During EXIT procedure, delayed placenta separation is accomplished by uterine relaxation, maintenance of uterine volume and uterine and placental perfusion. Uterine relaxation can also cause uterine atony and further obstetric haemorrhage after full delivery of the neonate. In order to maintain maternal haemodynamic stability, the dose of inhalational anaesthetic agents is decreased and oxytocin administered just before umbilical cord ligation to deliver the baby. This is accomplished through good communication and close coordination between the fetal medicine surgeon and the obstetric anaesthetist.[32]

Immediate post-operative complications are more frequent in comparison to standard Caesarean sections. In a study of 34 EXIT procedures, there were longer operating times, higher estimated blood losses and more wound infections compared with 32 matched controlled Caesarean deliveries.[33] However, there was no statistical difference in the length of post-operative hospital stay and haematocrit levels.

In subsequent pregnancies, there is a higher chance of uterine scar dehiscence or uterine rupture because of possible unusual uterotomy sites. Instead of a lower uterine segment incision, other areas may have been used in order to avoid the placenta. Lazar et al. showed that mothers who delayed pregnancy for 2 years following an EXIT procedure were able to have an uncomplicated delivery of at least one more child.[24]

Fetal considerations

Fetal circulation is preserved via the maintenance of placental perfusion and prevention of respiration. In some centres, the fetus is given direct injections of narcotics and muscle relaxants to avoid respiration and establishment of neonatal circulation as well as to reduce fetal movements to aid airway management.[7, 21] Others have argued that the same effects are obtained by fetal airway obstruction and fetal anaesthesia via the transfer of maternal anaesthetic through uteroplacental circulation.

OUTCOMES

Experience in our centre has demonstrated that an interventional delivery decreases mortality from 50% (n = 2) to 14.2% (n = 1). All deaths were associated with other fetal abnormalities, i.e. where airway obstruction was not an isolated feature.[27] Of seven children delivered by an interventional team, two are tracheostomy-dependent. A case series of 12 children with giant neck masses after EXIT procedures demonstrated more cranial nerve palsies, feeding difficulties and speech delays in this group of children. However, the complications were thought to be linked to the underlying pathology rather than the mode of delivery. For example, the neck mass itself could have damaged and distorted local anatomy or the surgical resection of the mass could have led to iatrogenic injury.[24] In our case series none of the children have cranial nerve palsies or feeding difficulties.

A successful interventional airway delivery service is dependent on careful planning and infrastructures, local guidelines and protocols, as well as a continuous audit cycle of outcomes.

FETAL THERAPY

Intrauterine treatment may be considered in cases where there is a high risk of *in utero* demise or severe disability and a low risk to the mother.[34] Fetal hydrops may occur as a result of cardiac failure from a highly vascular neck mass, such as teratoma or kaposiform haemangioendothelioma, where intrauterine surgical resection has been offered.[35]

Complete obstruction of the larynx in laryngeal atresia causes lung fluid congestion, *in utero* pulmonary hyperplasia, pulmonary hypertension and fetal cardiac failure. Fetal therapy for laryngeal atresia and CHAOS has been reported using percutaneous fetoscopic tracheal decompression.[36, 37] Intrauterine sclerotherapy of large fetal macrocystic lymphatic malformations with a single injection of OK-432 (penicillin-killed *Streptococcus pyogenes*) has also been described.[38] Other sclerosant agents could be used as OK-432 is not available in the UK.

In certain circumstances, *in utero* treatment is contraindicated; these include lethal or severely disabling structural and/or genetic fetal anomalies or serious maternal comorbidities.

CONCLUSION

Congenital airway obstruction is potentially life-threatening and associated with high mortality rates.[17, 21, 39, 40] If there is a delay in establishing airway and ventilation in the neonate, the risks of hypoxia, acidosis and anoxic brain injury, which are associated with neonatal morbidity and mortality, increase. In contrast, for those with effective airway access at delivery, the long-term outcome is excellent in most cases.[27]

Ultimately, with advances in fetal interventions, such as *in utero* surgery, fetal transcutaneous transuterine bronchoscopy, intrauterine sclerotherapy, fetal airway assessment and fetoscopic tracheal decompression, we can expect improvements in prognosis for neonates with congenital airway obstruction.

BEST CLINICAL PRACTICE

- ✓ A unit that undertakes interventional airway deliveries should be supported by an established framework, i.e. PICU, NICU, ECMO.
- ✓ A multidisciplinary team including specialists from fetal medicine, otolaryngology, neonatology, paediatric anaesthesia and obstetric anaesthesia is essential.
- ✓ Decide on the timing of intervention, nominate a team member to undertake endotracheal intubation and consider the time allowed for intubation.

FUTURE RESEARCH

There are exciting future developments in novel therapeutic concepts in airway reconstruction. For example, in the field of fetal tissue engineering, an airway construct can be designed according to gestation using autologous fetal cells.[41–43] The proof of principle has been provided in a large animal model of perinatal airway repair.[44]

KEY POINTS

- Effective airway access at interventional delivery improves long-term prognosis.
- Better antenatal detection has greatly improved perinatal management of airway problems in the newborn.
- Careful planning of the delivery makes for better outcomes.

CHAPTER 37

CERVICOFACIAL INFECTIONS

Nico Jonas and Ben Hartley

SEARCH STRATEGY

Data in this chapter may be updated by Medline and Scopus searches using the keywords: infection and child, neck, cervical node and cervical adenopathy, and focusing on the diagnosis and treatment of specific conditions. The Cochrane Library was also consulted.

TERMINOLOGY

Abscess formation refers to an accumulation of pus in a confined space as a result of an inflammatory response to a bacterial or parasitic infection or foreign material. The deep cervical fascia is arranged so as to create compartments or spaces between the various structures in the neck. A collection of pus in one of these spaces is often termed a **deep neck space infection** (**DNSI**).

Cellulitis refers to inflammation of subcutaneous or connective tissue and is usually characterized by fever and pain as well as redness, swelling and warmness of the affected area.

Fasciitis refers to inflammation of the connective tissue (fascia) that surrounds and binds muscles, blood vessels and nerves together.

Necrotizing fasciitis is an aggressive tissue infection that spreads rapidly across fascial planes causing necrosis of tissue along the way.

INTRODUCTION

This chapter will deal with cervicofacial infections in children. Because these infections usually present as a neck mass, we will also aim to discuss the general approach to a child with a neck lump.

Cervicofacial infections in children usually present as a neck swelling. The majority of infections are related to lymph nodes. These are rarely indicative of serious pathology. Lymphadenopathy secondary to the common acute upper respiratory infections that are a feature of normal childhood – notably pharyngitis and tonsillitis – is the most common cervicofacial infection in childhood. Lymphadenopathy is usually self-limiting but may progress to cellulitis, suppuration and abscess formation. Infections may also involve the parotid, the submandibular or the thyroid glands.

Congenital lesions do not always declare themselves at birth; they may present in older children. The onset of the swelling may be precipitated by an acute inflammatory episode.

Chronic infections are less common but need to be considered if the swelling persists.

In a very a small number of children, a neck swelling will be due to a malignancy. These are most often lymphoproliferative or connective tissue tumours. Squamous carcinoma is extremely rare in children. A child with a neck mass requires an entirely different approach to that required in an adult.[1] Open biopsy is rarely needed. Nevertheless, it is important to maintain an index of suspicion for malignancy in all persistent neck swellings in children.

BOX 37.1 Inflammatory adenopathy in children: Infective

Viral	Bacterial	Fungal	Parasitic
Upper respiratory: rhinovirus, adenovirus, enterovirus Common childhood illnesses: measles, mumps, rubella, varicella Infectious mononucleosis Cytomegalovirus (CMV) HIV	Acute lymphadenitis: *Streptococcus*, *Staphylococcus*, less commonly Gram-negative organisms Suppurative lymphadenitis with deep or superficial neck abscess; usually pyogenic organisms (*Streptococcus* and *Staphylococcus*) Mycobacteria: tuberculosis or non-tuberculous mycobacteria (NTM) – sometimes termed 'atypical mycobacteria' Other granulomatous bacterial infections: cat scratch disease, actinomycosis, brucellosis, tularaemia, bubonic plague, syphilis	Histoplasmosis Uncommon fungal infections (immunocompromised host) *Candida* and *Aspergillus*	Toxoplasmosis Filariasis

CLASSIFICATION OF CERVICOFACIAL INFECTIONS

- **Infections related to lymph nodes:**
  - Acute infective lymphadenopathy
  - 'Complicated/progressive' infective adenopathy causing cellulitis, suppuration and abscess formation
  - Chronic infective lymphadenopathy
- **Infections related to congenital lesions or malformations:**
  - Thyroglossal duct cysts
  - Dermoid cysts
  - Branchial anomalies
  - Lymphatic malformations / cystic hygromas
- **Infections related to acquired anatomical malformations:**
  - Plunging ranula
- **Infections of glands:**
  - Salivary gland infections
  - Thyroid gland infections
- **Infections of dental origin:**
  - Dental abscess
  - Ludwig's angina
- **Infected vascular structures:**
  - Infective thrombophlebitis
  - Lemierre's syndrome

AETIOLOGY OF INFLAMMATORY NECK NODES IN CHILDREN

Lymphadenopathy is one of the most common clinical problems encountered in paediatrics.[2] The precise incidence of lymphadenopathy is not known, but estimates of palpable adenopathy in childhood vary from 38% to 45%.[1] There are approximately 300 lymph nodes in the neck and they have considerable capacity to undergo growth and change.[3] With their high concentration of lymphocytes and antigen-presenting cells, lymph nodes are ideal for receiving antigens that gain access through the skin or gastrointestinal tract. They are barely perceptible in neonates, but a progressive increase in antigen exposure will lead to an increase in lymph node size until later childhood. Lymph node atrophy will start during adolescence and continues through later life.

BOX 37.2 Inflammatory adenopathy in children: Non-infective

Kawasaki syndrome
Sarcoidosis
Sinus histiocytosis with massive lymphadenopathy
Kikuchi-Fujimoto disease
PFAPA syndrome (periodic fever, apthous stomatitis, pharyngitis, cervical adenitis)
Langerhan's cell histiocytosis

Inflammatory lymphadenopathy can be classified into infective conditions (Box 37.1) and non-infective conditions (Box 37.2). Non-inflammatory disorders will need to be considered in the differential diagnosis of a neck mass, especially if there are unusual features.

CLINICAL ASSESSMENT OF A PATIENT WITH A NECK MASS

History

- **Age of child:** Most acute lymphadenitis presents in children older than 6 months. Swellings occurring at or shortly after birth are more likely to be pathological and may be neoplastic.
- **Duration of swelling:** A short history (a few days) suggests acute inflammation. After 6 weeks a swelling is regarded as chronic and further investigation should be considered – even earlier if there are suspicious clinical features.
- **Size:** Very large swellings or swellings that progressively enlarge despite antimicrobial treatment should be investigated.
- **Associated symptoms:** A preceding upper respiratory infection is often a feature of inflammatory lymphadenitis. Fever, rhinorrhoea, sore throat and malaise are common. With chronic swellings, enquire about weight loss, night sweats, chronic cough and swellings elsewhere in the body.
- **Contacts:** Enquire about tuberculosis, other infections and exposure to cats, farm animals and ticks. Recent travel should also be noted.

- **Medical history:** Identify any known illnesses. Note recent immunizations against polio, typhoid or DTP (diptheria, tetanus and pertussis). Document regular medication including carbamazepine, phenytoin or isoniazid.
- **Family and social history:** Identify any familial disease or congenital anomalies and any relevant social factors.

Site of the swelling

The anatomical site of the swelling within the neck provides important information about the possible aetiology.

LATERAL NECK SWELLINGS

Lymph nodes are distributed throughout the neck but the most common site is along the superficial and deep cervical chains. These lie deep to the sternomastoid muscle in the upper neck and along its anterior border in the lower neck. Enlarged lymph nodes are the most common cause of lateral neck swellings. The principal differential includes anomalies such as congenital cysts, which may also become acutely inflamed. Vasoformative lesions, haemangiomas and vascular malformations including lymphatic abnormalities may present as a lateral neck swelling. Benign and malignant neoplasms arising from the neural or connective tissue elements and rarely secondary lymph node metastases may present as a lateral neck mass.

CENTRAL NECK SWELLINGS

The principal causes of a neck swelling in the central area of the neck around the midline are thyroglossal duct cysts, lymph nodes and dermoid cysts. Thyroglossal duct or dermoid cysts may become acutely inflamed. Children can also develop inflammatory and neoplastic thyroid disease. Lymphatic vascular malformations can occasionally involve this region.

PAROTID SWELLINGS

Acute viral parotitis (mumps) is common and is a self-limiting infection. Although vaccination for measles, mumps and rubella (MMR) is now reducing the frequency of mumps and to some degree the clinical awareness of this condition, outbreaks still occur sporadically in the developed world. It remains a significant problem in the developing world.

Bacterial parotitis can occur in children and may be recurrent. It is usually characterized by acute painful swelling followed by resolution on antibiotics. Massaging the parotid will produce infected saliva or pus at the parotid duct opening opposite the second upper molar.

Occasionally, chronic inflammatory swelling persists and must be distinguished from neoplasia. Rhabdomyosarcoma or other connective tissue tumours can present in this way. Vascular malformations and haemangiomas can also present as swellings in the parotid region. Magnetic resonance scanning can be very helpful with this differential diagnosis.

The parotid gland in adults is mainly made up of parenchymal glandular tissue. In children, intraparotid lymphoid tissue is more prominent, hence parotid swelling is often due to lymphadenopathy (e.g. non-tuberculos mycobacteria, NTM), especially in the toddler age group.

SUBMANDIBULAR SWELLINGS

Enlarged lymph nodes, floor-of-mouth infections, acute sialadenitis, plunging ranula and occasionally lymphatic or vascular malformations can all cause swelling in the submandibular region. A more detailed discussion of salivary swellings can be found in Chapter 39, Salivary glands.

POSTERIOR TRIANGLE SWELLINGS

Most commonly posterior triangle swellings are lymph nodes but branchial anomalies, vascular malformations and neoplasia enter into the differential diagnosis.

Nature of the swelling

Classical signs of acute inflammation such as redness, tenderness and heat may be present. Chronic swellings usually do not show these signs. If abscess formation has occurred, the clinical sign of fluctuance may be present and the mass may feel cystic. A classical tuberculous abscess lacks the clinical features of acute inflammation and is described as a 'cold abscess'.

HEAD AND NECK EXAMINATION

A careful examination for a source of primary infection should be made. This should include examination of the pharynx, nose and ears as well as looking for any cutaneous lesion, including the scalp.

General examination

Fever, tachycardia or a rash should be noted. A general examination should include a search for any associated lymphadenopathy and hepatosplenomegaly. The otolaryngologist may wish to enlist the help of a paediatrician.

Investigation

In many cases no investigation is required. Symptomatic treatment of presumed viral infection or antibiotic treatment of bacterial infection with careful clinical follow-up will result in resolution.

Laboratory and skin tests

If the child is systemically unwell, a full blood count may demonstrate neutrophilia consistent with bacterial infection. A blood count may also be a screening investigation for suspected haematological malignancy. C-Reactive Protein (CRP) is raised in bacterial infections and can be useful in monitoring response to treatment.

Consider a 'Monospot 'test for infectious mononucleosis. Serological tests for toxoplasmosis, bartonella (cat scratch disease), or cytomegalovirus (CMV) should be considered for persistent lymphadenopathy. Mantoux or Heaf tests for tuberculosis may be helpful, particularly in the non-immunized.

Imaging

There is a limited place for plain radiographs, but calcification in a lymph node is highly suggestive of tuberculosis. A chest X-ray may be helpful in tuberculosis, and a lateral neck view may demonstrate a retropharyngeal mass. Ultrasound examination of a neck mass may be undertaken without sedation or anaesthesia. Ultrasound will help determine if a lesion is cystic or solid. An experienced radiologist can comment on the internal architecture of lymph nodes and may raise suspicion of malignancy. Benign characteristics include size less than 1 cm, oval shape with short : long axis ratio less than 0.5 to 1, normal hilar vascularity and a low resistive index with high blood flow on Doppler technology.[4] If an abscess is identified, sonography will help with determining the anatomical relationships of the abscess and with surgical planning.

Computed tomographic (CT) scanning may require general anaesthesia in small children. Good anatomical detail is provided and it is helpful in surgical planning. Neither ultrasound nor CT is absolutely accurate in the diagnosis of an abscess and in the presence of strong clinical features surgical exploration should be considered.[5]

Magnetic resonance (MR) scanning rarely adds useful information in the case of acute inflammatory lesions but is very useful for vascular malformations, salivary gland and soft-tissue masses.

SPECIFIC CERVICOFACIAL INFECTIONS

Viral infections

VIRAL UPPER RESPIRATORY INFECTIONS

Adenovirus, rhinovirus or enterovirus (Coxsackie A and B) may cause reactive lymphadenopathy. This is generally self-limiting.

INFECTIOUS MONONUCLEOSIS

This is an acute infection caused by Epstein–Barr virus (EBV). It occurs mainly in adolescence and is spread by close contact. Fever, fatigue, malaise and an exudative tonsillitis are characteristic (**Figure 37.1**). Cervical lymphadenopathy may be massive. Other lymphoid tissue including liver and spleen may be enlarged. There is a characteristic picture on the blood film with the presence of atypical lymphocytes. Serological tests such as Monospot or Paul–Bunnel will usually confirm the diagnosis. Although the aetiology is viral, intravenous antibiotics may be needed to treat any coexistent bacterial infection. Ampicillin and amoxicillin are contraindicated as they can cause a skin rash when used in Epstein–Barr virus infection.

In cases where the acute tonsillitis is associated with airway obstruction, steroids may be considered. On occasion, endotracheal intubation may be required to protect the airway until the swelling subsides, or acute –'hot' – tonsillectomy to remove the obstructive tonsils.[6, 7] Cases with hepatosplenomagaly should be managed in cooperation with a paediatrician. Patients should be warned that splenomegaly will last at least 4 weeks but can take as long as 8 weeks to settle and should refrain from contact sports during this time.[8]

HIV

Infection is associated with repeated opportunistic infections. Most cases of paediatric HIV infection are acquired from the mother by vertical transmission. Acute infection may mimic infectious mononucleosis. Persistent generalized lymphadenopathy including the cervical nodes becomes a feature as the disease progresses. Weight loss and recurrent fevers occur. Following HIV infection it may be years or decades before full acquired immune deficiency syndrome (AIDS) develops. There is significant evidence of increased life expectancy with early antiretroviral treatment.[9]

Investigation and management should be in cooperation with a specialist in paediatric infectious diseases.

Bacterial infections

MICROBIOLOGY

Group A *beta haemolytic streptococcus* and *Staphylococcus aureus* are the most common causative organisms for suppuration in the neck. Other bacteria that may be implicated include anaerobes (19%); *Haemophilus influenzae*, *Moraxella catarrhalis*[10] and beta lactamase-positive organisms.

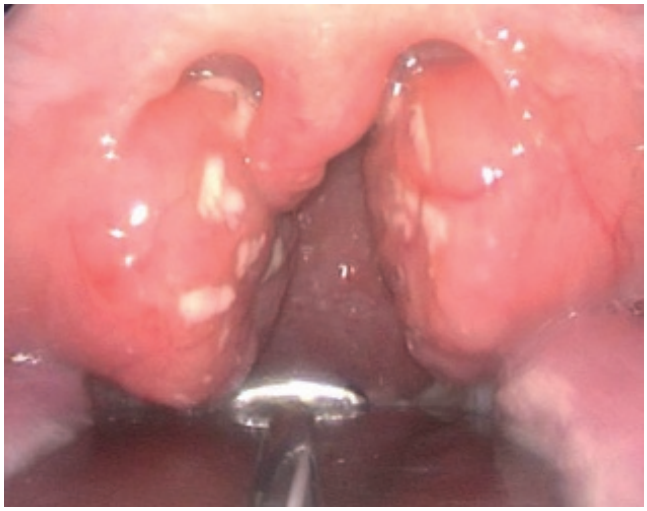

Figure 37.1 Exudative tonsillitis in infective mononucleosis.

ACUTE LYMPHADENOPATHY WITH SUPPURATION

Cervical abscesses

Bacterial infection within a cervical lymph node may progress to cause local cellulitis and abscess formation (Figure 37.2). Occasionally, a solid mass of inflammatory tissue forms due to coalescence of a group of lymph nodes and this is clinically referred to as a 'phlegmon'. The distinction between phlegmon and abscess is important, as abscesses usually require surgical drainage whereas phlegmons settle with intravenous antibiotics. The most important assessment is clinical. Abscesses are tender, usually reddened and exhibit the clinical sign of fluctuance, confirming their cystic nature. Imaging in the form of an ultrasound scan is helpful but not always required.

Many neck abscesses require surgical drainage. This may be performed by a neck incision, which is ideal for superficial lesions and the majority of deep cervical abscesses. A wide-bore needle aspiration may be adequate if the pus has coalesced and liquefied.

Dental abscess

An infected molar or premolar may cause extensive swelling extending into the face and neck and should be considered in the differential of a neck abscess (Figure 37.3).

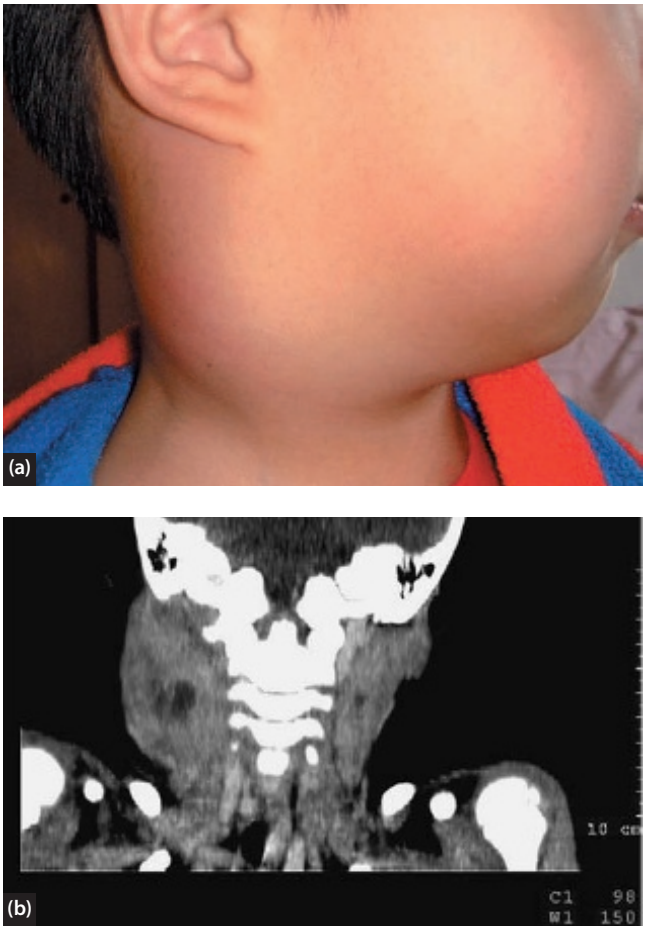

Figure 37.2 Cervical abscess. (a) Child with acute cervical abscess. **(b)** CT scan of the same child.

Deep neck space infections (DNSIs)

Deep neck spaces are described in relation to the hyoid bone. They can be suprahyoid, infrahyoid or comprise the entire length of the neck. A sound knowledge of the fascial layers and neck spaces is needed to correctly diagnose the affected space as well as plan the surgical approach. Deep neck space infection may lead to other severe and potentially life-threatening complications, such as mediastinitis, septic embolization, dural sinus thrombosis and intracranial abscess.

In paediatric patients, DNSIs are typically caused by the suppuration and perforation of parapharyngeal and retropharyngeal lymph nodes, which serve as a drainage pathway for adenoid and tonsillar infections in children aged 1–5 years. The retropharyngeal, parapharyngeal and peritonsillar spaces are therefore more frequently involved in children.[11]

Retropharyngeal abscess is now uncommon but should be recognized because of its potential to cause fatal airway obstruction.[12] The child is usually febrile, drooling and may adopt a characteristic posture with the neck flexed and the head extended. If suspected, the child must be admitted for intravenous antibiotics, rehydration and careful observation. Imaging is required to confirm the suspected clinical diagnosis, distinguish between drainable abscesses and cellulitis, define the precise extent of the disease, identify complications and also monitor infection progression. CT scanning with contrast is the modality of choice but may itself require anaesthesia (Figure 37.4).[13] In patients requiring a general anaesthetic the patient should be carefully intubated with the help of a skilled paediatric anaesthetist and arrangements should be made for surgical drainage if indicated as soon as the CT scan has been completed. Drainage can be via an intraoral or external approach.

Figure 37.3 Dental abscess.

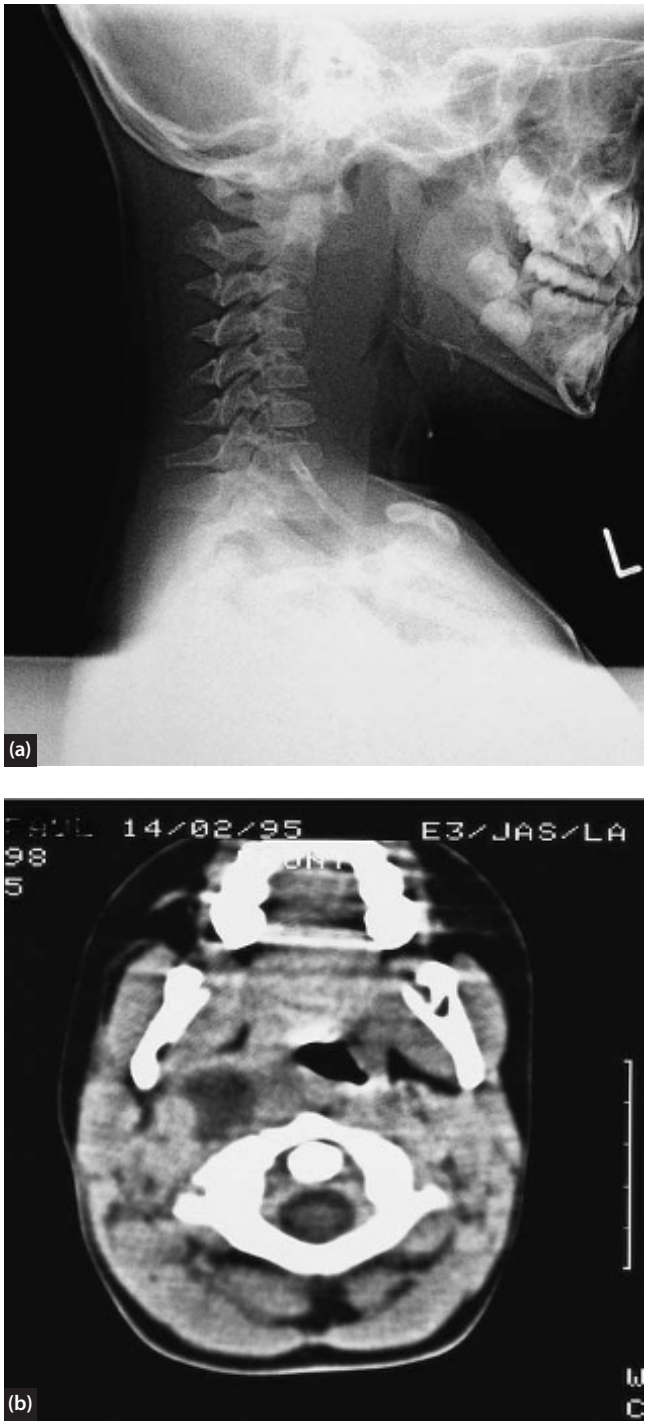

Figure 37.4 Retropharyngeal abscess. **(a)** Plain film showing large prevertebral shadow with compression of the airway; **(b)** CT scan of same child showing swelling filling the retropharyngeal space.

Ludwig's angina

This is a rapidly progressing cellulitis of the floor of mouth, involving the submandibular neck space. It is usually secondary to concomitant dental infections[14, 15] but has been described after frenuloplasty in an adolescent.[16] Causative organisms include *Streptococcus* species, Gram-negative rods and anaerobes. Patients usually present with swelling of the neck and submandibular space as well as firm induration of the floor of mouth, resulting in elevation and protrusion of the tongue, which can lead to airway obstruction.[17] Securing the airway is the mainstay of treatment, followed by intravenous antibiotics. Prompt initiation of antibiotics is usually sufficient and surgical intervention is reserved for persistent or progressive infections or when there is evidence of abscess formation.[18, 19] Surgical techniques for surgical decompression include intraoral and external approaches to ensure drainage of submaxillary and sublingual spaces.[20, 21]

Lemierre's syndrome

This is a septic thrombosis of the internal jugular vein. It is most often caused by the bacterium *Fusobacterium necrophorum*. It was common in the pre-antibiotic era, with a mortality rate exceeding 50%. Following an episode of upper respiratory sepsis the patient develops high spiking fevers with tenderness and fullness of one side of the neck. Pulmonary emboli may occur causing lung abscess formation (**Figure 37.5**). Incidence in the UK is rising, perhaps related to changing patterns of antibiotic use.[22]

Doppler ultrasound can detect flow rate and is useful in making the diagnosis. Unfortunately, it is suboptimal for detecting thrombosis deep to the mandible and clavicle.

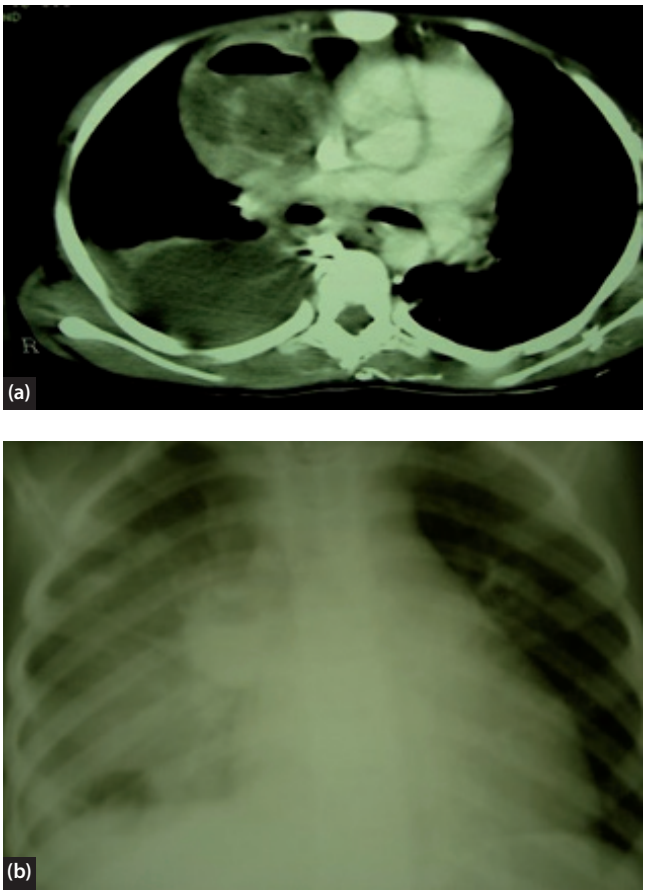

Figure 37.5 CT scan and chest X-ray demonstrating a lung abscess secondary to septic emboli from internal jugular vein thrombosis.

CT scan with intravenous contrast is considered by many to be the study of choice. Treatment with intravenous antibiotics and drainage of any abscess is usually curative. The role of anticoagulants is controversial and surgical treatment of the suppurating internal jugular vein is rarely required, although it has been used in cases of repeated septic emboli.

CAT SCRATCH DISEASE

This is a granulomatous condition characterized by lymphadenopathy with fever and malaise. The disease has been recognized for over 50 years but only recently has the causative organism been identified as the bacteria *Bartonella henselae*. It is spread by close contact with cats while kittens are more likely to carry the bacteria than adult cats. Fleas have been shown to serve as a vector for transmission among cats and viable *Bartonella henselae* has been isolated in the faeces of cat fleas. It has been postulated that transmission of *B. henselae* from cats to humans may be by inoculation with flea faeces containing *B. henselae* through a contaminated cat scratch wound or across a mucosal surface.[23–25]

Patients are mainly under 20 years of age and more than 90% have a history of feline contact.[26, 27] Serologic testing has a high sensitivity and specificity. Although there is no medical treatment, confirmation of the diagnosis by performing a blood test will reassure parents who often become concerned about possible malignancy. Lymphadenopathy may persist for months after other symptoms have disappeared.

TULARAEMIA

Tularaemia, named after Tulare County in California, is also known as rabbit fever or deer fly fever. It is caused by infection with the Gram-negative bacillus *Francisella tularensis*. It is transmitted to humans by rabbits, ticks or contaminated drinking water. Skin or mouth ulcers may be present with associated lymphadenopathy, fevers, malaise and headache. Diagnosis can be difficult but organisms can be isolated from blood cultures during periods of pyrexia. The diagnosis can also be confirmed by rising serological titres in the convalescent phase of the illness. The treatment of choice is streptomycin but tetracycline, aminoglycosides or chloramphenicol has also been used. Immunotherapy has shown promise in animals but is still not licensed in adult use.[28]

ACTINOMYCOSIS

Actinomycosis is caused by Gram-positive non-spore forming bacteria. The most common human pathogen is *Actinomyces israelii* but there are several other species which can rarely be pathogenic. Approximately 50% of cases are cervicofacial. Actinomyces are normal commensals in the oral cavity and infections arise from a breach of the mucosa (e.g. dental extraction). The most common presentation is a slow-growing painless mass near the mandible. Local lymph nodes may be involved and in a small number of cases metastasis of disease to liver or brain may occur. Untreated, the mass progresses to fibrosis and chronic suppuration with draining sinuses. A less common presentation is with an acute, warm, tender mass with fever. The presence of sulphur granules on pathological examination is suggestive but not diagnostic. If the diagnosis is suspected, special culture conditions increase the chance of culturing this organism. Most cases are treated by surgical excision followed by prolonged antibacterial therapy, usually penicillin for up to 6 months.

BRUCELLOSIS

Brucellosis is a zoonosis, i.e. an infection transmitted from animals to humans. It can be acquired through working with livestock or consumption of unpasteurized dairy products or infected meat products. It is caused by several species of the genus *Brucella,* which are small Gram-negative bacilli. There is lymphadenopathy involving the neck and other body regions associated with fever, malaise and migratory myalgia and arthralgia. Diagnosis is by serology and management is with tetracycline in adults and trimethoprim-sulphamethoxazole in children. Up to 10% of patients will present with relapse and treatment will have to be repeated.

SYPHILIS

This is a spirochaete infection caused by *Treponema pallidum*. Primary syphilis is associated with an ulcer (chancre) and local lymphadenopathy. Early presentation with a neck mass may occur in patients with HIV. It presents in the paediatric population as congenital syphilis and the majority of patients are asymptomatic at birth. If untreated, patients can present with late congenital syphilis. Head and neck manifestations include neurosyphillis, saddle nose deformity and Higoumenakis' sign, which is unilateral sternoclavicular joint enlargement caused by periosteitis in congenital syphilis.[29]

Serological diagnosis starts with venereal disease research laboratory (VDRL) and rapid plasma reagin (RPR) tests. Occasionally these tests can yield false-positive results and confirmation is required with treponemal-specific tests, *Treponema pallidum* haemagglutination assay (TPHA) or fluorescent treponemal antibody absorption (FTA-ABS) tests.[30, 31]

First-line treatment for uncomplicated infection consists of a single dose of intramuscular penicillin or oral azithromycin. Because of the poor penetration of penicillin into the central nervous system, treatment of neurosyphilis requires high-dose penicillin for a prolonged period (at least 10 days).[31, 32]

Mycobacterial infections

Two groups of mycobacterial infections involve the neck in children. The distinction is important and can be challenging. First there are infections caused by *Mycobacterium tuberculosis* (TB). Second are a group of infections caused by other mycobacteria. Commonly referred to as atypical

mycobacteria or environmental mycobacteria, these are most accurately termed non-tuberculous mycobacteria (NTM) or mycobacteria other than tuberculosis (MOTT). They include *Mycobacterium avium intracellulare*, *Mycobacterium scrofulaceum*, *Mycobacterium fortuitum* and *Mycobacterium haemophilum*.[33] They particularly affect children between the ages of 18 months and 3 years, presumably because younger children are less commonly exposed to the pathogens and because older children have developed immunity.

NTM is found throughout the environment and can be isolated from water, soil, dust animals and birds.[34–37] These organisms are low-grade pathogens in humans and cross infection is rare.

The typical presentation is of a painless, firm, enlarging mass in the neck. In NTM infection the overlying skin is frequently discoloured (**Figure 37.6**). In children with tuberculosis, weight loss, fever and anorexia may be present.

The differential diagnosis includes lymphoma. To exclude this, a tissue diagnosis is usually required. Biopsy specimens are sent for both histopathological examination and microbiology, including staining and culture specific to mycobacterium. The typical histopathological appearances of tuberculosis are of caseating granuloma formation. Acid- and alcohol-fast staining bacilli may be seen. However, it may not be possible histopathologically to distinguish tuberculous from NTM infection. Culture remains the cornerstone of diagnosis of opportunistic mycobacterium but may take several weeks. In this situation all patients should have a chest X-ray to identify features of tuberculosis. A tuberculous skin test is often helpful. A positive test in a non-immunized population (such as the US or children under 13 in most regions of the UK) is highly suggestive of tuberculous infection. Unfortunately, there is an incidence of positive testing with non-tuberculous infection and this test is not absolutely diagnostic for tuberculosis. In cases of doubt, antituberculous medication may be commenced pending the outcome of cultures. Genetic probing of the cultured organisms can also be used to try and make the distinction between tuberculous and NTM infection. Great promise is shown with the use of multiplex real-time PCR testing with targeting different housekeeping genes.[38]

The management of confirmed mycobacterium tuberculosis lymphadenopathy is medical treatment with a combination of antituberculous drugs. The management of NTM lymphadenopathy is controversial. Complete surgical excision of the involved nodes results in higher short-term cure rates compared to medical treatment.[39] Prolonged medical therapy is an alternative[40] but there is no evidence that it is any better than doing nothing and waiting for spontaneous resolution.[41] There is obviously a trade-off: with surgery there is a scar and possible injury to the facial nerve or its branches and, depending on the circumstance, this may or may not lead to a better cosmetic result than the scarring left after the disease has run its natural course; untreated NTM usually resolves in 3–6 months but a few cases can take a year or more.[42]

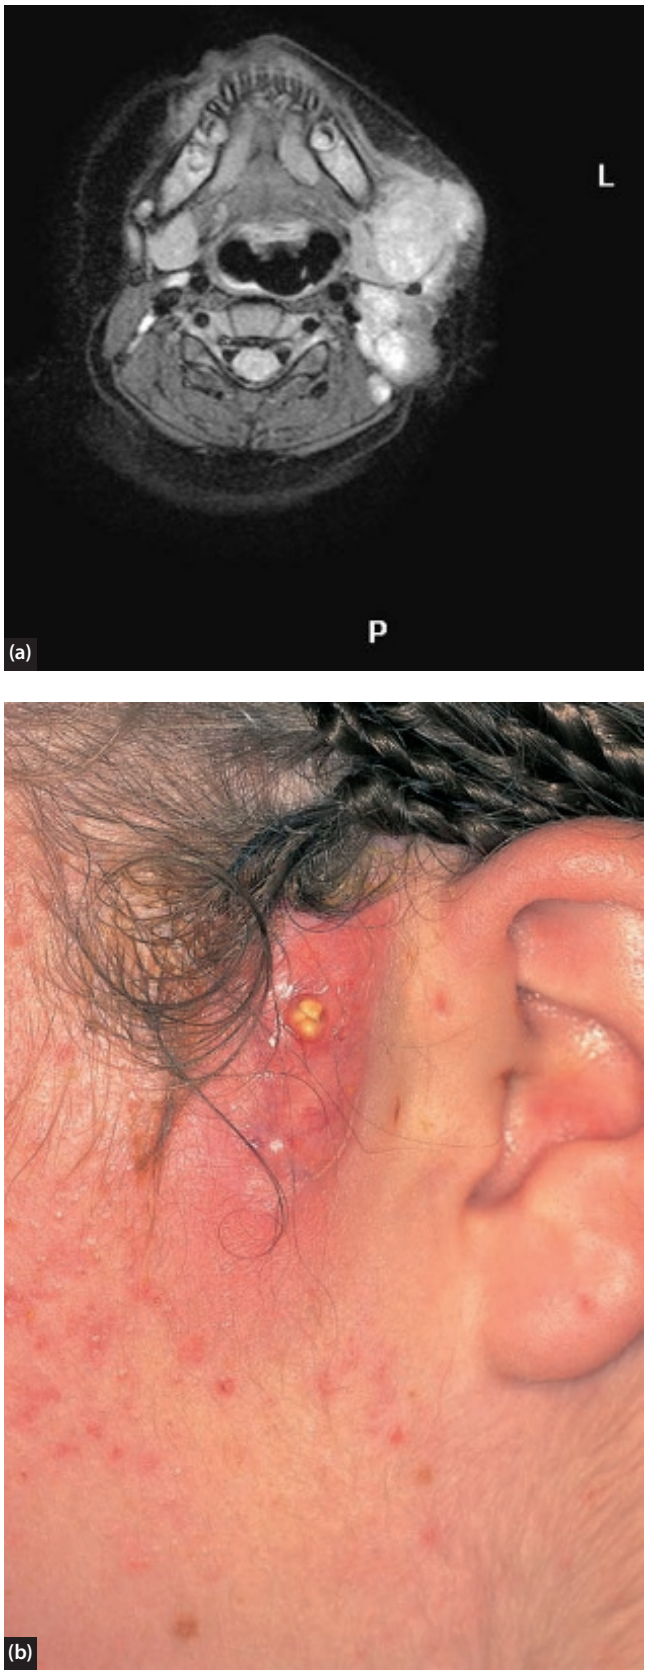

Figure 37.6 NTM. **(a)** MR scan showing large left neck mass; histology confirmed NTM. **(b)** Skin changes in NTM.

SINUS FORMATION AND DISCHARGE

If the nodes have been breached by the infection and there has been spread into the surrounding tissue, there is a risk of skin breakdown and formation of a sinus. These sinuses often persist for months with troublesome discharge. Once a sinus has formed, there is a stronger indication to perform surgery as the constant discharge is extremely disruptive to the life of an otherwise well child. Curettage has been advocated as a treatment for infection that has spread beyond the lymph nodes and is not amenable to complete excision. This may reduce the duration of the disease.

Primary medical treatment of non-tuberculous neck masses has been advocated using either macrolide antibiotics based on some *in vitro* experiments[43] or antituberculous therapy. This usually involves prolonged treatment as the organisms are notoriously resistant to antituberculous therapy. Whether such prolonged antibiotic therapy produces better results than doing nothing is currently unclear.[31]

Fungal infections

HISTOPLASMOSIS

Histoplasmosis is caused by the fungus *Histoplasma capsulatum*. It is associated with bird droppings and acquired via airborne spores. Infection in the central US is very common and typically asymptomatic. Pulmonary and systemic disease may occur in immunocompromised patients and is common in HIV/AIDS patients. Mucosal head and neck lesions may mimic squamous carcinoma and severe infections can cause lymphadenopathy.

The diagnosis is best established by urine antigen testing. Serum antigen tests can produce false-negative results in the first 4 weeks of the infection and blood cultures take 6 weeks to produce diagnostic growth.[44] Immunocompetent patients do not often require treatment as the infection usually resolves. Antifungals such as amphoterizine B and itraconazole are used to treat severe acute and chronic disseminated infections.

CANDIDA AND ASPERGILLUS

Mucosal candidiasis is a common problem in children but neck masses caused by these infections are extremely rare and limited to immunocompromised patients.

Parasitosis

TOXOPLASMOSIS

Infection with the parasite *Toxoplasma gondii* is usually through the ingestion of poorly cooked meat or of oocytes excreted in cat faeces. Cervical adenitis occurs in more than 90% of clinical cases.[45] Subclinical infection and positive serology may be found in asymptomatic individuals. It is estimated that up to a third of the world population carry *Toxoplasma* infection.[46]

Organisms can be detected by polymerase chain reaction in human blood samples.[47] The lymphadenopathy may persist for months and children may require a biopsy to rule out malignancy. Treatment is rarely required for cervical lymphadenopathy, which is self-limiting, but the infection responds to sulphonamides and pyrimethamine.

Non-infective inflammatory disorders

SARCOID

Sarcoidosis is a chronic multisystem disorder of unknown aetiology. It mainly occurs in the second decade of life and is rare in children. It causes generalized and pulmonary symptoms but may involve other parts of the body. Neck masses, parotid masses and facial nerve paresis, often bilateral, may result. Cervical nodes are typically bilateral and non-tender. The diagnosis is often suspected from the chest radiograph and can be confirmed by biopsy, which shows typical non-caseating granulomas. Angiotensin-converting enzyme blood levels are used in diagnosis and monitoring of sarcoidosis. Treatment is usually conservative although steroids, and in some cases more potent antineoplastic agents, can be used.

Conditions which simulate lymphoma

This heterogeneous group of benign lymphoproliferative disorders is characterized by prolonged unexplained cervical adenopathy which can give rise to concerns regarding lymphoma. Some authors refer to these conditions as 'pseudolymphomata'. They include Rosai–Dorfman disease, Castleman disease, Kawasaki syndrome and Kikuchi-Fujimoto disease.[48]

KAWASAKI SYNDROME

This is an acute multisystem vasculitis of unknown aetiology. It tends to affect children under 5 years of age and the clinical presentation is similar to many childhood infectious diseases. The diagnosis is clinical and children should have four of the five following criteria:

1. acute nonpurulent lymphadenopathy – usually unilateral
2. erythema, oedema and desquamation of the hands and feet
3. polymorphous exanthema
4. painless bilateral conjunctival infection
5. erythema and injection of the lips and oral cavity.

There may be a thrombocytosis and pericardial effusion. In the subacute stage, coronary artery aneurysms develop in 15–20% of cases. The goal of management is to reduce inflammatory responses with anti-inflammatory or gamma globulin therapy.[49] The vasculitis is self-limiting but unfortunately causes permanent cardiac damage in around 20% of untreated patients. All patients should have an initial echocardiogram and cardiac follow-up. A mortality of 1–2% is associated with this disease due to the cardiac sequelae.

SINUS HISTIOCYTOSIS (ROSAI–DORFMAN DISEASE)

Children present with massive cervical lymphadenopathy which is similar to infectious mononucleosis or lymphoma. This disease is thought to represent an abnormal histiocytic response to some precipitating cause, possibly a herpes virus or EBV.[50] Fever and skin nodules may be present. Treatment is expectant but biopsy is usually required to rule out malignancy. Histopathologic examination reveals dilated sinuses, many plasma cells and marked proliferation of histiocytes.

KIKUCHI-FUJIMOTO DISEASE

This is an idiopathic disorder, first described in Japan. It is characterized by lymph gland enlargement which may occur anywhere in the body but is typically cervical.

Fever chills and weight loss are common. Women and young adults are more commonly affected. The disease is self-limiting but biopsy is often performed to rule out malignancy. Histology shows a characteristic necrotizing lymphadenitis.

BEST CLINICAL PRACTICE

- ✓ A blood count is a useful screening investigation for haematological malignancy.
- ✓ Ultrasound will help determine if a lesion is cystic or solid. An experienced ultrasonographer can comment on the internal architecture of lymph nodes and may raise suspicion of malignancy.
- ✓ In NTM, once a sinus has formed there is a relative indication to perform surgery as discharge is extremely disruptive to the life of an otherwise well child.
- ✓ Needle core biopsies of suspicious lymph nodes under radiological guidance will usually be sufficient for histological diagnosis.
- ✓ Open biopsy may be the only way to exclude a lymphoma in the non-infective inflammatory lymphoproliferative disorders.

FUTURE RESEARCH

- ➤ The increasing survival of children with malignant disease, often with highly immunosuppressive chemotherapy, will produce therapeutic challenges in the management of infectious disease in the head and neck.
- ➤ Pooling of data on relatively uncommon conditions such as NTM may produce better treatment protocols.
- ➤ Imaging continues to be refined and, as spiral CT scanners permit higher-resolution images at lower radiation doses, imaging the architecture of cervical structures will improve.
- ➤ Aspiration biopsy cytology has proved disappointing in children and increasing specialization in pathology may expand the role of this technique.

KEY POINTS

- Lymphadenopathy is common in children and rarely requires investigation.
- Viral adenitis is the most common cause of neck swelling.
- Much anxiety can be caused by lesions that simulate lymphoma but careful clinical assessment supplemented by non-invasive investigations, and very rarely biopsy, will provide a diagnosis.
- Immunocompromised patients pose a particular challenge and liaison with a paediatrician is essential in this group of children.

DISEASES OF TONSILS, TONSILLECTOMY AND TONSILLOTOMY

Yogesh Bajaj and Ian Hore

SEARCH STRATEGY

Data in this chapter may be updated by searches of the Cochrane Library, Medline, PubMed and Ovid databases using the keywords: tonsils, tonsillitis, pharyngitis, sore throat, children, paediatric and carrying out further subsearches for anatomy, microbiology, immunology, complications and therapy. These were complemented by hand searches of current English language texts and the following journals: *Journal of Laryngology and Otology*, *Clinical Otolaryngology*, *Laryngoscope*, *Archives of Otolaryngology*, *Annals of Otolaryngology*, *International Journal of Pediatric Otolaryngology*. The information available from the published results of the National Prospective Tonsillectomy Audit available on the Royal College of Surgeons of England website (www.rcseng.ac.uk) has also been taken into account. In addition, the UK Department of Health (www.dh.gov.uk) and the National Institute for Health and Care Excellence (NICE) (www.nice.org.uk) websites were consulted.

DISEASES OF TONSILS

STRUCTURE AND FUNCTION OF TONSILS

The palatine tonsils are paired structures consisting of lymphoid tissue. They are located in the tonsillar fossa between the anterior and posterior tonsillar pillars formed by palatoglossus and palatopharyngeus muscles respectively. Along with the adenoids, the lingual tonsils, the tubal tonsils and the diffuse aggregates of pharyngeal submucosal lymphoid tissue, they make up Waldeyer's ring.

Histologically the tonsils consist of aggregates of lymphocytes arranged in a follicular manner and embedded in a stroma of connective tissue. The epithelial lining is stratified squamous, which invaginates into the parenchyma forming crypts.

The organisms cultured from the tonsils are very variable, with recognized differences in surface and core samples.[1, 2] The most commonly identified organism from the surface of a diseased tonsil is the group A beta-haemolytic streptococcus (GABHS). This organism is also found on culture in nearly 40% of asymptomatic individuals.[3, 4] Other organisms found on the surface include *Haemophilus influenzae*, *Staphylococcus aureus*, alpha-haemolytic streptococci, *Branhamella* spp, *Mycoplasma*, *Chlamydia*, anaerobes and respiratory viruses.[5, 6] In recurrent tonsillitis the samples grew a range of pathogens but the predominant organisms were *Haemophilus influenzae* and *S. aureus* including methicillin-resistant *Staphylococcus aureus* (MRSA),[7] mixed flora being quite common. Beta-haemolytic streptococci were less common.

Function: Role of tonsils within the immune system

The tonsils are composed of lymphoid tissue with germinal centres located immediately submucosally. Both T- and B-lymphocytes are present though B-lymphocytes predominate. Tonsil serves both the cell-mediated and humoral immune function. The tonsils have no afferent lymphatics. The B-cells have the capability to synthesize specific antibodies. On exposure to antigen, immunoglobulin IgG and IgA plasma cells are produced. Contact with allergens in the upper respiratory tract therefore enhances

local immunity and also contributes to the development of systemic immunity.

There is no evidence to suggest that tonsillectomy results in impaired immunity, presumably as a result of the extensive 'back-up' in the immune system.[8] The role of bacteria and viruses in this process is also controversial. The evidence suggests that they may act synergistically, with the presence of certain latent viruses (particularly Epstein–Barr virus, adenoviruses and herpes simplex) sensitizing the pathogenic bacteria present incidentally on the tonsils of asymptomatic individuals.[9]

INFLAMMATORY DISORDERS OF THE TONSIL

Acute tonsillitis

Acute tonsil inflammation may be a localized episode, in association with an upper respiratory illness or as a part of generalized systemic infection such as infectious mononucleosis. The causative organism usually is GABHS, although a range of other organisms including viruses and anaerobes may be implicated.[3, 4]

Acute tonsillitis is diagnosed mainly on the basis of clinical assessment. There is a short history of sore throat with fever and pain on swallowing. Examination generally reveals erythema of the tonsils and posterior pharyngeal wall, with obvious exudates on the tonsils occasionally. This is usually associated with tender jugulodigastric lymph node enlargement. Both bacteria and viruses play a part in acute inflammation of the tonsils, either separately or together. Also, there is no evidence to suggest that viral tonsillitis is more or less severe than bacterial tonsillitis. In most of the cases both viral and bacterial tonsillitis tend to resolve quickly without treatment.[4] Corticosteroids (oral or intramuscular), in addition to antibiotics, expedite the resolution of pain.[10, 11]

The management of acute tonsillitis is mainly symptomatic, i.e. using analgesia and hydration until the symptoms subside. Antibiotics will shorten the illness and may reduce the risk of sequelae.[12] In those patients in whom the illness shows no sign of improvement within 48–72 hours, antibiotics should be started, benzyl-penicillin being the drug of choice. If there is clinical concern about the severity of disease at the beginning, antibiotics should be started soon.

Evidence suggests that corticosteroids provide symptomatic relief of pain in sore throat, in addition to antibiotic therapy, especially in severe cases.[13]

Complications of acute tonsillitis

Acute tonsillitis can lead to septicaemia and local abscess formations. The non-infective complications of streptococcal tonsillitis include rheumatic fever and glomerulonephritis.

PERITONSILLAR ABSCESS (QUINSY)

A peritonsillar abscess is a collection of pus lateral to the tonsil. The clinical symptoms include severe usually unilateral sore throat, odynophagia, trismus and lymphadenopathy. The treatment includes antibiotics, needle aspiration of pus or incision and drainage.[14] The antibiotics usually given are intravenous high-dose penicillin or a cephalosporin.[15] Indication for interval tonsillectomy should take into account any background history of tonsillitis or more than one episode of quinsy on the same side. Tonsillectomy during the acute attack is not a very popular treatment option,[16] as the release of pus into the oral cavity either spontaneously or therapeutically carries with it the risk of aspiration in severely ill patients. Using local anaesthetic before incision also increases this risk. The initial management of choice is aspiration of the abscess using a wide-bore needle along with intravenous antibiotics, usually high-dose penicillin or cephalosporin.

RETROPHARYNGEAL ABSCESS

This is a rare but serious complication of acute tonsillitis, seen mainly in infants and children less than 5 years of age. It presents as the infection tracks into the lymphoid tissue between the posterior pharyngeal wall and the prevertebral fascia. The child is usually systemically unwell and there may be evidence of airway compromise or an associated neck abscess. The diagnosis can be confirmed by CT scanning. Treatment is initially high-dose intravenous antibiotics.[17] If pus collection is suspected, urgent incision and drainage is done under a general anaesthetic by an experienced anaesthetist.[18] The drainage is usually done perorally but occasionally external drainage via neck may be appropriate. Very rarely, tracheostomy is necessary. Retropharyngeal abscess due to tuberculosis requires specific antibiotic treatment.

PARAPHARYNGEAL ABSCESS

Occassionaly, peritonsillar and retropharyngeal abscess may be complicated by spread of infection to the parapharyngeal space. Pus collection in this space presents with severe trismus and possibly airway compromise in a systemically unwell patient. The diagnosis is confirmed by ultrasound or CT scanning, which also helps in treatment planning. Treatment includes high-dose broad-spectrum intravenous antibiotics and drainage of the abscess. Deep neck space sepsis may be complicated by progression to life-threatening infections including mediastinitis or retroperitoneal sepsis. It is essential to be proactive in managing these conditions.[19]

LEMIERRE'S SYNDROME

Lemierre's syndrome is a rare but potentially fatal complication of oropharyngeal infection. It is characterized by septic thrombophlebitis of the internal jugular vein, at times associated with metastatic abscesses. The causative organism is usually fusiform bacillus. This condition should be suspected when there is severe neck pain and septicaemia in a patient with infection in the upper aerodigestive tract.[20] Treatment is with antibiotics for 6 weeks, usually penicillin with metronidazole or Co-amoxiclav.[21] If there is evidence of spreading thrombophlebitis,

anticoagulation may be considered. There is significant mortality associated with this condition.

IMMUNE COMPLEX DISORDERS

Acute tonsillitis caused by GABHS can occasionally lead to diseases related to immune complex formation, generated as a response to the infection. The two important diseases resulting from this phenomenon are acute rheumatic fever and acute gomerulonephritis.

TONSILLITIS AND PSORIASIS

There is possibly some association between GABHS tonsillitis and exacerbations of psoriasis, as a result of an immune phenomenon. Some dermatologists and otolaryngologists advocate tonsillectomy, but there is no good evidence to suggest that this relieves the condition.[22]

RECURRENT TONSILLITIS

Significant numbers of patients suffer from recurring episodes of acute tonsillitis. These episodes may gradually settle or may continue for several years. The infections need to be treated depending on the severity of the individual episode. There is no evidence of benefit of long-term antibiotics for this condition.

CHRONIC TONSILLITIS

Some patients get chronic throat discomfort associated with production of smelly white debris from tonsillar crypts. Occasionally, these debris may become inspissated, calcify and form a tonsillolith. There is no evidence to show a relationship to identifiable tonsillar pathology in these patients.

Infectious mononucleosis

Infectious mononucleosis commonly presents as acute tonsillitis. It is caused by Epstein–Barr virus (EBV) and is commonly seen in young adults. In addition to the throat symptoms, patients have significant systemic upset, splenomegaly and derangement of haematological and liver functions.[23] The diagnosis is helped with the Monospot test, which has sensitivity of less than 50% in children and 70–90% in adults. The diagnosis is confirmed by specific antibody titres. Although this is caused by a virus, in 30% patients secondary bacterial tonsil infection occurs. For those admitted to hospital, high-dose intravenous penicillin or cephalosporins is given. Ampicillin must be avoided if infectious mononucleosis is suspected as 90% patients can develop a significant rash as a result of transient immunostimulation. The incidence of rash with amoxycillin in these cases is 30%.[24]

In those patients with significant swelling of the tonsils leading to compromise of the airway and swallowing difficulty, a short course of corticosteroids is beneficial.[11] Steroids should be preferably given in combination with antibiotics. The use of antiviral medications (acyclovir) is debatable and should be considered only in severe cases.[25]

Other infective conditions

Syphilis and tuberculosis infections in the tonsils are potentially difficult to diagnose. The lesion in syphilis classically takes the form of a punched-out ulcer but the appearances are variable, as for tuberculosis. The differential diagnosis of a neoplasm should be borne in mind and the final diagnosis made by biopsy of the lesion.

NON-INFLAMMATORY DISEASES

Tonsillar asymmetry

Asymmetry of the tonsils is not an absolute indication for tonsillectomy, but in children, as adults, the clinicians need to be aware of the possibility of neoplasia (lymphoma). One study to measure actual size in cases of apparent asymmetry in children did not show any significant difference in size.[26] In general, the apparent size of the tonsils is not well correlated with disease within them. There is a wide variation in the degree to which the tonsils are buried within the tonsillar pillars, which can give a false impression of the actual size of the tonsil. In general, the tonsils tend to involute during late childhood, but this rate of involution is variable between individuals and can vary between the two tonsils, which can at times give an asymmetrical appearance.

Spontaneous tonsillar bleeding

Spontaneous bleeding can happen from inflamed tonsils occasionally. Bleeding can also be secondary to minor trauma. This usually will respond to topical cautery under local anaesthetic. If it persists, tonsillectomy is an option.

Neoplasia

Asymmetrical tonsils arouse suspicion of neoplasia especially if the surface of one of the tonsils is irregular or ulcerated. Difference in size is not always an indication for biopsy in children, but any unusual appearances need to be investigated. Lymphoma can occur within the tonsils in adults as well as children. In adults, squamous cell carcinoma is the most common malignancy encountered.

TONSILLECTOMY AND TONSILLOTOMY

TONSILLECTOMY

Paediatric tonsillectomy is one of the most commonly performed operations. In the 1950s in the UK 200 000 tonsillectomies were performed annually, which dropped down to 49 187 in 2008–2009 (www.hesonline.nhs.uk). Of the tonsillectomies carried out in 2008, 27 400 were in children. Among those 25% were for obstructive symptoms and the rest for infections. The proportion performed for obstruction rather than infection seems to be rising year-on-year. This may be due in part to more stringent criteria being applied to surgery for infections as a result of better

evidence from trials in addition to increasing awareness of obstructive sleep apnoea and its consequences in children.

Evidence base for tonsillectomy

Adenotonsillectomy is the treatment of choice for otherwise healthy children with obstructive sleep apnoea, with improvement in 90% cases, including improvement in their behaviour, growth and development.[27, 28] However, for recurrent infections there is a widespread perception that high-quality evidence of the efficacy of tonsillectomy is lacking. Certainly, the evidence for benefit of adenotonsillectomy for recurrent infections was sparse until quite recently.[29] A Cochrane review in 1998 concluded that there was no evidence from randomized controlled trials (RCT) to guide clinicians for setting up guidelines for tonsillectomy in children or adults.[30] However, trials have been carried out since then and the evidence base is a little clearer.

For a long time, the only trial of value was that done by Paradise[32] published in 1984. The Paradise group randomized children with sore throats into surgical and non-surgical groups and their inclusion criteria are widely known and still used: seven sore throat episodes in a year, five a year for the last 2 years or three a year for the last 3 years. Recruitment took many years as few families were willing to undergo randomization and a large parallel cohort of non-randomized children undergoing surgery was also studied. Efficacy was measured on the basis of reduction in the number and severity of throat infections. This trial showed that in severely affected children tonsillectomy was efficacious for 2 years and sometimes for a third.

The North of England and Scotland Study of Tonsillectomy and Adenotosillectomy in Children (NESSTAC) was a large multicentre randomized controlled trial which used broadly the same inclusion criteria as Paradise, and which also had a large parallel cohort of non-randomized children undergoing surgery.[32] This trial demonstrated significant improvements in episodes of sore throat, need for consultations, quality of life and health costs compared to medical management.

Two further trials (one by Paradise[33] and the other from the Netherlands[29]) looked at children with milder symptoms, who did not meet the original Paradise criteria. They both failed to show a significant advantage of surgery over watchful waiting, so it seems that the original Paradise criteria for tonsillectomy are a reasonable threshold for considering surgical intervention.

Studies looking at quality of life (QOL) before and after operation suggest that tonsil disease has a marked adverse effect on QOL and there is significant benefit from surgery.[34] The Scottish tonsillectomy audit was a large-scale audit to look at patient satisfaction after tonsillectomy in more than 5000 patients. This audit reported 97% satisfaction rate 1 year after tonsillectomy.[35]

Guidelines

Various guidelines are produced by the British Association of Otolaryngologists – Head and Neck Surgeons (see ENTUK, www.entuk.org). For tonsillectomy, the recommendations are in line with those of Scottish Intercollegiate Guidelines Network (SIGN, www.sign.ac.uk). The SIGN guidelines for tonsillectomy are based on the Paradise criteria outlined above and reflect the results of randomized controlled trials. According to these guidelines, patients for tonsillectomy for both adults and children should meet all the following criteria:

- sore throats are due to tonsillitis
- the episodes of sore throat are disabling and prevent normal functioning
- seven or more well-documented, clinically significant, adequately treated sore throats in the preceding year, *or*
- five or more such episodes in each of the preceding 2 years, *or*
- three or more such episodes in each of the preceding 3 years.

