion and maintenance practices, and support education of staff and quality improvement initiatives; studies have demonstrated reduction in CLABSIs following deployment of these teams.[247,248]

A meta-analysis comparing skin antiseptic agents found that use of chlorhexidine gluconate for catheter site care reduced the risk of CLABSI by 50% compared with use of solutions containing povidone-iodine.[249] A randomized trial in VLBW infants showed that while chlorhexidine gluconate–containing dressings reduced colonization of central venous lines (compared with povidone-iodine), CLABSI rates were comparable with the two modes of catheter site care; of note, chlorhexidine was associated with high contact dermatitis rates in the most immature infants.[250]

There are some data describing the use of prophylactic vancomycin and antibiotic lock therapy with vancomycin in neonates, suggesting a reduction in CoNS bloodstream infection; however, these studies did not demonstrate reductions in length of stay or mortality. Given the concerns for potential development of antibiotic resistance with widespread use of prophylactic antibiotics, these practices are not recommended.[251–253] A similar concern regarding the possibility of fluconazole-resistant fungal infections, fluconazole-related toxicity, and lack of evidence regarding mortality or long-term morbidity reduction has limited the recommendation for prophylactic fluconazole to high-risk units, despite evidence of fungal CLABSI reduction with prophylactic fluconazole from randomized trials.[254]

Recent data suggest a plateauing of CLABSI rates despite continued use of CLABSI prevention bundles.[63] Future approaches may include additional customized interventions for high-risk subgroups, as well as strategies to more broadly decrease rates of bacteremia.[63,255]

Catheter Removal Following Central Line–Associated Bloodstream Infection

A retrospective review compared outcomes in patients in whom catheters were removed at the onset of infection with those in whom catheters were left in place.[256] Forty-six percent of infants in whom in-place catheter sterilization was attempted had complications, compared with 8% of infants whose catheters were removed. Infants with gram-negative infections were more likely to have complications if catheters remained in place.[256] A study of infants with CoNS CLABSIs found no difference in complications or mortality rate if catheter removal was delayed[160]; however,

• BOX 37.4 Central Line Insertion and Maintenance Bundle Elements

Components of Central Line Insertion Bundle

Component	Supporting Recommendations From 2011 CDC Prevention Guidelines
Utilize dedicated and trained personnel for central line insertion	• Designate only trained personnel who demonstrate competence for the insertion and maintenance of central lines. (Category IA) • Educate healthcare personnel regarding the indications for central line insertion, proper procedures for insertion and maintenance, and appropriate infection control methods. (Category IA) • Periodically assess knowledge and adherence to guidelines for all personnel involved in central line insertion and maintenance. (Category IA)
Perform appropriate hand hygiene	• Wash hands with conventional soap and water or with alcohol-based hand rubs before and after palpating catheter insertion sites, inserting, replacing, or dressing an intravascular catheter. (Category IB)
Utilize maximum sterile barrier precautions	• Sterile gloves should be worn for the insertion of central catheters. (Category IA) • Use maximal sterile barrier precautions, including a cap, mask, sterile gown, sterile gloves, and sterile full-body drape, for central line insertion. (Category IA)
Prepare skin with an appropriate antiseptic agent	• No recommendation can be made for the safety or efficacy of chlorhexidine in infants aged <2 months. (Unresolved issue) • Cutaneous antisepsis with a >0.5% chlorhexidine preparation with alcohol is recommended in most patient populations before central line insertion and dressing changes, but if there is a contraindication, tincture of iodine, an iodophor, or 70% alcohol can be used as alternatives. (Category IA) • Antiseptics should be allowed to dry according to the manufacturer's recommendation prior to placing the catheter. (Category IB)

Components of Central Line Maintenance Bundle

Component	Supporting Recommendations From 2011 CDC Prevention Guidelines
Assess and document daily whether or not central line placement or continued use is necessary: a. "Do we really need to place a central line?" b. "If there was no line in place today, would we place one?"	• Use a peripherally inserted central catheter instead of a short peripheral catheter when the duration of IV therapy will likely exceed 6 days. (Category II) • Promptly remove any intravascular catheter that is no longer essential. (Category IA)
Perform appropriate hand hygiene	• Wash hands with conventional soap and water or with alcohol-based hand rubs before and after palpating catheter insertion sites or dressing an intravascular catheter. (Category IB)
Assess central line dressing integrity and catheter insertion site daily (at minimum)	• Replace catheter dressing if damp, loosened, or visibly soiled. (Category IB) • Evaluate the catheter insertion site daily by palpation through dressing to discern tenderness and by inspection if dressing is transparent. If patient has local tenderness or other signs of possible CLABSI, opaque dressings should be removed and site inspected visually. (Category II)
Perform appropriate central line dressing change, when required: a. Two-person procedure b. Site cleansed with appropriate solution c. Cleansing solution allowed to air-dry completely	• Replace dressings on short-term central line sites at least every 7 days for transparent dressings, except in pediatric patients in which the risk for dislodging the catheter may outweigh the benefit of changing the dressing. (Category IB) • Antiseptics should be allowed to dry according to the manufacturer's recommendation. (Category IB)
Develop and use standardized intravenous tubing setup and changes	• In patients not receiving blood, blood products or fat emulsions, replace continuously used administration sets, including secondary sets and add-on devices, at no more than 96-h intervals, but at least every 7 days. (Category IA) • Replace tubing used to administer blood, blood products, or fat emulsions (those combined with amino acids and glucose in a 3-in-1 admixture or infused separately) within 24 h of initiating the infusion. (Category IB)
Maintain aseptic technique when changing IV tubing setup and changes	• Minimize contamination risk by scrubbing the access port with an appropriate antiseptic (chlorhexidine, povidone-iodine, an iodophor, or 70% alcohol) and accessing the port only with sterile devices. (Category IA)

Category IA: strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies. Category IB: strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale; or an accepted practice (e.g., aseptic technique) supported by limited evidence. Category IC: required by state or federal regulations, rules, or standards. Category II: suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale. Unresolved issue: represents an unresolved issue for which evidence is insufficient or no consensus regarding efficacy exists.

CDC, Centers for Disease Control and Prevention; *CLABSI*, central line–associated blood stream infection.

Data from Mobley RE, Bizzarro MJ. Central line-associated bloodstream infections in the NICU: Successes and controversies in the quest for zero. *Semin Perinatol.* 2017;41(3):166–174.

these patients were more likely to have persistently positive culture results when their lines were not removed with the first positive culture result (43% vs. 13% for immediate catheter removal). Patients with CLABSIs due to gram-negative or fungal pathogens should have their catheters removed as early as possible; patients with CLABSIs caused by CoNS should undergo catheter removal if the culture results are persistently positive or if the patient's condition is unstable.[160,256]

Prevention of Healthcare-Associated Pneumonia

Like CLABSI prevention efforts, best practice bundles for VAP prevention have been adopted in many hospitals. The key elements of VAP prevention as recommended by the CDC include surveillance for VAP (which does not include routine cultures), prevention of bacterial transmission, staff education, and risk reduction in the patient.[122,219] Key practices that may help reduce the risk of VAP include timely removal of tracheal tubes from patients, minimizing aspiration of pathogenic bacteria by elevating the head of the bed by 30 to 45 degrees, and performing oral hygiene with sterile water.[122] There is no clear evidence of the superiority of closed versus open suctioning systems in minimizing VAP risk.[122,123,126] Other important considerations include use of hand hygiene and gloves prior to management of ventilation equipment, developing standard practices for suctioning while minimizing contamination, and optimizing noninvasive ventilation strategies whenever feasible.[257]

Antibiotic and Adjunctive Therapies

Antibiotic choice should initially cover a broad spectrum of pathogens and should then be narrowed as soon as possible to cover the specific bacteria identified once sensitivities are known. Antibiotic use should be discontinued if infection is not proved and is not likely. Coverage for *Pseudomonas* spp. or other resistant gram-negative organisms should be considered in patients with rapid clinical deterioration.[2,160] However, empiric broad-spectrum antibiotic use should be limited as much as possible to avoid development of resistant infections.[258]

A recent meta-analysis on the prophylactic use of IVIG in preterm neonates included data on immunoglobulin M–enriched IVIG and found no reduction in mortality or adverse neurodevelopmental outcomes.[259] IVIG is therefore not recommended for routine use in suspected or proven sepsis.[259] Hemopoietic colony-stimulating factors (granulocyte and granulocyte-macrophage) are effective in raising the neutrophil count but have not consistently decreased HAI rates or mortality.[260,261]

The most recent meta-analysis of randomized controlled trials of enteral lactoferrin for prevention of sepsis and necrotizing enterocolitis provides low-certainty evidence of decrease in late-onset sepsis.[262] The meta-analysis also provides low-certainty evidence that lactoferrin supplementation in combination with probiotics decreases late-onset sepsis and NEC; however, there were few studies and concerns about methodological quality.[262]

Probiotic use has increased in NICUs over the past few years, with up to 10% of extremely preterm infants receiving some formulation, despite lack of FDA-approved options.[263] Meta-analyses of studies of probiotics are challenging to assimilate due to heterogeneity in studies; however, there does appear to be a benefit in reducing risk of NEC.[264–266] Conflicting results even between RCTs may in part be due to variability in probiotic composition, dosing, and target populations between studies.[267,268] The AAP, Canadian Pediatric Society, and ESPGHAN have issued statements advocating for caution regarding routine use of probiotics in preterm infants. The Committee on Fetus and Newborns states that current evidence does not support the routine, universal administration of probiotics to preterm infants, particularly those with a birthweight of less than 1000 g.[256,269]

Adverse Outcomes Related to Healthcare-Associated Infection

HAIs are a potentially modifiable contributor to a spectrum of adverse outcomes, across all gestational and postnatal ages, but especially in the most immature infants (Table 37.4). Studies from the NICHD NRN have demonstrated a striking increase in mortality in VLBW infants who experience late-onset infection (18% in infected infants vs. 7% in uninfected infants), with higher mortality rates for gram-negative or fungal sepsis.[2] Several studies have found the length of stay to increase because of sepsis: NICHD NRN data indicated that the mean length of stay increased from 60 to 79 days in VLBW infants, while the VON group found an increase in the length of stay of 4 to 7 days.[2,6,270] In the subset of infants with intestinal failure due to necrotizing enterocolitis, hospital length of stay and the duration of parenteral nutrition were greatly increased by the occurrence of infections.[96] A study of VAP in pediatric intensive care units and NICU populations noted an increased duration of mechanical ventilation (by 3 days).[271]

TABLE 37.4 Adverse Outcomes Associated With Bloodstream Infections in Very Low Birth Weight Infants in the Neonatal Intensive Care Unit

Adverse Outcome	Study	Adjusted Effect
Death	Stoll et al.[63]	2.4-fold increase (17% vs. 7%)
	Stoll et al.[2]	2.6-fold increase (18% vs. 7%)
	Makhoul et al.[94]	2.0-fold increase (17% vs. 9%)
Poor neurodevelopmental outcome	De Haan et al.[12]	OR 4.8 (1.5–15.9) (gram-negative BSI)*
	Mitha et al.[4]	OR 2.2 (1.5–3.1)†
	Schlapbach et al.[8]	OR 3.2 (1.2–8.5)†
	Stoll et al.[10]	OR 1.4 (1.3–2.2)*
Increased length of stay	Stoll et al.[63]	19–22-day mean increase
	Stoll et al.[2]	18.6-day mean increase
	Makhoul et al.[94]	27-day mean increase
	Atif[257]	9.2-day mean increase
Increased cost	Payne et al.[6]	$54,539 mean increase
	Donovan et al.[13]	$16,800 mean increase

*Bayley-II motor or cognitive score less than 85, blindness, deafness, or cerebral palsy.
†Cerebral palsy.
BSI, Bloodstream infection; *OR*, odds ratio.
Data from Cantey JB, Milstone AM. Bloodstream infections: epidemiology and resistance. *Clin Perinatol*. 2015;42:1–16.

There is also strong evidence that infections in VLBW infants are associated with an increased risk of adverse neurodevelopmental outcomes. Studies of ELBW infants have found that infants who experienced infection had impaired head growth, increased risk of cerebral palsy, lower Bayley mental and psychomotor development indices, and visual deficits.[5,7,10] An analysis by the NICHD NRN of trends from 2005 to 2012 noted a decrease in infections across all VLBW gestational ages in this time period, while also noting slight improvements in survival without major morbidity in infants born at 25 to 28 weeks' gestation; the authors suggest that at least some of this improvement may plausibly be related to the reduction in infection rates over the same period.[56]

Evidence regarding the adverse effects of excess antibiotic exposure continues to mount. Development of antibiotic resistance is a well-known concern, potentially facilitating the emergence and spread of resistant nosocomial pathogens within the NICU.[136,142,272–275] Several investigations into the impact of gut microbial alterations in early life have demonstrated associations between early antibiotic exposure, gut microbial dysbiosis, and the occurrence of GI dysfunction, necrotizing enterocolitis, sepsis, long-term immune dysregulation and GI disorders, and increased mortality.[276–279]

HAIs are also associated with significantly increased use of healthcare resources and healthcare costs.[6,280–282] One meta-analysis of the costs of HAIs in the United States estimated costs attributable to CLABSIs at $45,814 (95% CI $30,919 to $65,245), to VAP at $40,144 (95% CI $36,286 to $44,220), to SSIs at $20,785 (95% CI $18,902 to $22,667), and to catheter-associated UTIs at $896 (95% CI $603 to $1189).[282] A retrospective study of HAIs in NICUs calculated an incremental cost of $16,800 attributable to bloodstream infections,[13] whereas another study in VLBW infants found a more modest cost increase but still amounting to thousands of dollars ($1280 to $5875 per infection).[6] Attributable costs in a study of pediatric and neonatal VAP were estimated at $30,000.[271]

Decreasing HAI rates in the NICU can reduce the risk of adverse events in infants during their hospital stay, thereby decreasing the incidence of short-term and long-term adverse outcomes, length of stay, and direct healthcare costs. HAIs have therefore become a very important focus of quality improvement efforts in NICUs across the United States and the world.

Conclusion

Prevention of HAI is a cornerstone of excellence in NICU care. Although it is encouraging that HAIs in NICUs have greatly decreased over time, rates have plateaued in the past decade. CLABSIs and other HAIs continue to cause significant morbidity and death in the most vulnerable NICU patients in many countries of the world, as well as contribute to antibiotic use and development of antimicrobial resistance. Considerable work remains to be done in the United States and across the world to move closer to eliminating hospital acquired infections. Collaborative quality improvement approaches, ensuring adequate staffing of nurseries, and emphasizing "bundles" of good practices are key to accomplishing these goals. Clinicians must continue to focus on effective prevention strategies, including adherence to strict hand hygiene policies, minimal use of invasive devices, promotion of enteral nutrition especially breastmilk, surveillance of infection patterns, and education of all nursery staff members. Additional specialized prevention strategies may need to be considered in certain high-risk populations to maximize effective prevention.

38 Lung Development

ERIN PLOSA AND JENNIFER SUCRE

KEY POINTS

- Lung organogenesis is organized into five stages, beginning at embryonic day 25 in humans.
- The mechanisms of lung organogenesis, including branching morphogenesis, stretch/mechanotransduction, alveolarization, microvascular maturation, and cellular differentiation, depend on transcriptional regulation of cell–cell and cell–extracellular matrix signaling networks.
- Alveolarization and lung growth are primarily postnatal processes that extend to early adulthood to establish a surface area that matches growing metabolic needs.
- Disruption in the lung developmental program results in congenital lung malformations.
- The transition from intrauterine to extrauterine life requires the maturation of the surfactant system and the development of lung defense systems against infection and environmental injury.

The primary function of the lung is to exchange oxygen for carbon dioxide to meet the demands of aerobic cellular respiration. The oxygen consumption of the adult human ranges from 250 mL/min at rest to 2630 mL/min at peak exercise.[1] To accommodate these metabolic needs, a large surface area and a thin alveolocapillary membrane are required to enable efficient diffusion of oxygen, more so than carbon dioxide. Ultimately, the zone of gas exchange will attain a surface area of 50 to 100 m^2 and a volume of 2.5 to 3.0 L in the adult human. Therefore, the lung must develop in such a way to maximize the alveolar surface area to meet these needs. While a substantially large surface area is critical for oxygen uptake, the diffusion distance from the alveolus to the red blood cell must be relatively short to facilitate release of carbon dioxide. Meanwhile, a protective aqueous barrier protects the delicate alveolar epithelium, working in tandem with surfactant to mitigate surface tension and alveolar collapse. The result of normal lung development is a thin, expansive alveolar epithelial surface area intermingled with a well-approximated capillary network that facilitates the exchange of oxygen and carbon dioxide.

The trachea, airways, and alveoli are in constant contact with the external environment. Every inhalation brings large numbers of microorganisms, as well as potentially toxic particles and gases, into direct contact with epithelial surfaces. Lung organogenesis must also incorporate mechanisms for clearance of microorganisms and allergens that may result in epithelial infection or injury. Similarly, the lung must defend against nonparticulate gases that are potentially harmful. Oxygen, so critical to cellular function, can be the source of harmful reactive oxygen species that require detoxification, as do inhaled pollutants. The appropriate development and maintenance of these lung functions are critical to the health and survival of newborns.

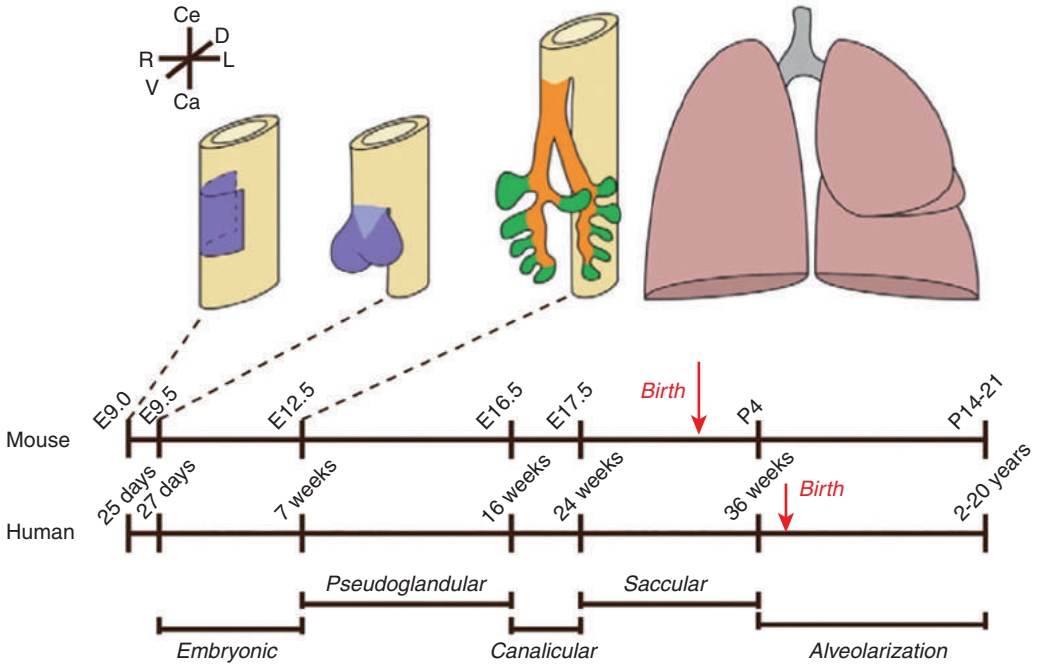
Key Events in Lung Development

Lung organogenesis begins early in human gestation (by day 25), and growth extends well into early adulthood.[2,3] Lung development is organized into 5 sequential stages (embryonic, pseudoglandular, canalicular, saccular, and alveolar), although the timing of these stages is somewhat imprecise, and considerable overlap may occur. Fig. 38.1 shows a timeline of fetal and postnatal lung development in the mouse lung versus the human lung.

Development of Airways and Gas Exchange Surfaces

The initial phase of lung development, the *embryonic phase*, is marked by the formation of the lung bud and the initial branching events. The lung bud is first recognizable as a laryngotracheal groove of the ventral foregut at 25 days of human gestation. The lung bud consists of epithelium and surrounding mesenchyme and begins the first in a series of dichotomous divisions that give rise to the conducting airways and five primordial lung lobes (two on the left and three on the right in humans). Tracheoesophageal fistulae, tracheal atresia, and tracheal stenosis result from errors in separation of the laryngotracheal groove, whereas failure to form the initial branches can result in pulmonary agenesis, most typically of the right lung.[4] Branching continues into the *pseudoglandular stage* of lung development. By 7 weeks of human gestation, the trachea, segmental bronchi, and subsegmental bronchi are evident. By the end of 16 weeks, all bronchial divisions are completed. It is important to remember that although the conducting airways will certainly enlarge as the fetus and newborn grow (airway diameter and length increase twofold to threefold between birth and adulthood), large airway branching ceases after 16 weeks of human gestation.

Closure of the pleuroperitoneal folds is a critical event of the pseudoglandular phase, reaching completion by 7 weeks and resulting in separation of the thoracic cavity from the peritoneal cavity. Failure to close the pleuroperitoneal folds results in congenital diaphragmatic hernia. Continuity is retained between these cavities, resulting in herniation of abdominal contents into the



• **Fig. 38.1** Comparison of Lung Development Events in Mice and Humans. thorax when the midgut returns to the peritoneal cavity from the umbilical cord at 10 weeks of human gestation. The structural consequence of congenital diaphragmatic hernia is pulmonary hypoplasia of the lung ipsilateral to the diaphragmatic defect as the bowel and solid viscera migrate into the thorax. Pulmonary hypoplasia may also extend to the contralateral lung as the mediastinum shifts because of accumulating abdominal viscera in the thorax.

The *canalicular phase* is marked by completion of the conducting airways through the level of the terminal bronchioles. Terminal bronchioles give rise to the pulmonary acinus, the rudimentary gas exchange unit, which is in turn comprised of a respiratory bronchiole and all of its associated alveolar ducts and alveoli. A terminal bronchiole and all the distal acinar structures constitute a lobule. Branching of these distal air spaces continues on a more limited basis during the canalicular phase, finally achieving a total of 23 airway subdivisions.

The *saccular phase* of lung development (24 to 38 weeks of human gestation) refines the relationships between the air spaces, capillaries, and mesenchyme, enabling an alveolocapillary membrane sufficient to participate in gas exchange (0.6 μm) by approximately 24 weeks of human gestation. Beyond this point, the efficiency of gas exchange is determined by the available surface area. Lengthening and widening of the terminal sacs expand the gas-exchange surface area. Each saccule consists of smooth-walled air spaces with thickened interstitial spaces containing a double capillary network. These will give rise to two or three alveolar ducts, further expanding the available surface area. Expansion of these acinar structures continues well into the third trimester of human gestation.

Postnatal lung development can be subdivided into additional stages.[3] True alveoli become evident as early as 36 weeks of gestation in the human fetus, initiating the *alveolar phase* of lung development. The development of primary alveoli is followed by a further expansion of the gas-exchange surface area through the formation of septa, or secondary crests (described further later). Postnatal alveolarization extends from term through 2 years of age. An initial phase of "*bulk alveolarization*" occurs within the first 6 months postnatally, with a more modest addition of secondary alveoli through the remainder of this period. The alveoli of the infant lung are different from adult alveoli. These immature secondary alveoli contain a double capillary bed, whereas adult alveoli are invested by a single capillary bed. *Microvascular maturation*, the next phase of postnatal lung development, occurs between the first few postnatal months of life through 3 years of age (discussed later).

There is considerable controversy regarding when the lung ceases to add alveoli. Estimates have ranged from as early as 2 years to as late as 20 years of age in humans.[5] This is further complicated by the observation that alveolar expansion can occur in response to pneumonectomy in adult animals[6] and humans.[7] The acquisition of alveoli after the maturation of the microvasculature has been termed *late alveolarization*. This activity has been most often demonstrated in subpleural regions of the lung and likely invokes mechanisms similar to secondary crest formation.

The addition of alveoli is not the only means for expanding the surface area of the lung. While alveolarization wanes over the first 3 years of life in the human, growth of the lung continues to expand the gas-exchange surface area. Between 2 years of age and adulthood, lung tissue expands with lung volume proportionately to the increase in body weight of the child. From four years of age to adolescence, lung volume increases at a pace disproportionately greater than body weight despite a slowed rate of alveolarization, suggesting that increased size of alveoli makes a significant

contribution to expanding lung volume in later childhood.[8] Thus owing to the combined processes of prenatal lung development, postnatal lung development, and lung growth, there is tremendous potential for expansion of the gas-exchange surface area that is developmentally programmed into the fetal lung to account for the growing needs of the infant, child, and adult for aerobic cellular respiration. The extent to which these developmental mechanisms can be harnessed after premature birth, with or without superimposed lung injury, is a topic of active investigation that relies on extrapolation of experimental data from mice.

Composition of Airways and Alveoli

As branching morphogenesis proceeds, the airway and alveolar epithelium gives rise to specialized cells that participate in gas exchange, surfactant production, mucociliary clearance, detoxification, and host defense through a process called differentiation. Differentiation occurs in proximal air spaces first, then proceeding to distal air spaces, lagging behind branching. Temporal as well as contextual signals foster the regionalization of epithelial cell types.

Proximal Airways

The proximal airway epithelium is tall and columnar, decreasing in height to a more cuboidal appearance more distally.[9] Four different epithelial cell types line the trachea and bronchi: undifferentiated columnar, ciliated, secretory/goblet, and basal cells. Undifferentiated columnar epithelial cells are joined by multiciliated cells between 11 and 16 weeks of human gestation. These cells are more prevalent in proximal airways and possess multiple motile cilia at the apical surface that beat in a coordinated fashion to clear mucous. Secretory cells can be seen as early as 13 weeks of human gestation and contain either mucous or serous granules, or both. The number of secretory cells with mucous granules peaks at midgestation during fetal lung development and declines in the third trimester relative to adulthood. Finally, immature basal cells expressing epidermal keratin have been noted as early as 12 weeks of human gestation. Basal cells play a critical role in regenerating injured large airway epithelium.

Cartilaginous support of the tracheobronchial tree begins and also proceeds in a centrifugal fashion beginning in the primitive trachea at 4 weeks, reaching the main bronchi by 10 weeks, and proceeding to the most distal terminal bronchioles by approximately 25 weeks of human gestation. Cartilaginous investment of airways is complete by the second month postnatally. Submucosal glands found between the cartilaginous tissue and surface epithelium play a major role in airway host defense. Submucosal gland development can be characterized by five stages: epithelial budding and invasion of the lamina propria, development of a lumen, initiation of tube branching, and repetitive dichotomous branching. The airways of infants and children contain relatively more submucous glands than those of adults. The glands are lined by mucous cells proximally and serous cells more distally, the latter constituting 60% of the total epithelial cell content of the glands. Serous cells secrete water, electrolytes, and proteins with antimicrobial, anti-inflammatory, and antioxidant properties, while the mucous cells produce primarily mucins. In addition to this host defense role, submucosal glands also contain a population of basal cells that respond to injury of the airway by replenishing the airway epithelium.

Muscular investment of the airways begins as early as 6 to 8 weeks of gestation as smooth muscle cells are identifiable around the trachea and large airways. Fetal airway smooth muscle is innervated and able to contract during the first trimester. Muscularization increases throughout fetal life and childhood such that there is an increased amount of smooth muscle relative to airway size when compared with adult airways. Moreover, the rapid increase in the amount of bronchial smooth muscle immediately after birth occurs regardless of the timing of delivery, term or preterm.

An additional airway cell deserves mention because of its association with a wide variety of pediatric diseases. Pulmonary neuroendocrine cells (PNECs) are found throughout the airways, often in innervated clusters known as *pulmonary neuroepithelial bodies* (NEBs) located at branch points in the bronchial tree.[10,11] Although they arise from foregut endoderm, the cell of origin is distinct from other epithelial components of the lung. PNECs have large numbers of dense core vesicles containing neuropeptides, including serotonin and calcitonin gene–related peptide/bombesin, and regulate bronchial tone by releasing their contents in response to stretch- and hypoxia-mediated stimuli. Recent evidence suggests that PNECs also function as airway sensors that trigger immune responses.[12] Pathologic conditions associated with PNEC/NEB hyperplasia include bronchopulmonary dysplasia (BPD), disorders of respiratory control (congenital central hypoventilation syndrome and sudden infant death syndrome), cystic fibrosis, chronic obstructive pulmonary disease, congenital diaphragmatic hernia, and pulmonary hypertension. Neuroendocrine hyperplasia of infancy is a rare form of interstitial lung disease of infancy associated with expansion of the number of PNECs and NEBs. Although the associations are strong, it remains unclear whether PNECs/NEBs play a primary role in these diseases or a responsive secondary role.

Distal Airways

The bronchiolar epithelium differs from the more proximal airway epithelium. In addition to being more cuboidal in appearance, the epithelium contains progressively fewer ciliated cells and goblet cells, which are ultimately absent from the terminal bronchioles. Instead, the nonciliated, secretory club cell is found in increasing numbers and density down the conducting airways, such that the club cell is the most abundant cell of the terminal bronchiole.[9] Club cells are first evident by 16 to 17 weeks of human gestation, initially exhibiting large glycogen stores that are replaced by secretory granules. Between 23 and 34 weeks of gestation there is a dramatic increase in club cell numbers in distal bronchioles. Club cells are critical to host defense and detoxification functions of the lung by producing high levels of cytochrome P450 and flavin monooxygenases in the lung. The club cell also plays an important role in immunoregulation in the distal airways. Important host defense products of the club cell include club cell secretory protein, surfactant protein A (SP-A), surfactant protein D (SP-D), leukocyte protease inhibitor, and a trypsin-like protease. Club cells produce a precursor form of surfactant protein B (SP-B) that may contribute to host defense. The secretion of antiproteases from club cells suggests that they modulate the protease–antiprotease balance in the distal part of the lung.

Alveolar Epithelium

During the fourth through sixth month of human gestation the epithelial cells lining the acini begin to differentiate further.[13] The cuboidal epithelial cells accumulate large glycogen stores and develop small vesicles containing loose lamellae. The large glycogen pools provide a ready source of substrate required for the production of increasing amounts of surfactant phospholipids, and they decrease in size as surfactant production advances

in the fetal lung. In cells destined to become type 2 cells, lamellar bodies become larger, more numerous, and more densely packed with surfactant phospholipids and proteins, whereas those cells destined to become type 1 cells, on losing their prelamellar vesicles and becoming progressively thinner, adopt a phenotype more suitable for gas exchange. Type 1 and type 2 alveolar epithelial cells are readily identified early in the saccular stage of fetal lung development. There remains considerable controversy regarding the origin of type 1 epithelial cells. These cells in culture demonstrate very slow turnover, with a doubling time estimated to be between 40 and 120 days, suggesting that functionally they are terminally differentiated in vivo. Furthermore, in response to epithelial denudation occurring with lung injury, type 2 cells rapidly proliferate to reestablish epithelial continuity and then lose phenotypic features such as lamellar bodies and acquire markers of type 1 cells, suggesting that rapid repopulation of type 1 cells requires a type 2 cell intermediary. More recent studies in animals have suggested that alveolar type 1 cells can be induced to exit their terminally differentiated state and proliferate.[14]

There is increasing appreciation for type 1 alveolar epithelial cells as more than just a passive membrane for gas exchange.[15] While a large surface area and small cytoplasm-to-nucleus ratio provides a thin alveolocapillary membrane to facilitate gas exchange, it also provides a large absorptive surface in the lung. The presence of water and ion channels, some distinct from those in type 2 cells, facilitates the maintenance of a relatively dry alveolus. Type 1 cells may also regulate cell proliferation locally, signal macrophage accumulation, and modulate the functions of local peptides, proteases, and growth factors.

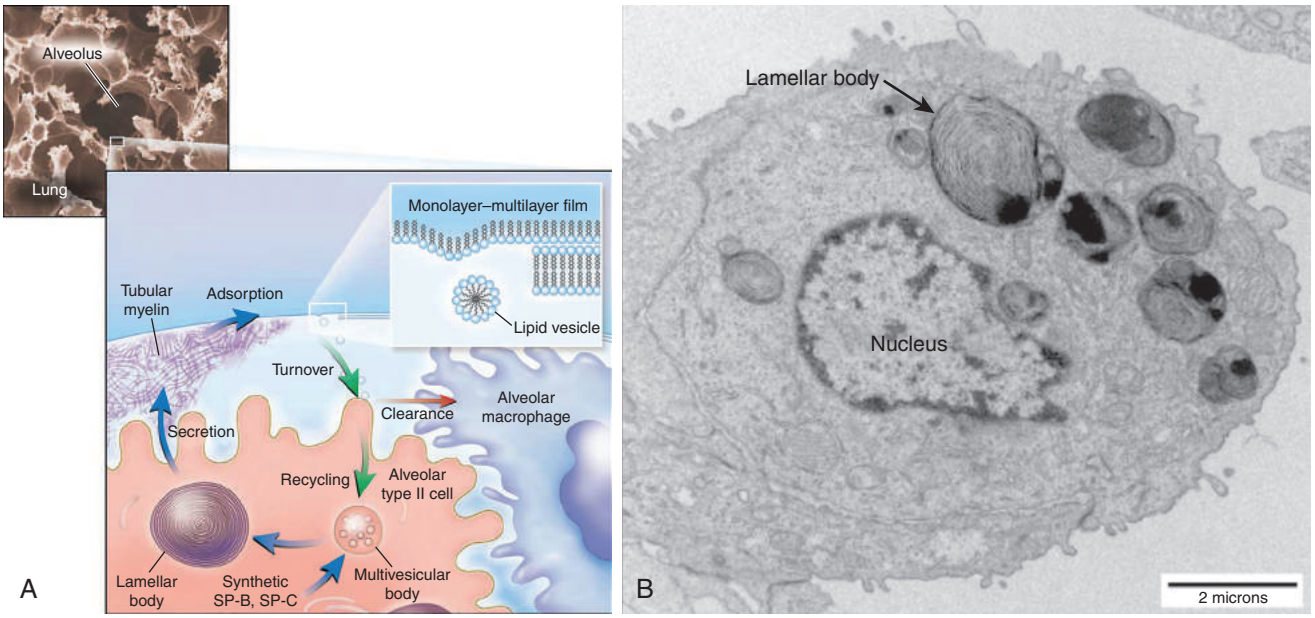
While most notable for its role in surfactant production (discussed later), the type 2 alveolar epithelial cell provides other important functions in the alveolus.[16] Type 2 cells are local progenitor cells and, like type 1 cells, contain ion and water channels as well as ion pumps that contribute to the movement of water and ions across the epithelium. Type 2 cells also contain and secrete important antioxidants (superoxide dismutases 1, 2, 3 and glutathione) and molecules of innate host defense (SP-A, SP-D, and lysozyme) to participate in detoxification and sterilization of the alveolar microenvironment.

More recently, it is becoming clear that alveolar type 2 cells may play a part in exacerbating alveolar disease. The type 2 cell participates in the coagulation–fibrinolysis cascade through the production of fibrinogen, urokinase-type plasminogen activator, and tissue factor, especially under pathologic circumstances. Type 2 cells are increasingly recognized as a source of cytokine and chemokine production in the lung, as well as growth factors that can promote fibrosis. Finally, cross talk between epithelial cells, cell matrix, interstitial cells, and local inflammatory cells can foster the resolution of injury and inflammation or prolong lung remodeling after injury, with detrimental effects such as lung destruction and fibrosis. Therefore, while previously heralded as the defender of the alveolus, type 2 alveolar epithelial cells play a much more complex role in alveolar health and disease.

Surfactant

Pulmonary surfactant is essential for maintenance of alveolar health. The alveolar epithelial cells secrete a thin layer of liquid to protect the gas-exchange surface. The surface tension generated by this aqueous layer opposes alveolar inflation and promotes alveolar collapse at the end of expiration owing to the law of Laplace, whereby the collapsing pressure on the alveolus is directly proportional to the surface tension and inversely proportional to the radius of the alveolus. The film of pulmonary surfactant at the air–liquid interface lowers surface tension as the alveolar surface area decreases with exhalation, thereby preventing end-expiratory atelectasis, maintaining functional residual capacity, and lowering the force required for subsequent alveolar inflations.

Pulmonary surfactant is a complex mixture of phospholipids, neutral lipids, and proteins that is synthesized, packaged, and secreted by type 2 alveolar epithelial cells.[17] The life cycle of surfactant is depicted in Fig. 38.2. Storage of surfactant occurs in



• **Fig. 38.2** (A) The life cycle of surfactant. (B) Electron micrograph of a type 2 alveolar epithelial cell showing the prominent lamellar bodies near the apical surface. *SP-B*, Surfactant protein B; *SP-C*, surfactant protein C. (From Whitsett J, Weaver T. Hydrophobic surfactant proteins in lung function and disease. *N Engl J Med*. 2002;347:2141–2148.)

the lamellar body, a lysosome-derived membrane-bound organelle that undergoes regulated secretion in response to a variety of stimuli, including stretch. In the alveolus, surfactant phospholipids transition through an extracellular storage form, tubular myelin. Phospholipid and protein components are recycled out of the surfactant monolayer at the air–liquid interface and taken back into the alveolar type 2 cell, where they can be repackaged into lamellar bodies. Alternatively, alveolar macrophages are able to engulf and degrade surfactant components.

The predominant surfactant phospholipid is saturated dipalmitoyl phosphatidylcholine (DPPC), with the remaining phospholipids consisting of monounsaturated phosphatidylcholine, phosphatidylglycerol, and other phospholipids (Table 38.1).[18] DPPC is the only surface-active component of lung surfactant capable of lowering surface pressure to nearly zero. The presence of unsaturated phospholipids and other lipid components such as cholesterol enables the monolayer to remain fluid at body temperature during the respiratory cycle. Phospholipid content in the fetal lung increases with advancing gestation because of increased activity of enzymes responsible for phospholipid synthesis within type 2 cells. The expression and activity of enzymes of the choline incorporation pathway, the predominant pathway for surfactant phospholipid synthesis, are not only developmentally regulated but are also induced by hormones. The inductive hormones that have direct clinical relevance are glucocorticoids and agents that increase intracellular cyclic adenosine monophosphate (cAMP) levels such as the β-adrenergic agonist (and tocolytic) terbutaline.

Surfactant contains a group of specific proteins with importance for surfactant function and host defense. The four surfactant proteins, SP-A, SP-B, surfactant protein C (SP-C), and SP-D, are subdivided on the basis of their physical characteristics into either hydrophobic (SP-B and SP-C) or hydrophilic (SP-A and SP-D) proteins. The hydrophobic surfactant proteins play a major role in the surface-active properties of surfactant, whereas the primary roles of the hydrophilic surfactant proteins are in host defense, immunomodulation, and surfactant clearance and metabolism.

Together the hydrophobic proteins, SP-B and SP-C, facilitate the mobilization of surfactant phospholipid from tubular myelin to the surface monolayer, promote spreading of phospholipids in the surfactant film, and assist in film stability at the end of expiration. SP-B plays a central role in alveolar health because of its critical function in surfactant homeostasis. SP-B is a secretory protein that exhibits strong association with membranes, unlike SP-C, which contains a membrane-spanning domain and covalently attached fatty acids (palmitate) that render it integral to phospholipid membranes.[19] Both SP-B and SP-C are synthesized as large precursor proproteins that undergo extensive posttranslational processing as they pass through the secretory pathway, ultimately reaching the lamellar body. SP-B is essential for the process of lamellar body formation, and the type 2 alveolar epithelial cells of infants with an inherited deficiency of SP-B are devoid of lamellar bodies. Because the lamellar body is where SP-C proteolytic processing is completed, infants with inherited deficiency of SP-B are also deficient in mature SP-C, instead accumulating a larger, nonfunctional precursor of SP-C. Thus, patients with inherited deficiency of SP-B, despite having relatively normal surfactant phospholipid profiles, make a pulmonary surfactant with very poor surface tension properties because of the combined defects in SP-B and SP-C. Conversely, because SP-C does not play either a direct or an indirect role in SP-B processing, animals with SP-C deficiency have normal SP-B, have normal lamellar bodies, and do not exhibit perinatal lethality due to surfactant dysfunction.

Like the enzymes of surfactant phospholipid production, SP-B and SP-C exhibit developmental and hormonal regulation of expression.[20] In human fetuses, SP-C messenger ribonucleic acid (mRNA) is detected as early as 12 weeks of gestation and SP-B mRNA by 14 weeks, yet the mature proteins are not detectable in fetal lung tissue until after 24 weeks. SP-B protein is not detectable in amniotic fluid until after 30 weeks of gestation, the amount increasing toward term.[21] This is due to developmental regulation of posttranslational events in the proteolytic processing of proSP-B and proSP-C.[22] Consequently, infants delivered prematurely have reduced levels of both surface-active components of surfactant—phospholipid and hydrophobic surfactant proteins. The rate of type 2 cell differentiation, and secondarily surfactant production, is modulated by the levels of endogenous corticosteroids and can be accelerated by prenatal administration of glucocorticoid to women in preterm labor. The response of the surfactant system to prenatally administered glucocorticoids involves all key lipid and protein components, and occurs primarily through increased gene expression, thus representing precocious maturation mimicking the normal developmental pattern. Endogenous thyroid hormones, prostaglandins, and catecholamines also have stimulatory effects on type 2 cell maturation as well as on clearance of lung fluid at birth. Certain proinflammatory cytokines (e.g., tumor necrosis factor [TNF]-α and transforming growth factor [TGF]-β) inhibit surfactant production in experimental systems and may downregulate surfactant in conditions such as sepsis and inflammation.

TABLE 38.1 Composition of Pulmonary Surfactant

Component	Percentage (by Weight)
Lipid	92
Saturated phosphatidylcholine	41
Unsaturated phosphatidylcholine	25
Phosphatidylglycerol	9
Other phospholipids	4
Cholesterol	8
Neutral lipids	5
Protein	10
Surfactant proteins	8

Development of the Pulmonary Vasculature

The primary role of the pulmonary vasculature is to supply blood flow to the acini for gas exchange.[23] During early fetal life the airways act as a template for pulmonary blood vessel development. The earliest pulmonary vessels form de novo in the tissue surrounding the lung bud in a process known as *vasculogenesis*. Mesodermal cells within the mesenchyme investing the developing lung tube differentiate into endothelial cells, proliferate, organize into chords, and develop a central lumen. As each new airway buds into the mesenchyme, a new plexus forms that adds to the pulmonary circulation, thereby extending the network of arteries and veins. By the fifth week of human gestation, a capillary network surrounds each bronchus, and circulation of blood between the right ventricle and the left atrium via this network is evident.

During the canalicular stage of lung development, new blood vessels form from preexisting vessels, a process known as *angiogenesis*. In contrast to vasculogenesis, angiogenesis is initiated by endothelial cell proliferation and sprouting from established vessels, resulting in extension of a vascular network into undervascularized regions. Vasculogenesis is the primary mode of pulmonary vascular development until the 17th week of gestation, when all preacinar airways and their accompanying vessels are present, whereas angiogenesis becomes the predominant mode of vascular development in the later stages of lung development. Although originally thought to be sequential processes, it is generally accepted that both occur concurrently during lung development, with angiogenesis dominating in the central part of the lung and vasculogenesis dominating in the periphery.[24] Interconnections between vascular networks arising from both angiogenesis and vasculogenesis increase in the saccular phase of lung development.

In the human lung a second circulatory system, the bronchial circulation, arises from the dorsal aorta and nourishes the cellular constituents of the lung itself. The bronchial vasculature develops after the pulmonary circulation, with bronchial vessels first apparent by 8 weeks of gestation. The network of bronchial vessels is extensive, with bronchial arteries demonstrated as distal as the alveolar ducts in the adult respiratory tree.

Vasculogenesis and angiogenesis are the primary mechanisms of vascular development throughout intrauterine life. The human lung at term contains only a small portion of the adult number of alveoli, and the air space walls are represented by a thick "primary septum" consisting of a central layer of connective tissue surrounded by two capillary beds, each of them facing one alveolar surface.[3] As alveolar architecture changes with the appearance of secondary septa, or secondary crests, folding of one of the two capillary layers occurs within the secondary septa. Microvascular maturation involves fusion of the juvenile double capillary network into a single capillary system present in the adult lung. Fusion is facilitated by the expansion of alveolar surface area and luminal volume, which compresses the interstitium, bringing the capillary networks in close proximity. This process is evident in the third postnatal week, during which lung volume increases by 25%, with a concomitant 27% decrease of the interstitial tissue volume. Subsequently, preferential growth of areas with a mature, fused capillary system continues.

Lastly, it is well known that lung volume increases about 23-fold between birth and young adulthood, while capillary volume expands 35-fold. It has been shown recently that this increase in capillary volume occurs by a third mechanism of vascular development: intussusceptive microvascular growth. This new concept in capillary network growth involves the formation of transluminal tissue pillars within capillaries that then expand, resulting in a net increase in capillary surface area.[3]

Muscularization of the pulmonary arteries begins early in development.[25] Initially the muscular investment of the vasculature is derived from the migration of bronchial smooth muscle cells from adjacent airways. Muscularization of the pulmonary arteries begins in the canalicular stage and continues through the remainder of gestation. Smooth muscle cells develop from the surrounding mesenchyme, altering their cellular shape and initiating expression of α-smooth muscle actin, a marker of their transformation into smooth muscle cells. A third phase of vascular muscularization, largely restricted to the distal part of the lung, involves the process of endothelial–mesenchymal transition, marked by endothelial cell division, separation and migration away from the endothelial layer, and expression of smooth muscle cell markers.

Muscularization of pulmonary arteries normally extends to the level of the terminal bronchiole and is minimal to absent in blood vessels surrounding respiratory bronchioles. Abnormal extension of smooth muscle along arterioles supplying acinar structures occurs in infants dying of persistent pulmonary hypertension of the newborn, as well as in infants with congenital diaphragmatic hernia and severe BPD.

Development of Pulmonary Host Defense

Every minute, the adult human lung takes in approximately 7 L of air contaminated with a variety of potential pathogens that can cause lung injury. The continuous exposure of the epithelial surface of the conducting airway to inhaled pathogens requires the presence of an efficient innate immune response system as a first line of defense against infection. The proximal and distal airway epithelial cells play a major role in clearing pathogens by secreting antimicrobial as well as anti-inflammatory molecules into the airways and alveoli. In the proximal airways, components of mucociliary clearance appear as early as 11 weeks of human gestation, including ciliated epithelial cells, goblet cells expressing mucins, and submucosal glands as described previously. The relative increase in the number of airway goblet cells over ciliated cells in prematurely born infants compared with term infants renders premature infants more prone to enhanced mucus production and obstruction caused by poor mucociliary clearance.

A number of microbial defense molecules are produced and secreted by epithelial cells into the airways.[26] They include lysozyme, C-reactive protein, lactoferrin, collectins, β-defensins, and the cathelicidin CAP-18/LL-37.[27] Two lung collectins originally identified as surfactant-related proteins, SP-A and SP-D, play a larger role in lung host defense than in surfactant biophysics. Although originally identified as products elaborated by epithelial cells lining airways (club cells) and alveoli (type 2 cells), they are secreted at other epithelial surfaces exposed to the external environment.[28–31] These collectins interact with microorganisms and inflammatory cells to facilitate microorganism clearance and modulate inflammatory and apoptotic responses.[32]

The basis for the interactions of the lung collectins with microbes and antigens centers on the binding of sugars by the carbohydrate recognition domains of these proteins.[33] Interactions between collectins and gram-negative bacteria depend on the ability of SP-A and SP-D to bind lipopolysaccharide, whereas interactions with gram-positive bacteria, including group B β-hemolytic streptococcus, depend on recognition of the gram-positive outer membrane component lipoteichoic acid.[34] The collectins bind a variety of fungi as well as *Pneumocystis carinii* and play an important role in inhibiting a variety of respiratory viruses, including influenza A virus and respiratory syncytial virus. Differences in the structure of the carbohydrate recognition domain provide SP-A and SP-D with altered affinities for different sugar molecules, allowing complementary functions and improving the diversity of microbial interactions.

The lung collectins also modulate the functions of a variety of immune cells, including macrophages, neutrophils, eosinophils, and lymphocytes.[35–37] The collectins enhance the local production of chemotactic factors to attract macrophages and neutrophils and cytokines that activate macrophages and eosinophils, as well as attenuate lymphocyte responses by inhibiting T-cell proliferation. Other direct effects on inflammatory cells include modulating the production of reactive oxygen and nitrogen species used in killing microorganisms.

Like the hydrophobic surfactant proteins, SP-A and SP-D exhibit both developmental and hormonal regulation of expression.[20] In human fetuses, SP-A mRNA is undetectable before 20 weeks of gestation, and SP-A is first detectable in amniotic fluid by 30 weeks of gestation, with the amount increasing toward term.[21] The SP-A gene promoter is induced by cAMP and glucocorticoids, although the response to glucocorticoids is biphasic, showing attenuation of SP-A expression at higher doses. Retinoids, insulin, and growth factors, including TGF-β and TNF-α, inhibit SP-A gene expression. Like SP-A, SP-D expression in the developing lung is quite low during the second trimester[38] but is detectable in amniotic fluid in the third trimester, increasing toward term. The levels of both SP-A and SP-D increase markedly in the first few days after preterm birth and can be modulated by the local microenvironment of pathogens, toxins, and reactive oxygen species.[39,40]

Development of Detoxification Systems

Although oxygen is an essential component of cellular processes, concentrations beyond the physiologic limits may be hazardous to cells. The lung is particularly susceptible to reactive forms of oxygen and free radicals since it is the organ with the highest exposure to atmospheric oxygen. The fetal lung is exposed to oxygen tensions of 20 to 25 mmHg in utero, and the transition to air breathing is associated with a fourfold to sevenfold increase in oxygen tension, presenting a significant oxidant stress. Oxygen free radicals arise from endogenous production through metabolic reactions or by exogenous exposure, such as air pollutants and cigarette smoke. Free radicals injure the lung through oxidation of proteins, DNA, and lipids. Therefore, an antioxidant detoxification system is especially critical during the transition of the fetal lung to air breathing.

Oxygen free radicals are highly toxic substances and exist in several different forms. Superoxide is produced by the reduction of molecular oxygen through the addition of an electron, hydrogen peroxide is produced from the transfer of a single electron to superoxide, and hydroxyl radicals are produced through the interaction of hydrogen peroxide with superoxide. The free electrons of free radicals promote peroxidation of membrane lipids, alter sulfhydryl and other groups on exposed amino acids in proteins, and cause direct damage to DNA. All of these changes have been described in the lungs of animals and humans exposed to high levels of oxygen, although the dose response differs by species and with age, leading to altered epithelial integrity, interstitial and air space edema, and infiltration of inflammatory cells. Reactive oxygen species have also been implicated in enhancing production of proinflammatory mediators by lung epithelial and resident inflammatory cells, through chromatin remodeling, triggering signal transduction pathways, and activating transcription factors.[41,42]

Antioxidants, both nonenzymatic and enzymatic, attenuate the effects of oxygen free radicals in the lungs. The major nonenzymatic antioxidants are glutathione, vitamin C (ascorbate), vitamin E (primarily α-tocopherol), β-carotene, and uric acid. Enzymatic antioxidants include superoxide dismutases (1, 2, and 3), catalase, thioredoxins, and a variety of peroxidases. Animal studies indicate that many of the antioxidant enzymes are induced before term delivery, and limited data suggest that the same is true for human fetuses.[43] However, premature animals fail to induce antioxidant enzymes in response to oxidative lung injury.[44] Thus, preterm infants are at significantly higher risk of oxidant lung injury owing to both increased need for oxygen in the treatment of respiratory distress syndrome and underdeveloped antioxidant defenses.

Mechanisms of Lung Development

Fetal and postnatal lung development depend on several key developmental processes: branching morphogenesis to promote branching of the lung bud into the surrounding mesenchyme, static and cyclic stretching of the lung that assist in promoting sacculation, alveolarization to enhance the expansion of the gas-exchange surface area, and vasculogenesis and angiogenesis to ensure that the developing epithelial surface area is invested with both a gas-exchange and a nourishing vascular supply.

Branching Morphogenesis

Branching morphogenesis is a fundamental mechanism of lung development. Branching is mediated by the accelerated growth of epithelial cells along the stalk of a branching airway with concomitant growth arrest at the branch tip.[45] This process requires extensive communication between epithelial cells and with the adjacent mesenchyme, as well as integration of microenvironmental cues from the extracellular matrix.[46] Classic tissue recombination experiments in which mesenchyme from proximal airways was transplanted to distal airways (and vice versa) indicate that the mesenchyme has an important inductive role in dictating the branching pattern and cell fate of the expanding epithelium.[47] More recently, murine modeling indicate that three modes of branching—domain branching, planar bifurcation, and orthogonal bifurcation—are the basic mechanisms that characterize development of the complex three-dimensional respiratory tree through the pseudoglandular phase.[48,49] These branching patterns are used repetitively during lung development and appear to be governed by a genetic clock orchestrating side branch formation, then planar bifurcation of a side branch, and planar rotation dictating the orientation of the bifurcation, thereby establishing a complex, three-dimensional structure.

Stretch and Mechanotransduction

The role of physical factors in modulating lung size is well established: normal lung growth requires adequate space in the chest cavity and appropriate tonic and cyclic distending forces. Genetic defects that compromise the thoracic skeleton and space-occupying lung masses such as congenital cystic adenomatoid malformations are associated with pulmonary hypoplasia due to the restriction of intrathoracic space. Denervation of the diaphragm to eliminate fetal breathing movements is associated with pulmonary hypoplasia, as is oligohydramnios.

Static Stretch: Fetal Lung Fluid Production

Fetal lung fluid is a product of the epithelial lining of the developing lung,[50,51] averaging 4 to 6 mL/kg/h. The resistance imparted by laryngeal abduction results in fluid accumulation to a total volume of 20 to 30 mL/kg during gestation, which generates an end-expiratory pressure of approximately 2 to 4 cmH_2O. The composition of fetal lung fluid is distinct from that of both amniotic fluid and plasma, as illustrated in Table 38.2. The increased chloride content of fetal lung fluid as compared with serum is the result of active chloride secretion by the tracheal and distal pulmonary epithelium, largely because of the chloride channel CLC-2/CLCN2. A variety of growth factors, hormones, and lipid mediators influence

TABLE 38.2 Composition of Human Fetal Lung Fluid Compared With Other Body Fluids

Component	Lung Fluid	Interstitial Fluid	Plasma	Amniotic Fluid
Sodium (mEq/L)	150	147	150	113
Potassium (mEq/L)	6.3	4.8	4.8	7.6
Chloride (mEq/L)	157	107	107	87
Bicarbonate (mEq/L)	3	25	24	19
pH	6.27	7.31	7.34	7.02
Protein (g/dL)	0.03	3.27	4.09	0.10

the production of fetal lung fluid during gestation, including enhancers (prolactin, keratinocyte growth factor, prostaglandin E_2, and prostaglandin F_2) and inhibitors (β-adrenergic agonists, vasopressin, serotonin, and glucagon).

While fetal lung fluid is an essential component of lung development, it presents a significant obstacle to the transition to air breathing on delivery. Three important events must occur to minimize the amount of fetal lung fluid and its potential impact on alveolar surface tension before the transition to air breathing: absorption, bulk removal, and maturation of pulmonary surfactant. Conversion of the pulmonary epithelium from a secretory to an absorptive surface is a critical event during the third trimester. Enhanced sodium transport across the alveolar epithelium is in part responsible for this change. Much evidence suggests that increasing expression of components of the epithelial sodium channel (ENaC) in the third trimester is a major factor in promoting sodium reabsorption from alveoli, with water passively following the movement of sodium.[51,52] Transgenic mouse pups that do not express the α subunit of ENaC die quickly after birth because of failure of fetal lung fluid clearance. Induction of ENaC subunits occurs at a transcriptional level in response to changes in extracellular matrix components, glucocorticoids, aldosterone, and oxygen. Drugs that increase intracellular cAMP levels (i.e., β-adrenergic agonists, phosphodiesterase inhibitors, and cAMP analogues), while not increasing the number of ENaC channels, increase the probability of a channel being open to sodium transport. In addition, glucocorticoid and thyroid hormones play an important role in priming the lung epithelium to be responsive to the actions of β-adrenergic agonists on sodium transport across lung epithelia near term. Thus, the prenatal use of glucocorticoids and tocolytics may improve lung function in prematurely born infants through enhanced lung fluid reabsorption as well as by increasing surfactant production. Epithelial water channels, consisting of aquaporin proteins, are also induced during the late fetal period.[53] While water channels are clearly essential for fluid movement across epithelial cell membranes, their importance for fetal lung fluid clearance is less certain in the face of perinatal survival of transgenic mouse pups that do not express aquaporin 5 and/or aquaporin 1.

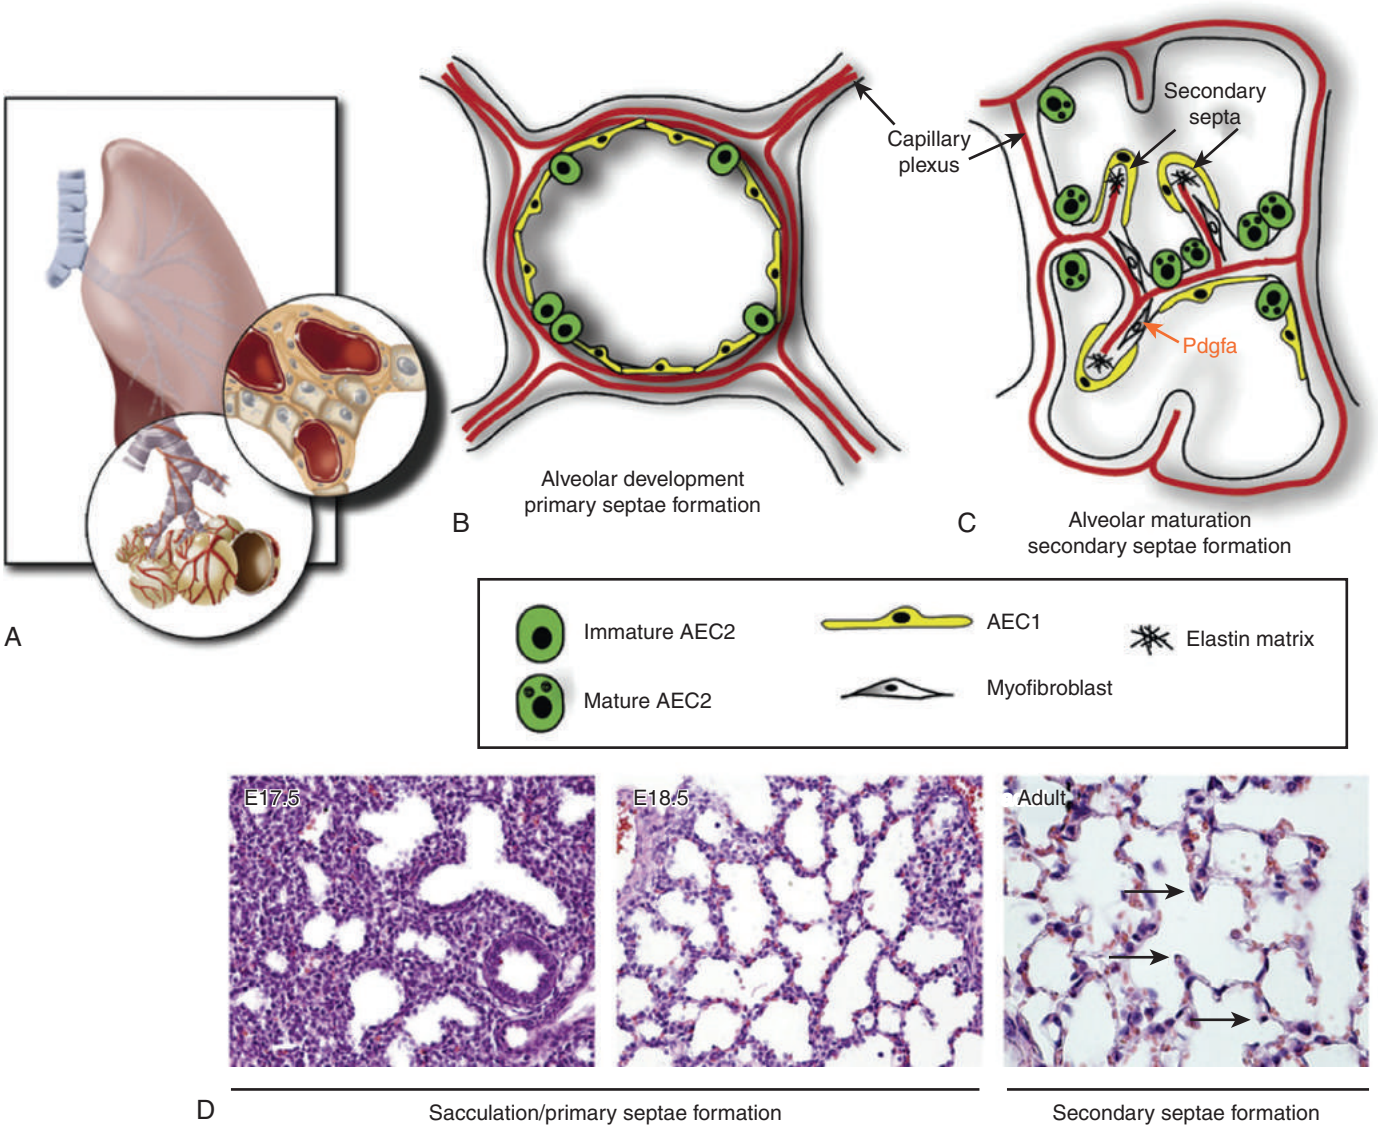
Conversion to an absorptive surface is not enough to minimize the amount of fetal lung fluid at the time of term delivery. The absence of uterine contractions is associated with an increased incidence of retained fetal lung fluid in infants born by cesarean delivery without the benefit of labor. On delivery of the head and neck, continued uterine contractions on the fetal thorax promote expulsion of bulk fluid from the fetal lung. However, animal studies suggest that the magnitude of the benefit of thoracic compression during labor is modest.[54] Instead, the primary mechanism by which labor facilitates clearance of lung fluid is through hormonal effects on fluid clearance, especially through catecholamine-induced changes in the open probability of ENaC channels. The onset of air breathing, associated with increased intrathoracic negative pressure, assists in the clearance of residual fetal lung fluid into the loose interstitial tissues surrounding alveoli. Fluid is then reabsorbed via lymphatics and pulmonary blood vessels. It is generally accepted that the amount of residual liquid in the lung after transition is complete is approximately 0.37 mL/kg body weight.

Cyclic Stretch: Fetal Breathing Movements

Fetal breathing movements, detectable as early as 10 weeks of gestation in the human fetus, is an essential stimulus for lung growth.[55] Sustained periods of fetal breathing increase in duration with advancing gestation. Fetal breathing occurs for 10% to 20% of the time at 24 to 28 weeks, increasing to 30% to 40% after 30 weeks of gestation. Originating from the diaphragm, fetal breathing is erratic in frequency and amplitude. The volume of fluid moved is small and insufficient to be cleared from the trachea. Respiratory rates range from 30 to 70 breaths per minute, while periods of apnea of up to 2 hours have been recorded. The frequency of fetal breathing varies with sleep state (inhibited during quiet sleep) and exhibits diurnal variation, with the lowest rates recorded early in the morning. Fetal breathing is hormonally responsive, and the inhibition of fetal breathing with the onset of labor is attributed to the action of increased levels of circulating prostaglandins. Maternal medications can influence the frequency of fetal breathing movements. Central nervous system stimulants are associated with increased fetal breathing (i.e., caffeine, amphetamines), whereas depressants are associated with decreased fetal breathing (i.e., anesthetics, narcotics, nicotine, ethanol). Animal studies have clearly shown that permanent cessation of fetal breathing, regardless of the cause, is associated with impaired fetal lung growth. However, the impact on fetal lung development of short-term alterations in fetal breathing frequency and amplitude is unknown. Together, constant distending pressure from the production and retention of fetal lung fluid and episodic cyclic fetal breathing are important mechanisms for lung growth during fetal life.

Alveolarization

While branching morphogenesis is the primary developmental program that establishes the conducting airways of the lung, it is important to remember that alveolarization is the developmental program that will establish the large surface area involved in gas exchange.[56] This process will result in a 20-fold increase in surface area between birth (with between 0 and 50 million alveoli) and adulthood (>300 million alveoli). The established dogma suggests that primitive saccules develop low ridges (primary septa) that subdivide the saccule into an alveolar duct containing primary alveoli and outpouchings between the ridges (secondary septa/crests) that establish secondary alveoli (Fig. 38.3), however these secondary septa have also been described as having a three-dimensional ring structure.[57] Septation is critical for the process of



• **Fig. 38.3** Alveolarization. (A) Alveolar development begins in late gestation as the endothelial plexus becomes tightly associated with the epithelium of the distal saccules. (B) Early alveoli contain several important cell types, including the flattened type 1 alveolar epithelial cells *(AEC1)* used in gas exchange and the cuboidal type 2 alveolar epithelial cells *(AEC2)* that make surfactant, which lie close to a double capillary network. (C) Maturation of the alveolar compartment is marked by the generation of secondary septa, which involves the development of alveolar crests, a process dependent on the development of myofibroblasts and the deposition of elastin. (D) Histologic sections stained with hematoxylin and eosin demonstrating the changes in distal lung morphology of the developing mouse lung, with secondary septa denoted by *arrows*. Pdgfa, platelet derived growth factor subunit A, found in myofibroblasts in mature alveolae. (From Morrisey EE, Hogan BL. Preparing for the first breath: genetic and cellular mechanisms in lung development. *Dev Cell*. 2010;18:8–23.)

microvascular maturation and also leads to the development of the pores of Kohn, allowing gaseous continuity between acini and a route for macrophages to move freely between alveoli.

The topic of alveolarization is rapidly evolving, receiving increasing attention because of observations that infants who die after severe BPD exhibit alveolar simplification with little evidence of secondary septation. It remains unclear to what extent the alveolarization potential may be permanently altered by preterm birth alone—in the absence of other injuries—and whether the developmental program can be resumed after preterm birth.

Interdependence of Alveolar and Vascular Development

Recent evidence suggests that the pulmonary capillary bed actively promotes normal alveolar development, maintains alveolar structures throughout life, and can contribute to degenerative lung disease in adulthood.[23] The observation that combined abnormalities in the airways and vasculature occur in BPD supports this hypothesis. Intraacinar arteries and veins continue to develop after birth by angiogenesis as long as alveoli continue to increase in number and size. This may well be a reciprocal process because vascular

growth around the distal air spaces suggests an inductive influence from the alveolar epithelial cells as well.

Molecular Basis for Lung Development

The developmental processes that contribute to lung organogenesis are under the regulation of interdependent signaling pathways mediated by secreted growth factors that are themselves under the control of large networks of transcription factors controlling gene expression. Gene regulatory networks common to other organs that depend on branching morphogenesis for organogenesis, most notably in the kidney and mammary gland, are also found in the lung. Selected regulatory networks are highlighted in the following sections.

Growth Factors in Lung Development

The initiation of branching morphogenesis is the result of the interplay of signals between the developing lung epithelial tube and its surrounding mesenchyme. Central to this process is the family of fibroblast growth factors (FGFs) that are produced and secreted by mesenchymal cells and bind to receptors on the plasma membrane of epithelial cells, setting up a system of mesenchymal–epithelial cross talk. In particular, FGF10, secreted by mesenchymal cells, binds to its receptor, FGF receptor 2 isoform IIIb (FGFR2IIIb), on nearby epithelial cells. This signal is strongest in the epithelial cells at the tip of branching airways owing to a focused FGF10 gradient within the mesenchyme. Binding of the FGF10 ligand to the FGFR2IIIb receptor results in activation of the mitogen-activated protein kinase (MAPK) pathway within epithelial cells, setting off a cascade of downstream signaling events that regulates cell adhesion, cytoskeleton, and cell polarity, all essential elements of cell migration.[58] One of the genes induced by FGF10/FGFR2IIIb signaling, *SPRY2*, inhibits the MAPK pathway, resulting in feedback inhibition of further FGF10/FGFR2IIIb signaling. Thus, a signal propagated by the mesenchyme has an effect that is tightly regulated within the epithelial cell.

Proper lung development requires exquisitely precise FGF10 signaling. Animals expressing reduced levels of FGF10 develop pulmonary hypoplasia with reduced numbers of large airways.[59,60] Furthermore, increased FGF10 signaling during fetal lung development in mice by intrapulmonary injections of recombinant FGF10 produced cystic structures with epithelial characteristics dependent on the location of the injection: proximally with club cells, distally with type 2 alveolar epithelial cells.[61] Together these data provide strong evidence that FGF10 signaling has diverse responses—from initiation of branching to differentiation of epithelial cells—depending on the temporal and/or spatial context of signaling.

Like branching morphogenesis, lung vascular development is a complex and highly organized process that requires multiple vascular signaling molecules to interact in a specific temporospatial sequence. Vascular endothelial growth factor (VEGF) is a critical growth factor in angiogenesis and vasculogenesis. The expression of the VEGF ligand by epithelial cells and VEGF receptors (VEGFRs) by endothelial cells of the developing human fetal lung reinforces the interdependence of the air space and vascular development. The expression of VEGF mRNA and protein is localized to the epithelial cells at the distal tips of developing lung branches, and the expression levels increase with time.[25,56] VEGF gene expression is induced in epithelial cells by the hypoxic environment of the growing fetal lung through the actions of the oxygen-sensing hypoxia-inducible factor family of transcription factors. From the single VEGF gene, five different VEGF protein isoforms are possible, although VEGFA (VEGF165) is the most studied. Each isoform has different affinities for each of the three VEGFRs (Flt-1/VEGFR1, Flk-1/kinase insert domain receptor/VEGFR2, and Flt-4/VEGFR3). Vascular endothelial cells express primarily VEGFR1 and VEGFR2, whereas VEGFR3 is expressed on the plasma membrane of the lymphatic endothelium. VEGFRs are expressed on the plasma membrane of endothelial cells surrounding the developing airways from very early in gestation, and expression of VEGFR2 is considered the earliest marker of an endothelial progenitor cell. In vitro and in vivo experiments have shown that VEGFA induces endothelial cell proliferation and migration, both key elements of vascular sprouting, as well as tube formation through interactions with VEGFR2. VEGFR1 appears to have more importance in transforming primitive endothelial tubes into stabler vascular networks, in part by reducing endothelial proliferation through downregulation of VEGF production. The embryonic lethality of animals with reduced VEGF expression attests to the critical importance of VEGF/VEGFR signaling to vascular development in the fetus, though not limited to the developing pulmonary vasculature.

Transcription Factors in Lung Development

The ligand–receptor interactions, important for branching morphogenesis and pulmonary vascular development, are in part determined by the actions of transcription factors on facilitating or reducing gene expression. Transcription factors are also critical in the differentiation of the lung epithelium in the airway epithelium as well as differentiation of type 1 and type 2 alveolar epithelial cells in the distal lung.

The most important transcription factor in the lung is thyroid transcription factor 1 (TTF-1), a product of the *NKX2-1* gene. TTF-1 is considered a master regulator of lung development, as transgenic mice null for *NKX2-1* exhibit complete absence of lung branching.[62] *NKX2-1* plays a prominent role in establishing cell fate proximally to distally along the branching lung epithelium, with expression ultimately becoming more restricted to club cells and alveolar type 2 cells. TTF-1 is critical for the expression of genes that are unique to differentiated epithelium, such as *SCGB1A1* expression in club cells and surfactant proteins in type 2 alveolar epithelial cells. DNA binding sites are found in the promoter regions of all four surfactant genes, *SCGB1A1*, and *NKX2-1* itself, setting up a positive feedback loop for sustained TTF-1 expression. TTF-1 function is highly dependent on phosphorylation of critical amino acids, although it remains unclear which kinase is involved in this process.[63] VEGFA expression is reduced in animals unable to phosphorylate TTF-1, providing another important link between epithelial and vascular development. TTF-1 is itself regulated by other transcription factors that bind to the promoter region of the *NKX2-1* gene, specifically hepatocyte nuclear factor 3β and GATA-binding protein 6. Thus the ability of networks of transcription factors to bind to gene regulatory elements of DNA in a coordinated fashion during fetal lung development enables the temporospatial expression of growth factor networks that foster branching morphogenesis, the process of differentiation that ultimately gives rise to the approximately 40 cell types that constitute the human lung and the coordination of both epithelial and vascular development.

Disorders of Lung Development

The normal developmental lung program usually proceeds in a stereotypical manner, but defects in these morphogenic processes during specific developmental windows result in recognizable human lung malformations. The most common congenital lung malformation is a collection of intrapulmonary airway branching lesions known as congenital pulmonary airway malformations (CPAMs), with an incidence of approximately 1 in 2500 to 8000 live births[64]. These lesions communicate with the tracheobronchial tree, retain normal blood supply and are divided into 5 subtypes, termed Stocker's classification, based on presumed site of origin, size, and nature of the epithelial lining (Table 38.3).[65,66] There is great variability in the clinical presentation for fetuses and newborns with CPAMs from asymptomatic to development of non-immune hydrops, with type 1 associated with development of bronchoalveolar carcinoma in adolescence or adulthood, and type 2 with 50% to 60% incidence of associated extrapulmonary major congenital anomalies.[65] For those CPAMs detected prenatally, the CPAM-volume ratio (CVR) on prenatal ultrasound has been used as a tool to predict clinical outcomes, although no clear parameters have been established for neonatal outcomes other than development of hydrops.[67,68] The specific molecular defect that results in CPAMs is unknown but proposed mechanisms include ectopic application of proximal branching morphogenesis programs in a distal location or focal obstruction during development that irreparably disrupts the branching.[69]

Less common than CPAMs is congenital lobar emphysema. These lesions represent 10% of congenital lung malformations, are connected to the tracheobronchial tree and consist of hyperinflation of one or more of the pulmonary lobes. They most commonly affect the left upper or right middle lobes and have the potential for air trapping and compression of neighboring lung tissue.[70]

Unlike CPAMs or congenital lobar emphysema, bronchopulmonary sequestrations do not communicate with the tracheobronchial tree and are supplied by systemic arterial circulation, typically the thoracic aorta or one of its divisions. These islands of non-functioning lung tissue are more commonly extralobar (85%) with systemic venous drainage, with a less common intralobar variant (15%) that drains through the pulmonary system to the left atrium.[70,71]

The most notable congenital lung malformation of the distal lung airspace is alveolar capillary dysplasia/ misalignment of the pulmonary veins (ACD/MPV). This rare, almost universally lethal lung malformation is diagnosed by the presence of distinct pathologic findings including (1) immature lobar development, (2) pulmonary capillaries located remote from the alveolus, and (3) pulmonary veins "misaligned" and contained within the same adventitial sheath as the small pulmonary arteries.[72,73] Infants with ACD/MPV become progressively and relentlessly hypoxic beginning at 24 to 48 hours of age. The majority of these infants (50% to 80%) will have major extrapulmonary congenital anomalies, including congenital diaphragmatic hernia, congenital heart disease, or intestinal atresias. This lung malformation is associated with mutations in FOXF1, and known chromosomal deletion of the region containing this gene in an infant with unexplained hypoxia and other anomalies should prompt consideration of ACD/MPV as a diagnosis.[74,75]

TABLE 38.3 Stocker's Classification of Congenital Pulmonary Airway Malformations

Type	Presumed Site of Development	Notable Features
0	Tracheobronchial	Dense non-cystic lesion
1	Bronchial/bronchiolar	Usually a large cyst(s) involving a single lobe, commonly symptomatic in newborn period, associated with bronchoalveolar carcinoma in older pediatric or adult patients
2	Bronchiolar	Smaller cysts 0.5–2 cm lined by simple cuboidal or columnar epithelial cells; associated with extrapulmonary anomalies
3	Bronchiolar/alveolar	Non-cystic mass of glandular tissue
4	Distal acinar	Cysts of variable size (often large) lined by type 1 and 2 alveolar epithelial cells; pneumothorax in older children

Novel Concepts in Lung Development

Stem/Progenitor Cells in the Lung

The ability of lung epithelium to replace cells damaged by normal aging or injury has become the focus of increasing attention.[76,77] Stem cells are undifferentiated and have an unlimited capacity for self-renewal. Asymmetric divisions allow self-renewal through one daughter cell while enabling the other daughter cell to become more terminally differentiated. Progenitor cells are more committed, and although capable of self-renewal, they exhibit more restricted cell fates. Thus far, experiments combining lineage tracing with animal models of lung injury have identified several epithelial progenitor cell types having the capacity for both self-renewal and replacement of a variety of specialized lung epithelial cells. Basal cells in large airways and submucosal glands, identified by the expression of tumor protein p63/p63 and cytokeratin 5, are able to self-renew and give rise to ciliated and secretory cells. Club cells in smaller airways, identified by the expression of club cell secretory protein, seem to be a more committed progenitor cell since they are able to self-renew but differentiate only into club cells or ciliated cells. A subset of club cells, termed *bronchoalveolar stem cells* (BASCs), located at the bronchoalveolar duct junction and resistant to certain forms of lung injury, appear to have a role in epithelial repair. BASCs are both club cell secretory protein and SP-C positive and thus have the potential to produce either club cells or alveolar type 2 cells. Also in the smaller airways, neuroendocrine cells can self-renew and give rise to club cells and ciliated cells following exposure to injury. The most limited lung epithelial progenitor cell is the alveolar type 2 cell, which divides rapidly to reestablish epithelial continuity in damaged alveoli and then transdifferentiates into alveolar type 1 cells. Less well studied are the mesenchymal progenitor cells that provide vascular and muscular components of the developing lung. Candidate cells have been identified that give rise to endothelial cells in the process of vasculogenesis and airway smooth muscle cells along the branching lung epithelial tubes.

Evidence for the existence of stem/progenitor cells in the lung is strong but limited largely to mouse models of lung development and lung repair. Therefore extrapolation to humans should be done with caution, as the murine transition between terminal bronchioles and alveoli is not equivalent to the transition in the human

lung. While the capacity for self-renewal is tantalizing, it necessarily means that such cells are at risk of autonomous growth such as cancer. Controversy exists around the potential to harness these populations of cells as a means for correcting abnormalities of lung development (pulmonary hypoplasia), genetic diseases of the lung (cystic fibrosis), and abnormal repair of injured lungs (BPD).

Epigenetic Regulation of Lung Development and Maturation

Regulation of normal development and the consequences of abnormal development are at the heart of understanding the implications of preterm birth and the development of potential lung protective therapies. The central dogma of DNA to RNA to protein is being challenged by increasing recognition of epigenetic mechanisms—histone modifications, modification of DNA and RNA, silencing RNA, and microRNA (miRNA) —for regulating gene expression. The evidence that miRNAs play an important role in normal fetal lung development is clear.[78] MiRNAs are small, noncoding RNAs (generally 19 to 22 nucleotides in length) found within cells that target genes for RNA degradation or inhibition of protein synthesis. There are more than 500 recognized miRNAs, some of which are particularly enriched in lung cell populations. MiRNAs are generated from a process that begins in the nucleus. Long primary miRNA is transcribed, processed, and exported from the nucleus, where further cytoplasmic maturation occurs before the mature miRNA is able to interact with regions of messenger RNA, usually in the 3′ untranslated region.

Emerging evidence indicates that miRNAs are essential for normal lung development, since targeted deletion of dicer, a key enzyme in miRNA processing, results in abnormal airway development and excessive apoptosis in the lungs.[79] The miR-17-92 cluster of miRNA is highly expressed in embryonic mouse lung, decreasing into adulthood as lung development progresses. Altered expression of miR-17-92 suggests a primary role for these miRNAs in maintaining E-cadherin expression in airway epithelial cells during branching morphogenesis. A novel class of noncoding RNAs, the long noncoding RNAs (or lncRNAs), similarly regulate lung development. These large nucleotides (>200 nucleotides in length) are less stable than mRNA, have fewer posttranslational modifications, and play a role in stabilizing chromatin, thereby regulating gene transcription. The expression of several lncRNAs is spatially and temporally correlated with transcription factors critical to lung development.[80] The best characterized is *NANCI* (Nkx2.1-associated noncoding intergenic RNA), which regulates neighboring Nkx2.1 expression. Knockdown of *NANCI* in vivo results in lung sacculation and epithelial differentiation defects.

Because of their role in regulating developmental and pathologic processes, noncoding RNAs are increasingly seen as targets for therapeutic interventions. The obstacles to using miRNA or lncRNA as therapeutic agents are similar to the obstacles encountered in other gene therapies, including mode of delivery, cell and tissue specificity, and the potential for off-target effects.

Summary

Lung branching morphogenesis is coordinated with pulmonary vascular development to provide a large surface area and thin alveolocapillary membrane to accomplish adequate gas exchange in the transition to air breathing and to meet the needs of a growing infant and child. Although occurring late in fetal lung development, maturation of the surfactant system is similarly critical in the transition to air breathing and the maintenance of patency of the gas-exchange surface. Although the fetal lung developmental program requires an array of transcription factors, hormones, and growth factors promoting branching morphogenesis, lung growth is equally dependent on intact neural input to modulate fetal breathing, stability of an appropriately sized thorax, and the presence of adequate lung and amniotic fluid. Furthermore, the maturation of the host defense and detoxification systems minimizes the effects of increased oxygen tension and exposure to potential pathogens accompanying the transition to air breathing. Premature birth impacts all of these functions, as illustrated in Table 38.4. BPD is the net result of multiple injuries to the underdeveloped lungs of premature newborns that compromise postnatal growth and development, thus impairing function. Integrated approaches to therapy that reflect the interdependency of these lung functions have the most promise for minimizing the impact of premature birth on childhood and, ultimately, adult lung function.

TABLE 38.4 Potential Impact of Premature Birth on Lung Development and Maturation

Event	Effect of Preterm Birth	Potential Consequences
Development of conducting airways	Branching: no effect; completed to the level of the respiratory bronchi by 24 weeks	None
	Tone: increased secondary to lung disease in part reflecting developmental deficiency of nitric oxide	Increased airway resistance
Alveolarization	Decreased in severe bronchopulmonary dysplasia; may also be compromised by excess glucocorticoids	Reduced lung growth and lung surface area with increased alveolar size; impaired pulmonary function
Development of alveolocapillary membrane	Minimal effect: reaches adult diameter by 24 weeks of gestation; glucocorticoids induce precocious thinning	Gas exchange largely dependent on surface area, not alveolocapillary diameter
Type 1 cell differentiation	Variable depending on timing of delivery	Gas exchange largely dependent on surface area

Continued

TABLE 38.4 Potential Impact of Premature Birth on Lung Development and Maturation —cont'd

Event	Effect of Preterm Birth	Potential Consequences
Type 2 cell differentiation	Variable immaturity and deficient surfactant production depending on timing of delivery; improved with prenatal administration of glucocorticoids	Developmental deficiency of surfactant content and composition results in respiratory distress syndrome.
Hydrophobic surfactant proteins (SP-B, SP-C)	Variable effect depending on timing of delivery and other factors such as infection that can impair gene transcription	High alveolar surface tension; respiratory distress syndrome
Hydrophilic surfactant proteins (SP-A, SP-D)	Variable effect depending on timing of delivery; both proteins appear relatively late in the third trimester	Compromised host defense: impaired ability to clear microorganisms from airways and/or alveolar space; impaired ability to modulate inflammatory responses
Club cell differentiation	Variable effect depending on timing of delivery; these cells appear in the middle of the second trimester, but antioxidant products appear late in the third trimester	Impaired antioxidant and antimicrobial defenses; may contribute to chronic lung disease and pneumonia
Mucociliary clearance	Variable effect depending on timing of delivery; goblet cells decrease in number toward term	Increased mucus production may obstruct small airways
Development of the pulmonary capillary bed	Variable effects depending on timing of delivery in parallel to alveolar development	Variable degrees of impaired gas exchange commensurate with impaired alveologenesis and any superimposed lung injury; pulmonary hypertension
Pulmonary arteries	Variable effects depending on presence and severity of associated lung disease	Pulmonary hypertension associated with chronic lung disease
Fetal lung liquid	Fluid loss: variable effects depending on magnitude and duration of fluid loss (i.e., prolonged premature rupture of membranes) as well as timing of delivery	Pulmonary hypoplasia
	Fluid retention: variable effects depending on timing of delivery because hormone surges near term and in labor promote reabsorption before delivery	Transient tachypnea of the newborn
Fetal breathing movements	Variable effects depending on timing of delivery but also depending on maternal exposure to substances that reduce fetal breathing movements	Unlikely to have effects in preterm infants unless coexisting conditions severely limit fetal breathing
Respiratory drive	Variable depending on timing of delivery	Apnea of prematurity

SP-A, Surfactant protein A; *SP-B*, surfactant protein B; *SP-C*, surfactant protein C; *SP-D*, surfactant protein D.

Neonatal Pulmonary Physiology

WILLIAM E. TRUOG AND WINSTON M. MANIMTIM

KEY POINTS

- Understanding the movement and maintenance of a volume of gas in and out of the lungs forms the basis of pulmonary physiology.
- Maintenance of functional residual capacity (FRC) is vital to adequate lung mechanics and gas exchange.
- There are multiple methods and techniques for measuring respiratory mechanics in healthy newborns and sick infants. However, to be clinically relevant, the results of these measurements must be interpreted within the context and limitations of these techniques.
- Understanding ventilation perfusion matching is key to understanding overall pulmonary gas exchange.
- Bronchopulmonary dysplasia (BPD) is characterized by complex and heterogenous pathophysiology that affects gas exchange involving large and small lung units and pulmonary vasculature.

Lung Volumes and Lung Mechanics

Knowledge of the functional components of lung volume and the mechanical properties of the lungs plays an important role in the understanding of neonatal respiratory physiology. The lungs have physical and mechanical properties including elastic recoil, airway resistance and inertance that resist inflation. The dynamic interactions between these properties are responsible for the effort required during normal spontaneous tidal breathing. A driving pressure is required to move a volume of gas into and out of the respiratory tract during a respiratory cycle that results in measurable airflow and volume changes. Functional residual capacity (FRC) is the volume of air in the lungs at the end of expiration of a normal, resting breath when alveolar pressure (P_A) equals atmospheric pressure (P_{atm}; Fig. 39.1A). Establishment of the FRC is vital to maintain adequate lung mechanics and gas exchange. FRC is maintained by the opposing forces of lung elastic recoil and chest wall outward recoil. Changes in the elastic properties of either the lung or the chest wall alter FRC.

Respiratory System Compliance

The lung contains elastic tissues that pull the lung to its deflated state. This property is called elastic recoil. Hooke's law requires that the pressure needed to inflate the lungs must be in proportion to the volume of inflation. The change in volume divided by the change in pressure is the lung compliance (Fig. 39.1B).

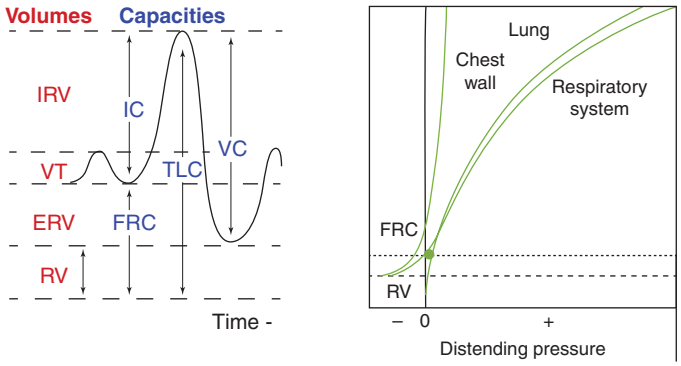
Conventionally, the volume of inflation is plotted on the *y*-axis, and the distending pressure is plotted on the *x*-axis. In this way the constant of proportionality is volume divided by pressure, or lung compliance. Throughout the range of tidal breathing the relationship between pressure and volume is linear. At higher lung volumes, as the lung reaches its elastic limit (i.e., total lung capacity), this relationship plateaus, making the pressure–volume relationship nonlinear. Static compliance is the change in volume for a given pressure during static, non flow conditions. On a static compliance curve, ventilation occurs at the steep portion where large changes in volume occur for small changes in pressure.[1] Dynamic compliance is the change in volume and pressure during spontaneous or mechanical breathing while there is airflow. It is predominantly influenced by the rate of respiration.

The total compliance of the respiratory system (C_{RS}) is comprised of the compliance of the lung (C_L) and chest wall (C_{CW}), where $1/C_{RS} = 1/C_L + 1/C_{CW}$. The tendency for the lung to collapse inward at the end of exhalation is balanced by the negative (subatmospheric) intrapleural pressure resulting from the outward recoil of the chest wall. FRC is maintained when these opposing forces are at equilibrium.[2] Inflation of the respiratory system above FRC requires a positive distending pressure that must overcome the elastic recoil of both the lung (alveolar pressure minus intrapleural pressure) and the chest wall (intrapleural pressure minus atmospheric pressure).[3] Deflation below FRC requires an active expiratory maneuver. Residual volume (RV) is defined as the volume of air that cannot be expired even with a forced deflation.

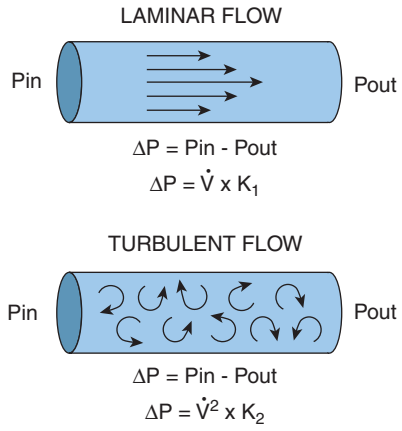
As depicted in Fig. 39.1B the infant's chest wall is composed primarily of cartilage. Therefore, C_{CW} is greater in infants, and the pleural pressure is less negative or only slightly sub atmospheric. As a result of the more compliant chest wall with very little outward distending pressure, the neonatal lung is more prone to collapse at the end of exhalation.[4] In newborn infants, FRC is maintained during spontaneous breathing by increasing expiratory resistance through laryngeal adduction (glottic narrowing), by maintaining inspiratory muscle activity throughout expiration, making the chest wall stiffer, and by initiating high breathing frequencies to limit the expiratory time, and causing the lungs to retain gas (gas trapping).[5,6]

Airway Resistance

A gradient of pressure (ΔP) is required for gas flow (V) to occur to overcome the nonelastic resistance of the lungs. Mathematically, resistance (R) = $(\Delta P)/V$. Physical resistance to gas flow arises due to friction between gas molecules against the walls of airways (i.e., airway resistance) and due to friction between the tissues of the lung and the chest wall (i.e., viscous tissue resistance). Resistance depends on the length and diameter of the airway as well as the density and viscosity of the gas. Airway resistance represents



• **Fig. 39.1** (A) Components of total lung capacity *(TLC)* include residual volume *(RV)*, expiratory reserve volume *(ERV)*, tidal volume *(VT)*, and inspiratory reserve volume *(IRV)*. Functional residual capacity *(FRC)* = RV + ERV; inspiratory capacity *(IC)* = VT + IRV. FRC is the volume of gas that remains in the lungs at the end of expiration when alveolar and airway pressures are at equilibrium. (B) An idealized plot of volume as a function of distending pressure for the lung, chest wall, and respiratory system (lung plus chest wall) of normal infant. The compliance curves are derived by instillation or removal of a measured volume of gas from the lung and allowing the respiratory system to come to rest against a shuttered airway. At this point only elastic forces are acting on the respiratory system, and airway pressure is equal to alveolar pressure. Intrapleural pressure can be measured with an esophageal balloon. Because airway pressure is equal to alveolar pressure, the distending pressure for the lung can be measured as *airway pressure minus intrapleural pressure*. The distending pressure for the chest wall is *intrapleural pressure minus atmospheric pressure*, and the distending pressure for the respiratory system is *airway pressure minus atmospheric pressure*. Compliance is the change in volume divided by the change in distending pressure. At FRC, the lung and chest wall distending pressures are equal but opposite and therefore the total respiratory system distending pressure is zero. The *shaded area* is the resting intrapleural pressure at FR.



• **Fig. 39.2** Gas flow ($\dot{V}$) through tubular structures occurs only in the presence of a pressure (P) gradient (Pin > Pout). For laminar flow, P is directly proportional to $\dot{V}$:

$$\Delta P = (\dot{V} \times 8 \times L \times \mu)/(\pi \times r^4).$$

In this case the constant of proportionality (K_1) is directly related to the length of the airway (L) and the viscosity of the gas (μ) and is indirectly proportional to the fourth power of the radius of the airway (r). When flow exceeds the critical velocity, its pattern changes from laminar to turbulent. For turbulent flow, ΔP is proportional to $\dot{V}^2$. The constant of proportionality (K_2) is directly proportional to the length of the airway and the density of the gas and inversely proportional to the fifth power of the radius of the airway.

approximately 80% of the total resistance of the respiratory system; tissue resistance and inertial forces account for the remaining 20%.[7] In the newborn, the small size of the airways makes them significantly more prone to high airway resistance with nasal resistance representing almost half of the total airway resistance.[8] In addition, neonates are preferential nose breathers. Therefore, any mucus or edema in the nasal passages can offer significant resistance to air flow.

The movement of gas through the airway is modeled by two basic patterns of flow, laminal and turbulent (Fig. 39.2). During laminar flow the pressure difference needed to move gas through the airway is directly related to the flow rate times a constant (airway resistance). During turbulent flow, however, this pressure is directly proportional to a constant multiplied by the flow rate squared. Gas flow becomes turbulent at branch points in airways, at sites of obstruction, and at high flow rates. Turbulence occurs whenever flow increases to a point that the Reynolds number exceeds 2000. This dimensionless number is derived from fluid dynamics and is calculated as $\mathrm{Re} = [p \times d \times V]/[u]$ where V is the volumetric flow rate, p is gas density, d is radius of the tube, and u the gas viscosity.[9] Obviously, turbulent flow is most likely to occur in the central airways, where volumetric flow is high, rather than in peripheral airways where flow is distributed across a large total cross-sectional area. Both types of flow exist in the lung, so the net pressure drop is calculated as follows[10]:

$$\Delta P = (K_1 \times \dot{V}) + (K_2 \times \dot{V}^2) \quad (1)$$

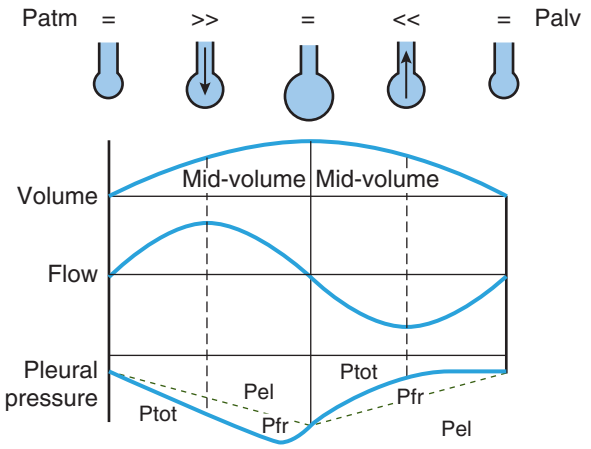
Inflation of the lung increases the length of airways and might therefore be expected to increase airway resistance; however, lung inflation also increases airway diameter. Because airway resistance varies with the fourth to fifth power of the radius of the airway, the effects of changes in airway diameter dominate, and resistance is inversely proportional to lung volume.[11] Airway resistance is lower during inspiration than during expiration, because pleural pressure becomes more negative during inspiration, and a greater distending pressure is applied across the lung. This distending pressure increases airway diameter as well as alveolar diameter and decreases the resistance to gas flow. During expiration, pleural pressure increases and airways are compressed. Collapse of airways is opposed by their cartilaginous support and by the pressure exerted by gas in their lumina. During passive expiration these defenses are sufficient to prevent airway closure. When intrapleural pressure is high, during active expiration, airways may collapse, and gas may be trapped in the lung causing dynamic hyperinflation. This problem may be accentuated in the small preterm infant with poorly supported central airways.

Inertance

Gas and tissues in the respiratory system also resist accelerations in flow, which is determined by gas density and the ratio of airways length to surface area. Inertance represents opposition to these accelerated forces and is assumed to be negligible during quiet breathing and physiologically significant only at rapid respiratory frequencies and high flow rates.

Dynamic Interaction

Compliance, resistance, and inertance all interact during spontaneous breathing (Fig. 39.3). This interaction is described by the equation of motion for the respiratory system:



• **Fig. 39.3** Gas flows from the atmosphere into the lung only if atmospheric pressure (P_{atm}) is greater than alveolar pressure (P_{alv}). At the end of exhalation, when P_{atm} equals P_{alv}, there is no gas movement in or out of the lung. During a spontaneous inspiration, the diaphragm contracts, the chest wall expands, and the volume in the intrathoracic space increases. As a result, pleural pressure (P_{pl}) decreases relative to P_{atm}, and a gradient is created between P_{pl} and P_{alv}, distending the lung, increasing alveolar volume, and decreasing P_{alv}. A gradient is also created between P_{atm} and P_{alv}, and gas flows from the atmosphere into the alveolar space. The rate of gas flow increases rapidly, reaches a maximum (peak flow), then decreases as the alveolus fills with gas and P_{alv} approaches P_{atm}. At peak inspiration, P_{alv} equals P_{atm}, and lung volume is at its maximum, as is P_{pl}. The *curved solid line* connecting the end of expiration to the end of inspiration is the total driving pressure for inspiration (P_{tot}). The *dotted line* represents the pressure needed to overcome elastic forces alone (P_{el}). The difference between the two lines is the pressure dissipated overcoming flow resistive forces (P_{fr}). During exhalation, this cycle is reversed.

$$P(t) = (V[t] \times 1/C) + (\dot{V}[t] \times R) + (\ddot{V}[t] \times I) \quad (2)$$

where $P(t)$ is the driving pressure at time t, $\dot{V}[t]$ is the lung volume above FRC, C is the respiratory system compliance, $\dot{V}[t]$ is the rate of gas flow, R is the resistance of the respiratory system, $\ddot{V}[t]$ is the rate of acceleration of gas in the airways, and I is the inertance of the respiratory system. If I is disregarded, the equation simplifies to

$$P(t) = (V[t] \times 1/C) + (\dot{V}[t] \times R) \quad (3)$$

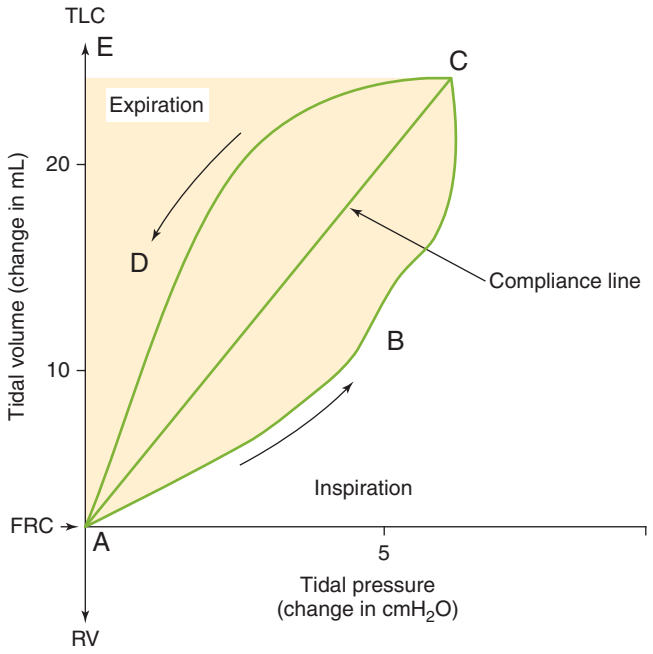
At times of zero gas flow (end expiration and end inspiration), the equation further simplifies to

$$P(t) = (V[t] \times 1/C) \text{ and } C = V(t)/P(t) \quad (4)$$

This series of equations and Fig. 39.3 demonstrate that at points of no gas flow (end of expiration and end of inspiration), only elastic forces are operating on the lung. During inflation or deflation of the lung, however, both elastic and resistive forces are important.

Work of Breathing

The work of breathing (WOB) is the amount of energy required to overcome the elastic and resistive elements of the respiratory system and move gas into and out of the lung during spontaneous breathing. WOB is defined as the cumulative product of distending pressure and the given volume displaced during inhalation or exhalation (Fig. 39.4):



• **Fig. 39.4** Inspiratory/expiratory pressure–volume loop showing the compliance line (*AC*, joining points of no flow); work done in overcoming elastic resistance (*ACEA*), which incorporates the frictional resistance encountered during expiration (*ACDA*); work done in overcoming frictional resistance during inspiration (*ABCA*); the total work of breathing during respiratory cycle is the sum of *ACEA* + *ABCA* equals *ABCEA*, or the entire *shaded area*. *FRC*, Functional residual capacity; *RV*, residual volume; *TLC*, total lung capacity. (From Wood BR. Physiologic principles. In: Goldsmith JP, Karotkin EH, eds. *Assisted Ventilation of the Neonate*. 4th ed. Philadelphia: Saunders; 2003:15–30.)

$$\text{WOB} = \int P \mathrm{d}V$$

where P is pleural pressure (in time) above resting pleural pressure and V is the volume (in time) relative to the resting thoracic volume.

In healthy infants, most of the WOB is done by the diaphragm during inhalation. Approximately one-third of the total inspiratory WOB is related to overcoming the resistance to gas flow in the airways.[12] Exhalation is usually passive because of the potential energy stored in the lung and the chest wall at the end of inhalation. The WOB is increased with increase in resistance, decrease in compliance or increased respiratory frequency when lung volumes decrease below FRC.

Time Constants

The distribution of gas within the lungs depends largely on the dynamic interaction between the compliance and resistance of the entire respiratory system. This relationship is called the time constant (Trs) and is the product of the resistance and compliance ($R \times C$). There are challenges to measuring changes in lung volumes and distending pressure of the respiratory system. Because of the difficulties associated with trying to achieve a steady state to measure static compliance, many investigators calculate the "dynamic compliance" and take advantage of the fact that gas flow in and out of the lung is transiently equal to zero at the end of inspiration and the end of expiration (see Fig. 39.3). Measuring

lung volume and distending pressures at these two points of rest allows calculation of compliance by division of the change in volume by the concomitant change in distending pressure. For passive mechanics, the behavior of the respiratory system during passive exhalation can be obtained relatively easily with the use of the occlusion technique by giving a positive pressure breath, then the airway is occluded, invoking the Hering Breuer reflex and a brief apnea.[13] Airway pressure is measured when the occlusion is released. The expired gas flow is measured with a pneumotachometer and integrated to volume; the flow is then plotted as a function of volume (Fig. 39.5A).

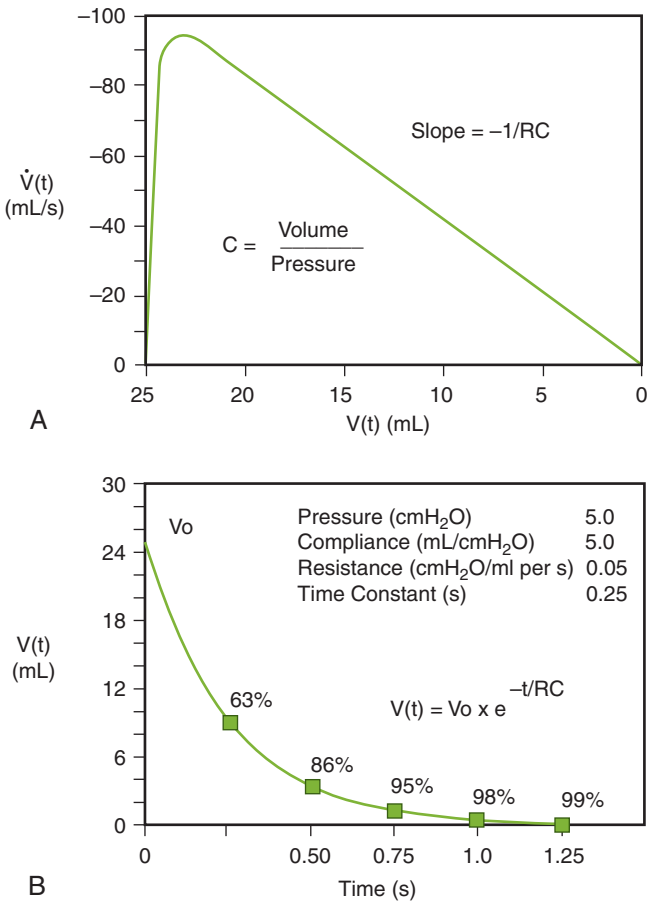
During a passive exhalation, no external forces are acting on the respiratory system [airway pressure or $P(t) = 0$], so the equation of motion simplifies to a first-order differential equation:

$$(V[t] \times 1/C) + (\dot{V}[t] \times R) = 0$$

Rearrangement yields the linear equation:

$$\dot{V}(t) = -\left(\frac{1}{RC}\right) \times (V[t]) \qquad (5)$$

where the slope is $-1/RC$, which can be determined by a linear regression of $\dot{V}(t)$ versus $V(t)$. This equation states that during passive exhalation, flow plotted against volume is a straight line with slope $-1/RC$. Since the volume can be calculated from the flow–volume curve, the pressure measured during the inspiratory hold can be used to calculate compliance and the slope of the line to calculate resistance. The quantity RC, i.e., the respiratory system time constant (Trs), in units of seconds, describes the rate at which the lung deflates during passive exhalation. It also implies the time it takes for the pressure within the alveoli to equilibrate (Fig. 39.5B). Time constants affect the rate of lung inflation in much the same manner.



• **Fig. 39.5** (A) Flow of gas out of the lung versus volume of gas remaining in the lung, $V(t)$, for a passive exhalation. Flow of gas out of the lung is negative by convention. After an initial sharp increase, flow decreases linearly as the lung empties. Static compliance of the respiratory system is obtained by division of the exhaled volume by the airway pressure at the beginning of the passive exhalation. Resistance is calculated from the slope of the flow–volume plot ($-1/RC$) and the compliance. This technique has the advantage of not requiring measurements of pleural pressure and being relatively unaffected by chest wall distortion. (B) $V(t)$ as a function of time for a passive exhalation. The graph is an exponential with the equation

$$V(t) = V_0 \times e^{-t/RC},\ V(t) = V_0 \times e^{-t/RC},$$

where V_0 is the starting volume, and e is the base of the natural logarithm (roughly 2.72). For this example, the time constant of the respiratory system (Trs) is roughly 0.25 s. Calculations show that when exhalation persists for a time equal to the time constant (t = 0.25 sec = 1 × Trs), 63% of the gas in the lung is exhaled. For t = 2Trs, 86% of the gas is exhaled; for t = 3Trs, 95% of the gas is exhaled; for t = 4Trs, 98% of the gas is exhaled; and for t = 5Trs, 99% of the gas is exhaled. If expiration is interrupted before t = 3Trs, gas is trapped in the lung. where V_0 is the starting volume, and e is the base of the natural logarithm (roughly 2.72). For this example, the time constant of the respiratory system (Trs) is roughly 0.25 s. Calculations show that when exhalation persists for a time equal to the time constant (t = 0.25 sec = 1 × Trs), 63% of the gas in the lung is exhaled. For t = 2Trs, 86% of the gas is exhaled; for t = 3Trs, 95% of the gas is exhaled; for t = 4Trs, 98% of the gas is exhaled; and for t = 5Trs, 99% of the gas is exhaled. If expiration is interrupted before t = 3Trs, gas is trapped in the lung.

Measurements of Respiratory System Mechanics

Respiratory system mechanics are objective measurements used to determine the severity of lung disease, changes in pathophysiology, response to therapeutic interventions, and progression of lung growth and development. Table 39.1 shows a summary of lung volumes and mechanics values obtained by different investigators using different techniques for healthy and sick infants and premature infants.

Lung mechanics in infants are typically measured during spontaneous breathing or during assisted ventilation or during short periods of apnea induced by taking advantage of the Hering–Breuer reflex. As previously described, a driving force is measured during a brief airway occlusion, when pressures equilibrate across airways during periods of no flow. The occlusion is then released and the flow and volume of gas are measured during the passive expiration. Calculations of compliance are affected by lung size; therefore, if lung compliances are to be compared, they must be corrected by dividing compliance by resting lung volume or FRC. The resulting value is called the *specific compliance*. For the normal newborn, resting lung volume is approximately 100 mL. In addition, lung compliance changes with volume history, meaning that it decreases with fixed tidal volumes and increases with periodic sigh that recruit poorly ventilated or collapsed air spaces resulting in improved lung compliance and oxygenation.[14] Variations in static compliance measurements are also associated with achieving steady state due to gas redistribution. Therefore, many investigators have suggested calculating dynamic compliance, which takes into account the movement of the gas in and out of the lungs, with the flow of gas transiently equaling zero at end of inspiration and end of expiration (see Fig. 39.3). The lung volumes and

TABLE 39.1 Lung Volumes and Respiratory Mechanics of Well and Sick Infants

Measurements	Units	Well Infant	Well Preterm Infant	RDS	BPD
Tidal volume	mL/kg	5–7	7.1–7.8	4–6	4–10
FRC	mL/kg	22–30	21–26	20–33	16–30
Compliance	mL/cmH_2O	1–2	1.1–1.6	0.3–0.6	0.2–1.0
Resistance	cmH_2O/L/s	25–50	52–97	60–160	30–170
Work of breathing	g cm/min/kg	500–1000		800–3000	1800–6500

BPD, Bronchopulmonary dysplasia; *FRC*, functional residual capacity; *RDS*, respiratory distress syndrome.
Although there are significant overlaps in the ranges of values, there is a general trend for infants with RDS and BPD to have significantly diminished lung compliance, increased airway resistance and increased work of breathing. distending pressures at these points of zero flow provide measurements for *dynamic compliance*. In normal newborns, dynamic compliance is generally assumed to be equal to static compliance. However, many respiratory disorders result in non-homogenous areas of the lungs with variable compliance and airway resistance (see Table 39.1). Therefore, dynamic measurement may underestimate the compliance of the entire respiratory system.[15]

Several investigators have noted that with obstructive lung disease, the expiratory flow-volume plot may not be linear but concave and does not fit into a straight line.[16] These studies found that the plots fit much better in a biexponential function, with one exponent describing the behavior of well-ventilated lung units (fast compartment) and the other describing the behavior of poorly ventilated lung units (slow compartment). This compartmentalization of lung units also affects lung inflation. During lung inflation, the fast compartment with short time constant fills rapidly, while the slow compartment with long time constant fills much more slowly, causing highly variable inspiratory time constants of the entire respiratory system. This phenomenon is typically manifested in infants with severe bronchopulmonary dysplasia (BPD) with very diverse time constants within the same lung.[17,18]

At higher respiratory rates, only the lung units with short inspiratory time constants are inflated resulting in a smaller ventilated lung. With smaller ventilated lungs, the measured dynamic compliance decreases as the respiratory rate increases. This phenomenon is termed the *frequency dependence of compliance* and is highly suggestive of inhomogeneous lung due to small airway obstruction.

The resistance of the total respiratory system can be calculated from measurements of driving pressure and the rate of gas flow and can be measured only when the lung is moving. The choice of driving pressure determines the site of the measurement. Most commonly the driving pressure is airway pressure minus atmospheric pressure (resistance of the respiratory system) or airway pressure minus intrapleural pressure (total lung resistance). Gas flow rates are calculated from measurements obtained from devices placed in the infants' airway via a face mask, nasal prongs, or an endotracheal tube. In the spontaneously breathing infant, driving pressure is generated by respiratory muscles creating a negative intrapleural pressure that can be measured via a catheter, balloon or transducer in the esophagus. For the ventilated and paralyzed infant, the driving force is the positive pressure at airway opening measured within the ventilator circuit as close as possible to the airway opening. Flow and volume are measured continuously and simultaneously to driving force.[19] If there are no leaks, all of the gas flow in and out of the infant's lungs will travel through a pneumotachometer, which calculates flow as the pressure drop across a fixed resistance or a hot wire anemometer, which calculates flow by measuring the transfer of heat from a heated wire in the circuit just proximal to the infant. In both dynamic and passive techniques, flow, volume and driving force are used to solve the equation of motion of the lung and yield values for compliance and resistance. Traditionally, resistance of the total respiratory system is calculated from measurements of distending pressure, volume, and flow (see Fig. 39.3). For this calculation, points of equal volume are chosen during inspiration and expiration. The gas flow and the distending pressure are measured at each point. The pressure needed to overcome elastic forces should be the same for inspiration and expiration, and therefore the pressures should cancel out. Total resistance, consequently, is equal to distending pressure at the inspiratory point minus distending pressure at the expiratory point divided by the sum of the respective inspiratory and expiratory point gas flows. Subsequently, investigators simplified these calculations by measuring distending pressure, gas flow, and volume (see Fig. 39.3), then fitting these measurements to the equation of motion (Eq. 3) using multiple linear regression techniques and solving for the coefficients $1/C$ and R.[20] Calculations of pulmonary function by modern ventilators use much the same process.

Ventilator graphics yield valuable bedside real-time display of continuous patient ventilator interactions on a breath-to-breath basis. The measurements of pressure, flow, and volume changes, either as time-based scalar display or as flow-volume or pressure-volume loop graphics, provide clinicians with valuable data to customize ventilator settings based on underlying lung mechanics and pathophysiology, such as in small airway obstruction, excessive inflation, asynchrony, or pressure or gas trapping. Measurements of respiratory mechanics are limited by the inability to accurately

measure and differentiate delivered tidal volume during patient-initiated and ventilator-driven breaths. In addition, the one compartment single breath analysis by the ventilator software may substantially underestimate the variability in lung mechanics in the different regions of the lung of newborn infants. Despite these limitations, understanding ventilator graphics could provide additional bedside information about respiratory physiology and the interaction between the ventilator and the ventilated newborn infants.[21]

Volumetric capnography, in the form of continuous partial pressure of carbon dioxide (pCO_2) monitoring combined with continuous flow-volume graphics, provides estimates of anatomical and physiologic dead space, pulmonary capillary blood flow, and efficiency of ventilation. Pattern recognition of displayed waveform can identify pathophysiologic conditions such as airway obstruction, over ventilation or central hypoventilation conditions. In the spontaneously breathing infant, the end-tidal carbon dioxide ($EtCO_2$) measurements provide information on functional lung alterations such as in infants with BPD.[22,23]

Chest wall measurement techniques involve the assessment of tidal breathing by estimating change in chest volume at the chest wall, instead of airflow at the airway opening. One such technique, respiratory inductance plethysmography (RIP), measures changes in the cross-sectional area of the chest by changes in inductance in coils with weak currents around the chest and abdomen. This method could precisely measure thoraco-abdominal asynchrony.[19,24] In addition to providing measurement of the changes in overall tidal volume, thoraco-abdominal asynchrony is also used to detect airway obstruction, to monitor sleep apnea, and to indirectly measure the WOB.[22]

Another modality is electrical impedance tomography (EIT) which is a radiation-free dynamic imaging technique that can detect regional changes in lung volumes. This method is accomplished by transmitting very small alternating electrical currents through the lungs from a belt-like array of electrical transmitter/receivers around the chest wall. The resulting voltages are used to construct a two-dimensional image showing the distribution of electrical impedance throughout the chest. By repeated scans the relative distribution of air in the lungs is mapped out during tidal breathing, and a measure of total and regional ventilation of the lungs is obtained.[19] Clinical and experimental studies using this technique have shown usefulness in a variety of pulmonary conditions including ventilation inhomogeneity in infants with BPD and chronic lung disease of infancy.[25,26]

Forced deflation is a form of spirometry for sedated and paralyzed, intubated, and ventilated infants that inflates the lungs manually to near total lung capacity (+40 cm H_2O) and holding them static for 3 seconds followed by a forced expiratory maneuver by application of a constant negative pressure (−40 cm H_2O) to the endotracheal tube until expiratory flow ceases. A pneumotachograph or flow sensor attached to the breathing tube measures the maximum expiratory flow-volume curves, and the curve with the highest forced vital capacity is used for analysis. Normative data are available for healthy infants and young children up to 5 years of age.[27,28] Alternatively, a combination of comprehensive physiologically integrated spirometry using raised-volume passive and forced expirations as well as multiple-breath nitrogen washout has been developed for in-depth investigation of lung function in infants. Static lung volumes and lung capacities at an airway opening pressure of +30 cm H_2O and variables from the best forced expiratory flow-volume curve were found to be dependent on infant's age, weight and body length.[29] Another technique to produce full forced expiratory maneuvers in sedated infants has been described and uses lung inflation to near total lung capacity (TLC) to a pressure of +30 cm H_2O. Forced expiratory maneuver is produced by rapid thoracoabdominal compression with an inflatable jacket. The rapid deflation produces expiratory flow-volume curves that can demonstrate flow limitations. Fractional lung volumes can be estimated by combining this method of estimating vital capacity with a measurement of FRC obtained by plethysmography. Reproducibility and normative data for infants using this technique have been published.[30–32]

The use of this technique has recently identified three distinct phenotypes—obstructive, mixed, or restrictive—of severe BPD in former premature infants.[33]

Oscillometry, also called forced oscillation technique (FOT), is an alternative method for measuring respiratory system mechanics in which a pressure sine wave [$P(w)$] of a given frequency (w) is superimposed on the infant's tidal breathing, either spontaneously or ventilator-driven, and a resulting flow [$V(w)$] is measured. The resulting high-frequency changes in flow and volume are separated out from the tidal flow/volume changes by signal processing. Pressure, flow, and volume changes are then used to calculate the mechanical impedance of the respiratory system (Zrs = resistance + compliance + inertance) at the imposed frequency. The oscillation frequency used determines the mechanical parameters measured by FOT.[34,35] Technical standards regarding oscillometry measurements, including hardware, software, testing protocols, and quality control, have been recently updated by both the American and European Thoracic Societies. Reference values are available for children but not in infants, and its application in newborns and infants remains experimental.[36]

FRC, a static lung volume, is usually measured by inert gas dilution techniques using helium (He) or sulfur hydrofluoride (SF_6) dilution or inert gas nitrogen (N_2) displacement during a period of tidal breathing (spontaneous or ventilator) and hence is called multiple breath washout (MBW) technique. For He or SF_6 dilution, the gas is first washed into the lungs by adding it to the inspired air. For N_2 washout, breathing gas is switched to 100% oxygen during expiration and continued until the end-expiratory nitrogen concentration is below 2%. The inert gas concentration in the expired breath is measured continuously using a mass spectrometer or ultrasonic flow sensor, and the expiratory airflow and/or volume are measured using a pneumotachometer or ultrasonic flowmeter. FRC is calculated as the ratio of exhaled net tracer gas volume to the difference in the starting and ending end-tidal tracer gas concentrations. The lung clearance index (LCI) describes the number of lung turnovers necessary to clear the inert gas from the lungs. A high LCI suggests poor ventilation homogeneity, which can be a sensitive measure of small airway disease.[37] The total volume of gas in the thorax at the end of expiration (thoracic gas volume) can be measured with a body plethysmography and application of Boyle's law. As the measured thoracic gas volume is larger than the measured FRC by inert gas dilution, the difference between these two volumes represents the volume of trapped gas. A critical relationship exists between FRC and the volume of gas that remains in the lungs after maximal inhalation or exhalation. With the use of a N_2 gas washout technique during maximal inspiratory and expiratory maneuvers, the closing capacity (CC) can be identified as the point in which the conducting airways begin to collapse, resulting in areas of lung collapse that do not participate in gas exchange.[38]

Pulmonary Gas Exchange

Overview

Human life stops promptly when pulmonary gas exchange stops or slows substantially. The movement of oxygen from ambient air to alveolar air to blood to tissue and the reverse movement of carbon dioxide from tissue to lung to the exhaled gas cannot stop or be profoundly impaired for more than a few minutes before death ensues. The body of knowledge summarized above relating to lung volumes, lung mechanics and WOB has focused on air movement. Understanding lung mechanics and volumes is often of limited use when complex lung disorders undermine assumptions of the lung as a single functioning "black box." The reality is that even in healthy infants, the lungs function as multiple discrete gas exchanging units. Subdividing of lung areas becomes particularly problematic when the adverse impacts of preterm birth are superimposed.

Placental gas exchange operates until the moment placental circulation is separated from the mother's, with cord clamping and first breaths. There is no "in-between" time as placental blood-blood countercurrent system of gas exchange ends. Placental gas exchange and nutrient transfer is sufficient to allow a doubling of fetal weight between 28 and 32 weeks and a tripling by 37 weeks of gestation. Yet placental gas exchange is associated with a maternal uterine artery to fetal umbilical vein gradient of about 40 to 50 mmHg. This gradient allows for a relatively hypoxemic fetal situation. No other organ system other than the respiratory system undergoes a dramatic and irreplaceable physiologic change in minutes following birth. The lung, as the meeting place of alveolar ventilation and pulmonary perfusion, must convert from exchanging gas through the placenta with its blood–blood interface—an organ designed to maintain a hypoxic environment—into one in which the need for increased oxygen delivery requires an immediate increase in efficiency.

Gas movement into and out of the airways and the maintenance of gas volumes during the respiratory cycle promotes effective gas exchange. The juxtaposition of alveolar gas and pulmonary capillary blood establishes and maintains maximal diffusion gradients for oxygen and carbon dioxide. Pulmonary gas exchange can fail for many reasons (Box 39.1). The next section of this chapter will focus on development of normal and impaired pulmonary gas exchange.

Tools Available for Assessing Pulmonary Gas Exchange

Calculated oxygen gradient: Measurement of arterial PO_2 and PCO_2 in a person breathing ambient air at sea level reveals a great deal about gas exchange—but such measurements treat the lung as a single black box, not composed of many acinar or more proximal level areas of alveolar ventilation and pulmonary perfusion matching (V_A/Q). The $AaPO_2$ gradient can be calculated by making the assumptions that arterial and alveolar PCO_2 are very similar, ($PaCO_2 \cong PACO_2$); that steady state conditions apply; and that inspired gas is heated and humidified to body temperature pressure saturated (BTPS) conditions before arriving in the acinar spaces. The exact formula is as follows with R, the respiratory exchange ratio, typically assumed as close to 1.0 in healthy infants.

$$PAO_2 = PIO_2 - PACO_2 \times \left[FIO_2 + (1 - FIO_2)/R\right]$$

where

$$PIO_2 = FIO_2 \times (PB - PH_2O)$$

Calculated PIO_2 plotted against SpO_2: Venous admixture summarizes the contribution of shunt (zero ventilation of perfused areas), low V_A/Q areas, and diffusion disequilibrium on overall gas exchange. It is calculated by the following formula in which O_2 content is measured in systemic arterial blood (CaO_2), pulmonary venous blood (C_cO_2) and mixed venous blood (CvO_2). Simultaneous measurement of these oxygen contents is a difficult feat in sick neonates, which is rarely performed outside cardiac catheterization laboratories.

$$\frac{\dot{Q}va}{\dot{Q}t} = \frac{C_cO_2 - C_aO_2}{C_cO_2 - C_vO_2}$$

Potential treatments of hypoxemia depend on differentiating the contributions of intrapulmonary shunt, (areas of zero ventilation) and of low V_A/Q areas to venous admixture (Fig. 39.6).[39]

Changes in the shape of oxyhemoglobin disassociation curves, or in the position of the curves obtained at different calculated PIO_2, allows inferences about shunt versus "low V_A/Q" contributing to arterial hypoxemia (Fig. 39.7).[40,41] In complex pulmonary disorders of infancy, it is likely that both shunt and low V_A/Q areas contribute to venous admixture. Improving one contribution to low PaO_2 without distorting other aspects of gas exchange (e.g., raising end expiratory pressure to improve low V_A/Q areas) may exacerbate the respiratory problems. Knowledge of the potentially unstable and rapidly changing nature of gas exchange abnormalities, in real time, may allow physicians to optimize and individualize treatment applications, by means superior to trial and error.

Nitrogen gradient: Because nitrogen does not participate in gas exchange directly, a gradient of arterial to alveolar nitrogen can develop (aADN2) if low V_A/Q areas are present. Assuming ideal alveolar gas composition, alveolar nitrogen is elevated in these areas and absorbed into pulmonary capillary blood. This gradient can be measured and provides another window into V_A/Q mismatch, without specifying the extent or location of these areas. Although nitrogen gradient has been used to measure low V_A/Q areas in respiratory distress syndrome (RDS), where it demonstrates that the major contribution to poor gas exchange is shunt, calculating aADN2 in complex disorders such as severe BPD has not been reported. Krauss et al. measured nitrogen gradients in both healthy term and preterm infants and infants with RDS and demonstrated that low V_A/Q areas do not appear to contribute substantially to gas exchange inefficiency.[42,43]

Trace inert gas technique: The shifting position of the neonatal oxy-hemoglobin dissociation curve and its sigmoidal shape make it difficult to use O_2 and CO_2 as tracers for V_A/Q inequality without many assumptions. Per Wagner PD et al., there is a method of infusing trace quantities of six inert gases of widely ranging solubility and measuring the retention of each gas in blood and excretion in expired gas.[44,45] Using the measured values,

• BOX 39.1 Some Causes of Pulmonary Gas Exchange Failure

- Extreme inspiratory gas hypoxia
- Hypoventilation
- Intrapulmonary and/or extrapulmonary (cardiac) shunt
- Severe ventilation perfusion mismatch (in addition to any shunt present)
- Respiratory gas diffusion disequilibrium

it is possible to estimate shunt, dead space, and a range of low and high V_A/Q lung areas (Fig. 39.8).[46] The technique offers a detailed way of understanding complex lung disorders and the impact of various therapies on V_A/Q matching (Fig. 39.9).[47] However, several assumptions are needed, including steady state conditions and the need to estimate or measure cardiac output. The technique is invasive and not easily applicable to bedside performance in critically ill infants.

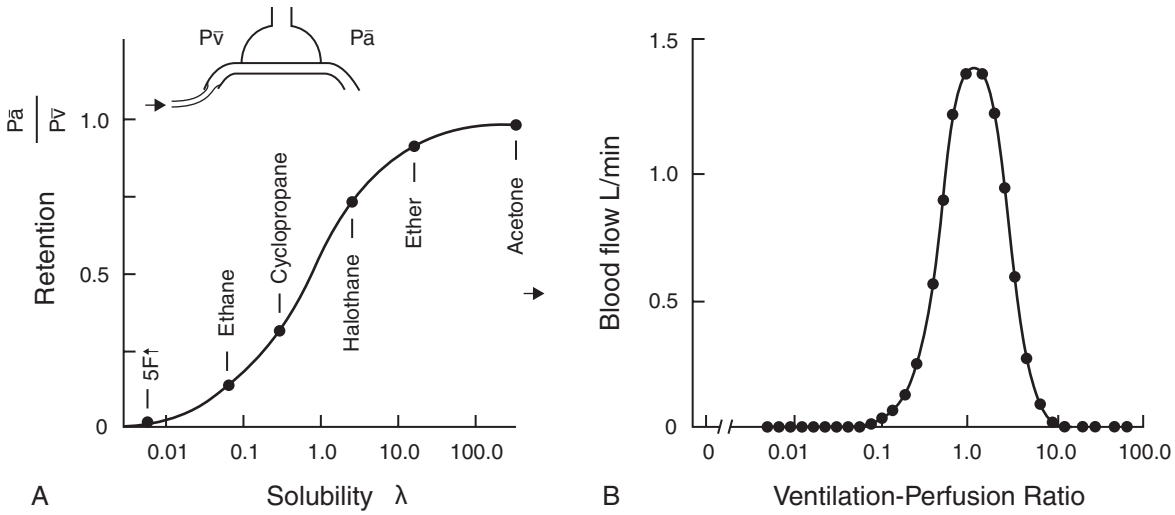
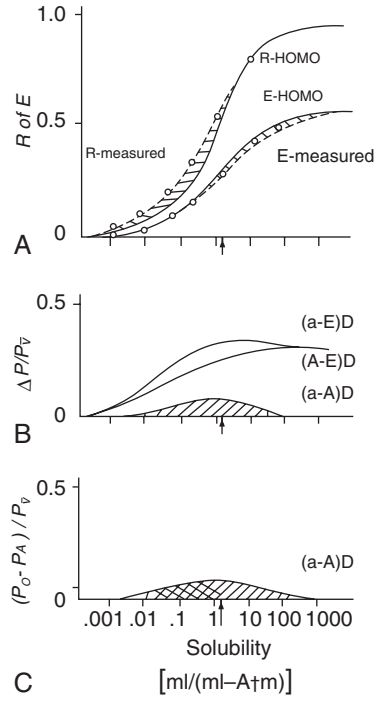
(B) Reducing ventilation:perfusion ratio (VA:Q) from 0.8 to 0.1 shifts the curve to the right. The right shift of each PIO_2–SpO_2 curve from the position of the dissociation curve *(dashed line)* is the PIO_2–PaO_2 difference (kPa), which includes $PaCO_2$/R. The 0.8 curve represents the normal adult curve, which intercepts a PIO_2 of 21 kPa (vertical line) at 97% SpO_2. *R*, Respiratory gas exchange rate. (From Quine D, Wong CM, Boyle EM, et al. Non-invasive measurement of reduced ventilation: perfusion ratio and shunt in infants with bronchopulmonary dysplasia: a physiological definition of the disease. *Arch Dis Child Fetal Neonatal Ed*. 2006;91(6):409-414.)



• **Fig. 39.8** (A and B) Retention-solubility curve showing typical arterial retentions measured with the multiple inert gas technique. This retention-solubility curve can be used to derive a distribution of ventilation-perfusion ratios (B) that is compatible with it. *Pā*, Partial pressure in arterial blood; *Pv̄*, partial pressure in mixed venous blood. West JB. State of the art: ventilation-perfusion relationships. *Am Rev Respir Dis*. 1977;116:919–943.



• **Fig. 39.9** Measured and homogeneous retention (*R*) and excretion (*E*) curves plotted against solubility with *R* and *E* values shown as open circles (*A*). *Hatched areas* between measured and homogeneous *R* and *E* curves occur because of effects of $\dot{V}A/\dot{Q}$ heterogeneity. Their sum is equal to the area under the (a–A)D curve (*B*). As seen in *B*, this area under (a–A)D curve can be found by subtracting (A–E)D curve from (a–E)D curve. *Arrow on abscissa* indicates solubility that is numerically equal to mean $\dot{V}A/\dot{Q}$ of the lung. *C* shows area to the left of mean $\dot{V}A/\dot{Q}$ represented by *double crosshatched area* and is taken as an index of low $\dot{V}A/\dot{Q}$ area. AaDo2 was 14 Torr; calculated low $\dot{V}A/\dot{Q}$ area was 0.07, for this animal. (From Truog WE, Hlastala MP, Standaert TA, McKenna HP, Hodson WA. Oxygen-induced alteration of ventilation-perfusion relationships in rats. *J Appl Physiol Respir Environ Exerc Physiol*. 1979;47:1112–1117, Fig. 1.)

Imaging techniques for quantifying V_A/Q matching: All the above-described techniques are limited by inability to characterize spatial resolution, including cephalad-caudad, proximal-distal, or even segmental differences in gas exchange, using single photon emission computed tomography[48] (SPECT), measured V_A/Q in infants greater than 36 weeks postmenstrual age with moderate and severe BPD. The authors showed that the percentage of lung ventilation associated with relatively normal V_A/Q (between 0.6 and 1.4) correlated inversely with days of assisted ventilation. Recent advances in magnetic resonance imaging (MRI) including ultra-short performance characteristics may provide comparable or improved resolution compared to computed tomography (CT) while still providing accurate estimates of location and severity of V_A/Q abnormalities.[49]

Principles of Ventilation Perfusion Matching

In the healthy adult lung, the overall V_A/Q_p is ~0.8, with ~90% to 95% of the flow of the two gases to areas with V_A/O_p ratios between 0.7 and 1.2, thus allowing for efficient O_2 and CO_2 exchange (see Fig. 39.8). In complex pulmonary disorders, this harmonious overall ratio can be undermined by many factors.

Alveolar ventilation: Alveolar gas must take a circuitous route to the acinar spaces of the developed lung to be available for gas exchange. Inspired gas is diluted by mixing with gas in the anatomical dead space and the physiological dead space. Anatomical dead space includes the conducting airways which do not take part in gas exchange. Physiologic dead space includes areas of the lung that receive part of the minute ventilation but participate minimally in gas exchange. Thus, the term "physiologic" may be inappropriate.

Gas exchange occurs in the acinar units, cumulatively identified as the FRC. This volume of gas helps buffer the inter breath fluctuations CO_2 and O_2 in alveolar gas and hence in pulmonary capillary blood. Any condition limiting the volume or distribution of FRC can have a major adverse impact on efficient gas exchange. A simplified summary of dead space (VDS), dead space

ventilation (V̇Ds), alveolar ventilation (V̇A), total minute ventilation (V̇) and tidal volume (VT), is expressed as follows:

$$\dot{V}A = (VT - VD_S) \times (RR)$$

$$\dot{V}A = [VCO_2 \times (PB - 47)]/PACO_2$$

$$\dot{V}D_S = \dot{V} - \dot{V}A$$

A factor relevant to ventilation in infancy is the relative scarcity of channels of collateral ventilation. Their relative presence or absence (Fig. 39.10) can impact ventilation perfusion matching.[50] For instance, the adverse effect of scarce collateral channels magnifies the risks of creating areas of zero ventilation. Abundant collateral ventilation mitigates the development of diminished FRC but can lead to "series emptying" of the airspaces. Lung gas flow modeling typically assumes parallel emptying. Very slowly emptying compartments, as occur in many illnesses, worsen the tendency for series ventilation as inhaled gas with minimal CO_2 content mixes with still exhaling parts of the exhaled minute ventilation, potentially impairing CO_2 elimination.

Pulmonary perfusion: Forward flow from the right ventricle is continuous but variable in velocity through the cardiac cycle, unlike ventilation, which is discontinuous. One feature of pulmonary perfusion in healthy newborns is that chronotropy is the main mechanism for improving cardiac output. Lusitropy and increased ejection fraction are less useful to the neonatal heart for increasing output. With unchanging tissue O_2 extraction, increased pulmonary blood flow is one mechanism to increase PaO_2. The increase in PaO_2 occurs because mixed venous blood will have higher PvO_2, so there is a lower chance of incomplete pulmonary capillary oxyhemoglobin desaturation. Shorter transit times in some acinar beds may limit the impact of this cardiac lung interaction.

Diffusion gradient: Simultaneous diffusion of O_2 and CO_2 is the whole point of V_A/Q matching. Establishing and maintaining the thinnest possible barriers for diffusion is crucial. The gas exchanging surface can be impaired because of alveolar edema or loss of acinar volume with surfactant deficiency. Terminal airspaces are covered on the airway side with type 1 and type 2 pneumonocytes. Type 1 pneumocytes cover most of the surface area and their unique structure renders them exquisitely thinned. Recent evidence suggests that pulmonary endothelial capillary cells demonstrate the same capacity for extreme thinness.[51]

Diffusing capacity is a difficult measurement, both to perform and to interpret. As a measure of lung function, it is dependent on lung volume, capillary transit time, and intrapulmonary blood volume. The goal is to measure the intrinsic properties of the membrane(s) that pose the barrier. Using CO as the marker gas, the formula for measuring diffusion is:

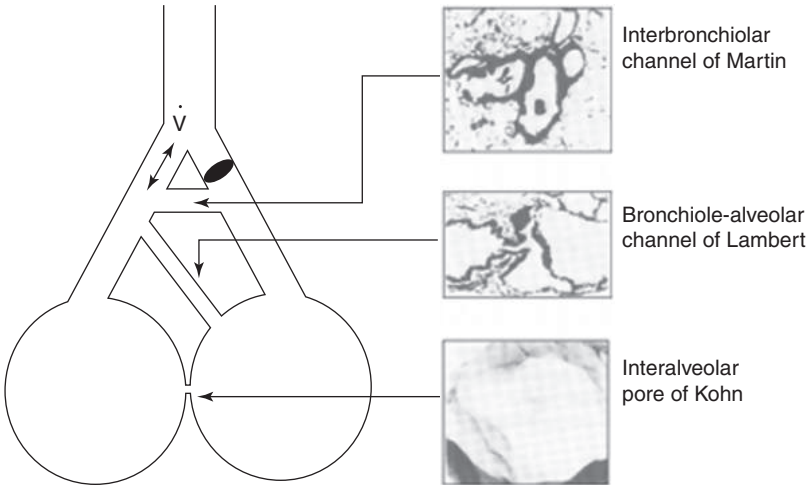
$$D_{LCO} = \dot{V}_A co/P_A co$$

Use of this formula and the technical challenges of measuring so-called steady state diffusing capacity have limited its usefulness in identifying specific conditions in infancy in which targeted therapies may be used. An example of this limited utility is that D_{LCO} can be influenced by changes in left atrial pressure and pulmonary blood flow.[52]

Impairments to infant pulmonary gas exchange: Tissue gas exchange cannot be accomplished at extreme altitude, no matter how efficiently ventilation and perfusion are matched, because of obligate alveolar hypoxia. Similarly, if hypoventilation results in inadequate removal of CO_2 and replenishment of alveolar stores of O_2, then gas exchange fails for reasons unrelated to ventilation perfusion matching. It also fails if profound anemia results in inadequacy of tissue delivery of oxygen no matter how efficient the matching of pulmonary perfusion and alveolar ventilation. Each of these factors can exacerbate gas exchange inadequacy associated with V_A/Q mismatching. Highlighted below are some but not all factors pertinent to infants with underlying complex pulmonary disorders.

Some Specific Conditions Impacting V_A/Q Matching

High altitude: The comparison of postnatal adjustment to birth in healthy infants was studied in a landmark paper by.[53] The authors noted a marked difference when comparing the transition of Tibetan infants born to mothers living for generations at high altitude to that of infants delivered to Han ethnic mothers who recently arrived at very high altitude. This finding suggests that the uneventful fetal to neonatal transition is influenced by genomic considerations and perhaps by epigenetic changes. How those population differences influence the exact mechanisms remain unclear.



• **Fig. 39.10** Pathways for collateral ventilation. (From Terry PB, Traystman RJ. The clinical significance of collateral ventilation. *Ann Am Thorac Soc*. 2016;13:2251–2257. Fig. 1.)

High FIO_2 inhalation and gas exchange: Differences exist in the effects of breathing high FIO_2 between adults and infants. Breathing FIO_2 of 1.0 or close to it has long been recognized as damaging to lungs, particularly to the capillary endothelium and alveolar epithelium. When healthy adults breathe an FIO_2 of 1.0, at least for brief periods, there is no interference with $\dot{V}_A/Q$ matching as judged by the inert gas technique.[54] However, in infant piglets conditioned with prior hyperoxic exposure, pulmonary hypoxic vasoconstriction is blunted, and shunt formation is increased compared to room air exposed control animals.[55] Impact on gas exchange will depend on the duration of the exposure to hyperoxia and the underlying state of maturity of the lungs and the capillary bed. Microvascular injury manifests itself as capillary leakage, raising the possibility of edema, surfactant inactivation and impaired gas exchange on multiple levels.

Elevated pulmonary vascular pressure and gas exchange: Neonatal pulmonary pressure is elevated at birth compared to later in infancy and demonstrates an exaggerated response to multiple stimuli. Increases in pulmonary pressure can induce profound increases in intrapulmonary shunt and extrapulmonary shunt (ductus arteriosus and foramen ovale, interatrial shunts). The increase in pulmonary pressure in response to alveolar hypoxia is more vigorous in lambs than in adult sheep, and the response begins at a higher PAO_2.[56] Vasopressor medications, used to elevate blood pressure systemically, can impair $\dot{V}_A/Q$ matching in lambs if the dose is sufficiently high to raise pulmonary arterial pressure and vascular resistance.[57]

Cardiac dysfunction and gas exchange: In addition to the anatomical locations that persist in their patency post-delivery as sites for right to left shunt, large left to right shunts can also impact $\dot{V}_A/Q$ matching and therefore gas exchange. Excessive pulmonary blood flow via a persistent ductus arteriosus (PDA) or ventricular septal defect (VSD) can have an adverse impact on $\dot{V}_A/Q$ matching as evidenced by lower values for arterial PO_2.

It is beyond the scope of this chapter to detail the impact of biventricular cardiac failure on the metabolic functions of the lung, However, adverse impacts on those functions may exacerbate gas exchange impairment. Enzymes found in abundance in the pulmonary microvascular endothelium include angiotensin converting enzyme and endogenous nitric oxide synthase. Alterations in any of these enzymes, among others, likely adversely impact $\dot{V}_A/Q$ matching.

Positive Pressure Ventilation and Gas Exchange

In the infant undergoing positive pressure ventilation, the degree to which lung inflation compromises venous return is related to the relative compliances of the lung and chest wall. If the infant's lung is poorly compliant and the chest wall is compliant, as in RDS, there is little effect of lung inflation on venous return. If the infant's lung is normally compliant but tight abdominal distention prevents descent of the diaphragm, intrathoracic pressure increases dramatically during positive pressure ventilation, and venous return and cardiac output can be impaired. This mechanism may help explain the circulatory instability of some infants after gastroschisis repair. A similar situation may arise in the preterm infant with pulmonary interstitial emphysema and massive lung overinflation. In such an infant, the heart is tightly compressed between the hyperinflated lungs and the other structures of the mediastinum and the diaphragm. Venous return may be severely limited and venous pressures so increased that massive peripheral edema often accompanies the reduction in cardiac output.

Pulmonary edema and gas exchange: Pulmonary edema is the abnormal accumulation of water and solute in the interstitial and alveolar spaces of the lung.[58,59] In the lung, fluid is filtered from capillaries in the alveolar septa into the alveolar interstitium and then into the lower-pressure extra alveolar interstitium. The extra alveolar interstitium contains the pulmonary lymphatics, which are crucial to maintaining a nonedematous microenvironment. The goal is to avoid net accumulation of interstitial fluid. Pulmonary edema results only when the rate of fluid filtration exceeds the rate of lymphatic removal. There are only three mechanisms by which pulmonary edema can occur: (1) the driving pressure for fluid filtration (filtration pressure) increases, (2) the permeability of the vascular bed (hence the filtration coefficient K_f) increases, or (3) lymphatic drainage decreases, or was insufficiently developed at birth.[60] All three mechanisms can contribute to complex lung disorders, especially BPD, with regionally variable effects on gas exchange.

Acknowledgment

The authors gratefully acknowledge the work of the previous authors of this chapter, Drs. Hansen, Richardson, and DiBlasi. Their contributions to earlier editions of this textbook made our task vastly easier, and we thank them for their previous work.

Neonatal Respiratory Therapy

DAVID J. DURAND AND SHERRY E. COURTNEY

KEY POINTS

- Most neonatal lung diseases are characterized by increased alveolar surface tension causing atelectasis. To offset this, pressure is applied to the upper airway through either noninvasive or invasive techniques. Regardless of the support technique applied, mean airway pressure (mPaw) is a good measure of the amount of support that is applied to offset these surface forces and improve ventilation/perfusion matching and oxygenation.
- There are multiple ways to provide noninvasive support. These include nasal cannula (NC) supplemental oxygen, high-flow nasal cannula (HFNC) which provides some level of positive pressure, nasal CPAP (NCPAP), and noninvasive ventilation modes, both synchronized and non-synchronized.
- There are multiple modes of mechanical ventilation, but all ventilator breaths can be characterized by when they start, how large they are, and the duration of the breath. Modes that support every breath and which provide consistent tidal volume (V_T) appear to be the best for most infants.
- High-frequency ventilation predominantly includes high-frequency jet ventilation (HFJV) and high-frequency oscillatory ventilation (HFOV). The mechanisms by which they provide gas exchange are complex, but the guidelines for adjusting them are simple. HFOV and HFJV are typically used for infants with severe lung disease.
- Noninvasive assessment of the respiratory status of an infant includes a physical exam, chest radiographs, and pulse oximetry. For ventilated infants, assessment of ventilator graphics plays a key role in optimizing ventilator support.

Respiratory Support

Respiratory support for most infants with immature and/or abnormal lungs falls into two broad categories: provision of supplemental oxygen and provision of pressure. Supplemental oxygen is one of the oldest therapies in modern neonatal care, while pressure applied to the upper airways and transmitted to the alveolar level is more recent but is fundamental to offsetting lung pathology. The techniques for providing these therapies can be thought of as a continuum extending from simple nasal cannula oxygen to nasal continuous positive airway pressure (CPAP) and noninvasive ventilation, to sophisticated forms of invasive mechanical ventilation. Moving through this continuum allows for the support of infants with more severe lung disease but is associated with concomitant complexity.

Supplemental Oxygen

Most neonatal lung diseases are characterized by atelectasis and ventilation/perfusion mismatch, resulting in impaired oxygenation. Other common neonatal conditions such as pulmonary hypertension and congenital cardiovascular anomalies can also result in right-to-left shunting and impaired oxygenation. Regardless of the cause, impaired oxygen delivery from the alveoli to the pulmonary capillary bed can lead to reduced oxygen content in the blood (hypoxemia) and tissue (hypoxia).

Administration of supplemental oxygen to newborns with lung disease has been part of routine neonatal care since the first part of the 20th century.[1] An increased F_IO_2 increases the alveolar O_2 tension (P_AO_2) in both well-ventilated and partially ventilated areas of the lung. The resulting increase in the alveolar-arterial O_2 gradient drives O_2 from the alveoli into the pulmonary circulation and partially compensates for the hypoxemia associated with ventilation/perfusion mismatch. However, supplemental O_2 does not improve the underlying atelectasis which may be causing the hypoxemia.

The primary goal of supplemental oxygen is to maintain adequate oxygen availability to the tissues, especially to the central nervous system and the heart. However, achieving the optimal level of supplemental oxygen support requires carefully balancing the toxicity inherent in oxygen supplementation and the potential damage to end organs caused by high arterial P_aO_2 levels against the potential damage caused by hypoxemia.

For infants with hypoxemia secondary to decreased ventilation/perfusion matching, correction of the ventilation/perfusion mismatch is at least as important as giving supplemental oxygen. In most acute neonatal lung diseases this means providing pressure to the upper airway to offset the surface forces leading to alveolar collapse and atelectasis. Thus, finding the ideal level of supplemental oxygen is almost always done in the context of simultaneously finding the ideal level of positive pressure support.

Early strategies to "normalize" oxygenation in preterm infants with the use of high F_IO_2 resulted in high rates of retinopathy of prematurity (ROP) and blindness. The early, liberal use of high levels of supplemental oxygen was then followed by a period when F_IO_2 was restricted, regardless of blood oxygenation level, and was associated with increased rates of neurologic damage and death.[2] The introduction of continuous oxygen monitoring, first with transcutaneous oxygen levels ($P_{TC}O_2$), then with saturation monitoring by pulse oximetry (S_pO_2), led to finer control of oxygenation and attempts to keep infants within tighter oxygenation target ranges.

Target Ranges of O_2 and CO_2

The ideal target ranges for oxygenation and ventilation are not certain and the ranges employed vary to some extent from center to center. General trends and guidelines are outlined below.

Target Ranges for P_aO_2 and S_pO_2

Infants, particularly preterm infants, have an inherently unstable respiratory system that makes it extremely difficult to maintain oxygenation saturation within a narrow range. In addition, preterm infants are easily destabilized by handling and procedures. Normal oxygen saturation for room air–breathing term or healthy preterm infants, after the immediate transition period, is greater than 93%, with P_aO_2 levels above 70 mmHg.[3] This is not surprising, since the mature and healthy infant lung has normal ventilation/perfusion matching and should be able to deliver "normal" amounts of oxygen to the blood.

The search for the ideal S_pO_2 target range in infants can be divided into three broad areas, each with its own body of research. The first is in delivery room resuscitation where recent research has focused on the rate at which the newborn's S_pO_2 should transition from the low intrauterine levels to higher postnatal levels. The second is the debate about the ideal S_pO_2 for infants with BPD, particularly to avoid or treat the pulmonary hypertension that often accompanies severe BPD. Both newborn resuscitation and BPD are addressed in more detail elsewhere in this textbook. The third area of research on ideal S_pO_2 target ranges is in preterm infants during the acute, post-delivery period. This has largely come down to a delicate balance between avoiding the higher S_pO_2 ranges which are associated with an increased risk of ROP and avoiding the lower S_pO_2 ranges which may be associated with increased mortality. Early data showed that ROP severity was associated with the duration of hyperoxemia and emphasized the importance of oxygen monitoring.[4] Higher rates of ROP and a more severe respiratory course appeared to occur in neonatal centers that tolerated higher S_pO_2 levels, and observational data indicated that decreasing the S_pO_2 target range could reduce the rates of ROP.[5–8] Subsequent randomized trials to compare the effects of targeting an S_pO_2 of 85% to 89% versus 91% to 95% had mixed results, with some studies suggesting an increased mortality in infants in the lower S_pO_2 range, and others not finding a difference between the ranges.[9–13] Taken together, these studies suggest that there is an increased risk of ROP but a decreased incidence of death or NEC in the higher target S_pO_2 range. However, the composite outcome of death or major disability does not differ between the groups.[14,15] The most recent European Consensus Guidelines for the Management of RDS suggest targeting S_pO_2 90% to 94%, with alarm limits set between 89% and 95%.[16]

Regardless of the exact target S_pO_2 range desired, maintaining infants within this range is often a challenge. Immature respiratory drive and a compliant chest wall, which increases the risk of atelectasis, frequently combine to make oxygenation inherently unstable. Preterm infants receiving supplemental oxygen appear to spend only half of the time with S_pO_2 within their target range.[17–19] The picture is also complicated because caregivers may tolerate higher than ideal S_pO_2 levels with the purpose of reducing the frequency of desaturation spells or attenuating their severity.[20] While S_pO_2 changes rapidly in response to the infant's oxygenation status, adjustments in F_IO_2 and/or level of positive pressure support may lead to gradual changes in gas exchange. Thus, there is always a risk of responding too slowly to changes in S_pO_2 and a simultaneous risk of over-correcting. In clinical practice, many infants experience hyperoxemia because F_IO_2 is not quickly returned to the basal level when a hypoxemic "spell" resolves.[20] In the end, optimal management of an individual infant's oxygenation status is usually a combination of clearly defined policies, careful S_pO_2 monitoring, and the judgment of experienced clinicians about how to respond to infants who stray from their desired target S_pO_2 range.

Policies of oxygenation monitoring should clearly identify both the intended range and the alarm limits of S_pO_2. Setting S_pO_2 alarm limits near the prescribed S_pO_2 target range can increase the proportion of time premature infants spend within the target range.[17] However, narrow alarm limit ranges will increase the number of times the monitor alarms and can lead to "alarm fatigue."[21] Staff compliance with S_pO_2 alarms, and their response to them plays an important role in keeping infants in the target S_pO_2 range. For this reason, staff education and communication are important components of maintaining infants within a target S_pO_2 range.[22–24]

Automated systems to adjust F_IO_2 to maintain S_pO_2 within a target range have been investigated in multiple trials and show consistent improvement in the maintenance of S_pO_2 within the target range as well as reductions in oxygen exposure and staff workload.[25–28] While theoretically attractive, this technology is not yet widely available for clinical use.

PCO_2 and pH Target Ranges

Tolerance to higher carbon dioxide levels may reduce the need for support and reduce the duration of ventilation. However, the results of clinical trials of permissive hypercapnia have been inconsistent. Initial trials suggested faster weaning of infants from mechanical ventilation when higher PCO_2 levels were tolerated.[29,30] On the other hand, there are data suggesting that hypercapnia impairs cerebral autoregulation in the newborn premature infant, suggesting a need for caution in tolerating acute hypercapnia.[31,32] The most recent large study of hypercapnia found no difference in the rate of death or BPD, and showed no difference in adverse sequelae at follow-up.[33,34] Taken together, these studies suggest that the optimal safe range of PCO_2 has yet to be determined. In clinical practice, most centers tolerate some degree of hypercapnia (e.g., PCO_2 in the 50s) in acute lung disease and tolerate a greater degree of compensated hypercapnia in infants with more chronic disease.

General guidelines:

- Rapid changes in PCO_2 should always be avoided. In particular, there is concern about the impact of PCO_2 changes on cerebral blood flow.
- Hypocarbia ($P_aCO_2 < 35$) should always be avoided. In most infants, hypocarbia represents excessive minute ventilation, with the associated risks of lung damage and cardiovascular compromise from excessive pressure and/or volume. Hypocarbia has also been associated with neurodevelopmental morbidity in multiple studies.[35] While hypocarbia was at one time used as a standard therapy for decreasing pulmonary vascular resistance in infants with pulmonary artery hypertension, that approach has almost disappeared with the ready availability of inhaled nitric oxide (iNO) as a far more safe and effective way to decrease pulmonary vascular resistance.
- The degree of hypercarbia which can be tolerated probably varies with post-natal age and with the degree of compensatory metabolic alkalosis. Most centers are comfortable tolerating PCO_2 levels in the 60s (with an acceptable pH) in infants with chronic lung disease.
- The target pH for most infants is usually around 7.25 to 7.35. Higher pH values typically represent hyperventilation and hypocarbia, whereas pH values less than 7.20 to 7.25 raise concerns about the potential impact of acidosis on cellular function, including adverse effects on myocardial function and cardiac output.

Types of Noninvasive Respiratory Support

In neonates, supplemental O_2 can be administered by itself or in conjunction with positive pressure techniques. The simplest ways of providing O_2 without positive pressure include the head box or tent, mask, and low-flow nasal cannula (NC). Other types of support, including high-flow nasal cannula (HFNC), NCPAP, noninvasive ventilation (NIV), and invasive mechanical ventilation all provide some level of positive pressure.[36]

Head Box or Tent O_2 Administration

With a head box or tent, gas at the desired F_IO_2 is delivered to a box or tent which is placed over the infant's head. The gas is typically heated and humidified and must be delivered at a flow rate that assures rapid exchange of gas in the hood and prevents accumulation of exhaled CO_2. This technique is simple but cumbersome, and somewhat limits access to the infant. Although widely used in previous years, O_2 supplementation via head box or tent has been almost entirely replaced by nasal canula oxygen.

Nasal Cannula O_2 Administration

NC devices deliver a constant flow of blended gas at a set F_IO_2 to the nostrils. Typically, the F_IO_2 is set with a blender that mixes 100% O_2 with room air, and the flow is set with a simple meter that can be adjusted to the desired rate, measured in L/min. At low flows, usually defined as less than 1 or 2 L/min, the gas is typically not heated or humidified. With low-flow NCs, the effective F_IO_2 is determined by the relative contribution to each breath of the gas from the NC and the amount of room air that the infant entrains or breaths from around the NC. During mouth breathing or crying, the infant is breathing exclusively room air and derives no supplementation from the NC. For any baby with a given inspiratory flow, increasing the NC flow will increase the amount of gas that the baby inhales from the NC and decrease the amount that is entrained from the surrounding room air, so that at some NC flow rate the baby's F_IO_2 is essentially the same as the F_IO_2 of the NC. However, the point at which the NC flow rate is sufficient to make the baby's F_IO_2 equal to the NC F_IO_2 is dependent upon multiple factors and is not easily measured.[37] In clinical practice, the exact inhaled F_IO_2 is not as important as the baby's oxygenation status, typically measured by pulse oximeter (S_pO_2). It is important to note that a NC at low flow rates does not provide any pressure to the lungs, so is most suited to infants who do not need some level of positive pressure.

High-Flow Nasal Canula

Depending on the size of the baby, cannula flows greater than 1 to 2 L/min can produce significant positive pressure at the nose, essentially providing a form of NCPAP. In general, NC flows above 2 L/min are considered HFNC, and the maximal HFNC flow used in NICUs is usually around 8 L/min. With HFNC most, or all, inspired gas reaching the baby is from the cannula rather than entrained room air. For this reason, HFNC systems should use gas that has been conditioned to avoid drying of the nose and mucosal damage. Conditioning of the gas includes heating and humidification, leading some to refer to this technique as HHHFNC (heated, humidified, high-flow nasal cannula).[38]

HFNC support is adjusted by varying the flow rate and F_IO_2. With HFNC, the effective pressure applied to the infant's upper airway increases as the HFNC flow increases. Depending on the HFNC flow rate, the size of the nasal cannula prongs, and the size of the infant, significant or even excessive levels of NCPAP can be delivered. The major advantage of HFNC is the simple nasal interface, typically with loose-fitting nasal prongs. This makes a system of support that is easy to manage and is generally perceived as comfortable for the infant. However, the significant disadvantage of HFNC as a method of providing NCPAP is that the level of NCPAP is not measured and is dependent on multiple factors. This leads to potentially under- or over-estimating the level of NCPAP support the HFNC is providing. HFNC may "wash out" CO_2 from the hypopharynx, so it can be effective in PCO_2 control if high or consistent levels of NCPAP are not required.[39]

Despite the widespread use of HFNC in preterm infants, the data on its efficacy compared to NCPAP is equivocal. The broad use of HFNC is largely due to ease of use, less risk of injury to nares, and perceived increased patient comfort with the use of an HFNC. In large trials comparing HFNC to NCPAP for support following extubation, there are no significant differences.[40,41] The data on the use of HFNC as a primary mode of support is mixed. Several trials have suggested that there is no difference between HFNC and NCPAP.[42,43] On the other hand, several large trials comparing HFNC to NCPAP as the initial mode of support concluded that HFNC has a significantly higher failure rate.[44–46] As suggested by recent reviews, the reduced nasal irritation seen with HFNC makes it an attractive option despite evidence that it is less efficient than NCPAP in preventing intubation.[47,48]

In most cases, the choice between HFNC and "real" NCPAP comes down to a balance between infant comfort, simplicity, and the ability to accurately measure and control the level of NCPAP. Given concerns about the effectiveness of HFNC in preventing intubation, it is probably most suited to infants at relatively low risk of requiring intubation or re-intubation.

Nasal Continuous Positive Airway Pressure

The care of preterm infants with respiratory distress syndrome (RDS) was revolutionized with the introduction of NCPAP in 1971.[49] Because RDS is characterized by decreased alveolar compliance and atelectasis, positive pressure applied to the upper airway will at least partially offset the surface forces leading to alveolar collapse. The prevention of alveolar collapse preserves functional residual capacity (FRC) and preserves lung compliance. This both improves ventilation/perfusion matching and decreases work of breathing. In addition to its effect at the alveolar level, NCPAP provides positive pressure to the entire airway. In patients with laryngomalacia, tracheomalacia, or bronchomalacia, positive pressure can also stabilize the "floppy airway" by preventing airway collapse during expiration. This is an important role for NCPAP in babies with congenital upper airway anomalies, as well as in babies with distal airway abnormalities associated with severe BPD.

There are several nasal interfaces for NCPAP, each with their own advantages and disadvantages. Probably the most common approach uses double nasal prongs which extend only a short distance into the nose, allowing relatively little leak and good transmission of pressure.[50] NCPAP can also be delivered through a mask that fits tightly over the nose, leaving the mouth uncovered. In many centers, alternating between the tight-fitting short prongs and the nasal mask is seen as an ideal compromise for effectively delivering the measured pressure, and providing an interface that does not cause nasal irritation or skin breakdown.

The positive pressure for NCPAP can be generated in several ways. With "ventilator CPAP," the CPAP circuit is attached to a conventional ventilator that is set to deliver a fixed CPAP level—essentially the same as ventilation with a frequency of 0 breaths/

min. The level of CPAP support and the F_IO_2 are set at the ventilator, and inspiratory gas heating and humidification are accomplished with a standard in-line humidifier. With "bubble CPAP," the pressure is generated by using a water column as an adjustable pop-off valve at the end of the expiratory limb of the respiratory circuit. The level of CPAP pressure is adjusted by the height of the water column above the end of the expiratory limb. This is an extremely simple system for monitoring the integrity of the CPAP device (lack of bubbles suggests there is an upstream leak or other problem) and for adjusting the level of CPAP (by adjusting the height of the water column). However, the depth of the water column is not an accurate predictor of the level of NCPAP delivered at the nasal interface.[51,52] There are commercial integrated bubble CPAP systems that incorporate heating and humidification and the "bubble" component. However, simple bubble CPAP systems can be easily assembled from standard NICU supplies.

One of the intriguing aspects of bubble NCPAP is the possibility that the bubbling at the end of the expiratory limb is actually advantageous. Bubbling results in small oscillations in pressure in the expiratory limb of the circuit which are transmitted "upstream" to the nasal interface and then to the airways.[53] It is not clear whether this oscillation has an actual clinical impact.