TONSILLECTOMY TECHNIQUE

The traditional methods of tonsillectomy are 'cold steel' techniques using metal instruments. Several other methods have been introduced with perceived advantages in terms of reduced bleeding, reduced pain, more rapid healing and ease of surgical technique. The National Prospective Tonsillectomy Audit (NPTA) was established in 2003 on behalf of the Royal College of Surgeons of England and ENTUK to look at the effect of surgical technique on complications of tonsillectomy. Data were collected on more than 50 000 patients and the results represent the nationwide practice and recommendations for the clinicians.[36] There are also good data available from the Swedish national tonsil registry which has prospective data on 37 530 patients undergoing tonsillectomy alone (17 319 patients) or adenotonsillectomy (20 211 patients).[37]

Cold steel tonsillectomy

The dissection technique is the most common method of cold steel tonsillectomy. In this technique, the tonsil is pulled medially and the mucosa overlying the tonsil capsule is incised. The dissection continues in the plane of loose areolar tissue between the tonsil tissue and the pharyngeal muscles using a dissector or gauze, and the tonsil is excised completely. The bleeding vessels are dealt with using diathermy or ligatures as required. Another technique is the guillotine technique, which involves using a specially designed guillotine to excise the tonsil.

In the NPTA, haemorrhage was defined as a bleed that prolonged the patient's stay in hospital, required blood transfusion or return to the operating theatre or for secondary haemorrhage readmission to hospital. The haemorrhage rates for various techniques are shown in Table 38.1. The Swedish registry gives similar results, with cold steel dissection and ties having a significantly lower bleed rate and less post-operative pain than any of the other techniques.

TABLE 38.1 Surgical techniques and primary and secondary post-operative haemorrhage

Surgical technique (n = 33 921)	Primary tonsillar haemorrhage rate (%)	Secondary tonsillar haemorrhage rate (%)
Cold steel and ties/packs	0.8	1.0
Cold steel and monopolar diathermy	0.5	2.4
Cold steel and bipolar diathermy	0.5	2.3
Monopolar diathermy forceps	1.1	5.5
Bipolar diathermy forceps	0.4	4.3
Bipolar diathermy scissors	0.6	4.6
Coblation®	1.0	3.6
Other	0.7	3.6

Diathermy tonsillectomy

Bipolar dissection tonsillectomy is an alternative method to traditional cold steel tonsillectomy. In a Cochrane review of dissection versus diathermy, it was demonstrated that diathermy reduced intra-operative bleeding but increased pain in the diathermy group with no difference in secondary haemorrhage rate.[38] In the NPTA, post-operative bleeding was more frequent with diathermy than with cold steel alone, and particularly worse with monopolar diathermy. Monopolar dissection is known to be associated with more post-operative pain than other techniques and has little to recommend it.

Recommendations from the NPTA are shown in Box 38.1.

BOX 38.1 Recommendations of the National Prospective Tonsillectomy Audit (2005)

- When a patient is counselled for surgery, the risk of tonsillectomy complications, and in particular post-operative haemorrhage, should be carefully explained to the patients/parents.
- This risk should be quantified, preferably using the surgeon's own (or department's) figures.
- National figures can be used, but this should be made clear to patients.
- Surgeons using monopolar diathermy should consider using an alternative technique. There are no advantages to using this instrument over other methods.
- All trainee surgeons should become competent in cold steel dissection and haemostasis using ties, before learning other techniques in tonsillectomy.
- Emphasis must be placed on teaching the correct use of, and the potential hazards of, diathermy and other 'hot' techniques. Checks should be made of the power settings before starting the operation.
- Inexperienced trainees must be supervised by a more senior surgeon until competency has been achieved. This recommendation is in agreement with the College's Standards on Good Surgical Practice issued in 2002.
- Irrespective of seniority and experience, surgeons who wish to start using new techniques, such as Coblation®, should undergo appropriate training.
- All ENT departments should have regular morbidity and mortality meetings to monitor adverse incidents affecting patient outcome. For tonsillectomy, data should be presented by the surgeon, indicating the technique used for dissection and haemostasis and power settings if applicable, type of instrument used, and any difficulties encountered.
- It is the responsibility of the surgeon, and if appropriate his or her trainer, to follow up any identified problems appropriately.

Coblation® tonsillectomy

This technique uses a specially designed probe which both coagulates and cuts the tissues. In the NPTA, post-operative bleeding rates were unacceptably high. It has been suggested that post-operative pain is less than conventional dissection but some studies have cast doubt on this and shown that morbidity was less with cold steel dissection.[39] The National Institute for Health and Care Excellence (NICE) advises that electrosurgery (diathermy and Coblation®) can be used for tonsillectomy but that surgeons must be appropriately trained.

Ultrasonic dissection

Ultrasonic dissection uses an oscillating blade, which acts as both a cutting and a coagulating device. Some studies claim reduced pain with this technique but evidence of benefits is lacking.[40]

Laser tonsillectomy

Using a laser as a tool to dissect out the tonsils has been claimed to have advantages in terms of reduced bleeding and post-operative pain, but studies have failed to confirm this. There is evidence that the rate of secondary bleeding[39] and pain is greater with laser.[42]

TONSILLOTOMY

Tonsillotomy involves removing a part of the tonsil lymphoid tissue, leaving the capsule intact. The technique is reminiscent of what was historically called guillotine tonsillectomy. Techniques include microdebrider, laser, or most recently radiofrequency ablation (Coblation®),[43] using the instrument from medial to lateral. The amount of tissue removed can be from just the lymphoid tissue up to the anterior tonsillar pillar, to leaving a cuff of tonsil tissue lining the tonsillar fossa, to taking the tissue all the way back to the capsule (sometimes called intracapsular tonsillectomy).

These techniques, particularly Coblation® tonsillotomy, have only recently started being trialled. Earlier studies have used the technique – when tonsils for example need

to be debulked in young children with obstructive sleep apnoea – but it was thought it might be desirable to leave some functioning lymphoid tissue.[44] Some studies have already shown that recovery-related outcomes (days until pain-free, secondary haemorrhage rate) for intracapsular tonsillotomy were better than for total tonsillectomy in children with obstructive symptoms.[45] In some parts of the world, such as Scandinavia, tonsillotomy has now become the most common operation performed for obstructive symptoms, more common than tonsillectomy.[43]

The fact that the muscle is disturbed less than in tonsillectomy may explain why post-operative pain can be reduced. If the technique is found to be of similar efficacy to tonsillectomy, with a similar or lower bleed rate, the technique could represent an important step forward in tonsil surgery, potentially being applicable to all tonsil surgery for children, except where the tonsils are needed for histology. With time it will become evident how much tonsil tissue to take to achieve the balance in terms of minimal complications and maximum benefit. This is an exciting area of research.

TONSILLECTOMY MORBIDITY

Pain

Significant morbidity is associated with tonsillectomy.[46] Post-tonsillectomy sore throat is normal for at least 1 week and on an average return to school or work can take 1–2 weeks.[35] Various articles have been written on the management of post-tonsillectomy pain (see 'Anaesthesia and analgesia' below).

Peri-operative complications

If the mouth is opened too widely during the tonsillectomy operation, the patient may experience temporomandibular joint dysfunction. Dissection beyond pharyngeal musculature can lead to injury to the glossopharyngeal nerve and rarely the carotid sheath. Non-traumatic atlantoaxial subluxation (Grisel syndrome) can occur secondary to any inflammatory process in the neck.

Bleeding

Bleeding after tonsillectomy can be primary (within 24 hours after the operation) or secondary (after 24 hours until 2 weeks). The NPTA reported that the readmission rate for bleeding was 4.57%, with 1.44% requiring return to theatre. The most likely explanation for secondary bleeding is infection with *Streptococcus* in the granulating tonsil bed. Treatment depends on the severity and potential cause of the bleed. Antibiotics are advised for secondary bleeding. Severe primary or secondary bleeds need to be controlled in theatre.

Infection

The first symptoms of post-tonsillectomy infection are fever and halitosis. Treatment should be administered according to the severity.

PERI-OPERATIVE MANAGEMENT

Post-tonsillectomy morbidity can be minimized by skilled anaesthesia, analgesia, and antiemetic and steroid treatments.

Anaesthesia and analgesia

In the UK, the technique used by anaesthetists is very variable. Total intravenous anaesthesia with propofol and remifentanil leads to fast wake-up, and propofol is a helpful antiemetic agent. Using inhalational agents for intubation obviates the need for muscle relaxants and speeds up the reversal process.

Adequate analgesia is important in the immediate post-operative period. Narcotics have a potent emetic effect and should be used with caution. Paracetamol is the drug of choice as it is safe and efficacious. Non-steroidal anti-inflammatory drugs (NSAIDs) have been shown to cause significantly less post-operative nausea and vomiting than narcotics. Also concerns that effect of these drugs on platelet adhesion might increase bleeding from the tonsil bed have been unfounded. Recent guidelines have suggested that codeine should not be used in children after tonsillectomy. Also aspirin should not be used in children because of the risk of Reye syndrome.[47] Studies have reported on injecting long- and short-acting local anaesthetic pre- or post-operatively into the tonsil beds. There is no current evidence to suggest any significant benefit from the use of these techniques.[48]

Steroid treatment

Use of pre-operative glucocorticoids has gained wide acceptance. A Cochrane review has shown that a single intravenous dose of dexamethasone was an effective and relatively safe treatment for reducing morbidity from paediatric tonsillectomy.[49] Some more recent studies have confirmed that a single dose of dexamethasone at induction reduces early incidence of nausea, vomiting and level of pain post-operatively.[50]

Post-op antibiotics

Using antibiotics prophylactically after tonsillectomy has been looked at in various studies.[51] A Cochrane review of these studies published in 2012 advocated against routine use of antibiotics after tonsillectomy.[52]

Day-case surgery

Tonsillectomy as a day-case procedure is gaining popularity. The main reasons for patients to stay in overnight are the risk of bleeding and associated morbidity from pain and vomiting. Day-case tonsillectomy in children has been demonstrated by numerous studies to be a safe alternative to surgery as an inpatient.[53, 54] Recently a study has demonstrated safety of adenotonsillectomy as a day-case procedure for children with mild obstructive sleep apnoea in a tertiary unit.[55]

BEST CLINICAL PRACTICE

- ✓ In acute tonsillitis clinical diagnosis alone should not be relied upon in distinguishing between a bacterial and a viral aetiology.
- ✓ Both throat swab culture and RAT are of questionable value in guiding prescription of antibiotics for sore throat.
- ✓ Widespread indiscriminate antibiotic prescription promotes the genesis of resistant organisms, allergy and anaphylaxis. There is no justification for routine use of antibiotics in children with sore throat. [Grade A]
- ✓ In those patients in whom the illness shows no sign of improvement within 48–72 hours or in whom there is clinical concern because of the severity of symptoms, antibiotic therapy is appropriate and the drug of choice remains benzylpenicillin. A 7-day course is usually adequate.
- ✓ A single dose of dexamethasone as adjuvant therapy reduces pain in acute pharyngotonsillitis.
- ✓ Aspiration using a wide-bore needle and syringe, together with antibiotic therapy, is now the management of choice for quinsy. As a significant proportion of peritonsillar abscesses grow anaerobes, metronidazole should be considered.
- ✓ Treatment of both parapharyngeal and retropharyngeal abscess is initially high-dose antibiotic therapy. When pus formation is suspected, incision and drainage under general anaesthesia, with the airway protected by intubation by a skilled and experienced anaesthetist is recommended.
- ✓ Ampicillin must be avoided in infectious mononucleosis as patients may suffer a severe rash in consequence.
- ✓ Systemic glucocorticoids are of value in infectious mononucleosis where there is extreme swelling of the tonsils with impending airway compromise.
- ✓ 'Cold steel' dissection tonsillectomy is widely available and associated with the lowest post-operative haemorrhage rates in the hands of most surgeons.
- ✓ Adequate analgesia is essential in the post-operative care of children following tonsillectomy.
- ✓ There is now a sufficient body of evidence supporting the use of peri-operative glucocorticoids to justify considering their use as routine. [Grade A]
- ✓ In secondary haemorrhage, surgery is rarely needed. Bleeding usually settles with antibiotic therapy alone.
- ✓ Continuing audit is essential; surgeons should familiarize themselves with the findings and recommendations of the NPTA.

FUTURE RESEARCH

- ➤ The role of the tonsil in the development of immunity needs to be more fully understood.
- ➤ Data to shed light on the natural history of recurrent tonsillitis and define any subgroups in which natural resolution of recurrent symptoms is likely to happen would be helpful.
- ➤ The precise place and value of antibiotic therapy is still not fully defined. Robust randomized controlled trials of antibiotic therapy versus placebo in sore throat/tonsillitis, both in the acute single episode situation and in recurrent tonsillitis, are required. The results should be applicable to everyday practice.
- ➤ High-quality randomized controlled trials of tonsillectomy versus standardized conservative management are essential to define the optimal management of recurrent tonsillitis. The trials need to consider outcomes other than reduction in number of episodes of tonsillitis.
- ➤ The morbidity of tonsillectomy remains significant. The optimal strategy for control of pain and emesis post-tonsillectomy still requires to be defined. The use of newer antiemetic agents and peri-operative glucocorticoids seems set to increase.
- ➤ The possibility that tonsillotomy, for instance by Coblation®, could be associated with better post-operative recovery than tonsillectomy is currently being investigated. With less tissue trauma, specifically to the muscle, recovery may be quicker. Given the great potential benefits, the key question that needs to be answered is how much of the tonsil to remove to keep the same effectiveness as tonsillectomy, and also if the bleed rate is truly less. If bleed rates are reduced, this could well represent a significant step forward in the continuing evolution of tonsil surgery.

KEY POINTS

- Acute tonsillitis is common and self-limiting.
- Complications are rare.
- Treatment is largely symptomatic with an emphasis on analgesia and rehydration.
- Antimicrobial therapy has a small but measurable effect on outcome.
- The tonsil rarely may be the site of presentation of lymphoma or malignant disease.
- Tonsillectomy is one of the most commonly performed surgical procedures in the developed world.
- The evidence base for current practice is poor.
- Tonsillectomy rates vary considerably in different populations. These variations are not accounted for by variations in disease prevalence.
- Improvements following surgery are particularly small in less severely affected children. The morbidity of surgery usually outweighs any potential benefit in this group.
- There is no evidence that the benefits of tonsillectomy for recurrent sore throat are prolonged beyond 2 years.

CHAPTER 39

SALIVARY GLANDS

Neil Bateman and Rachael Lawrence

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the following keywords: saliva, salivary, parotid, submandibular, sialendoscopy, parotitis and sialadenitis, supplemented by articles from the author's own library.

INTRODUCTION

Diseases of the salivary glands are uncommon in children. Many are similar to those pathologies occurring in adults but some present mainly in children and form the focus of this chapter. The surgical management of these conditions requires knowledge of the anatomy and experience of surgical techniques in children.

CONGENITAL ABNORMALITIES

Salivary gland aplasia

Aplasia or agenesis of the salivary glands is very rare but well recognized.[1] Some or all of the glands may be affected; children present with the effects of xerostomia such as dental caries, fissuring of the lips and oral ulceration. The diagnosis can usually be made with imaging in the form of ultrasound or MRI, augmented with radioisotope scanning if necessary. Lacrimo-auriculo-dento-digital (LADD) syndrome is a rare genetic disorder characterized by abnormalities in the lacrimal apparatus, dentition and digits. Patients may have no salivary glands.

The management of xerostomia in these cases is supportive and symptomatic, with artificial saliva and meticulous dental care.

Congenital salivary cysts

These present more commonly in the parotid gland and most often as a mass within the gland which is confirmed as cystic with ultrasound imaging. Distinguishing between a congenital salivary cyst and a branchial anomaly (see Chapter 41, Cysts and sinuses of the head and neck) may be difficult but the treatment is similar in both conditions. Treatment options include aspiration, sclerotherapy and surgical excision.

Congenital ductal abnormalities

Duplicate or imperforate ducts are rare. They are diagnosed by sialography or MR sialography. They may cause problems associated but ductal obstruction and stasis of saliva. If they are symptomatic, duct 'marsupialization' is the preferred treatment.

Ectopic salivary tissue

Ectopic salivary tissue may be found in the neck, the mandible and cervical lymph nodes and can cause discharging sinuses in these areas. The distinction between these lesions and branchial cleft sinuses can be difficult and in many cases the primary pathology is a first branchial cleft anomaly. The treatment is the same for

both conditions: surgical excision with complete preservation of the facial nerve.

Cystic fibrosis

Like other exocrine mucus-secreting glands, salivary glands are affected by the autosomal recessive disease cystic fibrosis. Abnormal mucus produced by the glands obstructs their ducts and causes progressive damage to the related parenchyma. The parotid gland, which produces mainly serous secretion, is less affected than the submandibular gland.[2]

ACQUIRED DISEASES

Mucous extravasation cysts

These mucocoeles are relatively common and usually caused by trauma that tears the duct of a minor salivary gland allowing mucus to escape into the surrounding tissues. The commonest site is the lower lip but these cysts are sometimes found in buccal mucosa or in the floor of the mouth. They present as soft, dome-shaped, swellings with a bluish hue. They are rarely more than a centimetre in diameter. Mucous extravasation cysts inevitably require excision as they do not resolve spontaneously.[2]

Ranula

A ranula is a fluid-filled lesion arising from the floor of the mouth. It is an extravasation pseudocyst and can be classified into two types: the much commoner simple or intraoral ranula, and the 'plunging' cervical type. A simple ranula is localized to the floor of the mouth. In the plunging type, extravasation of mucus occurs beyond the confines of the floor of the mouth and the mucus collection is therefore in the infra-mylohyoid compartment of the neck, with or without a clinically apparent intraoral collection.

AETIOLOGY

They may be congenital but are more frequently acquired as a result of obstruction to one of the sublingual salivary glands or ducts. This obstruction may be spontaneous but is sometimes due to trauma to the sublingual gland duct, following procedures on the floor of the mouth.

PRESENTATION

A ranula presents clinically as a smooth swelling in the floor of the mouth with a bluish translucent appearance. If of sufficient size, elevation of the tongue may occur with subsequent interference with swallowing, speech, mastication or respiration.[3] A plunging ranula may appear as a swelling in the neck. It can be difficult clinically to differentiate a plunging ranula from a lymphatic malformation. However, histologically a ranula is contained by loose connective tissue whereas a lymphatic malformation has a simple epithelial lining.

INVESTIGATIONS

Imaging is unnecessary for confirming the clinical diagnosis of a simple intraoral ranula.[4] However, if there is a history of previous surgery, if the ranula has a cervical component or of if the diagnosis is uncertain clinically, then MRI is preferred.[5–7]

TREATMENT

Simple aspiration or drainage of a ranula results in a high recurrence rate. Marsupialization of a plunging ranula is inadequate with a recurrence rate of 80%.[8] Both intraoral and plunging ranulas should be excised together with the sublingual gland as excision of the gland results in a low rate of recurrence.[9, 10] A retrospective analysis of 65 patients with a diagnosis of ranula showed that treatments which included complete sublingual gland excision were associated with the lowest recurrence rate (3.6%) and that a statistically significant difference was observed in the recurrence rate between complete sublingual gland excision and ranula excision alone.[10] Laser excision is reported as an alternative treatment for intraoral ranula, with reported low rates of recurrence and surgical complications.[11]

A transoral surgical approach is common for masses that are located intraorally and an external transcervical approach for those presenting predominantly submentally or in the neck. Care must be taken to identify and preserve the lingual nerve, which lies in close proximity.

Injection of the sclerotherapeutic agent OK-432 has been reported as a primary, non-surgical method for treating ranulas, but experience with paediatric patients is currently limited.[12, 13]

Viral parotitis ('mumps')

Mumps is the commonest disease of the salivary glands in childhood. It is a viral infection of the parotid glands, caused by a paramyxovirus, spread via droplets or contact. The incubation period is 2–3 weeks. The characteristic clinical course is a prodromal illness of malaise and pyrexia followed by painful swelling of the parotid glands, typically bilaterally. Less commonly, other salivary glands may be involved. Asymptomatic infection can occur in 20% of infected individuals. The diagnosis is made clinically, although it can be confirmed serologically. There is no specific treatment for this usually self-limiting condition and symptomatic management is usually all that is required.

The disease has become less common in the UK following vaccination which is given as part of the MMR (mumps, measles, rubella) vaccine at 12 months with a preschool booster.

Post-pubertal males may develop a painful orchitis with an associated risk of subfertility. Other potentially serious complications are sensorineural hearing loss, encephalitis and pancreatitis.

Human immunodeficiency virus (HIV)

The salivary glands, most commonly the parotid, may be involved in HIV infection. Parotid enlargement,

which may be painful or painless, should raise suspicions. The British HIV Association recommends considering HIV testing in all children with chronic parotitis.[14] There may be associated xerostomia. Multicystic change in the parotid glands results from lymphepithelial lesions termed benign lymphoepithelial lesions (BLEL) or benign lymphoepithelial cysts (BLEC). These are thought to result from localized ductal ectasia and/or ductal obstruction from lymphoid tissue hyperplasia.

The clinical picture is similar to Sjögren's syndrome although patients with HIV salivary gland disease do not have anti-Ro or anti-La antibodies. Imaging may show cystic disease or lymphadenopathy.

The management of HIV salivary disease is largely symptomatic and supportive. There is some evidence that it is controlled with anti-retroviral treatment.[15] Otherwise, cyst aspiration and sclerotherapy, surgical excision and the supportive treatment of any patient with xerostomia are the mainstays of treatment. Localized radiotherapy has some role to play in adults but is likely to have limited application in children.

For more information about HIV, see Vol 1, Chapter 23.

Acute parotitis of infancy

Acute pyogenic infection of the parotid gland in infancy presents with a painful enlargement of the gland with erythema of the overlying skin. The child is typically unwell, pyrexial and reluctant to feed. The commonest organisms are *Staphylococcus aureus, Streptococcus pyogenes* and anaerobes.

Ultrasound is useful to distinguish inflammatory change from a collection of pus. Treatment consists of intravenous antibiotics, adequate hydration and drainage of any collection. Incision and drainage should be performed with caution because of the superficial position of the facial nerve in infants. Needle aspiration in many cases is a safer option (**Figure 39.1**).

Acute suppurative sialadenitis

Acute bacterial sialadenitis may also occur in older children and is associated with salivary stasis. Obstructive causes include salivary stones, which are considered below. Where there is no obstruction to salivary flow, children with comorbidities (cystic fibrosis, malignancy, HIV and cerebral palsy) are more commonly affected.[16] The typical causative organisms are *Staphylococcus aureus, Streptococcus pyogenes, Streptococcus pneumoniae* and anaerobes. Children usually present with fever, pain, gland swelling and tenderness. Pus may be visible at the duct orifice of the affected gland. Treatment consists of broad-spectrum intravenous antibiotics, hydration and sialogogues.

Bacterial infection may lead to abscess formation which is diagnosed on imaging. Ultrasound is usually adequate to make the diagnosis. Drainage of any abscess is necessary but needs to take into account the superficial nature of the facial nerve in children.

Figure 39.1 Acute suppurative parotitis in a baby aged 3 weeks.

Juvenile recurrent parotitis

Juvenile recurrent parotitis (JRP) is characterized by acute intermittent painful swelling of one or both parotid glands often accompanied by overlying cutaneous erythema, malaise and pyrexia. The usual age of onset is between 3 and 6 years. The condition is most commonly unilateral although may occur bilaterally. The swelling often settles within 2–3 days but may last up to 2 weeks.

Acute attacks are treated symptomatically with analgesia and anti-inflammatory drugs. Antibiotics are often used empirically although their use is controversial in the absence of obvious clinical infection (such as purulent discharge from the duct).

The diagnosis is made clinically, often after more than one episode has occurred. Sialography may show appearances of sialectasis but is often difficult to perform in children and unnecessary to establish a diagnosis. Ultrasound, in the correct hands, should confirm the absence of any mass lesion in the glands. In the absence of a mass apparent clinically or on ultrasound, no further imaging is warranted.

Many authors report resolution of the condition spontaneously, usually around puberty, and this appears to be the case in the majority of patients.[18] For this reason, and to control the effects on life quality of recurrent attacks, recent efforts have focused on reducing the frequency of attacks. There has been considerable interest in the use

of therapeutic sialendoscopy in this area with a number of authors reporting long-term resolution with its use.[19, 20]

Sjögren's syndrome

Sjögren's syndrome is a multisystem autoimmune disorder. The salivary and lacrimal glands are characteristically affected. When Sjögren's syndrome occurs in children and adolescents, swelling of the glands predominates over xerostomia and ocular symptoms, and systemic manifestations are less common.[21, 22] When the diagnosis is suspected, rheumatoid factor, antinuclear antibodies, and anti-Ro and anti-La antibodies should be measured. The diagnostic criteria for adults have a lower sensitivity for diagnosing the condition in children and a multidisciplinary approach to both diagnosis and treatment is recommended.

GRANULOMATOUS CONDITIONS

These are disorders of the intraparotid nodes rather than of the gland parenchyma. The salivary glands are composed of parenchymal tissue (i.e. salivary gland acini and ducts) and a surrounding stroma. Some of the stroma is lymphoid tissue, and the proportion of lymphoid tissue is much higher in children than in adults. Some cases of 'sialomegaly' in children – particularly in the parotid – are caused by lymphoid rather than parenchymal pathology. Non-tuberculous mycobacterial infection (NTM) and less frequently cat-scratch disease (*Bartonella henselae* or *B. quintana*) may present in this way. Non-tuberculous mycobacterium results from infection with a variety of species of mycobacterium including *Mycobacterium avium-intercellulare, M. scrofulaceum, M. kansasii, M. haemophilum* and *M. fortuitum*. The presentation, investigation and management of these conditions are considered in Chapter 37, Cervicofacial infections.

Sarcoidosis

Sarcoidosis is rare in children. When the parotid gland is involved, this can take the form of gland swelling, often as part of Heerfordt syndrome (or uveoparotid fever). Facial palsy can also occur. Non-caseating granulomas may be identified in minor salivary glands on sublabial biopsy and this was used as a diagnostic test, but it is now rarely needed. Cervical tuberculosis (caseating granuloma) can present in the parotid lymph nodes. Treatment is medical (see Chapter 37, Cervicofacial infections).

Salivary gland stones

The presentation, investigation and management of salivary stones in children is similar to that in adults, but salivary stones are uncommon in children. They are more common in the submandibular than the parotid glands. Children are less likely to tolerate local anaesthesia and may require a general anaesthetic if surgery (e.g. sialendoscopy) is considered.[23, 24]

SALIVARY GLAND TUMOURS

Salivary gland tumours are extremely rare in children. They can be classified as:

1. vasoformative tumours (most commonly haemangioma)
2. neoplasms of salivary gland tissue origin
3. proliferative disorders of the perisalivary lymphoid tissue (lymphoma).

Vasoformative tumours

A retrospective review of 324 consecutive cases of paediatric salivary gland masses showed 192 to be haemangiomas (59.2%), 89 to be lymphangiomas (27.5%) and the remaining 43 (13.3%) to be other solid masses.[25]

In 1982 Mulliken and Glowacki[26] created a classification system of vascular anomalies, dividing them into tumours and malformations. This classification system was recently expanded at the 2014 International Society for the Study of Vascular Anomalies (ISSVA) workshop.[27] The distinction between neoplasm and vascular anomaly is highly important when considering the management of these lesions.

Haemangiomas are reported to account for almost 60% of salivary tumours in children. Eighty per cent occur in the parotid gland, with involvement of the submandibular region in 18% of cases, while 2% are associated with the minor salivary glands.[28] Although not truly salivary in origin, the management of vascular anomalies requires an extensive knowledge of salivary gland anatomy.

PRESENTATION

The diagnosis of a haemangioma is primarily based on history and clinical examination. Haemangiomas are typically not present at but grow rapidly after birth. They exhibit rapid growth initially. This period of growth slows and stops after 9–12 months and a subsequent process of involution then follows over the next 3–5 years. Lesions have varying degrees of compressibility according to the extent of their underlying fibro-fatty architecture.[29] Skin involvement makes the diagnosis obvious although the absence of skin lesions does not exclude the diagnosis as the tumour may be deeply placed and lie within the parotid gland. Where the growth pattern exhibited by the lesion is not consistent with the pattern typical of a haemangioma, consideration should be given to further investigation including histological examination.

INVESTIGATIONS

The diagnosis of a haemangioma is a usually clinical. However, if lesions are more complex, where there is diagnostic uncertainty or if surgical intervention is being considered, additional investigations may be

helpful in determining the extent of involvement. The use of ultrasound (colour-flow Doppler) is useful for diagnosing vascular malformations in addition to identifying cystic and semisolid masses in the major salivary glands. The use of CT and MRI may also help to delineate the extent and depth of surrounding tissue involvement.[29]

TREATMENT

Almost all haemangiomas will involute and surgery should be confined to management of bleeding or ulceration, or to cases where the diagnosis is in doubt.[30] Kasabach–Merritt syndrome, a consumptive coagulopathy, is another indication for active intervention.

If the haemangioma is of such a size or position as to be life-threatening, treatment may be required. Several treatment modalities have been described in the literature and include systemic and intralesional steroids and more recently propranolol. However, systemic steroid therapy is associated with side effects and rebound growth is often seen after cessation of therapy. Intralesional steroids have fewer side effects but are effective only in actively proliferating lesions.[31]

The incidental observation of a clear response of haemangiomata to beta-blockers was published in 2008.[32] This revolutionized the therapeutic approach for infantile haemangiomas. Propranolol has been shown to significantly reduce the size of parotid haemangiomas with minor side effects[33] and has become the first-line treatment of choice where active therapy is required. Sclerotherapy for expanding parotid lesions has been shown to be successful, and a recent study that combined sclerotherapy and propranolol for the treatment of 26 infantile parotid haemangiomas demonstrated this to be a safe and effective treatment method.[34] Where active treatment is necessary and no response to propranolol is observed, embolization and/or surgical excision may be necessary.

Pulsed-dye laser treatment may be used for residual superficial skin discolouration, however it does not penetrate deeply enough to treat a haemangioma within the parotid gland. Previously, systemic interferon was utilized for its anti-angiogenic properties, but significant side effects were reported so it is no longer recommended as a treatment in children with haemangiomas.[31]

Salivary gland neoplasms

Salivary gland neoplasms are uncommon in children comprising approximately 1% of all paediatric tumours and less than 10% of all paediatric head and neck tumours. Approximately 5% of salivary tumours occur in children. Over 95% are epithelial with a minor group being mesenchymal in origin. The most common benign neoplasm is a pleomorphic adenoma; the most frequent malignant epithelial salivary gland neoplasm is a mucoepidermoid carcinoma. Rhabdomyosarcoma is the most common malignant neoplasm of mesenchymal origin.[29]

PRESENTATION

The most common presentation for a tumour affecting the major salivary glands is a painless, slowly growing mass. Pain is rarely a dominant symptom, whether benign or malignant.[25] The parotid gland is the most commonly affected salivary gland and is involved in over 85% of all reported paediatric salivary gland tumours.[29, 35–37] Facial nerve palsy is rare but usually indicates malignancy. Evidence of cervical lymphatic metastasis is uncommon, reported in 3.5% of patients at presentation.[38] Although uncommon, tumours affecting the minor salivary glands do occur, with the majority located in the oral cavity.[29] They most commonly present as a lump or submucosal nodule that is frequently non-ulcerated and firm to palpation, with pink or flesh-coloured surfaces. Others are described as being fluctuant, with colour alterations ranging from a light blue hue to purple.[29, 39]

INVESTIGATIONS

All cases of salivary gland neoplasms in children should be treated as potentially malignant. As previously mentioned, the use of ultrasound is very useful for identifying cystic and semi-solid masses in the major salivary glands and is easy to perform, non-invasive and generally well tolerated by children.[29] However, limitations include an inability to establish the extent of a lesion (i.e. extension into the deep lobe of the parotid gland) and to accurately differentiate between benign and malignant tumours.

CT imaging is unhelpful in distinguishing benign and malignant disease. However, certain MRI features, such as T2 hypointensity, restricted diffusion, ill-defined borders, and focal necrosis, although not specific, should raise concerns about malignancy.[40]

Fine-needle aspiration cytology (FNAC), while well established and routine in adult practice, is controversial in children. Younger children often require general anaesthesia for this procedure and assessment of salivary gland histology is reported to be notoriously difficult. Occasionally, however, the use of a diagnostic fine-needle core biopsy may be considered under certain circumstances, such as in cases of suspected lymphoma where major and unnecessary surgery could be avoided.[29]

Benign salivary gland tumours

PATHOLOGY

Pleomorphic salivary adenomas (PSA) are the most commonly encountered benign tumours and account for approximately 30% of all paediatric salivary neoplasms. Presentation is commonly between the ages of 8 and 18 years and the majority occur within the parotid gland. However, they may also occur in the submandibular gland and minor salivary glands.[41]

TREATMENT

Although a benign tumour, there is a risk of recurrence up to 30 years following initial presentation, and a lifetime

risk of malignant degeneration of between 2% and 25%. Treatment of these benign tumours consists of complete surgical resection[41, 42] by either superficial or complete parotidectomy, dependent on the location of the tumour. Surgery must aim for a complete resection of the tumour with a surrounding cuff of normal salivary tissue and complete facial nerve preservation. Submandibular gland resection is indicated for tumours in the submandibular gland, with complete local resection for the minor salivary glands. Incomplete resection is the cause of recurrences. This is particularly problematic in children, since adjuvant radiotherapy cannot be used safely in children to salvage an unsatisfactory surgical procedure.

Malignant salivary gland tumours

PATHOLOGY

Malignancies of the salivary glands in children and adolescents are rare, with an estimated annual incidence of 0.08 per 100 000.[43] Most malignant salivary gland tumours present in the older child, at an average age of 13.5 years.[38] In comparison with adults, children with salivary neoplasms are more likely to have malignant disease.[29, 35–37]

The parotid gland is the most frequent site for malignant salivary tumours (82%), followed by the submandibular gland (7%), minor salivary glands (11%) and sublingual gland (less than 1%).[29, 38] Mucoepidermoid carcinomas are the malignant tumours most frequently described in childhood followed by acinic cell carcinomas and adenoid cystic carcinomas. These three cancers account for 80–90% of all malignant salivary gland tumours in children and adolescents. Adenocarcinomas, basal cell carcinomas and squamous cell carcinomas of the salivary glands are less common.[28]

TREATMENT

The rarity of salivary tumours in children is such that treatment should only be in specialist centres. Management will involve a multidisciplinary approach with input from a paediatric oncologist. These children and their families are best treated in a designated centre where the whole range of support services for children with cancer is available.

Clinical stage and histologic grade are the main prognostic factors. As with benign tumours, complete excision (superficial or total parotidectomy) with preservation of facial nerve is the treatment of choice. It is, however, vital to counsel the child and parents carefully prior to operation regarding the possible need for facial nerve sacrifice. The facial nerve is smaller and courses more superficially within the parotid in children than in adults. Neck dissection should be considered when there is clinical evidence of regional metastasis, high TNM stage, high histologic grade, and involvement of regional nodes.[44] Radiotherapy should only be used in selected cases because of the possibility of long-term adverse effects in paediatric patients. Long-term follow-up is essential to monitor for late recurrence. The overall survival is 70–90% at 5 years, and 26% develop a recurrence.[29]

BEST CLINICAL PRACTICE

- ✓ Excision of a ranula together with the cyst wall and the sublingual gland results in a low rate of recurrence.
- ✓ HIV testing should be considered in children with otherwise unexplained salivary gland swelling.
- ✓ Bacterial infections should be treated with intravenous antibiotics and hydration. Ultrasound imaging should be used to exclude an abscess.
- ✓ Care should be taken in draining parotid abscesses in children to avoid damage to the facial nerve.
- ✓ Almost all haemangiomas will involute and surgery is rarely needed.
- ✓ Malignancies of the salivary glands in children and adolescents are rare. A solitary salivary gland neoplasm in a child, however, is more likely to be malignant when compared with an adult.
- ✓ Salivary tumours should be managed by an appropriate multidisciplinary team and surgery should be undertaken by surgeons with appropriate training and experience in paediatric head and neck surgery.

FUTURE RESEARCH

- ➤ Clinical trials are needed in the management of Juvenile Recurrent Parotitis in order to determine whether there is any benefit from medical therapies or sialendoscopy.
- ➤ It would also be helpful to have better clinical studies on the utility of investigations such as imaging and fine needle aspiration cytology for diagnosis of salivary gland tumours in children.

KEY POINTS

- Salivary gland agenesis may present late in childhood with dental caries.
- A ranula is an extravasation pseudocyst and may present intra-orally or in the neck.
- Mumps is generally a self-limiting disease but with the potential for serious complications.
- HIV salivary gland disease may mimic Sjögren's syndrome clinically and is characterized by gland swelling and xerostomia.
- Bacterial sialenitis occurs as a result of salivary stasis.
- Juvenile recurrent parotitis is a self-limiting disease which generally resolves around puberty although there is current interest in the use of sialendoscopy.
- Parotid haemangiomas present with a rapid enlargement of one parotid gland shortly after birth. The diagnosis can usually be made with a combination of clinical history and imaging.
- Salivary tumours are rare in children. The proportion of malignant tumours is greater in children than adults.
- Pleomorphic salivary adenoma is the commonest salivary gland tumour in children.

CHAPTER 40

TUMOURS OF THE HEAD AND NECK IN CHILDHOOD

Fiona B. MacGregor and James Hayden

SEARCH STRATEGY

Systematic reviews were identified using the key words: childhood cancer, head and neck, thyroid cancer, rhabdomyosarcoma, nasopharyngeal carcinoma, neuroblastoma, lymphadenopathy, Hodgkin's lymphoma, non-Hodgkin's lymphoma, sarcoma, and palliative care; these subject headings were used to search the Cochrane database of systematic reviews. Individual articles were then identified using the same search terms in Ovid Medline. A hand-search of the ensuing bibliographies completed the search.

INTRODUCTION

This chapter will focus on the epidemiology of childhood cancers of the head and neck region and the general principles of assessing and managing malignancy in children. It will then discuss the more common histological types individually. The long-term sequelae of treatment in survivors, palliative care and future developments will be addressed.

EPIDEMIOLOGY

After trauma, cancer is the most common cause of death in childhood. Approximately one-third of childhood malignancies are leukaemias, 25% are brain and spinal tumours, 15% are embryonal (neuroblastoma, retinoblastoma, Wilms' tumour and hepatoblastoma) and 11% are lymphomas. The remainder are bone and soft-tissue sarcomas and miscellaneous tumours (see 'Miscellaneous tumours' below). Up to 12% of primary childhood malignancies originate in the head and neck area and so may present to the otolaryngologist. Lymphoma is the most common diagnosis in all series, followed by thyroid and neural tumours. Sarcomas and salivary gland tumours are less common; squamous cell carcinomas are rare.[1] The distribution of histological types varies greatly depending on the age and sex of the child, with neuroblastoma the most common in infants and thyroid carcinoma the most common malignancy in adolescent females. There is a bimodal age distribution of malignancy in children. The most common age group affected is 15–18-year olds, closely followed by those under 4 years of age.[1–3] Incidence of head and neck malignancies in children increased throughout the decades leading up to the 1990s in line with a general increase in cancer diagnoses in children, but has now stabilized. In parallel, the consistent use of effective multimodality treatments, including combination chemotherapy, surgery and radiotherapy, has resulted in a significant improvement in prognosis. A study from the UK observed 5-year survival rates of 42% for diagnoses made between 1968 and 1977[4] but modern treatment strategies have transformed the outlook for children with cancer. Survival rates well in excess of 80% are now commonplace in the developed world and services are improving wordwide.[5, 6] Early recognition is therefore increasingly important.[7, 8]

Some malignancies in childhood are inherited. The underlying aetiology of the non-inherited types remains unclear but certain chemotherapeutic agents, viruses (e.g. Epstein–Barr) and irradiation are known to play

a role. Other potential carcinogens are suspected but not proven (pollution, parental exposure to toxins, electromagnetic fields).[1, 9] There is some evidence that exposure to dietary carcinogens *in utero* may lead to malignancies in early childhood.[10]

PRESENTATION AND ASSESSMENT

The most common presentation of a malignancy in the head and neck region in childhood is the asymptomatic mass. Otalgia, rhinorrhoea, otorrhoea and nasal obstruction may be present in both benign and malignant disease. More worrying symptoms would include stridor, dysphagia and haemoptysis.[11] Reactive lymphadenopathy in children is extremely common and gives rise to frequent therapeutic dilemmas. See Chapter 37, Cervicofacial infections in children.) Studies have suggested that the best predictors of malignancy in cervical lymphadenopathy are the size of the node, the number of sites involved and the age of the patient. Other concerning features would be lymphadenopathy in the supraclavicular region, an associated abnormal chest X-ray or fixed lymph nodes.[12, 13]

Examination would involve a complete assessment of the head and neck region and systemic evaluation with particular regard to the presence of lymphadenopathy elsewhere and the presence or absence of abdominal masses. Flexible nasendoscopy is possible in many children (**Figure 40.1**). Imaging with the help of a paediatric radiologist can often obviate the need for biopsy. However, full assessment of a mass may require examination under anaesthetic with biopsy.

Figure 40.1 Flexible nasendoscopy under local anaesthetic in the clinic setting.

BIOPSY

Fine-needle aspirate (FNA), sometimes referred to as aspiration biopsy cytology (ABC), has a more limited role to play in the child than the adult. Young patients may simply not tolerate this method of biopsy. With particular regard to cervical lymphadenopathy, the most likely neoplastic diagnosis is lymphoma and at the present time it is recognized that excision biopsy is the best method of confirming and typing this histologically.[14, 15] FNA, often under ultrasound control, can be useful in the assessment of thyroid and salivary gland lesions and these tumours often present in older children who may tolerate such intervention.[16]

The biopsy specimen should be sent to the lab fresh to enable molecular in addition to histopathological studies to be undertaken.

IMAGING

Ultrasonography, CT and MR scanning can all have their part to play in further assessment. Imaging of the neck is more accurate than clinical examination in detecting lymphadenopathy. CT and MR scanning may require a general anaesthetic in a younger child and it is helpful to discuss the available imaging options with a paediatric radiologist prior to proceeding, to avoid unnecessary and additional anaesthetics. Positron emission tomography (PET) scanning is also becoming increasingly used in the assessment of neoplastic lesions in the head and neck in children, but is not always readily available.[11]

THE CHILD WITH CANCER

The history and subsequent investigations of a child presenting with a suspicious lesion of the head and neck region must be tailored to the age and maturity of the child. In most situations, when the child is old enough, he or she should be included in any discussion about investigations and treatment and should also be involved in consent for any procedures required.

The diagnosis of cancer in a child has a tremendous impact not only on the patient, but also on parents, siblings, other family members and friends. Immediate involvement of a specialist paediatric multidisciplinary oncology team is mandatory. An open and realistic approach should include an explanation of what to expect from the investigations and treatment, the side effects and some idea of prognosis. This is vital in maintaining trusting relationships with the child and his or her family, in reducing uncertainty, preventing inappropriate hope and allowing proportionate adjustment.

Parents may feel guilty that they waited too long before seeking medical advice. They may be concerned that they

have, in some way, caused their child's cancer. They can also feel guilty about making their child go through a series of invasive investigations and radical treatments. This can put an immense strain on the parents' relationship with each other and with other family members and friends, not least the child involved. Also, siblings of the affected child may resent the additional time and attention that their sick brother or sister receives. Support services are therefore vital in reassuring and supporting all the individuals concerned.

The amount of information that any child will require regarding their illness depends to some extent on the age and maturity of that individual. Most children aged 6 years or more (and some more mature younger children) need to know their illness has a name and what that name is. All children require an explanation of the procedures to be performed and reassurance that any intervention is not a 'punishment'. In children between the ages of 6 and 11, these procedures and side effects of treatment may provoke much more anxiety than the illness itself. For example, loss of hair or a limb seems much more real and distressing than the prospect of death. Alterations in physical appearance can cause great insecurity in a child or adolescent, resulting in isolation and poor self-esteem. Children aged around 11 and over will have fears surrounding the diagnosis and its prognostic implications in addition to the above. Children should be encouraged to talk about their feelings or, if they are too young, they can express themselves in drawings or play.[15]

ONCOLOGY SERVICES

The importance of centralization of paediatric cancer services is widely recognized.[7] This enables care to be provided by highly trained and specialist paediatric oncologists and allied staff, and facilitates the progress of research. There are now 20 centres within the United Kingdom Children's Cancer and Leukaemia Group – CCLG.[17] Working in conjunction with the medical staff are social workers, nurses, dieticians, psychologists and other healthcare professionals in order to provide comprehensive support for children and their families. The emphasis on centralization of paediatric oncology services, the sharing of data and the establishment of international working groups has resulted in the publication of a number of treatment protocols that are widely used in the management of children with cancer.[17]

The practicalities of investigating and treating children with cancer provide some particular challenges. Venous access for blood sampling and to administer chemotherapeutic agents can be difficult, and indwelling venous catheters are usually inserted at an early stage. Radiotherapy may require general anaesthesia in younger patients to ensure that the child remains still during irradiation. Other interventions (e.g. lumbar puncture and intrathecal injection) may also require general anaesthesia. Children tolerate the immediate side effects of chemotherapy and radiotherapy much better than adults but the long-term sequelae of such interventions can have a very significant effect on the health of childhood cancer survivors (see 'Long-term sequelae of treatment' below).

THE MORE COMMON CHILDHOOD CANCERS

Lymphoma

Lymphomas are malignant neoplasms of the lymphoreticular system. Most lymphomas of the head and neck region in the paediatric age group present with enlarged cervical lymph nodes.

Cervical lymphadenopathy in childhood is common and although the huge majority of cases will be due to reactive hyperplasia, it may be necessary to exclude malignancy. Lymph nodes in the neck larger than 2 cm are unusual in childhood and systemic symptoms such as weight loss, fever and organomegaly are usually indicators of serious pathology.[12] FNA has a limited role and excision biopsy will provide the diagnosis.[16, 18]

Hodgkin lymphoma

This is distinguished morphologically by the presence of Reed Sternberg cells which are large and multinucleated with abundant cytoplasm. It has the propensity to involve the lower cervical, supraclavicular and mediastinal lymph node groups. There were several classifications for lymphomas but the most widely recognized now is the 'World Health Organisation / Revised European American lymphoma' system (WHO/REAL).[19, 20]

Nodular Lymphocyte-predominant Hodgkin Lymphoma (nLPHD) is now recognized as a separate entity. Classic Hodgkin lymphoma (HL) is further subdivided into 4 types: (1) Nodular sclerosis classic HL, (2) Lymphocyte-rich classic HL, (3) Mixed cellularity classic HL, and (4) Lymphocyte-depleted classic HL. The commonest type in children and young adults (0–24 yrs) is nodular sclerosing classic HL. There is an association with previous infection with Epstein–Barr virus.[21]

Staging of disease is based on the Cotswolds modified Ann Arbor system (see **Table 40.1**)

Hodgkin lymphoma most commonly presents with lymphadenopathy in the neck and two-thirds of all children will have mediastinal lymphadenopathy at presentation. It rarely occurs under the age of 5 years and there is a male predominance. 'Constitutional' symptoms such as fever, night sweats and weight loss are present in 25–30% and this is associated with a more aggressive disease and a poorer prognosis.[11]

Following careful examination and biopsy confirmation, the diagnostic workup of a child with Hodgkin disease (following thorough examination and biopsy confirmation) would include a chest X-ray, routine blood tests (although abnormal results are usually nonspecific) and staging scans (CT chest and MRI abdomen). Recently, PET scanning has become a routine part of staging and of assessing effectiveness of treatment. There is no longer a place for staging laparotomies. Bone marrow biopsy and bone scan are

TABLE 40.1 Stages of Hodgkin lymphoma according to the Cotswolds revision of the Ann Arbor staging system

Stage I	Involvement of a single independent lymph node region or lymph node structure
Stage II	Involvement of 2 or more lymph node regions on the same side of the diaphragm
Stage III	Involvement of lymph node regions or lymph node structures on both sides of the diaphragm
Stage IV	Involvement of extranodal sites beyond 'E'-sites
Annotations	
A	No B symptoms
B	At least one of the following systemic symptoms • Inexplicable weight loss of more than 10% within the last 6 months • Unexplained persisting or recurrent temperature above 38 °C • Drenching night sweats
E	Involvement of a single extranodal site contiguous or proximal to known nodal site.

only indicated in children with more advanced disease.[22] (see Volume 1, Chapter 25, Hamato-oncology.)

Treatment depends on the age and physical maturity of the patient, the disease stage and bulk and the potential treatment sequelae. In the paediatric population, the trend is to treat in multimodality fashion so as to reduce the morbidity and mortality associated with high doses of chemotherapy or radiation therapy needed for single-modality treatment. Disease-free survival is over 90% in many series.[23] Those children with intermediate risk of disease (constitutional symptoms, bulky disease or spleen involvement) may require an increased number of cycles of chemotherapy and, in some cases, an increased dose or volume of radiation therapy. Modern chemotherapy treatment protocols with newer agents such as dacarbazine have reduced the risks of sequelae such as subfertility. Radiotherapy is far less frequently needed, also helping to reduce the risk of later complications. Haematopoetic stem cell transplantation can be indicated in some children who relapse following more conventional treatment but the risk of transplant-associated morbidity and mortality is not insignificant.[21]

Non-Hodgkin lymphoma

Approximately 60% of paediatric lymphomas are non-Hodgkin lymphomas (NHL). There is a male predominance. The low-grade, relatively indolent NHLs seen in adults are exceedingly rare in children. Paediatric NHLs tend to be aggressive with a propensity for widespread dissemination and half of these are small cell lymphomas (Burkitt and Burkitt-like). The classification of NHL is confusing and controversial but paediatric NHLs are usually divided into three main histological categories. These are lymphoblastic lymphoma (predominantly of T-cell origin), small non-cleaved cell lymphoma (Burkitt and non-Burkitt subtype of B-cell origin) and large cell lymphoma (B- or T-cell origin).[24] The Revised European American Lymphoma (REAL) classification is used in paediatric NHL and is a useful guide to management and prognosis of NHL.[19]

The relative frequency and incidence of NHL varies quite markedly from country to country. In equatorial Africa, Burkitt lymphoma accounts for approximately 50% of childhood cancers. In Europe and the US, approximately one-third are lymphoblastic lymphomas, one-third are Burkitt and Burkitt-like lymphoma and the rest are predominantly large cell lymphoma. In some parts of the world, an extremely high number of these tumours are positive for Epstein–Barr virus (EBV), e.g. parts of Africa. In contrast, the percentage of tumours positive for EBV in the US is much smaller. There is an increased incidence of NHL in association with immunosuppression and congenital and acquired immunodeficiency.[24]

Many childhood NHLs are rapidly growing neoplasms and a significant number of children will have widespread disease at the time of diagnosis, which may involve the bone marrow, central nervous system or both. Involvement of extranodal sites, especially Waldeyer's ring, can be a particular challenge in children. Apparent activity in Waldeyer's ring on imaging may not always represent disease, hence the need for caution during disease staging. Lymphadenopathy occurs in 50–80% of all patients and 45% have cervical lymphadenopathy at the time of presentation. Bone marrow involvement is not infrequent and the replacement of more than 25% of the bone marrow by 'blast' cells is usually assigned a diagnosis of leukaemia. Children with endemic Burkitt lymphoma frequently present with involvement of the jaw and this is particularly common in the younger age group.[24]

DIAGNOSIS AND STAGING

Because NHLs in children progress more rapidly, a speedy diagnosis is extremely important. A biopsy will provide tissue for histological confirmation and surgery then has little further role to play. Staging investigations will follow and will include relevant blood tests (full blood count, urea and electrolytes and liver function tests) lactic dehydrogenase (LDH) is a useful marker of disease – bone marrow biopsy and cerebrospinal fluid (CSF) examination. Staging laparotomy is not advocated in patients with NHL and ultrasonography, CT (chest) and MR (abdomen) scanning are used in assessing spread.[24] FDG-PET scanning is increasingly used. The Ann Arbor staging classification can be applied to NHL (see Volume 1, Chapter 25, Haemato-oncology) although a new staging system for

TABLE 40.2 The International Pediatric Non-Hodgkin Lymphoma Staging System

Stage I	Single tumour with exclusion of mediastinum and abdomen.
Stage II	Single extranodal tumour with regional node involvement, two or more nodal areas on the same side of the diaphragm, or primary gastrointestinal tract tumour with or without the involvement of associated mesenteric nodes, that is completely resectable.
Stage III	Two or more extranodal tumours above and/or below the diaphragm, two or more nodal areas above and below the diaphragm, intra-abdominal and retroperitoneal disease, including liver, spleen, kidney, and/or ovary localizations, regardless of degree of resection, with or without involvement of associated mesenteric nodes that is completely resectable, any paraspinal or epidural tumour, and a single bone lesion with concomitant involvement of extranodal and/or non-regional nodal sites.
Stage IV	Any of the stage I—III findings with initial involvement of the central nervous system, bone marrow, or both.

paediatric NHL has recently been proposed by an international expert panel (Table 40.2).[25]

TREATMENT

The treatment of choice in childhood NHL is multiagent chemotherapy. The rapid doubling time of high-grade NHL makes it particularly chemosensitive. Chemotherapeutic regimens vary depending on the histological classification of the disease. Newer agents such as rituximab (an antibody to the B-cell marker CD20) have a role in B-cell NHL, allowing lower doses of standard chemotherapy agents to be used and thereby reducing morbidity from treatment.[26] Radiation therapy has a limited role in NHL and is generally reserved for selected anatomical sites such as the cranium where a child has overt central nervous system disease. Some children with high-grade NHL may need intrathecally administered chemotherapy.[22, 24]

PROGNOSIS

Long-term event-free survival (EFS) is excellent in lymphoblastic lymphomas. It ranges from 80% to 90% in patients with limited disease and from 65% to 80% in patients with advanced disease. In Burkitt lymphoma, where chemotherapeutic regimes are more intense and shorter, the long-term EFS ranges from 90–100% in patients with limited disease to 75–85% in patients with extensive disease. Even in patients with extensive bone marrow disease, the EFS is improving. Large cell lymphomas are more of a challenge to treat because of their biological heterogeneity and long-term EFS ranges from 50% to 70%.[22, 24]

Patients who relapse after receiving dose-intensive multiagent chemotherapy have an extremely poor prognosis. These patients are treated with high-dose chemotherapy regimes with or without bone marrow transplantation or would be candidates for newer drugs in trials.

Rhabdomyosarcoma

Rhabdomyosarcomas account for up to 60% of all sarcomas in the paediatric population and 40% occur in the head and neck region. Nearly half of these tumours occur in children under the age of 5 years.[7] The prognosis for this tumour used to be extremely poor but over the last 30 years survival rates have increased dramatically, particularly with the introduction of multimodality therapy in which surgery, multiagent chemotherapy and radiotherapy have been combined.[27]

Histologically, rhabdomyosarcomas resemble normal fetal skeletal muscle before innervation. Two types are identified and these are embryonal (80%) and alveolar (20%). The alveolar type is found in older children and is often associated with nodal spread and typically a poor prognosis[28, 29] where such tumours also harbour a chromosomal translocation that fuses two transcription factor-encoding genes together including the *FOXO1* gene.[30]

PRESENTATION

Rhabdomyosarcomas of the head and neck occur most frequently in the orbit or parameningeal sites and these include the paranasal sinuses, nose, nasopharynx and middle ear. The most common presenting symptoms are pain and swelling. Paranasal rhabdomyosarcoma may present with a gradual onset of nasal obstruction and bloody nasal discharge. Tumours within the ear may present with symptoms of bloody discharge and persistent otalgia, despite treatment. A polypoid mass may be visible in the ear canal or nasal cavity.[29] The reported incidence of lymph node involvement varies between 3% and 36%.[28] Metastases occur by both haematogenous and lymphatic spread.

ASSESSMENT

Assessment should include a thorough examination of the upper respiratory tract and head and neck region including the cranial nerves. Flexible nasoendoscopy may be employed in the clinic. An MRI scan should be performed to evaluate the primary lesion and to rule out metastatic disease (Figure 40.2). A CT scan may be a useful complementary tool, particularly in the paranasal sinuses and skull base, to determine bony erosion and it is the best method to assess the chest. Bone marrow examination should also be performed. The Inter Group Rhabdomyosarcoma Study (IRS) recommends the clinical staging shown in Table 40.3. The majority of children are stage II at the time of assessment[31] as it is rarely possible to completely excise these tumours.

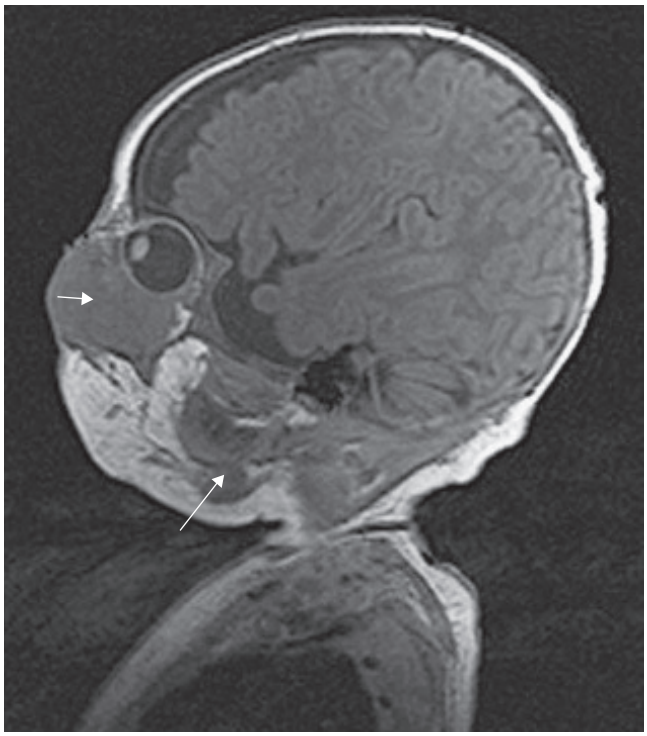

Figure 40.2 Paramedian T1-weighted MRI scan through the left orbit of a 3-month-old boy. There is a huge mass of rhabdomyosarcoma in the anterior orbit (short arrow) displacing the globe and submandibular lymphadenopathy (long arrow).

TABLE 40.3 Staging of rhabdomyosarcoma according to the IRS

Group I
Localized disease completely resected. No regional nodes
Confined to muscle or organ of origin
Contiguous infiltration outside muscle or organ of origin
Group II
Localized disease with microscopic residual disease, or regional disease (lymph nodes)
Group III
Incomplete resection or biopsy with gross residual disease
Group IV
Metastatic disease present at onset

TREATMENT AND PROGNOSIS

Since the establishment of the IRS Study Committee in 1972, protocols have been developed and are now widely adhered to. A multimodality approach has been adopted. In general, the role of surgery today is simply to evaluate the extent of the lesion and biopsy the tumour. Very occasionally, when the rhabdomyosarcoma is an easily accessible polypoid lesion, then wide surgical removal may be appropriate. A debulking procedure is rarely useful. Sophisticated skull base surgery can now be implemented in areas that were previously thought to be inaccessible, but is nearly always an adjunct to chemotherapy or radiotherapy.[29] Multiagent chemotherapy and radiotherapy are then implemented as appropriate.

Prior to 1960, approximately 10% of patients survived 5 years. Now the prognosis is excellent in patients with early tumours (over 80% survival). With more advanced tumours the prognosis is still relatively poor and in those with meningeal involvement the 5-year survival is less than 10%.[30] Although nodal mestastases at initial presentation are not synonymous with an unfavourable prognosis, development of nodes during follow-up does imply a poor outlook.[29, 31, 32]

Thyroid carcinoma

Thyroid carcinoma in the paediatric population is uncommon. In the US there are five new cases per million per year. It is much more common in adolescents than in younger children and is also much more common in females with a ratio of 4:1. Approximately 45% of these lesions in children will be differentiated papillary carcinomas with a further 45% of mixed papillary/follicular types with only 10% being follicular lesions.[33] Medullary thyroid carcinoma (MTC) is rare (only 10% of thyroid malignancies in children) and must be suspected in children with multiple endocrine neoplasia (MEN) types IIa and IIb (see 'Medullary thyroid carcinoma' below). Anaplastic and undifferentiated tumours are extremely rare in children and adolescents.

AETIOLOGY

A clear relationship has been established between the development of thyroid carcinoma and previous irradiation. In one study, as many as 17% of patients had previously received irradiation to the neck.[34]

PRESENTATION

Patients usually present with an asymptomatic solitary mass in the anterior or lateral neck. At presentation, there is often regional lymph node involvement (74%) and distant parenchymal metastases (25%).[32]

INVESTIGATIONS

Investigations will include an ultrasound scan, usually in conjunction with an ultrasound-guided FNA. Regional and distant metastases can be assessed with a chest X-ray and CT scan. Thyroid function tests and plasma thyroglobulin levels should be obtained and also plasma calcitonin where a diagnosis of medullary carcinoma is suspected.

TREATMENT

Controversy remains over the optimum treatment in differentiated thyroid carcinoma in children because the long-term mortality in these patients is low and serious operative and post-operative complications can occur following radical surgery. These include recurrent laryngeal nerve damage, hypocalcaemia and airway obstruction requiring tracheostomy.[32] It has become clear that these tumours in children are slow-growing and associated with prolonged survival rates, even in the presence of extensive disease. Some authors maintain that an aggressive approach is mandatory[35, 36] while others have adopted a more conservative approach with the use of lobectomy and subtotal thyroidectomy for small and isolated lesions.[33, 34, 37]

Ideally, treatment should include complete surgical excision if possible. Total or subtotal thyroidectomy should be performed if adjuvant radioiodine treatment is planned. Following surgery, a whole-body radioiodine scan is performed and ablative radioiodine treatment given if necessary. Plasma thyroglobulin can then be used as a tumour marker and suppressive levothyroxine should be given. Radiotherapy is rarely indicated in differentiated thyroid carcinoma in childhood.[11]

PROGNOSIS

A long-term study of 329 patients under the age of 21 confirmed only eight deaths over a long period of time and of these only two were disease related. The risk of progression of disease was more common in younger patients and those with residual cervical disease after definitive thyroidectomy. The majority of recurrences are in cervical lymph nodes or thyroid bed (54%), or lungs (16%).[37] The majority of relapses occur within the first 7 years but have been seen as long as 25 years after treatment.[33]

Medullary thyroid carcinoma

The detection of MTC in younger children is usually made following screening in 'high-risk' individuals who have a family history of MEN 2.[11] This is confirmed by elevated baseline levels of calcitonin or screening for the *RET* (rearranged during transfection) protooncogene on chromosome 10. If positive, the child should be considered for prophylactic total thyroidectomy.[11] See Volume 2, Chapter 63, Management of medullary cancer.

Nasopharyngeal carcinoma

In the US and Europe, nasopharyngeal carcinoma (NPC) is an uncommon tumour comprising only 1–2% of paediatric malignancies, but in other geographical locations, such as parts of Africa, 10–20% of childhood malignancies are due to NPC. There is a bimodal age distribution of this disease with an early peak of 10 to 20 years and a second peak between 40 and 60 years. NPC is one of few malignant tumours in childhood that emerges from the epithelium and there is an association with EBV. Males are twice as likely as females to develop NPC. Children with NPC almost invariably have the undifferentiated variant that is associated with higher rates of advanced locoregional disease and distant metastases.[38] Despite this, the 5-year disease-free survival is not significantly different to that of adults at 30–60%.[39]

PRESENTATION

Children may present with a cervical mass secondary to lymph node metastases. Other presenting symptoms and signs may include nasal congestion, epistaxis, otitis media with effusion, otalgia and cranial nerve palsy. As many as two-thirds of children with NPC have metastatic disease in the neck at presentation. Delay in the diagnosis occurs frequently because many of its symptoms mimic those of an upper respiratory tract infection.

ASSESSMENT

Nasopharyngeal examination and biopsy is required for tissue diagnosis. CT or MR scanning allows precise evaluation of the primary tumour and confirmation of the presence or absence of metastases, most particularly in the neck. The American Joint Committee in Cancer staging of NPC (see Volume 3, Chapter 8, Nasopharyngeal carcinoma) is used by most.

TREATMENT

Undifferentiated NPC is a radiosensitive tumour and as such is usually treated with external beam radiotherapy. Such therapy is limited to the primary tumour and its regional metastatic spread. Chemotherapy is required in patients with disseminated systemic disease. There is now evidence that combined chemotherapy and radiotherapy provides better disease-free survival as compared with radiotherapy alone and combined chemoradiotherapy – including consideration of Proton Beam Therapy is therefore becoming routine practice in the UK.[39, 40, 41] (see Volume 3, Chapter 8, Nasopharyngeal carcinoma).

Because of the tumour's close proximity to major structures, radiotherapy in this region is difficult to give and is associated with significant post-treatment morbidity. This includes mucositis, xerostomia, neck fibrosis and panhypopituitarism (see 'Long-term sequelae of treatment' below). Newer radiotherapy techniques, such as intensity-modulated radiation therapy (IMRT) and proton beam radiotherapy[39] may offer reduced morbidity following treatment as it becomes more readily available (**Figure 40.3**). As craniofacial surgical techniques improve, surgical resection is now becoming appropriate in certain situations, particularly in primary recurrence following treatment.

Neuroblastoma

Neuroblastoma is a common malignancy of early childhood and is the most common malignancy in infants younger than 1 year. These tumours arise from undifferentiated sympathetic nervous system precursor cells of neural crest origin. The adrenal gland is the most common site of origin and additional sites include the

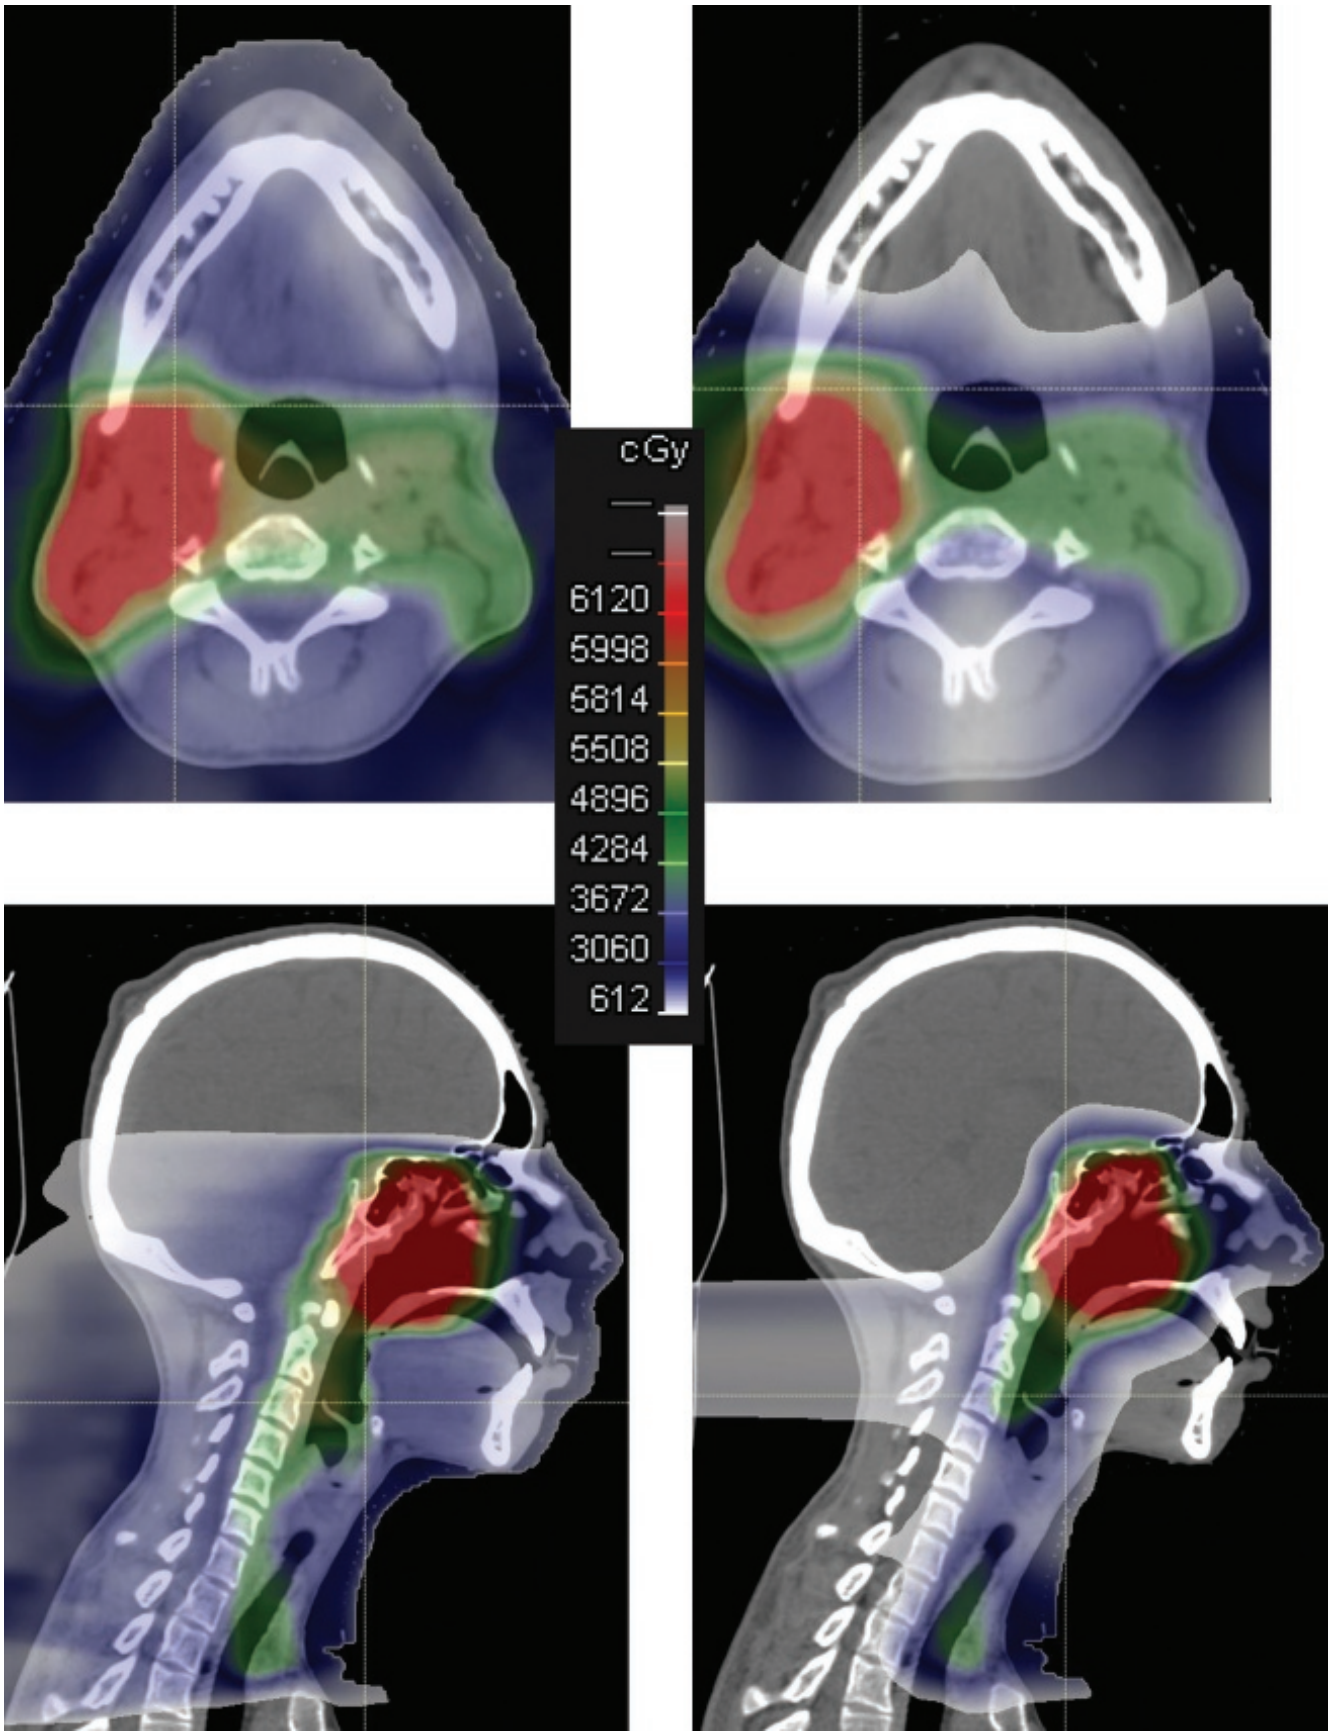

Figure 40.3 Sixteen year-old boy treated for nasopharyngeal carcinoma incuding a positive cervical lymph node. Panels on the left show planning scans using IMRT and on the right using Proton Beam Therapy. Note the reduced dose to the oral cavity and the brain using PBT. Image courtesy of Dr Danny Indelicato, Associate Professor, Department of Radiation Oncology, University of Florida.

sympathetic chain, posterior mediastinum and cervical regions. Neuroblastoma has a high propensity for lymphatic spread and regional lymph nodes are involved in up to 35% of cases. Metastases to the head and neck region are common, but primary neuroblastoma in the head and neck region is uncommon.[43]

PRESENTATION

Symptoms and signs will be dictated by the size and position of both the primary lesion and any metastases. Children with primary cervical neuroblastoma may present with a firm mass in the lateral neck, occasionally associated with a Horner syndrome (due to cervical sympathetic chain involvement). Classical ophthalmological manifestations include proptosis and periorbital ecchymosis (usually secondary to intraorbital metastatic deposits). Bilateral eye haematomas are a classical sign ('racoon' eyes). Chronic destruction of the ophthalmic sympathetic fibres in some children can lead to heterochromia of the irides. Involvement of the paranasal sinuses is also described.[43]

ASSESSMENT

A full assessment of the disease will include obtaining a histological diagnosis. Examination should include a visual assessment, intraoral inspection and a thorough neurological examination. MRI and CT scanning are usually employed to assess the primary and the extent of any metastatic spread (**Figure 40.4**). An iodine-123-metaiodobenzylguanidine (MIBG) scan is a useful method of assessing metastases. A bone marrow aspirate and trephine should be performed, with a bone scan reserved for those with a negative MIBG scan. Urinary catecholamine levels should be measured as they are raised in over 90% of cases.

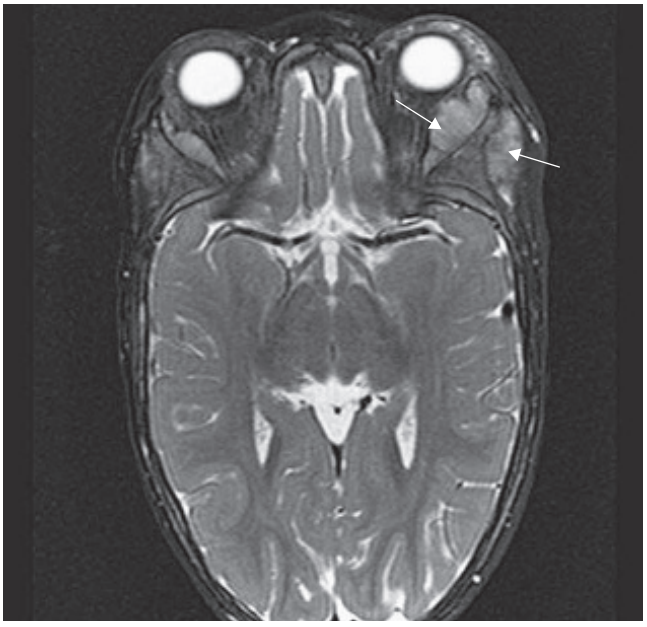

Figure 40.4 Metastatic neuroblastoma from an adrenal primary is extending out of both sides of the lateral orbital walls (more marked on left – arrows). Patient has incidental scaphocephaly.

TREATMENT

The choice of single modality or multimodality therapy depends on the individual patient. Localized cervical neuroblastoma may be treated by curative surgery. Multi-agent chemotherapy is usually indicated in patients if resection is incomplete, where there is amplification of the *MYCN* proto-oncogene or where there is evidence of metastases. The role of radiation therapy is becoming more clearly well-defined and many tumours are highly radiosensitive.[44, 45]

PROGNOSIS

In young patients with resectable disease, complete excision offers the best chance of cure and at least a 90% survival rate. Primary neuroblastoma of the head and neck has a better prognosis than that of other sites. Prognosis is poorer in children over the age of 1 year at presentation.[43]

MISCELLANEOUS TUMOURS

A large variety of tumours can rarely affect the head and neck region. The small numbers involved can make meaningful analysis of data difficult and it is not really feasible to address therapeutic questions in the context of randomized controlled trials. However, the UK CCLG have published guidelines for some of the rarer childhood cancers.[17]

Soft-tissue sarcomas

Sarcomas other than rhabdomyosarcoma can occur in the head and neck region of children. some features of these tumours are listed in **Table 40.4**. There is a bimodal age distribution with incidence peaking in the under-5s and in adolescents. Those in the younger age group tend to have lesions situated in the head and neck region while older children present with lesions in the extremities. In general, these tumours have a tendency to recur locally and to metastasize. The treatment is tailored to the individual case but in general involves chemotherapy often followed by surgery and radiotherapy (**Figure 40.5**). The prognosis remains relatively poor despite multimodality treatment.[29]

Squamous cell carcinoma

Squamous cell carcinoma (SCC) outside the nasopharynx is extremely rare in childhood. There is some evidence of an association between SCC and previous exposure to immunosuppressive medication, and also previous irradiation for laryngeal papillomatosis. Pre-existing xeroderma pigmentosum makes any patient extremely susceptible to the development of cutaneous SCC. The principles of management of SCC in the head and neck in children are the same as in adults.

Malignant teratoma (Germ cell tumour)

Malignant teratomas in the head and neck region are rare (most are benign) and usually present at birth, often as an airway emergency. Large tumours are usually diagnosed *in utero*, resulting in a multidisciplinary team being

TABLE 40.4 Some features of head and neck soft tissue sarcomas

Fibrosarcoma
Peripheral nerves
Slowly enlarging painless mass
Metastatic infrequent
Complete resection is treatment of choice
Good prognosis
Neurofibrosarcoma or Malignant Schwannoma
Neck, larynx, oropharynx (see Figure 40.5)
Foci of calcification typical
Peripheral nerves
Develops in 3–16% of children with Von Recklinghausen neurofibromatosis (NF1)
Arise from capillary pericytes
Skin lesions, lymphadenopathy
Can compress cervical spine
Multimodality treatment
50% five-year survival
Wide surgical excision
Cranial nerve deficits, local recurrence, lung metastases complicate treatment
Haemangiopericytoma
Nasal cavity and sinuses
Nasal mass, and epistaxis
Associated with HIV
Kaposi's Sarcoma
Ewing's Sarcoma

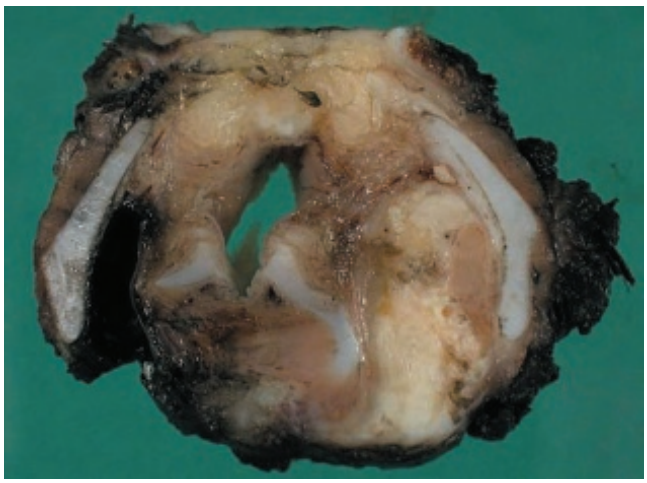

Figure 40.5 Cross-section of a laryngectomy specimen from a 12-year-old boy with residual synovial cell sarcoma despite chemoradiotherapy.

needed at delivery to secure a safe airway. Tracheostomy may be necessary. Assessment should include nasoendoscopy, alphafetoprotein (AFP) and beta human chorionic gonadotrophin (hCG) levels, and imaging. Metastases are rare. Treatment is surgical excision although salvage chemotherapy and radiotherapy may be required. The prognosis is good in the absence of metastases.

Chordoma

This is a rare slow-growing bony tumour which is locally aggressive and which arises from embryonic remnants of the notochord. The presentation depends on the site of origin which, in the head and neck region, is most commonly found in the nasopharynx and adjacent skull base. Patients present with headache and diplopia and compression of the lower cranial nerves can result in a number of neurological signs (see Volume 3, Chapter 8, Nasopharyngeal carcinoma). Biopsy is necessary for diagnosis and MR and CT scanning will delineate the tumour extent. Complete surgical excision is rarely possible because of the anatomical location and adjacent structures and so post-operative radiotherapy is usually employed. Proton beam therapy is increasingly employed in centres where it is available.

LONG-TERM SEQUELAE OF TREATMENT

The aim of cancer treatment in children is to maximize the chance of long-term survival and at the same time minimize the side effects, particularly in the longer term. With overall 5-year survival rates in children now over 80%, it is particularly important to examine the effects of the more recently employed multimodality treatments. The Childhood Cancer Survivor Study (CCSS) report that some 50.4% of survivors of childhood cancer have, by the age of 50 years, developed disabling or even fatal health conditions, as against 20% in a sibling control group.[46] Children tolerate the acute side effects of radiotherapy and chemotherapy reasonably well but other sequelae may not become apparent for several years.[47]

Second tumours may occur many years after treatment, particularly in a radiotherapy field.

Growth

Cranial radiotherapy can result in growth hormone deficiency and growth retardation and chemotherapy can also have significant effects on growth. Localized tumour treatments can also affect growth and function of specific organs or tumour sites. For example, radiotherapy to the maxilla in a child can result in asymmetrical growth of the midface.

Reproductive function

An important issue for survivors of childhood cancer is the impact of the disease and its treatment on reproduction and the implications for the health of any offspring. In males there is evidence for impaired spermatogenesis after treatment but it appears that any sperm produced carries as much healthy DNA as produced by the population in general. However, it is not always possible to predict fertility outcome in boys who receive treatment prior to puberty. Cryopreservation of sperm in young males (14–17 years) is effective but depends on the ability of the young patient to produce a specimen and, in the UK,

consent for storage requires him to be 'Gillick' competent (see Chapter 62, The paediatric consultation). Another technique is to harvest a 'wedge biopsy' of testicular tissue' for extraction of sperm. Radiotherapy to the hypothalamus or pituitary can result in precocious puberty in females and patients should therefore have their pubertal status checked regularly. There are now detailed CCLG guidelines on this topic.[17] Chemotherapy in general is less harmful to gonadal function in females but pelvic irradiation can affect ovarian function. Spontaneously conceived offspring of patients treated for cancer in childhood have no excess of congenital abnormalities or other diseases.[48]

Cardiac problems

Anthracyclines have a significant cardiotoxic effect and can cause cardiac failure in later life. Long-term echocardiogram surveillance is recommended for some follow-up regimes. Mediastinal radiotherapy can also result in impaired cardiac function (and an increased risk of breast carcinoma) and this should be monitored as appropriate.[49]

Thyroid disorders

Thyroid dysfunction can result from radiotherapy to the neck or to the hypothalmic/pituitary axis. Chemotherapy is a risk factor. Survivors require regular thyroid function evaluation. Radiotherapy to the neck is a recognized aetiological factor in the development of thyroid carcinoma in later years.

OTHER OTOLARYNGOLOGICAL MANIFESTATIONS OF TREATMENT

Radiotherapy to the head and neck region results in a large variety of long-term sequelae that can affect function and cosmesis. Damage to the major and minor salivary glands can cause xerostomia and subsequent tooth and gum disease. Post-radiotherapy scarring within the nasopharynx can result in middle ear effusions and subsequent deafness, and in the region of the midface can result in recurrent sinusitis, temporomandibular joint dysfunction and trismus. Certain chemotherapeutic agents – notably cisplatin – are known to cause deafness and tinnitus. Vincristine can cause bilateral vocal cord paralysis. Immunodeficiency with a propensity to develop opportunistic infections of the head and neck may complicate some chemotherapy regimens.[47]

Cognitive and psychological problems

Surgery and/or radiotherapy to the brain or adjacent structures can result in neurocognitive defects such as low IQ, learning difficulties and an increased risk of seizures. Survivors of childhood cancer are at an increased risk for a wide range of disabling psychological problems such as low mood, low self-esteem and anxiety.

Follow-up

It is important to follow up these children in the long term and to educate them and their parents about the possible late consequences of their treatment. It is also important to promote a healthy lifestyle and discourage cancer promoting behaviours such as smoking and excessive sun exposure.[48]

The dying child

The death of a child is one of the greatest tragedies that can befall a family. It is important to recognize that palliative care of the dying child should address not only the control of pain but the social, psychological and spiritual needs of children and their families. Planned terminal care for children has become increasingly community-based and therefore requires involvement of the primary healthcare team, including the patient's general practitioner at an early stage. An experienced and multi-skilled team is required with a named key worker and access to advice and support 24 hours a day. The child should participate in the planning and provision of this care as much as is realistically possible.[50]

Once the focus of treatment shifts from curative to palliative care, quality of life becomes of prime importance. Most children and their families will wish to maintain some semblance of normality while optimizing symptom control and minimizing medical intervention. For instance, many children will opt to remain at school for as long as they are able, mixing with friends and getting a break from the home environment. Others may benefit from a daily visit at home from a play specialist.[50, 51]

Regular respite should be offered to parents and it is important to explore the financial assistance, benefits and grants that families may be entitled to. Practical help with funeral arrangements should be given and it is important to continue to support the grieving family after their child's death and to withdraw support slowly and appropriately.[15, 50, 51]

NON-MALIGNANT CONDITIONS THAT RESEMBLE TUMOURS

Rosai–Dorfman disease

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) is an inflammatory condition of unknown aetiology. It typically causes massive bilateral cervical lymphadenopathy with fever and malaise in older children and young adults.[52] Histologically, it is characterized by histiocytes (an old-fashioned term for macrophages and dendritic cells) accumulating in large numbers in lymph nodes and occasionally other sites such as orbit, nose, oropharynx and salivary glands. In most cases it runs a benign course with spontaneous regression, but the disease can be quite prolonged. Excision biopsy of a lymph node is required to exclude lymphoma, and more extensive surgical debulking may be necessary for compressive symptoms.

Langerhans cell histiocytosis

Langerhans cell histiocytosis (LCH) can also present with lymphadenopathy, usually in the children under the age of 5 years. It is characterized by clonal proliferation of Langerhans cells and their accumulation in tissue. It is unclear whether this process is neoplastic or inflammatory

in nature. LCH is a spectrum of disease, ranging from unifocal (previously known as eosinophilic granuloma), which presents as a solitary bone lesion, to multifocal multisystem disease (previously known as Letterer–Siwe disease). The multifocal form can involve bone lesions (often in the mandible, causing jaw pain or loose teeth), skin eruptions (commonly on the scalp), pituitary gland lesions, chronic otitis media and bone marrow involvement. Fever, lethargy and weight loss may occur. LCH with cervical lymphadenopathy will usually be of the multifocal type. Diagnosis requires excision biopsy of an affected node for histological examination, together with radiology of the chest and any affected bones and MRI of the pituitary. Prognosis can be poor, especially under the age of 2 years, and aggressive treatment may be required with steroids and in severe cases cytotoxic chemotherapy. Mortality is approximately 10% overall, but 50% in multifocal disease in children under the age of 2 years.

Castleman disease

The main importance of Castleman disease is in the differential diagnosis of lymphoma. It presents as a mass of enlarged lymph nodes. The diagnosis is made on histology which shows a B-cell lymphoproliferative disorder, and some cases are thought to have a viral cause. Children most often have the unicentric form, with nodes confined to one area of the neck. Surgical excision is all that is needed. The multicentric condition is more common in adults and much more serious. It is sometimes associated with HIV infection and can run an aggressive course, requiring prolonged treatment with antivirals and monoclonal antibodies. For this reason, children with apparently unicentric disease should probably have imaging of the chest, abdomen and pelvis, and HIV testing.

Fibromatosis colli (sternomastoid tumour of infancy)

This condition is surprisingly common and important to recognize. It is often blamed on birth trauma but its aetiology is obscure and it is most likely an idiopathic fibrosing condition of the muscle. Fibromatosis colli is the preferred term as 'tumour' suggests neoplasia which is as frightening as it is inappropriate. It presents in newborns as torticollis and a palpable lump within the sternomastoid muscle. It is associated with developmental dysplasia of the hip so it is probably reasonable to get an ultrasound of the neck to confirm the diagnosis and the hips can be scanned at the same time. Treatment is simply physiotherapy to stretch of the muscle and encourage the baby to turn the head to the affected side. The tragedy of this condition is that, despite being common and simple to treat, it often goes untreated leaving the child to develop fibrosis and permanent contracture of the muscle. The torticollis becomes permanent and this can affect the development of the facial skeleton. The eyes and mouth develop on a cant so that even when the muscle is surgically released, the face remains abnormally aligned (Figure 40.6).

Figure 40.6 **(a)** Untreated fibromatosis colli on the right side presenting in childhood with contracure of the sternomastoid muscle. **(b)** After surgical release of both ends of the right sternomastoid muscle the resting position and range of movement of the neck are improved but note that the planes of the eyes and mouth are not parallel and the whole face has grown in an asymmetric fashion.

BEST CLINICAL PRACTICE

- ✓ The vast majority of enlarged cervical lymph nodes in children are harmless. Imaging should usually be considered before biopsy.
- ✓ FNA has a more limited role to play in the child than the adult.
- ✓ All children diagnosed with malignancy should be referred to a specialist centre.
- ✓ Children receiving chemotherapy should have central venous catheters placed for venous access and chemotherapy treatment.

FUTURE RESEARCH

- ➤ The long-term survival of children with cancer is improving, and a better appreciation of the long-term sequelae of treatment should result in an improved quality of life for children surviving cancer. We are likely to encounter more physical and psychological problems in adults related to cancer treatment in childhood.
- ➤ Basic science research should bring better understanding of the underlying aetiology of childhood cancer. This may help in introducing preventative measures such as vaccines and environmental interventions. Agreed protocols on the management of paediatric thyroid malignancy would be helpful. Centralization of services, the establishment of better databases and the implementation of multicentre trials will provide us with a better evidence base for the future management of childhood cancer.
- ➤ Better imaging techniques with wider access to sophisticated equipment will aid in more accurately assessing the initial disease and in detecting recurrence at an earlier stage. Greater knowledge of molecular genetics has resulted in new approaches to diagnosis and treatment. The advent of polymerase chain reaction (PCR) techniques has, for example, permitted the detection of cells bearing chromosomal translocations in the peripheral blood and bone marrow, thereby detecting minimal residual disease in lymphoma and even defining patients at high risk of relapse. Other novel strategies include the use of immunotherapy (immunotoxins or vaccines) to target specific cells or cell proteins. Radiotherapy techniques such as IMRT are allowing much greater flexibility in targeting tumours in awkward anatomical sites whilst avoiding some of the post-treatment complications. IMRT is an advanced mode of high precision radiotherapy where combinations of several intensity-modulated fields coming from different beam directions deliver a maximal dose to the tumour while minimizing the dose to surrounding tissues. Surgical advances, such as navigation systems with the use of endoscopes, mean that areas once inaccessible can now be approached surgically whilst maintaining good function and cosmesis. Proton beam therapy looks set to have a significant role in childhood malignancies.
- ➤ In conclusion, we have made major advances in the investigation and management of childhood malignancy in the last 30 years and a number of promising diagnostic and treatment developments promise much in the next 30.

KEY POINTS

- Head and neck tumours are uncommon in children. Early diagnosis is essential.
- Survival rates are improving.
- Multimodality treatment has improved the prognosis while reducing both early and long-term complications.
- Treatment should be provided by a specialized, centralized multidisciplinary paediatric oncology team.

ACKNOWLEDGEMENTS

I wish to thank Dr Greg Irwin, Consultant Paediatric Radiologist, Royal Hospital for Sick Children, Glasgow, for providing the MR images.

CHAPTER 41

CYSTS AND SINUSES OF THE HEAD AND NECK

Keith G. Trimble and Luke McCadden

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the following keywords: branchial arch, branchial cleft, branchial pouch, preauricular sinus, thyroglossal cyst, lingual thyroid, nasal dermoid and congenital midline cervical cord.

INTRODUCTION

A child with a congenital cyst or sinus in the head or neck is the quintessential paediatric ENT patient and can present a welcome diagnostic challenge in the humdrum of afternoon clinic. Although a preauricular sinus is common and easily diagnosed by the undergraduate student, it takes an experienced otolaryngologist to consider the infrequent first branchial cleft sinus diagnosis in a child with facial abscess repeatedly incised and drained elsewhere. For obvious reasons, an understanding of embryology of the branchial clefts is a prerequisite for the paediatric or adult otolaryngologist managing infected cysts or draining sinuses around the head and neck. Excluding reactive cervical lymphadenopathy as the most frequent cause of referral with neck lump and the common pilomatrixoma, which is slowly enlarging and fixed to the skin, thyroglossal duct cysts, branchial arch anomalies and dermoid cysts are seen in decreasing order of frequency.

This chapter discusses the best management of congenital cysts and sinuses of the neck, none of which is based on randomized controlled trials or meta-analyses, but rather single-surgeon, single-centre large case series or systematic review. Special mention should be made regarding modifications of Sistunk's procedure, which should be effecting lower recurrence rates following excision of thyroglossal duct cyst anomalies and endoscopic cautery of third pharyngeal pouch sinuses in older children to reduce complications of open surgery. Unusual entities such as the congenital midline cervical cleft and congenital sinus at the sternoclavicular joint (sinus sternoclavicularis) will also be discussed. Plunging ranulas, teratomas and vascular anomalies also present at birth but are discussed elsewhere in this book. Sternomastoid pseudotumours of infancy present as a painless unilateral mass low in the neck with decreased neck rotation and are easily managed with ultrasonography and physiotherapy; these are not discussed further in this chapter.

BRANCHIAL ANOMALIES

Branchial anomalies usually present as lateral neck masses with infection, cyst enlargement or an intermittently draining sinus. Treatment usually involves surgical excision with identification and preservation of nearby neurovascular structures. The embryology of the branchial apparatus is discussed in Volume 1, Chapter 53, Developmental anatomy of the thyroid and parathyroid glands. But it is worth noting the following brief points. The branchial arches are mesodermal structures that go on to form muscle, cartilage and bone. First and second branchial arch anomalies, therefore, will result in structural deformities of the face, as in Treacher Collins syndrome or hemifacial microsomia (see Chapter 19, Craniofacial anomalies). There are spaces between the arches on the

outside of the embryo, lined with ectoderm, called the branchial clefts. Branchial cleft anomalies, therefore, will result in a congenital sinus with an opening on a skin surface. This may be around the angle of the mandible or in the EAC (first branchial cleft sinus) or in the neck along the anterior border of sternomastoid (second branchial cleft sinus). There are also spaces between the arches on the inside of the embryo, as the arches bulge into the foregut. These are called the pharyngeal pouches and they are lined with endoderm. Pharyngeal pouch anomalies (third or fourth) will result in a sinus with an opening on a mucosal surface, typically in the left piriform fossa.

First branchial cleft sinuses

First branchial cleft sinuses are rare and account for less than 10% of branchial cleft anomalies.[1] The external opening in the neck varies in position but lies on a line between the tragus and the hyoid bone. The opening is often inconspicuous and appears as a skin-lined pit. The superior attachment of the sinus is variable: there may be an opening anterior to the tragus or the tract may form a true fistula running inferior to the floor of the EAC and opening at the osseocartilaginous junction in the external auditory meatus or rarely forming a frenulum-like band between the floor of the meatus and the umbo of the tympanic membrane (**Figures 41.1** and **41.2**).

Histology

The sinus (sometimes known as a collaural fistula) is usually a sizeable tract, often formed of cartilage, and lined with squamous epithelium. The original classification by Work and Work[2] divides them into two types according to the presence or absence of mesothelial elements within the wall.

- **Type I lesions** are of ectodermal origin and are present medial to the concha. They are usually superficial and simple in nature.
- **Type II lesions** are both ectodermal and mesodermal in origin and contain cartilage and hair follicles. The more inferior opening of the type II fistula is usually below the angle of the mandible and the tract is intimately related to the facial nerve trunk.

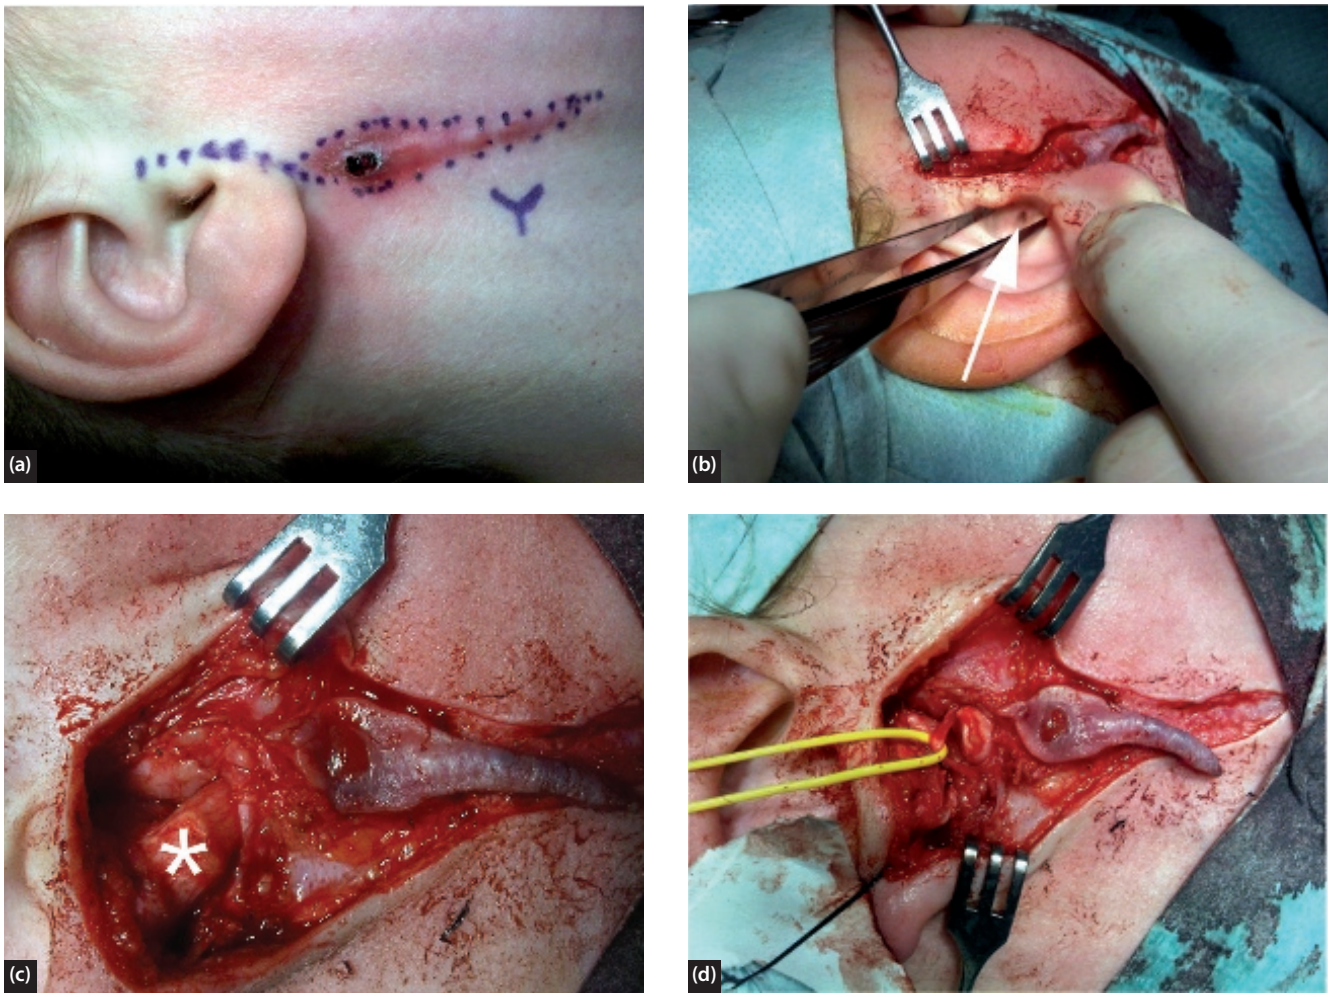

Figure 41.1 **(a)** Type 2 first branchial cleft anomaly with two previous incision procedures in another hospital. **(b)** Proximal fistula opening in floor of ear canal. **(c)** The fistula tract (*) passes over the angle of the mandible deep to the facial nerve trunk, intraparotid and terminates at the bony-cartilaginous junction of the external auditory meatus. **(d)** Yellow sloop over the main trunk facial nerve.

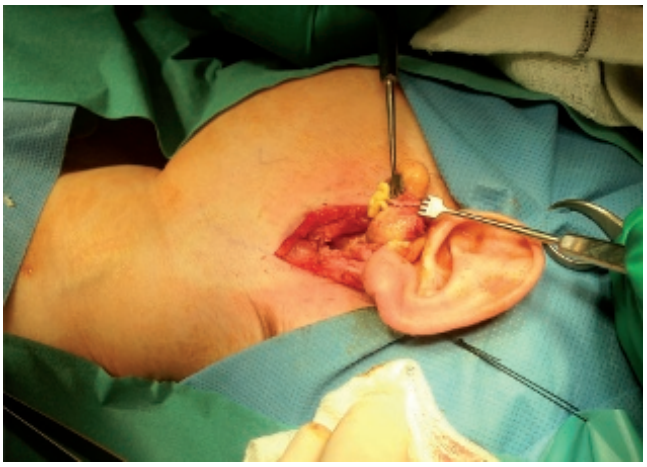

Figure 41.2 Type 1 first branchial cleft anomaly with ear canal duplication anomaly lateral to the facial nerve extending to the umbo of the tympanic membrane.

Presentation

The opening is present at birth and may become more obvious by the discharge of epithelial or sebaceous debris. The sinus may become acutely infected and may progress to abscess formation. Being lined with skin, these lesions do not discharge mucus.

Investigation

Cross-sectional imaging will usually show the tract, which is often substantial in calibre but will not clearly demonstrate its relationship to the facial nerve. MRI is preferable over CT in children to minimize exposure to ionizing radiation and provide excellent visualization of soft-tissue planes. However multislice helical CT may be preferred in some institutions because of cost, availability and speed of image acquisition which could obviate the need for sedation or anaesthesia. A radiopaque sinogram is not routinely indicated.

Treatment

Surgical excision of these lesions is usually advocated if at all symptomatic or if one or more episodes of infection have already occurred. Surgery is ill-advised during acute infection and a period of quiescence should be awaited followed by elective excision, which necessitates dissection of the tract in its entirety, assisted by intra-operative facial nerve monitoring.

A parotidectomy-type incision is modified to include the lower opening of the sinus. The sinus tract at this point can be followed for a small distance upwards; when its nature and direction are confirmed, the facial nerve trunk must be identified as it leaves the skull base and enters the parotid gland. The mandibular branch in particular should be followed so that it can be preserved while freeing the tract. Sharp dissection will often be required to free the nerve from the tract, particularly if multiple infections have ensued or previous attempts at incision and drainage have been made. In most instances the lesion will run deep to the branches of the facial nerve, which may be adherent if there has been recurrent infection, though the relationship is unpredictable. The superior part of the sinus tract also has an unpredictable relationship to the cartilages of the external auditory canal (EAC). It may terminate at the canal or may form a duplicated canal parallel and inferior to the EAC proper. The lesion does not extend medial to the cartilaginous canal but a strand may cross the lumen of the canal from the osseocartilaginous junction to be attached to the umbo.

Facial nerve exposure and protection is required in nearly every case of first branchial cleft sinus. If this is done, then risk to the facial nerve is minimized. The superficial position of the facial nerve in small children must be considered. The upper end of the lesion must be followed and excised to ensure that no squamous epithelium remains, and this may require opening of the EAC and use of the otological microscope and ear instruments.

Closure of the wound with suction drainage and, if necessary, light packing of the ear canal completes the operation.

Second branchial cleft sinuses

Second branchial cleft sinuses are the commonest of the branchial anomalies (up to 90%[1]) (**Figure 41.3**). The second branchial arch forms the epidermis of the upper neck and dorsal pinna. The mesoderm forms the facial muscles and the body of the hyoid, and the endodermal elements form the root of the tongue, the foramen caecum, the thyroid stalk and the tonsil. The second branchial cleft sits immediately caudal to these structures and it is persistence of this cleft that leads to the formation of the second branchial arch sinus.

Second branchial arch sinuses may be associated with branchio-oto-renal syndrome, especially if bilateral.

The second branchial cleft sinus presents as a congenital opening on the lower neck, anterior to the sternocleidomastoid muscle. The tract of the second branchial cleft sinus is directed proximally and medially to pass between the internal and external carotid arteries. The proximal end may communicate with the pharynx through the palatine tonsil to form a true fistula in some cases, although most lesions are not patent through their whole length. The sinus nearly always leaks clear or mucoid fluid from the distal external opening due to secretions from ectopic salivary tissue in the wall of the sinus itself rather than any leakage from the pharynx. In some cases the sinus may become infected and, on occasion, the infected tract may form an abscess in early infancy, requiring intravenous antibiotics or surgical drainage.

Second branchial cleft cysts are thought to be congenital in origin even though they rarely present in childhood and are much more common in young adults. They typically present as a spherical swelling inferior to the angle of the mandible, anterior to the sternocleidomastoid, although other unusual locations occur. It is helpful to

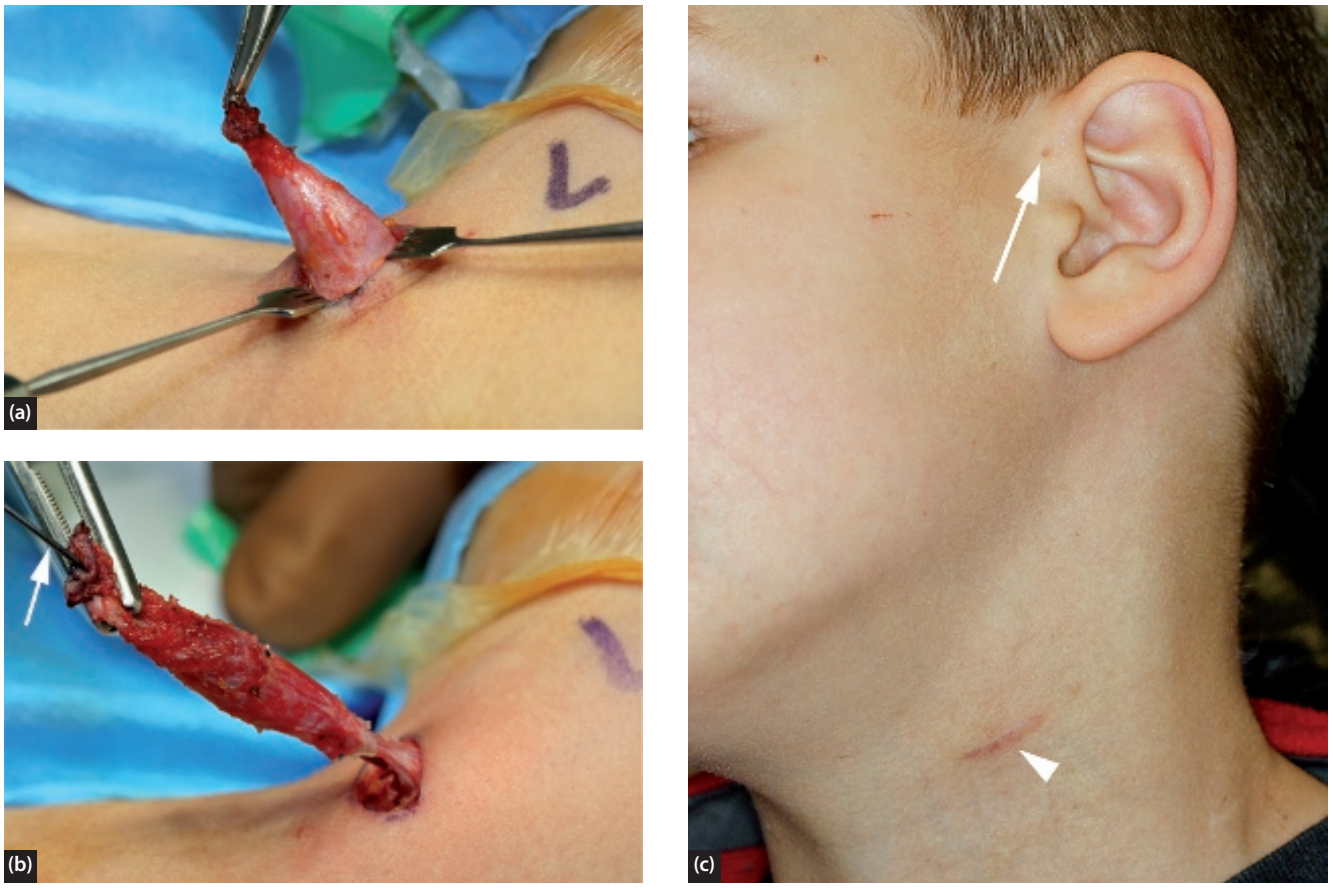

Figure 41.3 Second branchial cleft sinus tract dissection **(a)** peters out adjacent to the pharynx **(b)**. The white arrow indicates the lacrimal probe. **(c)** Post-operative image: note the asymptomatic preauricular sinus (white arrow) and the 1-week old post-operative scar (white arrowhead).

recall Bailey's classification of second branchial cleft cysts which provides a framework at the clinic for diagnosis and surgical planning of unusually placed cysts:

- **type I:** deep to platysma, anterior to sternocleidomastoid
- **type II:** abutting internal carotid artery and adherent to internal jugular vein (most common) (Figure 41.4)
- **type III:** extending between internal and external carotid arteries
- **type IV:** abutting pharyngeal wall and potentially extending superiorly to skull base.

Investigation

As a rule with second branchial cleft sinuses, the diagnosis is evident and no further investigation is required. Neck ultrasonography can characterize the size of tract or associated sharply demarcated cyst, and renal tracts can be imaged to exclude horseshoe or duplex kidney. However, a radiopaque sinogram is not routinely indicated. Cross-sectional imaging will usually show the close relations of a second branchial cyst and is particularly helpful for type III or IV presentations (Figure 41.5). MRI is preferable to CT in children to minimize exposure to ionizing radiation and provide excellent detail of soft-tissue planes.

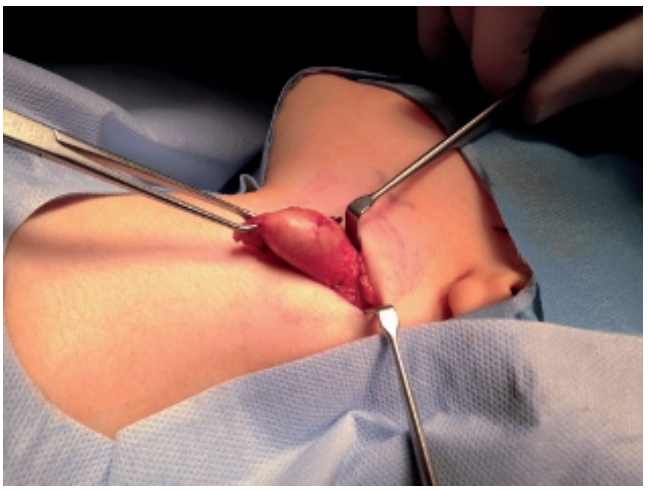

Figure 41.4 Excision of a common type II second branchial cleft cyst deep to the sternocleidomastoid muscle and abutting great vessels.

Treatment

Because of the risk of infection, excision of second branchial cleft sinuses is advisable. Surgery can be performed at any age and aims to excise the tract completely when no infection is present. A fusiform skin incision is made

Figure 41.5 **(a)** Pre-operative appearance of a type IV second branchial cleft cyst/sinus, **(b)** with coronal and **(c)** axial T2-weighted imaging.

around the external opening and the tract can be followed upwards with microbipolar dissection and counter traction with lacrimal retractors. If the distance between the external opening and pharynx is too great to allow good access, a second stepladder incision is made superiorly in the neck to enable the cranial portion of the tract to be visualized and excised; however, this is rarely necessary in the young child. The tract will be seen to enter the pharyngeal muscle at the level of the palatine tonsil and can be ligated and excised at this level. Although ipsilateral tonsillectomy is unnecessary in the vast majority of cases, tonsillectomy should be considered in the larger type IV second branchial cleft cyst that abuts the pharynx (Figure 41.5). Care must be taken to avoid the hypoglossal nerve in the superior part of the dissection. Complete excision of the sinus should prevent recurrence. Surgery for second branchial cleft cysts should be planned when infection has resolved, taking care to avoid injuring the internal jugular vein and hypoglossal nerve superiorly.

Third and fourth pharyngeal pouch sinuses

Third and fourth pharyngeal pouch sinuses are rare abnormalities, accounting for 1–2% of branchial lesions, which can present as a sinus, cyst, thyroid gland abscess or even a fistula from pharynx to skin.[3] They almost always occur on the left side. They tend to present in early childhood with associated infections or in neonates with airway obstruction. The third and fourth branchial arches are related to the thyroid, parathyroid and thymus and

therefore tracts may course close to or through these structures: both originate at the pyriform sinus. The third arch is associated with the glossopharyngeal nerve whereas the fourth is related to the superior laryngeal branch of the vagus nerve. This can explain the theoretical course of third and fourth pharyngeal pouch anomalies, however case reports to demonstrate these are lacking. A proposed theory by James[4] is to consider these as branchial anomalies of the pyriform fossa. Development may arise from the incomplete closure of the thymopharyngeal duct of the third pouch, a similar concept of how cysts may form in the thyroglossal duct tract.

Presentation

These anomalies present most commonly with some form of infection, often recurrent thyroid abscess, which is treated with incision and drainage without recognition of the diagnosis and rendering recurrence inevitable.

Investigation

Various investigations have been proposed: barium swallow, radioiodine scan, ultrasonography and CT. However, MR imaging alone is suitable followed by rigid endoscopy under anaesthesia to identify an opening in the pyriform sinus.

Treatment

Although wide-field extirpation of the cyst, tract and ipsilateral thyroid lobe using a hybrid open and endoscopic approach to the pyriform sinus was the standard treatment, modern management utilizes endoscopic cautery of the pyriform fossa sinus alone as first-line treatment. Bailey described successful endoscopic diathermy of the pyriform fossa opening in two cases in 2004 which has become first-line treatment to obliterate the tract and avoid recurrent infection.[5] Garabedian recognized a higher recurrence rate in neonates in a series of 20 children and recommended resection via open approach rather than endoscopic approach in this younger age group.[6]

PREAURICULAR CYSTS AND SINUSES

Embryology

The external ear begins to develop at week 6 of gestation. Auricular hillocks, three from the first and three from the second branchial arch, surround the first branchial cleft below the level of the mandible. The hillocks will form the pinna and the first cleft will form the external canal. As they ascend, some mandibular hillocks contribute to the tragus, while the remainder form the bulk of the auricle. A blind-ended sinus results from incomplete fusion of the hillocks. The sinus is skin-lined and may result in recurrent discharge and infections. While a sinus found above the line of the tragus is usually an isolated preauricular sinus/cyst, a sinus found below the level of the tragus is more likely related to a first branchial cleft anomaly and checking the EAC for fistula is imperative.

One inherited (autosomal dominant with variable penetrance) disorder to be recognized is branchio-oto-renal syndrome which involves structural defects of the outer, middle and inner ear, branchial cleft anomalies and renal abnormalities. Bilateral preauricular sinuses and bilateral second branchial cleft sinuses may be present with hearing loss. Mutations in the *EYA1* gene on chromosome 8q13 are found in 40% of patients.[7] Hearing assessment and ultrasound of renal tracts are recommended management.

Presentation

Preauricular cysts and sinuses are common, with an incidence ranging from 0.9% in the Western European population to 10% in East Africa.[8] The majority of preauricular sinuses will remain asymptomatic and can be managed conservatively. However, frequent discharge or abscess formation following preauricular lymphadenitis should prompt early intervention.

Treatment

If the sinus or cyst is symptomatic, local excision is the treatment of choice (**Figure 41.6**). The sinus is explored under general anaesthetic with a lacrimal probe which usually shows deep extension towards the roof of the ear canal for 10 mm or more. The punctum is excised with a fusiform skin paddle and excised in continuity with the entire tract, which is usually adjacent to the underlying cartilage; excising a portion of this reduces the risk of recurrence. Some will use methylene blue to guide dissection but others avoid this in case of spillage into the field, which makes dissection more awkward. If there is skin breakdown secondary to lymphadenitis in the surrounding area, this can be left alone, as it will settle following successful removal of all epithelial tract related to the preauricular cyst and sinus.

THYROGLOSSAL DUCT CYST

Embryology

Thyroglossal duct cysts are the most common congenital abnormality in the head and neck region. The thyroid develops from the foramen caecum, which lies in the midline of the tongue at the junction of the anterior two-thirds and posterior one-third. In normal development, the thyroid descends through the tongue, passing caudally with an intimate relationship to the hyoid bone and finishing in the anterior neck overlying the trachea and laryngeal cartilage. In around one-third of cases the duct has been found posterior to the hyoid bone, which has important implications in surgical treatment. The duct may fail to

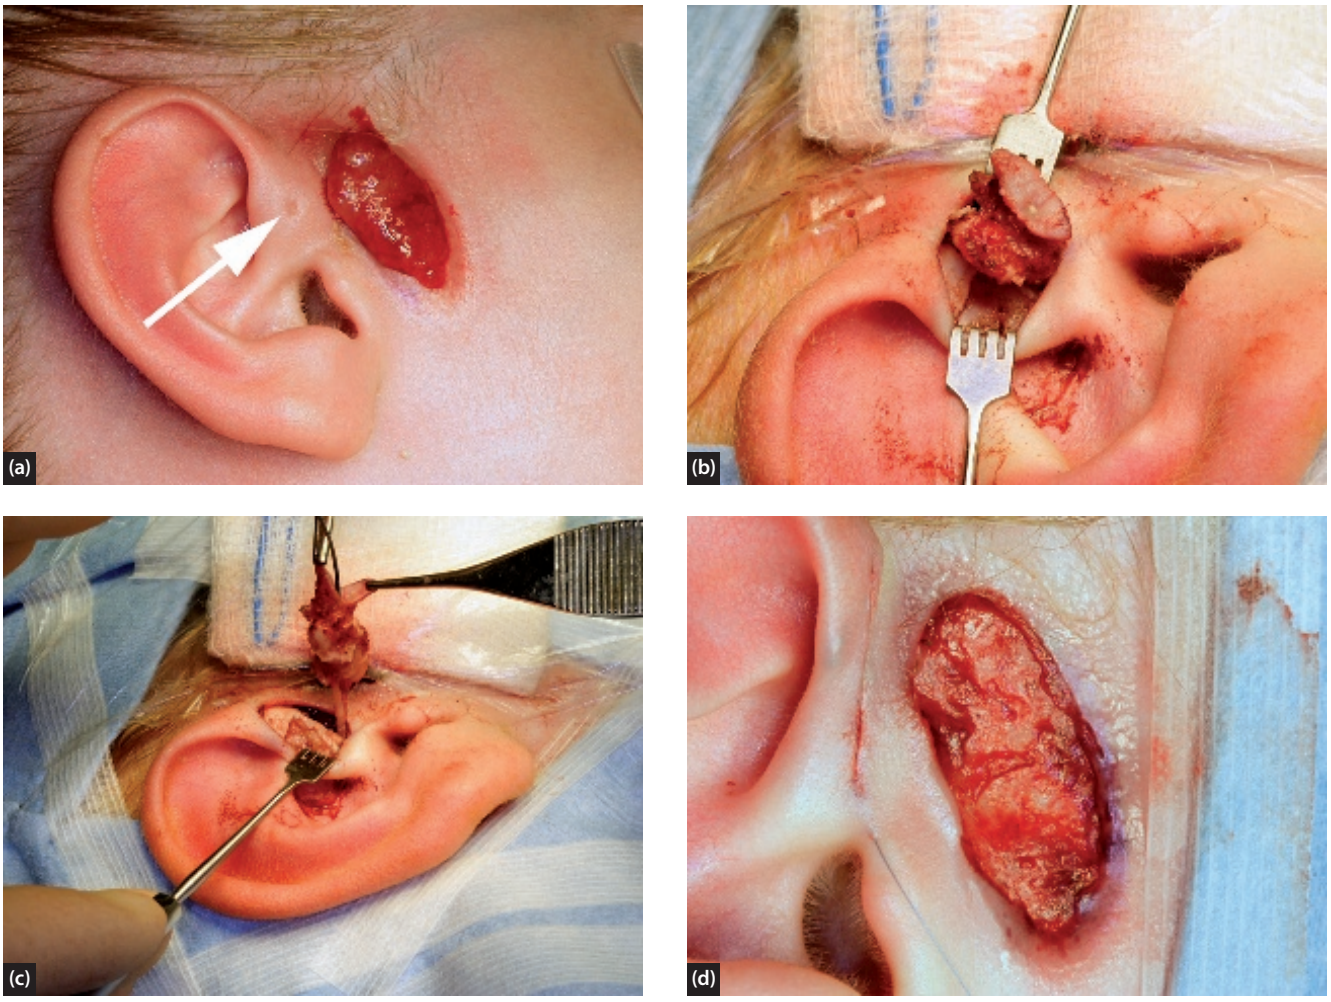

Figure 41.6 **(a)** Preauricular sinus right ear (white arrow) with lymphadenitis, skin breakdown and pre-parotid granulation tissue. **(b,c)** Excision of the sinus, cyst, sliver of cartilage and tract. **(d)** The area of skin breakdown heals by secondary intention following complete excision of the congenital epithelial tract.

involute during the weeks 8–10 of gestation and as a result an abnormal cyst may arise anywhere along the tract and may contain thyroid tissue.

Presentation

Despite being a congenital lesion, thyroglossal duct cysts often present later in childhood or early adulthood. The complaint is usually of a midline swelling in the neck although it can occur laterally, usually left-sided in around 10% of cases. The mass elevates on swallowing and tongue protrusion. It may present with a complication of infection or fistula formation to the skin if surgically drained.

Investigation

It is possible for the thyroglossal cyst to contain the only functioning thyroid tissue and therefore removal would result in hypothyroidism. Ultrasound is useful in confirming the diagnosis and the presence of a normal thyroid gland in the usual position. Cross-sectional imaging before revision surgery is advised to ascertain an intact hyoid bone or localize recurrent cyst.

Treatment

Treatment is nearly always surgical excision unless the cyst is very small and asymptomatic. If a fistula to the skin is present, this is excised with the underling cyst and tract. The definitive operation is that described by Sistrunk from the Mayo Clinic in 1920,[9] removing with the thyroglossal duct a portion of the hyoid bone, a portion of the raphe joining the mylohyoid muscles, a portion of each genioglossus muscle and the foramen caecum. If the surgery is performed as he described, recurrence rates can be kept below 5%; this was confirmed in a 2013 systematic review including 750 patients having primary surgery. Problems arise where there has been a deviation from Sistrunk's procedure resulting in an incomplete resection. Recurrence rates following incomplete excision rise to 27%.[10]

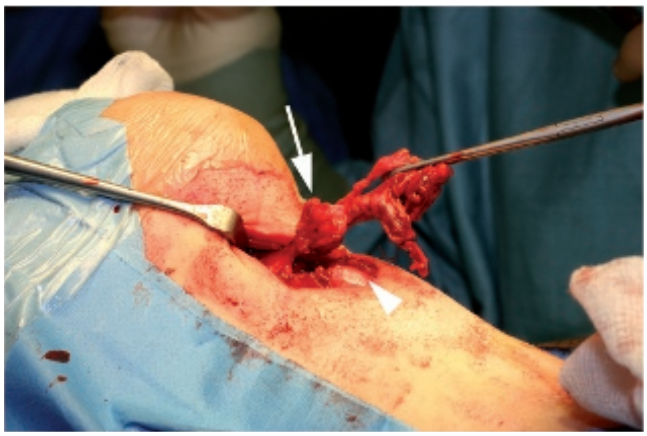

Figure 41.7 Extended Sistrunk procedure for thyroglossal duct fistula with skin paddle including fistula, soft tissue medial to straps, central hyoid (white arrow) and core of tissue towards foramen caecum. The white arrowhead indicates the laryngeal prominence/thyroid notch.

The operation has been developed further with an extended or modified Sistrunk procedure (Figure 41.7), which involves a wider block dissection incorporating the infrahyoid region to the thyroid isthmus initially used for recurrent disease but now applied to all patients to minimize complications.[11] Complications include haematoma, seroma, cyst recurrence, salivary fistula and hypoglossal nerve injury.

LINGUAL THYROID

Lingual thyroid is the result of failure of descent of the thyroid anlage from the foramen caecum of the tongue (Figure 41.8). It is a rare entity with prevalence of 1:100 000. Girls are more commonly affected.[12] In 70–80% of these cases, the lingual thyroid is the only thyroid tissue present. Up to one-third have hypothyroidism. Malignancy has been reported and seems to carry the same risk as thyroid in a normal cervical location.

Presentation

Depending on size, lingual thyroid can present with dysphagia, airway obstruction, haemorrhage or endocrine dysfunction. More often the patient is completely asymptomatic with suspicion only after other investigations, following routine ENT examination or detected on parental curiosity.

Investigations

Imaging will confirm lingual thyroid with either CT or MRI; sagittal views are particularly helpful. Unenhanced CT outlines the lingual thyroid well, given its hyperdensity compared with the surrounding tongue muscle, although MRI is preferred to avoid ionizing radiation. In addition to the lingual thyroid, imaging is used to identify if there is thyroid tissue in the normal cervical location. Ectopic thyroid has been reported in the oropharynx, larynx, infrahyoid neck, mediastinum, oesophagus and heart. Technetium (^{99m}Tc) thyroid scan will identify metabolically active thyroid tissue in the tongue base and no uptake in the neck. Thyroid function tests are usually normal but up to a third of patients demonstrate hypothyroidism; hyperthyroidism is rare.

Treatment

For small, asymptomatic lingual thyroids, suppression with TSH may be effective in checking growth. Reduction is often slow and dramatic results should not be expected. Paediatric endocrinology input is essential. Use of radioactive iodine for thyroid ablation is generally avoided in children. Surgical excision is occasionally required when significant obstructive symptoms are present or repeated or severe haemorrhage is an issue. Transoral resection is usually possible using nasotracheal intubation. For larger and deeper lesions, an external approach may be required. This may even necessitate planned tracheostomy for large masses where swelling and obstruction are inevitable. Lifelong monitoring of thyroid function is essential.

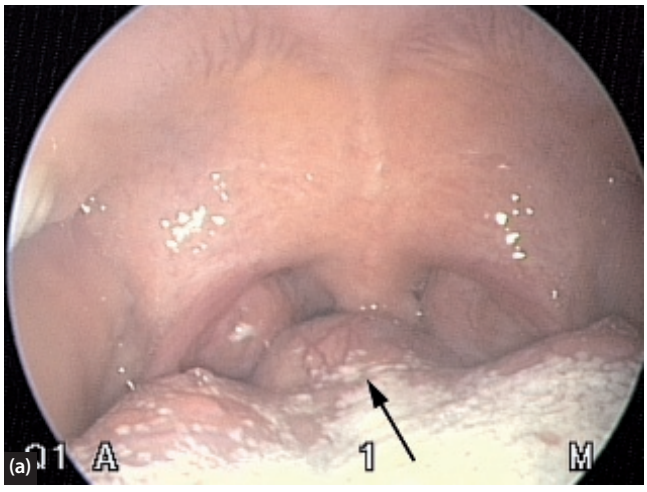

Figure 41.8 **(a)** Lingual thyroid arising from the foramen caecum on the tongue protrusion (black arrow). **(b)** Unenhanced axial CT imaging showing the lingual thyroid (white arrow).