In most North American NICUs, the typical levels of NCPAP for preterm infants range from 5 to 8 cmH_2O. There is some evidence that the higher end of this range is more effective in preventing extubation failure in preterm infants who still need supplemental oxygen at the time of extubation.[54]

Bi-Level NCPAP

A variation of NCPAP provides two alternating levels of NCPAP support, with the theoretical advantage of optimizing lung recruitment and minimizing atelectasis without causing overdistension. This approach is frequently used in adults and is termed BiPAP (biphasic positive airway pressure). In infants, it is usually referred to as SiPAP and can be thought of as providing alternating levels of CPAP, or as providing CPAP with intermittent sigh breaths, usually only 1 to 3 cmH_2O above the lower baseline CPAP level. Although SiPAP/BiPAP has a set rate with alternating upper and lower pressures, it typically does not provide ventilation in terms of a set respiratory rate or tidal volume. Rather, it provides varying levels of NCPAP, with the patient breathing spontaneously above these NCPAP levels. There is conflicting evidence about whether BiPAP can increase CO_2 elimination and oxygenation compared with NCPAP.[55,56] There is also conflicting evidence about whether BiPAP improves respiratory outcomes. There is some evidence that synchronized BiPAP (done using a Graseby capsule, described below) decreases the duration of respiratory support compared to NCPAP.[57] However, un-synchronized BiPAP does not appear to be superior to NCPAP in sustaining extubation.[58]

Noninvasive Ventilation

The use of a nasal interface, rather than an endotracheal tube, to provide ventilatory support dates to the early days of neonatal mechanical ventilation and remains an active area of research.[36,59] It is an attractive option because it may provide a higher level of support than NCPAP while avoiding the potential complications of an endotracheal tube. It is particularly attractive for less mature infants whose respiratory status is compromised by a combination of RDS, immature and collapsible chest wall, decreased respiratory drive and apnea, and decreased respiratory muscle strength and endurance.

The nomenclature of NIV can be confusing, reflecting the fact that there are multiple ways to apply a mechanical ventilatory breath to a nasal interface. The acronyms NIMV (nasal intermittent mandatory ventilation or noninvasive mechanical ventilation) and NIPPV (nasal intermittent positive pressure ventilation) are sometimes used interchangeably with NIV.

In preterm infants, the cycling positive pressure of NIV at the upper airway produces an intermittent respiratory stimulus which could decrease central apnea. In addition to this stimulatory effect, it is possible that NIV also decreases apnea by facilitating lung recruitment and decreasing the work of breathing. At least one study has suggested that unsynchronized NIV can significantly reduce apnea.[60] Compared to NCPAP, synchronized NIV appears to decrease the work of breathing in infants with RDS.[61–63]

Clinical trials comparing NIV to NCPAP for prevention of extubation failure have shown mixed results, probably because some studies have used an unsynchronized form of NIV and others have looked at synchronized NIV. Synchronized NIV has been shown in small studies to reduce extubation failure compared to NCPAP.[64–67] However, the largest trial of NIV vs NCPAP combined synchronized and non-synchronized NIV modes and showed only a marginal decrease in the rate of post-extubation failure.[68] Recent meta-analysis suggests that NIV may be superior to NCPAP for preventing extubation failure, but does not reduce BPD or death, and that synchronization may be important for the successful application of NIV.[69,70]

NIV, both synchronized and unsynchronized, has also been used in early RDS to decrease the need for intubation. Synchronized NIV appears to be superior to NCPAP in reducing the need for intubation.[71] The data from trials comparing unsynchronized NIV to NCPAP are mixed, with some showing a decrease in the need for intubation,[72,73] and others showing no difference.[74,75]

The practical use of NIV is limited by several important factors. The nose and upper airway act as a filter so that pressures set at the ventilator are attenuated at the alveolar level. In essence, what is delivered to the lung may be significantly less than what is set at the ventilator and cannot be easily monitored. With unsynchronized NIV breaths delivered through small nasal cannula prongs (e.g., RAM cannula), there appears to be no significant transmission of tidal volume to the infant, suggesting that the main effect of NIV may be a simple increase in mean airway pressure.[76]

The simplest form of NIV is conventional time-cycled pressure-limited ventilation that uses the same circuits and gas-conditioning devices used for invasive ventilation. This approach, sometimes termed NIMV (nasal intermittent mandatory ventilation) has the advantage of simplicity, but the lack of synchrony with the infant makes it a poor form of support. The non-synchronized breaths are frequently delivered as the infant is attempting to exhale, leading to increased work of breathing and inefficient pressure delivery.

Synchronization of NIV is limited by the synchronization method. Many of the older studies of synchronized NIV used a small pressure sensor (Graseby pressure capsule) which was placed on the abdomen to detect abdominal movement at the onset of inspiration. However, this technique is not available with commercially produced ventilators in the US. Other approaches to synchronizing NIV which rely on flow sensing are not ideal because of the problems with leaking around the nasal interface leading to undetected breaths and/or "auto-cycling" of the ventilator.

Noninvasive Ventilation and Neurally Adjusted Ventilatory Assist

Neurally adjusted ventilatory assist (NAVA) is a mode by which the ventilator pressure is adjusted in proportion to the electrical activity of the diaphragm, as measured by electrodes embedded within a special nasogastric or orogastric tube. Although used for both invasive and noninvasive ventilation, NAVA is a particularly attractive way to provide synchronized NIV. With NAVA, the triggering of breaths is very sensitive to spontaneous inspiratory effort and is not affected by the leaks that make flow-synchronized NIV problematic. It also has the advantage of adjusting the size of the mechanical breath to the infant's respiratory effort. In clinical trials, NAVA appears to be an effective technique for synchronizing both invasive and noninvasive support.[77–83]

Noninvasive High-Frequency Ventilation

Several investigators have explored delivering high-frequency oscillatory ventilation (HFOV) through a nasal interface.[84] It is unclear whether nasal HFOV is superior to NCPAP in terms of CO_2 exchange.[85,86] At least one study suggests that it is not superior to NIV in reducing extubation failure, but is associated with less feeding intolerance.[87] A review of European NICU practices suggests that this technique has been used in a number of European NICUs.[88] In the US, it remains an intriguing investigational technique.

Nasal Interface

With any form of NIV, the nasal interface employed is usually short prongs or a nasal mask. NCPAP prongs are attached to tubing that provides both an inspiratory and expiratory limb. Prongs should fit snugly into the nares without blanching the surrounding tissue. If a nasal cannula is used, there is no expiratory limb and the prongs used must be smaller than those used with NCPAP to provide for exhalation around the nasal prongs. The cannula thus delivers significantly less pressure than is measured at the ventilator.[76] The risks of nasal damage and obstruction sometimes observed during the use of NCPAP are also present with NIV. Proper application and maintenance of the nasal interface and avoidance of excessive force on the nasal septum are important to avoid these complications.

Complications of Noninvasive Support

The complications of NCPAP or NIV are related to the gas pressure that is applied to the alveoli and to direct contact of the interface with the nose. With any of the noninvasive modalities that provide positive pressure, there is the risk of providing too much pressure and over-inflating the lung, both increasing the work of breathing and potentially causing both acute and chronic lung damage. Excessive pressure can also reduce venous return, increase pulmonary vascular resistance, and reduce cardiac output.

If nasal prongs are too large or are applied with too much pressure over the nasal septum, they can produce erosions or pressure necrosis that sometimes requires the interruption of NCPAP or NIV. Avoiding these complications while keeping the nasal prongs in place is a task that requires careful observation and skill.

During the application of NCPAP or NIV, there is also a chance of gas being pushed into the stomach. A nasogastric catheter is often used to avoid excessive gas accumulation and consequent gastric distention.

Choice of Noninvasive Support

Noninvasive support can be useful in preventing progressive atelectasis and respiratory decompensation, both early in the neonatal course and following extubation.[36] While NCPAP is the standard against which other techniques are measured, there may be advantages to HFNC and/or synchronized NIV in selected patients. HFNC is an attractive way of providing support because it is less likely to cause nasal injury than NCPAP. However, it has the significant disadvantage of not providing easily measured and adjusted levels of NCPAP, so it is probably most useful in post-extubation infants, and as a primary form of support for infants who are at relatively little risk of needing intubation. Synchronized NIV may offer advantages over NCPAP or un-synchronized NIV in preventing intubation and reducing extubation failure, although data are not yet available on its impact on long-term outcomes such as mortality or BPD.

HFNC and various forms of NIV are likely to become a larger part of NICU respiratory support as neonatal caregivers continue to search for the best ways to support infants with non-invasive techniques. As with most techniques in the NICU, well-designed protocols, rigorous training of staff, and meticulous attention to detail may well be as important, or more important, than the specific modality employed.

Weaning From Noninvasive Support

There are multiple approaches to weaning a baby from noninvasive support with supplemental oxygen to being unsupported in room air. While the most conservative approach would be a gradual progression from NIV to NCPAP to HFNC to NC to no support, this approach is probably not necessary for all infants. An argument can be made that preterm infants, with their compliant chest walls and tendency to atelectasis, should remain on some form of positive pressure support as long as they have any ventilation/perfusion mismatch and need for supplemental oxygen. With this strategy, infants would remain on NIV, NCPAP, or HFNC until $F_IO_2 = 0.21$, then be transitioned to room air without support.

There is relatively little published data to guide the decision of when to wean from positive pressure (HFNC, NCPAP, NIV) to supplemental oxygen via low-flow NC, or to room air. One randomized study examined strategies for managing infants who were stable on NCPAP 4 to 6 cmH_2O with F_IO_2 less than 0.25, and concluded the optimal strategy was to discontinue NCPAP, but resume it for at least 48 hours if the infant failed the transition, with failure defined as increased work of breathing, increased apnea/bradycardia, F_IO_2 greater than 0.25, or PCO_2 greater than 65.[89] However, a recent study suggested that continuing NCPAP for 2 weeks beyond the point where infants who were stable on NCPAP 4 to 6 cmH_2O and F_IO_2 less than 0.25 resulted in significantly improved FRC through hospital discharge.[90] This would suggest that the possible advantages of improving lung volume should be carefully weighed against the difficulty of continuing NCPAP in a maturing infant.

There are also multiple approaches to weaning from NCPAP, including "sprints" on and off NCPAP, a gradual decrease in NCPAP pressure, and abrupt discontinuation of NCPAP. All of these approaches work, and there does not appear to be a major impact of strategy on the outcome.[91–93] A strategy of abrupt discontinuation of NCPAP may lead to earlier discontinuation than a strategy of gradual weaning.[94]

Regardless of the strategy used in transitioning an infant from noninvasive positive pressure support, it is essential to observe the infant closely for changes in gas exchange and work of breathing.

Invasive Mechanical Ventilation

For some infants, supplemental oxygen and the positive pressure of noninvasive support are not sufficient to compensate for the degree of lung disease. For these infants, invasive (via an endotracheal tube) ventilation is required. Mechanical ventilation is designed to achieve two things: oxygenation (via optimal mean airway pressure) and CO_2 removal (via minute ventilation) while causing minimal lung injury. This can be accomplished with multiple types of "conventional" ventilators which mimic normal tidal breathing, and with high-frequency ventilators which cause very efficient mixing of gas between the alveoli and the airway without tidal breathing.

Intubation

Neonatal intubation is a technically challenging procedure that requires significant time to master, often requires multiple attempts, and is associated with a significant risk of complications.[95,96] Although usually a quick procedure when performed by a skilled practitioner, it is still uncomfortable for the infant and associated with significant autonomic changes, including blood pressure, oxygenation, and cerebral perfusion pressure. Both the US and Canadian recommendations for all non-emergent intubations include the use of analgesia or a combination of analgesia and muscle relaxation; simple sedation is not sufficient.[97,98] Even skilled practitioners find that paralysis increases success and decreases the potential trauma of intubation. For this reason, some centers perform all elective intubations, including for surfactant administration, after what is essentially a rapid sequence anesthesia induction. In this case, infants need to be supported until they are fully recovered from the medications, usually within 20 to 60 minutes.

Although not directly addressed in the US and Canadian guidelines, the recommendation for analgesia with each intubation could be extrapolated to other laryngoscopic procedures such as surfactant instillation with intubate/surfactant/extubate (INSURE) or less invasive surfactant administration (LISA) techniques. The discomfort and attendant physiologic changes of intubation are largely associated with the laryngoscopy and stimulation of the laryngeal area, not just the placement of an endotracheal tube (ETT). However, providing adequate levels of analgesia for INSURE or LISA decrease the ability to immediately transition to noninvasive support following the surfactant instillation.

A significant advance in intubation techniques is the introduction of more sophisticated laryngoscopes into the NICU. These allow visualization of the upper airway with a small camera at the tip of the laryngoscope and allow members of the team other than the one performing the intubation to see the anatomy and the procedure. This is useful both for teaching and for instrumentation of the difficult airway.

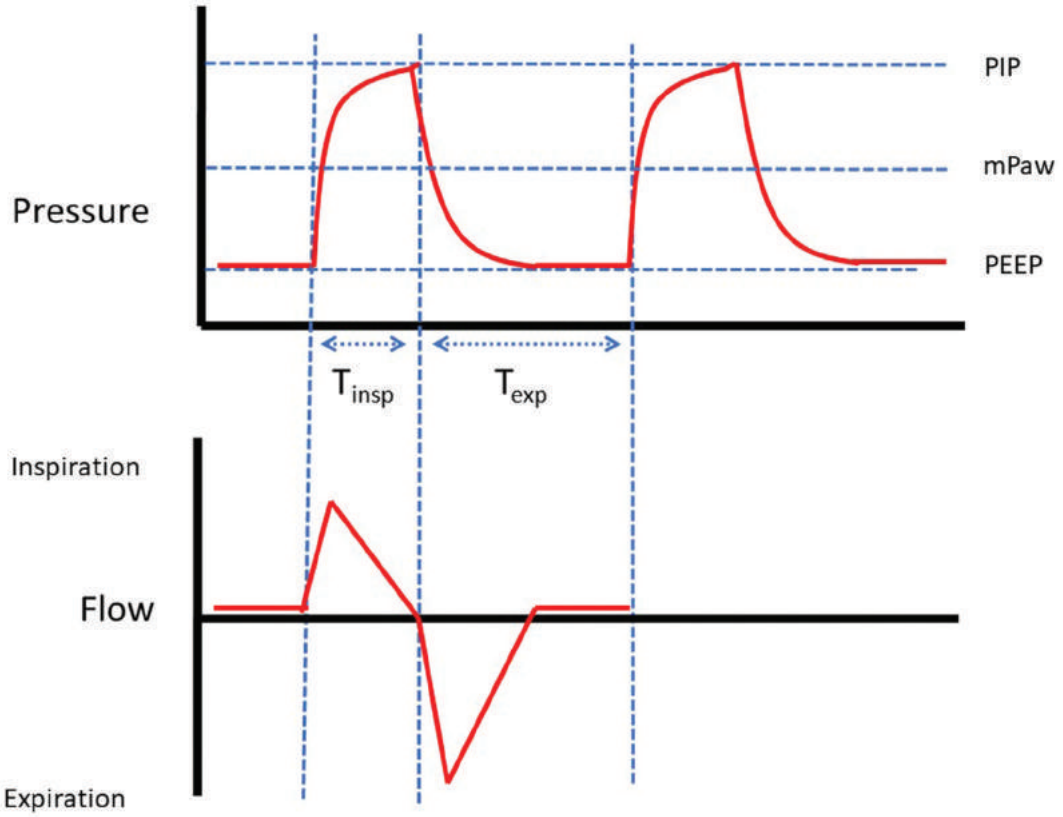
Conventional Ventilation

Despite the wide range of ventilator devices and strategies available, the fundamental physiology of mechanical ventilation follows a few simple rules. Most neonatal lung diseases are characterized by atelectasis, so providing optimal pressure to counteract surface forces is paramount for optimizing both oxygenation and ventilation. Basic principles and guidelines include the following:

- Oxygenation is impaired by the ventilation/perfusion mismatch which results from atelectasis. Assuming the lung is not over-distended, increasing mean airway pressure (sometimes abbreviated MAP, but more appropriately mPaw) will decrease atelectasis and improve oxygenation.
- Oxygenation can also be impaired by an over-inflated lung which reduces venous return to the heart.
- CO_2 exchange is impaired by inadequate minute ventilation which results from inadequate tidal volume and/or inadequate respiratory rate. Assuming adequate inspiratory and expiratory times (T_{insp} and T_{exp}), increasing minute ventilation will increase CO_2 exchange. For most infants with acute lung disease a V_T of approximately 5 mL/kg is appropriate.
- Synchrony between the infant and the ventilator will decrease the work of breathing and make both patient breaths and mechanical breaths more efficient. Synchronizing the ventilator with the patient includes matching the onset of the ventilator breath with patient inspiration, as well as matching the duration of the ventilator breath (T_{insp}) with the onset of patient exhalation. In lung diseases that are restrictive and without a significant obstructive component (e.g., RDS) the lung time constant ($R \times C_L$) is small, meaning there is rapid transmission of pressure from the upper airway to the alveolus, so short T_{insp} and short T_{exp} are effective. In small infants with significant RDS, T_{insp} as low as 0.2 to 0.3 seconds may be effective.

There are multiple neonatal ventilators on the market, each with multiple modes of ventilation, and each of these modes has multiple parameters which can be adjusted. To make matters more confusing, some modes have similar names but different mechanisms of action, or different names but similar modes of action. Although this leads to what seems like an unlimited number of choices about how to best ventilate an infant, these choices can be simplified by understanding the basic physiology and nomenclature of modern ventilation.[99,100] Regardless of the ventilator brand or mode of ventilation, it is helpful to think of a ventilator breath as characterized by several components which can be used to describe any conventional tidal mechanical breath (Fig. 40.1). Ventilator breaths can be described by the following:

- Onset of the breath, termed the *trigger*. Breaths that are initiated because a clock in the ventilator has determined it is time to deliver a breath are termed *time-triggered* breaths. Breaths that are initiated by the patient are termed *patient-triggered* breaths.
- Size of the breath, termed the *limit*. Historically most adult ventilators delivered a set volume with each breath (*volume-limited* breath) and most neonatal ventilators delivered a set inspiratory pressure with each breath (*pressure-limited* breath). More sophisticated neonatal ventilators can deliver both volume- and pressure-limited breaths. In addition, with some ventilator modes, the size of the breath is determined by constantly adjusting combinations of volume, pressure, and flow. There is good evidence that this technique of *volume-targeted* ventilation, compared to pressure-limited or volume-limited ventilation, reduces death, intraventricular hemorrhage (IVH), and BPD.[101]
- Duration of the breath or when the breath ends, termed the *cycle*. A breath that lasts for a fixed inspiratory time (T_{insp}) is termed *time-cycled*. A breath that is terminated when inspiratory flow drops below a certain point is termed *flow-cycled*. Because the decrease in inspiratory flow is dependent on lung



• **Fig. 40.1** Simplified Diagram of Pressure and Flow Versus Time With Time-Cycled Pressure-Limited (TCPL) Ventilation. T_{insp} begins when the breath is triggered, with flow rapidly increasing to maximum, then decreasing as pressure increases to peak inspiratory pressure *(PIP)*. At the end of inspiration, the breath cycles off and the patient is allowed to exhale. Early exhalation is typically at high flow, then drops as the lung approaches FRC which is maintained by positive end expiratory pressure *(PEEP)*. Note that mean airway pressure *(mPaw)* is influenced by every component of the pressure wave, including PEEP, PIP, T_{insp}, inspiratory and expiratory flow pattern, and rate.

compliance and respiratory effort, the duration of flow-cycled breaths is partially controlled by the infant.

- Inspiratory flow pattern which is either a fixed inspiratory flow *(constant-flow)* or can vary with patient demand *(demand-flow)*. With constant flow ventilators, there is the possibility that the flow is not sufficient to meet the patient's need during early inspiration, resulting in "flow starvation" which increases work of breathing and patient discomfort.

Below are some of the more commonly used neonatal ventilation modes, presented in the general order of development and clinical adoption.

Time-Cycled Pressure-Limited Intermittent Mandatory Ventilation

Time-cycled pressure-limited intermittent mandatory ventilation (TCPL IMV) is sometimes referred to as TCPL, IMV, or IPPV (intermittent positive pressure ventilation). It is the oldest form of neonatal mechanical ventilation, and is conceptually very simple, although of limited utility in most modern NICUs. Characteristics of TCPL IMV include:

- The size of the breath is pressure-limited, as the ventilator delivers a peak inspiratory pressure (PIP), then returns to end-expiratory pressure (PEEP). In general, adjusting PEEP affects FRC, and adjusting the driving pressure (PIP – PEEP) affects the tidal volume.
- The breaths are at a fixed rate and time-triggered—for example, at a rate of 30/min, a breath occurs every 2 seconds regardless of the infant's respiratory effort.
- The breaths are time-cycled so inspiration lasts a fixed period of time (T_{insp}) regardless of whether the infant is trying to inhale or exhale at the end of the ventilator breath.
- Bias gas flow is fixed at a set flow rate (L/min), which means there is a set maximal inspiratory flow rate and a constant flow of bias gas in the expiratory limb of the ventilator circuit.

The advantage of TCPL IMV is mechanical and conceptual simplicity, and it works well for paralyzed or heavily sedated patients for whom the ventilator is doing all the work of breathing. However, it is a difficult mode to use effectively in a spontaneously breathing patient. If the patient is trying to breathe spontaneously, the ventilator onset of inspiration and duration of inspiration do not synchronize with the patient's efforts. Not only are the baby's inspiratory efforts not supported but, more importantly, the baby may be trying to exhale while the ventilator is delivering a breath. In addition, the fixed flow of the gas on the inspiratory side of the circuit can be a limitation if the patient (particularly a large, strong infant) has a higher inspiratory flow

demand than the ventilator provides. For these reasons, TCPL IMV is rarely used except in anesthetized or paralyzed patients with no respiratory drive.

Synchronized Intermittent Mandatory Ventilation

The development of accurate flow sensors led to neonatal ventilators which can deliver breaths in synchrony with the patient's respiratory effort. The first of these modes to be developed was synchronized intermittent mandatory ventilation (SIMV). With SIMV, there is a fixed rate or number of breaths per minute (the "mandatory" part of the name) which last for a fixed duration (T_{insp}). However, the timing of these breaths coincides with at least some of the patient's breaths. For example, at a set SIMV rate of 30, if the baby is breathing 50 times a minute, the ventilator will sense the baby's respiratory rate and try to deliver 30 breaths that coincide with the onset of the baby's breath, rather than delivering a breath exactly every 2 seconds. The baby's other 20 breaths will be unsupported, with the baby inhaling from the bias gas flow which is maintaining PEEP. SIMV, which does not support all breaths, has been largely replaced by modes such as SIMV/PS or A/C which can support all breaths.[102] Characteristics of SIMV include:

- Size of the breath can be either volume-limited or pressure-limited.
- The breaths are delivered at a set rate, but the ventilator tries to synchronize these breaths with the patient's onset of inspiration. If the baby is apneic, the ventilator defaults to delivering time-triggered breaths at the set rate.
- Depending on the ventilator and the mode, breaths can be either time-cycled (fixed T_{insp}) or flow-cycled (duration of the breath varies according to the patient's inspiratory flow pattern). In general, if it is not specified as "SIMV with flow cycle," SIMV refers to time-cycled breaths with a fixed T_{insp}.
- One of the advantages of synchronizing the ventilator breath with the patient's breath is that a shorter T_{insp} is usually effective in delivering an adequate tidal volume since the ventilator is not "fighting" the baby to deliver the breath. Lower PIP and slightly shorter T_{insp} are often sufficient because the infant's inspiratory effort contributes to the generation of the V_T.

Assist/Control Ventilation

A logical extrapolation from SIMV, which supports some patient breaths, is a mode that supports all patient breaths. Sometimes referred to as "patient triggered ventilation" (PTV) in early studies, A/C ventilation supports every spontaneous patient inspiration with an *assisted* synchronous ventilator breath. Characteristics of A/C include:

- The size of the breath can be either volume-limited or pressure-limited, or in some ventilators, limited or targeted by a sophisticated combination of volume, pressure, and flow.
- The breaths are patient-triggered so the rate is set by the infant, as the ventilator delivers a breath with the onset of each inspiration. A backup rate is set so the ventilator will deliver a minimum number of breaths if the infant becomes apneic or does not trigger the ventilator.
- The breaths may be time-cycled (T_{insp} is set) or flow-cycled (T_{insp} is set by the patient's inspiratory flow).

The advantages of A/C ventilation include a reduction in spontaneous breathing effort relative to SIMV because A/C ventilation assists every inspiration.[103] Assisting every spontaneous inspiration in A/C mode ventilation appears to prevent diaphragmatic fatigue and can reduce the duration of weaning and ventilator dependency compared with IMV.[104,105]

One of the potential problems with A/C ventilation is *autocycling*. Successful A/C ventilation, if triggered by respiratory flow, depends on sensitive and accurate detection of when the infant has initiated a breath. If there is a leak around the endotracheal tube, the ventilator may be unable to distinguish this leak from the patient inspiratory effort and will deliver ventilator breaths at the maximal rate. Although there are ways to offset the effect of endotracheal tube leak ("leak compensation") careful observation of the infant and close attention to ventilator graphics is required to avoid autocycling. One of the clues that a ventilator in A/C mode is autocycling is a fixed respiratory rate at the minimum allowed T_{insp}. This is not a problem with A/C modes where the breaths are triggered by NAVA.

Pressure Support Ventilation

Pressure support ventilation (PSV) was originally developed as an adjunct to volume-limited SIMV in adult ventilators during weaning. As the rate of volume-limited breaths decreases, patients have spontaneous breaths between the mechanically supported breaths. The work of breathing for these unsupported breaths is increased because of the effort required to overcome the resistance of the ETT. Thus PSV *supports* these breaths with a small amount of *pressure* to compensate for the resistive load imposed by the ETT. That lead to the concept that PSV breaths should be small breaths between the larger breaths provided by SIMV.

Following are characteristics of PSV breaths:

- The breaths are patient-triggered. Each non-SIMV patient breath is supported with a PSV breath. PSV breaths are never delivered without patient inspiratory effort (i.e., there is no time-triggered PSV), so there is no "backup" or minimum PSV rate.
- The breaths are pressure-limited. There are modes similar to PSV where the breaths are volume-limited, but these are more correctly termed volume-support ventilation (VSV).
- The breaths are flow-cycled, so T_{insp} is determined by the infant's respiratory pattern.
- Because PSV does not have a set backup rate and will not support an apneic infant, it should be coupled with another form of ventilation with a set rate, typically SIMV.

In infants, when PSV is used as an adjunct to SIMV, it can reduce the spontaneous breathing effort compared with SIMV alone, even with PSV levels much lower than the peak pressures of the SIMV breaths.[106–108] More importantly, by reducing the need for high SIMV rates, PSV can facilitate weaning in comparison with SIMV alone.[109]

Although usually thought of as small breaths supporting the patient between larger SIMV breaths, PSV breaths can be set to approximate the size of the SIMV breaths they are between, in effect providing something like A/C.

Volume-Targeted Ventilation

Volume-targeted ventilation is a hybrid form of ventilation, combining pressure-limited and volume-limited features into a mode that automatically adjusts the peak positive pressure or the duration of the ventilator breath to maintain V_T within a narrow, targeted range. This requires accurate measurement of delivered tidal volume with each breath and breath-by-breath adjustment of inspiratory pressure and/or T_{insp}. While different ventilator models have different ways of providing (and names for) volume-targeted ventilation, they all have the advantage of providing consistent V_T to the infant. Volume-targeted breaths can be delivered in multiple triggering modes, including SIMV, PSV, and A/C.

Volume-targeted ventilation modes have been compared to pressure-limited modes in at least 20 clinical trials, involving over 1000 patients. Although many of these were small studies or had methodological problems, a recent Cochrane meta-analysis suggests that volume-targeted ventilation is superior to pressure-limited modes in terms of rates of death or BPD, pneumothoraces, severe IVH, and duration of ventilation.[101]

Choice of Conventional Ventilator Modes

Despite the wide variety of neonatal ventilators, each with multiple modes, and each with purported advantages, most babies can be managed with any modern neonatal ventilator and a few ventilator modes. Regardless of the device or the mode, several guidelines greatly simplify the management of infants supported with conventional ventilation:

- V_T should be maintained within a narrow range, typically around 5 mL/kg, to maximize the efficiency of ventilation and minimize the risk of pressure and volume-related over-distension injury. Some infants who seem to do well with V_T are slightly less than this. Very small infants may require V_T as large as 6 mL/kg as the in-line sensor will contribute to the dead space of the circuit. Infants with BPD and significantly increased dead space, as well as overly distensible airways and alveoli, may also need slightly larger V_T.
- Although pressure-limited and volume-limited modes can deliver fairly consistent V_T, changes in patient status including lung compliance and ETT leak can significantly influence delivered V_T. For this reason, volume-targeted modes seem to be the most efficient way to achieve consistent V_T delivery.
- mPaw should be optimized to avoid atelectasis and over-distension, both of which can be evaluated with a combination of ventilator graphics, chest radiograph, and blood gases. Adequate PEEP is an important component of optimizing mPaw and minimizing atelectasis.
- Ventilator support should be adjusted to maximize synchrony with the patient. This includes the timing of the onset of the ventilator breath and the duration of the ventilator breath.
- Modes which support all spontaneous breaths are preferable to modes that support only some breaths. This assures consistent V_T, with the assumption that consistent V_T minimizes atelectasis and over-distension, is more comfortable for the patient and is simpler to adjust. Although this can be approximated with SIMV/PSV, it is more efficient to use an A/C mode.
- Patient work of breathing should be "just enough." A patient who is not doing any respiratory work is at risk of losing respiratory muscle strength, while a patient who is struggling on the ventilator is probably inadequately (or inappropriately) supported. Unfortunately, there is no clear measure of acceptable or ideal work of breathing, and the judgement of "just enough work of breathing" varies by institution and caregiver.
- Provide adequate inspiratory flow so the ventilator can always meet the patient's inspiratory flow demand and avoid "flow starvation." This is particularly important in large, vigorous infants who can "demand" very high flows during early inspiration. Inadequate inspiratory flow decreases ventilator efficiency, increases work of breathing, and is uncomfortable.
- All breaths should be monitored with graphics that give information about pressure, volume, and flow.
- Staff should be well versed in the ventilator mode(s) used. It is better to use a few modes which are understood by all than to use multiple modes which are poorly understood.

High-Frequency Ventilation

High-frequency ventilation (HFV) accomplishes gas exchange by fundamentally different mechanisms than conventional ventilation. While conventional ventilation depends on the bulk flow of gas moving into and out of the alveoli, HFV depends on a highly efficient mixing of gas between the upper airway and alveoli. Because of this, HFV can provide oxygenation and ventilation without ever allowing the lung to collapse to FRC or expand to the volume of a full tidal breath. Avoiding the large pressure and volume swings that are seen with conventional tidal ventilation potentially protects the fragile lung from damage secondary to both atelectasis and over-distension.

The fundamental relationships between HFV settings and gas exchange can be summarized as follows:

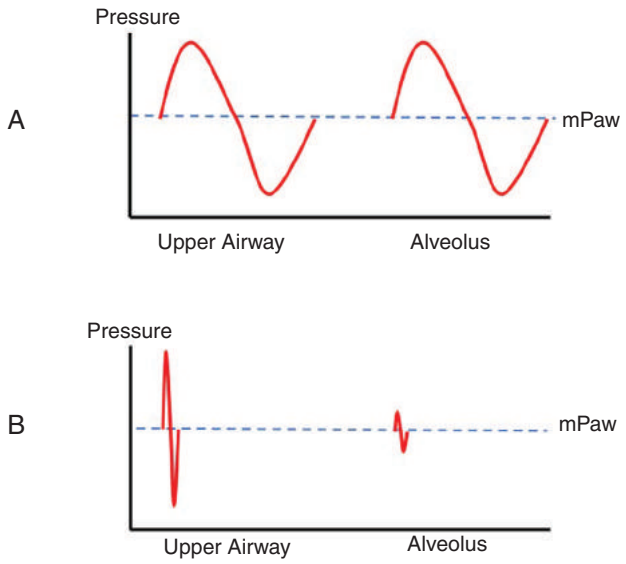
- Oxygenation is proportional to mean airway pressure (mPaw), similar to conventional ventilation.
- Ventilation (CO_2 exchange) is proportional to $F \times V_T^2$. The "V_T" in HFV is far smaller than the V_T in conventional ventilation and is typically less than dead space volume, so technically not a true tidal volume. With some HFV devices, "V_T" is directly measured, while with others it is assumed to be proportional to pressure amplitude or "delta pressure."
- This can be simplified into two simple rules:
  - Adjusting mPaw changes lung inflation and oxygenation
  - Adjusting amplitude changes "chest wiggle" and ventilation

It is important to note that changes in HFV "V_T" or amplitude have an exponential effect on CO_2 exchange ($F \times V_T^2$), compared to conventional ventilation where ventilation and V_T have a linear relationship ($F \times V_T$).

Another important difference between HFV and conventional ventilation is the fact that the airways act as a *low-pass filter* that attenuates high-frequency signals. The pressure transmission to the distal airways is greatly influenced by the resistance of the ETT and the airway, so only a small fraction of high-frequency delta pressure generated by the ventilator is transmitted to the terminal air spaces. In an infant with RDS, a pressure wave at a relatively low frequency of 1 Hz (i.e., rate of 60 breaths/min) is typically transmitted to the alveoli without attenuation (i.e., low frequency is *passed* through the airways filter). In this case, the alveolar pressures are the same as the set PEEP and peak inspiratory pressure. However, at a high frequency of 10 Hz (600 breaths/min) the pressure wave will be markedly attenuated (i.e., filtered, or not passed), with the alveolar pressure changes being much smaller than the pressures delivered to the upper airway. For this reason, the amplitude measured by the ventilator during HFV represents a relative value rather than the real pressure excursion in the distal airways. Although the amplitude of the HFV pressure wave is attenuated between the upper airway and the lower airways, the mPaw at the distal airway is essentially the same as at the upper airway (Fig. 40.2).

One consequence of this low-pass filtering effect with HFV is that changes in frequency have a seemingly paradoxical effect on CO_2 elimination. At high frequencies, decreasing F leads to less attenuation of the pressure wave, and increased amplitude ("V_T") at the alveolar level. And because the effect of V_T on ventilation is exponential compared to the linear association of F and ventilation ($F \times V_T^2$) the decreased F, and resultant increased effective V_T, will lead to increased CO_2 elimination and chest movement.

During conventional ventilation, gas exchange occurs by the filling and emptying of the distal air spaces and alveoli with fresh



• **Fig. 40.2** Low-Pass Filter Effect. (A) At low frequencies, the pressure changes are fully transmitted ("passed") between the upper airway and the alveoli, so pressures measured in the distal lung are the same as those measured in the upper airway. (B) At high frequencies, the upper airways act as a filter so the pressures do not have time to equalize between the upper airway and the distal lung and the pressure wave is attenuated. Note that mPaw measured at the upper airway is the same as mPaw measured at the alveolar level regardless of filtering.

gas with each breath. In contrast, during HFV, the volume of fresh gas delivered by each cycle is very small and does not reach the most distal portions of the lung. The gas exchange which occurs is best thought of as highly efficient mixing and is due to a combination of different mechanisms.[110] These include bulk flow into the more proximal portions of the lung, enhanced mixing of gas within the conducting airways, and out-of-phase movement between different regions of the lung that have different time constants. There is also enhanced diffusion of gas in large and medium-sized airways due to asymmetric velocity profiles during inspiration and expiration. Finally, there is molecular diffusion in the more distal air spaces that moves the different gas molecules from areas of higher concentration to areas of lower concentration.

Because of the effectiveness of HFV in enhancing alveolar ventilation, it is easy to quickly drive P_aCO_2 to very low values. For this reason, it is important to monitor P_aCO_2 values closely, especially when HFV is initiated or when settings are changed. Because of the very short inspiratory and expiratory times, it is extremely important to maintain the airway as patent as possible, ensuring a correct position of the ETT. Any obstruction will produce a decrease in pressure transmission and in V_T and can lead to gas trapping.

As with conventional ventilation, it is critical to ensure proper humidification of the inspired gas to prevent airway damage that can be produced by the high velocity of gas injected into the airway.

Types of High-Frequency Ventilation

There are multiple ways to generate high-frequency "breaths" in the upper airway. High-frequency ventilators are generally divided into HFOV, high-frequency jet ventilators (HFJV), and other devices such as high-frequency flow percussive ventilators (HFPV). While they share many physiologic similarities, they also have important design differences which impact the way they accomplish gas exchange.

High-Frequency Oscillatory Ventilation

High-frequency oscillatory ventilators deliver a sinusoidal pressure wave to the upper airway. The key factor differentiating HFOV from other high-frequency devices is the active push-pull effect on the pressure in the airways, giving the pressure wave its typical sinusoidal form. Some ventilators combine HFOV options with tidal ventilator modes, and some include HFV "tidal volume" monitoring targeting, allowing automatic adjustment of amplitude.

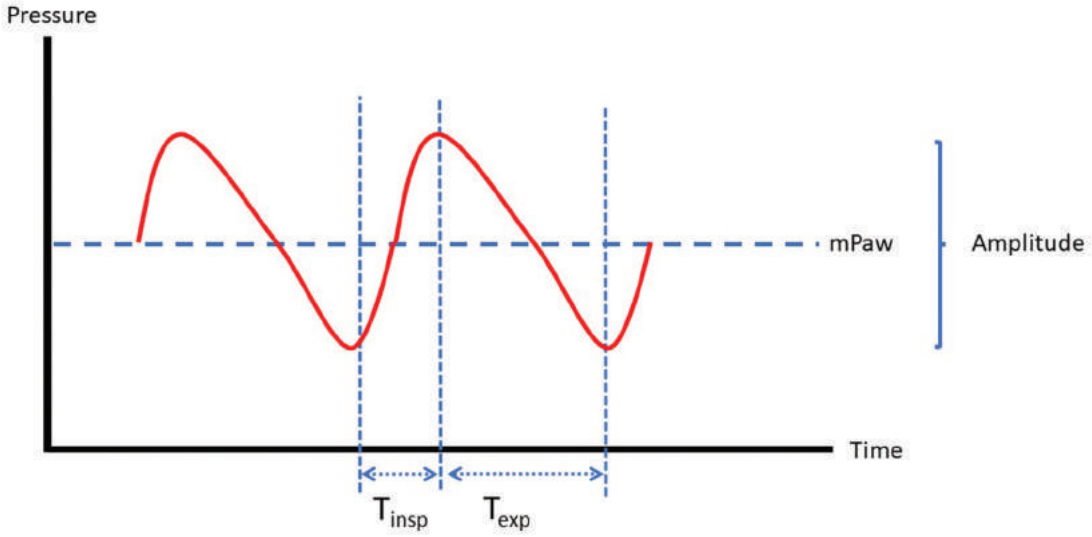
The sinusoidal pressure wave of HFOV generally has four main adjustable parameters:

- mPaw is directly adjustable, and is proportional to lung inflation, and therefore proportional to oxygenation. With sicker, less compliant lungs, a higher mPaw is used. Titration of mPaw is based on chest radiographic estimates of lung inflation as well as on patient oxygenation.
- Amplitude or "delta pressure" is the magnitude of the sinusoidal pressure wave and is an adjustable parameter. Because of the exponential relationship between amplitude and CO_2 exchange, small adjustments in delta pressure can have a marked effect on ventilation. The visible correlate of amplitude is the movement of the infant's chest wall, sometimes termed "chest wiggle." With increasing delta pressure, the amplitude of the chest movement increases.
- Frequency is directly set. Because of the low-pass filter effect of the upper airways, *decreasing frequency* will *increase the alveolar amplitude* (and "chest wiggle"), and will *increase CO_2 elimination*. Although F can be as high as 15 Hz (900 breaths/min), this may cause air trapping in all but the smallest and least compliant infants. More typically, an F of 10 to 12 Hz (600 to 720 breaths/min) is used in preterm infants with RDS. An F as low as 4 to 6 Hz may be used in larger infants or infants with diseases characterized by longer time constants (eg term infants with meconium aspiration). In most cases, an F is set for an infant, and is rarely adjusted; instead, amplitude (delta pressure) is used as the sole parameter adjusted to change ventilation.
- Inspiratory:Expiratory ratio. I:E ratio is typically not a pure sine wave, but instead has an "expiratory" phase longer than the "inspiratory" phase. This minimizes the gas trapping which can occur if the "expiratory" phase is too short. In most cases, I:E ratio is never adjusted (Fig. 40.3).

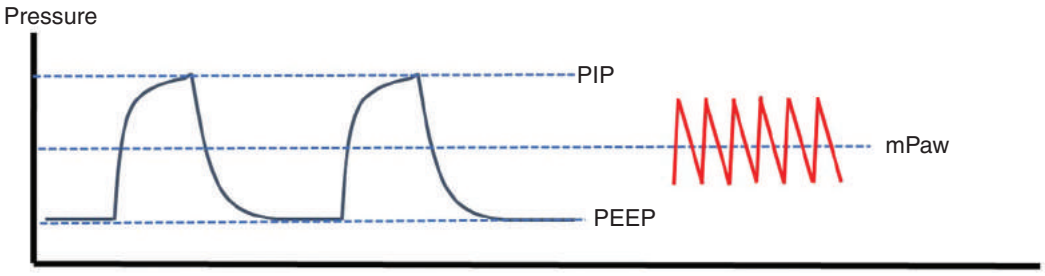
High-Frequency Jet Ventilation

Like HFOV, HFJV works by causing a highly efficient mixing of gas between the upper airway and the alveoli. Unlike the "push/pull" of HFOV oscillations, HFJV generates high-velocity gas pulses that are injected through a small-diameter opening into the airway connector. The high velocity of the gas injected into the airway produces a Venturi effect that pulls additional gas from the ventilator circuit, an effect termed *gas entrainment*. Expiration is passive, with the mixed gas diffusing back from the alveoli during the relatively longer "expiratory" phase. Like HFOV, HFJV is able to maintain a relatively high mPaw without the large alveolar pressure swings seen with conventional tidal ventilation (Fig. 40.4). Characteristics of HFJV include:

- Mean airway pressure is measured, not set directly. As with conventional ventilation, mPaw is primarily affected by PIP, PEEP, and rate.



• **Fig. 40.3** High-frequency oscillatory ventilation *(HFOV)* waveform produced by Sensormedics/Vyaire 3100. The diaphragm generates a sinusoidal push/pull, with a 1:2 inspiratory:expiratory time. mPaw and Amplitude (delta P) are adjusted independently to give separate control over oxygenation and ventilation. The frequency (breaths/s or Hz) and inspiratory:expiratory ratio can also be adjusted, although are usually left fixed for a given patient.



• **Fig. 40.4** Simplified comparison of pressure delivered to the upper airway with conventional tidal ventilation and high-frequency jet ventilators *(HFJV)*. HFJV can maintain a high mPaw without the large pressure swings between peak end-expiratory pressure *(PEEP)* and peak inspiratory pressure *(PIP)* that are seen with conventional tidal ventilation. As with high-frequency oscillatory ventilation *(HFOV)*, the HFJV pressure amplitude is attenuated at the lower airway and alveolar level while mPaw is maintained.

- Amplitude (delta pressure) is measured and, as with conventional ventilation, is the difference between PEEP and PIP.
- F is adjusted directly and is typically 7 Hz (420 breaths/min) for most small infants. For larger infants with longer time constants, or in infants with air leak, F is sometimes decreased to 4 to 6 Hz (240 to 360 breaths/min).
- T_{insp} is usually 0.02 sec and rarely adjusted for most small infants. With larger infants, T_{insp} may be increased as F is decreased.
- Conventional, tidal volume breaths can be used in conjunction with HFJV. The main role of these tidal breaths is as "sigh" breaths that help to treat atelectasis, usually at a rate of only 2 to 5/min. Compared to the HFJV breaths, these conventional breaths provide some alveolar recruitment but are a relatively small part of the ventilation. Most babies can be managed on HFJV without tidal breaths.

High-Frequency Percussive Ventilation

HFPV is a pressure-limited, time-cycled high-frequency mode that uses a flow-interruption device to deliver percussive pulses to the upper airway. It has been studied in multiple patient populations ranging from preterm infants to adults and is used by some US centers to provide HFV on transport because of its small size and simple operation.

Clinical Use of High-Frequency Ventilation

The indications for HFV differ widely between centers. One of the reasons for this variation is that most of the key HFV clinical trials were carried out before modern synchronized and volume-targeted ventilation strategies were developed. It is difficult to extrapolate from these studies to current care and draw firm conclusions about the superiority or inferiority of HFV versus conventional ventilation. Some studies of HFOV versus tidal ventilation have shown better outcomes, such as increased survival with no BPD.[111,112] However, others have not shown differences.[113,114]

A recent meta-analysis of 19 HFOV trials concluded that there may be a small reduction in the risk of chronic lung disease with HFOV, but that the evidence is relatively weak.[115] A recent

meta-analysis of HFJV trials found only one which met their criteria for inclusion in the review.[116] In this cross-over design trial, the secondary analysis showed that rescue treatment with HFJV was associated with improved survival.[117]

Most centers that use HFV use it as a rescue when conventional ventilation has failed, or for patients at high risk of lung damage from conventional ventilation where HFV offers theoretical advantages. This includes patients with severe restrictive lung disease where a high mPaw can be delivered without the high PIP seen with conventional ventilation. In patients with air leak syndromes (PIE, bronchopulmonary fistula), the short T_{insp} and long T_{exp} of HFJV "breaths" lead to less air leak from compliant airways than is seen with the longer T_{insp} of conventional tidal ventilation.[118] Because HFV is effective at providing ventilation with minimal tidal volumes, it also appears to offer some advantages over conventional ventilation in infants with hypoplastic lungs secondary to congenital diaphragmatic hernia or other prenatal conditions.[119] In addition, some centers use HFV as the initial and primary mode of ventilation in very low birth weight infants with a high risk for BPD because of the theoretical advantages of avoiding both atelectasis and over-distension in these infants.

Animal studies, human trials, and clinical experience suggest several broad generalities about HFV:

- HFV can safely and effectively support a wide range of patients. While there is limited data to support the superiority of HFV over conventional tidal ventilation, there is no doubt that it works well if used correctly.
- HFV is very effective in severe lung disease where decreased compliance leads to short regional time constants. As lungs improve, and time constants become longer, HFV has fewer theoretical advantages over conventional ventilation.
- There is a large overlap between HFOV and HFJV in the ability to support patients. While some centers use both types of HFV, others have found that they can manage patients successfully with only one type of HFV. Careful application of the correct ventilator strategy is usually more important than the device used.
- HFOV works particularly well for patients with uniform, non-compliant lungs, such as those with severe RDS. With HFOV, patients can be supported with a high mPaw to reverse or prevent atelectasis, without the high PIP that may be needed with conventional ventilation, and thus minimize the damage associated with over-distension.
- HFJV works particularly well for patients where air-trapping is a problem, such as treatment of PIE or broncho-pleural fistula. The ability to achieve adequate ventilation with very short HFJV Ti_{nsp} and long T_{exp} (I:E ratio of 1:12 at a rate of 240 breaths/min) leads to less air leak than with some forms of conventional ventilation and leads to better resolution of air leak that is already present. HFJV also works well with non-homogeneous severe lung disease, such as meconium aspiration, where the addition of sigh breaths can support patients without causing over-distension of long time-constant regions of the lung.
- The shorter the patient's time constant ($R \times C_{dyn}$), the higher the rate that can be used. For this reason, larger infants and infants with non-homogeneous lung disease are treated with lower F than smaller infants with more homogenous disease restrictive disease (where both R and C_{dyn} are low).

When to Initiate Invasive Mechanical Ventilation

Invasive mechanical ventilation, i.e., ventilation through an endotracheal tube, is typically reserved for patients with one or more of the following:

- Inadequate respiratory drive. Intractable apnea, sedation or analgesia, and underlying neuro-muscular compromise can all make infants incapable of sustaining spontaneous ventilation, or of being supported with noninvasive ventilation.
- Inadequate oxygenation. Atelectasis and ventilation/perfusion mismatch may be so severe that they cannot be reversed or prevented with CPAP or noninvasive ventilation. However, the degree of impaired oxygenation which can be tolerated and managed with noninvasive support varies widely depending on the infant's condition and center-specific guidelines.
- Inadequate ventilation. Atelectasis or other pulmonary conditions may compromise minute ventilation and effective CO_2 exchange despite noninvasive support. As with oxygenation, there is a wide range of what is considered acceptable, although most centers appear to agree that an infant with respiratory acidosis and a pH less than 7.20 to 7.25 will likely benefit from increased support. Note that the P_aCO_2 which is associated with this pH range is dependent upon whether the infant has acute or chronic, compensated hypercarbia.
- Unacceptable work of breathing. This is hard to characterize or quantitate, but most experienced clinicians have a sense of what they would consider unacceptable work of breathing, suggesting impending respiratory decompensation and failure. This is usually a complex mixture of the patient's gestational age, disease trajectory, degree of retractions and tachypnea, and degree of apnea or periodic breathing.

Weaning From Mechanical Ventilation

Although sometimes unavoidable, prolonged invasive mechanical ventilation is associated with significant complications, including laryngeal/tracheal injury leading to stenosis, over-distension, lung injury, loss of respiratory muscle strength and endurance, and BPD. For these reasons, consideration of weaning ventilatory support begins almost immediately after the initiation of invasive ventilation.

Weaning From High-Frequency Ventilation

In some centers, HFV is used for only the sickest infants, who are transitioned from HFV to conventional tidal ventilation when they are judged stable enough to be managed on "reasonable" conventional ventilation settings. In this case, the transition strategy usually entails approximately matching the HFV mPaw with the conventional mPaw and delivering an appropriate V_T, typically around 5 mL/kg.

However, many infants with resolving lung disease can be extubated directly from HFV to noninvasive support. Weaning infants from HFV, whether HFJV or HFOV, is essentially a process of decreasing the HFV amplitude until the infant is breathing spontaneously above the HFV. F_IO_2 should be weaned to approximately 0.4 or lower and mPaw should be weaned to 1 to 2 cmH_2O above the approximate level of CPAP or NIV that the infant will receive after extubation. If the amplitude has been weaned so that the infant is breathing spontaneously with reasonable estimated V_T, HFV can be thought of as providing "vibratory CPAP" rather

than real ventilation. At this point, patients can be extubated to NCPAP or NIV.

Weaning From Conventional Ventilation

Weaning from conventional mechanical ventilation is essentially the same as optimizing mechanical ventilation, and can be approached with several simple questions:

- Can the level of support (PIP in pressured-limited modes) be decreased without compromising delivered V_T, ventilation, oxygenation, or work of breathing?
- If in a SIMV mode, can the F be decreased without compromising ventilation or work of breathing?
- What is the expected time course of the need for support? Some babies can be weaned aggressively off ventilation in a period of hours to a few days, while others may require several weeks of ventilation, and not tolerate weaning attempts more than once a day, or even once every several days.
- With close observation of the baby's work of breathing, respiratory pattern, and V_T, as well as continuous S_pO_2 (and possibly $P_{TC}CO_2$) monitoring, weaning can frequently be done safely without blood gas measurements following each change.

There are no clear guidelines for the optimal time to extubate infants from invasive ventilation to noninvasive support. While extubation readiness tests have been described, a recent meta-analysis suggests that the evidence supporting their utility is not strong.[120] A number of investigators have looked at predicting successful extubation and found that, as expected, higher gestational age, lower level of support, and lower PCO_2 all predict successful extubation.[121–123] There is an online model for predicting extubation success of infants with less than 1250g birth weight based on data from 312 infants in a single NICU (www.extubation.net).[123]

There are several general principles for maximizing success at extubation:

- Most small preterm infants should be extubated to some form of noninvasive support, at least for a brief transition and observation period. There is some evidence that synchronized NIV is superior to NCPAP or HFNC, particularly in smaller infants.
- Caffeine is useful in preventing extubation failure in smaller infants.
- Larger infants or infants without lung disease (e.g., postoperative patients) can often be extubated directly to NC or to room air without support.
- A conservative approach is to wean infants to ventilator settings with a mPaw similar to that which can be provided with noninvasive support. Larger and less sick infants usually tolerate a decrease in mPaw following extubation.

Extubation Failure

Regardless of the strategy employed to optimize extubation, there will be some infants who fail and require re-intubation. In fact, there is a strong argument that if all infants are tolerating extubation, the criteria for extubation are too stringent. There are no published data on the optimal failure rate which balances aggressive extubation with minimizing the adverse effects of re-intubation.

There are several reasons an infant may fail extubation, and require re-institution of invasive support:

- Inadequate respiratory drive, resulting in intractable apnea. This usually results from a combination of respiratory center immaturity and increased work of breathing due to atelectasis or upper airway compromise.
- Atelectasis and ventilation/perfusion mismatch leading to increased work of breathing and increased need for supplemental oxygen.
- Upper airway compromise, either edema or stricture, from prolonged ETT presence, or tracheomalacia.

Inspired Gas Conditioning

During normal breathing, inspired gas is heated and humidified in the nasal passages and upper airways. In contrast to ambient air, medical gases are typically cold (≤15°C) and dry (<2% relative humidity). Exposure to dry and cold-inspired gas can produce inflammation of the airway epithelium, cause cold stress in preterm infants, increase the risk of airway damage, as well as adversely affect the mucociliary transport system. Even adults report discomfort from the drying effect of unconditioned NC gas.

Because of the relationship between temperature and the water carrying capacity of gasses, simply bubbling medical gas through unheated water will not adequately humidify the gas. The standard method for conditioning the inspired gases consists of a combined heater/humidifier device and heated breathing circuits.[124] Dry and cold medical gases are heated in the heater/humidifier chamber to 37°C and 100% relative humidity. The gas travels through the ventilator circuit, where it is heated to 39°C to prevent condensation. The gas temperature decreases as the gas travels through the ETT and gas is delivered at approximately 37°C and near 100% saturated at the distal end. Gas conditioning is recommended during HFNC, NCPAP, or nasal ventilation, as well as during invasive mechanical ventilation.

Other Respiratory Gases

In addition to supplemental O_2, several other respiratory gases can be used in the NICU.

Nitric Oxide

The discovery of iNO revolutionized the care of infants with pulmonary hypertension.[125,126] Nitric oxide is a potent endogenous signaling molecule with multiple actions, the most important of which, therapeutically, is its action as a pulmonary vasodilator. When administered as a respiratory gas, it crosses the alveolar/capillary space to work directly on the pulmonary vasculature. By stimulating the endothelial cGMP system, it causes Ca^{2+} mediated pulmonary arterial dilation. Because it is quickly and irreversibly bound to hemoglobin, iNO acts only at the pulmonary vascular level, with minimal systemic effects.

iNO is typically used in doses of 1 to 20 ppm. Delivery of iNO safely requires complex dedicated equipment, both because of the need for accurate delivery and monitoring of minute doses of iNO, and because it is a very reactive molecule that can rapidly combine with O_2 to form toxic radicals.

Nitrogen

Supplemental N_2 has been sometimes used to decrease the F_IO_2 to less than 0.21 for infants with congenital heart disease who

benefit from hypoxia-mediated pulmonary vasoconstriction. In these infants with single ventricle physiology (for example, hypoplastic left heart syndrome), it is important to maintain relatively high pulmonary vascular resistance to decrease the amount of blood that is shunted from the systemic to the pulmonary circulation.

Supplemental N_2 is mixed with room air to give an F_IO_2 of less than 0.21, typically in the range of 0.18 to 0.20. It is essential to have accurate monitoring of N_2 delivery rate and mixing, as well as the measurement of resultant F_IO_2 because an error in N_2 delivery could be disastrous.

Heliox

Although more commonly used in pediatric and adult ICUs, a mixture of helium and oxygen (Heliox) can be a useful tool for some infants with severe increased airway resistance, such as with severe BPD.[127] Helium is of lower density than N_2 so when mixed with O_2 it flows through narrow passages more readily because it has less turbulent flow than N_2 at the same concentration and flow rate. This will increase maximal gas flow and decrease the work of breathing. Heliox is usually an 80:20 mixture of He_2 and O_2 which can be blended with pure O_2, similar to how room air and O_2 are typically blended. However, the beneficial effects of Heliox are dependent on a relatively high concentration of He_2, so this therapy is ineffective in infants who require a high F_IO_2. This is one of the reasons this technique is not widely used in NICUs.

Pulmonary Drug Delivery

Direct pulmonary drug delivery is an important part of modern NICU care, including the delivery of liquid surfactant and the delivery of aerosolized drugs.

Surfactant

Surfactant replacement therapy is the best example of direct pulmonary delivery of a drug that is not a gas. Delivered below the vocal cords in one or more large boluses, it spreads rapidly and evenly over the alveolar surface. Interestingly, slow "drip" administration of surfactant leads to less even surfactant deposition.[128,129]

For many years, surfactant instillation was done by passing a thin catheter through an endotracheal tube so that it was positioned slightly above the carina. While highly effective, this technique requires the placement of an endotracheal tube that was typically left in for continued mechanical ventilation. This was followed by the development of the INSURE (INtubate, SURfactant, Extubate) technique that allowed effective surfactant delivery followed by rapid removal of the endotracheal tube. More recently, there has been interest in other techniques of surfactant instillation that can be accomplished without an endotracheal tube.[130,131] The use of a thin catheter, without placement of an endotracheal tube, is usually referred to as LISA (Less Invasive Surfactant Administration) and appears to be an effective approach to surfactant delivery. A recent meta-analysis suggests that LISA, compared to INSURE, is associated with a significantly lower rate of mechanical ventilation.[132] One significant limitation of both INSURE and LISA is that it must be performed in infants who are awake and vigorous so they do not require ventilatory support after completion of surfactant instillation. This makes administration of adequate analgesia prior to laryngoscopy impossible, a significant concern given recommendations to provide analgesia prior to laryngoscopy and intubation.[97,98]

Another approach to surfactant administration is through a laryngeal mask airway (LMA).[133] While the LMA approach is appealing in that it does not require laryngoscopy, it is limited by the size of commercially available LMA devices that do not extend to VLBW babies. LMA application of surfactant does not appear to be superior to INSURE in terms of neonatal outcomes.[132]

The twin desires of neonatologists to provide adequate surfactant and to avoid the potential complications of intubation have led to multiple attempts to aerosolize surfactant. Several studies have suggested that surfactant can be aerosolized and safely delivered to preterm infants.[134–137] However, the data on the efficacy of these techniques are limited. Further trials with more sophisticated aerosol delivery techniques are in progress.

There have been attempts to use surfactant as a vehicle for the administration of steroids, particularly budesonide, directly to the lung.[138] Because liquid surfactant spreads so well throughout the lungs, this is a theoretically good approach to achieving uniform, reliable pulmonary drug delivery. This approach is currently under evaluation in several large clinical trials and should still be considered experimental.

Aerosol Drug Delivery

Direct delivery of aerosolized drugs to the lungs is an attractive concept and is widely used in adult and pediatric intensive care units. However, the practical application of this technique for infants has been limited because the infant upper airway is superbly designed to act as a filter. If an aerosol is composed of particles that are too large, they are filtered out in the upper airway. And if aerosol particles are too small, they remain suspended in gas, do not condense at the alveolar level, and are exhaled. It appears that aerosols which contain particles of approximately 2 to 3 μm are most likely to be deposited at the alveolar surface.[139]

The amount of aerosolized drug which is deposited beyond the upper airway is significantly influenced by the route of administration. For drugs that are delivered to an infant on mechanical ventilation, the drug is often deposited in the ventilator circuit and/or endotracheal tube before it reaches the infant. Depending on where the aerosol is injected into the circuit, and the relationship between bias and inspiratory flow, much of the drug may be lost in the bias flow. For infants who are spontaneously breathing there is variation in the amount of drug which is actually entrained by the infant's inspiratory flow, as opposed to being lost to the surrounding room. Even with good delivery of the aerosol to the upper airway, there is likely to be variation in how much drug is deposited in the upper airway as opposed to reaching the small airways.

There are three commonly used techniques for generating aerosols in the NICU: jet nebulizers, vibrating mesh nebulizers, and metered-dose inhalers (MDIs):

- Jet nebulizers inject a high-pressure air source through a liquid reservoir, then through small holes which produce the aerosol. Jet nebulizers are simple and a good source for "blow-by" aerosol drug delivery for spontaneously breathing infants. However, the volume of gas needed to generate the aerosol makes mixing jet nebulization into the inspiratory limb of ventilator circuits problematic.
- Mesh nebulizers vibrate a thin mesh with holes of a specified diameter at a high rate, turning liquid into an aerosol. They can be designed to generate a specific particle size and have the advantage of not adding additional gas to a ventilator circuit.

- Metered dose inhalers use a small amount of propellant to generate a brief "puff" of aerosol. The amount of propellant is small, so it can easily be injected into a ventilator circuit. However, the fact that the "puff" is brief can cause issues for the synchronization of the aerosol delivery with inspiration.

Effective aerosol delivery to the distal air spaces is dependent on multiple factors, including:

- Particle size. Large particles (>3 μm) are more likely to be deposited in the upper airway.
- Where the aerosol is introduced to the respiratory gas. Options include "blow-by" to the spontaneously breathing infant in room air, and to the ventilator circuit of an infant on support. For ventilated infants, options further include the inspiratory limb of the circuit before the heater, after the heater, and close to the patient interface. The location is an important determinant of (1) whether there is adequate mixing of injected aerosol and bias flow gas, and (2) deposition of aerosol particles in the circuit before reaching the patient.
- For ventilated patients, the flow of bias gas through the circuit and the patient's inspiratory flow. If the infant's inspiratory flow is low compared to the bias gas flow, most of the aerosol may be lost in the bias flow.

Many drugs can be successfully aerosolized. However, the number of drugs for which aerosolization is an advantage in infants is limited. Most neonatal experience with aerosolized drugs is limited to bronchodilators, steroids, and mucolytics. Other categories such as antibiotics and prostacyclines, which have been used in older patients, should be considered investigational in infants.

Bronchodilators

Because severe BPD is characterized by airway obstruction, inhaled bronchodilators have long been used for the treatment of infants with BPD. Both beta agonist agents and anticholinergics have been studied and shown to improve lung mechanics in infants with BPD and significant airway obstruction.[140] Whether treatment with inhaled bronchodilators improves outcomes in BPD, as opposed to transient symptomatic improvement, is unclear.[141] There is no evidence that early administration of bronchodilators prevents BPD.[142] The role of inhaled bronchodilators in the management of infants with BPD appears to increase as infants mature from early preterm patients to older BPD patients.

Steroids

Steroids have a long history of use for the treatment of infants with evolving or established BPD. Because of the side effects of systemic steroids, there have been multiple attempts to find effective and safe steroids which could be delivered directly to the lungs. Inhaled steroids, similar to those used to treat asthma and other obstructive lung diseases in older patients, have been used with some success. Unfortunately, inhaled steroids have the same problems as inhaled bronchodilators in terms of variable deposition within the ventilator circuit and/or upper airway before reaching the distal airways. Like bronchodilators, there is likely some systemic effect from inhaled steroids which are either deposited in the upper airway or the distal smaller airways. Despite these variables, the studies of inhaled corticosteroids suggest that inhaled steroids have fewer systemic side effects than systemic corticosteroids, and can improve outcomes compared to placebo in some infants.[141] Like inhaled bronchodilators, the role of inhaled corticosteroids seems to increase as the infant with severe BPD matures into early childhood.

Mucolytics

Drugs that change the composition or structure of pulmonary mucous such as acetylcysteine or DNAase are attractive candidates for aerosolization. The theory is that they can facilitate the break-up of mucous plugs and reduce plug-related atelectasis. However, there are several problems with this in practice. Aerosolized drugs are preferentially distributed to open lung spaces, so are not concentrated where plugging occurs. Also, mucous which is too thin is, at least theoretically, also difficult for the airway cilia to transport, raising the question of how much mucolysis is too much. Finally, the degree to which improvement in atelectasis is due to mucolytic therapy vs changes in individual lung recruitment strategy vs disease progression is difficult to quantitate. Although there is some limited clinical experience with DNAse in infants, the data supporting its use are not compelling.[143,144] For these reasons, mucolytic therapy remains of limited use in most NICUs.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is a technique for providing support to infants with severe parenchymal lung disease, severe pulmonary hypertension, or severe myocardial dysfunction.[145,146] It is essentially the adaptation of intra-operative cardio-pulmonary bypass technology to provide long-term support to patients in an ICU environment. When initially introduced into routine neonatal practice in the late 1980s and early 1990s, its primary role was in the management of infants with a high predicted mortality rate from severe meconium aspiration syndrome and pulmonary hypertension. With changing obstetric practices, and far fewer post-term deliveries, the rate of severe meconium aspiration syndrome and associated pulmonary hypertension has significantly declined, leading to a decrease in the number of neonates needing ECMO. However, there continue to be enough infants with severe pulmonary hypertension or parenchymal disease (including infants with a congenital diaphragmatic hernia) that ECMO is an important part of the care of infants in quaternary medical centers. Despite advances in ECMO pump and circuit design, it remains a complex form of support that should only be administered in select regional centers with rigorous programs, typically in conjunction with programs for ECMO support of pediatric and/or adult patients.

One of the long-standing criteria for ECMO therapy in infants is a high predicted mortality rate, usually defined by oxygenation index (OI). OI is a measure of the amount of respiratory support required to achieve adequate oxygenation, and is calculated as:

$$OI = [(F_IO_2) \times 100 \times (mPaw)] / (P_aO_2)$$

Since F_IO_2 is almost always 1.0 in these patients, the calculation is simple to perform knowing just mPaw and P_aO_2. For example, if $F_IO_2 = 1.0$, mPaw = 20 cmH_2O, and $P_aO_2 = 50$, the OI is 40. In general, an OI less than 20 has a good prognosis, an OI above 40 has a high predicted mortality, and an OI between 20 and 40 has an intermediate risk which warrants consideration of possible ECMO.

Types of Extracorporeal Membrane Oxygenation

Extracorporeal support is categorized by whether blood is both drained and returned to the venous side of the circulation

(veno-venous or VV) or drained from the venous circulation and returned to the arterial side (veno-arterial or VA). There are multiple ways cannulae can be placed to achieve VA or VV support, including trans-thoracic (especially for post-operative cardiac patients), via the femoral vessels (mainly used in pediatric and adult patients), and via the neck vessels (primarily used in neonates).

Regardless of the type of ECMO, there are significant risks that limit its application to patients with severe disease who are treated in dedicated ECMO centers. Among these risks are:

- Bleeding. ECMO involves the circulation of blood through a series of plastic tubes, a membrane oxygenator, and a heater, all of which can promote clotting. For this reason, most patients on ECMO are on continuous anti-coagulation, with the attendant risks of bleeding internally or from cannula insertion sites or surgical sites. In addition, platelet consumption during ECMO is usually significant, requiring multiple platelet transfusions. Of particular concern is the risk for potentially devastating intra-cranial hemorrhage. Close monitoring of coagulation status is essential in ECMO patients.
- Clotting. To avoid bleeding, the anti-coagulation of ECMO patients is tightly controlled, so that clotting of the circuit and thrombosis is always a concern. While small clots in an ECMO circuit are common, large clots that can obstruct the circuit and/or embolize are a potentially devastating complication.
- Ligation of vessels. In the neonate, the vessels which are used to provide canula access are ligated. Early attempts to repair these vessels led to strictures at the anastomosis sites with resultant risk for clots. Since vessels accessed for ECMO include the carotid artery and internal jugular, there are concerns about the long-term implications of the loss of these vessels. Fortunately, the cerebral circulation of the neonate appears to adjust well to the loss of these vessels in early life.

Veno-Arterial Extracorporeal Membrane Oxygenation

Veno-arterial ECMO was the first form of ECMO successfully used in infants and remains an important form of support for infants with combined respiratory and cardiac compromise. In infants, VA ECMO is usually accomplished by passing a large catheter through the right internal jugular vein into the right atrium and another catheter through the right common carotid artery to the arch of the aorta. Venous blood is drained from the right atrium, then run through the ECMO circuit where gas exchange (CO_2 removal and O_2 addition) is accomplished in the membrane oxygenator. The blood, which has cooled slightly in the passage through the ECMO circuit, is warmed and then returned to the arterial circulation through the carotid artery catheter at the arch of the aorta. With adequate size catheters and good catheter placement, most of the infant's cardiac output is replaced with circulation through the ECMO circuit. Thus, a baby can be supported with minimal to no native lung function or cardiac function. As the infant's pulmonary and/or cardiac status improves, the ECMO flow is gradually decreased, allowing the infant's native circulation to take over. When ECMO flow has been weaned to a relatively small amount, usually around 100 mL/min, the infant can be de-cannulated.

Veno-Venous Extracorporeal Membrane Oxygenation

Veno-venous ECMO offers a significant advantage in the infant who needs ECMO but has adequate cardiac output because it does not involve the carotid artery. Instead, a double-lumen catheter is placed through the right internal jugular vein into the right atrium, positioned so venous blood is drawn from the right atrium into the venous lumen and arterialized blood returning from the ECMO circuit is injected into the right atrium and directed across the tricuspid valve. This is technically more difficult than VA ECMO because it requires very accurate placement of the catheter to avoid recirculation of blood within the right atrium. Unlike VA ECMO, VV ECMO requires cardiac function which can provide full right and left cardiac output. In addition to the advantage of not sacrificing the carotid artery, VA ECMO offers the theoretical advantage of sending fully oxygenated blood to the pulmonary circulation, possibly promoting the resolution of pulmonary hypertension. Also, unlike VA ECMO where arterialized blood is injected into the arch of the aorta, VV ECMO provides oxygenated blood leaving the left ventricle to the coronary arteries and may facilitate cardiac function by optimizing myocardial oxygenation.

Liquid Ventilation

In the 1960s it was shown that some liquid perfluorocarbons, such as perfluorooctylbromide (PFOB), could contain enough dissolved O_2 and CO_2 that they could support an animal that was spontaneously breathing PFOB. This led to the concept of liquid ventilation where a patient was ventilated with an oxygenated liquid, typically PFOB.[147,148] The rationale for this was that ventilating a lung with liquid removed the air-liquid interface and thus avoided the problems associated with excess surface tension in a surfactant deficient lung. In addition, the weight of the liquid PFOB tended to open dependent regions of the atelectatic lung, an effect sometimes termed "liquid PEEP." The liquid also acts as a lung lavage, removing particulate material (e.g., meconium) and inflammatory cells and cytokines. PFOB and other perfluorocarbons have the advantage of being almost totally inert, with minimal systemic absorption.

Liquid ventilation was initially designed to totally replace the gas in the patient's lungs, a technique termed total or tidal liquid ventilation. This was followed with a simpler technique, generally termed partial liquid ventilation (PLV) in which the lung was filled to approximately FRC with liquid perfluorocarbon, then was ventilated with a normal gas ventilator. Because perfluorocarbons are volatile, the instilled perfluorocarbon was gradually exhaled and needed to be regularly replaced with more instilled liquid.

Liquid ventilation, both tidal and partial, has been used successfully in a number of animal models and in a variety of clinical settings, including infants, children, and adults with severe lung disease. Although technically feasible and physiologically intriguing, it has not found a clinical niche in which it is both clinically affordable and feasible, and clearly superior to more routine therapies. It remains an interesting avenue for potential research but is not in routine clinical use.

Monitoring Respiratory Status

One of the most important aspects of newborn intensive care is continuous monitoring of cardiorespiratory status. This is particularly true for the infant at risk of respiratory decompensation, or the infant who is on some level of respiratory support.

Physical Exam

Although monitoring devices play a key role in the modern NICU, the role of direct physical examination of the infant cannot be over-emphasized. It is important to remember that the neurologically intact infant has finely tuned chemoreceptors for O_2 and CO_2 levels and pH, as well as chest wall stretch receptors.

Together, these systems are designed to find the best respiratory strategy for simultaneously optimizing oxygenation, ventilation, and work of breathing. In most infants, simple observation can provide a wealth of information:

- The triad of "grunting, flaring, retracting," and associated tachypnea, are the hallmarks of neonatal respiratory distress in the non-ventilated infant. Of these, grunting is probably the most sensitive indicator of a restrictive/atelectatic disease such as RDS, because it represents the infant's attempt to counteract alveolar surface forces with end-expiratory pressure. Progressive increase in grunting is usually a clear indication of worsening disease.
- Tidal volume and respiratory rate in the spontaneously breathing infant are key indicators of respiratory status. With diseases characterized by atelectasis, infants will tend to decrease their V_T and increase their respiratory rate because this is the best strategy for minimizing the work of breathing in the setting of decreased compliance. Progressively decreasing tidal volume and increasing respiratory rate are usually ominous indicators of worsening work of breathing.
- Tidal volume in mechanically ventilated infants is an essential clue to the relative efficacy of the mechanical ventilation strategy. While bedside graphic ventilator monitoring is an important tool in assessing spontaneous and ventilator-supported breaths, direct observation of chest movement is also an important tool for assessing ventilator breaths.
- Work of breathing on mechanical ventilation is an important clue to the success of the ventilator strategy. An infant who is struggling as demonstrated by some combination of tachypnea, retractions, forced exhalation, or general discomfort is often one with a sub-optimal ventilatory strategy. With ventilated infants this is sometimes viewed as "fighting the ventilator," but usually represents a normal reaction to a sub-optimal ventilator strategy.
- Periodic breathing and apnea can represent impending respiratory failure, particularly in the more premature infant who is not able to sustain a significantly increased work of breathing.

Chest Radiograph

Chest radiographs are important tools to assess the status of the lung. However, the technique may vary, particularly in terms of whether the radiograph is obtained at full inspiration. In addition to giving information about diagnosis and ETT position, the chest radiograph can give some clues to whether the lungs are over- or under-inflated. Worrisome signs on chest radiograph include:

- Flat diaphragms, suggesting over-inflation.
- Small, narrow heart, suggesting over-inflation or low circulating blood volume (or both).
- Bulging of inter-costal pleura, suggesting over-inflation.
- Obvious regional over-distension or cystic areas or PIE.
- Dense or opaque "white-out" lungs suggesting under-inflation.
- Regional atelectasis.

Respiratory and Heart Rate Monitors

Transthoracic impedance is the standard method used to monitor neonatal respiration. This technique is based on changes in the electrical impedance of the thorax, as measured by skin surface electrodes, caused by changes in lung volume during respiration. This technique is effective at detecting apneas of central origin but may miss obstructive apnea where chest wall movement despite an obstructed airway is interpreted as respiration. Accurate detection of central, obstructive, and mixed apneas generally requires other sensors such as the detection of gas exhalation by thermistors or CO_2 monitors. Transthoracic impedance monitors can also measure heart rate, and display heart rhythm.

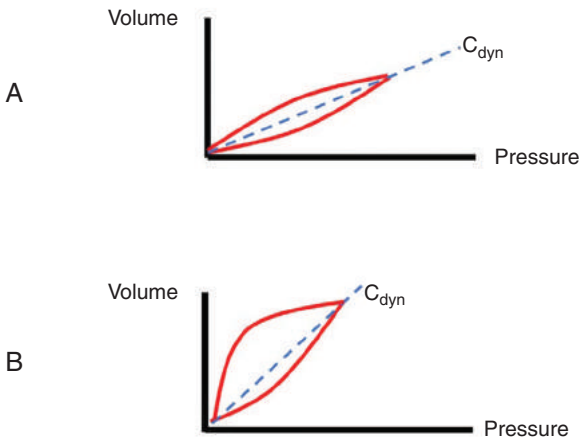
Graphics Monitoring During Conventional Ventilation

The integration of ventilator graphics into modern neonatal ventilators has markedly increased the amount of information available to clinicians for optimizing ventilatory support. This allows the monitoring of spontaneous breathing, assessment of respiratory system mechanics, and detection of excessive or insufficient V_T, hypoventilation, and gas trapping.[149] Different ventilators have different graphics options available, but most have basic similarities. The basic graphic data includes:

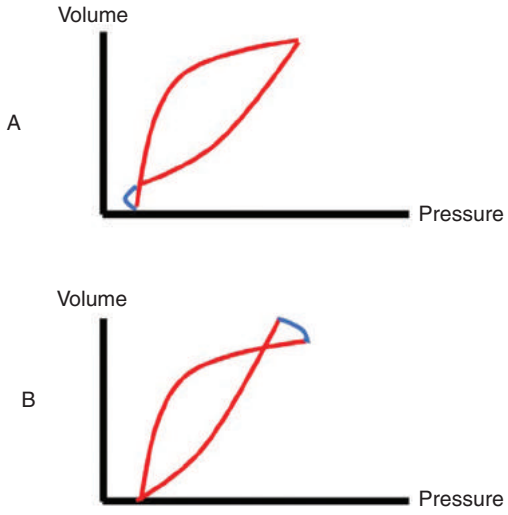
- Pressure. This is typically measured close to the hub of the endotracheal tube. In most cases, where T_{insp} and T_{exp} are adequate to allow pressure to be transmitted to and from the alveoli, the PEEP and PIP displayed are the same as at the alveolar level. If T_{insp} and/or T_{exp} are too short, relative to the lung time constant, then the alveolar pressure changes are smaller than the changes measured at the airway. This is usually seen with a high rate and inadequate T_{exp} where there is air trapping or "inadvertent PEEP."
- Flow. Flow sensors can be placed in the ventilator circuit close to the ETT, in which case they are referred to as mainstream or proximal flow sensors. Although mainstream flow sensors are usually small and typically have a dead space volume of less than 1 mL, the additional dead space can be a concern in small infants. Alternatively, flow sensors can be built into the ventilator. In small infants, mainstream flow sensors have better accuracy than those built into the ventilator because of the compressible gas volume and high bias gas flow in the ventilator circuit that may lead to inaccurate estimates of flow (and volume) delivered to the infant.
- Volume. Volume is calculated electronically by integrating the flow signal. Given the importance of optimizing V_T in the ventilated infant, it is probably the most important parameter to track.

The pressure, flow, and volume information can be displayed in multiple ways. The simplest way is scalar or "strip chart" display of each over time. This is particularly useful for looking at changes in breathing patterns over short periods of time, including breath-to-breath variation. The other way to display the same data is through Pressure-Volume (compliance) loops and Flow-Volume loops. With this approach, each successive breath is represented as a loop, frequently with the most recent loop overlaid on the last several loops. These Pressure-Volume and Flow-Volume loops contain information that is extremely useful in optimizing ventilatory support. Some of the most important information in these ventilator graphics are simple patterns that are easily recognized. These include:

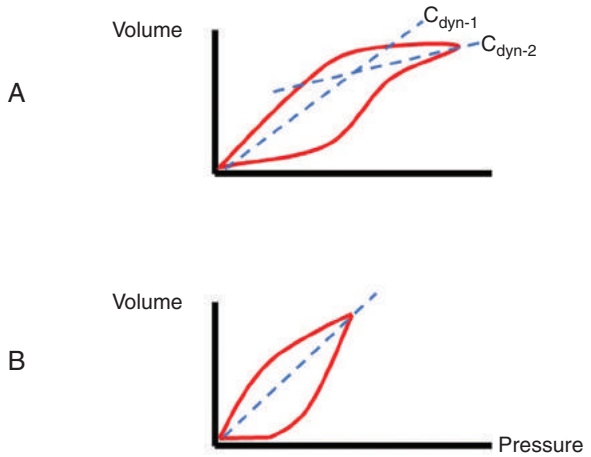
- Compliance and hysteresis, seen on Pressure-Volume loops (Fig. 40.5)
- Over-distension and inadequate PEEP, seen on Pressure-Volume loops (Fig. 40.6)
- Inadequate flow ("flow starvation") and active exhalation, seen on Pressure-Volume loops (Fig. 40.7)
- Endotracheal tube leak, seen on Flow-Volume loops (Fig. 40.8)
- Inadequate T_{exp}, seen on Flow-Time tracing (Fig. 40.9)



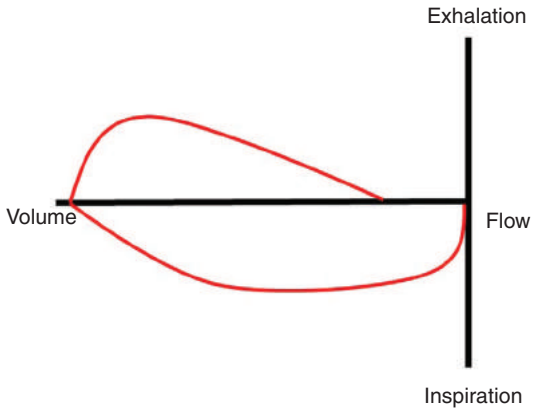
• **Fig. 40.5** Compliance and Hysteresis. (A) shows a simplified Pressure-Volume or compliance loop of a breath with low dynamic compliance (C_{dyn}). There is also low hysteresis, meaning the deflation (upper) part of the curve is close to the inflation (lower) part of the curve, typically indicating surfactant deficiency. (B) shows a Pressure-Volume loop of a breath with greater compliance. The slope of the C_{dyn} line is steeper, indicating more volume per pressure. There is also more hysteresis or deflation stability, with the flatter upper portion of the deflation limb showing that volume is maintained as pressure drops. This is typically seen with good surfactant function.



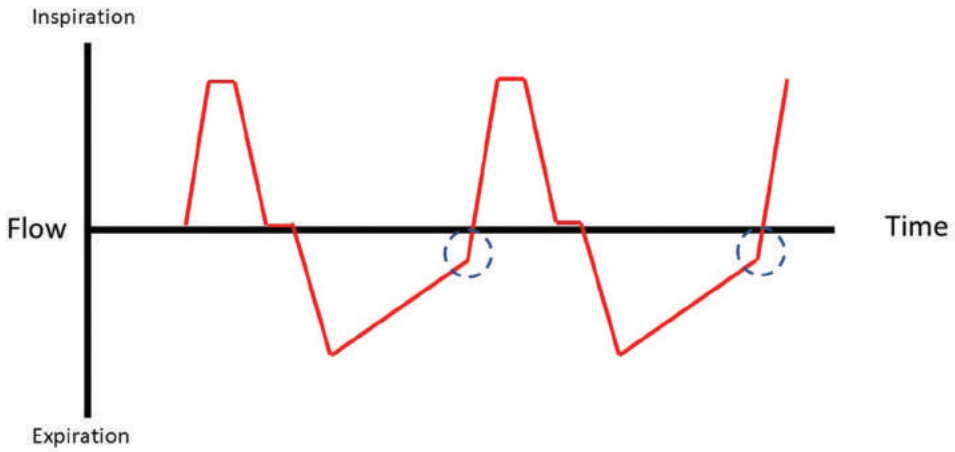
• **Fig. 40.7** Two Abnormal Pressure-Volume Loop Patterns. Part A shows a small "tail" or figure-8 (in *blue*) at the bottom of the pressure-volume loop. During early inspiration, pressure decreases to below peak end-expiratory pressure *(PEEP)* as volume is increasing. This occurs when the patient is drawing in a breath and there is inadequate flow to maintain PEEP, sometimes referred to as "flow starvation." Part B shows a figure-8 at the top of the compliance loop (in *blue*), as the patient actively exhales causing increased pressure and decreased volume. This occurs when the ventilator T_{insp} is too long or the V_T is too large and the infant actively tries to exhale during the ventilator inspiratory phase.



• **Fig. 40.6** Two Abnormal Pressure-Volume Curves. (A) shows a lung that is over-inflated. This pattern, sometimes described as "penguin leaning into the wind," results from having two C_{dyn} components. The C_{dyn-1} line shows the steep, good compliance in early- and mid-inflation, while the C_{dyn-2} line represents the decreased compliance that occurs when the lung is over-inflated. The point at which the curve "leans over" is the upper inflection point. (B) shows a compliance curve that is flat during early inspiration. This indicates pressure during early inspiration without associated volume increase, meaning peak end-expiratory pressure *(PEEP)* is inadequate and the lung is below its opening pressure at end exhalation.



• **Fig. 40.8** Endotracheal Tube Leak. This Flow-Volume loop shows a greater volume on inspiration (lower part of loop) than on exhalation (upper part of loop). The difference in volume between inspiration and expiration is due to a leak around the endotracheal tube. Since much of the leak probably occurs during inspiration, the exhaled V_T is likely a more accurate measurement of what is delivered to the lungs than the inspired V_T. Note that Flow-Volume loops are sometimes drawn as the mirror image of this.



• **Fig. 40.9** Inadequate T_{exp}. Simplified scalar plot showing flow over time. At end-expiration, the flow has not returned to zero before the next breath begins (dotted circle). This means the patient has not exhaled down to set peak end-expiratory pressure *(PEEP)*, so the short T_{exp} is causing air trapping, sometimes termed "inadvertent PEEP."

Blood Gas Measurement

Measurement or estimation of arterial blood gas status is key to the management of respiratory failure and lung disease in the neonate. Measurements of arterial oxygen tension (P_aO_2) and arterial carbon dioxide tension (P_aCO_2) are considered the reference standards for the assessment of respiratory status and adequacy of respiratory support. In addition to direct measurement of arterial blood gas values, there are indirect and noninvasive estimations.

Arterial Catheters

Repeated arterial blood sampling requires the placement of an arterial catheter. Typically, umbilical artery catheters (UACs) are used during the acute phase of respiratory failure. Samples obtained from a UAC are reliable, assuming proper sample handling and laboratory procedures are followed, and easily obtained without disturbing the infant. In addition to providing access for blood sampling, UACs can serve an important role in continuous direct blood pressure measurement.

In most cases, UACs can be placed relatively easily by skilled personnel. However, they cannot be placed in all infants and, even under the best of circumstances, are not without risks. Particularly important considerations in placing and maintaining a UAC are the risks of thrombi and emboli, vasospasm, and infection. Interference with blood flow to the lower extremities is a particular concern. Blue discoloration of the toes and/or foot are relatively common, and usually not a concern. However, blanching of any part of the lower extremity in any infant with a UAC in place indicates severe vascular compromise and is an indication for immediate removal of the UAC. UAC lines with the tip above the celiac plexus are associated with fewer complications than those with the tip below the renal or mesenteric artery.[150]

Although UACs can sometimes be maintained in place for up to several weeks, this is usually not done except in the sickest infants where there are no other options for vascular access. Patency of UACs is usually maintained by infusion of a solution of heparinized saline. UACs should not be used for the administration of medications unless there are no other alternatives. Vasoactive agents and hypertonic medications should never be infused through a UAC.

Percutaneously placed peripheral artery lines are frequently used in infants where a UAC cannot be placed, or for management of older infants in whom the UAC has been removed. The most common sites for peripheral artery cannulation are the radial, ulnar, posterior tibial, and dorsalis pedis arteries. Placement of these lines can be technically challenging and quite uncomfortable if local and/or systemic analgesia is not used. As with UACs, peripheral artery lines must be carefully observed for any evidence that they are causing distal vascular compromise, in which case they should be removed. Like UACs, peripheral artery line patency is maintained by a low-rate infusion of heparinized saline. Peripheral artery catheters should not be used for the administration of medications.

Arterial Puncture

Although it is technically possible to perform intermittent arterial punctures to obtain blood gases (and other labs), this is not ideal. Arterial puncture is usually more technically difficult and more painful than venous puncture. Because of the pain associated with arterial puncture, infants frequently respond with agitation, hyperventilation or apnea, and desaturation. In addition, an arterial blood gas gives a value that is only representative of a single point in time. Thus, the value of a blood gas obtained by arterial puncture is limited. In general, arterial punctures should be avoided in favor of less traumatic estimations of arterial blood gas status.

Capillary Blood Gas

Arterialized capillary blood is frequently used as an approximation of arterial blood for blood gas analysis. It is typically obtained by sampling from the medial or lateral plantar heel surface after warming the heel to increase capillary flow. The purpose of warming is to "arterialize" the blood by increasing flow and decreasing the time for O_2 and CO_2 exchange to occur in the capillary bed. Although there is a general rough correlation with P_aCO, individual capillary values may be significantly different than arterial values. In addition, capillary blood gases are painful and frequently lead to agitation and changes in respiratory status similar to those

seen with arterial puncture. Thus, capillary blood gas values are of limited value as a routine way of tracking respiratory status and should always be interpreted cautiously.[151] Capillary blood gases are probably most useful for following trends in pH, rather than for measuring exact PCO_2 values, and they are not at all useful for estimating P_aO_2.

Venous Blood Gas

For patients with an umbilical venous catheter or other central venous catheters, the measurement of venous blood gas values is technically simple. However, systemic venous gases are of limited value. The amount of O_2 which has been extracted, and CO_2 which has been added, to the blood at the level of the capillary bed varies widely and is impacted by multiple factors such as cardiac output and regional perfusion. In practical terms, the only certainty with systemic venous blood gases is that the venous PO_2 is lower than P_aO_2, and venous PCO_2 is higher than P_aCO_2.

Mixed Venous Saturation

Mixed venous saturation (S_VO_2) is the saturation of blood in the main pulmonary artery, where venous blood from the superior vena cava and inferior vena cava have been thoroughly mixed. In infants, S_VO_2 is usually approximated with blood sampled from the right atrium. This is particularly useful in the management of the infant on ECMO, where blood is continuously drained from the right atrium, and can be analyzed with continuous noninvasive monitoring as well as intermittent blood gases.

With normal lungs and pulmonary blood flow, blood leaving the lungs is approximately 100% saturated. With typical systemic oxygen demand and adequate systemic blood flow, approximately 25% of the O_2 carried by hemoglobin is removed by peripheral tissues, leaving blood returning to the heart approximately 75% saturated. Thus, S_VO_2 of 75% suggests adequate delivery of oxygen to peripheral tissues. In patients on ECMO, S_VO_2 significantly below 70% to 75% suggests inadequate tissue oxygenation and is typically dealt with by increasing ECMO flow to deliver more 100% saturated blood from the ECMO circuit to the patient.

Errors in Blood Gas Measurement

Errors in blood gas measurement are usually technique related, including the delay between obtaining the sample and analysis, contamination of the sample by air bubbles, or contamination of the sample by fluid used to maintain catheter patency. Common errors include:

- Delay in analysis, particularly if the blood is not chilled, results in continued metabolism by the red blood cells, with resulting consumption of O_2 and generation of CO_2.
- Contamination of the blood sample with an air bubble or with fluid allows the O_2 and CO_2 to equilibrate between the sample and the contaminant.
- If the contaminant is fluid or room air, PCO_2 in the blood will typically decrease, and the buffering capacity of the blood will compensate to maintain pH, resulting in what looks like a respiratory alkalosis and metabolic acidosis.
- Contamination with fluid will typically lead to a decrease in sample PO_2, while contamination with air will tend to move the blood PO_2 closer to atmospheric PO_2.

Noninvasive Estimation of Blood Gases

Pulse oximetry is a reliable continuous measurement of arterial oxygen saturation. Estimation of P_aCO_2 is more problematic. While there is a general correlation between P_aCO_2 and noninvasive estimates of PCO_2, the correlation can vary significantly in individual measurements.[152]

Pulse Oximetry

Pulse oximetry provides continuous real-time monitoring of oxygenation status and is such an essential component of modern critical care that many consider it the "other vital sign." Measurement of the oxygen saturation in arterial blood (S_aO_2) by pulse oximetry (S_pO_2) is based on the difference in the light absorption between oxygenated hemoglobin (Hb) and deoxygenated Hb in the red and infrared regions of the light spectrum. Since deoxygenated Hb absorbs more red light and less infrared light than oxygenated Hb, as S_aO_2 increases, the ratio of the absorption of red light to that of infrared light decreases. It is assumed that in circulation, changes in this ratio can be produced only by pulsating arterial blood. The amount of light absorbed by pulsatile blood is only a small fraction of the light absorbed by tissue and venous blood, so careful application of the S_pO_2 probe is essential. Pulse oximetry probes may be quite susceptible to movement artifact which can interfere with accurate measurement in the active infant. Different models of pulse oximeters use slightly different algorithms for calculating S_pO_2 so there is not always perfect agreement between different pulse oximeters, or between S_pO_2 and measured S_aO_2.[153,154]

The interpretation of S_pO_2 must be done in the context of the sigmoid-shaped relationship between P_aO_2 and S_pO_2. This is particularly true of S_pO_2 approaching 100% which may reflect a P_aO_2 of less than 80 or well above 100 mmHg. On the other hand, most S_pO_2 values below 80% are associated with P_aO_2 below 40 mmHg.

Transcutaneous Blood Gas Monitoring

Transcutaneous estimate of PO_2 ($P_{TC}O_2$) and PCO_2 ($P_{TC}CO_2$) is possible because of the diffusion of gas from the tissue bed to the skin surface. Particularly in preterm infants with thin skin and good perfusion, this can provide a reliable tool for following trends in blood gas values. Transcutaneous monitors combine O_2 and CO_2 sensors with a heating element that warms the skin under the sensors, causing an increase in local blood flow. With this increase in blood flow, the blood directly under the transcutaneous monitor probe is partially "arterialized" and the tissue bed has less opportunity to exchange O_2 and CO_2 with blood in the capillary. While this increases the accuracy of the transcutaneous estimate of PO_2 and PCO_2, the warming can cause local burns. For this reason, transcutaneous probes are not left in one position for more than several hours. Fortunately, there is data to suggest that lower temperatures can be used, resulting in less risk of burns.[155]

Multiple factors impact the blood flow under a transcutaneous sensor and therefore the accuracy of transcutaneous measurement. These factors include gestational age, sensor position on the body, systemic vasoconstriction, and any other factor which may impact systemic perfusion. In addition, if the sensor becomes partially dislodged from the skin, the sensor will read values for PO_2 and PCO_2 which are influenced by the air between the skin and the sensor. For these reasons, transcutaneous monitors are best thought of as devices for following trends in PCO_2, rather than for absolute values. Correlation of transcutaneous measurements with blood gas measurements may be helpful, but if capillary blood gases are used to correlate with the transcutaneous monitor, the accuracy of the capillary blood gas values are not necessarily reliable as discussed above. In general, $P_{TC}CO_2$ is most useful for following infants who are labile or require significant ventilator adjustments, such as immediately after beginning mechanical ventilation or when

changing ventilator modes. With simple and reliable S_pO_2 monitoring readily available, $P_{TC}O_2$ is of little use for most patients.

End-Tidal Carbon Dioxide Monitoring

In some circumstances, monitoring the partial pressure of CO_2 at the end of exhalation (end-tidal, $P_{ET}CO_2$) is a convenient way to obtain an estimation of alveolar PCO_2 (P_ACO_2), which is usually a close approximation of P_aCO_2.[156,157] This has the advantage of being a simple noninvasive way to continuously monitor PCO_2. However, particularly in infants with significant lung disease, the correlation between P_aCO_2 and $P_{ET}CO_2$ is low. Accurate assessment of P_aCO_2 by $P_{ET}CO_2$ requires an exhalation phase that is slow enough to obtain a measurement of true exhaled alveolar gas ("alveolar plateau") that is not mixed with dead-space gas. In general, $P_{ET}CO_2$ is most useful in large patients with relatively little lung disease who have a low respiratory rate and reproducible alveolar plateau to their exhaled CO_2 level. It is least accurate in small babies with small tidal volumes, high respiratory rates, and severe lung disease. Despite this, it can be a useful trending tool and can decrease unwanted hypercapnia and wide swings in PCO_2.[158,159]

One area where $P_{ET}CO_2$ detection can be extremely useful, even if it is not an accurate estimation of P_aCO_2 is confirmation of endotracheal tube placement. Small chemical CO_2 detectors are useful for confirming the placement of an endotracheal tube in the trachea immediately after intubation. In addition, continuous monitoring of $P_{ET}CO_2$ provides a near-instantaneous indicator of whether an endotracheal tube has become dislodged.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is a technique for assessing regional oxygenation.[160,161] Initially used to evaluate cerebral oxygenation, the technique has been used to assess regional oxygenation in other vascular beds including the kidney and intestine.[162,163] It is a theoretically attractive adjunct to other assessments of adequate oxygen delivery, particularly in patients with potentially altered systemic oxygen delivery such as sepsis or other forms of shock. It is also an intriguing option for monitoring patients with potentially impaired cerebral oxygenation, such as patients with HIE. However, it is not yet part of routine clinical monitoring in many NICUs.

Acknowledgment

Drs. Durand and Courtney wish to thank Drs. Eduardo Bancalari, Nelson Claure, and Deepak Jain for their expertise in this area and to acknowledge their significant contributions to previous versions of this chapter.

Control of Breathing

ESTELLE B. GAUDA AND RICHARD J. MARTIN

KEY POINTS

- Apnea of prematurity is universal in preterm infants and a manifestation of greater inhibitory (rather than excitatory) influences on the central respiratory network.
- In premature infants, excitation of peripheral arterial chemoreceptors by hypoxia predisposes to periodic breathing and the hypoxic ventilatory response is not sustained.
- The protective upper airway reflex (laryngeal chemoreflex) prevents aspiration, but in premature infants, profound bradycardia, apnea, and oxygen desaturation can occur in addition to laryngeal constriction.
- The excessively compliant chest wall and low lung volume in premature infants predispose them to intermittent hypoxia as a consequence of apnea.
- Caffeine is the mainstay of therapy for apnea of prematurity, although the optimal duration and dosing of therapy remain uncertain.
- By identifying the genetic mutations that are associated with marked abnormalities in respiratory control, we can obtain a better understanding of the key role of several neuromodulator systems.

How the respiratory network matures is of interest not only to physiologists, but also to clinicians who care for infants, newborns, and children with disorders of respiratory control. Neonatologists, in particular, are aware of the challenges of treating infants who are born prematurely. While breathing movements can be detected in the human fetus as early as 10 to 12 weeks' gestation, the purpose of fetal breathing is not gas exchange, but instead, the lung stretch that occurs during breathing is essential for lung development. The transition from fetal to neonatal life requires a rapid conversion from intermittent fetal respiratory activity not associated with gas exchange to continuous breathing on which gas exchange is dependent. Breathing in the most premature infants is akin to fetal breathing, which is episodic, punctuated by periods of disturbingly long apneic pauses interspersed with frequent periods of hyperventilation and sighs (augmented breaths). For the infant who is born prematurely, frequent apneas and periods of hypoventilation associated with oxygen desaturations and bradycardia are of significant concern. With maturation, breathing becomes more stable. Thus, the premature infant provides a unique opportunity to observe how the respiratory system matures in humans.

Even though breathing is more stable in term infants than in premature infants, the respiratory system at term gestation is still undergoing significant maturation and can become unstable in response to stressors such as infection or hyperthermia. In some term infants who appear well, subtle developmental abnormalities in the anatomy and neurochemistry of the respiratory system can lead to profound disorders of breathing. Careful epidemiologic, genetic, neurochemical, and neuroanatomic studies in human infants with disorders of respiratoryss control have allowed for a better understanding of genes that regulate the development of the respiratory system and how environmental factors in fetal and early neonatal life may adversely affect the normal development of systems that control breathing.

The purpose of this chapter is to better understand how infants breathe, why premature infants have apnea of prematurity, why term infants have apnea of infancy, and how environmental exposures modify mechanisms that control breathing during fetal and early neonatal life.

Animal Models of Control of Breathing

Much of our understanding of the basic mechanisms that lead to stable breathing comes from studies performed in newborn and adult animals. Earlier studies in newborn pigs, dogs, and cats, as well as the fetal and newborn sheep, characterized the developmental physiology, and much has been gained from these models. However, a more detailed understanding of the neuroanatomy, neurocircuitry, and neurochemistry has been obtained with in vitro models from fetal and newborn rats and mice. Of particular relevance, the stage of respiratory development of the rat born at term is similar to that of the human born at 25 to 29 weeks' gestation. Two different reduced in vitro preparations from rodents have been used to better delineate components of the respiratory network in the brainstem: (1) brainstem slices that include the area that contains the "pacemaker cells mediating rhythmogenesis," and (2) isolated brainstem spinal cord preparations from fetal and newborn rodents. Because the stability and viability of these in vitro preparations are best when tissues are used from the late embryonic stage or within the first week of postnatal life, data from these in vitro preparations are relevant only to respiratory control during very early development. Using these reduced models, specific regions of the brain involved in respiration could be identified and characterized. We now know that the groups of neurons that control the different phases of respiration have a genetic signature, allowing the use of genetic tools to manipulate the activity of the different regions and observe the physiologic responses in intact animals. Specifically, optogenetics and pharmacologic techniques are often combined to explore the functionality of the specific brain regions related to breathing in unanesthetized adult animals. Thus, what we know about how the respiratory network is integrated and functions is based on a significant amount of information obtained from well-designed in vitro and in vivo animal experiments using immunohistochemistry,

electrophysiology, fluorescent imaging, genetic manipulation, pharmacology, computational modeling[1,2] and more recently optogenetics in rodents.[3,4]

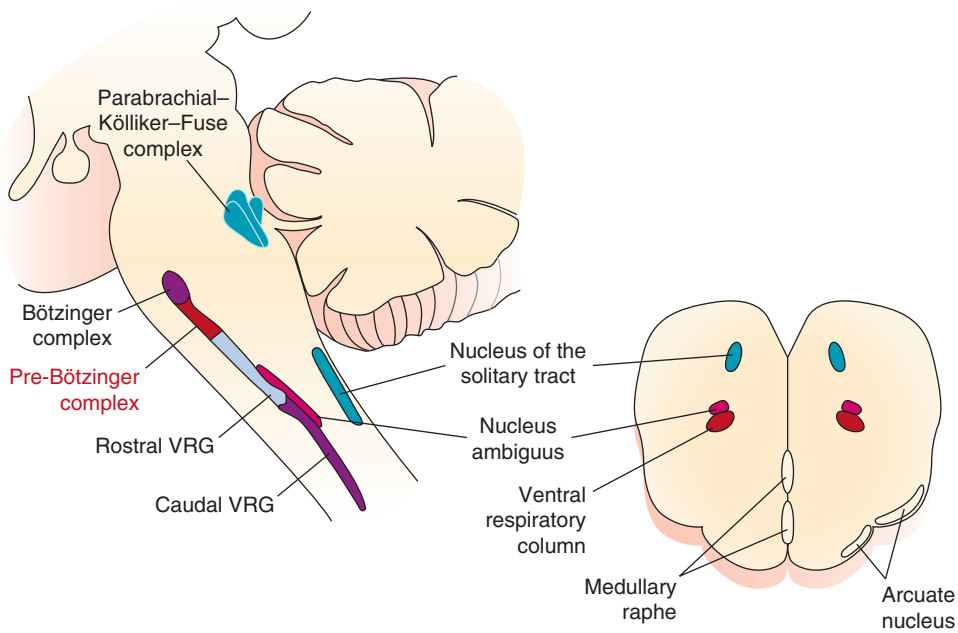
Respiratory Muscles

The diaphragm is the major muscle of respiration, but other muscles of respiration are also essential for unobstructed breathing at rest and augmented breathing during exercise and stress. Thus, the muscles of respiration include the pump muscles (diaphragm, intercostal muscles, and abdominal muscles) and muscles of the upper airway (alae nares, pharyngeal muscles, and laryngeal muscles). The diaphragm is innervated by the phrenic nerve, which originates in the spinal column (C3 to C5). The upper airway muscles are innervated by motoneurons originating in the brainstem, specifically, the nucleus ambiguus, the dorsal motor nucleus of the vagus, and the hypoglossal nucleus.[5,6] Different muscles are activated during different phases of the respiratory cycle: inspiration followed by post-inspiration and expiration. Upper airway muscles are particularly important in modulating the rate of inspiratory and expiratory airflow. During inspiration, the diaphragm, external intercostal muscles (in infants), and posterior cricoarytenoid (laryngeal dilator) contract.

During post-inspiration the diaphragm and the thyroarytenoid (laryngeal constrictor) contract. Diaphragmatic and thyroarytenoid post-inspiratory activity are common in newborns, both human[7] and animal.[8] Because the chest wall of newborns, particularly premature newborns, is highly compliant, diaphragmatic and laryngeal post-inspiratory activity of upper airway muscles is often audible, known as *grunting*, and is heard in infants with low lung volume disease states, such as surfactant deficiency and atelectasis to preserve lung volume. It is essential that the pump muscles, particularly the diaphragm and the upper airway muscles, contract in such a way that unobstructed breathing occurs. Because of lower airway tone or active closure of the glottis, premature infants may have an obstructed component during apnea. The resultant obstructed inspiratory efforts may prolong central apnea, resulting in so-called mixed apnea.

Brainstem Rhythmogenesis

As shown in the anatomic illustration in Fig. 41.1, the respiratory-related neurons are located in three main areas in the brainstem: (1) the dorsal respiratory group within the nucleus tractus solitarii (nTS); (2) the ventral respiratory column (VRC), which extends from the facial nucleus to the ventrolateral medulla at the spinal-medullary junction; and (3) the pontine respiratory group within the dorsolateral pons.[2,9] The VRC should not be confused with the ventral respiratory group (VRG). The VRC can be subdivided into a rostral part—involved in rhythmogenesis—and a caudal part, involved in pattern formation. Bulbospinal neurons are neurons that originate in the medulla (bulbo) and synapse with motoneurons in the spinal column such as the phrenic motoneurons. The rostral VRC contains both the rostral VRG, consisting of a large proportion of bulbospinal inspiratory neurons that project directly to the phrenic and external intercostal motoneurons



• **Fig. 41.1** **The anatomic relationship between the regions in the human brainstem that constitute the respiratory network.** These regions include specialized neurons in the dorsolateral pons (parabrachial and Kölliker-Fuse nuclei), nucleus of the solitary tract, and ventral respiratory column. The ventral respiratory column is organized rostrocaudally extending from the level just below the facial nucleus to the C1 level of the cervical cord. The ventral respiratory column consists of the Bötzinger complex, the pre-Bötzinger complex, and the rostral and caudal ventral respiratory groups *(VRGs)*. Vagal motor neurons of the nucleus ambiguus innervate the laryngeal muscles. The medullary raphé, arcuate nucleus, located just underneath the ventral medullary surface, contains neurons that depolarize in response to hypercapnia and hypoxia. The retrotrapezoid nucleus (not shown) is a CO_2/H^+ chemosensor and is located rostrally below the facial nucleus on the ventral medullary surface. (Modified from Benarroch EE. Brainstem respiratory control: substrates of respiratory failure of multiple system atrophy. *Mov Disord*. 2007;22:155–161.)

and the caudal VRG, containing bulbospinal expiratory neurons that project to abdominal and internal intercostal motoneurons. Propriobulbar neurons are neurons originating in the brainstem that send projections to other neurons in the brainstem.

Within the rostral VRC are two areas that are essential to the formation of respiratory rhythm: the pre-Bötzinger (PBC) and the Bötzinger complex. As outlined already, the PBC contains a core group of synaptically coupled excitatory neurons that have pacemaker properties, similar to the pacemaker cells in the atrioventricular node of the heart. These pacemaker cells are rostral to the nucleus ambiguus, have both intrinsic inspiratory and expiratory bursting properties, and are essential to maintaining respiratory rhythm.[10] Progressive destruction of the PBC disrupts rhythmogenesis, leading to death in animals.[11] Using immunocytochemistry to identify NK1 and somatostatin positive neurons and anatomical approaches, a similar area has been identified in the human brain. In individuals who had died of neurogenerative disease with central respiratory deficits, reduced numbers of neurons were identified in the area of the putative PBC as compared with the brains of individuals with neurodegenerative disease without central respiratory deficits.[12] Moreover, Bright et al. found that premature infants who died of sudden infant death syndrome (SIDS) had significantly lower levels of NK1 receptor binding (NK1R) in the nTS, and paragigantocellularis lateralis (PGCL) nucleus, the homologue of the PBC, than in premature infants who did not die of SIDS, and male sex was associated with less NK1R binding in the inferior olivary-cerebellar complex in preterm and term infants who died of SIDS vs control infants.[13] Both male sex and premature birth increase the risk of SIDS. In newborn rats, destruction of NK1R expressing neurons within the preBötC causes abnormal respiratory pattern, and, the more immature the circuit is at the time of destruction, the more permanent the change in the pattern of respiration.[14]

The post-inspiratory complex (PiCo) is another area, recently discovered, with autonomous rhythm-generating properties that controls post-inspiratory activity.[4] The PiCo is medial to the nucleus ambiguus and caudal to the nucleus of cranial nerve VII. The Bötzinger complex contains propriobulbar expiratory neurons that provide strong inhibitory inputs to inspiratory and expiratory bulbospinal neurons in the VRC.

Another important group of neurons are those within the retrotrapezoid nucleus (RTN) located along the ventral medullary surface beneath the facial nucleus. These neurons have chemosensitive properties and depolarize in response to increasing carbon dioxide (CO_2) concentration and decreasing pH and synapse with rhythm- and pattern-generating neurons in the VRC.[15] All these neuronal groups and networks that contribute to rhythmogenesis are present in newborn animals born at term (e.g., sheep, cats, and pigs) or born prematurely (e.g., rodents) in which rhythmogenesis is well established before birth. Episodic spontaneous fetal breathing movements occur in human fetuses as early as 10 weeks' gestation.[16] In rodents, respiratory rhythmogenesis is first detected at embryonic day 15 in rats and embryonic day 17 in mice.[17] The emergence of this respiratory-related activity in rats is coincident with the characteristic expression of NK1 receptors of the PBC.[17]

In summary, respiratory rhythm and inspiratory-expiratory patterns emerge from dynamic interactions between (1) excitatory neuron populations in the PBC and rostral VRG, which are active during inspiration and form the inspiratory motor output; (2) excitatory neurons in the PiCo, which are active during post-inspiration; (3) inhibitory neurons in the PBC that provide inspiratory inhibition within the network; and (4) inhibitory neurons in the Bötzinger complex, which are active during expiration and provide inhibitory inputs to inspiratory and expiratory neurons within the network and to phrenic motor neurons. Because of the limitations in performing mechanistic experiments in humans, much of what we know about how we breathe is extrapolated from animal models, but many similarities exist between animals and humans regarding the respiratory network. Harper et al.[18] have described the relationship between damage to specific brain regions observed on brain imaging and specific disorders of respiratory control in humans.[18]

Neurochemical Control of Respiration

Glutamate is the major neurotransmitter mediating excitatory synaptic input to brainstem respiratory neurons and respiratory premotor and motor neurons. Gamma aminobutyric acid (GABA) and glycine are the two major inhibitory neurotransmitters mediating inhibitory synaptic input in the respiratory network; they have a key role in pattern generation and termination of inspiratory activity.[19] GABA (via $GABA_A$ receptors) and glycine (via glycine receptors) mediate fast synaptic inhibition via activation of chloride channels.[20] Throughout development, glutamate always functions as an excitatory neurotransmitter; however, it is not the case that GABA and glycine are always inhibitory neurotransmitters. In early development, GABA and glycine mediate *excitatory neurotransmission* in many neuronal networks, including the respiratory network.[21] GABA and glycine signaling modify the level of chloride in the cell. Activation of the sodium (Na^+)-potassium (K^+)-chloride (Cl) cotransporter (NKCC1) and the potassium-chloride transporter (KCC2) on the cell modulates intracellular ion concentrations. Specifically, NKCC1 brings Na^+, K^+, and $2Cl^-$ into the cell, while activation of KCC2 moves K^+ and Cl^- outside the cell. Low expression of KCC2 during early development, resulting in a high NKCC1/KCC2 ratio, causes *high* intracellular chloride concentrations in immature neurons. When GABA then binds to $GABA_A$ receptors, a net outward movement of Cl^- ions occurs, leading to membrane depolarization. With maturation, KCC2 expression increases, reversing the NKCC1/KCC2 ratio and lowering intracellular Cl^- ions. Now when GABA binds to $GABA_A$ receptors, more Cl^- ions come into the cells, leading to hyperpolarization.[22,23] With brain injury, NKCC1 expression increases, making the GABAergic system less inhibitory. Moreover, myoclonic jerks are associated with midazolam exposure ($GABA_A$ receptor agonist) in premature infants.[24] $GABA_B$ receptors, which are metabotropic G protein-coupled receptors, also have a greater role in inhibiting respiratory rhythm in adult animals as compared with newborn animals.[25] Finally, the baseline excitatory and inhibitory influences mediated by glutamate and GABA-glycine, respectively, on major neuronal networks are further altered by many endogenously released neuromodulators that shape and fine-tune respiratory pattern and rhythm throughout development, as outlined in Table 41.1.

Genetic Mutations Affecting Respiratory Control

Some neuromodulators may be more critical in supporting respiratory rhythmogenesis than others. By identifying the genetic mutations that are associated with marked abnormalities in respiratory control, we can obtain a better understanding of the key

TABLE 41.1 Neurotransmitters and Neuromodulators That Mediate Respiratory Rhythm

Neurotransmitter/ Neuromodulator	Receptor Subtype	Source of the Endogenous Ligand	Excitatory or Inhibitory on Respiratory Rhythm	Comment
Glutamate	NMDA, AMPA, GluR	Ubiquitously expressed	Excitatory	Major excitatory neurotransmitter
Ach	M3	PAG, LC, X	Excitatory	
NE	α1-Adrenergic	LC	Excitatory	
Serotonin	5-HT2A2B, 5-HT3, 5-HT4	Raphé	Excitatory	
Dopamine	Likely D_1	PVN, hypothalamus	Excitatory	
ATP	P2X2	Ventral medulla; CO_2/H^{+-} sensitive cells in the RTN	Excitatory	
Adenosine	P2Y1	Ventral medulla	Excitatory	
Substance P	NK1	nTS, NA	Excitatory	
CCK	CCK1	nTS, raphé	Excitatory	
TRH	TRH-R (1 and 2)	Raphé	Excitatory	
GABA	$GABA_A$, $GABA_B$	Ubiquitously expressed	Inhibitory	Major inhibitory neurotransmitter (can be excitatory during fetal life)
Glycine	GlyR		Inhibitory	Can be excitatory during fetal life
NE	α2-Adrenergic	Pons	Inhibitory	
Dopamine	D4	PVN, hypothalamus		
Adenosine	A_1, A_2	Ubiquitous from metabolism of ATP that increases during hypoxia	Inhibitory	Contributes to respiratory depression at the baseline (A_1), and mediates HVD
Opioid	μ, δ, κ	nTS, PBN, PVN, raphé	Inhibitory	Prominent inhibitory effect during early development
PDGF	PDGF-β	nTS	Inhibitory	Contributes to HVD

Ach, Acetylcholine; *AMPA*, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; *ATP*, adenosine triphosphate; *CCK*, cholecystokinin; *GABA*, γ-aminobutyric acid; *GluR*, glutamate receptor; *GlyR*, glycine receptor; *HVD*, hypoxic ventilatory depression; *LC*, locus ceruleus; *NA*, nucleus ambiguus; *NE*, norepinephrine; *NMDA*, *N*-methyl-D-aspartate; *nTS*, nucleus tractus solitarii; *PAG*, periaqueductal gray; *PBN*, parabrachial nucleus; *PDGF*, platelet-derived growth factor; *PVN*, paraventricular nucleus; *RTN*, retrotrapezoid nucleus; *TRH*, thyrotropin-releasing hormone; *TRH-R*, thyrotropin-releasing hormone receptor; *X*, vagal nucleus.

Data from Doi A, Ramirez JM. Neuromodulation and the orchestration of the respiratory rhythm. *Respir Physiol Neurobiol*. 2008;164:96; and Simakajornboon N, Kuptanon T. Maturational changes in neuromodulation of central pathways underlying hypoxic ventilatory response. *Respir Physiol Neurobiol*. 2005;149:273.

role of several neuromodulator systems. For example, serotonergic neurons in the caudal medullary raphé nuclei have extensive projections to phrenic and hypoglossal motoneurons, the nTS, the RTN, and the PBC.[26] The serotonergic system has a significant influence on the modulation and integration of diverse homeostatic functions, including cardiorespiratory responses and thermogenesis.[27] Individuals with Prader-Willi syndrome, who may exhibit breathing abnormalities at birth,[28] have mutations in the necdin gene (*NDN*) on chromosome 15 leading to abnormalities in the brainstem serotonergic system.[29] Mice lacking the necdin gene also have abnormal brainstem serotonergic neurochemistry.[30] Medullary serotonergic neurons are also CO_2 sensitive.[31] In genetically modified mice that do not develop medullary serotonergic neurons, CO_2 sensitivity is reduced by 50%.[32]

In some infants who have died of SIDs/sudden unexplained infant death (SUID), neuropathologic studies have shown disruptions of the brainstem serotonergic system.[27,33] While specific single-gene mutations that regulate serotonin production and function have not been identified in infants who have died of SIDS, some studies have shown a higher proportion of specific polymorphisms in the 5′ regulatory region of the *SLC6A4* gene, which encodes serotonin transporter, which regulates the reuptake of serotonin from the extracellular space. Specifically, infants who have died of SIDS have an increased frequency of the long allele variant and the variable number 12-tandem repeat in intron 2 polymorphisms[34] in the promoter. The long allele occurs more frequently in African-Americans; African-Americans also have a 2.0-fold greater incidence of SIDS/SUID than whites. The higher risk of SIDS/SUID in non-Hispanic Blacks when compared to non-Hispanic whites has remained consistent even though the overall incidence of SIDS/SUID has decreased in both groups.[35–37] Effectively, the polymorphisms result in increased activity of serotonin transporter, thereby decreasing the time that serotonin stays in the synapse, leading to a relative serotonin deficiency causing dysregulation of the cardiorespiratory system.

Rett syndrome is an X-linked disorder with mutations in several genes, but the most common genetic defect (90%) is in the methyl CpG binding protein 2 gene (*MECP2*). Affected individuals are

normal at birth and then experience progressive deterioration leading to severe motor, cognitive, and autistic behaviors. They also have characteristic severe respiratory disturbances with prolonged apnea and hyperventilation that can be fatal. Genetically modified mice that lack the *MECP2* gene have reduced levels of norepinephrine and serotonin in the medulla and have breathing patterns similar to those of humans with Rett syndrome.[38] Pharmacologic treatment to increase brain norepinephrine and serotonin levels stabilizes breathing and prolongs the life of these mice.[39] A case report demonstrating the efficacy of fluoxetine and buspirone in reducing breathing dysregulation in a patient with Rett syndrome has been published.[40] Altered GABA neurotransmission might also be causative as suggested by experiments using stem cells from a patient with Rett syndrome that demonstrated that the functional switch of GABA neurotransmission from excitation to inhibition was impaired.[41]

Congenital central hypoventilation syndrome (CCHS), also known as *Ondine's curse*, is another rare autosomal dominant genetic disorder, occurring in 1 in 200,000 live births. Affected individuals characteristically have adequate ventilation during wakefulness but profound hypoventilation during sleep as well as impaired ventilatory responses to CO_2 and hypoxia during sleep and wakefulness.[42] Although the disorder most commonly presents during infancy, milder forms may present later in childhood or even during adulthood. More than 90% of individuals with CCHS have mutations in the *PHOX2B* gene.[43–45] *PHOX2B* is a homeobox gene located on chromosome 4 that is specifically expressed in limited types of neurons involved in autonomic processes.[46] Its expression is required for the development of the carotid body, nTS, and catecholaminergic neurons. It is also expressed in chemosensitive glutamatergic neurons in the RTN that receive polysynaptic inputs from peripheral arterial chemoreceptors.[15] *Neurons in the nTS that express PHOX2B also appear to be chemosensitive to CO_2 in preclinical models*. Thus, mutations in the *PHOX2B* gene alter the development of key structures that regulate the chemical control of breathing.

The *PHOX2B* gene has a stretch of 20 alanine repeats in exon 3. Most affected individuals have the classic mutation that adds additional alanine repeats to the 20-alanine repeat, resulting in a stretch of 25 to 35 alanine repeats instead of 20. This mutation is classified as polyalanine repeat mutations (PARMs). The severity of the disease is correlated with the number of extra alanines. Patients with $PHOX2B^{20/25}$ have 25 versus 20 alanines; they have the mildest disease, may never need 24-hour ventilatory support, and may present only after infection or exposure to agents that inhibit respiration. On the other hand, patients with 28 to 32 alanine repeats in the gene ($PHOX2B^{20/28\text{-}32}$) often need continuous ventilatory support. Fewer affected individuals with CCHS have non-polyalanine repeat mutations (NPARMs) resulting in deletions in exon 3 that cause frameshift mutations. Depending on the mutation, some patients require tracheostomy and long-term ventilation and/or diaphragmatic pacing.[47] While respiratory stimulants are not effective in increasing respiratory drive, drugs that cause respiratory depression may be harmful.[48]

From genetically modified mouse models with mutations in the *PHOX2B* gene, we know that its expression is essential for the development of the RTN in the brainstem and catecholaminergic and cholinergic traits in the autonomic nervous system.[49] The RTN contains putative central chemoreceptors that have intrinsic pH sensitivity and release the excitatory neurotransmitter glutamate, thereby stimulating breathing during hypercapnia.[50] However, abnormalities throughout the autonomic nervous system are often seen in patients with CCHS. Specifically, patients can present with Hirschsprung disease (Haddad syndrome) and neuroblastomas (neuroblastoma-Hirschsprung disease-CCHS syndrome).[51] As reviewed by Moreira et al.[49] Hirschsprung disease occurs in 80% of patients with NPARM and 10% of patients with PARM. Similarly, neural crest tumors are found in 1% of PARM patients and in 41% of NPARM patients.

Bronchopulmonary Reflexes That Modulate the Central Respiratory Network

The nTS in the brainstem is where sensory information from vagally mediated reflexes and chemical signals from the blood (arterial chemoreceptors) and cerebrospinal fluid (central chemoreceptors) and information from higher brain regions are integrated; neurons from the nTS synapse onto respiratory-related neurons, thereby augmenting or attenuating minute ventilation.

Essentially all bronchopulmonary reflexes that modify the depth and duration of inspiration and expiration are mediated through the vagus nerve. The vagus nerve has both myelinated and unmyelinated fibers. Myelinated vagal afferent fibers are activated via (1) slowly adapting stretch receptors (SARs), which are activated by volume and stretch of the lung (mediating the Breuer-Hering reflex); or (2) rapidly adapting receptors (RARs) that are activated in response to inhaled irritants (e.g., ammonia, cigarette smoke) and large inflations or deflations of the lung.[52] Activation of SARs changes the duration of inspiration and expiration, whereas activation of RARs causes sighs (i.e., augmented breaths) and cough. Unmyelinated vagal afferents, specifically C-fibers in the airway, are activated by a multitude of chemical stimuli, including CO_2 and capsaicin, in addition to lung edema and elevated temperature. Activation of C-fibers in the lung causes rapid shallow breathing and apnea. Table 41.2 lists bronchopulmonary and upper airway reflexes and their physiologic responses.

Slowly Adapting Stretch Receptors: Major Modulators of Respiratory Timing

The duration of inspiratory or expiratory effort is greatly influenced by mechanoreceptors that are activated by changes in lung volume. The most well-characterized vagally mediated bronchopulmonary reflex is the pulmonary stretch reflex mediated through SARs, discovered by Josef Breuer in 1868. In adult cats, Breuer showed that expansion of the lungs reflexively inhibits inspiration and promotes expiration and that deflation of the lungs promotes inspiration and inhibits expiration.[53] In humans the contribution of the Breuer-Hering reflex to tidal breathing is determined by occlusion of the airway at the end of expiration. The following occluded inspiratory effort is prolonged, and expiratory effort is shortened. Alternatively, the occlusion can be performed at end of an inspiratory effort; then the following occluded expiratory effort is prolonged and inspiratory effort is shortened.[54] With this technique, the Breuer-Hering reflex significantly contributes to tidal breathing in infants. The reflex is strongest at birth and then decreases during the first year of life.[55] When lung volume is increased on CPAP the resultant prolongation of expiration and slowing of respiratory rate is a manifestation of the Breuer-Hering reflex.[56]

TABLE 41.2 Airway Receptors and Reflex Responses

Receptor	Characteristics	Stimulant	Responses	Comment
Slowly adapting stretch receptors	1. Mechanoreceptors 2. Mediated by fast-conducting, myelinated vagal fibers 3. Located in lung parenchyma	Lung volume and transmural pressure	1. Breuer-Hering reflex 2. Termination of inspiration and prolongation of expiration 3. Bronchodilation 4. Tachycardia	Breuer-Hering reflex more active in infants than in adults
Rapidly adapting receptors	1. Mechanoreceptors 2. Irritant receptors 3. Located throughout the airways 4. Mediated by fast-conducting, myelinated vagal fibers	1. Inhaled irritants 2. Low lung volumes	1. Cough 2. Mucus production 3. Augmented breaths (sighs)	Responsible for inducing sighs in premature infants—restoring functional residual capacity
Bronchial and pulmonary C fibers	1. Located throughout the airway from the nose to alveoli 2. Stimulated by substances in the pulmonary circulation and inhaled 3. Slowly conducting, nonmyelinated vagal fibers	1. Capsaicin 2. Respiratory irritants 3. Lung edema 4. Inflammatory mediators	1. Rapid, shallow breathing 2. Apnea 3. Bronchoconstriction 4. Laryngoconstriction 5. Mucus secretion 6. Vasodilatation (pulmonary C fibers) 7. Bradycardia	J-receptors located in alveoli activated by lung edema
Laryngeal chemoreflex	1. Potent airway-protective reflex from aspiration 2. Receptors in laryngeal mucosa 3. Mediated by sensory fibers in the superior laryngeal nerve	1. Hypoosmolarity 2. Low chloride content	Response in newborns: 1. Hypoventilation/apnea 2. Laryngoconstriction 3. Swallowing 4. Bradycardia 5. Shunting of blood flow to brain, heart, adrenals Response in adults: 1. Cough 2. Arousal 3. Swallowing	May contribute to apnea and bradycardic events associated with oral feedings in premature infants. Immature responses are exacerbated during hypoxia

Rapidly Adapting Receptors: Cough, Augmented Breaths

Lung deflation, mechanical stimulation, and chemical irritants also stimulate vagal afferents of RARs, causing augmented breaths, cough, and increased mucus production.[53] RARs are also activated at low lung volumes. Newborns, especially premature newborns, have excessive compliance of the chest wall predisposing them to low lung volumes during tidal breathing. Activation of RARs and the resulting augmented breath are particularly important in restoring lung inflation in premature and term infants. The frequency of augmented breaths is inversely related to gestational age, with premature infants having the greatest frequency[57] when compared with term infants and adults.

C-Fiber Receptors: Apnea, Bronchoconstriction, Rapid Shallow Breathing

Pulmonary and bronchial C-fiber receptors are unmyelinated vagal fibers located throughout the respiratory tract, extending from the nose to the lung parenchyma. Pulmonary C-fibers are accessible from the pulmonary circulation, whereas bronchial C-fibers are accessible from the bronchial circulation and have similar sensitivity to various stimuli.[58] C-fibers are activated by a variety of substances: inflammatory mediators, capsaicin, lobeline, and phenylbiguanidine. Capsaicin and phenylbiguanidine are used experimentally to identify vagal afferents as C-fibers and characterize stimulus-response profiles. C-fiber simulation induces central and local effects—cough, apnea, laryngospasm, and bronchoconstriction—followed by rapid shallow breathing, bradycardia, and hypotension. Juxtacapillary receptors (J receptors) are composed of C-fibers located in the alveolar walls. They are activated by lung edema and congestion and cause rapid shallow breathing. By far the most common respiratory response from C-fiber stimulation is reflex apnea characterized by prolongation of the expiratory time from excitation of post-inspiratory neurons and continuous firing of central expiratory neurons.[58]

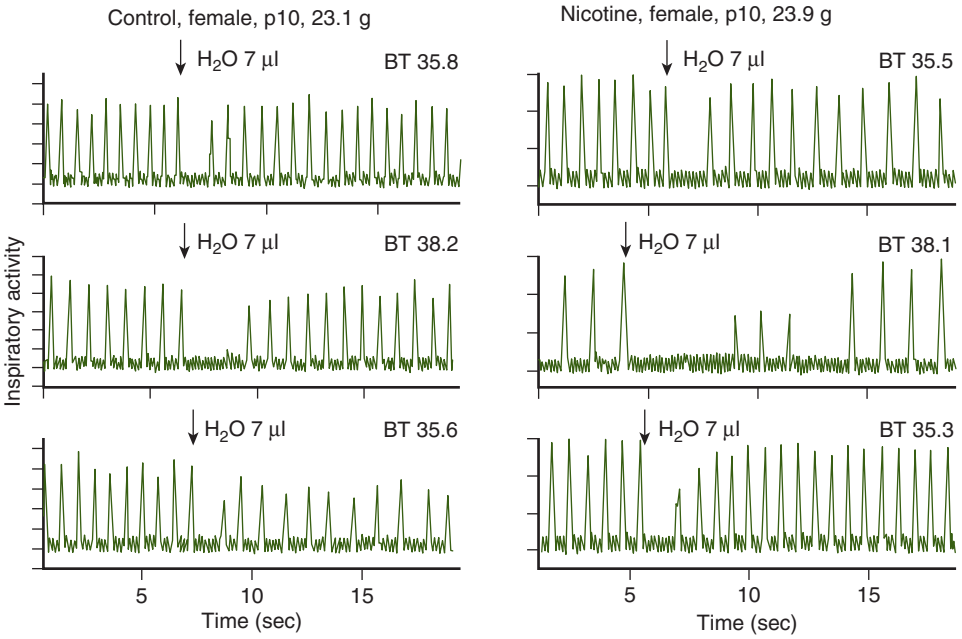
In newborns the stimulation of pulmonary C-fibers by chemical stimulants causes bronchoconstriction and apnea.[59] Capsaicin-induced apneic response and the sensitivity of the reflex were greatest in newborn rat pups younger than 10 postnatal days.[60] Bronchopulmonary C-fibers are also stimulated by acidosis, adenosine, reactive oxygen species, hyperosmotic solutions, and lung edema. Furthermore, inflammatory mediators in the local environment sensitize C fibers to other stimuli.[61]

Pulmonary C-fiber-mediated respiratory inhibition may cause persistent apnea beyond term gestation in infants born at the limit of viability who have lung inflammation from chronic lung disease.[7] Local C-fiber activation in the lung may also be

the mechanism accounting for the increase in apnea observed in infants with viral infections[62] and unlikely to be from direct viral invasion of the central nervous system.[63] Prenatal exposure to nicotine/tobacco smoke is a known risk factor for SIDS. In newborn rat pups, prenatal nicotine exposure sensitizes bronchopulmonary C fibers and prolongs apnea in responses to C-fiber stimulation. As outlined already, C-fibers are also activated by inflammation.[64] The epidemiologic association between infection, prenatal tobacco smoke exposure, and SIDS could be attributed to sensitization of bronchopulmonary C-fibers from tobacco smoke exposure, confounded by acute infection leading to prolonged apnea from which the infant does not recover.[65]

Laryngeal Reflexes

Receptors that respond to changes in upper airway pressure and chemicals are abundantly distributed throughout the laryngeal mucosa. These receptors can be slowly adapting, rapidly adapting irritant receptors, or C-fibers. Water receptors that are stimulated by hypo-osmolarity and low chloride content may also be involved. Stimulation of upper airway mechanoreceptors and chemoreceptors modifies the activity of upper airway muscles as well as the pattern and timing of diaphragmatic activity. The upper airway reflex that mediates significant cardiorespiratory effects that occur in newborns is the laryngeal chemoreflex (LCR). The LCR is one of the most potent defensive reflexes protecting the respiratory tract from inadvertent aspiration.[66] Laryngeal chemoreceptors are stimulated by liquid in the airway, which induces coughing, swallowing, and arousal in mature models. However, the response in immature models is apnea followed by hypoventilation, laryngeal constriction, and swallowing.[67] In addition to respiratory inhibition, bradycardia, peripheral vasoconstriction, and redistribution of blood flow also occur. The associated apnea and bradycardia can be life threatening in newborns,[67–70] and in newborns baseline hypoxemia enhances the severity of the apnea and bradycardia induced by the LCR.[71] Afferent fibers for this reflex travel in the superior laryngeal nerve, a branch of the vagus nerve. These afferents synapse with neurons in the nTS, which then send (1) excitatory projections to motoneurons of the recurrent laryngeal nerve in the nucleus ambiguus, causing constriction of the thyroarytenoid muscle (laryngeal constrictor), resulting in laryngospasm; (2) inhibitory projections to phrenic motoneurons in the cervical spinal cord, inhibiting diaphragmatic contraction, resulting in apnea; and (3) an excitatory pathway to cardiac vagal neurons in the nucleus ambiguus, causing bradycardia. The LCR occurs in the fetus and likely functions to prevent aspiration of amniotic fluid, which contains approximately half the chloride content of pulmonary fluid.[72,73] In premature infants the reflex may be involved in the apnea and bradycardic responses associated with feeds and gastroesophageal reflux (GER) that reaches the larynx or nasopharynx. Whether the immature response is still present in term infants or how the maturation of the reflex is affected by premature birth has not been determined. Studies in newborn animals show that the apnea associated with the LCR is prolonged during hyperthermia in newborn rats[74] and is further accentuated if the animal was exposed prenatally to nicotine.[75] This relationship is illustrated in Fig. 41.2.



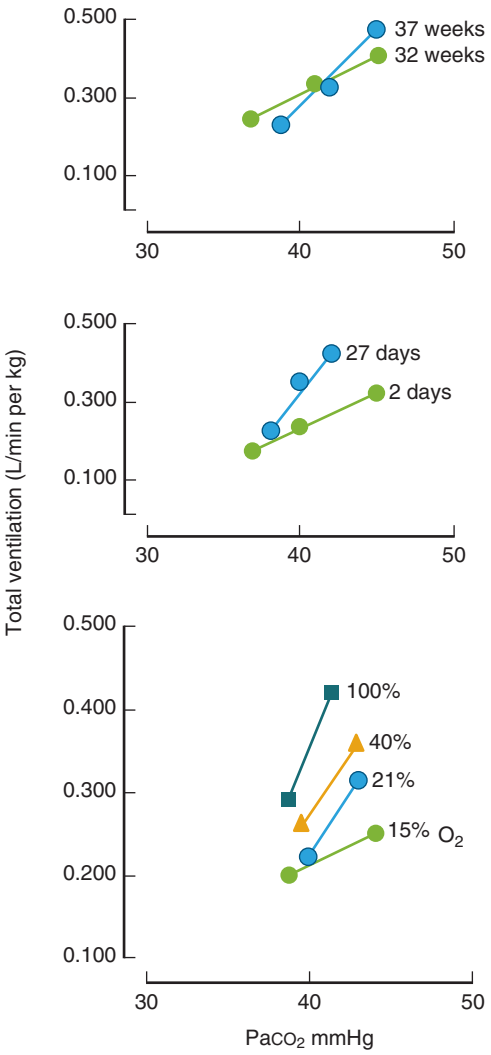
• **Fig. 41.2** Prenatal Exposure to Nicotine and Increased Body Temperature Prolongs the Laryngeal Chemoreflex in Rat Pups at Postnatal Day 10. Example of laryngeal chemoreflex from female postnatal day 10 rat pups during baseline conditions *(top panels)*, during mild hyperthermia *(middle panels)*, and during a final, recovery period *(bottom panels)*. The data displayed on the *left* were obtained from a rat pup born to a control dam, and the data displayed on the *right* were obtained from a rat pup born to a dam infused with nicotine during pregnancy. The *downward arrows* indicate the time at which small volumes of water were injected into the larynx, and the body temperature *(BT)* is listed to the right of each example. Note the prolonged apnea and respiratory disruption during hyperthermia compared with normothermic conditions, and note that maternal exposure to nicotine markedly prolonged the laryngeal chemoreflex in the rat pup shown on the right. (From Xia L, Leiter JC, Bartlett D Jr. Gestational nicotine exposure exaggerates hypothermic enhancement of laryngeal chemoreflex in rat pups. *Respir Physiol Neurobiol*. 2010;171:17–21.)

Because of profound inhibitory cardiorespiratory effects that are further accentuated by prenatal nicotine exposure, stimulation of the LCR may be an important reflex that is operative in some SIDS cases and infants with acute life-threatening events.[67,76–78] Overheating and prenatal exposure to nicotine are both risk factors highly associated with SIDS.[27]

Maturation of CO_2/H^+ Sensitivity of Central Chemoreceptors

In air-breathing animals, respiratory rhythmogenesis is primarily driven by the level of $Paco_2$ in the blood and cerebrospinal fluid and, to a lesser extent, by oxygen tension. For every 1 mmHg increase in $PaCo_2$, ventilation will increase by 20% to 30%. Specialized chemosensitive cells in the brainstem depolarize in response to changes in CO_2/H^+ concentration; they drive breathing through synaptic inputs to respiratory-related neurons.[79] Although peripheral arterial chemoreceptors in the carotid body also depolarize in response to increasing CO_2/H^+ concentration, these receptors are primarily responsible for modifying breathing in response to changes in oxygen tension (reviewed later). In fetal sheep, hypercapnia causes an increase in the depth of fetal breathing movements, with no change in respiratory rate. In humans, maternal exposure to CO_2 also increases fetal breathing.[80] Ventilatory responses to CO_2 are present immediately after birth in most mammalian species, and CO_2 sensitivity increases with maturation. However, in the newborn rat, CO_2 sensitivity is robust during the first several days of postnatal life; it declines markedly in the next 2 weeks of life and then gradually increases to reach adult levels by the end of the third week.[81] Premature and term infants tested at 2 days of postnatal age have modest ventilatory responses to 2% and 4% CO_2, although the strength of the ventilatory response is less in the more immature infants.[82] In premature and late preterm newborns, CO_2 sensitivity increases with postnatal age, reaching a mature response by four weeks of postnatal age (Fig. 41.3).[83,84] Similar to the response in the fetus, the increase in ventilation is predominantly due to an increase in tidal volume and not respiratory rate. If the increase in inspiratory effort against an occluded airway is used as an indicator of central respiratory drive, the increase in CO_2 sensitivity with postnatal development is due to an increase in central respiratory drive in human infants.[82] Premature infants with apnea of prematurity have reduced ventilatory responses to CO_2 compared with control infants of the same postconceptional age.[85,86] This finding suggests that infants with apnea of prematurity have reduced central respiratory drive to breathe when compared with infants who do not have apnea of prematurity at the same postconceptional age.

It is unknown whether the maturation of synaptic inputs from chemosensitive neurons to respiratory-related neurons in the brainstem or the maturation of intrinsic properties of chemosensitive neurons accounts for the increase in CO_2 sensitivity with early postnatal development. Although such studies of human infants are impossible, data from studies performed in neonatal rats show that intrinsic responses of chemosensitive neurons in the nTS and locus ceruleus are already mature at birth. It is less clear whether there is a developmental increase in the sensitivity of chemosensitive neurons in the medullary raphé, an increase in the number of chemosensitive neurons in the RTN, or both.[21] However, within the first several weeks of postnatal development in the rat, the size of brainstem neurons changes,



• **Fig. 41.3** The relationship between ventilatory responses to carbon dioxide and gestational age *(top panel)*, postnatal age *(middle panel)*, and the concentration of inspired oxygen *(bottom panel)*. $Paco_2$, Partial pressure of carbon dioxide. (From Rigatto H, Brady JP, de la Torre Verduzco R. Chemoreceptor reflexes in preterm infants: II. The effect of gestational and postnatal age on the ventilatory response to inhaled carbon dioxide. Pediatrics. 1975;55[5]:614–620; Rigatto H, De La Torre Verduzco R, Gates DB. Effects of O_2 on the ventilatory response to CO_2 in preterm infants. *J Appl Physiol*. 1975;39[6]:896–899.)

and both dendritic arborization in the nTS and astrocyte proliferation increase. Astrocytes contribute substantially to the pH of the extracellular milieu surrounding chemosensitive neurons.[21] It is likely that all these morphologic and neurochemical changes within and between neurons and astrocytes in the brainstem contribute to the maturation of CO_2 sensitivity in the early weeks of postnatal development.

Maturation of O_2 Sensitivity of Peripheral Arterial Chemoreceptors

The peripheral arterial chemoreceptors in the carotid body, located at the bifurcation of the carotid artery, are best known for reflex control of ventilation in response to changes in arterial oxygen tension.[87] However, specialized cells within the carotid

body also depolarize in response to changes in blood CO_2/H^+ concentration, reflexively increasing ventilation in response to acidosis and hypercapnia and decreasing ventilation in response to hypocapnia. Histologically, the carotid body chemoreceptors consist of (1) type 1 or glomus cells, similar to presynaptic neurons, which are chemosensitive and contain neurotransmitters and autoreceptors; (2) postsynaptic afferent nerve fibers from the carotid sinus nerve, which oppose glomus cells,[87,88] contain neurotransmitters and postsynaptic receptors, and have cell bodies in the petrosal ganglion;[87,88] (3) type 2 cells, similar to glial cells, which are not chemosensitive; (4) microganglion cells that express cholinergic traits;[89] and (5) blood vessels and sympathetic fibers innervating these vessels. In response to hypoxia or increased CO_2/H^+ concentration, type 1 cells depolarize. The major excitatory neurotransmitter in peripheral arterial chemoreceptors is ATP. ATP then binds to the rapid cation ligand-gated ion channel on postsynaptic receptors on the carotid sinus nerve. Neuromodulators, inhibitory (such as dopamine) and excitatory, further shape the response. Changes in ventilation during the first 30 seconds of hypoxia are used to assess the maturation of hypoxic chemosensitivity of the peripheral arterial chemoreceptors, while changes in ventilation in response to hyperoxia measure the contribution of peripheral arterial chemoreceptors on baseline breathing. Hypoxic and hyperoxic sensitivity do not follow the same developmental trajectory. Although oxygen tension less than 25 mmHg stimulates the carotid body in exteriorized fetal sheep, peripheral arterial chemoreceptors are not functional at any level of hypoxia for the first several days after birth in most mammalian species (for a historical overview, see Walker, 1984), including human infants (term and preterm). The rapid increase in arterial oxygen tension during the transition from fetal to neonatal life likely contributes to the resetting of the activation of the carotid body to higher oxygen tension. After birth, hypoxic chemosensitivity gradually *increases* with postnatal maturation and reaches adult levels by 2 to 3 weeks postnatally.[90,91] On the other hand, the contribution of peripheral arterial chemoreceptors to eupneic breathing determined by a drop in ventilation in response to hyperoxia gradually *decreases* with maturation; the drop in ventilation in response to hyperoxia is greatest in premature versus term infants and least in adults.[92,93] Moreover, premature infants who have a greater frequency of apnea and periodic breathing have a greater reduction in ventilation when exposed to fractional inspired oxygen of 100% (Dejours test). While activity from the peripheral arterial chemoreceptors is not essential for breathing to be established at birth, trophic factors from peripheral arterial chemoreceptors acting on central mechanisms that control breathing during early postnatal development are key in stabilizing rhythmogenesis so that breathing is maintained. The first two weeks of postnatal development appear to be the critical period for this trophic influence since sectioning of the carotid sinus nerve (the conduit for trophic support to the central respiratory network) results in the death of several mammalian species from respiratory failure several weeks after denervation.[94] Exposures during this critical period of development (reviewed in Gauda et al.[65]) that can lead to sustained alterations in chemoreceptor function include

- Environmental exposure to the extremes of oxygen tension (chronic or intermittent hypoxia and hyperoxia)[91,95,96]
- Nicotine exposure[97–99]
- Maternal separation—in male rats[100]
- Perinatal inflammation[101,102]

Hypoxic Ventilatory Depression: Consequences for the Neonate

Although the peripheral arterial chemoreceptors function to increase ventilation in response to hypoxia, minute ventilation significantly declines after 2 to 3 minutes of hypoxic exposure. This decline is commonly referred to as *hypoxic roll-off, hypoxic ventilatory decline*, or *hypoxic ventilatory depression*. Hypoxic ventilatory depression occurs in individuals of all ages, but it is most pronounced in the fetus and newborn.[103] Whereas the hypoxic ventilatory decline is usually still above baseline ventilation in mature models, the hypoventilatory response in newborns is usually below baseline ventilation and is often associated with apnea. This hypoxic roll-off is not because of a decline in activity of peripheral arterial chemoreceptors. Mechanisms accounting for hypoxic respiratory depression are most well characterized in the fetal animals in which the central brainstem nuclei mediating this response have been attributed to the pons. Transverse section of the upper pons results in a sustained hyperventilatory response to hypoxia in fetal and newborn sheep.[104] Hypoxia activates expiratory neurons in the ventrolateral pons, and chemical blockade of this area blocks the hypoxic respiratory depression in newborn rats.[105]

Several neuromodulators have been implicated in mediating hypoxic ventilatory decline, including norepinephrine, adenosine, GABA, serotonin, opioids, and platelet-derived growth factor, as shown in Table 41.1.[106] All these neuromodulators contribute to the ventilatory depression in newborns, but particular attention has been paid to adenosine. Degradation of intracellular and extracellular ATP is the main source of extracellular adenosine, which then mediates its cellular effects by binding to A_1, A_{2a}, A_{2b}, and A_3 adenosine receptors. In response to hypoxia, brain adenosine levels can increase 2.3-fold in fetal sheep[107] and 100-fold in rats in response to ischemia.[108] Non-specific adenosine receptor blockers, particularly caffeine and methylxanthines, are commonly administered to premature infants to increase central respiratory drive, and aminophylline inhibits hypoxic ventilatory depression in newborns.[109] A_1 adenosine inhibitory receptors are found on respiratory-related neurons.[103] Specific A_1 adenosine receptor agonists depress phrenic output in a reduced brainstem spinal cord preparation, whereas A_1 adenosine receptor blockers reverse this inhibitory effect.[110] In fetal sheep the hypoxic respiratory depression appears to be mediated by excitatory A_{2a} receptors because blockade of A_{2a} receptors eliminates hypoxic ventilatory roll-off in conscious newborn sheep.[107] Xanthines (e.g., caffeine, aminophylline) block both A_1 and A_{2a} adenosine receptors; therefore, their effectiveness in stabilizing ventilation and decreasing the frequency of apnea in premature infants may be by directly altering the ventilatory response to hypoxia as well as by nonspecifically increasing respiratory drive (see Apnea of Prematurity).

Effect of Sleep State on Breathing

Sleep state has a profound influence on breathing in the fetus and newborn, and most disorders of breathing that affect the young and old are worse during sleep. Active sleep (AS) and quiet sleep (QS) in infants are equivalent to rapid eye movement (REM) and non-REM sleep, respectively in older children and adults. Breathing during AS is mostly driven by inputs from the reticular activating system, with less influence from $Paco_2$, whereas breathing during QS is driven by chemical control. Similar to REM sleep in adults, AS is associated with paralysis of striated muscles. Although this

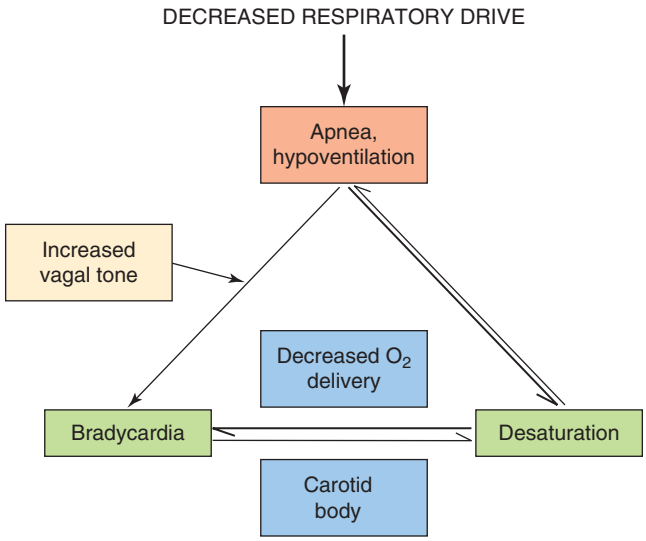
paralysis may be necessary to prevent the acting out of dreams, paralysis of striated muscles that are involved in breathing can be problematic for the newborn. Breathing becomes more irregular in AS and REM sleep because of inhibition of the intercostal muscles and upper airway dilating muscles. The discoordination between chest wall muscles and the diaphragm during AS causes paradoxical breathing: the chest wall moves inward during inspiration, with the abdomen moving outward. The more compliant the chest wall, the greater propensity for paradoxical breathing, which is common in the most immature infants. In addition, during inspiration, intrathoracic pressure becomes more negative, and this "suction pressure" causes narrowing or collapse of the compliant upper airway, particularly pharyngeal structures, leading to upper airway obstruction. Paradoxical breathing movements seen on physical examination or detected on inductive plethysmography are often interpreted as a sign of upper airway obstruction. During QS, breathing is characterized by smooth, regular breaths of consistent frequency and depth associated with tonic and phasic activity of the muscles of respiration that are in phase with each other. The chest wall and the abdomen move outward during inspiration, whereas they move inward during expiration. AS and QS can be reliably assessed at 30 to 32 weeks' gestation.[111] At this gestational stage, premature infants spend 80% of their sleep time in AS; the proportion decreases to 50% by term, and in adulthood, REM sleep accounts for only 20% of sleep time. Sleep state in normal infants also modifies the time to arousal and the ventilatory responses. The time to arousal on exposure to a hypoxic, somatosensory, or auditory stimulus is greater in AS than with QS in infants during the first 6 months of life.[112] The arousal latency in response to a hypoxic stimulus in AS is longer in preterm infants at 2 to 5 weeks' postnatal age than that of term infants at the same postnatal age.[113] The level of oxygen desaturation at the time hypoxic arousal occurs is similar in AS and QS.[114] Irregular respiratory patterns are more common during AS in both term and premature infants, however, periodic breathing and the ventilatory response to CO_2 are greater during QS.[115] Because of the complexity of the ventilatory response to hypoxia and the frequent occurrence of arousals induced by hypoxic exposure, assessment of the effect of sleep state on the ventilatory response to hypoxia in newborns is more difficult. Other than the clear difference in arousal in response to a hypoxic stimulus between the two sleep states, differences between sleep states in other respiratory parameters are more variable.[114] Recent data in preterm infants indicate that even long apneas or hypoxia fail to elicit arousals or any sign of sleep disruption.[116] Arousal may, therefore, not be the main mechanism for apnea termination in preterm infants.

Although most disorders of breathing, such as obstructive sleep apnea, become more severe during sleep, the breathing disorder that is most significantly influenced by sleep state in the newborn is CCHS. As noted previously, CCHS is characterized by abnormalities in chemical control of breathing; therefore, with maturation, as the frequency of QS increases, so does the severity of the disorder. During QS, CO_2 sensitivity is markedly impaired in affected individuals, and exposure to hypercapnia does not significantly increase minute ventilation.[117] Of infants who died of SIDS, their sleep state during their terminal event was unknown. However, adequate arousal mechanisms are key in preventing respiratory failure and death, and impaired arousal mechanisms are hypothesized to be causative in SIDS. Prone sleeping position increases the percentage of QS,[118] and QS is associated with increased time to hypoxic arousal in human infants.[114] A hypoxic microenvironment from rebreathing with defective arousal and auto-resuscitative mechanisms is hypothesized to have occurred in infants who have died of SIDS in the face-down (i.e., prone) sleeping position.[119] Therefore, sleep state can have a significant influence on the control of breathing during health and disease, especially in the newborn.

Thus far this chapter has outlined the neurocircuitry and neurochemistry of the respiratory network along with its synaptic inputs that undergo significant maturation during the newborn period. Because these pathways are less developed in premature infants, premature infants have apnea of prematurity, which often requires active therapeutic intervention and can delay hospital discharge. The components of the respiratory network, similarly to other developing organ systems, are plastic and uniquely vulnerable to pathologic processes in premature infants.[65] Therefore, the episodes of intermittent hypoxemia and bradycardia that accompany apnea of prematurity may be a cause of acute and chronic morbidities in this high-risk population.

Apnea of Prematurity

Respiratory pauses are universal features in infants born prematurely and are most prominent in the lowest gestational-aged infants. There is no consensus as to when a respiratory pause can be defined as an apneic episode. It has been proposed that apnea be defined by its duration (e.g., longer than 15 seconds) or accompanying bradycardia and desaturations. However, even the 5 to 10-second pauses that occur in periodic breathing can be associated with bradycardia or desaturation. It should be emphasized that periodic breathing (ventilatory cycles of 10 to 15 seconds with pauses of 5 to 10 seconds) is a normal breathing pattern that should not require therapeutic intervention. It is thought to be the result of dominant peripheral chemoreceptor activity responding to fluctuations in arterial oxygen tension. Episodic bradycardia and desaturation in preterm infants are almost invariably secondary to apnea or hypoventilation (Fig. 41.4).[120] The rapidity of the fall in oxygen saturation after a respiratory pause is directly proportional to baseline oxygenation, which is

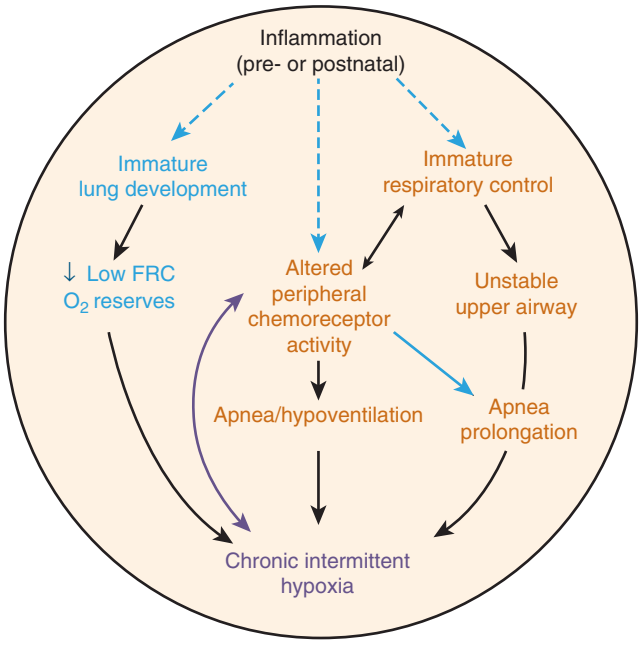


• **Fig. 41.4** The sequence of the events whereby apnea results in various combinations of desaturation and bradycardia. (From Martin RJ, Abu-Shaweesh JM. Control of breathing and neonatal apnea. *Biol Neonate*. 2005;87:288–295.)

related to lung volume and the severity of lung disease.[121] Prenatal and postnatal inflammation directly affect the developing lung and peripheral arterial chemoreceptors,[102] which further increases the frequency of oxygen desaturations during short respiratory pauses (Fig. 41.5).[121]

Apnea is classified traditionally into three categories on the basis of the absence or presence of upper airway obstruction: central, obstructive, and mixed. Central apnea is characterized by total cessation of inspiratory efforts with no evidence of obstruction. In obstructive apnea, the infant tries to breathe against an obstructed upper airway, resulting in chest wall motion without airflow through the entire apneic episode. Mixed apnea consists of obstructed respiratory efforts, usually following central pauses. The site of obstruction in the upper airways is primarily in the pharynx, although it also may occur in the larynx and possibly at both sites. It is assumed that there is an initial loss of central respiratory drive, and its recovery is accompanied by a delay in activation of upper airway muscles superimposed on a closed upper airway.[54] Mixed apnea typically accounts for more than 50% of long apneic episodes, followed in decreasing frequency by central apnea and obstructive apnea. Purely obstructive spontaneous apnea in the absence of a positional problem is probably uncommon. Because standard impedance monitoring of respiratory efforts via chest wall motion cannot recognize obstructed respiratory efforts, mixed versus obstructive apnea is frequently identified by the accompanying bradycardia or desaturation.[122,123]

Presentation of apnea can reflect a non-specific alteration in either the environment (e.g., thermal) or the general well-being of preterm infants. For example, neonatal sepsis can manifest itself as an increase in the frequency or severity of apnea, and the underlying cause must be treated. Studies using a rat pup model suggest that the systemically released cytokine interleukin-1β binds to its receptor on vascular endothelial cells at the blood-brain barrier.



• **Fig. 41.5** The consequences of the adverse effects of prenatal or postnatal inflammation on the developing lung and respiratory network leading to the emergence of chronic intermittent hypoxia in premature infants. *FRC*, Functional residual capacity. (From Di Fiore JM, Martin JM, Gauda EB. Apnea of prematurity—perfect storm. *Respir Physiol Neurobiol*. 2013;189:213–222.)

This binding induces the synthesis of prostaglandin E_2, which induces respiratory depression in the brainstem.[124] These studies provide insight into mechanisms whereby sepsis often manifests itself as apnea of prematurity. Anemia, presumably via decreased oxygen delivery, is also frequently implicated as a cause of apnea. Transfusion of packed red cells can provide some variable benefit for apnea of prematurity.[125] Furthermore, there may be some utility in reducing persistent intermittent desaturations in extremely low birth weight newborns younger than 7 days of age;[126] this is recently confirmed by Kovatis et al.[127]

Therapeutic Approaches

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) of 4 to 6 cmH_2O is a relatively safe and effective therapy for apnea of prematurity. Because longer episodes of apnea frequently involve an obstructive component, CPAP appears to be effective by splinting the upper airway with positive pressure and decreasing the risk of pharyngeal or laryngeal obstruction.[128] CPAP also has a beneficial effect in apnea by increasing functional residual capacity, thereby improving oxygenation status. At a higher functional residual capacity, the time from cessation of breathing to desaturation and resultant bradycardia is prolonged. Heated high-flow nasal cannula therapy has been suggested as an equivalent treatment modality to allow CPAP delivery while improving ease of care. Although this approach is used widely, its efficacy for the treatment of apnea of prematurity has not been studied in depth. For example, a recent small study in 10 premature infants with a crossover design suggested that work of breathing may be greater when infants are treated with heated high-flow nasal cannula therapy (HHFNC) versus CPAP therapy.[129] Non-invasive ventilatory strategies, using a nasal mask to deliver intermittent positive pressure, avoid the need for full ventilatory support in some infants and can be effective in reducing the need for reintubation for persistent apnea.[130] However, for severe or refractory episodes, endotracheal intubation and mechanical ventilation may be needed. Minimal ventilator settings should be used to allow for spontaneous ventilatory efforts and to minimize the risk of barotrauma.

Methylxanthines

Methylxanthines have been the mainstay of pharmacologic treatment of apnea of prematurity for several decades. Both theophylline and caffeine are used and have multiple physiologic and pharmacologic mechanisms of action. Xanthine therapy appears to increase minute ventilation, improve CO_2 sensitivity, decrease hypoxic depression of breathing, enhance diaphragmatic activity, and decrease periodic breathing. The likely major mechanism of action is through competitive antagonism of adenosine receptors. Adenosine acts as an inhibitory neuroregulator in the central nervous system via activation of adenosine A_1 receptors.[131] In addition, activation of adenosine A_{2a} receptors appears to excite GABAergic interneurons, and released GABA may contribute to the respiratory inhibition induced by adenosine.[132]

Methylxanthines have some well-documented short-term adverse effects. Toxic levels can produce tachycardia, cardiac dysrhythmias, feeding intolerance, and seizures (infrequently), although these effects are seen less commonly with caffeine at the usual therapeutic doses. Mild diuresis is caused by all methylxanthines. The observation that xanthine therapy causes an increase

in metabolic rate and oxygen consumption of approximately 20% suggests that caloric demands can be increased with this therapy at a time when nutritional intake is already compromised.[133]

A large, international, multicenter clinical trial was designed to test short-term and long-term safety of caffeine therapy for apnea of prematurity. In the neonatal period, caffeine treatment was associated with a significant reduction in the postmenstrual ages at which both supplemental oxygen and endotracheal intubation were needed.[134] Of even greater interest was the significant decrease in the incidence of cerebral palsy and cognitive delay in the caffeine-treated group, which was not sustained by 5 years of age,[135] but caffeine exposure was associated with a sustained beneficial effect on developmental coordination disorders at 5 years of age.[136] This finding raises interesting questions regarding possible mechanisms underlying this beneficial effect of caffeine on neurodevelopmental outcomes (Fig. 41.6). These beneficial effects include the observation in animal models that loss of the adenosine A_1 receptor gene is protective against hypoxia-induced loss of brain matter[137] and a potential benefit of caffeine on immune mechanisms that mediate lung and brain injury.[138] Recent data in rodent models also support a beneficial anti-inflammatory effect of xanthine therapy in immature lungs exposed to the proinflammatory effects of prenatal exposure to lipopolysaccharide, postnatal hyperoxia, or both.[139,140] The inhibitory effects of caffeine on adenosine receptor subtypes may differ depending on the xanthine concentrations; this should present a note of caution in the clinical situation when high doses of caffeine are considered. Data in an immature ovine model do not, however, demonstrate an adverse effect on developing white matter.[141] Interestingly, there was a reduced risk of motor impairment at 11 years of age in the multicentral trial cohort without clear academic benefit. The precise reasons for this selective benefit are not entirely clear.[142]

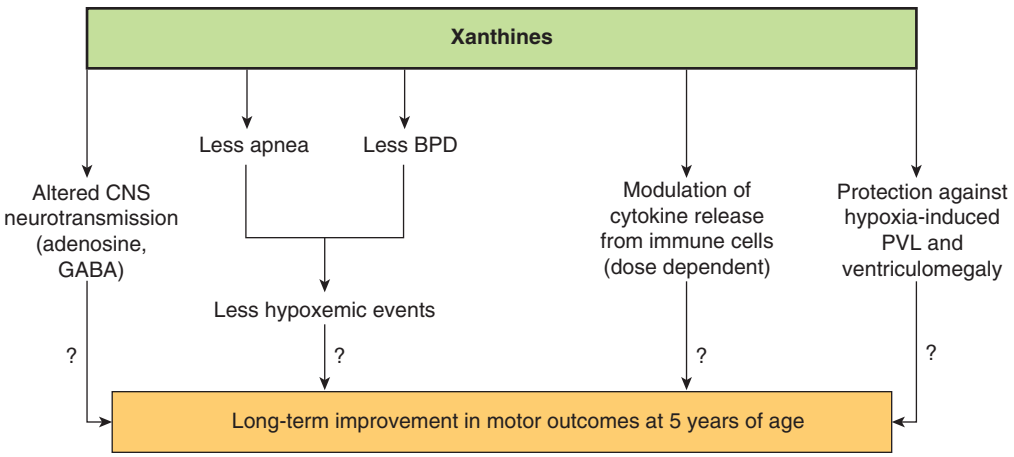
In recent years the practice of caffeine administration has expanded as a result of both increased use of non-invasive ventilation and the success of the earlier caffeine trial. Caffeine is now widely used in a prophylactic mode to prevent, rather than treat, clinically significant apnea; early onset of treatment appears beneficial.[143] Extended use beyond the apparent resolution of apnea has also been proposed to decrease intermittent hypoxic episodes.[144] As already suggested, increased dosing beyond the traditional caffeine citrate loading dose of 20mg/kg followed by a maintenance dose of 5 to 10 mg/kg every 24 hours should, however, proceed with caution pending further study. A recent small pilot randomized trial of high-dose caffeine therapy suggested an association between a high loading dose and cerebellar injury on magnetic resonance imaging in preterm infants.[145] Although measurement of serum caffeine levels is not widely practiced, these levels may not become subtherapeutic until 11 to 12 days after cessation of treatment.[146] Increased respiratory drive may increase within minutes after intravenous caffeine administration as measured by diaphragmatic activity in preterm infants.[147]

In conclusion, safety and efficacy have been clearly established for the timing and dosing of caffeine as employed in the international multicenter clinical trial cited earlier.[134] For infants with apnea and about to be extubated, clinicians can prescribe the drug with confidence.[148] However, in asymptomatic infants not on respiratory support xanthine therapy may not be warranted. It remains unclear whether earlier and longer duration therapy might confer additional benefit.