NASAL DERMOID

Dermoid cysts contain ectodermal and mesodermal elements. They occur along the lines of embryonic closure. Nasal dermoids are a rare entity representing 3% of all dermoids and 12% of head and neck dermoids.[13] Incidence is estimated at 1:30000 births.[14]

There is debate over the origin of these cysts. One theory is that they originate from an embryological aberration resulting in inadequate closure of the fonticulus frontalis, allowing dermal tissue to extend between the nasal bones and cartilage. Dura can also extend through this area. The other theory involves the prenasal space, which is an area that runs in the midline between the developing nasal bone and underlying cartilage from the brain to the nasal tip. There is a suggestion that there is persistence of residual dura in this space which forms a contact with the skin and then it retracts to result in a sinus, in which a cyst develops.

A punctum may lie anywhere on the nasal dorsum and may discharge or even have hairs extruding, which is considered pathognomonic. The cyst will lie somewhere between the columella and the glabella (**Figure 41.9**). A tract may also extend superiorly and intracranially. Occasionally the tract connects with a median upper lip sinus.

Presentation

Clinical presentation may be simply a small punctum or isolated mass, often presenting at birth or soon after. Recurrent infection may be a problem and erosion through nasal bones, and periorbital and intracranial spread are unusual complications (**Figure 41.10**). Familial links have been reported.[15]

There are some reported associations with other congenital anomalies such as hydrocephalus, aural atresia and cardiac abnormalities.[16]

Differential diagnoses include glioma, encephalocoele and nasal polyposis.

Treatment

Complete excision is the treatment of choice. Early surgical excision is advocated to reduce bony distortion or atrophy and minimize infective complications. Bradley published results for surgery on nasal dermoids in children.[17] Lesions were classified into simple or complex, depending on involvement outside of skin and histologically described as true dermoid or epidermoid. Hartley et al. published a series of 103 cases and suggest a pragmatic staging system depending on deep extension of the lesion (**Figure 41.11**):[15]

- **superficial:** remain within the soft tissue and readily excised, also the most common
- **intraosseous:** extend to frontal and nasal bones, requiring drill out for excision
- **intracranial extradural:** breech the anterior cranial vault; can be accessed and excised through a frontonasal osteotomy and peeled from the dura
- **intracranial intradural:** most complex and may require bicoronal flap and frontal craniotomy; endoscopic transnasal approach may be possible.

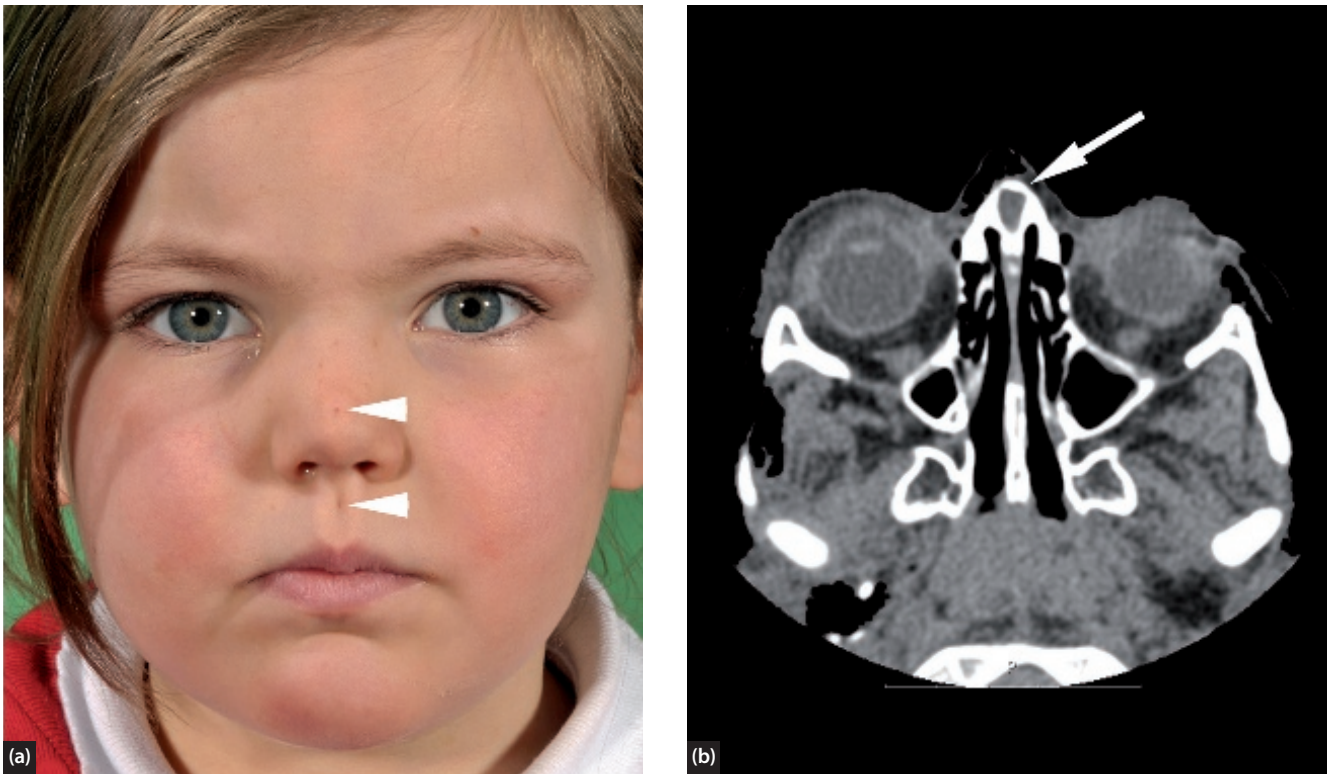

Figure 41.9 **(a)** Nasal dermoid sinus with associated philtrum sinus (white arrowheads). **(b)** Intraosseous extension nasal dermoid cyst deep to the nasal bones (white arrow).

Figure 41.10 **(a)** Complication of intraosseous nasal dermoid cyst/sinus/tract with acute abscess and erosion with loss of skin and left nasal bone. **(b)** Combined surgical approach via external rhinoplasty and direct bishop-mitre rotation flap to replace skin loss. **(c)** Post-operative nasal contour satisfactory with new bone growth.

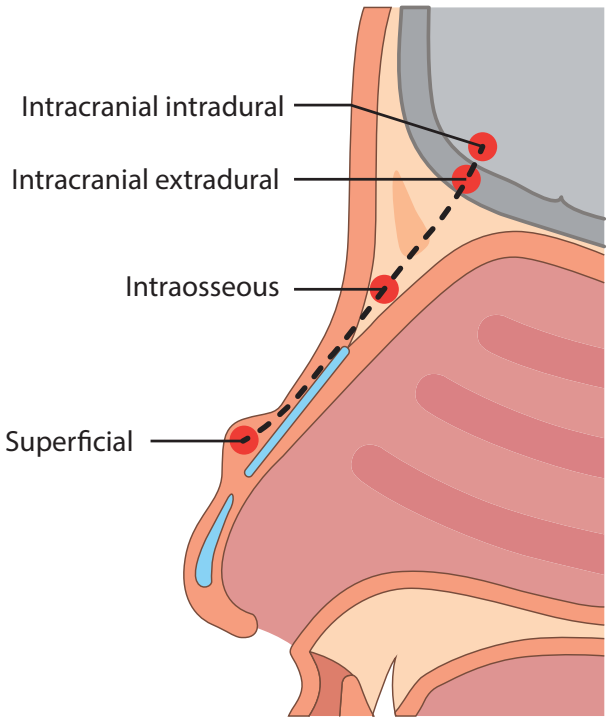

Figure 41.11 Hartley classification of nasal dermoids[15] (permission for reproduction granted from Elsevier publisher).

The position of the cyst or sinus does not predict the likelihood of intracranial extension. Extension has been reported in 4–45% of cases. Imaging is essential to exclude or confirm intracranial extension and planning surgical approach. Dual modality imaging with MR and CT is recommended for maximum understanding of bony and soft-tissue anatomy prior to surgical planning. Imaging is evaluated for size and location of the tract and signs of intracranial extension whether direct (intracranial high-signal cyst) or indirect (bifid crista galli, widened foramen caecum or cribriform plate defect).

Early surgical excision is recommended to prevent infections or further expansion, and consequent damage to surrounding tissue. In 1992 Koltai reported the external rhinoplasty approach for removal of complex nasal dermoids in children[18] and this has become the standard technique for superficial and intraosseous disease. The cosmetic results are good.[19] Identifying the superior limit and site of the dermoid will influence the surgical approach. Most will be adequately accessed via the external rhinoplasty approach or a direct midline incision as either allows access to the radix of the nose in a young child. Brow incisions and lateral rhinotomy are alternatives, and endoscopic techniques have been described more recently.[20, 21] If there is intraosseous extension, a median osteotomy of the nasal bones is required or in a young

child the otologic drill can be used to follow the disease superiorly. The post-operative appearance is very satisfactory and no bone reconstruction is required. A neurosurgical opinion is required for discussion around timing of surgery and to plan the single-stage craniofacial approach. In future, it may become possible to avoid an open craniotomy for some selected intracranial intradural lesions. Re et al. have described two paediatric cases of endoscopic endonasal removal of intracranial extradural dermoid cysts via hemitransfixion incision; however, resection of 1.5 cm superior septal cartilage is required for access to the nasal dorsum.[22] Long-term follow-up is required akin to management of cholesteatoma in the temporal bone; delayed interval MR imaging with diffusion restriction is advised to exclude recurrence.

CONGENITAL MIDLINE CERVICAL CORD AND CLEFT

Embryology

Congenital midline cervical cord/cleft (CMCC) is a rare congenital abnormality forming on the anterior neck which may extend to the mediastinum. It was first described by Bailey in 1924. Aetiology is unclear but it is felt to arise due to failed midline fusion of the second and third branchial arches.

Presentation

CMCC may present at birth with a cleft extending from the mentum to the sternum. There may be no external defect seen but a characteristic 'cord' seen or palpated below the skin when the neck is extended. If a cleft is present, serous discharge may be evident and the upper end will have a pseudonipple appearance.[23]

Imaging

CT or MRI allows characterization of the location and depth of the tract and differentiation from other midline congenital lesions.

Treatment

If there is no skin breakdown and the patient is asymptomatic, a conservative approach may be adopted. Surgery is indicated for cosmetic reasons and prevention of cervical contractures. Elective surgical excision is advocated using stepladder horizontal incisions or Z-plasty closure to avoid contracture (Figure 41.12).

SINUS STERNOCLAVICULARIS

Presentation

Sinus sternoclavicularis is usually present at birth with an asymptomatic sinus at or near the sternoclavicular joint, more often on the left side.

Imaging

Ultrasound allows characterization of the location and depth of the tract and confirmation of normal thyroid gland. Often no further imaging is required.

Treatment

If there is no skin breakdown and the patient is asymptomatic, a conservative approach may be adopted. Elective surgery is indicated for cosmetic reasons, usually involving excision of a blind-ending sinus which peters out adjacent to the sternoclavicular joint (Figure 41.13).

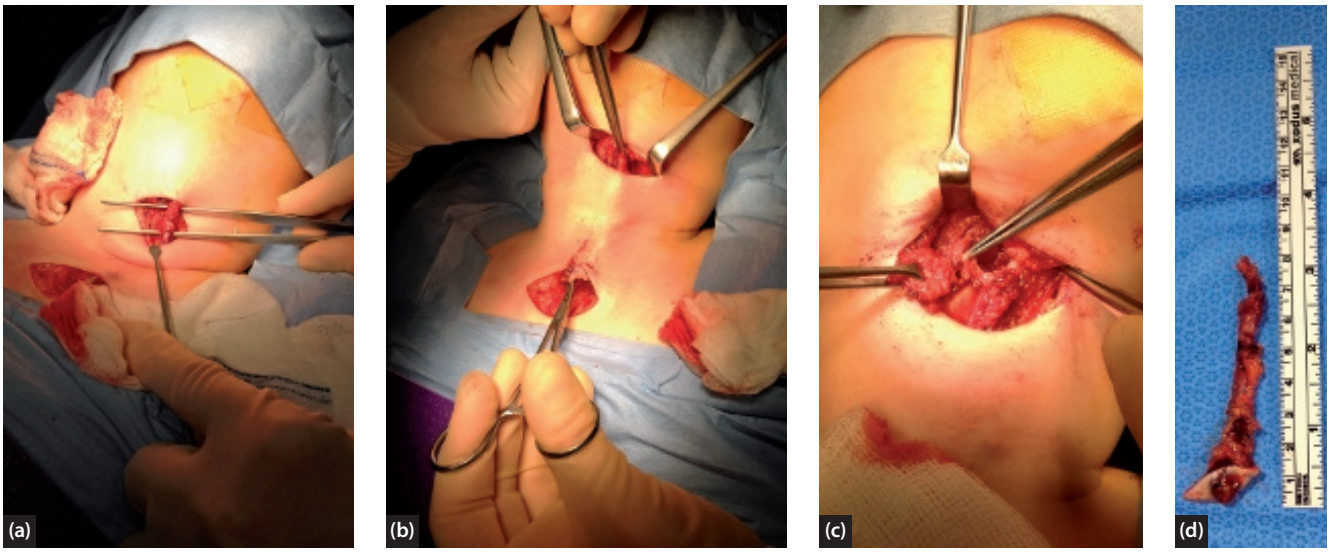

Figure 41.12 Unusual congenital midline cervical cord **(a)** with suprasternal sinus **(d)** removed using stepladder incision **(b)** attached to the thyroglossal tract **(c)**.

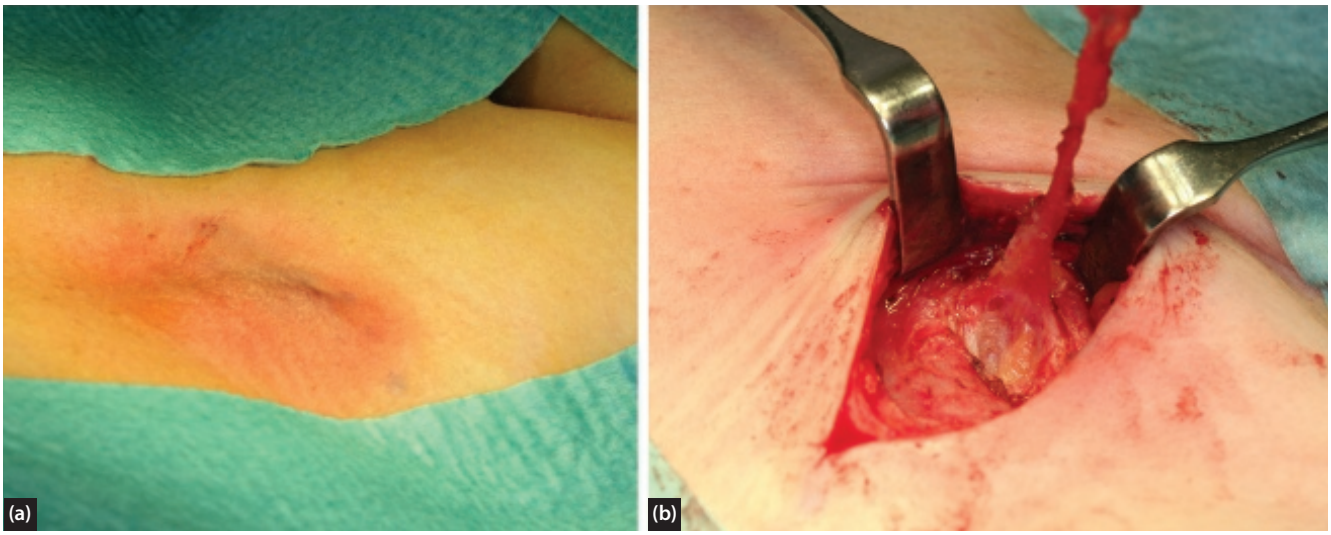

Figure 41.13 Excision of sinus sternoclavicularis.

KEY POINTS

- Congenital cervical anomalies can present as palpable cystic masses, infected masses, draining sinuses or fistulae.
- Thyroglossal duct cysts are most common, followed by branchial cleft anomalies and dermoid cysts.
- Branchio-oto-renal syndrome should be considered if bilateral preauricular pits and branchial sinuses present.
- Appropriate diagnosis and management of these lesions requires a complete understanding of their embryology and anatomy.
- Correct diagnosis, appropriate imaging, management of infection before planned surgery and complete surgical excision are essential to minimize recurrence.
- The extended Sistrunk's operation is the minimum procedure advised to reduce complication rate for thyroglossal cyst/ tract excision.

CHAPTER 42

HAEMANGIOMAS AND VASCULAR MALFORMATIONS

Daniel J. Tweedie and Benjamin E.J. Hartley

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: vascular anomaly, vascular malformation, lymphatic malformation, venous malformation and haemangioma.

INTRODUCTION

Vascular anomalies include a number of conditions of distinct pathology, which may be classified as either vascular tumours or vascular malformations. Historically, these diverse lesions have been poorly understood. This is reflected in varied and often incorrectly applied terminology, difficulties in diagnosis and inconsistent approaches to management. This chapter considers the advances in our understanding of vascular anomalies, the subsequent evolution of nomenclature, classification and current management strategies. Such considerations are central to the optimum treatment of children and adults with these conditions and their sequelae.

HISTORICAL PERSPECTIVES

Vascular anomalies were first described histopathologically by Virchow. He separated them into angiomas and lymphangiomas, with later classifications of both groups into simplex, cavernosum and racemosum, according to histological appearance.[1] This system took no account of the varied biological behaviour of these lesions, nor their clinical characteristics. Subsequent attempts at classification were based on pathological and embryological properties, which again failed to correlate well with clinical behaviour. Poor understanding was further compounded by the use of a multiplicity of descriptive terms (such as port wine stain and strawberry naevus), often erroneously or ambiguously for several pathologically distinct entities.

Edgerton in 1976 proposed a three-category system according to whether the lesions remained unchanged without treatment, resolved spontaneously or alternatively progressed and/or caused growth in surrounding structures.[2] While recognizing a range of outcomes, this scheme failed to consider the underlying histological basis for the observed clinical manifestations.

Mulliken and Glowacki in 1982 were the first to produce a practical clinical classification for vascular anomalies according to histological appearance, histochemistry and clinical behaviour, separating them into haemangiomas and vascular malformations.[3] This classification has been supported by subsequent clinical, radiological and biochemical studies.

Widespread confusion surrounding terminology and appropriate management of vascular anomalies persists nonetheless. This chapter addresses the biological basis, clinical manifestations and natural history of these distinct diseases, the understanding of which is central to their proper management.

CORRECT NOMENCLATURE

The dichotomous biological system of Mulliken and Glowacki[3] originally considered vascular lesions in infants and children as haemangiomas (with proliferating and involutional phases) or malformations (capillary, venous, arterial, lymphatic and fistulae). This simple classification has since been modified somewhat by the International Society for the Study of Vascular Anomalies (ISSVA) in 1996, taking into account advances in histopathology, histochemistry and radiological imaging (**Box 42.1**).[4] **Vascular tumours** now represent a group of lesions which includes haemangioma subtypes in addition to other rarer tumours, and **vascular malformations** are now described according to whether they are **slow-flow**, **fast-flow** or **complex**. In parallel with these adjustments, the ISSVA has recommended that older terms such as 'angioma' and 'birthmark' should be discarded. The suffix -oma should be used only in the context of a proliferating tumour and should therefore not be applied to vascular malformations.

BOX 42.1 Updated ISSVA classification of vascular anomalies (1996)[4]

Vascular tumours	Vascular malformations

• Infantile haemangiomas
• Congenital haemangiomas (RICH, NICH)
• Tufted angioma (with or without Kasabach–Merritt syndrome)
• Kaposiform haemangioendothelioma (with or without Kasabach–Merritt syndrome)
• Spindle-cell haemangioendothelioma
• Other rare haemangioendotheliomas
• Dermatological acquired vascular tumours (pyogenic granuloma, targetoid, glomeruloid and microvenular haemangiomas)
	Slow-flow malformations
	• Capillary malformation (CM)
	  • Port wine stain
	  • Telangiectasia
	  • Angiokeratoma
	• Venous malformation (VM)
	  • Common sporadic VM
	  • Bean syndrome
	  • Familial cutaneous and mucosal VM
	  • Glomerulovenous malformation
	  • Mafucci syndrome
	• Lymphatic malformation
	Fast-flow malformations
	• Arterial malformation (AM)
	• Arteriovenous fistula (AVF)
	• Arteriovenous malformation (AVM)
	Complex combined vascular malformations
	• CVM, CLM, LVM, CLVM, AVM-LM, CM-AVM

C, capillary; V, venous; L, lymphatic; AV, arteriovenous; M, malformation; RICH, rapidly involuting congenital haemangioma; NICH, non-involuting congenital haemangioma.

VASCULAR TUMOURS

Vascular tumours may or may not be present at birth, and grow by cellular (predominantly endothelial) hyperplasia. Haemangiomas are certainly the commonest type although a number of other vascular tumours are occasionally seen, most often acquired, sometimes in the presence of syndromes. Advances in histopathology have allowed further subdivision within these groups adding to the original haemangiomas grouping of Mulliken and Glowacki.

HAEMANGIOMAS

Presentation and natural history

Haemangiomas are the commonest tumours in white infants, present in up to 10–12%.[5] Two-thirds are found in the head and neck, with a female : male ratio of 3–5 : 1. This is in contrast to vascular malformations, which have no gender preponderance. Extremely premature infants (birth weight <1000 g) are at particular risk, with around 30% affected. They are less common in non-Caucasians. Most lesions are solitary, with multiple cutaneous lesions being associated with a higher risk of visceral involvement. Facial haemangiomas tend to be found in a segmental distribution, and particularly along lines of embryological fusion.

Haemangiomas have recently been subdivided according to presentation and behaviour as **congenital**, by definition present and obvious at birth, and **infantile**, the commoner variants, which usually proliferate from original pink macules during the first 2 months of life.[6] Congenital haemangiomas (CH) have been further categorized by rate of involution as **rapidly involuting** (RICH), **non-involuting** (NICH) or **non-progressive**.

Their precise appearance may vary significantly according to their depth (superficial, deep or visceral) and subsite, but location does not influence biological behaviour (**Figures 42.1** and **42.2a**). Cutaneous lesions may appear as a patch of erythema, a blanched area or telangiectasia with a peripheral pale halo, and they may be confused with other vascular anomalies such as venous malformations. The child may alternatively present primarily with visceral

Figure 42.1 Cutaneous frontal haemangioma, infantile type. This child presented at the age of 2 months with worsening stridor secondary to a subglottic haemangioma.

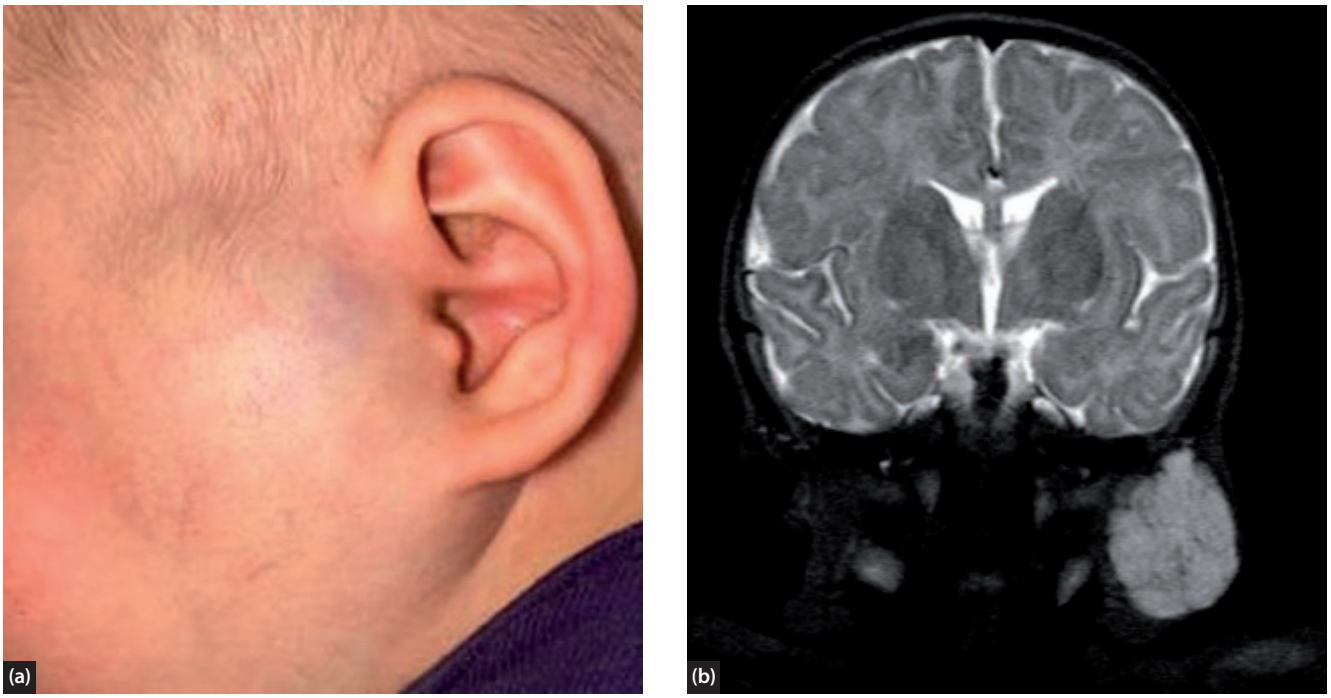

Figure 42.2 Parotid haemangioma. (a) Clinical appearance. Note the blue hue, hence the differential diagnosis of vascular malformation. **(b)** Coronal T2-weighted MRI of the same patient. The haemangioma is of moderately high-signal intensity, with small, scattered linear flow voids of associated vessels.

manifestations (such as stridor secondary to a subglottic haemagioma): only a small proportion of patients with cutaneous disease will also have visceral lesions, but around 50% of those with visceral haemangiomas will have no cutaneous manifestation. The overall picture, certainly for the infantile type, is one of proliferation and rapid tumour growth, resulting in a tense and minimally compressible mass which will tend to plateau in size by 4–8 months of life. This is reflected by progressive cutaneous and/or visceral effects which develop during early infancy. Alternatively, the progress of CH is more variable. Together with their presence at birth, this variability may also promote confusion with vascular malformations.

Involution of haemangiomas tends to begin at around 1 year of age, and continues for the next 5–7 years.[6, 7] An overlapping period of proliferation and involution may be seen.[5, 7] Some 50% of haemangiomas will have completely involuted by the age of 5 years and 70% by 7 years with some further involution seen in the remainder by age 12. The only factor associated with improved outcome is an early age of first involution. Importantly, patients and parents should be aware that permanent skin changes (loose skin, altered colouration, telangiectasia and scarring) may occur in over 50%, even after complete tumour involution.[7]

Most cases have no obvious genetic basis, although some may be inherited in an autosomal dominant fashion, with a possible locus on chromosome 5q.[8] Associations have also been noted. Large cervicofacial haemangiomas are seen in conjunction with other malformations in about 10% of cases (PHACES syndrome: **P**osterior cranial fossa malformation, including Dandy–Walker; **H**aemangiomas; **A**rterial anomalies, including absent carotid or vertebral vessels; **C**ardiac anomalies; **E**ye anomalies; **S**ternal anomalies, bifid or cleft).[9]

The majority of those affected are girls (90%), with a particular risk of thromboembolic stroke in childhood. Otherwise, there is thought to be an increased likelihood of laryngeal involvement in those with a facial haemangioma in a beard distribution,[10] and spinal, anorectal or urogenital abnormalities in patients with lumbosacral lesions.

Cellular basis

Histologically, haemangiomas comprise proliferating immature endothelial cells and disorganized vessels. Various theories for the development of haemangiomas have been proposed.[11] They are thought to arise as a result of abnormal angiogenesis, which leads to uncontrolled endothelial proliferation. This may be due to **intrinsic** endothelial cell anomalies (favoured by the chromosome 5q inheritance patterns), resulting in hyperplasia from a single abnormal cell, and/or as a result of an abnormal, **extrinsic** cellular environment. Implicated in either process is an interplay between a variety of angiogenetic markers, including fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF), and angioinhibitory substances, such as tissue metalloproteases. Glucose transporter-1 (GLUT-1) is a specific marker for infantile haemangiomas, with 97% of these lesions testing positive for this.[12, 13] GLUT-1 is otherwise only found in the placenta and endothelium of the blood–brain barrier. This may have implications for the diagnosis and management of infantile haemangiomas versus other lesions, which will not have the same cellular markers, and respond differently to treatments including propranolol. Apart from endothelial cells, other lineages are also involved, including mast cells, fibroblasts and macrophages. The up- and

down-regulation of these cells at various times is believed to account for the variability in proliferation and involution manifested clinically.

Diagnosis

The mode of diagnosis will depend typically upon the site and clinical presentation. Cutaneous lesions are most often diagnosed clinically, although they may be difficult to distinguish from the main differential diagnoses, namely macular stains, vascular malformations and other rarer vascular tumours.

Macular stains are common vascular cutaneous lesions, also known by a number of terms such as 'stork bite' or 'salmon patch'. These are flat, usually pink to red, and are typically seen on the face or neck. They are physiological and will tend to resolve, without the dramatic proliferation exhibited by haemangiomas. Vascular malformations are usually distinguished by being present at birth and growing proportionally with the child, although these differences may be subtle, particularly in congenital cases during infancy.

Investigations may be required in those difficult cutaneous cases or where visceral involvement and/or other associations are suspected. Diagnostic imaging, in the form of ultrasound, magnetic resonance imaging (MRI), computerized tomography (CT) with contrast or arteriography will usually distinguish haemangiomas very well. For deeper lesions, MRI is preferred, demonstrating a lobulated soft-tissue mass with flow voids (feeding and draining vessels). The mass is iso- or hypo-intense on T1 and hyper-intense on T2 weighting, respectively (**Figure 42.2b**). Alternatively, other modes of tailored investigation, such as diagnostic microlaryngobronchoscopy, may be appropriate for visceral lesions.

Complications

The sequelae and complications of haemangiomas will depend upon their anatomical subsite, size and depth. There may also be complications associated with related pathologies.

Permanent skin changes and cosmetic abnormalities are anticipated in a significant proportion of cases, particularly those with large superficial facial lesions and where involution has been slow or incomplete.[7] Excisional surgery and scar management (by means of Z-plasty and other releasing techniques) may be indicated. Ulceration affects fewer than 5% of cases. This is most commonly seen with perioral and perineal lesions, perhaps related to increased day-to-day skin trauma in these areas. The risks of associated infection are significant. Scrupulous wound care and antibiotic ointments may allow these areas to resolve, but excision or medical treatment may be required.

Obstruction of the visual axis by periorbital haemangiomas is occasionally seen, and demands a circumspect, multidisciplinary management approach. In the case of large periorbital lesions, vision may be obstructed as a result of the haemangioma protruding across the globe, or alternatively pressing on and distorting the cornea. In rarer instances, intraorbital lesions may compress the conal muscles, producing diplopia. The mammalian visual cortex is extremely sensitive to stimulus deprivation during the first year of life, such that permanent amblyopia may develop within as little as 1 week of such insults. Urgent referral to a paediatric ophthalmologist is therefore mandatory, stressing the importance of treatment without delay.

The ear canal may also become obstructed by parotid haemangiomas, occasionally resulting in conductive hearing loss, with the secondary risk of speech delay.[5] Active treatment should be considered in these circumstances, particularly for rare bilateral lesions, albeit on a non-emergency basis.

Airway obstruction by haemangiomas may occur at several possible levels, and it should be noted that in up to 50% of cases there may be no cutaneous manifestation to raise diagnostic suspicion. Nasal obstruction from cutaneous haemangiomas is often obvious, although endonasal disease may lead to insidious, progressive obstruction in infants, who are obligate nasal breathers. Subglottic haemangiomas (**Figure 42.3**) typically present with progressively worsening stridor from 2–3 months,

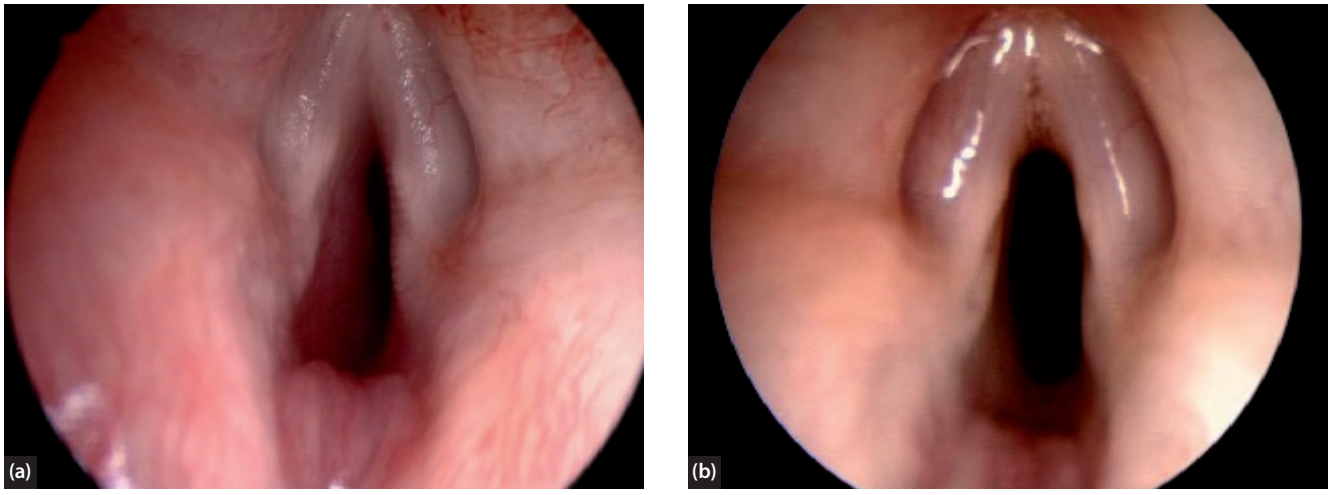

Figure 42.3 Subglottic haemangioma. (a) First presentation in a 3-month-old infant. **(b)** Same patient aged 6 months, after 3 months' treatment with propranolol.

with eventual airway obstruction, in the absence of other obvious precipitants or symptoms. Medical treatment with propranolol is now the mainstay of management of these cases, although tracheostomy and/or open excision via laryngofissure are occasionally still required.

Congestive cardiac failure is an unusual complication, seen most often in the context of either diffuse disease in the neonatal period or alternatively as a result of arteriovenous fistulation within large visceral haemangiomas, causing cardiac insufficiency.[10]

Management

Assuming a correct diagnosis is reached as early as possible, treatment of haemangiomas should be tailored according to the individual patient, taking into account the local and systemic effects of lesions and associated complications. For the majority of haemangiomas, particularly smaller ones, active monitoring and reassurance for the parents will usually suffice. But it is worth emphasizing that the onset and rate of involution are variable, and residual tumour, scarring and other skin changes may compromise the final cosmetic outcome. Lesions which are larger and affect function, or those resulting in significant complications, will usually require non-surgical treatment (typically propranolol) and/or surgical intervention. This is most appropriately delivered in a multidisciplinary setting, combining dermatologists, paediatricians and plastic, general paediatric and ENT surgeons as necessary. The merits of any intervention, medical and/or surgical, must be evaluated in each case, bearing in mind the long-term risks of waiting for natural resolution. Additionally, most medications are not licensed for these applications in young children, which should also be explicit from the outset.

Non-surgical treatment: Propranolol

Propranolol has revolutionized the management of children requiring active treatment for haemangiomas, largely replacing other medical treatments and, in many cases, surgery. Its efficacy was first described by Leauté-Labrèze and her team from Bordeaux, France, who noted a dramatic reduction in size of a nasal haemangioma in a child receiving propranolol for cardiomyopathy.[14] The mechanisms of action are not entirely clear. Vasoconstriction, a direct beta-blocker effect, will allow the haemangioma to become softer and paler, often within 24 hours of treatment, with decreased expression of FGF and VEGF and promotion of apoptosis perhaps accounting for accelerated resolution. Cyclic AMP (cAMP) and tyrosine kinase pathways are also now thought to mediate the actions of propranolol in promoting apoptosis.[15, 16]

Following successful use locally[17] at other paediatric centres, propranolol is the preferred option for children with subglottic haemangiomas and, with time and a better appreciation of the sequelae of propranolol use in children, this treatment can be considered for haemangiomas in other locations, particularly those impacting the vision, other functions, and large lesions in cosmetically sensitive areas. Patients are often managed jointly by ENT and dermatology departments, with additional input from other specialities as required. A full clinical assessment is made prior to treatment, and a number of blood tests are organized (to exclude anaemia, coagulopathy, diabetes, and renal, hepatic and thyroid abnormalities). Baseline pulse and blood pressure assessments, electrocardiography and echocardiography are also mandatory. Further radiological imaging and other investigations may be arranged in addition to the original diagnostic methods (including microlaryngobronchoscopy).

Although the precise regime varies between centres, a consensus statement in 2012 suggested a target dose of 1–3 mg/kg per day in three divided doses, after appropriate screening.[18] In our practice, propranolol is commenced at 1 mg/kg/day, in three divided oral doses. At this point, and at any time the dose is increased, pulse rate and blood pressure are checked every 30 minutes for the first 2 hours before allowing the child home. The dose is increased to 2 mg/kg/day after the first week of treatment, with further adjustments over the coming months to match the child's weight gain. Blood pressure is checked twice weekly for the first 2 weeks, and then weekly thereafter. Side effects are sought, typically minor (weakness, fatigue, altered sleep) or occasionally major (bronchospasm, hypotension, bradycardia and hypoglycaemia), although these are more often seen in neonates than in older children. Propranolol should not be used in asthmatics, or together with salbutamol and other selective beta-2 agonists.

Serial assessment (clinical and endoscopic, in the case of subglottic lesions) allows monitoring of initial response to propranolol. This is typically done at 6 weeks and then 3-monthly for the first year, covering the proliferative phase of disease. Weaning from propranolol in stages may then be possible, usually over about 4 weeks.

The response of infantile haemangiomas to propranolol occurs within a few days, during the proliferative period in 97% of cases.[19] Where minimal response is seen, one should consider differential diagnoses, and biopsy of the lesion, with staining for GLUT-1.

For smaller, superficial lesions, topical timolol has shown some benefits in the treatment of infantile haemangiomas.[20, 21]

Non-surgical treatment: Other

In some cases, the response to propanolol is less dramatic. In these circumstances, other medical treatments may be considered. These include corticosteroids, once the mainstay of medical management. Previous studies have confirmed resolution rates reaching 90% for haemangiomas treated with prednisolone 2–3 mg/kg/day, tapered down over several months.[22] But side effects are unfortunately frequently seen, including rebound lesion growth, Cushingoid facies, altered mood, gastritis and growth retardation. Oral steroids are therefore now seldom used for haemangiomas in our practice, given in conjunction with propranolol if the initial response to this has been limited, or if the lesions are large and complicated.

Injection therapy with corticosteroids and alpha-interferon has been used historically, with variable success reported, mainly for those patients with poor response to oral steroids. Similarly, systemic chemotherapy (with cyclophosphamide and vincristine) and radiotherapy have both been shown to arrest the proliferative phase of haemangiomas. However, these modalities may all produce serious local and systemic side effects and are not used routinely in our current practice. Other non-surgical treatments have included cryotherapy. While effective in some superficial lesions, it often results in unacceptable scarring, and has therefore fallen out of favour.

Compression therapy has been attempted, although formal data regarding its efficacy are lacking, and it is not usually a practical option for head and neck lesions, particularly in infants. Embolization is occasionally attempted for larger, highly vascular haemangiomas, particularly those associated with life-threatening complications. This is most often done to facilitate surgical excision, although there are reports of embolization alone leading to rapid regression.[23]

Surgical treatments

Excision, via a variety of methods, remains a reasonable option in some cases, particularly those with poor response to propranolol and other medical treatments. Alternatively, as a primary treatment, direct excision of cutaneous and subglottic disease, for example, will have the potential for complete cure from the outset, in contrast to medical therapy which requires a long period of treatment, regular follow-up and carries significant risks of its own. The relative benefits of surgery in this context should not be overlooked, and must form part of the initial multidisciplinary discussion of treatment options. It is also very reasonable in some cases to employ a dual modality approach, using propranolol to reduce proliferation, followed by excision as necessary.

Laser therapy, using a variety of types (carbon dioxide, pulsed dye, Nd-YAG, argon and KTP) has been used predominantly for cutaneous lesions. Partial laser-assisted excision of lesions around the eye, for instance, allows rapid clearance of the visual axis, in contrast to medical treatment, which may take longer to achieve the same effect. The laser energy may be delivered superficially or intralesionally, particularly for deeper haemangiomas. The authors caution against laser treatment for subglottic haemangiomas because of the risks of circumferential scarring and stenosis, and favour open excision via laryngofissure as a second-line treatment after propranolol.

OTHER VASCULAR TUMOURS OF CHILDREN

Kaposiform haemangioepitheliomas

Kaposiform haemangioepitheliomas are vascular tumours which behave far more aggressively than simple haemangiomas, from which they have only recently been definitively distinguished. They are often associated with thrombocytopaenia, known as Kasabach–Merritt syndrome (KMS). Consumptive thrombocytopaenia is believed to occur as a result of platelet trapping within extensive lesions. This may itself result in secondary coagulopathy, as clotting factors and fibrinogen are used up. Disseminated intravascular coagulation may then develop, with an overall mortality risk in KMS of 30–50%.[24] Importantly, in contrast to previous suggestions, KMS is not associated with simple haemangiomas.

Kaposiform haemangioepitheliomas can be distinguished clinically, histologically and radiologically from haemangiomas. Both may be seen congenitally, but haemangioepitheliomas tend to have equal gender incidence, and are more often seen outside the head and neck, sometimes in the retroperitoneum. Traditional therapeutic options have been similar to those for haemangiomas, although high-level evidence for these treatments in this context is lacking. In practice, given the high risk of KMS and other serious complications, multimodality treatment is often used, including corticosteroids, chemotherapy, embolization and/or excision, together with parallel treatment of coagulopathy. Propranolol has also been used with some success in a small number of cases, prescribed long-term after a brief initial course of chemotherapy.[25] It is important that heparins should not be used to manage the thrombocytopaenia of KMS, as they may lead to increased FGF release, itself associated with increased tumour proliferation.

Tufted angiomas

Tufted angiomas – also known as angioblastomas – are very similar to kaposiform haemangioepitheliomas. Indeed, these lesions may represent a spectrum of pathology rather than separate entities. KMS may complicate tufted angiomas in the same fashion, and treatment options are similar.

Pyogenic granulomas

Pyogenic granulomas are acquired vascular lesions which are very similar in appearance to haemangiomas but are typically seen in older children and young adults. In contrast to popular belief, they tend to arise suddenly and without a history of trauma. Treatment options include surgical excision, laser ablation and chemical or electrocautery.

Haemangiopericytomas and angiosarcomas

Congenital haemangiopericytomas are very rare tumours, found in the extremities of newborns. Biopsy and surgical excision may be required.

Angiosarcomas are uncommon malignancies in children. They typically arise in the liver and behave aggressively, metastasizing to the lungs. Prognosis is very poor.

VASCULAR MALFORMATIONS

Vascular malformations, in contrast to vascular tumours, have normal endothelial mitotic activity and are errors of morphogenesis.[4] They are present at birth, although some may not initially be obvious, and they grow with the child. They do not involute, but may vary in size with time according to inflation with fluid and/or blood and subsequent deflation. At a molecular level, the markers of proliferation (such as VEGF and FGF) and endothelial proteins (GLUT-1, merosin, Fcγ receptor II), seen frequently in association with vascular tumours, are not usually elevated in vascular malformations.

The clinical impact of these lesions is very variable, depending on location, size, subtype and shunts, ranging from mild cosmetic deformity to life-threatening airway obstruction or haemorrhage. Several varieties are described, according to their cellular components and flow characteristics (**Box 42.1**). These distinctions greatly influence appropriate management. Vascular malformations are associated with skeletal abnormalities in up to 35% of cases and other malformations and syndromes.

SLOW-FLOW VASCULAR MALFORMATIONS

Capillary malformations

Capillary malformations (CMs) occur in 0.1–0.3% of live births,[26] although they may be overlooked in the neonatal period as a result of generalized plethora and/or anaemia. Most involve the head and neck, particularly in the distribution of the trigeminal nerve (**Figure 42.4**). They consist of postcapillary venules within the papillary and superficial reticular layers of the dermis, hence the alternative term **venular malformations**. Initially presenting as flat, pink areas, they have a tendency to darken in colour with age (port wine stain) and to thicken, with a cobblestoned surface in two-thirds of affected adults. Some will develop associated pyogenic granulomas. This evolving appearance is believed to result from abnormal neural modulation of the sympathetic papillary plexus, with vessel thickening and dilatation in the absence of proliferation. Lesions may be graded I–IV (the Waner classification) according to the degree of vessel ectasia, thought to be related to the degree of sympathetic denervation.[27] This system correlates well with clinical severity and treatment outcomes.

Figure 42.4 Capillary malformation in the distribution of the maxillary division of the trigeminal nerve. Even in an infant, the skin in this affected area is slightly thickened and raised. Without treatment, this thickening is likely to progress with time.

Although most cases are isolated, some may be associated with syndromes and/or other vascular malformations. These include Sturge–Weber syndrome: CM in the distribution of the ophthalmic branch of the trigeminal nerve (CN V1), seizures of neonatal onset, cataracts, learning difficulties and ipsilateral leptomeningeal angioma. Importantly, patients with large facial CM in the distribution of V1 may have ocular involvement, including glaucoma, and/or central nervous system involvement without other features of Sturge–Weber syndrome. Klippel–Trénaunay syndrome (CM, varicose veins, central visceral varices, lower limb hemihypertrophy) is rarer, with complications including variceal haemorrhage and thromboembolic events. These features together with the addition of an arteriovenous malformation (AVM) comprise the Parkes Weber syndrome, presenting in childhood with an enlarged, warm extremity.

Rarer associated syndromes are also described, such as Cobb syndrome (CM overlying the spine, with associated spinal meningeal vascular malformations) and Wyburn-Mason syndrome (facial CM with associated unilateral AVM of the retina and intracranial optic pathway).

In keeping with other vascular malformations, CM may be associated with skeletal and limb abnormalities, even in the absence of other syndromic features.[28] This is particularly the case for lesions overlying the spine, especially if these are multiple and lumbar, for which MRI is indicated.

TREATMENT

In the first instance, careful clinical assessment should confirm the diagnosis, although further investigations (including imaging) may be necessary to exclude associated pathology. For example, suspected syndromic cases should undergo MRI (with gadolinium enhancement) to exclude cerebral and spinal lesions, although these may not always be evident in early life, such that serial scanning may be necessary. A supportive, multidisciplinary approach to treatment and follow-up is essential in these cases, often requiring parallel ophthalmological and neurological/neurosurgical input.

At a simple level, cosmetic cover-up creams may be beneficial. Tattooing with skin-coloured pigments has also been used, albeit not in routine practice. Neither of these approaches, however, will alter the lesions' natural history. Any specific treatment of CM must take into account a typically progressive deterioration in appearance, which may be accelerated by trauma and puberty,

and its associated psychosocial impact. Earlier intervention is therefore now considered in some centres, even before 1 year of life, although the relative benefits of such early therapy are likely to be more psychosocial than physical, and have not been unequivocally demonstrated.

Treatment options depend to some extent on vessel diameter. Pulsed dye laser is widely accepted as the treatment of choice for CM,[29] targeting the oxyhaemoglobin chromophore in abnormally dilated superficial vessels to allow selective thermolysis. Ultra-short laser pulses are used, particularly at wavelengths of 577 nm or 585 nm, limiting lateral thermal injury and related risks of scarring. Some lesions, particularly those which are thicker and more cobblestoned, may not respond well to pulsed dye laser, in which case other lasers (KTP, copper, argon) may be used, although scarring, hyper- and hypo-pigmentation are more likely.

Multiple treatments are typically needed, between two and six on average. Reviews of various studies suggest that the response will vary according to depth, colour and location of the lesion (best on the neck, then torso and face, worst on the hand and arm), as well as the extent of previous therapy and the age of the patient, although the optimum treatment age is not known. Recurrence of CM is common in these circumstances, up to 50% at 4–5 years, most probably representing persistence of vessels innervated by the abnormal papillary plexus. Interval treatments which touch up areas of residual vessel ectasia are therefore an alternative strategy. Depending on forthcoming clinical trials, future options might include laser speckle and photoacoustic imaging to allow more precise assessment of the local effect of laser treatment, or alternatively treatment with anti-angiogenic compounds such as imiquimod (used primarily, or just after laser therapy).[30, 31]

OTHER VARIANTS OF CAPILLARY MALFORMATIONS

Telangiectasias, visible dilated vessels in the skin or mucosal surfaces, are very common in the population, increasing in incidence with age. The great majority are **primary** or **essential**, with no obvious precipitant. In many cases, telangiectasias are found in a symmetrical malar distribution. Alternatively, **generalized essential telangiectasia** affects a smaller number, typically seen first on the distal lower limbs, then more proximally. The pathophysiology is unknown. Treatment options include active monitoring, cover-up creams, topical agents (including ketoconazole), systemic treatments (such as tetracyclines and acyclovir) and pulsed dye laser. **Secondary telangiectasias** are seen in systemic disorders such as hereditary haemorrhagic telangiectasia and chronic liver disease.

Angiokeratomas are vascular ectasias which involve the papillary dermis. Several variants are described, with elements of papillomatosis and hyperkeratosis in addition to vascular dilatation. Like other CMs, some have associations including Klippel–Trénaunay syndrome and Cobb syndrome. Importantly, some variants including **angiokeratoma circumscriptum** may be mistaken for melanoma; excision biopsy is indicated in these circumstances. Appropriate treatment depends on the subtype, with options including observation, laser therapy or excision.

Venous malformations

Venous malformations (VMs) are characterized by abnormal collections of veins, typically without a uniform smooth muscle layer, which have no demonstrable endothelial or pericyte mitotic activity and no increased expression of VEGF or FGF.[32–34] They are usually solitary and sporadic (**common sporadic**), but some patients have multiple lesions which may have an inherited basis, and a thorough family history should be sought. An autosomal dominant form results in a subtype termed **multiple glomangiomas**, and a number of other rare familial forms exist. These include Bean syndrome (blue rubber bleb naevus syndrome, BRBNS), characterized by multiple cutaneous VMs in association with visceral VM, particularly affecting the gastrointestinal tract and occasionally the airway (**Figure 42.5**). These carry a risk of life-threatening haemorrhage and often require endoscopic treatment. Patients with Turner syndrome may also have intestinal or lower limb VM. Recent work suggests that an abnormal gene on chromosome 9p coding for an endothelial receptor may be responsible for some familial disease.

All VMs are congenital, although again some are not initially apparent. Presentation is variable, depending upon size, depth and anatomical location. They most often involve the skin of the face, limbs and trunk, but they may also be found in viscera, including the aerodigestive tract, muscle and bones, particularly the mandible. Clinical manifestations therefore vary accordingly, but in general VMs increase in size as the child grows, do not regress, and may swell as a result of raised venous pressure (Valsalva manoeuvre, straining or crying, or when placing the patient with the affected area below the level of the heart, increasing venous drainage to the lesion). Thrombotic events and local infection, with resulting phleboliths, may alter their consistency with time, from soft and compressible to tender, lumpy lesions, especially as more blood flows in but cannot easily drain out. Pain from venous stasis and thrombosis is a strong diagnostic pointer to VM, rather than other vascular malformations. Associated bleeding may occur, in addition to low-grade consumptive coagulopathy.

TREATMENT

The diagnosis of VM is typically clinical, with biopsy undertaken only if there is any doubt. Imaging is usually warranted, both to determine the extent of lesions and to assess relations to large vessels and other hazardous structures. MRI is the most informative modality for deeper lesions, but CT and ultrasound are also helpful.

Many VMs are managed by reassurance and monitoring. Aspirin and compression may be used to limit thrombotic events.[35] Pain is one of the commoner indications for

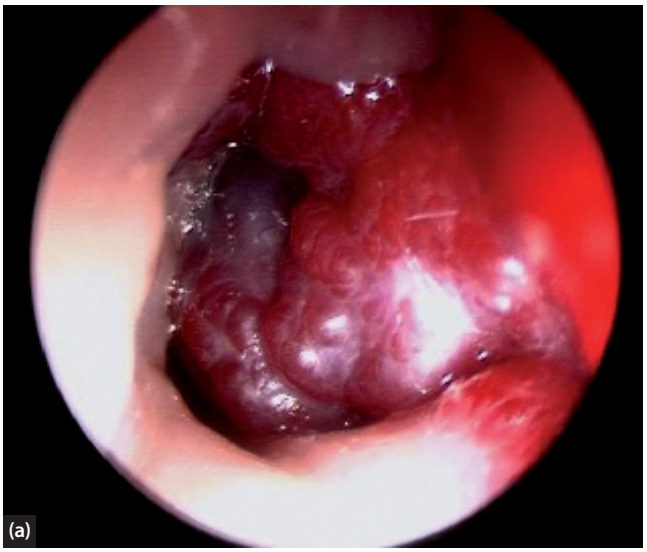

Figure 42.5 Venous malformation. **(a)** Large venous malformation of the upper trachea. This 15-year-old patient recently developed cutaneous venous malformations of the feet, suggesting the diagnosis of blue rubber bleb naevus syndrome. **(b)** Coronal T2-weighted MRI of the same patient, demonstrating numerous venous malformations of the upper aerodigestive tract.

active treatment, although this may also be considered for bleeding, cosmetic and functional reasons, depending on lesion location and size. Once again, a multidisciplinary approach should be adopted, as combinations of treatment, repeated visits and psychosocial support are often necessary.

Sclerotherapy is the primary non-surgical treatment for VM, performed by interventional radiologists under general anaesthesia. Typically, 3% sodium tetradecyl sulphate (STS), instilled as a foam under fluoroscopic guidance, is used. Alternatives at other centres include 95% ethanol and Ethibloc® (ethanol and cornflour), although the risks of tissue necrosis and neurological injury (e.g. the facial nerve branches) have been relatively high in our experience.[36] No controlled trials have assessed the relative efficacy of these agents. Single treatments, with post-injection compression and observation, may be suitable for smaller lesions, but repeated injections and compression are often required for larger VMs. With all forms of sclerotherapy, patients and parents should be aware of significant risks to local soft tissues and nerves, post-operative swelling, secondary infection and the additional risks of communication with deeper structures via fistulous channels, hence the need for prior assessment and imaging.

Superficial components of VM, or entirely superficial lesions, may be treated with laser. Nd:YAG is preferred, owing to the size of the vessels. This may be used in isolation, but it also offers the option of reducing vessel bulk in the skin, thereby facilitating surgical access to deeper components of extensive lesions.

Surgical excision is often extremely challenging. In addition to the friable, vascular nature of excised tissue, VMs often have large communications with major veins, particularly in the head and neck. Complete excision is required to eliminate the risks of recurrence, but the merits of this have to be balanced against major risks. As a result, surgery is often staged and/or combined with sclerotherapy and laser treatment, highlighting the importance of a long-term team approach to management.

Lymphatic malformations

Lymphatic malformations (LMs) are low-flow vascular malformations resulting from abnormal embryologic development of regions of the lymphatic system, although the precise mechanisms are uncertain. The overall result is a collection of varying-sized lymphatic spaces and channels, instead of the normal regular network of fine channels in the dermal papillae which travel to deeper lymphatics, with one-way valves to limit backflow. LMs are found in the head and neck in 75% of cases, from where they may extend into the thorax.

With an overall incidence of some 1:5000, LM accounts for 6% of all paediatric soft-tissue masses.[36, 37] Around half are diagnosed at birth and 90% by 2 years of age, although presentation is variable. This, together with eventual treatment options, depends on the extent of disease and its location, but also upon the size of cysts within it. **Macrocystic** refers to disease with a few large cysts (volume >2 cm^3) and **microcystic** to disease with smaller cysts, but in reality most lesions contain a mixture. Common presentations include cystic masses in the neck and face, but sublingual and tongue base disease may lead to macroglossia, progressive airway obstruction and mandibular distortion. As with other vascular malformations, LMs exhibit commensurate growth with the child. However, although they are usually initially soft and fluctuant, they tend to become firm and lumpy

with time, particularly after respiratory tract infections. Interestingly, these events may also lead to sclerosis within the lymphatics and eventual reduction in size, although the disease does not regress *per se*.

Several classification systems exist based on location. We prefer the dichotomous type 1 and type 2. Type 1 lesions are found below the level of the mylohyoid muscle, in the anterior and posterior triangles of the neck (Figure 42.6). They are more often predominantly macrocystic, and have a better prognosis. Type 2 lesions are found above the mylohyoid, involving the oral cavity, cheek and parotid regions (Figure 42.7). They are more microcystic, responding less well to treatment. In reality, a number of patients have cervicofacial disease of both types.

Alternatively, the De Serres staging proposal has been used.[38] LMs are staged I–IV:

- **Stage I:** unilateral infrahyoid
- **Stage II:** unilateral suprahyoid
- **Stage III:** unilateral suprahyoid and infrahyoid
- **Stage IV:** bilateral suprahyoid.

These stages correspond to the cyst size, functional deficits and treatment complexity associated with the distribution of disease. Low and lateral disease is generally macrocystic, relatively easily managed by surgery or sclerotherapy, with cosmetic but less significant functional deficits. High and medial disease is typically microcystic, involves the face and/or upper aerodigestive tract, and may require tracheostomy and long-term, multimodality treatment.

The diagnosis is usually obvious clinically, although single large cysts may be mistaken for other pathology in particular areas. These include the floor of mouth (ranula) and the lateral neck (branchial cyst, thymic cyst), for example. Imaging (particularly T2-weighted MRI) is useful in these circumstances, especially when treatment is considered, although the diagnosis may remain in doubt in some cases (see Figure 42.7). MRI will certainly help to differentiate macro- and microcystic disease, as well as demonstrating relations to surrounding structures, informing further management.

TREATMENT

As in the case of other vascular malformations, we manage LMs in a multidisciplinary setting. The most appropriate treatment options will be directed by age, the nature of the disease, related symptoms and the wishes of the parents and child. Some smaller, asymptomatic LMs may require no treatment at all, and are simply monitored, but the majority will require some form of therapy, because of relentless increase in size.

In terms of active treatment, our main options are sclerotherapy and surgery, used in isolation[37] or in combination.[36] In broad terms, surgical excision is the only means of achieving complete elimination of disease and cure, thereby offering a one-stop treatment option in selected cases (see Figure 42.6). In reality, the mixed cystic nature of many LMs and their complex anatomy means that they often require multimodality management, delivered in multiple stages. It should also be borne in mind that LM may cause significant bulk-related complications, such as airway obstruction, particularly in the neonatal period. Urgent interventions, such as tracheostomy and debulking surgery, may be required in advance of attempts at definitive treatment.

Sclerotherapy is performed by interventional radiologists under general anaesthesia, with fluoroscopic control. This form of treatment may be used at any time, including the neonatal period, as required. OK-432 (Picibanil, an inactive strain of group A *Streptococcus pyogenes*) was commonly

Figure 42.6 Lymphatic malformation: macrocystic, cervical disease (type 1). (a) Clinical appearance, aged 3 years. **(b)** Axial T2-weighted MRI of the same patient. The lesion consists of a few large fluid-filled cysts, of high-signal intensity, in the posterior triangle of the neck. **(c)** Appearance 3 months after uncomplicated surgical excision.

Figure 42.7 Mixed micro- and macrocystic lymphatic malformation of the tongue, floor of the mouth and upper neck (type 2 disease) in a 1-year-old infant (tracheostomized). (a) Gross enlargement of the tongue, protruding further as a result of disease in the floor of mouth. Note the microcystic disease on the dorsum, amenable to radiofrequency ablation (coblation). **(b)** Coronal T1-weighted MRI of the same patient, demonstrating mixed type 2 disease. **(c)** Immediate post-operative appearance following tongue reduction surgery (anterior wedge plus excision of a central core of tongue disease) and transoral floor of mouth clearance.

used until recently,[36] but has been discontinued owing to a lack of supply and withdrawal of USFDA approval for any indication. Our agent of choice is now 3% STS, injected as a foam. This is injected directly into larger cysts after aspiration of fluid, resulting in an inflammatory response with subsequent fibrosis and sclerosis. Multiple treatments are usually required, at intervals of a few weeks or months, since deeper parts of the malformations are difficult to access reliably. Such treatment is generally not beneficial for microcystic disease, as the penetration into adjacent areas is poor. Similar possible side effects may occur as for sclerotherapy to venous malformations. Parents and clinicians should be particularly aware of the likelihood of gross swelling of the injected areas after treatment, risking airway obstruction and worsening deformity.

Surgery may be performed with different objectives in mind. In some circumstances, particularly in the context of localized macrocystic disease of the neck, a single excision procedure may be straightforward and curative. Alternatively, debulking procedures, including in the neonatal period, will allow removal of an area of relatively accessible disease in order to preserve function. In our practice, the anterior cervical portion of large cervicofacial LMs may be cleared in this way within the first few days of life, with limited risk of neurovascular injury. This may obviate the need for tracheostomy, leaving the facial/parotid disease component to be addressed when the child is older and larger, such that the risks to the facial nerve and other structures are reduced. Transoral approaches may be necessary for disease of the tongue and sublingual regions, which is typically microcystic. Mucosal incisions through the floor of mouth, preserving the submandibular ducts and lingual nerves, allow safe access to sublingual disease. Tongue base and mucosal lesions have been treated with partial glossectomy (see **Figure 42.7**), laser or monopolar diathermy in the past, although we now favour Coblation® (radiofrequency ablation), which avoids lateral thermal injury and allows rapid recovery.[39]

For extensive, mixed disease, a combination of surgery for microcystic areas and sclerotherapy for larger cysts is usually undertaken. The relative merits of the different modalities at each stage of life will vary according to the patient and their disease. Apart from a comprehensive multidisciplinary approach, it is essential that parents are fully aware of the scope of each treatment, risks, prognosis and the long-term management entailed.

FAST-FLOW VASCULAR MALFORMATIONS

This group of lesions, like other vascular malformations, are congenital but may go unrecognized for several years, typically presenting in childhood or adolescence. They are distinguished by characteristics related to high blood flow, such as palpable thrills, audible bruits, warmth and redness.

Arteriovenous malformations

Although the ISSVA classification distinguishes a number of fast-flow malformations,[4] the majority have connections between arterial feeders and draining venous systems, centred on a nidus, and are therefore arteriovenous malformations (AVMs) rather than purely arterial lesions (Figure 42.8). Although far rarer in the head and neck than their slow-flow counterparts, AVMs are 20 times commoner within the cranial cavity. Growth is typically relentless but steady, with periods of acceleration in response to trauma, infection and hormonal changes of puberty. Many patients remain asymptomatic for some time, even into adulthood, but given their typical location, these lesions may rapidly produce significant sequelae and life-threatening complications including neural compression and high output cardiac failure. Schobinger in 1990 proposed a clinical staging classification for AVM, illustrating their natural history:[40]

- **Stage I:** Quiescence. Pink-bluish stain, warmth, AV shunt on Doppler
- **Stage II:** Expansion. As per stage I, with enlargement, pulsation, thrills/bruits and tense, tortuous veins
- **Stage III:** Destruction. As per stage II, with dystrophic skin changes, ulceration, necrosis, bleeding, pain
- **Stage IV:** Decompensation. As per stage III, plus cardiac failure.

MANAGEMENT

Owing to their location and possible complications, AVMs particularly demand a multidisciplinary approach to management at a specialist centre. Initial imaging is essential, typically involving ultrasound and colour Doppler to determine flow characteristics and fistulae, and MRI to evaluate extent. In contrast to the situation for slow-flow malformations, angiography is very useful to further delineate vascular anatomy, while also allowing access for embolization if required.