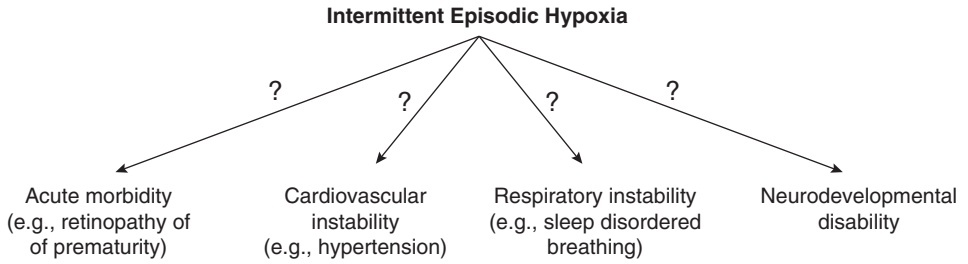
Doxapram has been proposed as an additional mode of pharmacotherapy in the face of apnea resistance to xanthine therapy. This is currently under study in Europe. However, until efficacy versus safety data become available, doxapram cannot be recommended.[149]

Gastroesophageal Reflux and Apnea of Prematurity

GER is often incriminated as a cause of neonatal apnea. Despite the frequent coexistence of apnea and GER in preterm infants, investigations of the timing of reflux in relation to apneic events indicate that they are rarely related temporally. When these events coincide, there is no evidence that GER prolongs the concurrent



• **Fig. 41.6** Multiple proposed mechanisms are demonstrated whereby xanthine therapy for apnea of prematurity may improve motor outcomes in former premature infants. These outcomes include functional changes in neurotransmitters in the brain, a decrease in hypoxemic episodes that accompany apnea, especially in the presence of bronchopulmonary dysplasia *(BPD)*, a proposed protective effect of adenosine receptor inhibition on hypoxia-induced white matter injury, and the beneficial effect of adenosine receptor blockade on inflammatory cytokine-mediated lung or brain injury. *CNS*, Central nervous system; *GABA*, γ-aminobutyric acid; *PVL*, periventricular leukomalacia. (Modified from Abu-Shaweesh JM, Martin RJ. Neonatal apnea: what's new? *Pediatr Pulmonol*. 2008;43:937–944.)



• **Fig. 41.7** Proposed acute and longer-term morbidities that might be a consequence of intermittent hypoxic episodes in early postnatal life. (Modified from Martin RJ, Wilson CG. What to do about apnea of prematurity. *J Appl Physiol*. 2009;107:1015–1016.)

apnea.[150] Although physiologic experiments in animal models reveal that reflux of gastric contents to the larynx induces reflex apnea, there is no clear evidence that treatment of reflux affects the frequency of apnea in most preterm infants. Therefore, pharmacologic management of reflux with agents that decrease gastric acidity or enhance gastrointestinal motility generally should be reserved for preterm infants who exhibit signs of emesis or regurgitation of feedings, regardless of whether apnea is present, and infants at specific risk (e.g., exhibiting neurodevelopmental delay or following gastrointestinal surgical repair). Extreme caution should be taken when histamine H_2 receptor blockers are used to change gastric pH since the use of these agents in hospitalized very low birth weight infants has been associated with an increased incidence of necrotizing enterocolitis and increased mortality.[151] Therapy for such infants should begin with non-pharmacologic approaches, such as thickened feeds because acid suppression therapy has been shown to alter the gastrointestinal microbiome and increase the risk of lower respiratory infection in infants[152] and necrotizing enterocolitis.[153] There remain considerable differences of opinion among neonatologists, pediatric gastroenterologists, and pediatric pulmonologists regarding the diagnosis and management of this problem.[154]

Resolution and Consequences of Neonatal Apnea

Apnea of prematurity generally resolves by 36 to 40 weeks' postconceptional age; however, apnea frequently persists beyond this time in more immature infants. Available data indicate that cardiorespiratory events in such infants return to the baseline normal level at 43 to 44 weeks' postconceptional age.[155] In other words, beyond 43 to 44 weeks' postconceptional age, the incidence of cardiorespiratory events in preterm infants does not significantly exceed that in term infants. The persistence of cardiorespiratory events may delay hospital discharge for a subset of infants. In these infants, apnea longer than 20 seconds is rare; rather, they exhibit frequent bradycardia to less than 70 to 80 bpm with short respiratory pauses.[156] The reason that some infants exhibit marked bradycardia with short pauses is unclear, but available data suggest a vagal phenomenon and benign outcome. For a few of these infants home cardiorespiratory monitoring, until 43 to 44 weeks' postconceptional age, is offered in the United States as an alternative to a prolonged hospital stay. The apparent lack of a relationship between persistent apnea of prematurity and SIDS has significantly decreased the practice of home monitoring, with no increase in the SIDS rate. Infants born prematurely experience multiple problems during their time spent in the neonatal intensive care unit, and many of these conditions can contribute to poor neurodevelopmental outcomes. For example, a history of hyperbilirubinemia has been associated with persistent apnea of prematurity in preterm infants and animal models.[157,158] The problem of correlating apnea with the outcome is compounded by the fact that nursing reports of apnea severity may be unreliable, and impedance monitoring techniques will fail to identify mixed and obstructive events. Despite these reservations, available data suggest a link between the number of days of assisted ventilation and the number of days of apnea after extubation with impaired neurodevelopmental outcome.[159] A relationship has also been shown between delay in resolution of apnea and bradycardia beyond 36 weeks' corrected age and a higher incidence of an unfavorable neurodevelopmental outcome.[160] Finally, a high number of cardiorespiratory events recorded after discharge via home cardiorespiratory monitoring appear to correlate with less favorable neurodevelopmental outcome.[161]

Recent studies have focused more on the incidence and severity of desaturation events because techniques for long-term collection of pulse oximetry data are now more advanced. Furthermore, it is likely that recurrent hypoxia is the detrimental feature of the breathing abnormalities exhibited by preterm infants. Recent data demonstrate that hypoxic episodes of at least 60 seconds' duration are associated with an unfavorable neonatal outcome in a large cohort of preterm infants.[162] Other clinically significant morbidities associated with intermittent hypoxic episodes include retinopathy of prematurity[163] and bronchopulmonary dysplasia.[164] Such associations between intermittent hypoxia and morbidity may well be causal. Fig. 41.7 summarizes proposed morbidities that might be attributable to intermittent hypoxic episodes in early life. Recurrent episodes of desaturation during early life and resultant effects on neuronal plasticity related to peripheral and central respiratory control mechanisms may serve as an important future direction for study.

Acute Neonatal Respiratory Disorders

NICOLLE FERNÁNDEZ DYESS, JOHN P. KINSELLA, AND THOMAS A. PARKER

KEY POINTS

- Marked hypoxemia in the newborn can be caused by parenchymal lung disease, pulmonary vascular disease, or congenital heart defects.
- Events occurring at delivery, as well as the response to supplemental oxygen and to continuous positive airway pressure, can provide important clues to the pathophysiology of hypoxemic respiratory failure in the newborn.
- The echocardiogram has become a vital tool in the clinical management of newborns with hypoxemic respiratory failure, primarily to assess for pulmonary hypertension and to interrogate shunts that may be contributing to hypoxemia.
- Although gestational age is a critical variable in the relative frequency with which different respiratory disorders affect newborns, a broad spectrum of potential causes must be considered in an individual baby of any gestational age.
- In extremely preterm newborns with respiratory distress, surfactant deficiency is the most common cause.
- Transient tachypnea of the newborn is one of the most common causes of respiratory distress in the term newborn.

The evaluation and management of respiratory distress in the newborn poses unique challenges and remains one of the most vexing problems facing neonatal caregivers. Although some of the pathophysiologic features of respiratory disorders in the preterm infant are similar to those in term newborns, the incidence of disorders varies by gestational age. Table 42.1 lists the most common causes of respiratory distress in newborns and demonstrates the relative frequency of each diagnosis. The traditional perspective of categorizing hypoxemia and respiratory failure in the newborn, due to cardiac, pulmonary vascular, or air space (lung) disease, is insufficient because of the inevitable complex interactions among the three. For example, the problem of persistent pulmonary hypertension of the newborn (PPHN) is defined by severe pulmonary vasoconstriction leading to suprasystemic pulmonary artery pressure with extrapulmonary right-to-left venoarterial admixture across the fetal channels of the foramen ovale and the ductus arteriosus. However, PPHN rarely occurs without concomitant parenchymal lung disease and disturbances in cardiac performance.

In this chapter, we present an algorithm for evaluation of the newborn with hypoxemia and respiratory distress. We then focus on common causes of neonatal respiratory failure, progressing from those most frequently encountered in preterm infants to those more commonly diagnosed in near-term and term infants.

Evaluation of the Newborn With Hypoxemia/Respiratory Distress

One of the most anxiety-provoking experiences for many clinicians (particularly those in training) is the initial evaluation and management of a newborn with hypoxemia and respiratory distress. Traditional textbooks provide a wealth of information about individual conditions once they have been identified. However, there are few sources designed to guide the clinician in an orderly fashion through a comprehensive diagnostic evaluation. In this section, we propose an approach to the evaluation of the hypoxemic newborn that may be useful in clarifying the cause of hypoxemia/respiratory distress and in determining the proper sequence of diagnostic and therapeutic interventions.

History

Marked hypoxemia in the newborn can be caused by parenchymal lung disease with ventilation–perfusion (V/Q) mismatch or intrapulmonary shunting, pulmonary vascular disease causing extrapulmonary right-to-left shunting (i.e., PPHN), or anatomic right-to-left shunting associated with congenital heart disease. Evaluation should begin with a history that includes assessment of risk factors for hypoxemic respiratory failure. A relevant history may include the results of prenatal ultrasound studies. Lesions such as congenital diaphragmatic hernia (CDH) and congenital cystic adenomatoid malformation are diagnosed prenatally with increasing frequency. Although many anatomic congenital heart defects can be diagnosed prenatally, vascular abnormalities (e.g., coarctation of the aorta, total anomalous pulmonary venous return) are more difficult to diagnose with prenatal ultrasonography. A history of a structurally normal heart by fetal ultrasonography should be confirmed by echocardiography in the newborn with cyanosis (see section on Echocardiography later).

Other historical information that may be important in the evaluation of the cyanotic newborn includes a history of severe and prolonged oligohydramnios causing pulmonary hypoplasia. Also important is a history of prolonged fetal bradyarrhythmia and/or tachyarrhythmia and marked anemia (caused by hemolysis, twin–twin transfusion, or chronic hemorrhage) that may cause congestive heart failure, pulmonary edema, and respiratory distress. Maternal illness (e.g., diabetes mellitus), medication use (e.g., aspirin or medications containing nonsteroidal anti-inflammatory drugs causing premature constriction of the

TABLE 42.1 Causes of Respiratory Distress

Cause	Frequency (%)

• BOX 42.1 Neonatal Respiratory Failure: History and Risk Factor Assessment

Prenatal

Prenatal ultrasound study results
History of oligohydramnios and duration
History of fetal brady/tachyarrhythmia
Maternal illnesses, drugs, medications
History of fetal distress or nonreassuring fetal heart tones
Risk factors for infection
Use of antenatal steroids

Delivery

History of positive pressure ventilation in delivery room
Meconium-stained amniotic fluid
Hemorrhage (acute fetomaternal or fetoplacental hemorrhage; abruption)
Birth trauma
Low Apgar score

• BOX 42.2 Physical Examination

Respiratory Distress (Retractions, Grunting, Nasal Flaring)

Suggests lung parenchymal disease (compliance), upper airway disease, or metabolic acidemia

No Significant Respiratory Distress (Tachypnea Alone)

Suggests hypoxemia caused by cyanotic heart disease without lung disease

ductus arteriosus, association of Ebstein malformation with maternal lithium use), and illicit drug use may contribute to acute cardiopulmonary distress in the newborn. Risk factors for infection that cause sepsis/pneumonia should be considered, including premature or prolonged rupture of membranes, fetal tachycardia, maternal leukocytosis, uterine tenderness, and other signs of intraamniotic infection. Additionally, the use of antenatal steroids should be ascertained in the event of a preterm delivery.

Events at delivery may provide clues to the cause of hypoxemic respiratory failure in the newborn. For example, if positive pressure ventilation is required in the delivery room, the risk of pneumothorax increases. A history of meconium-stained amniotic fluid is the sine qua non of meconium aspiration syndrome (MAS). Birth trauma (e.g., clavicular fracture, phrenic nerve injury) or acute fetomaternal or fetoplacental hemorrhage may cause respiratory distress in the newborn (Box 42.1).

Physical Examination

The initial physical examination provides important clues to the cause of cyanosis. Marked respiratory distress in the newborn (retractions, grunting, nasal flaring) suggests the presence of pulmonary parenchymal disease with decreased lung compliance. However, it is important to recognize that upper airway obstruction (e.g., Pierre Robin sequence or choanal atresia) and metabolic acidemia can also cause severe respiratory distress. In contrast, the newborn with cyanosis alone or cyanosis plus tachypnea (i.e., nondistressed tachypnea) typically has cyanotic congenital heart disease, most commonly transposition of the great vessels. Although pulmonary edema is a common complication of some forms of congenital heart disease and can lead to respiratory distress, this would be an unlikely presenting sign immediately after delivery when pulmonary vascular resistance (PVR) is still elevated.

The presence of a heart murmur audible in the first few hours after birth is an important sign in the newborn with cyanosis or respiratory distress. In this setting, it is unusual for the common left-to-right shunt lesions (patent ductus arteriosus, atrial septal defect, ventricular septal defect) to produce an audible murmur because PVR remains high and little turbulence is created across the defect. A murmur that sounds like a ventricular septal defect in the first few hours of life is most commonly caused by tricuspid regurgitation (associated with PPHN or an ischemic myocardium) (Box 42.2).

Response to Supplemental Oxygen

A marked increase (to 100%) in arterial oxygen saturation (Sao_2) with supplemental oxygen (by hood, mask, or endotracheal tube) suggests the presence of intrapulmonary shunt or V/Q mismatch caused by lung disease or reactive PPHN. The response to continuous positive airway pressure is also a useful discriminator between severe lung disease and other causes of hypoxemia. Most patients with PPHN have at least a transient increase in oxygenation in response to interventions such as high inspired oxygen concentration and/or initiation of mechanical ventilation. But if preductal Sao_2 never reaches 100%, the likelihood of cyanotic heart disease is high (Box 42.3).

• BOX 42.3 Short-Term Response to Supplemental Oxygen (High Fio_2 by Hood, Mask)

Minimal or Transient Change in Sao_2

Cyanotic heart disease, persistent pulmonary hypertension of the newborn

Marked Increase in Sao_2

Parenchymal lung disease, congenital diaphragmatic hernia with ductal-dependent systemic blood flow

Fio_2, Fraction of inspired oxygen; *Sao_2*, arterial oxygen saturation.

Interpretation of Pulse Oximetry Measurements

The interpretation of preductal (right hand) and postductal (lower extremity) arterial oxygen saturation, measured by pulse oximetry, provides important clues to the cause of hypoxemia in the newborn. Right-to-left shunting across the ductus arteriosus (but not the patent foramen ovale) causes postductal desaturation (with a >5% preductal–postductal saturation difference). However, it is important to recognize that variability in oximetry readings may be related to differences in available devices and may be affected by local perfusion.

If the measurements of preductal and postductal arterial oxygen saturation are equivalent, this suggests either that the ductus arteriosus is patent and PVR is subsystemic (i.e., the hypoxemia is caused by parenchymal lung disease with intrapulmonary shunting or cyanotic heart disease with ductal-dependent pulmonary blood flow) or that the ductus arteriosus is closed (precluding any interpretation of pulmonary artery pressure without echocardiography). It is uncommon for the ductus arteriosus to close in the first few hours after birth in the presence of systemic or suprasystemic pulmonary artery pressures.

The most common cause of preductal–postductal gradients in oxygenation is suprasystemic PVR in PPHN causing right-to-left shunting across the ductus arteriosus (associated with MAS, surfactant deficiency/dysfunction, CDH, non-CDH pulmonary hypoplasia, or idiopathic pulmonary hypertension [without accompanying pulmonary parenchymal disease]). However, ductal-dependent systemic blood flow lesions (hypoplastic left-sided heart syndrome, critical aortic stenosis, interrupted aortic arch, coarctation) may also present with postductal desaturation. Moreover, anatomic pulmonary vascular disease (alveolar capillary dysplasia, pulmonary venous stenosis, anomalous venous return with obstruction) can cause suprasystemic PVR with right-to-left shunting across the ductus arteriosus and postductal desaturation.

Finally, the unusual occurrence of markedly lower preductal Sao_2 compared with postductal Sao_2 suggests one of two diagnoses: transposition of the great vessels (TGV) with pulmonary hypertension (PH) or TGV with coarctation of the aorta (Table 42.2).

TABLE 42.2 Role of Pulse Oximetry in Evaluation of Neonatal Hypoxemic Respiratory Failure

Preductal Sao_2 = postductal Sao_2	Intrapulmonary shunt: PVR < SVR Cyanotic congenital heart disease with left-to-right shunting across the PDA Ductal-dependent pulmonary blood flow: pulmonary atresia/stenosis, tricuspid atresia, Ebstein anomaly PPHN: right-to-left shunt at PFO, PVR > SVR, ductus closed
Preductal Sao_2 > postductal Sao_2	PVR > SVR with right-to-left shunting across the PDA: PPHN: MAS, RDS, CDH Ductal-dependent systemic blood flow: HLHS, IAA, coarctation Anatomic pulmonary vascular disease: alveolar capillary dysplasia, pulmonary vein stenosis, TAPVR with obstruction
Preductal Sao_2 ≤ postductal Sao_2	TGV with pulmonary hypertension TGV with coarctation of the aorta

CDH, Congenital diaphragmatic hernia; *HLHS*, hypoplastic left-sided heart syndrome; *IAA*, interrupted aortic arch; *MAS*, meconium aspiration syndrome; *PDA*, patent ductus arteriosus; *PFO*, patent foramen ovale; *PPHN*, persistent pulmonary hypertension of the newborn; *PVR*, pulmonary vascular resistance; *RDS*, respiratory distress syndrome; *Sao_2*, arterial oxygen saturation; *SVR*, systemic vascular resistance; *TAPVR*, total anomalous pulmonary venous return; *TGV*, transposition of the great vessels.

• BOX 42.4 Chest Radiograph and Laboratory Evaluation

Chest Radiograph

Hypoxemia out of proportion to radiographic changes suggests congenital heart disease with ductal-dependent pulmonary blood flow or extrapulmonary right-to-left shunting with persistent pulmonary hypertension of the newborn.

Arterial Blood Gas, Complete Blood Count, Blood Pressure

Arterial blood gas: assess respiratory and metabolic acidemia
Complete blood count: for evidence of infection
Blood pressure: ductal-dependent systemic blood flow and closing of patent ductus arteriosus (e.g., coarctation)

Laboratory and Radiologic Evaluation

One of the most important tests to perform in the evaluation of the newborn with cyanosis is the chest radiograph (CXR). The CXR can demonstrate the classic findings of respiratory distress syndrome (RDS) (air bronchograms, diffuse granularity, underinflation), pneumonia (diffuse parenchymal lung disease), MAS (heterogenous parenchymal lung disease, often with adjacent areas of air trapping and atelectasis), or CDH. Perhaps the most important question to ask when one is viewing the CXR is whether the severity of hypoxemia is out of proportion to the radiographic changes. In other words, marked hypoxemia despite supplemental oxygen in the absence of severe pulmonary parenchymal disease radiographically suggests the presence of an extrapulmonary right-to-left shunt (idiopathic PPHN or cyanotic heart disease; Box 42.4).

Other essential measurements include measurement of arterial blood gas to determine the blood gas tensions and pH, a complete blood count to evaluate the newborn for signs of infection or evidence of symptomatic polycythemia, blood glucose to evaluate for symptomatic hypoglycemia, and blood pressure measurements in the right arm and a lower extremity to identify aortic obstruction (interrupted aortic arch, coarctation).[1]

Echocardiography

Echocardiography has become a vital tool in the clinical management of newborns with hypoxemic respiratory failure (Box 42.5). The initial echocardiographic evaluation is important to rule out structural heart disease causing hypoxemia (e.g., ductal dependent pulmonary blood flow lesions, anomalous pulmonary venous return). Moreover, it is critically important to diagnose congenital heart lesions for which inhaled nitric oxide (iNO) treatment would be contraindicated. In addition to the lesions mentioned earlier, congenital heart lesions that can present with hypoxemia unresponsive to high inspired oxygen concentrations (i.e., dependent on right-to-left shunting across the ductus arteriosus) include critical aortic stenosis, interrupted aortic arch, and hypoplastic left-sided heart syndrome. Decreasing PVR with iNO treatment in these conditions could lead to systemic hypoperfusion, worsening the clinical course and delaying definitive diagnosis.

Echocardiographic evaluation is an essential component in the initial evaluation and ongoing management of the hypoxemic newborn. As noted earlier, hypoxemia can be caused by intrapulmonary right-to-left shunting or V/Q disturbances associated with severe lung disease. In unusual circumstances, right-to-left shunting can occur across pulmonary-to-systemic collaterals. However, extrapulmonary right-to-left shunting at the foramen ovale and/or ductus arteriosus (PPHN) also complicates hypoxemic respiratory failure and must be assessed to determine initial treatments and evaluate the response to those therapies.

PPHN is defined by the echocardiographic determination of extrapulmonary venoarterial admixture (right-to-left shunting at the foramen ovale and/or ductus arteriosus), not simply evidence of increased PVR (i.e., elevated PVR without extrapulmonary shunting does not directly cause hypoxemia). Echocardiographic signs suggestive of PH (e.g., increased right ventricular systolic time intervals, septal flattening) are less definitive.

Doppler measurements of atrial-level and ductal-level shunts provide essential information when one is managing hypoxemic respiratory failure in a newborn. For example, left-to-right shunting at the foramen ovale and ductus arteriosus with marked hypoxemia suggests predominant intrapulmonary shunting, and interventions should be directed at optimizing lung inflation.

Finally, the measurements made with echocardiography can be used to predict or interpret the response or lack of response to various treatments. For example, in the presence of severe left-ventricular dysfunction with pulmonary hypertension, the left-ventricular dysfunction may contribute to pulmonary venous hypertension, such as occurs in congestive heart failure. Pulmonary vasodilation alone (without improvement in cardiac performance) may be ineffective in increasing oxygenation. In this setting, the echocardiographic findings include right-to-left ductal shunting (caused by suprasystemic PVR) and mitral insufficiency with left-to-right atrial shunting. Efforts to reduce PVR should be accompanied by targeted therapies to increase cardiac performance and decrease left-ventricular afterload. As such, careful echocardiographic assessment will provide invaluable information about the underlying pathophysiology and help guide the course of treatment. Furthermore, serial echocardiography is important to determine the response to interventions (e.g., pulmonary vasodilators) and to reevaluate cases where specific interventions have not resulted in improvement or with progressive clinical deterioration.

• BOX 42.5 Role of Echocardiography in Evaluation of Persistent Pulmonary Hypertension of the Newborn and the Use of Inhaled Nitric Oxide

Extrapulmonary Shunt

Right-to-left shunting at the arterial duct and/or foramen ovale is observed in infants with suprasystemic pulmonary hypertension.

If echocardiography demonstrates adequate left-ventricular performance, consider inhaled NO use after effective lung recruitment (see functional measurements below).

Anatomy

Inhaled NO use may be contraindicated in the presence of duct-dependent systemic blood flow (e.g., hypoplastic left heart syndrome).

Left-Ventricular Performance

Inhaled NO use may be contraindicated in the presence of left ventricular systolic/diastolic dysfunction (e.g., mitral insufficiency with left-to-right atrial shunting with right-to-left ductal shunting suggesting possible right ventricle–dependent systemic blood flow).

NO, Nitric oxide.

Persistent Pulmonary Hypertension of the Newborn

As described previously, PPHN is a syndrome associated with diverse neonatal cardiac and pulmonary disorders that are characterized by high PVR causing extrapulmonary right-to-left shunting of blood across the ductus arteriosus and/or foramen ovale. (The syndrome of PPHN and the role of iNO are discussed in more detail in Chapter 47.) However, because its relationship to respiratory failure in newborns is so vital to understanding the clinical pathophysiology and approaches to treatment, the current use of iNO and other approaches to PPHN treatment as they relate to specific respiratory diseases are discussed in the following sections.

Specific Pulmonary Conditions Causing Respiratory Distress in the Newborn

It is important to acknowledge that although gestational age is a critical variable in the relative frequency with which each of these disorders affect newborns, a broad spectrum of potential causes must be considered in an individual baby of any gestational age. We will start with RDS, the respiratory disease most commonly associated with prematurity, and then proceed to those more commonly encountered in newborns of progressively advancing gestational age.

Respiratory Distress Syndrome

More than half of extremely low birth weight newborns will have some type of respiratory distress (Fig. 42.1). In that population, RDS, historically known as *hyaline membrane disease* (HMD), is by far the most common diagnosis (51%), followed by transient tachypnea of the newborn (TTNB) (4%), and pneumonia/sepsis (2%). In preterm newborns at later gestational ages, the incidence

of any type of respiratory distress is much lower, and the proportion with TTNB increases. Compared with the incidences of the three diagnoses featured in Fig. 42.1, the incidence of other causes of respiratory distress (see Table 42.1) is very low in preterm infants, but the causes should be considered in those newborns with an atypical clinical course.

Risk Factors

The main risk factor for RDS, by far, is prematurity (see Fig. 42.1). Other factors that increase the risk of RDS include perinatal asphyxia, maternal diabetes, absence of labor, absence of prenatal steroid administration to the mother, male sex, and white race. The central feature of RDS is surfactant deficiency.

Pathophysiology

Because alveoli with insufficient (or dysfunctional) surfactant are unstable and tend to collapse, patients with RDS develop generalized atelectasis, ventilation–perfusion mismatching, and subsequent hypoxemia and respiratory acidosis. During breathing (either spontaneous or assisted), shear stress in the alveoli and terminal bronchioles occurs because of the repetitive reopening of collapsed alveoli and the overdistention of open alveoli.[2] These forces can quickly damage the fragile lung architecture, leading to leakage of proteinaceous debris into the airways (i.e., hyaline membranes). This debris (Fig. 42.2) may impair the function of what little surfactant is present, leading to a progression of respiratory symptoms and respiratory failure if not interrupted.

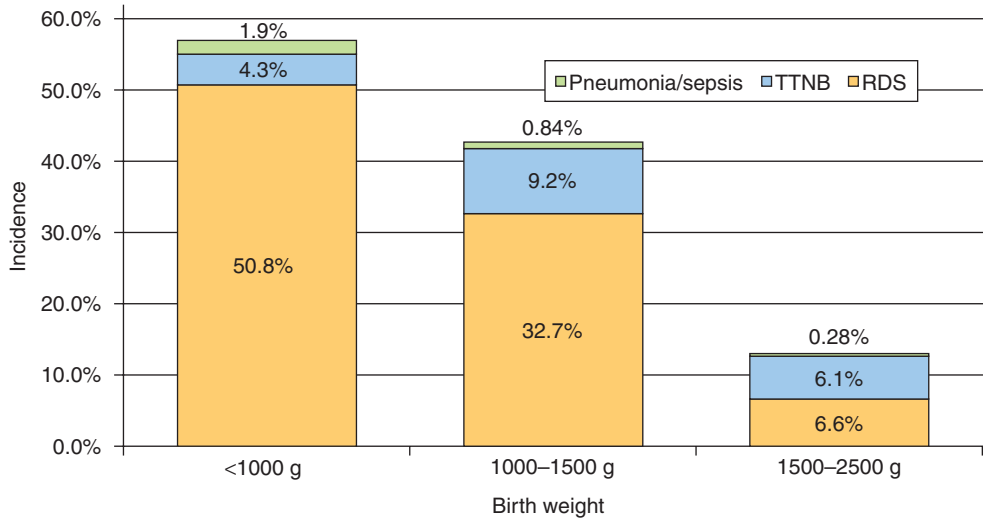
If supportive therapy is successful, the repair phase usually begins during the second day after birth with the appearance of macrophages and polymorphonuclear cells.[3] Debris is phagocytosed, and the damaged epithelium is regenerated. Interstitial fluid is mobilized into lymphatics, leading to the diuretic phase of RDS characterized by high urine output.

With uncomplicated RDS, the patient's condition improves by the end of the first week after birth. However, infants requiring high concentrations of oxygen and positive pressure ventilation for severe RDS may develop inflammation, progressive injury, and inappropriate repair of the growing lung, leading to bronchopulmonary dysplasia (BPD) (see Chapter 43).

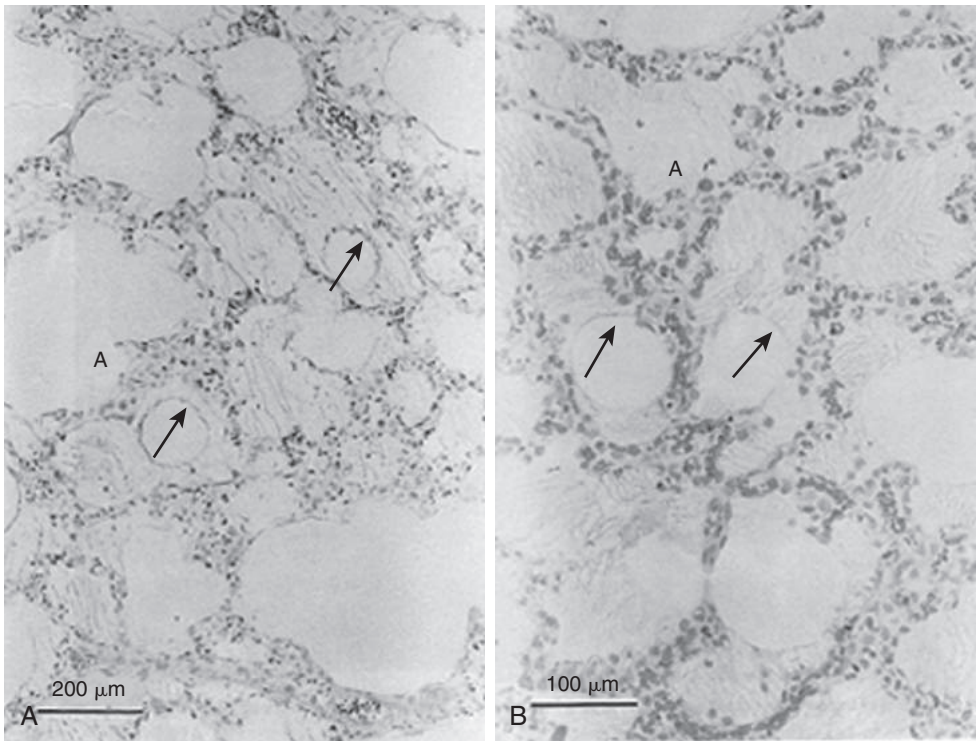
Surfactant Physiology

Surface tension is generated from molecular attractive forces within a liquid that oppose spreading; this is the reason that water "beads up" on a clean surface. According to Laplace's law, the pressure within a sphere is proportional to its surface tension and inversely proportional to its radius. Surfactants are surface-active materials that lower surface tension. Lung surfactant, composed of phospholipids and proteins, reduces surface tension as the radius of the alveolus decreases. In the absence of surfactant, there is high surface tension, so the pressure required to keep smaller alveoli open would exceed the pressure keeping open larger alveoli, resulting in collapse of the small alveoli into larger ones, as shown in Fig. 42.3. However, when lined with high-quality surfactant, the surface tension falls quickly as the alveolar radius gets smaller because the surfactant molecules become crowded during deflation (Fig. 42.4). When the radius is very small, the surface tension falls almost to zero, and the pressure required to keep smaller alveoli open is negligible, preventing collapse. During inflation, as the radius of each alveolus increases, surface tension increases even faster. This means that the pressure in the larger alveoli will be higher than that in smaller ones; this pressure difference will cause flow *to* the smaller alveoli, thereby improving gas distribution.

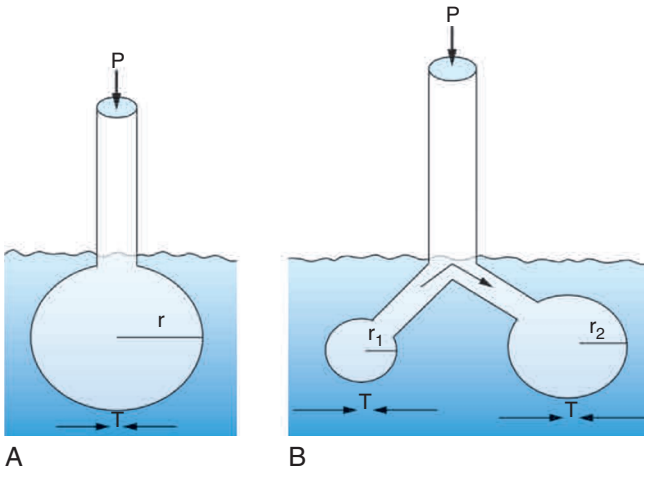
The cumulative result of surfactant sufficiency is a nonlinear pressure–volume relationship with maintenance of an adequate functional residual capacity (FRC) during expiration, compared with alveolar collapse in the surfactant deficient lung (Fig. 42.5A). Furthermore, during inflation, more pressure is required in the surfactant-deficient lung to achieve a similar tidal volume (see Fig. 42.5B), because of poor compliance ($\Delta V/\Delta P$) from having to reopen collapsed alveoli. For instance, to achieve a tidal volume of 5 mL/kg, an infant with RDS may require a pressure increase of 25 cmH_2O; dividing the volume change, ΔV, by the pressure change, ΔP, the calculated compliance is only 0.25 mL/kg per centimeter of water, approximately one-third of normal. For more information on surfactant, refer to Chapter 38.



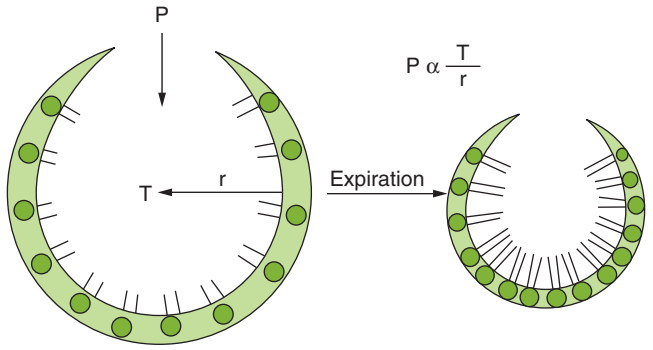
• **Fig. 42.1** Incidence of Respiratory Problems in Preterm Newborns. *RDS*, Respiratory distress syndrome; *TTNB*, transient tachypnea of the newborn. (Data from Rubaltelli FF, Dani C, Reali MF, et al. Acute neonatal respiratory distress in Italy: a one-year prospective study. *Acta Paediatr*. 1998;87:1261–1268.)



• **Fig. 42.2** Low power (A) and higher power (B) photomicrographs of lung tissue from an experimental animal with respiratory distress syndrome, flash frozen during inflation. Note the liquid–air interface (arrows). The alveolar debris forms hyaline membranes. (From the American Thoracic Society. Copyright 2017 American Thoracic Society. From Jackson JC, MacKenzie AP, Chi EY, et al: Mechanisms for reduced total lung capacity at birth during hyaline membrane disease in premature newborn monkeys, *Am Rev Respir Dis* 142:413–419, 1990.)



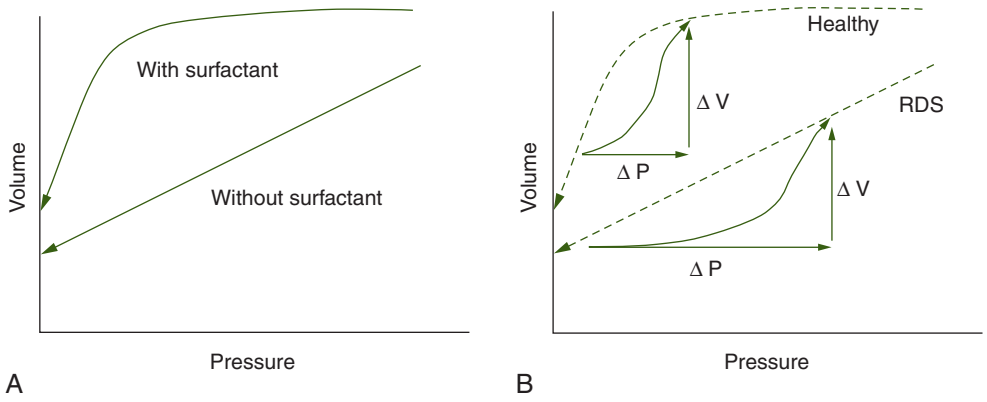
• **Fig. 42.3** Effect of Surface Forces Generated by Inflation of Bubbles Under Water. (A) A single bubble of radius *r* resists inflation and thus requires pressure *P* to overcome the surface tension *T*. (B) If the surface tension is the same in two bubbles of unequal size, the smaller one will collapse into the larger one, because of the Laplace relationship, $P = T/r$ (small *r* requires higher pressure for the bubble to stay inflated).



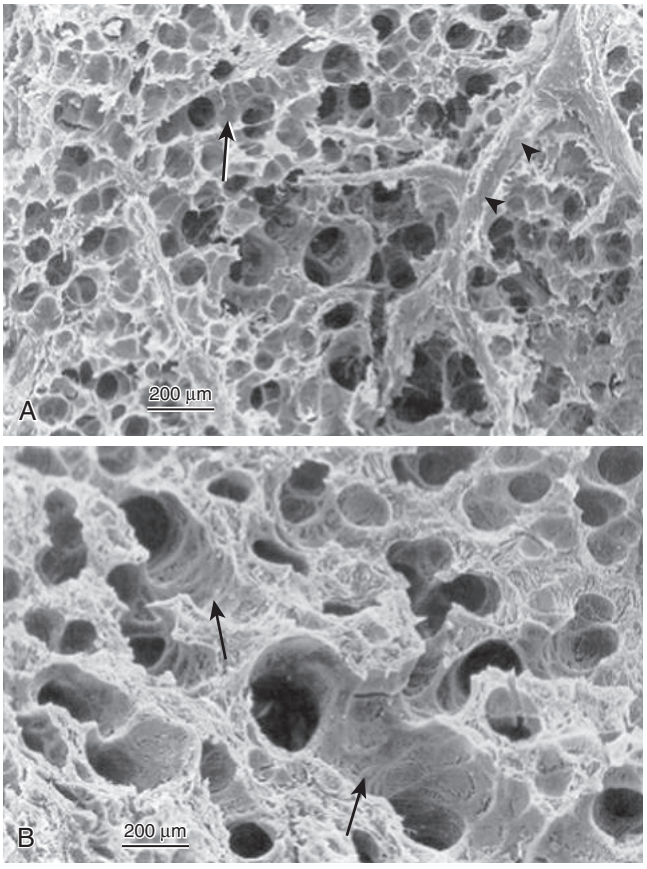
• **Fig. 42.4** Surfactant Molecules on Surface Crowding During Deflation. Less pressure (P) is needed to overcome the surface tension (T) as the radius (r) decreases due to surfactant crowding during deflation. (From Jackson JC. Respiratory distress syndrome. In: Osborn LM, DeWitt TG, First LR, Zenel JA, eds. Pediatrics. Philadelphia, PA: Mosby; 2005:1402–1404.)

Clinical Signs

In the absence of adequate functional surfactant in the newborn lung, there is inhomogeneous lung inflation with widespread alveolar collapse and overdistention of open alveoli (Fig. 42.6). Because reopening collapsed alveoli requires high pressure, the spontaneously breathing newborn with surfactant deficiency must generate highly negative intrathoracic pressure. Clinically, this is manifested by retractions of the chest wall and use of accessory muscles during inspiration. Because the rib cage in premature infants is so compliant, the sternum may deeply retract during inspiration. Newborns may also attempt to prevent alveolar collapse by "grunting." This partial closure of the glottis during expiration helps maintain an end-expiratory pressure, preserving FRC. The respiratory rate in infants with RDS is elevated in response to hypercarbia and hypoxemia. Furthermore, a consequence of widespread alveolar collapse is intrapulmonary shunting of blood



• **Fig. 42.5** Effect of Surface Forces on Pressure–Volume Relationships. During deflation (A) the lungs with surfactant retain gas even at very low pressures, because of falling surface tension as the alveoli get smaller. The alveoli without surfactant collapse as they get smaller. During inflation of respiratory distress syndrome *(RDS)* lungs (B), the starting lung volume (functional residual capacity) is lower, and much more pressure is required during inflation, compared with healthy lungs.



• **Fig. 42.6** Histology of Respiratory Distress Syndrome. Scanning electron micrograph of lung frozen during inflation with air in a healthy premature monkey (A) compared with one with respiratory distress syndrome (B). Lungs affected by respiratory distress syndrome have collapsed alveoli full of liquid and proteinaceous debris, with overdistended terminal airways. (From Jackson JC, Truog WE, Standaert TA, et al. Effect of high-frequency ventilation on the development of alveolar edema in premature monkeys at risk for hyaline membrane disease. Am Rev Respir Dis. 1991;143:865–871.)

past nonaerated lung tissue, limiting exchange of oxygen and carbon dioxide. Desaturation results from inadequate oxygenation, and pallor results from acidosis due to poor elimination of carbon dioxide. In addition, lungs that are poorly inflated have partially collapsed intrapulmonary vessels leading to pulmonary hypertension. The elevated pulmonary artery pressures lead to right-to-left shunting of unoxygenated blood across the patent ductus arteriosus to the descending aorta causing a differential between pre- and post- ductal oxygen saturations (see Chapter 47). The combination of increased work of breathing, oxygen desaturation, and acidosis causes lethargy, disinterest in feeding, and eventually apnea (Box 42.6).

On auscultation, there may be inadequate air entry from the fast inspiratory rate and low tidal volume, and fine inspiratory rales may be heard because of the reopening of collapsed, small airways. The onset of symptoms is always within hours after birth and, in severe cases, may occur almost immediately. In general, the respiratory distress from untreated RDS tends to worsen in the first 1 to 3 days after birth and then usually abates gradually thereafter (although the natural course may be interrupted by exogenous surfactant therapy or application of continuous positive airway pressure [CPAP]). This progressive worsening can be helpful in differentiating RDS from other newborn respiratory diseases.

• BOX 42.6 Clinical Signs of Respiratory Distress Syndrome

Tachypnea
Grunting
Increased work of breathing (nasal flaring, retractions)
Cyanosis
Pallor
Lethargy
Disinterest in feeding
Apnea

Laboratory Features

Initially, the arterial blood gases will show hypoxemia. $Paco_2$ is almost always elevated, but often to a lesser degree than anticipated because of tachypnea. As the infant tires, $Paco_2$ will rise further and cause respiratory acidosis. With imminent respiratory failure, there may be progressive metabolic acidosis due to inadequate oxygen delivery to tissues from poor peripheral perfusion.

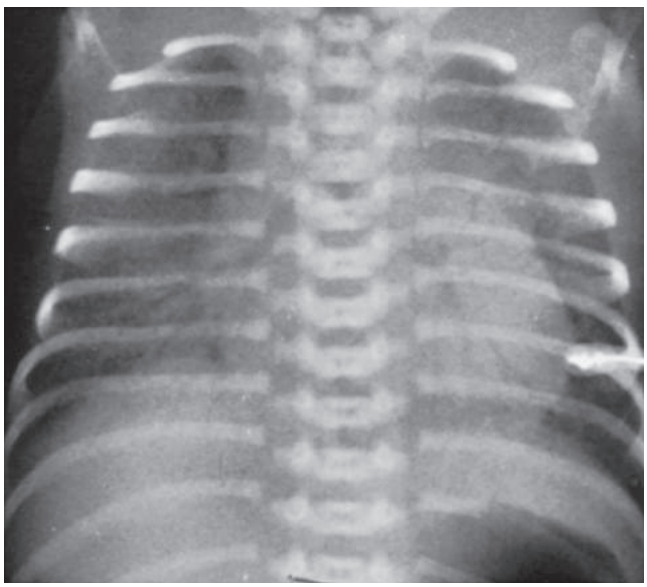
Radiographic Features

The classic radiographic findings of RDS include a reticulogranular (i.e., ground-glass) appearance, air bronchograms, and low lung volumes (in the absence of treatment with positive pressure) (Fig. 42.7). The lungs are diffusely and homogeneously dense because of widespread collapse of alveoli. The appearance is reticular (i.e., netlike) because the small airways are open (black) and surrounded by interstitial and alveolar fluid (white); in severe cases, the lungs may appear completely white on the radiograph. Air bronchograms are commonly seen because the large airways beyond the second or third generation are more visible than usual as a result of radiodensity from adjacent, engorged, peribronchial lymphatics and fluid-filled or collapsed alveoli. Low lung volume is due to widespread alveolar collapse and low FRC.

Treatment

Antenatal Steroids

Prenatal administration of steroids was shown in 1972 to be effective in reducing the risk of RDS.[4] A consensus panel convened by the National Institutes of Health in 1995 recommended that mothers at risk of preterm delivery between 24 to 34 weeks' gestation be given antenatal steroids.[5,6] A review of 27 published trials[7] concluded that prenatal administration of corticosteroids did not increase a mother's risk of death, chorioamnionitis, or endometritis, and treatment was associated with a reduction in neonatal death (RR 0.78, 95% CI 0.7 to 0.87), RDS (RR 0.71, 95% CI 0.65 to 0.78), and intraventricular hemorrhage (RR 0.58, 95% CI 0.45 to 0.75). Although the beneficial effects were maximized if delivery occurred between 24 hours and 7 days after treatment, there was also a benefit when delivery occurred within 24 hours.[8]



• **Fig. 42.7** Radiograph of a Patient With Respiratory Distress Syndrome. Note low lung volumes and a reticulogranular pattern. (From Welty S, Hansen TN, Corbet A. Respiratory distress in the preterm infant. In: Taeusch HW, Ballard RA, Gleason CA, eds. Avery's Diseases of the Newborn. 8th ed. Philadelphia: Elsevier; 2005:687–703.)

Repeat courses of antenatal steroids in the setting of persistently threatened preterm delivery are beneficial in reducing the occurrence and severity of RDS.[9] A study in 2007[10] found an association of repeat courses of antenatal steroids with cerebral palsy, but recent studies,[11,12] including a Cochrane review,[13] suggest that the evidence is inconclusive. However, repeat courses have been consistently associated with lower birth weight and smaller head circumference.[9,14] Additionally, although the most recent consensus panel in 2001[6] did not recommend repeated dosing of antenatal steroids, several studies in support of their use have been subsequently published.[9,14]

Recently, antenatal steroids have also been shown to be beneficial at periviable gestational ages (22 to 25 weeks)[15] and late preterm infants (34 to 37 weeks).[16,17] Further research on the use of antenatal steroids for threatened preterm delivery at periviable gestational ages is required, and their utilization at this time remains institutionally-dependent. Furthermore, although administration of antenatal steroids at 34 to 37 weeks' gestation reduced neonatal respiratory complications, it was associated with an increased risk of neonatal hypoglycemia and is not currently recommended.[18]

Continuous Positive Airway Pressure

In the early 1970s, Gregory et al.[19] first introduced CPAP therapy for newborns with RDS, primarily by an endotracheal tube. Since then, a variety of devices have been developed to deliver CPAP noninvasively.[20] Avery et al.[21] reported that centers that used early nasal CPAP therapy for RDS had a lower incidence of BPD, and, now, CPAP is a well-established therapy for infants with RDS across a range of initial severities. For more information on the principles and use of CPAP therapy and the risks and benefits of different modes of respiratory therapy, see Chapter 40.

The goals of CPAP therapy in preterm infants at risk of respiratory failure are to prevent end-expiratory alveolar collapse, reduce work of breathing, and better match ventilation to perfusion. If it is started in the delivery room, CPAP may help the newborn establish FRC, in addition to stabilizing the chest wall and reducing airway resistance. Furthermore, adequate expansion of the lungs at birth increases pulmonary blood flow. The prophylactic use of CPAP in the delivery room might make intubation for exogenous surfactant unnecessary,[22] and avoidance of intubation and mechanical ventilation may lower the risk of BPD. With advances in the use of CPAP since the first clinical trials of exogenous surfactant, several large trials (i.e., COIN,[23] SUPPORT,[24] VON-DRM[25]) have compared the use of early CPAP with prophylactic surfactant, and have found no difference in the primary outcome of death or BPD, suggesting that early CPAP use is at least comparable to intubation with prophylactic surfactant administration for the treatment of RDS. A meta-analysis[26] of studies enrolling babies less than 32 weeks gestation concluded that one additional infant could survive to 36 weeks without BPD for every 25 treated initially with nasal CPAP therapy in the delivery room rather than immediate intubation.

Others have compared the early use of CPAP to intubation for prophylactic surfactant followed by immediate extubation

(i.e., the InSurE technique) to limit complications from sustained endotracheal intubation and mechanical ventilation (including excessive tidal volumes and airway inflammation that may contribute to the development of BPD), and have additionally not found a benefit of InSurE over CPAP.[25,27–29] Additionally, there is a subset of infants who fail InSurE, requiring reintubation, leading some to recommend lung recruitment strategies after intubation but before surfactant administration (i.e., In-Rec-SurE technique) to decrease failure rates.[30] Further dilemma lies in the fact that, when compared to later surfactant administration, early surfactant (within 2 to 3 hours of birth) decreases the risk of pneumothorax, pulmonary interstitial emphysema, neonatal death, and BPD.[31] However, a subset of babies treated successfully with initial CPAP will later fail, eventually requiring intubation and surfactant administration, missing the advantages of early surfactant administration. As such, trials attempting to elucidate predictors of eventual CPAP failure have found that the most salient predictors are male sex, low birth weight, and, most importantly, Fio_2 requirements greater than 0.3 to 0.35.[32,33] Furthermore, research is ongoing regarding less invasive methodologies of surfactant administration that would avoid intubation and allow for early surfactant administration in combination with early CPAP use (see Exogenous Surfactant section below for more detail).[34–39]

The American Academy of Pediatrics Committee on the Fetus and Newborn supports the initial use of CPAP with ongoing assessment for surfactant need in the first 2 to 3 hours of life as an alternative to prophylactic surfactant.[40] Given the rapid evolution in published evidence contrasting and combining CPAP therapy and surfactant therapy, broad consensus regarding their use in preventing and treating respiratory distress in premature infants does not currently exist. However, most studies suggest that to maximize the benefit of either on survival and morbidity, they should both be started as soon as possible. Furthermore, the duration of mechanical ventilation should be kept to a minimum, and endotracheal intubation should be avoided, if possible.

Some centers report use of humidified high-flow nasal cannulas in infants with RDS to achieve the benefits of positive airway pressure with fewer of the perceived disadvantages of CPAP (e.g., challenges in keeping the nasal prongs in the nares, more difficult handling of the patient, and greater risk of pressure necrosis of the nasal septum).[41] However, the airway pressure generated from this therapy, although proven to produce a clinical effect, is variable, unpredictable, and unregulated, and the commercially available systems are not approved by the US Food and Drug Administration for this indication. It should be used only by practitioners aware of the balance of risks and benefits and those prepared to recognize and treat pneumothorax and respiratory failure. A 2015 review outlined the main advantages and disadvantages of the many types of CPAP delivery devices, as well as the implications for developing countries.[42]

Exogenous Surfactant

Historical Summary

The development of exogenous surfactant for treatment of RDS is one of the most important advances in the history of newborn medicine. This history is well told elsewhere.[43] The key milestones include von Neergaard's discovery in 1929 that surface tension contributes to lung recoil,[44] Gruenwald's demonstration in 1947 that lungs of stillborn infants have high surface tension,[45] Pattle's speculation in 1955 that absence of surfactant active material contributes to RDS,[46] Clements' description in 1957 of surfactant dysfunction in experimental animals,[47] and Avery and Mead's demonstration in 1959 that RDS in human infants is due to surfactant deficiency.[48] There was an increase in research interest and funding for RDS treatment after President John Kennedy's son, born at 34.5 weeks' gestation, died of RDS in 1963. In 1972, Enhörning and Robertson used natural surfactant to delay the progression of RDS in preterm rabbits,[49] and, in 1980, Fujiwara et al. demonstrated the first successful use of exogenous surfactant in human infants.[50] By 1990, exogenous surfactant was widely used throughout the developed world, and many large clinical trials have been conducted since then to refine and improve surfactant treatment and prevention of RDS. A meta-analysis of 13 randomized controlled trials suggests that animal-derived exogenous surfactant compared to standard therapy without surfactant reduces the risk of pneumothorax by 58%, the risk of pulmonary interstitial emphysema by 55%, the risk of death by 32%, and the risk of the combined outcome of BPD or death by 17%.[51] Notably, the "standard therapy" did not include use of CPAP started immediately after birth (see previous comments under Continuous Positive Airway Pressure).

Types of Surfactants Available for Clinical Use

A list of currently available surfactant preparations and sources in the United States can be found in Table 42.3. The first generation of commercially available artificial surfactants (e.g., colfosceril [Exosurf]), composed mainly of dipalmitoylphosphatidylcholine (DPPC) and lacking surfactant protein-B (SP-B) and SP-C, were eventually replaced by natural surfactants. A meta-analysis of 15 randomized controlled trials showed that natural surfactants were faster acting than artificial surfactants, with lower incidence of pneumothorax and death.[52] A new generation of synthetic surfactant products such as lucinactant and CHF5633 have synthetic peptides or proteins, such as KL4 in lucinactant, which mimics the actions of natural surfactant proteins.[53,54] Additional studies

TABLE 42.3 Commercially Available Surfactant Preparations in the United States and Their Sources

Brand Name	Generic Name	Constituents	Amount per Dose
Protein-Containing Animal Surfactants			
Curosurf	Poractant alfa	Porcine lung tissue	2.5 mL/kg (redose 1.25 mL/kg)
Infasurf	Calfactant CLSE	Bovine (calf) lung lavage	3 mL/kg
Survanta	Beractant	Bovine lung tissue	4 mL/kg
Alveofact	Bovactant	Bovine lung lavage	1.2 mL/kg
Peptide-Containing Synthetic Surfactants			
Surfaxin	Lucinactant	DPPC, POPG, PA, KL4	5.8 mL/kg

CLSE, Calf lung surfactant extract; *DPPC*, dipalmitoylphosphatidylcholine; *PA*, palmitic acid; *POPG*, palmitoyloleoylphosphatidylglycerol.
Modified from Walsh BK, Daigle B, DiBlasi RM, et al. AARC clinical practice guideline. Surfactant replacement therapy: 2013. *Respir Care*. 2013;58:367–375.

are underway comparing CHF5633 to poractant alfa, and evaluating the utility of using lucinactant as an aerosolized surfactant (Aerosurf).

Surfactant Selection

An important issue for clinical providers and managers is which surfactant to stock in their pharmacy because of the expense of the preparations and the need to standardize dosing guidelines. A 2015 meta-analysis of clinical trials[52] indicated that, compared with artificial surfactant, use of animal-derived surfactants leads to greater early improvement in ventilator support, fewer pneumothoraces, and fewer deaths, but may be associated with greater risk of necrotizing enterocolitis and grade 1 and grade 2 intraventricular hemorrhage. The most commonly used animal-derived surfactants that are commercially available include poractant alfa (from minced porcine lung; Curosurf) and beractant (from minced bovine lung; Survanta).[55] A recent meta-analysis of clinical trials comparing these two drugs for prevention or treatment of RDS in premature infants suggested that treatment with poractant alfa is associated with lower risk of death, BPD, and clinically significant patent ductus arteriosus and reduced need for repeated dosing.[56] However, other studies have found no difference.[57] Regardless, poractant alfa does have the advantage of being more concentrated than beractant, and the lower dosing volume may be advantageous.

Timing and Method of Surfactant Administration

In theory, surfactant would ideally be given with the first breath. This concept was evaluated by Kattwinkel et al.[58] by delivering the head of the infant, suctioning the nasopharynx, and then instilling calfactant into the airway before delivery of the shoulders. CPAP therapy was initiated immediately after delivery, but the trachea was not routinely intubated. The treatment appeared feasible and safe, but the sample size (23) was too small to prove that the approach was beneficial compared with surfactant instillation via an endotracheal tube during the first few minutes after delivery. Some have proposed administration of surfactant into the pharynx before the first breath in extremely preterm infants at high risk of RDS, but no clinical trials have yet been published.[59]

Animal studies suggest that surfactant is best distributed when administered as a bolus rather than by slow infusion over several minutes.[60] Additionally, a chest x-ray confirming satisfactory endotracheal tube position should be considered to avoid asymmetric surfactant administration. Although surfactant manufacturers recommend variable positioning of the infant during instillation to improve distribution of surfactant, there are no clinical trials supporting one particular method. Therefore, surfactant should be given as quickly as tolerated, with alveolar recruitment techniques, and with the least disruptive infant positioning.[61] Vigilance for endotracheal tube obstruction due to surfactant administration, particularly with smaller sized tubes, is recommended.

With persistent concerns about the risks of both endotracheal intubation and mechanical ventilation, even if brief, recent studies have sought to combine use of CPAP with less invasive, early surfactant delivery. There are ongoing studies evaluating the administration of surfactant through a small endotracheal catheter or feeding tube while CPAP is being provided (referred to as less invasive surfactant application [LISA], minimally invasive surfactant therapy [MIST], or surfactant without endotracheal tube intubation [SURE] technique), and the results have been promising.[34–36] Others have proposed administering surfactant via laryngeal mask airway to reduce the need for mechanical ventilation,[62] but there are obvious birth weight limitations to this approach. Preliminary clinical trials suggest that surfactant can be successfully aerosolized or nebulized,[37,38] but only one clinical trial comparing nebulized surfactant administration to CPAP alone has shown a decreased need for mechanical ventilation.[39] Furthermore, this finding was limited to a subgroup of more mature infants (32 to 33 weeks' gestation).

Number of Surfactant Doses and Dosing Intervals

A meta-analysis of two clinical trials that compared one dose versus multiple doses of animal-derived surfactant suggests a 49% reduction in the incidence of pneumothorax and a trend toward a 37% reduction in mortality when multiple doses are used.[63] Additionally, a repeat dose of surfactant improves oxygenation without significantly changing end-expiratory lung impedance or ventilation distribution.[64] There are no data to suggest that additional doses should be provided if the previous dose was ineffective or once the patient's ventilator and oxygen requirements are at minimal levels. The interval between doses is usually at least 6 hours, and most research protocols discontinue dosing after 48 hours. Late treatment with up to five doses of surfactant in ventilated premature infants receiving inhaled nitric oxide was well tolerated but did not improve survival without BPD.[65]

Clinical Care After Dosing

Because natural surfactants may work quickly, the clinician must be prepared after dosing to immediately lower Fio_2 while carefully monitoring the pulse oximeter. With improved lung compliance, the tidal volume and inspiratory pressures may change rapidly, resulting in the need to decrease respiratory support to avoid air leak syndromes and lung injury. Blood gases should be monitored by intermittent blood sampling. Positive end-expiratory pressure may be reduced if the starting levels are high, given that surfactant should help maintain FRC at a lower distending pressure.

A poor response to exogenous surfactant may occur if the patient does not have surfactant deficiency, but rather has lung hypoplasia, pneumonia, or congenital heart disease. Other causes for a lack of response may be poor distribution of the surfactant, such as administration down the right stem bronchus due to malposition of the endotracheal tube, plugging of the tube, or malposition of the tube in the esophagus. A less likely reason is an inadequate dose of surfactant.

Lastly, the rapid improvement in lung compliance after exogenous surfactant therapy may lead to excessive pulmonary blood flow from left-to-right shunting across a patent ductus arteriosus, increasing the risk of pulmonary hemorrhage.[66] (For more information, see the next section on Pulmonary Hemorrhage.)

Pulmonary Hemorrhage

Incidence and Clinical Signs

Pulmonary hemorrhage occurs in 3% to 5% of preterm infants needing respiratory support, usually at 1 to 3 days of age, with onset of pink or red frothy fluids in the endotracheal tube and sudden respiratory deterioration, cyanosis, pallor, hypotension, or

hypotonia.[67] The frequency is greater with increasing degree of prematurity and with intrauterine growth restriction.[68] The chest radiograph may show widespread "whiteout," unlike mucosal bleeding of the airway, which is usually accompanied by minimal clinical or radiographic changes. The hematocrit of the tracheal fluid after pulmonary hemorrhage is much lower than from a venous sample, indicating that the underlying problem is hemorrhagic pulmonary edema.

Etiology

Multiple factors likely contribute to neonatal pulmonary hemorrhage. There is a threefold increased risk after prophylactic synthetic surfactant,[69] leading to speculation that surfactant may have a direct cytotoxic effect that impairs membrane integrity in the alveolar capillary.[70] Alternatively, rapid improvement in lung compliance following exogenous surfactant treatment may cause volutrauma and subsequent pulmonary hemorrhage. Some have theorized that the decrease in pulmonary resistance associated with surfactant treatment of RDS facilitates a fall in PVR and left-to-right shunting through a patent ductus arteriosus, which increases the likelihood of pulmonary hemorrhage.[68] This theory is supported by evidence that infants who received early indomethacin therapy to close a large patent ductus arteriosus had a lower incidence of pulmonary hemorrhage.[71] Lastly, in some babies, left ventricular diastolic dysfunction may lead to pulmonary venous hypertension and increased wedge pressure, lowering the threshold for pulmonary hemorrhage.

Treatment

The mainstay of treatment includes careful suctioning of the trachea to prevent obstruction and increased ventilator pressure, particularly increased positive end-expiratory pressure, for pulmonary edema. High frequency ventilation could also be considered to provide higher mean airway pressures in cases of refractory pulmonary hemorrhage. Although a low platelet count and coagulopathy are rarely the cause, newborns should be checked for these and treated, if necessary. If anemia is severe, transfusion with packed red blood cells may be indicated, but this should be done very slowly to avoid compounding the pulmonary edema. Red blood cells and serum in the airspace impair surfactant function, causing a secondary surfactant inactivation. There is evidence that exogenous surfactant may help,[72,73] but no randomized controlled trials exist to prove benefit.[74]

Pulmonary Hypoplasia

Etiology and Incidence

Pulmonary hypoplasia and respiratory failure can develop in association with a number of conditions (Table 42.4). Most cause either restriction of normal fetal breathing motion or compression of the developing lung. Thus, among the most common causes of pulmonary hypoplasia are low amniotic fluid volumes, neuromuscular disorders, disease states causing pleural effusions/chylothoraces, and space-occupying lung lesions.

Inadequate amniotic fluid volume that limits normal fetal breathing can result from a number of circumstances. Because fetal urine is a primary contributor to amniotic fluid volume, any abnormality of renal development that limits fetal urine production or urine flow can result in pulmonary hypoplasia. In addition, preterm premature rupture of membranes (PPROM), particularly with persistent leak of amniotic fluid, can result in pulmonary hypoplasia.

One or both lungs of newborns with pulmonary hypoplasia are smaller than normal, including reduced numbers of lung cells, airways, blood vessels, and alveoli. Pulmonary hypoplasia is the cause of respiratory distress at birth in only 0.3% of newborns with respiratory symptoms,[75] but it is commonly fatal, especially in preterm infants. The incidence is about 1 per 10,000 live births, and 90% of cases are associated with congenital anomalies or pregnancy complications.[76] There is a continuum of severity of pulmonary hypoplasia—from negligible to severe—and all but the most severe cases are difficult to diagnose. This is especially true when one is attempting to diagnose pulmonary hypoplasia prenatally by imaging studies but is also true during clinical assessment of the newborn and even after postmortem examination of the lungs.

TABLE 42.4 Categories of Conditions Associated With Pulmonary Hypoplasia

Category	Representative Diagnoses
Restriction of thoracic space	Diaphragmatic hernia or eventration Intrathoracic mass Congenital cystic adenomatoid malformation Bronchogenic cyst Extralobar sequestration Thoracic neuroblastoma Pleural effusions Chylothorax Hydrothorax
Oligohydramnios	Renal Bilateral renal agenesis or dysplasia Bladder outlet obstruction (posterior urethral valves) Nonrenal Prolonged preterm rupture of membranes
Skeletal anomalies	Chondroectodermal dysplasia Osteogenesis imperfecta Thanatophoric dwarfism
Hydrops fetalis	Rhesus isoimmunization
Neuromuscular and central nervous system anomalies	Fetal akinesia Anencephaly Arnold–Chiari malformation
Cardiac anomalies	Hypoplastic right or left side of the heart Pulmonary stenosis Ebstein anomaly
Abdominal wall defects	Omphalocele Gastroschisis
Syndromes	Trisomy 13, 18, 21 Larsen syndrome Cerebrocostomandibular syndrome Jarcho–Levin syndrome Roberts syndrome Lethal multiple pterygium

Modified from Langston C. Pulmonary disorders in the neonate, infant, and child. In: Churg AM, Myers JL, Tazelaar H, Wright J, eds. *Thurlbeck's Pathology of the Lung.* 3rd ed. New York, NY: Thieme; 2005.

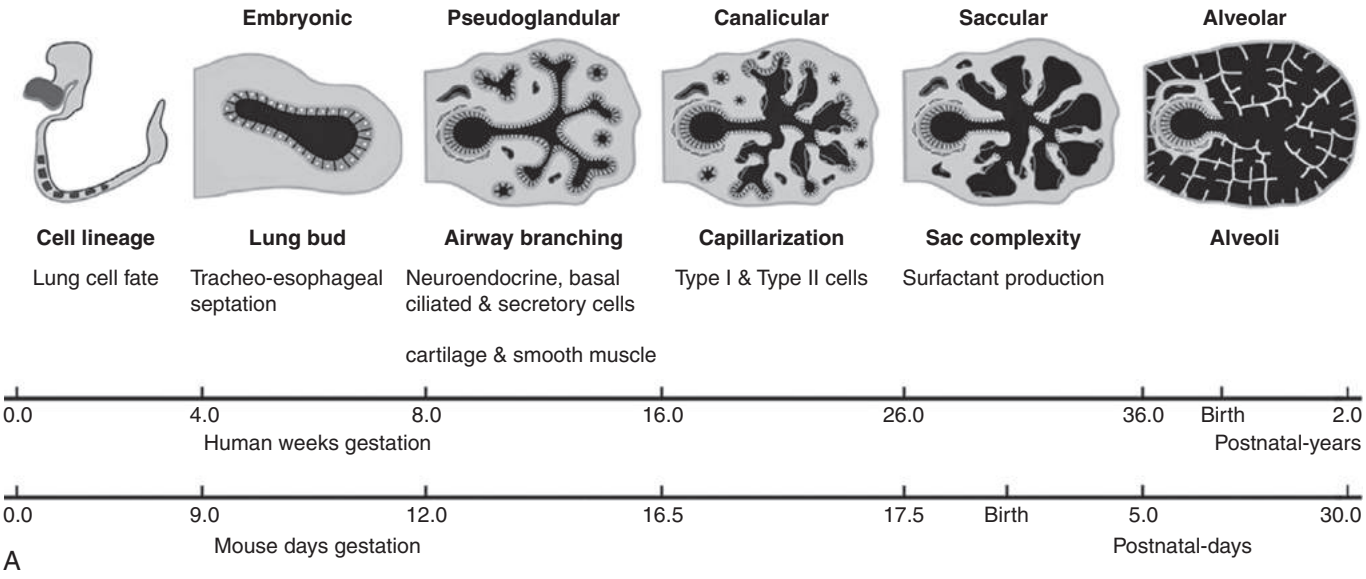
Prenatal Diagnosis

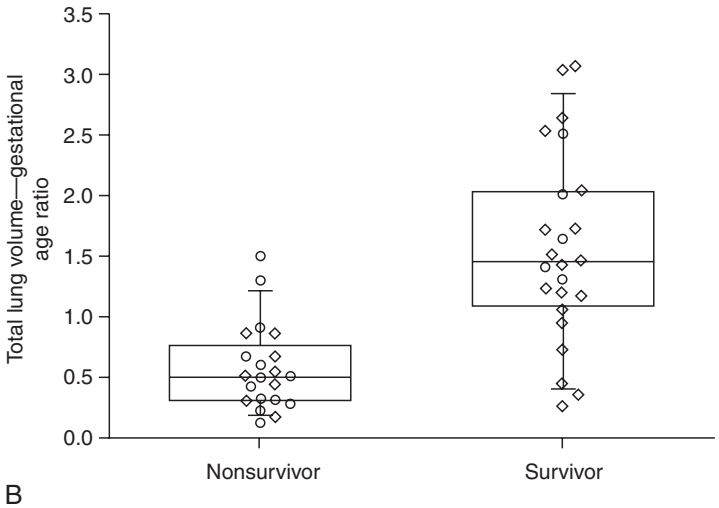
An accurate prenatal test predicting the degree of pulmonary hypoplasia would be important because it might affect the obstetric management. It would be particularly helpful to be able to discriminate lethal from nonlethal pulmonary hypoplasia, especially early in gestation, when termination of the pregnancy may be an option. However, quantifying the degree of fetal pulmonary hypoplasia is challenging even for the pathologist examining gross and microscopic lung sections. A recent review and meta-analysis of imaging parameters for prediction of fatal pulmonary hypoplasia found all to be poor to mediocre.[77,78]

Nonsurvivors with pulmonary hypoplasia due to fetal urinary anomalies were noted to have lower in utero lung volumes as determined by fetal magnetic resonance imaging (MRI), adjusted for gestational age,[79] but there was no clear separation between the survivors and nonsurvivors (Fig. 42.8B). Furthermore, there was considerable overlap of the confidence intervals before 26 weeks' gestation, which limits the usefulness of MRI assessment of fetal volume for prenatal counseling. Although there will continue to be advances in fetal imaging to assess lung volume, it will likely remain difficult to differentiate lethal from nonlethal pulmonary hypoplasia prior to birth given that there may not be a linear correlation between lung volume and lung function. Moreover, there may be additional underlying abnormalities that limit viability independent of lung size and function.

Prenatal Treatment

In cases where an infant is at risk for pulmonary hypoplasia due to PPROM, treatment of oligohydramnios with amnioinfusion with saline has been proposed to improve fetal survival by extending the latency period (the interval between premature rupture of membranes and delivery) and thus the gestational age at delivery.





• **Fig. 42.8** (A) Stages of lung development. (B) Measurement of fetal lung volume by magnetic resonance imaging and outcomes after delivery. (A from Kimura J, Deutsch GH. Key mechanisms of early lung development. Pediatr Dev Pathol. 2007;10:335–347. B from Zaretsky M, Ramus R, McIntire D, Magee K, Twickler DM. MRI calculation of lung volumes to predict outcome in fetuses with genitourinary abnormalities. Am J Radiol. 2005;185:1328–1334.)

A meta-analysis found that amnioinfusion reduced neonatal morbidity, neonatal sepsis, pulmonary hypoplasia, and puerperal sepsis and increased latency, but the authors recommended circumspection as the positive findings were mainly due to one trial with unclear allocation concealment.[80] When successful, the benefit may derive from restoration of back-pressure from the amniotic sac fluid to the lungs, stimulating fetal lung growth and development during the critical canalicular stage between 16- and 26-weeks' gestation (see Fig. 42.8A).

Pathology

A common method of defining pulmonary hypoplasia during postmortem examination is to calculate the ratio of lung weight to body weight. However, the lung weight to body weight ratio may be artificially elevated if the lungs are wetter than usual from edema, hemorrhage, inflammation, or lymphangiectasia, and this may lead to the false conclusion that the patient does not have pulmonary hypoplasia. Conversely, the ratio may be artificially low if the body is heavier than usual because of renal cystic disease, hydrops, ascites, tumors, hydrocephaly, and so forth. Therefore, a better method for postmortem diagnosis of pulmonary hypoplasia is to measure the lung volume by inflating the lung at physiologic pressure and then measuring the displacement of fluid when the lung is immersed.[76] This method facilitates comparison of postmortem estimates with in utero estimates of lung volume made during prenatal imaging. However, as previously noted, low lung volume does not necessarily correlate with abnormal lung structure and function. An alternative postmortem technique more physiologically relevant than lung volume is the radial alveolar count, which is proportional to alveolar surface complexity[76] and, thus, gas exchange surface area; however, this procedure is complex and time consuming.

Impairment of lung development before 16 weeks causes reduced airway branching, reduced cartilage development, reduced acinar complexity and maturation, delayed vascularization, and delayed thinning of the air–blood barrier (see Chapter 38). Impairment after 16 weeks typically causes reduced acinar complexity and maturation. These outcomes are predictable, given the time in gestation when these structures are developing (see Fig. 42.8A).

Because the growth of lung blood vessels parallels the development of the airways, pulmonary hypoplasia is invariably associated with decreased total size of the pulmonary vascular bed, decreased number of vessels per unit of lung tissue, and increased amount of pulmonary artery smooth muscle. This last phenomenon accounts for persistent pulmonary hypertension after birth.

Clinical and Radiographic Signs

The newborn with pulmonary hypoplasia often has immediate signs of respiratory distress and cyanosis indistinguishable from those in the newborn with severe RDS. However, respiratory failure from severe pulmonary hypoplasia often becomes maximally apparent within minutes of birth, whereas respiratory failure from RDS usually progresses over the first few hours after birth. The thorax may appear small or bell shaped, and, if oligohydramnios was severe, there may be flattening of the face and deformation (such as contractures of the extremities). Hypercarbia may be severe on the earliest blood gas measurement, despite aggressive mechanical ventilation. The hypoxemia from surfactant deficiency and lung immaturity may be compounded by right-to-left shunting of deoxygenated blood due to pulmonary hypertension, leading to severe desaturation. Early pneumothorax is common, in which case there may be asymmetry of breath sounds or malposition of heart sounds; in the setting of tension pneumothorax, there may be decreased cardiac output from impaired venous return to the thorax. Because lung immaturity and surfactant deficiency accompany pulmonary hypoplasia, particularly in preterm infants, the lungs may be radiographically dense with air bronchograms, as with RDS, but the lung volumes may be smaller and the diaphragms higher than in uncomplicated RDS.

Treatment

The ventilator strategy must be individualized. In some cases, a baby with smaller lungs may have relatively normal compliance, high pulmonary vascular resistance, and sometimes cardiac dysfunction. In other cases, the pulmonary hypoplasia may be associated with markedly abnormal lung structure, poor compliance, and impaired gas exchange. In the initial hours after birth, the goal should be to avoid excessive intrathoracic pressure from lung overdistention which may lead to catastrophic pneumothorax and which may also further aggravate pulmonary hypertension and right-sided heart afterload. Permissive hypercapnia is appropriate, and high-frequency ventilation may be necessary for adequate ventilation and reduction of very high arterial P_{CO_2} levels.

For preterm infants with pulmonary hypoplasia, exogenous surfactant should be considered early because there may be concomitant surfactant deficiency. One of the main causes of pulmonary hypoplasia in preterm infants is PPROM. When PPROM occurs at 15 weeks' gestation, the incidence of pulmonary hypoplasia is 80%, and when it occurs at 19 weeks, the incidence is 50%, whereas after 26 weeks the incidence is near zero.[81] The survival rate of infants born at less than 32 weeks' gestation after rupture of membranes before 24 weeks' gestation has been reported as 75% to 90%.[82,83] The major predictors of neonatal survival are later gestational age at PPROM and adequate residual amniotic fluid levels.[84]

To avoid adding hypoxic pulmonary vasoconstriction to the already high pulmonary vascular resistance, the preductal arterial oxygen saturation should be kept at 92% or higher. Although acidosis may compound hypoxic pulmonary vasoconstriction, hypercapnia is usually well tolerated and will allow a less aggressive ventilator strategy. Routine paralysis is usually not needed and leads to third spacing of fluid. Spontaneous breathing may be beneficial, and some infants with pulmonary hypoplasia have been managed with nasal CPAP.[85]

Because increasing ventilator support for persistent hypoxemia may exacerbate lung injury, efforts should be directed toward treatment of pulmonary hypertension, even though the component that is reversible is unpredictable. There are several small studies demonstrating the beneficial effects of iNO in pulmonary hypoplasia (the majority in preterm infants born after PPROM),[86,87] suggesting a therapeutic trial of iNO therapy is warranted in this population. Although not statistically significant, there was a 33% reduction in mortality among extremely preterm neonates with pulmonary hypoplasia and pulmonary hypertension in a recent cohort study.[88] Other medications such as sildenafil and milrinone may also minimize pulmonary hypertension. Frequent echocardiography should be used to assess response to these medications. Because systemic hypotension causes worse right-to-left shunting,

cardiotonic agents may be helpful, acknowledging that these medications may increase both systemic and pulmonary vascular pressures. For more detail, see the review by de Waal[86] which includes a good description of cardiovascular support agents, mechanisms of action, and physiologic targets. Before administering agents such as inhaled nitric oxide that are intended to increase pulmonary blood flow, severe left ventricular dysfunction with increased left atrial pressure (often indicated by left-to-right atrial level shunting in the setting of pulmonary hypertension) should first be corrected to avoid pulmonary edema and minimize the risk of pulmonary hemorrhage.[89]

In cases of profound pulmonary failure, extracorporeal membrane oxygenation may be appropriate for late-gestation preterm and term infants if there is potential for clinical improvement over the course of several days.

Pneumonia

Incidence and Etiology

Given the lack of specific signs, the diagnosis of pneumonia is often made based on supportive evidence of infection (prolonged rupture of membranes, maternal fever, neonatal lethargy and temperature instability, abnormal laboratory studies, etc.). In the absence of a positive culture, the diagnosis is rarely unequivocal. Nonetheless, the incidence of pneumonia has been estimated at ~2% in extremely low birth weight (ELBW) preterm infants (see Fig. 42.1).[75] Across all gestational ages, the same study suggests that pneumonia is the third most common acute respiratory disorder in newborns, behind RDS and transient tachypnea of the newborn (TTNB) (see Table 42.1). When a bacterial pathogen is isolated, group B streptococcus was the most frequent pathogen (36%) identified from data collected between 2005 and 2014, followed by *Escherichia coli* (25%) and viridans streptococci and other streptococci (21%). Others included *Haemophilus influenzae* (5%), *Staphylococcus aureus* (4%), enterococcus (3%), *Listeria monocytogenes* (1%), and klebsiella (1%).[90] Newborns can also acquire postnatal pertussis and viral pneumonia, commonly due to respiratory syncytial virus, adenovirus, and rhinovirus. Pneumonia can also begin in utero with infectious agents such as cytomegalovirus and herpes simplex virus (see Chapter 34).

Clinical, Laboratory, and Radiographic Signs

Bacterial pneumonia is usually accompanied by bacteremia because newborns are frequently unable to confine bacteria to the lung, and therefore, some infants will exhibit clinical signs of sepsis or shock, including poor perfusion and hypotension, in addition to respiratory failure. Blood culture findings will be positive in some newborns with pneumonia, but the presence of maternal antibiotics in the blood of the newborn reduces confidence in a negative result.

Leukopenia, increased percentage of immature granulocytes, and elevated levels of inflammatory markers increase the likelihood of sepsis/pneumonia, but with poor positive predictive value. Tracheal aspirate culture (but not Gram stain) obtained immediately after placement of an endotracheal tube may help with diagnosis and guide therapy, especially when the blood culture result is negative.[91]

Newborns with pneumonia often have diffuse pulmonary infiltrates on chest radiograph, but the radiographic appearance may be difficult to distinguish from RDS and TTNB. Because newborns are unable to localize pulmonary infection, lobar infiltrates are rarely an indication of pneumonia in this age group—plugging of airways with secretions is more likely.

Treatment

Administration of antibiotics directed at the most common organisms (see earlier discussion) should be started immediately when pneumonia is suspected. Ampicillin and gentamicin provide appropriate initial coverage but should be tailored to sensitivities if bacteria are isolated. If the blood culture result is negative, and the mother has been pretreated with antibiotics, some practitioners advocate continuing antibiotics beyond 18 to 24 hours (e.g., 5 to 7 days) if the clinical course is strongly suggestive of pneumonia.

Air Leak Syndromes

Leakage of air from the bronchoalveolar airspace can lead to a variety of air leak syndromes. Additionally, an aberrant connection can form between the pleural space and areas of the airway more proximal to the alveolus (bronchopleural fistula). In this section, we will focus on the most common air leak syndrome in the neonatal period: pneumothorax.

Etiology and Incidence

A pneumothorax is a collection of air within the pleural space, between the parietal pleural of the chest wall and the visceral pleural of the lung. It occurs more frequently in the neonatal period than any other epoch of life. Pneumothorax is associated with increased morbidity and mortality, especially in the extremely preterm infant where it is associated with prolonged hospitalization and higher rates of mortality, BPD, and intraventricular hemorrhage.[92,93] The risk of BPD is further increased in the setting of persistent pneumothorax (>7 days).[94] Although antenatal steroids and surfactant have reduced the rate of pneumothorax, it remains an important cause and complication of respiratory distress in newborns.

A major risk factor for pneumothorax is prematurity. Spontaneous pneumothorax occurs in 1% of term births and increases to 7% to 12% at gestational ages below 29 weeks.[95,96] Other risk factors include male sex, low birth weight, mechanical ventilation, elective cesarean delivery prior to 29 weeks' gestation, and underlying lung disease (i.e., RDS, pneumonia, MAS, pulmonary hypoplasia, pulmonary interstitial emphysema).[97,98] Chorioamnionitis and prolonged rupture of membranes are also independent risk factors for pneumothorax in preterm and very low birth weight (VLBW) infants, respectively. Protective factors include antenatal steroid treatment, surfactant administration, and, when mechanical ventilation is utilized, the use of high-frequency positive pressure ventilation, synchronization, volume-targeted ventilation, and low tidal volumes with higher rates.[99,100]

The association between the use of CPAP and rates of pneumothorax is the subject of debate. Some studies, like the COIN trial,[23] suggest that the use of CPAP increases the risk of pneumothorax, especially in late preterm and term neonates who have increased lung elasticity, decreased chest wall elasticity, increased lung distensibility, and decreased surface tension.[23,101] In the COIN trial,[23] extremely preterm infants (25 to 28 weeks' gestation) were randomized to either CPAP of 8 or intubation after delivery. Infants randomized to CPAP had a higher incidence of

pneumothorax. However, other studies,[102] like the SUPPORT trial,[24] do not endorse this association.

Clinical, Laboratory, and Radiographic Signs

Small pneumothoraces may be asymptomatic. When symptomatic, most are diagnosed in the first 3 days of life due to increased work of breathing and/or increased respiratory support, particularly an increase in supplemental oxygen requirement.[92] In addition, clinical exam may reveal asymmetric aeration. In the setting of a pneumothorax under tension, increased intrathoracic pressure may displace heart tones and the point of maximal impulse of the heart and lead to diminished cardiac return, causing hypotension and bradycardia. Knowledge of the exact onset of a pneumothorax is difficult to ascertain; one study suggests that there can be a delay of 1 to 10 hours between onset and diagnosis.[103]

Although transilluminating the chest may help detect a pneumothorax, its accuracy and reliability are not known. On blood gas assessment, infants may present with hypercarbia and hypoxemia; this is more common in preterm infants.[93] Radiographically, there are asymmetric lung markings in the setting of pneumothorax with the affected side appearing more translucent (black) due to the accumulation of air outside the lung. A visceral pleural edge may be seen with a paucity of more peripheral lung markings. In the setting of a tension pneumothorax, the mediastinum will shift away from the affected side. Small pneumothoraces may be difficult to discern on an anteroposterior chest radiograph and their detection can be improved with the use of a lateral or lateral decubitus (suspected side up) radiograph. Although ultrasound is becoming increasingly popular to augment the diagnosis of pneumothoraces, its use remains institutionally dependent.[104]

Treatment

There are three mainstays of treatment for pneumothoraces: observation, thoracentesis, or thoracostomy and chest tube placement. Use of Fio_2 at 1.0 has not been shown to hasten the resorption of a pneumothorax and may result in unnecessary supplemental oxygen exposure.[105,106]

Asymptomatic pneumothoraces in newborns without lung disease do not require treatment and often go undiagnosed. Additionally, Litmanovitz and Carlo showed that a subset of symptomatic neonates requiring respiratory support could also be managed expectantly.[107] Determinants of successful expectant management included increased gestational age, lower respiratory support requirements, and normal blood gases.

When active treatment is deemed necessary, insufficient evidence exists to recommend thoracentesis over thoracostomy and chest tube placement, or vice versa. A review of two studies recently suggested that initial thoracentesis may avoid the eventual need for thoracostomy and chest tube placement, particularly if an angiocath is used and is left in-situ.[108] In support of these findings, a more recent randomized trial also suggested thoracostomy and chest tube placement can be avoided in some infants initially treated with thoracentesis, with a number needed to treat of only three.[109] Complications of thoracostomy and chest tube placement include lung injury, insertion site and pulmonary infection, phrenic nerve injury, chylothorax, hemorrhagic pericardial effusion, and breast deformities later in life.[110,111] For persistent or difficult-to-control pneumothoraces, additional treatment options include pleurectomy, chemical pleurodesis, and selective intubation of the bronchus to the unaffected lung.

Transient Tachypnea of the Newborn

Definition and Etiology

TTNB is among the most common causes of respiratory distress in the newborn period, affecting 0.5% to 4% of all late preterm and term neonates.[112] The symptoms of respiratory distress typically start within the first several hours after birth and result from failure of adequate absorption of fetal lung fluid. Studies have consistently shown that risk factors for TTNB include prematurity, birth by cesarean delivery, and male sex.[113–115] Among babies born by elective cesarean delivery, a recent study suggests that delivery before 39 weeks increases the risk of TTNB by more than twofold.[116]

Early theories of lung fluid clearance focused on the role of thoracic compression during vaginal delivery and were supported by the observation that TTNB is more common among babies born by cesarean delivery.[117] However, more recent studies have demonstrated that the complex process of lung liquid clearance begins well before term birth.[118] During fetal life, the lung epithelium is responsible for the production of a substantial volume of alveolar fluid, a process that is essential for normal fetal lung growth.[119] With parturition, increased levels of epinephrine, glucocorticoids, and other hormones cause the lung epithelia to transition from a secretory to a resorptive phenotype.[120,121] Activated endothelial sodium channels (ENaC) at the apical surface of lung type II epithelial cells transport sodium and water from the alveolar space into the type II cells.[122,123] Sodium is then actively moved from the type II cell into the interstitium by sodium-potassium pumps (Na/K-ATPase), causing passive movement of water, which is then resorbed into the pulmonary circulation and lymphatics. Supporting a possible role for abnormal activity of ENaC and Na/K-ATPase in TTNB, genetic polymorphisms in β-adrenergic receptor–encoding genes (which regulate expression of these channels) are more common in babies with TTNB.[124]

Diagnosis

The diagnosis of TTNB remains challenging for clinicians. The most typical presenting symptoms, tachypnea/respiratory distress and the need for supplemental oxygen, are common among most neonatal respiratory disorders, and, unfortunately, there exist no specific diagnostic tests for TTNB.[125] For those reasons, the diagnosis remains one of exclusion, and vigilance for other, more severe disorders is imperative. Typically, symptoms of TTNB develop within the first several hours after birth. The degree of respiratory impairment, including the respiratory rate, use of accessory respiratory muscles, and impairment in gas exchange, differs widely. CXRs should be considered in any baby presumed to have TTNB. Although radiographs commonly show prominent perihilar markings and fluid in the fissures, clinicians and radiologists often disagree in their interpretation of these findings in TTNB.[126] Recent studies suggest a potential role for ultrasound in differentiating TTNB from other causes of neonatal respiratory disorders.[127,128]

Treatment

Antenatal steroids for mothers who deliver at 34 to 36 weeks' gestation decrease the incidence of TTNB.[16] Once a presumptive diagnosis of TTNB has been made, treatment is largely supportive.

Oxygen should be provided to maintain normal arterial oxygen saturations. The degree of tachypnea and respiratory distress should determine the amount of respiratory support needed and whether a baby is allowed to feed by mouth. Some recent studies suggest that prophylactic CPAP in the delivery room for late-preterm and term newborns born via cesarean section decreases duration of symptoms and NICU admissions in suspected TTNB.[129,130] A recent Cochrane review evaluating inhaled epinephrine has not shown a decrease in the duration of symptoms or length of hospital stay.[131] Other Cochrane reviews assessing the utility of inhaled beta 2 agonists and inhaled steroids have shown more promising results but warrant further study.[132,133] If there is a suspicion of pneumonia or sepsis, empiric antibiotic therapy should be considered. Furosemide administration to accelerate clearance of lung fluid has not been shown to attenuate the course of TTNB.[134] Prospective studies suggest that moderate fluid restriction for the first 72 hours reduced the duration of respiratory support and cost of hospitalization.[135,136]

Prognosis

Alternative or additional diagnoses should be considered in any infant who is deteriorating or requires mechanical ventilation. With supportive care, full recovery is to be expected after TTNB. However, compared with well infants of a similar gestational age, newborns with TTNB have a significantly prolonged hospital course.[113] Moreover, recent epidemiologic studies have suggested that newborns with TTNB are at increased risk of hospitalization due to respiratory syncytial virus bronchiolitis in the first year of life[137] and increased risk of the later development of asthma.[138–140]

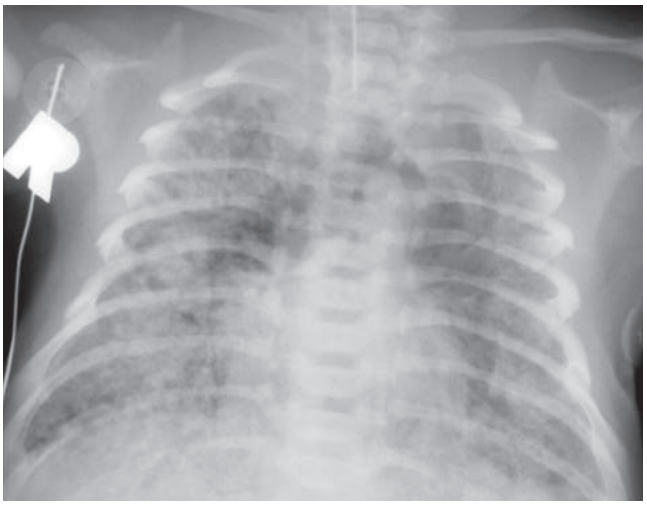
Aspiration Syndromes

Normally, there is a net egress of fluid from the fetal lung into the amniotic cavity, contributing significantly to the amniotic fluid volume. Hypoxemia or acidemia in utero can result in gasping, which may cause the fetus to aspirate amniotic fluid components. This may lead to a variety of aspiration syndromes depending upon the constituents of the amniotic fluid that is aspirated (i.e., sterile, infected, meconium-stained, and/or bloody fluid). This section will focus on the prototypical aspiration syndrome in the neonatal period: MAS.

Definition and Etiology

MAS is associated with inhalation of meconium and amniotic fluid during fetal life or at delivery and is often complicated by significant pulmonary hypertension. It is among the most common causes of hypoxemic respiratory failure in term newborns who require intensive care (Fig. 42.9). The incidence of MAS in babies born after 37 weeks' gestation ranges from 0.1% to 0.7%,[141–143] and one study suggests that the rate of MAS may have been declining in recent years.[144] Among babies born after 39 weeks' gestation with lung disease requiring mechanical ventilation, more than half have MAS.[145] Moreover, MAS is the primary diagnosis for a significant proportion of those newborns who require extracorporeal membrane oxygenation (ECMO) in the United States (26%) and the United Kingdom (51%).[146]

Although a significant percentage of term births are complicated by the passage of meconium before or at delivery, less than 10% of those exposed to meconium develop MAS. Among that 10%, fetal acidemia is believed to cause increased intestinal peristaltic activity that results in passage of meconium and fetal gasping, which draws meconium-contaminated amniotic fluid deep into the lungs. Supporting this theory, autopsy studies of babies who died of MAS demonstrate distal muscularization of small pulmonary arterioles, suggesting long-standing hypoxemia.[147] Recent work suggests that activation of inflammatory cascades may worsen the severity of MAS.[148,149] Particulate meconium in the distal airways causes check-valve obstruction of air passages and leads to regional hyperinflation and atelectasis. In addition, meconium inactivates surfactant, leading to secondary surfactant deficiency.[150] Moreover, babies with MAS are at high risk of persistent pulmonary hypertension, which significantly increases their morbidity and complicates their management.



• **Fig. 42.9** Chest Radiograph of Term Newborn With Severe Meconium Aspiration Syndrome. Note the anterior pneumomediastinum and small left anteromedial pneumothorax.

Prevention

Historically, prevention of MAS has focused on decreasing exposure of the fetal and newborn lung to the noxious effects of intrapulmonary meconium-contaminated amniotic fluid. Infusion of saline into the amniotic cavity (i.e., amnioinfusion) during labor has been studied as a means of both diluting meconium and relieving pressure on the umbilical cord, a potential cause of fetal acidemia. The largest trial investigating this practice[151] found no reduction in the risk of MAS. An alternative strategy for decreasing lung exposure to meconium is intrapartum oropharyngeal and nasopharyngeal suction of fetuses born through meconium-stained amniotic fluid. Although this practice was widely adopted in the 1970s, more recent studies have failed to demonstrate benefit,[152] and the practice is no longer endorsed by the American College of Obstetricians and Gynecologists.[153] Current American Academy of Pediatrics/American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care of the neonate no longer recommend intubation and tracheal suctioning for nonvigorous newborns born through meconium-stained amniotic fluid,[154–156] and there has been no increase in incidence or severity of MAS following this practice change.[142,143]

Clinical and Radiographic Signs

The clinical signs of MAS differ widely among babies and may relate to the degree of prenatal compromise, the timing, volume, and consistency of aspirated meconium, and the presence of associated problems. Clinical signs of MAS typically present immediately after birth with tachypnea, increased work of breathing, and cyanosis. Other common associated findings include metabolic acidosis, cardiac dysfunction and hypotension, and postductal desaturation indicative of right-to-left shunting of blood at the ductus arteriosus caused by pulmonary hypertension. Because of the potential for check-valve obstruction of small airways and failure to empty distal lung segments, pneumothorax can complicate the clinical picture. The risk of pneumothorax among ventilated babies with MAS ranged between 10% and 24%.[157,158] Like the degree of clinical signs, CXR findings differ widely. The classic CXR shows diffuse, fluffy infiltrates. However, some babies have milder initial radiographic findings, and there is often progression of visible parenchymal disease over time, likely related to secondary surfactant dysfunction.

Treatment

Approximately half of babies with MAS require mechanical ventilation. The ventilator strategy should be individualized to each baby and to the disease evident on the CXR. In general, because of the likelihood of increased airway resistance, a conventional strategy using slower rates with long inspiratory and expiratory times allows better gas dispersion and more adequate emptying during expiration. Gas trapping and regional or generalized hyperinflation can occur, particularly when rapid rates are used with a conventional mode of ventilation. Some babies respond better to ventilation with a high-frequency device, although there is also a significant risk of hyperinflation. When severe, hyperinflation impairs gas exchange, limits systemic venous return (adversely affecting cardiac performance), increases the risk of pneumothorax, and may exacerbate pulmonary hypertension.

The use of surfactant in MAS continues to be an area of active investigation. Surfactant lung lavage (SLL) demonstrated some promise in improving lung function in an animal model of MAS.[159] Although not definitive, clinical trials suggest that both bolus surfactant administration and SLL may favorably impact the duration of mechanical ventilation and hospital stay and the need for ECMO.[160,161] Furthermore, one recent multicenter retrospective study reported improved surfactant function during therapeutic hypothermia.[162]

In addition to management of parenchymal lung disease in MAS, special consideration must be given to other associated problems, particularly pulmonary hypertension. The risk of PPHN is quite high, exceeding 50% in some series. It has been demonstrated that iNO treatment improves oxygenation in MAS and is particularly efficacious when combined with a ventilator strategy that focuses on improving lung recruitment such as high-frequency oscillatory ventilation.[163]

Treatment with systemic antibiotics is often considered in babies with MAS given that intrauterine infection might be a precipitating factor in the initial passage of meconium, and in vitro studies suggest that the presence of meconium might facilitate the growth of bacteria in the lung. However, a recent Cochrane review and meta-analysis have not shown a benefit to antibiotic administration in neonates born through meconium-stained fluid or in neonates with MAS without evidence of sepsis.[161,164]

In spite of the availability of iNO treatment and high-frequency modes of ventilation, some babies do not respond to medical therapy and require treatment with ECMO. Babies with MAS treated with ECMO have a 94% survival rate, markedly higher than for newborns treated for other respiratory conditions.[165]

Congenital Diaphragmatic Hernia

CDH is a complex clinical syndrome caused by a developmental defect in the diaphragm, resulting in a spectrum of potentially severe cardiopulmonary abnormalities. The estimated incidence of CDH ranges from approximately 1 in 2500 to 1 in 7000 liveborn babies.[166] Approximately 80% to 85% of diaphragmatic hernias occur on the left side. In rare circumstances, they may be bilateral. As many as 30% to 40% of babies with CDH have additional congenital anomalies, most commonly of the heart, central nervous system, and genitourinary system.[166] The remaining 60% to 70% of babies have isolated CDH without other identifiable major anatomic malformations. CDH sometimes occurs in several well-recognized syndromes or in children with a chromosomal abnormality (particularly trisomy 18).

Medical and surgical management of the newborn with a CDH remains one of the most complex and challenging situations in the neonatal intensive care unit. A host of interrelated issues must be considered, including optimal mechanical ventilation strategies, the presence and treatment of pulmonary hypertension, evaluation of cardiac performance, and consideration of support with ECMO. (These management issues along with the clinical features and diagnosis of CDH are discussed in greater depth in Chapter 44.)

Surfactant Protein Deficiency

Overview

The details of surfactant biology and of RDS in premature newborns were presented earlier in this chapter. Term newborns may rarely present with a clinical syndrome dominated by respiratory failure that may be indistinguishable from surfactant deficiency in preterm infants. In the setting of unexplained and protracted respiratory failure in term infants, genetic alterations of surfactant-associated proteins, particularly surfactant protein B (SP-B), surfactant protein C (SP-C), and adenosine triphosphate (ATP)–binding cassette subfamily A member 3 (ABCA3), should be considered and ruled out. In addition, defective signaling of granulocyte–macrophage colony-stimulating factor, which regulates alveolar macrophages and surfactant catabolism, may cause progressive interstitial lung disease in infants.[167]

As described later, there is considerable overlap in the clinical presentation of babies with mutations of SP-B, SP-C, and ABCA3. Although onset, severity of clinical signs, and a family history of lung disease may offer clues to the underlying disorder, a full histologic and genetic evaluation should be considered. Genetic analysis of blood or buccal swabs for mutations of the genes encoding SP-B, SP-C, and ABCA3 are the definitive tests for each disease, but analysis is both costly and time consuming. Moreover, analysis is not routinely available, necessitating transport of specimens to a small number of laboratories specializing in these analyses. In addition, bronchoalveolar lavage (BAL) aspirate

should be analyzed by enzyme-linked immunosorbent assay for the presence of SP-B and pro-SP-C. Lung biopsy, performed by both standard microscopy and electron microscopy, can also provide important clues to the underlying diagnosis.

Surfactant-Associated Protein B Deficiency

Mature SP-B is a small hydrophobic protein (79 amino acids) that plays several key roles in the processing and function of normal pulmonary surfactant.[168] Transgenic mouse models suggest that SP-B is critical for phospholipid packaging into lamellar bodies, the formation of tubular myelin, and spreading/function of the surfactant monolayer. In addition, normal SP-B appears to be essential for normal processing of SP-C.[169] In all babies described to date with SP-B deficiency, the genetic mutation has been inherited from the parents (autosomal recessive) rather than occurring as a spontaneous mutation.[170] Although multiple genetic mutations have been described, approximately 70% of affected babies carry the 121ins2 mutation.[157] In a series of term babies referred for genetic evaluation of unexplained respiratory failure, 2 of 17 had detectable mutations of the SP-B sequence.[171]

Almost all babies with recognized deficiency of SP-B develop clinical signs of severe respiratory distress, including tachypnea, grunting, and retractions, within the first several hours of life. As for preterm newborns with RDS, CXRs classically reveal diffuse, hazy air space disease with visible air bronchograms. Severe PH may be a prominent feature of the disease. Treatment with surfactant is either ineffective or unsustained, and progressive respiratory failure is the rule with near 100% lethality in the first 6 months of life without lung transplant.[172] Lung transplant is currently the only effective long-term treatment, with a reported 5-year survival of 56%.[173] There is the potential for gene therapy in the future, but, to date, studies have been limited to animal models.[174–176]

Analysis of fluid obtained by BAL/tracheal aspirate from babies with SP-B deficiency should fail to detect any immunoreactive SP-B. The presence of pro-SP-C increases suspicion of SP-B deficiency because intact SP-B is necessary for normal posttranslational processing of the protein to mature SP-C. Histologic findings include alveolar cell hyperplasia, interstitial thickening, and variable degrees of fibrosis and alveolar proteinosis. Staining of lung tissue for pro-SP-B is variable but staining for mature SP-B should be minimal (because of cross-reactivity with epitopes on pro-SP-B) or absent. Initial DNA analysis focuses on the 121ins2 mutation. More exhaustive testing for other known mutations is warranted if initial testing is negative.

Surfactant-Associated Protein C Deficiency

Mature SP-C is a 35 amino acid hydrophobic protein. SP-C is believed to enhance spreading of surfactant and to participate in normal surfactant catabolism.[167] As with SP-B, multiple mutations of SP-C have been described; however, most of these mutations of the gene encoding SP-C arise spontaneously and result in sporadic disease. Whether the abnormal phenotype associated with SP-C deficiency arises from dysfunction of the alveolar surfactant or from accumulation of abnormal cellular SP-C and consequent type II cell injury is not known.

In contrast to babies with SP-B deficiency, babies with SP-C deficiency have a wide range of clinical presentations. Some may develop symptoms within the first several hours of life, similar to SP-B deficiency, whereas others present later in childhood or in adulthood with interstitial lung disease. In one series, half of children with SP-C deficiency presented in the neonatal period, and mortality was reported as 15%.[177] The reasons that underlie the variable onset, presentation, and severity of SP-C deficiency are not fully understood, but it is suggested that those individuals whose SP-C mutation lies within the specific BRICHOS chromosomal domain are at higher risk of neonatal presentation.[178] Corticosteroids are the mainstay of treatment of infants with SP-C deficiency, although many centers also administer azithromycin and/or hydroxychloroquine.[178]

In common with SP-B deficiency, the lung histopathologic features of patients with SP-C deficiency are nonspecific and widely variable. Common findings include accumulation of alveolar protein and macrophages and epithelial cell hyperplasia. Ultrastructural examination may reveal disorganized lamellar bodies with aggregates of small vesicles with electron-dense cores in the type II cells.[179] Allele-specific testing using the polymerase chain reaction for the most common 173T mutation provides an initial screen for SP-C deficiency. If the screen is negative, direct sequencing of the entire SP-C gene should be undertaken.

Adenosine Triphosphate–Binding Cassette Subfamily A Member 3 Deficiency

The ATP-binding cassette transporter proteins are essential for normal transport of compounds in numerous biologic systems.[180,181] Deficiencies of individual ATP-binding cassettes have been associated with clinical diseases in a number of different organ systems. ABCA3 is highly expressed in the lungs and is involved in the transport of lipids. Individuals lacking the gene for ABCA3 have abnormal accumulation of surfactant-rich lamellar bodies within their type II alveolar cells, with apparent inability to transport surfactant into the alveolar space. Shulenin et al.[182] detailed a variety of mutations within the ABCA3 gene in a substantial portion of term infants with unexplained respiratory failure and suspected surfactant protein deficiency.

The age at presentation for individuals with ABCA3 deficiency is highly variable, ranging from the immediate newborn period to later in childhood. There may be a family history of consanguinity. Clinical manifestations of disease in the neonate may be indistinguishable from those of neonates with SP-B deficiency, with onset of respiratory failure within hours of birth. The disease may be progressive and fatal. In addition, ABCA3 deficiency may also manifest as severe PPHN.[183] The treatment options for ABCA3 deficiency are limited. Some children undergo lung transplant, and recent case reports suggest that some patients may respond to corticosteroids, azithromycin, or hydroxychloroquine.[184–186] It has been reported that milder, transient neonatal symptoms may not prompt a diagnostic evaluation in the newborn period, although recurrent pulmonary symptoms may lead to later investigation.[187] These reports raise the possibility that deficiency of ABCA3 may be underrecognized in infants or children with a mild or normal phenotype.

The predominant pathologic findings of neonates with ABCA3 deficiency with neonatal respiratory failure include alveolar proteinosis,[188] type II cell hyperplasia with dense lamellar bodies, and accumulation of alveolar macrophages in the distal air space. Inheritance is believed to be autosomal recessive. Unlike SP-B deficiency, a single predominant mutation has not been described; rather, multiple distinct mutations affecting different protein domains have been identified.[189–191]

Thyroid Transcription Factor 1 Gene Mutation

Recent studies demonstrate that mutations of the gene (*NKX2-1*) encoding thyroid transcription factor-1 (TTF-1), which is expressed in the thyroid, lung, and brain, can result in neonatal respiratory failure. TTF-1 regulates structural lung development and plays a key role in the expression of SP-B, SP-C, and ABCA3. Histologic findings from these patients are heterogeneous and not diagnostic. Hamvas et al.[192] reported a series of 21 patients with *NKX2-1* mutations, 17 of whom had neonatal RDS (with or without PPHN). Some of these patients also had thyroid and/or brain abnormalities, while others had only respiratory disease evident at the time of diagnosis. Like with other interstitial lung disorders, treatment of symptomatic patients with steroids, azithromycin, and hydroxychloroquine may be beneficial.[193]

Surfactant-Associated Proteins A and D

Surfactant-associated proteins A (SP-A) and D (SP-D) are part of the innate immune system of the lung and maintain surfactant lipid homeostasis.[167] Although lung structural abnormalities have been described in mice lacking SP-A and SP-D, no phenotype attributable to abnormalities of either of these surfactant-associated proteins has been described in human infants.[194] Recent work suggests a role for mutations in the gene that encodes SP-A in adult-onset pulmonary fibrosis in rare circumstances.

Other Interstitial Lung Diseases

The interstitial lung diseases that occur in infancy are a heterogeneous group of disorders that overlap with the surfactant protein disorders and may involve one or more of the several components of the lung.[195] All produce considerable morbidity and mortality. Detailing each individually is beyond the scope of this chapter, but two entities, alveolar capillary dysplasia with misalignment of pulmonary veins (ACD/MPV) and pulmonary interstitial glycogenosis (PIG), have attracted considerable attention in recent years.[167,192,196]

Alveolar Capillary Dysplasia/Misalignment of Pulmonary Veins

ACD/MPV results from severe developmental abnormalities of the structure of the pulmonary circulation. In particular, alveolar capillary density is reduced, and capillaries typically reside in the center of abnormally widened alveolar walls rather than immediately proximate to the alveolar epithelium and air space. An additional histologic hallmark of the disease is abnormally positioned pulmonary veins, which are adjacent to the terminal bronchioles.[197] Most newborns with ACD/MPV experience respiratory failure and PPHN within the first several days of life. For reasons that are poorly understood, presentation may be delayed in some babies. The typical course of ACD/MPV is refractory respiratory failure and pulmonary hypertension, which ultimately leads to death. Some babies may respond to pulmonary vasodilators but only transiently.[198] Stankiewicz et al.[199] documented deletions of the Forkhead Box transcription factor (FOXTF) gene cluster on chromosome 16 in a series of ACD/MPV patients, and the FOXTF has recently been proposed to function through STAT3 signaling to promote lung angiogenesis.[200] Depending on the underlying chromosomal abnormality, 50% to 75% of patients with ACD/MPV have other malformations, most notably of the gastrointestinal, genitourinary, and cardiovascular systems.[195]

Pulmonary Interstitial Glycogenosis

PIG is an interstitial lung disease thought to be unique to infants that is characterized by a thickened lung interstitium and the accumulation of intracellular glycogen in immature interstitial cells.[201,202] It has been postulated that PIG represents a developmental lung disorder rather than one resulting from inflammation or other precipitants. Infants with PIG typically develop respiratory symptoms in the first few days of life, including tachypnea and hypoxemia; many require a period of assisted ventilation; and many have pulmonary hypertension.[203] In a series of 24 patients with PIG, Liptzin et al.[204] reports 63% had structural heart disease and 92% were treated with steroids. Many infants with biopsy-proven PIG treated with pulse steroid therapy have their respiratory symptoms abate or resolve altogether in the first year of life. Whether steroid treatment accelerates the abatement process has not been established and remains controversial.[205]

Summary

The initial evaluation of respiratory distress/hypoxemia in the newborn presents one of the most difficult challenges faced by pediatricians and neonatologists. An ordered approach using information derived from the history, physical examination, pulse oximetry measurements, radiographic and laboratory measurements, and echocardiography can help elucidate the cause of hypoxemia and respiratory failure and direct each step of clinical management. Recognizing the important contributions of parenchymal lung disease, pulmonary vasoconstriction, and cardiac performance is critical to successful clinical management of the newborn with respiratory failure.

Chronic Neonatal Respiratory Disorders

ROBERTA L. KELLER AND ROBIN H. STEINHORN

KEY POINTS

- Bronchopulmonary dysplasia (BPD), as determined near term corrected age in former preterm newborns < 32 weeks' gestational age is a marker for chronic respiratory morbidity.
- Newborns that are most immature and those born from an adverse intrauterine environment, affected by maternal vascular disorders and decreased intrauterine growth, are most susceptible to early neonatal respiratory illness.
- Early neonatal respiratory illness, marked by increased exposure to supplemental oxygen and use of mechanical ventilation, is associated with BPD and later respiratory morbidity.
- Former preterm newborns have evidence of lung dysfunction near the time of initial hospital discharge.
- Lung dysfunction, immune deficits and environmental factors confer vulnerability to lower respiratory tract infection and wheezing illness in infancy and early childhood.
- Composite respiratory morbidity outcomes ascertained during infancy primarily reflect resource utilization due to respiratory disease, vary widely in prevalence based on population of interest, and reflect a broad spectrum of severity.
- Dysplastic development of both the lung and airway in former preterm newborns occurs. However, the most prominent long-term morbidity of former preterm newborns is obstructive lung disease and wheezing illness or asthma.

Introduction

Chronic lung disease of infancy following preterm birth was first described by Northway and colleagues in 1967.[1] These investigators identified clinical, radiographic and histopathological findings of lung fibrosis and airway disease in former preterm newborns with death or ongoing pulmonary dysfunction after exposure to prolonged mechanical ventilation and hyperoxia. They termed this disorder bronchopulmonary dysplasia (BPD), reflecting dysplastic extrauterine development of the lung parenchyma and airways following preterm birth prior to or early in the alveolar stage of lung development. Subsequent investigations (1) confirmed and expanded the description of post-mortem lung histopathology, noting pulmonary vascular changes consistent with observed right ventricular hypertrophy and cor pulmonale, and (2) demonstrated fixed and reactive airway obstruction, with symptomatic lung disease, susceptibility to infection and chest wall deformity in survivors with BPD at a mean age of 18 years.[2,3] Many of the newborns cared for in these reports were born at ≥30 weeks' gestational age (GA). However, as approaches to preterm infant care evolved, rates of survival and successful separation from respiratory support improved for infants at these gestational ages and lower, prompting investigations of a clinical marker for subsequent morbidity and mortality. In a retrospective analysis of former preterm infants born at 25 to 32 weeks' GA, Shennan et al. evaluated the ongoing use of supplemental oxygen up to 38 weeks' post-menstrual age (PMA) as a predictor for later respiratory morbidity or death up to 2 years of age.[4] They proposed 36 weeks' PMA as the most appropriate time point to discriminate between those infants with and without morbidity and mortality. The use of supplemental oxygen with or without positive pressure at 36 weeks' PMA evolved into the clinical definition of BPD, used as a benchmark and quality metric for neonatal care, and as an endpoint for clinical trials designed to improve respiratory outcomes in extremely preterm newborns.[5,6]

With further advances in perinatal and neonatal care, including the use of antenatal steroids, exogenous surfactant and lung protective strategies for early respiratory support, histopathological airway disease and lung fibrosis became less prominent post-mortem findings in former preterm newborns.[7] The changing landscape of respiratory illness in low and extremely low gestational age newborns (ELGAN) and interest in further discriminating respiratory outcomes in former preterm infants were addressed in a National Institutes of Health (NIH) sponsored expert workshop in June 2000. Attendees developed a tiered, severity-based approach to the definition of BPD, proposing categories of mild, moderate, and severe BPD based on level of respiratory support at 36 weeks' PMA (degree of supplemental oxygen and use of positive pressure) for infants born at < 32 weeks' GA.[8] Investigators from the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network (NRN) subsequently validated this NIH consensus definition in follow-up of survivors of preterm birth at 18 to 22 months corrected age.[9] They demonstrated increasing proportions of infants with use of respiratory medications, rehospitalization for respiratory cause, growth failure and neurodevelopmental impairment with increasing severity of BPD. Notably, the addition of an abnormal chest radiograph demonstrating parenchymal lung disease did not improve discrimination for these later morbidities.

The NIH consensus definition has raised concerns as to its usefulness at both lower and higher levels of severity. Specifically, the discrimination of infants classified as no versus mild BPD may not be clinically important. Infants classified as severe BPD may represent too broad a category to be clinically meaningful, as it includes a spectrum spanning infants receiving support by nasal cannula and those remaining on mechanical ventilation. In October 2016, an NICHD expert panel proposed a modification of the prior consensus definition of BPD, still defined at

36 weeks' PMA, using various cut-offs for inspired oxygen concentration (FiO_2) and nasal cannula flow at different levels of BPD. Notable features of this modification were a change in terminology to Grades I-III, with the highest grade, Grade III, including only infants on mechanical ventilation with $FiO_2 > 21\%$ or infants requiring noninvasive pressure support with $FiO_2 \geq 30\%$ (e.g., continuous positive airway pressure [CPAP], high flow nasal cannula (HFNC) > 3 L/min); a special category IIIA would be assigned to infants that died prior to 36 weeks' PMA due to lung disease.[10] Alternatively, Abman and colleagues from the US-based Bronchopulmonary Dysplasia Collaborative proposed retaining the original NIH consensus categories while subdividing severe BPD into two subtypes: severe type 1 BPD would encompass infants supported by low flow nasal cannula with an $FiO_2 \geq 30\%$ or any administration of noninvasive positive pressure support or HFNC, and severe type 2 BPD for all infants supported with mechanical ventilation.[11] Neither group evaluated the ability of these particular cut-offs to predict later respiratory morbidity, but this task was taken on by Jensen and colleagues from the NICHD NRN, using the outcome of death or severe respiratory morbidity ascertained at 18 to 26 months of age.[12] Their exploration of discriminatory cut-offs for various levels of respiratory support at 36 weeks' PMA yielded three levels of BPD, termed Grades 1 to 3, defined solely by mode of support without regard for FiO_2. Grade 3 includes all infants on mechanical ventilation, Grade 2 all infants on noninvasive positive pressure or nasal cannula flow > 2 LPM and Grade 1 all infants on nasal cannula flow ≤2 LPM. Similarly, Isayama and colleagues found that the dichotomous classification of use of supplemental oxygen or any mode of positive pressure respiratory support (including nasal cannula flow >1.5 LPM) was the strongest predictor of respiratory outcome at 18 to 21 months corrected age, in data from the Canadian Neonatal Network.[13]

These proposed definitions of BPD as either a predictor or surrogate outcome for later respiratory morbidity do not address the underlying pathophysiology of chronic respiratory illness in former extremely preterm newborns. The evolution of the histopathology related to early respiratory insufficiency, with alveolar simplification accompanying less prominent fibrosis, generated the concept of a "new BPD," that develops in vulnerable preterm newborns born during the late canalicular or early saccular stage of lung development and characterized by extrauterine arrested alveolar and microvascular development.[7,14,15] Yet symptomatic and functional airway obstruction remains the most prominent manifestation of persistent pulmonary disease in former preterm newborns and is not explained by arrested lung growth nor the recovery from that arrest.[16] Additional contributions to chronic respiratory illness may be pulmonary vascular disease, susceptibility to infection, environmental exposures and the influence of other socioeconomic circumstances, each of which are variably related to lung parenchyma versus airway development and dysplasia.[17–19] Thus, early dysplastic, arrested lung growth and ongoing clinical airway disease suggest that these conditions may themselves be related but separate co-travelers that lay the path to chronic respiratory illness in former preterm infants.

Epidemiology of Bronchopulmonary Dysplasia and the Vulnerable Preterm Lung

The primary risk factors for BPD and its severity are related to the degree of immaturity at birth, reflected by gestational age or birth weight.[20–22] Various US-based publications including contemporary data from the population-based California Perinatal Quality Care Collaborative (CPQCC), the multicenter NICHD NRN and the nationwide Vermont Oxford Network (VON) collaborative, demonstrate these important relationships, and provide estimates of the incidence and severity of BPD in extremely preterm newborns born at 22 to 29 weeks' GA (Table 43.1). Overall incidence of (1) BPD or death at 36 weeks' PMA was 47% in CPQCC, (2) BPD among survivors at 36 weeks' PMA was 45% in the NICHD NRN, and (3) Grade 1/2 BPD (any use of nasal cannula or noninvasive positive pressure) was 41% and Grade 3 BPD (mechanical ventilation) was 4% in survivors at 36 weeks' PMA in VON. Given the variability in both the patient populations and the diagnostic criteria for BPD, these estimates are remarkably consistent, with outcomes reported in over 44,000 infants spanning 12 birth years. These estimates were determined by clinical prescription of respiratory support and could be affected by provider variability. However, the use of a physiologic challenge consisting of a monitored decrease in nasal cannula flow and FiO_2 at 36 weeks' PMA does not substantively affect the proportion of infants classified with BPD.[23–25]

In addition to immaturity, elements of the fetal environment influence early respiratory morbidity of BPD. Investigators in the multicenter ELGAN Study classified over 1000 singleton pregnancies into one of six presenting conditions leading to delivery at < 28 weeks' gestation. Their analyses produced two primary phenotypes for preterm delivery, an inflammatory phenotype, and a vascular (placental) phenotype, associated with maternal preeclampsia or fetal indications for delivery.[26] These delivery indications were used to evaluate risk of BPD, along with birth weight z-scores, reflecting fetal growth. Low birth weight z-scores (<−2 and between −2 and −1) conferred increased odds of BPD, with the greatest effect seen in newborns with the most severe intrauterine growth restriction, even when adjusting for delivery indication.[27] Other single center studies similarly reported that pre-eclampsia greatly increased the odds of BPD while adjusting for birth weight z-score and severe intrauterine growth restriction in combination with maternal vascular disease greatly increased the odds for BPD and BPD or death.[28,29] In the EPIPAGE-2 cohort, a French prospective population-based study of outcomes of prematurity, birth weight z-score was an independent predictor of BPD (decreasing z-score increased odds of BPD) while adjusting for GA and vascular/placenta-based complications of pregnancy.[30] Consistent with these findings, maternal vascular underperfusion identified in the placentas of extremely preterm newborns was also associated with increased odds of BPD.[31] These findings support the concept that the adverse fetal environment affects intrauterine lung growth and development, increasing the vulnerability of the immature lung to further insults.

When considering chronic neonatal respiratory disorders, it is important to recognize the interface of early respiratory support and supplemental oxygen due to respiratory insufficiency, with the markers and effectors of lung dysfunction and dysplasia a precursor to chronic lung disease. Laughon et al. demonstrated that the pattern of supplemental FiO_2 over the first 14 days of life is highly associated with later risk of BPD in newborns 23 to 27 weeks' GA enrolled in the ELGAN Study.[32] Regardless of the mode of respiratory support, newborns with consistently low FiO_2 (≤25%) in the first 14 days had an incidence of BPD of only 17%, whereas those with higher early and escalating FiO_2 had a BPD incidence of 67%, and newborns with an initial decrease and then escalation of FiO_2 had an intermediate BPD incidence of 51%. In refinement of this risk and vulnerability, these investigators also showed that

within each of these patterns, those newborns with birth weight z-score < −1 had an elevated risk of BPD.[33] In a secondary analysis of data from the Trial of Late Surfactant (TOLSURF) that enrolled preterm infants who remained mechanically ventilated at 7 to 14 days of life, cumulative supplemental oxygen exposure over the first 14 days of life accurately predicted later outcomes of BPD or death and BPD in survivors.[34] In multivariate modeling, cumulative mean airway pressure over the same 14-day time period was also an independent predictor of these adverse respiratory outcomes. Using data from the NICHD NRN for newborns 23 to 30 weeks' gestation, Laughon et al. found that gestational age, birth weight, mode of respiratory support and FiO_2 were all selected as important predictors of BPD or death over the first 28 days of life, but the importance of these variables shifted over time.[35] At days 1 and 3, gestational age and birth weight were the most influential factors, but at days 7 to 28, mode of respiratory support was the most important factor, and FiO_2 was the second most important factor at days 21 and 28. Taken together, these studies highlight the risks associated with the need for early or prolonged respiratory support, and the chronic consequences of that support.

Randomized trials designed to evaluate limitation of exposure to invasive mechanical ventilation and oxygen supplementation in extremely preterm infants have shown modest effects on the occurrence of BPD (primary noninvasive respiratory support vs. mechanical ventilation and surfactant). Moreover, these approaches may have unintended consequences (lower vs. higher oxygen saturation targets) and may not decrease later respiratory morbidity in at-risk populations. Two meta-analyses published in 2016 describe the effects of the primary strategy of providing noninvasive positive pressure (CPAP) versus intubation and mechanical ventilation.[36,37] These analyses had different approaches and their results differed somewhat. The meta-analysis from the Cochrane Library, using data from three trials, demonstrated decreased risk ratios for BPD (0.89; 95% CI 0.79, 0.99) and BPD or death (0.89; 95% CI 0.81, 0.97) with the strategy of applying and continuing CPAP soon after birth.[37] This strategy was accompanied by significant reductions in the use of mechanical ventilation and surfactant administration. The other study applied network meta-analyses to 2 of the 3 studies included in the Cochrane analysis, producing network odds ratios that had similar effect sizes as the reported risk ratios, but confidence intervals for BPD and BPD or death that crossed the null boundary. The implementation of noninvasive strategies has been widespread and short-term benefits may increase with use of noninvasive surfactant administration, for newborns meeting specific criteria[36]. However, broad clinical implementation of a strategy to limit invasive mechanical ventilation has been also been associated with an increase in overall duration of respiratory support and worse lung function parameters at school age.[38]

The international Neonatal Oxygenation Prospective Meta-analysis (NeOProM) collaborative aligned study protocols and shared data to allow for an individual patient data meta-analysis

of 5 double-blind randomized, controlled clinical trials.[39] These studies compared oxygen saturation targets of 85% to 89% versus 91% to 95% for extremely preterm newborns receiving supplemental oxygen. Although the primary outcome of the collaborative was the effect of oxygen saturation targets on neurodevelopmental disability, the group analyzed secondary outcomes and subgroup effects.[40] Importantly, mortality was increased in the lower oxygen saturation group up to 18 to 24 months corrected age, including at 36 weeks' PMA (risk difference 2.5%; 95% CI 0.5, 4.5%). Severe necrotizing enterocolitis (NEC) was also increased with lower oxygen saturation targets (risk difference 2.3%; 95% CI 0.8, 3.8). Among survivors, BPD, defined as oxygen supplementation at 36 weeks' PMA, was decreased by 5.6% (95% CI −8.5, −2.7%), relative risk (RR) 0.81 (95% CI 0.74, 0.90), an effect that was even greater in SGA infants (adjusted RR 0.54 (CI 0.37, 0.77). These results provide more direct insight into the effects of oxygen supplementation on the development of chronic respiratory disease in these vulnerable populations. However, the increase in mortality and NEC when targeting oxygen saturations < 90% suggests that more targeted strategies will be needed to improve respiratory outcomes.

Additional Risks to the Developing Lung

Pulmonary vascular disease (PVD) with or without pulmonary hypertension (PH) is a co-morbidity that impacts respiratory status and potential for recovery in former extremely preterm newborns, particularly in those with BPD.[41,42] Based on experimental models and human histopathology, aberrant vascular growth with a restricted vascular bed would be expected to accompany the dysplastic parenchymal lung development following preterm birth.[7,14,15,43,44] Published studies in this area pose a challenge to describing risks and outcomes for PVD/PH due to (1) heterogeneous study population inclusion criteria, (2) timing of evaluation, and (3) variable diagnostic criteria for PVD/PH, which lack standardization by echocardiography in this population (the diagnostic mode most commonly employed).[42,45–50] As a result, there is a broad range of estimated prevalence of PVD/PH in former preterm newborns at or around term corrected age, with higher prevalence among infants with a concurrent diagnosis of BPD, and increasing prevalence with increasing severity of BPD. In a meta-analysis of 25 published studies, Arjaans et al. provide prevalence estimates for the following populations: extremely preterm newborns with or without BPD (12%; 95% CI 9, 15%); extremely preterm infants with BPD (20%; 95% CI 14, 25); extremely preterm infants by NIH consensus BPD classification [none 2% (95% CI 0, 8%); mild 6% (95% CI 1, 13); moderate 12% (95% CI 4, 24%); severe 39% (95% CI 29, 49%)].[41]

The underpinnings of the development of PVD/PH in former preterm infants are of great interest as PVD/PH is strongly associated with the presence and severity of BPD, yet it does not affect all infants within any BPD classification equally. Arjaans et al. analyzed risk factors for the diagnosis of PVD/PH in their meta-analysis and found that newborns that were SGA had an increased risk of PVD/PH regardless of the diagnosis of BPD.[41] This is consistent with increased prevalence of PVD/PH in infants born from pregnancies with placentas affected by maternal vascular underperfusion, further implicating the adverse fetal environment as a critical area of vulnerability for extremely preterm newborns with respect to the lung.[31,51] Two additional prospective investigations further support the concept that the early clinical condition of extremely preterm newborns predisposes them to adverse respiratory outcomes. In survivors to 36 weeks' PMA, Mourani et al. performed echocardiograms at 7 days of age and demonstrated that interventricular septal wall flattening (a sign of elevated right heart pressure) at 7 days of age was associated with the later classification of BPD and with echocardiographic diagnosis of PVD/PH at 36 weeks' PMA.[52] Mirza and colleagues performed serial echocardiograms approximately every 48 hours until 14 days of age.[53] They found that 55% (32/58) of newborns had a delayed perinatal transition at 72 to 96 hours of age, defined as estimated right-sided pressure ≥50% of systemic blood pressure. This factor was the primary influence on the outcome of BPD or death in multivariate modeling, although delayed transition was also inversely related to gestational age. Further, of the 10 infants that had persistent PVD/PH by echocardiogram at 14 days, all ultimately died or were classified with BPD, consistent with the findings from Mourani et al. Newborns with concerning echocardiographic findings at the assessment time points of 72 to 96 hours and 7 days of age also had increased levels of respiratory support compared to those with more reassuring findings.[52,53] Overall, it is clear that the vulnerability conferred by immaturity and an adverse intrauterine environment creates susceptibility to PVD/PH, and that PVD/PH confers further risk of adverse outcomes for extremely preterm newborns with chronic respiratory disease.

The diagnosis of PVD/PH is associated with increased mortality. The meta-analysis of Arjaans et al. identified a risk ratio for mortality of 4.7 (95% CI 2.7, 8.3) in infants with and without a diagnosis of BPD.[41] Individual investigations have further delineated this relationship. In a single center study, Arjaans and colleagues demonstrated that among 28 infants with BPD complicated by PVD/PH, those with suprasystemic right-sided pressure estimates by echocardiogram at ≥36 weeks' PMA had worse survival curves than those with subsystemic pressure estimates (1-, 3-, and 7-month survival of 80%, 50%, and 30% vs. 94%, 83%, and 76%; log-rank $P = .03$).[54] Overall mortality was 39%. Similarly, mortality was 28% in 61 infants with BPD and PVD/PH in another single center cohort.[55] Finally, in a multicenter cohort of infants with severe BPD, Vyas-Read and colleagues identified that infants with interventricular septal wall flattening on echocardiogram had elevated mortality compared with infants with normal septal position (19% vs. 8%).[42] Septal flattening was a specific (82%) but not sensitive (37%) predictor of mortality relative to normal or missing echo findings. Beyond the echocardiographic assessment of PVD/PH and its relationship to BPD, data regarding vascular dysfunction lends further insight into the interface of structural and functional lung disease. Functional pulmonary vascular differences as assessed by reactivity at cardiac catheterization are present in former preterm newborns with BPD. Vasoreactivity in response to acute vasodilator testing was present in 35% to 77% of those infants selected for cardiac catheterization.[56–58] Frank and colleagues reported only one death among nine infants with a vasodilatory response, compared to five deaths among 17 nonreactive infants, a difference that was statistically significant when combined with the outcome of tracheostomy (11% vs. 53%, $P = .04$).[57] For abnormal vasoconstriction, increased pulmonary artery pressure has been described with withdrawal of supplemental oxygen in children with BPD during cardiac catheterization, similar to what is seen with respect to worsening PH by echocardiogram during respiratory infection (consistent with vasoconstriction triggered by the inflammatory stimulus).[59,60] Thus, PVD/PH in former preterm infants with BPD is both a structural and a

functional phenomenon, and the ongoing risks of PVD/PH may further influence the developing lung.

Individual infants may have multiple major comorbidities of prematurity following extremely preterm birth, with the most immature newborns at greatest risk. In a California population-based cohort of extremely preterm newborns (22 to 28 weeks' GA), the proportion of infants with more than one major neonatal morbidity increased with decreasing gestational age, while rates of survival free of major morbidity increased with increasing gestational age.[61] These results mirror data from the NICHD NRN and the French population-based EPIPAGE-2 cohort study.[21,62] BPD also is a strong predictor of impaired neurodevelopmental outcome, with early respiratory support metrics influencing later neurological status.[9,13,63] Consistent with these patterns, inflammatory conditions, such as sepsis and NEC, are overrepresented in preterm newborns that are later classified with BPD, and NEC is also a risk factor for PVD/PH.[22,41,64] These inflammatory conditions may impede extrauterine lung development and contribute to early and later respiratory insufficiency. Early inflammation is also an effector of airway disease; in data from the Tucson Children's Respiratory Study (TCRS), both bronchiolitis and pneumonia occurring at < 3 years of age are implicated in persistent clinical and functional obstructive airway disease in children born at term without neonatal respiratory illness.[65,66] Thus, inflammatory insults that occur before and after initial discharge may contribute to the later respiratory manifestations of extremely preterm birth, represented by airway obstruction and wheeze.

Pharmacological Prevention of Bronchopulmonary Dysplasia

Many controlled trials have investigated pharmacologic interventions to prevent BPD in high-risk preterm newborns.[6] However, relatively few interventions have consistently shown short-term benefit (i.e., decrease in incidence of BPD or BPD or death, or increase in survival without BPD), despite utilizing meta-analyses to increase power. Even fewer interventions have demonstrated longer-term respiratory benefit (reduction in incidence of respiratory morbidity after hospital discharge). Proposed pharmacological interventions have generally targeted decreasing inflammation and/or direct promotion of lung growth and repair; several drug classes have demonstrated short-term benefit with or without consideration of longer-term effects.

With respect to strategies to limit inflammation, systemic, inhaled, and instilled glucocorticoids have been studied to prevent BPD. There is well-known controversy regarding the use of systemic dexamethasone, as its administration has been associated with increased rates of neurodevelopmental impairment (NDI), including cerebral palsy, compared to unexposed newborn controls. This risk may be modified by (1) the timing of exposure, (2) the total dose of dexamethasone, and (3) the underlying risk of BPD, with dexamethasone conferring lower risk or no increased risk of NDI in newborns and infants at higher risk of BPD.[67,68] Early dosing (in the first week of life) of systemic hydrocortisone has also been studied. A recent meta-analysis demonstrated that early hydrocortisone modestly increased survival without BPD (risk ratio 1.19; 95% CI 1.04, 1.35; number needed to treat [NNT] 13) and decreased BPD (risk ratio 0.84; 95% CI 0.72, 0.98; NNT 14), but substantially increased rates of intestinal perforation (risk ratio 1.76; 95% CI 1.09, 2.84; number needed to harm [NNH] 28).[69] This increased risk of intestinal perforation was attributed to proximate or concurrent medical treatment of patent ductus arteriosus (PDA), although the meta-analysis also demonstrated a substantial decrease overall in treatment for PDA in newborns exposed to early hydrocortisone (risk ratio 0.66; 95% CI 0.49, 0.88; NNT 11).[69,70] Further, survival without moderate-to-severe NDI was higher in infants previously treated with hydrocortisone (risk ratio 1.14; 95% CI 1.03, 1.27; NNT 13). Early hydrocortisone was also evaluated in an individual patient data meta-analysis including four of the five studies analyzed in the conventional meta-analysis.[71] These analyses identified that the relationship of hydrocortisone and intestinal perforation only held in newborns that were also treated with indomethacin for PDA, and it demonstrated a modest increased in odds of late onset sepsis with hydrocortisone (odds ratio 1.34; 95% CI 1.02, 1.75; NNH 15).

The effects of late hydrocortisone (after the first week of life) were evaluated in the previously cited conventional meta-analysis, with data from only two studies. No significant effects were seen on either BPD-related or later follow-up outcomes.[69] A third trial of late hydrocortisone conducted by the NICHD NRN investigators has completed enrollment, but results are not yet available (NCT01353313, ClinicalTrials.gov, accessed November 17, 2021).

Inhaled budesonide, initiated in the first day of life and continued until 32 weeks' PMA, decreased the combined outcome of BPD or death with marginal statistical significance (40.0% vs. 46.3%; relative risk 0.86; 95% CI 0.75, 1.00).[72] Death was higher and survival with BPD was lower following inhaled budesonide. In follow-up at 18 to 22 months corrected age, mortality remained significantly increased in the inhaled budesonide group (relative risk 1.37; 95% CI 1.01, 1.86).[73] This effect on mortality has not been explained, although local or systemic effects of this potent glucocorticoid on susceptibility to infection have been considered.[74] There was no difference in rates of NDI nor several respiratory morbidities at follow-up, including use of selected respiratory medication and home respiratory support. In other work, early administration of up to 6 doses of instilled budesonide suspended in surfactant (beractant, AbbVie Inc., North Chicago, IL) decreased BPD or death compared to surfactant alone in very low birth weight (VLBW) newborns intubated with respiratory distress syndrome (risk ratio 0.58; 95% CI 0.44, 0.77).[75] Newborns treated with budesonide plus surfactant also transiently had lower levels of inflammatory markers in tracheal aspirate fluid and lower rates of treatment of PDA, an effect also demonstrated with inhaled budesonide.[72,75] There were no differences in neurodevelopmental or medical outcomes assessed at 2 to 3 years corrected age. Pilot studies of this formulation and a dose-response study of repeated doses of budesonide in calfactant (ONY Biotech, Amherst, NY) showed limited absorption of budesonide.[76,77]

Other trials have focused on pharmacologic interventions that directly enhance normal lung growth and development after preterm birth. Intramuscular Vitamin A, administered over the first 4 weeks of life, showed benefit for prevention of BPD or death in a trial conducted by the NICHD NRN in 1996–1997 (relative risk 0.89; 95% CI 0.80, 0.99; NNT 14).[78] A recent re-analysis of these trial data accounting for risk of BPD or death utilizing a contemporary risk calculator demonstrated that newborns in the lowest risk quartile were more likely to benefit from Vitamin A therapy.[79] Later outcomes have not been published.

Inhaled nitric oxide (iNO) has also been studied extensively, with broad variation in dose and timing of iNO exposure across trials. Due to this variability, no single point estimate was provided for iNO effect on BPD or death in the most recent meta-analysis

reported from the Cochrane Collaboration.[80] With early rescue therapy, early preventative therapy or later preventative therapy in higher risk newborns, risk ratios ranged from 0.92 to 0.94 and all 95% confidence intervals just crossed the null. In a subsequent individual participant data meta-analysis from three of the trials that included diverse populations, the analyses focused on evaluating differential benefits of iNO by maternal race. With these composite data, infants of non-Hispanic white mothers had no benefit of iNO on BPD or death (relative risk 0.99; 95% CI 0.87, 1.12) and infants of Black mothers had a significant benefit (relative risk 0.77; 95% CI 0.65, 0.91; NNT 7). The overall effect in these three trials was similar to that identified using the conventional meta-analysis approach (relative risk 0.89; 95% CI 0.81, 0.97), and a significant interaction p value indicated differential benefit of iNO across the four racial/ethnic groups evaluated: non-Hispanic white, Black, Hispanic, and other.[81]

Caffeine was found to be effective in the prevention of BPD in the Caffeine for Apnea of Prematurity (CAP) Trial (odds ratio 0.63; 95% CI 0.52, 0.76; NNT 10), with early initiation at <3 days more effective than later initiation.[82,83] In the CAP Trial, caffeine lowered the postmenstrual age at discontinuation of invasive ventilation, positive pressure ventilation and supplemental oxygen use, and decreased rates of treatment for PDA.[82,83] Caffeine stimulates diaphragmatic activity and increases sensitivity to carbon dioxide, together resulting in more effective respiratory effort. Thus decreased exposure to the effects of respiratory support is the most likely mechanism for caffeine's efficacy in prevention of BPD, although caffeine has shown variable direct effects on lung development and inflammation in experimental models of BPD. There are not published data on the effects of caffeine on later respiratory morbidity.

Overall, currently available pharmacological therapies leave at least 40% of at-risk preterm infants with the composite outcome of BPD or death. The effects on later respiratory morbidity are even less well-described, with a lack of broadly accepted definitions of outcomes following the well accepted classification of BPD at 36 weeks' PMA. Of interest, effective therapies for BPD also decrease treatment rates for PDA. It seems likely that safe and effective therapies for BPD, along with implementation of nonpharmacological practices that promote extrauterine lung and vascular growth and development, will best mitigate the short- and long-term effects of prematurity and adverse intrauterine and extrauterine environments.

Persistent Respiratory Morbidity in Former Preterm Newborns

The characterization of persistent respiratory morbidity in infancy and early childhood among former preterm newborns has predominantly been done through collection of resource utilization attributed to respiratory disease and presence of respiratory symptomatology, using medical record review, administrative databases, surveys of medical providers or standardized parent/caregiver-completed questionnaires. Domains of interest include:

- Home respiratory support
- Hospitalization for respiratory illness
- Respiratory medication use
- Respiratory symptoms

In the symptom domain, the occurrence of wheeze (and less frequently cough) is assessed, with specification for symptoms that occur with and without other signs of illness (e.g., cough or wheeze "apart from colds") and with minimum frequency (e.g., "more than twice per week").[84,85] Outcomes after reaching term equivalent age inform and validate the classification of chronic respiratory illness (BPD) as former preterm newborns approach term corrected age, at 36 and 40 weeks' PMA. Beyond this goal, however, there is interest in capturing this information to aid in counseling and support for children and families after hospital discharge and for consideration of standardized metrics to evaluate neonatal clinical practices and outcomes for clinical trials.[86] This is particularly the case as former extremely preterm newborns may have considerable morbidity even if they do not meet criteria for BPD.[18] However, drawbacks to this approach include a similar critique to those levied at the BPD classification: chronic respiratory morbidity is defined by the prescription of its treatment, which varies broadly across clinical settings and does not define the physiological respiratory dysfunction.[87] Even when confining this approach to infants with severe BPD followed in US-based tertiary subspecialty clinics, there is considerable variation seen in all domains of respiratory resource utilization by site.[88] Thus translating morbidity outcomes into specific pathophysiology is a challenge. Conversely, these metrics assess the burden of the chronic respiratory disorder and are likely to be meaningful to families of these children, lending support to their broad application.

Specific medication use may lend insight into pathophysiology. For instance, the report of bronchodilator and controller medications for asthma or wheezing, in combination with recent symptoms or reported physician-diagnosis of asthma, has been used as a component of asthma or recurrent wheezing definitions in epidemiological studies.[89–92] Medication use over the first 1 to 2 years following initial hospital discharge has been collected from various cohorts of extremely preterm newborns. Table 43.2 shows data from various studies for proportions of high-risk former extremely preterm infants reporting morbidity in each domain in the first two years. Although variably defined in these studies, wheeze and cough were reported in 29% to 58% of the infants.[84,93–96] In a similar cohort, the EPICure Study in the United Kingdom and Ireland reported respiratory symptoms "nearly all the time" in 32% and 14% of infants surveyed at 1 and 2 years of age, respectively.[97] These rates are likely elevated, based on data from large populations (over 30,000 infants) studied in the International Study of Wheezing in Infants, and the Vitamin D Antenatal Asthma Reduction Trial (VDAART).[91,98] Reported medication use for obstructive lung disease is also prevalent in high-risk former preterm infant cohorts; 40% to 50% of infants received bronchodilators in the first 2 years after discharge, 22% to 56% reported inhaled corticosteroid exposure and systemic steroids were reported in up to 16% of infants.[84,88,93–96] In data from linked national registries in the Netherlands, medications for obstructive airway disease were prescribed to 30% of infants born at < 32 weeks at 6 to 12 months of age, and only 16% of former full term newborns.[99] Similar rates were identified in a population-based study from Israel, using data extracted from the electronic medical record; rates of prescribed respiratory medications were 51% and 62% following initial hospital discharge in the first and second year of life among former VLBW newborns, compared to 41% and 44% among former term control infants.[100] In data from the Prematurity and Respiratory Outcomes Program (PROP), Ryan and colleagues further describe that the proportion of infants with medication exposure in the first year of life decreases with increasing gestational age. Seventy-two percent of

infants born at 23 to 24 weeks' GA reported exposure to at least one medication in the first year of life, declining to 40% of infants born at 28 weeks' GA.[96] This pattern was consistent for exposure to diuretics, inhaled bronchodilators and inhaled corticosteroids, and to a lesser extent, systemic steroids.

Respiratory hospitalization rates are also high in these high-risk cohorts, ranging from 19% to 29% in the first 2 years, by parent report (Table 43.2). Re-hospitalization for any indication in former preterm newborns is a substantial burden. Two European retrospective cohort studies reported hospitalization rates of 40% to 46% in year 1 and 25% in year 2 for infants born < 32 weeks' GA, while only 14% of infants born at term were hospitalized in the first year of life.[99,101] Raiser et al. reported that respiratory infection accounted for 42% and 47% of these hospitalizations among former preterm newborns in years 1 and 2.[101] Similarly, Houweling et al. reported that the most frequent discharge diagnoses for re-hospitalizations in former preterm infants in the first year of life were respiratory illness (acute bronchitis and bronchiolitis, acute upper respiratory infection).[99] The proportion of infants born < 32 weeks' GA with these hospital discharge diagnoses was 7%, compared to 3% in infants born at term.

The spectrum of morbidity changes over the first year after discharge. In the PROP cohort, the proportion of infants with exposure to at least one respiratory medication after discharge increased modestly over that year (25%, 32%, 32%, and 34% at 3, 6, 9, and 12 months corrected age).[96] Rates of exposure to inhaled bronchodilators increased from 13% to 31% and inhaled corticosteroids from 9% to 14%, while exposure to diuretics decreased over this time frame, from 11% to 2%. There was a similar pattern in data from the TOLSURF cohort, with a fall in use of home respiratory support over the same time. Respiratory hospitalizations fell from 3 to 9 months corrected age, and then increased slightly at 12 months.[95]

Composite Respiratory Morbidity Outcomes

Composite respiratory morbidity outcomes have been developed to include different combinations of measures from various respiratory morbidity domains, with incorporation of repeated events or exposures when measured at multiple time points. Table 43.3 shows the distribution of these composite outcomes and their description in both high-risk and broader populations of low gestational age newborns. These represent a broad spectrum of composite morbidity, ranging from outcomes requiring a single event, medication or diagnosis to others requiring persistent need for respiratory support or monitoring at or beyond the second year of life.[12,13,18,95,100,102] For those outcomes that might be considered less serious, two-thirds to three quarters are affected, even in

patient populations that are not selected for neonatal illness severity.[18,95,100,102] Conversely, in the high-risk TOLSURF cohort, 25% of infants have no respiratory morbidity reported by 12 months corrected age while ~50% of term-born children are free of respiratory morbidity in an Israeli population-based cohort at 1 and 2 years.[95,100] The relative risk of this composite respiratory morbidity outcome was 1.22 (95% CI 1.19, 1.26) and 1.30 (95% CI 1.27, 1.34) at these time points for former VLBW newborns. In contrast, composite outcomes representing more serious or pervasive morbidity with or without mortality occurred in 7% to 36% of infants; mortality ranged from 0.8% to 4.1% in these cohorts.[12,13,18,95] Generally, the more serious composite outcomes could be more useful in discriminating those infants with greater repercussions of chronic neonatal respiratory disease.

There has been interest in defining the severity of respiratory morbidity in former preterm newborns by their use of post-discharge therapies. Gage and colleagues surveyed pediatric pulmonologists from academic medical centers in North America, asking them to rank eight components of post-discharge respiratory morbidity.[103] From the cumulative ranks of these eight components (home supplemental oxygen > respiratory hospitalization > diuretic use > daily bronchodilator use > daily inhaled corticosteroid use > intermittent bronchodilator use > intermittent corticosteroid use), they developed a 8.5 point severity score which they applied to 940 former preterm infants born at < 30 weeks' GA or with a diagnosis of BPD at 4 to 9 months corrected age. Using their proposed cut-offs, only 7% of infants met the threshold for severe chronic lung disease and 58% were classified with no morbidity. The PROP investigators created a consensus Respiratory Morbidity Severity (RMS) scale, for which infants were assigned to one of 3 mutually exclusive categories based on their most severe morbidity component (Table 43.4).[18] In cross-tabulation with the postprematurity respiratory disease (PRD) composite outcome, 81% of infants (184/227) infants with no PRD were classified minimal/none on the RMS and 10/227 were classified as severe. Infants with PRD were almost evenly divided between moderate/mild RMS (237/497) and severe (233/497) RMS. The overall distribution of RMS was 28% minimal/none, 38% moderate/mild and 35% severe. Thus, the RMS does have greater discrimination than PRD. More recently, O'Brodovich et al. utilized the Delphi methodology to develop a Chronic Lung Disease of Prematurity Severity Scale (CLDPSS), employing the expertise of 91 pediatric pulmonologists, neonatologists, and pediatricians that provide outpatient care for former preterm newborns with chronic lung disease.[104] After proposing many of the same components as Gage et al, they iteratively developed a 100-point scale with individual items weighted by the relative importance the participants placed on that item. The CLDPSS is meant to be scored at 12 months corrected age but it has not yet been applied to any cohort and it is not yet clear how it will account for the trajectory of illness over

the first year. Table 43.4 aligns the RMS criteria with the CLDPSS components, to allow for comparisons. Score cut-offs for different levels of severity for the CLDPSS have not been proposed.

Antecedents and Covariates for Persistent Respiratory Morbidity

Multiple studies have demonstrated associations between BPD and increased rates of various markers of respiratory morbidity in the first several years after birth.[84,96,101] Infants with BPD enrolled in the PROP study had greater use of inhaled respiratory medication in the second half of the first year after initial discharge compared to infants without BPD; similar differences persisted into the second year of life in the UK-based EPICure Study.[96,97] These data are consistent with increased wheezing illness throughout childhood in infants with BPD.[92,97,105] Other relationships further shed light on early influences of later respiratory morbidity. In follow-up from UKOS at 24 months corrected age, lower birth weight z-score conferred increased odds for respiratory hospitalization, cough and inhaled medication use after adjustment for sex, BPD, and parental smoking.[106] Littner and colleagues showed a strong unadjusted relationship to GA for their composite respiratory morbidity outcome in over 5000 children born very low birth weight up to 2 years of age; this was also shown in univariate analysis of both PRD and RMS at 1 year in the PROP cohort.[18,100] In exploration of early neonatal illness severity, Stevens et al. identified that the highest quartile of supplemental oxygen exposure at days 1, 3, 7, 14, and 28 in former VLBW infants without a diagnosis of BPD was associated with increased rates of respiratory symptoms, medication use, and resource utilization at 12 months corrected age.[107] Further, in data from the PROP cohort, high supplemental oxygen exposure in the first 14 days of life independently predicted the composite outcome of PRD, and high and intermediate supplemental oxygen predicted severe or moderate/mild RMS; intrauterine growth restriction fell out of these multivariate models.[108] A subset of these infants underwent pulmonary function testing (PFT) at 1 year corrected age. High and intermediate oxygen exposure was associated with evidence of airway obstruction (lower $FEV_{0.5}$/FVC z-score). Consistent with these

findings, Mourani and colleagues investigated early illness markers for their 2-year composite morbidity outcome of late respiratory disease (LRD) from the Colorado/Indiana cohort.[19] They found that combined evidence of PVD/PH on echocardiogram and use of invasive mechanical ventilation were the most important predictor for adverse outcome. Together, these studies support that that early illness in the susceptible newborn contributes to chronic neonatal respiratory disease.

Two studies have undertaken extensive modeling of predictors of their composite respiratory morbidity outcomes at 1 and 2 years corrected age (the PROP and Colorado/Indiana cohorts, respectively).[18,102] Considering only characteristics that could be defined by 24 hours of age in the PROP cohort, perinatal models for PRD and RMS selected overlapping factors that increased the odds of adverse outcome, while adjusting for gestational age.[18] These included intrauterine growth restriction, male sex, parent history of asthma, intubation at birth, and public insurance anticipated for the infant's medical care. Maternal smoking during pregnancy was only selected as a predictor for PRD and when post-discharge environmental tobacco smoke exposure was substituted (determined by number of smokers in the home and smoking rules for home and vehicles) there was no substantial change in the effect of other characteristics on PRD. These modeling exercises support the concept that the vulnerable lung in extreme prematurity is a strong predictor of later respiratory morbidity, as intrauterine growth restriction reflects an adverse fetal environment, and intubation at birth occurs in those newborns that are more compromised (78% of this cohort). Cardiopulmonary resuscitation at birth (CPR) was not selected as an important factor in these analyses. Independently, 36-week models were developed incorporating additional infant characteristics available at 36 weeks' PMA. Almost identical perinatal characteristics were selected as PRD predictors. Additional variables selected for both 36-week models, which increased the odds of adverse outcome, included BPD (modified from the NIH consensus definition to no/mild, moderate, and severe), growth failure at 36 weeks' PMA and low breast milk exposure during hospitalization. Of interest, when comparing changes in odds ratios (at least 20%) from perinatal and 36-week models for PRD, decreased effects were found for gestational age, intrauterine growth restriction and male sex, and parent history of asthma dropped out. These changes suggest that these perinatal influences impact the intermediate outcome of BPD, which had similar accuracy for predicting PRD as models at both time points.

Morrow and colleagues presented a multivariate model for LRD at 2 years in the Colorado/Indiana cohort.[102] The models for PRD and LRD share some variables in common, and the direction of effect for each of these is consistent between the two cohorts, although co-variates differ between models. The Colorado/Indiana investigators also compared multivariate models for BPD and LRD. In this comparison, several factors had a substantial change in effect (change in odds ratio ≥20%) between these two outcome time points. Gestational age, birth weight z-score, cesarean section delivery and maternal preexisting hypertension had lesser effect in the LRD model, whereas maternal diabetes and chorioamnionitis had increased effect. LRD and the other composite long-term outcomes are comprised of events that occur after initial hospital discharge, so additional influences on their occurrence are likely to be important. For example, sociodemographic characteristics are associated with at least some of the components of these outcomes, including hospitalization and wheezing illnesses, and some of these characteristics may be markers for environmental influences on respiratory disease that were otherwise not measured.[92,109–111] Further delineation of different aspects of sociodemographic factors may help elucidate the underpinnings of the racial disparities found in these later outcomes in both studies.

Lower respiratory tract infection (LRTI), and hospitalization due to infection is common among former preterm newborns. Eighteen percent of infants born < 33 weeks' gestation were hospitalized for upper or lower respiratory tract conditions in the first year after discharge in a French-based registry.[111] These data are consistent with the proportion of children with respiratory hospitalization up to 1 to 2 years in the high-risk extremely low gestational age cohorts described in Table 43.2 (19% to 29%). Of children < 2 years admitted to a children's hospital pediatric intensive care unit with a respiratory illness, 17% were born at < 32 weeks' gestation, and 53% of these former preterm newborns had an LRTI as the cause for admission.[112] The susceptibility of former preterm newborns to LRTI may be due to various causes; T-cell dysmaturation due to extremely preterm birth was associated with later respiratory morbidity in a subset of former extremely low gestational age newborns enrolled in the PROP cohort.[113]

In another subset of infants from PROP, respiratory system function was assessed by respiratory inductance plethysmography just prior to initial hospital discharge.[114] Although infants classified with BPD had lower time to peak expiratory flow over total expiratory time (Tpef/Te) and other subtle findings indicating lower lung compliance or upper airway obstruction, these findings did not predict PRD. Other studies have shown obstructive lung disease prior to discharge in former preterm newborns across a range of illness severity and gestational ages.[87,115]

The short- and long-term follow-up of children enrolled in TCRS provide important context for considering the relationship of lung function in infancy to later symptomatic respiratory disease. The cohort is largely term born and children had no significant respiratory illness at birth. In the initial TCRS publication, the investigators demonstrated that infants who later went on to develop symptomatic LRTI with wheezing in the first year of life had diminished lung function at mean ~8 weeks of life as measured by Tpef/Te and respiratory conductance, when compared to infants without symptomatic LRTI.[116] At 6 years of age, children with persistent wheeze had a more atopic profile and greater exposure to maternal smoking than children with no history of wheezing illness.[117] In later follow-up, the TCRS investigators showed that airway obstruction in infancy as assessed by $Vmax_{FRC}$ continued to correlate with a pattern of obstructive airway disease up to 22 years of age.[118] Finally, those infants with an episode of pneumonia at < 3 years of age had worse lung function at 11 to 26 years of age than children without LRTI, with a more pronounced decrement in lung function than that found in children with LRTI but no pneumonia.[66] The children with pneumonia also had significant increased odds of current asthma and active wheeze up to age 29, compared with children without LRTI, whereas those children with LRTI without pneumonia had only increased odds for active wheeze. The known susceptibility of former preterm newborns to LRTI and wheeze early in life and their decreased lung function lay the foundation for chronic, prolonged, and recurrent wheezing illness and obstructive lung disease in these children.

Wheeze, Asthma, and Lung Function in Former Preterm Newborns

Meta-analyses solidify the data regarding increased rates of recurrent wheezing illness or asthma and airway obstruction in former preterm newborns. Been and colleagues identified an adjusted OR 1.46 (95% CI 1.2, 1.65) for wheezing illness/asthma throughout childhood; an estimate for children born < 32 weeks' GA was almost twice the overall odds for all former preterm children (OR 2.81; 95% CI 2.52, 3.12).[90] A meta-analysis demonstrated that percent predicted forced expiratory volume in 1 second ($\%FEV_1$) for children born preterm was consistently decreased throughout childhood, with this decrement more pronounced in children with a diagnosis of BPD at 36 weeks' PMA.[119] In addition to biological vulnerabilities, environmental exposures are likely an important modifier of chronic respiratory disorders after preterm birth. In the high-risk TOLSURF cohort, Wai and colleagues demonstrated that a diagnosis of BPD, public insurance status, and maternal breast milk exposure were mediators of persistent wheeze.[92] Well-established risk factors for increased risk of wheezing illness, such as atopic predisposition and environmental tobacco smoke, were not identified as mediators in this secondary analysis.

With respect to environmental tobacco smoke, Collaco et al. found that hair nicotine levels in former preterm newborns with BPD at < 3 years of age were more strongly associated with adverse respiratory outcomes than parental report of household smoking.[17] As expected, children with smokers in the home had higher hair nicotine levels than children without smokers in the home. However, 22% of the children without reported smokers in the home had hair cotinine levels above the proposed cut-off for smokers in the home, suggesting there may be additional sources of environmental tobacco exposure in these at-risk children, possibly related to socioeconomic factors such as neighborhood or housing conditions. Thus better objective measures of environmental risks may further elucidate which former preterm newborns are at highest risk for chronic respiratory illness after initial hospital discharge.[111]

Several studies have continued to follow former extremely preterm infants into later childhood and adolescence. At 6 years of age, the EPICure cohort described current wheeze in 36% of children with a diagnosis of BPD, 20% of children without BPD diagnosis and 13% of classmate controls.[97] Peak expiratory flows were decreased in former extremely preterm newborns with BPD compared to those without BPD, and those without BPD compared to controls. At 11 years of age, former preterm newborns had increased rates of current asthma compared to controls (25% vs. 13%), but differences in wheezing outcomes between children with and without a diagnosis of BPD were no longer statistically significant.[89] All measures of airway obstruction were impaired in former preterm newborns compared to controls, and for those with BPD compared to those without BPD. Further, metrics of obstructive airway disease were correlated with an asthma diagnosis. In follow-up data from UKOS, investigators describe overall rates of wheezing of 15% at 11 to 14 years and an asthma diagnosis of 9% at 16 to 19 years in these children born at < 29 weeks' gestation.[120,121] Pulmonary function studies at these ages also demonstrated considerable evidence of obstructive airway disease. Of interest, the primary research question in UKOS was focused on differences in lung function by initial mechanical ventilation mode, high frequency versus conventional. At 11 to 14 years, lung function was better in the high-frequency group, although rates of clinical illness did not differ. By 16 to 19 years, there was no difference in lung function between the groups and clinical illness favored the conventional ventilation group. In Australia, Doyle and colleagues evaluated three eras of population-based cohorts of extremely low birth weight/low gestational age newborns from 1991, 1997, and 2005.[38] They describe a transition in clinical respiratory support strategies to increased use of noninvasive support (CPAP), accompanied by increased total duration of assisted ventilation and supplemental oxygen use and increased diagnosis of BPD. At 8 years of age, rates of current wheeze range from 23% to 26% and were not different by cohort era. There was also worse pulmonary function in the most recent eras, as evidenced by more severe airway obstruction. A single center US-based study assessed 47 children born < 33 weeks' gestation (~70% moderate-severe BPD) from 4 to 20 years of age.[122] Both $\%FEV_1$ and percent predicted functional vital capacity (%FVC) increased over time, indicating ongoing lung growth. However, %FVC improved more rapidly than $\%FEV_1$, resulting in decreased FEV_1/FVC; this decrease was correlated with the duration of invasive mechanical ventilation. Taken together, these studies show increased prevalence of symptomatic lung disease (wheeze and asthma) at later follow-up (6 to 20 years) in former preterm newborns, and to a greater extent, functional evidence of obstructive lung disease. These long-term consequences may not be modifiable by changing neonatal respiratory strategies.

Conclusions

The precursors of symptomatic lung disease and diminished lung function at initial hospital discharge in former preterm newborns are due to immaturity and an adverse fetal environment related to placental vascular derangements, maternal smoking, and possibly other environmental exposures. The intensity of early respiratory support influences further dysplastic lung development, in part due to the degree of impaired lung and vascular development and function at birth. A diagnosis of BPD, regardless of the specific criteria used for this diagnosis, increases the risk for later morbidity complications, which are likely related to the degree of lung dysfunction (particularly expiratory airflow obstruction), immune deficits, and environmental factors. Risks of chronic neonatal respiratory disease can be identified at birth. Renewed focus on later interventions throughout infancy to improve long-term outcomes is indicated, given the recognition of obstructive lung disease while lung growth is ongoing.[16]

Anatomic Disorders of the Chest and Airways

SU YEON LEE, JORDAN E. JACKSON, SATYAN LAKSHIMINRUSIMHA, ERIN G. BROWN, AND DIANA L. FARMER

KEY POINTS

- Prompt diagnosis and early intervention are key in salvaging infants with life-threatening surgical disorders of the airway and chest.
- Improved prenatal ultrasound has shifted the diagnosis and management of disorders of the chest and airways into the fetal period.
- Increased utilization of video-assisted thoracoscopic surgery for congenital thoracic lesions has made surgical intervention on the infant chest less invasive and more tolerable.