Asymptomatic AVM may be monitored, although the clinicians and family should be aware of the risks of accelerated growth, making the clinical picture and its management more hazardous.[41, 42] The development of symptoms, both local and distal, will often prompt active treatment although this may itself be extremely challenging. The only reliable cure is complete excision of the central nidus and network of vessels, although in the head and neck and especially intracranially this may prove impossible. Benefits of surgery must be assessed against major risks, including death in some cases. Pre-operative embolization may be undertaken 24–72 hours pre-operatively to reduce blood loss.

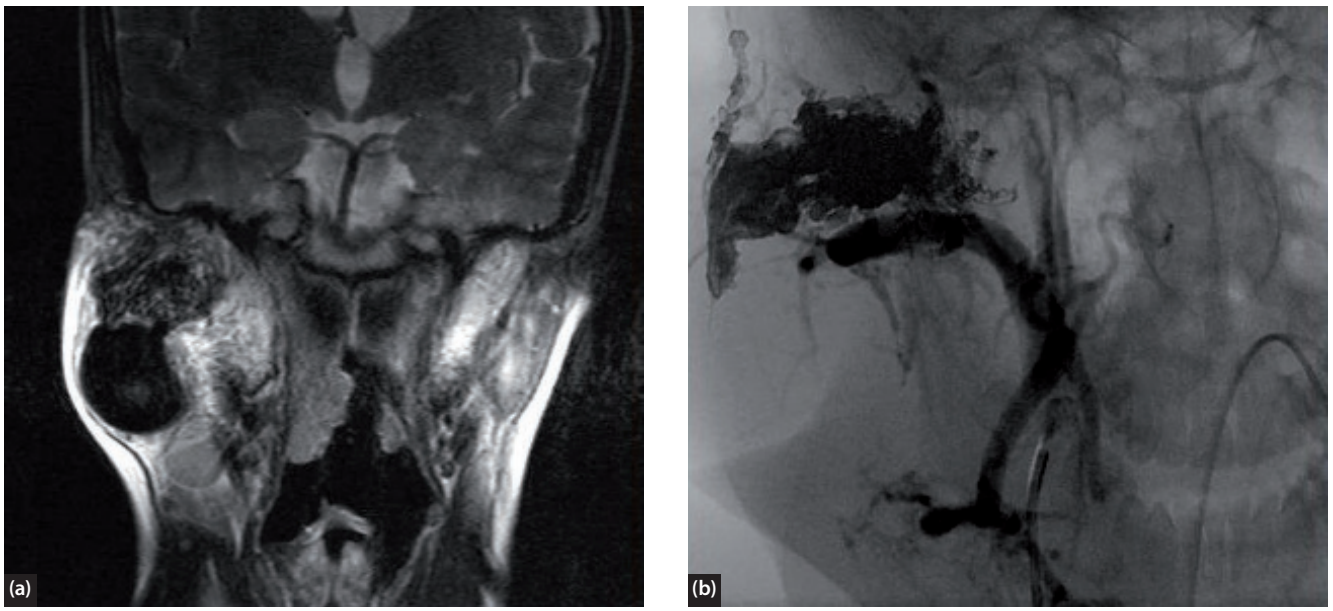

Figure 42.8 Large right arteriovenous malformation in a 15-year-old male. **(a)** Coronal T2-weighted MRI, demonstrating a large flow void (the nidus), and numerous interconnections with other vessels. **(b)** Angiographic appearance at the time of embolization. The nidus is clearly seen, along with multiple arteriovenous anastomoses with intra- and extracranial vessels.

Partial excision is ineffective, as new vascular channels will almost certainly develop. This is also true for embolization with curative intent. However, repeated trials of embolization may be used to palliate symptoms such as recurrent major epistaxis although this treatment carries risks including cerebrovascular thromboembolism and blindness. The relative merits of the various active therapies, as well as palliative options, must be communicated effectively with the patient and family.

COMPLEX COMBINED VASCULAR MALFORMATIONS

A number of complex malformations are possible, comprising various slow- and fast-flow subtypes and combinations of the two. Although the lesions themselves may differ in terms of presentation and behaviour, the principles of investigation and management are similar.

KEY POINTS

- Vascular anomalies, comprising vascular tumours and vascular malformations, are congenital lesions with complex underlying pathology, which account for a variety of presentations.
- Recent advances in histopathology and histochemistry, together with an evolving appreciation of their varied biological behaviour, have enabled precise classification of these lesions, replacing previous redundant and ambiguous nomenclature.
- A comprehensive understanding of these lesions is fundamental to accurate diagnosis and successful multidisciplinary management.

CHAPTER 43

DROOLING AND ASPIRATION

Haytham Kubba and Katherine Ong

SEARCH STRATEGY

Data in this chapter may be updated by an Ovid Medline search using the keywords: sialorrhoea (and its American spelling), drooling, saliva, hypersalivation and aspiration, supplemented by articles from the authors' own libraries.

DEFINITIONS

Sialorrhoea or **drooling** is the involuntary loss of saliva from the mouth. It is a normal feature of infancy but becomes rare in normal children as they develop oral motor control, sensory awareness and appreciation of social norms. Drooling beyond the age of 4 years is considered abnormal.

Anterior drooling, which is just another term for sialorrhoea, can be distinguished from **posterior drooling**, which is the spillage of saliva into the pharynx. Posterior drooling leads to an increased risk of aspiration. Aspiration of saliva typically presents with coughing and choking, often most obvious when the child is lying supine in bed, as well as recurrent pneumonias and concurrent evidence of aspiration of food and drink.

Drooling is distinct from **hypersalivation**, which is the excessive production of saliva. The majority of children who drool do not hypersalivate so the terms are not interchangeable.

CAUSES

Drooling may be a normal feature in young children up to the age of 4 years, and occasionally slightly older than this in children whose development is otherwise normal. Some children have a delay in achieving this particular motor milestone, perhaps due to a lack of awareness of social niceties but without any obvious physical deficit. The prognosis for these children is good and few require more than simple reminders and cues.[1]

Generally speaking, drooling is the result of a swallowing disorder, due to an impairment of the oral phase of the swallow. Inability to maintain lip closure, altered tone in the oral musculature, impaired oral sensation and difficulties controlling tongue movements all can lead to reduced frequency and efficiency of the swallow.[2–5]

Drooling accompanied by unclear speech (dysarthria) and difficulty chewing solid food may be labelled **oromotor dyspraxia**. The oromotor problems may be quite significant, with some children unable to manipulate food in the mouth with the tongue, resorting to pushing the food around their mouths with a finger. However, the problem is specific to the oral cavity and these children typically have no other developmental issues.

The majority of children who drool also present with other associated disorders affecting general development and muscle control, typically cerebral palsy. The drooling is primarily a motor issue. The drooling is not associated with any structural difference in the saliva glands[6] or in the amount of saliva produced.[2–4] Aspiration is a feature in those with bulbar palsy.

Some children (such as those with autistic spectrum disorders and intellectual disability) will drool because of a lack of awareness that saliva is pooling in the mouth or that the chin is wet, and that this is not socially acceptable. This is primarily a sensory issue.

In fact, most children who drool present with some combination of both a sensory issue and a motor impairment affecting their swallow.

PREVALENCE

Drooling is a common problem in children with neurodisability, although most do not receive any medical attention for this. Parents do not always know that effective treatments are available, or it may be that the family doctor, paediatrician or otolaryngologist does not know enough about the problem to make a recommendation. In 2005, we conducted a survey of 358 children in the 17 special schools for children with complex disability in the city of Glasgow. Twenty-six per cent suffered from sialorrhoea, most of moderate or severe degree, and this was most common in those with cerebral palsy. Only 21% had previously sought medical attention for the problem (J. Leonard and H. Kubba, unpublished data). Other studies have found prevalence figures of 40–58% specifically in children with cerebral palsy.[2, 7–9]

IMPACT ON THE CHILD AND FAMILY

Drooling might be seen as a trivial problem, especially for children with complex disabilities. Speaking to families, however, it becomes apparent that it has a surprisingly large impact on their day-to-day life. Children who are aware of their problem are very embarrassed and sialorrhoea is a very visible sign that they are 'different'. They may suffer discomfort from skin excoriation on the face or from having wet clothes. They are often avoided by their peers in school or nursery and they receive fewer physical displays of affection from their family members such as hugs and kisses. Families often restrict social activities such as visiting relatives or going out to eat. Frequent changes of clothes are a major time burden, and there is a significant cost associated with frequent washing and replacement of clothes. The impact of drooling is obvious and measurable[10–12] and treatment of the drooling, whether medical or surgical, can result in substantial improvements in quality of life for both child and family, and in the child's social interactions with their peers.[13–15]

THE MULTIDISCIPLINARY CLINIC

In most places, no coordinated care exists for saliva control problems and paediatricians see too few children with drooling to build up any useful experience.[16] A child with sialorrhoea can potentially seek help from a number of different specialists, each of whom might have only limited treatment options available. Treatment would depend on which specialist saw the child rather than which treatment would be best for the child. Thus, if the child sees a speech and language therapist, only exercises would be offered. If the child sees a paediatrician, only anticholinergic drugs would be offered. If the child sees a neurologist, only Botox injections would be offered, and if the child sees a surgeon, only surgery would be offered. There is a saying, 'When all you have is a hammer, everything looks like a nail.'

As a response to this problem, many children's services have set up multidisciplinary clinics for saliva control,[17, 18] mostly modelled on the service set up in the early 1970s at the Toronto Hospital for Sick Children.[19] Various specialists may be involved including developmental paediatricians, speech and language therapists, otolaryngologists, orthodontists and dentists. All benefit from having a variety of skills available so that all treatment modalities can be discussed and offered, including behavioural therapies, drugs, botulinum toxin injections, oral appliances, orthodontics and surgery, along with assessment of swallowing and dental health. Treatments are offered in a stepwise, progressive fashion starting with the least invasive options and tailoring the treatment to the specific circumstances of the child (**Figure 43.1**).[18–21]

HISTORY AND EXAMINATION

Look for evidence of aspiration

About a third of the children seen in the clinic aspirate as well as drool. This may be evident from a history of coughing and choking (often most evident at night) or frequent chest infections, or it may be evident on a clinical swallow assessment. If there is any doubt, a videofluoroscopic swallowing study (VFSS, also known as a modified barium swallow), or a fibre-optic endoscopic evaluation of swallow (FEES) should be performed (see below). The presence of aspiration makes a difference to almost all of the decision-making in the clinic. Children who do not aspirate can be safely observed, and there is plenty of time to see the effects of general growth and development on oral motor skills therapy: non-invasive treatments may be reasonable but surgery should not be performed until the child is at least 6 years old. If the child aspirates, however, intervention should not be delayed and the best chance of preserving lung function in the long term comes from aggressive management of the aspiration before 4 years of age.[22]

Assess general development

Most children with sialorrhoea will have general developmental delay often associated with a neurological disorder such as cerebral palsy. Cerebral palsy is a diagnosis that includes children with a very broad range of abilities and prognoses so it is good to ask a few questions about feeding, mobility, speech and communication.

For children with no known underlying neurological diagnosis, it is worth asking a few questions about speech, chewing, swallowing, social interaction and general developmental milestones. In young children there may be early signs of an autistic spectrum disorder or a specific oromotor dyspraxia that are only now becoming evident.

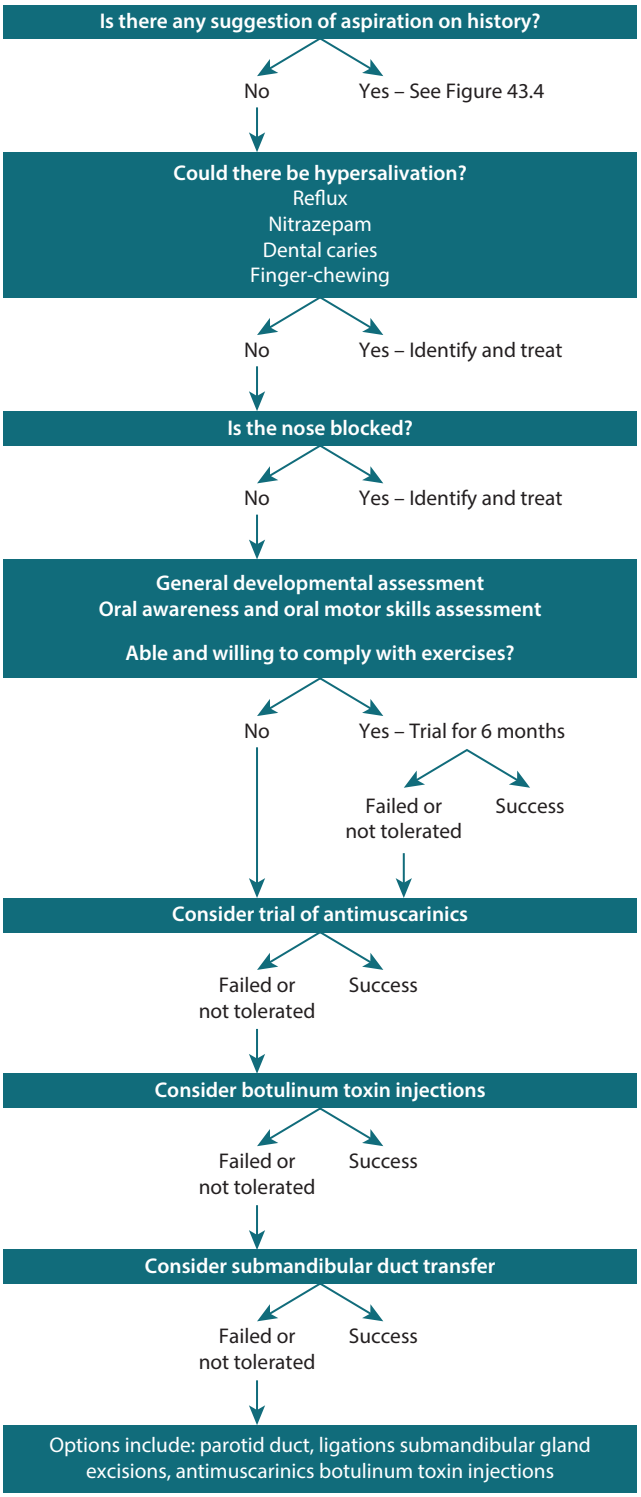

Figure 43.1 A suggested protocol for assessment and stepwise, progressive management of drooling in children.

Look for causes of hypersalivation

Most children with drooling produce a normal volume of saliva; the problem is in controlling it. There are some children, however, who genuinely produce too much saliva (true hypersalivation). This includes children with dyskinetic cerebral palsy, where hyperkinetic oral movements increase saliva production.[3] Other causes include habitual finger-chewing, dental decay, gastro-oesophageal reflux and drugs (particularly nitrazepam, often used for seizures). Where possible, these issues should be addressed before embarking on specific treatments for the sialorrhoea, otherwise success is unlikely. If the child requires nitrazepam for seizure control, there is not much we can do except to warn the family that interventions for saliva control are unlikely to control the problem completely, although they may still be worthwhile. If dental caries are found on examination, a referral for dental care should be the first step before any specific measures are undertaken for the saliva. With regard to reflux, there is a randomized controlled trial of cisapride and ranitidine therapy in children with drooling and proven reflux oesophagitis[23] that did not show any benefit for the drooling. Whether more modern drug treatments (specifically, proton pump inhibitors) would be beneficial is unknown, and there are anecdotal reports of reflux surgery (fundoplication) curing drooling that had been refractory to other measures.[18]

Look for causes of an open-mouth posture

The inability to form or maintain a lip seal is one of the most important factors producing a tendency to drool.[2, 5] Nasal obstruction will, of course, lead to a persistent open-mouth posture and this alone can lead to a significant drooling problem in young children. It should be straightforward to identify features of adenoid hypertrophy or perennial rhinitis on history and examination, and these should be treated on their own merits. In the Glasgow saliva control clinic series, 12% of children had adenoidectomy (with or without tonsillectomy) as the only treatment required for drooling.[18]

An open-mouth posture can also be caused by dental malocclusion, typically an anterior open bite, and the advice of an orthodontist can be very useful.

Many children seen in the clinic (particularly those with quadriplegic cerebral palsy who are in a wheelchair) have very poor posture due to inadequate support of the trunk and head (**Figure 43.2**). Poor trunk support leads to poor

Figure 43.2 Child with cerebral palsy showing poor posture due to poor trunk support in the wheelchair.

head control, which in turn leads to poor jaw control. No progress will be made with salivary continence until the trunk and neck are stable. The wheelchair may need to be modified or replaced. For children with a specific problem of drooling onto schoolbooks or a computer keyboard when they lean forward, use of a slant board is a very simple and effective way to lift and angle the book or computer to encourage a more upright head posture.

INVESTIGATIONS

In routine clinical practice, it is not common for clinicians to measure the severity of the drooling issue although there are certainly a few ways to do this. The simplest is to ask about frequency of bib changes or changes of clothing, but this is very subjective. The Teacher's drooling scale rates frequency of drooling on a scale of 1 to 5. The Drooling Severity and Frequency Scale (DSFS) takes this concept a little further by rating severity of drooling 1–5 and frequency 1–4 and then adding the two together.[24] The drooling quotient (DQ) measures the frequency of drooling in two standardized periods of 5 minutes (one at rest, one at play) with the child sitting up and at least 1 hour after meals. Every 15 seconds, the rater scores whether new saliva has appeared at the lips and the proportion of positive 15-second episodes is converted to a scale of 0–100.[25] This is obviously more time-consuming and difficult to measure than the simple rating scales mentioned above and it appears the DSFS correlates well enough with the DQ to be a good proxy in clinical practice.[26]

Symptom questionnaires and quality of life (QOL) scores have been developed in an attempt to capture the wider impact of the drooling on the child and family.[11, 12]

Various techniques exist to measure salivary flow including weighing cotton swabs that have been placed in the floor of mouth, or technetium scintigraphy, but salivary flow is rarely a useful measure in the context of the drooling child.

The most important area for investigation is in the context of aspiration. The presence or absence of aspiration has a big influence on decision-making and therefore it is crucial to complete a clinical assessment of the swallow (including neck auscultation) by an experienced speech and language therapist whenever aspiration is suspected, supplemented by either VFSS or FEES. VFSS involves X-ray screening while the child swallows various fluid or solid food textures mixed with barium. FEES uses transnasal flexible fibre-optic nasopharyngoscopy to achieve similar results, namely an assessment of the pharyngeal phase of swallow, in particular the presence of preswallow pooling, laryngeal penetration and/or aspiration, and post-swallow residue.

In most cases where aspiration is identified, a neurological cause will be evident. Where no neurological cause is known and an anatomical issue is suspected microlaryngobronchoscopy under general anaesthetic is mandatory to rule out laryngeal cleft or H-type tracheo-oesophageal fistula since it would be tragic to miss such treatable causes of aspiration and lung damage.

ROLE OF THE SPEECH AND LANGUAGE THERAPIST

It is very useful to have the opinion of an experienced speech and language therapist in clinic. They can assess oral motor skills appropriate for the child's age and development, and can judge likely ability and motivation to comply with behavioural therapy. They can also assess the safety of the swallow and risk of aspiration. Associated issues with speech and chewing can also be addressed.

Activities to increase oral awareness include water play to teach the concepts of 'wet' and 'dry' and the use of a mirror to provide visual feedback. Parents can incorporate exercises into play, such as blowing bubbles or toy trumpets. They can also encourage straw drinking, ensuring the straw is held in the lips only (not in the teeth) and progressively lengthening the straw over a period of weeks and using thicker drinks such as fruit smoothie or milkshake.

Issues with jaw strength and stability can be addressed through graduated strengthening exercises such as holding a chewy tube between the molar teeth against resistance as the therapist tries to gently pull the tube out of the mouth. Lip strength can be improved by holding a wooden tongue depressor between the lips for increasing lengths of time.

Behavioural modification may involve giving verbal cues to swallow or wipe, together with positive and negative reinforcement. So, for example, the child may enjoy reading a bedtime story and may be cued to swallow and/or wipe at the end of every page. Towelling sports wristbands can be very practical for wiping but also serve as a visual reminder of the need to wipe or swallow. Auditory cues to wipe and swallow, such as the timer on a microwave oven or the phone app 'Swallow Prompt' can also be used.

All these interventions rely on a degree of cooperation from the child and so are only of use in cognitively able children. With children who are able to comply, it is essential to have at least 6 months of speech and language therapy intervention before considering invasive treatment such as surgery.

There is no strong evidence base for any of these interventions, with clinical practice based on theory and experience rather than any controlled clinical studies.[27]

ROLE OF DENTAL AND ORTHODONTAL SERVICES

It can be very helpful to have the advice of a dentist. Dental caries can be a cause of salivary stimulation leading to hypersalivation. Restorations, extractions and advice on dental hygiene should precede any other interventions for drooling if this is the case.

Drooling does not itself predispose to dental caries[28] but all forms of saliva reduction treatment do, including drugs, botulinum toxin injections and surgery.[29, 30] Saliva has a protective effect for the teeth so families should be warned that treatment for drooling puts the child at greater risk for dental caries. Teeth should be brushed

twice a day with a fluoride toothpaste and there should be dental check-ups every 6 months, with preventative treatments such as fissure seals if appropriate.

Orthodontists can assess those children for whom malocclusion is a contributory factor to persistent open-mouth posture. In addition, there are some enthusiasts for the use of intraoral appliances, such as the ISMAR (Innsbruck Sensory Motor Activator and Regulator) to treat drooling. The device looks much like a dental retainer with an acrylic plate covering the hard palate, held in place with wires around the teeth. A projection is added to the posterior edge with a rotating bead which stimulates the soft palate and tongue to initiate a swallow. Only about a third of children with cerebral palsy will tolerate such a device but, in those who do, significant improvements are seen in eating and drooling.[31]

PHARMACOLOGICAL TREATMENTS

Antimuscarinic (less accurately known as anticholinergic) medication is by far the most common treatment used for drooling. These drugs stop acetylcholine from binding to receptors in nerve cells and therefore have wide-ranging effects on the central and peripheral nervous systems. In the context of saliva control, the effect of the drugs is to reduce the volume of salivary secretions. In doing so the saliva is also thickened and this can be unpleasant. Side effects are common and include dry eyes, dilated pupils with intolerance to bright light and impaired vision, constipation, urinary retention, worsening of seizure control, hallucinations and changes in sleep and behaviour. Anyone prescribing these drugs should be aware of their side-effect profile and should be able to discuss the recognition and management of side effects with the family. Some of these side effects are quite serious. As examples, impaired bladder emptying may lead to frequent urinary tract infections and any suspicion of this should be investigated with a post-micturition ultrasound of the bladder and measurement of residual volume. Constipation is common and sounds trivial but antimuscarinic treatment has been associated with toxic megacolon requiring defunctioning colostomy.[32] Optometry and sometimes ophthalmology advice may need to be sought for visual problems.[33]

Various drugs are in use and their names can be confusing. The most commonly used are hyoscine hydrobromide (also known as scopolamine hydrobromide but distinct from hyoscine butylbromide, which is not used for this indication), glycopyrronium bromide and trihexyphenidyl hydrochloride (also known as benzhexol hydrochloride). There are also anecdotal reports of atropine eye drops being used sublingually for drooling.[34]

A UK survey of paediatricians showed that hyoscine hydrobromide transdermal patches are the first-line treatment for most, with oral (or gastrostomy) glycopyrronium bromide second-line.[16] Hyoscine hydrobromide patches have the advantage of effectiveness and ease of use.[35] They can be applied to any area of thin, hairless skin and changed every 3 days. They are waterproof enough to survive showering. Their main drawback is their high incidence of significant side effects, up to 71% in one series.[36] Skin reactions to the adhesive are common and cessation of patch therapy is required. The other significant drawback is that it is awkward to adjust the dose for the age and size of the child. A full patch every 3 days is appropriate for most children of high school age but this would be too much for younger children, for whom half or even a quarter of a patch would be more appropriate. The patches can be cut with scissors but the dose release mechanism then becomes very unpredictable. Placing the patch over an occlusive dressing so that only half is in contact with the skin may lead to more controlled dosing but it is fiddly for parents to do this. Oral hyoscine hydrobromide seems anecdotally to be much less effective than the patch.

Trihexyphenidyl hydrochloride has the advantage of availability in syrup form, which makes for convenient dosing via the oral or gastrostomy route. The dose can be easily adjusted according to response up to a maximum of 2 mg/kg/day in two or three divided doses.

Glycopyrronium bromide is available as an oral solution and is very effective.[37] It has the distinct advantage of not crossing the blood–brain barrier unlike atropine, hyoscine and trihexyphenidyl. This should lead to significantly fewer central side effects although peripheral effects (on bladder, bowel, sweat glands and eyes) will still be seen and 20% of children will have to stop using the drug due to side effects.[38]

Our own experience in the Glasgow saliva control clinic has been that 45% of children discontinue transdermal hyoscine due to side effects, compared with 15% for trihexyphenidyl and 6% for glycopyrronium.[18] About half the adverse reactions to hyoscine patches were skin reactions to the adhesive: the remainder were visual problems, behaviour change and hyperactivity, constipation, urinary retention and sleep disturbance. Overall, only half the children who commenced antimuscarinics continued to use them as their definitive long-term therapy, the remainder moving on to more invasive options as outlined below.

BOTULINUM TOXIN INJECTIONS

Botulinum toxins are neurotoxic proteins produced by *Clostridium botulinum* bacteria. There are seven types of toxin but only A and B are used medically. The toxins produce their effect by blocking acteylcholine release from axons at the neuromuscular junction causing muscle paralysis. Their use in saliva control comes from their ability to block release of acetylcholine from parasympathetic secretomotor nerves in the salivary glands.

There is a variety of different brands of botulinum toxin available on the market and they are not interchangeable. Dosing is specific to each manufacturer and cannot easily be extrapolated from one brand to another as each has a protein of a slightly different molecular weight and with different diffusion and pharmacokinetic profiles. Botox is the brand of botulinum toxin A made by Allergan. It is now referred to by the generic name onabotulinumtoxin A. Dysport now has the generic name abobotulinumtoxin A. Myobloc and Neurobloc have the generic name

rimabotulinumtoxin B. Onabotulinumtoxin A (Botox) is the most common agent used for saliva gland injections as it has the largest molecular weight: although this gives it the slowest onset of action, it may also help limit its radius of diffusion and therefore should, in theory, reduce the incidence of side effects from spread of the drug. In reality, no convincing difference in effect has been seen between the various preparations.[39,40] Clinicians should familiarize themselves with the dosing, administration and side-effect profile of one formulation of toxin (in this context, probably onabotulinumtoxin A) and only use alternatives if the child has developed antibodies to the toxin as shown by reduced clinical effect over time. Switching to an alternative toxin type can restore effectiveness very well when this occurs.

No consensus exists on which glands should be injected or on how much toxin should be put into each gland. Many clinicians will inject an equal amount (25% of the total dose) into each of the submandibular and parotid glands,[41] others will inject mostly the submandibular glands (66% of total dose) with the remainder into the parotids[42] and others even inject either the submandibular or parotid glands exclusively. Since the majority of resting saliva secretion is from the submandibular glands it makes sense to direct the injections there to some degree.

There is a little more agreement about total dose. For most children the optimal dose is 80–100 units of onabotulinumtoxin A (Botox)[43] or around 4 units/kg bodyweight for those less than age 4 years, with larger doses causing more side effects but not any increase in effectiveness.[42] The same is true for rimabotulinumtoxin B (Myobloc): increasing the dose above 3000 units causes increasing side effects without any benefit in success rate.[44]

Success is somewhat subjective but a worthwhile response usually occurs in 50–80%[45,46] with most large series reporting success in around two-thirds of cases.[36,41,42,47] The toxin can take 2–6 weeks to take maximum effect. The effect of the toxin is often detectable clinically up to 6 months from injection to some extent but the median duration of a worthwhile response, when it occurs, is around 4 months.[41,42,45,46] Very occasionally, repeated injections cause gland atrophy with prolonged responses up to 18 months reported.[42]

Side effects from botulinum toxin injections are less common than with antimuscarinics.[36] The most common and worrying is dysphagia. This is most often a transient phenomenon, lasting just a few days and only apparent if specifically asked about. More severe dysphagia can last for weeks or months and require tube feeding. Reported rates are 7% for transient dysphagia with no intervention required and 3% for severe dysphagia requiring tube feeding.[42,48] Children undergoing botulinum toxin injections often have an abnormal swallow to start with but, if they are only just managing to feed orally, botulinum toxin has significant potential to tip them over into a situation where nasogastric feeding is required. Oral feeding may then be difficult to re-establish. Recent international guidelines urge caution in the use of botulinum toxin in children with swallow impairment.[20] The ideal candidate for botulinum toxin is the child who is already tube-fed, in which case any transient worsening of swallow is unlikely to have a major impact. For those who are orally fed, the decision to use botulinum toxin is one that should be approached with caution and a full discussion of the potential risks.

Botulinum toxin thickens the saliva[49] but this is uncommon as a clinical issue, seen in only 1.5% of one large series.[42] Spread to cervical muscles may cause torticollis, seen in 0.5% of a series of injections done without ultrasound,[42] or even total head instability requiring hospitalization, seen in 4% of another series done with ultrasound.[48]

In most centres, botulinum toxin injections are done under ultrasound guidance. There is no doubt that ultrasound allows more accurate placement of injections but, since the toxin is known to spread through fascial planes up to 4.5 cm from the injection site,[50,51] it is unclear how much difference this actually makes in practice. When injection is done by anatomical landmarks alone (**Figure 43.3**),[42] the success rate is no different to that in series where ultrasound guidance is used.[36,41,45–47] The use of ultrasound has been reported to produce impressively few side effects in one series[52] but, in general, most series report similar rates of complications regardless of whether ultrasound is used.[42,48]

There is a drawback to using ultrasound, namely the time required to do the procedure and the consequent need for general anaesthesia or sedation. If injections can be achieved quickly and effectively by anatomical landmarks alone, skin anaesthesia with local anaesthetic cream is usually all that is required and general anaesthesia can be avoided in 75% of cases.[42] Obviously, careful patient selection is required to achieve rates as high as this, but the very children who are ideal for botulinum toxin injection on the grounds of being tube-fed are also more likely to be tolerant of (and possibly less aware of) awake injection. This makes repeated, regular injections a viable long-term treatment option for this select group of children. For those children who would not be tolerant of awake injection, serious consideration must be given as to whether it is reasonable to give a general anaesthetic to a child three times a year for salivary botulinum toxin

Figure 43.3 Botulinum toxin injection into the left submandibular gland by palpation of landmarks, in this case under general anaesthesia.

injections on a long-term basis. Some clinicians do this but many would judge it inappropriate. There are those who perform botulinum toxin injections just once as a way to select candidates for a permanent surgical procedure, on the assumption that a response to botulinum toxin predicts a good response from surgery.[53] There is no evidence for this assumption and in fact many children with a poor response to botulinum toxin injection will go on to have surgery with good effect.[18]

In order to minimize complications, it is important to consider which botulinum toxin preparation to use (small molecules spread further) and to place the injections accurately. Also very important is the dilution of the toxin. More dilute preparations spread further[54] so the toxin should be made up with no more than 2 mL of saline in total.

There is a group of children, about a third of all those injected, who do not seem to respond to the toxin very well. Children who respond well to the first injection tend to respond well to subsequent ones, whereas those who do not respond well to the first injection tend not to respond well to subsequent injections, suggesting there are features intrinsic to the child which affect response.[42] The effectiveness of the botulinum toxin is not related to cerebral palsy subtype or clinical features[55, 56] and we do not yet understand why some children respond and others do not.

SURGERY

Anything from 22% to 47% of patients attending a multidisciplinary drooling service will end up undergoing surgery at some point in their treatment, usually once more conservative options have been exhausted.[17, 18] Surgery, of course, includes adenoidectomy for nasal obstruction and fundoplication for intractable reflux, but in this section we will consider specific salivary procedures only. Surgery has an advantage over botulinum toxin in that it is a one-off intervention with long-lasting results,[57] but obviously surgery comes with risks and discomforts and the need for a general anaesthetic.

The most important distinction to make is whether or not the child is at risk of aspiration. A swallowing assessment by a speech and language therapist is invaluable and, if there is any doubt, VFSS or FEES should be completed. For children who are not at risk of aspiration, the best long-term results come from bilateral submandibular duct transfer. The operation requires no external incision and is done entirely intraorally. The submandibular ducts are dissected free and tunnelled submucosally to the inferior border of the tonsil fossa where they are sutured in place behind the anterior pillar. The operation causes considerable pain and discomfort and it is not unusual for children to require 3–4 days in hospital for post-operative analgesia. Recovery usually takes 3 weeks. Families and children need to have a full and frank discussion of the likely post-operative pain before agreeing to surgery. This surgery should not usually be done in children who still have time to develop oral continence on their own, i.e. it would rarely be offered below the age of 6 years. Success from surgery is quite subjective to measure, but substantial or complete resolution of drooling can be expected in 80–88% of cases[18, 29, 58–61] and the results are well maintained when assessed 5–15 years later.[29, 58, 61–63] The main determinant of outcome is the severity of the child's underlying neurological disability[59, 60, 64] so the ideal candidates are those with reasonable swallow function, such as those with milder cerebral palsy (diplegic or hemiplegic) or oromotor dyspraxia.[65]

The most common complication of submandibular duct transfer surgery is ranula formation due to obstruction of drainage from the sublingual glands. This affects 4–20% of children after surgery.[59, 60, 61, 63] and on that basis many surgeons elect to excise the sublingual glands at the same time as the duct transfer. This prevents the ranulas but at the expense of longer operating times, greater blood loss, more pain and longer hospital stay.[66] Excision of the sublingual glands makes no difference to the control of drooling.[64, 66]

Another common complication from submandibular duct transfer is swelling of the submandibular gland, which may be transient or persistent. It occurs in 2–22% of cases[59, 60, 61] and the gland may need to be excised if the swelling is troublesome. Careful handling to prevent injury or twisting of the duct during surgery helps to reduce the incidence. Dry mouth is rare in most series but has been reported to occur in 10% by one author who also reported dental caries in 3% after surgery.[29] Aspiration pneumonia after surgery can be disastrous but should be rare if patient selection has been appropriate and aspiration excluded, although it certainly does still occur.[62, 63] Tongue swelling, lingual nerve injury and troublesome bleeding have also been reported.[62]

The morbidity from duct transfer has led to various alternative procedures being popularized. Four-duct ligation (parotid and submandibular ducts bilaterally) is very easy and very quick with little immediate post-operative morbidity.[67, 68] The initial results are similar to those of duct transfer (success 81%, ranula 10%, submandibular gland swelling 15%)[69] but the long-term results are poor, as the ducts tend to recanalize.[70, 71] Submandibular gland excision (with or without concomitant ligation of the parotid ducts) is effective for drooling[72, 73] and is a reasonable alternative to duct transfer. Surgeons have probably avoided it due to concerns about leaving two visible scars in the neck, but carers don't seem to mind the scars as much as we might think.[74] Tympanic neurectomy (transtympanic sectioning of Jacobson's nerve and the chorda tympani) has largely been abandoned due to poor results,[75, 76] as has cervical sympathectomy.[77] Parotid duct ligation has a role for salvage if initial submandibular duct transfer fails.[78]

CHRONIC ASPIRATION

Symptoms of aspiration should be actively sought in the history in all cases, particularly recurrent episodes of pneumonia or coughing and choking on secretions or drinks. A clinical swallowing assessment by an experienced speech and language therapist may be supplemented by VFSS or FEES to confirm the diagnosis. If no neurological cause

is obvious, a structural cause such as laryngeal cleft or H-type tracheo-oesophageal fistula should be actively excluded by means of microlaryngobronchoscopy under general anaesthesia (Figure 43.4).

Mild cases of aspiration can be managed by the speech and language therapist with advice on head positioning during swallow, modifications to food and drinks and other simple strategies. More severe cases will require restriction or complete cessation of oral intake with tube-feeding, usually by means of gastrostomy. If aspiration of gastric refluxate is an issue, fundoplication will often be performed at the same time as gastrostomy insertion. The role of the otolaryngologist in this context is to advance the case for fundoplication with the upper GI team, emphasizing that reflux could be contributing to the drooling and aspiration.

If aspiration of oral feed and gastric refluxate have been dealt with already, or if saliva is the obvious cause of coughing and choking, then saliva reduction becomes important. The younger the child is when saliva reduction is commenced, the more effective it is likely to be in reducing the frequency of pneumonia and preserving lung function.[22]

Management should occur in a stepwise fashion, starting with behavioural strategies and/or antimuscarinic drugs as the least invasive option. Botulinum toxin injections have been shown to reduce the symptoms of aspiration and to reduce the number of episodes of pneumonia and hospital admissions.[79, 80] If surgery is required, duct transfer would be disastrous and the only safe and effective option is bilateral submandibular gland excision with parotid duct ligation. This has been demonstrated to be effective in reducing episodes of pneumonia and hospital admissions.[81]

A small number of children with intractable aspiration have failed all other treatment modalities. In this circumstance, a permanent procedure to separate the air and food tracts can be truly life changing, albeit at the cost of a rather drastic operation and the loss of the ability to make voice. Most children with aspiration of this severity are non-verbal anyway and voice is not an issue. Laryngotracheal separation involves transecting the cervical trachea and bringing out the lower end as a permanent end-stoma. The upper end of the trachea can be closed off as a blind pouch or anastomosed end-to-side to the oesophagus. The procedure produces good results and may allow the resumption of oral feeds.[82, 83]

Total laryngectomy is technically simpler and heals predictably with few complications in the well child but has the disadvantage of being irreversible. Whether this matters in reality is debatable.

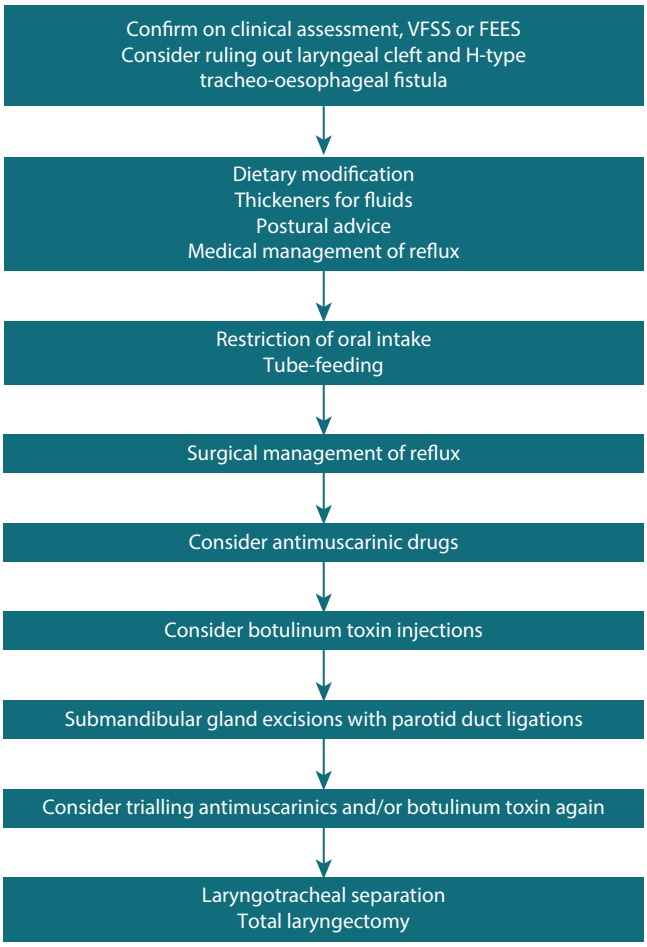

Figure 43.4 Progressive steps in the management of chronic aspiration.

BEST CLINICAL PRACTICE

- ✓ Assessment for aspiration is crucial in management and the advice of a speech and language therapist is invaluable.
- ✓ Causes of nasal obstruction and open-mouth posture should be sought and treated on their own merits.
- ✓ Drooling should be seen in the context of the child's overall development. If development is otherwise normal, the prognosis for the drooling is good.
- ✓ Speech and language therapy exercises require motivation and cooperation on the part of the child.
- ✓ Drugs, botulinum toxin and surgery all have drawbacks as well as potential benefits. The clinician should be able to discuss these with the family to help them make informed choices about treatment.

FUTURE RESEARCH

- ➤ None of the treatment options currently available is perfect and new therapies would be very welcome, particularly to reduce adverse effects.
- ➤ Reasonable evidence exists for the effectiveness and side-effect profile of each treatment modality in current use but studies are needed on treatment philosophies, pathways and decision-making.

KEY POINTS

- Drooling is common in children with neurodisability and it has a significant effect on quality of life.
- It is usually caused by poor swallowing.
- Oral exercises, antimuscarinic drugs, botulinum toxin injections and surgery each have a role in management.

CHAPTER 44

REFLUX AND EOSINOPHILIC OESOPHAGITIS

Ravi Thevasagayam

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: laryngopharyngeal reflux, gastroesophageal reflux, eosininophilic esophagitis, pediatrics and otolaryngology.

INTRODUCTION

The appreciation of the role of reflux in the genesis and propagation of head and neck conditions in the child is a relatively new phenomenon. Over the last 35 years there have been a large number of papers published on the subject. Eosinophilic oesophagitis is an even more recent clinical entity. As gastro-oesophageal reflux disease and allergic disease increase in prevalence among the general population, it stands to reason that we would encounter both these entities more commonly in clinical practice. This and increased awareness have, indeed, led to this increase. Unfortunately, despite the recent large volume of literature, there remains significant confusion. There is as yet no clear robust causality demonstrated for any otolaryngological condition although there is plenty of evidence of association. There remains no 'gold standard' diagnostic test for extra-oesophageal reflux disease. Dual pH/impedance manometry seems the most helpful relatively objective test available, although normative data is lacking and agreed thresholds for pathology elude us.

That said, it is important to remember that we are relatively early in the understanding of the condition although huge strides have already been made. The evidence for the association of reflux in a large variety of conditions of the head and neck is compelling. There is also very encouraging clinical data that antireflux therapy is helpful, particularly in reflux-mediated airway disease.

This chapter attempts to pull together the current evidence in what is a rapidly evolving field. The challenges are explained and hopefully a working understanding of the field as it stands is presented.

TERMINOLOGY

Gastro-oesophageal reflux occurs when stomach contents travel in a retrograde direction above the level of the lower oesophageal sphincter. The 'refluxate' will usually contain hydrochloric acid and pepsin and may include bile and pancreatic enzymes. This may occur to some extent physiologically in which case it is known as gastro-oesophageal reflux (GOR). At the point at which the patient develops symptoms, signs or histological changes, the term gastro-oesophageal reflux disease (GORD) is used. This refluxate may travel the length of the oesophagus and emerge from the upper oesophageal sphincter and result in disease within the realm of the otolaryngologist, particularly at the level of the larynx. The term in widespread use for this phenomenon is laryngopharyngeal reflux (LPR). However, there is now a greater appreciation that this may impact not just the laryngopharynx but also areas such as the lingual tonsil, pharyngeal tonsils, sinuses,

Eustachian tubes and trachea. Hence a more appropriate term is extra-oesophageal reflux (EOR). The term extra-oesophageal reflux disease (EORD) may be used when this reflux causes symptoms and pathology. For reasons that will be explained, patients may have EORD in the absence of GORD.

Note: As there are regional variations to the spelling of oesophagus/esophagus, GER, GERD, EER and EE (eosinophilic esophagitis) are synonymous with GOR, GORD, EOR and EO (eosinophilic oesophagitis).

PHYSIOLOGY AND MECHANISM OF INJURY

It has been known for many years that the pharynx and particularly the glottis and subglottis are sensitive to the injurious effects of reflux. In a classic study from the 1960s, intermittent application of gastric acid on canine vocal cords produced granulomas which were histologically similar to that of subglottic stenosis.[1]

In another famous study Little[2] created a standard mucosal lesion in canine subglottic larynges, which were then exposed to gastric contents, over 3–4 weeks. This resulted in a nine-fold increase in subglottic stenosis when compared to saline controls. This occurred despite the fact that the exposure to gastric contents was only for 1 minute every other day.

This would suggest that, especially in the presence of mucosal trauma, even minimal reflux exposure might result in significant pathology. Mucosal trauma to the subglottis might occur after endotracheal intubation.

Both the pepsin[3] and the acid probably cause the deleterious effects to the mucosa although bile acids may also play a role. As pepsin works optimally in a low pH environment, acid suppression has been a mainstay of therapy. While pepsin is generally thought to be inactive at high pH levels, there is some evidence that it may be active up to pH 6.5 and may alter the stress protein response which protects epithelium from damage.[4] Cellular damage in cultured hypopharyngeal cells is seen after pepsin exposure at a pH of 7.4.[5]

Low pH causes a reduction in ciliary motility,[6] which may increase the exposure time and potentiate the inflammatory effects of reflux. This may promote cough or throat clearing which may increase the inflammation. Acidification of the lower oesophagus and micro-aspiration may lead to bronchospasm and pulmonary disease.[7]

In addition to direct mucosal effects, there are also chemoreflexic effects on cord mobility. Acid applied to the glottis of piglets causes fatal apnoeas.[8] This chemoreflexive apnoea seems to be vagally mediated. Stimulation of the lower oesophagus produces laryngeal adduction and laryngospasm in puppies.[9] There has been an awareness of reflux-induced awake apnoea for 30 years.[10]

There are therefore many local effects and chemoreflexic effects of EOR. The presence of GORD makes EORD more likely but, of course, not inevitable. However, due to the differences in the sensitivity of the substrate, EORD can and often does occur in the absence of GORD. These differences have led to confusion, especially when using parameters for GORD in the assessment of EORD.

HISTORY AND EXAMINATION

As with all conditions, a full history provides key clues to nature of the disease. If an infant has the typical symptoms of reflux such as emesis, regurgitation, burping, feed refusal and back arching, then the connection is generally easily made. Sandifer syndrome occurs in children with GORD and causes irritability, and regurgitation after feeds with episodes of arching, crying and torticollis. Older children may complain of heartburn, abdominal pain, hoarseness, throat clearing or chronic cough. It is important to recognize that the child with reflux may have none of these symptoms. The key is to have a high index of suspicion that the child's symptoms are related to reflux.

Signs of increased work of breathing such as a history of tracheal tug, subcostal or intercostal recession should be inquired about if not detected in the examination.

A sleep history should be taken. Apnoeic and cyanotic spells are always significant. Apparent life-threatening events (ATLEs) should also be noted.

Chronic cough, especially if it is nocturnal, may be related to reflux. An abnormal voice or cry may be a manifestation of reflux laryngitis.

The frequency and severity of emesis should be noted. A temporal relationship of airway symptoms to meals where present is suggestive of reflux (and/or aspiration). Wet-sounding respirations, cough or 'wet burps' are often present. Irritability and increased noisy breathing after feeds may be seen. The duration of feeds is an important marker of the severity of airway compromise. Infants with airway issues tend to take a long time to take a feed and feeds taking over 30-40 minutes are considered significant.

A history of recurrent pneumonias or croups with multiple hospitalizations or antibiotic courses is very relevant. Signs of neurological impairment could potentiate the effects of reflux. This is because pharyngeal hypotonia and uncoordinated swallowing will lead to pooling of secretions in the hypopharynx. This will increase the exposure time of the larynx to refluxate and increase the risk of aspiration.

The infant should be examined with regard to the airway. Stridor or stertor may not be present at rest but may become apparent if the infant becomes agitated during the examination. Tachypnoea should be noted and in infants may be associated with head bobbing. Signs of increased work of breathing, which includes sternal and subcostal recession, may be seen. A pectus excavatum should be noted. There may be a 'wet sound' heard from the throat. Examination should include examination of the oral cavity to assess tonsil size.

BOX 44.1 Possible symptoms of extra-oesophageal reflux in children[4]

Airway symptoms	Feeding problems	General ear, nose and throat symptoms
Cough	Dysphagia	Nasal obstruction/congestion
Throat clearing	Odynophagia	Nasal pain
Recurrent croup	Gagging	Snoring
Wheezing	Choking	Snorting
Cyanotic spells	Globus sensation	Postnasal drip
Noisy breathing – stertor/stridor	Failure to thrive	Drooling
Hiccups		Oral sores
Recurrent pneumonia		Halitosis
Hoarseness		Taste/tongue problems
Tracheostomy problems, e.g. stomal granulations		Otalgia
Gurgly respirations		
Apnoea		
Sleep-disordered breathing		

The child's height and weight should be noted and plotted on a centile chart to assess failure to thrive, which may serve as an indication to intervene.

The examination in the neonate and potentially in the older child is usually completed with an awake flexible fibre-optic nasopharyngoscopy. This will provide information about the nasopharynx and the larynx. It is the investigation of choice to assess cord mobility and is excellent at visualizing laryngomalacia. In order to assess the area below the glottis, a microlaryngotracheobronchoscopy (MLTB) is performed in a spontaneously breathing infant under general anaesthesia. This allows better optical examination as well as offering the opportunity to perform endoscopic interventions.

Possible symptoms of EOR in children are listed in Box 44.1.

INVESTIGATIONS

Within the realm of gastroenterology clear guidelines exist for what constitutes GORD[11] and what reflux index (RI) scores (see below) are pathological. It is clear that certain levels of reflux exposure to the oesophagus are physiological and not associated with pathology. In view of differences described earlier between the oesophagus and the pharynx and airway, it seems likely that lower levels of reflux exposure may cause disease in the pharynx than would cause disease in the oesophagus. Early authors suggested than any reflux exposure in the pharynx was abnormal[3, 12] although there is increasing awareness that this is likely not the case. In neonates, it is clearly recognized that a certain degree of reflux is both physiological and common. That said, normative data are still not available for this. A threshold figure for pathological EOR does not exist as yet. In view of the variety of substrate tissue and the spectrum of disease, it is possible that a threshold figure for reflux exposure in any of the tests will never be achievable. What is clear is that the threshold figures for GORD do not apply to EOR although a diagnosis of GORD makes EOR more likely.

There is no one 'gold standard' test for EOR. Each of the tests described provides supporting information towards or against a diagnosis of EOR. A diagnosis of GORD will, however, make EOR more likely and treatment should be considered. Likewise, a reduction in the RI below threshold for GORD will not necessarily mean successful treatment of the EOR.

Contrast swallow

A contrast swallow has the advantage of demonstrating anatomical abnormalities such as a tracheo-oesophageal fistula, a hiatus hernia and achalasia. It may detect aspiration especially when used as part of a videofluoroscopic examination of swallow. It is a brief study and so is not a good investigation to detect reflux events. It is not routinely done in reflux unless an underlying anatomic abnormality is suspected.

pH monitoring

Ambulatory 24-hour pH monitoring has been the mainstay of diagnosing GORD in children. This is usually done passing the probe nasally, attempting to site the electrode 5 cm above the gastro-oesophageal junction. The position of the electrode can be determined directly if passed as part of an upper GI endoscopy or can be ascertained via a chest X-ray and repositioned. A wireless capsule can also be used, which has the advantage that it cannot be pulled out by the child. The probe remains in place for 24 hours and patient position, meals and symptoms are documented. pH monitoring provides excellent information regarding lower oesophageal acid exposure but does not provide evidence of non-acid reflux or about extra-oesophageal reflux. Dual probe pH monitoring attempts to provide more information about pH at the upper oesophagus and pharynx and has been widely used in the literature. Achieving a consistent position for the upper electrode has been difficult and drying has led to inaccuracy in pH reading.

A pH drop below 4 is considered significant and the reflux index (RI) refers to the percentage of the entire time of the study that the reading is below this. Within the realms of GORD a reflux index of less than or equal to 4% is considered normal or physiological. As explained, this may not apply to extra-oesophageal reflux but a high RI makes it more likely.

Multichannel oesophageal intraluminal impedance testing

For multichannel oesophageal intraluminal impedance testing a probe is passed like a pH probe which has several sensors along its length and measures changes in electrical resistance when a liquid, semi-solid or gas bolus passes between the electrodes. A combined impedance and pH probe can detect and distinguish acid and non-acid reflux as well as aerosolized, liquid or mixed reflux. Interpretation of the 24-hour study is time-consuming and subject to interobserver variability. Normative data are still lacking. Despite these limitations, pH/impedance monitoring is currently the most valuable investigation in refractory EOR.

As with pH monitoring, the symptom correlation remains difficult. This may be because symptoms such as hoarseness are not paroxysmal and airway symptoms caused by EOR may not occur within any 24-hour period.

Gastric emptying scintigraphy

This investigation may be useful to detect GORD and aspiration, but it is particularly helpful for delayed gastric emptying. It is not an investigation that is routinely done in the investigation of reflux.

Biopsy

Oesophageal biopsy is the mainstay of making a histopathological diagnosis of oesophagitis and eosinophilic oesophagitis. It may also be helpful in inflammatory bowel disease, coeliac disease and Barrett's oesophagus. Multiple biopsies are usually taken, as oesophagitis may be patchy. Absence of histological changes does not rule out GORD. Biopsies of the postcricoid and pharynx have been used to detect inflammation but clinical application is limited.

ENDOSCOPIC FINDINGS

When examining the laryngopharynx and trachea, various appearances have come to be associated with reflux. Many challenges exist, especially as the changes may represent inflammation and not specifically indicate reflux. Another issue is that the findings may exist on a spectrum and may be open to the interpretation of the operator, leading to some degree of interobserver variability. The value and specificity of the findings is therefore contested although there seems to be an evolving consensus that some findings are suggestive of reflux. Care must be taken in the interpretation of these findings in isolation without clinical correlation.

Posterior laryngitis was described by Delahunty[13] in 1972 as a sign of reflux laryngitis in adults (**Figures 44.1** and **44.2**). As the posterior larynx is in close proximity to the oesophageal inlet, it seems likely that this would be the most vulnerable extra-oesophageal site to reflux exposure (**Figures 44.3** and **44.4**). This relates to postglottic oedema and arytenoid oedema with loss of the normal arytenoid contour. It is suggested that severe arytenoid oedema, postglottic oedema and enlargement of the lingual tonsil may be pathognomic for GORD (**Figures 44.2**, **44.3** and **44.5**).[14]

The laryngeal 'pseudosulcus' refers to the appearance of a fold parallel to the free edge of the vocal cord. This may involve just the posterior cord or extend the length of the cord. It is thought to be a manifestation of infraglottic oedema (**Figure 44.6**). This finding appears to have a high sensitivity for reflux[15, 16] although its specificity is lower.

Other findings that have been described include generalized erythema, ventricle effacement and cord nodules.

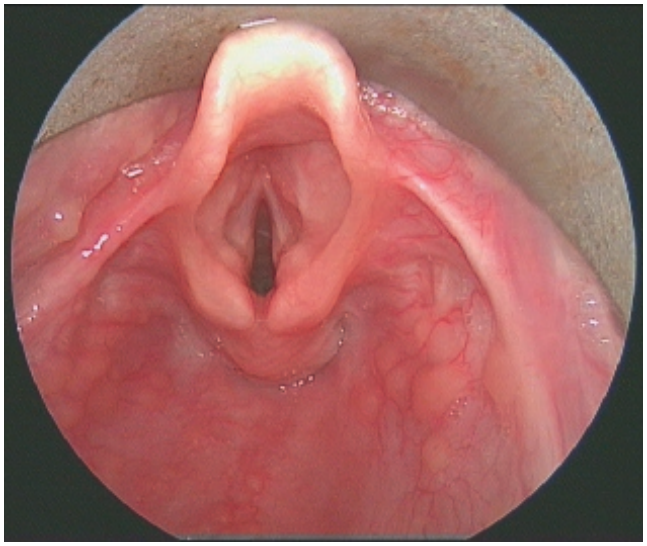

Figure 44.1 Larynx showing generalized erythema and ventricular effacement – a so-called 'active larynx'.

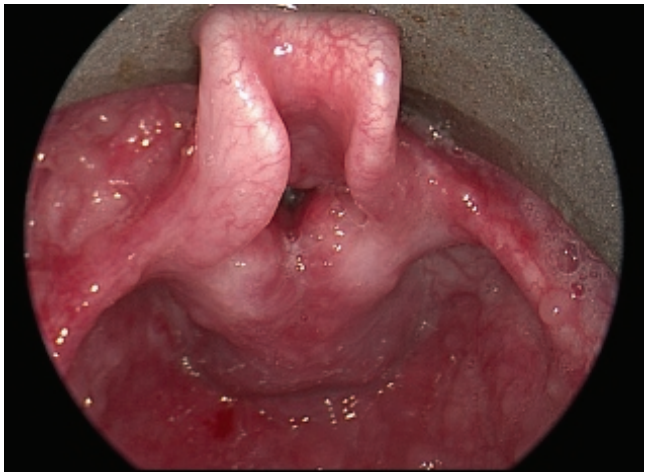

Figure 44.2 Laryngeal view of severe posterior inflammation.

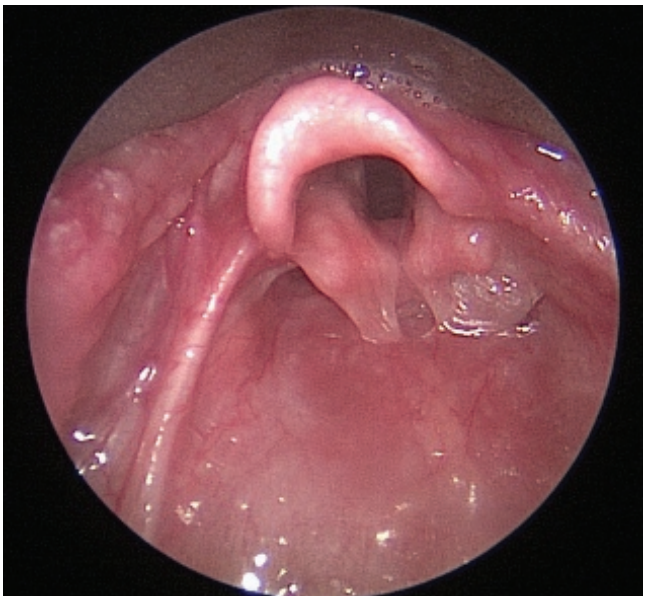

Figure 44.3 Larynx showing arytenoid inflammation and redundancy.

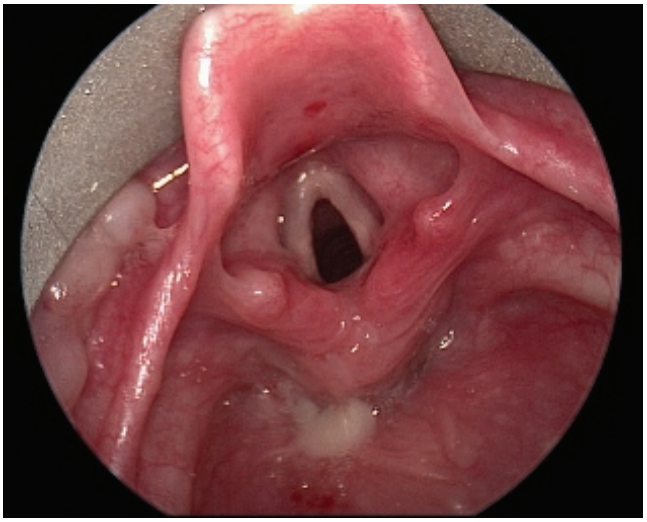

Figure 44.4 Laryngeal view showing an acute reflux episode bathing the posterior glottis.

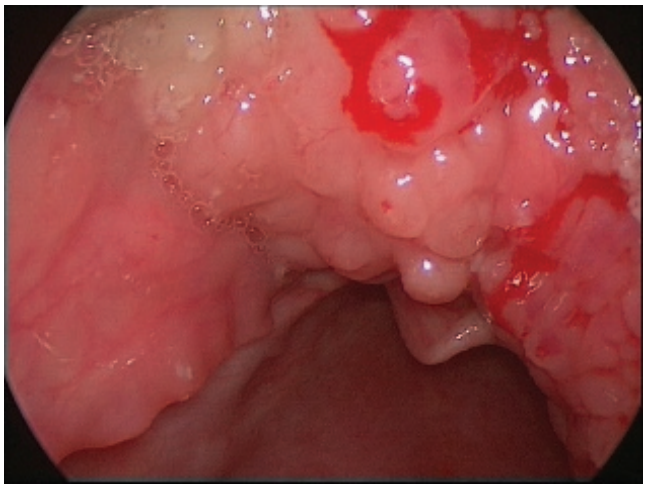

Figure 44.5 View of the valleculae demonstrating lingual tonsil enlargement.

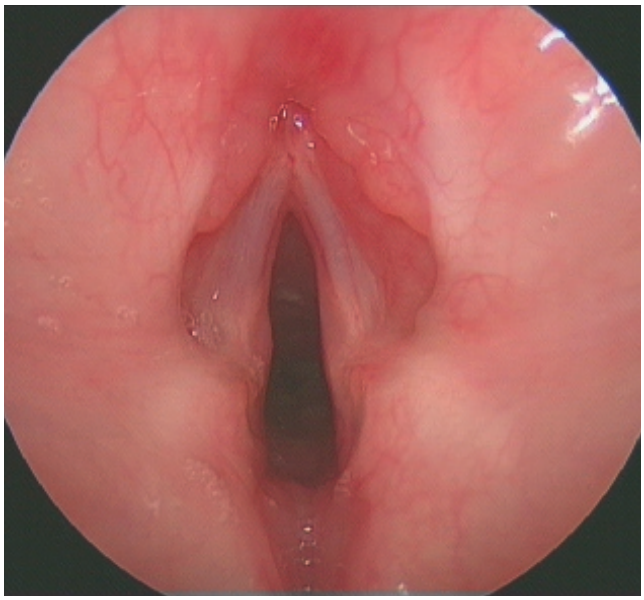

Figure 44.6 Vocal cords demonstrating vocal cord 'pseudosulcus'.

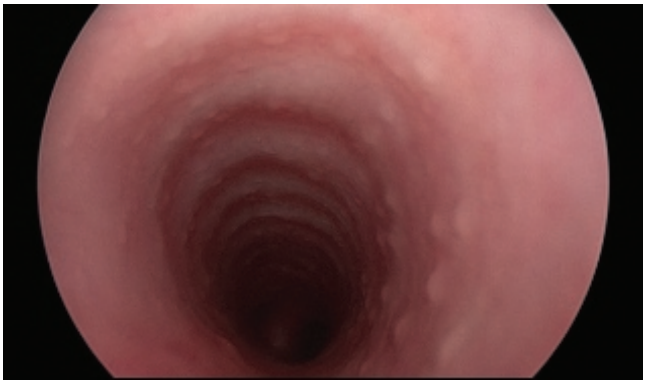

Figure 44.7 Tracheal view showing 'cobblestoning'.

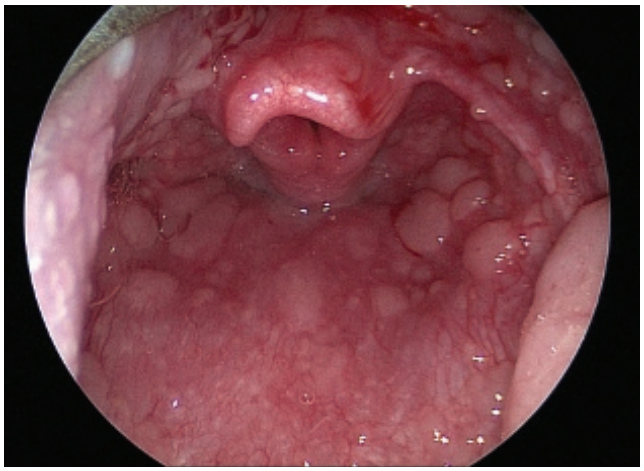

Figure 44.8 Laryngeal view demonstrating posterior pharyngeal wall 'cobblestoning'.

Findings seen in the pharynx and trachea include general oedema, erythema, indistinct tracheal rings and mucosal 'cobblestoning' (Figures 44.7 and 44.8). Blunting of the carina with loss of the normal sharp contour is also suggested to be significantly associated with reflux.[14]

The utility of these findings remains contentious. In addition to the issues raised earlier, all the mucosal changes have been demonstrated in the absence of reflux.[17] The findings appear to represent inflammation and reflux is a common source of non-acute inflammation. The findings should therefore alert the clinician to the possibility of reflux and direct the history and investigation. The clinician must be mindful that, in isolation, these findings have limitations.

THE PAEDIATRIC AIRWAY

It appears that EOR will impact the airway in different ways. Many of the typical endoscopic signs of mucosal change are seen in the airway although these are manifestations of inflammation, which may be the result of exposure to reflux or other irritant or inflammatory process. These may result in coughing or throat clearing, which may create more irritation and irritability. Coughing or increased work of breathing may worsen reflux, which may further exacerbate the problem. Aspiration of refluxate may cause or exacerbate pulmonary disease, the manifestations of which may promote multilevel airway pathology such as tracheobronchomalacia. This confluence of digestive, pulmonary and laryngotracheal involvement may have reflux as a unifying factor. This may be as cause or effect or both. It is the amalgamation and evolution of these effects that have rendered scientific study so difficult. In many ways, breaking down the airway manifestations into specific diagnosis may be unrealistic as reflux has been implicated in hoarseness,[18] laryngomalacia, subglottic stenosis, croup, ALTEs and chronic cough.[19] These conditions may of course coexist in the same patient and impact each other. The more general term of 'reflux-induced airway disease' may be helpful in thinking about these conditions more broadly.

Laryngomalacia

Laryngomalacia is the commonest cause of neonatal stridor. Children typically present within the first few days of life with high-pitched inspiratory stridor. The mainstay of assessment is awake flexible fibre-optic nasopharyngoscopy. The fibre-optic features may reveal foreshortened aryepiglottic folds with the classical 'omega'-shaped epiglottis. The other common finding is redundancy of the arytenoid mucosa, which prolapses forwards causing the obstruction (**Figure 44.9**). The appearances echo the findings of posterior laryngitis seen in reflux. This area is in close proximity to the oesophageal inlet and potentially most at risk from EOR.

Reflux appears to be found in the majority of patients with laryngomalacia[20–23] although it is not entirely clear whether it is causative. The increased work of breathing will result in increases in negative intrathoracic pressure, which will promote reflux. At this point the conditions may become self-perpetuating.

Figure 44.9 Laryngomalacia with arytenoid redundancy with prolapse into the glottis on inspiration.

Children with reflux tend to have more severe laryngomalacia, which is more likely to require surgical intervention.[21] Surgical treatment of laryngomalacia tends to reduce the severity of reflux if present pre-operatively.[24]

In view of the high incidence of reflux in infants with laryngomalacia, this diagnosis should always be sought and excluded in these cases. Infants with laryngomalacia who have coughing, choking, regurgitation and feeding difficulties may be considered candidates for empiric acid reflux suppression,[20] especially in the presence of emesis. A certain number of infants will clinically improve and acid suppression should be weaned based on symptom resolution. However, if responses to empirical therapy are poor, or the infant requires prolonged acid suppression, then the reflux status of these infants should be investigated in the usual manner.

It may be prudent to use antireflux therapy in all patients who have aryepiglottoplasty and supraglottoplasty surgery in the immediate post-operative period. This is to mitigate the risk of reflux on the raw surfaces created by the surgery.

Subglottic stenosis

Subglottic stenosis (SGS) and its treatment continues to be a challenge to the paediatric airway surgeon. In children the stenosis may be congenital or acquired. Acquired SGS generally occurs after some kind of trauma to the subglottis, the most common being endotracheal intubation.[25] Acquired SGS became recognized in the 1960s with the introduction of long-term intubation for the management of neonates needing ventilatory support.[26]

Animal models demonstrate that gastric acid in the presence of mucosal trauma such as might occur during endotracheal intubation may lead to stenosis.[2] Children with SGS seem to have high rates of GOR.[27, 28] In adults the clinical entity of idiopathic SGS, a condition of young adult women, is recognized, and there is intriguing

evidence that reflux plays a role.[29] While the role of reflux in the genesis of SGS remains somewhat unclear, it seems to be a significant cofactor.

GORD has been seen in over 80% of children undergoing laryngotracheal reconstruction (LTR).[30] The appearance of the so-called 'active larynx' (see **Figure 44.1**) has been recognized as a concern for the clinician contemplating performing an LTR. A cause for this finding of which reflux would be commonest should be sought and treated prior to reconstruction. The exposed mucosal surfaces and prolonged endotracheal intubation could serve as an environment in which reflux exposure could affect wound healing. This could lead to failure.[31] Reflux therapy has been seen to improve outcomes of endoscopic treatments for SGS and possibly reduce the number of children requiring surgery.[27]

Reflux certainly seems to occur in SGS and may well sometimes be causative and/or a cofactor in its genesis. Every attempt should be made to identify it. While it has been suggested that all LTR patients should have blanket empirical therapy, others have questioned its utility.[32] There is an evolving consensus that, where reflux is present and especially in the context of the 'active larynx', aggressive treatment is advisable. In view of the complexity and morbidity of surgery, the potential for the presence of reflux should be actively sought. The threshold for antireflux measures may be commensurately lower in this group of patients.

Apparent life-threatening events

An apparent life-threatening event (ALTE) is an episode of apnoea, choking or gagging that to the caregiver appears to be a near-death episode. Over half may be associated with reflux[33] although the significance of this is uncertain.

The mechanism may be multifactorial with both central and local factors at play. When the ALTE occurs suddenly in a well child, vocal cord closure may be occurring. A mechanism for reflux mediation through direct contact,[8] vagally mediated via the oesophagus,[9] or indeed via aspiration-associated reflux events[34] have been suggested. There is also evidence that short non-pathological central apnoea is associated with reflux[35] and it may be that this is a protective phenomenon. While causation has not been proven, where reflux is present, it may well be a cofactor. Fundoplication in children with ALTEs and reflux may be universally effective in eradicating the events when the fundoplication succeeds in stopping the reflux.[36]

Recurrent croup

Croup (acute laryngotracheobronchitis) is usually a viral illness characterized by a prodrome of an upper respiratory tract illness followed by hoarseness, a barking cough and various degrees of inspiratory and expiratory stridor. The illness is usually self-limiting and responds to supportive therapy although it can occasionally result in significant airway compromise. Croup is unusual before 6 months of age and in older children. As croup is usually self-limiting, a child requiring admission, particularly if requiring high-dependency or intensive care, should be viewed as atypical. Recurrent croup (i.e. more than two cases in a year) is also atypical and in all these clinical scenarios an underlying cause should be sought. There is some evidence that reflux may be present in this clinical scenario.[37–39] The exact mechanism is unclear but may relate to high rates of SGS in this group as well as other airway lesions. Convincing causative data are lacking at this time.

Recurrent respiratory papillomatosis

There is limited evidence that reflux may play a role in recurrent respiratory papillomatosis (RRP) control. Where present, it may affect the rate of recurrence and in some cases reflux control may hasten resolution.[40] There is also evidence that reflux control may reduce anterior commisure web formation.[41] The numbers of cases in the literature are too small to draw definitive conclusions but certainly in cases of RRP where there is demonstrable and symptomatic reflux antireflux therapy would seem to be sensible in view of the creation of raw epithelial surfaces that often accompany surgery.

NASOPHARYNX AND OROPHARYNX

Rhinosinsitis

The role of EOR in rhinosinusitis is extremely contentious. Nasopharyngeal reflux exposure obviously occurs during emesis. There is some limited evidence that reflux may adversely affect choanal atresia repair.[42] A significant proportion of children with nasal symptoms appear to have histologically proven GORD.[43, 44] Increased exposure times to low pH have been seen in children with chronic nasal disease.[45] In children with sinus disease and GORD there is some evidence that antireflux therapy may reduce the need for sinus surgery.[46]

In adults with refractory sinus diseases, increased nasopharyngeal altered pH and increased rates of gastro-oesophageal reflux have also been demonstrated.[47, 48] Early results demonstrating pepsin in nasal lavage seem encouraging and may represent a possible means of detecting reflux involvement in sinus disease.[47]

While definitive causative data are lacking, there is emerging evidence to suggest that reflux may have an impact in some cases of sinus disease. There is insufficient evidence to recommend routine screening of asymptomatic children with sinus disease. However, it seems sensible to take a reflux history in these patients and, if suggestive, investigate and treat, particularly if the sinus disease is proving refractory to conventional treatment.

Otitis media

As mentioned above, EOR appears to impact the nasopharynx and sinuses. In 2002, pepsin/pepsinogen was

detected in middle-ear effusions at much higher concentrations than were present in serum.[49, 50] The source of this could only be gastric and raised the possibility that reflux might play a role in otitis media with effusion (OME).

Low pH reduces ciliary motility in respiratory epithelium.[6] In animal experiments acid and pepsin instilled into the nasopharynx increased the opening and closing pressures of the Eustachian tube (ET) as well as the mucociliary clearance times.[51] These impact the ability of the ET to equalize middle ear pressure during swallowing and, in addition to impaired ciliary motility, may explain reflux-induced ET dysfunction. Potentially, this may represent a model for the role of reflux in acute otitis media (AOM), recurrent acute otitis media (RAOM) and OME.

Assessing the role of GOR/EOR in otitis media (OM) is challenging as both have a high incidence, particularly in younger children. Multiple studies have suggested that the prevalence of GORD in children with OM is higher than overall prevalence.[52] The prevalence of GORD in OME ranges from 17.6% to 64% and in RAOM from 61.5% to 64.3%.[52] Small studies have suggested that, where GORD is present, antireflux therapy may reduce the incidence of RAOM.[53]

Unfortunately, despite initial excitement about the reflux–otitis link, no cause-and-effect relationship has been demonstrated satisfactorily. While it remains an area of research interest, there is insufficient existing evidence to support antireflux therapy in OM.[52]

Adenotonsillar hypertrophy

The effect of reflux within the nasopharynx may also impact on the adenoidal pad as well as the ET and sinuses. Children under the age of 2 years undergoing adenoidectomy alone appear to have much higher rates of GORD than their counterparts having grommets alone.[54] Children under 18 months having adenoidectomy also have higher rates of GORD and synchronous airway lesions.[55] Whether this is cause or effect remains to be demonstrated. There is anecdotal evidence that treatment of GORD has resulted in reduction of adenotonsillar size and resolution of obstructive sleep apnoea (OSA).[56]

When assessing children who remain symptomatic post-adenotonsillectomy for OSA, reflux should be considered.[57] Children with a history of GOR appear also to have a higher rate of post-operative complications after adenotonsillectomy.[58]

More recently there has been interest in the presence of *Helicobacter pylori* (HP) in adenotonsillar tissue. Infection with the agent has been shown to be a significant factor in peptic ulcer disease.[59] The evidence seems contradictory, with some studies showing PCR detection of HP in the removed adenoid in impedance-demonstrated EOR.[60] Other studies have not found adenoidal HP despite a strong history of EOR.[61]

Some studies, particularly those using the rapid urease test, failed to demonstrate significant HP involvement in tonsil tissue.[62, 63] Using PCR techniques, HP detection in tonsils has led to the hypothesis that the tonsil is an extragastric reservoir for the organism.[64, 65] It is further postulated that HP may play a role in tonsillitis. While the findings are interesting, their true significance is unclear. This area may prove clinically relevant but as yet remains within the realm of research interest.

MANAGEMENT

The diagnosis of EORD disease is made on an individual basis based on history, clinical findings, pathology and investigations and sometimes on response to therapy. It is often helpful to enlist the aid of a paediatric gastroenterologist.

Other diagnoses for the symptoms should be considered, especially cows' milk protein intolerance. Elimination should be tried. This may involve maternal dietary modification if the child is breastfed.

Limited literature exists to determine the efficacy of therapy for EOR. Most of the literature deals with response of GORD to therapy and we may extrapolate the results to EOR although it is by no means clear that it is appropriate. Certainly, when GORD is established, therapy is indicated and there is a large body of evidence supporting pharmacological therapy. Where there is EOR but no GORD, the evidence for the efficacy of therapy is less clear.

Simple lifestyle changes are often tried in the first instance. Neonates are fed upright with feeds 'little and often'. Feed thickening may help with emesis. For adolescents smoking cessation, alcohol avoidance and weight loss if obese are recommended. Cessation of habitual throat clearing and vocal hygiene advice may be of benefit.

In patients with a strong clinical picture, an empirical antireflux therapy trial is not unreasonable. This is done on the basis that investigations such as pH/impedance are unpleasant for children and antireflux therapy is relatively benign. That said, it should be borne in mind that therapy is not always tolerated and that there are risks.

Pharmacological agents include barrier agents, prokinetic therapy, histamine-2 receptor antagonists and proton pump inhibitors (PPIs).

Barrier agents tend to contain either an alginate or sucralfate. These treatments act to create a barrier between the mucosa and the gastric content. They are generally well tolerated although constipation and diarrhoea may be seen. There may be a risk of aluminium toxicity with prolonged sucralfate use.

Prokinetic agents attempt to reduce reflux by hastening gastric emptying, however there is currently insufficient evidence to support the routine use of these drugs in view of the significant risks.[11]

Histamine-2 receptor antagonist therapy is a well-established therapy usually used twice daily. It has been shown to increase gastric pH for 9–10 hours in infants.[66]

The main issue with use is tachyphylaxis, which is a drawback to long-term use.

Proton pump inhibitor therapy is probably the most widely used therapy for EOR and is more effective at treating oesophagitis and GORD symptoms than H2 receptor antagonists.[11] In contrast to H2 receptor antagonists, the effect of PPIs does not diminish with time. The main risks of therapy of both groups of drugs are an increased rate of community-acquired pneumonia and gastroenteritis. While empiric trials of therapy are useful, treatment should be maintained on as low a dose as possible. If there is failure to show a rapid response to therapy, more detailed investigations should be sought, such as impedance/pH studies.

Consideration to surgical intervention is limited to patients refractory to maximal medical and lifestyle modifications. Certainly in this group it is important to have as much supporting evidence of reflux as possible and to have ruled out a non-reflux diagnosis prior to consideration of surgery. The chief mainstay of surgical intervention is fundoplication, with laparascopic techniques now largely replacing open techniques.

EOSINOPHILIC OESOPHAGITIS

Eosinophilic oesophagitis (EO) is a relatively new clinical entity. It was first described in the literature in the 1990s and over the past 20 years has become an increasingly diagnosed condition in gastroenterology. It first entered the otolaryngology literature in 2002 with a description of a child with the condition who had failed multiple laryngotracheal reconstructive procedures despite effective antireflux therapy.[67] The association between SGS and EO has been seen in other studies[68] with possibly as many as 10% of EO patients being affected.[69]

The condition itself is an inflammatory oesophagitis related to eosinophilia that appears to be immune-mediated. In adults it is known to be a cause of dysphagia and lower oesophageal food impaction and hence the need for biopsy of the oesophagus in this clinical scenario. Children more commonly manifest choking, gagging, nausea, vomiting, diarrhoea and food refusal. GORD-type symptoms including heartburn and regurgitation are common and EO may commonly be mistaken for this. Reflux may coexist with the condition, which may further confuse the picture. A poor or limited response to antireflux therapy should alert the clinician to this potential diagnosis.

Within the realm of otolaryngology a wide variety of airway symptoms have been described particularly cough, stridor, croup and dyspnoea.

The diagnosis is based on a finding of more than 15 eosinophils per high-power field on oesophageal biopsy.[70] The oesophageal appearances are typically of mucosal oedema, erythema and furrowing. The mucosa may also appear normal in almost a third of cases.[70] Multiple biopsies should be taken from different oesophageal sites. There does not appear to be any value in pharyngeal biopsy of affected individuals.[71]

There is a strong male preponderance. The majority of patients have evidence of atopy, particularly allergic rhinitis, asthma and atopic eczema. There may be evidence of food allergy and a strong family history of atopy.

Once the diagnosis is suspected, it is helpful to enlist the aid of a gastroenterologist. A pH/impedance study is helpful, as are multilevel oesophageal biopsies. The current treatment consists of swallowing topical corticosteroids. If food allergy is identified, food elimination or ultimately an elemental diet may be beneficial.

CONCLUSIONS

The true role of reflux in the genesis and propagation of disease within the head and neck remains hugely challenging and controversial. There is good causative evidence for its role in GORD and consensus exists for both its diagnosis and treatment. Unfortunately, no such evidence or consensus exists for EOR. The variety of substrate tissue and function located in such a small area, as well as the interaction of disease processes in each of these with each other, makes the picture even more confusing. Symptoms such as cough or voluntary mechanisms such as throat clearing may increase inflammation, irritability and indeed reflux itself that may in turn exacerbate the problem. This complexity and variability may render robust data and consensus some way off, especially within the realm of reflux-mediated airway disease.

Ultimately, the diagnosis of EORD is a clinicopathological one. Each patient must be viewed as an individual. The diagnosis is made, taking into account the available information from the history, examination, investigations and possibly response to trials of therapy. This will usually be a collaborative effort between gastroenterologist, otolaryngologist, pulmonologist and paediatric surgeon.

Both EO and EORD require a high index of suspicion. Care must be taken to assemble as much information to support or refute the diagnosis as possible. If therapy is instituted, this should be regularly reviewed and the patient weaned off as soon as practical. Parents and clinicians should be aware of the potential complications of therapy. If the initial response to therapy is poor, a re-evaluation should be undertaken.

EORD remains a hugely challenging and controversial area in paediatric otolaryngology. It is clear that reflux plays some role in either the genesis or propagation of a variety of conditions in some children. It is helpful for all clinicians to have an awareness of the condition as well as the limitations of the evidence. It seems likely that our knowledge and understanding will continue to advance exponentially.

FUTURE RESEARCH

- To establish normative values for extra oesophageal reflux using impedance testing.
- To establish a casual link for EOR and airways disease, sinus disease, ear disease and adenotonsillar disease.
- To determine if H Pylori plays a significant role in paediatric reflux mediated otolaryngological disease.

KEY POINTS

- Extra-oesophageal reflux is implicated in the genesis and propagation of various paediatric airway disorders. There is possibly an association with Eustachian tube disorders, rhinosinusitis and adenotonsillar hypertrophy but the evidence is weaker.
- Extra-oesophageal reflux is a clinicopathological diagnosis based on history, examination, investigations, endoscopic findings, exclusion of alternate diagnoses and response to therapeutic trials.
- There is no one definitive investigation that proves or excludes extra-oesophageal reflux disease.
- Extra-oesophageal reflux disease can occur in the absence of gastro-oesophageal reflux disease although it is more likely if oesophageal reflux disease is present.
- Eosinophilic oesophagitis is an immune-mediated inflammatory oesophagitis. It is more common in atopic individuals and there is a male preponderance. There are airway manifestations. It is diagnosed by histological appearance of oesophageal biopsy. It is treated by swallowing topical corticosteroids and by food allergen avoidance.

CHAPTER 45

OESOPHAGEAL DISORDERS IN CHILDREN

Graham Haddock

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: congenital anomalies of the oesophagus, acquired disorders of the oesophagus, achalasia, caustic oesophageal injury, other oesophageal injury, neonates, infants and children.

CONGENITAL ABNORMALITIES OF THE OESOPHAGUS

Introduction

Congenital abnormalities of the oesophagus are fairly common in paediatric surgical practice. Many of these arise during fetal foregut development when the oesophagus separates from the trachea, and many present early in the neonatal period, require prompt complex surgery and can have long-term sequelae. Some of the rare oesophageal abnormalities present later in life with symptoms which are often difficult to understand.

Oesophageal atresia with or without tracheo-oesophageal fistula

Oesophageal atresia (OA) with or without an associated tracheo-oesophageal fistula (TOF) (OA +/- TOF) is one of the most common conditions which present to neonatal surgeons. It is thought to affect between 1 in 2000 and 1 in 5000 live births.

The embryonic origin of OA and TOF is thought to be similar to that seen in laryngotracheal clefts. If the separation of the developing oesophagus and the trachea by the lateral mesodermal ridges fails, the result is an isolated TOF. The embryologic origin of the more complex OA + TOF is less clear.[1, 2]

There are a number of variants of OA + TOF. The commonest form, which accounts for approximately 85% of cases, comprises a blind-ending proximal oesophageal pouch with a fistula from the trachea or bronchus to the distal oesophagus. Isolated or long-gap OA accounts for approximately 10% of cases in most published series. Isolated TOF without OA (known as an H- or N-type TOF), OA with a TOF to both distal oesophagus and proximal oesophageal pouch, and OA with a TOF to the upper oesophageal pouch are much less commonly seen variations of this anomaly (Figure 45.1).

Antenatal maternal polyhydramnios, which can affect approximately half of pregnancies with the various forms of OA, may give a clue to the presence of this abnormality.

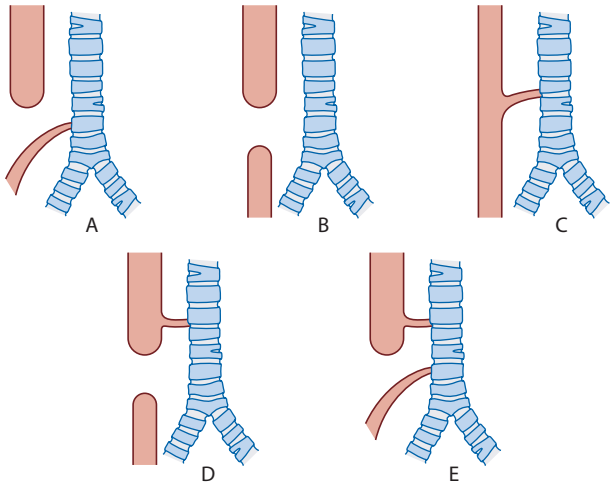

Figure 45.1 Types and incidences of oesophageal atresia with or without a tracheo-oesophageal fistula. Type A (OA with distal TOF): 85%; Type B (isolated OA): 8%; Type C (isolated H or N type TOF): 4%; Type D (OA with proximal TOF): 2%; Type E (OA with proximal and distal TOF): <1%.

A failure to identify the fetal stomach on antenatal ultrasound after 20 weeks' gestation may prompt a diagnosis of isolated OA, although this finding is not completely reliable. Either of these antenatal features should prompt the passage of an orogastric tube immediately after delivery of the newborn.

The newborn affected by any of the common variants of OA (but obviously not the baby with an isolated TOF) will present clinically with frothing at the mouth, choking episodes, cyanosis and respiratory distress. Attempts at feeding will clearly precipitate such symptoms and may cause aspiration and severe respiratory distress. Infants with an isolated TOF may present later in life with recurrent chest infections, symptoms of chronic respiratory disease and bronchospasm. Many will have been thoroughly investigated for cystic fibrosis. Some of these will present in the ENT clinic, hence otolaryngologists need to be aware of the clinical features so they can arrange appropriate investigations, including tracheobronchoscopy when indicated.

Many babies with OA will have associated anomalies. These might include vertebral anomalies, extra or missing ribs, anorectal malformations, cardiac abnormalities, renal or radial anomalies and limb deformities. These are often grouped together and are known as the VACTERL association. The aetiology of these associations is not clear.

The inability to pass an oro- or nasogastric (NG) tube in the newborn is virtually diagnostic. The tube should be a relatively large bore (at least 10 Fr) to avoid missing the diagnosis (**Figures 45.2a-b**). Thinner tubes may be seen to be curled up in the upper oesophageal pouch on a chest X-ray, which also confirms the diagnosis (**Figure 45.3**). Contrast studies or other imaging modalities are not required. The presence of gas in the abdomen on a plain abdominal or chest X-ray will indicate that the baby with OA has an associated TOF. Associated vertebral and rib anomalies can be detected on abdominal and chest X-rays (**Figure 45.2b**).

A comprehensive physical examination of the baby should be supplemented by a number of imaging modalities. An ultrasound scan of the kidneys is required to exclude associated renal anomalies. A cardiological assessment including echocardiography is essential pre-operatively to identify any life-threatening cardiac lesion and to locate the position of the aortic arch,[3] which can be on the right side in 2% of cases. A right-sided aortic arch may make the surgery even more challenging than usual.

In the older child suspected of having an isolated TOF, a pull-back ('tube') oesophagogram with the patient prone or in the left lateral position may make the diagnosis clear (**Figure 45.4**). Contrast may be introduced via an NG

Figure 45.2 Lateral (a) and AP **(b)** chest and abdominal X-rays of a newborn with OA and TOF. A large-bore tube has been placed under tension in the upper pouch. The stomach and intestine contain air which indicates the presence of a TOF. Vertebral anomalies can be seen in the mid thoracic spine.

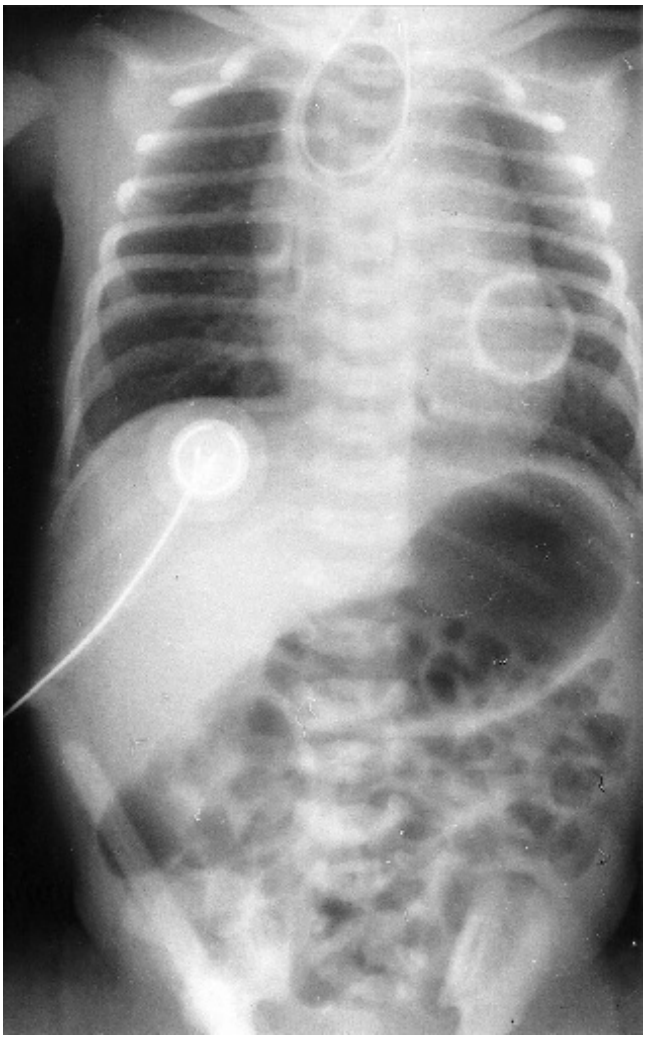

Figure 45.3 Thin nasogastric tube curled up in the upper oesophageal pouch in a newborn with OA and TOF.

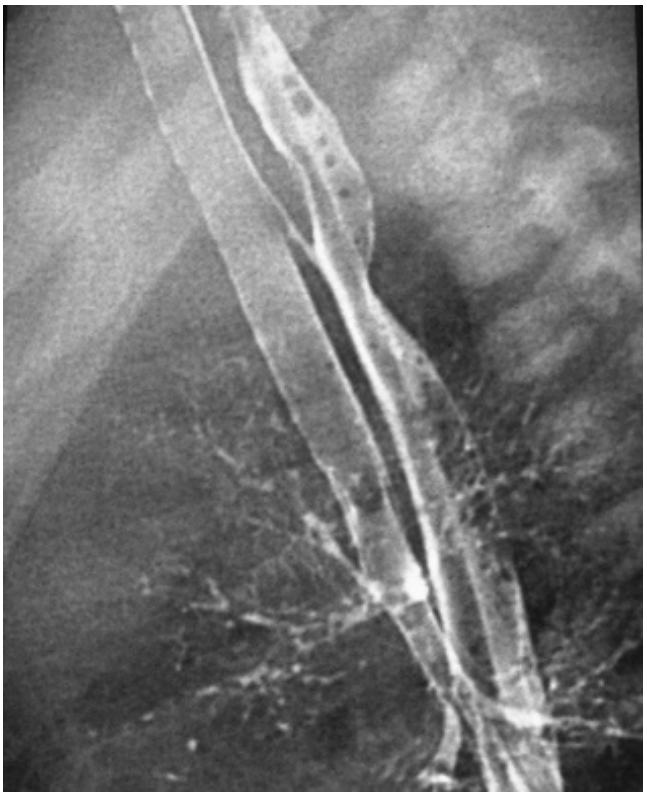

Figure 45.4 H or N-type fistula study demonstrating an isolated fistula between the oesophagus and the trachea.

tube. A tracheobronchoscopy may be needed to identify an isolated TOF and occasionally the fistula is concealed in a mucosal fold, making diagnosis difficult.

Early patient management should focus on maintaining a patent airway and preventing the aspiration of saliva and upper pouch secretions. The baby should be nursed prone with a sump suction (Replogle) tube in the upper pouch set on continuous aspiration. This tube should be injected regularly with air to prevent blockage. Endotracheal intubation and ventilation should be avoided if possible. Positive pressure ventilation in the presence of a TOF may result in large amounts of gas passing into the stomach and intestine. This trapped gas may have no easy route of escape, especially if the baby has an associated intestinal abnormality, like an atresia or anorectal malformation. Abdominal distension due to gaseous distention may impair ventilation and result in hypoxia, hypercapnia and acid-base upset. Gastrointestinal perforation in such cases can have a devastating outcome.[4]

Management of OA and TOF is ligation of the fistula and end-to-end anastomosis of the oesophagus. Prior to surgery, most paediatric surgeons will request that a bronchoscopy be performed to identify any upper pouch fistula and confirm the exact position of the TOF. This may allow the anaesthetist to position the endotracheal tube past the fistula to limit the passage of ventilated gas into the stomach.

Repair can be achieved through an open extrapleural thoracotomy[5, 6] or by using a minimal access thoracoscopic approach.[7–9] The site of the fistula is identified and dissected from surrounding structures. The fistula is divided and sutured closed as flush as possible with the trachea. A large-bore tube passed into the upper oesophageal pouch by the anaesthetists will help identify the pouch. Careful dissection will ensure that the trachea is not damaged during upper-pouch mobilization. A single-layer all-coats anastomosis of the ends of the oesophagus over a transanastomotic feeding tube is probably the most common form of primary surgical repair.

In cases where the gap between the ends of the oesophagus is too far apart for primary repair, there are a number of options for treatment. Ligation of the TOF with creation of a feeding gastrostomy may be the preferred approach initially. This would be followed by a delayed primary repair at a later stage. This approach would require long-term use of a sump suction tube in the upper oesophageal pouch to prevent aspiration of secretions and may require a period of long-term inpatient care. The creation of an open oesophagostomy (or spit fistula) may avoid the need for inpatient care and allow the infant to sham feed but

almost always precludes delayed primary repair at a later date as the length of the upper oesophagus is lost.

The Foker technique of lengthening of the oesophagus by applying traction using two lengths of thread attached to each end of the oesophagus has been reported to achieve delayed primary anastomosis in a shorter timeframe.[10, 11]

In cases of isolated or long-gap OA without a TOF, delayed primary repair remains the preferred approach for treatment.[12] If this is not possible, replacement of the distal oesophagus with a colonic, jejunal or gastric interposition may be required.[13–18] Occasionally, oesophageal lengthening procedures may have a role to play in achieving a safe primary or secondary oesophageal anastomosis.[19]

Complications of surgery to repair OA include anastomotic breakdown and leak, anastomotic stricture, refistulation and gastro-esophageal reflux. If the fistula is not sutured flush with the trachea, a blind-ending pouch can be left behind. Occasionally, this causes problems with intermittent airway obstruction. Most children without other associated congenital anomalies grow and develop normally. Associated very low birth weight and the presence of associated major cardiac defects have been shown to be good markers of poorer outcome in OA.[6, 20]

Congenital oesophageal stenosis

Congenital stenosis of the oesophagus is thought to represent the mild end of the spectrum of conditions caused by problems during the separation of the fetal trachea from the foregut tube during development. The majority of these anomalies affect the middle and distal oesophagus. Three types are described: those containing remnants of cartilage,[21] those with fibromuscular thickening and those with membranous webbing.[22] Stenoses in other parts of the oesophagus have other causes including peptic strictures at the lower end secondary to acid reflux.

Minor degrees of oesophageal stenosis may be completely asymptomatic. Failure to thrive and regurgitation of feeds may be seen when the narrowing is more severe. Sometimes the symptoms do not become apparent until the infant starts to eat solid foodstuffs.

Investigations include an upper gastrointestinal contrast swallow, which will reveal the area of narrowing, and upper gastrointestinal endoscopy. Oesophageal biopsy, particularly if deep, may reveal cartilage.

Dilatation of congenital oesophageal strictures rarely succeeds, especially if there is cartilage in the stenosis. Surgical resection of the area of narrowing and the cartilaginous tissue is usually required in severe cases. Reports of successful minimally invasive surgery for these abnormalities have been published.[21]

Oesophageal webs and rings

In addition to the more commonly encountered OA, a rare, membranous, mucosal atresia of the oesophagus has been reported which is indistinguishable from OA if the membrane is complete.[23] Some cases have been associated with a TOF. A mucosal membrane occludes the oesophageal lumen. In cases where the membrane is perforate, symptoms may be minimal or absent.

The diagnosis of an oesophageal web causing complete obstruction by failure to pass an oro- or nasogastric tube necessitates surgical intervention. The perforate or crescentic membrane usually presents later in life and can be identified on a contrast swallow examination or at upper gastrointestinal endoscopy.[24]

Resection of the membrane at thoracotomy is usually the only possible treatment for the complete membrane. In incomplete membranes, dilatation[24] or endoscopic incision of the membrane by cautery or laser with or without balloon dilatation should be considered.[25] Associated gastro-oesophageal reflux may require vigorous treatment, including possibly surgery, to prevent further stricture formation.

Oesophageal duplication and bronchogenic cysts

Oesophageal duplications appear as tubular or cystic structures in the posterior mediastinum (**Figures 45.5** and **45.6**). They are similar in many respects to other gastrointestinal duplications: they are all lined by gastrointestinal epithelium, have a well-developed smooth muscle wall, and are attached to the normal gastrointestinal tract at some point through their length.

Duplication cysts of the oesophagus, while rare, are the most common of the foregut duplication cysts. Their embryology is not clear. Associated vertebral anomalies might support the 'split notocord' theory of development.[26] This theory suggests that abnormal adhesion between

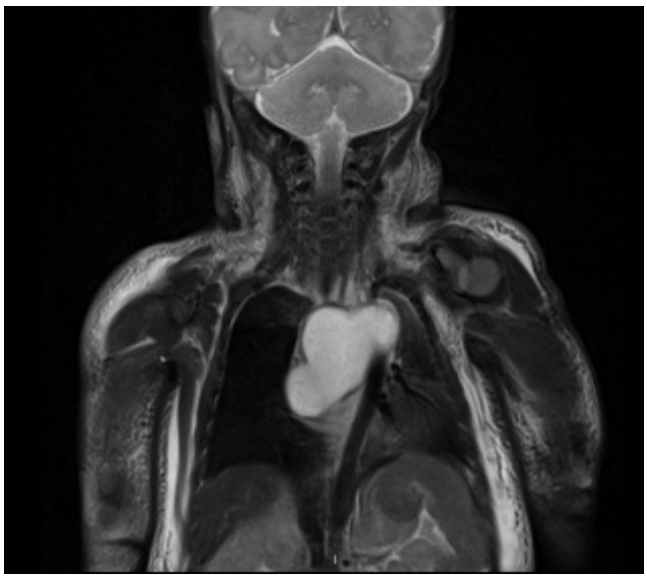

Figure 45.5 Coronal section of a T2-weighted MRI scan on a neonate with an antenatally diagnosed thoracic duplication cyst. The oesophagus and heart have been pushed to the left. The cyst was resected thoracoscopically. Histopathological examination confirmed the classical features of a foregut duplication cyst. It was lined by specialized gastric mucosa and otherwise comprised submucosa and well-formed muscularis propria.

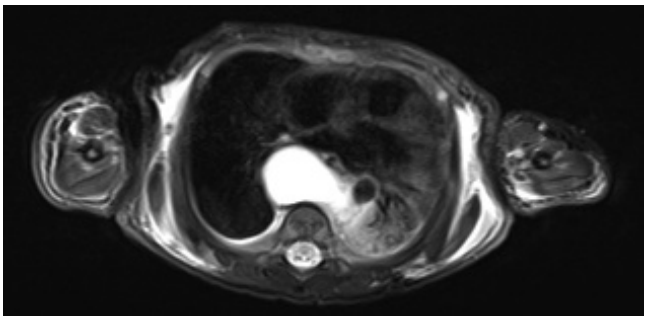

Figure 45.6 Transverse section of a T2-weighted MRI scan of the patient in Figure 45.5. Again the oesophagus can be seen pushed to the left.

ectoderm and endoderm prevents ventral notochordal fusion. Herniation of the yolk sac develops between the halves of the split notochord, resulting in foregut duplication and an associated vertebral anomaly. Alternatively, in those cases without associated vertebral anomalies it has been suggested that some oesophageal duplications occur due to incomplete recanalization after its solid phase of development.[27]

Bronchogenic cysts occur due to abnormalities in the budding process seen during the development of the tracheobronchial tree. Most of these mainly benign lesions are found within the lung parenchyma, but approximately 30% present as mediastinal masses. Occasionally, they are found in the oesophageal wall although they more usually compress the oesophagus from the outside. They are difficult to distinguish from oesophageal duplication cysts and may have a common embryological origin.[28, 29]

Oesophageal duplication cysts present most commonly in the neonatal period with respiratory distress caused by the cyst compressing the lungs and airways, but antenatal diagnosis of a thoracic cyst is becoming more common. Dysphagia can occur in older children. Smaller cysts may be asymptomatic and be detected on a routine chest X-ray. Erosion of the wall of the cyst by acid secreted by the gastric mucosa that can line these lesions can cause serious bleeding.

The diagnosis is usually suspected from the appearance seen on a chest X-ray. A contrast swallow may reveal a communication with the cyst or an indentation of the oesophagus. Chest CT or MRI are the most useful investigative tools (**Figures 45.5** and **45.6**).[30]

Excision of the duplication is the most appropriate treatment option. Excision may not be possible if the oesophagus and the cyst share a common wall. Excision of the bulk of the cyst with removal of the oesophageal mucosa may be an option in such circumstances. Open surgery is gradually being replaced by minimal access approaches to resection of these lesions.[31, 32] Percutaneous drainage under ultrasound guidance prior to definitive surgery may be helpful in newborns where the cyst is causing severe respiratory distress.[33]

Bronchogenic cysts should also be excised. This is usually fairly easy if the cyst is not part of the oesophageal wall but much more difficult if the cyst is within the oesophageal wall.

Oesophageal diverticula

True congenital oesophageal diverticula, which contain all layers of the wall of the oesophagus, are uncommon.[34] False or pulsion diverticula, which are herniations of the oesophageal mucosa between defects in the oesophageal muscular wall, are more common.

The symptoms caused by an oesophageal diverticulum depend on the size and position of the abnormality. Dysphagia can occur as a consequence of compression of the oesophagus from the diverticulum and is the most common presentation. Bad breath from debris retained in the diverticulum may also be obvious.

The diagnosis is usually made on contrast radiology or by endoscopic examination. Treatment requires resection of the diverticulum and repair of the resultant defect in the oesophageal wall and may require thoracotomy or thoracoscopy for lesions in the mid oesophagus.

Oesophageal bronchus

Oesophageal bronchus, where a bronchus takes its origin from the oesophagus, is the most common congenital bronchopulmonary foregut malformation and may be associated with OA and TOF.[35] It can present in different ways including with respiratory symptoms and signs with recurrent sepsis or from the consequence of the consolidated or collapsed lung. It may be found incidentally during investigation for other conditions.

A chest X-ray may reveal an opacity in the lung fields and a contrast or radioisotope study of the gastrointestinal tract for reflux may show contrast or tracer in the lung. An upper gastrointestinal (GI) endoscopy may reveal the fistula, usually in the middle or lower thirds of the oesophagus, and bronchoscopy will demonstrate the absence of a major bronchus. Angiography should be undertaken to demonstrate that the lung associated with the bronchus has an appropriate blood supply. A recent study has reported prenatal MRI findings in a patient with a fetus with an oesophageal bronchus.[36]

Resection of the bronchus and associated lung tissue is usually the treatment of choice. Anastomosis of the bronchus to the trachea may be possible in some cases.[37]

Congenital short oesophagus

Congenital short oesophagus is a rare anomaly that was first described clearly in 1958.[38] Since then, there has been considerable debate as to whether it is a true entity in itself; it has sometimes been described as a congenital hiatus hernia.

In this anomaly the oesophagus is short with an intrathoracic stomach and a hiatus hernia. Affected babies present with failure to thrive in the first few months of life.

Treatment options are very limited and may be technically extremely challenging.[39] A surgical procedure to treat gastro-oesophageal reflux may be possible.

ACQUIRED DISORDERS OF THE OESOPHAGUS

Achalasia of the cardia

Achalasia of the cardia is an uncommon motility disorder of the distal oesophagus in children which causes a functional obstruction at the level of the lower oesophageal sphincter. It tends to affect teenagers. In children it presents with vomiting, difficulty swallowing, respiratory symptoms, weight loss and occasionally chest pain. It can also cause night-time regurgitation. The swallowing difficulty usually starts with solid foodstuffs but can progress on to liquids. Bad breath may also be a feature.

The aetiology of this condition is poorly understood. An upper GI contrast study will reveal the classical appearance of a dilated, baggy oesophagus with a beaked appearance at the lower end (Figure 45.7). An upper GI endoscopy will reveal a baggy, dilated oesophagus which may contain food debris. This investigation may be important to exclude other even more uncommon conditions and allows an assessment of the presence or absence of inflammation. Affected patients have a high resting lower oesophageal sphincter pressure, failure to relax the lower oesophageal sphincter and poor oesophageal peristalsis on manometry studies.

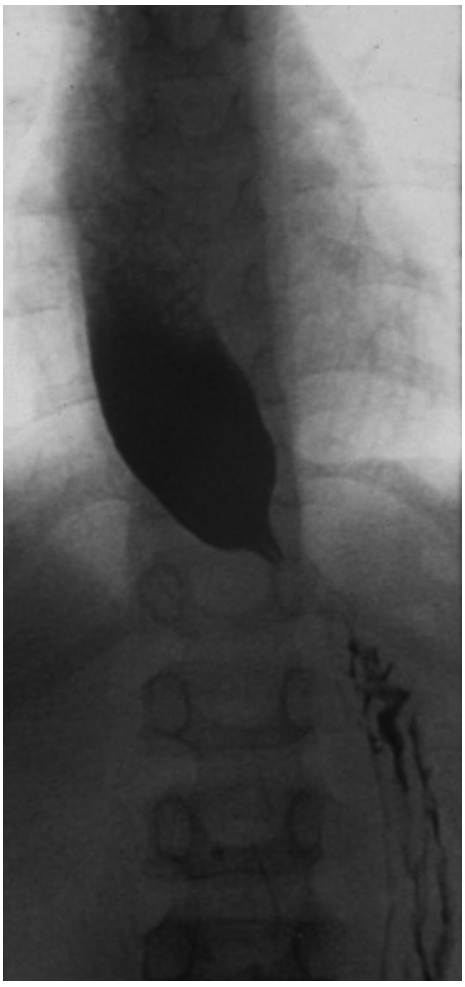

Figure 45.7 Upper GI contrast study in patient with achalasia of the cardia demonstrating massive dilatation of the oesophagus.

Given our poor understanding of this condition, there is no general consensus of how best to treat it. Drugs (including anticholinergics, calcium channel blockers and nitrates) have little to offer in affected children due to the high incidence of side effects and lack of sustained benefit. Pneumatic balloon dilatation under imaging control may have a place. Repeated dilatations are usually required and complications, including oesophageal rupture, are not uncommon. More recently, botulinum toxin (botox) has been successfully used in several centres.

The surgical management usually involves a myotomy of the lower oesophagus, which is extended onto the stomach, protected by an antireflux procedure performed at the same time. The commonest combination is a Heller cardiomyotomy and a partial fundoplication. This can be achieved laparoscopically.[40] More recently, peroral endoscopic myotomy has been described with comparable results to laparoscopic cardiomyotomy.[41, 42]

Oesophageal injury

Injuries to the oesophagus in children are usually due to the ingestion of noxious substances or foreign bodies. Iatrogenic injuries from instrumentation of the oesophagus during endoscopy or surgery are less common. Prompt identification of the problem is essential if perforation or fistulation to an adjacent structure is to be avoided.

SWALLOWED FOREIGN BODIES

Ingested foreign bodies are not uncommon in children. The nature of the swallowed item varies with the age of the child. Coins, batteries and parts of, or whole, small toys are common in infants and younger children. In older children inadequately chewed foodstuffs are more common, especially in the presence of an underlying oesophageal abnormality including a previously repaired OA or a peptic oesophageal stricture. Children with learning or behavioural difficulties are particularly prone to swallowing foreign bodies.[43]

In the majority of cases the history of ingestion will be known and prompt attendance at an emergency department by anxious parents likely. In some cases, where the history is not known, an inability to swallow food or liquids, drooling, respiratory difficulty, wheeziness, hoarseness or chest discomfort may be the presenting symptom.[44]

Initial assessment should include an evaluation of the airway. A chest and abdominal radiograph will reveal radioopaque foreign bodies. Where the swallowed item is a coin (Figure 45.8), a metal detector can be used to determine whether the coin is lodged in the chest or has passed into the stomach. Foreign bodies which pass into the stomach do not usually require treatment. One exception to this rule is in situations where mini magnetic toys or button batteries have been swallowed. In such cases fistulization between loops of small intestine and subsequent perforation can occur due to the magnets adhering across bowel loops,[43] and leakage of the contents of a battery can cause heavy metal poisoning. Button batteries are now extremely

powerful and can cause rapid and severe ulceration, with a risk of catastrophic erosion of the mediastinal great vessels. NHS England has published an important Patient Safety Alert, *Risk of death and serious harm from delays in recognising and treating ingestion of button batteries*, highlighting the seriousness of swallowing these batteries.[45] See also Chapter 34, Foreign bodies in the ear, nose and throat.

Of greater concern are those items which lodge in the oesophagus. They can get stuck at the level of the thoracic inlet, the cricopharyngeus muscle, the mid-oesophagus behind the heart at the level of the aortic arch and the oesophagogastric junction. Items which get stuck in the proximal oesophagus can obstruct the airway. Items which get stuck more distally are more at risk of causing perforation and mediastinitis. Damage to the oesophagus is caused by direct contact in the case of coins and contact, the release of electrical current and leakage of their contents in the case of batteries. Foreign bodies which are impacted in the oesophagus for some time can cause oesophageal perforation,[46] fistulization into adjacent structures including the great vessels and the trachea, with sometime catastrophic consequences.[46, 47]

Rigid or flexible oesophagoscopy under general anaesthetic and endotracheal intubation to protect the airway is usually the preferred treatment option where the foreign body is impacted in the oesophagus. Different types of graspers and basket devices for use with endoscopes have been developed specifically to remove coins. This is usually fairly straightforward, especially when the coin has a raised rim. Batteries are more difficult to remove due to their smooth edges. A catheter with a balloon on the end is sometimes successful when other techniques have failed.[44] Open safety pins are a particular challenge. These are best pushed into the stomach if the open end is proximal. Once in the stomach, the hinge end of the pin can be grasped and the pin removed, using an oesophageal overtube if one is available.

CAUSTIC INJURY

Ingestion of caustic substances by infants and toddlers is becoming increasingly common. Alkali, or less commonly acid, household cleaning or other agents contained in lemonade bottles stored under the sink are frequently implicated. Newer formulations of clothes and dishwashing liquid in tablet and 'liquitab' form are also implicated (**Figure 45.9**).[48] Impulsive behaviour and attention deficit hyperactivity disorder have been shown to be risk factors for such ingestion.[49]

A child who has swallowed a caustic substance usually presents immediately with symptoms of crying, spitting, coughing and stridor. Potential airway compromise is a serious concern in all such cases. Later symptoms include chest pain, dysphagia and vomiting. Signs of burn injury may be seen on the lips and in the mouth, although the absence of such signs does not exclude ingestion. Fever and tachycardia may also be obvious.

As in swallowed foreign bodies, the first concern in such cases should be the integrity of the airway. Oedema of the larynx caused by the caustic substance might occlude the airway. Prompt endotracheal intubation may be required.

The injuries caused by the ingestion of such substances can be severe. Mucosal slough and necrosis are common. Deeper injury and liquefaction of all layers of the oesophagus can also be seen even after brief exposure to a caustic substance. Attempts to wash the caustic substance away by drinking water may result in an exothermic chemical reaction which may only serve to worsen the injury. Other attempts to neutralize the ingested caustic substance may fail if the pH of the ingested substance is not known, and again may result in an unwanted exothermic chemical reaction.

Children suspected of ingesting caustic agents should be admitted for evaluation. A chest X-ray may be useful. Early intubation may be needed if the airway is at risk. All affected

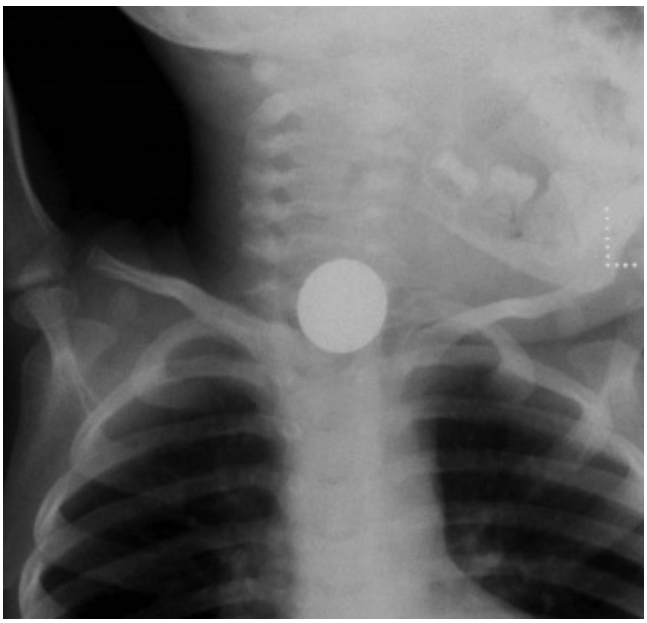

Figure 45.8 Coin impacted in the upper oesophagus in a toddler. The airway is at risk in this patient and prompt removal of the coin is required.

Figure 45.9 'Liquitabs' are increasingly implicated in caustic injuries.

children should be fasted and intravenous fluids administered. Early endoscopy is usually indicated in all cases to assess the extent and severity of the injury. The markers of superficial injury include mucosal erythema, oedema and mild mucosal damage. Deeper injuries will result in haemorrhage, exudates, mucosal sloughing, pseudomembrane formation and the development of granulation tissue. The deepest injuries will exhibit luminal narrowing or obliteration, severe oedema, eschar formation. Perforation and mediastinitis is possible in severe cases.

Blind passage of an NG tube is contraindicated in these patients. Placement of such a tube during the endoscopy is indicated to facilitate enteral nutrition and to maintain the integrity of the oesophageal lumen. The end of a blind-ending NG tube should be cut off to allow passage of a guidewire in the future. This may be helpful if the NG tube needs to be replaced or if a stricture develops (**Figure 45.10**) and might benefit from balloon dilatation under imaging control (**Figure 45.11**).[50]

The use of antibiotics and steroids to limit the effects of the injury and prevent stricture formation is controversial. Conflicting studies have shown both benefit and none. Serial balloon dilatations are the preferred treatment of a fibrous structure. Clearly, there is a risk of oesophageal perforation during this procedure. Placement of oesophageal stents is less well established. Oesophageal resection and replacement with a colonic or gastric tube may be required in long and the most resistant strictures.

In general terms, acid ingestion is less damaging to the oesophagus than alkali ingestion. Acid causes more damage to the stomach and the pylorus.

DRUG-INDUCED INJURY

Drug-induced oesophageal injury is very rare in children, and is most commonly seen in patients with an underlying structural abnormality. It usually only occurs where tablet or capsular formulations of the medication are used. The tablet or capsule gets stuck above a stricture and the release of its active agent causes oesophageal injury. Implicated drugs include non-steroidal analgesics, aspirin, slow-release potassium and the cycline family of antibiotics.

Symptoms of retrosternal chest pain and dysphagia may be reported. Endoscopic assessment is usually indicated.

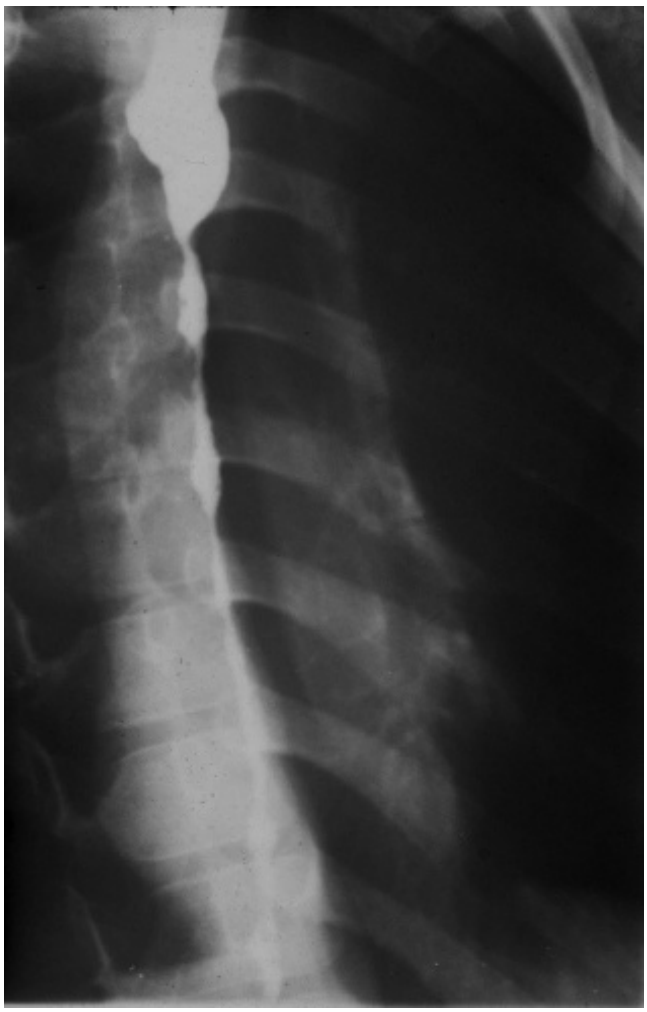

Figure 45.10 Upper GI contrast study in patient with a long oesophageal structure caused by the ingestion of a caustic substance.

Figure 45.11 Balloon dilatation of a short stricture in the mid-oesophagus. The stricture can be identified where the balloon narrows.

Stricture formation is rare and, when it occurs, should be treated on its merits. The offending medication should be discontinued.

RADIATION-INDUCED INJURY

Radiation-induced injury of the oesophagus in children is extremely rare but can occur when radiotherapy for thoracic tumours is necessary. It is more common when chemotherapy is administered alongside the radiotherapy. Symptoms include dysphagia and chest pain. Endoscopy may reveal mucosal oedema and aphthous ulceration. Treatment is largely symptomatic.

Mallory Weiss tear

The classical Mallory Weiss tear of the lower oesophagus after a severe bout of vomiting is not common in children. However, the more frequent use of upper gastrointestinal endoscopy in paediatric practice has resulted in its more frequent recognition as an entity in children. The vomiting causes a mucosal tear to develop at the oeosphagogastric junction which bleeds.

The presenting features are usually a protracted period of vomiting followed by a haematemesis. Bleeding is usually self-limiting and acid suppression therapy using either proton pump inhibitors or H2 receptor blockers is usually indicated to encourage healing of the tear. In severe cases, often in the presence of an underlying coagulopathy, use of oesophageal balloon tamponade or pharmacological agents may be required to stop bleeding.

Oesophageal perforation and rupture

In neonates and children, the most common cause of oesophageal perforation or injury is nasogastric intubation, upper gastrointestinal endoscopy or other instrumentation. Swallowed foreign bodies may also be implicated.[51] In some cases where the history is unclear, non-accidental injury may need to be considered.

The risk of mediastinitis should be considered in all such cases and appropriate intravenous antibiotic and antifungal therapy initiated. The child should be fasted and parenteral nutrition may be necessary. Contrast or cross-sectional imaging studies may be helpful in determining the extent of the injury.

In the majority of cases, the oesophagus will heal without direct intervention, although clearly foreign bodies should be removed.

BEST CLINICAL PRACTICE

- ✓ The inability to pass a naso- or oro-gastric tube in the newborn is virtually diagnostic of oesophageal atresia.
- ✓ In oesophageal atresia, otolaryngologists need to be aware of the clinical features so they can arrange appropriate investigations, including tracheobronchoscopy, in most cases,
- ✓ Cross-sectional imaging (CT or MRI) is the most useful investigation for cysts associated with the oesophagus,
- ✓ Ingested coins or similar items lodged in the upper oesophagus can cause airway obstruction – urgent removal is indicated,
- ✓ Ingested button batteries which lodge in the oesophagus should be removed as a matter of some urgency to prevent oesophageal injury,
- ✓ The ingestion of caustic substances can cause laryngeal and airway oedema, inflammation and obstruction,
- ✓ Attempts to wash or neutralize an ingested caustic substance can result in an undesirable exothermic reaction and injury.

FUTURE RESEARCH

- ➤ The development of thoracoscopic surgical techniques and instruments is likely to result in more of the congenital anomalies of the oesophagus being managed thoracoscopically.
- ➤ Basic science and genetic research into the causes and the embryology of congenital anomalies of the oesophagus continues to improve our understanding of these complex conditions.

KEY POINTS

- Antenatal maternal polyhydramnios, which can affect approximately half of pregnancies with the various forms of OA, may give a clue to the presence of this abnormality.
- The newborn affected by any of the common variants of OA (but obviously not the baby with an isolated TOF) will present clinically with frothing at the mouth, choking episodes, cyanosis and respiratory distress. Clearly, attempts at feeding will precipitate such symptoms and may cause aspiration and severe respiratory distress.
- True congenital oesophageal diverticula, which contain all layers of the wall of the oesophagus, are uncommon. False or pulsion diverticula, which are herniations of the oesophageal mucosa between defects in the oesophageal muscular wall, are more common.
- Button batteries are now extremely powerful and can cause rapid and severe ulceration, with a risk of catastrophic erosion of the mediastinal great vessels.
- In general terms, acid ingestion is less damaging to the oesophagus than alkali ingestion. Acid causes more damage to the stomach and the pylorus.

CHAPTER 46

ANATOMY AND EMBRYOLOGY OF THE EXTERNAL AND MIDDLE EAR

Peter Valentine and Tony Wright

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: external ear, middle ear, ossicles, facial nerve, Eustachian tube AND anatomy OR embryology OR development.

INTRODUCTION

The ear functions as an early warning system by detecting and locating potentially threatening environmental sounds. It is crucial for survival by accurately and rapidly detecting head movement so that the eyes can stay fixed on prey or predator. The ear plays a major part in the balance system, giving important information about sudden changes in the environment, both external and self, to avoid falls and injury. In addition, in many animals, and especially in humans, the ears form a major part of a communication system.

A three-dimensional appreciation of the complex temporal bone anatomy is crucial for the understanding of both the pathophysiology and surgery of the ear. Traditionally, the microscope has been used as the main tool to examine and operate on the temporal bone. In more recent years, endoscopic techniques have enhanced the visualization and magnification of vistas previously unseen.

Both convention and convenience have separated the ear into its three parts – external, middle and internal – for descriptive purposes. The structure of the internal ear is described in detail in Chapter 47, Anatomy of the cochlea and vestibular system: relating ultrastructure to function. This chapter deals with the external ear and the adult middle ear cleft including the mastoid air cell system and Eustachian tube. Finally, the embryology of the ear and subsequent development of the temporal bone, external ear and mastoid process are outlined.

THE EXTERNAL EAR

The auricle

The auricle (or pinna) projects at a variable angle from the side of the head and has some function in collecting sound. The lateral surface of the auricle has characteristic prominences and depressions (**Figure 46.1**), which are different in every individual, even identical twins. This unique pattern is comparable to fingerprints and can allow the identification of persons on the physiognomy of their auricles.[1] The curved rim is the helix, which often has a small prominence (Darwin's tubercle) at its posterosuperior aspect. Anterior to and parallel with the helix is another prominence, the antihelix. Superiorly, this divides into two crura, between which is the triangular fossa; the scaphoid fossa lies above the superior of the two crura. In front of the antihelix, and partly encircled by it, is the concha. This is divided into two portions by the descending limb of the anterior superior portion of the helix, known as the crus of the helix, which rests just above the external auditory meatus. The smaller superior portion is the cymba conchae and is the direct lateral relation to the suprameatal triangle of the temporal bone. The larger inferior portion is known as the cavum conchae. Below the crus of the helix and overlapping the external auditory meatus is the tragus, which is a small blunt triangular prominence pointing posteriorly. Opposite the tragus, at the inferior limit of the antihelix, is the antitragus. The intertragic notch separates the tragus from the antitragus. The lobule

lies below the antitragus and is soft, being composed of fibrous and adipose tissue. The medial (cranial) surface of the auricle has elevations corresponding to the depressions on the lateral surface, and possesses corresponding names, for example the eminentia conchae.

The body of the auricle is formed from elastic fibrocartilage and is a continuous plate except for a narrow gap between the tragus and the anterior crus of the helix, where it is replaced by a dense fibrous tissue band. This gap is the site for an endaural incision which, properly performed, should not damage cartilage or its perichondrium and which by splitting the soft-tissue ring surrounding the bony ear canal allows wide exposure of the deeper parts.

The cartilage extends about 8 mm down the ear canal to form its lateral third. The cartilage of the auricle is covered with perichondrium from which it derives its supply of nutrients, as cartilage itself is avascular. Stripping the perichondrium from the cartilage, as occurs following injuries that cause haematoma, can lead to cartilage necrosis with crumpled up 'boxer's ears'. The skin of the pinna is thin and closely attached to the perichondrium on the lateral surface. On the medial (cranial) surface, there is a definite subdermal adipose layer that allows dissection during pinnaplasty surgery. The skin of the auricle is covered with fine hairs and, most noticeably in the concha and the scaphoid fossa, there are sebaceous glands opening into the root canals of these hairs. On the tragus and intertragic notch coarse, thick hairs may develop in the middle-aged and older male.

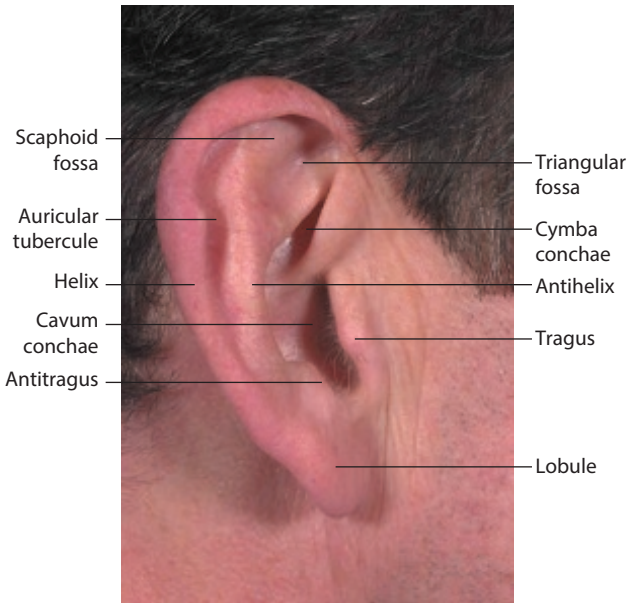

Figure 46.1 Right auricle.

The cartilage of the auricle is connected to the temporal bone by two extrinsic ligaments. The anterior ligament runs from the tragus and from a cartilaginous spine on the anterior rim of the crus of the helix to the root of the zygomatic arch. A separate posterior ligament runs from the medial surface of the concha to the lateral surface of the mastoid prominence. Intrinsic ligaments connect various parts of the cartilaginous auricle; that between helix and tragus has already been described and another runs from the antihelix to the posteroinferior portion of the helix. Extrinsic and intrinsic muscles are attached to the perichondrium of the cartilage. Temporal and posterior auricular branches of the facial nerve supply the extrinsic muscles and, while being functionally unimportant, they do give rise to the postauricular myogenic response following appropriate auditory stimulation.[2] There are three extrinsic muscles: auricularis anterior, superior and posterior, the last being supplied by the posterior auricular branch of the facial nerve. All three radiate out from the auricle to insert into the epicranial aponeurosis. The intrinsic muscles – six in number – are small, inconsistent and without useful function.