Anomalies of the Airways

Nasopharyngeal Obstructive Disorders

Respiratory distress caused by nasal obstruction may manifest as a serious, life-threatening event shortly after birth. Because newborns are preferential nasal breathers for the first 2 to 3 weeks after birth, nasal obstruction may cause severe cyanosis, particularly during oral feedings, with airway obstruction relieved only when the mouth is open to cry.[1] There are several causes of neonatal nasal obstruction, including congenital choanal atresia, nasal pyriform aperture stenosis, nasolacrimal duct cyst, and nasal hypoplasia. Buckling or, less commonly, dislocation of the nasal septum due to birth trauma can also cause breathing problems; most cases respond to decongestant and steroid nasal drops, but dislocations require surgical manipulation.[2]

Congenital Choanal Atresia

Caused by persistence of the buccopharyngeal membrane, congenital choanal atresia occurs in between 1 in 5000 and 1 in 9000 births and has a significant female preponderance. In the majority of choanal atresia cases, the obstructing membrane is of mixed bony and membranous composition.[3] Choanal atresia is most commonly unilateral, right-sided, and with female predominance (in ~2/3 of cases); bilateral malformations are more serious and constitute an emergency at birth.[1,4] Over half of all cases are associated with other congenital anomalies, bilateral cases more so than unilateral.[5] Choanal atresia can be associated with the *CHARGE association*, a constellation of the following anomalies:

- Colobomas of the eyes
- Heart defects
- Atresia of the choanae
- Retardation of growth or development
- Genitourinary defects
- Ear anomalies associated with deafness

The association was officially named *CHARGE syndrome* in 2004, when a common mutation in the *CHD7* gene on chromosome 8 was identified in 60% of cases.[6]

Because the newborn is a preferential nasal breather, there may be serious difficulties soon after birth, especially in cases of bilateral atresia. Unilateral atresia may present simply with unilateral discharge and feeding difficulties but may not present until later in childhood. While insertion of a 5- or 6-French catheter through the nose or visualizing airflow using a mirror under the nostril remains a common test, nasofiberscopy or nasal rigid endoscopy is the diagnostic tool of choice for confirmation of atretic choana by directly visualizing point of obstruction.[7] Computed tomography (CT) of the nasopharynx with intranasal contrast can also confirm diagnosis, evaluate the nature and severity of nasal obstruction, and help in surgical planning.[7]

Emergent management of choanal atresia is focused on ensuring that the oropharyngeal airway is patent, which may necessitate endotracheal intubation. A McGovern nipple, an orogastric tube, or a modified endotracheal tube can be used to overcome the seal between the palate and the tongue.[4,8] Tracheostomy is rarely necessary and typically only required when associated with other anomalies.[9]

Surgical repair is the mainstay of treatment and can be performed within a few days of birth. Patency can be established by various methods according to surgeon preference. With the improvement in transnasal technique with modern endoscopic biting and drilling instruments, it is currently the favored approach for both initial and revision surgeries.[7,10] Correction is accomplished by relieving the obstruction using dilators and removing hypertrophied posterior septal bone under endoscopic visualization.[10,11] The transnasal endoscopic approach works best with thin buccopharyngeal membranes and has low restenosis rate.[12] The transpalatal approach entails surgical correction of the

offending defect and is typically performed for thick bony membranes in older patients. However, despite the minimal rate of reoperation, this approach is associated with a higher rate of palate growth deformities.[13] While temporary stenting has been used to decrease restenosis rates, the use of stents remains controversial. It may not prevent restenosis and can be associated with complications, including alar injury, columellar tear, and vestibular stenosis.[14] Mitomycin C has also been used as an adjunct to surgical repair to improve patency, but its use is controversial and so it is not routinely used.[15]

Congenital Nasal Pyriform Aperture Stenosis

Nasal pyriform aperture stenosis is a rare cause of nasal obstruction and should be suspected when encountering difficulty in passing a nasal catheter. Pyriform aperture stenosis is characterized by excessive bone formation in the medial nasal processes of the maxillary bone. The condition may be isolated or associated with other anomalies, such as a solitary median maxillary central incisor tooth or, more seriously, midline defects such as pituitary hypoplasia with endocrine insufficiency, diabetes insipidus, or other manifestations of holoprosencephaly and craniosynostosis.[16] Similar to choanal atresia, an oral airway may be necessary to relieve the breathing difficulty. Although the obstruction can be suitably demonstrated by CT of the nasopharynx, because of its high association with holoprosencephaly, a karyotype analysis and brain CT and/or magnetic resonance imaging (MRI) may be required if brain abnormalities are suspected.[17] In most cases, nasal obstruction is mild and may respond to nasal decongestants. In refractory cases of obstruction, usually when the pyriform aperture is less than 5.7 mm, sublabial surgery is necessary to remove excessive bone, and nasal stenting is typically placed.[18] Novel methods of rapid maxillary expansion to enlarge the pyriform aperture are being investigated including the use of custom palate expansion devices or immediate surgical transverse enlargement of maxilla.[19,20]

Pierre Robin Syndrome (Robin Sequence)

Although this pattern of upper airway problems was first described by Pierre Robin in 1923, characterization of Pierre Robin syndrome remains difficult and controversial. A constellation of anomalies within the spectrum of cleft palate, micrognathia, and glossoptosis that results in airway obstruction, the Pierre Robin syndrome been linked to mutations in the *SOX9* and *KCNJ2* genes.[21,22] Given the varying definitions published, the incidence of Pierre Robin syndrome is difficult to pinpoint; it has been reported to occur in anywhere from 1 in 8500 to 1 in 30,000 births.[23] The hypoplastic development of the mandible is of clinical significance as the micrognathia can lead to airway obstruction and cyanosis.[24] Obstruction is common when the infant is in the supine position, during feeding, and in active sleep, when pharyngeal muscle tone is absent. Excessive air swallowing, followed by gastric distention, vomiting, and tracheal aspiration, is a frequent problem. The pharyngeal obstruction is maintained by the generation of large negative pressures in the lower pharynx during inspiration and swallowing.[25] Chronic obstruction leads to carbon dioxide retention, failure to thrive, and development of pulmonary hypertension with right ventricular failure.[26,27]

As with the imprecise diagnosis of Pierre Robin syndrome, the severity of respiratory obstruction and the management indicated are varied. Mild cases may present with only mild glossoptosis, and because oral feeds are tolerated without respiratory obstruction, these cases can be managed by side-to-side nursing and prone positioning.[28,29] In the event of respiratory symptoms with feedings or failure to thrive, a nasogastric tube for feedings may be required.[28] In severe cases of respiratory distress, nasopharyngeal intubation should be performed, typically by passing a 3.5-mm tube through the nose and into the hypopharynx.[30] This prevents the generation of negative pressure and greatly relieves the respiratory difficulty. The nasopharyngeal tube may be left in place for weeks or even months with proper management. Other treatments include tongue–lip adhesion surgery (glossopexy) to hold the tongue forward and tracheostomy if a nasopharyngeal tube does not adequately relieve the obstruction.[31,32] Mandibular distraction and velar extension appliances can be performed in attempts to avoid tracheostomy.[32,33] Nutrition can be maintained with a hypercaloric formula fed by nasogastric or gastrostomy tube. With adequate airway management and the passage of time, the problem becomes less threatening, especially after a few months, when the infant gains better control of the tongue.[34,35] Oral feedings can then be introduced, usually with a long lamb's nipple to help hold the tongue forward. With adequate nutrition and growth of the mandible, the problem usually resolves by 3 to 12 months of age, when cleft palate repair can safely take place.

Glossoptosis–Apnea Syndrome

Pierre Robin syndrome is not the only condition characterized by mechanical obstruction by the tongue. Infants with Beckwith–Wiedemann syndrome may have considerable breathing difficulties and apnea due to the associated macroglossia.[36] Infants with a normal-sized tongue who also have conditions such as unilateral choanal atresia, choanal stenosis, or swelling of the nasal mucosa may generate considerable negative pressure in the pharynx; this, combined with inadequate muscular control over the tongue, may lead to pharyngeal obstruction with respiratory distress, cyanosis, and severe episodes of apnea.[37]

Pharyngeal Incoordination

While the tongue provides the majority of force to move a food bolus into the esophagus, weakness and incoordination of the pharyngeal musculature can lead to disordered swallowing.[38] This incoordination causes choking and cyanosis with feedings and may be complicated by aspiration pneumonia.[39] Affected infants have difficulties in swallowing their own secretions. The condition may be seen in infants with severe hypoxic–ischemic encephalopathy and pseudobulbar palsy, Arnold–Chiari malformation, Möbius syndrome, and other facial malformations. Electromyography of the facial and pharyngeal muscles during rest, crying, and eating can aid in diagnosis.[40] Specifically, it can be used to assess the sucking and swallowing coordination in infants during bottle feeding. Drugs with antimuscarinic effects, such as atropine, can decrease secretions and may produce some relief. Although some infants may gradually improve, long-term management may require initiation of tube feedings or even gastrostomy in children who fail to improve.

Laryngeal Deformities

Laryngomalacia (Congenital Laryngeal Stridor)

A relatively common condition, congenital laryngeal stridor or laryngomalacia is the most frequent cause of stridor in infants.[41] Laryngomalacia is characterized by the prolapse of poorly supported supraglottic structures—the arytenoids, the aryepiglottic folds, and the epiglottis—into the airway during inspiration,

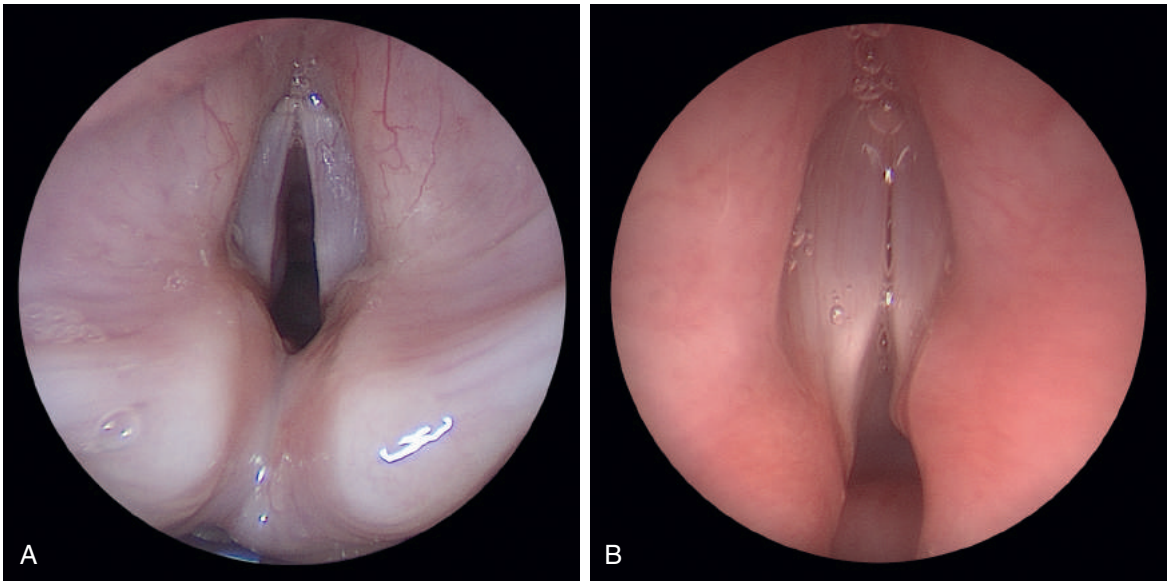
causing respiratory obstruction and difficulty with feeding.[42] Despite loud, high-pitched inspiratory stridor and significant chest retractions that typically present during the first month of life, the infant seldom has cyanosis, hypercarbia, notable feeding difficulty, failure to thrive, or an abnormal cry.[43] Laryngomalacia is worse in the supine position, with the neck flexed, and subsides in the prone position, with the neck extended.[43] Obstruction is worse during episodes of agitation and lessens when the infant is calmed. Severe forms of laryngomalacia may cause apneic events, pulmonary hypertension, or difficulties with feeding and/or weight gain.

Although a CT scan is effective at demonstrating the abnormal prolapse of the aryepiglottic folds supporting the diagnosis, confirmation should be obtained with flexible fiberoptic laryngoscopy.[44,45] Laryngeal ultrasound is an adjunctive tool for diagnosis that is non-invasive, and dynamic.[46] In some cases, gastroesophageal reflux or episodes of obstructive apnea may be associated with this condition.[43] Synchronous airway abnormalities are found in up to 30% of infants, including vocal cord paralysis, tracheomalacia, and subglottic stenosis.[47] Thus, the evaluation of stridor must include the examination of the entire upper airway and upper digestive tract. Stridor associated with laryngomalacia is usually loudest at 4 to 8 months, and most cases resolve with conservative management around 12 to 24 months.[48] Conservative therapy entails prone positioning, feeding and weight monitoring, and acid suppression therapy and most demonstrate improvement over roughly 18 months.[49] Approximately 20%, however, will have severe obstructive apnea, cor pulmonale, and/or failure to thrive and require a surgical intervention. In these cases, supraglottoplasty may be indicated, with 71% having complete resolution of symptoms and 94% having symptom improvement postoperatively.[50] Tracheostomy is reserved for supraglottoplasty failures.[51]

Vocal Cord Paralysis

Unilateral cord paralysis is usually left sided and typically presents without marked stridor or retractions manifesting as aspiration.[52] The infant may cough and choke during feedings, as laryngeal closure with swallowing is impaired. The condition is most frequently secondary to iatrogenic injury, usually caused by excessive stretching of the neck during delivery or injury during surgery; however, it can also be due to neurologic disorders.[53] Right-sided vocal cord paralysis has been reported as a complication of cervical extracorporeal membrane oxygenation (ECMO) cannulation.[54] Ligation of a patent ductus arteriosus (PDA) has also been associated with a high rate of left-sided vocal cord paralysis, probably secondary to recurrent laryngeal nerve injury during dissection.[55] A recent systematic review reported that 32% of low birth weight infants who undergo PDA ligation have left vocal cord paralysis demonstrated on laryngoscopy.[55] This increases their risk of developing bronchopulmonary dysplasia (BPD), reactive airway disease, and feeding problems requiring a gastrostomy tube. Laying the infant on the paralyzed side may decrease the amount of stridor, as the affected cord falls away from the midline. Diagnosis can be confirmed with flexible nasolaryngoscopy but may require direct laryngoscopy in the operating room (Fig. 44.1). The condition tends to improve over a period of several weeks or months, and speech and swallow therapy can be used in cases where improvement is not seen. Generally, medialization of the vocal cord (including injection laryngoplasty and thyroplasty) is not recommended in neonates less than 6 months of age; however, in children with gross aspiration and severe phonotory difficulty, it may be required.[56] Tracheostomy is preferred in severe cases of respiratory obstruction.[52]

Bilateral cord paralysis is a much more serious condition, accompanied by high-pitched inspiratory stridor; frequently, however, the cry is normal. Usually, severe central nervous system problems are to blame, such as hypoxic–ischemic encephalopathy, cerebral hemorrhage, Arnold–Chiari malformation, hydrocephalus, or brainstem dysgenesis. Associated problems may include pharyngeal incoordination with swallowing difficulty and esophageal dysfunction, recurrent apnea episodes, and tracheal aspiration of mucous secretions and formula. The stridor may resolve slowly if brain swelling subsides after birth, as is the case with ventriculoperitoneal shunt placement. The diagnosis may be suspected at laryngoscopy but should be confirmed by flexible fiberoptic bronchoscopy, rigid bronchoscopy, or ultrafast cine CT



• **Fig. 44.1** Vocal cord paralysis. (A) Bronchoscopy of a neonate demonstrating a normal glottis. (B) Bronchoscopy of an infant with bilateral true vocal cord paralysis causing obstruction. (Courtesy Dr. Jamie Funamura, UC Davis Health System, Sacramento, CA.)

scan. Tracheostomy is frequently required in about 50% to 60% of patients, and the prognosis usually is poor secondary to the underlying problems.[57,58]

Laryngeal Atresia

Laryngeal atresia is the result of failed recanalization of the larynx during embryologic development, resulting in a newborn with complete laryngeal obstruction presenting with severe respiratory distress. In some cases, the larynx may be completely obstructed by a laryngeal web seen in the delivery room during attempts to intubate the cyanotic infant. An endotracheal tube sometimes can be forced beyond the obstruction into the trachea. Otherwise, a large-bore needle should be inserted percutaneously into the trachea to maintain marginal gas exchange while preparations for emergency tracheostomy are made. Most infants with laryngeal atresia have other lethal malformations.[59,60] Most cases are now diagnosed prenatally from ultrasound findings consistent with congenital high airway obstruction syndrome (CHAOS), such as polyhydramnios and enlarged hyperechoic lungs with an associated flattened or inverted diaphragm.[61,62] The mother may be evaluated for ascites or hydrops fetalis due to impaired venous return to the heart, and the amniotic fluid lecithin level may be very low in such cases. In the absence of other lethal malformations, the characteristic ultrasound diagnosis may permit preparations for emergency tracheostomy after delivery of the infant or an ex utero intrapartum treatment (EXIT)-to-airway procedure, discussed later. Intrapartum fetoscopic tracheal decompression is being investigated.[63,64]

Congenital Subglottic Stenosis

Congenital subglottic stenosis, manifesting as inspiratory stridor from birth, is caused by partial obstruction of the cricoid probably due to incomplete canalization of the cricoid ring. In a full-term infant the normal subglottic lumen is 4.5 to 5.5 mm in diameter, whereas that of a preterm neonate is 3.5 mm in diameter. A subglottic diameter of 4 mm or less in a full-term infant or 3 mm or less in a premature infant is consistent with a diagnosis of subglottic stenosis. Subglottic stenosis is diagnosed by direct laryngoscopy supplemented with rigid bronchoscopy and chest radiography to evaluate other airway lesions and/or concomitant lung disease, as the latter may be common in the premature infant. Treatment consists of balloon dilation or endoscopic lysis with a carbon dioxide laser in cases of membranous stenosis. However, most cases severe enough to require intervention are cartilaginous and require an anterior cricoid split, obviating the need for and complications of tracheostomy in most cases.[65,66]

Congenital Subglottic Hemangioma

Subglottic hemangiomas are rare, accounting for 1.5% of all congenital abnormalities of the larynx.[67] They often occur in association with a cutaneous hemangioma and may cause inspiratory stridor and expiratory wheezing that progress with enlargement of the tumor.[68] This diagnosis is suspected when asymmetric subglottic narrowing is seen on plain radiographs and is confirmed by flexible and rigid endoscopy demonstrating a sessile vascular lesion, most commonly in the posterolateral subglottis.[69,70] Although intralesional injections of steroids is relatively successful over systemic administration of steroids, in many cases intubation or tracheostomy is eventually required.[71] Results of removal by carbon dioxide or potassium titanyl phosphate (KTP) laser have been encouraging, enabling treatment without tracheostomy; however, associated complications such as subglottic stenosis have been reported.[70,72] Finally, case reports using beta blockers (propranolol and acebutolol) have been successful in causing regression of subglottic hemangiomas, preventing the need for tracheostomy altogether.[73]

Laryngotracheoesophageal Cleft (Congenital Laryngeal Cleft)

In laryngotracheoesophageal cleft, a longitudinal communication is present between the airway and the esophagus, stretching from the larynx into the upper trachea or sometimes as far as the carina. This rare condition is reported in 1 in 10,000 to 1 in 20,000 births and is caused by failed fusion of the two lateral growth centers of the posterior cricoid cartilage, preventing proper fusion of the posterior cricoid lamina.[74] Affected infants have respiratory distress with inspiratory stridor and cyanosis, associated with tracheal aspiration of saliva and feedings. Chest radiographs may show evidence of aspiration pneumonia, and the cine esophagogram shows contrast material spilling into the trachea. The diagnosis can be established with direct laryngoscopy and bronchoscopy. Given the high association with other congenital anomalies and syndromes, such as tracheal atresia, tracheoesophageal fistula, and Opitz–Frias syndrome, a thorough evaluation of all organ systems and genetic karyotype are recommended.

Laryngotracheoesophageal clefts are classified, by severity of symptoms, into four groups (types I to IV), which are used to determine the management strategy and the need for surgical intervention.[75] For all types, initial management involves adequately securing the airway, including with an endotracheal tube or tracheostomy if necessary. Mild cases can sometimes be managed by conservative therapy, including swallow rehabilitation and antireflux medication.[76] In those who fail conservative management, endoscopic therapy including injection augmentation of the cleft may be attempted.[77] More severe cases require extensive reconstruction employing an anterior translaryngotracheal approach or even a partial upper sternotomy. Despite these reconstruction attempts, mortality remains high, up to 25% among all types of clefts and higher in cases with associated congenital anomalies and type IV clefts.[78,79]

Tracheal Deformities and Other Tracheal Disorders

Tracheal Agenesis

Tracheal agenesis is a rare condition that occurs in less than 1 in 50,000 births.[80] The trachea can be atretic just below the vocal cords but is most often absent all the way down to the carina.[81] Clinical manifestations include severe distress, absence of vocal sound, and severe cyanosis. Affected infants usually have additional congenital anomalies within the VACTERL association, including tracheoesophageal fistulas, severe cardiac malformations, and sometimes renal and anal anomalies.[82] Prenatal diagnosis is difficult, but prenatal presentation may manifest as CHAOS. If diagnosed prenatally, delivery via EXIT should be arranged to maximize the chances for survival.[82,83] Postnatal diagnosis should be suspected in cases of respiratory distress with immediate hypoxia, no audible cry, and a mechanical inability to intubate.[84] Despite the presence of a larynx, intubation cannot be accomplished at delivery; however, if the tracheal tube is positioned in the esophagus and connected to a mechanical ventilator,

reasonable gas exchange can be obtained via the tracheoesophageal fistula.[85] When the tracheal atresia is high, a tracheostomy can be performed in the remnant tracheal tissue. If survival seems possible, gastric division and a gastrostomy for feeding should be performed. Reconstructive surgery is not likely to be successful, however, and the prognosis is extremely poor, if not because of poor ventilation, then because of the underlying malformations.

Congenital Tracheal Stenosis

In congenital tracheal stenosis, a segment of the trachea is narrowed, usually starting in the subglottic region. The affected segment may be short or long; occasionally, the entire trachea is hypoplastic, and the bronchi may be involved. This disorder affects 1 in 64,500 live births and is usually caused by complete or nearly complete cartilage rings that narrow the trachea.[86] Affected patients may have inspiratory stridor, expiratory wheezing, feeding difficulties, and experience cyanotic episodes. Mild inflammation and small mucous plugs may cause life-threatening deterioration. In up to 60% of cases, other congenital malformations are also present, such as vascular ring anomalies, congenital heart defects, tracheoesophageal fistula (especially the H type), and hemivertebrae.[87] There also is an association with pulmonary agenesis.[87]

Patients with this deformity usually can be intubated, but the endotracheal tube cannot be advanced and should not be forced. Mechanical ventilation with generous levels of positive end-expiratory pressure (PEEP) may help stabilize the infant. Tracheostomy is not indicated and interferes with making the diagnosis.[88] Sometimes the diagnosis can be made by inspiration and expiration chest radiographs, using air as the contrast medium. However flexible fiberoptic bronchoscopy in the neonatal intensive care unit (NICU) or rigid bronchoscopy in the operating room is usually required for diagnosis.[87] Because it is important to examine the lower limits of the stenosis, it may be necessary to proceed with tracheobronchography, but this may sometimes cause acute decompensation and is controversial.[89] Ultrafast cine CT scan and MRI have become useful diagnostic techniques to define the lower limits of the stenosis.[90] In addition, three-dimensional (3D) CT reformats provide valuable information on the trachea–cardiovascular relationship and can allow for 3D printing of models to rehearse complex surgical interventions.[91]

In most cases, the stenosis requires treatment of some kind in the operating room. Balloon dilation alone is not likely to be successful in the case of a complete tracheal cartilage ring, because cartilage cannot be stretched. For short-segment stenosis, balloon tracheoplasty may be sufficient, where serial dilations during rigid bronchoscopy split the complete tracheal rings.[92,93] Some groups have used metallic stents to prevent restenosis with long-term success; however, granulation tissue over the stent can make removal difficult.[94] For longer-segment stenosis, slide tracheoplasty has become standard of care.[95] Backer et al. described the successful use of free autografts of resected trachea.[96] Additionally, rib cartilage and pericardial patch have been used for tracheoplasty.[97,98] Tissue bioengineering as future treatment with decellularization of trachea and recellularization with stem cells is currently being studied.[99]

The use of cardiopulmonary bypass has improved treatment and is advocated by some as averting the need for complex anesthesiology techniques.[100,101] Premature infants with congenital tracheal stenosis cannot undergo tracheal resection and tracheoplasty with cardiopulmonary bypass procedures. For these patients, aggressive balloon dilations are recommended, with splitting of the weaker posterior aspect of the tracheal rings.[102] With improvements in surgical techniques and the addition of ECMO to complex repairs, survival rates have improved to greater than 80%.[101] Those patients undergoing slide tracheoplasty who have concurrent distal bronchomalacia is predicted to have more adverse outcomes.[101]

Tracheobronchomalacia (Tracheomalacia)

Tracheobronchomalacia is characterized by dynamic collapse of the trachea during breathing secondary to delayed development of tracheal cartilage. This condition may be primary or associated with tracheoesophageal fistula, BPD, extrinsic tracheal compression, or prolonged intubation.[103] Tracheobronchomalacia should be suspected in infants presenting with respiratory distress, cyanotic spells, or persistent respiratory symptoms including expiratory stridor, recurrent respiratory infections, or persistent or recurrent wet cough. Chest radiographs are usually normal, with only a 62% sensitivity in diagnosing trachebronchomalacia.[104] With improvements in multidetector CT scanners and ultrafast cine CT scanners, diagnosis can be made with improved accuracy.[105,106] Bronchoscopy remains the gold standard for diagnosis, which shows approximation of the anterior and posterior walls of the trachea during expiration.[107] The bronchoscope may support the walls of the trachea, alleviating the respiratory distress by passage of the bronchoscope to the carina, while potentially disguising the extent of the abnormalities.

Factors associated with the development of tracheomalacia include immaturity, higher mean airway pressure, and prolonged mechanical ventilation.[108] Affected infants may have significant dynamic compression of the trachea. Because the trachea of premature infants is very compliant and may be excessively stretched and injured during mechanical ventilation, very immature infants are particularly prone to tracheomalacia. Some premature infants have greatly enlarged tracheas or tracheomegaly after prolonged mechanical ventilation.[109]

Many infants with tracheomalacia spontaneously improve by 1 to 2 years of age, when the cartilage has become strong enough to support tracheal patency and airway caliber increases. Severe cases with life-threatening episodes of airway obstruction necessitate tracheostomy with an elongated tracheostomy tube. However, current treatments for milder cases include tracheal intubation with continuous positive airway pressure (CPAP) or PEEP, which prevents tracheal collapse, and anterior aortopexy (fixation of the aorta to the sternum), which has the effect of supporting the attached trachea.[110,111] When aortopexy is performed, the majority occur via a left anterior thoracotomy, however there are reports of right anterior and muscle sparing approaches as well as thoracoscopic aortopexies.[112] Many of the most severely affected patients respond well to aortopexy. Posterior tracheopexy has also been performed for severe tracheomalacia with posterior membranous tracheal intrusions, and can be performed in conjunction with aortopexy.[113] Both thoracoscopic and muscle sparing thoracotomy approaches for posterior tracheopexy have been employed.[114,115] Tracheal stents have been limited due to higher failure rate than aortopexies and serious long-term complications including migration and erosion of stents.[116] 3D printed bioresorbable external splinting for airway support is currently being investigated.[117]

Tracheal Compression by Vascular Rings

Tracheal compression can be caused by several factors: (1) a double aortic arch, (2) a right aortic arch, (3) a left-sided origin of the (right) innominate artery, (4) a right-sided origin of the left common carotid artery, or (5) an anomalous origin of the left

pulmonary artery from the right pulmonary artery.[118] With a right aortic arch, the trachea is compressed by the main pulmonary trunk, aortic arch, and ligamentum arteriosus. The anomalous innominate or common carotid arteries form a tight crotch, which impinges on the anterior trachea. The anomalous left pulmonary artery returns to the left by passing between the esophagus and the trachea, compressing the trachea between the right and the left pulmonary arteries. Infants with tracheal compression have inspiratory stridor and expiratory wheezing, with symptoms usually appearing later in the neonatal period. Affected infants often lie with the head and neck hyperextended to stretch the trachea and make it less compressible. If the esophagus is compressed, feeding is associated with regurgitation.

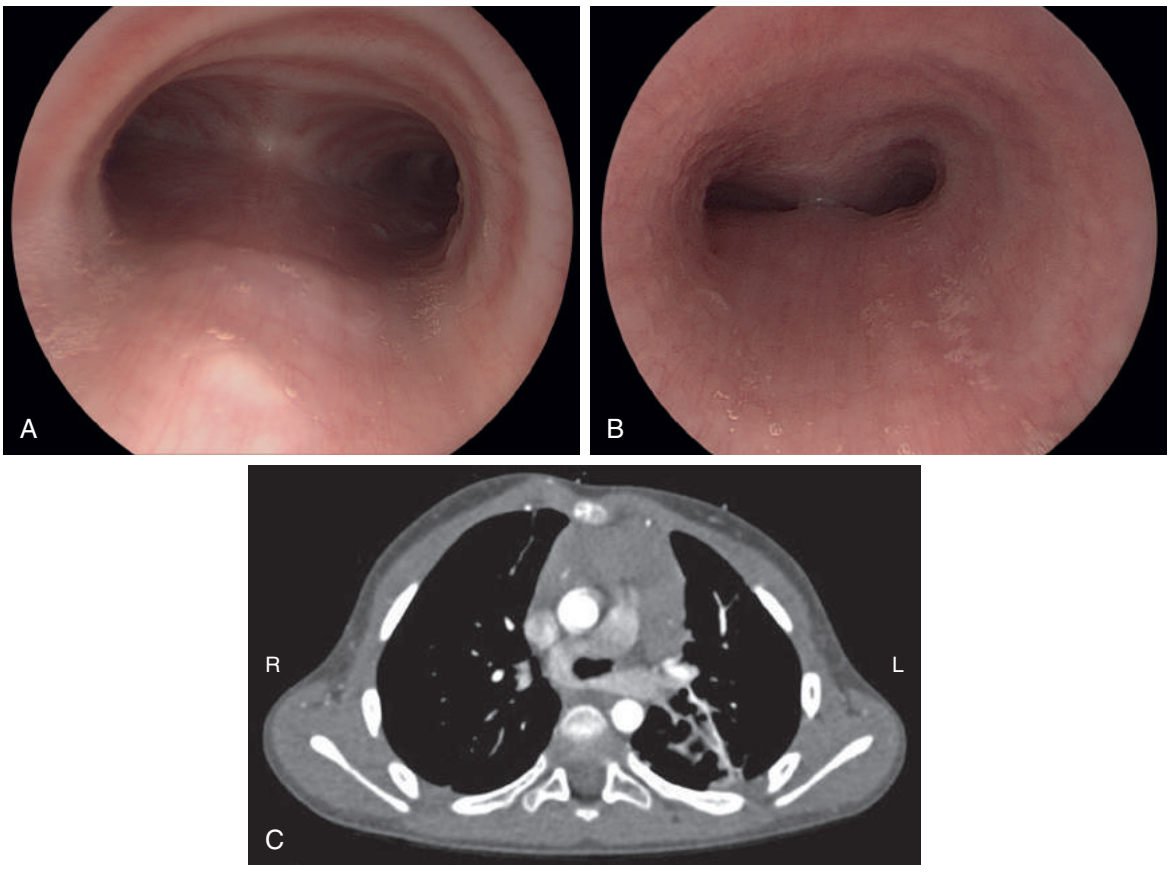
There are several methods of diagnosis. The chest radiograph may show mild overinflation, a right-sided aorta, and, with appropriate technique, evidence of tracheal narrowing. A barium swallow examination may show indentation of the esophagus. Bronchoscopy should reveal a pulsatile mass with narrowing near the carina (Fig. 44.2A,B). Cross-sectional imaging with CT and MRI has proven to be accurate in defining most vascular malformations and can give detailed imaging of the surrounding anatomy (Fig. 44.2C).[118] While echocardiography is less reliable in making the diagnosis of a vascular ring, it has been demonstrated that prenatal diagnosis by ultrasound avoided unnecessary delays in the repair of symptomatic vascular rings and that repair on identification of symptoms prevented the development of secondary tracheobronchomalacia.[119,120] Treatment involves surgical division of the vascular ring. Recently, minimally invasive techniques including a video-assisted thoracoscopic approach and endoscopic robotic-assisted techniques have been employed.[121,122] After surgical division of the vascular ring, the respiratory distress may persist for weeks or longer because of localized tracheal deformity (either stenosis or tracheomalacia), emphasizing the need for immediate repair on diagnosis. In cases of isolated vascular rings, repair provides treatment with minimal mortality and limited postoperative complications.[123]

Tracheal Compression by Extrinsic Masses

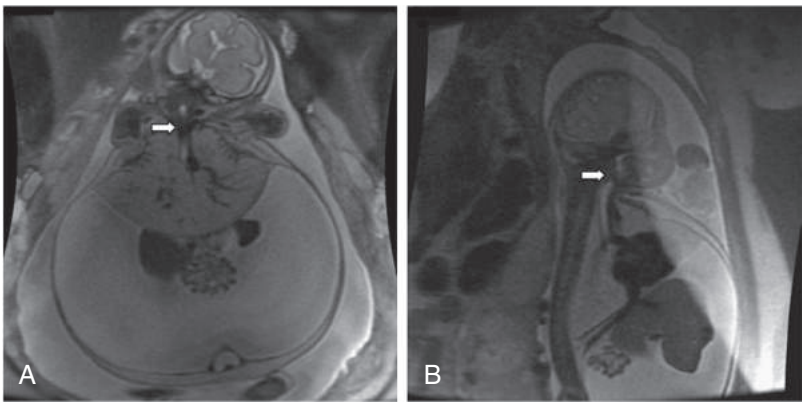
The trachea may also be compressed by a bronchogenic cyst, an enteric duplication cyst, a thoracic neurogenic tumor, or a mediastinal teratoma. These may be demonstrated by anteroposterior and lateral chest films and are especially apparent on CT scan.[124] Such masses may also compress the esophagus and can be demonstrated with a barium swallow.

Congenital High Airway Obstruction Syndrome (CHAOS) and the Ex-Utero (3HD) Intrapartum Treatment (EXIT) Procedure

CHAOS describes a spectrum of rare anomalies, including laryngeal web, laryngeal atresia, laryngeal cyst, and tracheal atresia



• **Fig. 44.2** Pulmonary artery sling. (A) Bronchoscopy of a normal distal trachea just above the level of the carina. (B) Bronchoscopy of a trachea with external compression by a vascular ring; in this case a pulmonary artery sling. (C) Contrast-enhanced computed tomography demonstrating the anomalous left pulmonary artery passing behind the trachea and in front of the esophagus. Compression of the trachea can be seen. (Courtesy Dr. Jamie Funamura, UC Davis Health System, Sacramento, CA.)



• **Fig. 44.3** Fetal MRI in the coronal (A) and sagittal (B) planes of a patient with fetal CHAOS. Note the atretic laryngeal segment (arrows). This lesion measured 7 mm and was deemed a poor candidate for fetal tracheoplasty. (From Saadai P, Jelin EB, Nijagal A, et al. Long-term outcomes after fetal therapy for congenital high airway obstructive syndrome. *J Pediatr Surg*. 2012;47(6):1095–100.)

• **Fig. 44.4** Direct laryngoscopy, bronchoscopy, and esophagoscopy are performed during an ex utero intrapartum treatment procedure. Using these methods, airway obstruction can be overcome and endotracheal intubation can be performed. (From Hirose S, Farmer DL, Lee H, et al. The ex utero intrapartum treatment procedure: looking back at the EXIT. *J Pediatr Surg*. 2004;39:375–380.)

or stenosis. Most cases are sporadic and the true incidence is unknown; thus the natural history of this disease is not well known. CHAOS is characterized by enlarged lungs, dilated distal airway, everted diaphragm, ascites, and ultimately nonimmune hydrops fetalis. Prenatal diagnosis is becoming more common with the progress of ultrasound and MRI techniques (Fig. 44.3).[125] The exact nature of the airway obstruction may not be entirely clear, and the time required to establish a safe airway soon enough after delivery carries various risks, including anoxic brain injury.

As with any anomaly that causes either direct respiratory airway obstruction or airway compression by means of mass effect, CHAOS poses a difficult problem for the clinical team during delivery. The EXIT procedure was developed as a solution to this problem: by preserving fetoplacental circulation throughout a scheduled cesarean section delivery, a safe fetal airway can be established before umbilical cord ligation (Fig. 44.4).[126] Infants with CHAOS still require postnatal airway reconstruction after delivery, but once a tracheostomy is in place, laryngeal or tracheal reconstruction is essentially an elective procedure and can be performed once the patient's overall status is optimized.[127] With EXIT, infants with CHAOS have a high chance at survival with low rates of hypoxemia-related complications in some small case series which show promising results.[128]

Disorders of the Mediastinum

Table 44.1 outlines the most common etiologies of mediastinal masses in children by location.[129]

Thymus

The thymus occupies the upper anterior mediastinum, and it is more prominent in the newborn period than at any other time of life. It may be so large as to reach the diaphragm or obscure both cardiac borders on radiographs. The normal thymus can be distinguished from an abnormal mass by the absence of tracheal deviation or compression. The thymus changes in position with respiration and is less prominent with deep inspiration. It also involutes with stress as well as with corticosteroid therapy. Absence of the thymic shadow in an infant should alert the clinician to the possibility of severe combined immune deficiency syndrome or DiGeorge syndrome with hypocalcemia and cardiac anomalies.[130]

The cardiothymic-to-thoracic ratio provides an index of thymic size. The shadow of the enlarged thymus is the most common radiopaque mass visualized in the anterior mediastinum of the newborn. The enlarged thymus causes little if any trouble in the neonatal period. Fletcher et al. and Gewolb et al. noted that a large thymus is present on the first day of life in infants at risk for hyaline membrane disease, presumably because of less-than-normal levels of glucocorticoids before birth.[131,132] The effect that glucocorticoids have on the thymus is also supported by a study that found that prenatal steroid administration causes thymic atrophy.[133] This steroid-induced atrophy, however, does not appear to have any clinical significance.

Thymomas and thymic carcinomas are extremely rare in the pediatric population, with the median age at diagnosis of 11.5 years.[134] The presence of myasthenia gravis occurs only 7% of the time, compared to roughly 50% of the time in adults.[135] There are not existing consensus guidelines for the management

TABLE 44.1 Mediastinal Mass Etiology by Location

Mediastinal Location	Type of Lesion	Most Common
Anterior	Solid	1. Thymic hyperplasia 2. Thymoma 3. Thymic carcinoma 4. Lymphoma 5. Teratoma
	Cystic	1. Thymic cyst 2. Lymphatic malformation
	Fatty	1. Lipoma 2. Thymolipoma
Middle	Cystic	1. Congenital foregut duplication cyst 2. Bronchogenic cyst 3. Esophageal duplication cyst 4. Neurenteric cyst
	Lymphadenopathy	1. Lymphoma 2. Metastatic disease 3. Infectious
Posterior	Solid	*Sympathetic ganglion tumors* 1. Neuroblastoma 2. Ganglioneuroblastoma 3. Ganglioneuroma *Nerve sheath tumors* 1. Schwannoma 2. Neurofibroma 3. Malignant peripheral nerve sheath tumor

of these rare tumors, however complete primary resection is preferred which may be accomplished thoracoscopically for thymomas. For thymic carcinoma, a malignant tumor of the thymus, the addition of multimodal therapy consisting of chemotherapy and radiotherapy is used if needed.[135,136] Unfortunately, despite this the prognosis remains grim with 21% 5-year overall survival with thymic carcinoma.

Congenital Mediastinal Teratoma

Mediastinal teratomas arise from primordial germ cells and are classified as being mature or immature. Mature teratomas are more common and contain all three embryonic cell layers (ectoderm, mesoderm, and endoderm). Immature teratomas are characterized by mature elements of all three germ layers but also have immature embryonic tissue interspersed.[137] Mediastinal teratomas rarely cause symptoms in the newborn infant. However, when an anterior mediastinal mass is associated with respiratory distress in the newborn, the strong likelihood is that the lesion is a mediastinal teratoma.[138] Teratomas can also cause chest pain, cough, and recurrent post-obstructive pneumonia secondary to bronchial obstruction. Chest radiographs show an anterior mediastinal mass with calcification; however, CT and MRI are the primary modes of diagnosis. Mature teratomas are invariably not malignant, and surgical resection via median sternotomy, posterolateral thoracotomy, or thoracoscopy is sufficient treatment.[139] Immature teratomas in children fortunately behave similar to mature teratomas and should be completely excised; however, there may be a role for chemotherapy before resection.

Prenatal diagnosis of a mediastinal teratoma is becoming more common with use of fetal ultrasound and fetal MRI. Large masses can cause compression of the mediastinum, leading to nonimmune hydrops and fetal demise.[140] If hydrops does not occur and the pregnancy is carried to term, delivery can be complicated by airway compression and cardiopulmonary failure. These cases can be managed by in utero resection in the case of hydrops or via an EXIT procedure near term followed by resection after stabilization.[141,142]

Congenital Bronchogenic Cysts

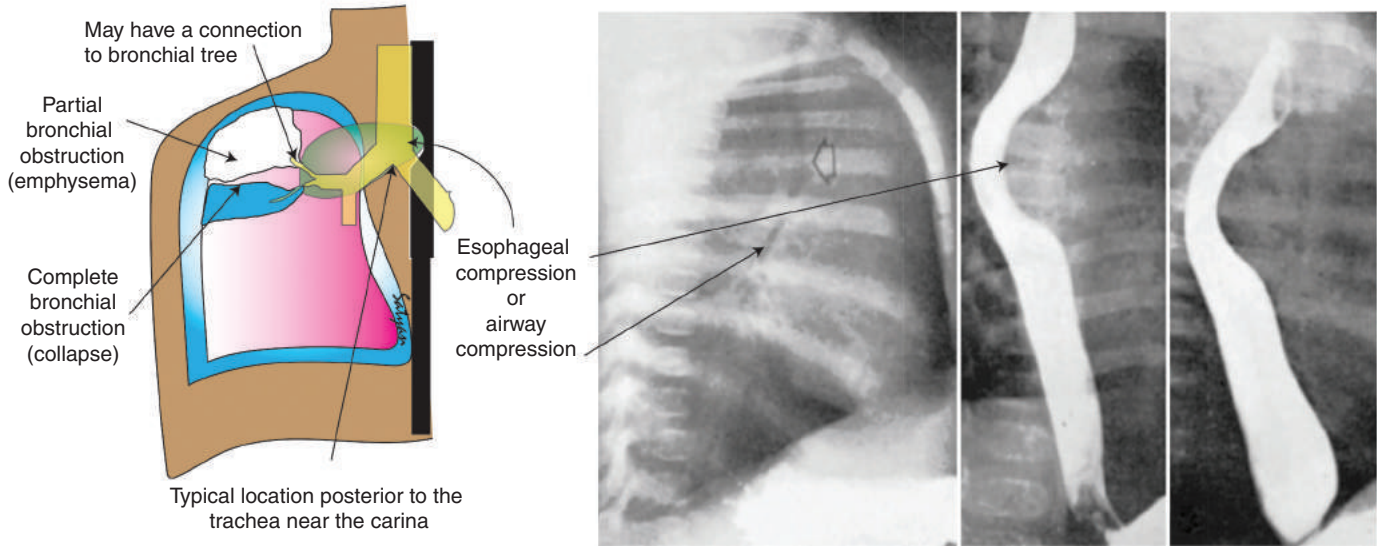
Bronchogenic cysts arise from the foregut during embryologic development and can be located in the mediastinum (just above the tracheal bifurcation), pericardium, abdomen, neck, and within the diaphragm.[143] While the majority are extrapulmonary, a minority of bronchogenic cysts are found within the lung, and some pathologists believe that these may not be distinct from intralobar sequestrations or type 1 congenital pulmonary airway malformations (CPAMs).[144]

Bronchogenic cysts can be seen on prenatal ultrasound, although they are more likely to present later as they increase in size over time, with airway compression, recurrent infection, hemoptysis, or pneumothorax.[145] Intrauterine airway compression can result in congenital lobar emphysema (CLE; see later discussion). In the newborn, bronchogenic cysts are encountered infrequently, and most do not come to the attention of the practitioner until later in infancy or during the second decade of life. Bronchogenic cysts seldom attain a large size and often contain clear fluid and debris. They are lined with columnar or cuboidal epithelium, and their walls generally contain smooth muscle, glands, and cartilage, the latter indicating their bronchial origin.[144] These cysts lie near the carina in the middle mediastinal space. They produce lung overdistension or atelectasis, depending on whether airway obstruction is complete or partial, and this is accompanied by respiratory distress in the newborn infant.

Imaging techniques and findings include:

- Radiographic examination: show a mass lesion at or just above the carina and displacing the lower trachea forward (Fig. 44.5).
- CT images: show sharply marginated cystic masses of soft tissue or water attenuation.
  - Specific criteria exist to distinguish these cysts from other mediastinal masses on CT.[146]
- MR images: hyper- or isointense to cerebrospinal fluid on both T1 and T2 images, with cyst wall enhancement with gadolinium.[146]
- Fetal ultrasound: Anechoic unilocular intrathoracic cyst, can be accompanied by polyhydramnios or hydrops.[147]
- Barium swallow examination: shows indentation of the esophagus, from external compression of the cyst pushing it backward at the level of the carina (see Fig. 44.5).
- Bronchoscopy: shows compression of the trachea and sometimes of one major bronchus, usually from the posterior aspect.

Sometimes a bronchogenic cyst may communicate with the airway and contain air. In the immediate newborn period, there may be retention of fetal lung fluid in the lung compromised by the bronchogenic cyst; the fluid may take days to clear. Treatment for bronchogenic cyst consists of surgical excision by partial or total lobectomy, either open or thoracoscopically, with uniformly good results. Early excision prevents eventual



• **Fig. 44.5** Bronchogenic cyst. Bronchogenic cyst is commonly located posterior to the carina and may be connected to the bronchial tree. Partial obstruction to the airway can result in overinflation (emphysema) of a lobe of the lung or retention of fetal lung liquid. Complete obstruction of the bronchus can lead to lobar collapse. These cysts can cause compression on the airway and be visible on a contrast upper gastrointestinal study. (Copyright Dr. Satyan Lakshminrusimha, UC Davis Health System, Sacramento, CA.)

development of symptoms in adulthood and malignant degeneration later in life.[148]

Esophageal duplication cysts are foregut cysts that are similar in development to a bronchogenic cyst, as both the foregut and the lungs arise from the same primordial tissue. Differentiation between the two occurs on histopathologic evaluation by determining the type of epithelium present, therefore an esophageal duplication cyst should remain on the differential when working up a patient with a mediastinal cyst concerning for a bronchogenic cyst.[149] Treatment consists of surgical excision, either open or thoracoscopically; esophagogastroduodenoscopy (EGD) may be a useful adjunct intra-operatively.

Neurenteric Cysts

Neurenteric cysts are rare lesions that result from the inappropriate separation of the embryonic notochordal plate and presumptive endoderm during development, including the persistence of the primitive foregut adhering to the notochord.[150] When the foregut descends from its early position in the neck, this adhesion to the notochord causes anomalies of the vertebral bodies. As the adhesion breaks off the duplicated portion of the foregut, it prevents complete descent into the thorax and abdomen along with the mature foregut. They often lie in the posterior mediastinum but with increasing size may project far into one or the other hemithorax. Their walls are composed of a mucosal layer, characteristic of their site of origin, and one or more muscular layers. They contain secreted fluid that is the same as that of their parent viscus.

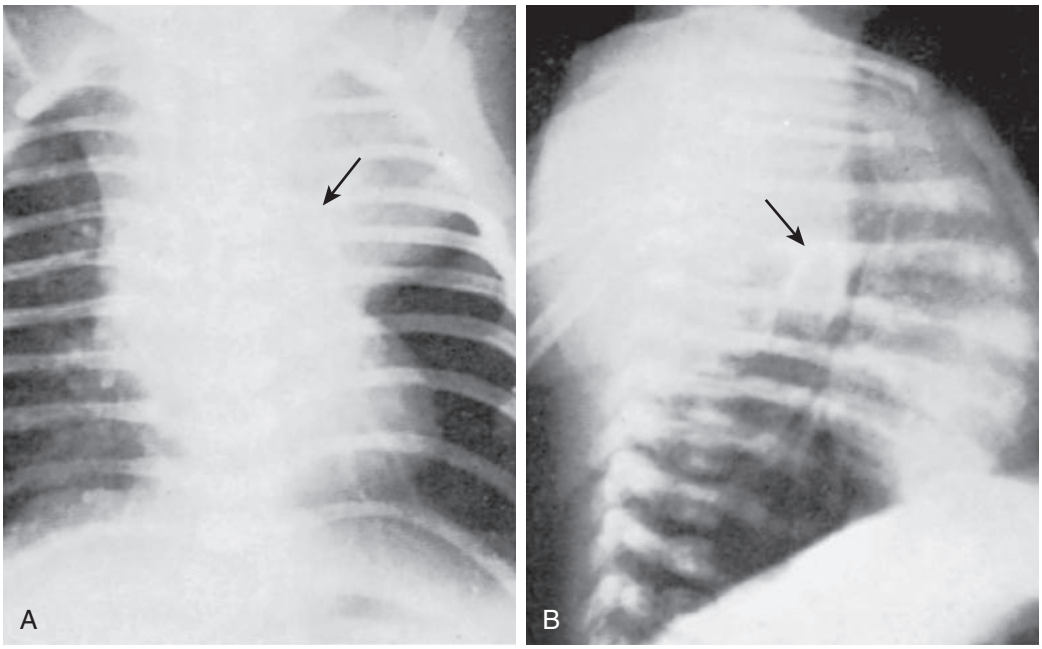
Clinical signs depend on the size and location of the cyst. Because most are posterior and lie close to the trachea, esophagus, and great vessels, they are seldom present without signs of abnormality. With their involvement with the spine, most have concurrent neurologic symptoms from spinal cord compression.[151] Cyanosis, tachypnea, and dyspnea often are present from birth.[152] Swallowing difficulties and vomiting are less frequent. Recurrent lower respiratory tract infections are findings in older infants with such cysts. Frank hemorrhage from the lungs or stomach is not uncommon. In most instances, hemorrhage indicates that the cyst is of gastrogenic origin, with peptic acid erosion into the trachea or esophagus.

It is recommended to perform careful radiographic evaluation of the spinal canal with CT scan and/or MRI, with MRI having proven superior in the delineation of the cyst and its relationship to the neural structures nearby.[153] Technetium scans may also be useful for delineating cysts lined with gastric mucosa. Radiographs of the chest show abnormal densities that are often difficult to distinguish from unusual cardiac contours. The barium swallow examination commonly shows displacement of the esophagus, usually forward because the mass is in the posterior mediastinum. The cyst may partially or totally compress the bronchus, with consequent lung overdistension or atelectasis. Sometimes the symptoms are intermittent as the cyst enlarges or empties. Bronchoscopy may show signs of external compression of the trachea or bronchus, usually from the posterior aspect.

Operative resection is indicated as soon as the diagnosis of a neurenteric cyst is made. It is neither necessary nor wise to delay exploration because all intrathoracic masses will eventually become symptomatic and have been known to cause paralysis and fatal meningitis. The goal of management is total surgical resection, most commonly via a posterior approach. Reports of recurrence range from 0% to 37%, with a link between partial resection and recurrence.[150]

Congenital Thoracic Neuroblastoma

Neuroblastoma, the most common solid tumor in the mediastinum of infants, arises from sympathetic neural tissue along the vertebral column and is therefore located in the posterior mediastinum. While neuroblastomas can arise anywhere in the sympathetic nervous system, thoracic neuroblastomas account



• **Fig. 44.6** Congenital thoracic neuroblastoma. The mass *(arrow)* is in the left upper hemithorax (A) and in the posterior mediastinum (B) on chest x-ray. (From Hope JW, Koop CE. Differential diagnosis of mediastinal masses. *Pediatr Clin North Am*. 1959;6:379.)

for approximately 20% of cases.[154] They may extend into the lungs, causing respiratory distress, or the spinal canal, causing neurologic signs such as Horner syndrome and paralysis. The chest mass may be identified incidentally on chest radiograph or during evaluation of respiratory distress (Fig. 44.6A,B). In older infants the diagnosis may follow chest radiography for lower respiratory tract infection, or radiographs may be taken to investigate dyspnea with physical exertion. Approximately 80% of neuroblastomas will demonstrate tumor calcification on CT scan. While CT scan can aid in diagnosis, MRI is essential to assess the degree of intervertebral tumor extension and can also evaluate for lymphatic spread, chest wall involvement, and liver metastases.[155] Distant boney metastasis is assessed by metaiodobenzylguanidine (MIBG) scintigraphy.[156] Diagnosis of thoracic neuroblastomas is also possible in the prenatal period using ultrasound.[157]

Despite some characteristic imaging findings specific to neuroblastomas, differentiation from other posterior mediastinal masses may be impossible before exploration. Encasement of the aorta or major branches, compression of the trachea or bronchus, and intraspinal tumor extension supports a diagnosis of neuroblastoma. Neuroblastoma clinical markers include:

- Elevation of urinary vanillylmandelic acid and homovanillic acid: may be present, but this finding is less common in the newborn, and its absence does not rule out neuroblastoma.
- Elevation of epinephrine, norepinephrine, and dopamine: may result in systemic hypertension, but this has not been reported in a thoracic neuroblastoma.
- Assays for various clinical biologic markers may be elevated, but not typically in the newborn:
  - Elevation of serum ferritin
  - Elevation of serum lactate dehydrogenase
- Bone marrow aspirate: obtained for cytologic evaluation of bone marrow involvement.
- Nuclear bone scan: performed to evaluate for bony metastases.
- Cytogenetic biologic markers: may be detected in the excised tumor tissue (e.g., cellular DNA ditetraploidy and increased N-*myc* oncogene copy number); these are markers of more aggressive disease, but are commonly negative in the newborn.[158]

Staging of neuroblastomas is typically done using the International Neuroblastoma Risk Group (INRG) staging based on clinical criteria and image-defined risk factors. Table 44.2 outlines the image-defined risk factors for neuroblastoma.[159]

The traditional International Neuroblastoma Staging System (INSS) categorizes the tumors into four stages, based on the extent of surgical resection. Neuroblastoma stages are as follows:

- L1: localized tumor not involving vital structures as defined by list of image-defined risk factors and confined to one body compartment
- L2: locoregional tumor with presence of one or more image-defined risk factors
- M: distant metastatic disease (except stage MS)
- MS: metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone

The associated risk stratification schema classifies tumors into low, intermediate, and high risk, depending on the histologic category of the tumor, as well as whether the tumor exhibits amplification of the *MYCN* gene and has favorable differentiation features. Based on these factors, tumors are then classified on a range from very low to high risk. Table 44.3 breaks down the INRG stages above with details including age, histologic category, grade of tumor, biologic markers, and pretreatment risk groups.

Regarding management of these tumors, treatment is guided by the Children's Oncology Group (COG) risk stratification which includes the above-mentioned low- to high-risk groups. Options for management include surgery, chemotherapy, radiotherapy, differentiation therapy, and immunotherapy.[160] Treatment for

TABLE 44.2 Pertinent Image-Defined Risk Factors for Neuroblastic Tumors

Location	Risk Factor
Ipsilateral tumor extension within two body compartments	Neck-chest, chest-abdomen, abdomen-pelvis
Neck	Tumor encasing carotid and/or vertebral artery and/or internal jugular vein Tumor extending to base of skull Tumor compressing the trachea
Cervico-thoracic junction	Tumor encasing brachial plexus roots Tumor encasing subclavian vessels and/or vertebral and/or carotid artery Tumor compressing the trachea
Thorax	Tumor encasing the aorta and/or major branches Tumor compressing the trachea and/or principal bronchi Lower mediastinal tumor, infiltrating the costovertebral junction between T9 and T12
Thoraco-abdominal	Tumor encasing the aorta and/or vena cava
Infiltration of adjacent organs/structures	Pericardium, diaphragm, kidney, liver, duodeno-pancreatic block, and mesentery
Conditions to be recorded, but *not* considered IDRFs	Multifocal primary tumors Pleural effusion, with or without malignant cells Ascites, with or without malignant cells

low-risk is often surgical resection alone, which has proven curative for most patients with a 97% 5-year overall survival rate.[161] Traditionally, these excisions have been done via open thoracotomy; however, with improvements in thoracoscopic technology, several groups advocate the use of video-assisted thoracoscopic surgery (VATS) for resection of thoracic neuroblastomas and report good results with no documented recurrences and with minimal complications.[162,163] Intermediate-risk tumors which are not amenable for upfront resection will receive neoadjuvant chemotherapy primarily in order to improve resectability. There is no reported difference in overall survival among patients with complete resection, minimal residual disease, or biopsy only in this intermediate-risk group, thus suggesting aggressive attempts at complete resection are unnecessary.[164] COG protocols for high-risk neuroblastoma include induction chemotherapy followed by surgical resection with a goal of complete resection; however, studies have not shown substantial survival benefit in patients with high-risk neuroblastoma undergoing gross total tumor resection.[165,166] For the induction chemotherapy, it has been shown that high-risk patients who receive four cycles of chemotherapy before surgical resection have a superior overall survival than patients who receive two.[167] Following operative intervention, consolidation therapy consists of chemotherapy and stem cell transplant. Additional therapies, including radiotherapy and immunotherapy, are also options for consolidation or maintenance therapy. The 5-year overall survival rate for high-risk patients is 40% to 50%.[167]

The outlook for neuroblastomas in extra-adrenal locations is better than that for their adrenal counterparts.[164] The outlook for neuroblastomas manifesting in the first 18 months of life also is good, especially in the distinct subgroup of neuroblastoma known as MS disease in which the tumor has only spread to the skin,

TABLE 44.3 International Neuroblastoma Risk Group Staging

INRG Stage	Age (mo)	Histological Category	*MYCN*	11q Aberration	Ploidy	Pretreatment Risk Group
L1/L2		Ganglioneuroma maturing; ganglioneuroblastoma intermixed				A Very low
L1		Any, except ganglioneuroma maturing or ganglioneuroblastoma intermixed	NA Amp			B Very low K High
L2	<18	Any, except ganglioneuroma maturing or ganglioneuroblastoma intermixed	NA	No Yes		D Low G Intermediate
	≥18	Ganglioneuroblastoma nodular; neuroblastoma	NA NA Amp	No Yes		E Low H Intermediate N High
M	<18		NA		Hyperdiploid	F Low
	<12		NA		Diploid	I Intermediate
	12 to <18		NA		Diploid	J Intermediate
	<18		Amp			O High
	≥18					P High
MS	<18		NA NA Amp	No Yes		C Very High Q High R High

NA, Non-amplified; *Amp*, amplified; blank field = "any"; diploid (DNA index ≤1.0); hyperdiploid (DNA index >1.0 and includes near-triploid and near-tetraploid tumors); very low risk (5-year EFS > 85%); low risk (5-year EFS > 75% to ≤ 85%); intermediate risk (5-year EFS ≥ 50% to ≤ 75%); high risk (5-year EFS < 50%).

liver, and less than 10% of bone marrow involvement. Many of these tumors are cystic in nature, and the histologic examination suggests that the neuroblasts are arranged in clumps rather than in sheets; this "neuroblastoma in situ" carries a high likelihood of spontaneous regression and therefore a good prognosis. In general, prognosis for children presenting less than 18 months of age is improved compared to older children.

Disorders of the Chest Wall

Abnormalities of the bone and muscle of the chest wall may be a mechanical hindrance to ventilation.

Skeletal Disorders

Although abnormalities involving bone are rare, they may be recognized immediately and are sometimes amenable to operative correction.

Defects of Sternal Fusion

Defects in fusion of the sternum are uncommon, occurring in less than 1 in 100,000 live births.[168] Complete separation of the two halves of the sternum allows protrusion of cardiovascular structures, a condition known as *ectopia cordis*.[169] Lethal malformations of the heart are commonly associated with this condition. Upper sternal clefts are the most common type of sternal fusion defect.[168] Early operation is advised to shield the underlying structures from injury, improve respiratory mechanics secondary to paradoxical chest motion, and because of the greater ease of approximating the separated parts in the first days of life compared with later.[170] A lower sternal cleft and ectopia cordis with a congenital heart defect may be associated with congenital apertures in the upper abdominal wall, in the pericardium, and in the anterior diaphragm, with a Morgagni-type diaphragmatic hernia, the so-called pentalogy of Cantrell.[168]

Pectus Excavatum

The most common sternal defect is pectus excavatum, occurring 1 in 400 to 1000 live births.[171] It is characterized by a posterior curvature of the sternum and lower costal cartilages, resulting in a "funnel chest" appearance. Pectus is three to five times more common in males and is sometimes associated with syndromes such as Marfan syndrome, Noonan syndrome, and Turner syndrome.[171] A family history of some type of anterior thoracic deformity was found in up to 42% of patients.[171] Only approximately one-third of cases of pectus excavatum are present in infancy.[172] Even in those cases that are present at infancy, it is rarely a severe deformity, and symptoms are minimal. As the deformity worsens, the heart may be compressed between the sternum and the vertebral column and displaced to the left, impinging on the space of the left lung. This compression may result in exercise intolerance, chest pain, and shortness of breath.[173] In addition to the physical symptoms, the chest deformity often leads to cosmetic concerns and psychological distress sufficient to warrant intervention.

Although routine chest radiographs may suffice in evaluating the severity of chest wall deformity, chest CT is typically preferred because this modality provides the bony and cartilaginous anatomic details as well as any information regarding cardiac compression necessary when considering surgical intervention. Using chest CT allows one to calculate the Haller index (HI), or the ratio of the transverse distance to the anteroposterior distance. A normal HI is about 2, and most cases of pectus excavatum that qualify for operative correction are greater than 3.25.[174] However, the indications for operative correction are debatable. Those patients with severe cardiac or pulmonary compression, abnormal cardiac or pulmonary function studies, or failed previous repairs are candidates for repair.[173] Periodic evaluation of cardiovascular status with echocardiogram and electrocardiography in addition to assessment of pulmonary function is appropriate in the presence of progressive deformity and during periods of rapid growth such as adolescence. In our opinion, correction should not be undertaken until the child is several years of age and then only in those few children in whom the deformity appears to be progressing. Serial photographs are the best way to document changes in pectus excavatum. Surgical correction involves insertion of a metal bar underneath the sternum. This can be done most commonly via a minimally invasive approach with the Nuss procedure or by an open approach with the Ravitch procedure when not a candidate for the Nuss procedure; results are excellent in the majority of patients.[175] Surgery is almost always associated with improved self-image and perceived functional activity.[176,177] Recurrences are possible during later active growth and may require repeat intervention, often with excellent outcomes.[178]

Poland Syndrome

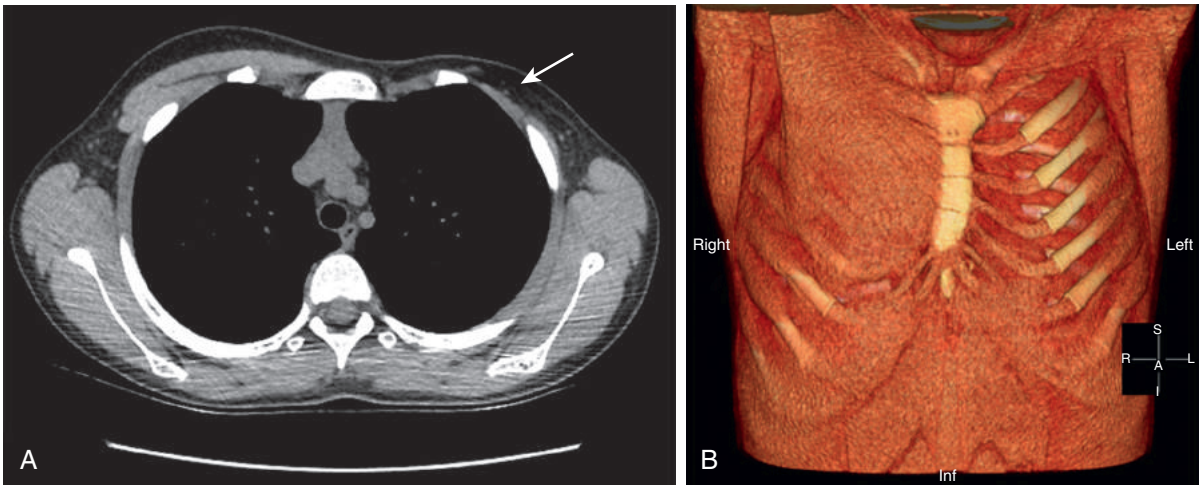
There is a great amount of diversity in the clinical manifestations of Poland syndrome; however, all children must have hypoplasia or absence of the pectoral muscles, typically only on one side. Additional manifestations include cartilage agenesis of the second through fifth ribs on the ipsilateral side, athelia, and amastia. There may be associated syndactyly, hemivertebrae, and scoliosis.[179] Breathing may be paradoxical and the cardiac impulse easily observed through the soft tissues, but there is rarely any severe respiratory distress that would necessitate emergent intervention. Later in childhood, although uncommon, there may be increasing respiratory symptoms with scoliosis-related lung disease and/or heart failure. CT scans are useful in assessing the configuration of the chest wall and its need for reconstruction when symptoms develop (Fig. 44.7A,B).[180] No operative intervention is required in infancy, although complex reconstruction with autologous rib grafts, chest wall implants, and latissimus dorsi flaps may be desirable in later childhood as well as mammoplasty in affected girls after puberty.[180,181]

Thoracic Dystrophies

Asphyxiating Thoracic Dystrophy (Jeune Syndrome)

First described by Jeune et al., asphyxiating thoracic dystrophy is an autosomal recessive chondrodystrophy, associated with short-limbed dwarfism and often polydactyly.[182] It is a rare deformity, occurring in approximately 1 in 100,000 to 130,000 live births. The ribs are horizontal, hypoplastic, and short, with flared costochondral junctions (Fig. 44.8). The thorax is small, bell-shaped, and rigid; this results in displacement of the liver and spleen well into the abdominal cavity. Some degree of lung hypoplasia may be present and, if present, is often severe and lethal.[183] The pelvis shows flaring of the iliac wings and acetabular abnormalities. Renal cystic dysplasia may be present, resulting in hypertension and renal failure. Patients can also have variable pancreatic, hepatic, and retinal abnormalities. Prenatal diagnosis with ultrasonography is possible.[184]

In the past, most patients with this condition did not survive the first month. Keppler-Noreuil et al. reviewed 118 cases published in literature and noted almost equivalent number of living to deceased patients at the time of report.[185] In those less than



• **Fig. 44.7** Poland syndrome. (A) Axial CT scan and (B) three-dimensional CT reconstruction demonstrating a congenital absence of the pectoralis major and pectoralis minor muscle *(arrow)*. • **Fig. 44.8** Asphyxiating thoracic dystrophy. Infants born with this condition have a small, bell-shaped thoracic cage often associated with hypoplastic lungs and a displaced liver and spleen. Many infants have cystic renal disease. Other malformations such as short limbs and polydactyly are common in this condition. (Copyright Dr. Satyan Lakshminrusimha, UC Davis Health System, Sacramento, CA.)

2 years of age, respiratory etiology was most common cause of death. In those between 3 and 10 years of age, renal etiologies were primary cause of death. There is paucity in data in those greater than 20 years of age, but with one patient reported at age 32 years. Davis et al. reported an operative technique for lateral thoracic expansion in 10 patients with chest wall deformities limiting thoracic capacity—including 8 patients with classic Jeune syndrome.[186] Three were younger than 1 year of age at the time of surgery, and six were ventilator dependent. All of the infants older than 1 year of age at the time of surgery improved, with measured lung volumes increasing in 2 of 3 studied and thoracic volumes by CT increasing in 4 of 5 studied. The only deaths were in 2 infants younger than 1 year of age at the time of surgery, suggesting that lateral thoracic expansion is a safe and effective procedure for patients beyond the first year of age. However, given that the Davis technique was two-staged and sequential, there have been efforts to investigate one-stage bilateral thoracic expansion.[187] A vertical expandable prosthetic titanium rib procedure has also been introduced for the purpose of progressive expansion of the chest cavity in patients with thoracic insufficiency.[188] There also has been a case report describing use of the Nuss procedure, as used in pectus excavatum repairs, in two patients with Jeune syndrome.[189] However, long-term improvements in lung function, specifically in patients with Jeune syndrome, have yet to be reported.

Other Thoracic Dystrophies

Severe underdevelopment of the thoracic rib cage, accompanied usually by lethal pulmonary hypoplasia, may be seen in other conditions, such as thanatophoric dwarfism syndrome, short rib–polydactyly syndrome, and campomelic dwarfism syndrome. Affected infants do not usually survive for long after birth.

Neuromuscular Disorders

Other causes of thoracic dysfunction are diseases of the nerves and muscles, including congenital myasthenia gravis, congenital spinal muscular atrophy (Werdnig–Hoffmann disease), congenital myotonic dystrophy, glycogen storage diseases, and congenital spinal injury. Such conditions are usually recognized in the context of the associated systemic muscular weakness. Newborns with myasthenia gravis have episodes of muscle weakness, poor feeding, weak cry, hypoventilation, and apnea with a positive response to an anticholinesterase medication. In congenital spinal muscular atrophy, there is lung hypoplasia associated with absent fetal breathing, and as a result the thorax is small. Other features include severe hypotonia, muscle fasciculation, respiratory failure, and early death; the inheritance is autosomal recessive. In congenital myotonic dystrophy, there is lung hypoplasia from absent fetal breathing; affected infants have respiratory distress at birth, rapidly need mechanical ventilation, and are soon ventilator dependent. Mothers of these

infants have myotonia, difficulty in relaxing muscle contractions; the inheritance is autosomal dominant.

Disorders of the Pleural Cavity

The pleural cavity lies between the parietal pleura, lining the chest wall, and the visceral pleura, lining the lung and other structures. The blood supply to both pleural surfaces is systemic. Venous drainage of the parietal pleura is to the systemic system and the visceral pleura to the pulmonary system. The pleural surfaces filter fluid into the pleural space and the pleural lymphatics then resorb fluid from the pleural cavity.[190] This process is hindered in the setting of abnormal lymphatic development or abnormal systemic venous pressures (because the thoracic lymphatic system drains directly to the systemic veins), resulting in chylothorax. Chylothorax can also occur because of surgical disruption of the thoracic duct or in the setting of lymphatic malformations. Other causes of hydrothorax in the newborn include hydrops fetalis, transudative pleural effusions associated with congenital lung lesions or group B streptococcal pneumonia, empyema (usually associated with nosocomial pneumonia), or fluid extravasation from a displaced central venous catheter.

Congenital Chylothorax

Congenital chylothorax is the most common prenatal diagnosis of pleural effusion. Without oral fat intake chylomicrons, most common indicator for chylothorax, it is difficult to distinguish between chylous and non-chylous effusion. It is rare, occurring in 1 in 10,000 births, with mortality ranging between 20% and 60%; mortality can be as high as 98% if associated with hydrops fetalis.[191] A large fetal chylothorax may evert the diaphragm, and can be the cause of nonimmune hydrops fetalis secondary to hypoproteinemia, and impaired venous return or cardiac function in the setting of increased intrathoracic pressure. Additionally, large fetal chylothorax can result in pulmonary hypoplasia and significantly contribute to mortality. Fetal chylothorax portends a worse prognosis for survival if it is bilateral or associated with hydrops, and prognosis is better if the effusion resolves without reaccumulation.[192]

In utero intervention may be undertaken in cases of large or bilateral effusions, or hydrops, and has been shown to improve survival.[192] Classically, these interventions include transabdominal thoracentesis (with ongoing ultrasound monitoring for fluid reaccumulation) and placement of an indwelling thoracoamniotic shunt (if the effusion reaccumulates), to allow continued drainage of fluid. More recently, in utero pleurodesis has been successfully performed using Picibanil (OK-432), with recent long-term follow up study suggesting comparable survival and neurodevelopmental outcomes to thoracoamniotic shunts.[193] Maternal dietary modification with low-fat, high-medium-chain triglyceride may delay reaccumulation of chylothorax.[194] Fetuses diagnosed with chylothorax should be evaluated for associated conditions that may affect their prognosis, including Down syndrome, Noonan syndrome, and Turner syndrome.

Newborns with congenital chylothorax often present with severe respiratory distress, requiring immediate respiratory support and urgent drainage of pleural fluid. Chest radiographs will show either unilateral or bilateral fluid accumulation, often with shift of the mediastinum. Aspiration of the fluid can confirm the diagnosis. Before feedings have been started, the fluid will be straw colored but will change to the classic milky-white appearance after feedings have been initiated. Characteristics of a chylous aspirate include a high cell count with a lymphocytic predominance, a high triglyceride level (usually above serum levels, but not present unless enteral feeds initiated), and high protein content (Table 44.4). The introduction of small-volume fat-containing feeds with resultant elevated fluid triglyceride levels can confirm the diagnosis if biochemical indices are otherwise not confirmatory. A review of 39 cases of pediatric chylothorax revealed that the composition was consistent with classic descriptions as above.[195]

TABLE 44.4 Characteristics of Chylous Effusions

Characteristic	Description
Appearance	Clear yellow (milky with fat-containing feeds)
Cell count	>1000 cells/mm^3
Lymphocyte proportion	>80%
pH	7.4–7.8
Triglycerides	>110 mg/dL
Cholesterol	65–220 mg/dL
Albumin	1.2–4.1 g/dL
Total protein	2.2–5.9 g/dL

Adapted from Straaten HLM, Gerards LJ, Krediet TG. Chylothorax in the neonatal period. *Eur J Pediatr* 1993;152:2–5; Costa F. Quilotórax. In: Maksoud JG, editor. Cirurgia pediátrica. 2nd ed. Rio de Janeiro: Revinter; 2003. pp. 624–630; Brodman RF. Congenital chylothorax: recommendations for treatment. *N Y State J Med* 1975;75:553–557.

Management of Chylothorax

Neonatal management of a congenital chylothorax includes replacement of protein, clotting factors, and immunoglobulins as needed. Ongoing respiratory support may be needed, and often a chronic chest drain is required to decrease respiratory compromise. Feeds are usually restricted, either providing medium-chain triglycerides (MCTs) only (because MCTs are generally absorbed directly from the intestine without processing to chylomicrons) or a nonfat diet. If these measures fail, a period of total enteric rest is undertaken, with parenteral nutrition administered, until resolution of the chylous effusion. Some practitioners believe that a period of enteric rest is necessary to decrease strain on the lymphatic system, because lymphatic efflux is still increased even with nonfat-containing diets.[196] Once chest drainage has resolved, feeds are reintroduced with a MCT-only formula for 3 to 6 weeks before transitioning to a normal diet.

While there are no controlled studies demonstrating that one strategy is superior to others to hasten resolution of chylothorax, one retrospective study comparing total parenteral nutrition (TPN) to MCT suggested that TPN is more effective than oral MCT in the treatment of congenital chylothorax.[196] A conservative approach was successful in 80% to 85% of patients.[195,197] The primary risk of this non-surgical approach is infection, because these children have prolonged hospitalizations with central venous access, chest drains, no enteral feeds, and protein and immunoglobulin losses. Children who were less likely to have spontaneous resolution of chest drainage included those children with elevated

central venous pressure, children who had more prolonged effusions, and children with higher output than those with surgical injury.

An adjunctive medical approach is the administration of somatostatin or its analogue, octreotide, to decrease pleural drainage. Somatostatin is delivered only via continuous infusion, whereas octreotide can also be given via intermittent subcutaneous injection, because of its longer half-life. The mechanism of effect is thought to be via decreased intestinal secretions and absorption of triglyceride, and therefore intestinal efflux and lymphatic return.[198] Some practitioners proceed quickly to the use of these medications, believing they decrease the volume and duration of chest drainage compared with conservative management; however, this has not been studied in a controlled setting, so the efficacy and risks of this approach are unknown.[199] Others use these medications once conservative measures have failed. Recent metanalysis has found that octreotide was effective in 47% of cases.[199] Potential risks of therapy include hormonal effects of glucose instability and hypothyroidism, and gastrointestinal effects such as cholelithiasis, hepatocellular injury, nausea, diarrhea, abdominal distention, and decreased intestinal perfusion. In this regard, monitoring of serum glucose, thyroid function, liver enzymes, and indicators of cholestasis during therapy is recommended. These serious side effects raise concerns, particularly regarding concomitant feeding during administration of the medications. Octreotide can be administered either subcutaneously or as continuous intravenous infusion. In most cases, dosing is titrated up until chest drainage is minimal. The infusion is usually continued for several days after chest drainage is controlled and then weaned off over several days.

Sildenafil and sirolimus are being investigated as potential adjuncts to conservative treatment. Sildenafil is thought to facilitate resolution of chylothorax by promoting new lymphatic vessel formation and remodeling. There is a case report demonstrating success with sildenafil in late preterm infants with congenital chylothorax secondary to pulmonary lymphangiectasis that was refractory to octreotide.[200] Sirolimus targets mammalian target of rapamycin (mTOR), which is upregulated in number of atypical lymphatic pathology. It has shown some promise in adults and older children with chylothorax secondary to lymphatic malformation, but needs further study including age-appropriate dosing regimens and efficacy in neonates.[201] Additionally, propranolol has been used as off-label treatment of chylothorax and chyloperitoneum in multiple case studies, but no definitive dosing, safety, or efficacy has been established.[202] Propranolol is thought to decrease abnormal lymphatic proliferation by downregulating vascular endothelial growth factor (VEGF).

Most practitioners recommend about 3 to 4 weeks of maximal medical therapy before proceeding with an operative intervention, while others recommend intervention in patients who drain more than 100 mL/year of age per day without slowing down after 10 to 20 days.[195] Effusions are unlikely to resolve after 6 weeks, and waiting too long for operative intervention may result in significant compromise to the child. Operative interventions include thoracic duct ligation via thoracotomy or thoracoscopy, pleurodesis, and/or placement of a pleuroperitoneal shunt.[203] For chylothorax after iatrogenic injury to the thoracic duct, lymphovenous anastomosis is being investigated.[204] Percutaneous thoracic duct embolization is another approach that was developed as a less invasive alternative to surgical thoracic duct ligation, which involves diagnostic lymphangiography followed by transabdominal catheterization and embolization to occlude the thoracic duct proximal to the leak.[205]

Congenital Thoracic Masses and Cysts

Fetal lung masses vary in the degree of abnormality of parenchyma and vasculature and probably represent a spectrum of developmental abnormalities that may be difficult to distinguish prenatally.[144,206] In fact, some investigators have suggested classifying these lesions solely on the basis of the vascular supply (systemic vs. pulmonary) and whether or not lung structure is normal, because the histology and probably the developmental pathways leading to the individual lesions are overlapping.[207] Some level and degree of fetal airway obstruction have been implicated as the cause of many of these lesions.[144] In prenatal series, CPAMs of the lung are frequently the most common lesion reported.[207] However, in postnatal series, CPAMs are often less common (with various imaging modalities and pathology available to clarify the diagnosis after birth), particularly when only cystic lesions are considered.[143,144,208] There are multiple reports of "hybrid" lesions, with features of both CPAM and bronchopulmonary sequestration (BPS), emphasizing that these lesions constitute a spectrum of anomalies.[143,144]

Congenital Pulmonary Airway Malformation of the Lung

CPAMs are the most common congenital lung lesions and develop from an overgrowth of abnormal lung tissue, extending from different levels of the airway. In general, they are unilateral. The lesions may communicate with the airways, allowing them to transition from being fluid filled in utero to air filled postnatally, but they do not contain normal alveoli. CPAMs were previously known as congenital cystic adenomatoid malformations (CCAMs), which were originally classified into three types based upon the size of the cysts and their cellular characteristics.[208] Subsequent revisions of this classification system have included less common proximal and distal lesions and have suggested new nomenclature based on the fact that not all lesions are either adenomatoid or cystic.[144] The term "congenital pulmonary airway malformation," initially proposed by Stocker, has now become the accepted terminology for these lesions. Table 44.5 shows the stages of lung development with the corresponding airway malformation and CPAM type. Consistent with this classification, persistent epithelial expression of the nuclear regulatory protein thyroid transcription factor 1 has been found in type 1 and 3 CPAMs (see later discussion), indicating developmental arrest in the pseudoglandular stage, and targeted fetal airway overexpression of the growth factor fibroblast growth factor 10 in rats produces CPAM-like lesions.[208,209]

Congenital Pulmonary Airway Malformation Types

There are 5 types of congenital pulmonary airway malformations. Table 44.6 outlines the characteristics for each of the 5 types of congenital pulmonary airway malformations (Fig. 44.9). Clinically, Type 0 CPAM lungs may be normal weight or small, but, regardless, this lesion is rapidly lethal because of severe, intractable respiratory failure. It is diffuse and bilateral, recurs in families, and can be associated with other anomalies, suggesting a genetic cause.[210]

For type 1 CPAMs respiratory distress depends on the size of the lesion, with some lesions detected only by incidental imaging or following infection or malignant transformation (see Fig. 44.9). There does appear to be a risk of malignant transformation in unresected or residual CPAM tissue. The specific link to neoplasm has not been elucidated, though the diagnosis of bronchoalveolar

TABLE 44.5 Stages of Airway Branching and Lung Development With Corresponding Congenital Airway Malformation

		CPAM TYPE	
Developmental Stage	**Developmental Events**	**Stocker**	**Adzick**
Embryonic 0–7 wk	Formation of tracheal bud and growth and branching to segmental bronchi	Type 0 Tracheobronchial Type 1 Bronchial/bronchiolar	Macrocystic
Pseudoglandular 7–17 wk	Completion of airway branching to terminal bronchioles (preacinar); gland formation	Type 2 Bronchiolar	
Canalicular 17–27 wk	Formation of respiratory bronchioles to prealveolar structures	Type 3 Bronchiolar/alveolar duct	Microcystic
Saccular 28–36 wk	Formation of secondary septae	Type 4 Distal acinar	
Alveolar 36 wk–2 yr	Formation of alveoli		

CPAM, Congenital pulmonary airway malformation.

TABLE 44.6 Types of Congenital Pulmonary Airway Malformations

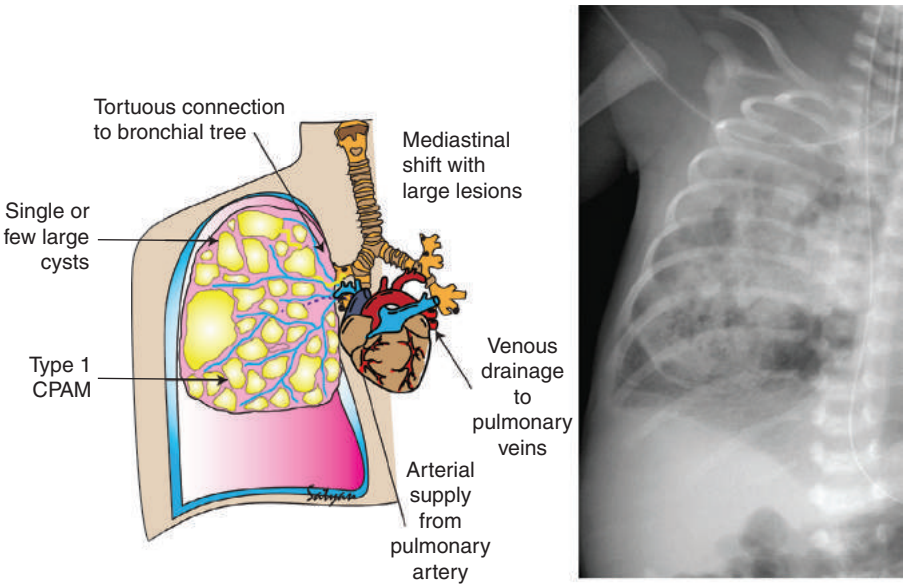
Type	Cases (%)	Characteristics	Cyst Size (cm)	Cellular Characteristics	Other
0	<2	Originate from tracheobronchial tree Normal lung lobulation No alveoli	<0.5	Ciliated pseudostratified epithelium	Affected usually die at birth
1	60–65	Originate from distal bronchi or proximal bronchioles Restricted to a single lobe Can be communicating	>2	Cuboidal or ciliated pseudostratified columnar epithelium	Malignant potential
2	15–20	Appear as multiple bronchiole-type structures Multiple small cysts	0.5–2	Ciliated cuboidal or columnar epithelium	50% associated with other anomalies
3	5–10	Solid cysts Involve entire lobe or lung	<0.5	Non-ciliated cuboidal epithelium	Often cause mass effect in the thorax
4	10	Confined to one lobe Peripheral location	Up to 7	Type I alveolar (flat) and type II (rounded) epithelial cells	Strong malignant potential

carcinoma (BAC) is made in relatively young patients (10 to 42 years), and a spectrum of malignancy has been described.[211,212] This is the only CPAM type that is associated with malignancy, and the young age of affected patients suggests that the CPAM lesion is the cause of the malignancy.[213] It is hypothesized that type 1 CPAM lesions serve as precursors to BAC, sharing similar differentiation profile, and high frequency of K-ras mutations.[214]

Type 2 CPAMs are most commonly associated with other anomalies, in 50% of cases, which include severe bilateral renal dysplasia or agenesis, agenesis of other genitourinary structures, sirenomelia, extralobar pulmonary sequestration, and diaphragmatic hernia.[215,216] Conotruncal cardiac malformations have also been described in association with type 1 and type 2 CPAMs, and ventricular septal defects have been diagnosed in fetuses and infants with all CPAM types.[217]

Type 3 CPAM infants and children may present with mild respiratory distress, or more severe symptoms if pneumonia occurs, or if the lesion ruptures, causing pneumothorax. However, type 4 CPAMs can also be detected by incidental imaging. These lesions are lined with type I alveolar (flat) and type II (rounded) epithelial cells. The presence of substantial portions of cells representing the more proximal areas of the lung should raise suspicion for pleuropulmonary blastoma (PPB), a distinction that is important (because of malignancy associated with PPB; see later discussion), but one that can be difficult.

The approach to diagnose CPAMs in utero has led to a different classification system, based on the natural history of these fetal lesions (see later discussion). Macrocystic CPAMs are defined when a lesion contains cysts that are greater than or equal to 5 mm (types 1 and 2 CPAMs), and microcystic CPAMs are defined as



• **Fig. 44.9** Illustration and chest x-ray at birth in a neonate with type 1 congenital pulmonary airway malformation (CPAM). Large cysts ranging from 1 to 10 cm are present in the lesion. If large, these lesions can lead to mediastinal shift and compress adjacent lobes of the lung. Some of these cysts may have a tortuous connection to the airway. Arterial supply to CPAM is commonly from the pulmonary arterial tree and venous drainage is to the pulmonary venous system. (Courtesy Dr. Satyan Lakshminrusimha, UC Davis Health System, Sacramento, CA.)

a solid lesion, with cysts less than 5 mm (type 3 CPAMs).[218,219] Some lesions categorized by these criteria on fetal ultrasound have been diagnosed as BPS after postnatal resection.[220]

Fetal Diagnosis and Natural History

Fetal diagnosis of a CPAM is often made when mediastinal shift because of mass effect from the lesion is identified and a cystic, intermediate, or solid mass is detected. This may occur during routine fetal ultrasonography or when the mother is referred for evaluation of polyhydramnios (thought to occur when the mass compresses the esophagus and thus limits fetal swallowing).[221] A systemic vascular supply identified on imaging is more consistent with a diagnosis of BPS.[222] Fetal MRI can be used to help distinguish a CPAM from other pulmonary pathology, including BPS and congenital diaphragmatic hernias (CDHs).[223] In a recent population base study of Western Europe, CPAM have an estimated prevalence near 1 in 10,000 live births.[224] Generally, growth of CPAM lesions increases until about 28 weeks' gestation, after which time it plateaus and the lesion regresses in size while the fetus continues to grow.[225]

Fetal and neonatal problems that arise as the result of a CPAM include the development of nonimmune hydrops and lung hypoplasia, which may be due to compression of the otherwise normally developing lung. Up to one-third of fetuses with large CPAM develop hydrops. Factors associated with the development of nonimmune hydrops include an everted ipsilateral hemidiaphragm, predominantly cystic lesions, lesions that exist into the third trimester, and lesions with a CPAM volume ratio (CVR) greater than 1.6.[226] Maternal steroids have been demonstrated to improve hydrops.[227] In a series evaluating fetal macrocystic and microcystic lesions, generally the fetuses with microcystic lesions had poorer outcomes, with intrauterine demise or early neonatal death.[218] Compared with normal lung, CPAM lesions have unregulated growth, with increased proliferation and decreased apoptosis, although they are relatively hypovascular.[228,229] In fetal CPAM tissue, increased Platelet-Derived Growth Factor subunit B (PDGF-β), decreased fatty acid binding protein-7 expression, and dysregulation of Ras, PI3K-AKT-mTOR signaling have been detected.[230–232]

Prenatal Management

Initial ultrasound evaluation of the fetus with possible CPAM should include assessment of lesion size with relevant indices, vascular supply, degree of mediastinal shift, ipsilateral diaphragmatic conformation (normal, flat, or everted), polyhydramnios, placentomegaly, and the presence of any other fluid collections (ascites, integumentary edema, pleural or pericardial effusion) indicating the development of fetal hydrops. Additional prenatal evaluation of a fetus with a known CPAM should include a full fetal survey to identify other anomalies, a karyotype, and an echocardiogram, to evaluate for congenital heart disease and to assess cardiac inflow patterns and outputs. These cardiac indices may help identify impending hydrops, mandating closer ultrasound follow-up and repeated echocardiographic measurements. Most referral centers recommend at least weekly follow-up ultrasound examinations evaluating lesion size and monitoring for development of hydrops until 28 to 29 weeks' gestation, at which point regression of the lesion should be occurring. Thereafter, ultrasound evaluations can be spread out to every 2 weeks. Some referral centers have advocated twice-weekly surveillance if the CVR is greater than 1.6, until 28 weeks' gestation.[221] In multiple studies, between 35% and 40% of fetal lung masses decreased in size or resolved by delivery.[220,225]

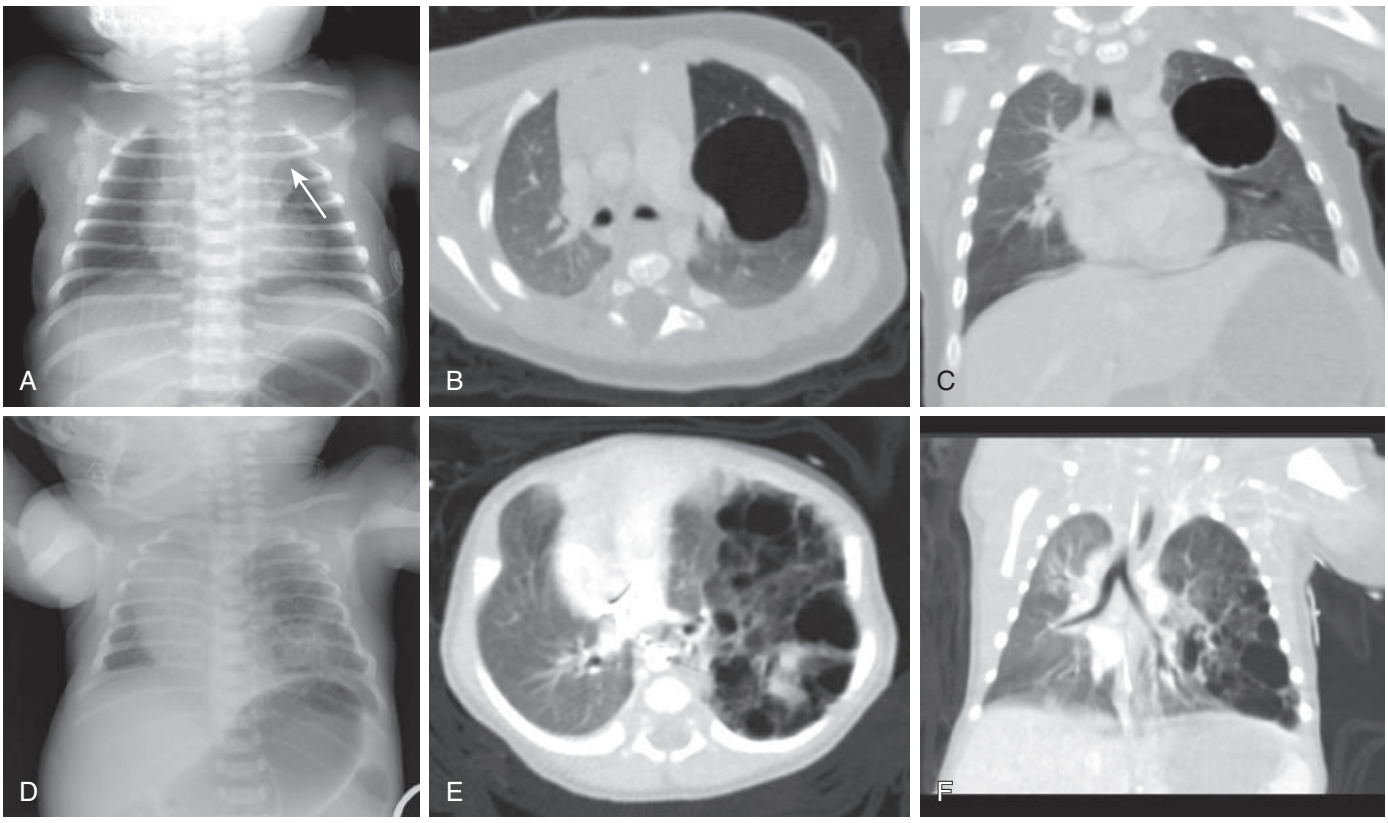
The diagnosis of hydrops in a fetus with CPAM portends a poor prognosis, with either fetal demise or preterm delivery of a compromised infant.[233] Thus impending or definite hydrops is an indication for fetal intervention. The specific intervention depends on the type of lesion. In fetuses with a macrocystic CPAM, a growing, dominant cyst, and impending or definite hydrops, placement of a thoracoamniotic shunt results in a decrease in cyst size and hemodynamic improvement, with relatively good neonatal survival.[234]

However, shunt placement at less than 21 weeks' gestation may be associated with chest wall deformity, which can compromise later respiratory function, so other interventions may need to be taken at that early gestation.[235]Additionally, shunt displacement is a complication and can lead to refractory tension pneumothorax requiring early surgical intervention.[236] Fetal thoracentesis is rarely effective as definitive treatment, because cyst fluid invariably reaccumulates, but it might serve as a temporizing measure until further treatment can be undertaken.[222] Sclerotherapy for patients with hydrops secondary to type II or III is unclear in efficacy and being further studied.[237] For fetuses with impending hydrops, heart failure, and a microcystic CPAM (or failed decompression of a large cyst), open fetal resection (lobectomy or pneumonectomy) improves the chances of survival, although mortality remains high (10 of 23 in one series), and non-survivors tended to be more premature.[238] This selected approach to fetal resection has resulted in resolution of hydrops and mediastinal shift in survivors.[221] For fetuses greater than 32 weeks' gestation, or in the case where fetal surgery is contraindicated because of preterm labor, an EXIT-to-resection procedure may provide a chance for survival. EXIT procedures have also been undertaken in later-gestation fetuses with persistent large lesions (mean CVR 2.2) despite other fetal interventions, although the impact of this strategy on survival and other outcomes is unknown.[238]

Before undertaking any fetal intervention, prenatal glucocorticoid therapy to accelerate fetal lung maturation should be administered. This practice, utilizing betamethasone (12 mg intramuscularly every 24 hours × 2 doses), led to the observation that fetuses with microcystic and hydrops resolved their hydrops after betamethasone exposure.[239] In this series, three fetuses with mild-to-moderate hydrops treated at 21 to 26 weeks' gestation avoided further fetal interventions, were delivered at term, and survived. This observation led to subsequent studies comparing the use of steroids with open fetal surgery in fetuses with macrocystic CPAMs that demonstrated the effectiveness of steroids in not only halting further growth of a CPAM but also causing regression.[227,240] Since this discovery, steroids have become the first line of treatment in fetuses with large microcystic CPAM lesions.

Postnatal Management

In fetuses that do not develop hydrops, the overall prognosis is good and probably depends on the type of lesion and the presence of other anomalies. Generally, the prognosis of a type 1 CPAM is good, particularly if fetal intervention is not required. Following resection, there is usually resolution of any symptoms associated with the lesion (Fig. 44.10A–C). Type 2 CPAMs have a worse prognosis, because of the association with additional serious malformations (Fig. 44.10D–F). Type 3 CPAMs are thought



• **Fig. 44.10** Congenital pulmonary airway malformation. (A) Chest radiograph of an asymptomatic child with a prenatally diagnosed congenital pulmonary airway malformation (CPAM) in the left upper lobe (*arrow*). (B, C) Axial and coronal CT images demonstrate a single 3.1 × 2.7-cm cystic lesion in the left upper lobe consistent with a type 1 CPAM. The child underwent uncomplicated left upper lobectomy at 3 months of age. (D) Chest radiograph of an infant with a prenatally diagnosed CPAM that had rapid enlargement of the cystic component, resulting in mediastinal shift and acute respiratory compromise, is shown. (E, F) Axial and coronal CT images show a multicystic mass with cysts ranging from a few millimeters to 1.5 cm consistent with a type 2 CPAM. Patient was found to have a multicystic lesion confined to the left upper lobe with compressive atelectasis of the left lower lobe and underwent left upper lobectomy. (Courtesy Dr. Chirag V. Patel, UC Davis Health System, Sacramento, CA.)

to be uniformly lethal from their earliest descriptions and can be associated with lung hypoplasia.[208] For fetuses with large microcystic CPAMs, fetal resection, if indicated, may mitigate hypoplasia. However, case series have described substantial spontaneous regression of microcystic CPAMs, with an increased rate of in utero resolution compared with macrocystic lesions.[220] In a large series from a single referral center, neonatal survival was 98%.[238] Five infants underwent fetal procedures, with one death, and there were two neonatal deaths. At a different center, there was one postnatal death out of 75 births. Thirteen fetuses underwent fetal treatment including four open fetal resections, three thoracentesis, and six EXIT procedures.[241] Fig. 44.9 illustrates postnatal imaging with associated management of select infants.

Approximately 75% of newborns with a prenatally diagnosed CPAM are asymptomatic at birth.[242] The remainder may present with respiratory distress with or without pulmonary hypertension, which can be severe enough to require ECMO support.[225] The likelihood of respiratory distress is best predicted by a CVR of greater than 0.84, and the severity of the respiratory distress usually increases as the size of the CPAM increases.[243] For newborns with prenatally diagnosed CPAMs, lesions may be detected on chest radiograph, as solid masses, or fluid or air-filled cysts. Mediastinal shift, mass effect, or areas of air trapping due to airway obstruction may be appreciated. Some centers use ultrasound as an adjunctive modality in the neonatal period, but many surgeons prefer a CT scan as the definitive imaging study, which also can detect lesions that are no longer present on fetal ultrasound.[244] CT scans can also determine if there are multiple bronchopulmonary malformations, which may also require resection, and the use of intravenous contrast allows for definition of the vascular supply, helping to differentiate CPAMs from BPS. For asymptomatic newborns, surgeons will often defer this study until several months of age, because surgical resection is also deferred. However, there is some evidence that early elective surgical correction has similar outcomes as delayed operation, and can be recommended for patients with prenatal diagnosis.[245]

The usual surgical approach is lobectomy for the majority of lesions confined to a single lobe. More diffuse lesions might require bilobectomy or pneumonectomy. These surgical approaches are likely to result in the removal of normal lung but may also decrease the risk of air leak and infection after resection, and compensatory lung growth does occur after lobectomy.[246] Additional postoperative complications may include prolonged pleural effusion, pneumothorax, pneumonia, and wound infection.[247] The need for resection in asymptomatic newborns remains controversial, and there is no consensus on this topic.[248] Those who argue for watchful waiting cite the risks of surgery and anesthesia, the overtreatment of "nondisease," and a lack of evidence of the associated malignancy risk as factors for not resecting asymptomatic lesions. Those who argue for intervention say that resection prevents complications of disease, including the risk of malignancy, the psychological benefit of removing the lesion, and the improvement in lung volume after resection. Canadian Association of Pediatric Surgeons currently recommend elective resection of asymptomatic CPAM lesions as a level 3 evidence. Systemic review from the American Pediatric Surgical Association evidence-based practice committee provided level 4 evidence and grade D recommendations regarding observational strategy for CPAM and optimal timing for CPAM resection.[249] There remains widely varied recommendations for resection and management of asymptomatic lesions.

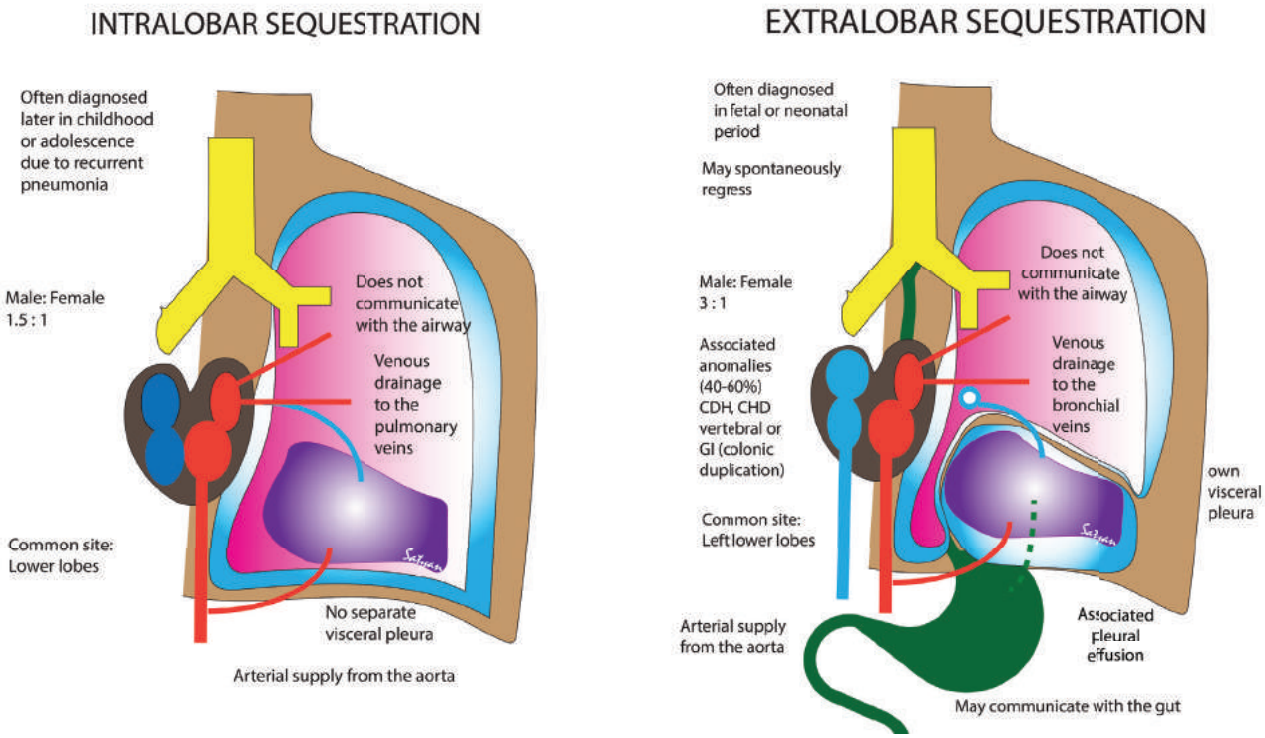
Generally, children who have undergone resection for CPAMs are healthy. Pulmonary function data demonstrate normal total lung capacity, forced vital capacity, forced expiratory volume or maximal work capacity, and no correlation between age at lobectomy and pulmonary function.[250] There are some reports of reactive airway disease and lower respiratory tract infection, and, in more severely affected children, chronic lung disease and pulmonary hypertension.[251] With these possible complications, poor tolerance for respiratory syncytial virus infection is expected in 6 to 12 months following resection; prophylaxis with palivizumab is recommended in first year of life.[252]

Bronchopulmonary Sequestration

BPS is a rare congenital malformation consisting of nonfunctional lung parenchyma that does not have a normal connection to the tracheobronchial tree. The lesions have a systemic arterial supply. Sequestrations are categorized into *extralobar* sequestrations, which are lesions that have their own pleural investment and systemic (80% of the time) venous drainage (and are therefore separate from the lung), and *intralobar* sequestrations, which are integral to the lung pleura and drain via the pulmonary venous system (Fig. 44.11). Intralobar lesions usually require lobectomy for removal because they are invested within the lung. The origin of an intralobar sequestration is somewhat controversial. Some experts believe it is not a congenital lung lesion but is rather always acquired after lung infection and injury, because inflammation, fibrosis, and cystic degeneration are its primary pathologic features.[253] In a large pathologic series, intralobar lesions account for ~75% of BPS and is usually diagnosed prior to 20 years of age with recurrent lower respiratory tract infection.[253] Others believe that intralobar sequestration can be congenital in origin but is relatively rare in that setting when compared to extrapulmonary sequestration.[208,254]

Extralobar sequestrations probably originate as an independent bud from the foregut that derives its blood supply from splanchnic vessels.[255] Usually the connection to the foregut is lost during development, although some lesions have persistent connections to the esophagus or the stomach (also referred to as bronchopulmonary foregut malformations). As accessory lobes, they occur within both the thorax and abdomen. Hybrid lesions with features of both a CPAM and a sequestration can occur.[256] Extralobar sequestrations are situated on the left side in 65% of cases, with the most common location between the lower lobe and the hemidiaphragm in approximately 75% of cases.[257] Extrapulmonary BPS can also occur in the abdomen, the neck, the mediastinum, and the diaphragm itself.[257] It has male predominance, and commonly occurs in association with other anomalies, including foregut duplication cysts, bronchogenic cysts, CPAMs, pericardial defects, and ectopic pancreas. In addition, approximately 5% of children with a CDH will have extralobar sequestration.[258] Histologically, these lesions appear as normal lung, except with dilated airway structures and, commonly, lymphangiectasia. A normal-appearing bronchus is present about 50% of the time. Associated pleural effusions are not uncommon and may be secondary to torsion of the vascular pedicle with resultant venous obstruction and elevated pressure or lymphatic abnormalities.[259]

Fetal diagnosis of intrathoracic BPS is suspected when there is an echogenic mass, which may also contain cysts. Depending on its size, the mass may be associated with some degree of mediastinal shift.[260] It can be difficult to distinguish BPS from a CPAM, but when a systemic arterial supply is identified, the diagnosis of BPS

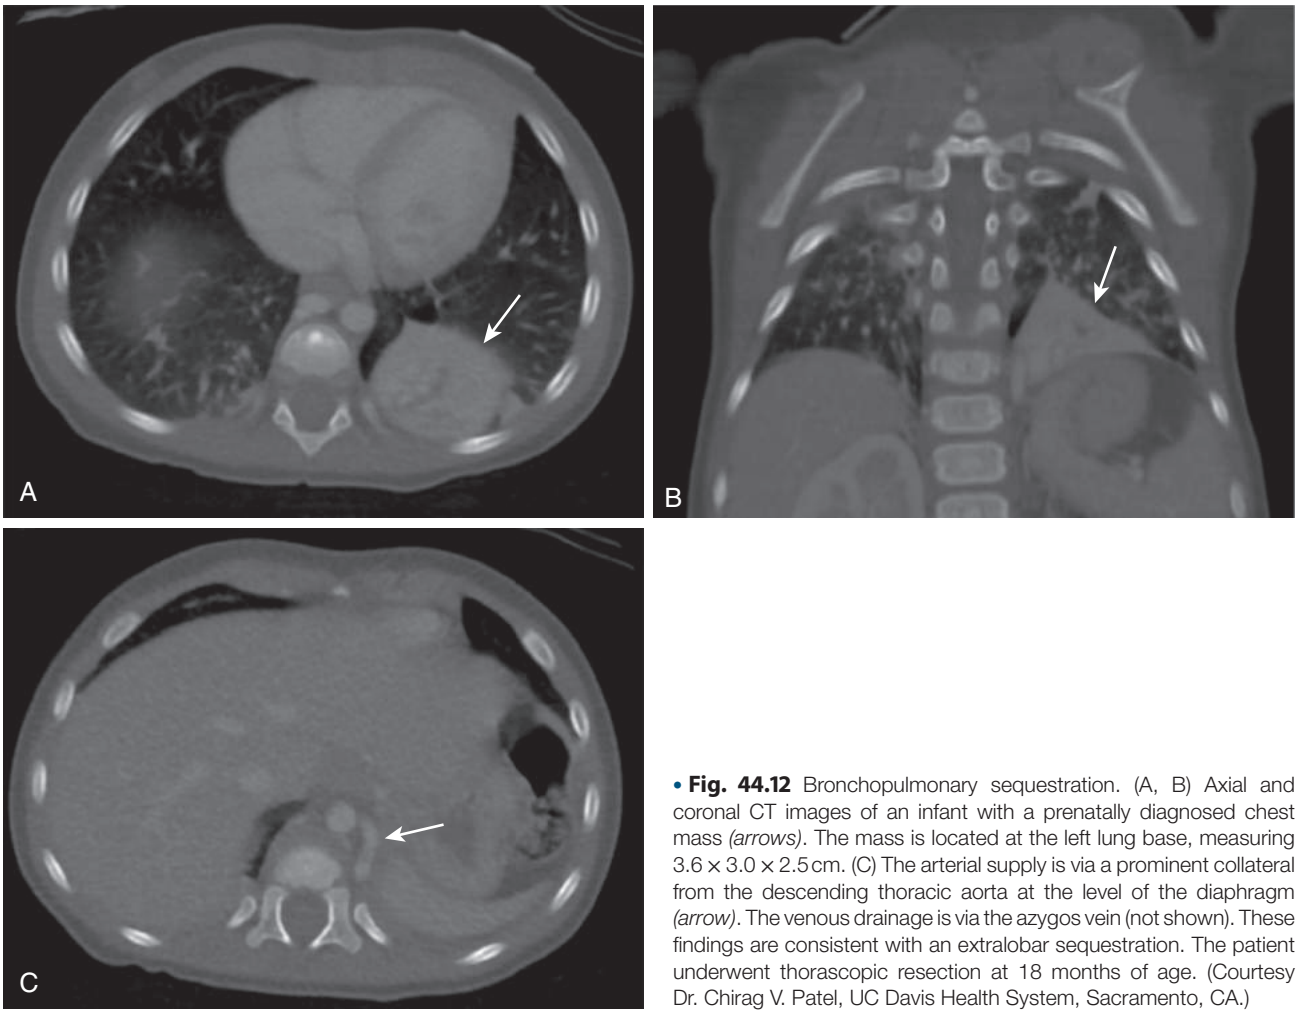


• **Fig. 44.11** Differences between intralobar and extralobar sequestration. Intralobar sequestrations are most common but less often present during neonatal period. Arterial and venous supply and relation with pleural reflection are shown. (Copyright Dr. Satyan Lakshminrusimha, UC Davis Health System, Sacramento, CA.)

is highly likely. If there is also an associated ipsilateral pleural effusion, the diagnosis is almost certainly BPS. If the diagnosis is still in doubt, fetal MRI can be used to help distinguish between the two.[260] Infradiaphragmatic masses also need to be distinguished from neuroblastoma, other tumors (such as lymphangioma), and adrenal hemorrhage.[261] As with CPAM, BPSs often regress spontaneously over time, and if there are no associated anomalies, the prognosis for the fetus is good.[252] Close ultrasound follow-up is prudent, however, until regression is documented. When pleural effusion occurs, there is a risk of development of tension hydrothorax. In these cases, repeated fetal thoracentesis or placement of a thoracoamniotic shunt can avert or resolve hydrops fetalis, which may improve the chances for survival.[236,259,262]

On postnatal imaging, BPS may be present as a radiographic density on plain film. The presence of linear or cystic lucencies within the radiopaque density suggests a persistent communication between an extralobar sequestration and the GI tract.[263] An upper GI study can demonstrate communication with the GI tract and is indicated for surgical planning if feeding difficulties are present. Ultrasound can also be useful in demonstrating the lesion (most easily seen if it is located at the lung base), and Doppler studies can identify a systemic feeding vessel and venous drainage. The use of contrast-enhanced CT provides the best visualization of the parenchymal abnormalities but has variable sensitivity for delineation of the vascular supply, although the lesion itself can often be demonstrated even when it has resolved by fetal imaging (Fig. 44.12A–C). Magnetic resonance with angiography can also be useful in demonstrating the lesion and its blood supply. Conventional angiography can identify the vasculature, but this has been replaced by the imaging modalities discussed above.

Symptomatic BPSs are usually identified in the first 6 months of life, with respiratory distress or feeding difficulties. Less commonly, recurrent infection, congestive heart failure (because of a high output state), or pulmonary hemorrhage is present. Distress at birth can be severe, particularly with large lesions complicated by a pleural effusion or hydrops fetalis. For neonates that present with symptoms in the first week of life, early resection is indicated.[252] Because the lesion is completely separate from lung, sequestrectomy is not a complex operation and can be done thoracoscopically. However, the feeding vessels can be very large in more severe cases and thoracotomy may be considered. The primary risk associated with an unresected BPS is recurrent infection, although this risk is not well quantified, as there are probably adults with persistent, small, asymptomatic lesions. Consequently, as with CPAM, there is controversy as to whether fetal lesions that are not identified on plain film should be further investigated in asymptomatic infants and, in general, whether asymptomatic lesions should be resected. However, since sequestrectomy can now be accomplished thoracoscopically with rapid recovery and short hospitalization, most lesions are surgically resected.[264] In addition, this approach may preserve rib architecture and limit later chest wall deformity.[265] Early resection may limit infectious complications associated with unresected lesions, because secondary changes such as emphysema might be averted. Some have attempted coil embolization of the feeding vessels with hope of complete or partial involution of the lesion.[266] However, coil embolization has also resulted in partial vascular occlusion and incomplete regression, transient lower limb ischemia due to distal migration of embolic material, sepsis, and other blood vessel complications.[267] Because of this, thoracoscopic resection is the current standard of care.



• **Fig. 44.12** Bronchopulmonary sequestration. (A, B) Axial and coronal CT images of an infant with a prenatally diagnosed chest mass *(arrows)*. The mass is located at the left lung base, measuring 3.6 × 3.0 × 2.5 cm. (C) The arterial supply is via a prominent collateral from the descending thoracic aorta at the level of the diaphragm *(arrow)*. The venous drainage is via the azygos vein (not shown). These findings are consistent with an extralobar sequestration. The patient underwent thoracoscopic resection at 18 months of age. (Courtesy Dr. Chirag V. Patel, UC Davis Health System, Sacramento, CA.)

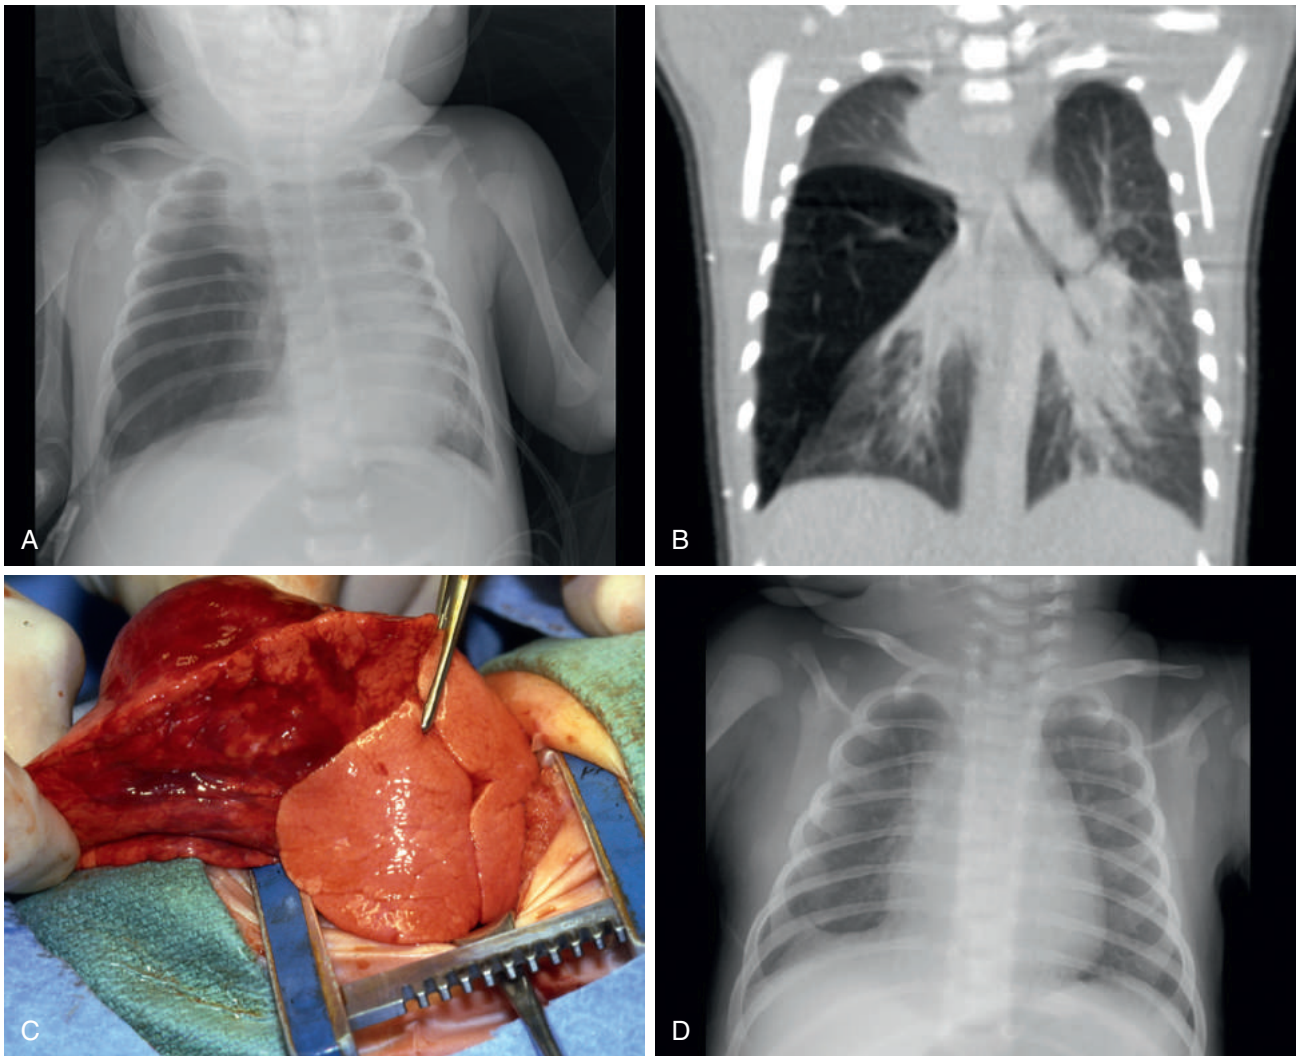
Other Cystic Lesions

Additional cystic lung lesions include CLE, PPB, and acquired cysts (pneumatoceles or emphysema, in association with infection or BPD, respectively). Extrapulmonary cystic lesions include foregut cysts (bronchogenic or enteric duplication cysts) and neuroenteric cysts, which are less common than the other lesions and usually present later in infancy or childhood.[144]

Congenital Lobar Emphysema

CLE occurs in 1 in 20,000 to 30,000 live births.[268] Because there is no evidence of lung destruction (true emphysematous changes), the common term CLE is a misnomer with this lesion, which is also known as *congenital lobar over inflation*.[144] CLE is thought to arise from an obstructed lobar bronchus, which can either be intrinsic (including malacia) or extrinsic in origin. While the cause varies, the fundamental mechanism is that air can pass into the affected bronchus but is unable to leave, causing air trapping and lobar overexpansion. The upper lobes are most commonly affected, with the left upper lobe the single most commonly affected lobe.[268] Lesions occupying multiple lobes are infrequent. Although the affected lobe is larger than usual, the number of alveoli in the involved area is within normal limits. The exception to this is the subset of these lesions with *polyalveolar lobe*, which was present in 27% of CLE in one series and has an overlapping clinical presentation with CLE.[268] In polyalveolosis, the total number of alveoli is increased severalfold from normal, but the conducting airways are normal in size and number. This form of lung hyperplasia is consistent with pathophysiology associated with fetal airway obstruction.[144]

CLE can be detected on fetal ultrasound, although it is difficult to make the correct diagnosis. Clinical reports have described the appearance of the lesion by ultrasound as cystic and/or echogenic, with mediastinal shift present, and subsequent regression with advancing gestation.[268] As expected, these lesions are suspected to be CPAM or BPS, based on these findings. Fetal MRI can be helpful in characterizing the lesion, although it is not diagnostic.[269] The postnatal clinical presentation and histology (after resection) distinguish CLE from the other lesions. The majority of children with CLE present with respiratory distress, cyanosis, or recurrent pulmonary infections in the first 6 months of life, up to 82% in one series.[270] The severity of symptoms depends on the size of the affected lobe, the compression of the surrounding tissue, and the extent of mediastinal shift. Chest radiographs demonstrate a hyperinflated lung (transitioning from fluid filled to air filled over the initial postnatal days), with compression of other areas of the lung and mediastinal shift (Fig. 44.13A). These findings are generally diagnostic. In children with less severe presentation, bronchoscopy or CT scan can be helpful in management decisions, because some surgeons will elect to manage



• **Fig. 44.13** Congenital lobar emphysema. (A) Chest radiograph showing significant hyperinflation of the right lung with mediastinal shift to the left. (B) Coronal chest CT image demonstrating hyperaeration of the right middle lobe consistent with congenital right-sided lobar emphysema. (C) Intraoperative photo showing the right middle lobe characteristically "popping out" of the thoracotomy incision prior to resection. (D) Chest radiograph 3 days after right middle lobe resection showing normalization of lung volume on the right with resolution of mediastinal shift. (A, B, and D, courtesy Dr. Chirag V. Patel, UC Davis Health System, Sacramento, CA; C, courtesy Dr. Clifford C. Marr, Sutter Medical Center, Sacramento, CA.)

these patients expectantly, with resolution of symptoms in some cases (Fig. 44.13B).[269] Thoracoscopic lobectomy is the mainstay of treatment.[271] After resection, prognosis is generally good, with compensatory lung growth present on the affected side (Fig. 44.13C and D).[272] Airway obstruction continues to be a feature of the disease on pulmonary function tests, although these findings could be consistent with either compensatory lung growth exceeding airway growth (dysanapsis) or intrinsic, diffuse airway abnormality.

Pleuropulmonary Blastoma

PPB is a rare but malignant lesion arising from the lung or the pleura. Lesions can be predominantly cystic (type I), mixed cystic and solid (type II), or predominantly solid type (III) and can occur in association with other congenital lung lesions. The average age of diagnosis of type I, II, and III PPBs is 8 months, 35 months, and 41 months, respectively, and overall survival of type I PPBs is 91%, while survival in type II and IIII patients is 71% and 53%, respectively.[273] The diagnosis and resection of this lesion are essential, because of the risk of metastasis, recurrence, and associated malignancies.[274] Although these lesions tend to present later in childhood than CPAMs, there is overlap in the timing of presentation, and PPB can be detected on fetal ultrasound; thus the consideration of this diagnosis in the perinatal period is relevant for counseling and surveillance, even if a newborn is not symptomatic.[274]

Symptomatic infants usually present with respiratory distress. Before resection, most lesions are thought to be CPAMs, based on their appearance on fetal ultrasound or postnatal CT scan. The treatment of choice for PPBs is surgical resection. Many studies have failed to show statistical benefit for chemotherapy in patients with type I lesion.[273,275] Type II and type III lesions should undergo both systemic chemotherapy and surgical resection, with unclear benefit for radiation therapy.[276,277] Resected lesions contain

cuboidal or columnar epithelial cells with underlying rhabdomyosarcoma cells (or other sarcomas). The malignant cells may not be widespread in the lesion, making the diagnosis of PPB challenging even by histology.[278] Because of the difficulty in distinguishing CPAMs from PPBs, careful histologic evaluation of prophylactically resected CPAMs is recommended, as those with stellate and spindle cells should be followed closely.[278] Furthermore, PPBs may require a more extensive resection than CPAMs, so this distinction is important in determining surgical approach as well.[213] PPB can be associated with a DICER1 gene mutation in 50% to 75% of instances, so genetic testing is necessary; DICER1 mutations can also be associated with cystic nephroma, ovarian tumors, and thyroid pathology.[276,277] In addition to DICER1, kindreds also demonstrated multiple malignancies, suggesting that familial surveillance for disease might be indicated.[276,277]

Postinfectious Pneumatoceles

Pneumatoceles are thin-walled, air-containing cystic structures resulting from alveolar and bronchiolar necrosis. In our experience, the most common infection associated with pneumatoceles in the newborn (maybe because of its higher frequency of infection) is *Staphylococcus aureus* pneumonia.[279] Other infections seen in the NICU that are associated with development of pneumatocele include pneumonia caused by *Klebsiella pneumoniae, Streptococcus pneumoniae, and Enterobacter*.[280] Pneumatoceles are often present on initial chest radiograph documenting the infiltrate, although they can also occur later in the process (Fig. 44.14). Given the thin wall, pneumatoceles can rupture, resulting in a pneumothorax that may be under tension or compress the lung tissue through mass effect, resulting in worsening respiratory status.[279,280] Acutely, urgent interventions may be needed to improve ventilation and oxygenation in the setting of rupture. Placement of chest drains into the pneumatoceles in the absence of rupture, either percutaneously or under direct visualization via VATS, can be considered; however, the majority of these cysts are regressive and resolve spontaneously.[279,280] For patients with chronic ventilator dependence, in particular former premature infants with BPD, resection of the affected lobe could be considered.

Hyperinflation and Emphysema in Chronic Lung Disease

Similar to postinfectious pneumatoceles, frank cysts or hyperinflated lung may develop in association with chronic lung disease of prematurity (like BPD) or with certain developmental lung abnormalities. This cystic hyperinflation can cause compression of more functional areas of the lung, with consequent respiratory compromise.[281] While this very severe chronic lung disease complication of prematurity rarely occurs today, affected infants can acutely decompensate or remain ventilator dependent despite maximal medical therapy. Evaluation of six infants with BPD and decompensated lobar hyperinflation in one series revealed extensive lobar bronchomalacia, with almost complete collapse of the affected airway through the expiratory phase or the entire respiratory cycle.[282] Lobectomy results in acute improvement, although ultimately only half of infants who are so treated survived.

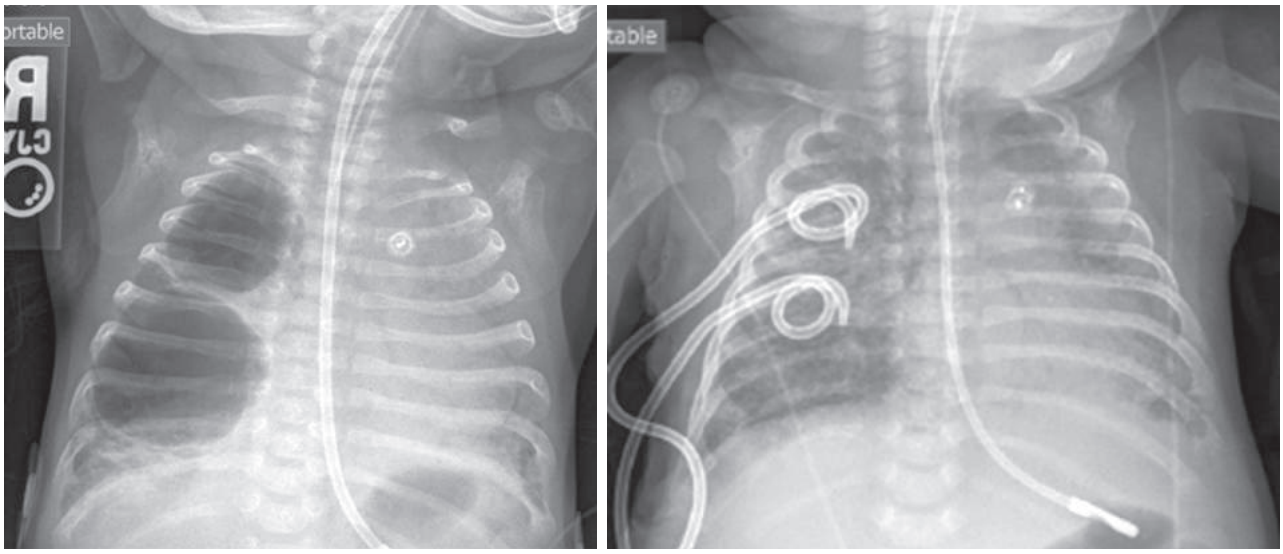
Miscellaneous Cysts

Lymphatic, lymphangiomatous, mesothelial, and parenchymal cysts can be detected in the thorax, so these lesions may need to be included in the differential diagnosis of cystic lesions.[144]

Disorders of the Diaphragm

Congenital Diaphragmatic Hernia

CDH is a disorder of pulmonary alveolar and vascular hypoplasia that results from failure of formation of the diaphragm.[283] This may be due to primary deficiency of the embryonic pleuroperitoneal fold, which is one of the critical primordial diaphragmatic structures that must fuse at 6 to 8 weeks' gestation to form an intact diaphragm.[284] Failure of this event results in herniation of abdominal contents into the hemithorax, and the subsequent



• **Fig. 44.14** Postinfectious pneumatoceles. Chest radiographs from a former preterm infant with pneumatoceles secondary to *Staphylococcus aureus* pneumonia. Cysts are compressing the lung and causing mediastinal shift *(left)*. Placement of draining thoracostomy tubes decompressed the cysts and decreased mediastinal shift, but the infant ultimately succumbed to respiratory failure secondary to bronchopulmonary dysplasia. arrest of preacinar airway branching at 10 to 14 weeks' gestation is consistent with this early developmental defect. Pulmonary hypoplasia is bilateral, although the lung ipsilateral to the hernia is most affected. Airway diameter is substantially decreased, but increase in airway muscle occurs as a later postnatal event.[285] Although acinar alveolar counts are normal, overall alveolar hypoplasia is present due to the branching defect (<10 million vs. 150 million alveoli in normal term births).[286]

Because of the interdependence of lung and vascular growth, both alveolar and capillary surface areas are decreased.[287] Vascular branching is impaired, with a decreased diameter of the vessels and increased muscle mass that is inversely related to the degree of lung hypoplasia.[287] Some morphometric reports have demonstrated abnormal distal extension of the muscular media to the intra-acinar arteries, whereas others have not demonstrated abnormal distal muscularization.[287,288] The mechanism of developmental lung and vascular hypoplasia is unknown but may include decreased static transthoracic pressure (secondary to open communication with the peritoneal cavity) and decreased phasic pressure alterations (secondary to impaired fetal breathing movements). Compensatory alveolar growth does occur in survivors, although it is more pronounced in the contralateral lung, and relative perfusion to the ipsilateral lung can be persistently diminished.[289,290] These findings are consistent with evidence of greater injury present in the more hypoplastic and vulnerable ipsilateral lung, compared with the contralateral lung in survivors of CDH, with consequent impairment of lung growth.[289]

Ninety-five percent of CDHs are posterolateral (Bochdalek) hernias.[284] The remaining 5% are either anterior, retrosternal, or peristernal (Morgagni). CDH is more common on the left side (75% to 80% of cases) than the right, probably because of slightly later fusion of the left-sided structures. Bilateral hernias account for 1% to 2% of cases (Fig. 44.15). Morgagni hernias are much less frequent in occurrence and usually are not associated with substantial lung hypoplasia, although they may be associated with pericardial, sternal, and abdominal wall defects as part of the pentalogy of Cantrell spectrum. There is a predominance of males to females in CDH (1.4 to 1.6:1 ratio), and the occurrence of CDH (including stillbirths) is about 1 in 4000 births.[284,291] Additional

anomalies occur in about 40% of affected infants and fetuses.[283,291] Musculoskeletal (including ribs, vertebrae, and digits) and cardiac anomalies are most common, although the patterns of malformation differ in association with right-sided CDH compared to left-sided CDH.[292] CDH can be associated with aneuploidy (most frequently trisomy 18), and it can present in autosomal recessive (e.g., Fryns syndrome), sex-linked (e.g., Simpson–Golabi–Behmel syndrome), and autosomal dominant (e.g., Cornelia de Lange syndrome) disorders.[292] With the exception of these disorders, recurrence rate is quoted at 1% to 2%, and more recent genetic studies have identified micro-deletions in affected infants through use of microarray technology.[284] It is unclear whether or not infants with isolated CDH (no other anomalies found by prenatal and postnatal investigation) are at increased risk for these minor chromosomal aberrations, because large-scale investigations have taken place with very limited positive findings. Single gene mutations have been identified in animal models and some humans as causal in CDH, and certain areas of the genome may be critical regions, wherein other causal genes might be found.[284,293]

In recent population-based studies, overall survival among liveborn affected infants ranged from 57% to 73%.[294,295] This is slightly improved from a 52% to 61% survival rate just a decade ago.[291,294] Those patients with left-sided diaphragmatic hernias fare better than those with right-sided hernias, with survival rates being 73% to 69%, respectively; however, this difference is not statistically significant. While the survival rate is similar, those patients with right-sided CDH have higher rates of pulmonary morbidity, including an increased need for tracheostomy, long-term vasodilatory therapy, and greater likelihood of requiring supplemental oxygen at the time of hospital discharge.[295] Survival of liveborn infants with isolated (no additional anomalies) CDH has been higher (63% to 77%) than survival in liveborn infants with other anomalies or chromosomal aberrations (19% to 43%).[291,296] Survival is low (<10%) in affected infants with chromosomal abnormalities, and there is a risk of intrauterine fetal demise in both isolated (2%) and non-isolated (11%) CDH. Although individual referral centers have reported survival rates ranging from 75% to 93%, there have been studies documenting a hidden mortality, demonstrating that a proportion of liveborn neonates die within hours of birth and before arrival at a surgical center.[297,298] In a study from Ontario, Canada, survival decreased from 67% to 58% for multicenter compared to population-based data, after accounting for infants who never reached a referral center.[298]

Both population-based and center-based studies have identified some risk factors for mortality for liveborn infants undergoing full resuscitative measures and ongoing neonatal care. All of these are probably related to the severity of the CDH, with respect to the degree of lung and vascular hypoplasia. For instance, prenatal diagnosis has been associated with increased mortality and may be due to the identification of more severe CDH (because mediastinal shift will be more pronounced and present earlier in gestation; see later discussion).[283,291,296] A multicenter, retrospective Children's Hospital Neonatal Database analysis of 677 children with CDH identified six variables independently associated with mortality and hospital length of stay greater than 109 days: infants that were small for gestational age, those with major birth anomalies, 5-minute Apgar scores less than or equal to 3, acidosis at the time of referral, those requiring ECMO, and those with bacteremia.[299] Other postnatal factors that are associated with increased mortality include prematurity (<37 weeks) and air leak, conditions associated with immature lung development, and/or increased risk for lung injury.[300]

Interestingly, two studies have shown somewhat conflicting data regarding the timing of term delivery and survival. For infants receiving ECMO support, late-term (40 to 41 weeks' gestation) infants had somewhat better survival compared with early-term (38 to 39 weeks' gestation) infants, although the relationship was not statistically significant, and fewer ECMO-related complications were seen in the late-term group.[301] However, overall survival was slightly better for early-term (37 to 38 weeks' gestation) versus late-term (39 to 41 weeks' gestation) infants in another study that included infants not receiving ECMO support.[301] However, among 928 infants born following spontaneous vaginal delivery in the US with isolated CDH, mortality was lowest at 40 weeks gestation.[302] Based on these results, we recommend delivery as close to the due date as possible in infants with CDH.

Other data show that infants not born at a tertiary center but subsequently transferred to a tertiary center have higher survival rates than those that are born at a tertiary center, which may reflect the hidden mortality associated with more severe, prenatally diagnosed CDH.[303,304] For those infants who do undergo surgical repair, the need for a prosthetic patch is associated with subsequent mortality, indicating a larger diaphragmatic defect and probably more severe lung hypoplasia.[283]

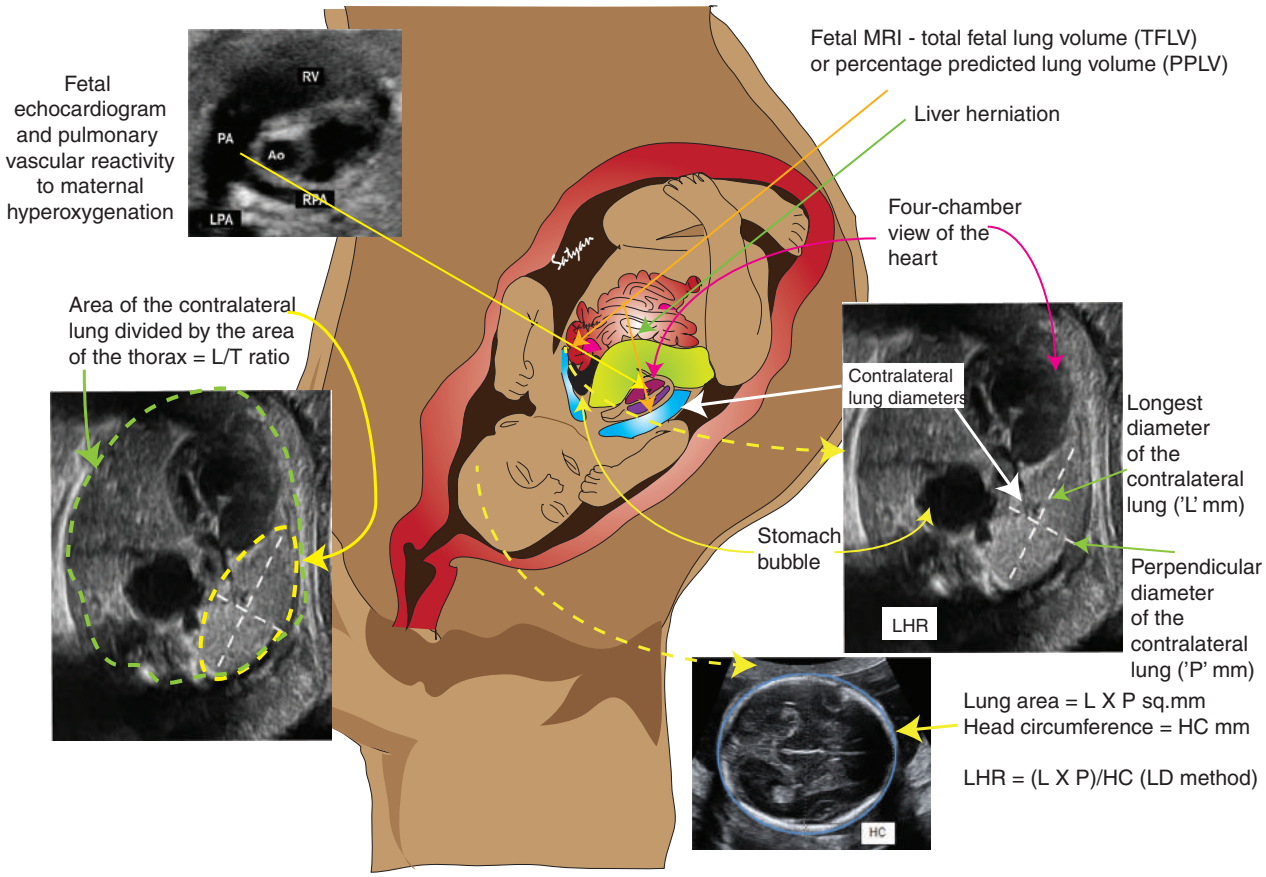
Prenatal Diagnosis and Management

CDH is usually suspected on prenatal ultrasound when mediastinal shift away from the side of the hernia is appreciated. Prenatal detection rates are higher with left-sided than right-sided hernias, and bilateral hernias can be difficult to discern because of the distorted anatomy. CDH in fetuses with additional anomalies are also detected at a higher rate than CDH in isolated cases.[291] Fetal MRI can be helpful in determining the diagnosis, if the anatomy is difficult to identify. A prenatal diagnosis of CDH mandates careful evaluation for other anomalies, including a fetal echocardiogram, because of the high rate of additional anomalies and their association with lower survival rates. Some of this evaluation may be limited by the anatomic distortion caused by the hernia. A karyotype and other genetic analysis (as indicated) are also recommended. Additional prognostic information regarding the severity of the hernia can be gathered during prenatal evaluation by ultrasound and MRI, although the prognostic ability of these measures is likely center dependent, as survival varies to some extent across centers. One useful discriminator of CDH severity is herniation of the liver into the hemithorax.[283,300] Liver herniation can occur with both right-sided and left-sided CDH. In left CDH, the left lobe of the liver herniates in the thorax; thus, the course of the hepatic vasculature is distorted and indicative of liver herniation. Herniation of the liver is also predictive, with one study showing a significantly higher survival rate in fetuses without liver herniation (74%) versus those with herniation (45%).[305] Further research looking at the predictive nature of prenatal ultrasound in the assessment of liver herniation has demonstrated that sonographic measurements (liver-to-thorax ratio and stomach position) are predictive of survival outcomes in those with isolated left-sided CDH.[306] The prenatal liver-to-thorax ratio can also be predictive of the need for ECMO.

Other prenatal discriminators of severity that have been used include stomach herniation and polyhydramnios (a later finding, secondary to gastrointestinal obstruction or esophageal dysmotility). Several measures have been developed as intrauterine estimate of lung size (Fig. 44.16) The lung-to-head ratio (LHR) is widely used for this purpose.[307] It is the perpendicular area of the lung contralateral to the hernia at the level of the cardiac atria divided by the biparietal diameter. It has been used predominantly in mid-gestation (22 to 27 weeks' gestation), with an LHR $\leq$ 1.0 combined with liver herniation accepted as the most severe group of CDH. LHR has been studied in left CDH, although it has also been extrapolated to right CDH and probably has prognostic ability; LHR thresholds for severity could be lower in right CDH, since the normal right lung is larger than the left lung.[308] Investigators have developed nomograms for normal LHR over 12 to 32 weeks, which has led to an observed-to-expected (O/E) LHR measurement, employing the mean LHR at any gestational age as the "expected LHR," which increases with advancing gestational age because of a more rapid increase in lung area compared with head circumference.[309] It follows that the LHR $\leq$ 1.0 will represent a higher O/E LHR earlier in gestation than it does later in gestation, and the O/E LHR will be higher with right CDH than left CDH for a given LHR and gestational age.[310] In a large database of 354 fetuses with isolated CDH (including 25 fetuses with right CDH), the O/E LHR was predictive of survival, independent of liver herniation.[311] Subsequent analyses of this data have stratified fetuses with and without liver herniation, because survival does differ between these groups for a given O/E LHR range.[309] In these analyses, survival was less than 20% for fetuses with isolated left CDH and O/E LHR less than or equal to 25%. Fetuses with a higher O/E LHR of 26% to 35% survived in greater numbers: 30% if liver was herniated and almost 60% if liver was not herniated. The lower bound of the 95% confidence interval for O/E LHR in unaffected fetuses is 60%.[311] Decreasing O/E LHR was also related to increasing time on assisted ventilation, prolonged hospitalization, and an increased risk for prosthetic patch repair.[310] In the recently concluded trial of fetal endoluminal tracheal occlusion (FETO), stratification was performed using O/E LHR and these measurements correlated well with survival to discharge, 6-month survival, and 6-month survival without oxygen supplementation.[312]

Fetal MRI techniques have also been pursued for prognostic information in CDH. Liver herniation can be determined by fetal MRI, and at some centers it is the preferred technique for this determination. A number of different nomograms to determine lung volume as a percent of normal (based on estimated fetal size or gestational age) have been developed. Büsing et al. evaluated seven published nomograms for estimation of relative fetal lung volume in 68 fetuses with isolated left CDH evaluated at their center.[313] They generated receiver operating characteristic curves for each of the seven equations and found high (0.800 to 0.900) area under the curve (AUC) for prediction of survival, regardless of technique used. In this dataset, prediction of need for ECMO was not as strong (AUC 0.653 to 0.739), although individual centers have found that relative fetal lung volume is a very useful predictor of the need for subsequent ECMO support.[314]

Early attempts at fetal intervention for CDH focused on an anatomic repair of the diaphragmatic defect; however, this approach was quickly abandoned after survival outcomes did not improve.[315] Fetal intervention has since shifted its focus to enhancing intrauterine lung growth via endoscopic temporary balloon tracheal occlusion. Only fetuses likely to be the most severely affected newborns are candidates if additional anomalies are not found after careful investigation. A randomized controlled trial evaluating this technique was terminated prematurely because of unexpectedly high survival in the control group, with no difference in survival between tracheal occlusion and standard care infants.[315] The tracheal occlusion procedure was complicated



• **Fig. 44.16** Antenatal diagnosis and assessment of lung volume of congenital diaphragmatic hernia (CDH). Lung volume can be assessed by ultrasound by estimating lung to thoracic (L/T) ratio and lung area-to-head circumference ratio (LHR) and observed to expected LHR (O/E LHR). Fetal MRI can be used to estimate total fetal lung volume (FTLV) or percentage predicted lung volume (PPLV). (Modified from Chandrasekharan PK, Rawat M, Madappa R, et al. Congenital diaphragmatic hernia —a review. *Matern Health Neonatol Perinatol*. 2017;3:6; copyright Dr. Satyan Lakshminrusimha, UC Davis Health System, Sacramento, CA.)

by premature delivery (mean gestational age 30.8 weeks), often stemming from premature rupture of the membranes, and this may have compromised survival in the intervention group. With development of smaller instruments, this technique can now be accomplished as a fully endoscopic procedure, and the incorporation of a second procedure to remove the tracheal balloon (i.e., plug–unplug) has also decreased the need for delivery by EXIT procedure, allowing for vaginal delivery in the majority of cases.[315] The European FETO task group has been performing minimally invasive tracheal occlusion in fetuses with LHR less than or equal to 1.0 with promising results demonstrating an improved survival to discharge and a later mean gestational age at the time of delivery (33.5 weeks).[316] This was attributed to the less invasive nature of the procedure. With operator experience, the procedure has been accomplished more rapidly, and shorter procedures were associated with lower rates of premature membrane rupture. Elective prenatal removal of the intratracheal balloon (i.e., unplug) was accomplished at a median of 34 weeks in 70% of the cases. Survival to neonatal discharge was 47% (98 of 210); 6 deaths were fetal and 10 deaths occurred secondary to difficulty with removal of the intratracheal balloon. From their historical experience, the investigators cite an expected survival of only 24%. In a subset of these fetuses, and some expectantly managed with CDH, Cannie et al. evaluated changes in relative lung volume over gestation by fetal MRI.[317] They found that relative lung volume was largely unchanged in fetuses without intervention, and it tended to increase more consistently in fetuses with CDH when tracheal occlusion was undertaken at greater than or equal to 29 weeks' gestation ($n = 8$). Most recently, a small randomized controlled trial comparing FETO to standard postnatal management found that 50% of fetuses treated with tracheal occlusion survived to 6 months of life compared with 4.8% in the postnatal treatment group.[318]

Two recent trials published in 2021 by Deprest et al. evaluated infants with isolated left CDH with moderate (O/E LHR of 25% to 34.9% or 35% to 44.9% with intrathoracic liver)[319] or severe lung hypoplasia (O/E LHR < 25%) (Fig. 44.17).[312] Infants with moderate hypoplasia underwent FETO intervention at 30 to 31 6/7 weeks' gestation followed by removal of the balloon at 34 weeks. Gestational age at birth was lower with FETO and survival to NICU discharge and 6-month survival were not statistically significant. The FETO intervention in left CDH with severe pulmonary hypoplasia was performed at 27 to 29 6/7 weeks' gestation followed by balloon removal at 34 weeks. 40% of intervention cases delivered prior to 34 weeks' gestation (vs. 0% in control arm). However, there was a significant increase in survival to NICU discharge, 6-month survival, and 6-month survival without supplemental oxygen.

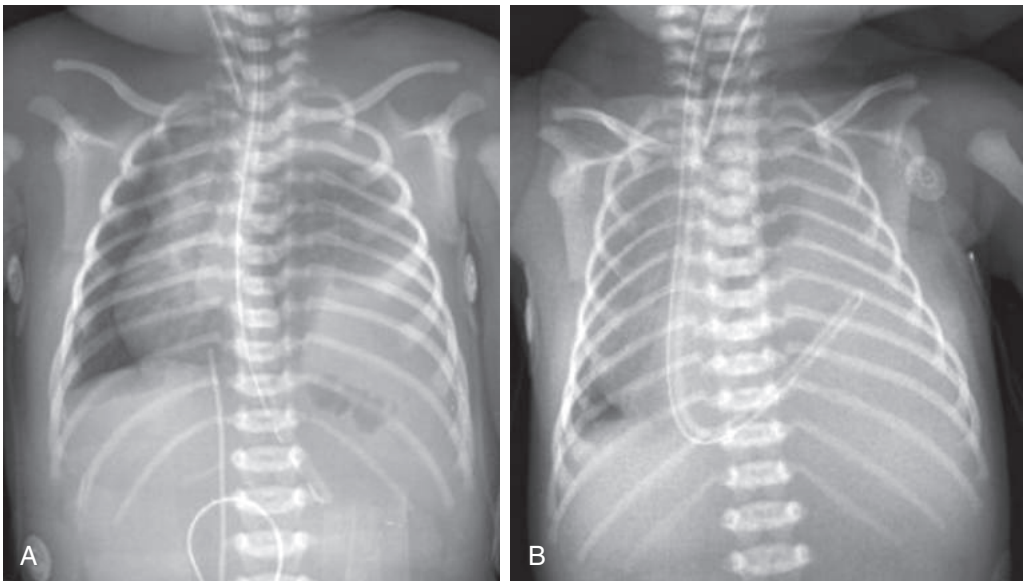
Postnatal Diagnosis and Management

Most newborns with CDH will present immediately or within several hours of birth with respiratory distress, cyanosis, decreased breath sounds on the hernia side, and a scaphoid abdomen. An occasional infant will not have symptoms until several days or months of age and often will have feeding intolerance and mild respiratory distress.[300] An initial chest radiograph will show a smaller lung on the hernia side, with bowel gas in the chest and shift of mediastinal structures (Fig. 44.18A,B). The findings of a small lung, with no mediastinal shift and usually without concern for herniated bowel, should raise suspicion for other diagnoses, which may require an alternate surgical approach or may not require surgery at all (see later discussion).

Delivery Room Management: Newborns with a fetal diagnosis of CDH require a resuscitation team capable of intubation and low umbilical venous line placement along with a respiratory therapist at delivery (Fig. 44.19). A discussion with the obstetric team regarding optimal cord management is important prior to delivery. Delayed cord clamping is feasible in CDH and has been associated with some physiological benefits in animal models.[320,321] However, clinical trials are needed before this is implemented in wide practice. Mask ventilation should be avoided to prevent additional air entering the stomach. Most infants with CDH and respiratory distress need endotracheal intubation and mechanical ventilation, and a Replogle (Covidien—Medtronic, Minneapolis MN) orogastric tube for continuous gastric suction to minimize accumulation of thoracic intraintestinal air and reduce lung compression. The optimal initial oxygen concentration for resuscitation of an infant with CDH in the delivery room is not known. However, routine use of 100% oxygen is probably not needed and use of ~21 to 50% oxygen[322] and titrating to target preductal oxygen saturation as recommended by the neonatal resuscitation recommendations may be adequate.[323]

Hypoplastic lungs with small alveoli have poor compliance, and thus ventilation is severely reduced.[324] Combined with the restrictive pulmonary vascular bed and consequent pulmonary hypertension, this leads to severely impaired oxygenation. Because these physiologic challenges cannot be overcome without lung growth, most high-volume centers use a gentle ventilation strategy. This strategy attempts to achieve adequate oxygen delivery and preserve the potential for lung growth while minimizing oxygen toxicity and ventilator-induced lung injury (barotrauma and volutrauma). Actual targets for ventilation and oxygenation vary somewhat, but consistency in care within a center is important.[325] The ventilation target is often an arterial partial pressure of carbon dioxide ($PaCO_2$) of 50 to 65 mmHg (permissive hypercapnia). For oxygenation, a more liberal strategy allows for a preductal (right upper extremity) and post-ductal (descending aorta or lower extremity) arterial saturation (SaO_2) differential, with oxygenation targets based on preductal oxygen saturation ($SpO_{2)}$ (permissive oxygenation). Oxygenation targets are generally preductal SpO_2 between 85% and 95% for infants on supplemental oxygen. Ventilator pressures are limited, with either positive inflation pressure (PIP) targeted at less than or equal to 25 to 28 cmH_2O or mean airway pressure on high-frequency ventilation at less than or equal to 15 cmH_2O. Aggressive weaning strategies are used to achieve gentle ventilation goals and to minimize lung injury. Lung recruitment with surfactant and high PEEP or mean airway pressure are not effective strategies to achieve persistent improvements

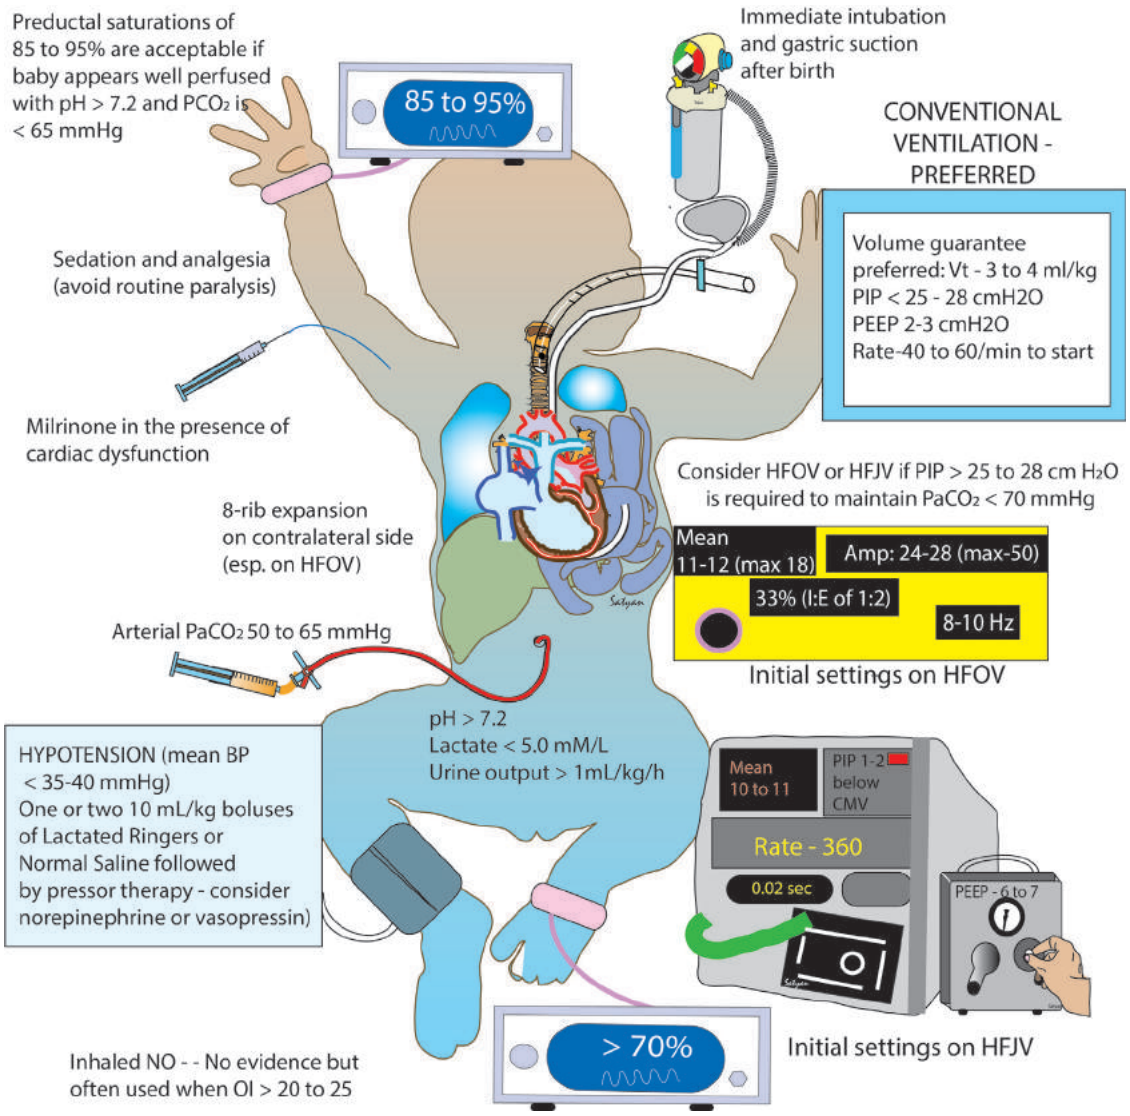


• **Fig. 44.18** Left congenital diaphragmatic hernia. (A) Radiograph of an infant with congenital diaphragmatic hernia (CDH) without liver or stomach herniated into thorax. He subsequently underwent primary repair of the diaphragmatic defect, was extubated within several days of surgery, and was discharged to home without supplemental oxygen. (B) Radiograph of an infant with severe CDH with liver and stomach herniated into thorax. He subsequently required extracorporeal membrane oxygenation (ECMO) support, underwent prosthetic patch repair for diaphragmatic aplasia, and succumbed to respiratory failure and pulmonary hypertension after decannulation from ECMO support. (Copyright Dr. Satyan Lakshminrusimha, UC Davis Health System, Sacramento, CA.)

in oxygenation in CDH, and increases in PIP to achieve transient improvements in oxygenation lead to further increases in ventilator support, with worsening compliance because of lung injury and edema.[325] There are also some centers that advocate low PEEP and high ventilator rates (which are physiologic in lung hypoplasia). With high ventilator rates, gas trapping and auto-PEEP may be an important factor, so limitation of the PEEP set on the ventilator is important.[304] In addition, low PEEP (2 to 3 cmH_2O) is associated with higher lung compliance in infants with CDH than PEEP of 4 to 6 cmH_2O.[326] Routine use of high-frequency oscillatory ventilation (HFOV) with relatively high mean airway pressure for infants with CDH did not result in any improvement in outcomes compared to conventional ventilation in a randomized controlled trial.[327] However, to this day there are no trials evaluating low mean airway pressure strategy on HFOV or other modalities of high-frequency ventilation such as jet ventilation.

Employment of gentle ventilation strategies has been associated with improved survival at individual centers;[325] however, regardless of actual targets for ventilation and oxygenation and preferential mode of ventilation, it is likely that other aspects of care, such as infant stimulation and positioning and sedation and feeding practices, affect survival and other outcomes. Although there are a number of ancillary treatments employed in infants with CDH (prenatal glucocorticoids, surfactant replacement therapy, inhaled nitric oxide, and other pulmonary vasodilator therapies), there are no studies documenting broad efficacy of these treatments in term infants with CDH. In fact, in one randomized trial, the use of inhaled nitric oxide was associated with higher ECMO use compared to placebo in CDH.[328] In addition, the use of prostaglandin infusion to maintain ductal patency and improve right heart function in cases of prolonged pulmonary hypertension has been advocated.[325] Two randomized trials to evaluate milrinone/placebo and inhaled nitric oxide/sildenafil in CDH are currently recruiting subjects.[329,330] The one ancillary treatment that has shown benefit is the use of ECMO, which improved survival to hospital discharge in the United Kingdom Collaborative study, although the effect dissipated at follow-up with later deaths among initial survivors.[331]

ECMO can be used to rescue newborns with CDH, particularly those with lung injury evident by pneumothorax, and it may be used in the setting of gentle ventilation (where pneumothorax is a less frequent occurrence), to avoid prolonged high ventilator pressures or fraction of inspired oxygen (FiO_2).[332] Both veno-venous (VV-ECMO) and veno-arterial (VA-ECMO) approaches have been utilized in infants with CDH. Although CDH has become the most common indication for neonatal ECMO (other than cardiac defects), its efficacy is difficult to assess given the absence of clinical trials. Among infants eligible for ECMO (birth weight > 1.8 kg, gestational age > 32 weeks without major cardiac or chromosomal abnormality), approximately 29% of patients with CDH need ECMO. However, those with CDH who go onto ECMO have a 40% to 50% survival rate based on observational data.[300] Because ECMO is a temporary therapy designed to allow for resolution of a reversible process, it is unlikely that all infants with CDH will benefit from ECMO support; some will have lethal pulmonary hypoplasia. Thibeault and Haney described persistent pulmonary hypertensive changes in vessels of infants with CDH dying after ECMO support, and others have described recurrent pulmonary hypertension.[333,334] The results of ECMO in CDH greatly depend on patient selection criteria, which varies widely among institutions. The primary indication for ECMO should be failure of conventional therapy. This failure can be characterized by persistent preductal SpO_2 less than or equal to low 80 s, hypotension resistant to fluid/inotropic support, peak inspiratory pressures less than 30 cmH_2O, or worsening metabolic acidosis.[332]



• **Fig. 44.19** Management guidelines for congenital diaphragmatic hernia following admission to the NICU. *HFOV*, high-frequency oscillatory ventilation; *Vt*, tidal volume; *PIP*, peak inflation pressure; *PEEP*, peak end expiratory pressure; *HFJV*, high-frequency jet ventilation; *$PaCO_2$*, arterial partial pressure of carbon dioxide; *NO*, nitric oxide; *PPHN*, persistent pulmonary hypertension of the newborn; *OI*, oxygenation index = mean airway pressure in cmH_2O X oxygen concentration as % ÷ PaO_2 in mmHg). (Modified from Chandrasekharan PK, Rawat M, Madappa R, et al. Congenital diaphragmatic hernia —a review. *Matern Health Neonatol Perinatol*. 2017;3:6; copyright Dr. Satyan Lakshminrusimha, UC Davis Health System, Sacramento, CA.)

Survival following ECMO is also related to degree of pulmonary hypoplasia as reflected by the lowest $PaCO_2$ in the first 24 hours after birth.[335] If the lowest $PaCO_2$ during the first 24 hours is > 70 to 80 mmHg, mortality is higher. For those who do go on ECMO, a duration of ECMO support greater than 2 weeks and the use of renal replacement therapy for renal insufficiency have been identified as independent predictors of mortality. Survival among both of these groups was approximately 20% (2 of 11 for prolonged ECMO and 4 of 18 for renal insufficiency).[336] Longer ECMO runs, renal complications, and multiple complications were also independently associated with mortality in infants with CDH in an analysis from the Extracorporeal Life Support Organization database.[337] Thus, failure to decannulate an infant at less than 10 to 14 days of support is probably an indicator of severe lung and vascular hypoplasia. In these severely affected infants, it often takes longer than 4 weeks to resolve pulmonary hypertension, and therefore awaiting resolution of pulmonary hypertension in these cases before decannulation would require prolonged ECMO support.[251] Prolonged ECMO runs are prone to mechanical complications, which may further prolong the ECMO run or be irrecoverable. Thus, it is unclear to what degree prolonging ECMO support could increase survival in CDH, unless there is still evidence of reversibility in the infant's condition. In the case of availability of a specific therapy, such as perfluorocarbon partial liquid ventilation, wherein lung growth might be induced, the benefits of continuing ECMO support might become evident.[338] This therapy, however, is still controversial, with recent clinical studies showing that perfluorocarbon ventilation does not improve pulmonary vascular remodeling and CDH-associated pulmonary hypertension.[338] Otherwise, strategies to limit the duration of ECMO support in CDH could be employed, accepting ventilator settings at decannulation that are significantly higher than what might otherwise be acceptable for newborns coming off ECMO support. These strategies could include prevention of complete lung collapse with

aggressive pulmonary toilet, because re-recruitment of lung volume can be difficult in these infants (which may be related to small-caliber airways that have been damaged by pre-ECMO support regimens). Also, for infants cannulated pre-repair, performance of the CDH repair post-ECMO decannulation could further limit time on ECMO support. Surgical repair of the diaphragmatic defect while on ECMO is associated with higher mortality, even after adjusting for other markers of CDH severity.[339] This phenomenon may be related to hematologic complications from the repair (which are independently associated with decreased survival).[337] However, some centers advocate CDH repair as soon as possible after stabilization on ECMO support. In addition, some centers utilize an "EXIT-to-ECMO" approach for fetuses with high-risk criteria based on fetal evaluation (low relative lung volume).[340] These fetuses are intubated and ventilated during an EXIT procedure. If they meet certain criteria for adequate gas exchange, they are delivered for conventional management. If they do not meet these criteria, they are cannulated and placed on ECMO support. Using this strategy, Kunisaki et al. reported a 71% (10 of 14) survival with 11 infants going directly to ECMO support and 7 of 11 surviving. Most infants required prolonged mechanical ventilation and hospitalization.[340]

Repair of the diaphragmatic defect usually occurs after some degree of stabilization of cardiopulmonary status, either with conventional therapy or ECMO support. Prior studies demonstrated that lung compliance improves before surgery after a short period (several days) of stabilization in infants with CDH, and that compliance worsens with early surgery in almost all infants.[341] Keller et al. studied infants with severe CDH (liver herniation and LHR < 1.4) and found that, although compliance did not improve before surgery after a period of stabilization, compliance did improve within 24 hours after surgery.[342] In low-risk infants that do not require ECMO, the Congenital Diaphragmatic Hernia Study Group found that the timing of surgery did not seem to affect survival and that those who underwent surgery at age 0 to 3 days, 4 to 7 days, or greater than 8 days had similar mortality rates when adjusted for known risk factors.[343] Thus, the rationale for delayed surgery is sound with respect to lung function, but specific clinical parameters to guide the timing of elective CDH repair remain unknown. Some centers advocate very delayed surgery, while awaiting complete resolution of pulmonary hypertension.[344] However, this approach can be problematic, because pulmonary hypertension may require weeks for resolution.[345] Subsequent failure to reduce the hernia contents is likely to delay establishment of enteral nutrition, with a consequent increased risk of infection and complications from parenteral nutrition. The achievement of even modest reduction in FiO_2 before surgery allows for a transient increase, if needed, after surgery, and even in cases where FiO_2 remains high, the modest improvement in lung function that occurs with surgery may help with further recovery for the infant in the most severe cases. Another issue with respect to timing of surgery arises when an infant also has congenital heart disease that requires neonatal surgery. Most centers will undertake CDH repair and then proceed to the cardiac surgery once the infant meets reasonable hemodynamic criteria for that surgical intervention.[346] In newborns who might require urgent cardiac surgery, survival is unlikely unless the lung hypoplasia and pulmonary hypertension are very mild. In a large series of 280 infants with CDH and congenital heart disease, overall survival was 41% but only 5% for infants with single ventricle physiology and 18% (2 of 11) for infants with total anomalous pulmonary venous return.[347]

Surgical repair of CDH involves reduction of the hernia contents and closure of the diaphragmatic defect. The surgical approach traditionally has been via laparotomy (subcostal incision on the side of the hernia), to abrogate the detrimental effect of thoracotomy on lung function. However, some surgeons will preferentially do a thoracotomy for a right CDH repair. With the advance in endoscopic technology, thoracoscopic and laparoscopic repairs are being performed in selected patients.[348] These patients include infants who have achieved low ventilator settings and FiO_2 before surgery. Despite both thoracoscopic and laparoscopic repairs being feasible, there are questions about the safety and efficacy of these approaches, with minimally invasive techniques being linked to higher rates of reoccurrence, as well as intraoperative acidosis and hypercapnia, particularly with thoracoscopic repair.[349] Additional randomized controlled trials are needed to determine the efficacy of minimally invasive repairs and to define the specific patient populations who are most appropriate for a minimally invasive repair.

Regardless of the surgical approach, when the diaphragmatic defect cannot be closed primarily, a prosthetic patch is used to bridge the gap. There is significant variability among surgeons in the need for patch repair, however. Clinical series have demonstrated that it is more common in the case of liver herniation and right-sided CDH (which may also be an association with herniated liver).[350,351] Patch repair can be accomplished with use of a polytetrafluoroethylene (PTFE/Gore-Tex, W.L Gore & Associates, Inc., Flagstaff, AZ) or a bioabsorbable intestinal mucosa (Surgisis, Cook Medical Inc., Bloomington, IN) material. Polypropylene (Marlex, Bard Davol, Warwick, RI) and other materials have been used sporadically.[348] Use of an abdominal silo and/or prosthesis to close the abdominal wall is sometimes necessary and may decrease the need for a prosthetic diaphragm.[348] Temporary abdominal closures with skin or vacuum-assisted closures have also been used, most commonly in children who are repaired while on ECMO.[352] Some surgeons advocate construction of a latissimus dorsi flap for initial CDH repair when primary closure of the diaphragmatic defect cannot be accomplished.[348] This technique allows for some potential for diaphragmatic function in the innervated flap, which usually remains abnormal at late follow-up even with primary repair.[348] However, the technique is time consuming and may not be tolerated in patients during the acute neonatal period, so others have reserved this technique only for hernia recurrence.[353] Generally, use of a prosthetic patch for diaphragmatic closure is associated with increased risk of hernia recurrence, although the actual risk varies widely and may be dependent on multiple factors, including surgical technique and the type of patch used.[354] Recurrent herniation may be associated with small bowel obstruction. It is also associated with persistent chest wall deformity, which might be due to the severity of the underlying disease or the complication of re-herniation (requiring multiple surgical procedures). Some surgeons have moved toward use of composite patches (more than one material), which may decrease the risk of recurrence by allowing for both durability and accommodation of rapid growth in infancy.[348]

Another area of variable practice is related to the intraoperative placement of a thoracostomy tube. Some of this controversy is related to the application of negative pressure, because that creates additional transpulmonary pressure and potential for barotrauma and lowers lung compliance.[326] However, negative pressure drainage is not necessary. Because the ipsilateral thorax will fill with fluid after reduction of the hernia contents as a result of the hypoplastic lung, placement of an anterior thoracostomy tube in a supine infant will prevent the accumulation of excess pleural fluid (which can occur with chylothorax). Chylous pleural effusion will cause respiratory compromise. However, it may be difficult

to ascertain the cause of this deterioration because mediastinal structures remain shifted for some period of time postoperatively and may be modestly more exaggerated with tension hydrothorax. Chylothorax is not uncommon after CDH repair. In a recent meta-analysis, patients with patch repair have 2.5 times higher risk of developing chylothorax.[355] Both surgical trauma and underlying hemodynamics due to right heart failure may contribute to the cause of this problem in infants with CDH (see Chylothorax earlier, for diagnosis and management).

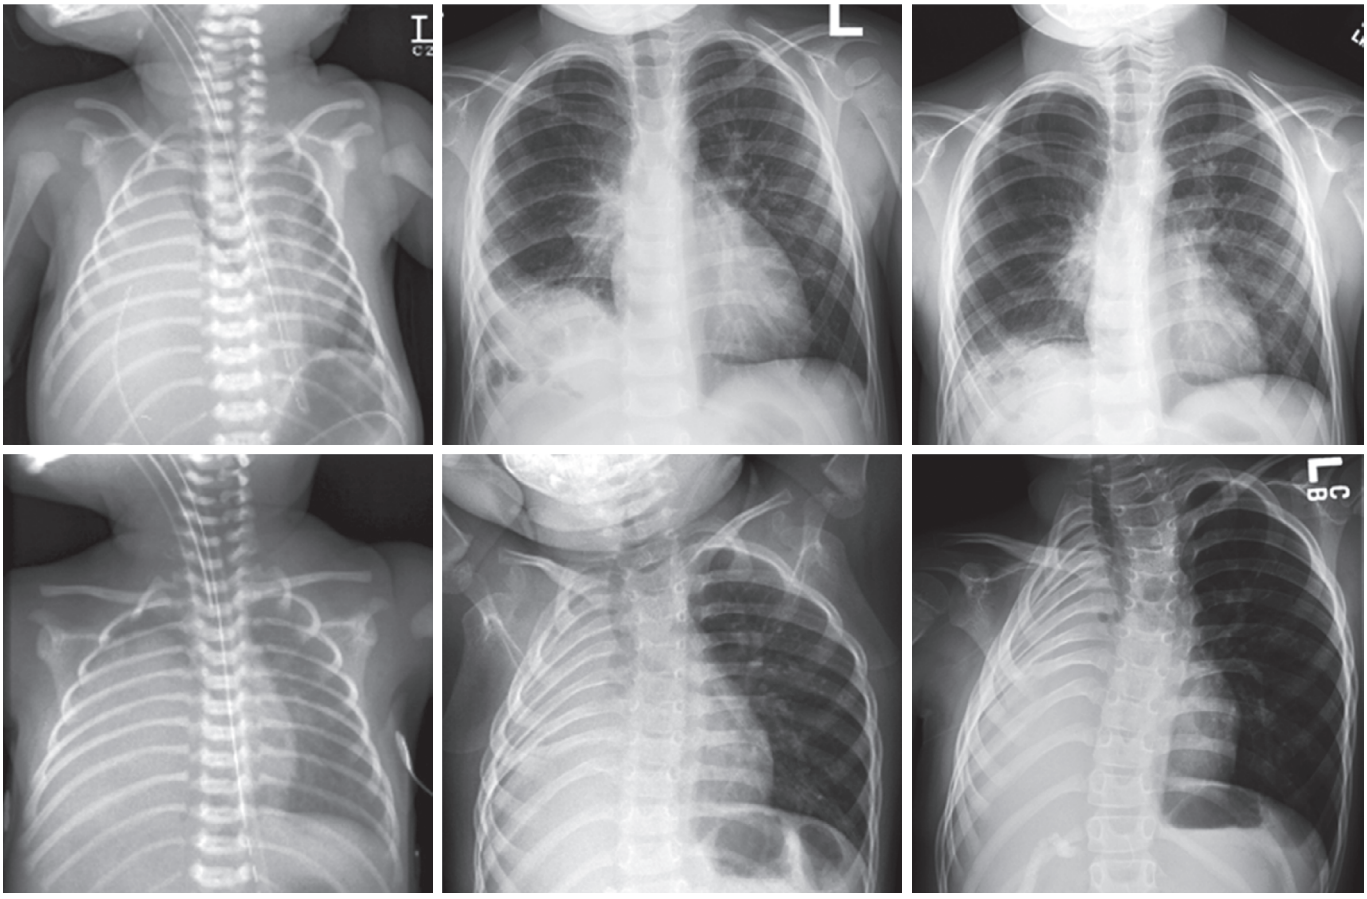
Long-Term Morbidity

Survivors of CDH have substantial pulmonary and gastrointestinal morbidity at follow-up.[354] Early gastroesophageal reflux following repair occurs in up to 40% of CDH patients and is more common in patients who undergo patch closure or have an intrathoracic stomach.[356] In addition, failure to thrive is common with many patients requiring supplemental enteral feedings via gastrostomy tube. Although low lung volumes and restrictive lung disease may be seen in the first months of life, obstructive lung disease is the most common finding in early childhood and at later follow-up.[357] Children requiring prosthetic patch repair and prolonged mechanical ventilation are most likely to have later morbidity, but the relative contribution of anatomic abnormalities, physiologic derangements, and secondary injury to these outcomes is unknown. Developmental delay and hearing loss also occur and require careful follow-up for early identification and intervention.[354]

Hepatopulmonary Fusion

Hepatopulmonary fusion probably represents a severe form of CDH. It has been described variably in the literature as both CDH and severe eventration.[358] All reported cases have occurred on the right side, although there is a report of a late-presenting left CDH with fusion of liver and lung tissue.[359] It is not clear if this is the same entity that other authors have described, because these infants usually present in extremis, with respiratory failure and pulmonary hypertension.[358,360]

The embryology of this defect is speculative, and the distinction between severe CDH versus eventration is probably not critical. However, the diaphragm is not intact, it is usually moderately to severely hypoplastic, and there is fusion of hepatic and pulmonary tissue without pleura or liver capsule present, no dissectable plane, and a fibrous membrane adherent to the liver and the lung.[361] In cases where hepatopulmonary fusion is determined or suspected, there is a lack of mediastinal shift, consistent with severe right lung hypoplasia rather than a mass effect from a large right CDH with herniated liver[362,363] (Fig. 44.20).



• **Fig. 44.20** Congenital diaphragmatic hernia and hepatopulmonary fusion. Chest radiographs in two infants with respiratory distress at admission to the intensive care nursery and at 3 and 5 years of age (*left to right*). *Top row*, Infant with right congenital diaphragmatic hernia with liver herniated into thorax and diaphragmatic aplasia. Note mediastinal shift into left hemithorax, with subsequent improvement in aeration and then normalization of right lung volume. *Bottom row*, Infant with hepatopulmonary fusion. Surgical repair required resection of hypoplastic nubbin of lung. Note lack of mediastinal shift at presentation, compensatory growth of left lung with trachea deviated to the right, and scoliosis.

The suspicion of this diagnosis is important because the surgical approach may differ. The need to separate the liver and the lung (usually requiring ligation or resection of part of the hypoplastic lung because of the risk of air leak and hemorrhage) will require a thoracotomy. MRI has been utilized preoperatively to help make this distinction and found enhanced lung tissue adherent and conforming to the dome of the liver in a case of hepatopulmonary fusion, suggestive of the anatomy subsequently encountered at the time of surgical repair.[362] The goal of surgery is to separate the thoracic and abdominal cavities, often requiring placement of a prosthetic patch. If these children survive, later growth of the right lung is much more restricted than it is in children with severe right CDH. Whether this is due to more pronounced ipsilateral lung hypoplasia, less pronounced contralateral lung hypoplasia, or the need for resection at the time of surgical repair is unclear. However, chest wall deformity and scoliosis are significant problems in these children.

Congenital Eventration of the Diaphragm

Congenital eventration of the diaphragm occurs when the hemidiaphragm is partially or completely replaced by fibroelastic tissue, leading to a thinned, pliable portion of the diaphragm. Unlike CDH, the diaphragm is intact with normal insertion points. However, it is elevated, and thus intra-abdominal organs are present in the thorax but still confined to below the diaphragm. It can therefore be difficult to distinguish eventration from a diaphragmatic hernia with a sac. In recent series, the right side was affected more often (~75% compared to ~25%), and bilateral eventration was very rare.[363,364] Overall, diaphragm eventration is rare, occurring in 0.02 to 0.07 out of 1000 births, and affects males in 60% to 80% of cases.[365] Approximately 18% of children with eventration have associated anomalies, with the most common being hypoplastic lungs, congenital heart disease, and pectus excavatum.[363] Eventration accounts for 5% to 7% of all diaphragm diseases.[365]

The peak age of diagnosis is 0 to 3 months, with a mean age of around 10 months.[363] With diaphragmatic eventration, assessment of hemidiaphragm movement is critical. In instances of paradoxical movement, the abnormally elevated diaphragm muscle can result in collapse of the affected alveoli and negatively affect lung ventilation and/or lung development.[364] In this instance, surgical repair may result in improved outcomes; when paradoxical motion is absent, repair may not be beneficial.[364] As many as 50% of children with congenital diaphragm eventration are without symptoms.[363]

The most common symptoms in infants < 12 months[363]:

- Rapid breathing
- Vomiting
- Difficulty breathing

The most common symptoms in children > 12 months[363]:

- Recurrent respiratory infections
- Chest tightness
- Cough or expectoration

Diagnosis is usually made by fluoroscopy of the chest, ultrasound of the diaphragm, or dynamic contrast-enhanced MRI. Small eventrations that are asymptomatic can be observed. Surgical intervention for symptomatic eventration involves plication of the diaphragm to eliminate the paradoxical movement, decrease lung compression, and strengthen the respiratory action of the respiratory muscles.[366] The diaphragm can be approached via the abdomen or chest using either open or laparoscopic/thoracoscopic techniques, with no difference in recurrence rates between the types.[365,367] Results are generally good, with severe lung hypoplasia being uncommon and surgery resulting in improvement in symptoms with low rates of recurrence. However, infants with associated conditions, particularly neuromuscular disorders, may not survive.

Diaphragmatic Paresis

Diaphragmatic paresis occurs most commonly secondary to vaginal birth trauma and is associated with phrenic nerve injury from ipsilateral brachial plexus palsy. While overall rare, the exact incidence is unknown.[368] As mentioned, it is associated with brachial plexus palsy, but of those patients who have brachial plexus palsy, only 2% of them develop phrenic nerve injury and diaphragm paresis. The most notable risk factors for diaphragm paresis secondary to birth trauma are macrosomia, shoulder dystocia, and breech presentation.[369] Diaphragm paresis has also been reported after surgical trauma, most commonly cardiac surgery.[368,370]

Paresis of the diaphragm leads to an elevated hemidiaphragm on chest radiograph and paradoxical movement evident by ultrasound or fluoroscopy (Fig. 44.21A,B). It generally presents as symptomatic respiratory distress, difficulty weaning from ventilator, and even respiratory insufficiency.[368,371] Phrenic nerve conduction studies may be used to make the definitive diagnosis.[369]

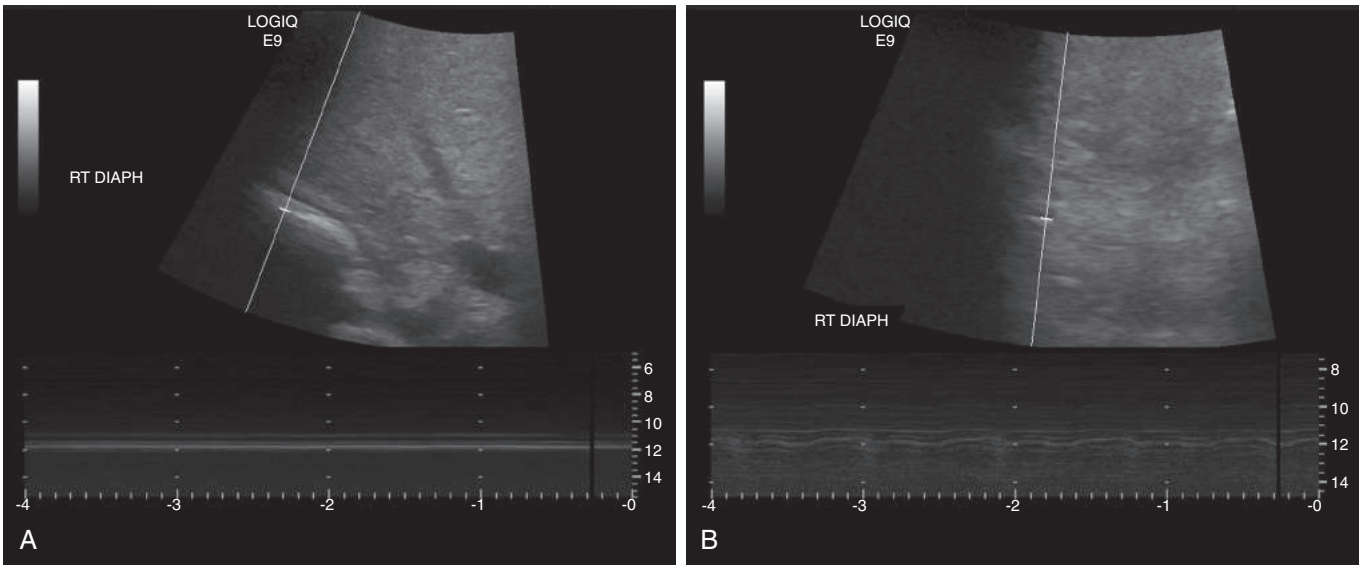
Management of diaphragmatic paresis secondary to phrenic nerve injury remains controversial. These injuries can recover on their own over time so a conservative approach using prolonged mechanical ventilation is an option.[368] Many observe a waiting period of 2 to 4 weeks to allow for possible improvement followed by diaphragmatic plication if persistently symptomatic.[372] Surgical repair entails diaphragmatic plication in an approach similar to that for diaphragm eventration. Repair may reduce need for mechanical ventilation and other modes of respiratory support. Plication of the diaphragm can be done via thoracic or abdominal approach and by open or minimally invasive techniques with the end result being fixation of the redundant folds of diaphragm tissue and an overall flattening of the diaphragm.

Neonatal Scimitar Syndrome

Scimitar syndrome is a rare constellation of cardiopulmonary anomalies, consisting of anomalous pulmonary venous drainage from the right lung to the inferior vena cava. Additional anomalies, including hypoplasia of the left heart or aorta, hypoplasia of the right lung, anomalous arterial supply to the right lung with or without pulmonary sequestration, pulmonary hypertension, dextroposition of the heart, and atrial septal defect (ASD), may also be detected.[373]

Scimitar syndrome may be suspected on fetal ultrasound, because of findings of cardiac dextroposition with a small right pulmonary artery.[374] The presentation of scimitar syndrome in the first days after birth is usually severe, with tachypnea, pulmonary hypertension, respiratory distress, and early heart failure.[375] Some infants will present later with failure to thrive. Chest radiograph reveals an elevated right hemidiaphragm with the mediastinum shifted to the right, consistent with primary lung hypoplasia. The classic finding of the scimitar vein is often not appreciated.

Surgical approaches are varied as they depend on the anatomic and pathologic features present in each specific case. Regarding pulmonary status, and because these infants have a normally developed diaphragm, the surgical approach will depend on hemodynamic effects of the anomalous venous return and the sequestration (if present). Thus, careful hemodynamic and vascular assessment are critical and may be accomplished through cardiac



• **Fig. 44.21** Diaphragmatic paresis. M mode ultrasound images of a newborn with tachypnea and moderate respiratory distress. (A) Absence of right diaphragmatic excursions is consistent with complete diaphragmatic paralysis. (B) Left diaphragm has low-amplitude excursions with normal inspiratory and expiratory motion. (Courtesy Dr. Chirag V. Patel, UC Davis Health System, Sacramento, CA.)

catheterization and angiography or, in some cases, by magnetic resonance angiography. The classic operation involves a long intra-atrial baffle being constructed from the entry point of the scimitar vein into the inferior vena cava to the left atrium through an ASD, which requires cardiopulmonary bypass. Pulmonary vein stenosis can complicate the hemodynamic status and this classic operative technique, and medical or surgical treatment for additional cardiac lesions may need to be addressed. Another technique involves anastomosing the scimitar vein directly to the left atrium through a right thoracotomy which avoids baffles, an extracorporeal circuit, and also addresses any stenosis present.[376] Some infants will require pneumonectomy, others ligation or coil embolization of systemic feeding vessels, and others no intervention because the hypoplastic lung may have very little blood flow.

Acknowledgments

The authors would like to acknowledge Dr. Benjamin A. Keller and Dr. Shinjiro Hirose for their writing of the 10th edition of this chapter.

45 Developmental Biology of the Heart

ELLEN DEES AND H. SCOTT BALDWIN

KEY POINTS

- The heart forms from cardiac mesoderm as a symmetric linear tube with connections to the primitive arterial and venous systems. The heart tube is formed by 3 weeks' gestation in the human.
- The heart tube loops, establishing laterality, and undergoes septation into four chambers with connections to the systemic and pulmonary arteries and veins. The heart is fully formed by 9 weeks' gestation.
- External populations of cells migrate into the developing heart, making important contributions to the cardiac valves, coronary arteries, and cardiac chambers.
- Congenital heart malformations arise when these processes are altered or incomplete.

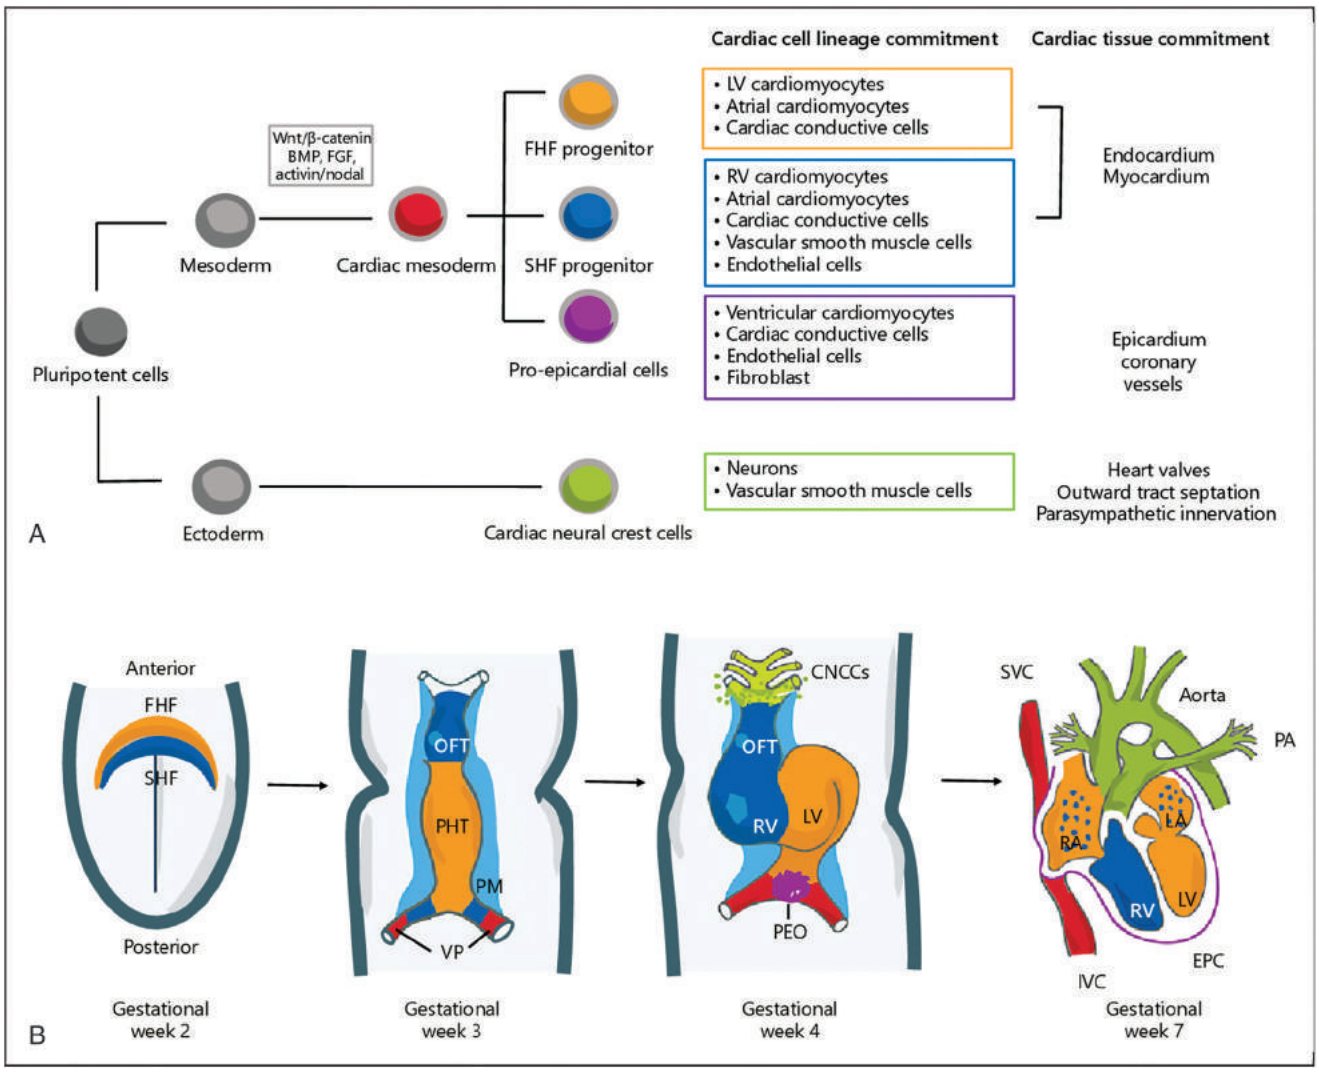
Overview of Cardiac Developmental Anatomy

This chapter is a review of embryonic and fetal cardiac anatomy, including the cell types that contribute to the developing heart, and genetic regulation of heart development. We will follow the heart from its stages as a linear tube with inflow and outflow segments, through cardiac looping and septation into a four-chambered heart with separate pulmonary and systemic circulations. Understanding these processes is of interest to clinical neonatologists caring for neonates and infants with normal and abnormal cardiac physiology.

Heart development begins at gastrulation as a field of cells; cardiac mesoderm (Fig. 45.1A) is specified and moves ventrally and midline within the embryo, fusing into a tube. This occurs in the human embryo by 3 weeks, post-fertilization, or approximately week 5 after the last menstrual period (Fig. 45.1B). At the posterior/dorsal end of the tube is the venous pole, or sinus venosus, connecting to the systemic and placental venous system. At the anterior/ventral end of the tube is the arterial pole, or outflow tract, which connects to the developing aorta. The heart tube itself is divided into an atrial segment, adjacent to the venous pole, and atrioventricular (AV) canal, and a ventricular segment adjacent to the arterial pole. Each of these segments is histologically and functionally distinct from the beginning—atrial and ventricular myocytes have distinct characteristics even when isolated from the primitive mesoderm. By the time the heart tube is formed, differentiating cardiomyocytes have generated functional contractile units mature enough to begin spontaneous contractions. These are initially peristaltic in nature, moving blood in one direction from the venous inlet to the arterial outlet. This is initially clear fluid, but red blood cells begin to enter the circulation from blood islands in the yolk sac soon after the heart starts to beat.[1] For the first 6 weeks, the yolk sac remains the exclusive source of hematopoietic cells, until the liver (and to a lesser extent spleen) takes over. The bone marrow gradually becomes populated with hematopoietic cells beginning in the second trimester of pregnancy, and by birth is the major source of blood cells.[1] Development of a circulatory system early is critical to maintaining nutrition and oxygen delivery to developing tissues, which are at this point beyond the ability to depend on simple diffusion of nutrients.

From the primitive heart tube state, the heart undergoes significant growth and morphologic alterations. The symmetry of the heart tube is lost and well-defined left and right structures acquire their functions as the heart undergoes a dramatic change in shape, via a process known as cardiac looping. This occurs in the human embryo during weeks 4 to 5 of gestation (see Fig. 45.1B). From this stage, the heart realigns and septates the inflow and outflow segments, septates the atria and ventricles, and forms the atrioventricular and semilunar valves in processes that will be detailed in this chapter. The "final product" will be a mature heart, formed by gestational week 7 (or 9 weeks after the last menstrual period; Fig. 45.1B) with the following structures:

1. A **venous pole or sinus venosus** *(red)* that is now connected to systemic veins from the upper body (superior vena cava), lower body (inferior vena cava [IVC]), liver, and coronary circulation, all of which pass into the **right atrium (RA)**.
2. A separate **left atrium (LA)**, connected to the venous system separately by ingrowth of **pulmonary veins** from the lungs.
3. An **atrioventricular canal** that begins as a single unrestricted opening, and septates into two atrioventricular valves. The **tricuspid valve** opens from the right atrium into the right ventricle, and the **mitral valve** opens from the left atrium to the left ventricle.
4. A **primitive ventricle** that has expanded and septated into two distinct and separate chambers, a **right and left ventricle**. By processes known as compaction and trabeculation, the working myocardium of each ventricle becomes highly organized and adapts to the unique requirement of a pulmonary (RV) or systemic ventricle (LV).
5. An **arterial pole or bulbus cordis** that forms the two separate outflow tracts of the heart. The distal part of the bulbus cordis is the **arterial trunk**, which undergoes septation in a spiral fashion creating an anterior **pulmonary artery** connecting



• **Fig. 45.1** Cell types and morphology in heart development. (A) Pluripotent cells from the bilayer disc commit to mesoderm and ectoderm lineages as shown; endoderm is also specified and gives rise to the gut (not shown). Ectoderm gives rise to neural tissues, including neural crest cells *(green)*. Cardiac mesoderm forms three populations within the heart as shown: first heart field *(orange)*, second heart field *(blue)*, and proepicardium *(purple)*. The eventual cell types and tissues formed from each are as shown. (B) Schematic of cardiac morphology at the cardiac crescent, heart tube, looping heart, and mature heart are shown. Colors match the lineage markers described above. (From Tan CMJ, Lewandowski AJ. The transitional heart: from early embryonic and fetal development to neonatal life. *Fetal Diagn Ther*. 2020;47:373–386.)

to the lungs and a posterior **aorta** connecting to the body. The proximal part of the bulbus cordis is the **conus**, which is retained by the right ventricle. At the junction between conus and the pulmonary artery, the **pulmonary valve** forms. The **aortic valve** forms at the junction between the left ventricle and the aorta.

6. Paired **dorsal aortae** connected to the **aortic sac** that have extensively remodeled into a single leftward **aortic arch** and **descending aorta**. This connects proximally to the **coronary arteries**, the head and neck arteries, and to a temporary structure important in fetal life, the **ductus arteriosus**.
7. Networks of coronary arteries that have formed within the myocardium of the heart. These connect to the aorta as the right and left coronary arteries.
8. Networks of myocytes that have differentiated into the conduction system of the heart, including the sinoatrial node, the atrioventricular node, and the His-Purkinje system of the ventricles.

Cell Types Within the Heart and Their Origins

The mature heart has three cell layers: the endocardium, a single cell thickness epithelial lining; the myocardium, made up of myocytes that perform the contractile work of the heart; and the epicardium, a single cell thickness epithelium covering the external surface of the heart. Beyond this, the heart resides within a pericardial sac, similar in composition and function to the pleura covering the lungs.

The heart proper has its embryonic origin from a field of lateral plate mesodermal cells referred to as the cardiogenic mesoderm (Fig. 45.1A and B; *orange/red*). The primitive heart tube arises from the primary heart field (Fig. 45.1A and B, *orange*) and has two layers, an endocardium and a myocardium, both arising from cardiac mesoderm. A subset of cells from the endocardium undergoes an epithelial-to-mesenchymal transition to form the endocardial cushions. These cells will be vital to proper valve development and to complete septation of the atria and ventricles. The myocardium primarily remains muscle, but a subpopulation of these cells also differentiate into Purkinje fibers of the conduction system.

The outflow tracts of the heart are arguably the most complex genetically and morphologically, and thus most prone to developmental defects. The secondary heart field is a population of cardiac mesoderm adjacent to the original heart field that migrates into the heart during looping (Fig. 45.1A and B, *blue*). The secondary heart field contributes significantly to the right ventricle and outflow region of the heart, to the atrial and ventricular septa, and to parts of the atria.[2–5]

Neural crest cells are an important population that also migrate into the developing outflow tract, interacting with the secondary heart field myocardium (Fig. 45.1A and B, *green*). Neural cells originate from the ectoderm in the anterior rhombencephalon and migrate as a sheet through the pharyngeal region and into the aortic arches, truncus, and proximal conus.[6–10] Here they interact with endocardial cushion cells to septate the great arteries and close the conal septum.[11] These neural crest cells are also important to the development of the nearby parathyroid, thyroid, and thymus glands. They also innervate the heart and form much of the smooth muscle of the proximal aorta.[6]

Another external population of cells that make important contributions to the mature heart is a cluster of cells dorsal and inferior to the heart tube known as the proepicardial organ (Fig. 45.1A and B, *purple*).[12,13] The origin of these cells is a subject of debate; one leading theory is that they are derived from liver primordium.[12] These cells expand as an epithelial sheet covering the surface of the heart to form the epicardium. From the epicardium, subgroups of cells delaminate and migrate into the myocardium beneath in a process known as epithelial to mesenchymal transformation. These cells differentiate into vascular smooth muscle, vascular endothelial cells of the coronary arteries, and cardiac fibroblasts, which make up a sizable population of cells residing within the myocardium, between myofibers. A recent study using multiple lineage markers in tandem showed that only about 4% of the coronary endothelium comes from the pro-epicardium, while the contribution to fibroblast and smooth muscle population is much higher. This study identified a population of circulating endothelial progenitors as an important source of cardiac endothelium.[14]

Thus in addition to cardiomyocytes arising from at least two populations of mesoderm, the heart is composed of cells from epithelial and neural crest origins that migrate in with spatial and temporal precision during cardiac development. The next several sections will highlight the steps of this process.

Gastrulation and the Cardiac Crescent

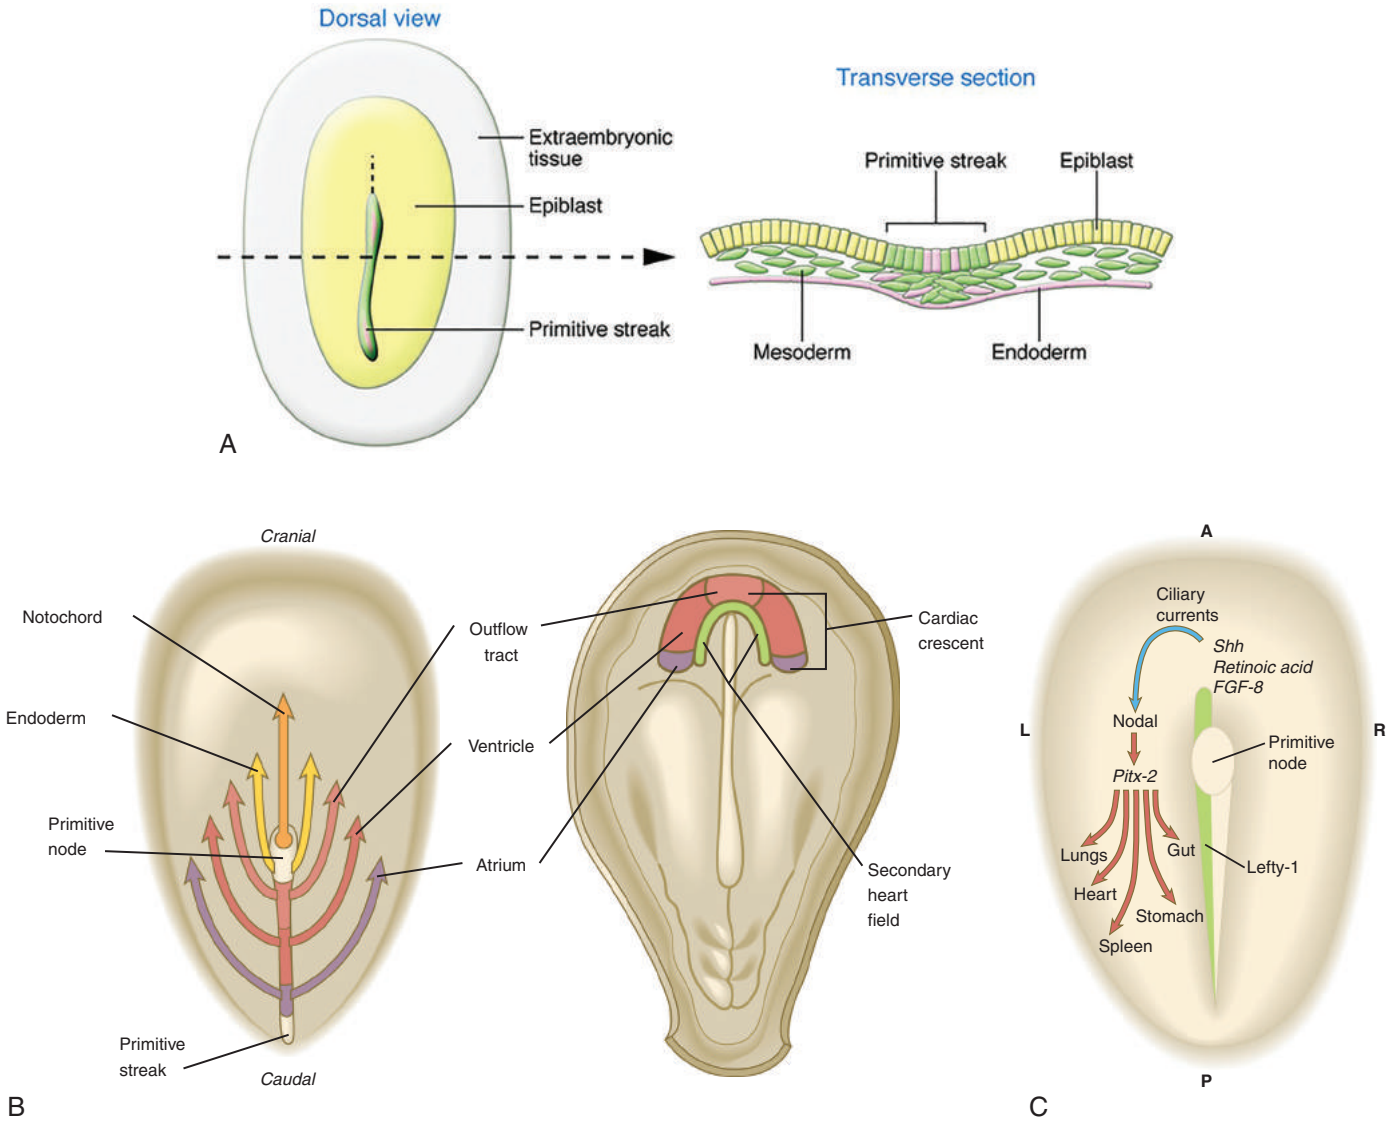
Much of what is known about the early stages of embryonic development comes from studies of avian, zebrafish, and mouse models extended, with some acknowledged gaps, to human development.[15–27] In its earliest stages, the embryo exists as a bilayer disc of two epithelial sheets of cells suspended between two fluid-filled cavities, the yolk sac and the amniotic cavity (Fig. 45.2A). The ventral layer (facing the yolk sac) is the hypoblast, which will eventually be relegated to extraembryonic structures. The dorsal layer (facing the amniotic cavity) is the epiblast, which will form all three embryonic germ layers: the ectoderm (nervous system and skin), mesoderm (heart, skeleton, muscle, and connective tissue), and endoderm (gut). Mesoderm and embryonic endoderm separate from the primitive ectoderm by a process known as gastrulation. Gastrulation begins as a groove that forms in the epiblast starting at the tail end (caudal) and gradually extending cranially to an endpoint known as the prechordal plate (Fig. 45.2A). The groove is known as the primitive streak, and its leading edge is the primitive node. Along the primitive streak, epiblast cells delaminate from the epithelial sheet and invade the potential space between the epiblast and hypoblast, forming a crescent of cells cranial to the prechordal plate and extending along both sides (Fig. 45.2B). Genetic and fate mapping studies also show that the relative position of cells during migration is key to their ultimate position within the heart. Specifically, the apex of the crescent is formed from cells that have migrated through the primitive streak closest to the primitive node, and these are precursors of the outflow tract myocardium. The cells on either side of this region have migrated through the mid-portion of the streak and are ventricular myocyte precursors. The most lateral and caudal cells are those which have migrated through the most posterior part of the streak and will become atrial myocytes (Fig. 45.2B). Finally, the secondary heart field mesoderm lies medial and extends along the entire crescent such that it is continuous with both the outflow and inflow segments of the crescent (Fig. 45.2B, green). Fate-mapping studies using live-cell tracking and time-lapse imaging demonstrate that these cells move as a cohort (tissue motion) rather than individually migrating; this is a way to maintain cells' relative positions within a tissue, and eventually, an organ.[19]

Genetic Control of Gastrulation

The earliest known marker of the cardiomyocyte lineage is the transcription factor Mesp1, expressed in the mesoderm at the onset of gastrulation.[28,29] Mesp1 acts as a switch between pluripotency (phenotypically linked to mesenchymal, migratory, and proliferative characteristics) and differentiation.[28,30]

At the primitive node, growth factors of the wingless integrated or Wnt family are expressed which block differentiation and promote proliferation and migration.[31] Surrounding structures, including the neural tube and endoderm, secrete inhibitory factors forming the boundaries of the crescent-shaped heart field.[32,33]

Thus as the migrating cells make their way into the cardiac crescent, they exit the region of Wnt expression and enter a field of active Wnt inhibition. The cardiac mesoderm then begins to differentiate into cardiomyocytes under the control of a different class of growth factors, bone morphogenetic proteins (BMP).[34] Early markers of the differentiated cardiomyocyte phenotype include transcription factors Islet 1, TBX5, GATA4, and Nkx 2.5. The mechanisms for the shifts in gene expression are complex and involve many epigenetic factors including modification of chromatin structure in differentiating cells and enhancer and repressor regulatory elements.[35] Factors such as GATA4 function both to



• **Fig. 45.2** Gastrulation and the formation of the three germ layers. (A) Schematic view of gastrulation, showing the primitive streak as it appears from a dorsal view and in transverse section. In the transverse section, the process of epithelial to mesenchymal transformation (EMT) can be appreciated, as mesoderm and endodermal cells (shown in *green* and *pink*, respectively) delaminate from the epiblast *(yellow)* and migrate to form new structures. (B) Formation of the cardiac crescent, with primary and secondary heart fields. In the primary heart field, the cell position at migration determines its fate within the crescent and heart tube as shown. (C) Genes regulating left-right asymmetry during gastrulation, with ciliary currents creating a gradient of Nodal expression to the left side of the embryo, initiating a cascade of other signaling molecules as shown. (A from Acloque H, Adams MS, Fishwick K, et al. Epithelial-mesenchymal transitions: the importance of changing cell state in development and disease. *J Clin Invest*. 2009;119(6):1438–1449; B, C from Carlson BM. *Human Embryology and Developmental Biology*. 5th ed. Philadelphia: Elsevier; 2014:105.)

modify chromatin structure, for example, cause "unwinding" of specific segments of DNA rendering it accessible to transcription, and to bind to certain gene promoters to enhance transcription directly.[35] Furthermore, Gata4 recruits TBX5 to muscle-specific gene promoters in the primary heart field; in mice TBX5 deletion causes abnormal development of the left ventricle. In humans, TBX5 haploinsufficiency causes atrial septal defect (ASD), conduction defects and limb anomalies, but can also be associated with hypoplastic left heart syndrome.[36,37] Similarly, both NKX 2.5 and Islet1 function by binding to regulatory elements of cardiac-specific genes, including chromatic structure and transcription enhancer elements; there is additional complexity in this system from the interdependency and to some extent redundancy of GATA4, NKZ2.5, and TBX5.[35,38]

The basic left-right asymmetry of the embryo is set during gastrulation by concentration gradients of the factors sonic hedgehog (shh) and fibroblast growth factor 8 (see Fig. 45.2C). This gradient is created by ciliary motion at the primitive node and causes a cascade of downstream genes to be activated, including nodal, lefty, and pitx-2.[39–41] All of these are markers of left-sidedness,

whereas as far as currently understood right-sidedness is specified entirely by the absence of these factors. When the strict left/right gradient of gene expression is altered, the result is abnormalities of left/right structures in the heart, lungs, and/or gut known as heterotaxy (see section below and Fig. 45.4).

Looping and Laterality of the Heart Tube

When initially formed the cardiac crescent is a symmetric structure, and it next fuses into an initially symmetric heart tube. This primitive heart tube forms as the cardiac crescent moves ventrally and medially, such that the two arms of the crescent fuse into a tube (Fig. 45.3A).[42] The developing foregut dorsally and the neural tube cranially help to push the heart tube into its new position. As fusion of the heart fields occurs, the heart begins to beat. In a human fetus, this happens at approximately 23 days' gestation or early week 6 after the last menstrual period.

The heart tube next begins to undergo a dramatic change in shape known as looping. Here the heart tube loses its symmetry, and distinct left and right morphology can be identified (Fig. 45.3B). Morphologically, cardiac looping involves some degree of differential growth, with a higher proliferation of myocytes along the outer curvature than the inner.[43] The primary contribution to the morphologic change during looping, however, is a substantial migration of cells from the developing secondary heart field.[3,44–46] Of note, this migration of secondary heart field cells occurs both at the arterial and venous poles of the heart. All of this serves to elongate the outflow tract and enlarge the ventricular segment. Recent detailed lineage tracing and studies in chick heart tubes confirm that the entire right ventricle arises from the secondary rather than the primary heart field.[47] The atria and sinus venosus also incorporate secondary heart field cells, and this portion of the heart tube is shifted cranially from its original position. Overall, the heart tube increases fivefold in length during looping.[48] In addition to cell migration and proliferation, there are mechanical forces literally pulling, twisting, and realigning structures of the primitive heart tube. This is thought to involve the cytoskeleton, including non-muscle myosin,[49] the motor protein dynein,[50–52] microtubules,[53] and non-muscle actin bundles.[54]

Genetic Control of the Secondary Heart Field and Cardiac Looping

Genetically, the secondary heart field is characterized by transcription factors Tbx1, islet 1, Mef2c, Tbx20, and growth factors Fgf 8 and Fgf 10. Knockout of any of these genes in mice causes outflow tract defects.[55–62] Interestingly, a second wave of Mesp1 expression late in gastrulation signals the migration of the secondary heart field cells into the developing heart.[63] TBX1 expression in the secondary heart field coordinates this migration at both the arterial and venous segments of the heart tube.[64] As the secondary heart field cells move into the outflow tract of the heart, they stop expressing many of their original genetic markers and express more general myocardial markers such as Hand1, Nkx2-5, Tbx5, Gata4, and Mef2.[21,45,46,56,65,66] These are factors already well-studied in the primary heart field to contribute to myogenesis.[38,67–75] Defects in the expression of these genes in the secondary heart field can lead to right ventricular hypoplasia and outflow tract abnormalities, including tetralogy of Fallot.[65,66]

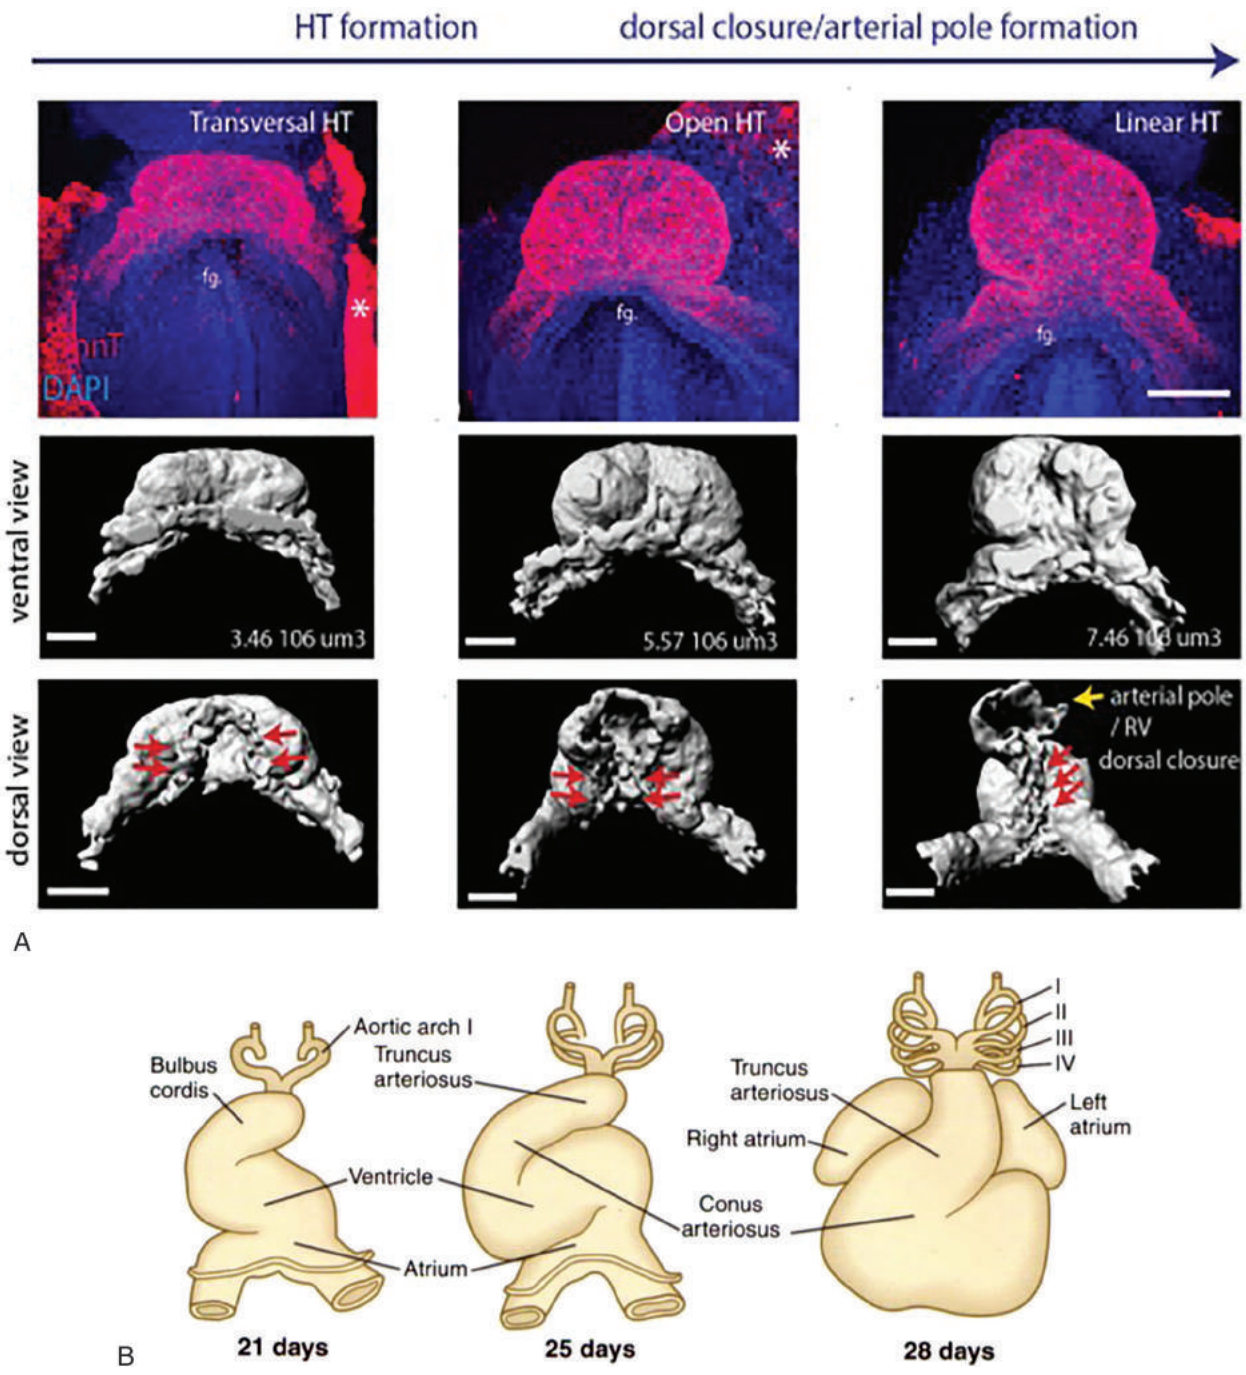
Clinical Abnormalities in Cardiac Looping and Laterality

Normal looping occurs to the right (D-looping), that is, the sinus venosus and atria move toward the left and posterior, and the ventricles and bulbus cordis move to the right and anterior. Importantly, the venous pole also moves cranially such that it lines up with the arterial pole along the horizontal body axis (Fig. 45.3B, 28 days). The bulbus cordis remains to the right of the primitive ventricle. This repositioning is critical for proper atrioventricular and ventriculoarterial connections. Also with looping, an outer and an inner curvature of the heart is established. The anterior outer curvature is an area of rapid myocardial growth and expansion to form the ventricular chambers. The posterior inner curvature undergoes slower growth and acts rather like a fulcrum for the looping process. The inner curvature myocardium contributes to the atrioventricular canal and is critical to the formation of the endocardial cushions.

Sometimes, looping can occur to the left, with the venous pole and atria moving rightward and the ventricles and arterial pole moving leftward. This is referred to as L-looping (Fig. 45.4A shows normal looping; compare to L-looping in Fig. 45.4B). Cardiac connections are conventionally defined by (1) atrial situs (solitus, right atrium on the right side vs. inversus, right atrium on the left side); (2) ventricular looping (D or L); and (3) great artery relationships (S, normal with aorta to the right and posterior to the pulmonary artery; D, malposed with aorta to the right but anterior; or L, malposed with aorta to the left and anterior). Normal cardiac connections then are defined as (S,D,S).

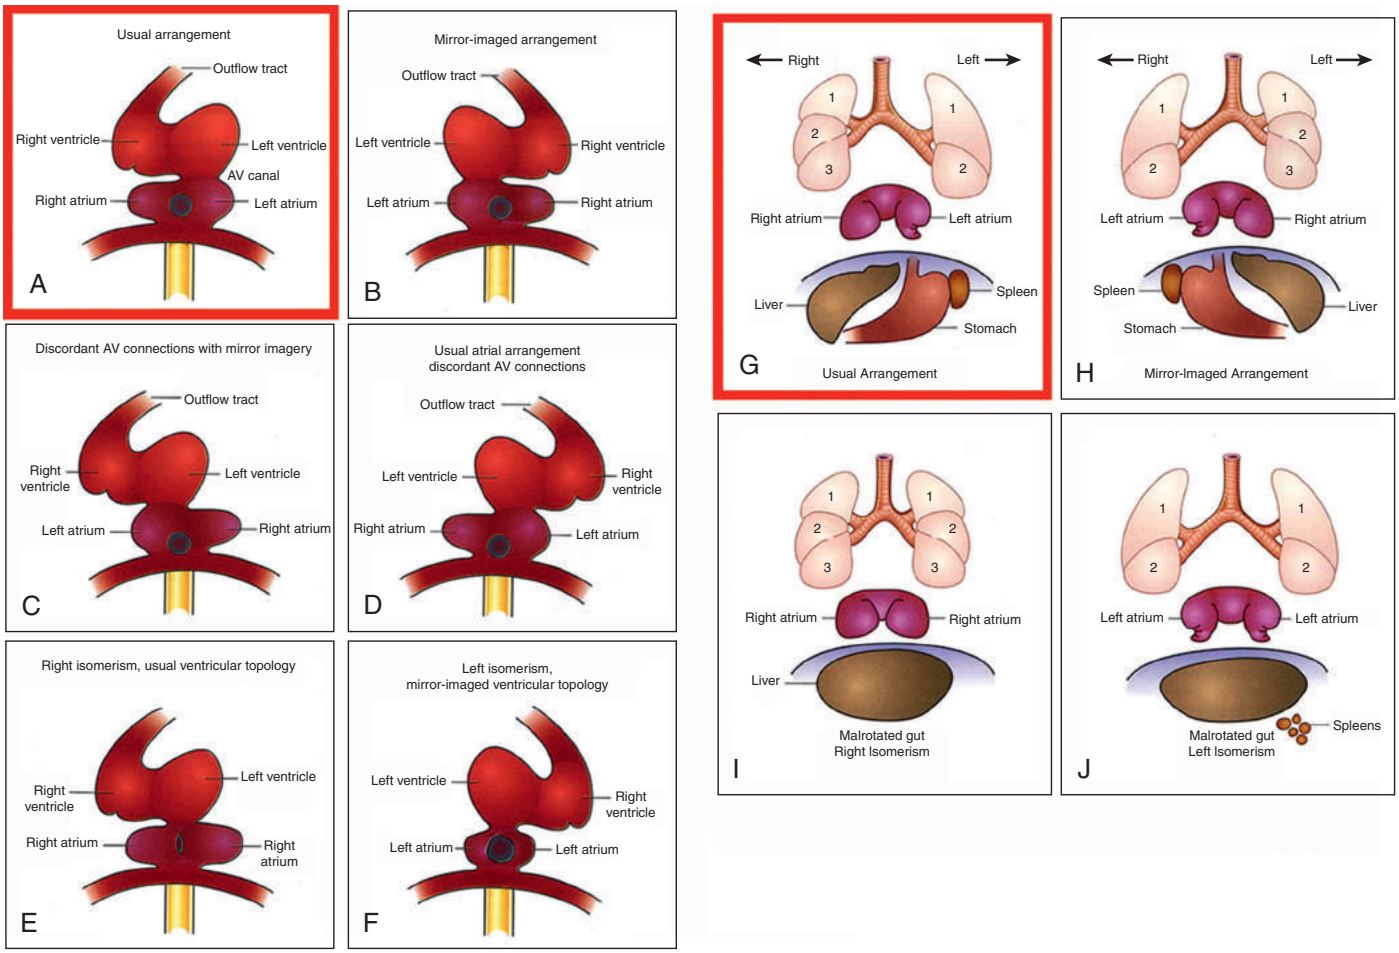
If there is complete mirror imagery, the cardiac connections and physiology are normal, but the heart is on the right side of the body (dextrocardia) and atrio-ventricular and ventriculo-arterial connections are reversed, or (I,L,L). Sometimes there is both atrioventricular and ventriculoarterial discordance, an entity referred to as congenitally corrected transposition. Here the atrial situs may be normal, ventricles looped to the left, with the bulbus cordis to the left of the primitive ventricle (Fig. 45.4D). When the great arteries septate, there is usually L malposition of the great arteries, so the aorta is to the left of the pulmonary artery (S,L,L). The resulting circulation is: right atrium to left ventricle to pulmonary artery; left atrium to right ventricle to aorta. In isolation, then, this defect allows for normal circulation—although with the right ventricle, which is structured to pump to the low-pressure pulmonary circulation, as the systemic ventricle. Alternately, this physiology can occur with atrial situs inversus, D looping of the ventricles, and D malposition of the great arteries, (I,D,D; Fig. 45.4C). Often however there are additional cardiac defects ranging from a ventricular septal defect (VSD) with pulmonary valve stenosis to more complex defects involving hypoplasia of one of the ventricles or hypoplasia, aplasia, or malformation of one or more valves.

L-looping may also be associated with more global defects known as heterotaxy syndromes. Heterotaxy syndromes are a heterogeneous group of congenital defects, with the commonality being abnormal left-right asymmetry of the embryo.[76] In heterotaxy, left-right assignments along the body axis are randomized. Thus it is possible to have mirror image asymmetry, or bilateral symmetry, with either two right sides or two left sides. This is often termed right or left isomerism (Fig. 45.4E, F and I, J). This can affect the abdomen, lungs, and heart. In the abdomen, the gut, liver, and spleen may be reversed from normal (abdominal situs inversus). There may be malrotation of the bowel and anomalies of



• **Fig. 45.3** Fusion of the heart tube and looping. (A) Mouse embryos immunostained for cardiac troponin T *(red)*, a marker of cardiac muscle, and Dapi, a marker of cell nuclei. (A adapted from Ivanovitch K, Temino S, Torres M. Live imaging of heart tube development in mouse reveals alternating phases of cardiac differentiation and morphogenesis. *Elife*. 2017;6:e306686; B from Carlson BM. *Human Embryology and Developmental Biology*. 4th ed. Philadelphia: Elsevier; 2009:457.)

the biliary tree. The spleen, being a normally left-sided structure, can be duplicated in left isomerism (polysplenia), and absent in right isomerism (asplenia). Lung abnormalities in heterotaxy manifest in the bronchial and lung anatomy as shown in Fig. 45.4. In the heart, heterotaxy causes randomization of atrial sidedness. As discussed above, the atria may be normal (situs solitus) or left-right reversed (situs inversus); sometimes it is unclear (situs ambiguous; including bilateral right or bilateral left atria). Clinically, the atria are most practically defined by their venous return, systemic to the right atrium and pulmonary to the left. But in heterotaxy, this is not always possible, as the pulmonary or systemic veins may return to both atria. The pulmonary veins grow in from the



• **Fig. 45.4** Normal and abnormal looping patterns. (A) Diagram of normal cardiac D-looping with normal AV connections. (B-D) Several common abnormal looping patterns, including mirror image L-looping with normal AV connections (B); discordant AV connections with atrial situs inversus (C); and with normal atrial situs (D). Both (C) and (D) are usually associated with discordant ventriculoarterial connections, creating congenitally corrected transposition. (E, F) Right and left atrial isomerism. (F) Bilateral right-sidedness and bilateral left-sidedness generally found along with anomalies of the systemic and pulmonary veins, of cardiac septation, and of the inflow and outflow tracts. Right and left isomerization syndromes also go along with abnormal sidedness on other asymmetric organs of the chest and abdomen, or heterotaxy. (G) Normal visceral organ arrangement. (H) Mirror image, or situs inversus. (I) Right isomerism. (J) Left isomerism. (Adapted from Brown N, Anderson R. Symmetry and laterality in the human heart: developmental implications. In: Harvey RP, Rosenthal N, eds. *Heart Development*. Academic Press; 1999:449, 459.)

developing lungs normally joining the back wall of the left atrium. When the left-right cues are scrambled, the pulmonary veins often return ipsilaterally: left-sided veins to left-sided atrium and right-sided veins to right-sided atrium. Likewise, the systemic veins may return to either or both atria in heterotaxy—for example, a right superior vena cava to right atrium and left superior vena cava to left atrium. This is because the systemic veins start out as paired symmetric structures (see section on systemic veins), with the involution of certain structures occurring as part of the establishment of left-right asymmetry in the embryo. Finally, certain patterns of additional cardiac defects often accompany asplenia/right isomerism. These include failure of septation of the ventricles resulting in a single ventricle, pulmonary underdevelopment (stenosis or atresia of the pulmonary valve), bilateral superior vena cava, and anomalous pulmonary venous return. For polysplenia/left isomerism, commonly associated defects include endocardial cushion defects (see below), left-sided obstructive lesions such as coarctation of the aorta, and interruption of the inferior vena cava with azygous continuation to the superior vena cava.

Ventricular Inlet Septation: Endocardial Cushions

After cardiac looping, the orientation of the heart tube has changed drastically, but the progression of blood flow through it remains in essentially the same sequence: into the heart from the venous pole, through the common atrium into the common ventricle, and out the conotruncus to the aorta. Inflow and atrial segments are leftward, and the ventricle and outflow are to the right. If the

process arrests near this point, a heart may form with its entire inlet portion aligned over the leftward ventricle (a double inlet left ventricle) or its entire outlet portion aligned over the rightward ventricle (a double outlet right ventricle). Both entities are seen in humans. What are very rarely seen are a double inlet right ventricle and a double outlet left ventricle—even if there is L-looping and/or dextrocardia, this basic sequence is maintained.

During the next phase of heart development, the atrioventricular (inlet) and ventriculoarterial (outlet) structures will realign and septate, such that there is a valved inlet and a valved outlet for each ventricle. In human embryos, this occurs during weeks 6 to 7 of gestation.[77,78] These valves are formed primarily from the endocardial cushions. The endocardial cushions are also critical to complete ventricular and atrial septation, completing the portions of the septum adjacent to the AV valves (detailed further in sections on atrial and ventricular septation). Thus the endocardial cushions form the crux of the heart: a point in the center of the heart at which separate AV canals are to the left and right, and atrial and ventricular septa are aligned above and below.

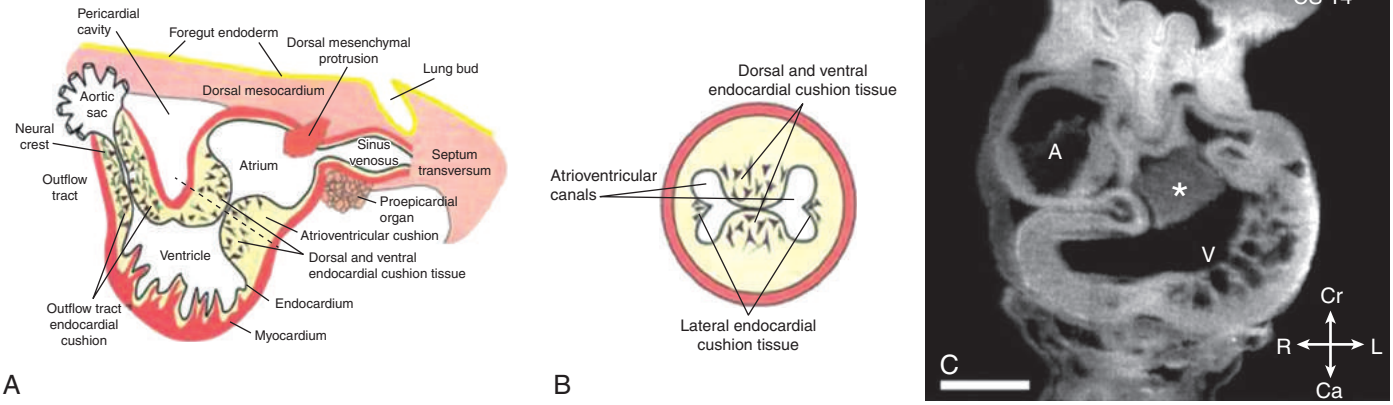
The endocardial cushions initially appear as swellings in the atrioventricular and conotruncal segments of the primitive heart by 6 weeks' gestation (Fig. 45.5). The swellings are caused as cells from the inner lining of the heart (endocardium) delaminate and migrate into the extracellular matrix in between the endocardium and the myocardium. The delaminating cells change phenotype in a process known as epithelial to mesenchymal transformation (EMT). The cells lose their epithelial, or sheet-like, characteristics and acquire a mesenchymal phenotype, losing junctions with neighboring cells, invading into the matrix, and proliferating faster.[18,79–81] In both the AV canal and in the conotruncus, four distinct cushions form, named by their anatomic locations. For the AV canal these are: superior (ventral), inferior (dorsal), left lateral, and right lateral (Fig. 45.5B). In the conotruncus they are: right superior, right dorsal, left inferior, and left ventral. The AV and conotruncal cushions are separate with one important exception: the left ventral conal cushion and the superior AV cushion are in continuity along the inner curvature of the heart (Fig. 45.5A). This proximity will persist in the fully septated heart as aortic-mitral valve continuity. The atrioventricular canal septates as the superior and inferior cushions grow and extend, finally fusing in the midline. This results in complete separation of the AV canal into left (mitral) and right (tricuspid) sides. The AV valves form from remnants of the cushions: a leftward mitral valve with two leaflets, and a rightward tricuspid valve with three.

Clinical Abnormalities of the AV Canal

Failure of complete fusion between the superior and inferior cushions in the midline results in a cleft within the anterior leaflet of the mitral valve. This is a mild form of an endocardial cushion defect, often associated with a primum atrial septal defect (see section on atrial septation) and known as a partial atrioventricular canal. The septal leaflet of the tricuspid valve also forms from the superior and inferior cushions and can also be affected, although this is less often clinically significant. More profound failure of proper AV cushion expansion and fusion results in a complete atrioventricular canal. Here the crux of the heart is unformed. There remains a common orifice overlying both ventricles, with defects in the adjacent atrial and ventricular septa. The common atrioventricular valve has a leaflet structure based on the unseptated AV canal, with four or sometimes five separate leaflets corresponding to the two lateral, the superior (referred to as anterior bridging), and inferior leaflets.

Ventricular Outflow Tract Septation: Endocardial Cushions and Neural Crest

While the AV cushions form a three-dimensional crux of the heart, the conotruncal cushions form a three-dimensional spiral, completing an almost 180-degree rotation. The outflow tract



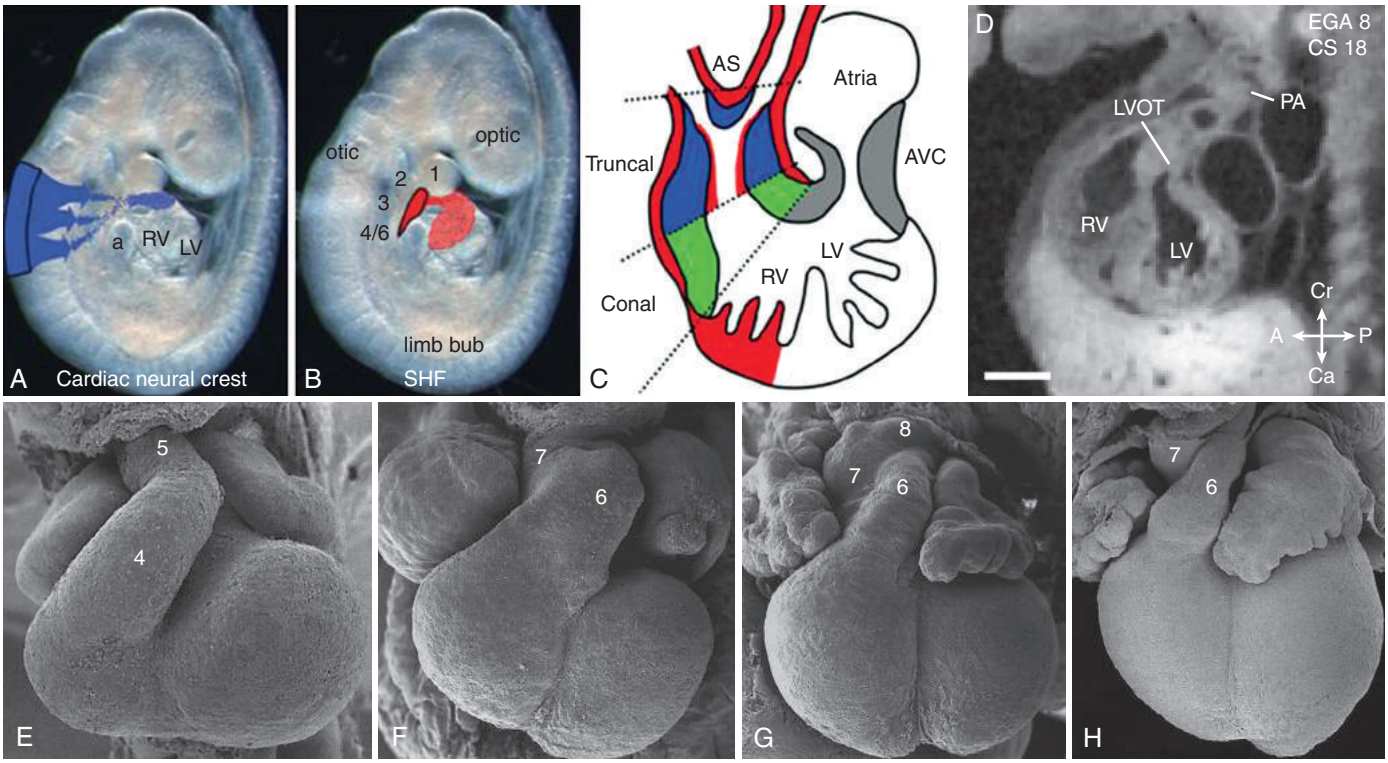
• **Fig. 45.5** Formation of the endocardial cushions. (A) Schematic diagram of cushion formation in the inflow and outflow tracts by epithelial to mesenchymal transition in the looped heart tube. Also shown are the neighboring tissues and cell populations contributing to the developing heart at this stage. (B) Schematic of the septating AV canal. (C) EFIC (episcopic fluorescence image capture) image of a sectioned paraffin-embedded human embryos at 6 6/7 weeks. Seen are atria (A), ventricles (V), and AV cushions (*). Scale bar = 0.515 mm. Human cardiac development in the first trimester: a high-resolution magnetic resonance imaging and episcopic fluorescence image capture atlas. *Circulation*. 2009;120:347.)

myocardium arises from the secondary heart field (Fig. 45.6B and C, red). During septation of the outflow tracts, the primitive outflow tract is separable into two segments: the truncus adjacent to the aortic sac and the conus adjacent to the ventricular myocardium (Fig. 45.6C, *blue* and *green*, respectively). The right superior and left inferior cushions are within the truncal region and will contribute to the aorticopulmonary septum. This region undergoes important interaction with the migrating neural crest cells (Fig. 45.6A, *blue*). The right dorsal and left ventral cushions are within the conus region and are important for pulmonary and aortic valve formation and for completion of septation between the ventricles at the level of the pulmonary and aortic valves. The interface between the two sets of cushions is a critical region for the formation and remodeling of the ventricular outflow tracts.[45,82,83]

Specifically, continuity between the superior AV cushion and left ventral conus cushion is maintained in the development of the left ventricular outflow tract. The conus is entirely maintained over the developing right ventricular outflow, creating a "neck" of tissue between the inflow and outflow segments.

Clinical Conotruncal Defects and DiGeorge Syndrome

Clinically, there are several defects seen in humans related to abnormal conotruncal development. These include truncus arteriosus, interrupted aortic arch, tetralogy of Fallot, double-outlet right ventricle, and conotruncal ventricular septal defects. In truncus arteriosus, the conotruncus completely fails to septate, leaving a single outflow tract aligned over both ventricles with an outlet VSD. In interrupted aortic arch, there is a posterior deviation of the conal septum, leading to a VSD and failure of proper arch development. In tetralogy of Fallot, there is an anterior deviation of the conal septum, with multi level pulmonary outflow tract obstruction, a VSD with aortic override, and hypertrophy of the right ventricle. In double-outlet right ventricle, there is the failure of a complete rotation of the conotruncal cushions such that there is malalignment of both great arteries over the anterior right ventricle, along with a ventricular septal defect.[84,85]



• **Fig. 45.6** Septation of the outflow tracts. Contribution of neural crest (A, *blue*) migrating into secondary heart field (B, *red*) in developing outflow tracts in the mouse embryo. Jul 28 2009;120:347; E-H adapted from Steding G. *The Anatomy of the Human Embryo*. Basel: S. Karger AG; 2009.)

Human DiGeorge syndrome is characterized by cardiac conotruncal and arch defects along with developmental defects of the parathyroid, thyroid, and thymus glands.[6] A deletion of up to three megabases in chromosome 22 (22q11) has long been known to be associated with DiGeorge, based on kindred studies in families with the syndrome.[57,86–88] In humans, the defect is autosomal dominant, with variable penetration, meaning that one copy of the gene deletion is sufficient to cause disease and that the disease severity varied from family member to family member. Experimentally, chick models of neural crest ablation show a very high prevalence of conotruncal defects along with abnormal parathyroid, thyroid, and thymus development.[6,9,10,89–91] More recently, mouse models of DiGeorge syndrome implicated TBX1 as a single gene defect mimicking the human DiGeorge phenotype.[55,57,92] Homozygous mutations of TBX1 caused the obliteration of the third, fourth, and sixth pharyngeal arches with embryonic lethality and caused most of the extra-cardiac defects as well, along with an abnormal ear, jaw, and pharynx.[55] Heterozygous mutants, which are analogous to the human disease state, showed more variable disease.

Interestingly, isolated TBX1 mutations appear to be very rare as causes of clinical DiGeorge syndrome;[86,88,93] most patients have a larger megabase deletion. Since the link between TBX1 and DiGeorge syndrome was discovered, a better understanding has gradually emerged. As already discussed, TBX1 is a transcription critical for proper patterning and incorporation of the secondary heart field into the developing heart. Importantly, TBX1 expression is not found in neural crest cells but is critical for interactions between the neural crest and secondary heart field.[94–96] There are clearly other modifying genes important to the pathogenesis of conotruncal defects, notably Wnt factors,[97] the BMP inhibitor Smad7,[98] and retinoic acid signaling genes.[99] Interestingly, overexpression of TBX1 in mouse models are also associated with conotruncal defects suggesting that there are critical levels of TBX1 necessary for proper outflow tract development.[95,100]

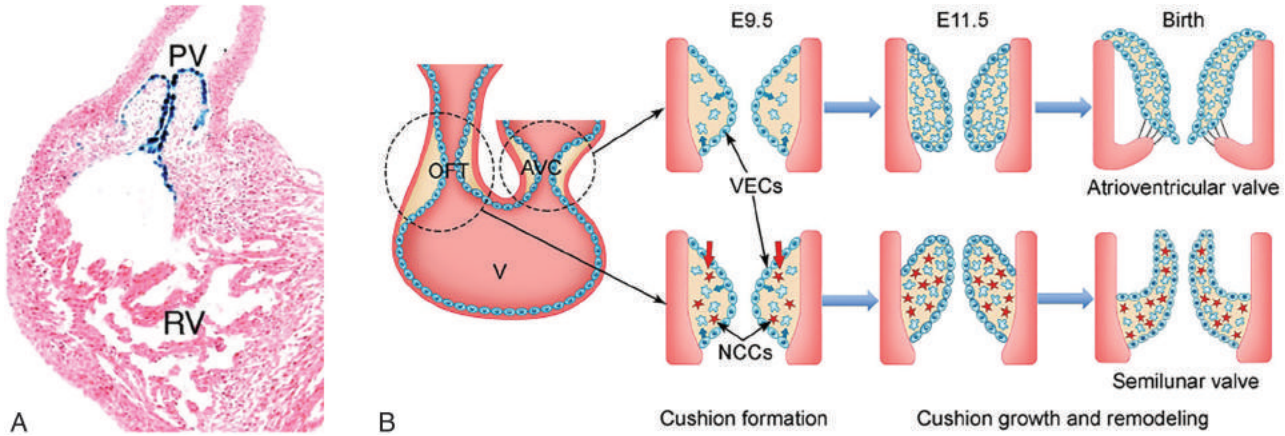
Separation of Aorta and Pulmonary Artery

Within the truncus segment, septation is also occurring during the remodeling of the conus. This normally occurs as the truncal cushions fuse in a spiral fashion. Starting at the level of the AV valves, the newly forming pulmonary artery is directly anterior to the aorta. Further along the outflow tract, the pulmonary artery and aorta are more left-right to one another, as the spiral extends. As the aorta arches to the left, the proximal transverse arch passes anterior to the pulmonary artery, completing a 180-degree turn of the spiral. This sequence is seen in Fig. 45.6E.[78] This rotation not only involves the truncal cushions but also the myocardial tube.[101,102]

If this 180-degree twist does not occur or is incomplete, the result is transposed great arteries. This is defined by the aortic valve being anterior to the pulmonary valve. The left-right orientation of the valves is most commonly preserved (aortic rightward), although it can vary within a 90-degree range from directly anterior-posterior to directly side by side. L-transposition, aortic leftward, is most often associated with L-looped ventricles or heterotaxy syndromes and is rare in isolated transposition. Transforming growth factor-β (TGF-β) signaling, important in left-right patterning and extracellular matrix remodeling and many other processes in normal development, appears to play an important role in this process both in mouse models and in human disease.[103–106]

Cardiac Valve Formation

Cardiac valve development begins with the endocardial cushions during week 7 of gestation, but the formation of mature atrioventricular (mitral and tricuspid) and semilunar valves (aortic and pulmonic) takes several weeks for completion.[18,20,77,78,80,107,108] As the endocardial cushions enlarge, they protrude into the lumen of the developing heart and outflow tracts, as shown in Fig. 45.7A. Here, subject to the constant flow of blood, the protrusions



• **Fig. 45.7** Cardiac valve formation and maturation. (A) Endothelial marker Nfatc1 expression marks the endocardial surface of the valves, with mesenchymal cushion tissue underlying. *PV*, pulmonary valve; *RV*, right ventricle. (B) Schematic of semilunar valve formation and remodeling in the outflow tract (OFT) and AV canal (AVC). Valve endocardial cells (VECs) undergoing epithelial to mesenchymal transformation and populating the cushions, as do migrating neural crest cells (NCCs). This is followed by growth, thinning, and elongation of the atrioventricular and semilunar valves. (A from Wu B, Wang Y, Lui W, et al. Nfatc1 coordinates valve endocardial cell lineage development required for heart valve formation, *Circ Res*. 2011;109:183–192; B from Wang Y, Fang Y, Lu P, et al. NOTCH signaling in aortic valve development and calcific aortic valve disease. *Front Cardiovasc Med*. 2021;8:682298.)

condense and elongate (Fig. 45.7B). Endocardial cells overlying the cushions proliferate slowly, and there is programmed cell death (apoptosis) of mesenchymal cells underneath and an influx of neural crest cells. The valves undergo extensive remodeling of the leaflets and of the extracellular matrix. In the case of the semilunar valves, this remodeling process of the endocardial cushions continues through the last trimester of pregnancy and into the neonatal period.[109,110]

Clinical Valve Abnormalities and Noonan Syndrome

Clinical valve disease is common in human disease and is generally related to incomplete growth and maturation processes of valve leaflets, leaving them immature, thickened, and unable to open and/or close properly. Noonan syndrome is characterized by cardiac malformations including a dysplastic pulmonary valve, systemic features of short stature, facial abnormalities, and a risk of myeloproliferative disease.[111] Linkage studies of families with Noonan syndrome suggest a candidate gene on chromosome 12, the PTPN11 gene.[112] The PTPN11 encodes for SHP-2, a signaling molecule important to growth factors, cytokines, and hormones,[112] although other causative alleles have also been identified.[111] Human mutations in the gene have been shown to cause over-activation of the SHP-2 protein.[111,113] This suggests a gain of function mechanism for the pathogenesis of Noonan syndrome, an interesting distinction from the more familiar concept of loss of functioning protein causing disease. Likewise, mutations in the Notch1 receptor and various components of the Notch signaling pathway have been associated with the formation of aortic valves and with multiple stages of cardiac development.[114,115]

Development of the Ventricles and Ventricular Septum

Most of the ventricular septum is muscular and made up of a protrusion of ventricular myocardium that starts at the apex of the primitive ventricle and extends into the ventricular cavity. The early septating ventricle, then, appears as a bilobed structure[77,78] (Fig. 45.8A). As the septum extends upward, the separation becomes nearly complete (Fig. 45.8B). There is controversy as to how the septum extends so quickly to form a wall between the left and right ventricles. Part of the answer seems to be rapid proliferation in these myocytes, which retain the ability to divide even as a working myocardium. This property is lost soon after birth, as the mature myocardium is for the most part incapable of proliferation. Small muscular ventricular septal defects are very common in newborns. One study screening asymptomatic newborns found an incidence of 53 per 1000 neonates with small muscular VSDs; only 1/10 of these had physical exam signs of their VSD. Nearly ninety percent of these small defects were closed by 10 months of age.[116] These data and others suggest continued low-level proliferation in human ventricles after birth.

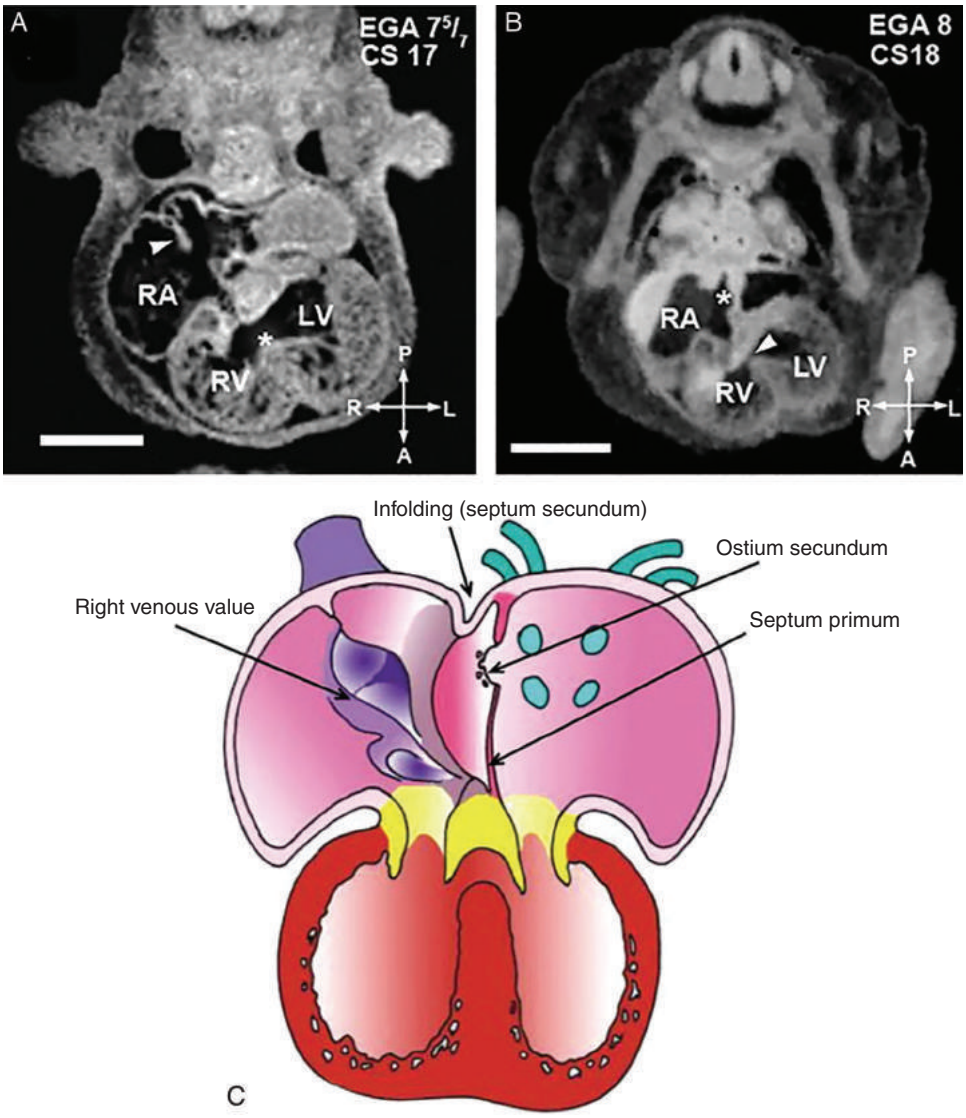
While most of the mass of the ventricular septum grows and extends from the ventricular apex, there are two important regions of the complete ventricular septum that are completed by endocardial cushions, as discussed in the above sections. First, the AV endocardial cushions form the posterior septum adjacent to the AV valves. Second, the conal cushions form the conal septum below the great arteries.

The left and right ventricles differ not only in their relative positions to one another but also in their basic muscular structure and in their function. Each ventricle can functionally be subdivided into inflow and outflow regions. The RV, as we have discussed, has a conal segment as well, and is therefore referred to as a tripartite ventricle. In the mature heart, the LV is a high-pressure system, connected to systemic pressures, while the RV is connected to the lower-pressure pulmonary circulation. The LV form follows its function, with concentric rings of myofibrils that contract with a slight twisting motion, which allows for an efficient ejection of blood. In the embryo, the myocardium thickens and arranges itself in processes known as trabeculation and compaction. Trabeculation refers to projections of muscular tissue into the lumen of the ventricle, such that the inner surface is no longer smooth-walled but ridged. The process of trabeculation is regulated by endocardial to myocardial signaling in the form of Tie2 and retinoic acid signaling.[117] Additional genetic factors shown to have a role in trabeculation include Notch 1, Neuregulin, and Bmp10.[32] Compaction refers to the alignment of myocytes from random and loosely packed, as they are in the immature myocardium, into bundles of tightly packed and well-coordinated myocytes working as a unit in the mature myocardium.[75] Non-compaction of the LV is recognized clinically as a "spongy" appearing myocardium and is increasingly recognized as a form of cardiomyopathy although can remain entirely asymptomatic. This entity is linked to genes regulating cell cycle regulators including the oncogene N-myc.[32]

Development of the Atria and Atrial Septum

Like the ventricular septum, the atrial septum begins as a ridge of muscular tissue, posterior and midline, which expands to divide the right side of the atrium containing the orifice of the sinus venous from the left side of the atrium containing the orifice of the common pulmonary vein. This structure is known as the septum primum, and it grows toward the fusing AV cushions (see Fig. 45.8A, *arrow*). As discussed above, the fusing AV cushions will form the inferior portion of the atrial septum (Fig. 45.8B, *asterisk*). Prior to septum primum and the cushions completing atrial septation, however, small perforations appear, enlarge, and coalesce within the primum septum (Fig. 45.8C). This is referred to as the ostium secundum. Soon afterward, a new crescent of atrial septum forms on the right atrial side of the septum primum and begins extending alongside the septum primum; this is referred to as the septum secundum. During fetal life, blood flow from the right atrium into the left prevents fusion of these two septa. The septum secundum is significantly more rigid than the septum primum, which flaps open to allow continued right to left flow. After birth and separation from the low resistance placenta, the left atrial pressure rises significantly and the atrial shunt reverses.

Failure of the cushions to form the inferior-most part of the atrial septum results in a primum atrial septal defect (Fig. 45.8C, *yellow*). Such defects do not close spontaneously and may be associated with other endocardial cushion defects, most commonly a cleft mitral valve. Finally, there is a small contribution to the atrial septum near the junctions of the superior and inferior vena cava (Fig. 45.8C, *purple*). Defects in this process result in a sinus venosus ASD, and there are superior or inferior types. Such defects again result from deficiency of atrial septal tissue and do not close spontaneously.



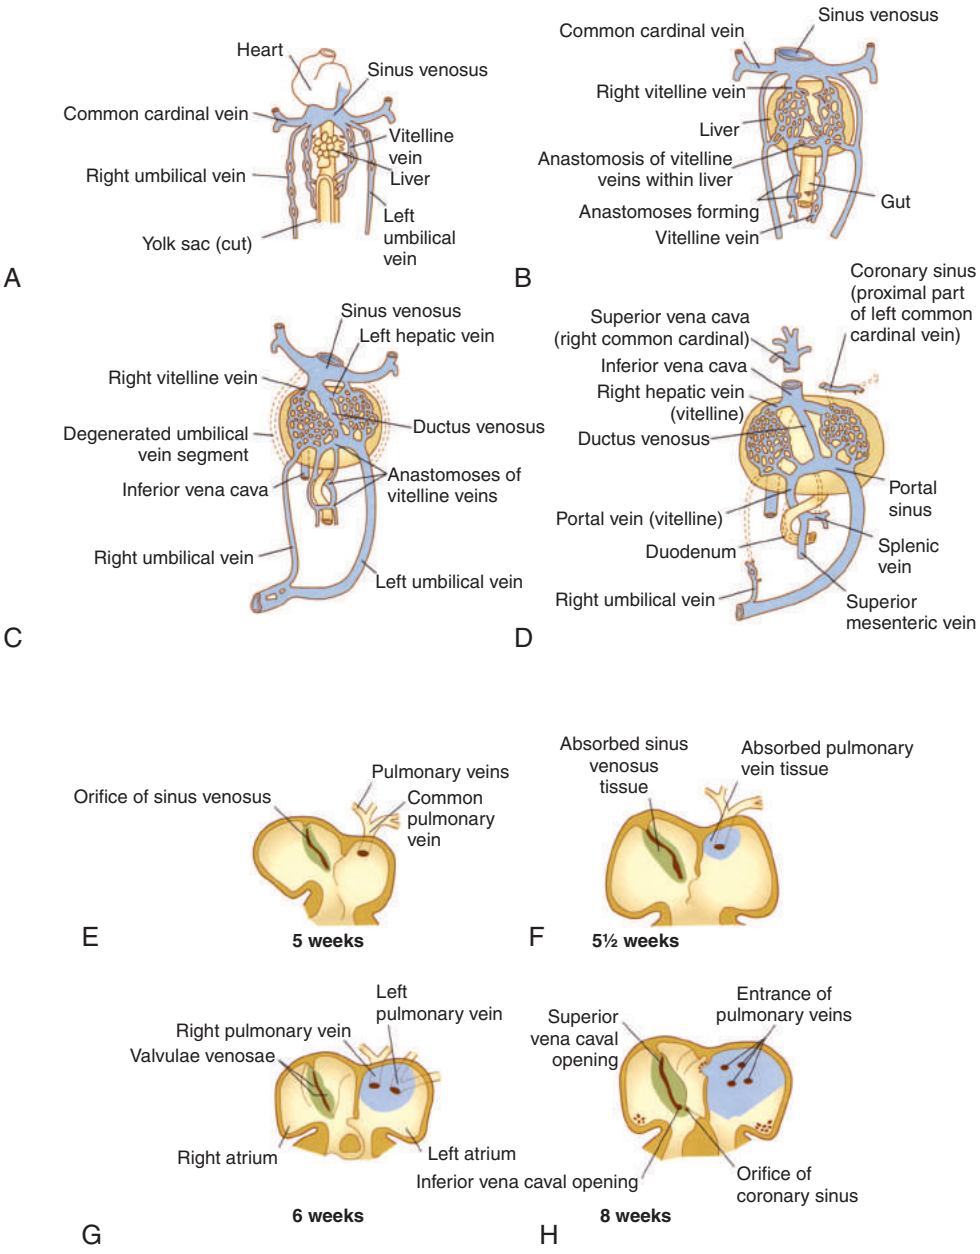
• **Fig. 45.8** Atrial and ventricular septation. (A, B) Human fetal MRI images in transverse plane showing four chambers of the heart (*LV*, Left ventricle; *RA*, right atrium; *RV*, right ventricle). Orientation as shown by the arrows: P (posterior), A (anterior), R (right), and L (left). (A) Fetus at 7 5/7 weeks' gestation. The atrial septum primum is marked by the arrowhead, with the foramen primum below allowing shunting of blood from RA to LA. Between the ventricles, the muscular intraventricular septum is forming but is not yet complete (*). Scale bar is 1.25 mm. (B) Fetus at 8 weeks' gestation. Here the atrial septum primum (*) is fused with the endocardial cushions inferiorly; not seen is the foramen ovale that allows continuous right to left atrial shunting in the fetus. The arrowhead shows a small residual ventricular septal defect in the inlet (posterior) septum, not yet closed by endocardial cushion tissue. Scale bar is 1.5 mm. (C) Schematic of atrial septation, structures as labeled and described in the text. (A, B adapted from Dhanantwari P, Lee E, Krishnan A, et al. Human cardiac development in the first trimester: a high-resolution magnetic resonance imaging and episcopic fluorescence image capture atlas. *Circulation*. 2009;120:345–346.) (C from Naqvi N, McCarthy KP, Ho SY. Anatomy of the atrial septum and interatrial communications. *J Thorac Dis*. 2018; 10:S2837-S2847.)

Systemic and Pulmonary Vein Development

The sinus venosus of the primitive heart tube is a symmetric structure and receives three sets of paired (left and right) systemic veins: the vitelline, umbilical, and common cardinal (Fig. 45.9A). This is the situation at 4 to 5 weeks' gestation.[118]

The vitelline veins return from the yolk sac, a structure that communicates with the primitive gut via the vitelline duct. The duct normally regresses completely, but an occasional remnant can be seen as a Meckel diverticulum.[1] Distally, the vitelline veins regress along with the duct and proximally lose their connection to the sinus venosus proximally by 6 weeks. The midportions of these vessels, however, expand within the liver to contribute to the hepatic and portal veins and contribute a small segment to the inferior vena cava.

The umbilical veins return from the placenta carrying oxygenated blood. These are the first to develop, by 3 weeks' gestation. As the liver develops, the umbilical veins develop connections to the



• **Fig. 45.9** Systemic and pulmonary vein development. (A–D) Stages of development of the systemic veins (weeks 3–7), and (E–H) stages of development of the pulmonary veins (weeks 5–8) as described in the text. (From Carlson BM. *Human Embryology and Developmental Biology*. 4th ed. Philadelphia: Mosby; 2009:452–453.)

liver venous plexus and the connection to the sinus venosus involutes. Outside the embryo within the umbilical cord, the left and right umbilical veins fuse into one; thus there is a single umbilical vein in the newborn. Within the embryo, the left and right segments remain separate, and the left umbilical vein becomes connected to the right hepatic veins via a new channel that forms, the ductus venosus (Fig. 45.9C and D). This circulation is formed by the seventh week of gestation. Again the umbilical veins are carrying oxygenated blood to the right atrium. This flow is primarily directed toward the atrial septum, and therefore primarily then the foramen ovale into the left atrium and systemic circulation.

The cardinal veins carry the venous return from the embryo proper. The left and right common cardinal veins are relatively short segments that connect to the sinus venosus. On each side, anterior and posterior cardinal veins join to form the common cardinal vein: the anterior carrying the venous return from the upper body, and the posterior from the lower body. The right anterior and right common cardinal vein will form the superior vena cava in the mature circulation. The left common cardinal vein and left segment of the sinus venosus form the coronary sinus, which receives venous return from the coronary system. These structures are pulled rightward as the IVC forms, such that the opening (os) of the coronary sinus ends up in the right atrium once atrial septation is complete. The inferior vena cava is more complex, and made up of five segments, coming from urogenital, mesenteric, and hepatic venous channels fusing together to the right of the spine as their leftward paired counterparts involute. As numerous vessels go into making the IVC, interruption of the IVC can

sometimes occur at various segments. This is most often in the setting of heterotaxy but can occur in isolation. When the IVC is interrupted, one of two major vessels that connect the lower and upper body venous systems generally enlarge to receive the flow and shunt it into the SVC. These are the rightward azygous vein, which runs from the suprarenal segment of the IVC to the SVC, and the leftward hemiazygos vein, which takes a more tortuous course from the leftward lumbar and renal veins up into the thoracic cavity, where it turns rightward to join the azygous vein. Thus an interrupted IVC generally has either azygous or hemiazygos continuation to the SVC.

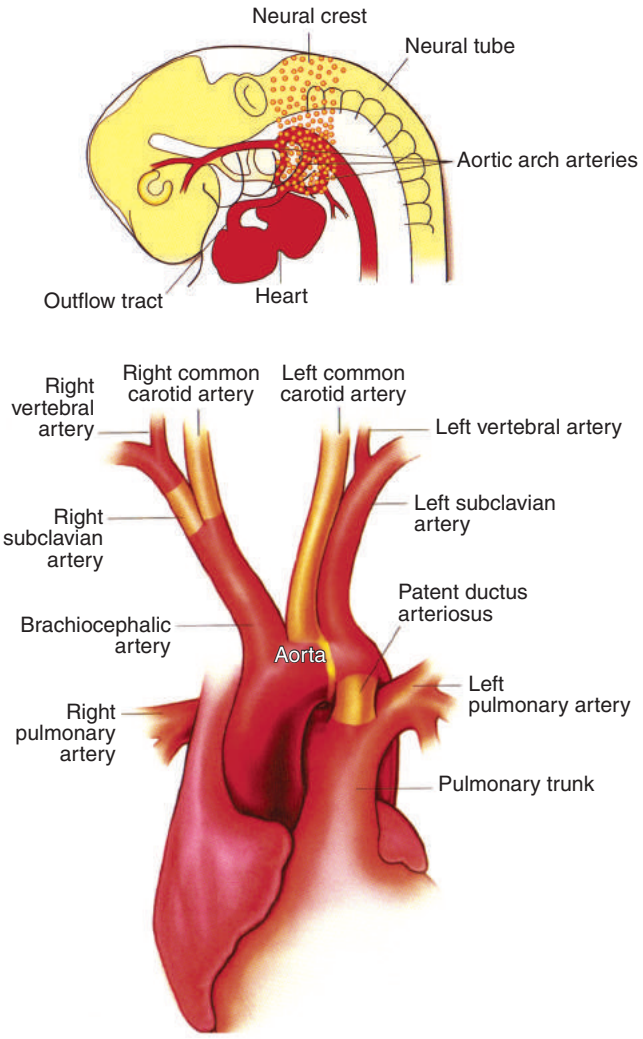
The pulmonary veins grow in progressively from the developing lung vasculature, first as a common pulmonary vein from both lungs. This vein fuses into the back of the left atrium.[119] As the atrium expands, the common pulmonary vein becomes increasingly absorbed into the back wall, such that at first two, then four of its distal branches eventually enter independently into the atrium, two from the left and two from the right lung (Fig. 45.9E–H). In the original atrial segment the heart tube is not part of the functioning atria in the mature heart, instead relegated to the right and left atrial appendages.

Aortic Arch Development

The primitive heart tube connects to the aortic sac, the precursor to the ascending aorta, and begins pumping to the developing systemic circulation of the embryo as soon as it is formed. The aortic sac connects to paired dorsal aortae posteriorly via an aortic root, which gives rise to a series of arches, the branchial arches (Fig. 45.10). It is along these arches that the neural crest migrates into the conotruncus and supports the development of the arch arteries. Again these are paired structures, and there is a total of six pairs, although not all are patent at the same time. Arches 1 and 2 mostly regress completely, although parts contribute to some of the arteries of the face. Arch 3 does not persist as an arch, but contributes to the formation of the carotid arteries, both left and right. The left limb of arch 4 remains in continuity with the aortic root. Together they make up the true aortic arch and its first branch, the brachiocephalic (innominate) artery. The right limb of arch 4 becomes part of the right subclavian artery, which retains its proximal connection with the brachiocephalic artery.[10] This arch remodeling has occurred by 7 weeks' gestation (Fig. 45.11). In some cases, either independently or as part of another developmental cardiac defect, the right limb of arch 4 remains patent and the left forms the left subclavian artery—this forms a right aortic arch with mirror-image branching. Arch 5 is small and never fully develops. Arch 6 forms with the developing pulmonary artery vasculature and makes up the proximal left and right pulmonary arteries and the ductus arteriosus.[9] The ductal arch persists throughout fetal life as another means of right to left shunt, allowing blood from the right ventricle to bypass the pulmonary circulation and cross over into the descending aorta.

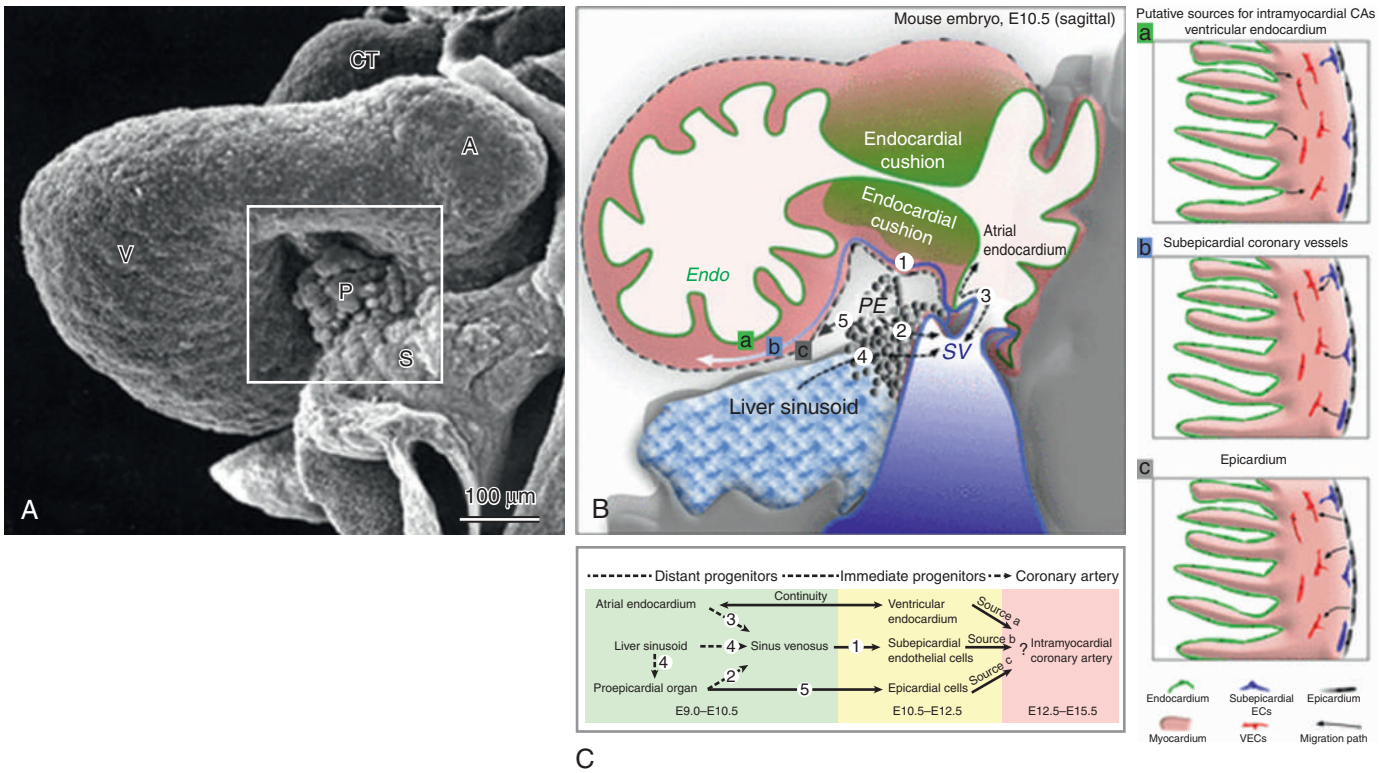
Coronary Arteries

The coronary arteries were for many years assumed to "sprout" from the ascending aorta and grow over the surface of the heart. This is now known to be incorrect. The coronary arteries form in situ within the myocardium and then connect to a coronary stem that forms within the aorta from peri-truncal capillaries.[120–124] The coronary vessels themselves form from several sources. One



• **Fig. 45.10** Aortic arch development. *Top*, Migration pattern of neural crest cells into pharyngeal arches 3, 4, and 6. *Bottom*, Normal aortic arch at term. Most of the pharyngeal arch segments have regressed. The third arch persists in part as the left and right common carotid arteries. The left fourth arch persists as the true aortic arch, while a portion of the right fourth arch makes up the proximal right subclavian artery. The sixth arch persists as the ductus arteriosus (ductal arch). (From Kirby ML. Contribution of neural crest to heart and vessel morphology. In: Harvey RP, Rosenthal N, eds. *Heart Development*. Academic Press; 1999:180–181.)

is the proepicardial organ (see Fig. 45.5A).[124–126] This is in close proximity to the sinus venosus, and there appears to be some movement of cells from one population to the other.[120] The proepicardial organ is a transient structure that spreads out over the surface of the heart as an epithelium, forming the epicardium. Early studies using lineage tracing methods in chick embryos suggested that the majority of coronary arteries, both endothelium and smooth muscle, were formed from the epicardium.[124,125] More recent studies have shown that while this is true for the smooth muscle component of the coronary arteries, the endothelium is more complex in origin. These studies have used detailed transgenic lineage tracing methods in mice to show important contributions from the endocardium[127] and sinus venosus.[128–130] The endocardium-derived cells invade the myocardium from the inner surface of the heart, migrating toward the epicardial



• **Fig. 45.11** Coronary vessel origins. (A) Scanning electron micrograph showing the developing proepicardial organ (P), Sinus venosus (S), atrium (A) ventricle (V), and conotruncus (CT). (B) Schematic of a mouse embryo at the same stage (E10.5) showing the various origins of the coronary plexus, including endocardium (endo, *green*), proepicardial organ (PE, *gray*), and sinus venosus (SV, *blue*). The panels at the right (*a,b,c*) correspond to magnified views as labeled in (B); *arrows* show migration paths of each cell type into the myocardium *(pink)*, using the same color coding as in (B); endocardium is in *green*, epicardium arises from the PE *(black)*, and subendocardial ECs are subendocardial endothelial cells arising from the sinus venosus *(blue)*. In *red* are the vascular endothelial cells (VECs) that form the coronary vessels. (C) Differentiation path of the various cell types with timing in the mouse embryo; numbers correspond to migration paths shown in (B). (A from Hiruma T, Hirakow R. Epicardial formation in embryonic chick heart: computer-aided reconstruction, scanning and transmission electron microscopic studies. *Am J Anat*. 1989;184132; B, C from Tian X, Pu WT, Zhou B. Cellular origin and developmental program of coronary angiogenesis. *Circ Res*. 2015;116:517.)

surface and differentiating into coronary artery endothelial cells. The cells from the sinus venosus migrate and expand within the subepicardial space, invading the myocardium as a distinct population from the epicardium. To add to the complexity of cell lineages, this process is not uniform throughout the ventricular myocardium. The coronaries within the ventricular septum appear to form differently from the ventricular free wall.[120,127] Regardless of ultimate origin, the coronary vessels form, grow and fuse with one another to form a working vasculature. This corresponds with the process of growth and trabeculation of the ventricles. With the increasing complexity and thickness of the myocardium, simple diffusion of nutrients from the blood inside the heart is no longer adequate. It is at this point, that the coronary artery plexus grows into the aorta just above the aortic valve. Signaling from the neural crest, epicardial-derived cells, and recently discovered intra-aortic cardiomyocytes all appear to play an important guiding role.[131–133] Occasionally this process can go awry, and a coronary artery (usually the left) can join into the pulmonary artery instead of the aorta. This does not damage the fetal myocardium given the low oxygen state of the fetus, with little difference in oxygen tension between the aorta and pulmonary artery. After birth, however, ischemia sets in rapidly, causing myocardial infarction in infancy.

Conduction System

The AV canal myocardium, part of the primitive heart tube, does not persist in the adult heart. There is no muscular connection between the mature atrial and ventricles. The process for isolation of the atrial and ventricular muscle appears to occur as the epicardium of the AV sulcus establishes continuity with the developing endocardial cushions beneath; this occurs all along the ventricular margin of the AV canal.[134] The only remaining connection that remains between atria and ventricles is within the conduction system, the AV node.[135–137] Occasional muscular bridges of tissue remain as accessory muscle connections, which can be clinically important as substrate for arrhythmias (specifically AV reciprocating tachycardia, a common form of supraventricular tachycardia).

Lineage tracing studies show that the cells of the conduction system differentiate in situ from myocytes.[138–142] There is evidence that the developing coronary vasculature is a source of signaling for this transdifferentiation to occur; the conduction system

tends to develop alongside coronary vessels.[139] Conduction system myocytes express different markers, junctions, and have different action potential profiles that allow for automaticity.[142–146] Under normal conditions, the automaticity of the remaining conduction system is suppressed as the dominant pacemaker of the heart forms, the sinoatrial node. Lineage tracing studies in early chick embryos showed that the SA node arises from a population of cardiac mesoderm outside of the primary and secondary heart fields that coalesce in the heart near the right sinus horn.[147] Activation mapping of embryonic chick heart conduction shows that the primitive SA node begins to function soon after cardiac looping (the site of earliest activation prior to this actually being in the left sinus horn).[147]

Conclusion

We have reviewed heart development, with attention to the morphology, cell biology, genetics, and physiology of the heart as it forms and remodels. The field of developmental biology of the heart continues to advance rapidly on all of these fronts. New technologies allow earlier and earlier visualization of the developing human heart, recently as early as week 6 gestation by cardiac MRI,[77] and week 10 to 11 by cardiac ultrasound.[148–155] Novel genetic techniques allow us to apply what is learned from animal models to humans, and to recreate human disease in animal models with greater and greater specificity. The common goals to be applied to human disease are early recognition of congenital heart malformations, prevention where feasible, and state-of-the-art intervention to allow an abnormal heart to function as normally as possible. Currently, such intervention is surgical and cardiac catheterization based and continues to evolve. In the future, gene therapy, cardiac stem cell grafting, and in vitro tissue engineering will likely be added to the therapeutic potential for patients with congenital heart malformations.

Cardiovascular Compromise in the Newborn Infant

SHAHAB NOORI AND ISTVAN SERI

KEY POINTS

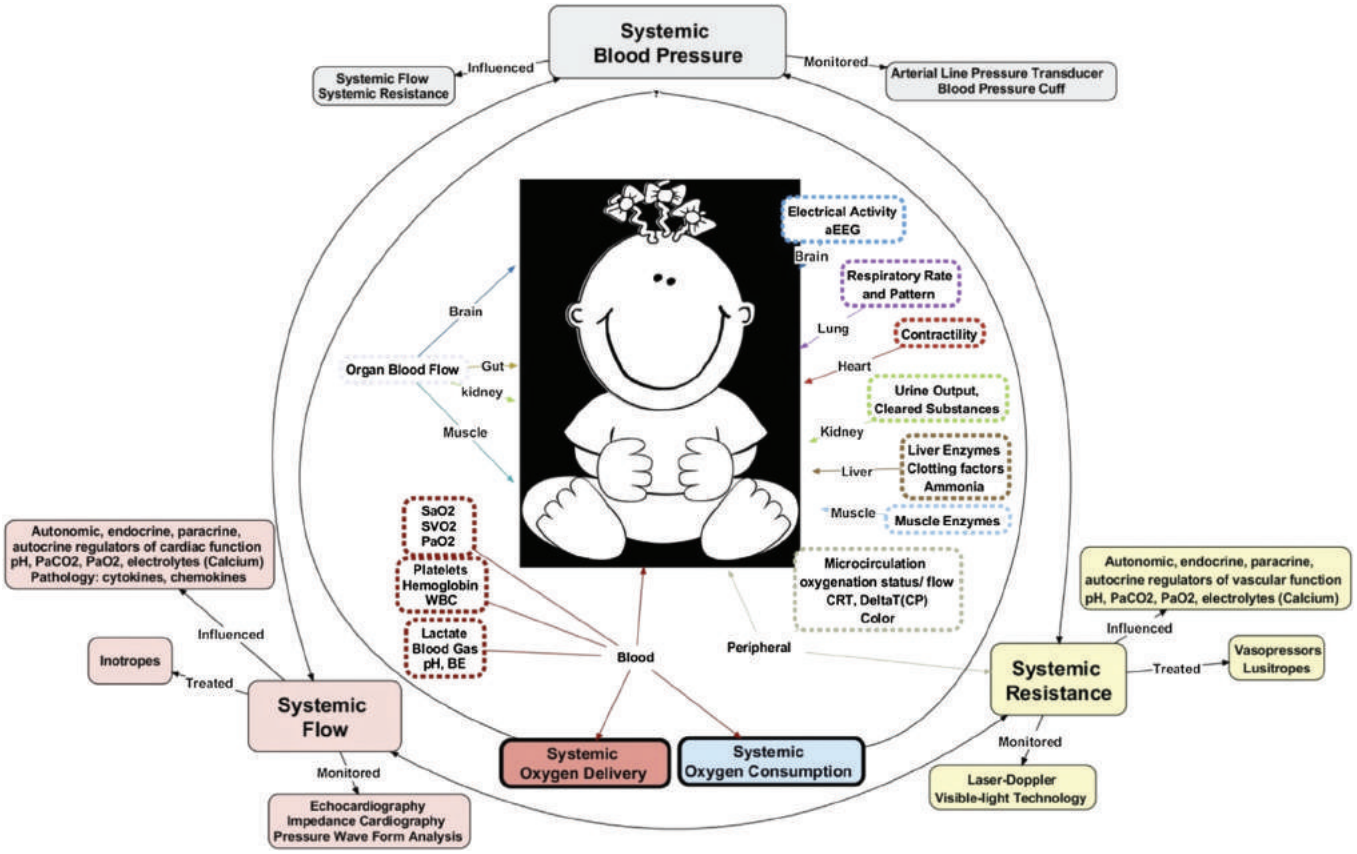
- It is difficult to diagnose neonatal shock in its *uncompensated phase* during the immediate transitional period, while it is even harder to diagnose neonatal shock in its *compensated phase* using standard clinical monitoring and clinical approach.
- It is unclear what gestational- and postnatal-age-dependent blood pressure and systemic and organ blood flow values represent hypotension and poor tissue perfusion (respectively), warranting timely intervention in the neonate.
- Although there is some recent evidence that management of neonatal hypotension/systemic blood flow improves clinically relevant outcomes, more data are needed.
- A thorough understanding of the principles of developmental cardiovascular physiology, the etiology, pathophysiology, and clinical presentation of neonatal shock, and the mechanisms of action, pharmacokinetics, and pharmacodynamics of medications used to treat cardiovascular compromise are essential for neonatal care providers.
- Recent advances in bedside monitoring technologies such as near-infrared spectroscopy and the application of point of care ultrasonography in assessing cardiovascular function hold promise for early diagnosis and better management of circulatory failure in neonates.

Although the prevalence of hypotension in neonates admitted for intensive care is unclear, up to 50% of very low birth weight (VLBW) neonates present with blood pressure values considered to be low in the immediate transitional period.[1] However, VLBW neonates account for only approximately 25% of all patients diagnosed with hypotension in neonatal intensive care units. The lack of clear data on the prevalence of neonatal hypotension is primarily due to the uncertainty about the lower limit of the gestational- and postnatal-age-dependent normal blood pressure range in neonates.[2] This is illustrated, among others, by the significant differences in the prevalence of the use of vasopressor/inotropes in preterm neonates during the transitional period among different intensive care units.[3–5] In addition, depending on the ability of the patient to compensate for the cardiovascular compromise, a given blood pressure value in a given patient might represent appropriate systemic and organ blood flow while at another point in time, it may signal compromised tissue perfusion. Therefore, considering only blood pressure and the fairly inaccurate indirect clinical signs of tissue perfusion makes it difficult if not impossible to accurately diagnose neonatal shock in time. Also, a timely diagnosis is one of the cornerstones of initiating effective treatment modalities.

As long as pulmonary gas exchange is adequate, shock is caused by hypovolemia, cardiac failure, vasoregulatory failure, or a combination of these etiologies. Shock has been defined as a "state of cellular energy failure resulting from an inability of tissue oxygen delivery to satisfy tissue oxygen demand."[6] According to this definition, when oxygen delivery is inadequate to meet oxygen demand, the organs start failing and, if corrective measures are not effective, will result in irreversible organ damage and ultimately death. Although oxygen delivery to the organs is dependent on several factors, it is fundamentally driven by both the oxygen content of the blood and the volume of blood flowing to those organs. Because oxygen content is primarily determined by the hemoglobin concentration and oxygen saturation, with less contribution from the dissolved oxygen (see later discussion), it is relatively easily evaluated and monitored in the neonatal intensive care unit. However, reliably assessing systemic and organ blood flow and tissue oxygen delivery and consumption at the bedside is challenging because, to provide adequate information on the rapidly changing hemodynamic status of the critically ill neonate, it requires continuous monitoring of key hemodynamic parameters in absolute numbers (Fig. 46.1).

Recent advances in our ability to monitor systemic and organ blood flow and tissue oxygenation as well as vital organ (brain) function at the bedside will likely lead to a better understanding of the complex hemodynamic changes associated with neonatal cardiovascular compromise.[7,8] These advances should lead to the development of treatment modalities more appropriately based on the etiology, pathophysiology, and phases of shock, thereby improving clinically relevant outcomes. The impact of treatment using some of these advances is currently under investigation.[9]

At present in clinical practice, tissue perfusion is routinely assessed by monitoring heart rate, blood pressure, capillary refilling time, acid-base status, serum lactate levels, and urine output. However, Doppler ultrasound and near-infrared spectroscopy



• **Fig. 46.1** Tools of Comprehensive Hemodynamic Monitoring. Tools used to provide a global *(outside circles)* and regional *(inside the circles)* assessment of developmental hemodynamics. Global monitoring of the relationship among systemic flow, blood pressure, and resistance and arterial/venous oxygen content provides information on systemic oxygen delivery and consumption. Regionally monitored parameters provide direct or indirect information on a specific organ blood flow, function, and vital or non-vital blood flow regulatory assignments. *aEEG*, Amplitude-integrated electroencephalography; *BE*, base excess; *CRT*, capillary refill time; *$PaCO_2$*, arterial partial pressure of carbon dioxide; *PaO_2*, arterial partial pressure of oxygen; *SaO_2*, arterial oxygen saturation; *SvO_2*, venous oxygen saturation; *WBC*, white blood cells. Transitional cardiovascular physiology and comprehensive hemodynamic monitoring in the neonate: relevance to research and clinical care. *Semin Fetal Neonatal Med*. 2014;19:45–53.)

(NIRS) data have highlighted that these parameters are relatively poor indicators of acute changes in organ blood flow and tissue oxygen delivery in critically ill neonates.[10–14] These observations and the very limited evidence that treatment of neonatal cardiovascular compromise and hypotension improves outcomes[3,15–17] call for a paradigm shift in our thinking about pathophysiology, diagnosis, and treatment of neonatal shock. This suggests that the assessment of the hemodynamic status in critically ill neonates should include the complex interactions between blood flow and blood pressure as well as tissue oxygen delivery and consumption.[18] A comprehensive, real-time hemodynamic monitoring and data acquisition system has been developed,[7,19,20] although its use is limited to clinical research at present. However, integration of point of care echocardiography and NIRS in clinical management of circulatory compromise has now been used at a number of centers and preliminary results are encouraging.[21] The reader is referred to the recent review on the applications and limitations of various advanced hemodynamic monitoring tools in neonates.[22]

Principles of Developmental Cardiovascular Physiology and Pathophysiology, Phases, and Etiology of Neonatal Shock

Principles of Oxygen Delivery

Oxygen is essential for mitochondrial respiration but is not stored in the body. Thus, interruption of oxygen supply to cells can result in irreversible damage (sometimes within minutes), particularly in vital organs such as the brain and myocardium.

The primary function of the cardiorespiratory system is to provide adequate oxygen delivery to tissues. Accordingly, shock is defined as inadequate systemic tissue oxygen delivery (see earlier). Oxygen delivery can be expressed as

$$DO_2 = \text{cardiac output (CO)} \times \text{arterial oxygen content } (CaO_2)$$

where

$$CO = \text{heart rate (HR)} \times \text{stroke volume (SV)}$$

and

$$CaO_2 = [1.34 \times \text{hemoglobin concentration (Hb)} \times \text{arterial oxygen saturation } (SaO_2)] + [0.003 \times \text{arterial partial pressure of oxygen } (PaO_2)]$$

Stroke volume is the result of a complex interplay among preload, afterload, and contractility (Fig. 46.2), all three of which are, at present, impossible to monitor reliably and continuously at the bedside. Although these parameters are more fully described below, in brief preload is the end-diastolic volume of the ventricle (a three-dimensional reflection of pre-contractile myocardial cell fiber length), and, up to a point, the greater the preload, the larger the stroke volume (the Frank-Starling relationship). Afterload is the force the ventricle must generate against the systemic or pulmonary vascular resistance. As long as appropriate perfusion pressure is ensured, the lower the afterload, the higher the cardiac output. Contractility (the intrinsic ability to generate force per unit time) may be assessed noninvasively but not continuously by echocardiogram. Since at present most of the measures of cardiac contractility are both preload and afterload dependent, contractility is not truly an independent variable. In addition, cardiac output in neonates is considered more dependent on heart rate than contractility because the ability of neonates to augment their stroke volume is limited when compared to children or adults.

From this simple model, it is easily appreciated that if there is an acute decline in CaO_2, by a decrease in either the hemoglobin concentration or SaO_2 or both, the cardiac output will increase in response to maintain DO_2. On the other hand, because neither hemoglobin concentration nor SaO_2 can be physiologically increased rapidly, other than increasing tissue oxygen extraction and selective blood flow distribution, there is no acute compensation for a low cardiac output due to decreases in myocardial contractility and/or preload.

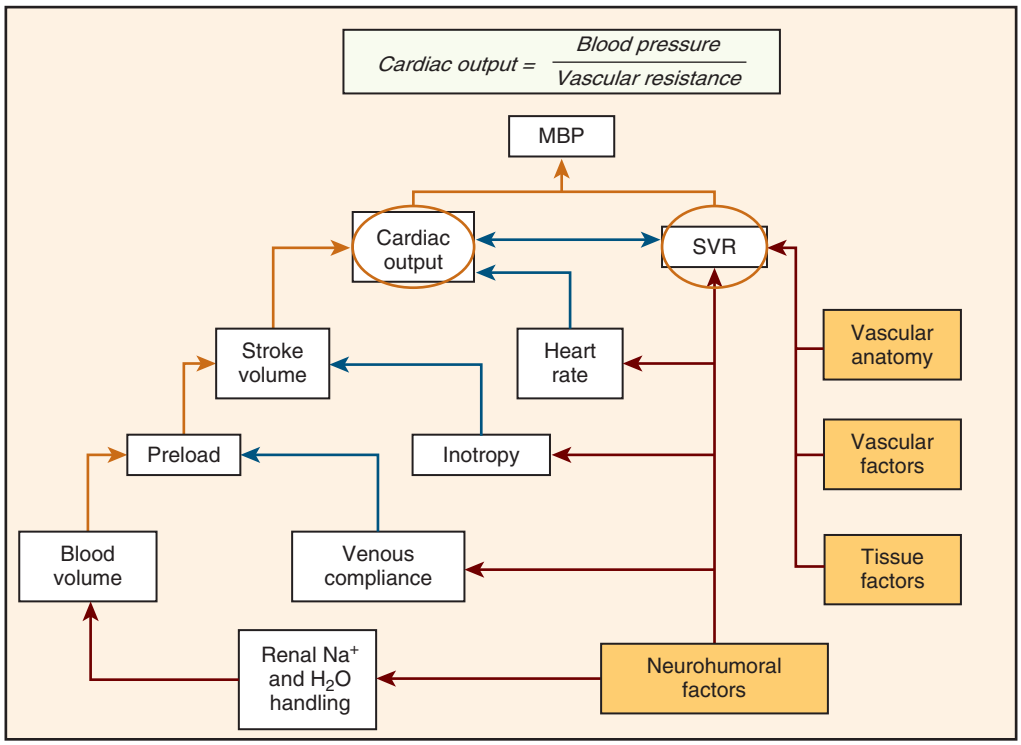
The purpose of oxygen delivery is to provide for oxygen consumption (VO_2), which can be expressed as

$$VO_2 = CO \times (CaO_2 - CvO_2)$$

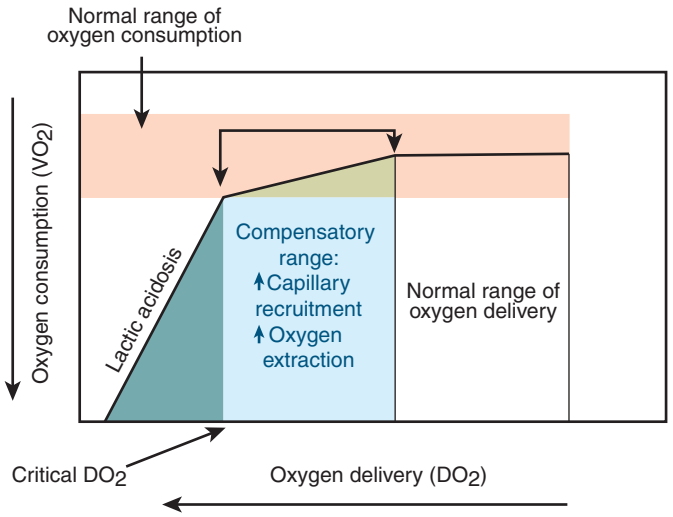
where CvO_2 is the mixed venous oxygen content.

This relationship is based on the Fick principle, from which, knowing the flow rate and arterial-venous content difference of a trace element (in this case, oxygen), one can calculate the uptake or removal rate of the tracer.

Normally DO_2 and VO_2 are well matched, with O_2 extraction being approximately 25%. Accordingly, if the SaO_2 is 100%, SvO_2 would be expected to be 75%. If cardiac output falls, VO_2 may be maintained constant by capillary bed vasodilation and recruitment and/or by increased O_2 extraction by the tissues. Increased O_2 extraction is manifested as a lower CvO_2 and therefore greater $CaO_2 - CvO_2$ difference. The relationship between DO_2 and VO_2 may be graphically displayed as in Fig. 46.3. Once oxygen extraction is maximal, at the critical DO_2 threshold, anaerobic metabolism ensues, resulting in lactic acidosis. If not reversed, the oxygen debt accumulates, and organ failure and death will ensue. In general, during aerobic metabolism 38 mol adenosine triphosphate (ATP) is produced per 1 mol glucose, whereas during anaerobic metabolic conditions, 2 mol ATP and 2 mol lactate are produced per 1 mol glucose.



• **Fig. 46.2** Factors Regulating Cardiac Output, Blood Pressure, and Systemic Vascular Resistance. From a physiologic standpoint, SVR and cardiac output are the regulated (independent) variables and MBP is the dependent variable. *MBP*, Mean blood pressure; *Na*+, sodium; *SVR*, systemic vascular resistance. (Modified from Klabunde RE, www.cvphysiology.com.)



• **Fig. 46.3** Relationship Between Oxygen Consumption and Delivery. In the normal range of oxygen delivery, oxygen consumption is unaffected by changes in the delivery rate of oxygen to the tissues. As oxygen delivery decreases below the normal range, tissue oxygen consumption remains in the normal range for a while because of activation of local compensatory mechanisms such as capillary recruitment and increased oxygen extraction. However, when oxygen delivery decreases to the "critical" point, compensatory mechanisms can no longer satisfy tissue oxygen demand, and anaerobic metabolism commences, resulting in significantly decreased adenosine triphosphate and increased lactate production.

Before reaching the stage of delivery-dependent VO_2, the SvO_2 can be used as a proxy for DO_2. Assuming VO_2, hemoglobin concentration, and SaO_2 are constant over a short period of time, a decline in SvO_2 represents a decrease in cardiac output. This relationship is clinically important, as SvO_2 can be measured intermittently via a venous catheter, ideally placed in the pulmonary artery in a patient without intracardiac shunts in order to obtain a true mixed venous sample. Central venous oxygen saturation ($ScvO_2$) may also be used as a proxy for DO_2, measured via a venous catheter with its tip at the superior vena cava—right atrial junction. It is of note that the location of the catheter tip is critical; if the tip is located lower in the right atrium, it will sample more desaturated blood streaming from the coronary sinus and/or hepatic veins. However, for several reasons, measurement of $ScvO_2$ is not done routinely in neonates in neonatal intensive care units except for some neonates with congenital heart disease in the postoperative period following surgical correction of the underlying cardiac condition.

In general, these principles are valuable guides to understanding and managing global DO_2 and VO_2, but they do not readily assist with the assessment of individual organ DO_2. Furthermore, the limitations of measuring VO_2, DO_2, and even just $ScvO_2$ are often daunting. However, advances in noninvasive regional tissue oxygen saturation (rSO_2) monitoring via NIRS have increasingly allowed for such assessments in different tissues including the brain, kidneys, intestine, and muscle (see later discussion).

Finally, there is a class of neonates where calculations using the Fick principle can be critical in directing therapy. Newborns with congenital heart disease and intracardiac shunts may have perturbations in the usual pulmonary to systemic blood flow ratio (Qp:Qs). Normally, of course, in patients with the two circulations in series and no shunts, Qp:Qs = 1. By comparing the oxygen utilized by the body with the oxygen taken up by the lung, Qp:Qs can be estimated.

$$Qs = VO_2/(CaO_2 - CvO_2)$$

and

$$Qp = O_2\text{uptake}/(CpvO_2 - CpaO_2)$$

where pv and pa represent pulmonary vein and pulmonary artery, respectively.

After substituting and eliminating common terms

$$Qp{:}Qs = (SaO_2 - SvO_2)/(SpvO_2 - SpaO_2)$$

This formula requires two assumptions unless saturation values are determined directly, as done in the cardiac catheterization laboratory: first, $SpvO_2$ is 95% to 100%, and second, SvO_2 measured through a central venous line reflects a mixed venous sample. A Qp:Qs ratio of < 1 would suggest the presence of a right-to-left shunt and, typically, decreased pulmonary circulation, both of which result in less oxygenated blood entering the systemic circulation with resultant cyanosis. A Qp:Qs ratio of>1, in turn, would suggest left-to-right shunting with resultant pulmonary overcirculation. Of note is that changes in Qp:Qs ratio in either direction will affect oxygen content and/or oxygen delivery to the organs.

The value of this calculation can be illustrated with the following example. A newborn infant with hypoplastic left heart syndrome (HLHS) is found to have an SaO_2 of 95% and an SvO_2 of 80%. Using the formula just given, assuming a $SpvO_2$ of 100% and recognizing that SaO_2 and $SpaO_2$ are the same in this patient, we arrive at a Qp:Qs ratio of 3:1. If systemic blood flow is to be preserved, the single right ventricle will need to sustain a fourfold increase in cardiac output while the significant pulmonary overcirculation will lead to the development of congestive heart failure. The inability of the right ventricle to sustain such an increase in cardiac output will then lead to inadequate systemic blood flow, resulting in shock. Importantly, both conditions can be present at the same time. However, by maintaining an SaO_2 within the target range of 75% to 85% in these patients, the Qp:Qs ratio will shift closer to 1:1, providing a simplistic rationale for using such an SaO_2 target range. However, in patients with HLHS, the effects of shunting on blood oxygen content and/or delivery are far more complex as systemic oxygen availability is determined, along with other factors, by the relationship among $SpvO_2$, SaO_2, SvO_2, and cardiac output.[23] Accordingly, in addition to a targeted SaO_2 range, management of these patients must be guided by the difference in systemic arterial and venous oxygen saturations and other indicators of tissue perfusion (see also Chapter 50).

Developmental Regulation of Cardiac Output and Its Determinants

Cardiac output is the product of stroke volume and heart rate and is determined by the amount of blood returning to the heart (preload), the strength of myocardial contractility, and the load against which the heart must pump (afterload). Unlike preload, afterload is in general more difficult to conceptualize and therefore often used interchangeably with the simpler but less accurate term, vascular resistance. However, although afterload is altered by changes in vascular resistance, other factors also determine its magnitude. Afterload is the load or force the heart faces during contraction and is affected by the impedance of the central vasculature, the

resistance of the peripheral vascular beds, the ventricular mass, blood pressure, and the inertia of the blood. In addition, it is affected by myocardial contractility and preload as well. If the myocardial function is intact, cardiac output depends solely on preload and afterload according to the relationships described by the Starling curve.

Therefore, low cardiac output and thus low systemic blood flow can result from various combinations of abnormalities of the three determinants of cardiac output: low cardiac preload, poor myocardial contractility, or high cardiac afterload. In addition, extremes of these variables in the opposite direction (i.e., high cardiac preload, increased myocardial contractility, or low cardiac afterload) can contribute to cardiovascular insufficiency, albeit not as commonly. This is due to the fact that these three variables as well as heart rate affect one another. For example, in an infant of a diabetic mother with hypertrophied cardiomyopathy, increased contractility and low afterload can further compromise systemic flow by reducing preload and worsening left ventricular outflow tract obstruction.

Preload

Decreases in preload lead to diminished stroke volume and cardiac output and are most often caused by low effective circulating blood volume. This can be due to loss of circulating blood volume following hemorrhage (absolute hypovolemia), or the circulating volume may be inadequate for the vascular space as in vasodilatory shock or as a side effect of administration of lusitropes (relative hypovolemia). Because approximately 75% of the circulating blood volume is on the venous side of the circulation at any given point in time, the increases in venous capacitance caused by venodilation significantly contribute to relative hypovolemia under these circumstances. The interaction between the respiratory and cardiovascular system is complex, and the provision of positive pressure respiratory support alters this interaction.[24] Excessive mean airway pressure, especially in compliant lungs, increases pulmonary vascular resistance and decreases pulmonary blood flow with a resultant decrease in systemic blood flow. Because preload is also augmented by the negative intrathoracic pressure generated at each spontaneous inspiration, the positive intrathoracic pressure associated with positive pressure mechanical ventilation reduces venous return and hence preload and cardiac output.[25,26] However, the impact in neonates with low lung compliance ventilated on appropriate positive pressure ventilatory settings appears to be modest.[27–29]

Contractility

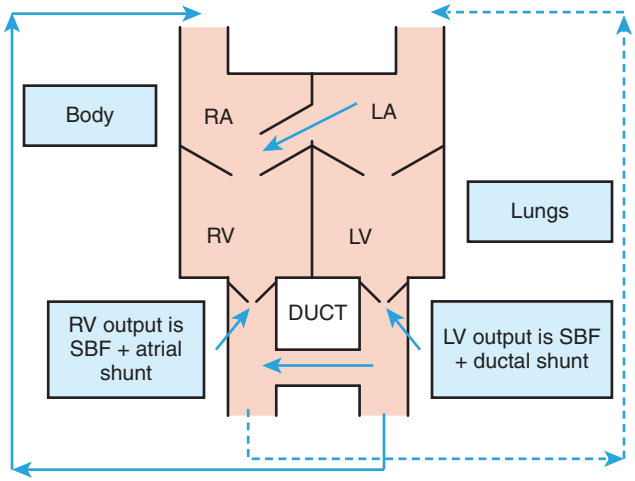
The strength of myocardial contractility depends on the filling volume and pressure, and the maturity and integrity of the myocardium.[30] Thus, decreases in preload (hypovolemia, cardiac arrhythmia), as well as prematurity (especially extreme immaturity), hypoxic insults, and infectious (viral or bacterial) agents,[31] all negatively affect the ability of the myocardium to contract with resultant decreases in cardiac output.

Afterload

If cardiac afterload is too high, the ability of the myocardium to contract and pump may become compromised, and cardiac output may fall.[32,33] Such increases in afterload are associated with enhanced endogenous catecholamine release during the period of immediate postnatal adaptation along with loss of the low-resistance placental circulation. Similar increases in afterload are seen in hypovolemia, hypothermia, or when inappropriately high doses of vasopressor-inotropes are being administered to a patient with intact cardiovascular adrenoreceptor responsiveness.[34] High afterload can affect either ventricle and if the output of one of the ventricles is reduced, this will affect the function of the other ventricle, especially when the fetal channels are closed. For instance, if the right ventricular output is low because of high pulmonary vascular resistance, the amount of blood traversing the lungs to the left ventricle will be reduced, leading to low systemic blood flow with blood pooling in the systemic venous system.

Changes in Preload, Contractility, and Afterload During Transition

With delivery and the separation of the placenta, the fetal circulation begins its transition to the mature (adult-type) circulation in which the systemic and pulmonary circuits are in series and, with the closure of the fetal shunts between the two circulations, the right and left cardiac outputs are equal. However, some component of the normal transition (e.g., removal of placental circulation) is rather abrupt while others (cessation of flow through the ductus arteriosus and foramen ovale) are more gradual.[35,36] With the initiation of breathing resulting in lung expansion and the separation of the placenta, the pulmonary vascular resistance drops precipitously and systemic vascular resistance increases, respectively. The resultant increase in the left ventricular (LV) afterload could lead to a decrease in myocardial contractility, which in selected populations of vulnerable preterm infants may result in decreased cardiac output. In addition, the above-mentioned changes in the pulmonary and systemic vascular resistance lead to an evolution in ductal flow pattern from a purely right-to-left to bidirectional and, eventually, purely left-to-right ductal flow. In healthy term infants, LV stroke volume and output increase in the first few minutes after birth. This change coincides with increasing net left-to-right ductal shunting.[37] The increase in LV preload from ductal shunting likely explains the increase in LV output, and the increase in LV output may offset the potential impact of the left-to-right ductal shunt on the systemic circulation. Therefore, there is usually no evidence of circulatory compromise in the healthy neonate. Subsequently, the ductus arteriosus constricts and then closes in the vast majority of term neonates within 24-to-48 hours. Therefore, in the healthy term neonate, the rapidly constricting ductus arteriosus prevents the development of hemodynamically significant left-to-right shunting across the ductus. However, the transition to adult-type circulation is prolonged in preterm, especially in extremely preterm infants and can result in circulatory compromise.[38] Indeed, by 2 months of age, less than 50% of preterm infants born at <26 weeks' gestation close their ductus arteriosus spontaneously[39] and, as the right-sided pressures fall, blood will shunt left-to-right from the systemic circulation back into the pulmonary circulation. In most VLBW neonates, pulmonary vascular resistance (PVR) initially decreases relatively rapidly for physiologic and non-physiologic reasons.[40] Physiologic mechanisms most important in the postnatal decrease of PVR include the mechanical effects of initiation of breathing on PVR and the increased postnatal oxygenation-associated direct, paracrine, and endocrine vasodilation.[41] Iatrogenic causes include surfactant administration or the inappropriate targeting of higher arterial oxygen saturations.[38,42] With the left-to-right ductal shunting, pulmonary overcirculation develops and left ventricular output, the gold standard of bedside assessment of systemic perfusion, cannot be used as a measure of systemic perfusion (Fig. 46.4).[43]



• **Fig. 46.4** Impact of Left-to-Right Shunting Across the PDA and PFO on LVO and RVO Measurements. Effect of left-to-right shunting across the PDA and foramen ovale on LVO and RVO. Under these circumstances, LVO represents the sum of total pulmonary venous return and ductal blood flow, whereas RVO measures the sum of systemic venous return and left-to-right shunting across the PFO. *LVO*, Left ventricular output; *PDA*, patent ductus arteriosus; *PFO*, patent foramen ovale; *RVO*, right ventricular output; *SBF*, systemic blood flow. (From Kluckow M, Seri I. Cardiovascular compromise in the preterm infant during the first postnatal day. In: Seri I, Kluckow M, eds. *Neonatology Questions and Controversies: Hemodynamics and Cardiology*. 3rd ed. Philadelphia: Elsevier; 2019:471–488.)

Indeed, under these circumstances, left ventricular output measures systemic perfusion and ductal blood flow. In earlier studies investigating the post-transitional changes in systemic perfusion and/or the effects of vasoactive agents on cardiovascular function, this fact has often not been acknowledged.[33,44] Therefore, the conclusions drawn from some of these studies[33] need to be reevaluated. More recent studies have acknowledged this hemodynamic paradigm and used right ventricular output to assess systemic perfusion in the VLBW neonate during the transitional period. However, right ventricular output only represents systemic perfusion as long as left-to-right shunting across the foramen ovale does not become significant. In many preterm neonates, however, as left-to-right shunting across a nonconstricting patent ductus arteriosus (PDA) increases during the first 12 to 36 hours, left atrial volume and pressure increase, often leading to the development of a significant left-to-right shunt across the foramen ovale.[45] The left-to-right shunt through the patent foramen ovale (PFO) will then render the use of right ventricular output as a measure of systemic blood flow inaccurate because right ventricular output now represents systemic inflow and PFO flow.[43] This hemodynamic scenario results in the lack of an acceptable conventional measure of systemic blood flow in these neonates. To circumvent this problem, superior vena cava (SVC) flow has been used as a measure of upper body blood flow in preterm neonates with the fetal channels open.[11,46] The use of SVC flow has provided novel insights into the mechanisms of transitional hemodynamics, such as the observation that intraventricular hemorrhage (IVH) develops in many VLBW neonates as systemic blood flow improves, resulting in reperfusion of the brain (see discussion below).[47] However, the vulnerability of SVC flow measurements to error and the technical difficulties associated with its use as a surrogate measure of systemic blood flow have forced these measurements to remain primarily a research rather than a clinical tool.[48–50]

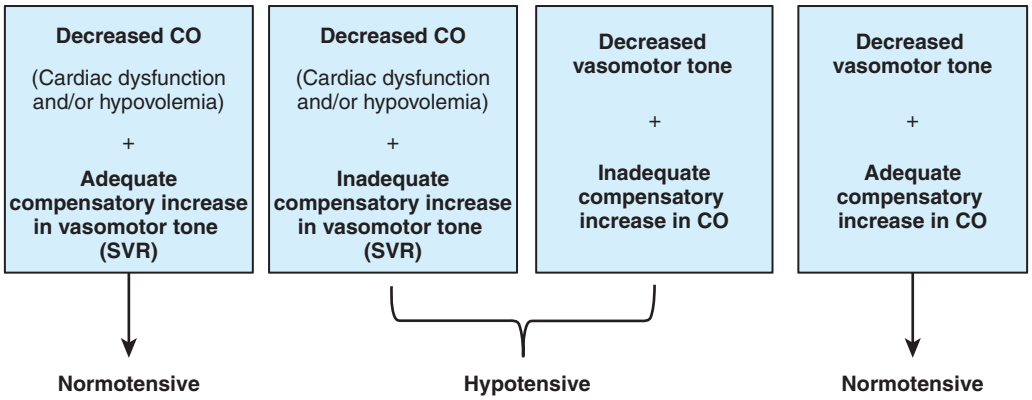
Developmental Regulation of Systemic Blood Pressure

Systemic blood pressure is the product of systemic blood flow and systemic vascular resistance. There is an association between low blood pressure and central nervous system injury in the preterm neonate.[3,51–55] Yet, blood pressure correlates only weakly with blood flow in this patient population during the period of immediate postnatal adaptation when the fetal channels are open.[11] Thus, in preterm infants during the first postnatal day, blood pressure may be low because resistance (vasomotor tone) is low even in the presence of normal or high blood flow (Fig. 46.5). Alternatively, blood pressure may be normal or high because resistance is high in the presence of normal or low blood flow.[10] The lack of clarity surrounding the nature of the relationship between blood pressure and systemic blood flow during the transitional period results, at least in part, from our inability to appropriately define the normal blood pressure range[2] and systemic blood flow (see earlier), and to characterize the developmental regulation of organ blood flow and vital organ assignment (see later discussion) in the preterm neonate. Indeed, the recent findings of a higher rate of survival without severe morbidity and a lower rate of severe IVH and cerebral injury among preterm infants with isolated (asymptomatic) hypotension who were treated compared to those who were not treated highlights the complexity of the blood pressure and blood flow interaction during the postnatal transitional period.[3] These findings also challenge the "permissive hypotension" strategy[56] stemming from the uncertainty surrounding the nature of the relationship between blood pressure and systemic blood flow during the transitional period as well as from the potential side effects of vasopressor-inotropes, especially when not appropriately titrated.[57]

Developmental Regulation of Organ Blood Flow and Its Autoregulation and Vital Organ Assignment

Cerebral Blood Flow Autoregulation

Even very immature preterm neonates autoregulate their cerebral blood flow (CBF).[14,58,59] However, the autoregulatory blood pressure range in this patient population is believed to be narrow, and thus "normal" blood pressure is very close to the lower elbow of the autoregulatory curve.[60,61] Some data suggest that CBF autoregulation is different during the cardiac cycle with CBF being pressure-passive mainly during diastole in preterm infants <34 weeks' gestation.[62] Organ blood flow autoregulation is impaired in preterm neonates who are sicker and/or more immature.[1,59,63,64] In these patients, changes in blood pressure are mirrored by changes in CBF with a high coherence, and these babies are at higher risk for cerebral injury.[59,64–66] Similarly, impairment of the autoregulatory system in dampening the impact of changes in blood pressure on CBF can increase the risk of brain injury in preterm infants.[67] Factors that impair cerebral and other organ blood flow autoregulation include birth asphyxia, acidosis, infection, hypoglycemia, tissue hypoxia and ischemia, and sudden alterations in arterial carbon dioxide tension ($PaCO_2$).[60] It is of clinical importance that the CO_2-CBF reactivity is more robust than the pressure-CBF



• **Fig. 46.5** Pathophysiology of Neonatal Cardiovascular Compromise in Primary Myocardial Dysfunction and Primary Abnormal Vascular Tone Regulation With or Without Compensation by the Unaffected Other Variable. This figure illustrates why blood pressure can remain in the "normal" range when there is appropriate compensatory increase in either vasomotor tone or cardiac output. In the hypotensive scenarios, the compensatory mechanisms have been exhausted. *CO*, Cardiac output. (From Wu TW, Noori S, Seri I. Neonatal hypotension. In: Polin RA, Yoder MC, eds. *Workbook in Practical Neonatology*. 5th ed. Philadelphia: Elsevier; 2014:230–243.)

reactivity, as 1 mm Hg change in $PaCO_2$ results in ~4% change in CBF, whereas 1 mm Hg change in blood pressure is associated with only a ~1% to 2% change in CBF.[68,69] The impairment of CBF autoregulation in the preterm neonate during the immediate postnatal period has been proposed to contribute to cerebral injury with loss of vascular reactivity to both blood pressure and CO_2.[65,66] However, the finding that impaired autoregulation may also be a consequence of a preceding ischemic insult[60] makes clarification of this question particularly difficult.

Vital Organ Assignment

The vessels of the vital organs respond to decreased perfusion pressure and/or oxygen delivery with vasodilation (i.e., high-priority vascular beds), whereas the vessels of the nonvital organs, with low-priority vascular beds, vasoconstrict. Several lines of evidence in human neonates and developing animals suggest that the assignment of the forebrain circulation to a high-priority vascular bed may not be complete at birth.[70–72] For instance, in response to hypoxic exposure, the forebrain vessels of newborn dogs vasoconstrict like those of a nonvital organ whereas the hindbrain vessels vasodilate.[71] The finding that CBF autoregulation also appears in the brainstem first and in the forebrain only later in gestation[70] supports the notion that there are developmentally regulated differences in the timing of the blood flow autoregulatory functions and vital organ assignment characteristics between the forebrain and the hindbrain. The cellular mechanisms responsible for the assignment of vital and nonvital organ status from a blood flow regulatory standpoint are poorly understood. Based on these findings, it is tempting to speculate that the diminished capacity of the forebrain vessels to vasodilate in the very preterm neonate during the complex process of cardiovascular transition after delivery may contribute to hypoperfusion of the forebrain. These neonates may present with blood pressure values in the perceived normal range while being in the compensated phase of shock. Because this early phase of shock is difficult to recognize immediately after delivery, forebrain hypoperfusion can go unnoticed. Similarly, the subsequent evolution to the reperfusion phase as a result of the eventual adaptation of the cardiovascular system to the extrauterine environment may not be detected clinically. This proposed vital organ assignment-associated hypoperfusion-reperfusion cycle might contribute to cerebral injury in the very preterm neonate (see below).[73]

Developmental Regulation of Cerebral Oxygen Demand-Delivery Coupling

Very little is known about the regulation of oxygen demand–oxygen delivery coupling in neonates, especially in the transitional period. Yet, several lines of evidence indicate that the very preterm neonate is unable to couple cerebral oxygen demand with blood flow, and instead increases oxygen extraction when oxygen demand is increased.[72,74] This phenomenon may be linked to the developmental delay in the vital organ assignment of the forebrain immediately after delivery (see earlier discussion).

Phases of Shock

From a pathophysiologic standpoint, three phases of shock depicting advancing severity have been identified.[18,75]

In the "compensated phase," complex neuroendocrine and autonomic compensatory mechanisms maintain perfusion and oxygen delivery in the normal range to the vital organs (brain, heart, and adrenal glands) at the expense of decreased perfusion to the remaining organs (nonvital organs). This is achieved by vasodilation and vasoconstriction of the vessels to vital and nonvital organs, respectively, in response to a fall in perfusion pressure and/or oxygen delivery.[76,77] Blood pressure is maintained within the normal range, and heart rate increases. As perfusion of nonvital organs is decreased because of the compensatory vasoconstriction of their vascular beds, there often are clinical signs of compromised nonvital organ function such as decreased urine output. In addition, signs of poor peripheral perfusion can often be detected, such as cold extremities and prolonged capillary refill time.

If adequate treatment is not commenced, compensatory neuroendocrine and autonomic mechanisms begin to be exhausted and hypotension develops as the shock enters its "uncompensated phase." Systemic perfusion (cardiac output) will decrease, perfusion of all organs including the vital organs becomes compromised, and lactic acidosis develops.[75]

If treatment is ineffective in the uncompensated phase of shock, multiorgan failure develops and shock may enter its "irreversible phase," where permanent damage to the various organ systems occurs and further interventions will be ineffective in reversing the patient's condition.

Pathogenesis of Neonatal Shock

Etiologic Factors

The etiologic factors leading to the development of neonatal shock include hypovolemia, myocardial dysfunction, abnormal peripheral vasoregulation, or a combination of two or all three of these factors.

Hypovolemia

Hypovolemia may be absolute (loss of intravascular volume), relative (increased venous capacitance), or combined, such as is often seen in septic shock (Fig. 46.6). Hypovolemia results in cardiovascular compromise primarily by the decrease in cardiac output (systemic blood flow) caused by the decrease in preload. In addition, if blood loss is the primary cause of hypovolemia, the associated decrease in oxygen carrying capacity contributes to the development of the circulatory compromise. Because of the weak relationship between blood pressure and blood volume in hypotensive preterm neonates, hypovolemia was traditionally thought to be a relatively uncommon primary cause of circulatory compromise, especially during the first postnatal day.[78,79] However, given the difficulty in assessing intravascular volume, especially during the transition, hypovolemia can be difficult to detect clinically. Therefore, the true contribution of hypovolemia to circulatory failure is uncertain. Interestingly, recent studies comparing the effects of delayed umbilical cord clamping or cord milking with immediate cord clamping found increased blood pressure and decreased use of vasopressor-inotropes suggestive of improved hemodynamic status in the delayed cord clamping and cord milking groups.[80–82] In addition, patients with delayed cord clamping have higher blood volume and fewer receive transfusions.[82–84] These findings imply that hypovolemia might be a more common presentation in preterm neonates who receive standard care with immediate cord clamping than previously thought.

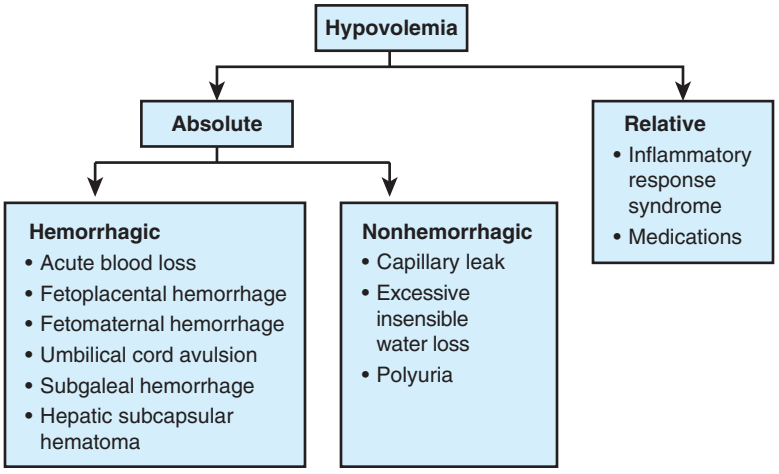
Absolute hypovolemia in the newborn can be due to several conditions. Intrapartum fetal blood loss is usually caused by open bleeding from the fetal side of the placenta, and therefore it is likely to be detected. More difficult to diagnose is the closed bleeding of an acute fetomaternal hemorrhage or an acute feto-placental hemorrhage. The latter can occur during delivery when the umbilical cord comes under some pressure (breech presentation or nuchal cord). Because the umbilical vein is more compressible, it is occluded before the artery and blood continues to be pumped into the placenta. If the cord is clamped early, the excess blood remains trapped in the placenta. This probably happens to some degree in all babies with tight nuchal cords who, as a group, have lower hemoglobin levels.[85] However, in some neonates, a tight nuchal cord may also cause severe circulatory compromise.[86] Postnatally, acute blood loss may occur from any site and is frequently associated with perinatal infections or severe asphyxia-induced endothelial damage and the ensuing disseminated intravascular coagulation. Finally, acute abdominal surgical problems and conditions associated with the nonspecific inflammatory response syndrome and subsequent increased capillary leak with loss of fluid into the interstitium can lead to significant decreases in the circulating blood volume. Iatrogenic causes of absolute hypovolemia include inadequate fluid replacement in conditions of increased insensible losses in the very preterm neonate and gastroschisis before closure of the defect, or the inappropriate use of diuretics.