Arterial branches of the external carotid supply the auricle. The posterior auricular appears to be the dominant artery and supplies the medial surface (except the lobule), the concha, the middle and lower portions of the helix and the lower part of the antihelix. The anterior auricular branches of the superficial temporal supply the upper portions of the helix, antihelix, triangular fossa, tragus and lobule.[3] The superior auricular artery has a constant course and connects the superior temporal artery and the posterior auricular artery network. This branch can provide a reliable vascular pedicle for retroauricular flaps.[4] A small auricular branch from the occipital artery may assist the posterior auricular in supplying the medial surface.

Both cranial branchial nerves and somatic cervical nerves supply the auricle. Their distribution is heterogeneous and the overlap may be extensive; however, the greater auricular nerve prevails on the lateral and medial surfaces.[5] The essential features are described in Table 46.1.

The lymphatic drainage from the posterior surface is to the lymph nodes at the mastoid tip, from the tragus and from the upper part of the anterior surface to the preauricular nodes, and from the rest of the auricle to the upper deep cervical nodes.

TABLE 46.1 Sensory innervation of the auricle

Nerve	Derivation	Region supplied
Greater auricular	Cervical plexus C2, 3	Medial surface and posterior portion of lateral surface
Lesser occipital	Cervical plexus C2, 3	Superior portion of medial surface
Auricular	Vagus X	Concha and antihelix Some supply medial surface (eminetia concha)
Auriculotemporal	Vc mandibular	Tragus, crus of helix and adjacent helix
Facial VII		Probably supplies small region in the root of concha

The external auditory canal

The external auditory canal extends from the concha of the auricle to the tympanic membrane and is approximately 2.4 cm long. The supporting framework of the canal wall is cartilage in the lateral one-third and bone in the medial two-thirds. The diameter of the canal varies greatly between individuals and between different races. In adults, the cartilaginous portion runs inwards, slightly downwards and forwards. The canal is straightened, therefore, by gently moving the auricle upwards and backwards to counteract the direction of the cartilaginous portion. In the neonate, there is virtually no bony external meatus as the tympanic bone is not yet developed, and the tympanic membrane is more horizontally placed so that the auricle must be gently drawn downwards and backwards for the best view of the tympanic membrane.

In the adult, the lateral cartilaginous portion is about 8 mm long and is continuous with the auricular cartilage. The medial border of the meatal cartilage is attached to the rim of the bony canal by fibrous bands. There are two horizontal fissures, described by Santorini, that lie anteroinferiorly in the cartilaginous portion that possibly increase flexibility but allow passage of infection or tumour into the parotid gland. The bony canal wall, about 1.6 mm long, is narrower than the cartilaginous portion and itself becomes smaller closer to the tympanic membrane. The medial end of the bony canal is marked by a groove, the tympanic sulcus, which is absent superiorly. Although the tympanic bone makes up the greater part of the canal, and also carries the sulcus, the squamous bone forms the roof. Therefore, there are two suture lines in the canal wall with the tympanosquamous anteriorly and the tympanomastoid posteriorly. These suture lines may be more or less developed; they project into the canal with overlying closely adherent skin, which can make raising an intact tympanomeatal flap a challenge. The tympanomastoid suture is a complex suture line between the anterior wall of the mastoid process, a portion of the squamous bone and the tympanic bone.

Apart from these intrusions into the canal, there are two constrictions: one at the junction of the cartilaginous and bony portions and the other, the isthmus, 5 mm from the tympanic membrane where a prominence of the anterior canal wall reduces the diameter. Deep to the isthmus, the anteroinferior portion of the canal dips forwards forming a wedge-shaped anterior recess between the tympanic membrane and the canal. This recess can be a difficult spot for access either in the clinic or at surgery.

The external canal is lined with keratinizing stratified squamous epithelium, which lacks the rete pegs and skin appendages in the thin skin of the bony canal. Body skin normally grows directly from the basal layers towards the surface where it is shed into the surroundings. Excess proliferation in the scalp trapped by the hair is dandruff. If this pattern of growth were to occur in the external ear canal, the canal would soon become filled with desquamated skin. Instead of maturation taking place directly towards the surface, there is outward, oblique growth of the epidermis of the canal skin[6] and pars flaccida so that the surface layers effectively migrate towards the external opening of the canal. The normal rate of migration is about 0.1 mm/day,[7] although this range is hugely variable and in some conditions there is complete failure of migration with a consequent build-up of shed keratin in the ear canal. It has been postulated that patients who are prone to cerumen impaction may lack a 'keratinocyte attachment destroying substance' (KADS) based on the observation they have much longer sheets of desquamated keratin which are in continuity with the stratum corneum, when compared to patients with no issue.[8,9]

The skin of the pars tensa has a different derivation from that of the deep canal and cell divisions occur randomly within the layer of basal cells. The effect of this, in a circular sheet with the handle of the malleus forming a central boundary extending halfway down the membrane, is to create outward mass migration of the skin of the pars tensa. Ink dots applied to the surface have an outward pattern of movement. However, if a hole is made in the tympanic membrane and a graft laid underneath the membrane (an underlay graft), migration of the skin from the outer edge of the perforation is directed centrally to cover the graft. This occurs because the boundary conditions have altered and fortunately provides the basis for the healing of grafts and for the re-epithelialization of mastoid cavities. Even a small piece of pars tensa skin has this ability and so is a precious material and needs to be preserved during ear surgery if a bare area needs covering. However, the property of canal skin to migrate can also bring problems with the formation of cholesteatoma if the skin becomes displaced into the middle ear cleft.

At the outer limits of the ear canal are some short hairs that project towards the opening of the canal. There are fine vellus hairs and larger terminal hairs called tragi (Greek: 'goat'), which tend to be more prominent in males in whom they are a second sexual characteristic. These hairs are oriented with their tips laterally and increase in number and length from the bony-cartilaginous junction laterally, so helping to prevent the entrance of foreign bodies. In the skin of the cartilaginous canal are clusters of ceruminous and sebaceous glands. The ceruminous glands are modified apocrine sweat glands that open into the root canal of the hair follicles and produce a watery, white secretion that slowly darkens, turning semi-solid and sticky as it dries. Since these glands are apocrine sweat glands, they respond to many stimuli such as adrenergic drugs, fever and emotion which, along with direct mechanical stimulation, can all produce an increase or altered secretion.

The sebaceous glands produce an oily material (sebum) from the breakdown of their fat-containing cells which is usually excreted into the root canals of the hair follicles. The mixture of desquamated cells, cerumen and sebum forms wax. Human earwax is a Mendelian trait consisting of wet and dry forms. Dry wax, lacking cerumen, is yellowish or grey and brittle, while wet wax is brownish and sticky. The wet phenotype is dominant over the dry type, and is frequently seen in populations of European and African origins. East Asians show the dry phenotype and there are intermediate frequencies among the Native American and Inuit of Asian ancestry. A single-nucleotide polymorphism in the *ABCC11* gene is responsible for the determination of earwax type, with the *AA* genotype corresponding to dry wax and *GA* and *GG* to wet wax.[10] There is dispute with regard to the specific antibacterial activity of cerumen in

in vitro studies.[11,12] However, the areas of skin that take part in cerumen production have all the components of an active local immune system and probably protect the canal by an antibody-mediated local immune response.[13]

Wax is not usually found in the deep ear canal and a lump of 'wax' overlying the upper portion of the tympanic membrane (pars flaccida or attic region) is rarely true wax, but is nearly always associated with an underlying cholesteatoma as it is, in fact, dried-up, oxidized keratin. The sense of the old adage 'beware the attic wax' is still just as true today as it was in the past.

The arterial supply of the external meatus is derived from branches of the external carotid. The auricular branches of the superficial temporal artery supply the roof and anterior portion of the canal. The deep auricular branch of the first part of the maxillary artery arises in the parotid gland behind the temporomandibular joint, pierces the cartilage or bone of the external meatus and supplies the anterior meatal wall skin and the epithelium of the outer surface of the tympanic membrane. Finally, auricular branches of the posterior auricular artery pierce the cartilage of the auricle and supply the posterior portions of the canal. The veins drain into the external jugular vein, the maxillary veins and the pterygoid plexus. The lymphatic drainage follows that of the auricle.

The external auditory canal receives its sensory innervation from the trigeminal, facial, glossopharyngeal and vagus nerves. Frequently, patients can cough when undergoing microsuction of the canal which is caused by stimulation of the vagus nerve via Arnold's nerve, its auricular branch.

The relationships of the external canal are depicted in Figure 46.2 and a coronal section through the external canal and middle ear are shown in Figure 46.3.

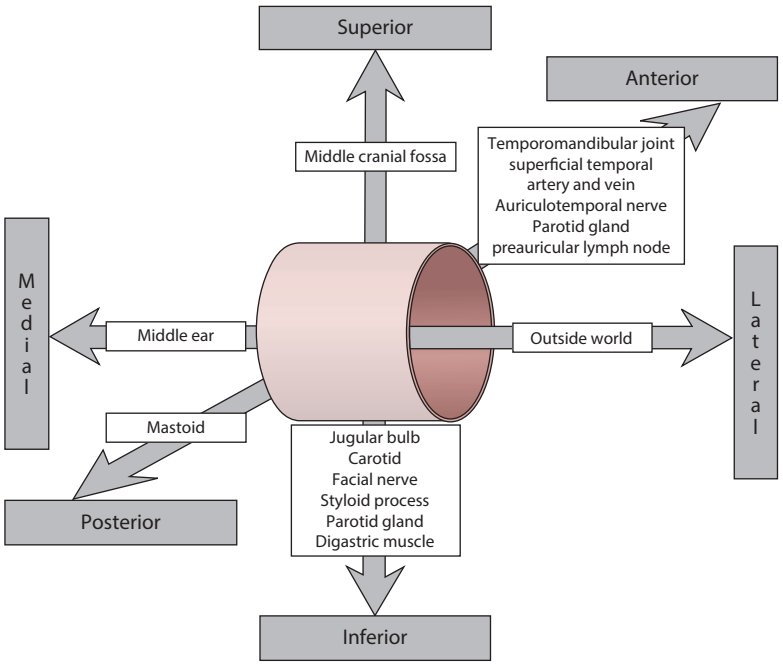

Figure 46.2 Relationships of the right external auditory canal.

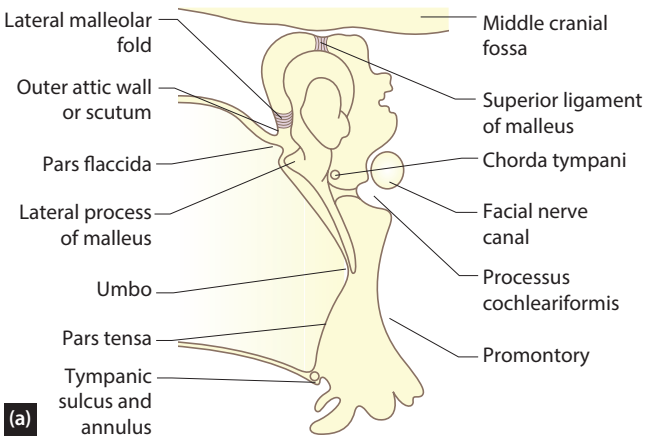

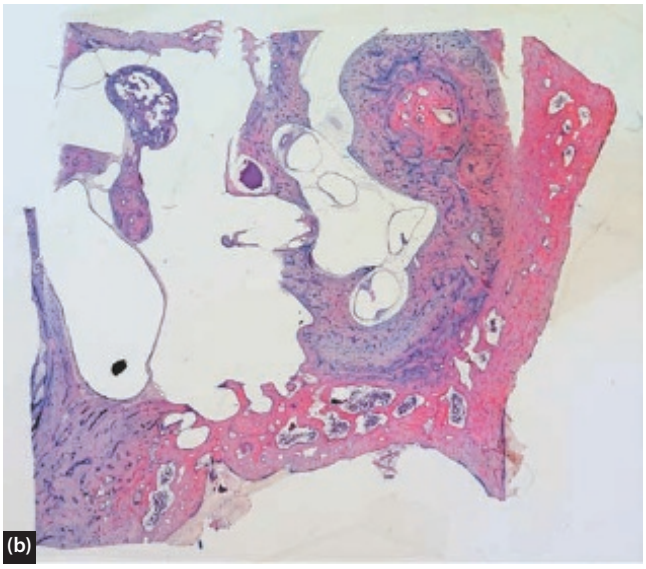

Figure 46.3 (a) Diagram of a coronal section through the external canal and middle ear at the level of the malleus handle. **(b)** Photomicrograph of a more posterior coronal section, including the malleus and the stapes.

THE MIDDLE EAR CLEFT

The middle ear cleft consists of the tympanic cavity, the Eustachian tube and the mastoid air cell system. The tympanic cavity is an irregular, air-filled space within the temporal bone between the tympanic membrane laterally and the osseous labyrinth medially. It contains the auditory ossicles and the tendons that attach them to the middle ear muscles. Other structures, including the tympanic segment of the facial nerve, run along its walls to pass through the cavity.

The tympanic membrane

The tympanic membrane lies at the medial end of the external auditory meatus and forms the majority of the lateral wall of the tympanic cavity. It is slightly oval in shape, being broader above than below, forming an angle of about 55° with the floor of the meatus. Its longest diameter from posterosuperior to anteroinferior is 9–10 mm, while perpendicular to this the shortest diameter is 8–9 mm. Most of the circumference is thickened to form a fibrocartilaginous ring, the tympanic annulus, which sits in a groove in the tympanic bone, the tympanic sulcus. The sulcus does not extend into the notch of Rivinus at the roof of the canal, which is formed by part of the squama of the temporal bone. From the superior limits of the sulcus, the annulus becomes a fibrous band which runs centrally as anterior and posterior malleolar folds to the lateral process of the malleus, the handle of which is clearly visible within the tympanic membrane. This leaves a small, triangular region of tympanic membrane above the malleolar folds within the notch of Rivinus, called the pars flaccida, which does not have a tympanic annulus at its margins. The pars tensa forms the rest of the tympanic membrane and is concave towards the ear canal but each segment is slightly convex between the lateral attachment of the annulus and the centre of the membrane where the tip of the malleus handle is attached at the umbo (Figure 46.4).

Figure 46.4 Endoscopic photograph of the right tympanic membrane.

Both the pars tensa and pars flaccida comprise three layers. There is an outer epithelial layer, the epidermis, which is continuous with the skin of the external meatus; a middle, mainly fibrous layer, the lamina propria; and an inner mucosal layer continuous with the lining of the tympanic cavity. The lamina propria of the pars tensa has radially oriented fibres in the outer layers and circular, parabolic and transverse fibres in the deeper layer. This arrangement probably accounts for the complex pattern of tympanic membrane displacement during sound stimulation. In the pars flaccida, the lamina propria is less marked and the orientation of the collagen fibres seems random.

The arterial supply of the tympanic membrane arises from branches supplying both the external auditory meatus and the middle ear. These two sources interconnect through extensive anastomoses within the connective tissue layer of the lamina propria. The epidermal vessels originate from the deep auricular branch of the maxillary artery coming from the external auditory meatus, whereas the mucosal vessels arise from the anterior tympanic branches of the maxillary artery, the stylomastoid branch of the posterior auricular artery and probably from the middle meningeal artery.

Branches of the auriculotemporal nerve (Vc), the auricular branch of the vagus and the tympanic branch of the glossopharyngeal nerve supply the tympanic membrane. These also run in the lamina propria and, while variations and overlap are considerable, both the vascular supply and innervation are relatively sparse in the middle part of the posterior half of the tympanic membrane.

The tympanic cavity

The tympanic cavity is traditionally divided into three compartments: the epitympanum (upper), the mesotympanum (middle) and hypotympanum (lower). The epitympanum, or attic, lies above the level of the malleolar folds and is separated from the mesotympanum and hypotympanum by a series of mucosal membranes and folds. The hypotympanum lies below the level of the inferior part of the tympanic sulcus and is continuous with the mesotympanum above. With the advent of endoscopic ear surgery, the mesotympanum may be considered as that part of the middle ear visible through the external canal with a microscope. The retrotympanum lies posterior to it and includes both the posteriomedial and posterior walls of the tympanic cavity, whereas the protympanum is anterior to the promontory and is contiguous with the tympanic portion of the Eustachian tube.

THE LATERAL WALL

The lateral wall of the tympanic cavity is formed by the bony lateral wall of the epitympanum superiorly, the tympanic membrane centrally and the bony lateral wall of the hypotympanum inferiorly. The lateral epitympanic wall is wedge-shaped in section and its sharp inferior portion is also called the outer attic wall or scutum (Latin: 'shield'). It is thin and easily eroded by cholesteatoma, leaving a telltale sign on a high-resolution coronal CT scan.

Three holes are present in the bone of the medial surface of the lateral wall of the tympanic cavity. The petrotympanic fissure is a slit about 2 mm long which opens anteriorly just above the attachment of the tympanic membrane. It receives the anterior malleolar ligament and transmits the anterior tympanic branch of the maxillary artery to the tympanic cavity. The chorda tympani, which carries taste sensation from the anterior two-thirds of the same side of the tongue and secretomotor fibres to the submandibular gland, enters the medial surface of the fissure through a separate anterior canaliculus (canal of Huguier) which is sometimes confluent with the fissure. It then runs posteriorly between the fibrous and mucosal layers of the tympanic membrane, across the upper part of the handle of the malleus and then continues within the membrane, but below the level of the posterior malleolar fold (**Figure 46.5**). The nerve reaches the posterior bony canal wall just medial to the tympanic sulcus, enters the posterior canaliculus and then runs obliquely downwards and medially through the posterior wall of the tympanic cavity until it reaches the facial nerve. The point of entry of the chorda tympani into the facial nerve bundle is quite variable. Usually this is at the level of the inferior third of the facial canal on its anterior wall, but on occasions the chorda can leave the skull base by a separate foramen before it joins the facial nerve.[14] During cortical mastoidectomy, the fibrous strands of the tympanomastoid suture line can often be confused with the chorda tympani although the angle of the white strands of the suture line is different from the angle of the chorda.

THE ROOF

The roof of the epitympanum is the tegmen tympani, a thin bony plate that separates the middle ear space from the middle cranial fossa. Both the petrous and squamous portions of the temporal bone form it; and the petrosquamous suture line, which does not close until adult life, can provide a route of access for infection into the extradural space in children. Veins from the tympanic cavity running to the superior petrosal sinus pass through this suture line. There is a bony crest, known as the cog, which projects from the tegmen tympani caudally to lie anterior to the head of the malleus and can be of variable size. This structure divides the larger posterior epitympanic space from the smaller anterior epitympanic space, where residual cholesteatoma may be left if not formally explored in canal wall-up surgery (**Figure 46.6**).

THE FLOOR

The floor of the tympanic cavity may consist of compact or pneumatized bone with spines and trabeculae. It separates the hypotympanum from the dome of the jugular bulb and its thickness can vary according to the height of the jugular fossa. Occasionally, the floor is deficient and the jugular bulb is then covered only by fibrous tissue and a mucous membrane. This should be kept in mind when raising the inferior portion of a tympanomeatal flap. At the junction of the floor and the medial wall of the cavity there is a small opening, the inferior tympanic canaliculus, that allows the entry of the tympanic branch of the glossopharyngeal nerve or Jacobson's nerve into the middle ear from its origin below the base of the skull. This also carries preganglionic parasympathetic fibres from the inferior salivary nucleus on their course to the otic ganglion.

THE ANTERIOR WALL

The anterior wall of the tympanic cavity is rather narrow as the medial and lateral walls converge. The lower third of the anterior wall consists of a plate of bone covering the carotid artery as it enters the skull and before it turns anteriorly. This plate, which can be wafer thin or up to 3 mm thick, is perforated by the superior and inferior caroticotympanic nerves carrying sympathetic fibres to the tympanic plexus and by tympanic branches of the internal carotid artery. In around 2% of cases, the bone

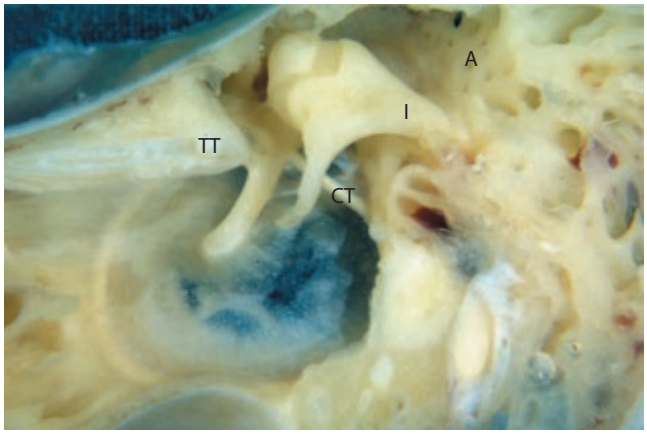

Figure 46.5 The tympanic membrane viewed from the middle ear. The corda tympani (CT) runs superior to the tensor tympani (TT) in its passage across the tympanic membrane, and lies medial to the anterior malleolar ligament in the anterior attic. The aditus to the mastoid antrum (A) lies posterosuperior to the short process of incus (I).

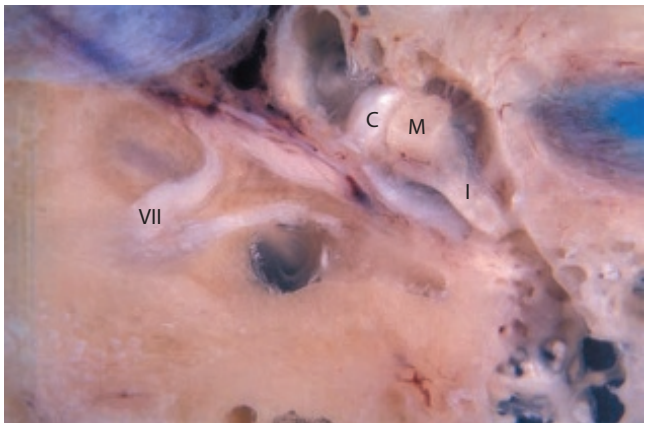

Figure 46.6 A specimen cut axially at the level of the labyrinthine and intratympanic segments of the facial nerve (VII), showing a small cholesteatoma (C) lying between the head of the malleus and anterior epitympanic space. The ossicular heads resemble a scoop of ice cream in a cone, which can be readily seen on a high-resolution axial CT scan. I, incus; M, malleus.

is dehiscent so that the artery is exposed in the protympanum.[15] The middle third of the anterior wall comprises the tympanic orifice of the Eustachian tube which can be irregular, rectangular or triangular in shape and average 5 × 4 mm in diameter.[16] Just above this is a canal containing the tensor tympani muscle that subsequently runs along the medial wall of the tympanic cavity enclosed in a thin bony sheath. The upper third is usually pneumatized and may house the supratubal recess, a small niche that can be separated from the anterior epitympanic space by the tensor fold.

THE MEDIAL WALL

The medial wall separates the tympanic cavity from the internal ear. The promontory is a rounded elevation occupying much of the central portion of the medial wall. It covers part of the basal coil of the cochlea and usually has small grooves on its surface containing the nerves which form the tympanic plexus. Sometimes the groove containing the tympanic branch of the glossopharyngeal nerve may be covered by bone, thereby forming a small canal (**Figure 46.7**). The promontory gently inclines forwards to merge with the anterior wall of the tympanic cavity in the protympanum but is more steeply sloped posteriorly.

Behind and above the promontory is the oval window. This is a nearly kidney-shaped opening that connects the tympanic cavity with the vestibule, but which in life is closed by the footplate of the stapes and its surrounding annular ligament. Its size naturally varies with the size of the footplate, but on average it is 3.25 mm long and 1.75 mm wide. The oval window lies at the bottom of a depression or niche that can be of varying width depending on the position of the facial nerve superiorly, and the prominence of the promontory inferiorly (**Figure 46.8**).

The round window niche lies below and a little behind the oval window niche from which it is separated by a posterior extension of the promontory forming a bony ridge called the subiculum. Another ridge of bone – the ponticulus – leaves the promontory above the subiculum and runs to the pyramid on the posterior wall of the cavity. Occasionally, this structure can resemble a bridge with a medial communication between the sinus tympani and posterior sinus, a space lying behind the posterior crus of the stapes. The round window niche is most commonly triangular in shape, with anterior, posterosuperior and posteroinferior walls. The latter two meet posteriorly and lead to the sinus tympani. The round window membrane is usually out of sight, obscured by the overhanging edge of the promontory forming the niche and mucosal folds within it. The membrane is roughly oval in shape, about 2.3 × 1.9 mm in dimension and lies in a plane at right angles to the plane of the stapes footplate. It tends to curve towards the scala tympani of the basal coil of the cochlea, so that it is concave when viewed from the middle ear, and it appears to be divided into an anterior and posterior portion by a transverse thickening. A further ridge of bone inferiorly running between the basal helix of the cochlea and the bone over the jugular bulb can used as a convenient landmark to separate the retrotympanum from the hypotympanum. Although first identified by Proctor,[17] this has been renamed by Marchioni et al.[18] as the finiculus (Latin: 'borderline').

The facial nerve canal (or Fallopian canal) runs above the promontory and oval window in an anteroposterior direction. It has a smooth, rounded lateral surface that often has microdehiscences and when the bone is thin or the nerve exposed by disease, there are two or three straight blood vessels clearly visible along this line of nerve. These are the only straight blood vessels in the middle ear and indicate quite clearly that the facial nerve is very close by. The facial nerve canal is marked anteriorly by the processus cochleariformis, a curved projection of bone, concave anteriorly, which houses the tendon of the tensor tympani muscle as it turns laterally to the handle of the malleus. Behind the oval window, the facial canal

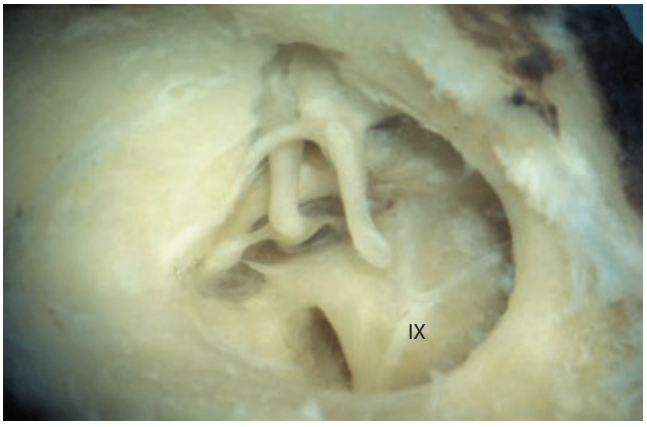

Figure 46.7 The medial wall of the mesotympanum seen after removal of the tympanic membrane. The tympanic branch of the glossopharyngeal nerve (IX) can be seen crossing the promontory. Note the notch of Rivinus in the roof of the canal.

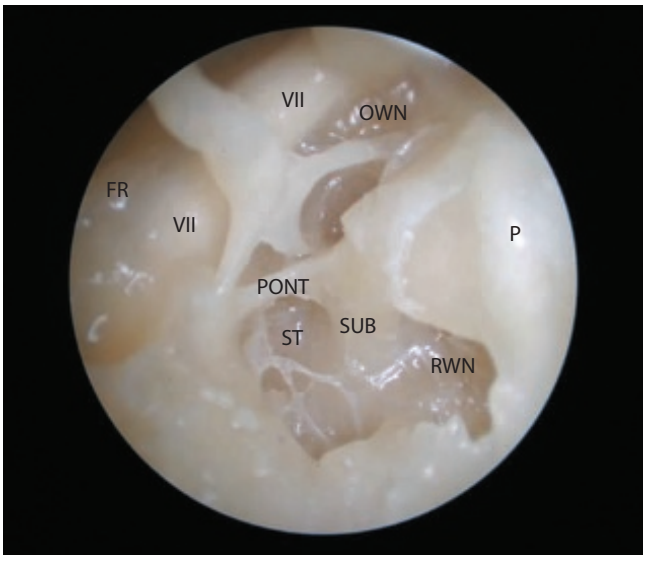

Figure 46.8 Endoscopic view of the retrotympanum showing the relationship between the oval window niche (OWN), round window niche (RWN), promontory (P), facial nerve (VII) and facial recess (FR). The sinus tympani (ST) lies medial to the facial nerve between the ponticulus (PONT) and subiculum (SUB).

starts to turn inferiorly as it begins its descent in the posterior wall of the tympanic cavity (Figure 46.9).

The region above the level of the facial nerve canal forms the medial wall of the epitympanum. The dome of the lateral semicircular canal is the major feature of the posterior portion of the epitympanum, lying posterior and extending a little lateral to the facial canal. During a cortical mastoidectomy, the triangular relationship of the lateral semicircular canal, the short process of the incus and the seventh nerve is often quite helpful. In well-aerated mastoid bones, the labyrinthine bone over the superior semicircular canal may be prominent, running at right angles to the lateral canal and joining it anteriorly at a swelling which houses the ampullae of the two canals. In front and a little below this, above the processus cochleariformis, may be a slight swelling corresponding to the geniculate ganglion, with the bony canal of the greater superficial petrosal nerve running for a short distance anteriorly.

THE POSTERIOR WALL

The posterior wall is wider above than below and has in its upper part a large irregular opening – the aditus ad antrum – that leads back from the posterior epitympanum into the mastoid antrum (Figure 46.10). Below the aditus is a small depression, the fossa incudis, which houses the short process of the incus and its suspensory ligament. Below the fossa incudis and medial to the opening of the chorda tympani nerve is the pyramid, a small hollow conical projection with its apex pointing anteriorly. This houses the stapedius muscle and tendon, which inserts into the posterior aspect of the head of stapes. The canal within the pyramid curves downwards and backwards to join the descending portion of the facial nerve canal.

The facial recess is a groove which lies between the pyramid and facial nerve and the annulus of the tympanic membrane (Figure 46.11). This is shallower lower down where the facial nerve canal forms only a slight prominence on the posterior wall. The facial recess is, therefore, bounded medially by the facial nerve and laterally by the tympanic annulus, with the chorda tympani nerve running obliquely through the wall between the two. The chorda always runs medial to the tympanic membrane, which means that the angle between the facial nerve and the chorda allows a posterior tympanotomy to be cut, thereby accessing the middle ear from the mastoid without disruption to the tympanic membrane (Figure 46.12). This angle can be small or large depending on the site of origin of the chorda from the facial nerve.

The sinus tympani is a posterior extension of the mesotympanum into the posterior wall and lies deep to the facial nerve, pyramid and stapedius muscle. It varies in size and, when extensive, is probably one of the most inaccessible sites in the middle ear when operating with the microscope. A surgical view can be enhanced using a 45° endoscope introduced from the opposite side of the ear being observed. The medial wall of the sinus tympani becomes continuous with the posterior portion of the medial wall of the tympanic cavity in the retrotympanum, and it is bounded superiorly by the ponticulus and inferiorly by the subiculum. Its importance is that cholesteatoma which has extended here from the mesotympanum is extremely difficult to eradicate. As the sinus can extend as far as 9 mm

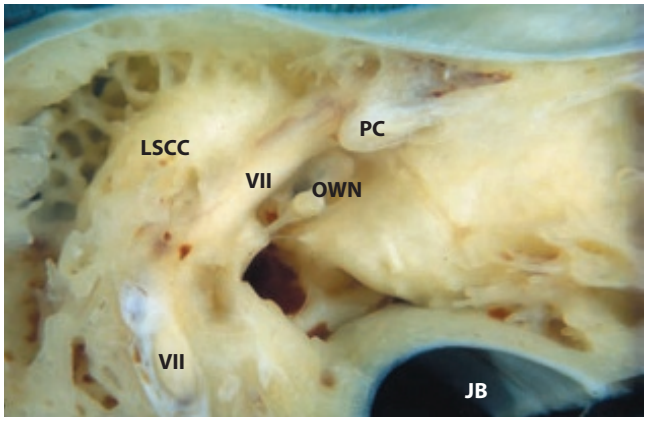

Figure 46.9 A specimen cut to show the medial wall of the tympanic cavity. The processus cochleariformis (PC) marks the anterior position of the intratympanic portion of the facial nerve, which passes between the lateral semicircular canal (LSCC) and oval window niche (OWN). Note the jugular bulb (JB) in the floor of the tympanic cavity.

into the mastoid bone when measured from the tip of the pyramid,[19] a retrofacial dissection inferior to the posterior semicircular canal may be required should the disease be out of reach using a transcanal endoscopic approach.

The relationships of the middle ear space are shown diagrammatically in Figure 46.13.

The contents of the tympanic cavity

The tympanic cavity contains the ossicles, two muscles, the chorda tympani and the tympanic plexus. The ossicles are the malleus, incus and stapes that form a semi-rigid bony chain for conducting sound. They can be seen photographed with a scale in Figure 46.14. The malleus is the most lateral and is attached to the tympanic membrane, whereas the stapes is attached to the oval window.

THE MALLEUS

The malleus is the largest of the three ossicles, measuring up to 9 mm in length. It comprises a head, neck and handle or manubrium. The head lies in the epitympanum and is suspended by the superior ligament, which runs upwards to the tegmen tympani. The head of the malleus has a saddle-shaped facet on its posteromedial surface to articulate with the body of the incus by way of a synovial joint. Below the neck of the malleus, the bone broadens and gives rise to the lateral process, the anterior process and the handle. The lateral process is a prominent landmark on the tympanic membrane and receives the anterior and posterior malleolar folds from the tympanic annulus. The chorda tympani crosses the upper part of the malleus handle on its medial surface above the insertion of

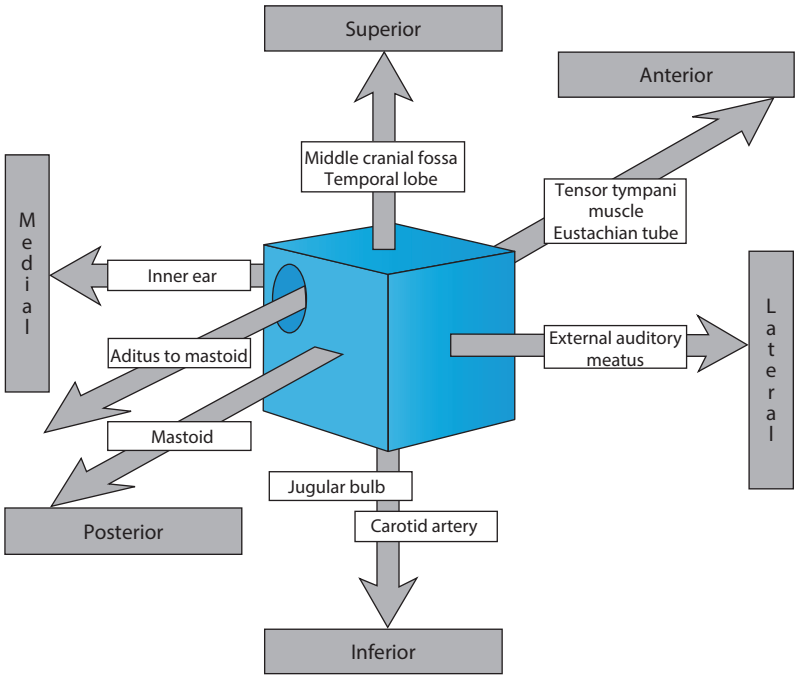

Figure 46.13 The relationships of the right middle ear.

Figure 46.14 Stapes, incus and malleus with scale.

the tendon of tensor tympani, but below the neck of the malleus itself. The neck of the malleus connects the handle with the head and amputation of the head by cutting through the neck leaves both chorda tympani and tensor tympani intact. A slender anterior ligament arises from the anterior process to insert into the petrotympanic fissure. The handle runs downwards, medially and slightly backwards between the mucosal and fibrous layers of the tympanic membrane. While it is very closely attached to the membrane at its lower end, there is a fine web of mucosa separating the membrane from the handle in the upper portion before it becomes adherent again at the lateral process. This can be opened surgically to create a slit without perforating the membrane to allow a prosthesis to be crimped around the malleus handle in certain types of ossicular reconstruction. On the deep, medial surface of the handle, near its upper end, is a small projection into which the tendon of the tensor tympani muscle inserts.

THE INCUS

The incus articulates with the malleus and has a body and two processes. The body lies in the epitympanum and has a cartilage-covered facet corresponding to that on the malleus. The body of the incus is suspended by the superior incudal ligament that is attached to the tegmen tympani. The short process projects backwards from the body to lie in the fossa incudis to which it is attached by a short suspensory ligament. The long process descends into the mesotympanum behind and medial to the handle of the malleus, and at its tip is a small medially directed lenticular process. This has sometimes been called the fourth

ossicle because of its incomplete fusion with the tip of the long process, thereby giving the appearance of a separate bone or at least a sesamoid bone. The lenticular process articulates with the head of the stapes.

THE STAPES

The stapes is shaped like a stirrup and consists of a head, neck, the anterior and posterior crura and a footplate. The head points laterally and has a small cartilage-covered depression for a synovial articulation with the lenticular process of the incus. The stapedius tendon inserts into the posterior part of the neck and upper portion of the posterior crus. The two crura arise from the broader lower part of the neck and the anterior crus is thinner and less curved than the posterior one. Both are hollowed out on their concave surfaces, which gives an optimum combination of strength and lightness. The two crura join the footplate, which usually has a convex superior margin, an almost straight inferior margin and curved anterior and posterior ends. The average dimensions of the footplate are 3 mm long and 1.4 mm wide, and it lies in the oval window where it is attached to the bony margins by the annular ligament. The long axis of the footplate is almost horizontal, with the posterior end being slightly lower than the anterior. There is great variation in the shape of the two crura.

THE STAPEDIUS MUSCLE

The stapedius arises from the walls of the conical cavity within the pyramid and from the downward curved continuation of this canal in front of the descending portion of the facial nerve. A slender tendon emerges from the apex of the pyramid and inserts into the stapes. The muscle is supplied by a small branch of the facial nerve.

THE TENSOR TYMPANI MUSCLE

This is a long, slender muscle arising from the walls of the bony canal lying above the Eustachian tube. Parts of the muscle also arise from the cartilaginous portion of the Eustachian tube and the greater wing of the sphenoid. From its origins, the muscle passes backwards into the tympanic cavity where it lies on the medial wall, a little below the level of the facial nerve. The bony covering of the canal is often deficient in its tympanic segment where the muscle is replaced by a slender tendon. This enters the processus cochleariformis (see **Figure 46.9**) where it is held down by a transverse tendon as it turns through a right angle to pass laterally and insert into the medial aspect of the upper end of the malleus handle. The muscle is supplied from the mandibular nerve by way of a branch from the medial pterygoid nerve.

THE CHORDA TYMPANI NERVE

This branch of the facial nerve enters the tympanic cavity from the posterior canaliculus at the junction of the lateral and posterior walls. It runs across the medial surface of the tympanic membrane between the mucosal and fibrous layers and passes medial to the upper portion of the handle of the malleus (see **Figure 46.5**) above the tendon of tensor tympani to continue forwards and leave by way of the anterior canaliculus, which subsequently joins the petrotympanic fissure.

THE TYMPANIC PLEXUS

The tympanic plexus is formed by the tympanic branch of the glossopharyngeal nerve (Jacobson's nerve) and by caroticotympanic nerves, which arise from the sympathetic plexus around the internal carotid artery. The nerves form a plexus on the promontory and provide the branches to the mucous membrane lining the tympanic cavity, Eustachian tube and mastoid antrum and air cells. The plexus also provides branches to join the greater superficial petrosal nerve and the lesser superficial petrosal nerve that contains all the parasympathetic fibres of the glossopharyngeal nerve.

THE MUCOSA OF THE TYMPANIC CAVITY

The middle ear mucosa is essentially mucus-secreting respiratory mucosa bearing cilia on its surface.[20] The extent of the mucociliary epithelium varies in normal middle ears, being more widespread in the young. Three distinct mucociliary pathways can be identified – epitympanic, promontorial and hypotympanic, the latter being the largest. Each of these pathways coalesces at the tympanic orifice of the Eustachian tube.[21] The mucous membrane lines the bony walls of the tympanic cavity, and it extends to cover the ossicles and their supporting ligaments in much the same way as the peritoneum covers the viscera in the abdomen. The mucosal folds also cover the tendons of the two middle ear muscles and carry the blood supply to and from the contents of the tympanic cavity. These folds separate the middle ear space into compartments. As a result, the only route for ventilation of the epitympanic space from the mesotympanum is via two small openings between the various mucosal folds – the anterior and posterior isthmus tympani. Likewise, the Prussak space is found between the pars flaccida and the neck of the malleus, bounded by the lateral malleolar fold. This space can play an important role in the retention of keratin and subsequent development of cholesteatoma. The mucosal folds have been described in detail by Proctor[22] and are depicted in **Figure 46.15**.

THE BLOOD SUPPLY OF THE TYMPANIC CAVITY

Arteries supplying the walls and contents of the tympanic cavity arise from both the internal and external carotid system. The overlap between branches is extensive and there is great variability in the supply between individuals. **Table 46.2** outlines the general distribution of the arterial supply although the anterior tympanic and stylomastoid arteries are the biggest.

The Eustachian tube

The Eustachian tube is a dynamic channel that links the middle ear with the nasopharynx. In adults, it is about

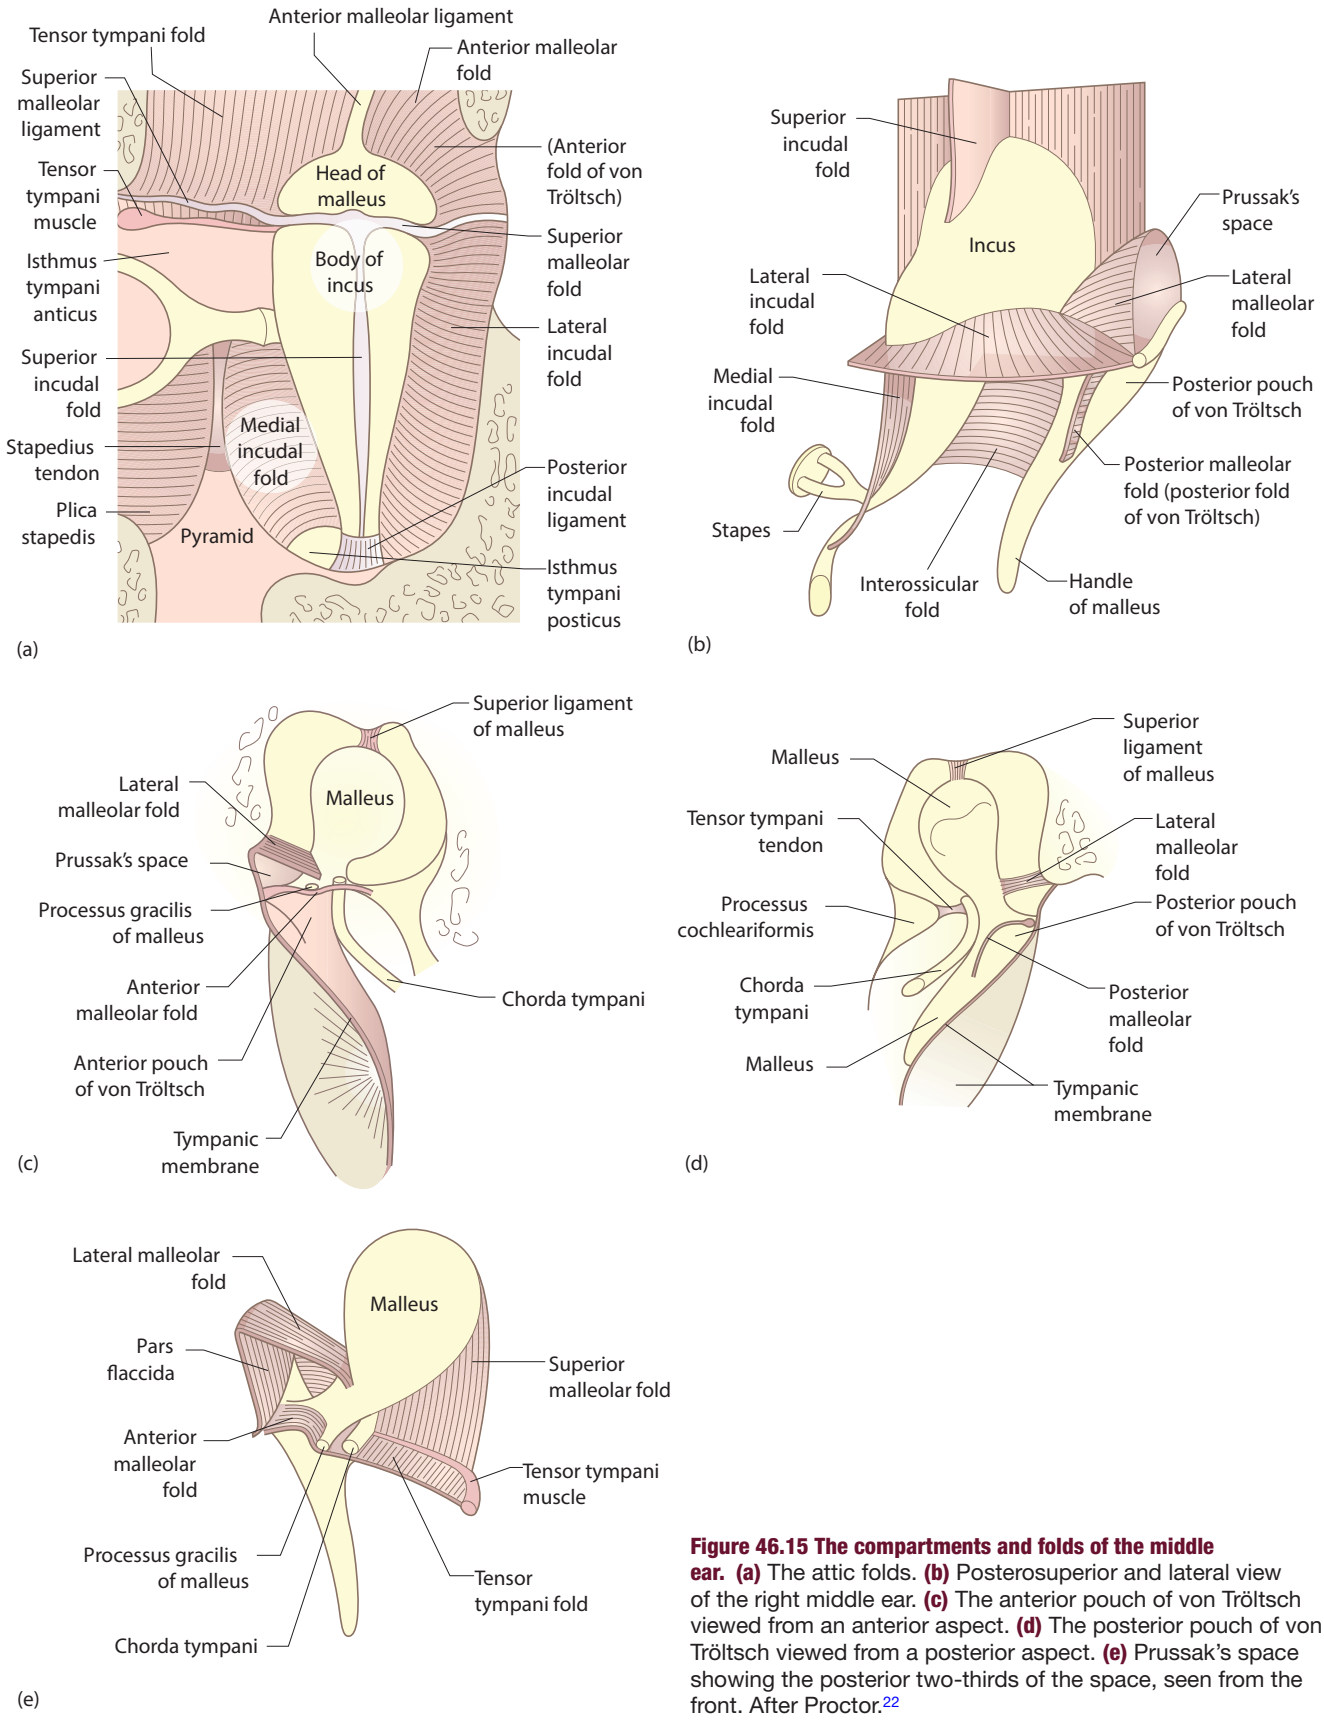

Figure 46.15 The compartments and folds of the middle ear. **(a)** The attic folds. **(b)** Posterosuperior and lateral view of the right middle ear. **(c)** The anterior pouch of von Tröltsch viewed from an anterior aspect. **(d)** The posterior pouch of von Tröltsch viewed from a posterior aspect. **(e)** Prussak's space showing the posterior two-thirds of the space, seen from the front. After Proctor.[22]

TABLE 46.2 Blood supply to the middle ear

Branch	Parent artery	Region supplied
Anterior tympanic	Maxillary artery	Tympanic membrane Malleus and incus Anterior part of tympanic cavity
Stylomastoid	Posterior auricular	Posterior part of tympanic cavity Stapedius muscle
Mastoid	Stylomastoid	Mastoid air cells
Petrosal	Middle meningeal	Roof of mastoid Roof of epitympanum
Superior tympanic	Middle meningeal	Malleus and incus Tensor tympani
Inferior tympanic	Ascending pharyngeal	Mesotympanum
Branch from artery	Artery of pterygoid canal	Meso- and hypotympanum
Tympanic arches	Internal carotid	Meso- and hypotympanum

36 mm in length, a size that is normally reached by the age of 7 years. It runs downwards from the middle ear at 45° and is turned forwards and medially. The tube can be considered to consist of two unequal cones, connected at their apices. The lateral third is bony and arises from the anterior wall of the tympanic cavity. This joins a medial cartilaginous part, which makes up two-thirds of the tubal length, just after its narrowest portion, called the isthmus (Figure 46.16). The tube is lined with respiratory mucosa containing goblet cells and mucous glands, having a carpet of ciliated epithelium on its floor. At its nasopharyngeal end, the mucosa is truly respiratory; however, in passing along the tube towards the middle ear, the number of goblet cells and glands decreases, and the ciliary carpet becomes less profuse.

The bony portion is about 12 mm long and is widest at its oval-shaped orifice in the anterior wall of the tympanic cavity. It runs through the squamous and petrous portions of the temporal bone, gradually tapering to the isthmus, where the diameter is only 0.5 mm or less. A thin plate of bone forms the roof, separating the tube from the tensor tympani muscle above. The carotid canal lies medially and can impinge on the bony Eustachian tube. In cross section, the tube is triangular or rectangular with the horizontal diameter being the greater (Figure 46.17).

The cartilaginous part of the tube is about 24 mm long and consists of a fibrocartilaginous skeleton to which are attached the peritubal muscles. At its upper border, the cartilage is bent over to resemble an inverted 'J', thereby forming a longer medial cartilaginous lamina and shorter lateral cartilaginous lamina. The cartilage is fixed to the base of the skull in a groove between the petrous part of the temporal bone and the greater wing of the sphenoid, which terminates near the root of the medial pterygoid plate. Thus, the back (posteromedial) wall is composed of cartilage and the front (anterolateral) wall comprises cartilage and fibrous tissue. The apex of the cartilage is attached to the isthmus of the bony portion, while the wider medial end protrudes into the nasopharynx, lying directly under the mucosa to form the torus tubarius. In the nasopharynx, the tube opens 1–1.25 cm behind

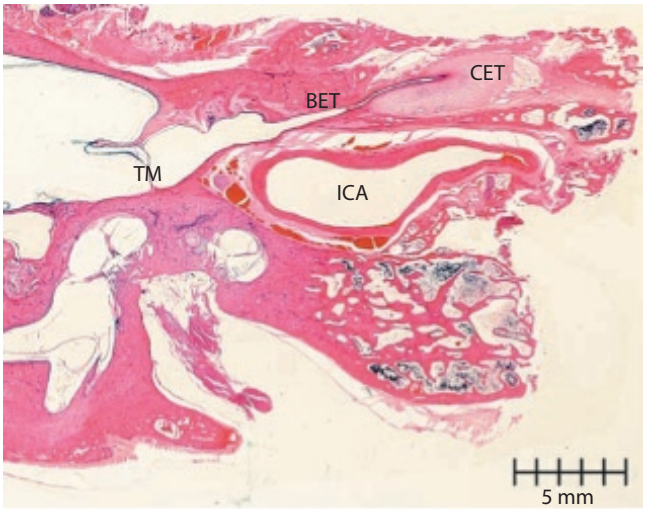

Figure 46.16 Photomicrograph of the left Eustachian tube in axial section, showing its bony (BET) and cartilaginous (CET) portions. The tympanic membrane (TM) is retracted towards the Eustachian orifice and note the adjacent position of the internal carotid artery (ICA).

and a little below the posterior end of the interior turbinate. The opening is almost triangular in shape and is surrounded above and behind by the torus. The salpingopharyngeal fold stretches from the lower part of the torus downwards to the wall of the pharynx. The levator palati, as it enters the soft palate, results in a small swelling immediately below the opening of the tube. Behind the torus is the pharyngeal recess or fossa of Rosenmüller. Lymphoid tissue is present around the tubal orifice and in the fossa of Rosenmüller and may be prominent in childhood.

MUSCLES ATTACHED TO THE EUSTACHIAN TUBE

The tensor palati muscle arises from the bony wall of the scaphoid and from along the whole length of the lateral cartilaginous lamina that forms the upper portion of the front wall of the cartilaginous tube. From these broad

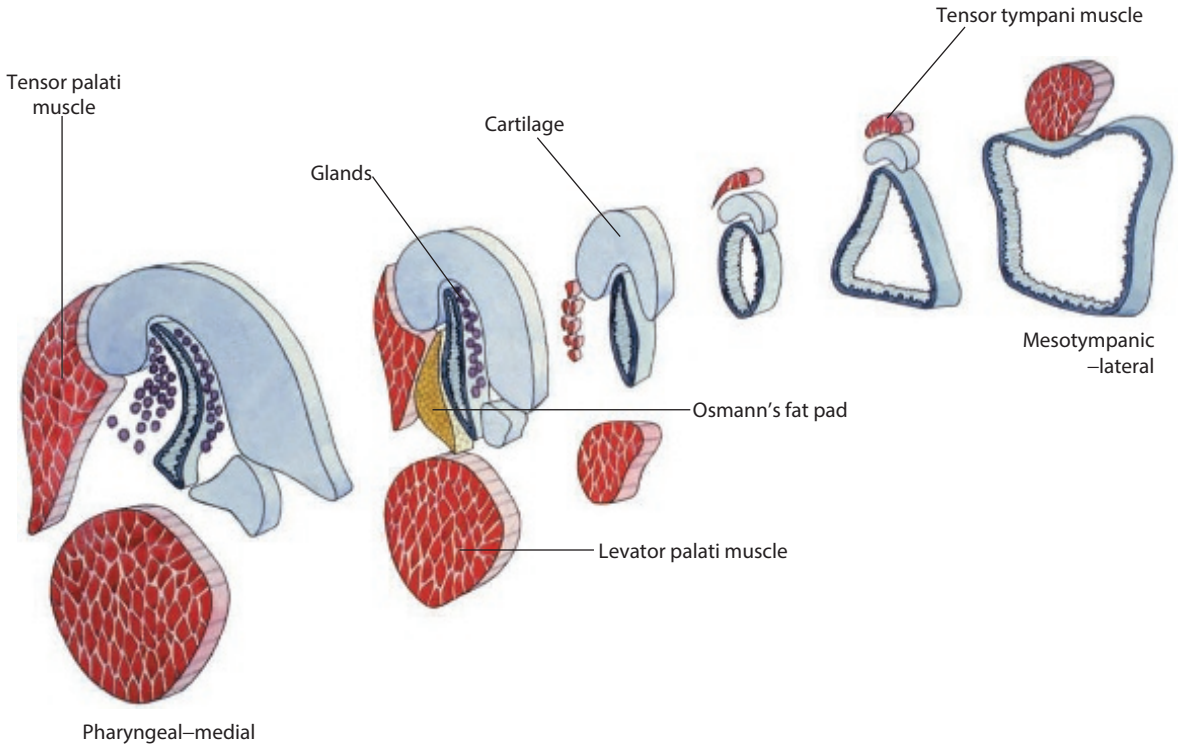

Figure 46.17 Schematic view of the right Eustachian tube. Redrawn from Sade and Ar.[23]

origins the muscle descends, converges to a short tendon that turns medially around the pterygoid hamulus and then spreads out within the soft palate to meet fibres from the other side in a midline raphe. The tensor palati separates the tube from the otic ganglion, the mandibular nerve and its branches, the chorda tympani nerve and the middle meningeal artery. It is supplied by the mandibular nerve.

The salpingopharyngeus is a slender muscle attached to the inferior part of the cartilage of the tube near its pharyngeal opening, and it descends to blend with the palatopharyngeus.

The levator palati contains a few fibres that arise from the lower surface of the cartilaginous tube and originates from the lower surface of the petrous bone, just in front of the opening for the entrance of the carotid, and from fascia forming the upper part of the carotid sheath. It first lies inferior to the tube, then crosses to the medial side and spreads out into the soft palate. Both the salpingopharyngeus and the levator palati are supplied from the pharyngeal plexus.

The ascending pharyngeal and middle meningeal arteries supply the Eustachian tube. The veins drain into the pharyngeal plexus and the lymphatics pass to the retropharyngeal nodes. The nerve supply arises from the pharyngeal branch of the sphenopalatine ganglion (Vb) for the ostium, the nervus spinosus (Vc) for the cartilaginous portion and the tympanic plexus (IX) for the bony part.

The mastoid air cell system

The mastoid antrum is an air-filled sinus within the petrous part of the temporal bone. It communicates with the middle ear by way of the aditus and has mastoid air cells arising from its walls. The antrum, but not the air cells, is well developed at birth and by adult life has a volume of about 2 mL. The roof of the mastoid antrum and mastoid air cell space form the floor of the middle cranial fossa, while the medial wall relates to the posterior semicircular canal. More deeply and inferiorly is the dura of the posterior cranial fossa and the endolymphatic sac. The latter emerges through the operculum on the posterior surface of the petrous bone and derives from the endolymphatic duct, which has passed through the vestibular aqueduct. Posterior to the endolymphatic system is the sigmoid sinus, which curves downwards only to turn sharply upwards to pass medial to the facial nerve and then becomes the dome of the jugular bulb in the middle ear space. The posterior belly of the digastric muscle forms a groove in the base of the mastoid bone. The corresponding ridge inside the mastoid lies lateral not only to the sigmoid sinus but also to the facial nerve and is a useful landmark for finding the nerve itself. The periosteum of the digastric groove on the undersurface of the mastoid bone continues anteriorly and part of it becomes the endosteum of the stylomastoid foramen and subsequently of the facial nerve canal.

The outer wall of the mastoid lies just below the skin and is easily palpable behind the pinna. Macewen's triangle is a direct lateral relation to the mastoid antrum and is formed by a posterior prolongation of the line of the zygomatic arch and a tangent to this that passes through the posterior border of the external auditory meatus. The relationships of the mastoid antrum are shown in Figure 46.18.

In most of the population, the mastoid air cell system is fairly extensive with air cells extending into the mastoid tip,

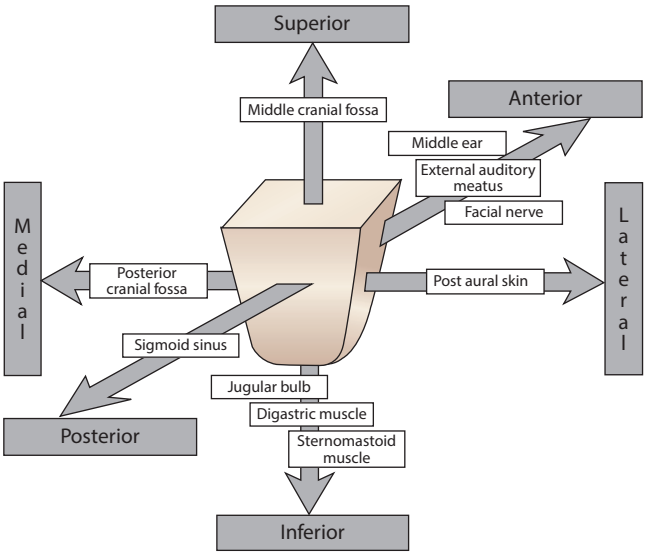

Figure 46.18 Relationships of the right mastoid antrum.

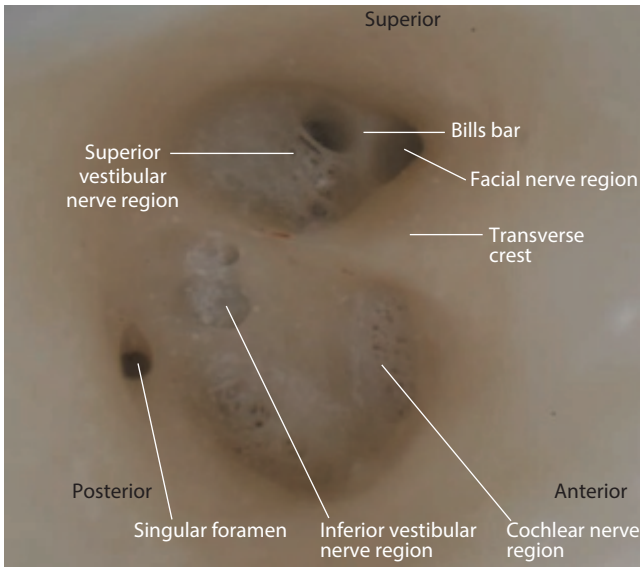

Figure 46.19 Endoscopic view of the apex of the left internal auditory meatus.

the retrofacial region, the sinodural angle and anteriorly into the petrous apex and arch of the zygoma. Alternatively, the mastoid antrum may be the only air-filled space in the mastoid process when the name acellular or sclerotic is applied. This condition occurs in perhaps 20% of adult temporal bones and is seen in individuals with chronic ear disease. In normal ears, the lining of the mastoid is a flattened, non-ciliated epithelium without goblet cells or mucus glands.

The petrous apex lies at the most medial aspect of the temporal bone and is shaped like a foreshortened pyramid, pointing anteriorly and medially. The posteromedial surface of the petrous apex is part of the posterior cranial fossa, while the superior aspect of the bone forms the floor of the middle cranial fossa. The internal carotid artery and the internal auditory meatus run through the bony petrous apex. At the apex of the petrous bone is the trigeminal nerve running into Meckel's cave with the abducent nerve passing close to its roof. Gradenigo's syndrome is the result of infection at the petrous apex and comprises a lateral rectus palsy, facial pain and discharging ear. Historically, the petrous apex has been the most difficult to access surgically but this has been advanced by the development of endoscopically assisted trans-sphenoidal techniques.

The internal auditory meatus

This is a short canal, nearly 1 cm in length and lined with dura, which passes into the petrous bone in a lateral direction from the cerebellopontine angle. It transmits the facial, cochlear and vestibular nerves and the internal auditory artery and vein. The meatus is closed at its outer lateral end, or fundus, by a plate of bone that is perforated for the passage of nerves and blood vessels to and from the cranial cavity.

The bony plate separating the fundus from the middle and internal ears has a transverse crest – the crista falciformis – on its inner medial surface, which separates a small upper region from a larger lower area (**Figure 46.19**). Above the crest and anteriorly is the opening of the facial canal carrying the facial nerve (VII). This is separated, by a small vertical ridge known as Bill's bar, from the posterior region that transmits the superior vestibular nerve through several small foramina to the superior and lateral semicircular canals, to the utricle and a part of the saccule. Below the transverse crest, the cochlear nerve lies anteriorly and leaves the meatus through the cochlear area, which comprises a spiral of small foramina and a central canal. The inferior vestibular nerve passes through one or two foramina behind the cochlear opening to supply the saccule. Just behind and below the inferior vestibular foramen is the foramen singulare, which contains the singular nerve. This runs obliquely through the petrous bone close to the round window to supply the sensory epithelium in the ampulla of the posterior semicircular canal.