Relative hypovolemia, that is, a decrease in the effective circulating blood volume, may occur in pathologic conditions leading to vasodilation, such as those associated with the nonspecific inflammatory response syndrome (sepsis, necrotizing enterocolitis [NEC], asphyxia, major surgical procedures, use of extracorporeal membrane oxygenation [ECMO]). In addition, the use of afterload-reducing agents (e.g., milrinone, PGE_2) may cause significant vasodilation (especially venodilation), thereby decreasing the effective circulating blood volume.

Finally, absolute and relative hypovolemia most frequently occurs in conditions associated with the nonspecific inflammatory response syndrome such as sepsis, asphyxia, and major surgical procedures.

Myocardial Dysfunction

Both systolic and diastolic cardiac dysfunction can cause circulatory failure. As echocardiographic assessment of diastolic function is complex and not well established, except in extreme



• **Fig. 46.6** Etiology of Hypovolemia in Neonates. Etiological factors of absolute (hemorrhagic and non-hemorrhagic) and relative hypovolemia are shown.

cases, diastolic dysfunction often goes undetected. Nevertheless, diastolic dysfunction is recognized to be the primary cause of circulatory failure associated with hypertrophic cardiomyopathy in infants of diabetic mothers. In addition, extrinsic factors such as pericardial effusion evolving to tamponade and tension pneumothorax can lead to diastolic dysfunction. Systolic dysfunction, on the other hand, is easier to diagnose using echocardiography.

Acquired heart disease presenting as circulatory compromise includes cardiomyopathies, postasphyxial myocardial dysfunction due to hypoxic-ischemic injury, viral myocarditis, and myocardial dysfunction in the late stages of septic shock. For more detail on structural heart disease and cardiomyopathies, see Chapter 50.

Among the different types of congenital heart disease, structural heart defects that produce a ductus arteriosus–dependent systemic circulation such as the hypoplastic left heart syndrome, critical coarctation, and critical aortic stenosis, if not diagnosed prenatally or immediately after delivery, classically present as acute circulatory compromise with pallor, tachypnea, impalpable pulses, and hepatomegaly as the ductus starts closing. The presentation may be initially misdiagnosed as sepsis.

Abnormal Peripheral Vasoregulation

Peripheral vasodilation causes circulatory compromise by resultant decreases in perfusion pressure. However, patients with intact myocardial function usually present with normal or high cardiac output as they attempt to compensate for the decrease in organ blood flow. Pathologic peripheral vasodilation in neonates occurs primarily in conditions associated with the nonspecific inflammatory response syndrome such as sepsis, NEC, severe asphyxia, major surgical procedures, use of ECMO, or respiratory distress syndrome of prematurity. It is of clinical importance that preterm neonates born to mothers with chorioamnionitis, especially if they have evidence of funisitis (fetal vessel inflammation), frequently present with hypotension and hyperdynamic, vasodilatory cardiovascular compromise at birth or shortly afterward.[87–89]

Clinical Presentations of Shock in Neonates Associated With Multiple Etiologic Factors

Transitional Circulatory Compromise of the Very Preterm Neonate

The transitional circulatory changes at birth and in the first 12 to 24 hours after birth denote a period of unique circulatory vulnerability, especially for the extremely preterm infant. As mentioned earlier, the timing of umbilical cord clamping has a significant effect on volume status and systemic hemodynamics. During normal postnatal adaptation, pulmonary vascular resistance falls, systemic vascular resistance rises with removal of the placenta from the circulation, the ductus arteriosus closes, and the foramen ovale is closed by the reversal of the atrial pressure gradient. During this time frame, the left ventricle must double its output. Given that the very preterm infant's cardiovascular system is adapted to the low-resistance intrauterine environment and its myocardium is immature, it is not surprising that these patients have difficulties during this critical period. In addition, as discussed earlier, developmentally regulated factors such as the state of vital organ assignment of the forebrain and cerebral oxygen demand-flow coupling make cardiovascular adaptation of the very preterm neonate an even more complex process. It is important to note that there is much more to understand about the complex interactions between immediate postnatal cardiovascular adaptation and immaturity, organ development, myocardial and vasoregulatory function, and vital organ assignment.

Low Preload and Immediate Umbilical Cord Clamping

Following delivery of a preterm infant, immediate clamping of the umbilical cord had been the standard of clinical care since the 1960s. However, as this practice may be associated with inadequate transfer of blood from the placenta to the newborn, the approach to the timing of cord clamping has recently changed. Both animal and human studies have demonstrated that delayed umbilical cord clamping increases blood volume (preload), confers a more gradual rise in left ventricular afterload, and allows for a smoother cardiorespiratory transition in the first few minutes after birth. These beneficial effects are likely responsible for the observation that preterm infants delivered with delayed cord clamping have higher brain tissue oxygen saturation and indices of CBF compared to those with immediate cord clamping.[90,91] Interestingly, initiation of breathing seems to be a key factor in aiding the effective placental transfer of blood to the infant.[92,93] However, as cord milking, compared to immediate cord clamping, also improves hemodynamics and indices of CBF,[81,94] it appears that the most important factor in improving systemic blood flow and reducing the incidence of circulatory compromise during the transitional period is placental transfusion itself rather than the process of maintaining a placental connection to preterm infants for a period of time immediately after birth. But a recent RCT reported a higher rate of severe IVH with cord milking as compared to delayed cord clamping among preterm infants <32 weeks' gestation, which is concerning.[95] The reason for this increased risk of IVH is unclear although a rapid rise in CBF has been postulated. In a subset of the population studied in that RCT, cerebral oxygen saturation was monitored in the delivery room.[96] Arterial oxygen saturation was higher in the cord milking group without a difference in cerebral tissue oxygen saturation. Therefore, as a group, those who underwent cord milking did not seem to have excessive CBF. However, it is possible that in selected vulnerable individuals, a rapid increase in the preload and CBF played a role. Therefore, while cord milking could reduce the risk of cerebral ischemia by rapidly increasing circulating blood volume (preload) and improving systemic blood flow, it might increase the risk of IVH through yet unidentified mechanism(s), and its use is currently not recommended.

The improvement in systemic hemodynamics with placental transfusion, including CBF, explains, at least in part, the finding of a lower incidence of overall peri/intraventricular (P/IVH) in preterm infants with delayed cord clamping compared to those with immediate cord clamping.[97] This finding along with a host of other benefits has initiated support for the use of delayed cord clamping by the American College of Obstetricians and Gynecologists[98] as well as by the Neonatal Resuscitation Program.[99] However, little is known about the optimal timing of cord clamping after delivery, the populations who benefit most from it, the position of the baby relative to the placenta, and the preferred mode of respiratory support before clamping the cord.[97,100] Finally, although cord milking appears to exert a better hemodynamic response compared to delayed cord clamping in preterm infants delivered via c-section,[81] the higher rate of IVH[95,101] associated with cord milking renders its use potentially harmful. It is clear that more needs to be understood about the most appropriate way or ways to promote placental transfusion in the preterm neonate.

Myocardial Dysfunction and High Afterload

As mentioned earlier, the abrupt increase in left ventricular afterload following the sudden removal of the low-resistance placenta can be detrimental to the immature myocardium. There is a normal inverse linear relationship between heart rate-corrected velocity of circumferential shortening (VCF_C, an index of contractility) and wall stress (WS, an index of afterload). Even in term infants, the myocardium is particularly sensitive to a rise in afterload as demonstrated by a steeper inverse relationship between VCF_C and WS compared to the mature heart of older children.[102] As preterm infants have anatomically and functionally immature myocardium, they are especially prone to systolic dysfunction. Indeed, the ensuing systolic dysfunction is thought to be one of the key factors in the development of low cardiac output in a subset of high-risk preterm infants during the transitional period.[103,104]

Patent Ductus Arteriosus

As mentioned earlier, a significant proportion of preterm infants fail to constrict and close their ductus arteriosus. The impact of prolonged left-to-right shunting on the pulmonary circulation and the resultant systemic hypoperfusion are discussed in Chapter 48. However, even a short exposure to significant left-to-right PDA shunting in susceptible preterm infants can result in pulmonary hemorrhage and systemic hypoperfusion and hypotension during the transitional period. Furthermore, it is important to recognize that ductal shunting can have significant hemodynamic effects before it can be clinically detected. In healthy term neonates, PDA shunting changes to predominantly left-to-right within the first few minutes after birth.[37,105] Although no data are available on PDA shunting at the time of delivery in preterm infants, a small study showed exclusively left-to-right shunting in most of the patients studied by 20 minutes after birth.[106] In a larger study population of preterm infants, by 5 hours after birth the vast majority of patients had a completely or at least predominantly left-to-right shunt across the ductus arteriosus.[38] The heart significantly increases its output in an attempt to compensate for the left-to-right ductal shunt. There is some evidence that, at least in a subset of preterm neonates, this compensation may be inadequate in the early postnatal period.[37,38] Indeed, preterm infants with low SVC flow have a larger PDA compared to those with normal SVC flow but only during the first 6 to 12 postnatal hours.[47] This suggests that inadequate adaptation to ductal shunting early after birth may contribute to cerebral hypoperfusion immediately after delivery. Therefore, with regard to the negative effect of PDA shunting on CBF, the most vulnerable period might be the first 6 to 12 hours of postnatal life.[103]

Respiratory Support and Hemodynamics

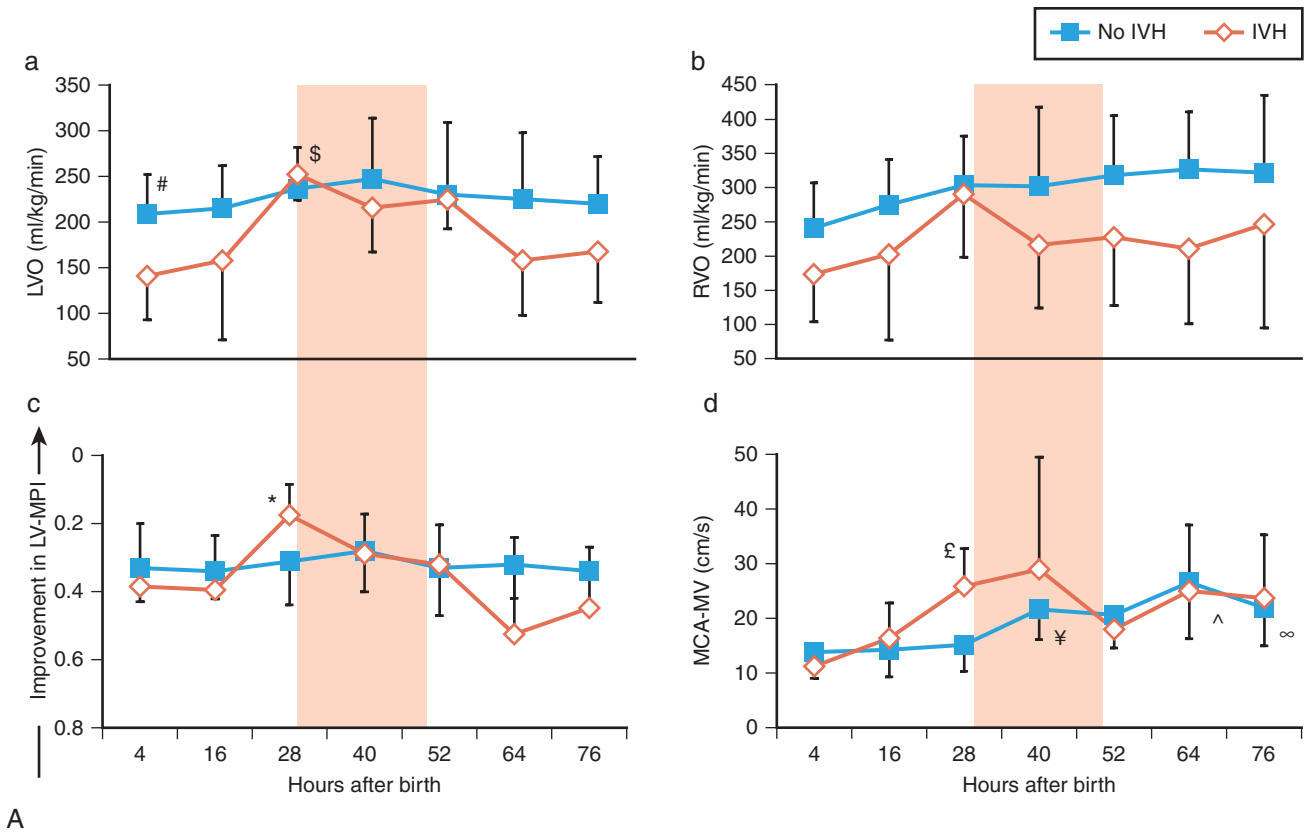
Extremely preterm infants commonly require respiratory support during the transitional period. However, positive intrathoracic pressure associated with the provision of respiratory support could potentially adversely affect venous return and result in decreased preload and cardiac output.[24] In poorly compliant lungs, for example in patients with respiratory distress syndrome prior to administration of surfactant, the effect on venous return is minimal.[27] However, in compliant lungs, venous return can be severely impaired.[26] These findings highlight the importance of understanding the possible adverse effects of respiratory support on pulmonary and systemic hemodynamics so that the most appropriate settings and weaning strategies can be employed.

Permissive hypercapnia is a commonly used strategy aimed at reducing both the need for ventilator support and ventilator-induced lung injury in preterm infants.[107,108] However, little is known about the safety and the optimal carbon dioxide (CO_2) range of permissive hypercapnia.[109–114] In addition to its direct effects on cerebral hemodynamics (see below) and due to the immature renal compensatory mechanisms of the preterm neonate, permissive hypercapnia invariably leads to more severe respiratory acidosis during the transitional period. The effects of acidosis on the cardiovascular system in the neonate in general and the preterm infant, in particular, are largely unknown.[115] In adults, respiratory acidosis decreases myocardial contractility and systemic vascular resistance but, presumably due to the resultant lower afterload, also increases cardiac output.[116] In hemodynamically stable preterm infants, an observational study showed no association between acidic pH and indices of myocardial function and contractility, and systemic vascular resistance (SVR) during the first three postnatal days.[115] While this finding might be considered reassuring, it is important to note that the cardiovascular effects of an acidic pH in hemodynamically unstable neonates are not known.

Ischemia-Reperfusion

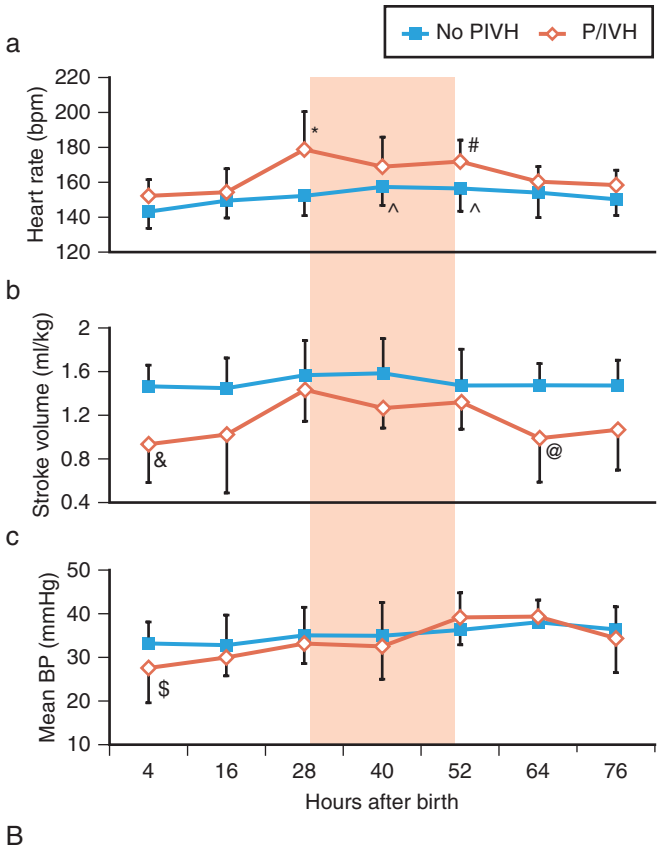
It has long been recognized that preterm infants presenting with low CBF during the immediate postnatal period are at greater risk for developing P/IVH,[117] The decrease in CBF in these patients has been documented using different techniques.[47,118] In addition, in some patients with low SVC flow, it was observed that P/IVH occurred after improvements in SVC flow.[47] Similarly, higher cerebral regional oxygen saturation ($CrSO_2$) and lower oxygen extraction were recently reported in preterm infants during the 24 hours before detection of P/IVH.[119] These findings might suggest that cerebral reperfusion leads to the development of P/IVH. However, these observations are not universal as others have only documented persistently low CBF for over a week after birth.[120] Advances in NIRS technology have made continuous monitoring of indices of CBF feasible (see section on diagnosis).[121] When, during the first three postnatal days, extremely preterm infants were comprehensively evaluated by, among others, continuous monitoring of $CrSO_2$ using NIRS and periodic cardiac function, systemic and cerebral perfusion assessments using ultrasonography, a phase of initial cerebral ischemia, and lower systemic perfusion (Fig. 46.7A and 46.7B) followed by a reperfusion phase preceding the detection of P/IVH were documented (Fig. 46.8).[122] The cerebral hypoperfusion and reperfusion coincided with low cardiac output and improvement in cardiac output, respectively.

Although, as mentioned earlier, myocardial dysfunction may contribute to the occurrence of low cardiac output, this finding has not been consistently documented.[104,122] There is some evidence that altered cerebral hemodynamics predisposing to P/IVH could be present already in the delivery room. Indeed, a case-control study found lower $CrSO_2$ among preterm infants who later developed P/IVH.[123] The lower $CrSO_2$ could be the result of inadequate placental transfusion as lower hematocrit is associated with an increased risk of developing P/IVH.[124] Furthermore, higher mean airway pressure in the delivery room may also result in lower $CrSO_2$ possibly by negatively impacting cardiac output or CBF.[125] Therefore, the initial low cardiac output predisposing to cerebral hypoperfusion[47,122] is likely multifactorial. Such factors include a decreased preload, especially with immediate cord clamping

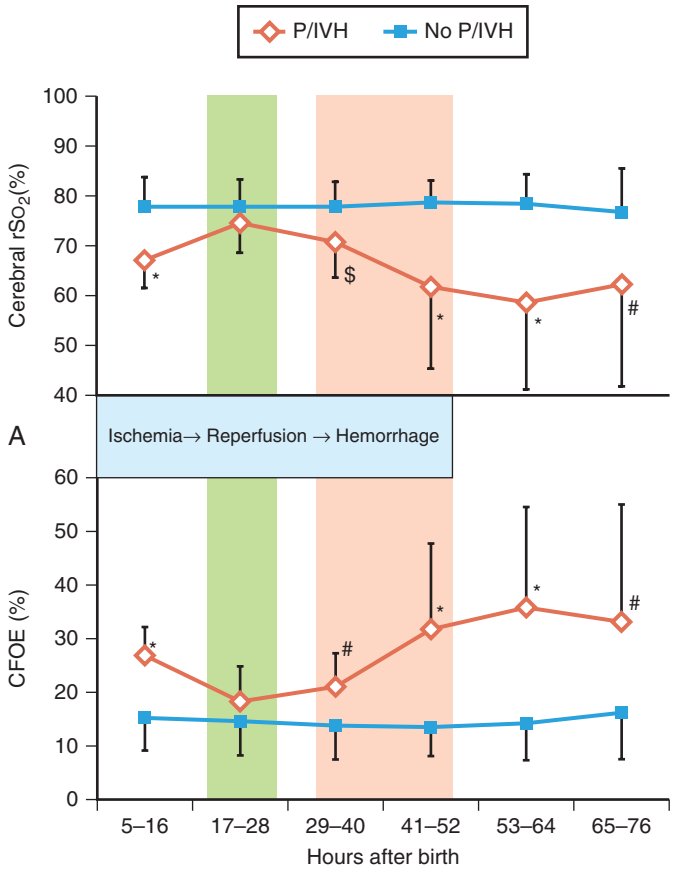


• **Fig. 46.7A** Changes in Selected Hemodynamic Parameters (Left and Right Ventricular Output, Left Ventricular Myocardial Performance Index and Middle Cerebral Artery Mean Velocity) During the First 76 Hours in Very Preterm Neonates With and Without Periventricular/Intraventricular Hemorrhage. Changes in LVO (*a*), RVO (*b*), left ventricular myocardial performance index (LV-MPI) (*c*) and MCA-MV (*d*) in the two groups during the study are shown. There was a trend for a lower LVO in the P/IVH group at baseline with a trend for improvement before the occurrence of P/IVH (highlighted in pink). Lower MPI (i.e., better function) and higher MC-MV in the P/IVH group preceded occurrence of P/IVH. The pattern of changes in LVO between the two groups tended to be statistically significant (P = 0.068) while in RVO, MPI and MCA-MV did not reach statistical significance between the two groups. Statistically significant differences between groups: $^{*}p = 0.04$ and $^{£}p = 0.016$. No-P/IVH group; compared to baseline: $^{¥}p = 0.02$, $^{\wedge}p < 0.0001$, $^{\infty}p = 0.044$.Differences approaching statistical significance and suggesting a difference between the groups: $^{\#}p < 0.055$, and within the P/IVH group compared to baseline: $ p = 0.07. The values represent the mean ± SD of the data obtained upon entry into the study and every 12 hours thereafter. *LVO*, Left ventricular output; *MCA-MV*, middle cerebral artery mean velocity; *MPI*, myocardial performance index; *P/IVH*, periventricular/intraventricular hemorrhage; *RVO*, right ventricular output. (From Noori S, McCoy M, Anderson MP, et al. Changes in cardiac function and cerebral blood flow in relation to peri/intraventricular hemorrhage in extremely preterm infants. *J Pediatr*. 2014;164: 264–270.e1–e3.)

and/or with the use of inappropriately high mean airway pressure, and a poor myocardial contractility in the setting of myocardial immaturity, high afterload, and uncompensated ductal shunting.[103] On the other hand, the reperfusion phase could also be a consequence of the recovery of cardiac function potentiated by hypercapnia and/or the inappropriate titration of medications used in the management of neonatal shock. As increases in CO_2 result in increases in CBF, permissive hypercapnia may also exaggerate the reperfusion phase. Although a recent RCT with two different threshold targets of permissive hypercapnia with the goal to decrease the rate of bronchopulmonary dysplasia or death did not show a higher rate of P/IVH within the higher hypercapnia target population,[107] epidemiologic data reveal an association between hypercapnia and P/IVH.[126–128] Furthermore, $PaCO_2$ values above the low-to-mid 50 mm Hg strongly correlate with indices of increased CBF, suggesting a significant rise in CBF with the use of more extreme levels of permissive hypercapnia.[111] Hypercapnia also attenuates CBF autoregulation, likely putting preterm infants at higher risk for uncontrolled increases in CBF.[111,129] As hypotensive preterm infants also have impaired CBF autoregulation,[130] excessive and abrupt increases in blood pressure with the inappropriate use of vasopressors/inotropes can result in sudden, excessive increases in CBF, which in turn might potentiate the reperfusion injury.[103] As mentioned earlier, the safe threshold for permissive hypercapnia is unknown, and therefore the risk and benefits of permissive hypercapnia above mild values, especially in the most vulnerable population during the first 3 postnatal days, should be carefully considered.



• **Fig. 46.7B** Changes in Selected Hemodynamic Parameters (Heart Rate, Left Ventricular Stroke Volume, and Mean Blood Pressure) During the First 76 Hours in Very Preterm Neonates With and Without Periventricular/Intraventricular Hemorrhage. Changes in heart rate (*a*), left ventricular stroke volume (*b*), and mean blood pressure (*c*) in the two groups during the study are shown. Heart rate significantly increased in the No-P/IVH group (ANOVA p = 0.004), while there was only a trend for an increase in the P/IVH group (ANOVA p = 0.051) during the study. Compared to the No-P/IVH group, left ventricular stroke volume in patients of the P/IVH group was lower at the baseline but similar before the occurrence of the P/IVH. Mean blood pressure (c) tended to increase in the P/IVH group (ANOVA *P* = .052) while it remained unchanged and relatively stable in the No-P/IVH group (ANOVA *P* = .2). In addition, mean blood pressure at baseline also tended to be lower in patients in the P/IVH group. The pattern of changes in heart rate and stroke volume, but not in mean blood pressure, was different between the two groups. See text for details. No-P/IVH group; compared to baseline: ^p = 0.007. Between groups: *p = 0.004, # p = 0.03, & p = 0.007, @ p = 0.048, $ p = 0.085. The values represent the mean ± SD of the data obtained upon entry into the study and every 12 hours thereafter. Area highlighted in pink represents the period when P/IVH occurred. *bpm*, Beats per minute; *P/IVH*, periventricular/intraventricular hemorrhage. (From Noori S, McCoy M, Anderson MP, et al. Changes in cardiac function and cerebral blood flow in relation to peri/intraventricular hemorrhage in extremely preterm infants. *J Pediatr*. 2014;164:264–270.e1–e3.)



• **Fig. 46.8** Changes in Cerebral Regional Oxygen Saturation (rSO_2) and Cerebral Fractional Oxygen Extraction (CFOE) in Two Groups With (Red) and Without (Blue) Peri/Intraventricular Hemorrhage (PIVH) During First 3 Postnatal Days. The No-P/IVH group exhibited stable cerebral rSO_2 (A) and CFOE (B) values while the P/IVH group presented with a characteristic pattern of changes. The P/IVH group had lower cerebral rSO_2 and higher CFOE during the first 12 hours of the study followed by normalization of these parameters *(highlighted in green)* just before the two study periods when P/IVH was detected *(highlighted in pink)*. These findings suggest initial cerebral hypoperfusion followed by a period of reperfusion before the occurrence of the bleeding. After the second study period, cerebral rSO_2 decreased and CFOE increased suggesting a decrease in CBF during and after the development of P/IVH. Statistically significant differences between the two groups: *p < 0.005, # p < 0.04 and $ p < 0.05. The values represent the mean ± SD of the data obtained in each 12-hour data collection period. (From Noori S, McCoy M, Anderson MP, et al. Changes in cardiac function and cerebral blood flow in relation to peri/intraventricular hemorrhage in extremely preterm infants. *J Pediatr*. 2014;164:264–270.e1–e3.)

Vital Organ Assignment

As discussed earlier, compared to most other organs, blood supply to the brain is relatively protected during hypoxia by its vascular property; hence, the brain is considered a vital organ. However, this vascular capacity undergoes a maturation process with the vessels of the forebrain (including the cerebral cortex and basal ganglia) reacting like those of a non-vital organ in the very preterm infants during the early postnatal period.[70–73] This developmentally regulated phenomenon has significant implications as most extremely preterm infants are in compensated or uncompensated shock, with lower systemic flow, immediately following delivery. In these infants, instead of vasodilating, the vessels of the forebrain vasoconstrict just like those of the non-vital organs (e.g., kidneys or intestine). Accordingly, immaturity of vital organ assignment in the forebrain likely contributes to the observed cerebral ischemia even in non-hypotensive extremely preterm neonates during the immediate postnatal period (see above).

Vasopressor-Resistant Hypotension

Although the pathologies of transitional hemodynamics described earlier may or may not present with low blood pressure (compensated versus uncompensated phase of shock), there is a group of preterm neonates in whom persistent hypotension that is resistant to conventional vasopressor-inotropic support develops.[131,132] The underlying systemic hemodynamic changes of this condition have also been characterized.[133] These babies are more likely to be extremely preterm (≤27 weeks) and/or have been critically ill or suffered a degree of perinatal asphyxia. Generally, corticosteroid-responsive refractory hypotension manifests during the first 2 weeks of postnatal life, although it may also occur at later times.[131] The problem may be apparent as early as the first postnatal day and may persist beyond and represent a state of vasodilatory shock with normal to high systemic blood flow and possibly supranormal cardiac output. There are striking analogous features of this presentation in preterm neonates to those of vasodilatory shock described in adults, particularly the lack of responsiveness to vasopressor-inotropes. Potential mechanisms for the uncontrolled vasodilation include dysregulated cytokine release, excess nitric oxide synthesis, overactivation of the K_{ATP} channels in the vascular smooth muscle cell membrane in response to tissue hypoxia, and downregulation of the cardiovascular adrenergic receptors. In the preterm infant, the foregoing mechanisms are exacerbated by immaturity-associated relative adrenal insufficiency[134] or by preceding asphyxia or may be secondary to transitional circulatory failure. Recently, polymorphism in the glucocorticoid receptor gene was shown to be associated with refractory hypotension in premature infants.[135] In the term neonate, congenital diaphragmatic hernia has been associated with relative adrenal insufficiency and refractory hypotension.[136]

Sepsis

Although clinical evidence of circulatory compromise is a leading feature of many infectious processes in the newborn, only limited data are available on the hemodynamics in neonatal septic shock.[137] In older subjects, two distinct hemodynamic patterns occur: warm shock, characterized by loss of vascular tone, increased systemic blood flow, and low blood pressure; and cold shock, characterized by increased vascular tone, low systemic blood flow, and eventually falling blood pressure. Cold shock has been well described in the newborn,[138] whereas the warm shock pattern is more difficult to recognize clinically unless the blood pressure and the cardiovascular status, in general, are being closely monitored. A study in preterm infants demonstrated high cardiac output and low systemic vascular resistance consistent with the presence of warm shock.[139] Another study also found higher left ventricular output in preterm infants with septic shock compared to a control group, suggestive of vasodilation as the dominant pathophysiologic factor.[137] However, because a significantly higher proportion of neonates in the septic group had a PDA, the increase in left ventricular output in this study could have been due, at least in part, to the presence of the left-to-right shunt rather than high systemic flow per se. We don't know how common myocardial dysfunction is in neonates with septic shock. In older children, about half of them have either systolic or diastolic dysfunction,[140] and the prevalence of myocardial dysfunction in fluid- and catecholamine-refractory septic shock is even higher.[141] The mediators of neonatal warm septic shock remain unclear, but in adult sepsis, dysregulated cytokine release and upregulated nitric oxide productions as well as deficiency of vasopressin production, play important roles. The significance of this to newborn sepsis remains unclear, but it may have relevance to the vasopressor-resistant hypotension seen in preterm babies.[142]

Diagnosis of Circulatory Compromise

There is no agreement regarding what constitutes the gold standard in diagnosing circulatory compromise in the neonate. However, blood pressure remains the most commonly used criterion for diagnosis and initiation of treatment in this patient population.[3,143,144] As mentioned earlier, available data suggest that sole reliance on blood pressure can lead to inaccurate or, in other cases, significantly delayed diagnosis of circulatory compromise, especially in the very preterm infant during the immediate postnatal period. On the other hand, it is clear from the observations about vasodilatory shock that continuous blood pressure monitoring is imperative. The other commonly used clinical signs of circulatory compromise, such as increased heart rate, slow skin capillary refill time (CRT), increased core-peripheral temperature difference, low urine output, and acidosis due to increased lactate production, aid in establishing the diagnosis of circulatory compromise in the preterm or term infant but also have significant limitations.

With recent advancements in biomedical technology, the armamentarium of devices for bedside cardiorespiratory monitoring has broadened enabling the clinician to perform intermittent and/or continuous assessment of systemic and regional perfusion in neonates (Table 46.1). While being used mostly for research applications, these devices have also started to be increasingly utilized for routine clinical care.[7,21]

Heart Rate and Blood Pressure

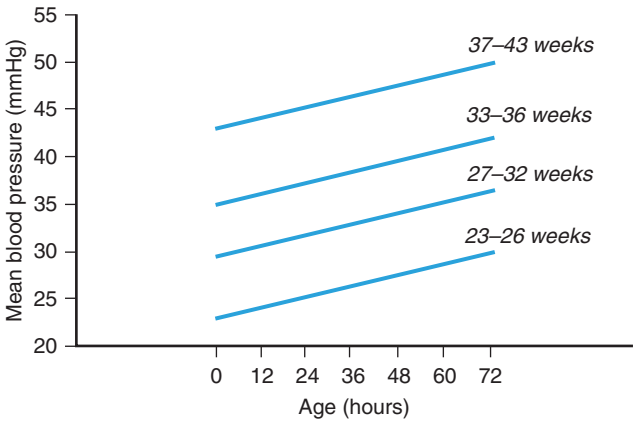
Heart rate is continuously, accurately, and routinely monitored in neonates requiring admission to neonatal intensive care units (NICUs). Because many factors other than those regulating the cardiovascular system affect heart rate, it has a limited yet widely utilized role in the diagnosis of circulatory compromise. As for the blood pressure, in babies with invasive arterial access, continuous and accurate measurement of this parameter is routinely done. The accuracy of the noninvasive oscillometric method is less certain, especially when severe hypotension develops. Normal ranges for blood pressure in babies of different gestations have been defined in the literature (epidemiologic definition of hypotension), and it is clear that gestation and postnatal age are the dominant influences on blood pressure.[2] The nomogram from the data of Nuntnarumit et al. in Fig. 46.9 shows the 10th percentile for mean blood pressure of babies from different gestations at different postnatal ages.[145]

The normal gestational- and postnatal-age-dependent blood pressure range is not known, primarily because it is affected by additional factors such as disease severity, history of perinatal insult, presence of infection or ductal shunting, and interindividual variations.[1,2,146] In addition to the epidemiologic definition of hypotension, increasing severity of hypotension can be defined from a pathophysiologic standpoint as the blood pressure value at which CBF becomes pressure-passive (autoregulatory blood pressure threshold; the definition used for the pediatric and adult patient population), brain function is affected (functional blood pressure threshold), and tissue ischemia develops (ischemic

TABLE 46.1 Systemic and Regional Hemodynamic Parameters Most Commonly Monitored in Neonates

	Parameter	Technology/Method	Purpose and Acquisition [C, I or C/I]
Systemic perfusion (BP and CO)	Heart rate	ECG (electrodes)	In conjunction with stroke volume gives flow status [C]
	BP	Arterial line/cuff (oscillometry; Doppler-US)	Perfusion pressure [C/I]
	Stroke volume/CO	Echocardiography	Systemic, pulmonary (CO) and organ blood flow, cardiac function [I]
		IEC	Systemic blood flow (CO) [C]
Systemic oxygenation	SPO_2	Pulse oximetry	Oxygenation on the arterial side [C]
CO_2 status	TCOM	CO_2 diffusion through skin	Effect on cerebral vasculature (changes in CBF) [C]
Regional perfusion	Regional O_2 saturation	NIRS	Tissue oxygenation and (indirectly) organ perfusion [C]
Peripheral perfusion	Microcirculation (oxygenation; blood flow velocity; capillary recruitment)	Visible light technology	Peripheral perfusion [C]
		Laser Doppler flowmetry	Peripheral perfusion [C]
		OPS and SDF	Peripheral perfusion [C]
Indirect assessment of perfusion	Capillary refill time	Visual	Systemic perfusion (indirectly) [I]
	Delta T (C-P)	Temperature	Systemic perfusion (indirectly) [I]
	Color	Visual	Peripheral perfusion [I]
Organ function	Brain electrical activity	aEEG	Assessment of brain activity [C]
	Urine output	Urinary catheter	Assessment of renal function [I]

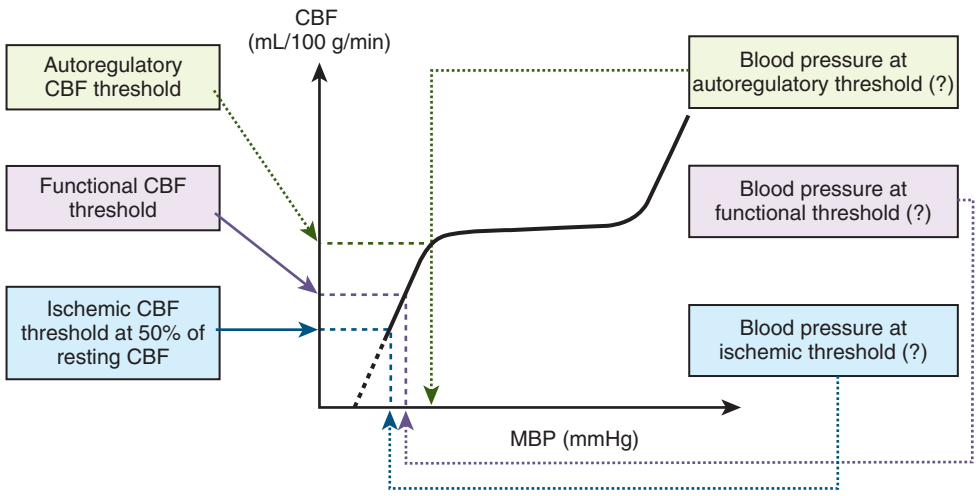
Various components of systemic perfusion (BP and CO) and oxygenation, carbon dioxide production and elimination, regional (organ) and peripheral (microcirculation) perfusion, and organ function (aEEG) that can be monitored at the bedside along with the indirect methods used in the clinical practice to assess perfusion and organ function. Acquisition can be continuous [C], intermittent [I], or both [C/I]. *aEEG*, Amplitude-integrated electroencephalography; *Delta T (C-P)*, difference core and peripheral temperature; *OPS*, orthogonal polarization spectral (imaging); *SDF*, side-stream dark-field imaging; *TCOM*, transcutaneous CO_2 monitoring; *US*, ultrasonography. Transitional cardiovascular physiology and comprehensive hemodynamic monitoring in the neonate: Relevance to research and clinical Care. *Semin Fetal Neonatal Med* 2014;19:45–53.)



• **Fig. 46.9** Gestational and Postnatal Age-Dependent Nomogram for Mean Blood Pressure Values in Neonates During the First 3 Days of Postnatal Life. The nomogram is derived from continuous arterial blood pressure measurements obtained from 103 neonates with gestational ages between 23 and 43 weeks. Each line represents the lower limit of 80% confidence interval of mean blood pressure for each gestational age group. Thus, 90% of infants for each gestational age group are expected to have a mean blood pressure equal to or greater than the value indicated by the corresponding line (the lower limit of confidence interval). (From Nuntnarumit P, Yang W, Bada-Ellzey HS. Blood pressure measurements in the newborn. *Clin Perinatol*. 1999;26:981–996.)

blood pressure threshold, Fig. 46.10).[1] Some data are available for the autoregulatory and functional blood pressure threshold in very preterm neonates during the first few postnatal days.[72,130] However, there is no information on the ischemic threshold in very preterm neonates, and very little is known about these pathophysiologic measures of hypotension in the term neonate or in any neonate beyond the transitional period. Perhaps the best method to define hypotension would be the demonstration of causation between gestational- and postnatal-age-dependent blood pressure values and clinically relevant outcome measures such as mortality or long-term neurodevelopmental disability. However, because there are no data available on this interaction, there is uncertainty about the normative values. Besides, treatment may have its own side effects; hence there is controversy about when and how to intervene in the critically ill neonate with suspected hypotension and circulatory compromise.[15,16,147]

In clinical practice, hypotension during the first postnatal day is usually defined in one of three ways: as a mean blood pressure less than 30 mm Hg, a mean blood pressure below the patient's gestational age in weeks at the time of birth, or, more recently, a blood pressure value that is accompanied by clinically detectable evidence of circulatory compromise (decreased urine output, poor peripheral perfusion, and/or lactic acidosis). A threshold of 3 or 5 mm Hg below the gestational age in weeks for mean blood pressure also has been used for initiating vasopressors-inotropes.[148]



• **Fig. 46.10** Definition of Hypotension by Three Pathophysiologic Phenomena of Increasing Severity: Autoregulatory, Functional, and Ischemic Thresholds of Hypotension. CBF, cerebral blood flow; MBP, mean blood pressure. (From Noori S, McLean CW, Wu T-W, et al. Cerebral circulation and hypotension in the premature infant: diagnosis and treatment. In: Perlman JM, Cilio MR, eds. *Neurology: Neonatology Questions and Controversies*. 3rd ed. Philadelphia: Elsevier; 2019:1–26.)

However, in preterm neonates with clinically asymptomatic hypotension (blood pressure value in mm Hg below the gestational age in weeks), antihypotensive treatment is associated with improved outcomes (see below).[3] Thus, at present the clinician must rely on his/her understanding of developmental hemodynamics, pharmacodynamics, and the pathophysiology of the transitional period as well as the findings in the literature to make the most appropriate decision at the bedside of the individual patient with hemodynamic compromise.

As mentioned earlier, there is only a weak relationship between mean blood pressure and SVC flow, a surrogate measure of systemic blood flow in preterm neonates with the fetal channels open in the immediate postnatal period.[11] Thus, if blood pressure alone is used to guide treatment, patients in the unrecognized compensated phase of shock may not be treated appropriately. For instance, in the extremely preterm neonate with mean blood pressure between 20 and 40 mm Hg in the immediate postnatal period, the state of systemic blood flow and CBF is unclear based on the blood pressure values alone. Recent advances in our ability to apply complex, continuous cardiovascular monitoring providing data in absolute numbers using impedance-based electrical cardiometry, NIRS, and amplitude-integrated EEG combined with the intermittent use of Doppler flow measures hold the promise of gaining a better understanding of the hemodynamic changes occurring during transition and beyond in the neonatal patient population.[7]

Capillary Refill Time (CRT)

Several studies have attempted to validate this widely used clinical tool for accuracy. However, there is no validated standard for assessing decreased peripheral perfusion and its relationship to systemic flow in the newborn. Further, in the different types of shock (warm vs. cold shock), the state of peripheral perfusion is different (vasodilation vs. vasoconstriction). Hence it is impossible to objectively assess the practical utility of this clinical tool in neonates. Accordingly, in VLBW neonates, a poor correlation was found between the capillary refill time, assessed on the forehead, sternum, and toe, and mean blood pressure, urine output, and SVC flow.[149] An earlier study documented a similar lack of tight relationship in VLBW neonates; only when CRT was greater than 5 seconds did it have any clinically relevant degree of specificity.[150] Although a CRT of ≤3 seconds is traditionally accepted as normal, a CRT of 4.23 ± 1.47 seconds with a range of 1.63 to 8.78 seconds was reported in a large population of healthy newborns during the first 72 postnatal hours. CRT does not appear to change during the first 72 postnatal hours in healthy term newborns.[151] Environmental, axillary, hand, and foot temperatures have been reported to indirectly relate to CRT.[151] Interestingly, the duration of the pressure applied when eliciting CRT affects the measurement in term neonates less than 4 hours after delivery.[152] This study also found an unanticipated moderate, direct correlation between blood pressure and CRT with a prolongation of CRT at higher blood pressures in this patient population.[152] In general, interobserver variability has been reported to be fair, but a variation in the measurement among the different sites (sternum, forehead, hand, and feet) may be significant, although this issue needs to be more systematically studied.

Core-Peripheral Temperature Difference

There are few data to support the accuracy of this test in older infants.[153] As for preterm neonates less than 30 weeks' gestational age, there was also no relationship between this measure and SVC flow in the immediate postnatal period.[150] However, because SVC flow measurements have their limitations, these studies need to be repeated when a more accurate and continuous measure of systemic blood flow assessment becomes available for neonates with fetal channels open.

Low Urine Output and Hyperkalemia

Urine output is a frequently utilized clinical measure to assess renal perfusion and function. However, because urine output is low during the first postnatal day as a result of delivery-associated increases in stress hormones (catecholamines, vasopressin, renin-angiotensin) causing renal vasoconstriction and increased tubular reabsorption of sodium and water, its value in assessing

compensated shock during the transitional period is limited. After the first 2 to 3 days, however, a decrease in urine output may be the earliest clinical sign of compensated shock in neonates of all gestational ages. In addition, a relationship has been documented in very preterm infants between low SVC flow and subsequent low urine output and hyperkalemia.[154] However, because hyperkalemia may occur in the very preterm neonate without oliguria (i.e., nonoliguric hyperkalemia of the extremely preterm neonate),[155] and because there could be other causes of hyperkalemia (acidosis), hyperkalemia alone should not be used as a measure of poor systemic perfusion.

Lactic Acid, pH, and Base Excess

In a large series, pH and base excess were found to have little relationship with low SVC flow in preterm babies in the immediate postnatal period.[154] This finding is likely explained by the lack of a strong relationship between pH, base excess, and lactic acid levels in neonates.[156] However, because serum lactate levels can be sequentially followed routinely on blood gases, and because changes in serum lactate are informative of changes in the cardiovascular status, this indirect measure of cellular oxygen delivery and consumption has been used in clinical practice. Interestingly, combining a CRT of >4 seconds with an elevated serum lactate concentration of >4 mmol/L has a specificity of 97% for detecting a low SVC flow state in VLBW neonates during the first postnatal day.[149] One needs to keep in mind, though, that a given serum lactate level primarily represents past hemodynamic events and not necessarily the present state of cardiovascular function. Thus, as with urine output, by the time lactic acidosis develops and is detected, the initiating event may or may not be present anymore. It is not a surprise, therefore, that rising lactate levels are more predictive of adverse outcomes than a high value early on followed by a subsequent decline.[156]

Organ Blood Flow

With the use of Doppler ultrasonography and, more recently NIRS, blood flow to various organs can be assessed at the bedside. As for CBF, several methodologies have been studied in both preterm and term neonates including Doppler ultrasonography, xenon clearance, and NIRS.[14,58,59,157–160] Because peripheral arteries tend to be too small for size measurement, Doppler studies in such vessels are limited to parameters of velocity from which it is not possible to derive blood flow. Consequently, peripheral artery Doppler tends to be more useful for assessing changes over a time frame in which it is unlikely that the vessel size will have changed.[58] Xenon clearance is not practical outside a research setting. However, advances in NIRS technology have allowed for continuous assessment of brain, renal, mesenteric, and muscle oxygenation (i.e., blood flow) at the bedside in the critically ill neonate (see next section).[161–163]

Near-Infrared Spectroscopy (NIRS)

NIRS uses changes in tissue oxygenation over time or the difference between oxygenated and deoxygenated hemoglobin to indirectly assess flow. The technology has been very useful as a research tool. In addition, with a better understanding of biophysical principles that govern light behavior in tissues, and the associated advances in software algorithms and sophisticated NIRS probe development, continuous assessment of regional tissue oxygenation (rSO_2) has become available and gained evidence-based application in neonatal intensive care.[164,165]

Indeed, commercially available monitors with up to six channels are now being applied to infants, typically on the forehead to gauge cerebral rSO_2 and over the flank, to measure renal rSO_2. Although more validation is needed using invasive measurements,[166–168] it is evident that when cardiac output and/or mean arterial blood pressure fall, the renal rSO_2 declines. First, cerebral rSO_2 may be preserved, but interference with global cerebral blood flow can also be detected with this monitor, provided that certain conditions are met. These monitors are useful during cardiac surgical procedures on infants,[169–171] where precipitous drops in cerebral rSO_2 may be the only warning of a malpositioned venous or arterial cannula while on cardiopulmonary bypass. In addition, emerging findings suggest that monitoring rSO_2 in critically ill term and preterm neonates without congenital heart disease during transition to extrauterine life[163] and treatment for various conditions such as preterm neonates with a PDA,[162,172] asphyxiated infants with or without cooling,[159,173–176] or term neonates receiving ECMO[177–179] provides clinically useful information.[163–165,180] Whether titration of therapy based on rSO_2 measurements in neonates with critical conditions other than congenital heart disease requiring surgery[169] improves patients' outcomes remains unknown.[181] In our experience, however, renal rSO_2 reliably declines well before signs of uncompensated shock such as hypotension or acidosis develop (see later discussion), enabling earlier intervention.[19]

Echocardiographic Systemic Blood Flow Measures

In the mature circulation, systemic blood flow is the cardiac output. Although the output of both ventricles will be the same, cardiac output is traditionally measured from the left ventricular output. In clinical practice, Doppler ultrasound offers a noninvasive but noncontinuous method to measure cardiac output. Measuring blood flow directly in the pulmonary artery and ascending aorta enables us to evaluate outputs from the right and left ventricles, respectively. However, as discussed earlier, in transitional circulation of the newborn infant, neither ventricular output will consistently reflect systemic blood flow because of the shunts across fetal channels. The use of SVC flow as a surrogate for systemic blood flow has been a valuable research tool offering insights into hemodynamic events unfolding during the immediate postnatal period when shunting across fetal channels precludes the use of traditional measures of systemic blood flow assessment (see earlier discussion).[182]

Doppler measures of left ventricular output have been validated against more invasive measures in neonates and older subjects.[183] Right ventricular output and SVC flow are less well validated but correlate well with left ventricular output in neonates with no confounding shunts.[11,45,184] Despite this, the validity of these measures has been questioned based on a comparison to cardiac output thermodilution measures in critical care patients.[185] However, thermodilution itself has an intrinsic error in that the volume of the required cold saline injection influences cardiac output.[186]

Recently, functional magnetic resonance imaging has become the "gold standard" for cardiac output measurements. However, this method is utilized primarily for research applications, and its use for bedside assessment in neonates remains limited due to a number of technical and logistical difficulties.[187] Thus, finding an ideal gold standard method capable of continuous bedside cardiac output measurements in absolute numbers remains elusive.

There are significant intrinsic errors in Doppler flow measures as well. Intraobserver variability rates of around 10% and interobserver variability rates up to 20% are common.[38,188] Most of the error relates to the vessel size measurement that is derived from its diameter. Thus, small differences are magnified in the conversion to a cross-sectional area. The other major problem of Doppler flow measurements is that there is reliance on ultrasound technology and echocardiographic skill that may not often be available 24 hours a day in many neonatal intensive care units.

In neonates, most studies quote a normal range for left and right ventricular output between 150 and 300 mL/kg/min.[189–192] It is important to note that, in the transitional neonatal circulation, left ventricular output can be affected by ductal shunting to a greater extent than the right ventricular output is affected by atrial shunting. Therefore, right ventricular output is a better measure of low flow than left ventricular output during the first 1 to 2 postnatal days. Accordingly, a relationship has been documented between indirect measurements of systemic (and thus cerebral) perfusion such as right ventricular output and blood pressure (and cerebral function) in preterm infants during the first 2 postnatal days. This is a period when ductal shunting significantly decreases the accuracy of left ventricular output measurements reflecting systemic blood flow.[192] SVC flow may also be used to estimate systemic flow in the early postnatal period. The normal range in well preterm babies is between 40 and 120 mL/kg/min, with the median rising from 70 mL/kg/min at 5 hours of age to 90 mL/kg/min at 48 hours.[11]

In summary, the mainstay of diagnosing neonatal circulatory compromise has been a combination of blood pressure measurement and evaluation of specific clinical parameters. However, none of these parameters has a sufficient degree of accuracy to allow it to be relied on as the sole evaluator of systemic blood flow and tissue perfusion. Therefore, the addition of echocardiographic and NIRS hemodynamic assessment to blood pressure monitoring and thorough continuous clinical evaluation of the patient are necessary to better understand changes in organ blood flow and tissue perfusion, especially in preterm neonates during the vulnerable period of immediate transition to extrauterine life. The goal should be to maintain normal systemic blood flow and thus oxygen delivery in the presence of an acceptable blood pressure using the normal range for blood pressure that controls for gestation and postnatal age and following the indirect clinical and laboratory signs of tissue perfusion (urine output, serum lactate levels, CRT). If there is no immediate access to echocardiography or NIRS technology, the clinician will have to rely on blood pressure monitoring while recognizing the limitations of this approach. Over the past decade, training in functional echocardiography for neonatologists has become available in a structured format in several programs in the United States and abroad,[193–195] although the medicolegal implications of such training remain largely unknown.[196]

Measurement of Systemic Blood Flow Using Electrical Impedance Velocimetry

Electrical velocimetry (EV) measures left cardiac output by continuous, noninvasive measurement of thoracic electrical bioimpedance.[197] It has also been validated against invasive methods of cardiac output measurements with very good correlations in animals,[198] and children[199] and against echocardiography in healthy term neonates during the first two postnatal days.[200] However, its evidence-based value in pediatric clinical practice in general[201] and neonatology, in particular, remains to be established.[202,203]

Treatment of Neonatal Shock

Selection of the most appropriate treatment strategy for neonatal shock requires identification of its pathogenesis. As described earlier, the most frequent etiologic factors responsible for neonatal cardiovascular compromise are inappropriate peripheral vasoregulation, resulting in vasodilation or vasoconstriction, and dysfunction of the immature myocardium. Although absolute hypovolemia was thought to be a less frequent primary cause of neonatal hypotension, especially in preterm infants in the immediate postnatal period,[79] recent findings suggest that this assumption is incorrect.[81]

Association Between Systemic Hypotension, Hypoperfusion, and Their Treatment and Mortality or Neurodevelopmental Impairment

The impact of hypotension and/or its treatment on mortality, brain injury, or neurodevelopmental impairment is unclear, primarily because it is assumed that treatment will improve outcomes, and therefore the common practice has been to treat hypotension.[73] Consequently, there have been no prospective studies evaluating the impact of untreated hypotension on clinically relevant short- and long-term outcomes. There have been two attempts at conducting prospective randomized controlled trials (RCT), each with a no-treatment arm, and with neither achieving its objectives.[148,204] The first RCT was a pilot study and found that such a trial is not feasible, at least in the US, primarily due to difficulty in obtaining consents but also because of the clinicians' bias favoring treatment.[204] The second RCT also had difficulty with recruitment and had to be terminated early at 7.7% of the target sample size.[148] Accordingly, the study was significantly underpowered to draw any meaningful conclusion on the impact of untreated hypotension. In addition to the paucity of data from RCTs on the effect of treatment on the outcome, the gestational- and postnatal-age-dependent definition of hypotension based on physiology, pathophysiology, and clinically relevant outcome measures is lacking.[2,146]

One prospective RCT found that hypotensive VLBW neonates overall had a higher rate of severe P/IVH than their non-hypotensive counterparts.[205] Interestingly, hypotensive infants responding with an increase in blood pressure to targeted titration of vasopressors/inotropes had similar rates of P/IVH when compared to non-hypotensive controls. The authors also did not find an association between abnormal ultrasound findings and the use of dopamine or epinephrine. At follow-up at 2 to 3 years of age, no difference was found in the rate of abnormal neurologic status and/or developmental delay between the formerly hypotensive but successfully treated and the control patients. Indeed, a lack of response to dopamine was found to be associated with a greater risk of IVH, whereas a strong response was associated with a decreased risk among preterm infants <28 weeks' gestation.[206] Although the results of the above studies suggest that carefully titrated use of dopamine or epinephrine in hypotensive preterm infants might be safe and even have potential benefits, the small sample size and the lack of untreated hypotensive controls in the RCT do not allow for generalization of the findings. Of note is that, although dopamine was found to be neuroprotective in an asphyxiated lamb model,[207] evidence in the human neonate is needed to establish the clinical relevance of this finding. On the other hand, there is an association between dopamine use and impaired cerebral autoregulation

in preterm infants.[208,209] However, it is unknown whether dopamine plays a role in the observed impairment in cerebral autoregulation or the impairment is simply reflective of illness severity necessitating vasopressor-inotrope use in the first place.

In the last decade, there has been a move toward less aggressive treatment of hypotension with some completely disregarding blood pressure values. This approach has provided a glimpse into the effect of isolated hypotension. A recent analysis from the French national prospective population-based cohort study found worse outcomes in preterm neonates with untreated isolated (clinically asymptomatic) hypotension.[3] They matched 119 extremely preterm infants with untreated isolated hypotension to 119 who were treated during the first 3 days of postnatal life. Hypotension was defined as the mean blood pressure value in mm Hg less than gestational age in weeks and the matched patients had no clinical signs of inadequacy of cardiovascular function. The treated group had a higher rate of survival without severe morbidity and a lower rate of severe IVH and cerebral injury. Of note, the association between treatment and better outcome was even stronger when hypotension was defined as mean blood pressure 5 mm Hg below the gestational age in weeks. This dose-effect relationship strengthens the possibility of causality.

Volume Administration

Volume administration is the most commonly used intervention for the treatment of hypotension in neonates.[144] However, observations that low blood pressure is frequently associated with normal or even high ventricular output and low index of resistance[13] and that dopamine is more effective in increasing blood pressure than volume administration[44] question the effectiveness of volume administration, primarily when isotonic saline is being used. Therefore, particularly in the preterm infant during the immediate postnatal period, only cautious, limited fluid resuscitation has been recommended.[16] In addition, expansion of blood volume using delayed umbilical cord clamping or cord milking has been shown to improve systemic hemodynamics in preterm infants.[81,90,91,94]

As myocardial dysfunction frequently contributes to the development of neonatal hypotension[210] and aggressive volume administration in this patient population increases pulmonary, cardiovascular, gastrointestinal, and central nervous system morbidity and mortality,[44,211,212] judicious use of fluid administration is warranted.[213] On the other hand, combined relative and absolute hypovolemia is clearly a major contributing etiologic factor to neonatal shock in neonates with sepsis and/or in the postoperative period in patients undergoing major surgery. Indeed, early and aggressive fluid resuscitation of neonates and children presenting with sepsis has been documented to decrease mortality[214] and has been recommended by the international "surviving sepsis campaign"—which recently published guidelines for the management of septic shock and sepsis-associated organ dysfunction in children.[215]

Further controversy has emerged concerning the type of fluid administered to preterm neonates with cardiovascular compromise. Most studies have shown that isotonic saline is as effective as 5% albumin in increasing blood pressure.[216,217] In addition, albumin may impair gas exchange and induce a fluid shift from the intracellular compartment[218] and is associated with increased mortality.[219] Therefore, given the documented comparable efficacy of isotonic saline and albumin in the face of differences in cost and the suggested increased mortality and morbidity associated with albumin administration,[44,211,212] isotonic saline has been the initial choice of treatment in the neonatal patient population. A recent multicenter study found isotonic saline to be the most commonly used solution for fluid bolus in the neonates.[220] The most frequent indications for fluid bolus were hypotension followed by poor perfusion and metabolic acidosis. Interestingly, in 40% of cases, there was minimal or no response to the saline bolus. Indeed, the blood pressure response to colloids, at least in the shorter run, might be better than normal saline. An RCT found that in hypotensive, mostly preterm neonates, albumin administration resulted in a greater likelihood of achieving normotension and decreased the subsequent use of vasopressors when compared to isotonic saline.[221] However, the findings of this study need to be replicated before the routine use of albumin can be considered as the initial treatment for neonatal cardiovascular compromise. Therefore, unless evidence of serum or blood loss or hypoalbuminemia is present, volume support in hypotensive preterm and term infants at present is still provided in the form of 10 to 20 mL/kg of isotonic saline.[17,18,213,222] It is also important to note that, because of the unbalanced nature of isotonic saline, caution should be exercised with the administration of large amounts over a short period of time, as this may worsen the metabolic acidosis.[223,224] Besides isotonic saline and albumin-containing solutions, other fluid replacement options are also available (Table 46.2).[17,213] Lactated Ringer's solution has lower chloride content than isotonic saline and 5% albumin and therefore carries a lower risk of the development of hyperchloremic acidosis. However, it has yet to be adequately studied in the neonatal population.[17] In adults, the use of lactated Ringer's solution is associated with better outcomes in patients with septic shock. A recent secondary analysis of a cluster-randomized trial of balanced crystalloids (either lactated Ringer or Plasma-Lyte A) versus isotonic saline found a lower 30-day in-hospital mortality in the balanced crystalloid group in critically ill adults with sepsis.[225] Another fluid choice is Plasma-Lyte A, the composition of which is very similar to plasma, making it an attractive option as a fluid bolus (see Table 46.2). However, there is no published data on the use of Plasma-Lyte A as a fluid bolus in the neonate. However, when used as a maintenance or replacement fluid, a recent RCT of Plasma-Lyte A versus moderately hypotonic saline solution in acutely ill children at or beyond 6 months of age found a greater risk of developing electrolyte disorders in the Plasma-Lyte A group.[226] Interestingly, there are no studies yet on the safety and efficacy of the use of whole blood transfusion for treatment of hypotension and shock in neonates in the transitional period or beyond.

Should careful volume administration be ineffective, pharmacologic cardiovascular support with a vasopressor-inotrope or an inotrope is recommended.[18] However, based on the recent findings of the aforementioned studies on using delayed cord clamping or cord milking, it is likely that once clinical practice changes as per the recommendations of expert panels,[98,99,227] the need for volume administration in the immediate transitional period will decline.

If there is an identifiable volume loss, the type of fluid lost should be replaced. In cases of blood loss, transfusion with packed red blood cells after the initial crystalloid or colloid bolus or packed red blood cells suspended in fresh frozen plasma with a hematocrit around 55% may be used. In cases of increased transepidermal water losses, higher free water administration without an increase in sodium supplementation is indicated. When polyuria is present, the composition and volume of the replacement fluid may be adjusted to the urinary sodium and free water losses. However,

TABLE 46.2 Electrolyte Content, pH, and Osmolarity of Various Fluid Replacement Options

Fluid Type	Na (mmol/L)	K (mmol/L)	Cl (mmol/L)	Mg (mmol/L)	Ca (mmol/L)	Acetate (mmol/L)	Gluconate (mmol/L)	Lactate (mmol/L)	pH	Osmolarity (mOsmol/L)
Plasma-Lyte A	140	5	98	1.5		27	23		7.4	294
0.9% NaCl	154		154						5.5	308
Lactated Ringer's	130	4	110		1.5				6.2	275
5% albumin*	145±15	<2							6.4–7.4	

Plasma-Lyte A (Baxter), 0.9% NaCl (Baxter), Lactated Ringer's (B. Braun Medical Inc.), 5% albumin (Flexbumin 5%, Takeda Pharmaceutical Company).
*No data available on osmolarity or electrolyte content other than sodium and potassium.

the replacement of half of the excessive urinary losses with 0.45% saline will usually suffice.

Dopamine and Dobutamine

Dopamine and dobutamine treatments were introduced in the management of neonatal hypotension in the early and mid-1980s, respectively, without appropriately designed randomized and blinded clinical trials. Thus, as mentioned earlier, we have no clear evidence that the use of these sympathomimetic amines (or any other sympathomimetic amine) improves neonatal mortality or morbidity. By examining the drugs' effect on neonatal myocardial contractility, and systemic and organ blood flow, a number of studies have extended their focus beyond the dopamine- and dobutamine-induced heart rate and blood pressure changes.[32,33,44,58,133,228–232] Some of the earlier studies, however, used left ventricular output to assess the impact of these medications on systemic blood flow even when shunting across fetal channels occurred.[33,44,232] Therefore, the conclusions drawn in these studies need to be carefully reevaluated.[43]

Hemodynamic Effects of Dopamine

Dopamine, an endogenous catecholamine, is the sympathomimetic amine most frequently used in the treatment of hypotension in preterm infants.[4,146,233] It exerts its cardiovascular actions via the dose-dependent stimulation of the cardiovascular dopaminergic, α- and β-adrenergic, and serotoninergic receptors. In addition, by stimulating epithelial and peripheral neuronal dopaminergic and adrenergic receptors, the drug exerts significant renal and endocrine effects independent of its cardiovascular actions.[233] Although dopamine affects all three major determinants of cardiovascular function (preload, myocardial contractility, and afterload), the drug-induced increases in myocardial contractility[44,232] and peripheral vascular resistance (afterload)[33,44,232] are the most important factors in increasing systemic blood pressure and improving the cardiovascular status.

The original dose-range recommendation of 2 to 20 μg/kg/min of dopamine was based on pharmacodynamic data obtained in adults without cardiovascular compromise. However, changes in cardiovascular adrenergic receptor expression caused by critical illness[234] and relative or absolute adrenal insufficiency and immaturity,[235,236] as well as the dysregulated production of local vasodilators during severe illness, decrease the sensitivity of the cardiovascular system to dopamine, resulting in the emergence of hypotension resistant to conventional doses of the drug.[133,237–239] Thus, with the advancement of the disease process, higher doses of dopamine and other sympathomimetic amines may be needed to exert the same magnitude of cardiovascular response. Therefore, dopamine administration should be tailored to the drug's pharmacodynamic effects in a given patient at the bedside rather than driven by the conventional dose recommendations based on data obtained in healthy adults. Indeed, although many neonatologists do not advance the dose of dopamine beyond 20 μg/kg/min, there is no evidence that, when required to normalize blood pressure, high-dose dopamine treatment with or without additional epinephrine administration has detrimental vasoconstrictive effects.[222,240] However, there are no data available on changes in cardiac output and organ blood flow in response to high-dose catecholamine treatment in vasopressor-resistant neonatal shock, and close attention should be paid to signs of inappropriate vasoconstriction when this therapy is applied. Several earlier studies have shown that administration of low-dose hydrocortisone ameliorates the need for high-dose vasopressor administration in most patients.[34,133,134,238,239]

As hypotension and circulatory failure are most common in the first postnatal days, a period in which significant shunting at the PDA level is often present in VLBW infants, assessment of the cardiovascular effects of vasopressors/inotropes using echocardiography is challenging. This is especially true with regard to estimating the magnitude of the PDA shunt. Therefore, one needs to be cautious in interpreting these studies. With that caveat in mind, several studies suggest that dopamine does not worsen left-to-right PDA shunt. Rather, in hypotensive preterm neonates with a significant left-to-right shunt across the PDA, dopamine administration increased systemic blood pressure, pulmonary pressure, and SVC flow, used as a surrogate of systemic blood flow in these patients.[228] Similarly, dopamine administration has not been associated with evidence of increased pulmonary vascular resistance and decreased right ventricular output in neonates without a significant left-to-right shunting across the PDA.[241,242] This finding suggests that when pulmonary blood flow is increased, vasoconstrictive mechanisms may be upregulated in the pulmonary circulation, resulting in more effective α-receptor-mediated, dopamine-induced pulmonary vasoconstriction. The findings of an earlier study demonstrating a variable pulmonary resistance response to dopamine in preterm neonates with a hemodynamically significant PDA support this notion.[243]

The vasodilatory dopamine receptors are primarily expressed in renal, mesenteric, and coronary circulations.[233] Dopamine has been shown to selectively decrease renal vascular resistance[231,233] and increase glomerular filtration rate[244] in preterm infants as early as the 23rd week of gestation. However, dopamine appears to decrease mesenteric vascular resistance in preterm infants only beyond the first postnatal day,[58,231,245,246] and the effect may be variable.[232] Similarly, there are some differences in the reported magnitude of the drug-induced increases in ventricular function, cardiac output, and systemic vascular resistance.[33,44,232,241] These findings may be best explained by differences in intravascular volume status, gestational and postnatal age, developmentally regulated expression of cardiovascular adrenergic and dopaminergic receptors, and severity of adrenergic receptor downregulation among different populations of critically ill infants studied. It is important to note that none of the studies found evidence for a direct effect of dopamine on cerebral blood flow as long as blood pressure was in the autoregulatory range.[44,58,231,232] Thus, dopamine administration appears to be devoid of potentially harmful selective hemodynamic effects in the brain. As expected, in hypotensive neonates, dopamine (or epinephrine) increases both blood pressure and CBF.[230] As discussed earlier, there is an association between dopamine exposure and impaired cerebral autoregulation in preterm infants,[208,209] a finding most likely reflective of illness severity.[1,59,63,64]

Hemodynamic Effects of Dobutamine

Unlike dopamine, dobutamine is a relatively cardioselective sympathomimetic amine with significant α- and β-adrenoreceptor–mediated direct inotropic effects and limited chronotropic actions.[247] Dobutamine administration is usually also associated with a variable decrease in total peripheral vascular resistance and, at least in adults, with improved coronary blood flow and myocardial oxygen delivery.[247] Dobutamine's cardiovascular effect is dose-dependent with limited data suggesting an improvement in myocardial function and cardiac output at moderate to high doses.[246,248,249] However, and as seen with the other cardiovascular medications, there is a significant individual variability in the hemodynamic response to and the clearance of dobutamine.[248,249] Therefore dose-titration should always be individualized and the hemodynamic response followed by close monitoring of cardiac output and function, if possible.[7] Furthermore, unlike dopamine, dobutamine increases myocardial contractility exclusively through the direct stimulation of myocardial adrenergic receptors. Because myocardial norepinephrine stores are immature and rapidly depleted in the newborn, and because dobutamine may decrease afterload, newborns with primary myocardial dysfunction and elevated peripheral vascular resistance are most likely to benefit from dobutamine treatment.[32,250] However, dobutamine may offer few hemodynamic benefits if the primary underlying pathophysiology is not poor myocardial contractility. Indeed, a recent placebo-controlled pilot trial showed dobutamine to have no effect on SVC flow.[229] Interestingly, although the addition of dobutamine to dopamine in preterm infants with RDS was effective in increasing blood pressure, it was associated with supranormal cardiac output states and low systemic vascular resistance.[12] Whether the benefits of supranormal cardiac output by providing adequate tissue oxygen delivery throughout the body outweigh the risks of sustained hypercontractility, potentially resulting in myocardial injury, remains to be investigated.

There are few data available on direct renal, cerebral, or pulmonary hemodynamic effects of dobutamine in the newborn.[251] A nonrandomized study comparing the effects of dopamine and dobutamine on blood pressure and mesenteric blood flow in preterm infants found that both drugs increased blood pressure and were equally effective in decreasing mesenteric vascular resistance.[245] Because dobutamine does not stimulate the dopaminergic receptors, β-adrenoreceptor–induced selective vasodilation may be responsible for the observed mesenteric vasodilation in dobutamine-treated patients.

Dopamine Versus Dobutamine

Randomized studies have uniformly demonstrated that dopamine is more effective than dobutamine in increasing blood pressure in the preterm infant, and a meta-analysis of these studies confirmed that dopamine was more successful than dobutamine in treating hypotension, with fewer infants in the dopamine group facing treatment failure.[252] However, there was no difference in short-term adverse neurologic outcomes between the two groups. In the absence of long-term outcome data, no firm recommendations can be made regarding the choice of drug in treating hypotension of preterm infants in the immediate postnatal period. In addition, no information was forthcoming on changes in systemic blood flow. However, when carefully titrated to a predetermined "optimum" hemodynamic effect, dopamine (and epinephrine) increased blood pressure and CBF in hypotensive VLBW neonates during the first postnatal day.[230] Neurodevelopmental follow-up of patients enrolled in this study at 2 to 3 years of age did not reveal evidence of an independent vasopressor-inotrope–associated increase in morbidity (see earlier).[205] Although the findings of this study provide some reassurance against the possibility of a dopamine- (or epinephrine-) associated increase in neurodevelopmental morbidity in VLBW neonates during the first postnatal day, the original study[230] was not sufficiently powered to put these concerns to rest.

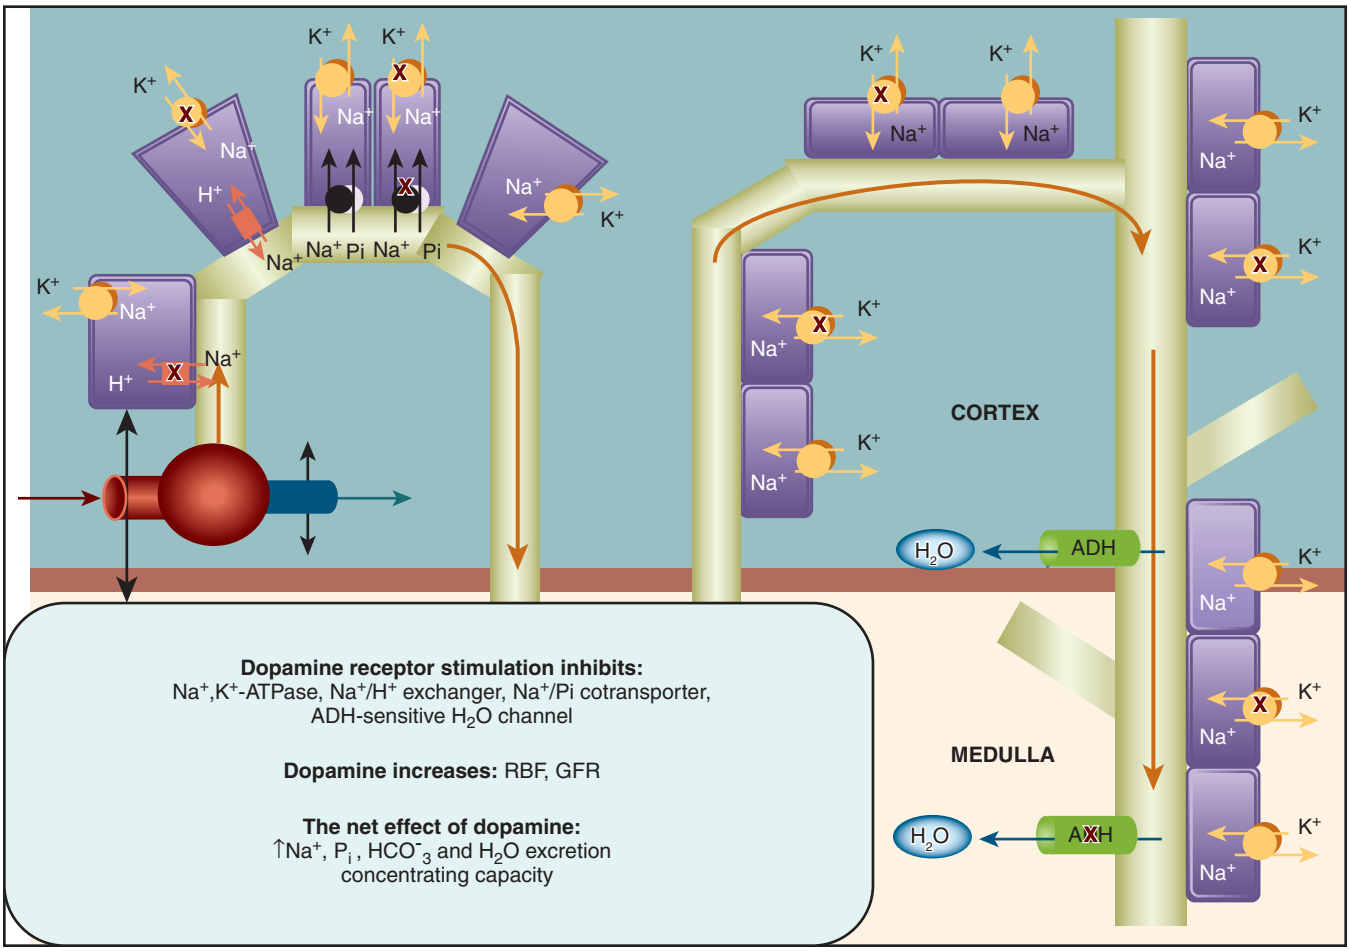
As discussed earlier, because of the weak relationship between blood pressure and systemic blood flow in very preterm neonates during the immediate postnatal period, an increase in blood pressure does not necessarily guarantee that tissue perfusion has improved along with the blood pressure.[10–13,43] Although one study using laser Doppler showed no evidence of peripheral vasoconstriction even with dopamine doses greater than 10 μg/kg/min,[253] an earlier study demonstrated impairment in systemic blood flow with higher doses of dopamine in a subset of patients, despite improvements in blood pressure.[32] Therefore, if there is evidence of peripheral vasoconstriction, especially in VLBW neonates during the first postnatal day, high-dose dopamine treatment should only be attempted if systemic blood flow can be monitored by functional echocardiography, NIRS, and/or other advanced perfusion monitoring techniques. However, in present clinical practice these measures of blood flow monitoring, with the possible exception of NIRS, are not routinely available, and the neonatologist must rely on monitoring blood pressure and the indirect measures of cardiovascular function. If evidence of vasoconstriction is present with higher doses of dopamine (or epinephrine), the neonatologist should consider accepting blood pressure values in the lower range for gestational and postnatal age and decrease the dose of vasopressor-inotrope to levels where significant α-adrenoreceptor stimulation is less likely.[43,233] In these cases and depending on the pathophysiology of the cardiovascular compromise, the addition of dobutamine or milrinone should be considered and the blood pressure maintained in the low-normal range. As systemic hypotension has been linked to poor long-term neurodevelopmental outcomes in the VLBW neonatal patient population,[51,53] careful

consideration of the lowest acceptable perfusion pressure in the given patient is warranted. A combination of dobutamine or milrinone and low-dose dopamine may achieve the most important goals of treatment by maintaining blood pressure and systemic blood flow in acceptable ranges if monitoring of both cardiovascular parameters is possible. In most of these patients, physiologic glucocorticoid and mineralocorticoid replacement with hydrocortisone is likely to be effective, although the potential side effects of early hydrocortisone exposure in preterm neonates should be kept in mind (see later discussion).[43,136] In summary, as maintenance of appropriate perfusion pressure is necessary to ensure appropriate tissue oxygen delivery (systemic and organ blood flow) and because both hypotension and low systemic blood flow have been associated with impaired neurodevelopmental outcomes, the primary goal of management of the hypotensive very preterm neonate should be the correction of both measures of cardiovascular function.

In hypotensive term and preterm neonates beyond the immediate postnatal period, where vasodilatory shock is the more likely presentation, dopamine (or epinephrine) administration in doses tailored to the cardiovascular response is warranted and appears to be beneficial[230,250,254,255] unless evidence of primary myocardial dysfunction is present.[222,233]

Epithelial and Neuroendocrine Effects

Independent of the just-described cardiovascular effects, dopamine exerts direct renal[233] and endocrine[233] actions in the newborn. Via its actions on renal blood flow and glomerular filtration rate as well as through its direct effects on sodium, phosphorous and water transport processes, and Na^+K^+-ATPase activity in renal tubules, dopamine increases sodium, phosphorus, and free water excretion (Fig. 46.11) and may increase the hypoxic threshold of renal tubular cells during episodes of hypoperfusion and hypoxemia.[233] Via its renal vascular and epithelial actions,



• **Fig. 46.11** Effects of Dopamine Along the Nephron. Dopamine increases renal blood flow (RBF) by selective renal vasodilation and by increasing mesangial cell surface area and glomerular hydrostatic pressure via the preferential dilation of the afferent arteriole *(black arrows)*. These changes result in an increased single-nephron glomerular filtration rate (GFR). Indeed, administration of dopamine to normotensive preterm neonates results in increased sodium, phosphorous, and free water excretion (Seri, 1993 and 1995). These effects are primarily caused by the drug-induced inhibition of Na^+-K^+-ATPase, Na^+/H^+ exchanger, and the Na^+/Pi cotransporter in the proximal tubule as well as inhibition of antidiuretic hormone (ADH)-induced phosphorylation of water channels in the collecting duct (Seri, 1995). The proposed resultant increase in bicarbonate excretion has not been documented in preterm infants. **X** *(in red)* = inhibition of enzyme or transporter function. (From Kelly L, Seri I. Renal developmental physiology: relevance to clinical care. *NeoReviews*. 2008;9:e150–e161.)

dopamine also potentiates the diuretic effects of furosemide[256] and theophylline.[257] Although dopamine has the theoretical potential to attenuate renal side effects of indomethacin, the data in the literature are contradictory.[233] Differences in the level of maturity, disease severity, ductal shunting, intravascular volume status, and indomethacin dose may be responsible for the conflicting results. Among its endocrine actions, the dopamine-induced decreases in plasma prolactin, thyrotropin, and growth hormone levels[233] may be of clinical importance. The decrease in plasma prolactin may attenuate the preterm infant's propensity to edema formation but may also have a modulating effect on immune function.[233] The inhibition of thyrotropin release necessitates the postponement of routine neonatal thyroid screening until after dopamine administration has been discontinued.[233,258] Dopamine, compared to dobutamine, decreases serum TSH and T4 levels by approximately 70% to 80% and 50%, respectively.[258] Indeed, as dobutamine does not stimulate dopaminergic receptors, its administration is devoid of neuroendocrine effects. The potential impact on long-term neurodevelopmental outcome and immunologic function of the drug-induced alterations in neuroendocrine function is not known in the preterm and term neonates.

Epinephrine, Norepinephrine, and Other Cardiovascular Agents and Hormones

Epinephrine

In an RCT, low to medium doses of epinephrine, when titrated to optimal hemodynamic response, have been shown to increase blood pressure and CBF in hypotensive VLBW neonates.[230] Because of epinephrine's significant effect on glycogenolysis, its administration is associated with an increase in serum lactate levels independent of the drug's cardiovascular actions.[57] This effect should be kept in mind when following serum lactate levels to assess the changes in cardiovascular status due to epinephrine administration. Therefore, the epinephrine-induced improvement in perfusion cannot be ascertained by following serum lactate levels alone, because these levels will likely increase despite drug-induced improvement in the cardiovascular status. A recent double-blinded cross-over RCT of epinephrine versus dopamine for neonatal septic shock showed no difference in the reversal of shock by 45 minutes and mortality in 28 days.[259] It is of note that on analysis stratified for gestational age groups, epinephrine seemed to be favored in neonates $\leq 30^{6/7}$ weeks' gestation.[259] Finally, in a recent meta-analysis on the use of epinephrine versus dopamine in patients with pediatric and neonatal septic shock, the drugs showed similar efficacy in the three available RCTs.[260]

It is not known whether there is a difference in the cardiovascular response and/or side effects of sympathomimetic amines with the combined use of epinephrine and dopamine compared to the use of increasing doses of dopamine beyond 20 μg/kg/min with or without dobutamine. In preliminary publications, there have been no detrimental vasoconstrictive effects reported using either high doses of epinephrine with or without dopamine, or norepinephrine in sick neonates and children.[261–263] These findings are best explained by the down-regulation of cardiovascular adrenergic receptors and thus the decreased cardiovascular sensitivity of critically ill preterm infants to catecholamines, necessitating escalating sympathomimetic support. However, in a retrospective study of VLBW infants with dopamine-resistant hypotension, epinephrine administration was associated with an increase in blood pressure and heart, no effect on urine output, and worsening metabolic acidosis.[264] Therefore, one must be extremely careful when escalating treatment with these potent vasopressor-inotropes in order to decrease the risk of unwarranted severe vasoconstriction and compromised tissue perfusion. As referred to earlier, with the appropriate use of low-dose hydrocortisone in patients with evidence of relative adrenal insufficiency, high-dose vasopressor support is rarely required.

Norepinephrine

Norepinephrine is the drug of choice for the treatment of septic (vasodilatory) shock in adult patients and is being increasingly used in children with septic shock.[215,265] However, due to a number of developmentally regulated factors, the pharmacokinetics and pharmacodynamics of norepinephrine are different in neonates. Unfortunately, limited data are available on the effectiveness and safety of norepinephrine in the neonatal population.[266] An observational study in late preterm and term neonates with persistent pulmonary hypertension of the newborn (PPHN) treated with inhaled nitric oxide (iNO) who also presented with signs of circulatory failure, found that medium doses of norepinephrine improved systemic and pulmonary cardiovascular function by decreasing the pulmonary artery–to–aortic pressure gradient and improving cardiac performance.[267] Another observational study also found improvement in blood pressure, urine output, and lactic acidosis in term infants with refractory hypotension unresponsive to conventional treatment.[268] A recent retrospective study of preterm infants with septic shock and refractory hypotension to epinephrine or dopamine reported improvement in blood pressure and urine output but no change in pH or base deficit 8 hours after initiating norepinephrine therapy.[269] Forty-three percent of patients were also receiving hydrocortisone, which likely had an impact on the finding. Another retrospective study of preterm infants with cardiovascular compromise (mostly due to sepsis or pulmonary hypertension) also found improvement in blood pressure and oxygenation but no change in pH, lactate, or urine output following initiation of norepinephrine infusion.[270] Ninety-four percent of the patient were on other vasopressor-inotropes, and more than half also received hydrocortisone. Despite normalization of blood pressure in all except one of the patients, 1 hour after starting norepinephrine, 45% of the patients died. Although some of the above findings are encouraging, the routine use of norepinephrine in the treatment of neonates with PPHN and cardiovascular compromise requires further investigation.

Milrinone

There are limited data available on the pharmacokinetics, pharmacodynamics, and cardiovascular effects of milrinone, a phosphodiesterase-III (PDE-III) inhibitor in the neonatal patient population.[271–273] It has been widely used to reduce afterload in neonates with congenital heart disease with low cardiac output syndrome after surgery.[274] As for its use in term infants without congenital heart disease, milrinone administration has been shown in a small case series to improve the oxygenation index without compromising systemic blood pressure when given to term neonates with PPHN treated with iNO during the first 2 postnatal days.[275] Another small retrospective study found improvement in indices of cardiac function about 24 hours after initiation of milrinone in late preterm and term infant with pulmonary hypertension treated with iNO.[276] The preferential effect of milrinone on the pulmonary circulation in neonates with PPHN treated with iNO may be due to the upregulation of PDE-III in pulmonary vessels in response to iNO administration.[277] It is unclear

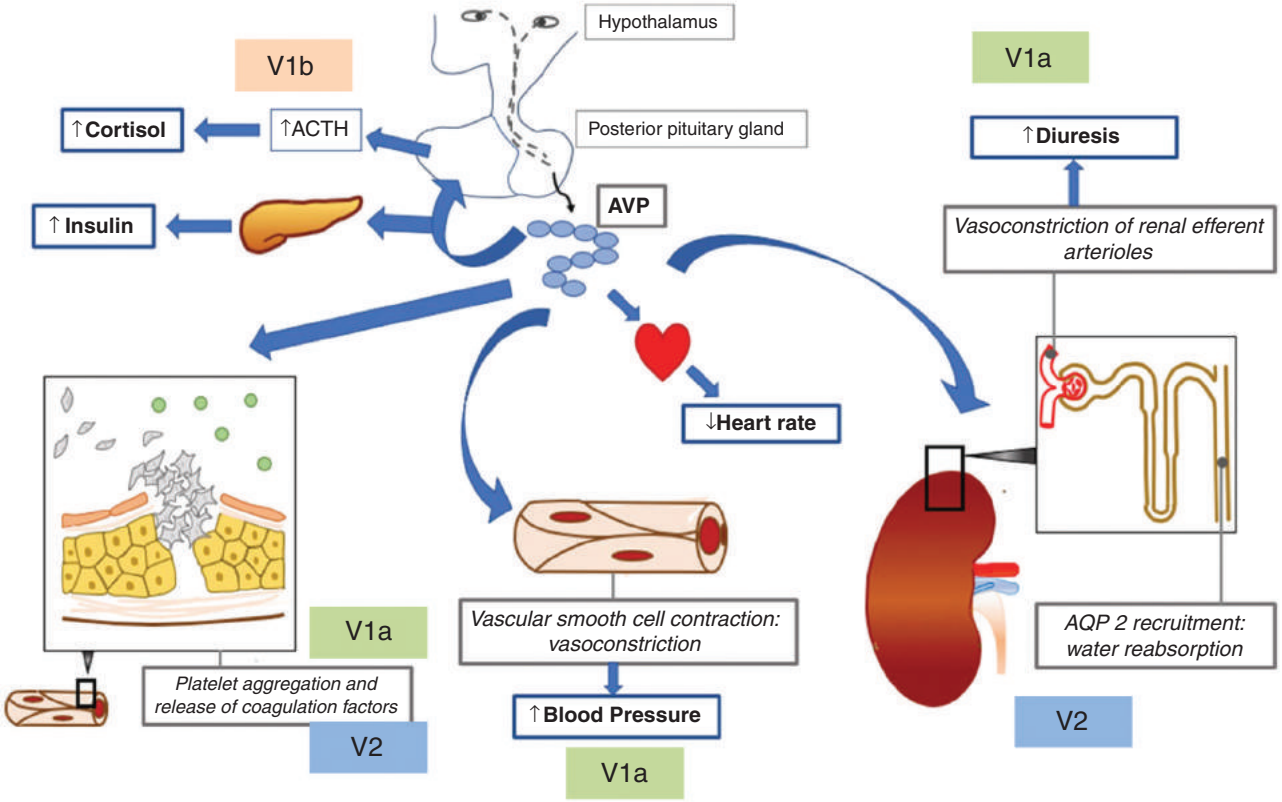
if milrinone has a positive inotropic effect in neonates.[278] A retrospective study of 1446 neonates exposed to milrinone found that 42% of the infants had adverse effects attributed to the drug administration.[273] Arterial hypotension prompting vasopressor-inotrope administration and thrombocytopenia were the most frequently noted adverse effects. A recent case-control study found hypotension to be particularly severe after initiating milrinone in patients with hypoxic-ischemic encephalopathy receiving hypothermia and inhaled nitric oxide therapies.[279]

A randomized placebo-controlled blinded clinical trial also investigated whether the use of milrinone would minimize or prevent the suspected increase in systemic vascular resistance and the associated systemic hypoperfusion in VLBW infants during the first postnatal day.[280] However, there was no improvement in the incidence of low SVC flow used as a surrogate of systemic blood flow in patients treated with milrinone compared to the placebo group. These findings may be explained, at least in part, by the little-appreciated complexity of the pathophysiology of cardiovascular compromise in the very preterm neonate after delivery.[281] They further suggest that systemic and cerebral hypoperfusion and reperfusion in this patient population may not solely occur because of the inability of the immature myocardium to pump against the sudden postnatal increase in systemic vascular resistance.[73,122]

Vasopressin

Vasopressin acts on various organs and vascular beds via three receptor subtypes.[282] The stimulation of V_{1a} receptor is responsible for its vasoconstrictive effects in the systemic vascular bed and renal efferent arterioles. Stimulation of this receptor also leads to platelet aggregation (Fig. 46.12). Yet, the hemodynamic effects of this receptor subtype are more complex and, in animal models, stimulation of the V_{1a} receptor is associated with both an increase and decrease in coronary blood flow and contractility.[283] The activation of the V_{1b} receptor results in ACTH and insulin release from the anterior pituitary gland and the pancreas, respectively. V_2 receptors are involved in the recruitment of aquaporin in the collecting ducts and promote renal absorption of free water. V_2 receptor stimulation also leads to the release of clotting factors.

Despite the multiple physiologic roles of vasopressin, the primary cardiovascular effect of exogenous vasopressin in the systemic circulation is vasoconstriction. However, in the pulmonary circulation, low doses of vasopressin have been shown to induce



• **Fig. 46.12** Effects of Vasopressin on Various Organs and Vascular Beds. Vasopressin (AVP, arginine vasopressin) is synthesized in the hypothalamus and carried via the nerve tracts to the posterior pituitary gland. Once secreted from the posterior pituitary gland into the bloodstream, it acts on different vasopressin receptor subtypes. The stimulation of V_{1a} receptor is responsible for its vasoconstrictive effects in the systemic vascular bed and renal efferent arterioles. Stimulation of this receptor also leads to platelet aggregation. The activation of the V_{1b} receptor results in adrenocorticotropic hormone (ACTH) and insulin release from the anterior pituitary gland and the pancreas, respectively. V_2 receptors are involved in the recruitment of aquaporin (AQP) in the collecting ducts and promote renal absorption of free water. V_2 receptor stimulation also leads to the release of clotting factors. (Modified from Demiselle J, Fage N, Radermacher P, et al. Vasopressin and its analogues in shock states: a review. *Ann Intensive Care*. 2020;10:9.)

vasodilation in adults. In neonates with pulmonary hypertension including patients with a congenital diaphragmatic hernia, several case series have also reported improvement in oxygenation and a decrease in pulmonary pressure following low-dose vasopressin administration.[284–287] However, as expression of vasopressin receptors is developmentally regulated, it is unclear if vasopressin truly induces selective pulmonary vasodilation in the neonatal population.[288]

Its systemic pharmacodynamic profile makes vasopressin a good candidate for the treatment of circulatory failure when the underlying pathophysiology is primarily that of vasodilation such as in septic shock without myocardial dysfunction or systemic inflammatory response following cardiac surgery. However, there are only case series reporting improvement in systemic hemodynamics in preterm and term infants with refractory hypotension or septic shock.[289–293] In adults, some RCTs have demonstrated a reduction in mortality with the use of vasopressin in septic shock.[294,295] A randomized pilot study compared vasopressin to dopamine as the first line of treatment in hypotensive preterm infants.[296] This study found that vasopressin resulted in similar improvement in blood pressure and urine output compared to dopamine. In addition, the vasopressin group had less tachycardia. Interestingly, a recent meta-analysis of the available three RCTs and five prospective clinical trials in the pediatric age groups found no clinical benefit of vasopressin or terlipressin use on mortality and length of stay and the results suggested a potential increase in the risk of ischemic events compared to conventional vasopressor-inotrope use.[297]

Clinical scenarios in which the use of a vasopressor without significant inotropic effect may be advantageous include hypotensive neonates with hypertrophic cardiomyopathy. In such cases, increasing inotropy will worsen the dynamic obstruction of left ventricular outflow tract and lead to worsening systemic hypoperfusion. Apart from volume administration and the use of beta-blockers, a pure vasopressor without significant inotropic effects such as phenylephrine and vasopressin can be helpful. Indeed, a recent case series reported improvement in blood pressure and oxygenation after starting vasopressin in neonates with hypertrophic cardiomyopathy.[298] Although, as discussed earlier, vasopressin acts on a number of organ systems, RCTs in adults have not shown an increase in adverse cardiac effects or coagulation problems in the vasopressin arm.[294,299] However, a metanalysis of RCTs in adults has shown an increased risk of digital ischemia.[295] Vasopressin-induced hyponatremia has been reported in adults, and the limited experience in neonates indicates that it is a common side effect of vasopressin administration.[291,298] Therefore, more data on the safety and efficacy of vasopressin are needed before it can be introduced in the routine clinical care of critically ill neonates with vasodilatory shock.[300]

Steroid Administration

Steroid Administration as Primary or Rescue Treatment

Over two decades ago, a small RCT showed that low-dose hydrocortisone improved blood pressure but was less effective than dopamine in hypotensive preterm infants.[301] However, given the concerns over adverse long-term effects of steroids (primarily dexamethasone) and inadequate data on their efficacy, steroids are not recommended for first-line treatment of hypotensive preterm infants.[236,302]

As for rescue treatment, there is now overwhelming evidence provided by descriptive studies and confirmed by randomized blinded prospective trials that brief steroid treatment stabilizes the cardiovascular status and decreases the need for vasopressor-inotropic support in the critically ill preterm and term newborn with vasopressor-resistant hypotension. Because there is overwhelming evidence that early and/or medium-to-high cumulative doses of dexamethasone have detrimental effects on the developing brain, and because in addition to glucocorticoids, mineralocorticoids also have significant effects on the cardiovascular system, even low-dose dexamethasone administration to treat vasopressor-resistant hypotension has fallen by the wayside in recent years.[238] This section, therefore, addresses only the actions, side effects, recommended doses, and remaining clinically relevant concerns of hydrocortisone administration to treat vasopressor-resistant hypotension in the critically ill neonate. It is of note that the available evidence for the effectiveness of low-dose hydrocortisone to increase blood pressure and decrease vasopressor-inotrope requirement in the preterm neonate is so strong that it would take 74 and 188 future studies demonstrating no effect of hydrocortisone on blood pressure increase and on the decrease in vasopressor requirement, respectively, to eliminate the statistical power of the present findings.[303]

Rationale for Hydrocortisone Treatment

Because in most patients and after some time, cardiovascular stability will be achieved by the use of vasopressors-inotropes and/or inotropes alone, it is important to understand the rationale for hydrocortisone administration, especially because the drug has its own side effects.

First, it is widely accepted although not proven that the sooner one normalizes blood pressure and systemic perfusion, especially in the VLBW neonate during the immediate postnatal period, the better the outcome. However, because normal blood pressure in the first 24 hours may not guarantee normal cerebral perfusion (see earlier discussion), and because an association but not causation has been documented between hypotension and adverse outcomes, stabilization of the cardiovascular status with little blood pressure fluctuation remains an intuitively desirable goal but one without much direct evidence to support it.

Second, and more importantly, hydrocortisone specifically addresses the underlying etiology of the cardiovascular instability in most critically ill neonates and thus is the logical choice of treatment. Indeed, findings of developmental endocrinology and cardiovascular physiology as well as recent clinical data support a role for hydrocortisone use in critically ill hypotensive neonates, especially in VLBW neonates.[236] In critical illness, desensitization of the cardiovascular system to catecholamines takes place through the downregulation of cardiovascular adrenergic receptors and second messenger systems.[234] This process is attenuated or prevented by the regulatory actions of glucocorticoids on the expression of cardiovascular adrenergic receptors and second messenger systems. In addition, the direct increase in myocardial and vascular smooth muscle cell contractility induced by mineralocorticoids also plays an effective role.[304,305] Furthermore, corticosteroids contribute to the maintenance of capillary integrity, inhibit catecholamine metabolism and reuptake of norepinephrine into sympathetic nerve endings, increase the expression of angiotensin type 2 receptors in the myocardium, and inhibit prostacyclin production and the induction of inducible nitric oxide synthase. Each of these actions of corticosteroids aids in maintaining the sensitivity of the

cardiovascular system to catecholamines in response to acute stress or critical illness.

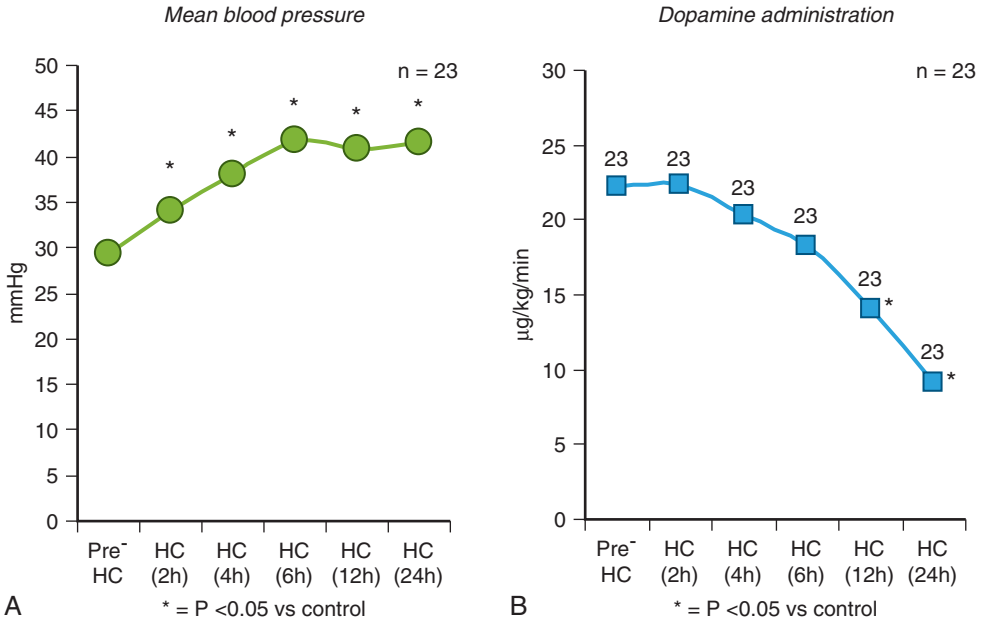
Third, because of the role of glucocorticoids in the physiologic regulation of adrenergic receptor expression, the emergence of vasopressor resistance in itself may indicate a state of relative adrenal insufficiency. Indeed, the findings of several studies indicate that critically ill preterm and term infants are likely to develop relative adrenal insufficiency because of their immature adrenal function[235,306,307] and hypothalamopituitary axis,[308,309] respectively. It is important to emphasize that, based on these findings, it appears that in the VLBW neonate, adrenal unresponsiveness to endogenous or exogenous ACTH[235,306] and in the late preterm and term neonate, unresponsiveness of the hypothalamopituitary axis to stress[308,309] are the primary causes for the development of relative adrenal insufficiency. Thus, these patients have limited capacity to mount sufficient adaptive increases in endogenous steroid production to prevent the development of cardiovascular adrenergic receptor downregulation and desensitization of the cardiovascular system to catecholamines during their illness. Therefore, in critically ill preterm and term infants with vasopressor-resistant hypotension, steroid administration also serves as hormone substitution therapy.

Clinical Applications of Hydrocortisone

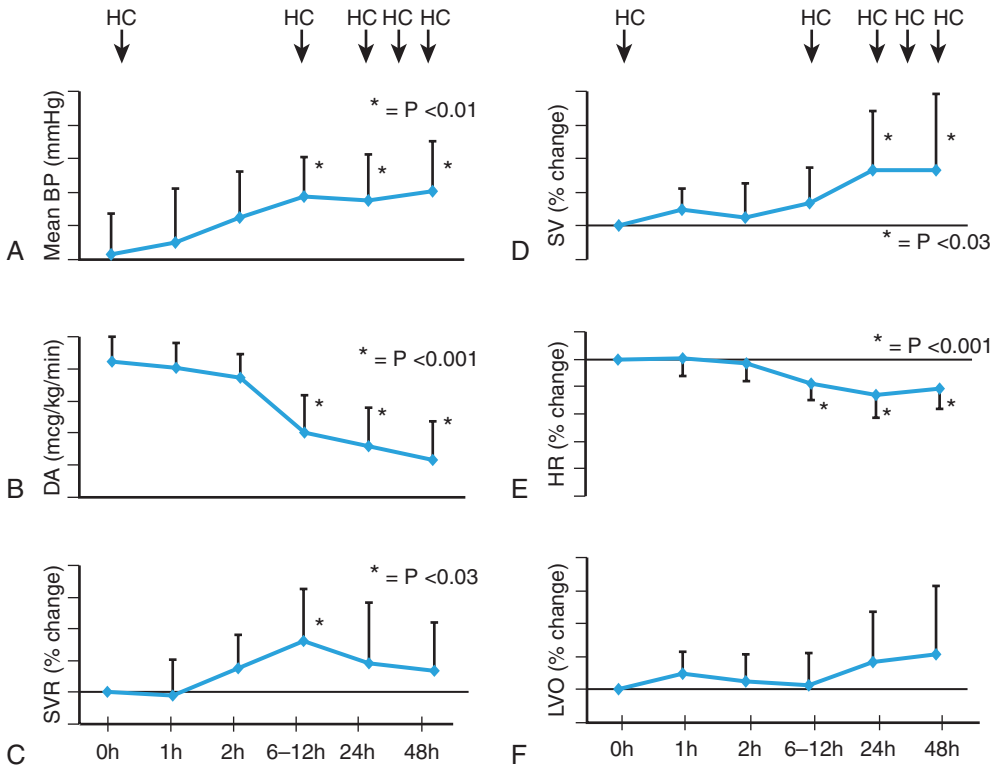
As mentioned earlier, the use of hydrocortisone as primary treatment in hypotensive preterm infants is not recommended. On the other hand, although long-term effects need to be further studied (see below), there is justification for the use of hydrocortisone as a secondary rescue treatment. Available evidence indicates that hydrocortisone in preterm and term infants with vasopressor-resistant hypotension increases blood pressure within 2 hours of the initiation of treatment (non-genomic effects) and decreases vasopressor requirement within 8 to 12 hours of the first dose of the drug (genomic effects) (Fig. 46.13).[133,237,238] A study in preterm infants without a PDA also documented that the hydrocortisone-induced improvement in blood pressure is associated with improvements in all aspects of cardiovascular function including stroke volume and tissue perfusion (Fig. 46.14).[133] It is important to note that due to the decreased clearance of hydrocortisone, lower and less frequent dosing is sufficient to induce the desired hemodynamic effects in preterm and term infants.[133,236,310,311]

Short-term Side Effects

As for the side effects of early or late low-dose hydrocortisone administration, the potential occurrence of short- and long-term sequelae is of great interest. As for the short-term side effects, it has been repeatedly documented that coexposure of preterm neonates to indomethacin and hydrocortisone during the first postnatal week significantly increases the risk of spontaneous gastrointestinal (mostly ileal) perforations.[312,313] This serious untoward effect curtails the use of hydrocortisone in the VLBW neonate during the first postnatal week—the very patient population in whom vasopressor-resistant hypotension and relative adrenal insufficiency are most prevalent during the immediate postnatal period. It is interesting to note that preliminary findings of one of these studies might suggest that VLBW neonates



• **Fig. 46.13** Effect of Hydrocortisone on Mean Blood Pressure and the Dose of Dopamine During the First 24 Hours of Hydrocortisone Treatment in 23 Preterm Neonates With Vasopressor-Resistant Shock. (A) Mean blood pressure (mean ± SD) and (B) dopamine requirement (mean ± SD) during the 12 hours before and the first 24 hours after the first dose of hydrocortisone. Before hydrocortisone administration, blood pressure remained low (A), despite significantly increased dopamine doses (B, ∗ = $P < .05$ vs. baseline [0 h]). However, mean blood pressure increased significantly by 2 hours after the first dose of hydrocortisone (A, ∗ = $P < .05$ vs. baseline [0 h]) and continued to rise until 6 hours of hydrocortisone therapy, remaining stable thereafter (A, ∗ = $P < .05$ vs. baseline [0 h]; ∗ = $P < .05$ vs. HC [2 h]). In addition, the dose of dopamine significantly decreased by 12 and 24 hours of hydrocortisone therapy (B, ∗ = $P < .05$ vs. baseline [0 h]). (From Seri I, Tan R, Evans J. Cardiovascular effects of hydrocortisone in preterm neonates with pressor resistant hypotension. *Pediatrics*. 2001;107:1070–1074.)



• **Fig. 46.14** Effect of Hydrocortisone on Systemic Hemodynamics and Dopamine Requirement During the First 48 hours of Hydrocortisone Treatment in 15 Preterm Neonates With Vasopressor-Resistant Shock. Changes in mean BP (A) and dopamine dosage *(DA)* (B) and percentage changes relative to baseline (0 hour) in SVR (C), stroke volume *(SV)* (D), heart rate *(HR)* (E), and left ventricular output *(LVO)* (F) are shown at 1, 2, 6 to 12, 24, and 48 hours after the first dose of hydrocortisone. *HC* with arrows indicate the approximate timing of hydrocortisone doses. Significant P values for pairwise comparisons versus the baseline (0 hour) with adjustment for multiple comparisons (Bonferroni) are shown. See text for details. *BP*, Blood pressure; *SVR*, systemic vascular resistance. (From Noori S, Friedlich P, Wong P, et al. Hemodynamic changes following low-dose hydrocortisone administration in vasopressor-treated neonates. *Pediatrics*. 2006:118:1456–1466.)

with low baseline serum cortisol levels may be at lower risk for developing ileal perforations when treated with low-dose hydrocortisone and a cyclooxygenase inhibitor during the first postnatal days.[312] However, this observation needs to be confirmed before it can be used to predict the likelihood of spontaneous intestinal perforation based on the basal serum cortisol level alone. As for the other short-term side effects of hydrocortisone, one earlier study found an increase in the incidence of systemic fungal infections.[314] However, none of the other studies have documented a significant increase in bacterial or fungal infections in neonates. Finally, hydrocortisone administration–associated transient hyperglycemia and hypertension have been reported in a few cases in the literature.

Long-term Side Effects

As for the potential long-term side effects, the most pressing question is whether low to moderate doses of hydrocortisone interfere with neurodevelopment, especially in preterm neonates.

Two placebo-controlled trials showed that early, low-dose hydrocortisone treatment for the prevention of BPD used in the first 10 postnatal days was not associated with an increased incidence of cerebral palsy[313,315] and neurodevelopmental impairment.[315] Findings of one of the trials even suggested improvement in some measures of neurodevelopmental outcome at 18 to 22 months, corrected age when compared to controls.[316] On the other hand, the 5- to 7-year follow-up of a small RCT of early hydrocortisone treatment for prevention of BPD showed a lower performance intelligence quotient and a higher need for physiotherapy in the hydrocortisone group.[317]

As for the use of higher cumulative doses of hydrocortisone for the treatment of evolving bronchopulmonary dysplasia outside the immediate transitional period, the results of a study examining structural and functional brain development at an age of 8 years suggest that hydrocortisone, used for the treatment of bronchopulmonary dysplasia in ventilator-dependent preterm neonates at a median age of 18 days and at cumulative doses over 50 mg, does not interfere with brain development.[318] In addition, case-control studies have shown no difference in cerebral and cerebellar tissue volumes on MRI at term equivalent in preterm infants treated with hydrocortisone for BPD compared to the controls.[319,320] A small RCT on hydrocortisone with a cumulative dose of 17 mg/kg starting moderately early (at 10 to 21 days) also showed no difference in regional brain volume at term equivalent compared to the controls.[321]

Although overall, hydrocortisone appears to be safer than dexamethasone, the lack of power of the RCTs and the retrospective nature of the observational or retrospective studies warrant caution before the use of early or late and low- to medium-dose hydrocortisone could be declared safe in preterm neonates, at least from a neurodevelopmental standpoint.

Extracorporeal Membrane Oxygenation (ECMO) for Circulatory Support

ECMO or extracorporeal life support (ECLS) has been used for decades to provide cardiorespiratory support for neonatal cardiorespiratory failure refractory to conventional management.[322] There are two types of ECMO: veno-venous (VV) and veno-arterial (VA). In VV ECMO, blood is drained from the venous system via one of the ports of the cannula placed in the right atrium via the internal jugular vein. The blood first flows through the circuit and the oxygenator, and the oxygenated blood is then returned to the right atrium via a different port in the venous cannula. Therefore, VV ECMO does not provide direct cardiac support, although improved blood oxygen content in the heart and coronary arteries may improve cardiac function. Furthermore, as the oxygenated blood first circulates through the pulmonary vasculature, VV ECMO can improve cardiac function by reducing pulmonary vascular resistance in conditions such as persistent pulmonary hypertension (PPHN) with circulatory failure, wherein elevated pulmonary vascular resistance contributes to the circulatory collapse. In VA ECMO, blood is also drained from the venous system via cannula with a single port placed in the right atrium through the internal jugular vein. Blood is then returned to the arterial system via an arterial cannula typically placed in the right common carotid artery in the neonate and advanced to the transverse aortic arch. By bypassing the heart, VA ECMO also provides direct circulatory support and is the preferred modality when significant circulatory support is needed. Such conditions include refractory septic shock,[323] acute myocarditis associated with severe myocardial dysfunction, low cardiac output following repair of congenital heart defects, or severe hypertrophic cardiomyopathy seen in infants born to diabetic mothers. The recent surviving sepsis campaign international guidelines suggest using VV ECMO in children with sepsis-induced pediatric acute respiratory distress syndrome and using VA ECMO as a rescue therapy in children with refractory septic shock.[215]

In the past two decades, the number of neonates placed on ECMO for cardiac indications has increased. The survival of neonates receiving ECMO support for cardiac indications varies significantly and depends on the primary diagnosis. However, the overall survival is approximately 50%, which is lower than the survival of infants treated with ECMO for respiratory indications.[324] Of note is that neonates tend to have a better outcome than older children.[325,326] For example, survival among 191 neonates with group B streptococcal sepsis treated with ECMO was 71%.[327] However, little is known about the impact of various ECMO treatment strategies on outcomes. A recent study of children (older than 30 days) with refractory septic shock demonstrated a higher survival using a high (>150 mL/kg/min) ECMO blood flow strategy during the early phase of ECMO support.[328]

In summary, neonatal ECMO provided for circulatory failure is a relatively effective last resort for the sickest and most complex neonatal patients cared for in experienced neonatal centers.

General Supportive Measures

Maintenance of a normal intravascular volume, arterial pH, and serum ionized calcium concentration is necessary for the optimum cardiovascular response to catecholamines. A previous study found that metabolic acidosis of less than 7.25 may compromise myocardial function in the preterm infant,[329] and so it has been recommended that the arterial pH be maintained at or above this range in cases of acidosis with a significant metabolic component. On the other hand, respiratory acidosis has been shown to have no to minimal effect on cardiac function, contractility, and systemic vascular resistance in hemodynamically stable preterm infants during the transitional period.[115] However, and as discussed earlier, respiratory acidosis has significant effects on cerebral hemodynamics, and its cardiovascular effects in neonates receiving cardiovascular support are not known (see section on respiratory support and hemodynamics). Therefore, more data are needed to define the optimal pH and acid-base status in preterm and term infants receiving respiratory support. Administration of sodium bicarbonate[329] or, in cases with severe combined respiratory and metabolic acidosis, the administration of tromethamine, rapidly improves arterial pH. However, the efficacy and potential short- and long-term adverse effects of such supportive treatment measures have not been studied in the neonatal patient population, and there is indeed very little evidence that bicarbonate administration for metabolic acidosis caused by tissue hypoperfusion is beneficial.[330] Finally, although positive pressure ventilation may raise pleural pressure and has the potential to reduce venous return, it may also reduce left ventricular afterload by reducing transmural pressure and decreasing or eliminating the work of breathing. Decreasing or eliminating the work of breathing will also decrease or eliminate the concomitant cardiac output diverted to respiratory muscles. Therefore, the net hemodynamic effect of positive pressure ventilation is improved systemic oxygen delivery independent of any potential improvement in pulmonary gas exchange. On the other hand, excessive positive pressure and lung hyper-expansion are associated with decreases in pulmonary and systemic blood flow.

In summary, sustained stabilization of the cardiovascular status with the provision of appropriate blood pressure, cardiac output, and tissue perfusion and oxygenation remains a difficult task in most critically ill hypotensive neonates. Treatment of these patients requires the ability to continuously monitor the most important measures of cardiovascular function (blood pressure, systemic blood flow, and tissue oxygenation); a thorough understanding of the pathogenesis and pathophysiology of neonatal shock; and the mechanisms of action, pharmacodynamics, and potential side effects of sympathomimetic amines and other medications used in the management of neonatal shock.

Persistent Pulmonary Hypertension

ERICA MANDELL, ROBIN H. STEINHORN, AND STEVEN H. ABMAN

KEY POINTS

- Persistent pulmonary hypertension of the newborn (PPHN) can occur with parenchymal lung disease, with pulmonary hypoplasia, or without associated lung disease (*idiopathic*) and has an incidence of 0.2% in term infants and up to 2% in preterm infants.
- Maternal factors such as diabetes, high body mass index, smoking, use of selective serotonin receptor inhibitors or nonsteroidal anti-inflammatory drugs, and cesarean delivery increase the risk of PPHN. Postnatal factors include perinatal asphyxia, hyperoxia, hypoxia, infection, and lung inflammation.
- Medical management of PPHN requires careful optimization of right and left ventricular function. Lung recruitment strategies should be optimized in patients with parenchymal lung disease.
- Inhaled nitric oxide improves oxygenation and reduces the need for extracorporeal membrane oxygenation support in term and near-term infants with PPHN.
- Extracorporeal membrane oxygenation support is indicated for term and near-term neonates with severe pulmonary hypertension and/or hypoxemia that is refractory to inhaled nitric oxide therapy and optimization of respiratory and cardiac function.
- Chronic pulmonary hypertension occurs most often in a subset of infants with congenital diaphragmatic hernia and/or bronchopulmonary dysplasia and substantially increases morbidity and mortality.
- Surviving infants of moderate to severe PPHN are at high risk of neurodevelopmental impairment and should undergo neuroimaging and neurodevelopmental follow-up.

Introduction

Persistent pulmonary hypertension of the newborn (PPHN) can be seen with many cardiopulmonary disorders with an incidence ranging from 0.4 to 6.8 per 1000 live births and 5.4 per 1000 live births in late preterm infants.[1,2] The etiology of PPHN in preterm infants is usually secondary to hypoxemic respiratory failure related to significant lung pathology soon after birth such as respiratory distress syndrome (RDS), preterm premature rupture of membranes (PPROM), or oligohydramnios causing pulmonary hypoplasia.[3,4] In the term infant, PPHN is most commonly seen with conditions such as congenital diaphragmatic hernia (CDH), meconium aspiration syndrome (MAS), and transient tachypnea of the newborn (TTN). Mortality of *all* newborns with PPHN has been reported at 7.6% and 10.7% infants with severe PPHN.[2] Surviving infants with PPHN have increased risk of long-term morbidities, including ~25% neurodevelopmental impairment at 2 years.[5] PPHN is defined as the failure to achieve or sustain the normal decrease in pulmonary vascular resistance (PVR) at birth. PPHN can produce severe respiratory distress and hypoxemia secondary to severe pulmonary vascular disease remodeling (Fig. 47.1) in term and near-term infants. Chronic pulmonary hypertension is associated with lung diseases such as bronchopulmonary dysplasia (BPD) and CDH and is a common complication of congenital heart disease. This chapter will review the pathophysiology of PPHN, diagnosis and clinical treatment of newborns with severe PPHN disease, and outcome data.

Normal Fetal Pulmonary Vascular Development and Transition at Birth

During fetal life, placental vascular resistance is low and PVR is high. This state of physiologic pulmonary hypertension is needed to maintain the patterns of blood flow that support gas exchange by the placenta. In the human fetus, only 10% to 20% of the combined ventricular output is directed to the pulmonary vascular bed with most of the right ventricular output crossing the ductus arteriosus to the descending aorta. Throughout gestation both pulmonary artery pressure (PAP) and pulmonary blood flow progressively increase with the developing growth of the lung vasculature.[6] Despite the marked increase in cross-sectional area of the pulmonary vascular bed, high PVR is maintained and even increases during gestation when corrected for gestational age.[6] This persistent elevation in PVR throughout gestation is mediated by changes in fetal pulmonary vessel vasoregulation. Initially, the fetal pulmonary circulation is poorly responsive to diverse stimuli, but reactivity to vasoconstrictor and vasodilator agonists increases during late gestation.[7] This normal maturational change in vasoregulation leads to increased vascular tone and sustained elevations in PVR in late gestation.[9,10]

The elevated PVR throughout fetal life is maintained by many factors, such as mechanical compression of pulmonary blood vessels from fluid-filled alveoli, hypoxic pulmonary vasoconstriction, increased production of circulating *vasoconstrictors* (endothelin-1, thromboxane, and leukotrienes), low levels of *vasodilator* products (nitric oxide [NO] and prostacyclin [PgI_2]), and abnormal smooth muscle cell reactivity leading to enhanced myogenic tone.[10,11] The vasodilatory response to oxygen and acetylcholine emerges in late gestation.[12–14]

At birth, a rapid and dramatic decrease in PVR redirects half of the combined ventricular output to the lung and increases pulmonary blood flow by 8- to 10-fold. Increased pulmonary blood flow increases pulmonary venous return and left atrial pressure, promoting functional closure of the one-way valve of the

foramen ovale. Clamping of the umbilical cord removes the low-resistance placental circulation, thus increasing systemic vascular resistance (SVR). The largest drop in PVR and pulmonary arterial pressure (PAP) occurs shortly after birth, although both will continue to fall during the first few months of life until levels are similar to that of typical adult circulation pressure levels. As PVR falls below systemic levels, blood flow through the patent ductus arteriosus reverses. During the first several hours of life the ductus arteriosus functionally closes, largely in response to the increased oxygen tension of the newborn. This effectively separates the pulmonary and systemic circulations and establishes the normal postnatal circulatory pattern.

These normal transitional changes in the pulmonary vasculature are initiated by ventilation of the lung and an increase in oxygen tension at birth and are mediated by alterations in several vasoactive compounds prior to birth and immediately following delivery. The fetus prepares for the extra-uterine transition late in gestation by increasing pulmonary vascular expression of NO synthases and soluble guanylate cyclase (sGC) (Fig. 47.2). At the time of birth, pulmonary endothelial NO production increases

markedly, partly as a response to increased oxygen tension and shear stress. NO exerts its actions through sGC[15] to increase the levels of cyclic guanosine monophosphate (cGMP), a central mediator responsible for vascular relaxation. Phosphodiesterase 5 (PDE5) catalyzes the breakdown of cGMP and, similarly to sGC, exhibits peak expression and activity in the immediate newborn period.[16,17] The arachidonic acid–prostacyclin pathway also plays a significant role in the pulmonary vascular transition at birth (see Fig. 47.2). The enzyme cyclooxygenase acts on arachidonic acid to produce prostaglandin endoperoxides. Prostaglandins activate adenylate cyclase to increase cyclic adenosine monophosphate (cAMP) concentrations in vascular smooth muscle cells, which, similarly to increases in cGMP concentrations, leads to vasorelaxation. Phosphodiesterase 3A catalyzes the breakdown of cAMP.[12]

Pathophysiology

Infants who develop PPHN after birth display failure of the normal cardiopulmonary transition. The first reports of PPHN described term newborns with profound hypoxemia who lacked radiographic evidence of parenchymal lung disease and echocardiographic evidence of structural cardiac disease.[18,19] In these patients, refractory hypoxemia was caused by sustained elevations of PVR and low pulmonary blood flow leading to right-to-left extrapulmonary shunting of deoxygenated blood across the patent ductus arteriosus or patent foramen ovale. Because of the persistently elevated PVR and blood flow through these "fetal shunts," the term *persistent fetal circulation* was originally used to describe these findings.

PPHN physiology can complicate the clinical course of term or preterm neonates with many different causes of hypoxemic cardiopulmonary failure, such as meconium aspiration, sepsis, pneumonia, asphyxia, CDH, and respiratory distress syndrome. As a result, the term *persistent pulmonary hypertension of the newborn* now denotes a syndrome characterized by sustained elevation of PVR and hypoxemia due to right-to-left extrapulmonary shunting of blood flow across the ductus arteriosus or foramen ovale. Hypoxemic respiratory failure in term infants is often presumed to be secondary to PPHN physiology, however, many hypoxemic newborns lack echocardiographic findings of extrapulmonary shunting across the PDA or PFO. Thus, PPHN describes hypoxemic newborns with evidence of extrapulmonary shunting.

The clinical presentation of infants with PPHN includes labile hypoxemia and often includes the findings of a gradient in oxygen saturations between pre-ductal (right upper extremity) and post-ductal values greater than 10%.[20] The presence of a pre- and post-ductal oxygen saturation gradient over 10% suggests the presence of extrapulmonary right-to-left shunting at the ductus arteriosus. Infants with PPHN can have wide swings in arterial oxygen saturation levels, which is due to rapid changes in pulmonary blood flow and right-to-left shunting associated with acute changes in PVR in response to minimal stimulation. Physical exam findings are often subtle but may include a loud second heart sound and a systolic murmur of tricuspid regurgitation. A chest radiograph is often helpful to differentiate primary parenchymal lung disease (meconium aspiration syndrome [MAS] or respiratory distress syndrome [RDS]) from other non-pulmonary etiologies of PPHN. Typical radiographic findings in *idiopathic* PPHN include pulmonary vascular oligemia, normal or slight hyperinflation, and a lack parenchymal infiltrates. In primary PPHN, the degree of hypoxemia is disproportionate to the severity of radiographic findings of lung disease.

PPHN is associated with many diverse cardiopulmonary disorders (Table 47.1) with an incidence ranging from 0.4 to 6.8 per 1000 live births and 5.4 per 1000 live births in late preterm infants.[1,2] One year mortality of *all* newborns with PPHN has

PPHN, Persistent pulmonary hypertension of the newborn.

been reported at 7.6%, rising to 10.7% for infants with severe PPHN.[2] Surviving infants with PPHN are at increased risk of long-term morbidities, including ~25% neurodevelopmental impairment at 2 years.[5]

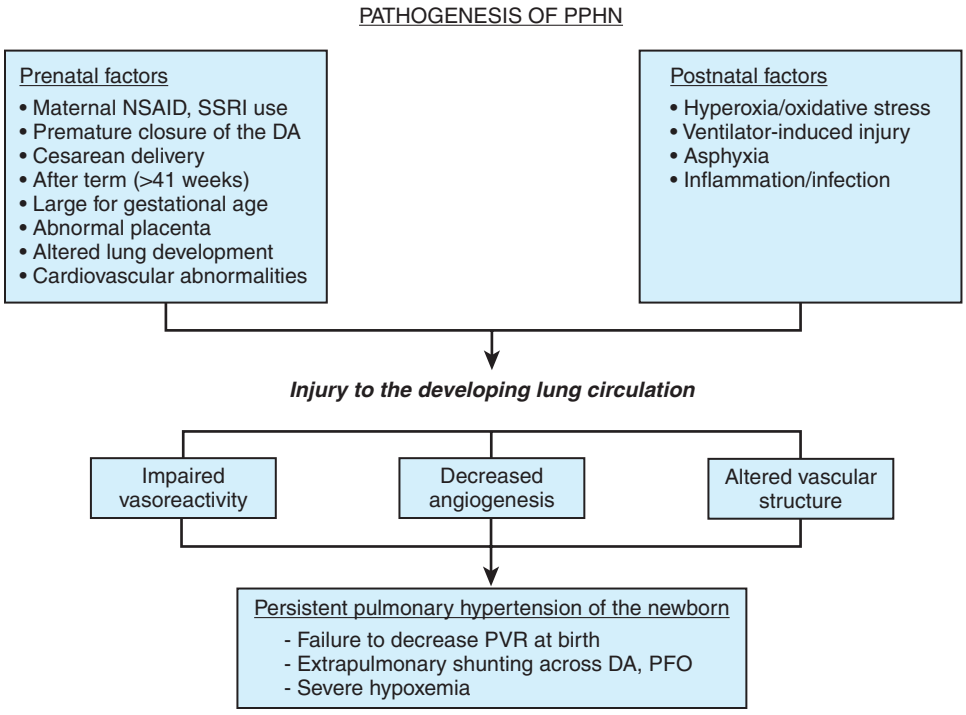
In 2019 the Pediatric Task Force of the World Symposium on Pulmonary Hypertension (WSPH) updated the WSPH Classification of pulmonary hypertension to differentiate PPHN as an important cause of pediatric PH.[21] Because of its specific anatomic and physiologic characteristics, PPHN was assigned a separate subcategory within WSPH Group 1, or pulmonary arterial hypertension, as Group 1.7. In Group 3 pulmonary hypertension (pulmonary hypertension due to lung disease or hypoxia), developmental lung diseases are specifically listed because of the important role that abnormal lung vascular growth plays in the pathogenesis of impaired lung development and pulmonary hypertension. CDH, BPD, and several other developmental lung disorders, such as surfactant protein deficiencies and alveolar capillary dysplasia (ACD), are now understood to be important causes of pulmonary hypertension in infants.

The etiology of PPHN is broad, but can generally be classified into one of three categories: *(1)* maladaptation: pulmonary vessels have normal structure and number but have abnormal vasoreactivity (respiratory distress syndrome [RDS], meconium aspiration syndrome [MAS], sepsis, or pneumonia); *(2)* excessive muscularization: increased smooth muscle cell thickness and abnormal distal extension of muscle into vessels that are usually not muscularized (chronic fetal hypoxia, idiopathic PPHN); and *(3)* underdevelopment: lung tissue hypoplasia associated with decreased pulmonary artery number (congenital diaphragmatic hernia [CDH], oligohydramnios) (see Table 47.1). There are many disorders associated with PPHN in the newborn period (see Table 47.1). Idiopathic PPHN is the least common, occurring in about 10% of cases. More commonly, PPHN is usually associated with an acute respiratory condition, such as meconium aspiration syndrome, respiratory distress syndrome, or pneumonia, and is referred to as *secondary PPHN*. This designation is imprecise, however, as many patients often have elevated PVR that involves overlapping categories. For example, infants with CDH-related PPHN may be due not only to underdevelopment of the pulmonary vasculature, but also to abnormal maladaptation and vasoreactivity, events that often culminate in chronic pulmonary vascular disease. Similarly, in infants with PPHN secondary to MAS the pulmonary vasculature can exhibit excessive muscularization of vessels in addition to abnormal vasoreactivity. In many cases it can be more difficult to separate chronic intrauterine remodeling from acute pulmonary vasoconstriction due to parenchymal lung disease.

Risk Factors

Based on the significant remodeling found in lethal cases of PPHN, intrauterine events have been presumed to affect pulmonary vascular growth, reactivity, and structure (see Fig. 47.1).[22] Pulmonary vascular development *in utero* can be disrupted by environmental, placental, toxic, or other influences (Fig. 47.3). Case-control surveillance studies indicate that maternal risk factors of black or Asian maternal race, elevated body mass index (>27 kg/m^2), diabetes, and asthma predict a higher risk of PPHN. Neonatal risk factors include male sex, large for gestational age infants, birth by cesarean delivery, and delivery before 37 weeks' gestation or after 41 weeks' gestation.[23]

Recent animal and epidemiologic studies also suggest that maternal exposures can alter fetal pulmonary vascular development and function. There are strong associations between PPHN and maternal smoking, and two classes of maternal medications, nonsteroidal anti-inflammatory drugs and selective serotonin receptor inhibitors, have also been implicated.[24] Exposure to nonsteroidal anti-inflammatory drugs such as aspirin or ibuprofen during the third trimester can cause constriction of the fetal



• **Fig. 47.3** Pathogenesis of persistent pulmonary hypertension of the newborn *(PPHN)*. *DA*, Ductus arteriosus; *NSAID*, nonsteroidal antiinflammatory drug; *PFO*, patent foramen ovale; *PVR*, pulmonary vascular resistance; *SSRI*, selective serotonin receptor inhibitor.

ductus arteriosus, which in turn can trigger pulmonary vascular remodeling and PPHN. Based on the findings of a recent epidemiologic study, the relationship is complex and may be dependent on the specific agent and the timing of exposure,[25] however aspirin use during late pregnancy remains a consistent risk factor for PPHN. Use of selective serotonin receptor inhibitors during the last half of pregnancy has been associated with an increased incidence of PPHN in several population studies, although the severity of PPHN has not been well described, and other studies have not found this association.[26–28] Maternal depression is a risk factor for adverse pregnancy outcomes, as such maternal physical and psychologic well-being remain the primary factors guiding antidepressant therapy during pregnancy and the postpartum period.

Several postnatal events can disrupt the perinatal transition and contribute to the pathogenesis of PPHN (see Fig. 47.3). Birth by elective cesarean delivery delays the decrease in pulmonary arterial pressure and increases the risk of PPHN,[29] and delivery before 39 weeks' gestation likely amplifies this effect. When compared with matched controls, infants with PPHN are more likely to have been born by cesarean delivery, born to diabetic mothers, mothers of advanced maternal age, mothers of Black race, or mothers with asthma or a high body mass index—in addition to being born before 37 weeks' gestation.[2,23,30] Perinatal asphyxia with resultant fetal hypoxemia, ischemia, acidosis, and cardiac ventricular dysfunction prevents the necessary perinatal adaptation, delays the normal decrease in PVR, and increases the risk of PPHN.[31] Acute perinatal asphyxia is associated with reversible pulmonary vasoconstriction, while chronic *in utero* asphyxia can induce vascular remodeling that is less responsive to acute vasodilation.[32]

The adoption of therapeutic hypothermia for management of neonatal encephalopathy in the term and near-term infant has led to concern that this therapy would increase risk of PPHN in asphyxiated infants. Deep levels of hypothermia (30°C to 32°C) have been shown to increase mean pulmonary arterial pressure in neonatal lambs[33] and have been associated with increased use of extracorporeal membrane oxygenation (ECMO) and inhaled nitric oxide (iNO) in human studies.[34] Furthermore, hypothermia shifts the oxygen dissociation curve to the left and decreases PaO_2 at a given peripheral capillary oxygen saturation (SpO_2). However, pooled analysis of randomized trials of standard therapeutic hypothermia (33.5°C) has not shown an increased incidence of PPHN (25% vs 20%) in treated infants.[35,36]

Patients with severe hypoxemia who are not responding as expected to conventional therapies should be evaluated for developmental lung diseases associated with refractory PPHN. Children with Down syndrome (trisomy 21) commonly develop pulmonary hypertension in association with structural heart defects but also have a 10-fold increased risk of idiopathic PPHN. In a Dutch cohort, PPHN was documented in 5.2% of Down syndrome infants,[37] and other studies have shown that Down syndrome infants are overrepresented in neonates requiring ECMO support.[38] Polymorphisms of genes for bone morphogenetic protein receptor or other transforming growth factor β receptors, other critical growth factors, or vasoactive enzymes (e.g., NO synthase, phosphodiesterase) have not been shown to increase the risk of neonatal PPHN. Additional systematic evaluation for genetic etiologies of refractory or prolonged PPHN should include: inherited surfactant dysfunction disorders, such as SP-B/C or ATP-binding cassette A3 gene (ABCA3) deficiency[39,40]; genetic disruption of distal lung development, such as TTF-1 and Nkx 2.1; FOXF1 mutations leading to alveolar capillary dysplasia (ACD),[41] T-Box transcription factor 4 gene (TBX4)[42]; genetic variants in corticotropin releasing hormone (CRH) receptor 1 and CRH-binding protein[43]; and inborn errors of metabolism, such as methylmalonic acidemia. Genotype analysis of neonates with PPHN have also identified polymorphisms in carbamoylphosphate synthase, a key urea cycle enzyme that maintains substrate availability for endogenous nitric oxide production[44,45] and genetic variants for cortisol signaling (*CRHR1* and *CRHBP*), as well as increased levels of 17-hydroxyprogesterone.[43]

Abnormal Pulmonary Vasoregulation in PPHN

Disruptions of the NO–cGMP, prostacyclin–cAMP, and endothelin signaling pathways play an important role in the vascular abnormalities associated with PPHN. The NO–cGMP pathway has been a topic of particularly intense investigation in the last two decades. Decreased expression and activity of endothelial nitric oxide synthase (eNOS) has been documented in lamb models of chronic intrauterine pulmonary hypertension,[46,47] and decreased eNOS expression has been found in umbilical venous endothelial cell cultures from human infants with meconium staining who developed PPHN.[48] These important findings were rapidly followed by clinical testing of iNO, leading to its adoption as the primary vasodilator therapy for PPHN. However, numerous other signaling abnormalities limit the effect of endogenous or exogenous NO. In PPHN, expression and activity of soluble guanylate cyclase is decreased, and cGMP phosphodiesterase activity is increased, leading to lower cGMP levels and limitations of NO-induced vasodilation. Oxidant stress associated with vascular dysfunction and/or exposure to hyperoxia can oxidize and reduce soluble guanylate cyclase activity and increase cGMP phosphodiesterase activity, accentuating these vascular abnormalities.

Prostacyclin is important in the normal pulmonary vascular transition, although less is known about abnormal prostacyclin–cAMP signaling in PPHN. Data from animal models suggest reductions in prostacyclin synthesis and downstream adenylate cyclase responses, analogous to the abnormalities reported for NO–cGMP signaling.[49,50] In addition, production of thromboxane, a vasoconstrictor arachidonic acid metabolite, plays a role in pulmonary hypertension produced by chronic hypoxia.[51] Elevated levels of circulating endothelin 1 (ET-1), a potent vasoconstrictor, have been demonstrated in lambs and newborns with PPHN.[52,53] Endothelin effects are mediated through two receptors: ET_A receptors on smooth muscle cells that mediate vasoconstriction and ET_B receptors on endothelial cells that mediate vasodilation. In PPHN, the balance of endothelin receptors is shifted to the vasoconstrictor (ET_A) pathways.[54] Endothelin may also affect vascular tone by increasing production of vasoconstrictor reactive oxygen species such as superoxide and hydrogen peroxide[55] and by decreasing expression and activity of peroxisome proliferator–activated receptor γ, which maintains the vasodilatory balance in the fetal lung.

Disorders Associated With Pulmonary Hypertension at Birth

Congenital Diaphragmatic Hernia

Worldwide, CDH affects approximately 2.3 in every 10,000 live births.[56,57] CDH includes abnormal diaphragm development, herniation of abdominal viscera into the chest, and a variable degree

of lung hypoplasia. Herniation occurs most often in the posterolateral segments of the diaphragm, and 80% of the defects occur on the left side. Severe CDH develops early in lung development and involves an arrest in the normal patterns of airway branching in both lungs, resulting in reduced lung volume and impaired alveolarization. Abnormal distal vascular and air space growth is likely because of the loss of stretch-induced stimulation of lung development from impaired fetal breathing movements due to disruption of the diaphragm. The pulmonary vascular findings include vascular remodeling superimposed on hypoplasia or pruning of the pulmonary vascular bed, producing increased vascular tone and altered vasoreactivity after birth.[58]

After birth, PVR often remains at suprasystemic levels, resulting in pulmonary hypertension, extrapulmonary right-to-left shunting across the foramen ovale and ductus arteriosus, and profound hypoxemia. High PVR in the newborn with CDH is related to multiple factors, including the small cross-sectional area of pulmonary arteries, structural vascular remodeling, and vasoconstriction with altered reactivity. The mediators of altered pulmonary vascular reactivity in CDH remain under investigation, with substantial evidence pointing to disruptions in NO–cGMP and ET-1 signaling.[59] The level of vascular endothelial growth factor, a key stimulator of angiogenesis, is increased in the lungs of infants with CDH who died; this has been interpreted as a compensatory mechanism for reduced eNOS expression and NO production.[58] In some infants, chronic pulmonary hypertension will persist for months or years, including structural and functional abnormalities of pulmonary circulation in the ipsilateral and contralateral lung. Cardiac catheterization of infants with prolonged pulmonary hypertension has revealed numerous vascular abnormalities, including left pulmonary artery hypoplasia or stenosis, pulmonary vein stenosis, and delayed venous return.[60]

In addition to pulmonary vascular disease, it is important to appreciate that structural and functional abnormalities of the left ventricle create a relative left ventricular hypoplasia that impairs filling and creates pulmonary venous hypertension. Often, newborns with severe CDH have severe pulmonary hypertension with right-to-left shunting at the ductus arteriosus but have left-to-right shunting at the atrial septum because of high left atrial pressure from left ventricular dysfunction.[61] This circulatory pattern will diminish the clinical response to iNO during the first few days after birth and produce significant pulmonary and systemic hemodynamic instability. Some infants may have exceptionally severe left ventricular dysfunction that leads to dependence on the right ventricle for systemic perfusion; this subset of patients may benefit from a management approach that maintains patency of the ductus arteriosus, reduces left ventricular afterload, and delays the use of iNO until left ventricular performance improves.[62,63] In addition to its role in the acute setting, left ventricular dysfunction can contribute to the severity of pulmonary hypertension during the late and chronic courses in infants with CDH.

Alveolar Capillary Dysplasia

Unlike pediatric and adult pulmonary hypertension, few genetic factors have been identified for PPHN. A notable exception is alveolar capillary dysplasia with misalignment of lung vessels, a rare but universally lethal cause of pulmonary hypertension in the newborn.[64] Shortly after birth, affected infants typically exhibit cyanosis, minimal parenchymal disease, and respiratory distress refractory to all known therapies, including extracorporeal support, although later presentations (at several weeks or months of age) have been recognized. More than 50% of infants exhibit other anomalies, most commonly affecting the genitourinary, cardiovascular, and gastrointestinal systems. The diagnosis is established by direct examination of lung tissue by lung biopsy or autopsy. Characteristic findings include simplification of lung architecture, widened and poorly cellular septa with a paucity of capillaries, and strikingly muscularized small arterioles. "Misaligned pulmonary veins" have been described within the same adventitial sheath as pulmonary arteries; these were recently identified to be congested bronchial veins that represent intrapulmonary vascular anastomoses creating right-to-left intrapulmonary shunts and profound refractory hypoxemia.[65] Approximately 10% of reported alveolar capillary dysplasia cases have a familial association, and mutations or deletions in the transcription factor forkhead box F1 gene (*FOXF1*) or deletions upstream of *FOXF1* are identified in 40% of infants with alveolar capillary dysplasia.[41] A murine model of forkhead box F1 deficiency has been studied, which demonstrates the importance of the forkhead box F1 in embryonic development of the pulmonary vasculature.[66]

Pulmonary Hypertension in Premature Infants

Birth at 23 to 26 weeks' gestational age is associated with high rates of PPHN,[3] usually secondary to hypoxemic respiratory failure related to significant lung pathology soon after birth such as RDS, PPROM, or oligohydramnios causing pulmonary hypoplasia. Moreover, data from the Neonatal Research Network of Japan suggest that the incidence of PPHN in extremely preterm infants is increasing. In 2003 they reported 54 cases which increased to 147 cases in 2012, with the annual increase seen mostly in infants born at 22 to 24 weeks' gestation.[67] In a large prospective study, echocardiographic findings suggestive of pulmonary hypertension, such as ventricular septal wall flattening and right ventricular dilation, were found in approximately 40% of extremely low-birth-weight-babies at 7 days of age and predicted bronchopulmonary dysplasia (BPD) and late pulmonary hypertension.[68] The off-label use of iNO in premature infants has increased dramatically in the past two decades, with the greatest increased use among infants born extremely preterm (23 to 26 weeks' gestation).[69] Observational studies have shown a favorable response to iNO therapy in preterm infants born after extreme preterm premature rupture of membranes (PPROM) and resultant oligohydramnios.[3,70]

BPD has emerged as an important cause of chronic pulmonary hypertension, with an incidence of 16% to 25% in infants with BPD.[68] Severe or prolonged pulmonary hypertension increases the risk of late morbidity, ICU readmission, and death to nearly 50%.[71] The pathogenesis of pulmonary hypertension associated with BPD involves complex interactions between prenatal factors, such as growth restriction, preeclampsia, oligohydramnios, or fetal inflammation, and postnatal injury due to ventilator-induced lung injury, hyperoxia, hemodynamic stress, and infection. The result is impaired angiogenesis, abnormal vascular signaling, and vascular pruning, resulting in a reduction in the alveolar–capillary surface area. Identifying pulmonary hypertension in infants with BPD requires a high index of suspicion and systematic longitudinal evaluation. Echocardiography remains the most practical screening tool and should be considered in infants who continue to have cyanotic spells or require oxygen supplementation at 36 weeks' corrected gestational age.

In infants with evidence of significant pulmonary hypertension by echocardiogram, cardiac catheterization may provide a more accurate quantification of the severity of disease, as well as allow vasoreactivity testing.[72]

Clinical Evaluation and Diagnosis

PPHN typically presents as respiratory distress and cyanosis within hours of birth and may be associated with a variety of lung and/or cardiac disorders (see Table 47.1). Clinically, PPHN is most often recognized in the term or near-term neonate but should also be considered in premature neonates who have cyanosis out of proportion to their parenchymal lung disease.[73] While PPHN is often associated with signs of perinatal distress, such as asphyxia, low Apgar scores, or meconium staining, idiopathic PPHN can present without signs of acute perinatal distress.

PPHN is characterized by labile hypoxemia that is poorly responsive to supplemental oxygen. An important goal for the initial clinical evaluation is to rule out cyanotic cardiac disease and to determine whether a hypoxemic infant has PPHN-type physiology. Because a patent foramen ovale and ductus arteriosus are normally present early in life, elevated PVR in the newborn will produce extrapulmonary shunting of blood through these fetal channels, leading to severe and potentially unresponsive hypoxemia. In the presence of right-to-left shunting across the patent ductus arteriosus, "differential cyanosis" is often present, which is difficult to observe by physical examination but may be detected by a gradient in PaO_2 and/or oxygen saturation between the right radial artery versus descending aorta sites.[20] Considering that the left subclavian artery may have either a preductal or a postductal origin from the aorta, the oximeter probe should be applied to a foot for postductal pulse oximetry monitoring. Saturation differences greater than 5% to 10% generally indicate the presence of PPHN, but it is important to remember that a similar pattern of postductal desaturation may be observed in ductus-dependent cardiac diseases, including hypoplastic left-sided heart syndrome, coarctation of the aorta, or interrupted aortic arch.

Not all newborns with hypoxemia have PPHN physiology. In many infants, an intrapulmonary shunt or ventilation–perfusion mismatch resulting from parenchymal lung disease is the predominant abnormality rather than shunting of blood flow across the patent ductus arteriosus and patent foramen ovale. In this setting, hypoxemia is the result of pulmonary arterial blood perfusing the nonaerated lung regions. Although PVR is often elevated in hypoxemic newborns without PPHN, high PVR does not contribute significantly to hypoxemia in these cases. Rapid improvement in response to supplemental oxygen or increased mean airway pressure suggests ventilation–perfusion mismatch due to primary lung disease, although this may not be obvious with severe parenchymal lung disease. Furthermore, most infants with PPHN have at least a transient improvement in oxygenation in response to interventions such as high inspired oxygen concentration therapy and/or mechanical ventilation. Therefore these clinical findings can only suggest and not confirm the diagnosis. At present, there is no single biochemical marker that has emerged with sufficient sensitivity and specificity for the diagnosis and management of PPHN.

Radiographic findings are variable, depending on the primary disease associated with PPHN. Classically, the lung on a chest x-ray in idiopathic PPHN is oligemic, normally or slightly hyperinflated, and lacks parenchymal infiltrates. In general, the degree of hypoxemia is disproportionate to the severity of radiographic evidence of lung disease. Laboratory findings may include hypoglycemia, hypocalcemia, polycythemia, and thrombocytopenia.

Echocardiography is the gold standard to confirm the diagnosis and is an important tool for monitoring the response to therapy. The initial echocardiographic evaluation rules out structural heart disease causing hypoxemia or ductal shunting (e.g., coarctation of the aorta or total anomalous pulmonary venous return), determines the predominant direction of shunting at the patent foramen ovale and patent ductus arteriosus, and assesses ventricular function. The diagnosis of PPHN is made with certainty if bidirectional or predominantly right-to-left shunting across the foramen ovale or ductus arteriosus is observed, although other signs such as flattening or left deviation of the intraventricular velocity, tricuspid regurgitant velocity, and increased right ventricular dilation also suggest the diagnosis. The echocardiogram is also critical for the evaluation of right and left ventricular function. In some infants, predominant right-to-left shunting at the ductus arteriosus associated with left-to-right shunt at the foramen ovale is observed, indicating a significant contribution of left ventricular dysfunction to the underlying pathophysiology. When severe left ventricular dysfunction accompanies pulmonary hypertension, pulmonary vasodilation alone may be ineffective in improving oxygenation and must be accompanied by targeted therapies to increase cardiac performance and decrease left ventricular afterload. Thus careful echocardiographic assessment provides invaluable information about the underlying pathophysiology and will help guide the course of treatment.

Traditional echocardiographic evaluations of the right ventricle (RV) in infants with PPHN focus on the tricuspid regurgitation jet (TRJV) and the PDA shunt direction. However, cardiac function can be significantly decreased in infants with PPHN secondary to persistent RV afterload or prolonged hypoxemia.[74] Thus, while TRJV can be elevated in infants with PPHN, it is not reliably measurable and its absence does not consistently correlate with clinical outcomes.[75,76] Malowitz and colleagues have also demonstrated that echocardiography measurements of tricuspid annular plane systolic excursion (TAPSE) and right ventricle global longitudinal peak strain (GLPS) in addition to a predominant right-to-left shunt across the PDA to be more predictive of progression to death or ECMO in infants with PPHN.[75]

General Management

In 2015, the American Heart Association and the American Thoracic Society published guidelines for management of pediatric pulmonary hypertension, including PPHN (Box 47.1).[63] The general management principles for PPHN include maintenance of normal temperature (except for those undergoing therapeutic hypothermia), electrolytes (particularly calcium), glucose, hemoglobin, and intravascular volume. Mechanical ventilation is usually required to optimize lung volumes, although few guidelines exist to standardize ventilator management. Some advocate a "gentle ventilation" approach, with avoidance of paralysis and blood gas goals consisting of PaO_2 of 50 to 70 mmHg and $PaCO_2$ of 40 to 60 mmHg. This strategy has never been rigorously tested[77] but may well be the optimal strategy for infants still in the early phases of disease. When significant parenchymal lung disease is present, lung recruitment strategies, such as high-frequency ventilation, improve lung expansion and amplify the response to iNO.[78,79] However, care should be taken to avoid settings that may cause lung overdistension, which can lead to inflammatory

• BOX 47.1 American Heart Association and American Thoracic Society Management Guidelines for Persistent Pulmonary Hypertension of the Newborn

1. Inhaled nitric oxide therapy is indicated to reduce the need for extracorporeal membrane oxygenation (ECMO) support in term and near-term infants with persistent pulmonary hypertension of the newborn (PPHN) or hypoxemic respiratory failure who have an oxygenation index that exceeds 25 (class I, level A).
2. Lung recruitment strategies can improve the efficacy of inhaled nitric oxide therapy and should be applied in patients with PPHN associated with parenchymal lung disease (class 1, level B).
3. ECMO support is indicated for term and near-term neonates with severe pulmonary hypertension and/or hypoxemia that is refractory to inhaled nitric oxide therapy and optimization of respiratory and cardiac function (class I, level A).
4. Evaluation for disorders of lung development, such as alveolar capillary dysplasia and genetic surfactant protein diseases, is reasonable for infants with severe PPHN whose condition fails to improve after vasodilator, lung recruitment, and/or ECMO therapy (class IIa, level B).
5. Sildenafil use is a reasonable adjunctive therapy for infants with PPHN who are refractory to inhaled nitric oxide therapy, especially with an oxygenation index that exceeds 25 (class IIa, level B).
6. Inhaled prostacyclin analogues may be considered as adjunctive therapy for infants with PPHN who are refractory to inhaled nitric oxide therapy and have an oxygenation index that exceeds 25 (class IIb, level B).
7. Intravenous administration of milrinone is reasonable therapy for infants with PPHN and signs of left ventricular dysfunction (class IIa, level B).
8. Inhaled nitric oxide can be beneficial for preterm infants with severe hypoxemia that is primarily due to PPHN physiology rather than parenchymal lung disease (class IIa, level B).
9. Inhaled nitric oxide therapy and other pulmonary arterial hypertension–targeted drug therapies should be used cautiously in individuals with congenital diaphragmatic hernia, especially in those with confirmed or suspected left ventricular dysfunction (class IIa, level B).

From Abman SH, Hansmann G, Archer SL, et al. Pediatric pulmonary hypertension: guidelines from the American Heart Association and American Thoracic Society. *Circulation*. 2015;132(21):2037–2099.

changes, pulmonary edema, and decreased lung compliance, all of which can exacerbate pulmonary hypertension.

The use of surfactant should be considered only for infants with parenchymal lung disease. Single-center trials have shown that surfactant improves oxygenation, reduces air leak, and reduces the need for ECMO in infants with meconium aspiration.[80] A multicenter trial showed benefit in infants with parenchymal lung diseases such as meconium aspiration syndrome and sepsis.[81] This trial also demonstrated the greatest benefit for infants with earlier or milder disease (oxygenation index 15 to 22) but no benefit in the subset of newborns with idiopathic PPHN. A recent systematic review and metanalyses of surfactant therapy for neonates with meconium aspiration syndrome showed that those who received bolus surfactant needed ECMO less often than controls. However, the limited number of studies and neonates enrolled led the authors to conclude that more studies are urgently needed to evaluate the efficacy and cost-effectiveness of this therapy.[82] A retrospective study of infants in the CDH study group registry suggested that surfactant therapy for infants with CDH who were on ECMO did not increase survival or decrease the length of ECMO, length of intubation, or subsequent need for supplemental oxygen.[83]

Acidosis is a pulmonary vasoconstrictor, particularly when combined with hypoxia,[84] and pH should be maintained above 7.30. However, alkalosis (pH > 7.45) is not recommended. The use of alkalosis was frequent before the approval of iNO therapy, based on studies that found transient increases in PaO_2 after acute hyperventilation.[85] However, the pulmonary vascular response to alkalosis is transient, and prolonged alkalosis may paradoxically worsen pulmonary vascular tone, reactivity, and permeability edema.[86] Furthermore, alkalosis produces cerebral vasoconstriction, reducing cerebral blood flow and oxygen delivery to the brain, and may be associated with worse neurodevelopmental outcomes.[87] Similarly, there is no evidence to suggest that the use of sodium bicarbonate infusions to induce alkalosis provides any short-term or long-term benefit.[1]

Systemic hemodynamics should be optimized, with use of intravascular volume to provide sufficient preload and cardiotonic therapy to enhance cardiac output and systemic O_2 transport. Systemic hypotension may worsen right-to-left shunting, impair oxygen delivery, and worsen gas exchange in patients with parenchymal lung disease. In addition, high right ventricular systolic pressure reduces systolic flow through the right coronary artery, and low systemic blood pressure leads to a decline in right coronary artery diastolic flow, so correction of both hemodynamic abnormalities is key to avoiding right ventricular ischemia.[88] However, the goal is more complex than simply increasing blood pressure, and careful attention should be paid to right and left ventricular function and the choice of medication. Frontline agents typically include dopamine (5 to 20 μg/kg/min) and milrinone (0.2 to 0.99 μg/kg/min). Milrinone, which inhibits cAMP phosphodiesterase 3 (PDE3) activity in cardiomyocytes and pulmonary and systemic arterial smooth muscle, is viewed as an "inodilator" that may be especially useful in the context of left ventricular dysfunction and pulmonary venous hypertension.[89] Anecdotal evidence also supports the use of arginine vasopressin for severe PPHN (Table 47.2), based on its ability to raise systemic pressure via V_1 receptors, and to reduce pulmonary arterial pressure via activation of NO synthase.[90]

Infants who fail to respond to medical treatment, as evidenced by failure to sustain improvement in oxygenation with good hemodynamic function, may require treatment with ECMO. ECMO is the only proven lifesaving rescue modality for severe PPHN, although it is also costly, labor-intensive, and associated with potential adverse effects, such as intracranial hemorrhage and ligation of the right common carotid artery. The oxygenation index (calculated as [mean airway pressure × FIO_2 × 100]/PaO_2) is used to gauge the severity of disease, with an oxygenation index greater than 40 used as an indication for transfer to an ECMO center. Even with all available therapies, the mortality for PPHN remains between 5% and 10%.[2]

Oxygen

Supplemental oxygen is a mainstay of PPHN therapy to maintain oxygen delivery to the brain and other tissues and for its pulmonary vasodilator properties. Alveolar hypoxia and hypoxemia should be avoided, as both are pulmonary vasoconstrictors and contribute to the pathophysiology of PPHN. However, the degree of hyperoxic ventilation needed for optimal pulmonary vasodilation remains under investigation. The use of oxygen concentrations greater than 60% has not been shown to provide any additional benefit in pulmonary vasodilation, and hyperoxic ventilation increases oxidant stress and lung injury which may paradoxically impair the

TABLE 47.2 Pharmacologic Management of Persistent Pulmonary Hypertension of the Newborn

Drug	Dose	Mechanism of Action	Adverse Reactions/Safety Monitoring	Indications
Inhaled nitric oxide	5–20 ppm	Activates soluble guanylate cyclase in vascular smooth muscle cells Selective pulmonary vasodilator Low doses (<10 ppm) enhance ventilation–perfusion matching with parenchymal lung disease ("microselective effects")	Rebound PH with rapid discontinuation of inhaled nitric oxide therapy Methemoglobinemia with higher doses	Hypoxemic respiratory failure with PPHN
Sildenafil (Revatio)	Intravenous: loading dose: 0.4 mg/kg in 3 h Maintenance dose 1.6 mg/kg/day	Selective PDE5 inhibitor that increases vascular cGMP levels and pulmonary vascular relaxation	Hypotension (particularly with rapid loading dose) Hypoxemia	PPHN refractory to inhaled nitric oxide therapy and other conventional therapies
Milrinone	Intravenous: loading dose: 0.75 μg/kg/min for 3 h (for infants with hypotension or severe illness, may choose to not use loading dose) Maintenance dose: 0.2–0.33 μg/kg/min. Increasing by 0.33 μg/kg/min to a maximum of 0.99 μg/kg/min	PDE3 inhibitor that increases cAMP levels Improves cardiac performance through reduced systemic afterload, enhanced contractility, and pulmonary vasodilation	Hypotension, thrombocytopenia, arrhythmias	Left ventricular dysfunction, poor cardiac output
Prostacyclin	Flolan: Inhaled: 20–100 ng/kg/min. Start at 2 ng/kg/min and increase to 20 ng/kg/min within 3 h Continuous intravenous infusion: starting dose: 1-2 ng/kg/min, incremental increases as tolerated, monitor newborn for tachyphylaxis Remodulin: Continuous infusion: 1.25 ng/kg/min to start, titrate up slowly to 10 ng/kg/min Can be delivered subcutaneously in the same dosing range	Activates adenylate cyclase in vascular smooth muscle cells Pulmonary vasodilator	Ventilation–perfusion mismatch may complicate use in the setting of lung disease Nonselective vasodilator, can cause systemic hypotension Risk of rebound PH with sudden withdrawal Flushing, diarrhea	PPHN refractory to iNO therapy and other conventional therapies
Bosentan	Enteral: 1–2 mg/kg every 12 h	Dual ET_A and ET_B receptor inhibitor	Hepatotoxicity, edema, anemia, teratogen Monitor monthly LFT results	PPHN refractory to iNO and other conventional therapies Generally used for chronic PH (CDH, BPD)
Vasopressin	0.0003–0.004 units/kg/min	Predominantly used for enhancement of systemic hemodynamics in severe PPHN May have pulmonary vasodilator effects via activation of eNOS	Hypotension, arrhythmias Hyponatremia: increases cAMP level in distal tubules, leading to decreased urine volume	Systemic hypotension refractory to catecholamines?

vasodilator response to iNO. Therefore the oxygen concentration and PaO_2 should be titrated to maximize pulmonary vasodilation. Studies in newborn lambs suggest that the lowest PVR can be maintained with a preductal SpO_2 in the 91% to 97% range with preductal PaO_2 between 60 and 80 mmHg,[91,92] although randomized studies have not been performed in infants with PPHN. Overall, oxygen should be used like any other drug in the therapeutic context, considering its potential benefits and side effects.

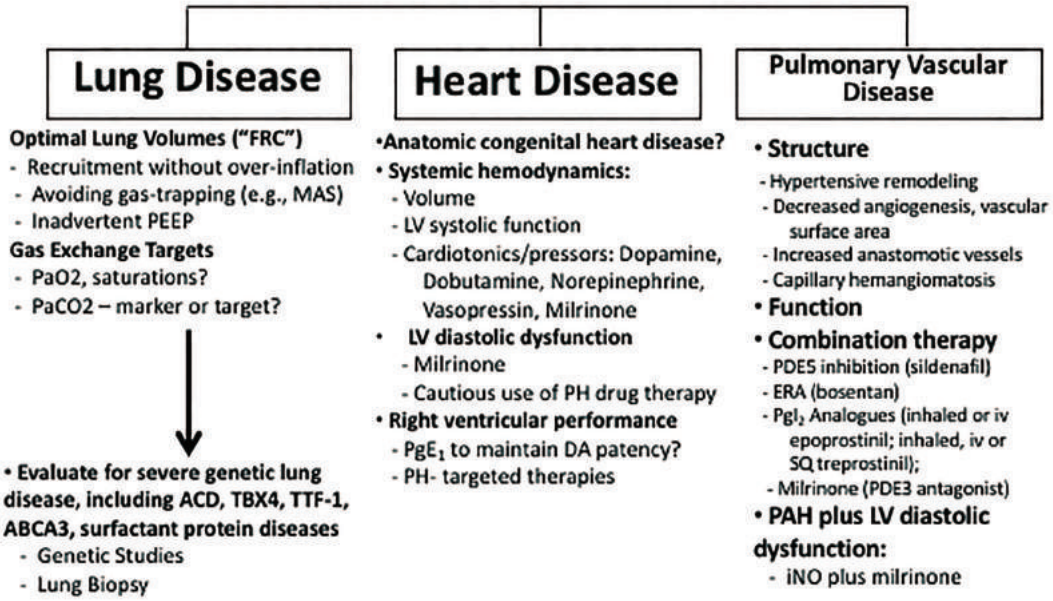
Inhaled Nitric Oxide

The primary goal of PPHN therapy is selective pulmonary vasodilation. Inhaled NO (iNO) is the only United States Food and Drug Administration (FDA) approved specific pulmonary vasodilator therapy for late preterm and term infants with PPHN, based on extensive safety and efficacy data from large placebo-controlled trials.[63] Endogenous NO is produced by endothelial cells and causes pulmonary vasodilation through the generation of cGMP. Studies have shown that inhaled NO diffuses from the alveolus into the smooth muscle cells and leads to selective pulmonary vasodilation. It is inactivated by hemoglobin in the circulation and hence has minimal systemic vasodilator effect.[79,93] Inhaled NO is a rapid and potent pulmonary vasodilator and because NO is a small gas molecule, it can be delivered as inhalation therapy to air spaces approximating the pulmonary vascular bed causing decreased intrapulmonary right-to-left shunting and improved V/Q matching.

Inhaled NO immediately improves oxygenation and decreases the need for ECMO support in newborns with PPHN who have an oxygenation index greater than 25.[94] The appropriate starting dose is 20 ppm; higher doses in nonresponders did not improve immediate responses or outcomes,[94] and treatment with high NO doses (80 ppm) increases the risk of methemoglobinemia.[95] The reported incidence of high levels of methemoglobinemia is very low with the use of an iNO dose less than 40 ppm[78,96,97] and data from a retrospective study of term and preterm infants indicated that high levels of methemoglobinemia (>2.5%) were observed in infants requiring FiO_2 greater than 60% at the time of methemoglobinemia measurement.[98] Similarly, to term infants, preterm infants with early PPHN, particularly after prolonged preterm rupture of membranes or oligohydramnios, will show marked improvement in oxygenation after treatment with iNO.[73] Recent reports indicate that iNO use ranges from 4% to 8% in extremely preterm infants.[99]

The optimal window for introduction of iNO therapy remains uncertain. The initial randomized trials studied term and near-term infants with severe PPHN and an oxygenation index of 25 to 40.[94,96] A subsequent large trial tested earlier use of iNO in infants with moderate respiratory failure (median oxygenation index of approximately 20) but did not report reductions in ECMO use/death relative to controls[5,100] (16.7% vs 19.5%). Once an infant has stabilized, weaning can generally be accomplished in 4 to 5 days. Prolonged need for iNO therapy without resolution of disease should lead to a more extensive evaluation to determine whether other underlying anatomic lung or cardiovascular disease is present, such as pulmonary venous stenosis, alveolar capillary dysplasia, and severe lung hypoplasia.

The response to iNO is both therapeutic and diagnostic (Fig. 47.4). Up to 40% of infants will not respond or sustain a response to iNO. Failure to respond to iNO is most commonly associated with inadequate lung recruitment. Thus, lung recruitment optimization with the use of PEEP to achieve and maintain functional residual capacity (FRC) (approximately 8 to 9 posterior rib expansion on anteroposterior chest x-ray) often ensures adequate lung recruitment and improves iNO responsiveness. Under- or over-inflation of the lung can increase PVR secondary to the mechanical compressional effects on the extra-alveolar and intra-alveolar pulmonary blood vessels. Atelectasis, under-inflation, increases intrapulmonary right-to-left shunting from inadequate ventilation and oxygenation leading to worsening hypoxia and hypercarbia. Lung over-inflation can impede venous return and cause systemic hypotension. In the true non-responders despite optimal lung recruitment, the clinician should carefully analyze the relative roles of parenchymal lung disease, pulmonary vascular disease, and cardiac dysfunction for each infant. For instance, if severe air space disease is associated with PPHN, strategies such as high-frequency ventilation that optimize lung expansion are likely to be effective, and the two therapies used together are more effective than either used



• **Fig. 47.4** An integrative approach to persistent pulmonary hypertension of the newborn *(PPHN)* newborns with poor responsiveness to iNO therapy. *FRC*, Functional reserve capacity; *MAS*, meconium aspiration syndrome; *LV*, left ventricle; *PH*, pulmonary hypertension; *PAH*, pulmonary arterial hypertension.

individually.[78] Considering iNO is usually delivered with high concentrations of oxygen, these therapies could interact and lead to enhanced production of reactive oxygen and reactive nitrogen metabolites, both of which may contribute to vasoconstriction and/or inadequate responses to iNO.

Other Therapeutic Agents

Phosphodiesterase Inhibitors

Increased activity of PDE5 has been consistently reported in experimental models of PPHN.[16,101] More recently, in vitro and in vivo studies have shown that even brief periods of hyperoxia independently increase the activity of PDE5, by a mechanism that appears to involve reactive oxygen species.[101–103] This finding could partially explain why some infants do not respond favorably to iNO.

Sildenafil is the best studied of the available phosphodiesterase inhibitors and can be administered by the enteral and intravenous routes. A small randomized trial found that enteral administration of sildenafil improved oxygenation and survival in term and late preterm neonates with PPHN.[104] In a subsequent dose-finding study, intravenous administration of sildenafil improved oxygenation in neonates with and without concurrent iNO treatment,[105] and may diminish the rebound pulmonary hypertension that can be seen during weaning of iNO. Sildenafil may be a useful adjunct in patients with partial or poorly sustained responses to iNO, but a recent multicenter trial did not find that intravenous sildenafil reduced treatment failure or time on iNO.[106] Sildenafil is generally well tolerated, although hypotension can occur, particularly if a loading dose is given too rapidly.[105] The availability of sildenafil as an enteral preparation also makes it feasible for long-term therapy for infants with chronic pulmonary hypertension associated with CDH[107] and BPD,[108] although this aspect of treatment needs more study and long-term follow-up. Other phosphodiesterase inhibitors include tadalafil, which has a longer half-life than sildenafil and has shown some benefit in PPHN refractory to iNO,[109,110] and vardenafil, which is being studied mostly in pre-clinical models at this time.

Prostanoids

Prostacyclin (PGI2) is a potent drug that induces vasodilation through activation of adenylate cyclase and increasing cAMP in pulmonary arterial smooth muscles. Unlike iNO, intravenously delivered PGI2 can potentially worsen ventilation-perfusion matching in the setting of lung disease. Epoprostenol was approved by the FDA in 1995 for the treatment of adult pulmonary arterial hypertension. While intravenously administered prostacyclin remains a mainstay of therapy for pulmonary hypertension in adults, rapid dosage escalation is often necessary for acute disease and can produce systemic hypotension. Its utility in the neonatal intensive care unit setting is also limited by the need for a dedicated central venous catheter, the potential to worsen ventilation–perfusion matching, and other systemic side effects including pain.

Aerosolized prostacyclin has been widely adopted in adult critical care units for the treatment of pulmonary hypertension.[111] While fewer reports describe its use in infants, case series indicate that continuous inhaled prostacyclin therapy (50 to 100 ng/kg/min) is well tolerated and improves oxygenation in infants with severe PPHN and inadequate response to iNO.[112,113] The risks include airway irritation from the alkaline solution needed to maintain drug stability, rebound pulmonary hypertension if use of the drug is abruptly discontinued, and inconsistent drug delivery due to drug loss into the circuit. New and more stable preparations are emerging that are specifically designed for intermittent nebulization, such as iloprost or treprostinil.[114–116] Treprostinil is particularly promising because it is also suitable for systemic administration, including by the subcutaneous route.[117]

Milrinone

Inhibition of PDE3, which metabolizes cAMP, might also enhance cAMP signaling in PPHN.[118] Milrinone, a PDE3 inhibitor, has been shown to decrease pulmonary arterial pressure and resistance and to act additively with iNO in animal studies.[119] In a 2006 report, the addition of intravenous milrinone therapy for neonates with severe PPHN and poor iNO responsiveness was associated with improvement in oxygenation without hemodynamic compromise.[120] As milrinone can improve both right and left ventricular function,[89] perhaps its greatest utility is in the setting of PPHN with LV dysfunction, in which lowering systemic vascular resistance with milrinone may improve LV performance and by lowering pulmonary venous pressure, can reduce right-to left-shunting. However, milrinone can reduce systemic blood pressure and cause systemic hypotension,[121] which may further impair myocardial perfusion and worsen cardiac function. Milrinone should be used with particular caution in preterm infants due to the risk for systemic hypotension and perhaps intraventricular hemorrhage.[122,123]

Endothelin Receptor Antagonists

ET-1 is a potent vasoconstrictor synthesized by vascular endothelial cells that acts through two receptors, ET_A and ET_B. The ET_A receptor plays a critical role in vasoconstriction, and selective blockade of the ET_A receptor causes fetal pulmonary vasodilation.[124] *ET-1* gene expression and ET-1 levels are increased in the lungs and pulmonary arterial endothelial cells in the fetal lamb model of PPHN.[125,126] Long-term intrauterine ET_A receptor blockade following ductal ligation decreases pulmonary arterial pressure and distal muscularization of small pulmonary arteries in utero, decreases right ventricular hypertrophy, and increases the fall in PVR at delivery in newborn lambs with PPHN.[127] Thus it is likely that ET-1, acting through the ET_A receptor, contributes to the pathogenesis and pathophysiology of PPHN. Use of bosentan, a nonspecific ET-1 receptor blocker, is an established therapy for pulmonary hypertension in adults. Two recent trials have shown that bosentan is well tolerated in neonates with PPHN. One single-center trial reported that bosentan led to substantial improvements in oxygenation in an iNO-naïve population of PPHN infants.[128] However, the FUTURE-4 multicenter trial found that bosentan as an adjunctive therapy with iNO therapy did not improve PPHN outcomes, reduce the time to receipt of iNO therapy, or reduce the time to extubation, possibly in part due to inconsistent intestinal absorption.[129]

Magnesium Sulfate

Other therapies that have been trialed for treatment of PPHN include intravenous (IV) magnesium sulfate ($MgSO_4$). A randomized controlled study comparing clinical efficacy of IV magnesium sulfate vs. oral sildenafil in infants with PPHN did not find $MgSO_4$ to be more effective than oral sildenafil in lowering

oxygen index (OI) and pulmonary artery pressure.[130] In addition, the duration of mechanical ventilation was longer and the need for inotropic support was greater with $MgSO_4$.

Outcomes

In the late 1980s and early 1990s, studies began reporting on the high risk of death and abnormal neurodevelopmental outcomes for survivors of PPHN.[131] One study showed that severity of oxygenation at presentation (measured by the alveolar–arterial oxygen difference) correlated well with survival but not with long-term outcome.[132] Other reports indicated that low Apgar scores and prolonged hypocarbia were predictive of adverse neurodevelopmental outcomes.[131,133]

The long-term outcome data for the largest iNO trials are summarized in Table 47.3, which also provides the most comprehensive outcome data for PPHN infants treated with and without iNO. Overall, these results highlight that neurodevelopmental impairment is frequent in this population (14% to 30%) and is not reduced by iNO therapy.[5,133,134] In each of these trials, a trend toward higher motor impairment was observed in the iNO group, and in the early iNO trial reported by Konduri et al. (2007),[5] the difference in the Bayley psychomotor developmental index was statistically significant. The Neonatal Inhaled Nitric Oxide Study Group (2000)[132] reported that the rate of disability was not affected by the need for ECMO, leading the authors to speculate that the timing of brain injury was most likely before ECMO.

Neurodevelopmental impairment is high even for those infants with moderate PPHN (oxygenation index of 15 to 25). The overall rates of neurodevelopmental impairment were similar to those of other trials that enrolled patients with more severe disease, and early iNO use did not translate into improved outcomes.[5] The proportion of infants with medical problems, such as the need for home medications, oxygen, and gastrostomy feedings, also tended to be higher in the early iNO group, although these differences were not statistically significant.

More than 33,400 newborns have been treated with ECMO for respiratory failure, with a cumulative overall survival to discharge of 73% (www.elso.org; September 2021). Neuroimaging abnormalities are identified in 10% to 20% of infants during or after ECMO,[135] and mild to major neurodevelopmental impairment is described in 15% to 25% of neonatal ECMO survivors. However, determining the role of ECMO versus other disease factors in the neurodevelopmental outcomes for ECMO survivors is difficult. From the pre-iNO era, the UK Collaborative Randomized Trial of ECMO provides the most direct comparison of outcomes after ECMO versus conventional treatment and included neurodevelopmental assessments at ages 1, 4, and 7 years. At age 1 year, a significant survival benefit (68% vs. 41%) was observed in the ECMO-treated group versus the conventionally treated group,[136] and survivors demonstrated similar rates of impairment or disability. At the 4-year follow-up, there continued to be a higher proportion of survivors without disability in the ECMO-treated group versus the conventionally treated group (50% vs. 37%),[137] although the rates of disability were similar at age 7 years (55% vs. 50%).[138] The high rate of neurodevelopmental impairment in both groups suggests that the underlying disease process, rather than the treatment, is the major influence on neurodevelopmental outcome. Several more recent studies also indicate that ECMO survivors may be at risk of academic problems,[139] so these children will benefit from detailed assessment as they reach school age. Recent data from the extracorporeal life support organization (ELSO) registry indicates that neonatal ECMO rates have decreased dramatically from 80% in 1990 to about 8% in 2017[140] which likely reflects improvements in medical management. However, there are still significant morbidities associated with ECMO therapy, likely reflecting infants that are more critically ill with significant comorbidities being managed with ECMO.[140]

TABLE 47.3 Neurodevelopmental Outcomes for the Major Inhaled Nitric Oxide Clinical Trials

Study	Number of Participants	Initial OI	Age at Follow-Up (Months)	NDI (%)		Bayley Mental Developmental Index		Bayley Psychomotor Developmental Index		Cerebral Palsy (%)

Summary

Persistent pulmonary hypertension complicates the course of up to 10% of neonates with respiratory failure. It is associated with a diverse set of cardiopulmonary conditions, and its pathophysiologic mechanisms are characterized by vascular dysfunction, injury, and remodeling that occur before and after birth. In the last 20 years, experimental work on the basic mechanisms of vascular regulation of the developing pulmonary circulation has improved the range of therapeutic approaches for neonates with PPHN. In particular, iNO has proven to be a selective and effective pulmonary vasodilator for infants with PPHN, although successful clinical management requires meticulous care for all aspects of the associated lung and cardiac disease. Current research is focused on developing a better understanding of cellular responses in the remodeled vasculature and will likely elucidate additional signaling pathways and lead to new therapeutic strategies. More work is needed to further reduce mortality and improve neurodevelopmental outcomes of sick newborns with pulmonary hypertension, especially in patients with lung hypoplasia and advanced structural vascular disease.

Patent Ductus Arteriosus in the Preterm Infant

RONALD I. CLYMAN

KEY POINTS

- Clinical signs of a symptomatic patent ductus arteriosus (PDA) usually appear later than echocardiographic signs and are related to the degree of left-to-right ductal shunting.
- Factors known to play a prominent role in regulation of ductal patency involve those that promote constriction (oxygen, endothelin, calcium channels, catecholamines, and Rho kinase) and those that oppose it (intraluminal pressure, prostaglandins, nitric oxide, carbon monoxide, potassium channels, and cyclic adenosine monophosphate and guanosine monophosphate).
- Closure of the ductus arteriosus occurs in two phases: (1) "functional" closure of the lumen by smooth muscle constriction, within hours after birth and (2) "anatomic" occlusion of the lumen over the next several days, due to neointimal thickening and loss of smooth muscle cells from the inner muscle media.
- The most important mechanism that prevents the preterm ductus from constricting after birth is its increased sensitivity to the vasodilating effects of prostaglandin E2. Inhibitors of prostaglandin production (e.g., indomethacin, ibuprofen, acetaminophen) are usually effective in promoting ductus closure in preterm infants.
- Early surgical ligation, while eliminating the detrimental effects of a PDA on lung development, may create its own set of problems for the preterm infant that counteract those benefits (e.g., postligation hypotension, bronchopulmonary dysplasia, vocal cord paralysis, neurodevelopmental abnormalities).
- While there may be general consensus on the efficacy of cyclooxygenase inhibitors for treatment of a PDA, questions about proper dosage, treatment duration, optimal timing, and treatment criteria remain controversial.
- Although a moderate-to-large PDA increases pulmonary blood flow and edema and decreases systemic blood pressure, it is not clear which is preferable: (1) to close the PDA (surgically or pharmacologically) or (2) to deal with the pulmonary edema and hypotension through other means, while awaiting spontaneous ductal closure.
- Further investigation is needed to determine which preterm infants are most likely to benefit from ductal closure and which might be best left untreated.

Introduction

The ductus arteriosus represents a persistence of the terminal portion of the sixth branchial arch. During fetal life, the ductus arteriosus serves to divert blood away from the fluid-filled lungs toward the descending aorta and placenta. After birth, constriction of the ductus arteriosus and obliteration of its lumen separate the pulmonary and systemic circulations. In full-term infants, obliteration of the ductus arteriosus takes place through a process of vasoconstriction and anatomic remodeling. In the preterm, the ductus arteriosus frequently fails to close. The clinical consequences of a patent ductus arteriosus (PDA) are related to the degree of left-to-right PDA shunt with its associated change in blood flow to the lungs, kidneys, and intestine.

Diagnosis

Phase contrast magnetic resonance imaging offers the most accurate measurements of ductal shunt volume, and the effects of a PDA on left ventricular and systemic blood flow volumes.[1] Unfortunately, these measurements are difficult to obtain in extremely immature, sick preterm infants. Two-dimensional echocardiography and color Doppler flow mapping is the current standard for assessing the presence, magnitude, and direction of PDA shunting. Ductus diameter ≥1.5 mm (or >50% of the diameter of the left pulmonary artery), left atrial-to–aortic root (LA/Ao) ratio ≥1.5, reversal of forward blood flow in the descending aorta during diastole, and end diastolic flow velocity in the left pulmonary artery ≥0.20 m/s are signs consistent with a moderate-to-large PDA shunt.[1,2] Unfortunately, the interobserver repeatability of all echocardiographic parameters is relatively poor.[3]

Clinical signs of a PDA (systolic murmur, hyperdynamic precordial impulse, full pulses, widened pulse pressure, and/or worsening respiratory status) usually appear later than echocardiographic signs and are less sensitive in determining the degree of left-to-right shunt. Certain signs such as continuous murmur or hyperactive left ventricular impulse are relatively specific for a PDA but lack sensitivity; conversely, worsening respiratory status, while a sensitive indicator, is relatively nonspecific for a PDA. Tachycardia is not a useful or reliable indicator of a PDA in preterm infants. Infants with large left-to-right shunts may have evidence of cardiomegaly and increased pulmonary arterial markings on their chest x-rays; however, in general, the chest x-ray and electrocardiogram are not useful in diagnosing a PDA. Although elevated plasma concentrations of brain natriuretic peptide (BNP) and N-terminal pro-BNP (NTpBNP) have been found to

correlate with the presence of a moderate sized left-to-right PDA shunt, changes in BNP and N-terminal pro-BNP concentrations have poor sensitivity and specificity in predicting increases or decreases in PDA shunt magnitude and cannot be used to replace echocardiography in the management of PDA shunts.[4,5] Although there has been little consensus in the past about what constitutes a clinically important PDA, recent studies have shown that moderate and large PDA shunts are associated with significant neonatal morbidities, whereas small PDA shunts have similar outcomes as no PDA shunts.[6–8] Although PDA shunt magnitude plays a significant role in creating its hemodynamic significance, equally important are the duration of shunt exposure, infant's gestational age, ventricular diastolic function, and need for invasive respiratory support.[7,9–12]

Incidence (Table 48.1)

Functional closure of the ductus occurs in almost 50% of full-term infants by 24 hours, in 90% by 48 hours, and in all by 72 hours. The rate of ductus closure is delayed in preterm infants; however, essentially all preterm infants who are ≥30 weeks' gestation (including those with respiratory distress syndrome) will close their ductus by the fourth day after birth. Infants born at less than 30 weeks' gestation have a 65% incidence of persistent ductus patency beyond day 4. Even among the most immature infants (≤27 weeks' gestation), spontaneous closure can occur during the neonatal period. However, when it does occur, it usually occurs late during the NICU hospitalization (average age = 61 ± 37 days).[13–19] Among preterm infants discharged from the hospital with a persistent PDA, 86% will achieve PDA closure by 1 year of age. The remainder will require continued observation or device closure.[13–19]

Factors like surfactant administration, infection, being small for gestational age at 26 to 29 weeks, and excessive fluid administration increase the likelihood of developing a symptomatic PDA.[13,20–27] On the other hand, being small for gestational age at 23 to 24 weeks, nonwhite, or having received antenatal glucocorticoids reduce risk of PDA.[28–34]

Regulation of Ductus Patency—Vasoconstriction and Vasorelaxation

In Utero Regulation

Ductus arteriosus patency is determined by the balance between dilating and constricting forces. Smooth muscle tone in the ductus arteriosus is determined by the phosphorylation and dephosphorylation of myosin light chains. The fetal ductus has a high level of intrinsic tone due to elevated levels of intracellular calcium (Ca^{2+}) which activate myosin light chain kinase, producing myosin light chain phosphorylation and smooth muscle constriction.[35] Extracellular Ca^{2+} enters the smooth muscle cytosol primarily through voltage-operated Ca^{2+} channels (Ca_L and T-type channels) and transient receptor potential (TRP) channels in the plasma membrane.[36,37] Calcium is also released from intracellular stores in the sarcoplasmic and endoplasmic reticulum (SR and ER) through ryanodine receptors and inositol 1,4,5-trisphosphate receptors (IP3Rs).[37,38]

The contractile proteins in the fetal ductus (smooth muscle myosin, calponin, and caldesmon) are more differentiated and more sensitive to the contractile effects of Ca^{2+} than they are the aorta and the pulmonary artery.[39–42] Increased Rho kinase activity in the ductus increases smooth muscle sensitivity to Ca^{2+} by inhibiting myosin light chain dephosphorylation. Endothelin-1 plays a role in the elevated basal tone of the fetal ductus arteriosus by inducing IP3 and releasing Ca^{2+} from the sarcoplasmic reticulum.[43,44] Recently, a role for serotonin in promoting fetal ductus tone has been suggested since selective serotonin reuptake inhibitors constrict the ductus in utero.[45]

The factors that oppose ductus arteriosus constriction in utero are better understood. The elevated vascular pressure within the ductus lumen (due to the high resistance in the constricted pulmonary vascular bed) plays an important role in opposing ductus constriction.[46]

K^+ channels buffer ductus tone by regulating the rate of extracellular Ca^{2+} entry into the smooth muscle cells. When K^+ channels are open, K^+ exits the cell turning the membrane potential more negative (i.e., hyperpolarizing the cell). Hyperpolarization

inhibits extracellular Ca^{2+} influx through voltage-gated L-type Ca^{2+} (CaL) channels. Several K^+ channels [voltage-gated (Kv), Ca^{2+}-activated (K_{Ca}), and ATP-dependent (K_{ATP})] K^+ channels are present in fetal ductus smooth muscle cells. Their relative contribution to resting membrane potential depends on the animal species and the stage of development.

The fetal ductus also produces vasodilators that help to maintain ductus patency. Prostaglandins (PGs) are the dominant vasodilators that oppose ductus constriction in the later part of gestation.[47] Inhibitors of PG synthesis constrict the fetal ductus. PGE_2 is the most potent PG produced by the ductus and appears to be the most important prostanoid to regulate ductus patency.[48,49] The ductus is extraordinarily sensitive to the vasodilating effects of PGE_2. In the ductus, all three of the PGE receptors (EP2, EP3, and EP4) participate in vasodilation by activating adenylate cyclase and increasing ductus smooth muscle cyclic adenosine monophosphate (AMP) (which inhibits myosin light chain kinase and myosin light chain phosphorylation, thereby inhibiting the sensitivity of the contractile proteins to calcium).[42,50] Low levels of phosphodiesterase (the enzyme that degrades cyclic AMP) in the fetal ductus account for the vessel's increased sensitivity to PGE2.[51,52] PGE_2, acting through EP3 receptors (in lamb) and EP4 receptors (in rabbit), also activates the K_{ATP} and Kv channels, respectively, increasing outward K^+ current, hyperpolarizing the cell, and further inhibiting Ca^{2+} influx.[50,53]

Both isoforms of the enzyme responsible for synthesizing PGs (cyclooxygenase [COX]-1 and COX-2) are expressed in the fetal ductus.[54] In the fetal mouse, COX-2 appears to be the COX isoform responsible PGE2 production, whereas in the fetal sheep, both COX-1 and COX-2 play a role.[54,55] High circulating PGE_2, originating from the placenta, also regulates fetal ductus behavior,[56] due to low in utero pulmonary clearance.[57,58]

Nitric oxide, formed mainly by eNOS, is made by the fetal ductus arteriosus and appears to play an important role in maintaining ductus patency in rodent fetuses early in gestation.[47] NO activates soluble guanylyl cyclase increasing ductus smooth muscle cyclic GMP (cGMP) and cGMP-dependent protein kinase (PKG). PKG decreases intracellular Ca^{2+} by inhibiting Ca^{2+} influx, stimulating its removal, and by inhibiting the Rho-kinase pathway. PGE_2 and NO are coupled for reciprocal compensation since cyclooxygenase inhibition upregulates NO.[59] The importance of NO in maintaining in utero patency in larger species has not been conclusively demonstrated (see below).[60]

Carbon monoxide (CO) relaxes the ductus arteriosus.[61,62] Under physiologic conditions the amount of CO made by the ductus does not seem to affect ductus tone; however, in circumstances where its synthesis is upregulated, for example, endotoxemia, CO may exert a relaxing influence on the ductus.[63,64] Hydrogen sulfide (made by ductus endothelial and smooth muscle cells) also has been identified as another endogenous factor that inhibits fetal ductus tone by opening K_{ATP} channels.[65,66]

Chronic Inhibition of Prostaglandin Signaling In Utero

Short term, pharmacologic inhibition of PG signaling produces ductus constriction, in utero, however, chronic inhibition produces the opposite effect in mice: a persistent PDA in utero and a persistent PDA after birth.[55,67–69] It is now clear that, in addition to its role in maintaining fetal ductus patency, PGE2 is essential for vascular homeostasis and the induction of pathways necessary for postnatal closure.[70,71] Depletion of the PG EP4 receptor decreases the expression of several genes that control postnatal oxygen-induced ductus constriction (see below). Chronic inhibition of PG synthesis decreases Ca_L- and K^+-channel genes (Ca_Lalpha1c, Ca_Lbeta2, Kir6.1, and Kv1.5), which regulate Ca^{2+} entry and phosphodiesterase expression, which increases the ductus's sensitivity to cAMP- or cGMP-dependent vasodilators.[71] Both ablation of the PG EP4 receptor or its chronic blockade produce marked reductions in α-SM actin, SM22α, myosin heavy chain, and serum response factor by altering Wnt/β-catenin signaling.[70,72] Global deletion of the EP4 receptor blocks postnatal ductus closure. However, vascular smooth muscle-specific EP4-gene deletion does not have the same effect which suggests that vascular smooth muscle EP4 alone may not be sufficient for mediating DA closure.[70]

Similar to its effects during rodent gestation, pharmacologic inhibition of PG synthesis by indomethacin during human pregnancy also is associated with an increased incidence of PDA after birth.[73] However, in the human newborn, this appears to be due to indomethacin's ability to produce ductus constriction in utero. Constriction in utero produces ischemic hypoxia, increased NO production, and smooth muscle cell death which prevent the ductus from constricting after birth and make it resistant to the constrictive effects of postnatal indomethacin.[74,75] These changes are similar to the events that occur postnatally (see below). Although paracetamol (acetaminophen) also inhibits fetal ductus PGE_2 production, it rarely causes fetal ductus closure in pregnant women.[76]

Postnatal Regulation (Box 48.1)

In the full-term newborn, closure of the ductus arteriosus occurs in two phases: (1) "functional" closure of the lumen within the first hours after birth by smooth muscle constriction, and (2) "anatomic" remodeling of the vessel over the next days by extensive neointimal thickening and loss of smooth muscle cells from the inner muscle media.

Several factors promote ductus constriction in the full-term newborn following delivery: (1) an increase in arterial PO_2, (2) a decrease in blood pressure within the ductus lumen (due to the postnatal decrease in pulmonary vascular resistance), (3) a decrease in circulating PGE_2 (due to loss of placental PG production and increased removal by the lung), and (4) a decrease in the number of PGE_2 receptors in the ductus wall.[50,57,77] Although the newborn ductus continues to be sensitive to the vasodilating effects of NO, it loses its ability to respond to PGE_2.[78,79]

The postnatal increase in arterial PaO_2 plays an important role in postnatal ductus constriction. Infants born at higher elevations have an increased incidence of PDA.[80] Oxygen-induced contraction can be demonstrated in the presence of inhibitors of PG, NO, and endothelin signaling and in the absence of endothelial cells. This suggests that these endothelial-derived vasoactive substances are not essential for normoxic constriction. In most species, oxygen appears to constrict the ductus arteriosus through mechanisms that are both dependent and independent of smooth muscle membrane depolarization.[36] Oxygen depolarizes ductus smooth muscle cells by inhibiting K^+ channels.[81,82] Following depolarization Ca^{2+} enters the ductus smooth muscle through L-type and T-type voltage dependent, Ca^{2+} channels.[43,83–85] Several O_2 sensitive K^+ channels have been found in the fetal ductus (including Kv1.5 and Kv2.1). These vary with species and gestational age and may account for the differing sensitivity of the ductus to oxygen.[86,87] Increased oxygen tensions also inhibit ductus K_{ATP} channels (by increasing mitochondrial ATP production), have a

direct effect on the Ca^{2+} L-channels, voltage-dependent T-type Ca^{2+} channels, and store-operated Ca^{2+} channels, and inhibit the forward mode of the Na^{+}/Ca^{2+} exchanger.[37,38,85,88,89] Oxygen also increases smooth muscle sensitivity to Ca^{2+} by activating Rho kinase mediated pathways.[36–38,90,91]

Mitochondria in the ductus smooth muscle cells are important upstream oxygen sensors. Elevated PO_2 causes mitochondrial fission, mediated by dynamin-related protein-1, which increases electron transport chain complex I activity and the production of reactive oxygen species (superoxide and H_2O_2).[81,91–95] Inhibition of mitochondrial fission selectively inhibits O_2-induced H_2O_2 production and ductus constriction, without altering constriction to other agonists.[92,93] In most species H_2O_2 appears to stimulate vasoconstriction by increasing Ca^{2+} influx and Ca^{2+} sensitization by regulating K^{+} channels, Ca^{2+} channels, and Rho kinase. However, in some species H_2O_2 acts only as a vasodilator, or as both a vasodilator and a vasoconstrictor (depending on its concentration).[96,97]

In the chicken ductus, reactive oxygen species induce their own amplification pathway by activating neutral sphingomyelinase and increasing ceramide production. Ceramide, which activates NADPH oxidase, amplifies the formation of reactive oxygen species by transferring electrons from NADPH to oxygen.[98,99]

• BOX 48.1 Changes That Lead to Ductus Closure After Birth

- Decreased ductus intraluminal blood pressure after postnatal pulmonary vasodilation
- Removal of placenta as a source for PGE_2 production
- Increased pulmonary clearance of circulating PGE_2
- Decreased circulating PGE_2 concentrations
- Decreased prostaglandin receptors (EP4) after birth
- Decreased intracellular cAMP and cGMP concentrations
- Increased arterial oxygen tension
- Increased H_2O_2 release by mitochondria
- Oxygen responsive K^{+} channels close resulting in smooth muscle cell depolarization
- Smooth muscle cell depolarization increases extracellular calcium entry into cytoplasm through voltage dependent calcium L-and T-channels
- Increased calcium release from sarcoplasmic and endoplasmic reticulum
- Increased Rho kinase activity increases smooth muscle calcium sensitization
- Increased cytochrome p450 3A13 activity
- Increased isoprostane production
- Increased endothelin production
- Decreased serum osmolality after birth activates TRPM3 receptors
- Increased myosin light chain kinase activity
- Decreased myosin light chain kinase phosphatase
- Profound hypoxia develops in muscle media as vessel constricts
- Increased VEGF and PDGF production occurs as a result of ductus constriction
- Mononuclear cells and platelets attach to luminal endothelial cells
- Endothelial cells detach from basement membrane and proliferate
- Fragmentation of internal elastic membrane
- Hyaluronic acid, fibronectin, fibulin-1, and chondroitin sulfate accumulate in subendothelial space and in muscle media
- Smooth muscle cells from the muscle media migrate into neointima forming mounds that occlude residual ductus lumen
- Anoxia of the muscle media causes smooth muscle cells to die

Studies in animals suggest that a cytochrome P450 hemoprotein also appears to be involved with oxygen-induced constriction.[100–103] This mechanism may have parallels in preterm human ductus since cytochrome P450 inhibitors increase the incidence of PDA.[104,105] Oxygen also activates the epidermal growth factor receptor (EGFR) in ductus smooth muscle cells. EGFR inhibition attenuates oxygen-induced constriction.[92]

During the transition from fetus to newborn isoprostanes are formed nonenzymatically by free radical-mediated peroxidation of phospholipid-bound arachidonic acid. In mice, isoprostanes have both contractile and vasodilatory effects on the ductus by activating both thromboxane and EP4 receptors, respectively. With advancing gestation, the balance shifts in favor of the contractile effects of thromboxane stimulation.[106]

Oxygen also increases the potent vasoconstrictor, endothelin-1.[107] The role of endothelin-1 in postnatal ductus closure is still unclear due to the marked species variation in its contribution to oxygen-induced ductus constriction.[44,82,108–110] The postnatal increase in PaO_2 also has profound modulatory effects on other vasoactive systems.[111] Elevated oxygen tensions can increase the ductus's contractile response to neural mediators and can decrease the formation of vasodilator PGs.[35,112] Although the contractile effects of oxygen play an important role in postnatal ductus constriction, they are not essential for postnatal ductus closure. For example, mice lacking the endothelin A receptor have diminished oxygen-induced ductus constriction, however, their ductus closes normally after birth.[44]

Developmental Regulation (Box 48.2)

In contrast with the full-term ductus, the premature ductus is less likely to constrict after birth. The intrinsic tone of the extremely immature ductus is decreased compared to the ductus at term.[35] This may be due to the presence of immature smooth muscle myosin isoforms, with a weaker contractile capacity, and to decreased Rho kinase expression and activity.[39,41,43,90,91] Ca^{2+} entry through L-type Ca^{2+} channels appears to be impaired in the

• BOX 48.2 Factors Contributing to Ductal Patency in Preterm Neonates

- Immature smooth muscle isoforms
- Decreased calcium entry through calcium L-channels
- Decreased Rho kinase activity (decreased calcium sensitization)
- Increased potassium K_{Ca} channels (which are not regulated by oxygen)
- Decreased potassium K_v channels (which are regulated by oxygen)
- Decreased endothelin production
- Increased circulating PGE_2 concentrations
- Decreased pulmonary clearance of circulating prostaglandin E2
- Increased prostaglandin receptors (EP4) after birth
- Increased EP4 receptor coupling with adenyl cyclase
- Increased cyclic AMP production
- Decreased cyclic AMP degradation by phosphodiesterases
- Increased postnatal PGE_2, nitric oxide, and other vasodilator production
- Decreased antenatal exposure to cortisol
- Increased serum osmolality after birth
- Decreased ductus wall thickness
- Decreased postnatal constriction
- Both decreased ductus wall thickness and decreased postnatal constriction protect premature ductus from developing profound postnatal ductus muscle media hypoxia and prevent anatomic changes needed for permanent closure

immature ductus (especially under hypoxic conditions).[43,88,91] The potassium channels that promote ductus relaxation also change during gestation (switching from K_{Ca} channels, which are not regulated by PaO_2, to Kv channels, which can be inhibited by increased PaO_2).[86,113,114] Reduced expression and function of the putative oxygen-sensing Kv channels appear to contribute to ductus patency in the preterm rabbit, sheep, baboon, mouse, and chicken.[91,113,114] In contrast, a decrease in Kv channel expression occurs with advancing gestation in the rat, which suggests that in that species DA closure may occur by eliminating Kv channels.[86]

Premature infants have elevated circulating concentrations of PGE_2, which may play a significant role in maintaining ductus patency during the first days after birth. This is due to the decreased ability of the premature lung to clear circulating PGE_2.[57,77] Probably the most important mechanism preventing the preterm ductus from constricting after birth is its increased sensitivity to the vasodilating effects of PGE_2. The increased sensitivity to PGE_2 is due to both increased cyclic AMP production (from enhanced receptor coupling with adenyl cyclase) and decreased cyclic AMP degradation by phosphodiesterase.[51,115]

PGs may be the most important factor opposing ductus constriction in utero and immediately after preterm birth, but by the end of the first week there is enhanced production of NO and other vasodilatory inflammatory molecules within the ductus wall. Smooth muscle glucose, glycogen, and ATP concentrations also become depleted within the ductus smooth muscle, making it more difficult to maintain active constriction.[116–118] As a result, inhibitors of PG production become less effective toward the end of the first postnatal week.[119–121] Inhibitors of NO production have been used successfully as adjunctive therapy to close the PDA in situations where indomethacin was ineffective in constricting the ductus by itself.[122,123]

PGs may also contribute to persistent ductus patency in full-term infants since indomethacin can produce a substantial degree of ductus constriction even in full-term infants.[124,125] However, this is more likely to occur in those born at 37 weeks' rather than at 42 weeks' gestation.

Several other prenatal and postnatal factors also affect the rate of ductus constriction in preterm newborns. Circulating concentrations of thyroid hormones and cortisol increase with advancing fetal gestation and play a role in ductus arteriosus maturation. Preterm infants treated with thyroid hormone have a lower incidence of PDA.[126,127] Similarly, full-term infants with congenital hypothyroidism have an increased incidence of PDA that appears to respond to thyroid hormone replacement therapy.[128] Elevated fetal cortisol concentrations also foster ductus maturation by increasing its sensitivity to oxygen.[34,129] Both prenatal and postnatal glucocorticoid exposure reduces the incidence of PDA in premature humans and animals.[29,34,130–135] However, caution must be used when administering postnatal glucocorticoids since the risk of necrotizing enterocolitis is increased when administered concurrently with indomethacin or ibuprofen.[134,136]

Prenatal administration of vitamin A has been shown to increase both the intracellular Ca^{2+} and contractile response of the preterm ductus to oxygen in addition to stimulating PDGF-mediated smooth muscle cell migration, proliferation, and hyaluronic acid and fibronectin production.[137–139] Although vitamin A did not increase the rate of PDA closure in two randomized controlled trials (RCTs), the need for ductus ligation among AGA infants was significantly decreased.[140,141]

Other factors include serum hyperosmolality and brain natriuretic peptide (both of which have direct effects on the DA), caffeine (which is associated with decreased PDA but has no direct effect on the DA), and glutamate (however, glutamine supplementation in RCTs does not alter the incidence of PDA).[142–148] Although phototherapy has occasionally been associated with PDA, it has not been found to alter the incidence of PDA in RCTs.[149,150]

Anatomic Closure-Histologic Changes

Anatomic remodeling of the ductus arteriosus is essential for permanent luminal closure. Fragmentation of the internal elastic lamina and progressive intimal thickening start in the second half of gestation and accelerate after postnatal constriction. As the intima increases in size, it occludes the already constricted lumen. The increase in intimal thickening is due (1) to migration of smooth muscle cells from the muscle media into the neointima and (2) to proliferation of luminal endothelial cells. The process of intimal cushion formation starts with accumulation of hyaluronan (HA) below the luminal endothelial cells, loss of laminin and collagen IV from their basement membrane, and separation from the internal elastic lamina. The hygroscopic properties of HA create an environment well suited for cell migration.[151] The endothelial and smooth muscle cells of the ductus arteriosus differ from those of the adjacent vessels in their sensitivity to transforming growth factor β (TGFβ) which increase their HA production.[152] PGs, acting through the EP4 receptor, play a stimulatory role in ductus HA production and neointimal thickening by activating pathways that involve cyclic AMP, cAMP-protein kinase A, Epac (exchange protein activated by cAMP), phospholipase C, alpha1G T-type voltage dependent channels, fibulin-1, cysteine-rich protein CCN3, and Wnt/β-catenin.[85,153–158]

Accompanying the increase in HA in the neointimal space is an increase in fibronectin (FN) (which facilitates ductus smooth muscle cell migration) and chondroitin sulfate (CS) (which interferes with elastin assembly).[151,159,160] Intimal cushion formation is associated with disruption of the internal elastic laminae (IEL) underlying the ductus luminal endothelial cells. Ductus endothelial cells have high levels of tissue-type plasminogen activator which activates the elastolytic enzyme matrix metalloproteinases 2 at sites of IEL disruption.[161] In the aorta, well-developed elastic laminae surround smooth muscle cells and prevent the vascular wall from collapsing. In contrast, smooth muscle cells in the ductus are surrounded by thin, fragmented elastin fibers that do not prevent it from collapsing during vasoconstriction.[162] The disruption of elastin fiber assembly around ductus smooth muscle cells is not due to increased elastase activity or decreased tropoelastin production. Rather, it appears to be due to developmental mechanisms that reduce insolubilization of elastin and prevent formation of intact elastic laminae. PGE_2 also plays a critical role (through an EP4-cSrc-PLCγ-signaling pathway) in inhibiting thick elastin fiber formation in the ductus. Lysyl oxidase, which catalyzes elastin cross-linking, is degraded when the EP4 receptor is stimulated.[163] Impaired assembly of thick elastic laminae facilitates smooth muscle cell migration by removing a physical barrier. In addition, the accumulation of soluble, truncated tropoelastin acts as a smooth muscle cell chemoattractant.[164] It is interesting to note that when EP4 expression is decreased in the EP4 knockout mouse and Brown-Norway rat, the DA's elastic laminae appear abnormally well developed, similar to the aorta, and intimal cushions fail to develop.[162,163,165]

Antenatal betamethasone and the postnatal increase in PaO_2 also stimulate ductus smooth muscle proliferation and migration

by increasing ADP-ribosyltransferase 3 expression and activating the RhoA-ROCK-PTEN pathway, respectively.[166,167]

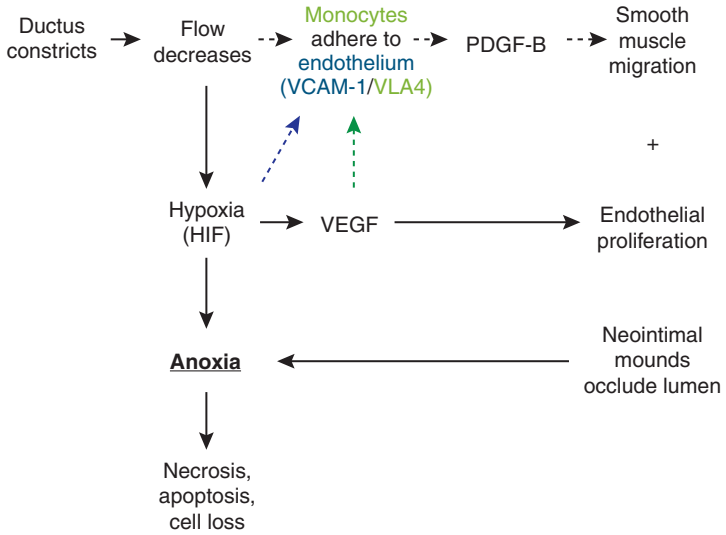
Relationship Between Vasoconstriction and Anatomic Closure (Fig. 48.1)

In full-term animals, both the loss of vasodilator regulation and the anatomic events that lead to permanent closure appear to be controlled by the degree of ductus smooth muscle constriction. Constriction produces ischemic hypoxia of the vessel wall.[168] Experimental models that alter the ability of the ductus to constrict at term prevent the normal histologic changes that occur after birth.[46,55,69,169–171] Ductus luminal blood flow provides oxygen and nutrients to the inner half of the ductus wall. Because of the thickness of the term ductus, intramural vasa vasorum are needed to provide oxygen and nutrients to the outer half of its wall. These collapsible, intramural vasa vasorum provide the ductus with a unique mechanism for controlling the maximal diffusion distance for oxygen and nutrients across its wall. Ductus constriction obliterates vasa vasorum flow to the outer muscle media, which turns the entire thickness of the muscle media into a virtual avascular zone.[172] The profound ischemic hypoxia that follows the constriction inhibits local production of PGE_2 and NO, induces local production of hypoxia-inducible factors like HIF1α and vascular endothelial growth factor (VEGF), and produces smooth muscle apoptosis in the ductus wall. VEGF plays a critical role in the migration of the ductus smooth muscle cells into the neointima and in the proliferation of intramural vasa vasorum.[173] The hypoxic muscle media and shift from laminar to turbulent/stagnant flow in the constricted lumen induce expression of genes known to be essential for remodeling (HIF1α, vascular cell adhesion molecule 1 [VCAM-1], E-selectin, IL-8, MCSF-1, CD154, IFNγ, IL-6, and TNFα).[117,174] Circulating mononuclear cells adhere to newly expressed VCAM-1 and E-selectin adhesion molecules and become activated monocytes/macrophages that produce PDGF. PDGF stimulates smooth muscle migration and proliferation into the neointima.[117] The inflammatory response following postnatal ductus constriction appears to be necessary for neointimal remodeling since the extent of remodeling is determined by the degree of mononuclear cell adhesion.[117] In mice, platelets play an essential role in ductus luminal closure by forming a platelet plug to fill the small residual lumen that persists after postnatal constriction.[175]

In preterm infants, the ductus frequently remains open for many days after birth. Even when it does constrict, the premature ductus frequently fails to develop profound hypoxia and anatomic remodeling. The preterm infant requires a greater degree of ductal constriction than the term infant to develop a comparable degree of hypoxia. In contrast with the full-term ductus, where vasa vasorum are needed to provide oxygen and nutrients to the outer two-thirds of the ductus wall, intramural vasa vasorum are absent from the ductus wall of infants born before 26 weeks' gestation where luminal blood flow can provide all the oxygen and nutrients the thin-wall ductus requires. The absence of intramural vasa vasorum leaves the preterm ductus without a mechanism to rapidly increase the diffusion distance across its wall during postnatal constriction. As long as any degree of luminal patency exists, the thin-wall preterm ductus fails to become profoundly hypoxic and fails to undergo anatomic remodeling after birth. As a result, the preterm ductus requires complete cessation of luminal flow before it can develop the same degree of hypoxia as found at term. Once the preterm ductus develops the same degree of hypoxic ischemia as the term ductus, most of the anatomic changes seen at term will occur.[35,122] However, if the premature ductus does not develop the degree of ischemic hypoxia needed to induce cell death and anatomic remodeling, it will continue to be responsive to vasodilators and continue to be susceptible to vessel reopening.

Genetic Regulation

Recent studies have used genome-wide transcriptome analysis to examine differences in gene expression between the ductus and



• **Fig. 48.1** Ductus Remodeling: Role of Constriction, Hypoxia, and Mononuclear Cell Adhesion in Neointima Formation and Smooth Muscle Cell Death. Postnatal constriction produces hypoxia in the ductus wall. The hypoxic smooth muscle and endothelial cells increase their expression of vascular endothelial growth factor *(VEGF)* and vascular cell adhesion molecule 1 (VCAM-1), respectively. VEGF is required for endothelial cell proliferation. VEGF also attracts circulating mononuclear cells (expressing very late antigen-4 [VLA-4]) to the endothelial cell surface. Under very low flow conditions, the weakly adherent VLA-4$^+$ mononuclear cells attach to VCAM-1 on the endothelial cell surface and release PDGF and MMP-9 (which promote smooth muscle migration into the neointima). Tight constriction and loss of luminal flow are essential for VEGF expression, mononuclear cell adhesion, neointimal formation, and luminal occlusion.

the aorta (as well as the effects of oxygen and preterm birth on ductus gene expression). Genes related to neural crest migration (e.g., TFAP2b), TGF-beta signaling, matrix molecules (like fibronectin and lysyl oxidase), actin-myosin interactions, potassium, and Ca^{2+} ion signaling, as well as PG, endothelin, and angiotensin II signaling have increased expression in the ductus compared with the aorta. Mutations in several of these ductus-dominant genes/pathways (examined in either mouse knockout models or human genetic syndromes) are associated with persistent ductus patency in term neonates.[44,55,72,175–215] Single nucleotide polymorphisms (SNPs) have also been associated with isolated, nonsyndromic, persistent ductus patency in term infants (e.g., in TGFBR2).[216]

Although several pathways appear to be commonly involved in DA regulation among different species or different genetic backgrounds, the relative expression and importance of single orthologous genes frequently differ.[176,177,217–222] For example, endothelin receptor stimulation may account for 44% of the oxygen induced contraction in the rat, whereas it only contributes to 13% of the contraction in the rabbit, and has a negligible role in the human ductus.[82,110] Oxygen depolarizes the ductus smooth muscle cells by inhibiting K^+ channels.[81,82] In the rabbit, an increase in the expression of Kv channels appears to be responsible for the developmental increase in the oxygen-induced contraction.[114] In contrast, in the rat, Kv channel expression decreases with advancing gestation.[86] Ductus patency is critically dependent on vasodilator PGs in most species; however, notable exceptions exist in the guinea pig, chicken, and emu ductus, where locally derived PGs do not appear to play a significant role in ductus patency.[223–226]

Genetic and familial factors also play a role in persistent ductus patency in preterm infants.[227,228] Single nucleotide polymorphisms (SNPs) in several genes have been associated with preterm PDA (ATR type 1, IFNγ, estrogen receptor-alpha PvuII, TFAP2B, PGI synthase, TRAF1) and CYP2C9.[229–233] There is a growing body of evidence to suggest that SNPs in TFAP2B may be responsible for some of the PDAs that occur in preterm infants (especially those that are unresponsive to indomethacin).[232] TFAP2B regulates genes that are important in ductus smooth muscle development.[234] However, race, ethnicity, and ancestral background appear to be important modifiers of TFAP2B's effects. TFAP2B polymorphisms are associated with important changes in DA gene expression and persistent PDA in preterm infants but only when present in infants with European ancestry.[235,236]

Hemodynamic and Pulmonary Alterations

The pathophysiologic features of a PDA depend both on the magnitude of the left-to-right shunt and on the cardiac and pulmonary responses to the shunt. The PDA left-to-right shunt lowers systemic blood pressures (both systolic and diastolic) and adds to the incidence of inotrope-dependent hypotension often observed among preterm infants (born before 28 weeks' gestation) at the end of the first week.[237,238]

There are important differences between immature and mature infants in the heart's ability to handle the increased volume load from the PDA. The immature fetal ventricles have less cardiac sympathetic innervation and are less distensible than at term and generate less force per gram of myocardium.[239] The relative lack of left ventricular distensibility in immature infants is more a function of the ventricle's tissue constituents than of poor muscle function. As a result, left ventricular distension secondary to a large left-to-right PDA shunt may produce a higher left ventricular end-diastolic pressure at smaller ventricular volumes. The increase in left ventricular pressure increases pulmonary venous pressure and causes pulmonary congestion.

Studies in preterm animal and human newborns have shown that despite these limitations, preterm newborns are able to increase left ventricular output and maintain their "effective" systemic blood flow, even with left-to-right PDA shunts equal to 50% of left ventricular output. With shunts greater than 50% of left ventricular output, "effective" systemic blood flow falls, despite a continued increase in left ventricular output.[237,240] The increase in left ventricular output associated with a PDA is accomplished not by an increase in heart rate, but by an increase in stroke volume.[237,240] The presence of a PDA does not affect myocardial contractility.[241] Instead, stroke volume increases primarily as a result of a simultaneous decrease in afterload resistance and increase in left ventricular preload. Several weeks of PDA exposure causes the left heart to remodel to a larger, more spherical shape with an increase in wall thickness. This returns to normal values following PDA closure.[241]

Despite the ability of the left ventricle to increase its output in the face of a left-to-right ductus shunt, blood flow distribution is significantly rearranged. This redistribution of systemic blood flow occurs even with small shunts.[237] Blood flow to the gastrointestinal tract and kidneys is decreased due to a combination of decreased perfusion pressure and localized vasoconstriction. Mesenteric blood flow is decreased in both fasting and fed states in the presence of a PDA as is mesenteric regional oxygen saturation, although the latter has not been universally observed.[242–244] Significant decreases in organ blood flow and oxygenation may occur long before there are any signs of left ventricular compromise and may contribute to the decreased glomerular filtration rate that has been observed with ductus patency.[240,245–248] Cerebral blood flow and oxygenation are also compromised in the presence of a moderate-to-large left-to-right PDA shunt due to the limited ability of the preterm newborn to autoregulate cerebral blood flow.[249,250] Small-for-gestational age infants are at even greater risk for having low cerebral oxygen saturations due to an increased incidence of impaired cerebrovascular autoregulation.[251,252] Recent evidence suggests that any negative impact of a PDA on neonatal brain growth may have more to do with its effects on cerebral oxygen saturation than on the magnitude of the shunt or the treatments used to close it.[253] In contrast with the effects of a PDA on mesenteric and renal oxygen saturations, cerebral oxygen saturations may be preserved in the presence of a moderate-to-large PDA if cerebral autoregulation remains intact.[254] Therefore, as long as continuous cerebral oxygen monitoring demonstrates that cerebral oxygenation is not compromised, it may be reasonable to delay treatments to close the PDA while awaiting spontaneous closure.[253]

The decreased ability of the preterm infant to maintain active pulmonary vasoconstriction may be responsible in part for early development of a "large" left-to-right PDA shunt.[255–257] Randomized, controlled trials have shown that the presence of a PDA increases the incidence of early hemorrhagic pulmonary edema/pulmonary hemorrhage.[258–261] Therapeutic maneuvers or prenatal conditions that lead to a rapid postnatal drop in pulmonary vascular resistance, like surfactant replacement or intrauterine growth retardation, can exacerbate the amount of left-to-right shunt and lead to pulmonary hemorrhage.[25,262,263]

In premature animals, a wide-open PDA increases the hydraulic pressures in the pulmonary vasculature on both the arterial and venous sides of the capillary bed. In addition, the increased pulmonary blood flow and immature precapillary arterial tone cause the

pulmonary vascular hydraulic pressure head to shift downstream toward the capillary fluid filtration sites increasing the rate of fluid transudation into the pulmonary interstitium.[264,265] Extremely premature infants (gestational age ≤28 weeks) have both increased alveolar capillary permeability and lower plasma oncotic pressures compared with more mature infants.[266] As a result, any increase in microvascular perfusion pressure increases the rate of fluid and protein transudation. If plasma proteins enter the alveolar space, surfactant function is inhibited and alveolar surface tension is increased.[267] The increased FiO_2 and mean airway pressures required to overcome these early changes in compliance may play a role in the development of chronic lung disease.[248,268,269] Depending on the gestational age and the species examined, changes in pulmonary mechanics may occur as early as 1 day after birth or not before several days of exposure to a PDA left-to-right shunt.[264,270]

Although preterm animals with a PDA have increased fluid and protein transudation into the lung interstitium, a simultaneous increase in lung lymph flow appears to eliminate the excess fluid and protein flux into the lung.[265] This compensatory increase in lung lymph acts as an "edema safety factor," inhibiting fluid accumulation in the lungs. As a result, during the first days after birth there is no net increase in water or protein accumulation in the lung and there is no change in pulmonary mechanics.[21,248,264,271,272] This delicate balance between the PDA-induced fluid filtration and lymphatic reabsorption is consistent with the observation, made in human infants, that closure of the ductus arteriosus, within the first 24 hours after birth, has no effect on the course of the newborn's hyaline membrane disease. However, after several days of mechanical ventilation, there is a decrease in pulmonary capillary surface area which increases both the pulmonary microvascular pressure and rate of hydraulic fluid filtration.[273] As a result, it is not uncommon for infants with a persistent PDA to develop pulmonary edema and alterations in pulmonary mechanics at 6 to 10 days after birth. In these infants, improvement in lung compliance occurs following closure of the PDA.[248,274–278]

Preterm baboon newborns, delivered at 67% term gestation and mechanically ventilated for 2 weeks, have been used to examine the effects of a PDA on pulmonary mechanics.[270] Baboons were either treated with a cyclooxygenase inhibitor to close the ductus or allowed to have a moderate-size PDA persist for the 2-week experiment. Exposure to a persistent PDA did not alter surfactant secretion, pulmonary epithelial protein permeability, or presence of surfactant inhibitory proteins, nor did it alter the expression of pro-inflammatory or tissue remodeling genes. In contrast with full-term baboons, which mobilize lung fluid rapidly after birth, preterm newborns (with both an open and closed ductus) mobilize lung fluid much more slowly.[270] A persistent PDA led to a small but significant increase in lung water at 2 weeks after delivery. The indomethacin or ibuprofen used to constrict the PDA increased expression of alveolar epithelial sodium channels, which facilitate fluid removal from the alveolar compartment. This finding may account for the decreased incidence of pulmonary edema and hemorrhage observed in infants treated with prophylactic indomethacin or ibuprofen.[258–261]

Pharmacologic closure of the PDA was associated with improved lung development in the preterm baboons. In contrast to the animals with an open ductus, where an arrest in alveolar development (the hallmark of the new "BPD") was noticeable by 2 weeks after birth, pharmacological closure of the PDA led to improved alveolarization.[270] Whether the improvement in alveolarization is due to the closure of the ductus or the pharmacologic agents (indomethacin/ibuprofen) used to close it is unknown at this time. Neutrophil counts are elevated in the tracheal fluid of human infants with a PDA and indomethacin can decrease tracheal neutrophil accumulation.[279] However, the decreased neutrophil accumulation occurs in both those who close and in those who fail to close their PDA after indomethacin.[280] The same improvements in pulmonary mechanics and alveolar surface area have not been observed after surgical ligation of the PDA. Early surgical ligation increases the expression of genes involved with pulmonary inflammation and decreases the expression of pulmonary epithelial sodium channels (that are critical for alveolar water clearance).[281] These changes may contribute to the lack of improvement in pulmonary mechanics after PDA ligation. In addition, early surgical ligation impedes lung growth.[270,282,283] These findings raise the possibility that early ductus ligation, while eliminating the detrimental effects of a PDA on lung development, may create its own set of problems that counteract many of the benefits derived from ductus closure.[284,285]

Not all of the changes associated with a PDA are necessarily detrimental to the immature infant with respiratory distress syndrome. Persistence of the left-to-right shunt maintains an elevated Pao_2 in the presence of atelectasis. This phenomenon is due to recirculation of oxygenated arterial blood through lungs that are not fully expanded.[237,286] Decreases in systemic arterial O_2 content have been observed after PDA closure, despite the absence of any alterations in pulmonary mechanics.

Treatment

Treatment Options for Closing a Patent Ductus Arteriosus

Open surgical ligation produces definitive ductus arteriosus closure, however, it is associated with several important morbidities: thoracotomy, exposure to surgical anesthesia, pneumothorax, chylothorax, scoliosis, and infection.[287] In addition, following PDA ligation, between 20% and 60% of ELBW infants will develop unilateral vocal cord paralysis (which increases the requirements for tube feedings and respiratory support and persists well beyond the neonatal period).[288–292] Post-ligation cardiac syndrome and profound hypotension during the postoperative period is another complication that affects 30% to 50% of infants with birthweights ≤1000 g.[293] The incidence of profound postoperative hypotension is inversely related to the infant's corrected age and appears to be due to impaired adrenal stimulation, low cortisol release, and decreased vascular tone.[294,295] Early surgical ligation also contributes to the development of bronchopulmonary dysplasia.[284,285] Neurodevelopmental abnormalities are also more frequent following early PDA ligations.[296] Therefore, avoiding or delaying ligation appears to be beneficial since many of the morbidities associated with ligation (post-ligation hypotension, vocal cord paralysis, bronchopulmonary dysplasia) and abnormal neurocognitive development appear to be reduced when ligation is delayed.[284,288,296–299] In a recent study of preterm infants undergoing PDA ligation, short-term respiratory improvement was only observed in infants with the worst lung disease prior to ligation, that is, those requiring high-frequency ventilation. Those managed with conventional ventilation prior to ligation had no respiratory improvement at 7 days after ligation and required higher respiratory support in the early postoperative period.[300]

In full-term infants, transcatheter PDA device closure (TCPC) has replaced surgical ligation as the treatment of choice. With the approval of the Piccolo device, the use of TCPC in the premature population (even for infants with birthweights <1000 g) has become a feasible alternative to surgical ligation.[301–304] TCPC may decrease overall exposure to mechanical ventilation and the risks of post-ligation cardiac syndrome, however, no RCTs have compared TCPC outcomes with approaches that rely on pharmacologic treatment or conservative management/nontreatment of the PDA.[305,306] Although infrequent, major adverse events (5% to 10%) and death (2%) related to the procedure do occur, and, as expected, their incidence increases as the size of the infant and the center's experience with the procedure decreases.[304,307,308]

Inhibition of PG synthesis with nonselective inhibitors of COX-1 and COX-2 (e.g., indomethacin and ibuprofen) appears to be an effective alternative to surgical ligation.[257] However, both drugs have been associated with several potential adverse effects in the newborn. Indomethacin produces significant reductions in renal, mesenteric, and cerebral blood flow.[309–318] Indomethacin also has noxious effects on gut mucosa and reduces cerebral oxygenation.[318–320] Alterations in creatinine clearance and oliguria (that are minimally responsive to dopamine or furosemide therapy) are common problems after indomethacin. Furosemide, when used in combination with indomethacin, actually increases the incidence of acute renal failure.[321–324] Renal function returns to normal after the initial doses of indomethacin.[325] There are some reports that COX inhibitors may affect glomerular development in neonatal animals; however, these finding have not been consistently observed.[326–328] Indomethacin's action on these organ systems may not be due entirely to its inhibition of PG synthesis.[329–331] Indomethacin also has effects on lipoxygenase activity, and histamine and endothelin release, although the relevance of these effects to any neonatal morbidities is still unknown.[332–334]

Although indomethacin produces significant physiologic alterations, and has been associated with several morbidities, none of the controlled, randomized trials that have examined the relationship between indomethacin and neonatal morbidity have found an increase in the incidence of necrotizing enterocolitis, gastrointestinal perforation, retinopathy of prematurity (ROP), chronic lung disease, or cerebral white matter injury following indomethacin treatment.[335] Neither indomethacin by itself, nor in addition to enteral feeding, has been shown to increase the incidence of gastrointestinal perforations. In fact, infants receiving small "trophic" enteral feedings during indomethacin treatment attain full enteral feedings at a faster rate than those kept *nil per os* during treatment.[336] On the other hand, the combination of indomethacin *and* postnatal steroids does increase the incidence of gastrointestinal perforations and necrotizing enterocolitis.[135,136,337]

Indomethacin's cerebral vasoconstrictive effects are frequently cited as a concern for neonatologists; however, a Cochrane systematic review found that indomethacin prophylaxis is more likely to decrease rather than increase the incidence of periventricular leukomalacia.[317,335,338] There is no evidence that prophylactic indomethacin has any adverse effect on neurodevelopmental outcome at 18 months; in fact, there is evidence that it may have long-term benefits at 4.5 and 8 years especially in preterm male infants.[339–342]

While there may be general consensus on the efficacy of indomethacin for treatment of a PDA, questions about proper dosage, treatment duration, and optimal timing of treatment remain quite controversial. Indomethacin's plasma clearance depends on postnatal age.[343–347] Therefore, a dosage regime recommended for infants at the end of the first week (when the half-life of the drug is 21 hours) may lead to elevated and prolonged plasma concentrations when used in infants on day 1 (when the half-life is 71 hours).[346,347] Conversely, a single loading dose of indomethacin (0.2 mg/kg), without subsequent maintenance doses, can be effective in closing a PDA when administered within the first 24 hours following delivery.[348,349]

Many variations in dosage regimens have been evaluated.[350,351] A prolonged low-dose course of indomethacin (0.1 mg/kg every 24 hours for 5 to 7 days) may increase the rate of permanent closure especially in infants who still have residual ductus flow after completing the standard short course (2 to 3 doses over 24 hours), and may decrease indomethacin's impairment of renal function.[352–355] This dosage regimen still needs further evaluation since a higher NEC rate was observed in the infants receiving prolonged maintenance indomethacin.[350] Although some have suggested that the dose of indomethacin be increased when conventional dosing fails to produce ductus closure, a randomized controlled trial examining this approach found that the rate of ductus closure was not substantially improved despite a nearly 3-fold increase in serum indomethacin concentrations.[356–358] More worrisome was the fact that the higher indomethacin concentrations produced significant increases in the incidence of moderate/severe ROP and late renal dysfunction.[359]

The postnatal age at which indomethacin is administered plays an important role in determining its effectiveness. With advancing postnatal age, dilator PGs play less of a role in maintaining ductus patency (see above).[30,32] Even when indomethacin concentrations have been maintained in the "desired" range, the drug's ability to produce complete ductus closure declines during the first days after birth.[121,309,343,345,360] Despite its decreased effectiveness, it may still be advisable to attempt PDA closure with indomethacin before proceeding to surgical ligation or TCPC even in cases of advanced postnatal age.[361]

Recurrence of a symptomatic PDA can occur after initial successful treatment. The rate of reopening, which is greatest among the most immature infants, appears to be related to the timing and completeness of ductus closure after the treatment course.[121,248] Permanent anatomic closure requires tight constriction of the ductus lumen and the development of ductus wall hypoxia (see above). Among infants delivered before 28 weeks' gestation, 80% of those that closed their ductus clinically following indomethacin treatment, will reopen their ductus and develop clinical symptoms if there is any evidence of luminal patency on the Doppler examination performed at the end of indomethacin treatment.[121] The thinner the ductus wall, the less likely it is that profound hypoxia and anatomic remodeling will occur even with tight constriction. Only 9% of infants delivered between 26 and 27 weeks' gestation will reopen their PDA if the ductus is found to be closed by Doppler/echocardiography; in contrast, 20% of those delivered before 26 weeks are likely to reopen their PDA despite evidence of ductus closure on a prior echocardiogram.[362] Early treatment produces a tighter degree of ductus constriction and as a result produces higher rates of ductus wall hypoxia and permanent closure.[121] Recurrence of a PDA can also occur after bacterial infections when circulating PGE_2 concentrations reach the pharmacologic range.[26] Bacterial endotoxin increases NO production and tumor necrosis factor α (but not PGE_2) in the ductus wall which may explain why indomethacin is less effective in closing the PDA after infection.[363]

Ibuprofen, another nonselective cyclooxygenase inhibitor, appears to be as effective as indomethacin in producing PDA closure in very low-birth-weight infants (at least in infants

with a mean gestational age of 28 weeks).[364,365] Compared with indomethacin, it has a reduced rate of NEC and renal insufficiency.[366,367] Oro-gastric administration of ibuprofen appears to be as effective as IV administration.[366] In contrast with indomethacin, ibuprofen does not appear to affect mesenteric blood flow and has less of an effect on renal perfusion, oliguria, and cerebral blood flow.[310,318,329,331,368,369] Unfortunately, most of the studies that have compared ibuprofen with indomethacin have not included extremely low-birth-weight infants (≤25 weeks' gestation), which is the group that is most resistant to pharmacologic ductus closure and where the optimal age-appropriate dosing schedule for ibuprofen is still under consideration.[370,371] Some of the higher ibuprofen dose options are concerning because of ibuprofen's effects on total and free serum bilirubin concentrations.[372,373] Ibuprofen does not have the same effects as indomethacin on cerebral autoregulation. As a result, prophylactic ibuprofen does not appear to have the same intracranial hemorrhage sparing effect that is seen with indomethacin (see below). In contrast to indomethacin, ibuprofen alters pathways regulating intestinal microbial colonization, mucus production, and epithelial defense.[374]

Paracetamol (acetaminophen) also appears to be an effective agent for inducing PDA closure. Acetaminophen's vasoconstrictive effect appears to be mediated through inhibition of the peroxidase moiety of PGH2 synthetase.[375,376] Numerous randomized clinical trials (RCTs) and subsequent meta-analyses suggest that acetaminophen is as effective as indomethacin and ibuprofen.[377–390] However, only one of the RCTs exclusively enrolled infants that were at high risk for having a persistent PDA (i.e., those born before 28 weeks' gestation). In one multi-center trial enrolling infants less than 28 weeks' gestation who still had a moderate-to-large PDA at the end of the first week, indomethacin had the greatest rate of constriction (when compared with the rate of spontaneous PDA constriction [20%] during the 7 to 10 days after enrollment: relative risk [95% CI] = 3.21 [2.05 to 5.01]), followed by ibuprofen = 2.03 (1.05 to 3.91), and acetaminophen = 1.33 (0.55 to 3.24).[391] Recent concern has been raised about acetaminophen's safety profile based on reports of neurocognitive impairment after prenatal exposure and of hypotension following intravenous administration.[392,393]

Indomethacin and Intracranial Hemorrhage

Previous RCTs have shown that indomethacin can decrease the incidence of intracranial hemorrhage (ICH) in preterm infants and experimental animals.[339,394–396] This has not been the case with ibuprofen or paracetamol. The effects of indomethacin on ICH do not appear to be due to its effects on ductus patency.[394,395] Indomethacin decreases cerebral blood flow, decreases reactive postasphyxia cerebral hyperemia, and accelerates maturation of the germinal matrix microvasculature.[397–401] Since most intracranial hemorrhages occur within the first 3 days after birth, the beneficial effects of indomethacin have only been seen when it has been given prophylactically, during the first 18 hours after birth.[402] The RCTs that demonstrate a beneficial effect of prophylactic indomethacin on ICH were performed prior to the year 2000. During the last 21 years the overall rate of ICH in the neonatal population has been steadily decreasing and more recent studies have found a more limited effect of prophylactic indomethacin on the rate of ICH.[403–406] In addition, infants who are coagulopathic or have platelet counts below 100×10^9/L may be at increased risk for intracerebral bleeding when COX inhibitors are administered.[407]

Patent Ductus Arteriosus and Neonatal Morbidity: To Close or Not to Close the Patent Ductus Arteriosus

Although a prolonged, persistent left-to-right shunt through a PDA shortens the life span of animals and humans, there is controversy about whether or not the PDA needs to be closed during the neonatal period.[55,408–415] Since preterm infants have a high rate of spontaneous PDA closure during the first 2 years, routine early treatment runs the risk of exposing infants to drugs or procedures they might not need. At this time it is not clear which is preferable: (1) to close the PDA (either pharmacologically or surgically) in the preterm neonate, or (2) to deal with the PDA-induced pulmonary edema and hypotension more "conservatively" while awaiting spontaneous PDA closure. A "conservative," expectant management approach might include: dopamine, which decreases PDA shunting by increasing pulmonary vascular resistance; fluid restriction, which minimizes PDA symptoms but fails to reduce the PDA shunt and is associated with decreased systemic blood flow; and increased serum creatinine, diuretics, and/or increased end-expiratory pressure, which improves pulmonary edema and compliance but has only a small effect on the left-to-right PDA shunt.[27,416–421]

RCTs, which initiated "prophylactic" pharmacologic PDA treatment within 12 hours of birth in either all infants or just those with echocardiographic evidence of a large PDA reported a decrease in a number of short-term morbidities ([1] severe early pulmonary hemorrhage, [2] severe grades of IVH [but only when indomethacin was the treatment used], [3] presence of a symptomatic PDA, [4] dopamine-dependent hypotension, [5] need for higher levels of ventilator support, and [6] need for surgical PDA ligation) compared with postponing treatment until later in the first postnatal week.[258,259,261,335,339,422,423] However, there were no differences in the incidence of long-term morbidities like BPD, NEC, or neurodevelopmental impairment. In addition, 40% to 50% of infants in the prophylactic treatment group were treated unnecessarily since their PDA would have closed spontaneously by 7 days.[14]

Little information exists about the consequences of exposure to a persistent moderate-large PDA shunt for greater than 1 week. Two small RCTs, performed more than 40 years ago, found that a persistent untreated symptomatic PDA prolonged the need for respiratory support and increased pulmonary morbidity.[269,424] Whether these findings still are applicable in the setting of modern neonatal respiratory care (with "gentle ventilation," acceptance of elevated arterial PCO_2, and less tracheal intubation) is a question starting to be addressed by RCTs. In contrast with the earlier RCTs described above, more recent trials have focused on the most immature infants (<28 to 29 weeks' gestation) with moderate-large PDA shunts which are likely to persist for several weeks. The PDA-TOLERATE RCT and the "Nonintervention versus Oral Ibuprofen" RCT enrolled infants with moderate-large PDAs that persisted beyond the first week and compared early routine PDA treatment (starting at 8 days) with a conservative, expectant management approach.[425,426] Neither trial observed a difference in the incidence of BPD, NEC, or mortality. However, both trials suffered from having a low rate of PDA closure in the early intervention arm of the study resulting in prolonged PDA exposure (>14 days) in both groups. Similar problems (either unexpectedly low rates of drug-induced PDA closure or higher rates of spontaneous closure) existed in two additional pilot RCTs that enrolled infants within 72 hours of birth.[427,428] As a result, little difference existed

in the duration of PDA exposure between the study treatment arms for more than 50% of the study population. More effective PDA closure strategies will need to be devised for future RCTs if we are ever to learn whether early routine closure of the PDA will or will not decrease the incidence of BPD or late morbidity.

Another problem for future RCTs is knowing which infants to enroll, that is, determining who actually is at risk for increased morbidity when a PDA is present. An association between PDA and BPD or late morbidity only exists when *both* moderate-to-large shunts persist beyond 7 to 14 days *and* mechanical ventilation/tracheal intubation is required for ≥10 days.[6–8,10–12,429] Infants requiring shorter intubation durations have the same incidence of BPD whether or not a PDA persists for several weeks after birth.[10–12] This suggests that routine early PDA treatment may have no benefit, as far as the outcome BPD is concerned, for infants requiring intubation for less than 10 days. What about infants who are intubated for ≥10 days? Might routine PDA treatment be justified in this group of infants? Unfortunately, none of the reported RCTs have focused on this group of infants. All RCT populations have been diluted with infants for whom closing the PDA had little or no consequence. Early screening tools need to be developed (like the one proposed by El-Khuffash et al.[9]) to discriminate between infants who are the most appropriate candidates for enrollment in future trials and those who should be excluded.

In the absence of current RCTs several cohort-controlled observational studies have examined whether exposure to moderate-to-large PDA shunts for greater than 8 days increases morbidity.[405,430] These studies found no increase in the incidence of NEC, ROP, or death but did find an increased incidence of BPD and BPD/death among infants that were exposed to a moderate-to-large PDA for greater than 2 weeks. In addition, the longer infants were exposed to a PDA before PDA treatment was initiated, the less likely PDA treatment was associated with a reduction in BPD and BPD/death.[405,430] These findings are consistent with several recent observations: (1) during the past decade, as the use of PDA treatment has decreased, there has been a significant increase in adjusted local mortality among infants weighing less than 750 g; (2) neonatal centers that do not treat the PDA or consider PDA treatment only after the first postnatal week report significantly higher rates of BPD and BPD/death than centers that regularly screen and treat the PDA as part of their admission care.[403,431–437]

Whether exposure to a moderate-to-large PDA shunt for more than the first 7 to 14 days actually contributes to the development of BPD and BPD/death is a question that awaits testing in appropriately designed RCTs. At this time what we do know is that neither a delay of 2-to-5 days before starting PDA treatment, nor treatment that starts only after infants have been exposed to a moderate-to-large shunt for more than 2 weeks appear to affect the incidence of BPD and BPD/death. Further investigations will be needed to determine which infants are most likely to benefit from PDA treatment and which infants might best be left untreated.

Perinatal Arrhythmias

TERRENCE CHUN AND BHAWNA ARYA

KEY POINTS

- The term *supraventricular tachycardia* (SVT) encompasses several different arrhythmias that may have different diagnostic and therapeutic requirements.
- Tachycardia mechanisms may be caused by conduction reentry, enhanced automaticity, or triggered automaticity.
- Isolated atrial and ventricular ectopy is common in the fetus and neonate and usually does not require any therapy.
- Congenital forms of complete heart block may result in slow heart rates but may not require pacemaker implantation.
- Fetal arrhythmias are rare but, when present, can result in significant hemodynamic compromise.
- Management of fetal arrhythmias is complex and involves evaluation of multiple factors, including (1) severity of rhythm abnormality, (2) fetal comorbidities and signs of heart failure, (3) maternal comorbidities, and (4) gestational age at diagnosis.

The cardiac conduction system in the normal human heart enables a synchronized and orderly activation of the myocardium and chambers to provide optimal cardiac output. This sequence begins even in the earliest stages of cardiac development. However, disorders of cardiac rhythm can occur at any stage of life, from the fetus to the infant to the adult. These can range from transient and mild disturbances in rhythm to recurrent or persistent arrhythmias that can have significant hemodynamic consequences. Some abnormalities, such as isolated atrial or ventricular ectopy, can be more bothersome to the care provider than to the patient. Other disturbances, such as incessant tachyarrhythmias, can progress to heart failure and hemodynamic collapse. While the incidence of cardiac arrhythmias is increased in the setting of congenital heart disease (CHD), many of these abnormalities are commonly seen in the setting of an otherwise structurally normal heart. Knowledge of the spectrum of cardiac rhythm disturbances is important for prompt recognition, referral, and management. In this chapter, the etiology and common mechanisms of various arrhythmias, as well as differential diagnosis and treatment strategies, will be discussed in separate sections. The unique issues surrounding the diagnosis and management of arrhythmias in the fetus will also be addressed.

Conduction System of the Human Heart

To properly understand the mechanisms of arrhythmogenesis, it is important to recognize the core elements of the normal cardiac conduction system. The embryogenesis of the heart and the conduction system are beyond the scope of this chapter. However, the components of the cardiac conduction system are relatively set by the second trimester of gestation and provide the substrate for many of the observed arrhythmias.[1]

Sinus Node

The sinus node resides in the area between the vena cava and the right atrium and is predominantly located near the superior vena cava to the right-atrial junction.[2] However, there is no anatomic feature that is visible on gross inspection. Functional electrophysiology testing studies and animal studies have demonstrated that the nodal tissue can span the lateral wall of the right atrium, extending from the superior vena cava to the inferior vena cava.

The sinoatrial nodal tissue is histologically distinct from the atrial myocardium and has no contractile components. Electrical impulses are generated by automatic action potential behavior. Activation of the adjacent atrial myocardium by the sinus nodal tissue results in a wave of depolarization that propagates by cell-to-cell activation in a superior-to-inferior and a right-toward-left (in the structurally normal heart) fashion.

Atrioventricular Node

The atrioventricular (AV) node is a more organized area of conduction in the right atrium near the crux of the heart. More well-defined than the sinus node, the compact AV node is located in the posterior portion of the interatrial septum just anterior to the tricuspid valve and (in most cases) provides a singular conduction channel into the bundle of His and the distal conduction system.[1]

The majority of the atrial propagation wave depolarizes the mass of the atria. However, impulses that reach the area of the AV node enter the transition zone of conduction "input" into the AV node. Overall conduction velocity is slowed through the compact AV node but then exits the node into the specialized conduction fibers of the His–Purkinje system.

His–Purkinje System

In the normal heart, the atrial and ventricular myocardium are electrically isolated from each other by the AV rings (tricuspid and mitral annuli). The penetrating bundle of His is usually the only conductive tissue that traverses the AV rings into the ventricles. The bundle of His is insulated from the ventricular myocardium until it gives off branches. The first branch from the His bundle enables activation of the septum. Next, the bundle bifurcates into the right- and left-bundle branches. The left bundle divides into anterior and posterior fascicles. At the terminus of each of these

bundle branches, the specialized conduction tracts fan into an intricate network of short Purkinje fibers that insert into numerous sites on the ventricular myocardium. Electrical impulses that are conducted through the His–Purkinje system result in activation of the ventricular myocardium in a highly organized and synchronized fashion, translating into a mechanically efficient contraction of both left and right ventricles almost simultaneously.

Neonatal Arrhythmias

Abnormalities in Cardiac Conduction

When the normal sequence of cardiac activation is disturbed, the result can be an irregularity in the cardiac rhythm. However, in many cases, these disturbances will only be detected on electrocardiography or rhythm monitoring and have no manifestations on physical examination or otherwise. AV block can occur at any level of the conduction pathway if anything impedes the propagation of the impulse through that conduction segment. This can be functional (because of negative vagal stimulation) or anatomic (as can be seen following cardiac surgery).

First-Degree Atrioventricular Block

Any conduction delay that prolongs the PR interval beyond the normal range for age is considered a first-degree AV block. By definition, impulses must still be conducted such that a 1:1 AV relationship persists. In the neonate, the normal PR interval is generally between 80 and 120 ms, up to 140 ms in the first few months of life, and up to 160 ms in the first 6 months of life.[3] In general, first-degree AV block is benign and does not require any special treatment. It can be a normal variant or may be the result of influences that prolong the overall conduction time through the AV node and His–Purkinje system. Increased vagal tone is a common cause of PR prolongation. In the newborn, this can be a manifestation of vagal stimulation caused by a nasogastric or orogastric tube stimulating the oropharynx. More pathologic causes of PR prolongation can include neonatal lupus syndrome or myocarditis. Although there is evidence that significant PR prolongation has a negative impact on cardiac output in the adult heart, there is no indication that this is true in the neonate with a structurally and functionally normal heart. Even when the PR interval is extremely prolonged, there is usually no hemodynamic impact, and the cardiac examination remains essentially unchanged.

Second-Degree Atrioventricular Block

Second-degree AV block is ascribed when there is incomplete conduction from the atrium to the ventricle; that is to say, not every P wave is conducted to a QRS complex. This usually manifests as a skipped beat on physical examination or on cardiac monitoring. Mobitz type I conduction block, also known as the *Wenckebach pattern*, describes a pattern wherein the AV conduction becomes progressively prolonged with each successive beat. The PR interval becomes gradually longer, and after a number of beats (usually two or three, although this can certainly be longer), there is failure to conduct for a single beat. The subsequent P wave is then conducted with a normalized PR interval, and the cycle begins anew. Mobitz type II conduction block is present when there is a cyclical lack of conduction; however, the progressive PR prolongation seen in the Wenckebach pattern is lacking. Mobitz type I conduction can be seen in conditions of increased vagal tone (as described previously), whereas Mobitz type II is practically unheard of in the neonate in the absence of any other heart disease.

Third-Degree Atrioventricular Block

Third-degree, or complete AV block, occurs when there is a complete lack of conduction between the atria and the ventricles. In most situations of complete AV block, there is an escape depolarization mechanism, either junctional or ventricular in origin, which ensures that cardiac output is maintained. Complete AV block can be congenital or acquired. Congenital complete AV block is a particularly challenging entity and is described in a subsequent section. The most common causes of acquired complete heart block are infections or neonatal myocarditis. In addition, acquired complete heart block can occur as a complication of neonatal cardiac surgery in 1% to 3% of cases that involve surgical intervention near the interventricular septum.[4]

Ventricular Preexcitation

Ventricular preexcitation occurs when the ventricular myocardium is activated abnormally, usually by an accessory bypass tract. The ventricular depolarization pattern is thus a combination (fusion) of early activation of a portion of the ventricles through an accessory pathway and the remainder of activation occurring via the normal His–Purkinje system. In general, these bypass tracts bridge the AV groove that typically separates the atria from the ventricles and result in an anomalous electrical connection to the ventricles.

There are three electrocardiographic features that define this "Wolff–Parkinson–White" pattern: (1) short PR interval, (2) a slurred "delta wave," and (3) widened QRS duration. How evident this pattern is on electrocardiogram (ECG) can vary depending on the location of the accessory pathway (and thus how early the preexcited portion is activated) and how quickly the ventricles are also activated by the His–Purkinje system. In the newborn heart, the rapid transit time through the AV node and His–Purkinje system can result in a very minimal amount of preexcitation being evident, and appreciation of the presence of the Wolff–Parkinson–White pattern can be delayed, sometimes for years.[5] Usually, this diagnosis is made only when the newborn patient experiences a tachyarrhythmia (as discussed later).

Abnormalities in Cardiac Rhythm

Alterations in the normal cardiac rhythm can occur by one of several mechanisms and sometimes in combination. These include: (1) enhanced automaticity, (2) reentry mechanisms, and (3) triggered automaticity.

Certain areas of the heart have a tendency to exhibit spontaneous automaticity, such as the sinus node and the AV junction. Sometimes an abnormal cluster of cells can have a particular tendency toward this behavior. Gradual depolarization of the tissue during phase 0 of the action potential (electrical diastole) eventually crosses the action potential threshold, resulting in the depolarization–repolarization sequence, after which it returns to electrical diastole until the gradual depolarization occurs again.[1] After the action potential begins in the abnormal ectopic focus, the adjacent myocardium is also depolarized, which then propagates a wavefront outwards from that locus. Automatic rhythms tend to exhibit "warm-up" and "cool-down" behavior, gradually (although sometimes briskly) accelerating and then decelerating back to normal. Even when persistent, there tends to be beat-to-beat variability, and the rate can also be influenced by external influences such as autonomic tone, metabolic states, or hormonal influences. In addition, automatic rhythms can be "overdrive" suppressed when driven by a faster rhythm from another source.

Triggered automaticity occurs when excitable tissue spontaneously depolarizes to the activation threshold, beginning an action potential in that cell or cells that are then perpetuated to the adjacent myocardium. This can occur in fairly normal tissue but can be particularly enhanced by conditions of acidosis, mechanical stimulation, myocardial injury, or inflammation. Increased automaticity is often observed in the presence of certain drugs, such as inotropic medications like dopamine or epinephrine or stimulant medications like caffeine.

Reentry rhythms are some of the more instantly recognizable tachyarrhythmias in neonates and young infants. In contrast to the gradual nature of automatic rhythms, reentry has a very abrupt onset and termination. During the rhythm, the rate tends to be fairly stereotyped and consistent. Reentrant rhythms require several prerequisites to perpetuate. First, there must be an arrhythmia "circuit" present with both antegrade conducting and retrograde conducting limbs. Next, there must be differential conduction between the limbs of the arrhythmia circuit, whereupon one limb must exhibit slowing or unidirectional block. Finally, all elements of the arrhythmia circuit must be able to support a repetitive rhythm at a fixed rate.

Ectopic Beats

Premature Atrial Complexes

Isolated atrial ectopy is commonly seen in children and, in particular, during the newborn period. There are no ethnic predilections toward ectopy. Premature atrial complexes can be observed during fetal monitoring and have been reported to occur in up to 25% to 50% of normal newborns;[6] however, in the vast majority of cases, this resolves within the first few months of life. Premature atrial complexes are caused by an early triggered depolarization of the atria from an ectopic focus that is separate from the sinus node. On surface ECG this manifests as a P wave that is earlier than would be expected from the preceding rhythm, and the ectopic P wave has a very distinct axis and morphology from the normal sinus P wave. In this manner, one can differentiate the premature atrial complex as originating from a location separate from the sinus node.

Most atrial ectopy in the neonate is conducted normally, meaning that the premature atrial complex is followed by a normal-appearing QRS complex. The PR interval may be measured as different from normal, which is more a reflection of the atrial depolarization beginning in an abnormal location (and thus either closer or further than the sinus node) rather than indicating any defect in AV conduction. When a premature atrial complex is closely coupled to the preceding beat, the conducted QRS complex may have an abnormal appearance. This "aberrant conduction" may just be slightly wider than normal, or it may have the appearance of a complete bundle branch block. This is caused by the early impulse failing to conduct, as the refractory period for that segment has been exceeded. Aberrantly conducted premature atrial complexes are often mistaken for premature complexes because of their wider appearance but can be distinguished by the presence of a preceding P wave. Blocked premature atrial complexes can occur if the ectopic beat occurs early enough after the preceding beat. While this effect is more pronounced where this is impaired AV conduction, it is most commonly observed in the setting of normal nodal conduction and results from the early atrial impulse failing to conduct because of the refractory period of either the AV node or the His–Purkinje system. Blocked premature atrial complexes are identified by the presence of the ectopic P wave (usually with the T wave of the preceding beat) that has no QRS complex following. Often, there will be a sinus pause before the next normally conducted sinus return beat. In most instances, isolated premature atrial complexes in the newborn do not require any treatment.

Premature Ventricular Complexes

Isolated ventricular ectopy is also commonly observed in the normal neonate, although to a lesser extent than atrial ectopy.[6] Ventricular ectopic beats are usually distinguished by a widened QRS complex with a T-wave axis that is different when compared with the normal QRS–T complex. Importantly, there is no P wave that precedes the premature QRS complex. In isolation, ventricular ectopy has no pathologic implications for infants who have no other signs or symptoms to suggest any cardiac pathology.

Tachyarrhythmias

While a number of tachyarrhythmias can be observed during childhood, only a subset of distinct arrhythmias is observed with any frequency in the fetus and neonate (Table 49.1). The most common of these are orthodromic reciprocating tachycardia (ORT), atrial ectopic tachycardia, and atrial flutter.[7]

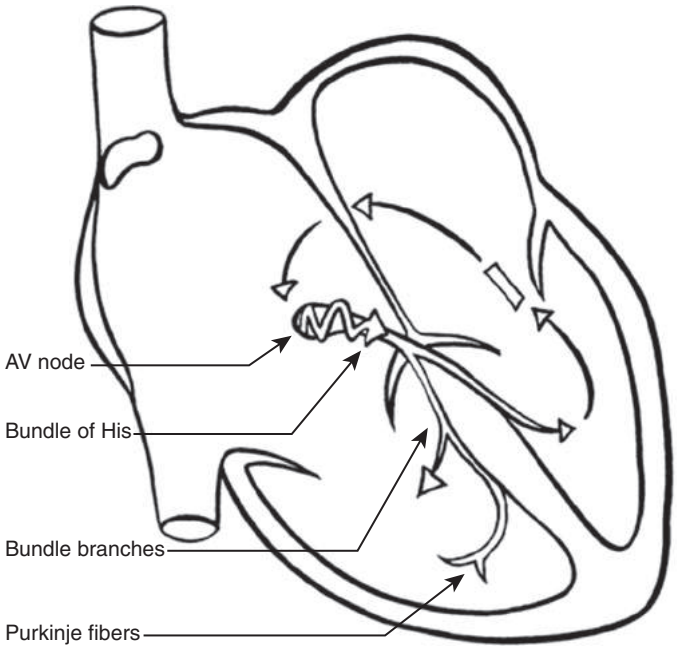
Orthodromic Reciprocating Tachycardia

ORT is the most common form of supraventricular tachycardia (SVT) in the fetus and the neonate.[8] It is the arrhythmia mechanism most commonly associated with SVT, so the terms are often used interchangeably. The tachycardia circuit for this reentrant arrhythmia utilizes the normal conduction system as the antegrade limb, and an accessory pathway provides the retrograde limb for the tachycardia (Fig. 49.1). When conditions are appropriate, impulses conducted through the His–Purkinje system to the ventricles are then carried in a retrograde fashion over an accessory pathway to the atria, which then reaches the AV node to start the cycle again. If not in their refractory periods, the atria, AV node and His–Purkinje system, ventricles, and accessory pathway all perpetuate a rapid repetitive SVT rhythm. In the fetal and neonatal heart, this form of SVT will manifest with very fixed rates that typically range between 240 and 300 beats per minute (bpm).

TABLE 49.1 Differentiating Neonatal Tachyarrhythmias

VA Relationship	Differential Diagnosis
A > V	Atrial ectopic tachycardia
	Atrial flutter
Short VA (VA < AV)	ORT (SVT)
	JET (VA-associated)
Long VA (VA ≥ AV)	Sinus tachycardia
	Atrial ectopic tachycardia
	PJRT
V > A	Ventricular tachycardia
	JET (VA-dissociated)

A, Atrial activity; *AV*, atrioventricular; *JET*, junctional ectopic tachycardia; *ORT*, orthodromic reciprocating tachycardia; *PJRT*, permanent form of junctional reciprocating tachycardia; *SVT*, supraventricular tachycardia; *V*, ventricular activity; *VA*, ventriculoatrial.



• **Fig. 49.1** Mechanism for Orthodromic Reciprocating Tachycardia. Antegrade conduction through His–Purkinje system depolarizes ventricles. Retrograde conduction from ventricles, over an accessory pathway, to atria.

So-called *retrograde* P waves may be visible on the ST segment or the T wave as evidence of the conduction time between the activation of the ventricles, passage through the accessory pathway, and subsequent reactivation of the atria. The measured RP interval can be used to aid in the differential diagnosis of the various forms of SVT, which can consequently be used to help guide specific management and prognosis.

When an accessory pathway only conducts in a retrograde direction, it is called a *concealed* accessory pathway; that is to say, there is no evidence of pathway conduction during normal sinus rhythm conditions, and the pathway only conducts from ventricle to atrium during reciprocating tachycardia. A manifest accessory pathway is one whose presence is known during normal sinus rhythm. These are the pathways that cause the ventricular preexcitation of Wolff–Parkinson–White syndrome (discussed previously). Manifest pathways are usually conducted bidirectionally; antegrade conduction results in preexcitation on resting ECG, and retrograde conduction is utilized during reciprocating tachycardia, resulting in a narrow QRS complex without preexcitation (Fig. 49.2).

For the neonate on continuous heart rate monitoring in the intensive care unit, such episodes of SVT are usually quite apparent by the abrupt onset and spontaneous termination of a rapid heart rate. In the absence of any monitoring, the development of SVT may not be as obvious. In contrast to older children who are able to report complaints of palpitations, neonates and young infants rarely give any indication of the tachyarrhythmia occurring within. Sometimes, pallor, diaphoresis, or a change in respiratory pattern may be evident to the outside observer. However, despite the rapid heart rates, SVT is generally well tolerated. Most episodes of ORT are self-limited, persisting only for seconds or minutes at a time; sometimes, episodes can last 30 to 60 minutes or more before terminating spontaneously. In rare instances, the SVT can be incessant, lasting for hours or sometimes a day or more. In these cases, delay in recognition and diagnosis can lead to a tachycardia-induced dilated cardiomyopathy and can possibly result in eventual cardiovascular collapse.

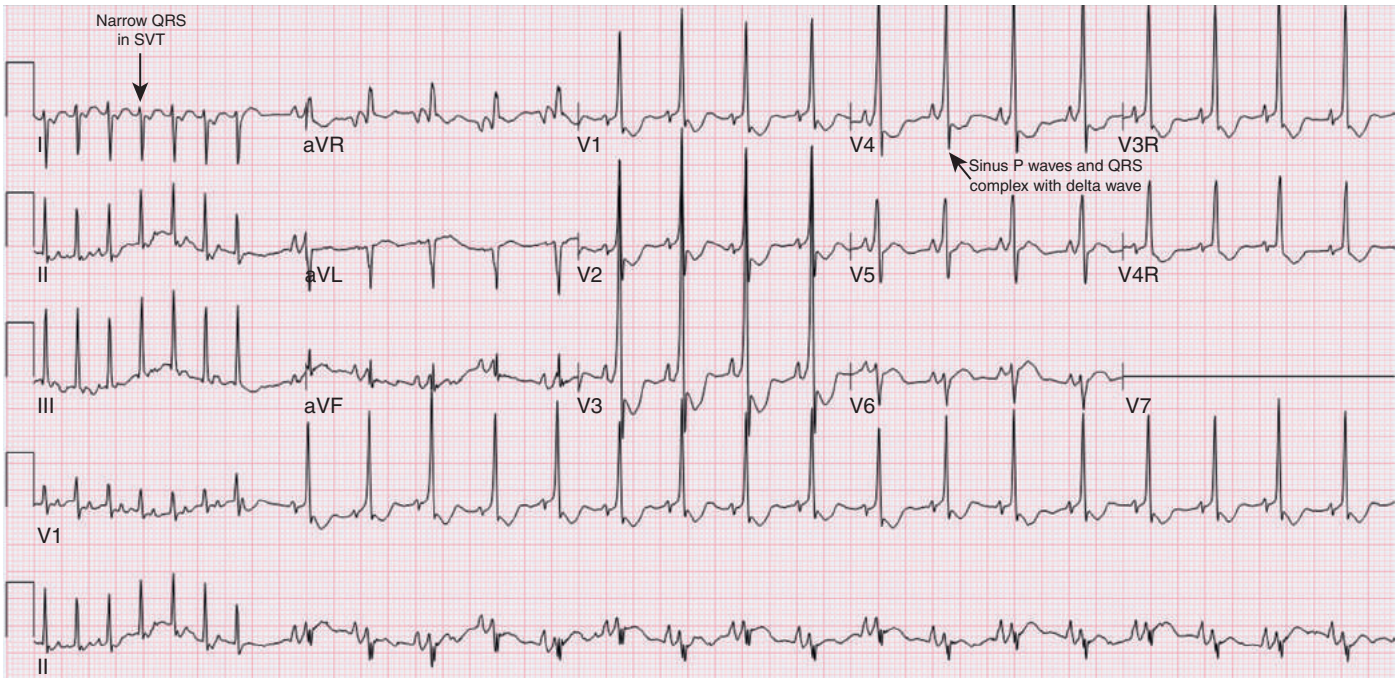
Acute management of ORT is directed at terminating the tachycardia and restoration of sinus rhythm. Slowing or transient blockade of AV nodal conduction is the mechanism by which most therapies work and includes vagal maneuvers (such as knee-chest position or diving reflex) and administration of adenosine. Initial adenosine doses of 0.05 to 0.1 mg/kg by rapid intravenous (IV) bolus are recommended for the neonate, with escalating doses as necessary. Direct current cardioversion for immediate arrhythmia termination can also be considered for the infant with impending collapse, although the risks versus benefits of this approach must be considered. For chronic medical therapy in infants prone to recurrent episodes of SVT, β-blockade in the form of propranolol is often used as a first-line agent. In some institutions, digoxin is used alone or in combination with propranolol. While calcium channel blockers are readily used in older children and adults for this indication, this class is generally avoided in a young infant due to the potential for significant myocardial depression. Second-line agents include sotalol, flecainide, and amiodarone. These medications are discussed further in the Management Considerations for Neonatal Tachyarrhythmias section later.

Permanent Form of Junctional Reciprocating Tachycardia

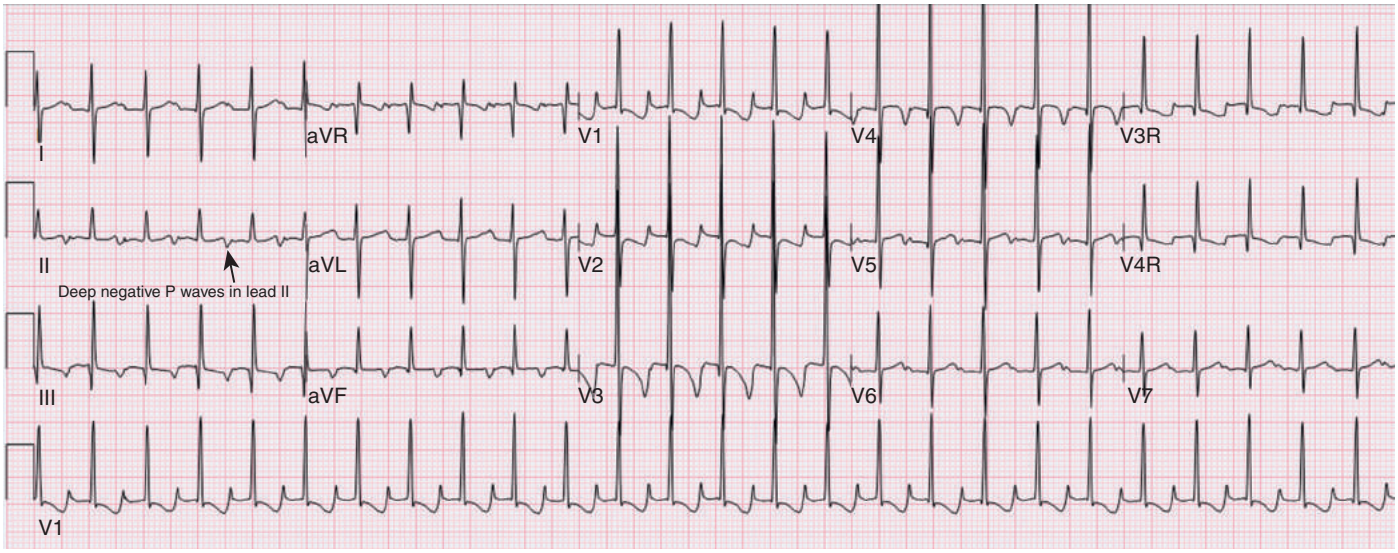
An unusual but particular vexing variant of ORT is the permanent form of junctional reciprocating tachycardia (PJRT). This is a reentry form of SVT that has rates that are usually far slower than the usual form of ORT, sometimes seemingly at the upper limits of the normal range for the newborn, around 180 to 200 bpm. However, PJRT has a tendency toward being an incessant arrhythmia, often spontaneously reinitiating immediately after tachycardia termination. The mechanism for PJRT is usually a concealed accessory pathway, typically located in the posterior septum or posterior tricuspid annulus. The conduction velocity of this retrograde limb is slower than in most other types of accessory pathways, resulting in a very long RP interval. Another hallmark feature is the presence of strongly negative retrograde P waves in the inferior leads, particularly lead II (Fig. 49.3). These infants often escape early detection as the tachycardia rates are not dramatically elevated, which can lead to delayed diagnosis and presentation with tachycardia-induced cardiomyopathy or congestive heart failure.[9] Treatment can be challenging as the arrhythmia has a tendency toward spontaneous reinitiation, even after successful termination of tachycardia. Medical therapy includes the drugs described above, although most infants with PJRT will require multiple agents for successful control of this arrhythmia.

Atrial Ectopic Tachycardia

Atrial ectopic tachycardia (AET) is a less common cause of SVT than ORT but is still well-represented among perinatal tachyarrhythmias. This is also known by other monikers, such as *ectopic atrial tachycardia* or *focal atrial tachycardia*. In contrast to reciprocating tachycardias, AET is not caused by a bypass tract but rather by a focus of cells in the atria that are more excitable than the sinus node and exhibit enhanced or triggered automaticity. As atrial activation originates from a location other than the sinus node, the P waves on surface ECG are usually quite distinctly different from normal (Fig. 49.4). The result is paroxysmal bursts of tachycardia, although prolonged and even incessant tachycardia can also be



• **Fig. 49.2** Wolff–Parkinson–White Syndrome. Spontaneous termination of orthodromic reciprocating tachycardia. Note change from narrow QRS in tachycardia, then wide preexcited QRS during subsequent sinus rhythm.

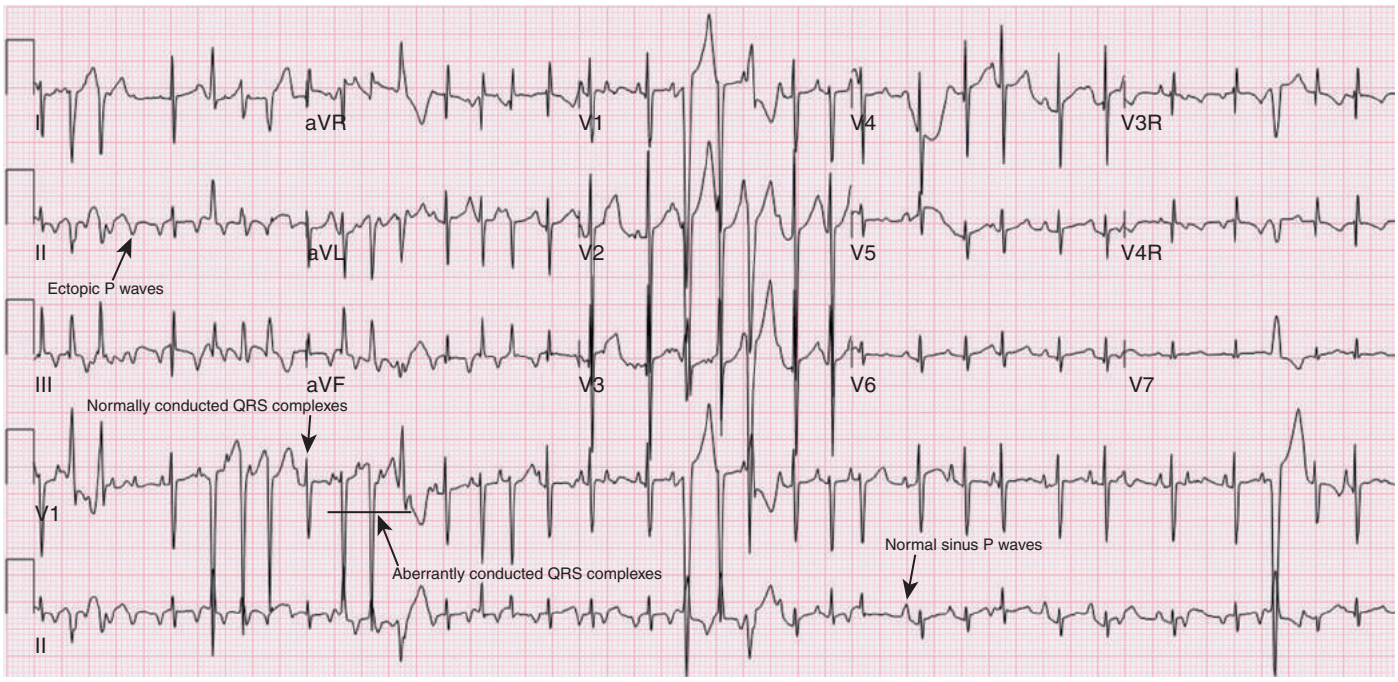


• **Fig. 49.3** Permanent Form of Junctional Reciprocating Tachycardia. Typical appearance of permanent junctional reciprocating tachycardia, with long ventriculoatrial time (ventriculoatrial > atrioventricular) and strongly negative P waves in inferior lead II, III, and aVF.

seen, which can lead to the development of tachycardia-induced cardiomyopathy.[10] This arrhythmia is often catecholamine-sensitive, with increased clinical signs during periods of activity or stimulation. Heart rates often vary during sustained tachycardia, and the rates can range from slightly faster than sinus rhythm to well over 300 bpm at times. Since the tachycardia does not depend on intact AV nodal conduction, intermittent AV block (such as 2:1 conduction or Wenckebach pattern) can sometimes be seen, and this feature is often used to aid in the correct diagnosis. By the same token, nodal blockade does little to affect this arrhythmia. Adenosine administration usually only transiently blocks the AV nodal conduction while the atrial arrhythmia continues unabated. While direct current cardioversion may interrupt the arrhythmia, it is likely to reinitiate spontaneously because of its paroxysmal nature.

Junctional Ectopic Tachycardia

Another automatic supraventricular arrhythmia of childhood is junctional ectopic tachycardia (JET). This is caused by increased automaticity of the cells around the AV junction resulting in direct activation of the His–Purkinje system. Heart rates range from



• **Fig. 49.4** Atrial Ectopic Tachycardia. P waves with unusual axis "march through" the tracing, with more P waves than QRS complexes on tracing. Wide aberrantly conducted QRS complexes are caused by "Ashman phenomenon" of conduction.

170 to 210 bpm and demonstrate the usual warm-up and cool-down behavior. The atrial activity may be conducted retrograde from the junctional activity or may be completely dissociated from it. JET can be either acquired or congenital. The acquired form can occur in up to 20% of patients following cardiopulmonary bypass for certain congenital cardiac surgeries[11] and can cause hemodynamic embarrassment because of the inherently unstable nature of those patients, even though the arrhythmia itself is fairly self-limited. The congenital form of JET is quite rare but, like atrial tachycardia, can be an incessant arrhythmia. Such patients can present with tachycardia-induced cardiomyopathy.[10]

Neonatal Atrial Flutter

Atrial flutter is a macro-reentrant arrhythmia that occurs entirely within the atria, with a depolarization wavefront that typically runs in a counterclockwise direction around the tricuspid valve annulus. The atrial rate is usually 300 bpm or greater, and the continuous atrial activation gives it a characteristic "sawtooth" pattern in the inferior leads, particularly lead II and III (Fig. 49.5). The atrial rate is exceedingly consistent and entirely independent of the ventricles, although varying degrees of AV conduction can be observed. While older infants and children might conduct every other (2:1) or every third (3:1) atrial impulse, the neonatal AV node has brisker conduction capability, so it may conduct each impulse (1:1), resulting in a very rapid ventricular rate. Administration of adenosine can be diagnostic by blocking AV nodal conduction while the flutter waves continue uninterrupted.

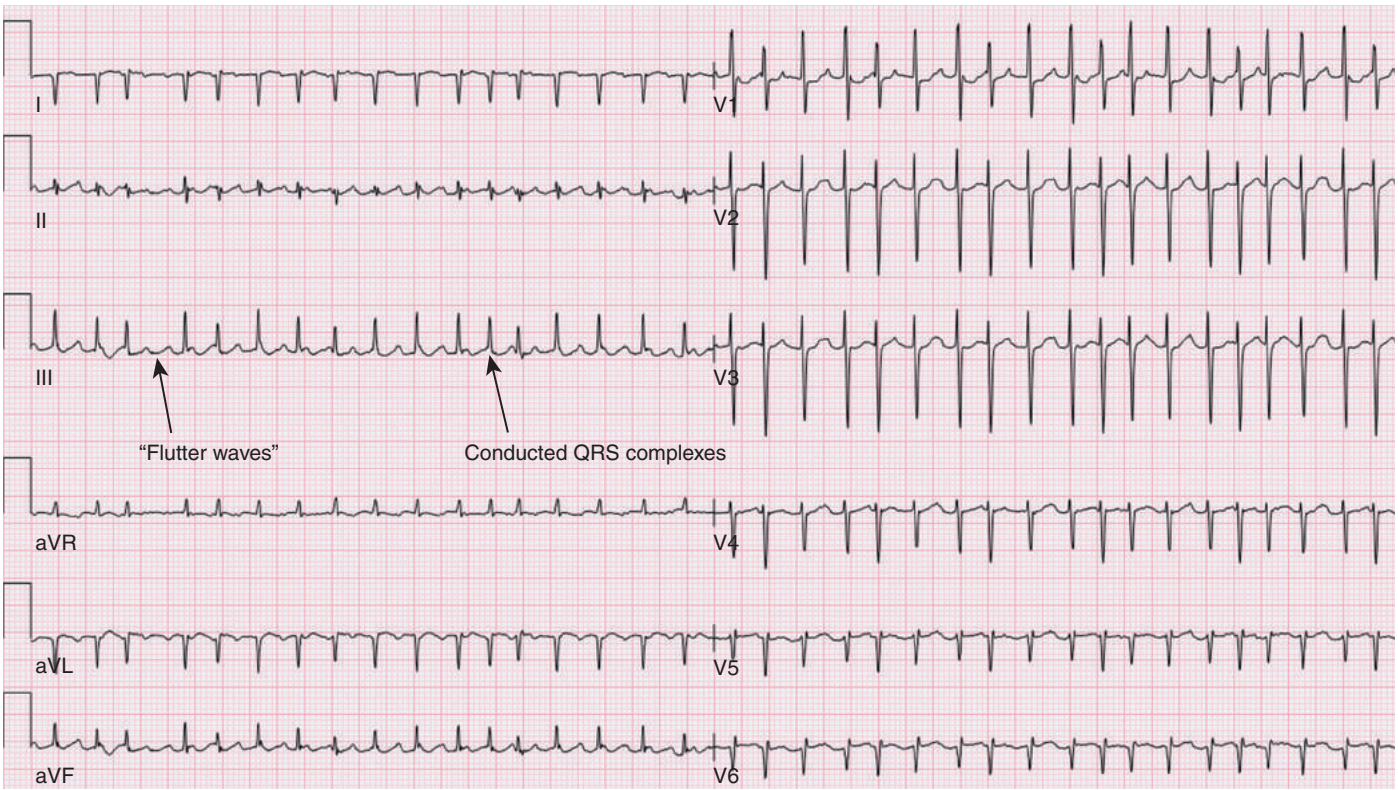
Medical therapy may be used to slow the ventricular rate. However, in most cases, direct current cardioversion is required; this is highly effective, and the recurrence risk is low.[12] In the fetus, there is often 1:1 conduction with a very rapid ventricular rate. When undetected and untreated, this can result in congestive heart failure, which manifests as hydrops fetalis. Detection and diagnosis may be difficult as it is unusual to be able to obtain a rhythm recording or ECG. A fetal echocardiogram may be able to demonstrate rapidly contracting atria (as discussed later). When necessary, fetal flutter may be treated by administering antiarrhythmic medications to the mother, although high maternal doses are often required to achieve adequate transplacental transfer to the fetus.

Ventricular Tachycardia

Ventricular tachycardia (VT) is a fairly uncommon arrhythmia in the perinatal period. It can take varied forms, ranging from a benign accelerated ventricular rhythm to a potentially life-threatening polymorphic VT. The latter is rarely encountered and occurs only in the setting of severe metabolic derangements or electrolyte disturbances or in the setting of an underlying congenital primary arrhythmia syndrome. VT may be suspected on the basis of a wide QRS complex tachycardia, although the differential diagnosis of such a rhythm includes a supraventricular rhythm conducted aberrantly, such as with a preexcitation pattern (as discussed earlier) or when conducted with a bundle branch block. However, in most instances, monomorphic VT is generally a benign entity in infancy and rarely requires intervention other than medical therapy.[13]

Accelerated idioventricular rhythm (AIVR) is a benign arrhythmia. Sometimes considered as "slow VT," AIVR is caused by enhanced automaticity of the ventricles and is usually due to intrinsic catecholamine states, electrolyte disturbances, or other conditions that predispose to increased automaticity. The hallmark is a monomorphic rhythm that originates in the ventricles but at rates that are only slightly faster than the normal sinus rates. This is generally well tolerated hemodynamically unless the infant is otherwise extremely compromised by other medical factors.

In contrast to the stability of monomorphic ventricular arrhythmias, polymorphic VT is a much more disorganized and potentially life-threatening arrhythmia and must be recognized



• **Fig. 49.5** Atrial Flutter. The atrial rate is approximately 360 beats per minute, with "flutter waves" visible in leads II, III, and aVF. Note that not all flutter P waves conduct equally to the number of QRS complexes.

and managed emergently. The ECG in polymorphic VT exhibits a rapid wide QRS complex, and the QRS morphology varies from beat to beat, indicating generally disordered ventricular depolarization. Cardiac output can be severely reduced. A particular variant of polymorphic VT is known as *torsades de pointes* (TdP). Literally "twisting about a point," the amplitude and axis of the QRS morphology rotate and undulate and can eventually degenerate into a more chaotic ventricular fibrillation. It is rarely seen in the neonate, except in the setting of primary arrhythmia genetic syndromes that are associated with sudden cardiac death, such as the long QT syndrome (LQTS) (as discussed later).

Management Considerations for Neonatal Tachyarrhythmias

Appropriate treatment of neonatal tachyarrhythmias depends largely upon prompt recognition and accurate diagnosis. The most common substrates for tachycardia in this subset are ORT and AET, in addition to neonatal atrial flutter. Orthodromic tachycardia can acutely respond to vagal maneuvers and (more reliably) to IV adenosine administration, although these methods will have little to no effect on either AET or neonatal flutter. Because of the increased likelihood of recurrent reentry tachycardia during early infancy, medical therapy is commonly utilized to decrease this possibility. Many infants can show no outward signs that they are experiencing tachycardia until incessant tachyarrhythmias result in dilated cardiomyopathy and cardiovascular collapse. Older infants and children will usually give more outward signs of being in a tachyarrhythmia, so they are less likely to present with cardiomyopathy and cardiovascular collapse.

Medical therapy for neonatal tachycardia varies considerably across institutions.[14] Digoxin selectively inhibits the sodium-potassium adenosine triphosphatase channel, which causes an increased intracellular sodium concentration. Other cardiac effects include a positive inotropic effect and an increased vagotonic effect. It is this latter effect that is suspected of contributing to the antiarrhythmic properties of the drug. In many institutions, digoxin was historically used most commonly for acute and chronic management of SVT, although its utilization varies greatly.[15]

Propranolol (Vaughan-Williams class II) is a nonspecific β-blocker medication that binds β-adrenergic receptors. This decreases overall sensitivity to adrenergic stimulation and has some direct effects on myocyte membrane potential. While the overall success of propranolol versus digoxin is comparable,[16] digoxin was less likely to succeed initially as monotherapy. In addition, digoxin is contraindicated in the Wolff–Parkinson–White syndrome because of enhancement of accessory pathway conduction properties, so ventricular preexcitation must be excluded before initiation of digoxin. The drug is also generally ineffective for AET. Enteral propranolol is increasingly used as first-line therapy for neonatal SVT, preferentially in high-volume treatment centers.[15] Particularly in the preterm newborn, the risk of β-blocker–associated hypoglycemia exists, so monitoring of blood glucose during initiation of propranolol therapy is recommended in this population.

Second-line agents include flecainide and sotalol, as well as amiodarone, and are highly effective in controlling the arrhythmia in incessant forms of neonatal SVT.[17] These drugs require closer monitoring because of their proarrhythmic effects. All three can potentially prolong the QT interval and potentially provoke ventricular arrhythmias. Flecainide (Vaughan-Williams class Ic)

inhibits the fast inward sodium current of the myocardial action potential and prolongs conduction through all cardiac tissues, particularly those of the His–Purkinje system and ventricular myocardium. This can result in a decreased ability of the conduction system to perpetuate SVT and is a very effective drug for treating SVT. Flecainide is bound by milk protein, and significant fluctuation in drug serum levels has been reported in neonates transitioning to oral feeds;[18] it can also prolong the QRS complex.

Vaughan-Williams class III medications used to treat perinatal SVT include sotalol and amiodarone. This class of drugs prolongs the action potential duration by extending the repolarization phase of the myocardium, thus increasing the overall refractory period of the tissue. This decreases the ability of the myocardium to support the repeated depolarizations necessary to support SVT. Sotalol exhibits β-blocker effects (class II) in lower doses and in higher doses exhibit more class III effects. Amiodarone is highly effective for acute and chronic management of tachyarrhythmias in the neonate; however, it must be judiciously used as it can have an effect on hypotension, bradycardia, heart block, cardiovascular collapse, and hypothyroidism. It has been reported to cause "neonatal gasping syndrome" and to leach plasticizers from polyvinyl chloride containers and syringes.[19] Because of the pharmacokinetics of amiodarone, it is usually administered by loading doses (in both IV and enteral dosing) for 7 to 10 days, after which the dose is decreased to a maintenance dose.

While commonly performed in older children, percutaneous catheter ablation for supraventricular arrhythmias is rarely performed in neonates and small infants. Technical issues and catheter size limit conventional mapping and ablation techniques. Late complications and deaths caused by injury to adjacent coronary artery structures have also been reported.[20]

While most ventricular arrhythmias in neonates are controllable and self-limited, certain conditions may predispose them to more life-threatening forms of VT. Particularly in cases in which defibrillation must be performed, for hemodynamically unstable VT or ventricular fibrillation, additional therapies must be considered. Reversible causes of TdP, such as electrolyte disturbances or drug-induced TdP, should be addressed by aggressive correction of the imbalance or removal of the offending agent(s). However, when no such cause can be identified, the etiology is often found to be a congenital arrhythmia syndrome, commonly LQTS (as discussed later). In more-affected infants, treatment with β-blocker medications may be used, and in severe cases with recurrent episodes of TdP or ventricular fibrillation in which the anticipated risk of sudden cardiac arrest is excessive, implantation of a pacemaker or a defibrillator might be considered; however, this must be weighed against the acute implantation issues and longer-term complications.

Bradyarrhythmias

Neonatal forms of bradycardia are few. In general, bradycardia is defined as sustained heart rates less than 100 bpm. This can be the result of normal physiologic causes or secondary to arrhythmias or abnormalities in conduction. Sinus bradycardia represents the most common mechanism in the neonate. This can be a normal physiologic variant (it is not uncommon to encounter a normal term neonate with a sinus rate of 90 bpm in the first 24 to 48 hours after birth, especially during sleep) or secondary to other causes (such as therapeutic hypothermia). Another common mechanism is vagal stimulation, which can be provoked by the presence of oral or nasal feeding tubes, endotracheal tubes, or episodes of gastroesophageal reflux.

Blocked Premature Atrial Complex

Atrial ectopy is commonly encountered in the fetus and newborn (discussed previously). In most instances, the premature atrial complex (PAC) normally conducts to a normal-appearing QRS complex. However, PACs that occur earlier in relation to the preceding QRS complex may find the conduction system or ventricular myocardium refractory to stimulation. Thus the PAC is not followed by any ventricular depolarization. This is described as a "blocked PAC." Most often, this is observed when a PAC occurs in the early portion of the preceding T wave, such that the ventricles are still in their refractory period and cannot depolarize. Conditions that affect the refractoriness of either the AV nodal conduction or myocardial refractoriness, such as increased vagal tone or metabolic acidosis, can also increase the likelihood that a PAC is blocked. Following the premature atrial depolarization, there is typically a delay before the subsequent sinus return beat. When atrial ectopy is frequent, as in blocked atrial bigeminy, the net effect is a functional "halving" of the sinus rate (Fig. 49.6).

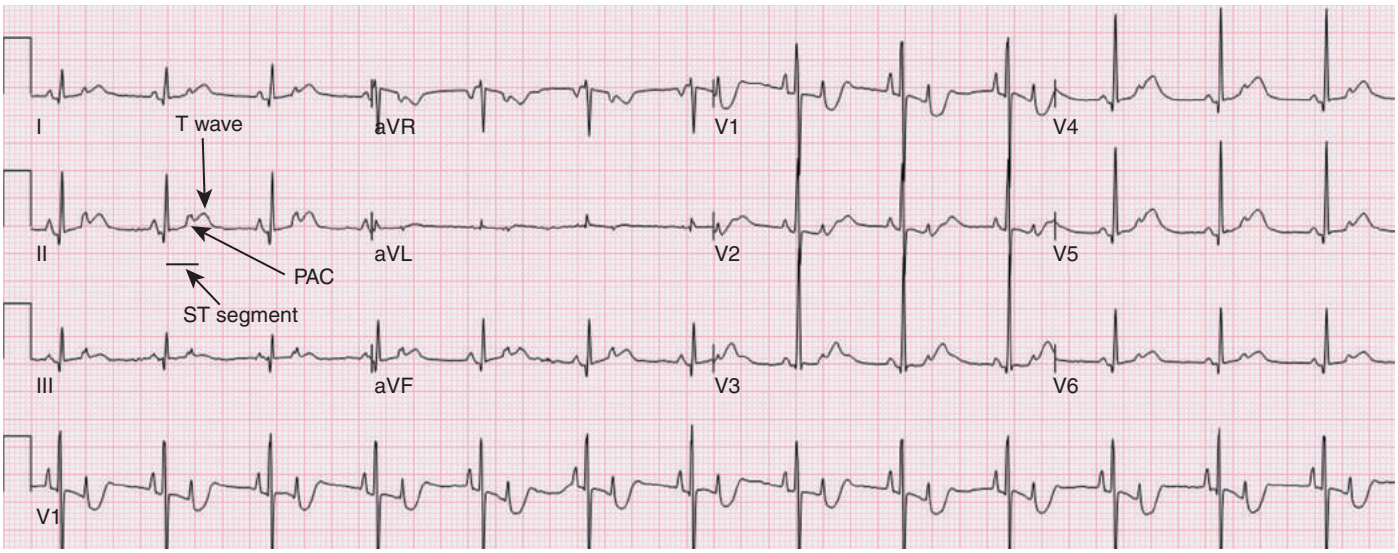
Long QT Syndrome

In severe forms of congenital LQTS, the QT prolongation can result in bradycardia in the fetus or the newborn. When the repolarization phase becomes significantly prolonged, the subsequent sinus P wave may fail to conduct normally or at all as the ventricular myocardium is still refractory to stimulation. As a result, the functional heart rate is halved since the ventricular rate is conducted 2:1 from the sinus rate. This can have significant implications as the bradycardia may not be tolerated by the patient. Chronotropic medications for this condition may do little to improve the functional heart rate as increasing the frequency of sinus P waves does not shorten the refractory period of the ventricular myocardium. Permanent pacemaker implantation may be necessary. In addition, the functional nature of this "2:1" heart block can result in irregularities in the conduction pattern (Fig. 49.7). This can result in profound QT prolongation as well as triggering VT and TdP.

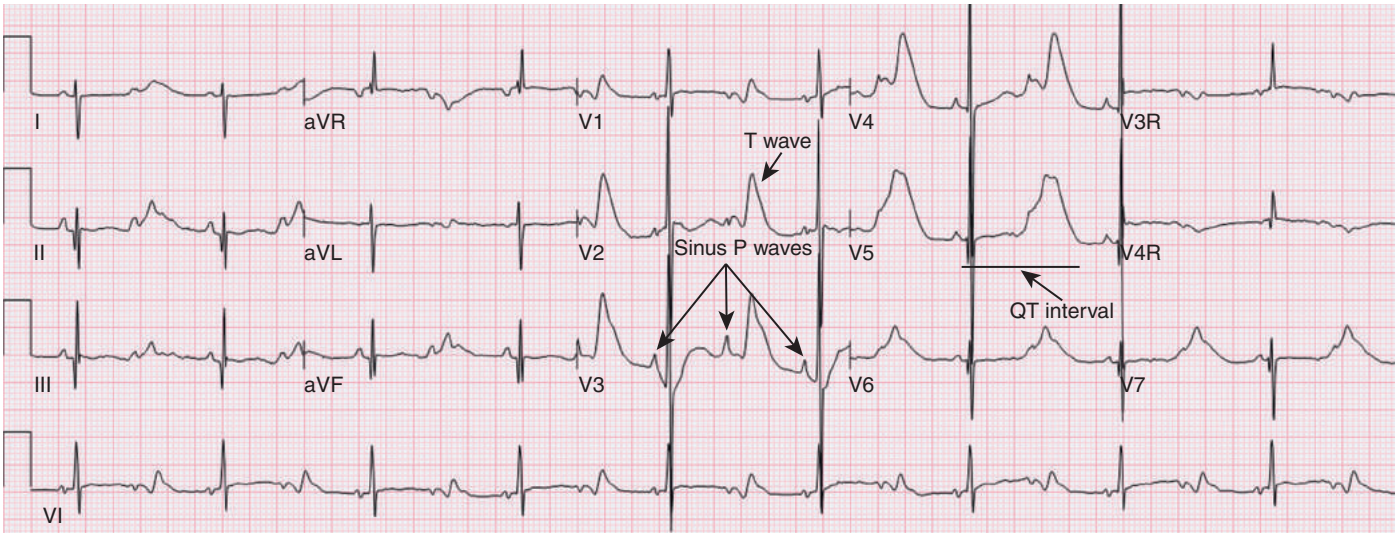
Congenital Complete Atrioventricular Block

Congenital complete AV block (CCAVB) is the absence of AV conduction. This is rather uncommon, occurring in only 1 in 15,000 to 1 in 20,000 births.[21] It is commonly associated with maternal lupus, although it also occurs in the absence of any known maternal disease. Fetal exposure to maternal autoantibodies (most commonly anti-SSA/Ro and anti-SSB/La antibodies) results in fibrosis of the AV nodal structures, leading to a progressive destructive process. There is some evidence that early treatment with high-dose maternal steroids could delay or even arrest this process;[22] however, the reported response rate to therapy is highly variable,[23–25] so the risk-benefit ratio of this therapy must be weighed on an individual basis. When detected, the fetus is monitored frequently for the development of hydrops fetalis, a sign of congestive heart failure in the fetus.

Complete heart block can also occur in the fetus or newborn in the setting of CHD, most commonly those defects that involve "L-transposition of the great arteries" or "ventricular inversion." In these conditions, fetal looping of the heart results in the His bundle being a far more superficial structure than normal and therefore prone to fibrosis. Development of complete heart block



• **Fig. 49.6** Premature Atrial Complexes. Premature atrial complexes (PAC) occurring on ST segments fail to conduct to ventricles resulting in "blocked atrial bigeminy."

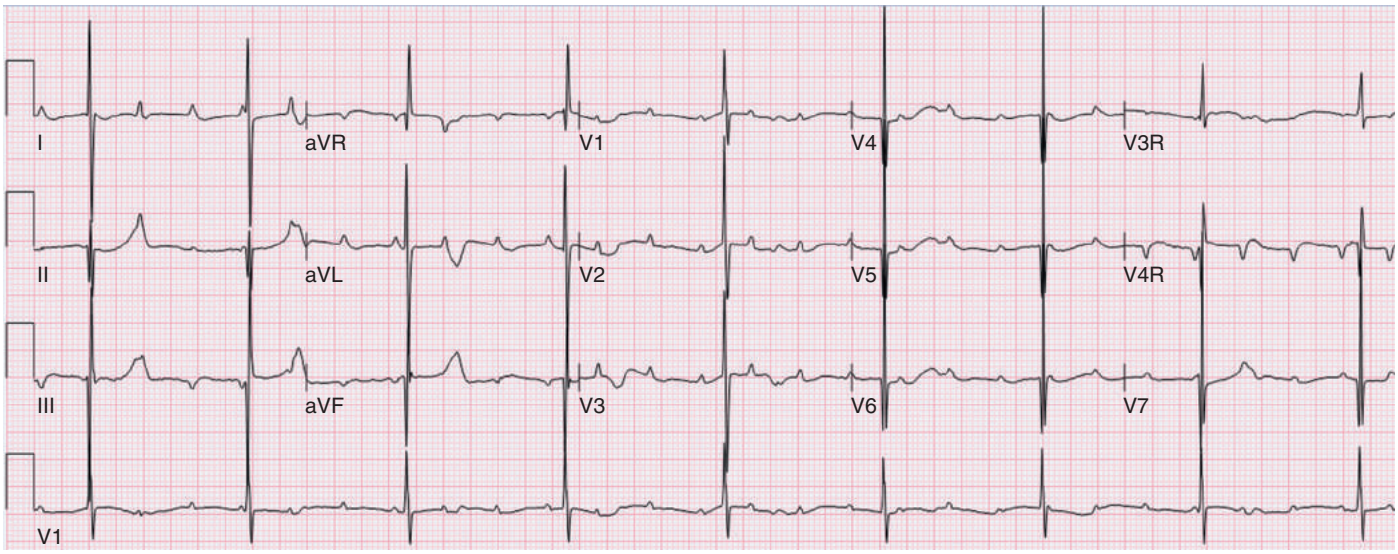


• **Fig. 49.7** Long QT Syndrome With 2:1 Functional Heart Block. The sinus rate is 110 bpm. The QT interval is profoundly prolonged (QTc = 751 ms), so every other sinus P wave cannot conduct because of the ventricular refractory period.

in this setting can occur at any stage of development and often does not occur until later childhood or adulthood.

In most cases of CCAVB, the region around the bundle of His remains intact and can exhibit normal properties of automaticity. This "junctional escape rhythm" typically results in a normal narrow QRS complex and ventricular contractility, despite the lack of AV conduction. It has the appearance of a normally conducted sinus beat but is completely dissociated from the sinus nodal P waves occurring above (Fig. 49.8). The escape rate in the fetus and neonate is often 60 to 80 bpm and can provide adequate cardiac output. There are many instances in which CCAVB is completely undetected in the newborn period and remains undetected for many years. The QRS complex may be wide (greater than 70 ms in the newborn) if there is extensive damage to the junctional region, implying that the escape rhythm arises from a location lower on the septum or from the ventricular myocardium itself.

However, a slower junctional escape rhythm, usually when the rate is below 50 bpm, is inadequate to support normal cardiac output. Signs of congestive heart failure may become manifest. In the fetal circulation, where the pulmonary vascular bed is largely bypassed by the ductus arteriosus, this will manifest as hydrops fetalis or intrauterine fetal demise. Management of the fetus with inadequate junctional escape rate and signs of poor cardiac output are addressed in the Fetal Rhythms section of this chapter. For the postnatal patient, signs of low cardiac output would include respiratory distress (with pulmonary congestion), poor perfusion, metabolic acidosis, low urine output, and frank edema. This can present a clinical challenge. Heart rate and blood pressure may be augmented by inotropic and chronotropic drip medications such as isoproterenol, epinephrine, and dobutamine. In some centers, temporary transvenous pacing may be utilized for emergent rescue, but this can be challenging because of the size disparity between



• **Fig. 49.8** Congenital Complete Atrioventricular Block. The sinus nodal rate is approximately 150 bpm, but there is complete atrioventricular dissociation with a junctional escape rate of 50 bpm.

commercially available temporary pacing leads and the small vessel size in this population.[26] Permanent pacemaker implantation is indicated if there is evidence of ventricular dysfunction or low cardiac output in the neonate with a heart rate less than 55 bpm (or less than 70 bpm in the setting of concurrent CHD) or if there is evidence of a wide QRS complex escape rhythm.[27,28] Box 49.1 summarizes the absolute and relative indications for pacemaker implantation in the neonate with CCAVB.

Fetal Arrhythmias

Fetal arrhythmias occur in 1% to 2% of pregnancies, with resultant hemodynamic compromise, hydrops fetalis, and fetal demise occurring in 10% of cases.[29,30] The arrhythmias may develop late in the second or third trimester; this is particularly true for premature contractions, atrial tachycardias, and VTs, which often do not manifest before 25 to 26 weeks' gestation and, in some cases, only in the third trimester.[31,32] Fetal arrhythmias require close monitoring, as even benign rhythms may have a small risk of complications. The standard modality for prenatal evaluation of fetal arrhythmias is via fetal echocardiography, focusing on the mechanical atrial and ventricular systoles and their relationship to one another (Fig. 49.9A and B) as a surrogate for AV synchrony/dyssynchrony.[33–35] Investigation of the fetus referred for an abnormal rhythm should focus on causes of impaired AV conduction and causes of abnormal atrial or ventricular rhythms, including varying degrees of AV block, congenital LQTS, myocarditis, intracardiac tumors, and structural CHD. Differentiation between types of arrhythmia mechanisms is helpful in determining the most optimal therapy and the likelihood of success of arrhythmia treatment.

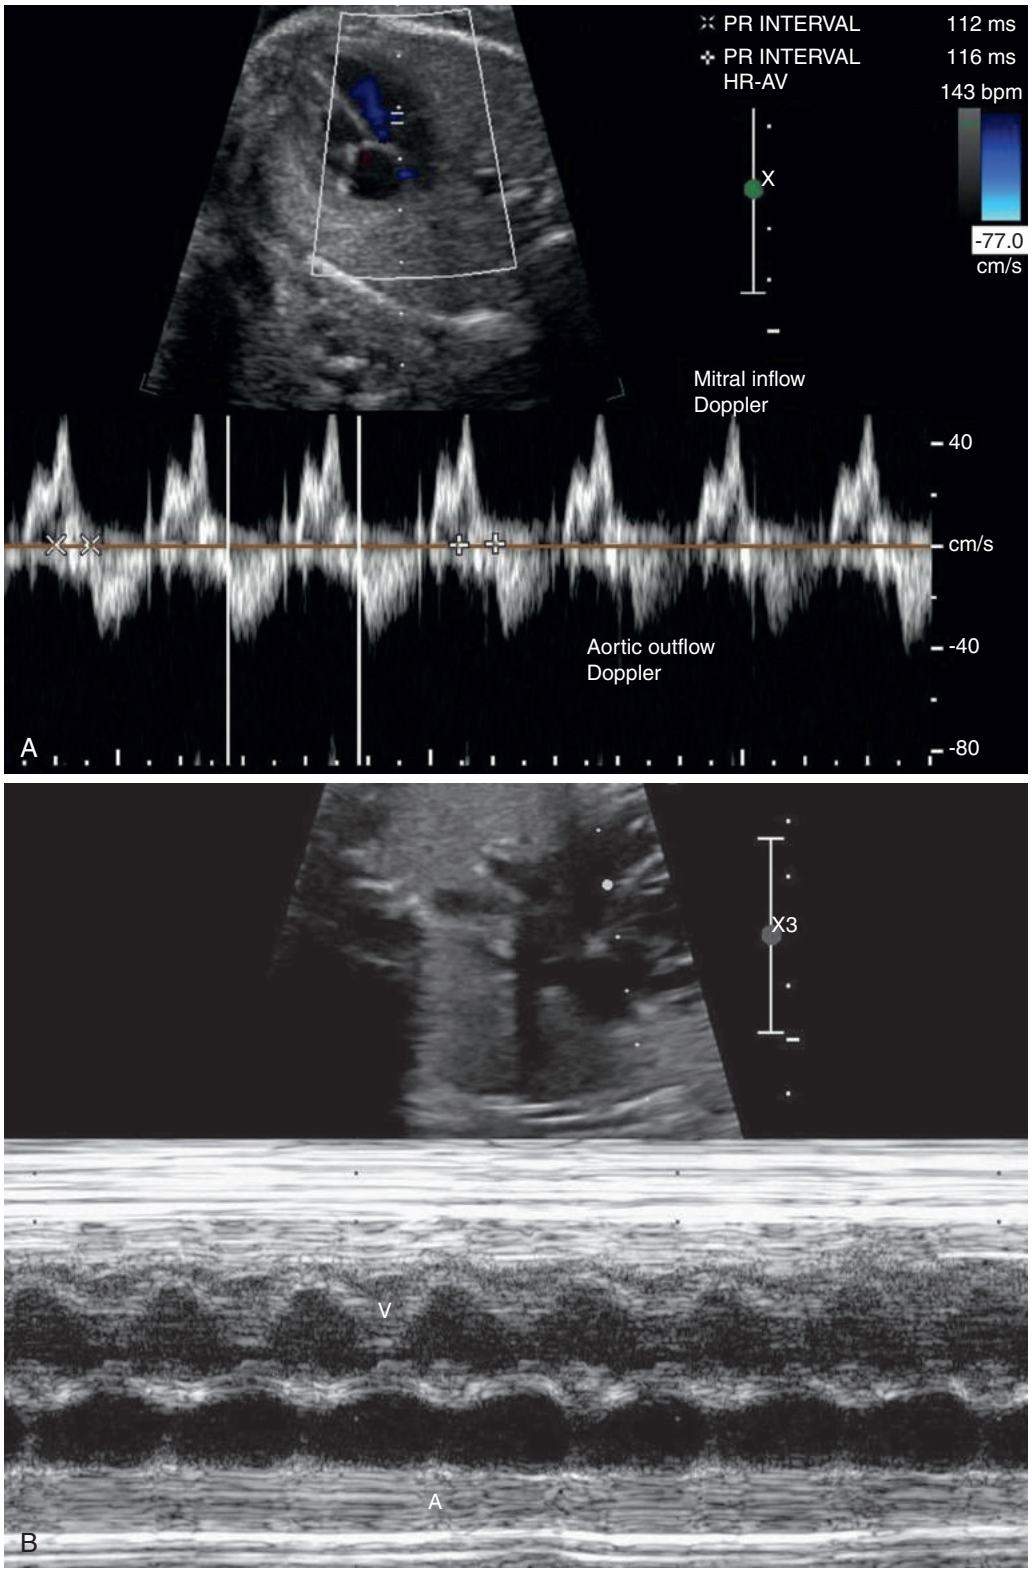
Benign Arrhythmias

One of the most common reasons for referral to the fetal cardiologist is irregular fetal heart rhythms, noted in 1% to 3% of pregnancies.[36] The causes of these irregular rhythms are often isolated premature atrial contractions.[37] Rarely, they may be ventricular in origin. The vast majority of these atrial ectopic beats are benign; premature atrial contractions have a small risk (0.5% to 1%) of developing into a fetal tachycardia.[38] However, 2% of cases may be associated with fetal LQTS, atrial flutter, and second-degree AV block.[39]

• BOX 49.1 Indications for Permanent Pacing in Congenital Complete Atrioventricular Block

- Permanent pacemaker implantation is indicated for patients with CCAVB with symptomatic bradycardia.
- Permanent pacemaker implantation is indicated for patients with CCAVB with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction.
- Permanent pacemaker implantation is indicated for CCAVB in asymptomatic neonates or infants when the mean ventricular rate is ≤50 bpm or lower. Ventricular rate alone should not be used as implant criteria, as symptoms due to low cardiac output may occur at faster heart rates.
- Permanent pacemaker implantation is indicated for CCAVB in neonates or infants with complex CHD when bradycardia is associated with hemodynamic compromise or when the mean ventricular rate is <60–70 bpm.
- Permanent pacemaker implantation is reasonable for asymptomatic CCAVB beyond the first year of life when the mean ventricular rate is ≤50 bpm or there are prolonged pauses in ventricular rate.
- Permanent pacemaker implantation is reasonable for CCAVB with left ventricular dilation (z score ≥3) associated with significant mitral insufficiency or systolic dysfunction.
- Permanent pacemaker implantation may be considered for CCAVB in asymptomatic adolescents with an acceptable ventricular rate, a narrow QRS complex, and normal ventricular function, based on individualized consideration of the risk/benefit ratio.

CCAVB, congenital complete atrioventricular block; *bpm*, beats per minute.
From Writing Committee Members, Shah MJ, Silka MJ, et al. 2021 PACES expert consensus statement on the indications and management of cardiovascular implantable electronic devices in pediatric patients. *Heart Rhythm*. 2021;18(11):P1925–1950.



• **Fig. 49.9** Fetal echocardiogram performed from a coronal view of the fetus demonstrating a four-chamber view of the heart with normal fetal heart rate (146 bpm) with 1:1 atrioventricular conduction via (A) normal mitral valve inflow and aortic valve outflow spectral Doppler. The measurement between the inflow and outflow is the PR interval (XX and ++ = 116 ms). (B) M-mode diagonally across the four-chamber heart measures the movement of the atrial (A) and ventricular (V) free wall. *bpm*, Beats per minute; *HR-AV*, heart rate measured from aortic valve Doppler.

Management of Benign Arrhythmias

The 2014 American Heart Association scientific statement for the diagnosis and treatment of fetuses with irregular rhythms[40] recommends that fetuses with frequent ectopic beats (bigeminy, trigeminy, or more than every 3 to 5 beats on average) should have a baseline fetal echocardiogram to assess cardiac structure and function and to determine the mechanism of the arrhythmia (Fig. 49.10). Medical treatment is not recommended for premature atrial contractions. If frequent ectopy continues, weekly fetal heart rate monitoring to assess for progression to tachycardia should be performed until it resolves. In fetuses with less frequent extrasystoles, a fetal echocardiogram is indicated if the irregular rhythm persists beyond 1 to 2 weeks or if there is difficulty differentiating a benign rhythm from a pathologic one.[40] A postnatal ECG should be performed if an irregular rhythm is auscultated after birth.

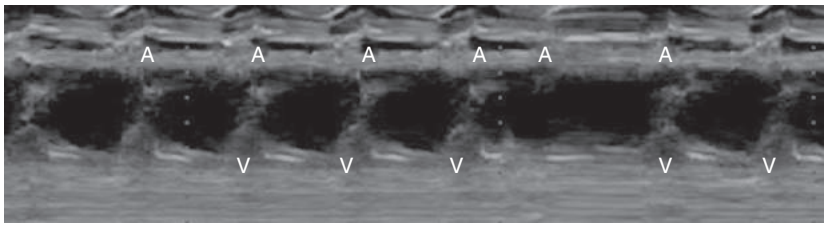
Fetal Tachycardias

Fetal tachycardia constitutes a rare but important cause of perinatal morbidity and mortality. Sustained SVT includes ORT (70%), atrial flutter (30%), and rare tachyarrhythmias and usually occurs at rates greater than 220 bpm.[36] The type of SVT can be determined using the mechanical PR interval derived from either the spectral Doppler of the mitral inflow and aortic outflow or the superior vena cava and aorta. Management for a given fetus can then be assessed based on the type of suspected SVT (Table 49.2). VT is a much less common cause of fetal tachycardia as are chaotic or multifocal atrial tachycardia.

In general, the goal of in utero treatment of fetal tachycardias is not conversion to 100% sinus rhythm but instead to establish sufficient sinus rhythm to allow resolution of hydrops and ventricular dysfunction. Management depends on the gestational age at presentation, degree of fetal compromise, maternal conditions, and potential risks to the mother from therapy.[40] Emergent delivery should be reserved for the hydropic fetus who exhibits persistent tachycardia refractory to medical management.[37] Delivery can be considered as a primary management strategy if the fetus is near term and if delivery incurs no significantly increased risk to the neonate.[40]

Orthodromic Reentrant Tachycardia

ORT accounts for approximately 70% of fetal tachycardias.[36] It usually presents with intermittent or sustained heart rates in the range of 240 to 260 bpm and is identified on fetal echocardiogram by the short RP interval (ventriculoatrial [VA] activation time),



• **Fig. 49.10** M-mode of the Fetal Heart Demonstrating an Isolated Premature Atrial Contraction. There is normal atrioventricular conduction at a normal rate until the fifth labeled atrial beat (A) that is early (ectopic) and results in a blocked ventricular beat (V).

TABLE 49.2 Fetal Supraventricular Tachycardia (SVT)

SVT Category	Gestational Age	Typical Rates	Atrioventricular Relationship	Onset/Termination	Transplacental Therapy
Short VA SVT • AVRT, ORT, AVNRT • Accounts for 60%–70%	>18 weeks	>180 bpm (210–320 bpm)	• 1:1 • VA interval less than ½ of the VV interval • VA/AV ratio <1	• Sudden onset/offset • Blocks in the AV node, terminates with non-conducted atrial beat	• First line: digoxin • Second line: sotalol or flecainide (± digoxin) • Third line: amiodarone
Long VA SVT • EAT, PJRT	>12 weeks	170–220 bpm	• 1:1 but may be variable (EAT) • VA interval greater than ½ of the VV interval • VA/AV ratio >1	• Gradual onset and offset (EAT) • Terminates with a nonconducted ventricular beat	• First line: flecainide • Second line: sotalol • Third line: amiodarone
Atrial flutter • Accounts for 25%–30%	>28 weeks	Atrial rate: 300–550 bpm Ventricular rate: 180–240 bpm	• Variable AV conduction (primarily 2:1 or 3:1) • Fixed ventricular rate		• First line: sotalol or flecainide • Second line: add digoxin • Third line: switch to amiodarone

In the setting of hydrops, may require combination therapy (digoxin+sotalol or digoxin+flecainide).
VA, ventriculoatrial; *AV*, atrioventricular; *VV*, ventriculoventricular.

1:1 AV relationship, and fast ventricular rate (Fig. 49.11). This rhythm results from conduction down the AV node to the ventricles and retrogrades through an accessory pathway to the atrium. Generally, reentrant ORT presents between 28 and 33 weeks' gestation.[41] Progression to hydrops is not uncommon, with risk factors being tachycardia duration, fetal immaturity, and concurrent structural heart disease.[29,41]

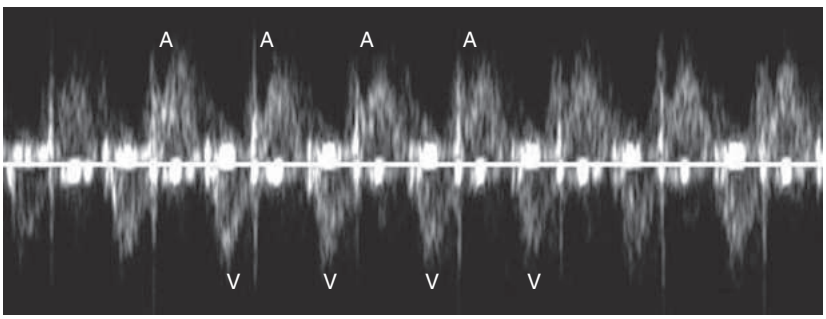
Intrauterine fetal treatment is recommended if delivery does not offer a lower risk. The first-line and second-line antiarrhythmic therapy choices are controversial, as are the management strategies after initial treatment failure. The use of combination therapies presents a greater risk for maternal and/or fetal complications, and thus monotherapy is recommended. Digoxin, flecainide, and sotalol as monotherapy have all been used successfully as first-line therapies for reentrant SVT,[42–44] though the use of digoxin is controversial because of the very small risk of atrial fibrillation with rapid antegrade conduction across an accessory pathway.[45] There is no study to date that supports one as the superior treatment option. All three of these medications, as well as amiodarone, have also been used as second-line therapy.[40] Amiodarone has a more significant toxicity profile for the mother and fetus and should be reserved as a third-line treatment for life-threatening arrhythmias. It should be discontinued once hydrops resolves. Verapamil and procainamide are no longer used to treat fetal tachyarrhythmias.[40] Transplacental transfer of drugs is reduced in the setting of hydrops; thus, direct fetal treatment (to the fetal buttock/thigh or intracordal) concomitantly with transplacental therapy has been described for restoration of sinus rhythm. These strategies should be limited to severely hydropic fetuses who cannot be delivered because of early gestational age, as there is an associated risk of fetal death.[46,47]

After delivery, up to 50% of reentrant SVT cases will not have postnatal recurrence.[29] Thus, medical treatment must be reassessed relative to the length of time since the last occurrence and the mechanism of clinical tachycardia.

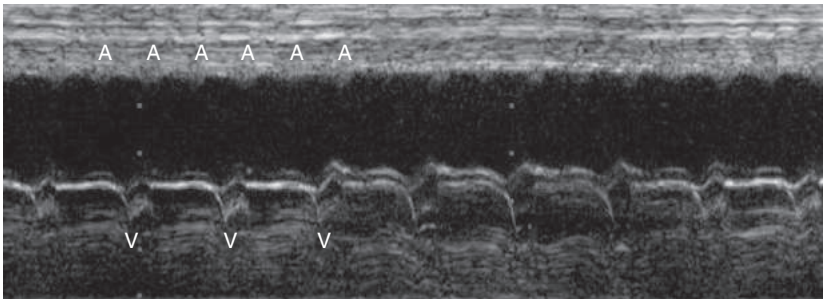
Atrial Flutter

Atrial flutter accounts for approximately 30% of fetal tachycardias.[36] It is associated with fetal myocarditis, structural CHD, and in utero exposure to SSA/SSB antibodies. It is typically characterized by atrial rates of 300 to 500 bpm and slower ventricular rates (150 to 170 bpm) because of a physiologic block in the AV node. It is best identified on fetal echocardiogram using an M-mode across an atrial free wall, interventricular septum, and ventricular free wall (Fig. 49.12). Atrial flutter is more likely to present later in pregnancy than reentrant SVT, at around 31 to 34 weeks gestation. It is generally a well-tolerated rhythm because of the lower ventricular rates.[33,36] However, the rhythm can remain undiagnosed prenatally because of the relatively normal fetal ventricular rates.[34] The lack of variability in the heart rate provides a clue to the diagnosis. Atrial flutter can co-occur with reentrant SVT in 12% to 33% of affected fetuses.[12]

Sotalol has been shown to be effective in converting 50% to 80% of fetuses with atrial flutter without mortality[44] and is considered first-line therapy. Digoxin is also recommended as first-line therapy, and amiodarone may be considered; however, procainamide is contraindicated.[48] Transesophageal pacing of synchronized cardioversion is recommended after delivery to restore sinus rhythm. Sinus node suppression may rarely occur due to in utero therapy, and backup external pacing should be available after cardioversion. Postnatal medical treatment should be reassessed given that atrial flutter may not recur.[40]



• **Fig. 49.11** Fetal Mitral Inflow and Aortic Outflow Spectral Doppler Demonstrating Reentrant Supraventricular Tachycardia. There is 1:1 atrioventricular conduction (A and V labels) at a steady rate of 238 beats per minute. The RP interval is 100 ms.



• **Fig. 49.12** M-mode of the fetal heart demonstrating 2:1 atrial flutter with an atrial rate of 120 beats per minute and a ventricular rate of 260 beats per minute. *A*, Atrial flutter waves; *V*, ventricular activation.

Sustained Ventricular Tachycardia

Fetal VT is associated with AV block, cardiac tumors, myocarditis, and ion channelopathies. LQTS should be suspected when tachyarrhythmia and bradyarrhythmia coexist.[49] Fetuses with LQTS can develop rapid TdP and monomorphic VT with subsequent development of ventricular dysfunction, AV valve insufficiency, and hydrops. Fetal magnetocardiography or ECG can confirm the diagnosis by identifying a prolonged QTc interval.[50–52] Intrauterine IV magnesium is recommended as first-line therapy for VT greater than 200 bpm, and treatment should be limited to less than 48 hours. If maternal magnesium levels are less than 6 mEq/L and there are no signs of toxicity, redosing can be considered. IV lidocaine, oral propranolol, or mexiletine may also be considered in conjunction with magnesium, especially in the setting of hydrops. If LQTS can be excluded, then sotalol, flecainide, and amiodarone are alternative therapies and have been shown to be successful in terminating fetal VT. Dexamethasone and IV infusion of immunoglobulin (IVIG) have been used in the setting of antibody-mediated or myocarditis-associated VT.[40]

Rare Tachycardias

Less common tachycardias such as AET and PJRT can be differentiated by the long RP interval (VA time) on fetal echocardiogram. The two can be differentiated by the gradual warm-up phase and variable AV nodal block at faster rates characteristic of AET and the sudden onset and consistent heart rate of PJRT. AET generally occurs at rates of 180 to 250 bpm and is most refractory to treatment both before and after birth.[36] These fetal tachycardias occur in the late second or third trimester. Multifocal atrial tachycardia is rare (associated with Costello syndrome) and usually occurs in the last weeks of pregnancy.[53] JET is commonly associated with SSA antibody exposure in the fetus and can be seen in the presence or absence of AV block. For AET and multifocal atrial tachycardia, treatment is recommended for average heart rates greater than 200 bpm with normal cardiac function or greater than 160 bpm with cardiac dysfunction.[40] Digoxin is recommended as the first-line therapy, though flecainide and sotalol may be considered. Flecainide or sotalol are recommended for PJRT or rapid AET. Similar therapies can be used for the medical management of fetal JET, though amiodarone has also been used. Fetuses that develop JET in the setting of anti-SSA antibody exposure can be treated with dexamethasone as well. After the delivery of a fetus with these rare tachycardias, continued medical treatment is usually required.

Sinus Tachycardia

Sinus tachycardia at rates of 180 to 190 bpm may mimic other pathologic tachycardias; however, ventricular dysfunction and hydrops are uncommon. Sinus tachycardia is associated with maternal infection, anemia, drug/medication use, hyperthyroidism, or trauma. Treatment of the underlying cause is recommended.[40]

Arrhythmia Medications

Relatively high doses of antiarrhythmic agents must be administered during pregnancy because maternal circulating blood volume and renal clearance are both increased. Thus, timing and strategies for fetal arrhythmia management must be carefully considered (Table 49.3). In most cases, treatment should be initiated in the hospital with close observation of maternal and fetal well-being. A baseline maternal ECG and electrolytes, as well as a cardiology consultation, should be obtained before the initiation of medications to assess for maternal risk factors such as preexcitation or LQTS. Serial maternal ECG, electrolyte concentrations, and drug levels should be monitored throughout the duration of therapy. Oral medication administration is recommended, except for IV magnesium and lidocaine and for digoxin loading doses.[40] Most arrhythmia medications demonstrate diminished transplacental transfer in the setting of hydrops, with the efficacy of digoxin decreasing to 25%.[37] However, flecainide and sotalol have been shown to be efficacious in the setting of hydrops.[40] If the maternal PR, QRS, or QT intervals are noted to prolong during therapy with digoxin, flecainide, or sotalol, respectively, doses should be decreased, and close observation is recommended. Serious maternal adverse reactions are rare and have resolved with discontinuation of therapy.[40]

Fetal Bradycardia

Fetal bradycardia is defined as a persistent heart rate of less than 120 bpm. Causes include sinus bradycardia secondary to sinus node dysfunction, channelopathies, maternal exposures/conditions, fetal central nervous system involvement, and blocked atrial bigeminy, which is associated with a 10% risk for conversion to SVT. The most common cause of fetal bradycardia is congenital AV block, occurring in approximately 1:20,000 live births.[54] Approximately 50% of fetal AV block is secondary to structural heart disease, and 40% is due to immune-mediated mechanisms,[55,56] and an additional 10% is idiopathic. Fetal congenital heart block at low heart rates is associated with significant morbidity and mortality, especially when associated with maternal autoimmune disorders. Management of fetal bradycardia is focused on frequent fetal echocardiographic evaluations to assess for the development of ventricular dysfunction, hydrops, or fetal heart rate less than 55 bpm. Treatment of nonimmune-mediated heart block is directed at augmenting fetal ventricular rates. For immune-mediated AV block, several therapies may be considered and are controversial.[22]

Benign Fetal Bradycardia

Maternal treatment with β-blockers, sedatives, and other medications has been associated with sinus node suppression. Fetuses with exposure to maternal anti-SSA/SSB antibodies or those with myocarditis may develop inflammation and fibrosis of the sinus node. Finally, fetuses with heterotaxy syndrome may develop

TABLE 49.3 Fetal Tachyarrhythmia Treatment Strategies

Tachycardia Duration	Treatment Strategy
Intermittent SVT OR Sustained* SVT <200 bpm without hydrops or hemodynamic compromise	• Observe without therapy • At least weekly fetal heart rate monitoring • Periodic fetal echocardiogram
Sustained* SVT ≥200 bpm with/without hydrops OR Intermittent SVT with hydrops or hemodynamic compromise	• Gestational age <37 weeks: transplacental antiarrhythmic therapy • Gestational age >37 weeks: deliver

*Sustained: >12 hours in a 24-hour monitoring period or >50% of echo scan time.
SVT, Supraventricular tachycardia.

bradycardia secondary to a low-atrial rhythm in left-atrial isomerism or dual sinoatrial nodes in right-atrial isomerism. In these conditions, fetal heart rates range between 90 and 130 bpm. No treatment is recommended.[40]

Blocked atrial bigeminy may result in fetal heart rates between 75 and 90 bpm with 2:1 AV conduction and can be mistaken for second-degree AV block. There is an increased risk of the development of fetal SVT, occurring in approximately 10% of fetuses with blocked atrial bigeminy.[40] Fetal echocardiography may demonstrate normal AV conduction followed by an early atrial beat coupled to the preceding ventricular beat, in which case the AV node is refractory. This results in failure of conduction to the ventricle (see Fig. 49.10). Management of blocked atrial bigeminy is the same as for isolated premature atrial contractions.

Ion Channelopathies

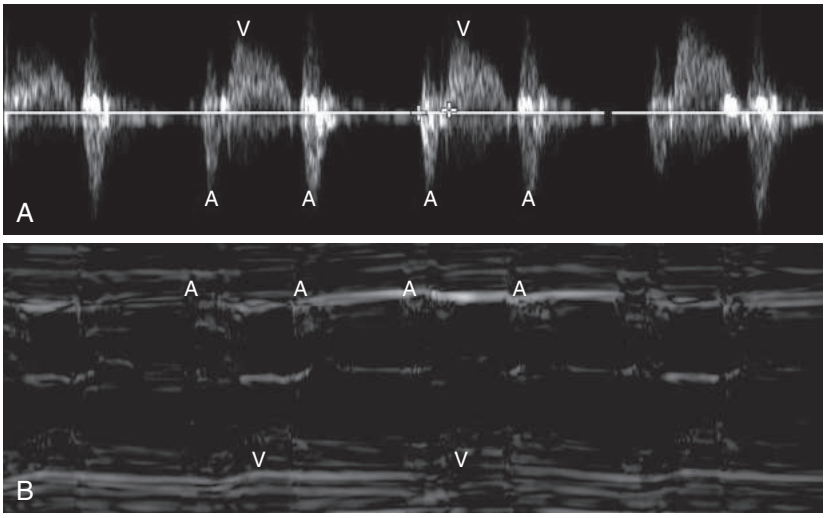
Congenital LQTS should be considered in the setting of persistent bradycardia in an otherwise asymptomatic fetus.[57] Measurement of the QTc can be performed by magnetocardiogram or fetal ECG.[50–52] Fetal treatment is not recommended; however, the development of VT requires treatment as delineated in the Fetal Tachycardia section. Management involves close observation prenatally, correction of maternal electrolyte abnormalities, and avoidance of maternal exposure to QT-prolonging medications. Postnatal evaluation includes an ECG and continued observation and management of arrhythmias associated with LQTS.[40]

Atrioventricular Block

Structural CHD accounts for 50% of fetal AV block. Fetuses with heterotaxy syndrome with left-atrial isomerism congenitally corrected transposition and AV canal defects are most at risk for the development of AV block. In a fetus, the combination of congenital AV block, complex structural CHD, and hydrops fetalis is associated with a high rate of in utero demise.[58] AV block can be diagnosed by fetal echocardiogram by evaluating the atrial and ventricular rates and the AV relationships (Fig. 49.13A and B).

Maternal anti-SSA (Ro) and anti-SSB (La) antibodies are present in the majority of fetuses that develop isolated AV block. The presumed mechanism is that the fetal cardiac structures are a target for immune complex deposition, namely the AV node and the myocardium. Ro-52-specific antibody has shown a very close association with immune-mediated congenital AV block.[59] The risk of heart block in mothers with anti-SSA/SSB antibodies is 2% to 3%, with a recurrence rate after one affected child as high as 12% to 17%.[60,61] Autopsy specimens typically reveal progressive fibrosis of the AV nodal structures in affected fetuses. The process typically spares the His–Purkinje system so that the slower "escape rhythm" tends to be relatively reliable. Damage to the ventricular myocardium and the presence of endomyocardial fibroelastosis is also found in affected fetuses.[62] The risk of transfer of maternal antibodies to the fetus, and therefore the risk for development of AV block, is highest between 16 and 26 weeks' gestation.[60] Close follow-up with a fetal echocardiogram to evaluate fetal heart rate, PR interval for prolongation, and ventricular function is recommended every other week during this critical time period for all fetuses with exposure to anti-SSA/SSB antibodies. Fetal heart rate monitoring should be performed at standard intervals by the obstetrician. In recent years, home fetal heart rate monitoring, performed by the pregnant woman twice to three times daily, has been utilized between 16 and 26 weeks gestation in order to detect evolving second-degree heart block quickly and allow for immediate admission and treatment to limit progression to third-degree AV block.[63]

Treatment of AV block depends on the cause, ventricular rate, and degree of heart failure. β-sympathomimetics such as terbutaline, salbutamol, and isoprenaline are reasonable to use in fetuses with heart rates less than 55 bpm or with higher heart rates if there is significant CHD or signs of cardiac dysfunction or hydrops. Although terbutaline may increase the fetal heart rate, improvement in survival has not been demonstrated. Terbutaline is well tolerated; however, maternal heart rates of up to 100 to 120 bpm and benign ectopy have been reported.[64] Immune-mediated AV block may benefit from dexamethasone (4 to 8 mg/day) or IVIG therapy. Dexamethasone has been shown to reduce inflammation, reverse or stabilize second-degree block, and improve hydrops or myocardial fibrosis and function.[62] Risks associated with the use of dexamethasone include



• **Fig. 49.13** (A) Fetal mitral inflow and aortic outflow spectral Doppler and (B) M-mode of the fetal heart demonstrating 2:1 atrioventricular block with an atrial rate of 120 beats per minute and ventricular rate of 60 beats per minute. *A*, Sinus atrial activity; *V*, ventricular depolarization.

fetal growth restriction, oligohydramnios, effects on the central nervous system, and maternal diabetes. A trial of dexamethasone may be considered in fetuses with second-degree AV block or first-degree AV block with signs of cardiac inflammation (valve insufficiency, ventricular dysfunction, effusion) to prevent progression from completing AV block, though its use has not been well established.[40] The treatment of mothers with hydroxychloroquine before 10 weeks' gestation has been associated with a reduced risk of anti-SSA/SSB antibody-mediated fetal cardiac disease and may be used in high-risk pregnancies.[65]

Congenital Heart Disease

NATASHA GONZÁLEZ ESTÉVEZ AND DEIDRA A. ANSAH

KEY POINTS

- Congenital heart disease (CHD) is the most common birth heart defect encountered in the clinical setting, affecting 1% of live births.
- Surgical outcomes for all forms of CHD continue to improve. Early detection through fetal echocardiography, physical examination, and pulse oximetry screening allows for improved neonatal management and decreased short-term and long-term morbidity.
- The etiology of CHD remains elusive in many cases. Advances in cellular biology and genetic testing will continue to improve our understanding of its origins.
- An in-depth understanding of neonatal cardiac anatomy and physiology is necessary for proper management of infants with CHD.

General Considerations

Fetal-to-Postnatal Transition

The hemodynamic state of the fetus differs significantly from that of the newborn. In the fetus, a relatively low systemic vascular resistance exists because of the presence of the placenta, and the pulmonary vasculature maintains a high resistance. Central shunts exist for nutrient-rich blood from the placenta to be delivered to the fetal circulation both within the heart (foramen ovale) and on the arterial side of the circulation (ductus arteriosus).

The ductus venosus serves as a flow regulator between the umbilical vein and the inferior vena cava (IVC), largely bypassing the hepatic and portal venous systems. Based on studies in fetal sheep, less than one-half of the umbilical venous return enters the left lobe of the liver and reaches the ductus venosus near its insertion into the IVC, returning as relatively nutrient-rich blood.[1] The lateral position of the IVC within the right atrium results in streaming of placental blood across the foramen ovale and into the left atrium. The most desaturated blood to return to the right atrium comes from the coronary sinus, which combines with the venous return from the superior vena cava (SVC) and is directed across the tricuspid valve into the right ventricle. The nutrient-rich blood deriving from the umbilical vein, which has crossed the foramen ovale to enter the left side of the heart, predominantly supplies the heart and brain. Output from the right ventricle supplies the lungs and flows right-to-left through the ductus arteriosus to supply the remainder of the body. In the fetus, the presence of the ductus arteriosus, which is nonrestrictive, results in both ventricles being subjected to a comparable afterload. Compared with the postnatal heart, this results in an increase in right ventricular workload and some restriction to filling of the right ventricle, thus the right ventricle carries the primary workload of the fetal heart. The ventricles exist in parallel in the fetal heart and output is described as combined cardiac output.

At birth, several important transitions take place that allow the fetus to adapt to extrauterine life. First, the gradual decline in pulmonary vascular resistance (PVR) that was occurring during the last trimester of pregnancy undergoes an abrupt drop with the first breath taken by the newborn (Fig. 50.1). This decline in PVR results in a more than 20-fold increase in pulmonary blood flow and reversal of flow (left-to-right) in the ductus arteriosus before its closure.[2] Second, the shunts present in the fetus undergo closure such that blood flow transitions from parallel to flow in series through the body. The ductus venosus closes largely because of lack of flow following separation of the placenta, although some contractile elements may be present in the vessel wall.[3] The foramen ovale becomes occluded as the flap of the septum primum abuts the septum secundum following the increased pulmonary blood flow that increases filling of the left atrium. Small residual left-to-right shunts at the foramen ovale may persist and in 20% to 30% of the population a patent foramen ovale may exist throughout life (see "Atrial Septal Defects" later in the chapter). Closure of the ductus arteriosus is mediated by decreased blood flow and increased arterial oxygen tension; in contrast, patency of the ductus can usually be maintained by exogenous prostaglandin administration. The third important transition at birth is an increase in the combined ventricular output as the metabolic demands of the body increase at birth.

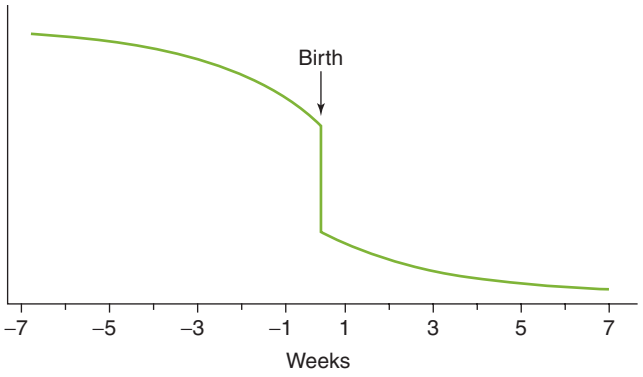
The dramatic hemodynamic changes that occur at birth continue to evolve over the next few months. There is a continued decline in PVR during the first 6 to 8 weeks after birth. In addition, the right ventricle remodels to a thinner and more compliant ventricle and the left ventricle becomes the dominant ventricle of the heart.

Nomenclature

Differing nomenclatures have evolved to define cardiac anatomy and spatial relationships. While the brief summary of nomenclature that is given here is based on the segmental approach of Anderson et al.[4] the embryologic approach of Van Praagh[5] is equally valid and used by several institutions.

The segmental approach to describing cardiac anatomy includes:

1. Cardiac position
2. Visceral sidedness
3. Systemic and pulmonary venous connections
4. Atrial sidedness and their connections



• **Fig. 50.1** Change in Pulmonary Vascular Resistance. A gradual decline in pulmonary vascular resistance is seen during the latter part of gestation followed by an abrupt decline at birth. A gradual decline occurs postnatally over the next 6 to 8 weeks.

5. Atrioventricular (AV) valves
6. Ventricular relationship
7. Ventriculoarterial connections
8. Great vessel number and position

The description of cardiac position in the chest can be separated into where the heart is located and the direction in which the apex of the heart is pointed. Normally, the heart is in the left chest with the apex pointed to the left. Dextro- (right) or meso- (midline) position of the heart can occur with decreased right lung volume, severe scoliosis, or an elevated left diaphragm. A preliminary assessment of the position of the heart in the chest can be determined by a chest x-ray. The normal leftward-pointing apex of the heart (levocardia) can vary to mesocardia (apex pointing midline) or dextrocardia (apex pointing rightward). The orientation of the apex of the heart is defined by echocardiography or cross-sectional imaging.

Visceral sidedness is often defined separately for the abdominal organs, the cardiac structures, and the lungs, although they frequently follow one another. Sidedness is referred to as solitus (normal), inversus (mirror image), or ambiguous (isomerism or indeterminate). In the latter situation, effort is made to define whether the organs that appear on both sides are right-sided (liver, right atrium, and trilobed lung) or left-sided (stomach/spleen, left atrium, bilobed lung) structures since this can have prognostic and therapeutic importance. For instance, patients with bilateral right-sidedness typically lack a spleen and require lifelong antibiotic prophylaxis for encapsulated organisms. Additionally, these patients can have malrotation of the intestines and are at risk for volvulus.

Venous connections of the superior and inferior venous systems must also be delineated. The usual connection of the SVC to the right atrium may also be accompanied by a persistent left SVC to the coronary sinus, with or without a bridging brachiocephalic vein. The IVC is derived from various embryologic vessels. Interruption of the IVC can occur due to failure of fusion of any of the embryological parts. Lower extremity blood flow is consequentially routed to the SVC through the azygous or hemiazygous systems. Various pulmonary venous connections are described below.

Atria can be solitus with the morphologic right atrium on the right (normal), inversus, mirror image, common, or indeterminate. The right atrium is typically identified by the presence of a coronary sinus, the presence of the crista terminalis (the muscular ridge separating the muscular and smooth portions of the right atrium, the large sailed-shaped appendage, and the coarse pectinate muscles of the free wall). The left atrium is characterized by its smooth walls and narrow, finger-shaped appendage. Atrial morphology can be discerned by several imaging modalities such as echocardiography, cross-sectional imaging such as magnetic resonance imaging and computed tomography and more historically angiography. When the morphologic right atrium connects to the morphologic right ventricle (and similarly on the left), the connection is *concordant*. A *discordant* connection occurs when the morphologic right atrium connects to the morphologic left ventricle as in corrected transposition of the great arteries (TGA). When both atria connect to one ventricle (as in double inlet left ventricle) or a single ventricle, the type of connection is referred to as *univentricular*. An *ambiguous* connection occurs in cases of atrial isomerism.

The AV valves generally remain committed to their respective ventricles throughout embryology. As such, the tricuspid valve, when present, connects to the morphologic right ventricle, and the mitral valve connects to the morphologic left ventricle. The tricuspid valve has three leaflets and is distinguished from the mitral valve by the septal attachments of its papillary muscles and the slight inferior position of the septal leaflet of the tricuspid valve relative to the anterior leaflet of the mitral valve. When the AV valves fail to undergo septation, a common AV valve is found, as in children with a complete AV septal defect. The position of the AV valves and their chordal attachments are used to define whether the valves are malaligned or straddling. A malaligned AV valve is not completely positioned over its respective ventricle, which is sometimes referred to as *overriding*. If the chordal attachments of an AV valve cross the septum and connect to the other ventricle, an AV valve is referred to as straddling.

The morphology of the ventricles, the associated AV valve, and the outflow portion of the ventricle can generally be used to identify the right and left ventricles. The right ventricle, besides being associated with the tricuspid valve, is more heavily trabeculated at its apex and anterior free wall than the left ventricle. The right ventricle is described as tripartite and consists of an inflow, body, and outflow. The inflow includes the tricuspid valve, the papillary muscles which are responsible for anchoring the valve leaflets, and the chordae tendineae, which are the fibrous cords anchoring the tricuspid valve to the papillary muscles. The body includes the trabeculated muscular portion of the ventricle and the outflow which extends toward the pulmonary valve in the form of a tract. Along this outflow tract is the infundibulum or conus, which is a muscular separation between the tricuspid and semilunar valves.[6] The left ventricle is more smooth-walled with finer trabeculations at its apex than the right ventricle, and in normal anatomy demonstrates fibrous continuity between the mitral and aortic valves. When the ventricular morphology is uncertain, the ventricles are said to be indeterminate. A common ventricle is defined by virtual absence of the interventricular septum.

The great vessels are largely defined by their branching pattern. The pulmonary artery bifurcates shortly after exiting the heart into the right and left pulmonary arteries that undergo subsequent branching to supply the segments of the lung. The right pulmonary artery is positioned anterior to the right upper bronchus while the left pulmonary artery is posterior to the left upper bronchus. The pulmonary arteries typically follow the situs of the lungs such that mirror image pulmonary artery branching is seen in situs inversus, bilateral branch pulmonary arteries anterior to the upper bronchus are seen in right isomerism, and branch

pulmonary arteries posterior to the upper bronchus are seen in left isomerism. The aorta is normally left sided, and courses over the left mainstem bronchus giving rise to three head and neck arterial branches. A right aortic arch crosses over the right mainstem bronchus before crossing back to the left side of the spine in the thorax and can have several different branching patterns. While the aorta is typically posterior and rightward to the main pulmonary artery, the relative position of the vessels can vary greatly. Most commonly, in d-transposition of the great arteries, the aorta is anterior and rightward to the main pulmonary artery. In situations where only a single semilunar valve is present, a truncus arteriosus (or common truncal artery) is found that gives rise to both the aorta and pulmonary artery.

The ventriculoarterial connections are said to be concordant when the right ventricle connects to the pulmonary artery and the left ventricle gives rise to the aorta. The ventriculoarterial connection is discordant when the opposite occurs. The ventriculoarterial connection can also be double, single, or common. If both great arteries arise from one ventricle, a double outlet occurs. The definition of a double outlet connection is somewhat controversial. For example, in the case of double outlet right ventricle (DORV) with normally related great vessels, some clinicians have proposed basing the definition on whether greater than 50% of the aorta overrides the right ventricle, while others define the double outlet on whether a subaortic conus exists that results in mitral–aortic discontinuity. From a patient management perspective, both situations are relevant for either placement of the ventricular septal defect (VSD) patch or the potential for development of subaortic obstruction, respectively. A single outlet occurs when severe pulmonary hypoplasia occurs such that no main pulmonary artery segment is present. A common outlet occurs in truncus arteriosus.

Clinical Evaluation of the Newborn

Even with the technologic advances in prenatal and postnatal echocardiography and genetic testing, a careful history and physical examination are needed in every newborn with suspected congenital heart disease (CHD). Birth history, including complications during pregnancy, labor, and delivery, is important to document. Often the child with cyanosis because of structural heart disease has an unremarkable birth history. A difficult labor or delivery may point toward noncardiac causes of cyanosis such as persistent fetal circulation, infection, or pneumothorax. For the child with poor systemic perfusion, a history of premature rupture of membranes or maternal fever may suggest sepsis as a cause for the diminished cardiac function. Hematologic abnormalities that may cause cardiovascular dysfunction in the neonate, such as polycythemia or anemia, may be suggested by a history of placental abruption or twin–twin transfusion.

Family history is critical to review with the biologic parents. There is a genetic basis for a growing number of congenital heart defects (see later). A sibling with CHD more than doubles the likelihood of future children having CHD.[7] A history of CHD in either of the parents also increases the chance of developing a congenital heart lesion.[8,9]

Physical examination of the newborn should initially include a general assessment looking for dysmorphic features and the degree of distress of the infant. The child with cardiac obstructive physiology may have shallow, rapid respirations with intercostal and suprasternal retractions. Cyanosis may or may not be seen depending on the degree of hemoglobin desaturation (roughly 5 g of hemoglobin must be desaturated to be clinically evident). Vital signs, including four extremity blood pressures, should be determined along with preductal and postductal oxygen saturation measurement. Palpation of the precordium may identify an overactive or displaced cardiac impulse or the sensation of a thrill caused by turbulent flow. Palpation of the abdomen for a liver edge or spleen tip can often provide an indication of volume overload or neonatal infection. Assessment of femoral and upper extremity pulses is essential. Simultaneous palpation of the right branchial and right femoral pulses allows assessment of comparable timing and intensity of the pulsations. Perfusion and capillary refill of the extremities are also important to determine.

Auscultation is often challenging in the sick neonate. However, characterizing the presence, timing, intensity, position, and radiation of murmurs that are present may provide a clue to the underlying diagnosis. In the tachypneic and tachycardic child, it is critical to listen over the head and liver for a continuous murmur that may indicate an arteriovenous malformation (AVM). The presence of a click or gallop over the precordium may indicate valvar disease or cardiac failure. Assessment of the second heart sound is particularly important. It has been suggested that the presence of physiologic splitting of the second heart sound nearly always suggests a structurally normal heart.[10]

Signs of CHF in the newborn may be subtle and include resting tachypnea (with no periodic variation), sinus tachycardia, and an enlarged liver. Tachypnea may be accompanied by nasal flaring and intercostal and subcostal retractions, particularly in situations where elevated pulmonary venous pressures are present. Grunting respirations are a particularly concerning sign in a newborn and often accompany severe heart failure and decreased systemic perfusion.

Because many infants with CHD are asymptomatic in the newborn period and have a normal physical examination and because routine prenatal ultrasound does not detect all defects, it has been recommended that pulse oximetry screening should be added to the routine newborn screening panel.[11] The screen specifically targets critical congenital heart defects or those that usually require an intervention in the first month of life and can lead to death or significant morbidity if not diagnosed in a timely manner. Since this recommendation, there have been several studies focusing on the feasibility, implementation, and impact of the screen.[12]

Laboratory Assessment of the Neonate

As mentioned previously, initial laboratory assessment should include measurement of preductal and postductal oxygen saturations in the right hand and foot, respectively, in a left aortic arch with normal branching. Values less than 93% are considered abnormal. The *oxygen challenge test* is performed by increasing the inspired oxygen concentration to 100% for at least 5 minutes. Oxygen saturation values that increase into the normal range may be useful to distinguish an admixture cyanotic heart lesion from lung disease, although this test does not discriminate with 100% accuracy. History and physical examination should be included and guide the need for further evaluation. A decrease in postductal oxygen saturations compared with preductal values suggests right-to-left shunting because of an increase in PVR. The unusual situation in which the preductal saturation reading is less than the postductal reading occurs when TGA is combined with pulmonary hypertension and a patent ductus arteriosus (PDA).

An electrocardiogram (ECG) should be obtained in the initial evaluation of the newborn with suspected CHD, although in the absence of an arrhythmia, it rarely provides a specific diagnosis. The neonatal ECG demonstrates prominent rightward forces and may have an upright T wave in the right precordial leads in the first few days after birth, and thus it may not be diagnostic of right ventricular hypertrophy. Age-dependent standards are available and should be referred to when evaluating the ECG (Table 50.1). Certain lesions may have distinctive findings on ECG such as extreme right axis deviation and Q waves in leads I and aVL (complete AV septal defect), preexcitation and right atrial enlargement (Ebstein anomaly), and Q waves in leads V1–V3 (congenitally corrected TGA).

A chest x-ray should also be obtained in every newborn that is evaluated for CHD. The chest x-ray may help to determine the heart size, shape, and border contours as well as pulmonary vascular markings. A prominent thymic shadow in the newborn may make identification of classic chest x-ray findings difficult, such as the "boot-shaped" heart in tetralogy of Fallot (TOF), the "egg on a string" in transposition, and the "snowman" appearance in supracardiac total anomalous pulmonary venous return (TAPVR), although the massively increased heart size typically found with Ebstein anomaly will not be missed. An absent thymic shadow may suggest DiGeorge syndrome (22q11 deletion), although genetic testing is still required. Increases in pulmonary vascular markings typically found in left-to-right shunt lesions may not be immediately apparent in the newborn because of the relatively high PVR and may take days or weeks to become apparent. Often, decreased pulmonary vascular markings in lesions with diminished pulmonary blood flow, such as tricuspid or pulmonary atresia, will be apparent in the newborn period. Presence of a PDA, however, will improve pulmonary blood flow in these lesions. Echocardiography is truly the mainstay in the diagnosis of CHD in the neonate. The suspicion of CHD warrants immediate consultation with a pediatric cardiologist and evaluation of the neonate by echocardiography.

Genetics and Congenital Heart Disease

About 30% of children with a chromosomal abnormality will have congenital heart disease.[13] There are an estimated 400 genes associated with CHD,[14] and the understanding of the genetic basis of CHD is progressing at a rapid pace. Blue et al. depicted the evolution of genetic testing and its impact on elucidating relevant genetic associations with CHD over the past several decades (Fig. 50.2).[15]

Cardiogenesis is driven by a complex interplay between several processes including but not limited to transcription factors, signaling pathways, chromatin modifiers, and protein development. Thus, the genetic pathways that drive cardiac development are multifactorial. Disruptions in genetic pathways can include point mutations, aneuploidy, and copy number variations all occurring as de novo mutations or due to Mendelian inheritance with varying penetrance. We will briefly review some of these genetic variations and associated congenital heart defects.

Point mutations are an alteration of a single nucleotide sequence in a particular gene. This generally results in one of three outcomes. The result can be inconsequential because the alteration is coding for the same amino acid. In contrast, a missense mutation can occur if the new codon corresponds to a different amino acid. Lastly, a nonsense mutation can occur resulting in a stop codon terminating the gene transcription altogether. An estimated 2% of CHDs are due to point mutations.[16] For example, HAND 1 and 2 are transcription factors that play a role in regulating ventricular looping and development. A loss of function mutation in HAND 1 can result in an arrest at the ventricular looping stage of cardiogenesis and the mutation has been identified in patients with hypoplastic left heart syndrome (HLHS), right heart hypoplasia, and double outlet right ventricle (DORV).

Copy number variants are the deletion or duplication of specific regions of DNA usually involving a significant number of base pairs. These are estimated to cause 10% to 15% of CHD.[16] An example of this type of mutation is 22q11 deletion, also known as DiGeorge syndrome or velocardiofacial syndrome

TABLE 50.1 Electrocardiogram: Age-Dependent Standards

Age Group	QRS axis	PRI	QRSD	QV6 (mm)	RV1 (mm)	SV1 (mm)	RV6 (mm)	SV6 (mm)	SV1 + RV6
<1 day	59–163	0.08–0.16	0.031–0.075	2	5–26	0–23	0–11	0–9.5	28
1–2 days	64–161	0.08–0.14	0.032–0.066	2.5	5–27	0–21	0–12	0–9.5	29

Advances in the genetics of congenital heart disease: a clinician's guide. *J Am Coll Cardiol*. 2017;69:859–870.)

which is commonly associated with conotruncal anomalies such as interrupted aortic arch (IAA), TOF, and truncus arteriosus (TA). 22q11 deletion alters the expression of TBX1, a key transcription factor in the development of the pharyngeal pouches and arches. In addition to CHD, the manifestations of the syndrome, although phenotypically heterogenous, can include parathyroid gland absence leading to hypocalcemia, thymic aplasia, neurodevelopmental delays, and characteristic facial features.[17]

Aneuploidy is the loss or gain of an entire chromosome or chromosomal segment. For example trisomy 13, 18, and 21 are all additions of chromosomes 13, 18, and 21. These defects are associated with cardiac disease 80% to 100% of the time in trisomy 13 and 18[18] and 40% to 55% of the time in trisomy 21.[19] Turner syndrome is the loss of an X chromosome. CHD can occur in up to 50% of patients with Turner, and lesions are commonly associated with the left side of the heart such as bicuspid aortic valve and coarctation of the aorta.[20] Wolf-Hirschhorn syndrome is the partial deletion of the short arm of chromosome 4 and is associated with CHD about 50% of the time. Common lesions associated with Wolf-Hirschhorn syndrome include atrial septal defects, ventricular septal defects, and pulmonary stenosis.[21]

Despite advances in the understanding of the genetic basis of CHD, the genetic basis of more than half of children with CHD is not known. It is likely that altered interactions with noncoding regions of the genome impact the degree to which genes that regulate cardiac development are expressed. There may also be gene–environment interactions, yet to be defined, which impact cardiac development.

The Genetic Work-Up of Congenital Heart Disease

A child with suspected CHD should be carefully evaluated for dysmorphic features that may indicate an associated syndrome. Similarly, newborns with suspected genetic syndromes should be screened for congenital heart disease. Fig. 50.3 demonstrates a genetic screening algorithm. Genetic testing should be performed not only in patients with suspected CHD but also in the setting of suggestive physical features, family history, or positive prenatal genetic testing. Fluorescent in situ hybridization (FISH) is the use of fluorescent probes to map specific deoxyribonucleic acid (DNA) sequences and is the test of choice for identifying 22q11, while single-gene disorders such as Noonan syndrome require whole-exome sequencing.

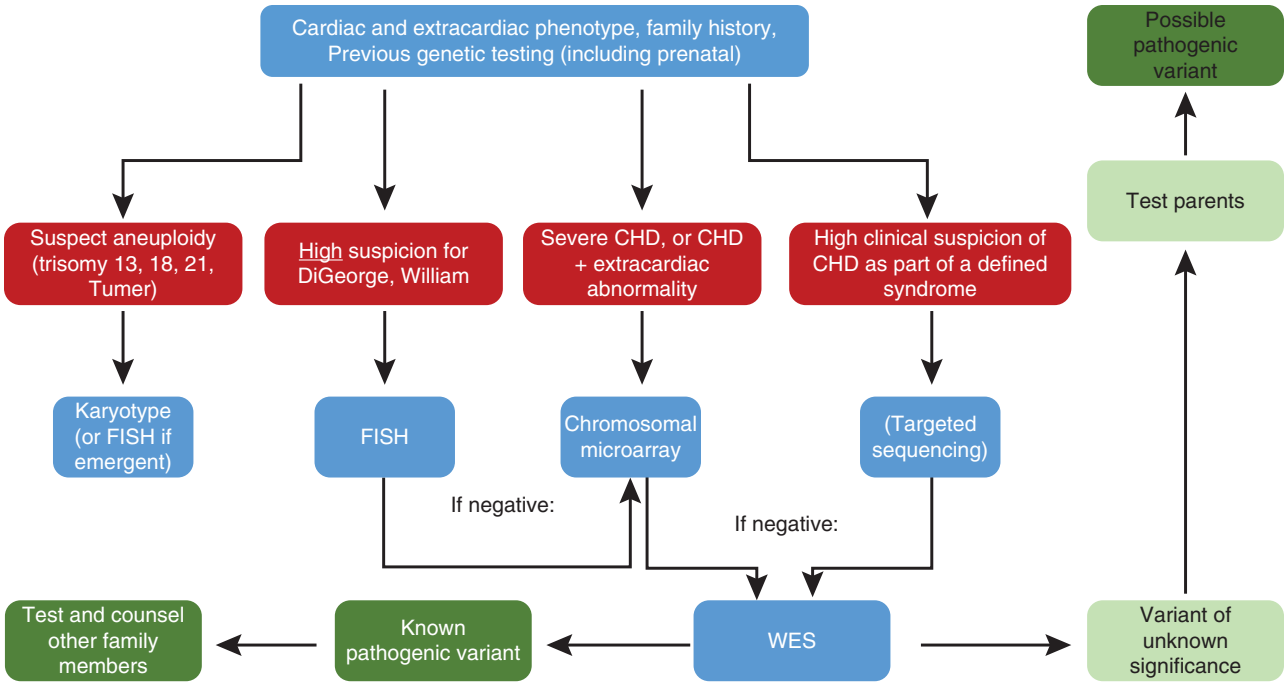
Genetic testing is not only useful for prognostic information for the individual patient but plays a significant role in pre- and postnatal family counseling and future family planning. Referral to a consulting genetics team allows for the consideration of services available to the infant, screening of additional family members, and discussion of the risks to future pregnancies.

Heart Transplantation

Although many congenital heart defects can be corrected or palliated, cardiac transplantation must be considered in instances where there is intrinsic cardiac dysfunction such as cardiomyopathy or in circumstances where surgical repair has not sufficiently corrected a child's hemodynamics. In those cases, cardiac transplantation may be the only therapeutic option.

The first heart transplant in an infant was reported in 1968.[22] Since that time, understanding of transplant immunology and medical management has made heart transplantation in infants and children an important option for inoperable patients or those with end-stage cardiac disease. The indications for pediatric heart transplant were defined by the American Heart Association as:[23]

1. Need for ongoing intravenous inotropic or mechanical circulatory support
2. Complex CHD not amenable to conventional surgical repair or palliation or for which the surgical procedure carries a higher risk of mortality than transplantation
3. Progressive deterioration of ventricular function or functional status despite optimal medical care
4. Malignant arrhythmia or survival of cardiac arrest unresponsive to medical therapy, catheter ablation, or an automatic implantable defibrillator



• **Fig. 50.3** An Algorithm for Genetic Testing in the Congenital Heart Disease Patient. *CHD*, congenital heart disease; *FISH*, fluorescence in situ hybridization; *WES*, whole exome sequencing. (From Zaidi S, Brueckner M. Genetics and genomics of congenital heart disease. *Circ Res*. 2017;120:923–940.)

5. Progressive pulmonary hypertension that could preclude future transplantation
6. Growth failure secondary to severe CHF unresponsive to conventional medical therapy
7. Unacceptably poor quality of life

Children aged 11 to 17 years account for the greatest number of transplants in the pediatric population. Fig. 50.4 demonstrates the reasons for heart transplantation among different pediatric age groups. Examples in the neonate for which cardiac transplantation has been used as primary palliation include hypoplastic left heart syndrome with significant cardiac or extracardiac comorbidities, pulmonary atresia with intact ventricular septum and presence of coronary sinusoids, complex heterotaxy or unbalanced complete AV septal defects with poor common AV valve function, and single ventricle hearts where the dominant semilunar valve is severely insufficient. When considering transplantation there is a balance between the success of palliative surgery and the availability of organs for transplantation. For example, survival of patients undergoing surgical palliation of hypoplastic left heart syndrome (HLHS) has continued to improve.[24,25] With the availability of infant donors increasing only slightly over this period of time (Table 50.2), the balance for treatment of these newborns has shifted toward surgical palliation with the Norwood or hybrid Norwood procedures as the preferred treatment option over transplant. As a result, a decreasing frequency of neonatal transplants has been seen over the last 30 years.[26,27]

Given the limited availability of organs, survival to transplant remains an obstacle in pediatric heart transplantation. Specifically in the neonate, the donor pool has remained limited as infant mortality has improved.[27,28] The use of ABO-incompatible heart transplant protocols has emerged as an option for mitigating the limited neonatal donor pool.[29,30] Evidence supporting use of these protocols has been demonstrated by comparable outcomes for ABO-incompatible and ABO-compatible heart transplantation in children. One philosophy is that the immature immune system of the neonate may slow the production of donor-specific antibodies.[31,32] This may also explain an observed survival advantage in children who receive their transplant prior to 1 month of age versus those between 1 and 12 months.[33] Other considerations may be an immunologic window where graft rejection and transplant coronary artery disease are limited.

Once transplanted, the long-term survival of infants who undergo heart transplantation in general is quite good. The 10-year survival in infants continues to improve, with reported rates as high as 74%.[27]

Ventricular Assist Devices

Over the past several years, mechanical circulatory support devices have increasingly been developed for the pediatric population to serve as a bridge for postoperative cardiac recovery or heart transplantation. While the availability of devices for neonates lags far behind older children and adults, options are now available.

The mechanical circulatory support device approved for use in children is the Berlin Heart EXCOR pediatric ventricular assist device (VAD). This is a pneumatically driven device that comes in five sizes, with the smallest of the devices delivering a volume of 10 mL per stroke. One or two devices can be implanted to support one or both ventricles, respectively. Studies have looked at survival and complications in infants in the 3 to 5 kg range and a corrected gestational age of at least 37 weeks of age, in comparison with older children.[34] Early mortality was increased in association with lower body weight. In the 33 infants included in the study who were less than 5 kg, 64% died following VAD implantation.

Given the challenges of the use of current VADs in infants, other devices continue to be developed[35,36] and are either in the experimental stage or available for compassionate use. The development of these smaller devices has been supported, in part, by

Murmurs in the Newborn—Congenital Cardiac Lesions

Patent Ductus Arteriosus and Aortopulmonary Window

Most children are born with a *patent ductus arteriosus (PDA)* that typically closes within the first week of life. Prematurity is a risk factor for a persistent PDA. Persistent PDA in term infants occurs more commonly in females and may have a genetic component in some patients, as suggested by an animal model of inbred poodles[37] and linkage to chromosome 12.[38]

The pathophysiology of a PDA largely depends on the degree of shunting from the aorta to the pulmonary artery, which is determined by the inner diameter and length of the PDA and the relative pulmonary and systemic vascular resistances. If the PDA diameter is small, the ductus itself will provide the primary site of resistance to flow, and the shunt will be small. In the case of a larger PDA, low PVR may allow for a significant shunt that places the patient at risk for developing heart failure and, eventually, pulmonary vascular disease. The low resistance pathway through the lungs provides a route for diastolic run-off from the aorta that can lead to decreased coronary perfusion pressure, resulting in myocardial ischemia and systemic steal, resulting in end-organ dysfunction.

Clinically, patients with a small shunt will be asymptomatic. With a larger PDA shunt, the progressive decline in PVR postnatally will cause an increase in left-to-right shunt flow with signs of increasing heart failure. The murmur in a child with a PDA is generally continuous and has been described as a "machinery" murmur in the left infraclavicular region. The character of the murmur, however, varies greatly, although the continuous nature is generally present once the PVR has declined. Examination of the patient with a PDA will also include a wide pulse pressure because of decreased diastolic pressure and bounding pulses.

The diagnosis of PDA, when suspected on examination, can nearly always be confirmed by echocardiography. Even in the face of high PVR with limited left-to-right shunting, differences in the pulse waveforms between the aorta and pulmonary artery will allow left-to-right and/or right-to-left shunting to be observed by color Doppler imaging. As the degree of left-to-right shunting increases the left heart becomes volume overloaded, which also can be assessed by echocardiogram. In addition, retrograde flow will be seen in the proximal descending aorta when a large shunt is present. Cardiac catheterization is rarely needed unless device closure of the PDA is considered.

The prognosis for small PDAs is quite good, and debate exists as to whether closure of "silent" PDAs, incidentally identified by echocardiography, should be performed.[39] With the most recent recommendations from the American Heart Association suggesting that PDAs do not require subacute bacterial endocarditis prophylaxis,[40,41] there is little need to close these small vessels.

Because of the long-term concerns of pulmonary overcirculation and the development of pulmonary vascular disease, closure of hemodynamically significant PDAs is recommended particularly in the preterm infant. In the preterm infant closure is usually attempted medically with the use of prostaglandin inhibitors such as indomethacin and ibuprofen. Surgical ligation and division can readily be performed through a lateral thoracotomy. However, coil or device closure in the catheterization lab has a lower morbidity and success rates equal to surgery.[42,43] As a result, catheter closure of PDAs has become the preferred method in nonpremature infants. Success of device closure depends in part on the weight of the infant and size and shape of the PDA. With the current array of devices available, closure can be safely performed in most infants weighing more than 4 kg and can be considered in some infants weighing between 2.5 and 4 kg.[44,45] Percutaneous closure of the PDA in the extremely low birth weight population (<2 kg) is being increasingly explored with good efficacy and low adverse event rates.[46,47]

Aortopulmonary (AP) window occurs when there is direct communication between the aorta and main pulmonary artery and is a rare lesion with an incidence of 0.2%.[48] Nearly half of patients with an AP window will have an associated cardiac anomaly. These lesions nearly always result in a large degree of left-to-right shunting. Patients will show signs of CHF on examination and have physical and laboratory findings similar to those for a large PDA. Generally, all AP windows should be closed surgically when they are identified.

Ventricular Septal Defect

VSDs are the most common type of CHD (excluding bicuspid aortic valve). Generally, VSDs are classified into four types (Fig. 50.5):

1. Membranous/Perimembranous
2. Muscular (e.g., apical muscular defects)
3. Inlet (e.g., atrioventricular septal defects)
4. Outlet (e.g., subpulmonary defects)

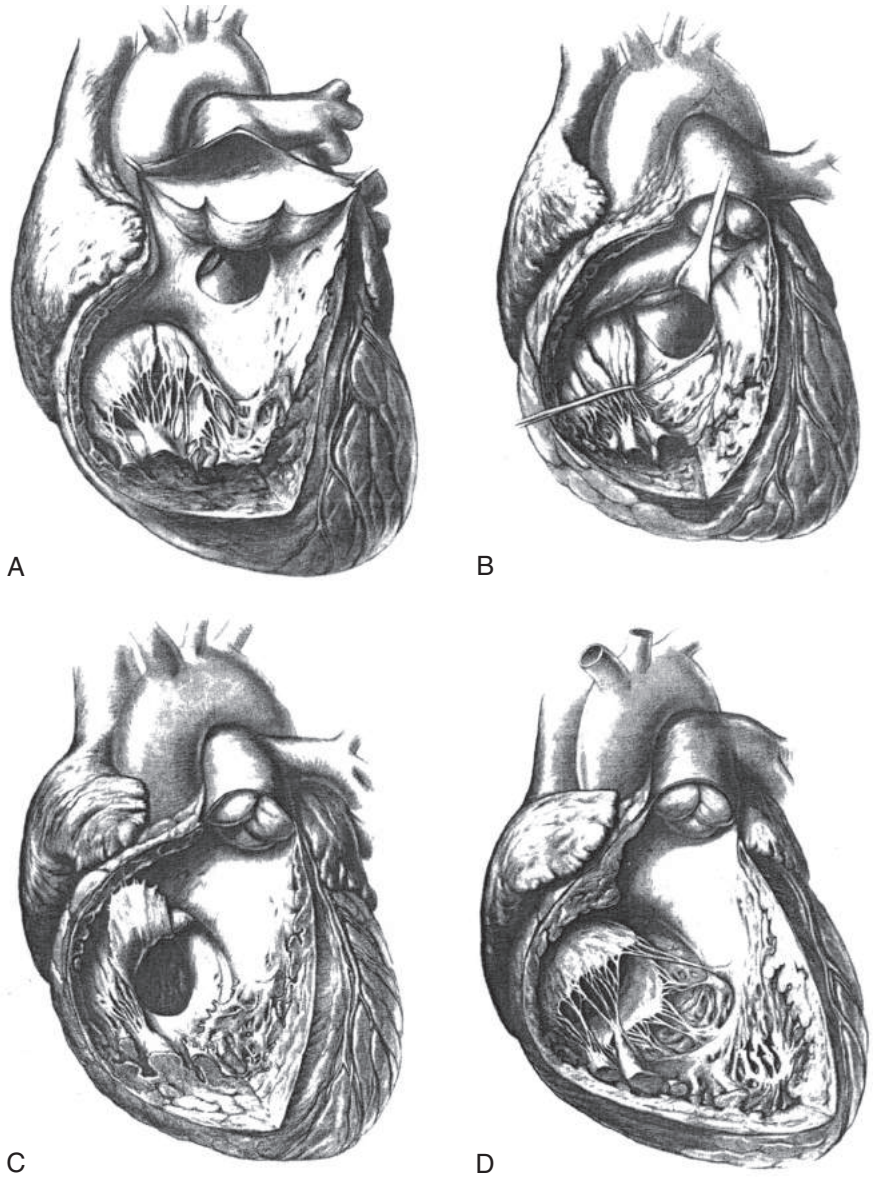
The perimembranous VSD is the most common of the four types and has variably been referred to as membranous, paramembranous, or infracristal. From the right ventricular side of the heart, these defects lie under the septal leaflet of the tricuspid valve below the crista supraventricularis and posterior to the papillary muscle of the conus. Muscular VSDs can occur in isolation or as multiples ("Swiss cheese septum") and, as the name implies, can occur anywhere in the muscular septum. Apical muscular VSDs are the most common and are sometimes difficult to accurately size by echocardiography because of the heavy trabeculations at the apex of the right ventricle. Inlet VSDs are located posterior and inferior to perimembranous defects, and although the nomenclature is controversial, this is the location of the defect in patients with complete atrioventricular septal defects. The location of the VSD in patients with outlet defects is above the crista supraventricularis and typically undermines the right aortic valve leaflet. A variety of synonyms have been used for outlet VSDs including subarterial, subaortic, supracristal, and conal VSD.

The clinical importance of any VSD is dependent upon the size of the defect and the relative pulmonary-to-systemic vascular resistance, which together determine the degree of left-to-right shunting. An additional consideration with outlet VSDs is the degree to which the right coronary cusp of the aortic valve prolapses into the defect and results in aortic insufficiency. Defects whose cross-sectional area is equal to, or greater than, the cross-sectional area of the aortic valve will not restrict flow leaving the left ventricle and entering the right ventricle. In this case, the degree of shunting will be determined by the relative resistance to flow in the pulmonary and systemic vascular beds. The normal postnatal decline in PVR will result in a progressive increase in left-to-right shunting and signs of CHF. A small percentage of children do not have the usual postnatal decline in PVR and may never develop signs of pulmonary overcirculation and heart failure despite the presence of a large VSD. This is an indication for early surgical closure of the defect.

When the VSD is small relative to the aortic valve, the defect itself will be the primary point of resistance to shunt flow. In this case, changes in PVR will have little impact on the degree of left-to-right shunting.

An important associated lesion that is critical to rule out is coarctation of the aorta. The coarctation results in a fixed elevated systemic vascular resistance that can result in significant left-to-right shunting even in the presence of a small VSD. In this case, medical therapy is often unable to control CHF symptoms, and surgery is needed.

The volume of shunted blood is most accurately quantitated at cardiac catheterization based on the step-up in oxygen saturation from the right atrium (mixed venous) to the pulmonary artery and is represented as the ratio of pulmonary-to-systemic blood flow (Qp:Qs). Generally, a Qp:Qs less than 1.5 is considered below the threshold for surgery, while a Qp:Qs greater than 2.0 is an indication for surgery. The Qp:Qs can also be estimated by echocardiography and by magnetic resonance imaging (MRI). Modern era management of isolated ventricular septal defects is rarely determined by Qp:Qs quantification and relies more heavily on clinical evaluation.



• **Fig. 50.5** Anatomic Varieties of Ventricular Septal Defect. (A) Subpulmonary defect. (B) Membranous defect. (C) Inlet (atrioventricular septal defect type) defect. (D) Apical muscular defects. (From Mavroudis C, Backer CL. *Pediatric Cardiac Surgery*. St. Louis: Mosby Year Book; 1994.)

The examination of the patient with a VSD depends on the magnitude of the shunt. Small defects that provide considerable restriction to flow often have the loudest murmur. The rapid drop in PVR immediately after birth often allows VSD murmurs to be heard in the newborn nursery, although the full extent of the murmur, and perhaps a thrill at the lower left sternal border, may not be appreciated for several weeks. The murmur may have a more ejection quality in the newborn nursery in the face of high PVR and somewhat elevated right ventricular pressure. The more typical holosystolic murmur will be more apparent as the PVR falls.

With large VSDs, little or no murmur may be heard depending on the PVR. With low PVR, signs of heart failure will likely be present including tachypnea with nasal flaring and retractions, tachycardia, diaphoresis, poor feeding, and diminished weight gain. A systolic murmur at the lower left sternal border (caused by flow across the VSD) or upper left sternal border (caused by increased flow across the right ventricular outflow tract [RVOT]) may be heard along with a diastolic inflow rumble (an absence of silence) at the apex. If PVR is high, the pulmonic component of the second heart sound may be increased although difficult to appreciate. Occasionally, large defects may allow transient right-to-left shunting to occur, particularly when the infant is crying.

In patients with an outlet VSD, the holosystolic murmur is often present, but the murmur is located higher on the left sternal border. Care should be taken to listen for the diastolic decrescendo of aortic insufficiency at the mid-left sternal border or at the apex.

The evaluation of the infant with a suspected VSD should include an ECG, chest x-ray, and echocardiogram. In infants, the ECG may not be distinctive unless an inlet VSD is present. Obtaining a chest x-ray, even in the neonate, is important in order to assess heart size and pulmonary vascular markings. It can also be an important tool in the follow-up of newborns with VSDs

when used to assess progression in left-to-right shunting as the PVR declines. Echocardiography is the gold standard for characterizing the location and size of VSDs. Associated lesions, such as coarctation of the aorta, can also be readily assessed by echocardiography. Doppler studies can estimate the degree of restriction by calculating the pressure drop at the defect. M-mode measurements can be used to determine left ventricular dimensions, which will be increased when a significant left-to-right shunt is present. As mentioned above, cardiac catheterization can accurately quantitate the degree of shunting but is rarely needed in the initial assessment of the newborn with VSD.

Up to 80% of small, muscular VSDs and 30% to 50% of perimembranous defects will close spontaneously. It is uncommon for these defects to increase in size, although the degree of left-to-right shunting can increase as PVR drops. Occasionally, inlet VSDs will undergo closure secondary to chordal attachments of the AV valves, but closure is generally present at birth if it is going to occur. Outlet VSDs virtually never close and have the associated risk of progressive aortic insufficiency because of prolapse of the right coronary cusp into the defect.

The short-term consideration in following patients with VSDs is the management of CHF if the left-to-right shunt is excessive. Medications that are used include diuretics to augment fluid shifts and less frequently afterload reduction with agents such as angiotensin-converting enzyme inhibitors. The primary goal in controlling CHF is to allow the newborn to grow adequately and hopefully allow progressive closure of the VSDs. Weight gain is a useful and objective measure to follow.

The long-term goal of therapy or intervention is to prevent the development of irreversible pulmonary vascular occlusive disease. Shunts with a Qp:Qs greater than 2.0 are at long-term risk of developing Eisenmenger disease, and closure of the defect is warranted beyond 2 to 4 years of age when further decline in defect size is unlikely.

If medical therapy fails to control heart failure and the infant exhibits failure to thrive, surgical closure of the defect in the first 6 months of life is usually necessary. Surgical closure is also indicated in the 6- to 12-month-old child with a large VSD who has not demonstrated signs and symptoms of CHF due to lack of decline in PVR. In these infants, irreversible changes in the pulmonary vasculature may occur if the pressure load is not removed from the lungs. As mentioned previously, defects with a Qp:Qs greater than 2.0 and outlet defects also require closure. The use of pulmonary artery banding is falling out of favor for palliation of patients with VSDs unless the patient's clinical condition precludes complete repair. There is growing use of hybrid procedures where the surgeon and interventional cardiologist work together to close defects in small children.[49] This combined approach has successfully been applied to the closure of muscular VSDs in infants that are positioned in a location that is difficult for the surgeon to visualize from a right atrial approach.

Atrial Septal Defects

Although atrial septal defects (ASDs) rarely produce a murmur in the neonatal period, the systolic murmur they generate later in life makes them appropriate for this section. As discussed earlier, atrial level shunting through the foramen ovale in utero allows the nutrient-rich placental blood to gain access to the left ventricle and ascending aorta. In the immediate postnatal period, careful echocardiography examination of the interatrial septum will usually identify residual left-to-right or bidirectional shunting through the foramen ovale. Measurement of the size of the shunt provides an indication of whether there will be a persistent septal defect. An opening less than 6 mm in a term infant will most likely close and is referred to as a patent foramen ovale (PFO) to distinguish it from a true ASD. ASDs that represent congenital lesions are classified as:

1. Secundum
2. Primum
3. Sinus venosus
4. Coronary sinus

Secundum defects are the most common and, when present in the neonate, allow for left-to-right or bidirectional shunting. The direction of the shunt, and the reason an ASD murmur is typically not heard in the neonate, is that right ventricular compliance remains low until the RV remodels postnatally. The reduced RV compliance increases right atrial pressure and limits the amount of left-to-right atrial level shunting. Primum ASDs are in the spectrum of atrioventricular septal defects and will be considered in the next section. Sinus venosus defects occur when the wall separating the upper or lower right pulmonary vein is deficient so that pulmonary venous return from either or both veins enters into the right atrium. This results in a left-to-right shunt. This variant of anomalous pulmonary venous return will be considered in greater detail further in the chapter. Coronary sinus defects result from an "unroofing" of the coronary sinus so that the coronary sinus enters at the left atrium–right atrium junction where the septum is deficient. Often, this lesion is associated with a persistent left SVC that enters into the coronary sinus.

In later childhood, when the compliance of the right ventricle increases and left-to-right shunting through an ASD increases, the classic physical findings of fixed splitting of the second heart sound can be auscultated. A systolic ejection murmur at the left upper sternal border and a diastolic right ventricular inflow murmur at the lower left sternal border become apparent in lesions with a Qp:Qs more than 2.0. ECG will often demonstrate an RSR pattern in the right precordial leads with evidence of right ventricular hypertrophy. Cardiomegaly with a prominent main pulmonary artery segment and increased vascular markings will be seen on chest x-ray. Echocardiogram remains the gold standard for identifying and sizing the defects.

It is uncommon for infants and children with an isolated ASD to develop heart failure. Typically, intervention for a significant ASD is performed to prevent the long-term sequelae of pulmonary vascular disease. As such, closure is rarely performed before the age of 3 to 4 years. Device closure of secundum ASDs is now routinely performed in the catheterization lab when children are greater than 15 kg, although surgical closure is still performed when lesions are large or the rim of tissue between the ASD and aorta is deficient.

Atrioventricular Septal Defects

A variety of terms have been used to describe atrioventricular septal defects including AV canal defect, endocardial cushion defect, and common AV orifice. In addition, there is a spectrum of AV septal defects:

1. *Complete*—common AV valve is present along with a significant primum ASD and inlet VSD.
2. *Intermediate*—common AV valve annulus although separate AV valves along with a primum ASD and inlet VSD.
3. *Transitional*—completely separate AV valves along with a primum ASD and inlet VSD.

4. *Partial*—separate AV valves with a primum ASD and no VSD.

These four groups have some therapeutic relevance with regard to the degree of AV valve abnormality that must be considered at surgery, although each has a cleft between the anterior bridging leaflet and the lateral leaflet of the left-sided (mitral) valve that must be addressed. In infants with a complete AV septal defect, it is important to assess whether the right and left ventricles are *balanced*, that is, equally developed so that a two-ventricle repair is possible, and the degree of AV insufficiency, which has prognostic importance in the surgical outcome. AV septal defects are common in children with Down syndrome.

In the immediate postnatal period, variations in PVR that occur, particularly in infants with Down syndrome, can result in a right-to-left shunt through a nonrestrictive primum ASD and/or inlet VSD and result in systemic desaturation. Many infants with complete AV septal defects will develop heart failure in the first 2 months of life as PVR falls. A small percentage of infants will not have a decline in PVR, making the lack of heart failure a troubling sign and an indication for early surgical repair.

While diagnosis largely rests on the echocardiogram, AV septal defects can be suspected on ECG with the presence of a superior frontal QRS axis (ranging from −30 to −120 degrees), evidence of right ventricular hypertrophy, and Q waves in leads I and aVL. Echocardiogram is used to define the type of AV septal defect and identify associated anomalies (Fig. 50.6). As mentioned above, critical assessment of relative ventricular sizes and the degree of AV valve insufficiency is necessary. Interrogation of the RVOT is also needed due to the associated pulmonic stenosis or TOF that can occur with complete AV septal defects.

Correction of complete AV septal defects is performed surgically at 4 to 6 months of age. While awaiting surgery, care must be taken not to treat minor desaturation episodes with excessive oxygen since oxygen-induced lowering of PVR can rapidly worsen heart failure and lead to further desaturation, a spiral that can be difficult to reverse. Diuretics and afterload reduction are often needed to control heart failure, and some cardiologists will start these medications in the immediate postnatal period because of the high likelihood of infants developing CHF. Complete repair (septation atria, ventricles, and AV valves) is preferred. It is very rare that palliative banding of the pulmonary artery is needed to control heart failure symptoms. As mentioned above, early repair should be considered in the infant who does not have a decline in PVR and the development of heart failure, because of the concern of early development of irreversible increases in PVR, particularly in non-Down syndrome complete AV septal defect patients.

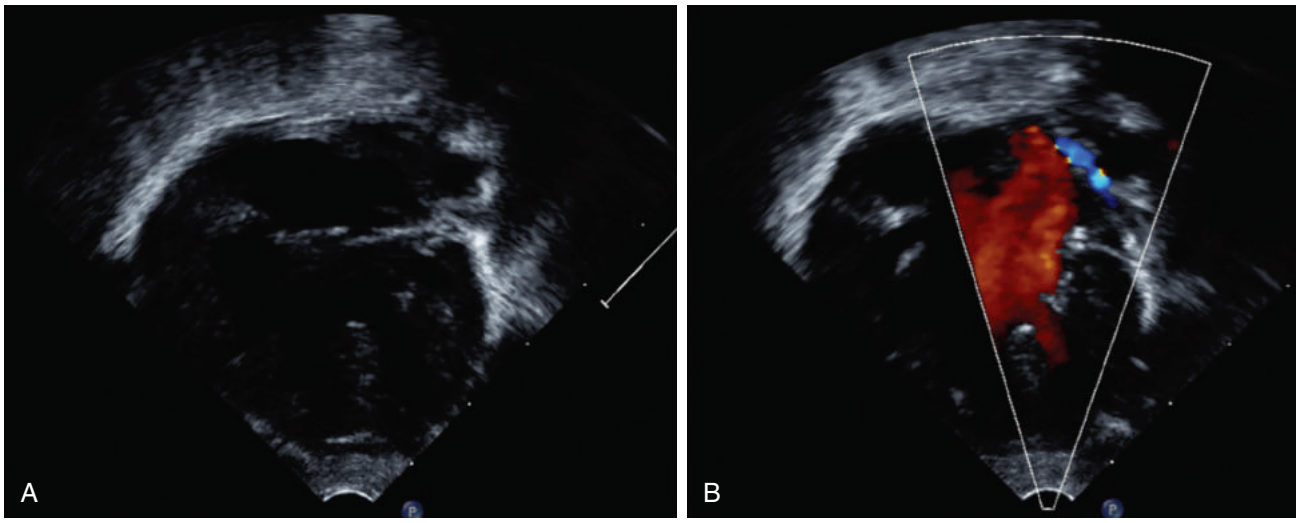
Peripheral Pulmonic Stenosis

Peripheral pulmonic stenosis (PPS) can range widely in its severity. In many instances, mild narrowing of the distal branch pulmonary arteries occurs in the neonate and produces a murmur that is heard widely throughout the chest. The murmur caused by this mild PPS is considered by some to be an "innocent murmur" of infancy and usually resolves by 2 to 4 months of age. This lesion likely reflects mild hypoplasia of the branch pulmonary arteries because of decreased in utero pulmonary blood flow and the postnatal transition where these vessels must accommodate the entire cardiac output following ductal closure.

More severe PPS is seen in cases of congenital rubella syndrome or in association with Williams or Noonan syndrome. Branch pulmonary artery stenoses can also occur with TOF. In these cases, multiple levels of obstruction may exist that require catheterization or surgical intervention.

In isolated or mild PPS, minimal right ventricular pressure overload occurs. With increasing stenosis, right ventricular pressure overload will result in right ventricular hypertrophy and, in later stages, right atrial enlargement on ECG. Echocardiogram can interrogate the proximal pulmonary arteries, but more-distal lesions require other imaging modalities such as MRI or cardiac catheterization.

Intervention to treat severe branch stenoses should be considered when right ventricular pressure is greater than 75% of systemic pressure or any clinical or laboratory evidence of right ventricular dysfunction is present. Surgical management is possible for proximal areas of stenosis, although the treatment preferred by most clinicians is balloon dilation or expandable stent placement in the cardiac catheterization laboratory. Repeated



• **Fig. 50.6** Echocardiographic View of Complete Atrioventricular Septal Defect. The large primum atrial septal defect and inlet ventricular septal defect are seen. (B) With color Doppler, inflow across the atrioventricular valve is seen.

interventions may be needed to enlarge vessels as the patient grows or to dilate other areas of stenosis that develop.

Pulmonic Stenosis

Isolated pulmonary valve stenosis is a common cause of a systolic ejection murmur in the neonatal period. While cases typically occur sporadically, pulmonic stenosis can be related to underlying genetic defects such as Noonan syndrome, Alagille syndrome, and Williams-Beuren syndrome.[50]

The degree of pulmonic stenosis determines the pathophysiology of the disease process. As the stenosis of the valve worsens, right ventricular pressure increases along with the degree of right ventricular wall stress. Right ventricular hypertrophy will develop if the stenosis is left untreated. In severe or critical pulmonic stenosis (discussed later in the section), heart failure can develop in the neonate accompanied by cyanosis due to right-to-left shunting at the atrial level.

The degree of stenosis is generally classified based on the pressure drop across the pulmonic valve with mild stenosis defined as a gradient less than 30 mmHg, moderate stenosis as a gradient of 30 to 60 mmHg, and severe stenosis as higher than 60 mmHg. While these definitions were initially based on cardiac catheterization, current follow-up of patients with pulmonic stenosis utilizes echocardiogram, which overestimates the gradient compared with direct hemodynamic measurement obtained from cardiac catheterization. Thus some use an *echo gradient* of less than 40 mmHg as mild pulmonic stenosis.

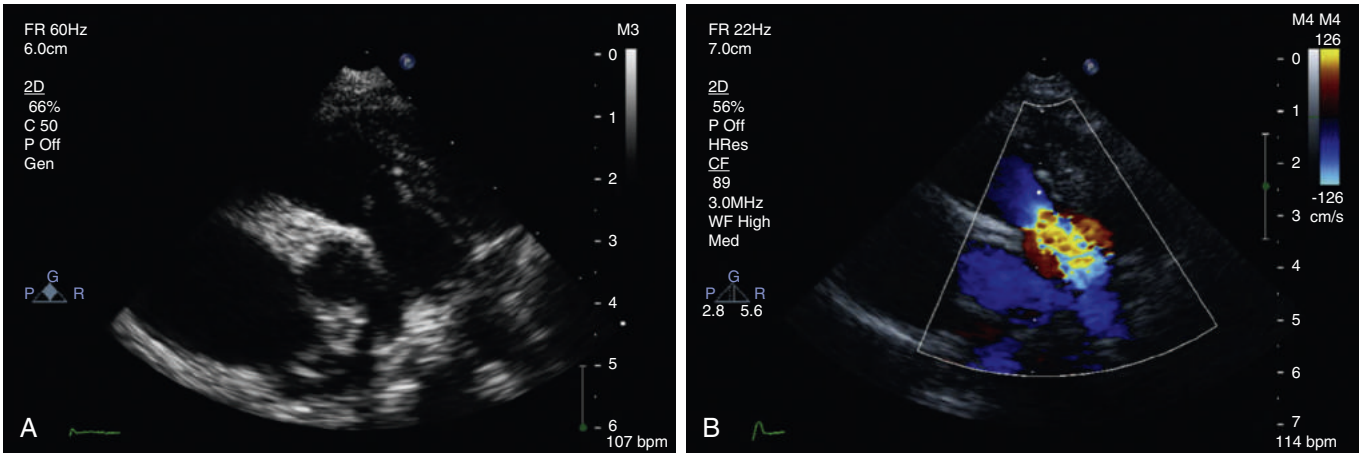
Consideration of the valve gradient is critical because of the prognostic significance of the value. In older children, mild stenosis rarely progresses.[51] In infants, however, follow-up of patients with echo gradients over 40 mmHg found that 29% developed progressive valve stenosis, with half of those showing an increase in the first 6 months of life.[52] A systolic ejection murmur of pulmonic stenosis can be heard in the neonatal period at the upper left sternal border. Typically, although the fast heart rate in the neonate may make it difficult to appreciate, a systolic ejection click just after the first heart sound (S1) can be heard in most of these infants and is an important feature to distinguish pulmonic stenosis from other lesions. Much like PPS (see earlier), the murmur of pulmonic stenosis radiates throughout the lung fields. As the gradient across the valve worsens, a thrill may be palpable at the upper left sternal border. As the degree of stenosis progresses further and becomes severe, the murmur and click will diminish and may even be absent as right ventricular dysfunction worsens. Of note is that while progressive pulmonic stenosis may be able to be estimated on the basis of the murmur, the clinical condition of the infant may not change appreciably until the degree of stenosis becomes severe.

The findings of laboratory studies in infants with pulmonic stenosis will vary depending on the degree of stenosis. ECG will demonstrate right ventricular hypertrophy in most patients with moderate stenosis, although the study may be normal when mild stenosis is present. Chest x-ray is often normal unless poststenotic dilation of the main pulmonary artery has developed. Echocardiography will be diagnostic. The valve will have varying degrees of dysplasia that is characterized by thickened, poorly mobile leaflets that dome during systole. Turbulence distal to the valve will be seen by color Doppler imaging (Fig. 50.7), while pulse wave Doppler is used to determine the degree of stenosis. As discussed previously, Doppler echo generally gives a value of stenosis that is 20% to 30% higher than the peak-to-peak pressure gradient measured as cardiac catheterization.

Treatment of isolated pulmonic stenosis, even in the neonate, can readily be performed by balloon valvuloplasty in the cardiac catheterization laboratory. The exception may be in infants with Noonan syndrome where the degree of valvar dysplasia may prevent an adequate result, although most will initially attempt a balloon valvuloplasty before progressing to surgery. Valvuloplasty should be considered in infants with moderate to severe stenosis (peak gradient of greater than 50 mmHg).[53] Mild or moderate pulmonary insufficiency, should it develop after balloon valvotomy, is usually well tolerated. Recurrent stenosis and more significant pulmonic insufficiency are found more often when valvuloplasty is needed in the neonatal period.[54]

Aortic Stenosis

Similar to stenosis of the pulmonic valve, aortic valve stenosis can produce a murmur in the neonatal period. However, aortic stenosis is more likely to be progressive than pulmonic stenosis.[55] Levels of obstruction of the left ventricular outflow tract can also occur at the subvalve and supravalve levels. Subvalvar stenosis is rarely diagnosed in the neonatal period but often progresses later in life



• **Fig. 50.7** Pulmonic Stenosis. (A) Short-axis view of pulmonic stenosis with a thickened-appearing pulmonic valve. (B) Using color Doppler imaging, turbulence in the main pulmonary artery is seen above the pulmonic valve.

as a fibromuscular ridge beneath the aortic valve. Supravalvar stenosis can present in the newborn period and is often associated with Williams syndrome.[56]

As with pulmonic stenosis, the pathophysiology and physical findings associated with aortic valve stenosis depend on the degree of obstruction. The most common aortic valve abnormality addressed in the neonatal period is critical aortic stenosis associated with decreased left ventricular function. This medical emergent situation is addressed in detail later. Mild (aortic valve gradient <30 mmHg) and moderate (valve gradient of 30 to 60 mmHg) aortic valve stenosis are not commonly encountered in the neonatal period. When they are, these milder forms of stenosis are generally associated with a bicuspid aortic valve and tend to progress with age. The rate of change of progression throughout infancy and childhood is quite variable and necessitates frequent follow-up of these patients.

The murmur in the newborn with aortic stenosis may be difficult to localize to the upper right sternal border as in older children. A thrill is usually palpable at the suprasternal notch with even mild aortic valve stenosis, with a precordial thrill felt as the degree of stenosis increases. Usually a click from the stenotic aortic valve is heard at the apex or lower left sternal border.

Electrocardiography may be of limited benefit in the newborn with mild or even moderate aortic valve stenosis, although some degree of left ventricular hypertrophy may be seen. Chest x-ray is of limited benefit in following these patients, with the focus of the diagnostic assessment being the echocardiogram. On echocardiogram, the aortic valve can be characterized. Fused leaflets that are thickened and domed are seen. Pulsed Doppler is used to determine the gradient across the valve while color Doppler imaging can define the presence of aortic insufficiency.

Initial management of moderate aortic valve stenosis is balloon valvotomy in the cardiac catheterization laboratory. The balloon is sized in an effort to limit aortic insufficiency, which is much less well tolerated than insufficiency of the pulmonic valve. If significant aortic valve insufficiency is present or develops, surgical repair or valve replacement is needed. In neonates and infants, the Ross procedure is usually the procedure of choice.[57] In this procedure, the pulmonary valve is removed intact from the patient and sewn into the aortic position, and a homograft is placed in the pulmonic position. Interestingly, the pulmonary autograft generally demonstrates good growth and excellent function in the aortic position. While the child will outgrow the pulmonary homograft, replacing it and managing progressive pulmonic stenosis are much easier than addressing the aortic valve.

Cyanosis in the Newborn

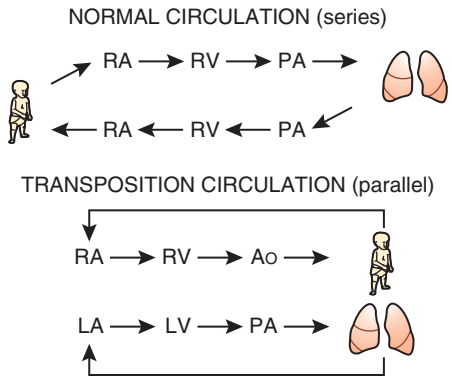
Congenital heart defects that present with cyanosis do so because of a right-to-left shunt. The shunt results in mixing of the systemic and pulmonary venous returns thereby leading to cyanosis. This mixing can occur between the atria, ventricles, or great vessels. Defects presenting predominantly with cyanosis can be further subclassified by the amount of associated pulmonary blood. If there is no restriction to pulmonary blood flow, cardiac output to the lungs will increase as the normal postnatal drop in PVR occurs. Clinically, this results in signs of congestive heart failure (CHF) such as tachypnea, poor feeding, hepatomegaly, and pulmonary edema. Much of the neonatal management is aimed at balancing the ratio of systemic to pulmonary blood flow. Defects with restriction to pulmonary blood flow typically present with cyanosis without associated symptoms of CHF. If the restriction is severe, pulmonary blood flow may be dependent upon a left-to-right shunt through the ductus arteriosus. These patients typically have some degree of right ventricular hypertension. If the ductus closes, profound cyanosis results. This is termed ductal dependent pulmonary circulation and initial management includes maintaining patency of the ductus arteriosus with prostaglandin E_1 (PGE_1).

Transposition of the Great Arteries

Transposition of the great arteries (TGA) accounts for 5% of all CHD and is the most common cyanotic cardiac defect that presents with cyanosis in the newborn period. There is a strong male predominance (60% to 70%). TGA is rarely associated with chromosomal abnormalities or extracardiac malformations. It can, however, be associated with dextrocardia and lateralization defects like heterotaxy, in particular right isomerism (asplenia).[58] It has been associated with exposure to maternal hyperglycemia as well as high maternal intake of vitamin A.[58–60]

In the most common form of TGA (D-TGA, complete transposition, or simple transposition), the aorta arises from the right ventricle anteriorly and rightward of the pulmonary artery, which arises from the left ventricle. Desaturated blood returns to the right ventricle and is recirculated to the body via the aorta, while oxygenated blood returns to the left ventricle and is recirculated to the lungs. The result is separate, parallel circulations (Fig. 50.8). Survival is dependent upon communication between the two circulations, typically in the form of bidirectional shunting at the PFO and PDA. With absent or small communications between the circulations, severe systemic acidosis and hypoxia develop after birth resulting in death.

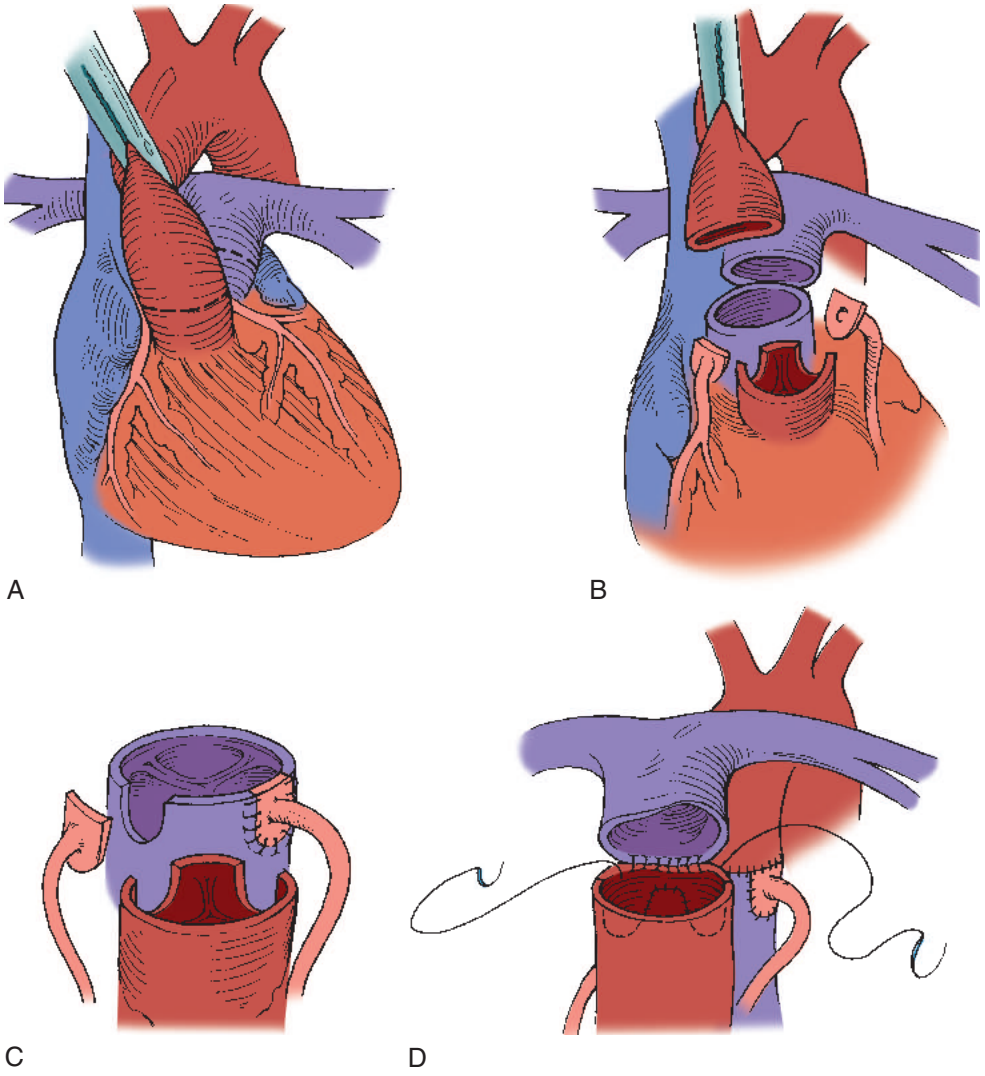
Prenatal diagnosis of DTGA has been shown to improve postnatal outcomes as it allows for prenatal planning of postnatal management.[61] DTGA is a difficult diagnosis to make likely owing to the presence of a normal 4 chamber view. This has been improving with the addition of outflow views to screening ultrasounds. However, prenatal detection rates for DTGA still remain lower than for other critical CHD.[62] In addition, consistent identification of patients with critical D-TGA who will require a balloon atrial septostomy within the first 24 hours of life has been inadequate.[63]



• **Fig. 50.8** Series and Parallel Circulations. The series circulation in the normal newborn is compared with the parallel circulation in transposition of the great arteries (TGA). In TGA, survival after birth is dependent on mixing at either the atrial, ventricular, or great vessel level. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle. (From Wernovsky G. Transposition of the great arteries. In: Allen HD, Gutgesell HP, Clark EB, Driscoll DJ, eds. *Moss and Adams' Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adult*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2001:1027–1084.)

In TGA physiology, cyanosis is apparent within the first few hours of life and is not responsive to oxygen supplementation. Cardiac examination is typically normal except for a loud single S2. This is because of the arrangement of the great vessels; the louder closure of the anterior aortic valve obscures the closure of the more posterior pulmonary valve. Reversed differential cyanosis, higher saturations in the lower body than in the upper body, is a phenomenon that can briefly happen during the first few hours of life as the PVR remains elevated and the duct is able to shunt bidirectionally. Chest x-ray may be normal or reveal a narrow mediastinum with slight predominance of the right ventricle resulting in an "egg on a string" appearance. Pulmonary vascular markings are normal to slightly increased. ECG is typically normal but may reveal right atrial enlargement and right ventricular hypertrophy. Echocardiogram reveals the transposed great vessels and is used to determine the size of the PFO and PDA, coronary anatomy, as well as define any associated cardiac defects.

Initial management of infants with TGA is aimed at maintaining communication between the systemic and pulmonary circulations. PGE_1 is started to maintain patency of the ductus arteriosus (dose of 0.03 to 0.1 mcg/kg/min). The lowest effective dose is used, as there are side effects to the use of PGE_1, the most common of which is apnea and may require respiratory support. In patients with a restrictive PFO, or with persistent hypoxia and acidosis despite a PDA, a balloon atrial septostomy (BAS) is performed within the first 24 to 48 hours of life to encourage mixing at the atrial level. Persistent pulmonary hypertension of the newborn can further complicate the clinical status leading to persistent hypoxia and acidosis even after balloon atrial septostomy. These children tend to have worse outcomes and may require extracorporeal membrane oxygenation (ECMO) as a bridge to surgery. In the setting of adequate mixing, pulmonary overcirculation may develop as PVR drops. Surgical treatment is the arterial switch procedure (Fig. 50.9), typically performed within the first week after birth.[64,65]



• **Fig. 50.9** Arterial Switch Operation for Dextro-Transposition of the Great Arteries. (A) The *dashed lines* depict the planned location of transection of the great vessels. (B) The coronary arteries are removed with surrounding aortic wall as "buttons." (C) The coronary buttons are translocated to the posterior neoaortic root. (D) The Lecompte maneuver brings both pulmonary arteries anterior to the neoaorta. The aortic suture line is completed, incorporating the coronary buttons. The coronary donor sites are filled in with patches of autologous pericardium, and the pulmonary anastomosis is completed. (From Wernovsky G, Jonas RA. Transposition of the great arteries. In: Chang AC, Hanley FL, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore: Williams & Wilkins; 1998:289–301.)

While TGA is usually an isolated lesion, 40% to 45% of patients have an associated VSD, 10% have a VSD with left ventricular outflow tract obstruction, and 5% have left ventricular outflow tract obstruction alone. In addition, there is a wide variety in coronary artery anatomy in patients with TGA. This can affect the surgical technique used for transfer of the coronary arteries and thus add to the complexity and risk of surgical correction.

The clinical presentation of patients with TGA and VSD depends upon the size of the VSD. Those with a restrictive VSD present like patients with TGA and intact ventricular septum. Those with a large VSD may not demonstrate any symptoms initially. As PVR drops, symptoms of pulmonary overcirculation develop. In general, presence of a VSD does not provide for adequate mixing, and balloon atrial septostomy is still warranted for patients with persistent hypoxia and inadequate atrial level mixing. Patients with restricted pulmonary blood flow (TGA with VSD and pulmonic stenosis or LVOT obstruction) appear clinically similar to patients with TOF. The timing and type of surgical repair in patients with complex TGA are variable and beyond the scope of this chapter.

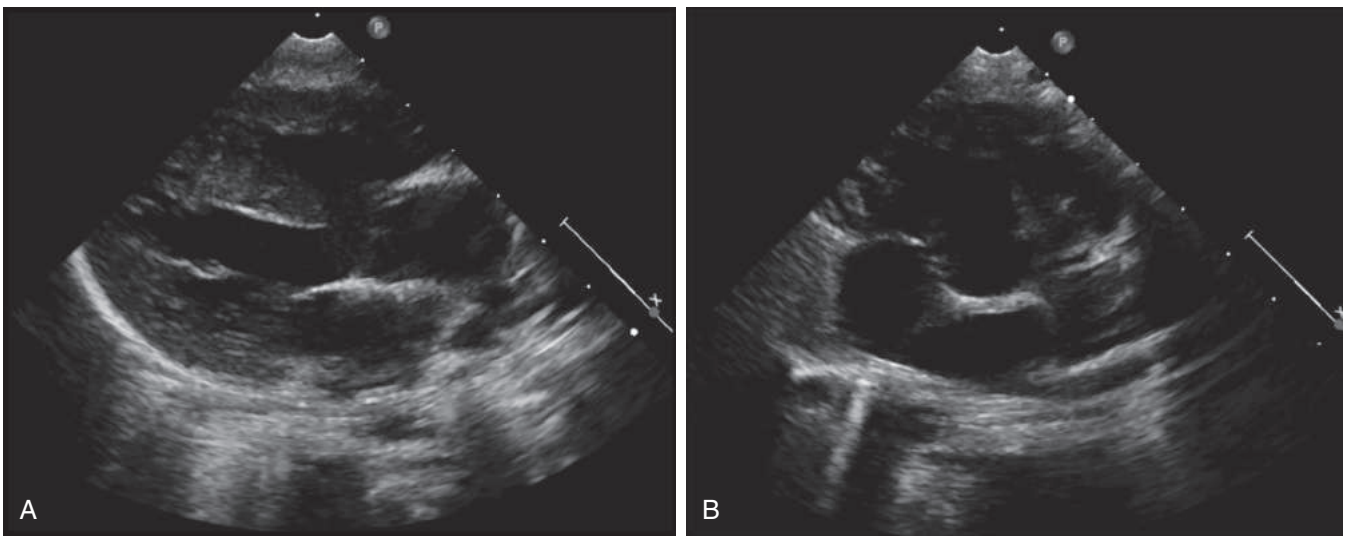
Tetralogy of Fallot

Tetralogy of Fallot (TOF) is the most common cyanotic CHD and comprises about 10% of all CHD. It consists of a VSD, overriding aorta, RVOT obstruction, and right ventricular hypertrophy (Fig. 50.10). The severity and location of the RVOT obstruction are variable and lead to a spectrum of diseases. Anterior deviation of the infundibular septum, infundibular hypertrophy, a small, thickened and frequently bicuspid pulmonary valve, and small main pulmonary artery can jointly or independently create the classic multilevel obstruction at the subvalvar, valvar, or supravalvar level. Complete obstruction of the RVOT (pulmonary atresia) with a VSD is an extreme form of TOF. TOF is associated with a right aortic arch in 25% of cases,[66] and aberrant coronary arteries in 5% to 6% of cases[67] both of which can affect surgical planning.

The etiology of TOF is heterogeneous. Maternal diabetes, phenylketonuria, and retinoic acid exposure have been associated with TOF. In addition, genetic syndromes including 22q11 deletion (20%), trisomy 21, 18, and 13, Alagille syndrome, Holt-Oram syndrome, and VACTERL/VATER association have been associated with TOF. Prenatal diagnosis of TOF can be as high as 90%.[68] It allows for identification of cases in which there will be ductal dependent pulmonary circulation and thus the need for PGE_1 at birth.

The pathophysiology and clinical presentation of TOF are directly tied to the severity of the RVOT obstruction. With mild RVOT obstruction, the predominant shunt through the VSD is left to right. Cyanosis is minimal, and symptoms of heart failure are the typical presenting symptoms. The main and branch pulmonary arteries are usually of normal size. With moderate RVOT obstruction, the shunt through the VSD is right to left or bidirectional but the prograde flow through the RVOT is adequate, resulting in mild cyanosis. The main and branch pulmonary arteries may have areas of focal stenosis or be diffusely small. These patients may have instances of hypercyanotic spells ("Tet spells"), which are periods of increased cyanosis brought on usually by agitation. With severe RVOT obstruction, there is minimal or no prograde flow across the RVOT. Pulmonary blood flow is thus dependent upon left-to-right shunt through the PDA. These patients are severely cyanotic, and PDA closure leads to cardiovascular collapse. The main and branch pulmonary arteries may be confluent and small. With pulmonary atresia (pulmonary atresia VSD or tetralogy pulmonary atresia), the pulmonary vascular bed is variable. The pulmonary arteries can be confluent, normal-sized, and fed entirely by the ductus arteriosus; confluent and small with a small ductus; or virtually absent with pulmonary blood flow supplied by multiple AP collateral vessels.

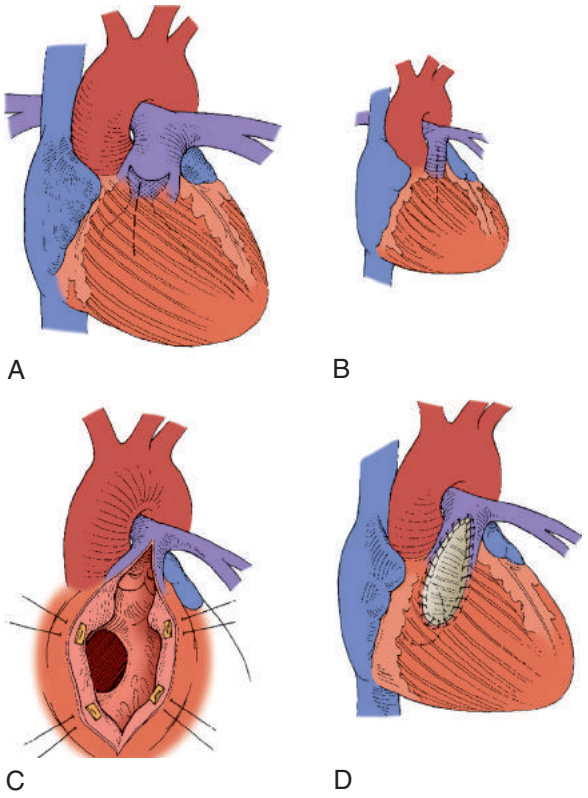
In general, physical exam findings will also vary depending on the degree of obstruction to pulmonary blood flow. A loud systolic ejection murmur can be appreciated as there is turbulence of flow across the pulmonary outflow. The murmur will be louder and shorter with increasing pulmonary obstruction. Those with pulmonary atresia and major aortopulmonary collateral arteries (MAPCAs) can have continuous murmurs heard best over the back but no pulmonary stenosis murmur. The ECG is usually consistent with right axis deviation and right ventricular hypertrophy. The CXR can have a classic "boot-shaped"



• **Fig. 50.10** Echocardiographic View of Tetralogy of Fallot. (A) Some of the anatomic features of tetralogy of Fallot are readily demonstrated on the long-axis echocardiographic view including the hypertrophy of the right ventricle, the ventricular septal defect (VSD), and the aorta overriding the VSD. (B) The short-axis view on echocardiogram shows the infundibular or right ventricular outflow tract stenosis.

appearance due to right ventricular hypertrophy. However, this is much less likely with early repair. A right-sided aortic arch can also be seen on CXR if present. Echocardiogram easily shows all components of TOF and allows for evaluation of the arch, coronary anatomy, and presence of PFO and PDA. For more complex variants including discontinuous branch pulmonary arteries and/or presence of MAPCAs, other imaging modalities may be used to further delineate anatomy prior to surgical correction.

Initial management of TOF depends upon the amount of pulmonary blood flow. Patients without significant symptoms or hypoxemia undergo a complete repair in the first 4 to 6 months after birth. Complete repair consists of VSD closure and relief of RVOT obstruction through a combination of infundibular muscle resection, pulmonary valvotomy, or RVOT patch that can extend out to the branch pulmonary arteries as needed (Fig. 50.11). Valve sparing repair, consisting of infundibular muscle resection and supravalvar patch augmentation extending into the branch pulmonary arteries if necessary, can also be performed when the pulmonary valve annulus and valve function are deemed adequate. In patients with significant cyanosis or ductal-dependent pulmonary circulation, initial management includes PGE_1. This can be followed by palliation with a systemic-to-pulmonary artery shunt in the newborn period (modified Blalock–Taussig [BT] shunt) and complete repair at a later date or a complete anatomic correction in the newborn period. The recent trend has been toward earlier complete correction in symptomatic infants.[69–72]

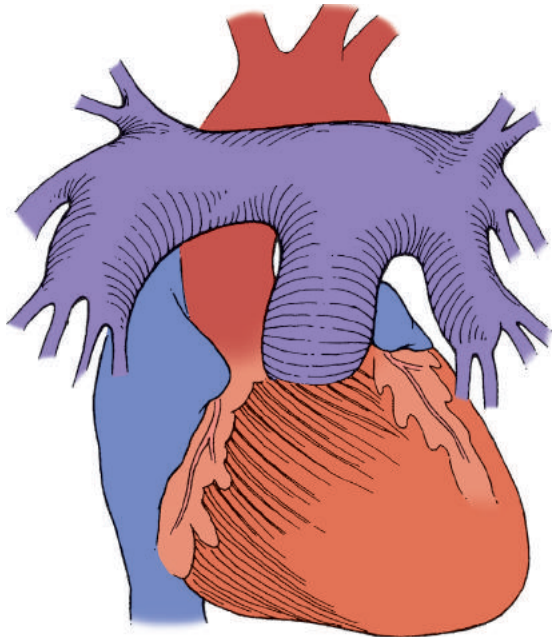


• **Fig. 50.11** Repair of Tetralogy of Fallot. (A) *Dashed line* depicts a nontransannular incision, used when the pulmonary valve and annulus are of adequate size. (B) A transannular incision *(dashed line)* is used when there is annular hypoplasia. (C) An example of transventricular exposure of the ventricular septal defect. Alternatively, the ventricular septal defect may be closed via a right atriotomy through the tricuspid valve. (D) External view of patch closure of the transannular incision. (From Spray TL, Wernovsky G. Right ventricular outflow tract obstruction. In: Chang AC, Hanley FH, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore: Williams & Wilkins; 1998:257–270.)

Tetralogy of Fallot Absent Pulmonary Valve

TOF with absent pulmonary valve (APV), or APV syndrome, is a spectrum of disorders with a rudimentary pulmonary valve. The resultant pulmonary valve stenosis and insufficiency cause dilation of the right ventricle and main and branch pulmonary arteries that is apparent in utero (Fig. 50.12). There is a higher risk of fetal heart failure, hydrops, and in utero demise with APV. This risk can be as high as 50%.[73] Most cases also have a malalignment VSD and lack a ductus arteriosus. Extrinsic compression of the airways from the dilated pulmonary arteries results in airway abnormalities as well as pulmonary hypoplasia. There is a high prevalence of 22q11 deletion among patients with APV.

Physical examination reveals a characteristic "to and fro" murmur of pulmonary stenosis and insufficiency. A prominent right ventricular heave and hepatomegaly are present secondary to the right ventricular volume overload. There is a wide range of symptoms, depending upon the degree of right ventricular volume overload and degree of airway disease. At one end of the spectrum is an asymptomatic neonate with mild cyanosis and the gradual development of heart failure symptoms during the normal postnatal decline in PVR. At the other end of the spectrum is a critically ill infant with severe cyanosis and respiratory failure caused by the combination of right-to-left shunt through the VSD and underlying airway disease. Mechanical ventilation is frequently necessary and occasionally unsuccessful secondary to airway compression by the dilated pulmonary vasculature. PGE_1 is not helpful since there is usually no ductus arteriosus. iNO and 100% oxygen can



• **Fig. 50.12** Tetralogy of Fallot With Absent Pulmonary Valve. Severe dilatation of the main and branch pulmonary arteries is seen and is frequently associated with bronchial compression and large and small airway disease. The intracardiac anatomy is usually similar to that in standard tetralogy of Fallot. (From Spray TL, Wernovsky G. Right ventricular outflow tract obstruction. In: Chang AC, Hanley FH, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore: Williams & Wilkins; 1998:257–270.)

be used to encourage forward pulmonary flow. ECMO may be needed until surgery is performed. Urgent surgery is required in these infants.

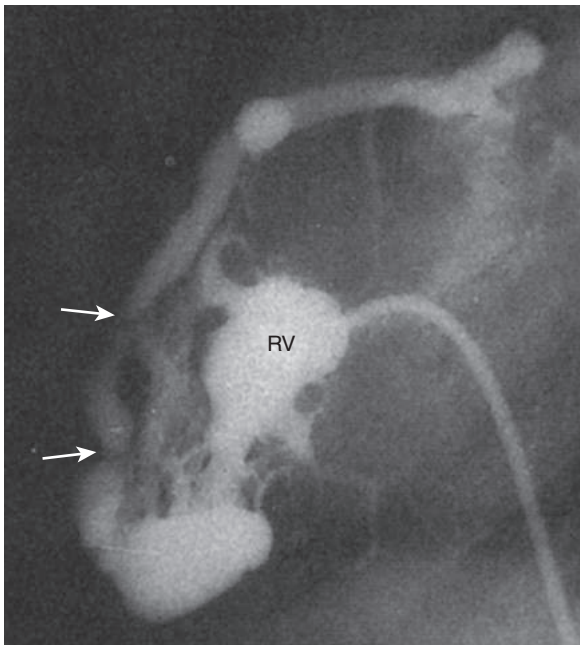
Surgery consists of VSD closure, pulmonary artery plication, relief of RVOT obstruction, and insertion of a valve or homograft in the RVOT position. This differs from the traditional approach in TOF where the pulmonary outflow is often left unguarded. In TOF with APV the goal is to limit pulmonary insufficiency with a functional valve and thus stop the dilation of right sided structures. There is significant variation in surgical technique between centers.[74,75] The surgical mortality and short-term and long-term outcomes are related primarily to the severity of pulmonary artery dilation and airway compression. More severely affected infants have a higher surgical mortality and need for prolonged postoperative ventilation. There is up to a 42% rate of death in infancy.[73] Those with less significant pulmonary artery dilation have lower postoperative mortality and long-term outcomes similar to patients with TOF.

Pulmonary Atresia With Intact Ventricular Septum

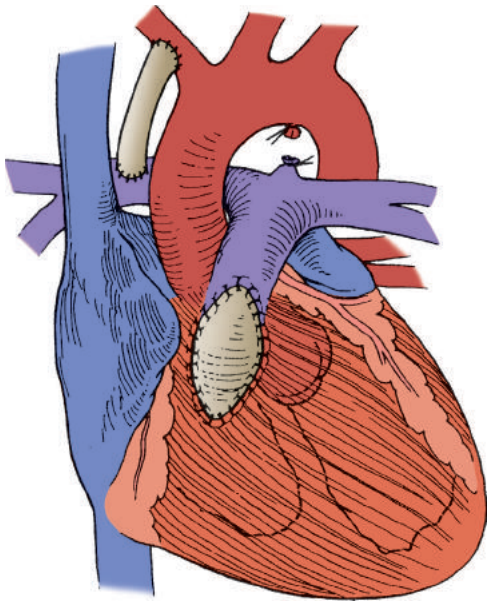
In pulmonary atresia with intact ventricular septum, the pulmonary valve leaflets are fused or fail to form. Without egress from the right ventricle, systemic venous return passes through the PFO and mixes with pulmonary venous return. Pulmonary blood flow is dependent upon the PDA, with the left ventricle providing cardiac output to both the systemic and pulmonary circulations. The tricuspid valve is usually abnormal owing to tricuspid insufficiency. Tricuspid valve and right ventricular size vary, ranging from nearly normal-sized structures to nearly atretic tricuspid valve and diminutive right ventricular chamber. The latter patients may have sinusoidal channels in the right ventricular myocardium that communicate with the coronary circulation as a way to decompress the RV. The high right ventricular pressure results in retrograde perfusion of the coronary arteries, termed right ventricle-dependent coronary circulation (Fig. 50.13).

Pulmonary atresia with intact ventricular septum presents with cyanosis. Cardiac examination reveals a single loud second heart sound. A murmur is typically not present, other than from the PDA. However, if there is significant tricuspid insufficiency, a pansystolic regurgitant murmur can be heard at the left lower sternal border. ECG typically reveals a relative lack of right-sided forces with a QRS axis between 0 and 90 degrees. The P wave is peaked from right atrial enlargement. Pulmonary vascular markings on chest x-ray are typically decreased. Heart size can go from mildly enlarged to severely enlarged depending on the size of the right sided structures. Echocardiography confirms the diagnosis and can be used to look for coronary sinusoids. Cardiac catheterization is performed in patients where coronary sinusoids are known or suspected to completely define the extent and connections of the sinusoids.

Initially, PGE_1 is used to maintain ductal patency until a more permanent source of pulmonary blood flow is provided. In patients with right ventricle–dependent coronary circulation, the outcome of surgical repair is often poor. In these cases, decompression of the right ventricle can invariably result in decreased coronary perfusion and is contraindicated. A systemic-to-pulmonary shunt followed by staged single ventricle palliation is often tried, but proceeding directly to heart transplantation may be appropriate in some cases. In patients without right ventricular coronary–dependent circulation, an egress from the right ventricle to pulmonary arteries is created by surgical valvotomy and/or RVOT augmentation or through transcatheter intervention via valve perforation and valvuloplasty (Fig. 50.14).[76,77] At times, additional pulmonary blood flow is provided by a modified BT



• **Fig. 50.13** Lateral Angiogram From a Newborn With Pulmonary Atresia and Intact Ventricular Septum. Following injection of contrast through the hypertrophied and diminutive right ventricle, there is retrograde filling of tortuous coronary arteries through sinusoidal connections to the right ventricle *(arrows)*. *RV*, Right ventricle.



• **Fig. 50.14** Newborn Surgical Palliation for Pulmonary Atresia With Intact Ventricular Septum and Normal Coronary Arteries. A right ventricular outflow tract patch is placed, the ductus is ligated and divided, and a modified Blalock-Taussig shunt is placed. (From Wernovsky G, Hanley FL. Pulmonary atresia with intact ventricular septum. In: Chang AC, Hanley FL, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore: Williams & Wilkins; 1998:265–270.)

shunt or other systemic-to-pulmonary shunt (PDA stent). The postoperative course can be complicated by low cardiac output or a circular shunt.

Tricuspid Atresia

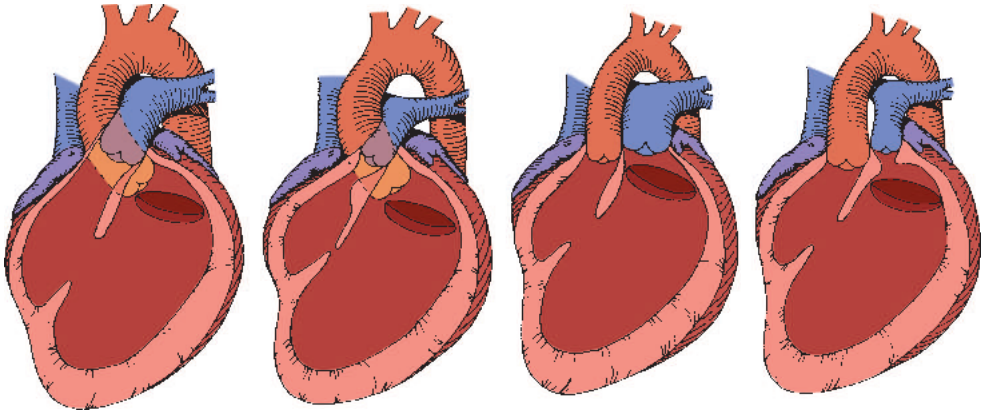
In tricuspid atresia, there is no outlet from the right atrium to the right ventricle. Systemic venous return passes from the right atrium, through a PFO or ASD, to the left atrium and then the left ventricle. The ASD is rarely restrictive. More than 90% of patients with tricuspid atresia have an associated VSD, allowing blood to pass from the left ventricle to the right ventricle and then the pulmonary arteries (Fig. 50.15). The size of the VSD determines the amount of pulmonary blood flow. The VSD is usually muscular and can become more restrictive over time. Patients with a small or absent VSD have a very hypoplastic right ventricle and pulmonary artery. The majority of pulmonary blood flow comes from the PDA. If a large VSD is present, pulmonary blood flow is prograde through the pulmonary valve, and the ductus is not necessary postnatally. Tricuspid atresia can be further classified based on the relationship of the great arteries. Most commonly, there are normally related great arteries with the above-mentioned considerations. The second most common variant of tricuspid atresia is with TGA. In this variant, pulmonary blood flow is derived from the left ventricle, and it is the systemic blood flow which must pass through the VSD and may be limited. This may lead to an associated coarctation or hypoplastic aortic arch. The third classification is with congenitally corrected TGA, which is the least common.

Clinically, cyanosis is present at birth, the extent of which is dependent upon the degree of restriction to pulmonary blood flow. A holosystolic murmur consistent with a VSD and a prominent left ventricular impulse are present on exam. ECG is nearly diagnostic of tricuspid atresia and reveals a classic left axis deviation and left ventricular hypertrophy. Chest x-ray reveals variable pulmonary vascular markings, depending on the size of the VSD and relationship of the great vessels. Echocardiogram demonstrates a fibromuscular plate in place of the tricuspid valve and a variably small right ventricle and pulmonary valve. The relationship of the great vessels can also be determined by echocardiogram. The degree of obstruction at the VSD or across the RVOT can be evaluated.

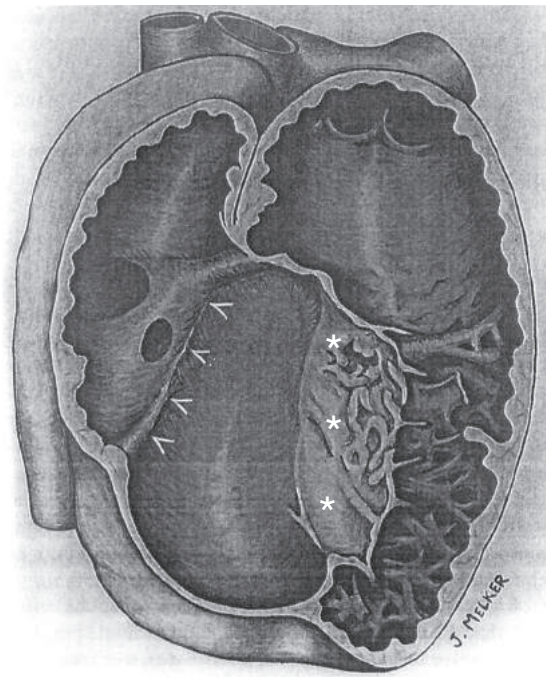
PGE_1 is used initially to maintain ductal patency. If there is restriction to flow at the atrial level, a balloon septostomy can be performed. Further management depends on the amount of pulmonary blood flow and the relationship of the great vessels. Patients with ductal-dependent pulmonary blood flow will have a systemic-to-pulmonary artery shunt placed (modified BT shunt) in the neonatal period. Those with adequate pulmonary blood flow undergo an SVC-to-pulmonary-artery anastomosis (bidirectional Glenn) at approximately 6 months of age, with completion of the Fontan procedure around 3 years of age. Patients with transposition, or more complex anatomy, undergo more extensive palliative procedures initially but continue down the pathway to Fontan palliation.

Ebstein Anomaly of the Tricuspid Valve/Tricuspid Valve Dysplasia

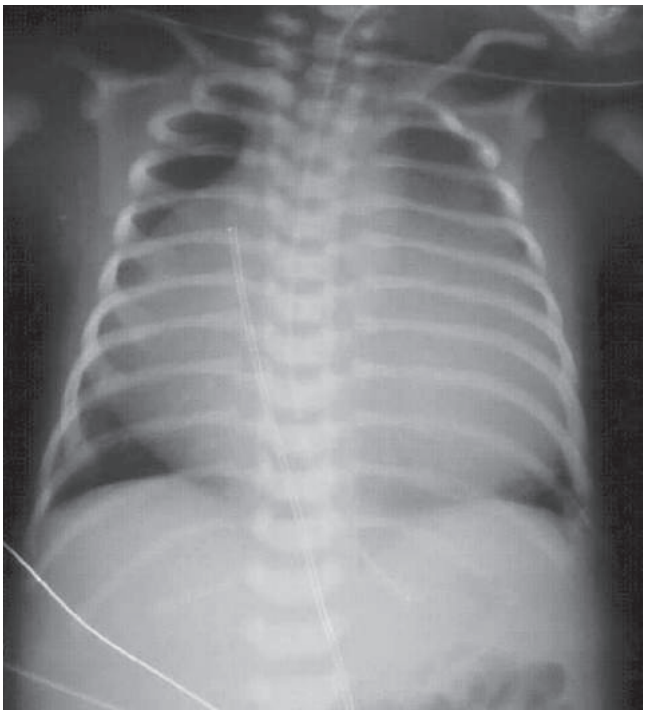
Ebstein anomaly of the tricuspid valve and the closely related tricuspid valve dysplasia are rare forms of CHD of the tricuspid valve. The presentation is variable, and there is considerable overlap between the two, more appropriately considered as a spectrum of tricuspid valve disease. For Ebstein anomaly, dysplasia of the tricuspid valve, with downward displacement of the septal and posterior leaflets, is the defining feature (Fig. 50.16). The anterior leaflet, although normally positioned in the valve annulus, frequently has abnormal chordal attachments and is large and redundant. The tricuspid valve abnormality can be accompanied by tricuspid regurgitation, right atrial dilation, abnormal right ventricular myocardium, and an increased risk of Wolff–Parkinson–White syndrome. In addition, functional and true pulmonary atresia can occur with severe Ebstein malformation. With displacement of the tricuspid valve, a significant portion of the right ventricle becomes atrialized, making it an ineffective pumping chamber. In this setting it can be difficult to differentiate functional pulmonary atresia from true pulmonary atresia. Severe Ebstein anomaly of the tricuspid valve is associated with heart failure in utero and a perinatal mortality as high as 45%.[78,79] Tricuspid valve dysplasia in its severe form can also lead to severe tricuspid regurgitation and severe dilation of the right atrium and ventricle. In this case, there may be mild displacement of the septal and posterior leaflets, but



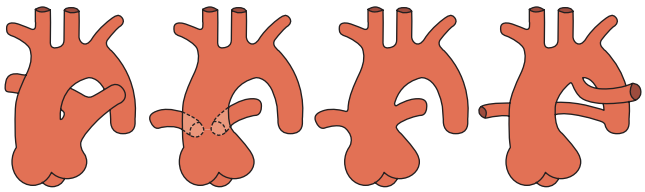
• **Fig. 50.15** Anatomic Variants in Tricuspid Atresia. (A) Normally related great vessels with a large ventricular septal defect (VSD) and normal-sized pulmonary arteries (PAs). (B) Normally related great vessels with a small VSD and PAs. (C) Transposed great arteries (left ventricle aligned with the PA, right ventricle with the aorta) with a relatively small VSD and aorta. Many patients with this variant have coarctation as well (see text). (D) Transposed great vessels with a VSD, subpulmonary obstruction, and small PAs. (From Fyler DC. Tricuspid atresia. In: Fyler DC, ed. *Nadas' Pediatric Cardiology*. Philadelphia: Hanley & Belfus; 1992:659–667.)



• **Fig 50.16** Inferior Displacement of Tricuspid Valve Leaflet Into the Right Ventricular Cavity. The *white arrowheads* indicate the normally positioned tricuspid valve annulus. The asterisks (*) indicate varying degrees of inferior or apical displacement of the septal leaflet of the tricuspid valve. The area between the true annulus and the displaced valve leaflet is considered "atrialized." (From Epstein ML. Congenital stenosis and insufficiency of the tricuspid valve. In: Allen HD, Gutgesell HP, Clark EB, Driscoll DJ, eds. Moss and Adams' Heart Disease in Infants, Children and Adolescents: Including the Fetus and Young Adult. Philadelphia: Lippincott Williams & Wilkins; 2001:810–819.)



• **Fig. 50.17** Chest Radiograph in a 1-Day-Old Newborn With Ebstein Anomaly of the Tricuspid Valve. Note the massive cardiomegaly and relative pulmonary oligemia and hypoplasia.



• **Fig. 50.18** Types of Truncus Arteriosus. The classification of truncus arteriosus is determined by the origin of the pulmonary arteries (see text for details).

it does not meet criteria for Ebstein anomaly. There is considerable overlap within the two and quite variable presentation.

The clinical presentation is variable and depends upon the degree of displacement of the tricuspid valve leaflets and severity of RVOT obstruction. In many patients, symptoms are mild and do not present until later in life. In more severe disease, cyanosis results when a right-to-left shunt occurs at the atrial level, secondary to the tricuspid regurgitation and elevated right atrial pressures. Cardiac examination reveals a holosystolic murmur at the lower left sternal border with associated gallop and clicks. Neonates with severe Ebstein present with marked cyanosis, cardiomegaly, and ductal-dependent pulmonary blood flow. Chest x-ray is characteristic in severe cases with severe cardiomegaly evident at birth (Fig. 50.17). Death can occur because of the significant heart failure and hypoxemia. Clinical improvement may occur as the PVR drops, improving the right ventricle's ability to contribute to pulmonary blood flow.

Initially, management of the severely cyanotic infant is aimed at promoting pulmonary blood flow. PGE_1 is used to maintain ductal patency. Supplemental oxygen, inhaled nitric oxide, and mild respiratory alkalosis can have marginal success in improving pulmonary blood flow by lowering PVR. After several days, attempts are made at weaning the PGE_1. If unsuccessful, surgical options are considered. Options include tricuspid valve repair or replacement, ventricle repair, or other palliative procedures such as right ventricular exclusion with a fenestrated patch and placement of a modified BT shunt.[79] While surgical outcomes have improved, the need for neonatal repair for symptomatic disease remains a risk factor for death.[80,81]

Truncus Arteriosus

In truncus arteriosus, a single arterial trunk gives rise to the pulmonary, systemic, and coronary circulation. The arterial trunk typically overrides a VSD. Truncus is classified by the origin of the pulmonary arteries (Fig. 50.18). In type I, a small pulmonary artery arises from the arterial trunk and bifurcates in the right and left branch pulmonary arteries. The right and left pulmonary arteries can also arise from separate ostia that are either close to one another (type II) or some distance apart (type III).[82] Type IV is similar to TOF with pulmonary atresia. The truncal valve has between one and six cusps. It is occasionally insufficient but rarely stenotic. Truncus usually occurs as an isolated cardiovascular defect although it has been associated with microdeletion of chromosome 22q11.[83]

As the PVR drops over the first several weeks after birth, increased shunting from the arterial trunk to the pulmonary arteries occurs, and pulmonary overcirculation develops. If left

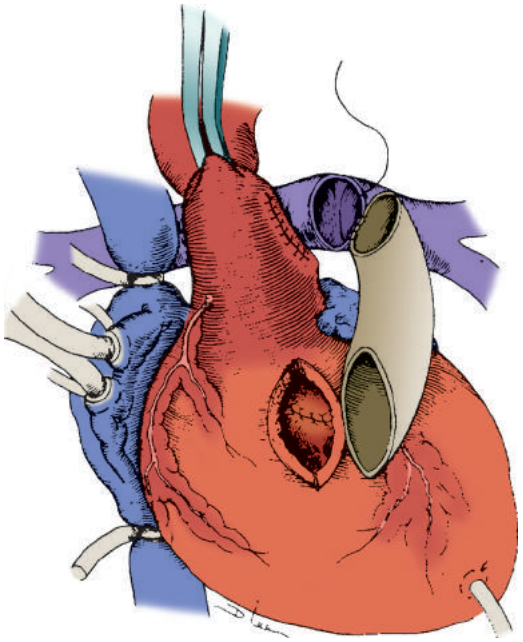
untreated, symptoms of heart failure develop. Long-term pulmonary vascular disease occurs.

The clinical presentation of truncus changes with the PVR. Initially, infants are minimally cyanotic and do not appear to be in distress. As pulmonary overcirculation occurs, symptoms of heart failure develop. Cardiac examination reveals a hyperdynamic precordium and a loud single S2. As PVR drops, the pulses become bounding, and the pulse pressure widens because of run-off into the pulmonary arteries. A low-pitched diastolic inflow rumble may be heard at the apex. In addition, a systolic ejection murmur may be present with truncal valve stenosis and a medium- to high-pitched diastolic murmur may be heard from truncal valve insufficiency. Chest x-ray typically reveals cardiomegaly with pulmonary vascular markings that increases over the first few weeks of life. ECG demonstrates right, left, or biventricular hypertrophy. Echocardiogram is used to demonstrate the anatomy and evaluate for associated cardiac defects such as right aortic arch, coronary artery anomalies, interrupted aortic arch, and secundum ASDs.

Initially, heart failure symptoms are managed medically. Surgical repair is typically performed within the first 2 months of life because of the difficulty in controlling heart failure. The usual repair involves closure of the VSD so that the arterial trunk arises from the left ventricle. A right-ventricle-to-pulmonary-artery conduit is then placed (Fig. 50.19). The right-ventricle-to-pulmonary-artery conduit needs to be replaced several times over the course of the patient's lifetime.

Total Anomalous Pulmonary Venous Return

In TAPVR, the pulmonary veins return to a systemic vein or directly to the right atrium, rather than to the left atrium. Both systemic and pulmonary venous return pass through the right atrium, right ventricle, and pulmonary artery, creating pulmonary overcirculation and right heart volume overload. An ASD is present in all cases. The right-atrium-to-left-atrium shunt supplies the systemic cardiac output. If the ASD is restrictive, then systemic output will be limited.



• **Fig. 50.19** Anatomy and Repair of Truncus Arteriosus. After the branch pulmonary arteries are removed from the common trunk (and the resulting aortic defect is closed), a ventriculotomy is performed. The ventricular septal defect is closed through this incision, and a conduit is placed from the right ventricle to the pulmonary arteries. (From Behrendt DM, Dick M. Truncus repair with a valveless conduit in neonates. *J Thorac Cardiovasc Surg*. 1995;110:1148–1150.)

Several common patterns of anomalous pulmonary venous return are seen (Fig. 50.20).[84] Most commonly, the anomalous veins drain in a supracardiac fashion, entering the left innominate vein or SVC via a vertical vein and draining into the right atrium via the SVC. Cardiac drainage occurs when the anomalous veins drain into the right atrium via the coronary sinus. Alternatively, a descending vein may pass through the diaphragmatic hiatus and enter the hepatic or portal venous system resulting in infracardiac drainage. Rarely, a mixed pattern of drainage may exist, or the anomalous veins may drain directly into the right atrium. Drainage directly into the right atrium occurs almost exclusively in patients with heterotaxy.

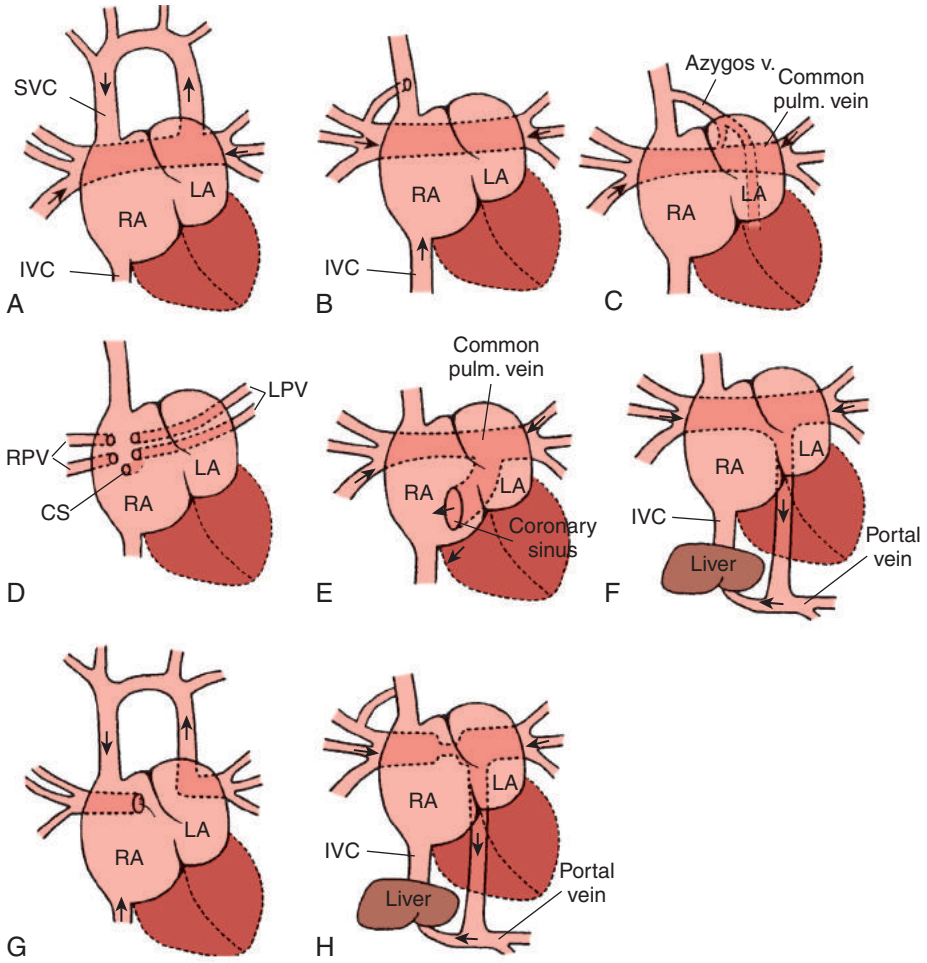
The clinical presentation of TAPVR varies, depending upon the degree of obstruction to pulmonary venous flow. Patients with unobstructed pulmonary venous flow will have minimal symptoms in the newborn period, and cyanosis is usually not apparent. Symptoms of right heart failure develop over time because of the progressive right heart volume overload. Physical examination may reveal a right ventricular heave, fixed split S2, and a soft systolic ejection murmur in the pulmonic area. Chest x-ray may demonstrate cardiomegaly due to an enlarged right atrium, right ventricle, and main pulmonary artery. Pulmonary vascular markings increase over time. ECG reveals peaked P waves and right ventricular hypertrophy. Patients with moderate restriction to pulmonary blood flow are typically cyanotic in the newborn period. There is usually adequate mixing of venous return to allow for oxygen delivery to tissues. These patients may, however, benefit from supplemental oxygen, mechanical ventilation, and sedation to decrease oxygen consumption. The presentation of patients with obstructed pulmonary blood flow will be discussed later in this chapter under obstructive lesions.

Treatment of TAPVR is surgical. In most cases, a pulmonary venous confluence is seen near the left atrium. Cardiac catheterization is used to define pulmonary venous anatomy if the pulmonary veins are not well seen by echocardiography. During surgery, the pulmonary venous confluence is anastomosed to the left atrium, the ASD is closed, and the connections to systemic veins are ligated. In the absence of pulmonary venous obstruction and in the setting of uncomplicated anatomy, surgical mortality is low and long-term results are good. Late pulmonary venous obstruction occurs in approximately 20% of cases, with relatively poor surgical and interventional cardiac catheterization results.

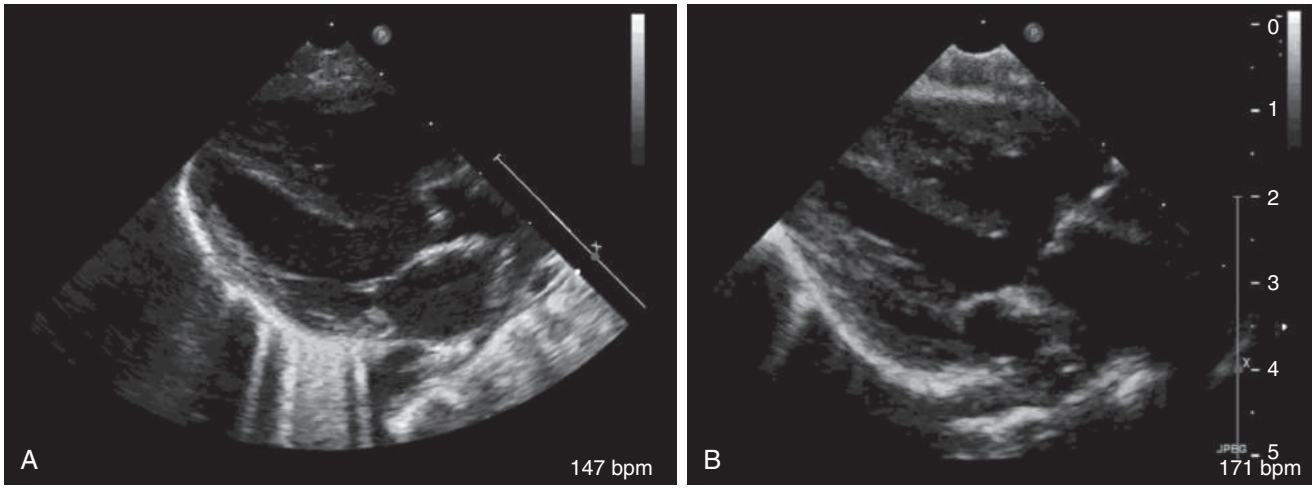
Double Outlet Right Ventricle

DORV is a relatively rare, diverse group of lesions characterized by the origination of both great vessels from the right ventricle and by the persistence of the subaortic and subpulmonary conus. There are multiple anatomic variations of this lesion that are commonly classified by the relationship of the great vessels to one another and/or by the location of the VSD to the great vessels (Fig. 50.21).[85–87] With this in mind, there are four types of DORV, each with a slightly different neonatal presentation and surgical management.

DORV of the tetralogy type typically has normally related great vessels with a subaortic VSD. The VSD directs flow into the



• **Fig. 50.20** Anatomic Varieties of Total Anomalous Pulmonary Venous Return. (A–C) Supracardiac. (D, E) Cardiac. (F) Infracardiac. (G, H) Mixed. See text for details. *CS*, Coronary sinus; *IVC*, inferior vena cava; *LA*, left atrium; *LPV*, left pulmonary vein; *Pulm*, pulmonary; *RA*, right atrium; *RPV*, right pulmonary vein; *SVC*, superior vena cava; *V*, vein. Philadelphia: Churchill Livingstone; 2000:409–420.)



• **Fig. 50.21** Echocardiographic Views of Double Outlet Right Ventricle. (A) The aorta is committed to the right ventricle, and the ventricular septal defect is below the aortic valve. (B) The great vessels are transposed in this patient with the pulmonary artery overriding the ventricular septal defect.

aorta. Because the subaortic conus is pulled anteriorly, the subpulmonary conus is typically smaller, resulting in variable obstruction to pulmonary blood flow. The clinical presentation and surgical management are similar to those of TOF.

DORV of the transposition type typically has malposed great vessels with the aorta located either anterior to or rightward of the pulmonary artery. The VSD is subpulmonary and directs flow into the pulmonary artery, resulting in transposition-like physiology. This lesion is frequently associated with variable obstruction to aortic blood flow and coarctation of the aorta. Surgical repair consists of baffling the VSD to the pulmonary valve and performing an arterial switch. In the setting of coronary artery anomalies that prevent an arterial switch, the left ventricle is baffled to both the aortic and pulmonary valves, and a right-ventricle-to-pulmonary-artery conduit is placed. Arch obstruction is corrected if needed.

In DORV with a "doubly committed" VSD, the VSD is below both great vessels. The physiology and clinical presentation are variable, depending upon the size and orientation of the VSD and the degree of outflow tract obstruction. Surgical repair is directed at closing the interventricular communication without obstructing either ventricular outflow.

The least common variety of DORV is that in which the VSD is remote from both great vessels. Because of the distance between the VSD and the great vessels, a two-ventricle repair is difficult and often impossible. Pulmonary banding is frequently performed in the newborn period to limit pulmonary blood flow, delaying attempts at a biventricular repair or single ventricle palliation until several months of age. Complex procedures such as intricate intracardiac baffles, RV to PA conduit, root translocation, double root translocation, and truncal switch can be performed. If no viable pathway is achieved, single ventricle palliation is pursued.

Lesions That Present Primarily With Heart Failure

Hypoplastic Left Heart Syndrome

HLHS is an anatomically heterogeneous lesion characterized by varying degrees of underdevelopment of the left ventricle, hypoplasia or atresia of the aortic and mitral valves, and hypoplasia of the aortic arch. While accounting for only 1.4% to 3.8% of all congenital heart defects, HLHS accounts for 23% of cardiac deaths in the first week of life and 15% of cardiac deaths in the first month after birth.[88] HLHS is likely multifactorial in cause. There is a slight male predominance. While there is no clear genetic cause, familial clustering of various left heart obstructive lesions has been noted.

It is theorized that the growth of developing vascular structures is dependent upon flow. HLHS likely results from in utero obstruction of left ventricular inflow or outflow. The fetal left ventricle is predominantly filled with blood that passes through the foramen ovale. Restriction to flow or reversal of flow through the foramen ovale could then result in decreased flow to the left heart and its underdevelopment. Similarly, several studies have documented the progression of severe aortic stenosis to HLHS in utero.[89,90] The progressive left ventricular hypertrophy, dilation, and fibrosis associated with severe aortic stenosis can lead to decreased ventricular compliance, elevated left atrial pressures, and reversal of flow through the foramen ovale in utero. Prenatal cardiac intervention is still in its infancy, and much continues to be learned about fetal intervention, but successes with in utero balloon dilation of the aortic valve suggest that the progression to HLHS can be altered.[91]

Because of the underdevelopment of the left heart structures, pulmonary venous return must exit the left atrium through the foramen ovale. Pulmonary venous blood then mixes with systemic venous return in the right atrium and enters the right ventricle. Right ventricular output then passes either into the pulmonary circulation or through the ductus arteriosus into the systemic circulation; that is, the pulmonary and systemic circulations are in parallel. The ratio of systemic to pulmonary blood flow is determined by the relative resistance of the vascular beds. As the normal postnatal drop in PVR occurs, pulmonary flow increases at the expense of systemic flow. Thus, the management of HLHS is dependent upon an adequate egress from the left atrium and a balancing of the resistances of the pulmonary and systemic vascular beds.

Most cases of HLHS are now diagnosed prenatally when an abnormal four-chamber view of the heart is noted on a screening obstetric ultrasound. Ideally, delivery should occur at a tertiary care center. In the absence of prenatal diagnosis, postnatal presentation is somewhat variable and dependent upon ductal patency and the degree of restriction to flow at the atrial septum. The infant with an unrestrictive atrial septum and PDA is largely asymptomatic at birth and may be missed in the newborn period. Cyanosis is minimal and pulmonary overcirculation is mild, while PVR is high. Cardiac exam is relatively unremarkable. The second heart sound is single and loud. A third heart sound becomes apparent as heart failure develops. As PVR drops and ductal closure occurs, feeding difficulties and respiratory distress become apparent, with rapid progression to cardiovascular collapse. Physical examination following ductal restriction is significant for lethargy, pallor, and diminished or absent pulses. Chest x-ray typically reveals a relatively normal-sized heart and pulmonary edema. ECG is nonspecific but may reveal relative lack of left-sided forces.

The patient with a restrictive atrial septum presents with tachypnea and profound cyanosis shortly after birth. The elevated left atrial and pulmonary venous pressures result in pulmonary venous congestion that is apparent on chest x-ray.

The preoperative management of patients with HLHS is directed at balancing the ratio of pulmonary-to-systemic blood flow (Qp:Qs) to allow for sufficient oxygenation of blood while maintaining adequate systemic cardiac output. Prostaglandins should be started immediately postnatally to ensure ductal patency. Echocardiography is utilized to confirm cardiac anatomy and determine the degree of restriction to flow through the foramen ovale. If the atrial level shunt is restrictive with profound cyanosis and metabolic acidosis, a balloon atrial septostomy, surgical septectomy, or emergent stage I palliation should be performed (see later in the section). If the restriction was present in utero, pathologic fibrosis and arterialization of the pulmonary veins and medial hypertrophy of the pulmonary arterioles occur. Even following atrial septostomy, lung disease can persist and PVR can remain high. Oxygen and iNO may be needed to maintain saturations in an appropriate range. This subset of patients has a high mortality rate.

A small group of patients will have adequately balanced pulmonary and systemic blood flow at the time of presentation. A small degree of restriction to flow through the foramen ovale may be associated with slight cyanosis but has the beneficial effect of restricting pulmonary blood flow. In the absence of acidosis or end-organ dysfunction, this state is generally tolerated until stage I palliation is performed.

An unrestrictive ASD allows increased pulmonary blood flow as the PVR falls. Because of the parallel arrangement of the circulations, increasing pulmonary flow decreases systemic flow. In this setting, there is increasing oxygen saturation associated with inadequate oxygen delivery to the tissues. Worsening metabolic acidosis and end-organ dysfunction ensue. The ratio of pulmonary-to-systemic blood flow is balanced by manipulating the resistances of the pulmonary and systemic vascular beds. The success of these therapies is monitored by measurement of oxygen saturation, mixed venous saturation, lactate, and arterial blood gases.

PVR can be manipulated through mechanical ventilation and alteration in the amount of oxygen delivered. Mechanical ventilation with high positive end-expiratory pressure can limit pulmonary blood flow. PVR can also be increased by adding carbon dioxide or nitrogen to the ventilator circuit to reduce the fraction of inspired oxygen (FiO_2) to 0.17.[92,93] Both CO_2 and nitrogen have been shown to decrease the Qp:Qs and decrease oxygen saturation. Only hypercarbia has been shown to improve systemic oxygen delivery.[94] The goal of this therapy is to maintain normal lactate, systemic oxygen saturation at 75% to 85%, and mixed venous oxygen saturation approximately 25 percentage points lower than systemic saturations. Mechanical ventilation is typically required when manipulating inspired gas. Mechanical ventilation alone has been associated with increased infection risk, more labile preoperative hemodynamics, and increased mortality. Both elective mechanical ventilation and alteration of the inspired gas mixture may be less in favor in the current era.[95]

Vasoactive medications can be used to alter systemic vascular resistance and improve ventricular function. Use of these medications is determined by clinical presentation and echocardiographic findings. Milrinone can be used to provide some afterload reduction, if tolerated by blood pressure. The inotropic effects of milrinone are also an advantage if ventricular function is poor. In addition to decreasing pulmonary blood flow, afterload reduction has the added benefit of decreasing tricuspid valve regurgitation if it is present. Milrinone also dilates the pulmonary vascular bed, so care should be taken when it is used. While counterintuitive, when faced with an unoperated patient with high oxygen saturation and low peripheral blood pressure, the gentle addition of milrinone may improve blood pressure simply by increasing systemic blood flow.[95]

The immediate goal of surgical palliation is to provide stable unrestricted systemic and coronary blood flow and reliably restrict pulmonary blood flow. There are several strategies for stage I palliation. Traditionally, aortic arch reconstruction was performed using pulmonary artery tissue, and pulmonary blood flow was supplied using a modified BT shunt (Norwood procedure, Fig. 50.22). A recent modification of a right ventricle-to-pulmonary artery conduit has been used to supply pulmonary blood flow (Sano modification, Fig. 50.23). The Sano modification has the presumed benefit of providing pulsatile flow to the pulmonary arteries without AP diastolic run-off and coronary steal. The downside of this procedure is the need for a ventriculotomy. A hybrid procedure that combines stent placement in the ductus arteriosus by the interventional cardiologist and pulmonary artery banding by the surgeon is an approach being taken by a number of institutions and provides a relatively noninvasive stage I palliation for HLHS.[96] Each of these procedures has pros and cons and advocates and detractors.[96–98] Longer-term prospective studies are needed to determine the optimal approach to stage I palliation. In the low-risk patient, survival following the first stage nears 80% to 90%.

The remaining palliative surgeries occur outside the newborn period. Stage II palliation unloads the right ventricle and begins to separate the pulmonary and systemic circulations. The superior cavopulmonary anastomosis (bidirectional Glenn) is usually performed between 4 and 6 months of age. During this procedure, the conduit providing pulmonary flow is removed, and the SVC is anastomosed to the pulmonary artery.

Stage III palliation completely separates the pulmonary and systemic circulations. An inferior cavopulmonary anastomosis (Fontan completion) is performed by one of several techniques at around age 3.

Obstructed Total Anomalous Pulmonary Venous Return

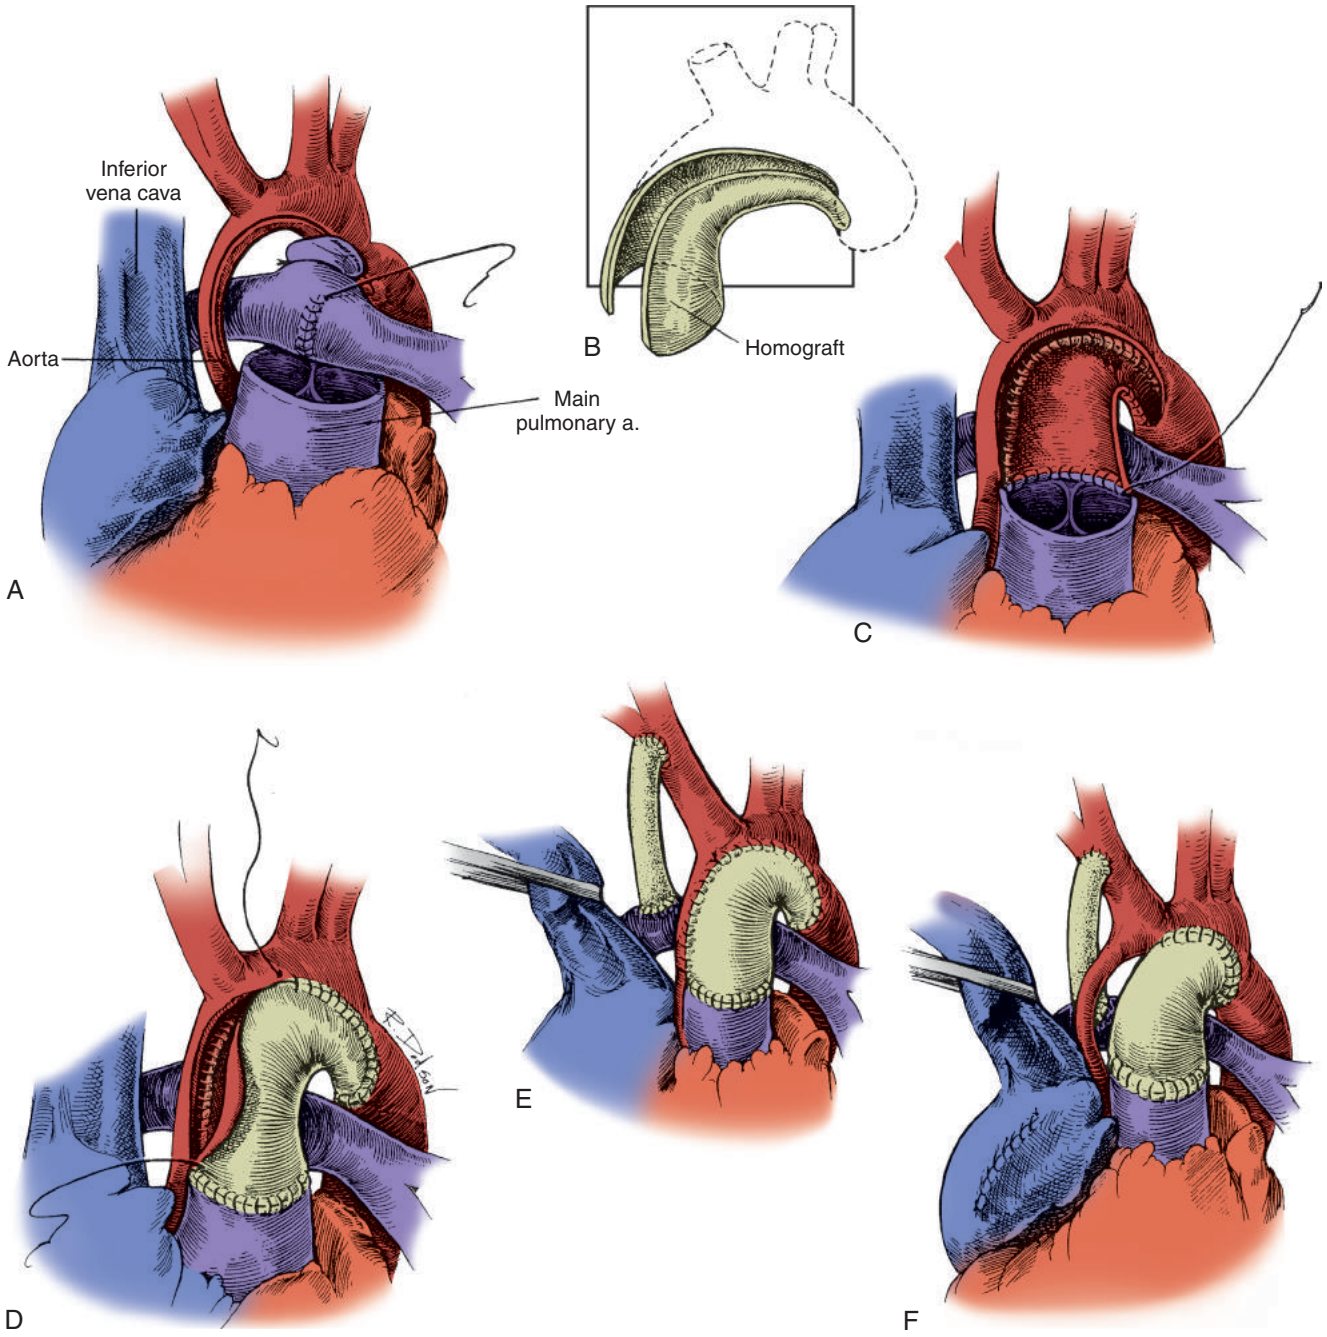
Obstructed TAPVR represents one of the few remaining neonatal surgical emergencies in pediatric cardiology. While obstruction can occur with any type of TAPVR, it is most common in infradiaphragmatic TAPVR. Physiologically, obstruction to pulmonary venous flow results in pulmonary venous hypertension that is transmitted to the pulmonary capillary bed, resulting in pulmonary edema. Pulmonary blood flow is severely limited. Newborns thus present with profound cyanosis and respiratory distress that are not responsive to medical management. Prostaglandins may help minimize the obstruction by maintaining patency of the ductus venosus, but patency of the ductus arteriosus does not improve the clinical picture as the limitation to pulmonary blood flow is not due to insufficient antegrade flow but rather obstructed outflow. Chest x-ray reveals a normal cardiac silhouette with pulmonary venous congestion that may be interpreted as interstitial pneumonia (Fig. 50.24). Echocardiography can be challenging in these patients. The pulmonary veins can be small due to limited flow, making them difficult to detect by two-dimensional imaging and color Doppler. Surgical treatment is the same as for unobstructed TAPVR. The postoperative course is frequently marked by PVR lability, right ventricular hypertension, and low cardiac output syndrome. The risk of mortality, need for prolonged ventilation, and incidence of late postoperative obstruction all increase when obstruction is present preoperatively.[99]

Cor Triatriatum

Embryologically, the pulmonary veins enter a common pulmonary vein that initially has no connection to the left atrium.[100] During normal development, the common pulmonary vein becomes incorporated into the left atrium, resulting in the usual pattern of two right and two left pulmonary veins entering the left atrium. Abnormal incorporation of the common pulmonary vein can result in cor triatriatum, a condition in which the common pulmonary vein joins the left atrium through a single opening. If the opening is small and restrictive, the clinical presentation is similar to that of obstructed TAPVR. If the opening is nonrestrictive, no symptoms are present. Surgical resection of the membrane that separates the left atrium and common pulmonary vein is an effective treatment. Significant preoperative pulmonary venous obstruction increases surgical mortality.

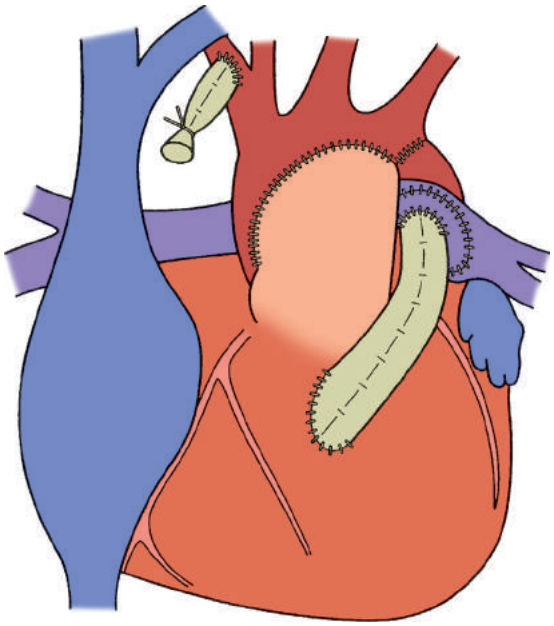
Mitral Stenosis

Congenital mitral stenosis is a rare form of CHD with several subtypes. The stenosis can occur in the supravalve region, at the valve annulus, or within the mitral valve support apparatus. Typical



• **Fig. 50.22** Stage I Palliation for Hypoplastic Left Heart Syndrome: Classic Norwood Procedure. (A) The main pulmonary artery (*a*) is transected and the distal end oversewn. The ductus arteriosus is ligated, and an incision is made from the proximal ascending aorta around the aortic arch to the level of the ductus. (B) A pulmonary homograft is utilized to create a patch to reconstruct the neoaorta. (C, D) This homograft patch is used to connect the proximal main pulmonary artery and pulmonary (neoaortic) valve to the ascending aorta and transverse arch. (E) A modified Blalock–Taussig shunt is placed from the base of the innominate artery to the right pulmonary artery. (F) An alternate technique utilizing a circumferential tube graft from the proximal main pulmonary artery to the distal transverse aortic arch. *Not shown*: Atrial septectomy is performed to provide unobstructed egress from the pulmonary veins to the right ventricle. (From Castañeda AR, Jonas RA, Mayer JE Jr, et al. *Cardiac Surgery of the Neonate and Infant*. Philadelphia: Saunders; 1994.)

congenital mitral stenosis is characterized by thickened leaflets, short or absent chordae tendineae, obliteration of interchordal spaces, and two separate papillary muscles. Supravalvar mitral ring occurs when there is connective tissue outgrowth on the atrial surface of the mitral valve leaflets, leading to a smaller mitral valve effective orifice. The mitral valve orifice can also be stenotic secondary to a parachute mitral valve, when most or all chordae tendineae insert onto only one papillary muscle. Another form of obstruction occurs with a double orifice mitral valve, where a tongue of tissue connects the anterior and posterior mitral valve leaflets.



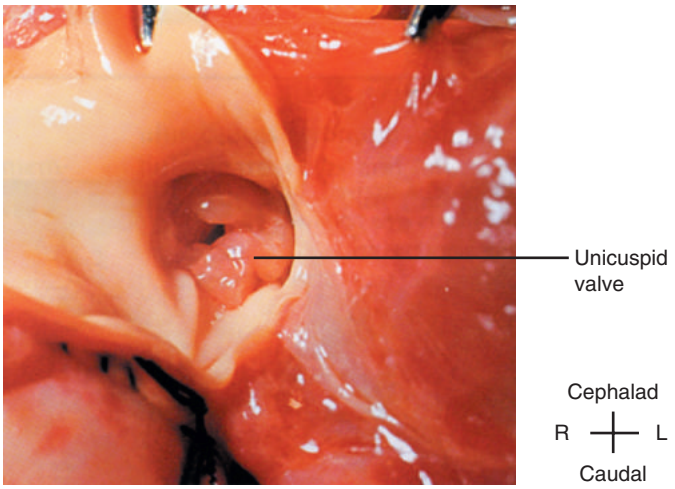
• **Fig. 50.23** Right Ventricle–Pulmonary Artery, or Sano, Modification of Stage I Reconstruction. The arch reconstruction is similar to that shown in Fig. 50.22. The Blalock–Taussig shunt is replaced with a Gore-Tex tube inserted from the right ventricle to the main pulmonary artery. (From Sano S, Ishino K, Kawada K, et al. Right ventricle–pulmonary artery shunt in first-stage palliation of hypoplastic left heart syndrome. *J Thorac Cardiovasc Surg*. 2003;126:504–510.)

• **Fig 50.24** Chest X-ray in a 1-Day-Old With Obstructed Total Anomalous Pulmonary Venous Return.

A mitral arcade or hammock occurs when the leaflets are connected directly or by short chordae to the papillary muscles. Congenital mitral stenosis frequently occurs in conjunction with other left-sided obstructive lesions.

Symptoms from mitral stenosis usually occur in the first 2 years of life and may consist of shortness of breath, respiratory distress or wheezing, cyanosis, and pallor. Cardiac examination reveals a rumbling apical diastolic murmur, loud first heart sound, and loud split second heart sound. Opening snap of the mitral valve may be heard. Chest x-ray reveals left atrial enlargement and pulmonary venous congestion. ECG reveals right ventricular hypertrophy with normal, bifid, or spiked P waves suggesting left atrial enlargement (LAE). Echocardiogram is used to define mitral valve anatomy and localize the area of obstruction. Doppler can be used to determine valve gradient and estimate right ventricular pressure.

Treatment options for congenital mitral valve stenosis include balloon mitral valvuloplasty, surgical mitral valvuloplasty, and mitral valve replacement. There has been improvement in outcomes for mitral valve interventions in the first year of life with acceptable survival, but reintervention remains common especially in the long term.[101] Patients with additional left-sided obstructive lesions or associated defects frequently require single ventricle palliation.



• **Fig. 50.25** Congenital Aortic Stenosis. Frontal view through opened aorta demonstrates stenotic and dysmorphic aortic valve with commissural fusion. (From Litwin SB. *Color Atlas of Congenital Heart Surgery*. St. Louis: Mosby; 1996.)

Critical Aortic Stenosis

Patients with critical aortic stenosis have severe left ventricular outflow tract obstruction that limits systemic cardiac output (Fig. 50.25). The result is ductal-dependent systemic perfusion. While the obstruction can occur below the valve, at the valve, above the valve, or as a combination of these, this section focuses on outflow tract obstruction resulting from morphologic problems of the aortic valve. Severe aortic valve stenosis is defined as a Doppler-derived pressure gradient greater than 60 mmHg. Moderate stenosis is defined as gradient of 30 to 60 mmHg, while mild stenosis is a peak gradient less than 30 mmHg. In the setting of depressed left ventricular function, the Doppler echocardiogram-derived gradient may be significantly lower and underestimates the severity of the stenosis.

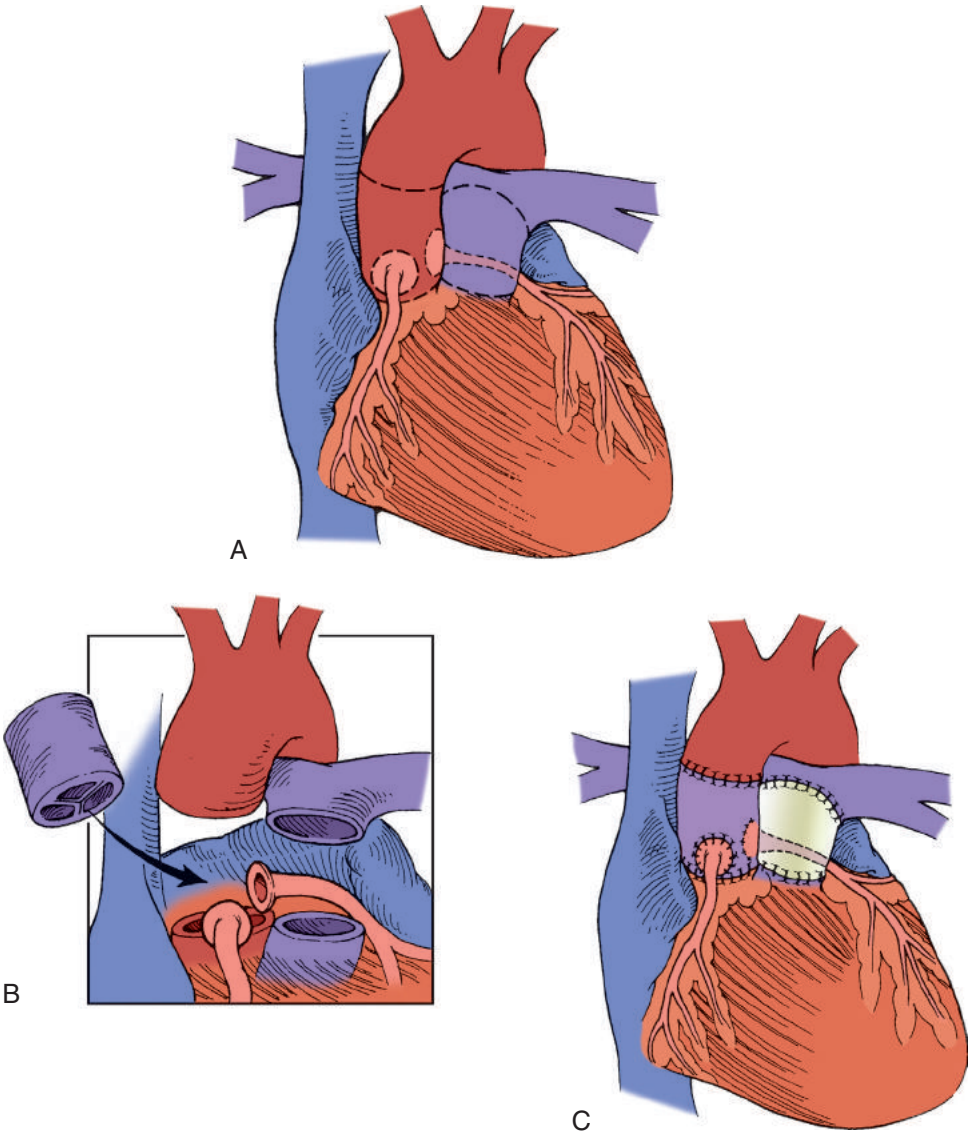
Aortic valve stenosis is detectable in utero. The long-standing pressure overload on the left ventricle causes left ventricular hypertrophy and scarring (endocardial fibroelastosis). In some cases, as discussed above, the disease progresses to HLHS. Growing experience with fetal intervention suggests that, with proper patient selection, it is possible to alter the course of critical aortic stenosis in the fetus through early intervention.[91,102,103]

Clinically, critical aortic stenosis presents in the newborn period with signs of decreased systemic perfusion: pallor, decreased pulses, and prolonged capillary refill. A harsh systolic ejection murmur is

heard on examination in the aortic area. The volume and quality of the murmur correlate with the severity of stenosis in the setting of normal left ventricular function. If left ventricular function is depressed, the murmur may be soft despite severe stenosis. ECG reveals left ventricular hypertrophy with possible T-wave abnormalities. Heart size is typically normal on chest film, although the aortic knob may be prominent due to post stenotic dilatation, and pulmonary congestion may be present. Echocardiogram is used to define the location and severity of the left ventricular outflow tract obstruction. Aortic stenosis is commonly found with other left-sided obstructive lesions, with possible underdevelopment of left heart structures. These findings may alter the treatment plan and lead to single ventricle palliation. Published models have attempted to identify echocardiographic findings that predict the suitability of a two-ventricle repair in neonates with critical aortic stenosis with variable results.[104–108]

Initial management of infants with critical aortic stenosis is directed at the treatment of cardiogenic shock. Endotracheal intubation, mechanical ventilation, secure vascular access, inotropic support, sedation, and paralysis are all frequently necessary. PGE_1 maintains ductal patency and provides systemic output. A small PFO must be present for pulmonary venous return to cross the atrial septum and enter the systemic circulation via the right ventricle and ductus arteriosus. A balloon septostomy may be necessary to decompress the left atrium.

Further management depends on left ventricular size and the presence of other left heart obstructive lesions. Patients with multiple levels of left heart obstruction, a small mitral valve, hypoplastic aortic arch, or small left ventricle may be best suited for single ventricle palliation. Options for two-ventricle palliation include balloon valvuloplasty in the cardiac catheterization lab, surgical valvotomy, or the neonatal Ross procedure (Fig. 50.26).[109]



• **Fig. 50.26** Ross Procedure: "Autograft" Aortic Valve Replacement. (A) *Dashed lines* depict surgical incisions around coronary arteries, aorta, and pulmonary artery. (B) Following removal of the coronary arteries and adjacent "buttons" and the diseased aortic valve, the patient's native pulmonary valve ("autograft") is positioned in the aortic root. (C) Completed repair with reimplanted coronary arteries and a cadaveric homograft valve inserted in the pulmonary position. (From Chang AC, Burke RP. Left ventricular outflow tract obstruction. In: Chang AC, Hanley FH, Wernovsky G, Wessel DL, eds. *Pediatric Cardiac Intensive Care*. Baltimore: Williams & Wilkins; 1998:233–256.)

Outcomes of all procedures depend, in part, on relief of obstruction, presence of aortic valve regurgitation, associated cardiac lesions, and severity of end-organ dysfunction at the time of initial presentation. The mortality of each of the interventions is relatively high. Regardless of the treatment chosen, critical aortic stenosis is a lifelong illness. Patients require close follow-up and multiple procedures throughout their lifetime.

Coarctation of the Aorta

Coarctation may occur anywhere from the transverse aortic arch to the bifurcation of the iliac arteries. Most commonly, there is a discrete narrowing distal to the left subclavian artery, across from the aortic insertion of the ductus arteriosus in a *juxtaductal* position. Conversely, there can be long segment narrowing of the transverse aortic arch, otherwise referred to as a hypoplastic aortic arch. A bicuspid aortic valve occurs in 70% of cases. Other left-sided obstructive lesions tend to occur with coarctation of the aorta. There is a 2:1 male-to-female preponderance and an association with Turner syndrome.

In neonates with a discrete juxtaductal narrowing, the PDA widens the narrowed area and provides relief from the obstruction. The net shunt through the PDA is left to right. These patients have equal oxygen saturations in the upper and lower extremities. In patients with a severe coarctation or a diffusely hypoplastic arch, descending aortic flow originates from a right-to-left shunt through the ductus arteriosus. Differential upper and lower extremity oxygen saturations occur in these patients, with the upper extremities having greater saturation than the lower extremities.

The clinical presentation of coarctation of the aorta depends upon the severity of the narrowing. Mild coarctation often does not present in infancy. Detection typically occurs when upper extremity hypertension and diminished or absent femoral pulses are noted on examination. Infants with more severe coarctation or aortic arch hypoplasia present with diminished lower extremity perfusion following ductal closure. Physical examination reveals an infant with poor perfusion and absent femoral pulses. Cardiac examination may reveal a systolic ejection click if a bicuspid aortic valve is present. A systolic ejection quality murmur is heard that radiates to the back and left infraclavicular area. Chest film demonstrates a large heart with increased pulmonary vascular markings. ECG reveals right ventricular hypertrophy. Echocardiogram is used to define the location and extent of aortic narrowing. Additional left-sided obstructive lesions are ruled out. Right ventricular hypertrophy and right ventricle hypertension are also frequently noted.

Treatment of the infant presenting with coarctation of the aorta is similar to that of infants with aortic stenosis. Intubation and mechanical ventilation are frequently necessary. Vascular access is obtained for inotropic support, and PGE_1 is started to open the ductus arteriosus. Metabolic derangements are corrected. Ideally, the infant is stabilized before surgery. Surgery is typically indicated at the time of diagnosis, even in relatively asymptomatic patients. In most cases a lateral thoracotomy is performed, the area of coarctation is excised, and an end-to-end anastomosis is performed. If long segment narrowing is present, patch material may be used to augment the arch, and a more extended end-to-end anastomosis is performed. This may require a sternotomy. Balloon angioplasty of native coarctation is not typically performed in infancy because of the risk of aneurysm, recoarctation, and vascular injury at the site of access.

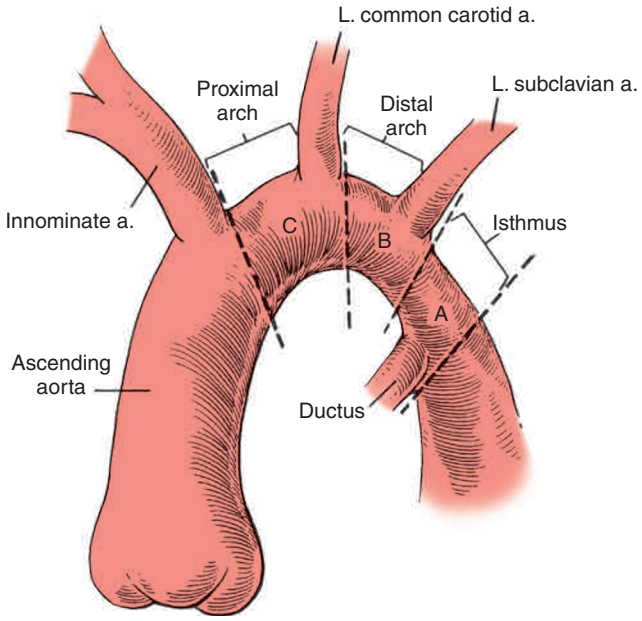
Surgical mortality is around 5%.[110,111] Re-coarctation occurs in 10% to 15% of children and can be successfully managed with balloon angioplasty on most occasions.[112] If a VSD is present, this is typically closed at the time of surgery.

Interrupted Aortic Arch

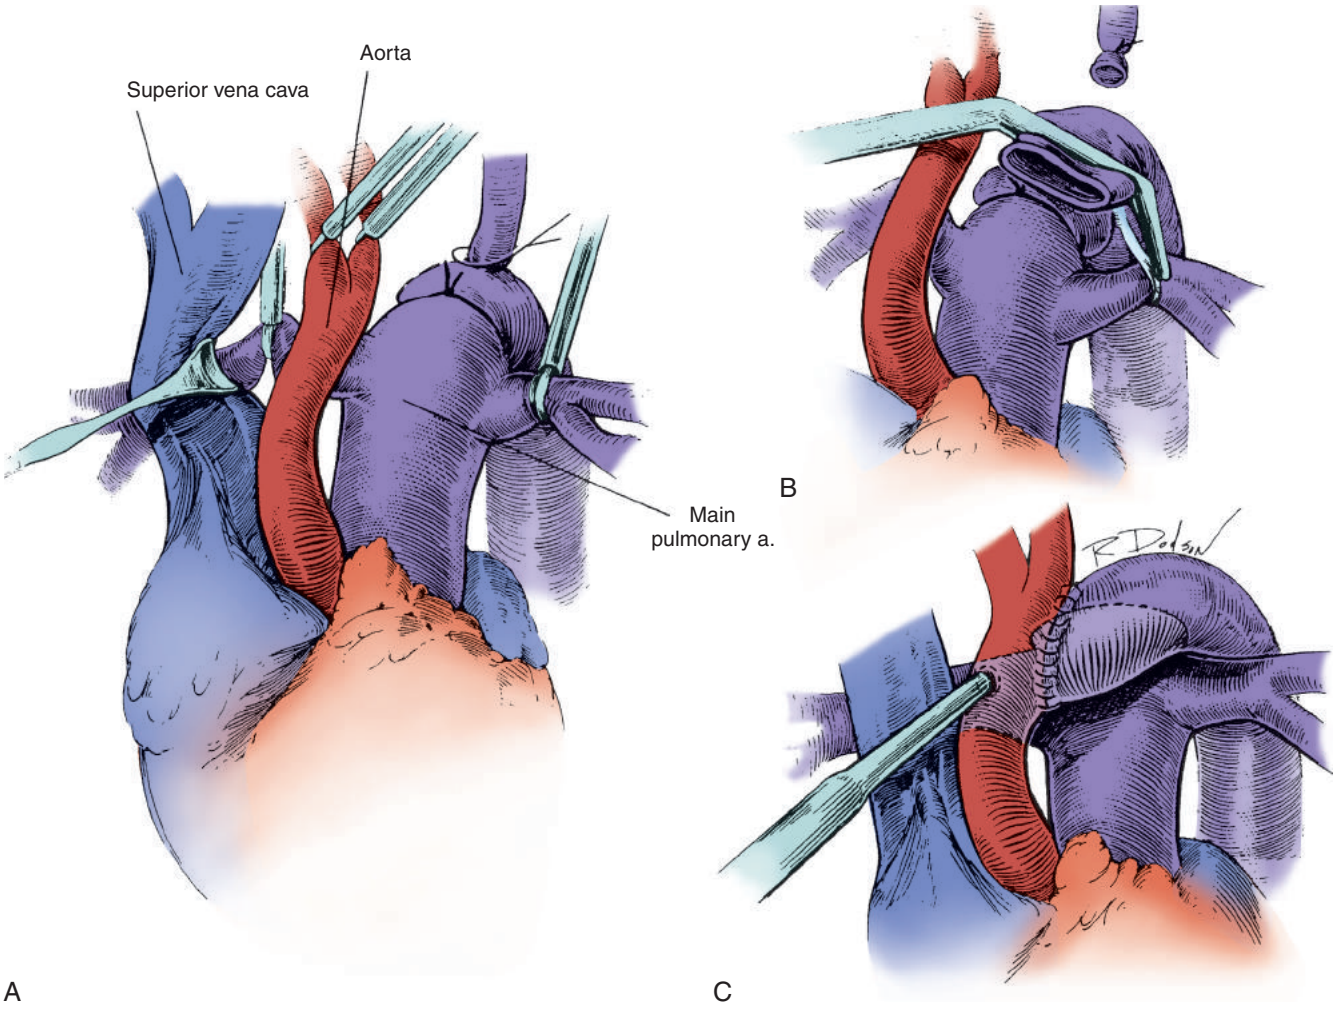
Interrupted aortic arch is a relatively rare anomaly that is defined simply as complete separation of the ascending and descending aorta. Interrupted aortic arch can be classified by the location of the interruption relative to the head and neck vessels (Fig. 50.27): type A, distal to the left subclavian artery; type B, between the left subclavian and left carotid; and type C, between the left carotid and innominate artery. All types of interruption occur in conjunction with posterior malalignment of the infundibular septum; this results in a VSD and varying degrees of left ventricular outflow tract obstruction. Aberrant arrangements of the head and neck vessels are common, with 50% of patients with type B interruption having an aberrant right subclavian artery that arises from the descending aorta. Interrupted aortic arch is associated with 22q11 deletion.

The clinical presentation of interrupted aortic arch is similar to that of other left-sided obstructive lesions. Descending aortic flow is entirely dependent upon right-to-left shunting through the PDA. Ductal closure causes cardiovascular collapse. Initial management is as described for coarctation of the aorta. PGE_1 should be started as soon as possible, as all other resuscitative efforts will have no benefit until postductal circulation is established.

Surgical repair is performed after metabolic acidosis resolves and end-organ function is improved. Continuity is established between the ascending and descending aorta via end-to-end anastomosis, homograft insertion/patch augmentation to connect the two segments, or jump grafts (Fig. 50.28). The VSD is typically closed. In



• **Fig. 50.27** Anatomic Classification of Interrupted Aortic Arch–Types A, B, and C. *Dashed lines* indicate the potential areas of discontinuity (interruption) in the aortic arch. See text for details. *a*, Artery. (From Castañeda AR, Jonas RA, Mayer JE Jr, et al. *Cardiac Surgery of the Neonate and Infant*. Philadelphia: WB Saunders; 1994.)



• **Fig. 50.28** Surgical Repair of Interrupted Aortic Arch, Type B. (A) The branch pulmonary arteries and arch vessels are snared, and a ligature is placed around the ductus arteriosus. (B) The proximal descending aorta is controlled with a clamp. To adequately mobilize the descending aorta, the left subclavian artery may need to be divided (as shown). Following resection of the ductus arteriosus, the proximal (pulmonary artery) end is oversewn. (C) The descending aorta is anastomosed directly to the ascending aorta. An alternative strategy is anastomosis of the left subclavian and left common carotid arteries combined with homograft patch augmentation of the inferior surface of the arch. Ventricular septal defect closure, when present, is also performed (not shown). *a*, Artery. (Source: Castañeda AR, Jonas RA, Mayer JE Jr, et al. *Cardiac Surgery of the Neonate and Infant*. Philadelphia: WB Saunders; 1994.)

patients with a small LVOT that is not suitable for systemic circulation, aortopulmonary amalgamation or a Ross-Konno type procedure can be performed with the goal of a biventricular repair.[113] In patients with severe left ventricular hypoplasia, a two-ventricle repair may not be possible, and a staged repair or single-ventricle palliation is performed.[114,115] Surgical mortality is less than 10% but higher in patients with additional anomalies.[115] Repeat operation because of left ventricular outflow tract obstruction and balloon angioplasty for recurrent arch obstruction are both common.

Anomalous Origin of the Left Coronary Artery From the Pulmonary Artery

When the left coronary artery arises from the pulmonary artery, inadequate oxygen delivery to the left ventricle results. Coronary artery perfusion occurs primarily during diastole. As pulmonary artery pressures drop postnatally, perfusion pressure of the left coronary artery falls, resulting in ischemia and infarction of the left ventricle. If collateral vessels connect the right and left coronary circulations, flow in the left coronary artery reverses. A left-to-right shunt occurs, resulting in coronary artery steal. Mitral valve regurgitation secondary to papillary muscle ischemia and left ventricular dilation develops.

Clinically, symptoms typically develop in the first month after birth. If adequate collateral vessels and myocardial oxygen delivery exist, the patient may present later in life with angina-like symptoms or even a murmur of collateral flow. In the infant, attacks of irritability, pallor, and diaphoresis with feeds are a common presentation. Cardiac examination reveals a displaced point of maximal impulse (PMI), gallop rhythm, and nonspecific murmur. If mitral regurgitation is present, a holosystolic, regurgitant quality murmur is heard. Chest x-ray reveals massive cardiomegaly. The ECG demonstrates a QR pattern and inverted T waves in leads I and aVL.

Leads V_5 and V_6 may also have deep Q waves, inverted T waves, and ST segment depression. Echocardiography may suggest the diagnosis but is not always reliable as the left coronary occasionally appears to arise from the aorta. Color Doppler may demonstrate retrograde flow in the left coronary with flow into the pulmonary artery. Cardiac computer tomography (CT) can be employed for further evaluation. Cardiac catheterization is diagnostic.

Symptoms of CHF are managed medically. Surgical reimplantation of the left coronary artery to the aorta restores normal coronary perfusion pressure. If the usual two-vessel coronary blood supply is reestablished, there is gradual normalization of left ventricular size and function, as viewed by echocardiography.[116,117] If myocardial damage is severe or the left coronary artery cannot be reimplanted surgically, cardiac transplantation is performed.

Systemic Arterial Malformations

Vascular anomalies are placed in two major groups: hemangiomas and malformations. Hemangiomas are tumors that demonstrate endothelial hyperplasia and undergo a period of proliferation and involution. Malformations result from abnormal vascular morphogenesis. They have normal endothelial cell turnover and grow accordingly with surrounding structures. Vascular malformations are further subcategorized by the type of vascular tissue involved (arterial, venous, and lymphatic). Because of their association with high output failure in the newborn period, two types of systemic vascular malformations will be discussed further: AVMs and arteriovenous fistulas (AVFs). An AVM results from multiple microfistulas between small arteries and veins. An AVF results from a connection between a large artery and vein.

Hemodynamically significant AVFs and AVMs present with high-output heart failure and cyanosis in the newborn period. They can even present in fetal life with development of heart failure and even hydrops if severe. An effective large left-to-right shunt occurs through the direct arterial–venous connections. Heart rate, stroke volume, plasma volume, and cardiac output are increased. The fistulous connection lowers systemic vascular resistance, promoting a right-to-left shunt through the ductus arteriosus, particularly if the normal postnatal drop in PVR has not occurred. The increased systemic venous return increases right atrial pressures and promotes right-to-left shunting through the foramen ovale.

Cardiac examination reveals a hyperdynamic precordium. A prominent second heart sound, S3, and S4 may be heard. Systolic murmurs may be present secondary to tricuspid valve regurgitation or increased flow across the pulmonary valve. Increased tricuspid valve flow may create a diastolic sound. Bruits may be heard over the vascular malformation. When a malformation is suspected, care must be taken to auscultate areas where malformations are likely such as the head, liver, and chest. Arteries proximal to the malformation are typically dilated with bounding pulses, while distal ones are small with diminished pulses. ECG is nonspecific and may demonstrate right atrial and right ventricular enlargement. Chest x-ray reveals cardiomegaly with increased pulmonary vascular markings. Echocardiogram demonstrates generalized cardiomegaly. Treatment, if necessary, requires interventional closure of the anomalous vascular connections or the surgical removal of associated anatomic abnormalities.

Cardiomyopathy