DEVELOPMENT OF THE HUMAN EAR

The outer and middle ears

The 9 months from implantation of the fertilized and dividing egg – the blastocyst – to birth is divided into three periods, namely, pre-embryonic, embryonic and foetal. The pre-embryonic stage lasts 21 days, the embryonic stage 35 days and the foetal stage is the longest phase at 210 days.

During the embryonic phase there is rapid growth and differentiation of the ecto-, meso- and endoderm, so that by the end of this period all the major organ systems have been formed and the late embryo has an external shape that is obviously human. In the foetal period there are changes in the shape, size and orientation of the various structures, as well as rapid overall growth, but no new tissues develop.

During growth from the fertilized egg into the fully formed foetus, animals pass through phases that represent, to a certain degree at least, their evolutionary precursors.

The phrase 'ontogeny recapitulates phylogeny' has been used to express this reflection of earlier forms. In mammals, a phase is reached during early embryonic life when the mesenchyme surrounding the primitive foregut and pharynx differentiates into a maxillary and mandibular swelling on each side of the midline just above and below the buccopharyngeal membrane. This membrane then breaks down and a space, which will later become both nasal and buccal cavities, is formed. Further down the embryo and in the mesenchyme surrounding the pharynx, five or six parallel thickenings develop as bands that surround the pharynx. These are the branchial arches, which are numbered 1 to 5 from head to tail. They are formed anterior to the 40–43 paired somites that subsequently give rise to the trunk and limbs. On the external surface a groove develops between each branchial arch and this is matched by a cleft or pouch on the inner pharyngeal surface. In each branchial arch a bar of cartilage, a group of muscles, an associated artery and a cranial nerve, supplying these structures and their derivatives, all develop. The cranial nerve is called the post-trematic nerve. In addition, a nerve from the arch lower down supplies the inner endodermal surface of the arch above and is called the pretrematic nerve.

The first arch has the trigeminal nerve (V), the second arch the facial (VII) and the third arch the glossopharyngeal (IX). These are the post-trematic nerves. The pretrematic nerves are the chorda tympani (from VII) running to the first arch (V) and Jacobson's nerve (the tympanic branch of IX) running to the second arch (VII).

DERIVATIVES OF THE FIRST AND SECOND BRANCHIAL ARCHES

The innervation of the lower arches and indeed their derivation are much less clear (**Table 46.3**). In fish, the layers between the arches break down to form the gill clefts, but in mammals this does not occur although grooves on the external surface of the embryo do develop and for a very short time come into contact with the endoderm lining the pharynx. However, mesoderm rapidly intervenes and develops into the normal adult structures. Occasionally there is failure of this system when the various branchial arch defects can occur as sinuses (blind-ended tracts opening onto an epithelial surface) as a cleft or groove fails to regress, or less commonly as fistulae (a tract running from one epithelial surface to another) when the ecto-endodermal junction breaks down.

The first pharyngeal pouch on the inside expands due to the rapid growth of the surrounding mesenchyme and, after dragging in some of the second pouch endoderm, results in the formation of the Eustachian tube, middle ear and mastoid antrum. In creating these large spaces the neural structures are forced to take a convoluted path to stay within mesenchyme and yet remain bound to their original arch structures and the derivatives. The facial nerve is a good example as it turns posteriorly from the geniculate ganglion, then inferiorly and then anteriorly in order to leave the skull.

The endoderm of the slit-like sac that is the precursor of the middle ear lies against the ectoderm of the first pharyngeal groove by the fourth week. Mesenchyme grows in between these two layers to form the middle layer of the future tympanic membrane. The underlying sac expands and as it reaches the developing ossicles and labyrinth, the epithelium is draped over these structures and their associated muscles, tendons and ligaments, so that a complex series of mucosal folds is formed.

The future Eustachian tube lumen and middle ear spaces are formed by 8 months' gestation and the epitympanum and mastoid antrum are developed by birth. A few mastoid 'air cells' may be present at birth, albeit filled with amniotic fluid. However, development of the mastoid air cell system does not occur until after birth, with about 90% of air cell formation being completed by the age of 6 with the remaining 10% taking place up to the age of 18.

The ossicles develop from the outer ends of the first arch (Meckel's) and second arch (Reichert's) cartilages that lie above and below the first pharyngeal pouch. The process begins at 4 weeks and adult shape, size and ossification are present by 25 weeks. The muscles attached to the ossicles

TABLE 46.3 Derivatives of the first and second branchial arches

Cartilage	Post-trematic nerve	Pretrematic nerve	Artery
First arch derivatives			
Meckel's Malleus Incus 'Mandible' Anterior malleolar ligament Sphenomandibular ligament	Mandibular V	Chorda tympani VII	
Second arch derivatives			
Reichert's Stapes superstructure Styloid process Lesser cornu of hyoid Stylohyoid ligament	Facial VII	Tympanic branch IX	Stapedial

arise from the arches that give rise to that part of the ossicle to which the muscle attaches.

Thus the tensor tympani is attached to the upper part of the handle of the malleus, which is derived from the first arch and is, therefore, supplied by a branch of the Vth (mandibular) nerve. In a similar way the stapedius muscle is supplied by the VIIth (facial) nerve. The chorda tympani, which is the pretrematic nerve of the second arch that supplies endodermal structures of the first arch (i.e. taste to the anterior two-thirds of the tongue and submandibular gland secretomotor fibres) has to run through mesoderm since it cannot run through air. This mesoderm subsequently becomes the middle layer of the tympanic membrane and is the physical connection between the first and second arches.

The external ear canal develops from the first pharyngeal groove in a complex fashion. A complete description is beyond the scope of this chapter and may be sought from Michaels and Soucek.[24] It is sufficient to say that the meatus deepens by proliferation of its ectoderm and that an anteriorly placed bud of epithelial cells expands vertically to form the skin, which will cover the future tympanic membrane. This clump of cells then opens up as a slit to form the canal lumen and produce the pars tensa and deep external canal epithelium. These two types of skin both have migratory properties so that the ear canal becomes self-cleansing.

The external auricle or pinna develops from a series of small cartilaginous tubercles that surround the first pharyngeal groove. These enlarge and coalesce, although it seems that the majority of the auricle is derived from the second arch cartilages and that the tragus is the only contribution from the first arch. The rudimentary pinna has formed by 60 days although it apparently continues to grow throughout life.

Failure of formation of the first and second branchial arch structures gives rise to problems which range from failure of adequate skin migration with 'ear canal cholesteatoma' (which are very rare) through bat ears, accessory auricles and preauricular sinuses, to complete failure of formation of the external ear canal and middle ear. There are also the rare first arch fistulae (collaural fistulae), which comprise a tract between the external ear canal and the skin of the cheek, with the fistula path passing through the parotid gland and frequently between branches of the facial nerve.

The internal ear (labyrinth)

The internal ear initially develops independently of the middle and external ears, although the two become interconnected by the stapes superstructure, becoming attached to the stapes footplate, thereby giving continuity to the auditory pathway.

The development of the labyrinth can be thought of as the initial development of the generalized structure of the membranous labyrinth, followed by a period of encasement by the bony labyrinth and the production of a further series of spaces within this bony shell that in turn become the perilymphatic spaces of the complete structure. These different activities are happening at different times in different parts of the labyrinth so that damage or derangements at specific times give rise to many peculiar and varied abnormalities.

Within the first few days of embryonic life (i.e. at about day 22 or 23) ectodermal thickening forms on the side of the head end of the embryo close to that part of the developing neural tube and neural crest cells, which will later become the brain and brainstem and the cranial nerves, respectively. The ectodermal thickening is the otic placode, which deepens and then sinks below the surface as the sides close in to form an otic pit which eventually loses connection with the surface and forms the otocyst (Figure 46.20).

Associated with the otocyst is the cluster of neural crest cells that later become the separate facial (geniculate), auditory (spiral) and vestibular (Scarpa's) ganglion cell bodies. The otocyst then undergoes a series of spectacular changes, which result in the full-sized outline of the adult membranous labyrinth by 25 weeks' gestation.

The semicircular canals start to develop at around 35 days as three flattened pouches that grow out at right angles from each other from the utricle. At the centre of each semicircular ridge, the opposing epithelial surfaces meet, fuse and then coalesce to be replaced by mesoderm. The superior canal is the first to be fully formed by 6 weeks.

As these developments are taking place, the cochlea starts to be formed. The saccule, which has separated from the utricle, starts to put out a single pouch-like process that grows and then begins to coil from base to apex to reach its full 2.5 coils by 25 weeks.

Within the membranous labyrinth the sensory cells of the three cristae, two maculae and the organ of Corti are beginning to develop from areas of ectodermal specialization. This is encouraged either by the ingrowth of nerve endings from the cochleovestibular ganglion, which was originally outside the otocyst, or by the development of the sensory cells encourages neural ingrowth (Figure 46.21).

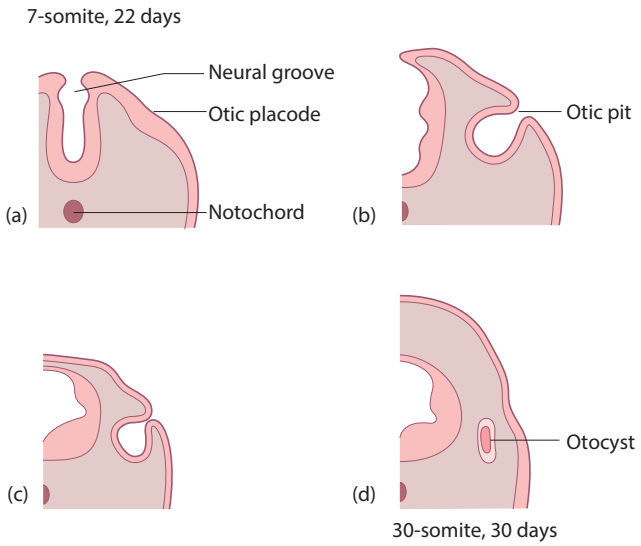

Figure 46.20 Development of an otocyst.

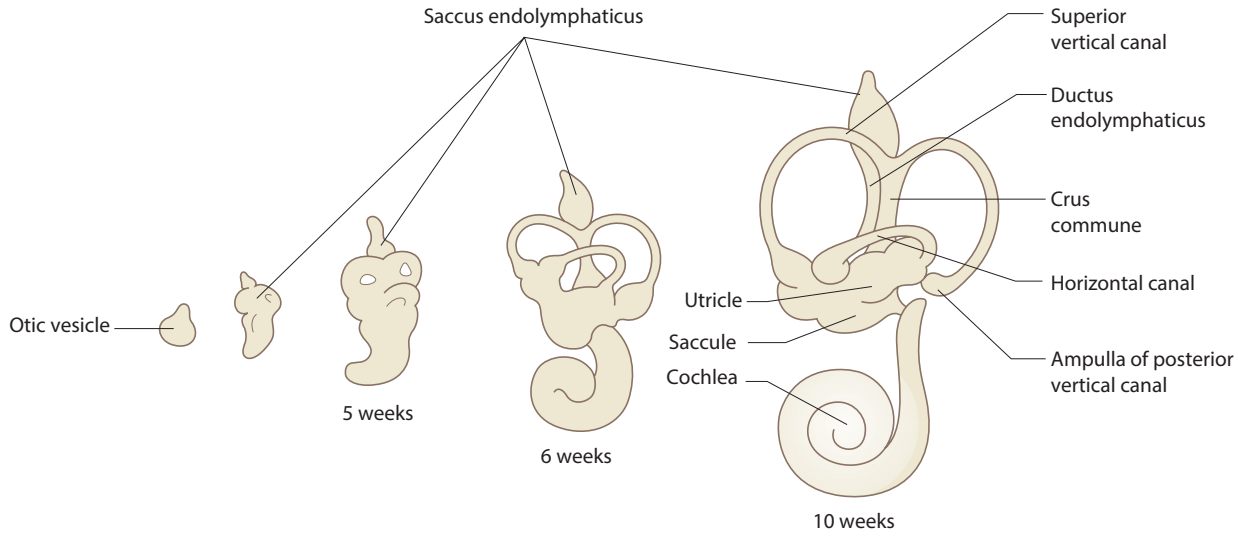

Figure 46.21 Development of the membranous labyrinth.

TABLE 46.4 Development of communication channels passing through labyrinth

	Channel
Internal auditory meatus	Persisting channel in cartilage model around VII and VIII nerves
Subarcuate fossa	Persisting vascular channel
Vestibular aqueduct	Fifth and sixth ossification centres fuse around the endolymphatic duct
Cochlear aqueduct	Resorption of precartilage
Fossula ante fenestram	Resorption of precartilage
Fossula post fenestram (inconstant)	Resorption of cartilage
Oval window	Otic capsule becomes footplate of stapes and annular ligament
Round window	Persisting cartilage becomes round window niche and membrane

The organ of Corti starts developing as a single block of heaped up ectodermal cells at about 11 weeks. Within this mass develop inner and outer hair cells and then specialized supporting cells. The tunnel of Corti appears between inner and outer pillar cells as clusters of stereocilia and a single kinocilium are developing on each hair cell. The cochlear kinocilium regresses, leaving the adult configuration of stereocilia, and the spaces between the outer hair cells open up as the supporting cells (the Deiters cells) change shape. Differentiation progresses from base to apex so that at any one time various stages of development can be seen in appropriately prepared material.

Epithelium close to the sensory regions develops into the specialized cell groups that maintain the ionic and electrical stability of the endolymph. These regions are the stria vascularis of the cochlear duct and the 'dark cell' regions of the vestibular sensory epithelium.

The bony labyrinth

The mesenchyme enclosing the otocyst becomes chondrified to form the otic capsule. As the membranous labyrinth expands, the otic capsule remodels and in places undergoes dedifferentiation to form fluid-filled spaces that eventually become the perilymphatic spaces. This dedifferentiation does not occur where nerves enter the sensory cell regions. Elsewhere, the perilymphatic spaces become continuous and a communication with the cerebrospinal fluid is formed by the development of the cochlear aqueduct, which runs to the posterior cranial fossa from the scala tympani in the base of the cochlea.

Ossification of the cartilaginous otic capsule begins in or around week 16 from a variable number of centres that finally fuse without leaving telltale suture lines. This dense bony mass is the petrous bone. Interestingly, this is frequently the last part of a whale to decompose and is sometimes the only remains of those eaten by sharks.

There are certain channels that remain within the otic capsule with one of the most important being the oval window where part of the otic capsule becomes the stapes footplate and the annular ligament, thereby allowing sound from the middle ear to enter the labyrinthine fluids (Table 46.4).

The temporal bone

Four separate elements eventually fuse to form the temporal bone, which is one of the most complex and interesting parts of the bony anatomy of the body. These four parts are the petromastoid complex, the squamous portion, the tympanic bone and the styloid process.

The petromastoid is derived from petrous bone described above and the continuing growth of its outer layers which form the roof of the middle ear, the lateral wall of the Eustachian tube, the floor of the middle ear, the canal of the facial nerve and the petrous apex.

The squamous bone develops in mesenchyme and starts to ossify from a single centre close to the roof of the zygoma as early as 8 weeks. The posteroinferior portion grows down behind the tympanic ring to form the lateral wall of the foetal mastoid antrum.

The tympanic bone also forms in mesenchyme, but from several centres around the external meatus. These form the major part of a ring with a groove on the inner aspect that becomes the sulcus for the tympanic membrane. Even by late foetal life the bony ear canal is unformed and only after birth do anterior and posterior protuberances grow to form the floor of the canal. These crescentic swellings eventually fuse laterally leaving a gap in the middle of the floor. This is the foramen of Huschke, which is usually closed by adolescence. The tympanic bone fuses with the mastoid process of the petromastoid and with parts of the squamous and petrous bones as the tympanomastoid, tympanosquamous and petrotympanic sutures. The petrotympanic suture has a canal for the chorda tympani nerve.

The styloid develops from two centres at the cranial end of the second arch (Reichert's) cartilage. The part close to the base of the skull starts to ossify before birth, but the styloid process itself does not start to ossify until after, and fusion of the two parts may not occur until after puberty.

Much of the growth of temporal bone occurs after birth with enlargement of the whole structure and major growth of the mastoid process so that the stylomastoid foramen, which was initially close to the surface, becomes buried by the development of the mastoid tip. At the same time there is generalized downwards rotation of the petrous bone so that the tympanic membrane moves from being almost horizontal in the neonate to an angle of about 55° with the horizontal in the adult. With these changes, the floor of the middle cranial fossa flattens and the relations of the geniculate ganglion, the semicircular canals and the internal auditory meatus change so that middle cranial fossa surgery in the baby is anatomically a different experience from that in the adolescent.

CHAPTER 47

ANATOMY OF THE COCHLEA AND VESTIBULAR SYSTEM: RELATING ULTRASTRUCTURE TO FUNCTION

Jonathan Gale and Andrew Forge

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: structure, anatomy, cell biology; inner ear, endolymph, perilymph; cochlea, vestibular hair cell, supporting cell, organ of Corti, inner hair cell, outer hair cell, spiral ganglion, stria vascularis, spiral ligament, basilar membrane, tectorial membrane, Reissner's membrane , utricle/utricular, saccule/saccular, crista, macula/maculae, type1 hair cell, type 2 hair cell and dark cells.

INTRODUCTION

The inner ear (Figure 47.1a,b) collects, packages and delivers sensory information relating to hearing via the cochlea, and balance via the vestibular system. It is responsible for mechanoelectrical transduction, the conversion (transduction) of movements – initiated by sound waves in the cochlea or by changes in the position of the head in space in the vestibular system – into electrical signals that can then be passed to the brain along the auditory or vestibular nerves. It is formed of a series of bony channels that enclose interconnected fluid-filled tubes (the membranous labyrinth), the inner walls of which are lined by epithelial tissues (Figures 47.1a,c and 47.2). In humans and higher primates, the bony channels are in the temporal bone (Figure 47.1c), the hardest bone in the body, which is fused with the skull. In other mammals, the inner ear is contained within a bony auditory bulla which is not fused with the skull but fills a recess in it and which can be isolated relatively easily.

The bony channels are filled with perilymph, which surrounds the membranous canals (Figure 47.1a). Perilymph is essentially a typical extracellular fluid, similar, but not identical, to cerebrospinal fluid (CSF) or serum; it has a high sodium ion (Na^+) and low potassium ion (K^+) concentration.[1] The perilymphatic compartment connects with the arachnoid space of the brain via the cochlear aqueduct so there is potential continuity between cochlear perilymph and CSF, although the exact compositions of the two fluids are different from each other and also from serum, indicating that perilymph is produced or at least significantly modified locally in the inner ear and is not derived directly from CSF (or serum).

The fluid inside the lumen of the membranous canals is **endolymph** (Figure 47.1a). This has an unusual composition for an extracellular fluid. It is high in K^+ (~140 mM) and low in Na^+ (~1 mM). In the cochlea, endolymph also has a high positive electrical potential of around +80 mV, the endocochlear potential (EP), but although the compartments are interconnected a similar electrical potential is not observed in the vestibular system. The boundary between perilymph and endolymph lies at the level of the junctions between the epithelial cells that surround the endolymphatic spaces. These junctions form a permeability barrier, the maintenance of which is essential for the function of the inner ear.

Three types of epithelium surround the endolymphatic compartment: sensory epithelia, ion-transporting epithelia, and relatively unspecialized non-sensory epithelia (Figure 47.2a,b). The vestibular system of mammals contains five sensory epithelial patches or sheets: the **maculae** of the **utricle** and **saccule**, and the three **cristae**, one

in each of the **semicircular canals** (SCCs) (Figures 47.1a, 47.2a, 47.3). The sensory epithelium of the cochlea is the **organ of Corti**, named after the Italian anatomist Alfonso Corti. It comprises a relatively narrow strip of cells running along an acellular basement membrane and coiled in a spiral (Figures 47.2b and 47.4a,b,c). All of the sensory epithelia are composed of two main cell types: sensory hair cells and non-sensory supporting cells (Figures 47.3d and 47.4b,c). Each hair cell is surrounded and separated from its neighbours by supporting cells so that hair cells do not come into direct contact with each other. Viewed from above, each sensory epithelium appears as a more or less regular mosaic of cells at the apical (luminal [endolymphatic]) surface of the epithelium, sometimes referred to as the **reticular lamina**, with each hair cell surrounded by and thus in contact with several supporting cells, and each supporting cell contacting several other supporting cells (Figures 47.3e,f and 47.4d,e,f). The bodies of the supporting cells also intervene between the basal ends of the hair cells and the acellular basement membrane underlying the

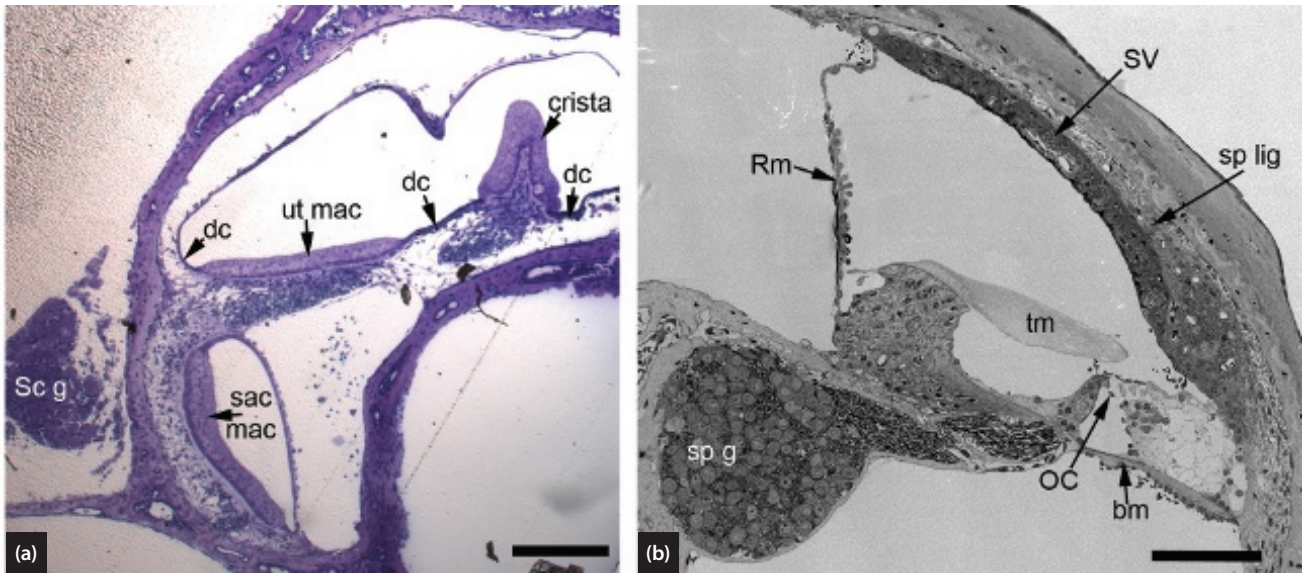

Figure 47.2 **(a)** Cross section through the vestibular labyrinth showing the relationship of the vestibular organs. ut mac = utricular macula; sac mac = saccular macula; crista = crista ampullaris; dc = dark cells; Sc g = Scarpa's ganglion. epithelium (which is known as the 'basilar' membrane in the organ of Corti) so that only the supporting cells and not hair cells are in contact with the basement membrane (Figures 47.3d and 47.4b,c). The sensory epithelia thus have the appearance of a pseudostratified epithelium. Each sensory epithelium is also covered by a specific acellular extracellular matrix structure: the **otoconial membrane** in macular organs (Figure 47.3g,h); a **cupula** overlying each the crista (Figure 47.3j); and the **tectorial membrane** in the cochlea (Figures 47.4b,g). The hair cells derive their name from the organized bundle of rigid projections at their apical surface (Figures 47.3f and 47.4d,e). Mechanical deflection of the hair bundle caused by either sound waves or changes in head position results in the opening and closing of cation-permeable **m**echanoelectrical **t**ransduction (**MET**) channels that modulate the flow of K^+ ions from endolymph into the hair cells, altering the hair cell's resting electrical potential and so its excitability. Thus, the hair cells are the mechanotransducers that convert auditory or vestibular-evoked mechanical stimuli into electrical signals.

The ion-transporting epithelia, the dark cell regions of the vestibular system and the stria vascularis of the cochlea (Figure 47.2a,b) are involved in active (energy-consuming) ion transport that is necessary to maintain the unusual endolymph composition and positive charge. The comparatively less specialized epithelia, including Reissner's membrane in the cochlea and those which constitute the 'roof' and linings of the saccule, utricle and ampullae of the semicircular canals (Figure 47.2a,b) and the membranous semicircular canals themselves, form important permeability barriers separating the perilymph from endolymph. If these membranes rupture or break down, the permeability barriers are disrupted, leading to fluid mixing and physiological dysfunction. It is thought such an event may occur to Reissner's membrane in Ménière's syndrome.

GENERAL CHARACTERISTICS OF HAIR CELLS

The hair bundle and cuticular plate

The hair bundle is composed of rows of **stereocilia** that increase in height in one particular direction across the apical surface of the hair cell, and a single kinocilium located behind the row of longest stereocilia (Figures 47.5a and 47.6a), but which is absent from the hair bundles of mature hair cells in the cochlea (Figure 47.5b). Stereocilia are really giant microvilli, plasma membrane-bound projections from the apical surface of the hair cell that enclose a packed array of filaments of the cytoskeletal protein, actin[2–4] (Figure 47.5d–f). The kinocilium is composed of microtubules similar in form to motile cilia but they are not motile.[5] In cochlear hair cells, the kinocilium is present only during development, reducing down as the cochlea matures to remain only as the basal body in the apical cytoplasm at one side of the stereociliary bundle (Figure 47.5c).[6] The position of the kinocilium (or the basal body) and the longest row of stereocilia define the polarity of the asymmetric hair bundle (Figures 47.3f, 47.4d,e and 47.5a,b). Deflection of the stereocilia towards the longest ones opens MET channels, K^+ enters and the hair cell becomes depolarized. Deflection in the opposite direction closes the transducer channels and the hair cell becomes hyperpolarized. The transducer channels are located at the tips of the stereocilia of the shorter rows but not in the longest stereocilia.[7]

The parallel actin filaments in the stereocilia (Figure 47.5e,f) are closely packed and are cross-linked by a number of different proteins such as espin, fimbrin, fascin and plastin 1, the last being the second most abundant protein in stereocilia after actin.[2, 8–13] The high

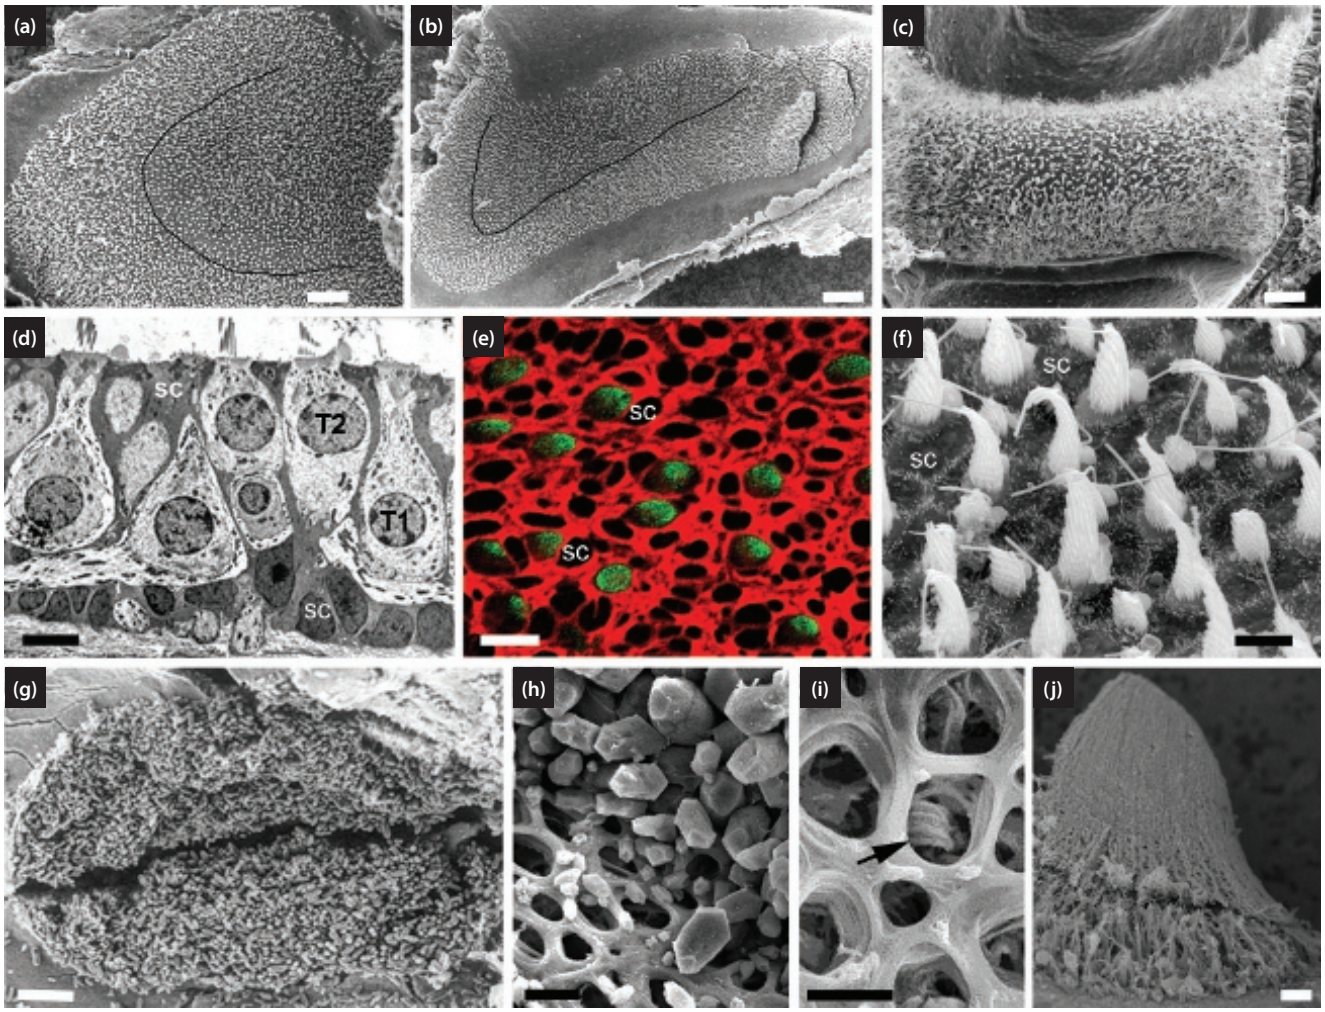

Figure 47.3 Vestibular sensory epithelia. (a) Utricular macula. Scanning electron microscopy of the entire intact utricular macula viewed from above after removal of otoconial membrane. Curved line indicates approximate location of line of hair bundle polarity reversal in the striolar region. Scale bar: 100 µm. **(b)** Saccular macula. As above for the utricular macula. Scale bar: 100 µm. **(c)** Crista ampullaris. Scanning electron microscopy of the upper surface of the crista 'saddle'. Scale bar: 100 µm. **(d)** Transmission electron microscopy of a thin section from a vestibular sensory epithelium (utricular macula of guinea pig). T1 = Type 1 hair cell; T2 = Type 2 hair cell; sc = supporting cell. Note that nuclei of each cell type are at different levels in this pseudostratified epithelium. Scale bar: 5 µm. **(e)** Human utricular macula labelled for filamentous actin (f-actin) with fluorescent-phalloidin (red) and an antibody to calretinin (green, labelling hair cells). Apical surface view to show reticular lamina. Phalloidin labels f-actin in the unusually wide junctional complexes around each cell. Each hair cell (green) is separated from its neighbours by intervening supporting cells (sc). Scale bar: 10 µm. **(f)** Apical surface of utricular macula. Hair cells are easily identified by the hair bundles that project out of the surface of the epithelium. Each hair cell is separated from its neighbour by intervening supporting cell (sc). Scale bar: 5 µm. **(g)** Scanning electron microscopy of the surface of the utricular macula with the otoconia still in situ covering the surface. Scale bar: 100 µm. **(h)** Higher magnification view of the utricular macular surface showing the perforated sheet of extracellular matrix component of the otoconial membrane beneath crystal-like otoconia. Scale bar: 5 µm. **(i)** Hair bundle (arrowed) projecting up into the otoconial matrix. Note that the hair bundle is aligned with a perforation in extracellular matrix component of otoconial membrane (utricle). Scale bar: 5 µm. **(j)** Cupula overlying a crista ampullaris. Scale bar: 10 µm.

density of actin filaments and the extensive cross-linking between them imposes rigidity on the shaft of the stereocilium, which tapers significantly at its proximal end (Figure 47.5a,g) where it is embedded into the **cuticular plate** (Figure 47.5a,c,d), a rigid platform formed of a meshwork of actin filaments and other proteins in the apical cytoplasm of the hair cell (Figure 47.5a,c,d).[14–17] As a result, when pushed at its tip, the stereocilium pivots at the taper like a stiff rod. The fundamental nature of this stereociliary rigidity for all hair cells is evidenced by the hearing impairment and vestibular disorders that result from mutations in genes that encode for such actin-cross-linker proteins. Mice with such mutations are often recognized by erratic and/or circling behaviours, for example the 'jerker' mouse strain, which has a mutation in the gene for the cross-linking protein espin, and in which stereocilia are thinner than normal.[10–13] Loss of plastin 1 results in progressive hearing loss and balance dysfunction and progressive thinning of stereocilia.[9, 12] Actin filaments descend from the stereocilium into the cuticular plate as a rootlet, which is cross-linked into the actin meshwork (Figure 47.5h).[15] The rootlet is formed of densely packed

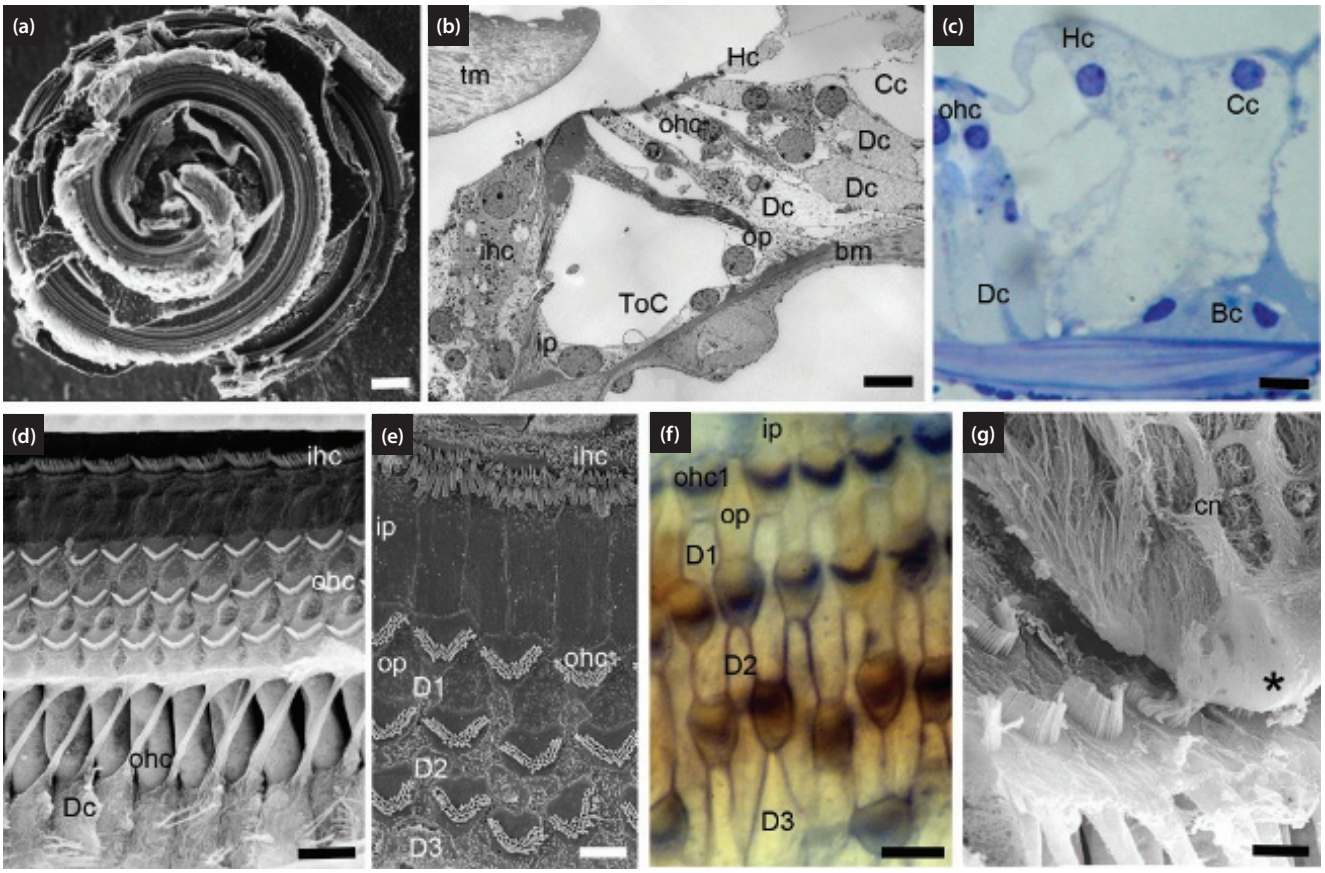

Figure 47.4 **(a)** Whole cochlear modiolus. Scanning electron microscopy showing the organ of Corti spiralling down from the apex for two and a half turns. Scale bar: 100 µm. **(b)** Cross section of the organ of Corti. Transmission EM of a thin section of the organ of Corti. The tectorial membrane (tm) retracts away from the surface of the organ of Corti during processing (see panel (g)). The tunnel of Corti (ToC) is created by the arch formed by the phalangeal processes of the inner and outer pillar cells. Scale bar: 10 µm. **(c)** Supporting cells to the outer, lateral side of the organ of Corti. Scale bar: 10 µm. **(d)** Surface and underside of the organ of Corti (gerbil): scanning electron microscopy of the apical surface with outermost (lateral) supporting cells removed to expose the outermost (third) row of Deiters' cells (Dc) and the outer third row of outer hair cells (ohc). The body of the Deiters' cell surrounds the base of the ohc and its phalangeal process ascends at an angle to the apical surface where the head expands. The hair bundles of the inner hair cells (ihc) in a single row. Scale bar: 10 µm. **(e)** Luminal surface of organ of Corti (mouse). Hair cell/supporting cell mosaic formed when the apical surfaces/heads of various supporting cells that join with and intercalate between individual hair cells. The head of the inner pillar cell (ip) and outer pillar cell (op) are indicated. Scale bar: 5 µm. **(f)** Human organ of Corti: reticular lamina at apical surface across the outer hair cell region (ohc1 = first row outer hair cell). Heads of various supporting cells surrounding each hair cell are indicated. Scale bar: 10 µm. **(g)** Tectorial membrane in situ over the organ of Corti. Radial filaments comprise the body of the tectorial membrane which has a greater density at the outer tip (*). The upper surface is covered by the densely packed fibres forming the covernet (cn). Scale bar: 5 µm. For all panels: Ihc or ihc = inner hair cell; ohc = outer hair cell; ip = inner pillar cell; op = outer pillar cell' Dc = Deiters' cell; HC or Hc = Hensen cell; Cc = Claudius cell; bm = basilar membrane; tm = tectorial membrane; Bc = Boettcher cells; D1, D2, D3 = heads of the three rows of Deiters' cells.

actin filaments (Figure 47.5e). The actin bundling protein TRIOBP plays a key role in the formation and maintenance of the rootlet.[18] In addition to actin, the cuticular plate contains spectrin,[19] another actin cross-linking protein that has elastic, deformation-resisting properties, and tropomyosin,[16, 17] a protein that binds around actin and stiffens it. Around its lateral margin, the cuticular plate is linked to the lateral plasma membrane at the level of the intercellular junction[15, 16] with which, on the supporting cell side, actin and other cytoskeletal proteins are also associated (Figures 47.6b,c,d and 47.7e,h). This may provide a means of support for the cuticular plate so that the stereocilia themselves are supported on a rigid platform, enhancing their ability to respond to small displacement forces.

Various members of the myosin family of motor proteins (types 1c, 6, 7a and 15 – all unconventional, non-muscle isotypes) are also localized in the cuticular plate region and the stereocilia. In addition, immunolabelling for myosins 6 and 7a shows these two proteins to be highly expressed throughout the hair cell cytoplasm, providing a distinguishing marker label for hair cells from their earliest differentiation during development and into adulthood (Figure 47.6e). Mice with mutations in the genes for myosins 6, 7a or 15 all show deafness and balance disorders and abnormalities in their stereociliary bundles.[20] In the mouse mutant where myosin 6 is defective (Snell's waltzer), stereocilia are fused and greatly lengthened.[21] Interestingly, a similar anomaly is seen in the human organ of Corti and

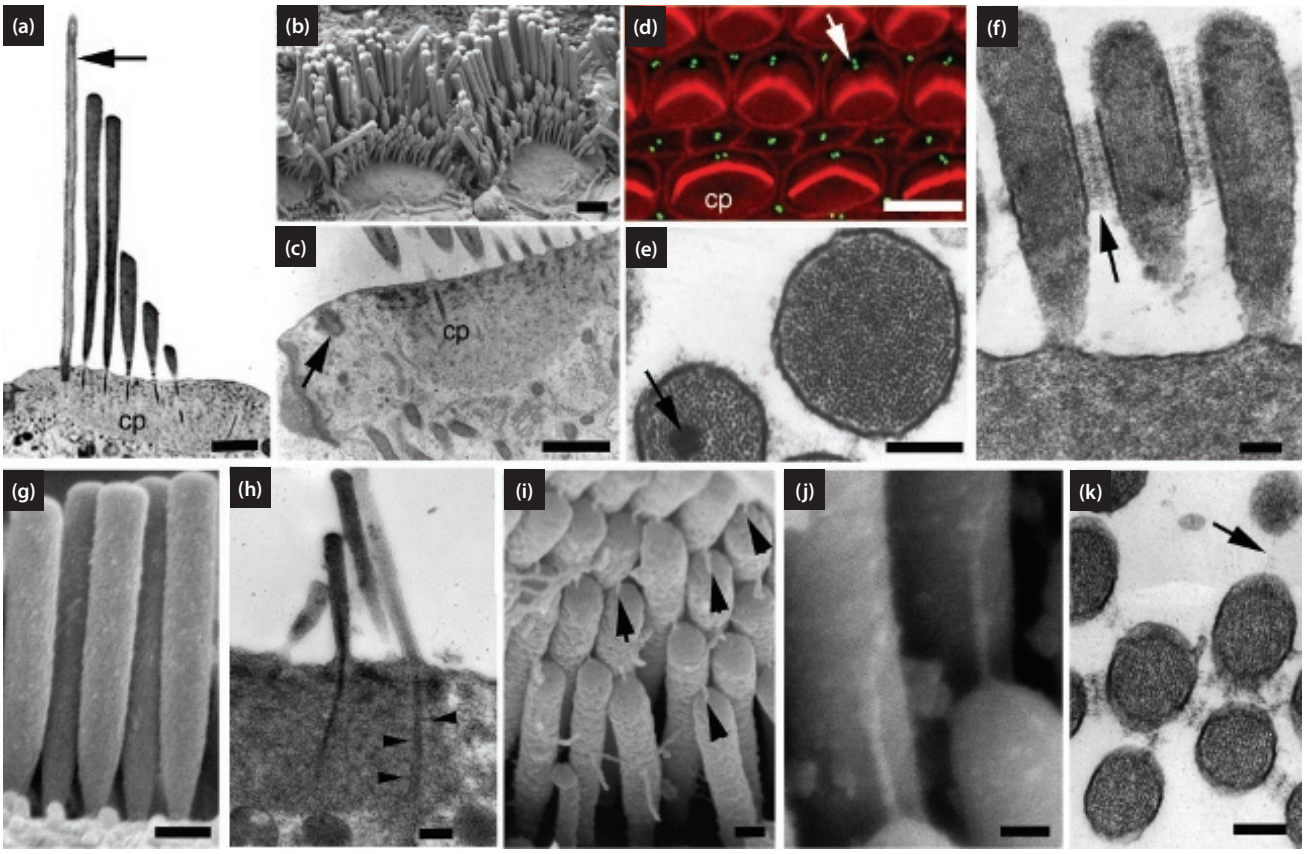

Figure 47.5 The hair bundle. **(a)** Hair bundle from utricular macula (TEM) shows stereotypical features. Filaments in rootlet are more densely packed (arrow). Scale bar: 100 nm. **(f)** Parallel closely packed filaments of actin in stereocilia. Lateral cross-links between the shafts of adjacent stereocilia in the same row appear to interdigitate at the midpoint of the space between them (arrow). Scale bar: 100 nm. **(g)** Individual stereocilia taper at their proximal end where they embed into the cuticular plate. Scale bar: 500 nm. **(h)** Stereociliary rootlets are cross-linked (arrowheads) before they descend into the filamentous meshwork that constitutes the cuticular plate. Scale bar: 250 nm. **(i)** Tip links (some arrowed) from the top of a short stereocilium to the shaft of the adjacent longer one in the direction of line of polarity in saccular macula of newt. Scale bar: 100 nm. (Figure courtesy of Dr Ruth Taylor, UCL Ear Institute.) **(j)** Higher-power view of tip links between stereocilia on outer hair cells showing branching at their ends. Scale bar: 50 nm. **(k)** Lateral cross-links between neighbouring stereocilia in the same row and adjacent rows. Arrow indicates apparent tip link. Scale bar: 100 nm.

vestibular system from elderly people and may be related to age-related hearing loss and balance dysfunction.[22, 23] It has been suggested that myosin 6 may be involved in holding the apical plasma membrane of the hair cell onto the cuticular plate in the regions between the stereociliary bases so that individual stereocilia can be maintained and, when it is defective, that membrane region becomes detached. In mice where myosin 15 is mutated (shaker-2) stereocilia are greatly reduced in height.[24, 25] Myosin 15 is thought to form a complex with other proteins including whirlin and Esp8 that regulates the height of stereocilia.[26–29] Mutations in the myosin 7a gene are responsible for Usher syndrome type 1B.[30] The mutant mouse strain carrying this mutation (shaker-1) shows hair bundles in which groups of stereocilia are separated from each other at the hair cell apex and the kinocilium is misplaced, suggesting an effect on maintenance of orientation and inter-stereociliary stabilization.[25] Myosin 7a may have a role in the various cross-links that are present between stereocilia (see below).

The stereocilia in an individual hair bundle are connected by a variety of fibrillar extracellular cross-links (**Figure 47.5**).[31] The most critical of these is the 'tip link' which runs from the top of one stereocilium to the shaft of an adjacent longer one along the line of morphological polarity and thus generating the line of functional

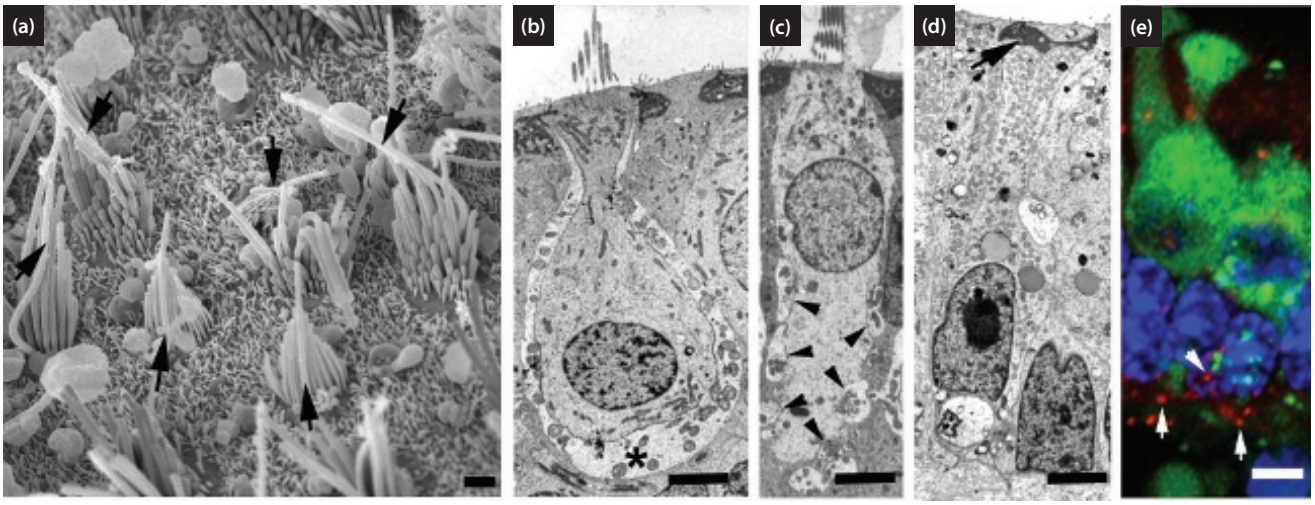

Figure 47.6 Hair cells and supporting cells in vestibular sensory epithelia. **(a)** Hair bundles across the line of polarity reversal in the striolar region of utricular macula. Kinocilia (arrowed) behind row of longest stereocilia. The polarity of the bundles changes by 180° (indicated by the direction of arrows) in the striolar region. Scale bar: 1 µm. **(b)** Type 1 hair cell. The flask-shaped cell body is entirely enclosed within the calyx terminal of a single afferent nerve (asterisk). Scale bar: 2 µm. **(c)** Type 2 hair cell. polarity (**Figure 47.5i,j**).[32, 33] The tip link is thought to be the gating element that controls the opening of the MET channel.[34–37] As the bundle moves in the excitatory direction, tension on the tip link opens the channel; when the bundle moves in the opposite direction, tension is relieved and the channel closes. The tip link is composed of two coiled filamentous proteins that are adherent end-to-end: cadherin 23 (cdh23) and protocadherin 15 (pcdh15).[38–40] Unsurprisingly, mutations in the genes that encode for either of these proteins cause both hearing impairment and vestibular disorders: mutations in the cdh23 gene result in Usher syndrome type 1D in humans and are responsible for the 'waltzer' mouse strain; mutations in the gene encoding pcdh15 are associated with Usher syndrome type 1F and the 'Ames waltzer' mouse (the names of the mouse strains indicate the movement abnormalities resulting from defects in the vestibular system). At its upper end, around the point of its insertion into the membrane of the shaft of the longer stereocilium, the tip link is associated with a complex of proteins that may regulate tip-link tension thereby controlling transduction channel opening, as well as 'adaptation', the closure of the channel that occurs with sustained excitatory deflection of the stereocilia, of particular relevance in vestibular hair cells. Proteins involved in maintaining tip-link tension include myosin 7a, Sans and harmonin,[41] and again defects in these are associated with hearing impairment and vestibular dysfunction: Usher type 1B in humans and the shaker 1 mouse strain in the case of myosin 7a; Usher type 1C from defects in harmonin; and Usher type 1G from mutations in *Sans*.[38] In addition, myosin 1c localizes to the region near the upper insertion point of the tip link and is thought to be involved in adaptation.[42]

In addition to the tip link, there are 'lateral links' that connect the shaft of one stereocilium to all its neighbours. There are thought to be at least three different types of lateral link between stereocilia.[31] Ankle links, which are present in the hair cells of mammalian vestibular organs and the auditory and vestibular hair cells of non-mammalian vertebrates but not in those of the organ of Corti, connect stereocilia at their proximal ends. Shaft connectors are present along the mid-region of the stereociliary shaft (**Figure 47.5f,k**). Top-connectors link stereocilia just below the level of the tip links. The different types of lateral link were initially identified through the use/generation of antibodies that specifically label each subpopulation separately.[31] This indicates significant differences in protein composition between the links. Mice with defects in the genes for these different stereociliary cross-linking proteins also have hearing impairment and balance dysfunction. Lateral links may have a role in holding the bundle together, thereby stabilizing it and aiding the mechanical coupling of deflections of the stereocilia, such that the stereocilia in a hair bundle all move as a single unit. In agreement with this, mice with mutations in genes that encode lateral link proteins exhibit splaying of the stereocilia and thus loss of efficient MET, indicating the critical role for lateral cross-links in maintaining hair bundle cohesion.[31]

The basolateral plasma membrane

The basolateral membrane of a hair cell is characterized by the presence of a variety of ion channels essential for shaping the response of the cells to mechanical excitation.[43] Outwardly rectifying K^+ channels open when the hair cell is depolarized by the MET current that is generated

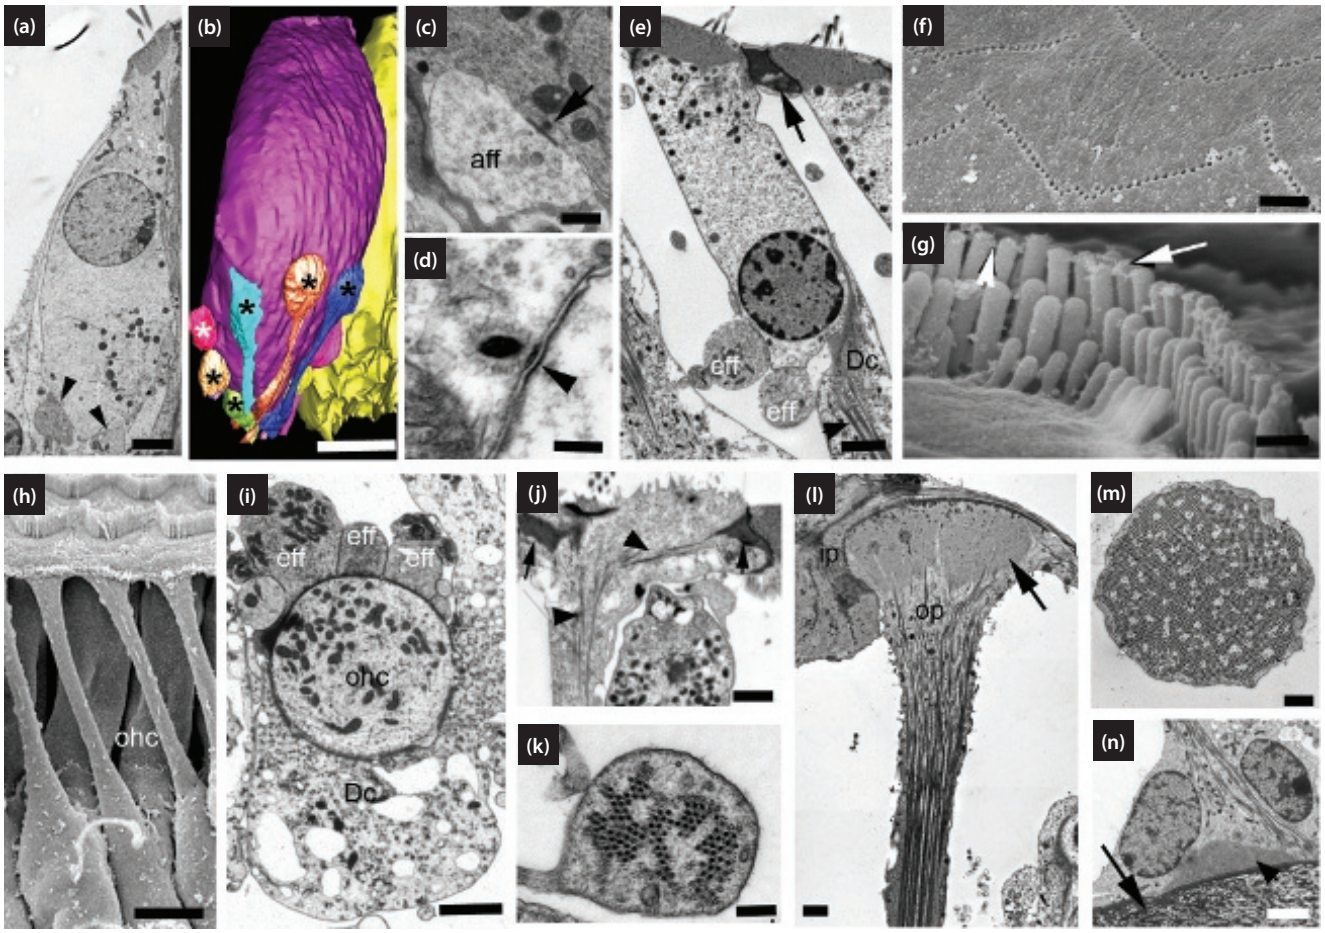

Figure 47.7 Ultrastructure of hair cells and supporting cells in the organ of Corti. **(a)** Inner hair cell. Flask-shaped cell closely surrounded by supporting cells. Terminals of afferent synapse at the base of the cell (arrowheads). Scale bar: 2 µm. **(b)** 3D reconstruction from serial sections of an inner hair cell and its innervation. (Figure courtesy of Dr Anwen Bullen, UCL Ear Institute.) **(c)** Afferent nerve terminal and synapse. A TEM section through the postsynaptic terminal and the presynaptic ribbon in the inner hair cell side (arrowed). The circular ribbon opposes the postsynaptic density of the membrane of the afferent nerve terminal (aff). Scale bar: 1 µm. **(d)** Ribbon synapse. Higher power view showing the ribbon surrounded by neurotransmitter vesicles. Arrowhead indicates postsynaptic density of the membrane of the afferent terminal. Scale bar: 100 nm. **(e)** Outer hair cell. Efferent nerve terminals (eff) around the basal pole of the outer hair cell. The lateral surfaces of the outer hair cell bodies are surrounded by extracellular space (the space of Nuel). There is contact with a Deiters' cell (Dc) around the basal pole and with the head of a Deiters' cell at the apical surface (arrow). The head of the Deiters' cell contains a wide, deep cytoskeletal assembly at the level of the intercellular junctions and the hair cells' cuticular plates. Arrowhead indicates a microtubule bundle in the body of a Deiters' cell below the outer hair cell. Scale bar: 2 µm. **(f)** Underside of tectorial membrane showing indentations of the insertions of the tips of the longest stereocilia of each outer hair cell stereociliary bundle. Scale bar: 1 µm. **(g)** Outer hair cell stereociliary bundle. The tips of the longest stereocilia are crowned with fibrillary material (arrows) that attaches each stereocilium into its indentation in the underside of the tectorial membrane, probably composed of stereocilin. Scale bar: 0.5 µm. **(h)** Deiters' cell: consists of a main cell body region that at its upper end encloses the base of an outer hair cell (ohc); a phalangeal process that ascends at an angle to the apical surface; and an expanded head region at the apical end that contacts an outer hair cell, two cells away along the row from that which the cell body encloses. Scale bar: 5 µm. **(i)** Horizontal/oblique section through the Deiters' cell (Dc) body where it encloses the base of outer hair cell (ohc) in a cup-like fashion, open on the side towards the modiolus. Efferent nerve terminals (eff) contact the basal pole of the outer hair cell at the opening. Scale bar: 2 µm. **(j)** Deiters' cell head. Wide, deep cytoskeletal assemblies (arrow) attached at intercellular junctions with outer hair cells. Microtubule bundle (arrowheads) run across the head parallel to the apical surface and down phalangeal process. Scale bar: 2 µm. **(k)** Deiters' cell phalangeal process in horizontal cross section. The process encloses bundles of microtubules. Scale bar: 200 nm. **(l)** Outer pillar cell (op). The phalangeal process is filled with parallel microtubules. The expanded apical head region forms a buttress beneath the widening head of the inner pillar cell. The junction between the outer and inner pillar cells is supported by a dense, wide cytoskeletal assembly in the outer pillar cell (arrow) into which the microtubule bundles terminate. Scale bar: 2 µm. **(m)** Outer pillar cell phalangeal process in horizontal cross section. The process is filled with many closely packed microtubules in seemingly regular arrays. Scale bar: 1 µm. **(n)** Inner pillar cell, base. The cell body rests on a thin bony lip (arrow) extending out from the modiolus. Microtubules bundles descend from the phalangeal process to the very base of the cell and are associated with a dense triangular-shaped cytoskeletal assembly (arrowhead) that anchors the cell to the underlying bone. Scale bar: 2 µm. *(Continued)*

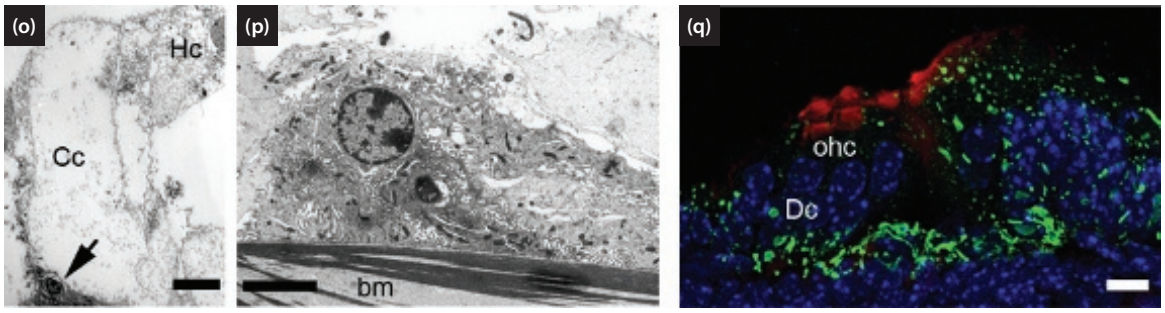

Figure 47.7 (Continued) Ultrastructure of hair cells and supporting cells in the organ of Corti. **(o)** Hensen's (Hc) and Claudius (Cc) cells. Hensen's cell covers the outermost extracellular space of the organ of Corti and does not reach the basilar membrane. Claudius cells are unusually devoid of organelles. They cover the Boettcher cells (arrow). Scale bar: 10 µm. **(p)** Boettcher cells sit on the basilar membrane (bm). They have a dense cytoplasm and numerous interdigitating infoldings. Scale bar: 5 µm. **(q)** The organ of Corti contains many gap junction complexes. Immunohistochemical labelling for connexin 26 (green) reveals gap junction plaques. F-actin is labelled using fluorescent phalloidin (red) and cell nuclei using DAPI (blue). There are numerous large gap junctions between adjacent supporting cells across the entire organ of Corti. Scale bar: 10 µm.

by hair bundle deflection. The resulting outward flow of K^+ through these channels repolarizes the hair cell membrane. The same depolarization also leads to the opening of voltage-gated Ca^{2+} channels and thus an influx of Ca^{2+} that triggers the fusion of intracellular vesicles with the plasma membrane and release of neurotransmitter at the synapses on to the primary afferent nerve endings. In this way, stereociliary deflection opens MET channels, causing depolarization in the hair cells, release of neurotransmitter onto afferent nerve fibres and thus activation of action potentials in neurons, i.e. neural discharge. In addition, hair cells in some rodent species also possess inwardly rectifying K^+ channels that are opened by cell hyperpolarization to restore hair cell resting potentials. Ion channels with these general properties can have different physiological characteristics in terms of their voltage dependence, the speed with which they respond (fast or delayed) and the size of the current that flows through them.[44] Although the general features of a hair cell are well conserved across many species, different types of hair cell are recognized depending on their location (auditory or vestibular), innervation pattern (afferent or efferent) and species of origin. The different types and numbers of ion channels expressed are characteristic features of particular types of hair cell.[44] In addition to the expression of different ion channels, hair cells in the organ of Corti show other specializations of their basolateral plasma membrane that are associated with particular unique functions that these cells perform (see 'Outer Hair Cells' below).

GENERAL CHARACTERISTICS OF SUPPORTING CELLS

The supporting cells provide mechanical support to the epithelium and thus to the hair cells. Their cell bodies contact each other and rest on the basement membrane that underlies the sensory epithelium (Figures 47.3d and 47.4b,c). Rod-like **phalangeal processes** extend from the cell body, interdigitating between the hair cells, to the luminal surface where they expand to fill the spaces between hair cells (Figures 47.3d,e,f and 47.4d,e,f). Supporting cells possess a fairly extensive cytoskeletal system that is particularly well developed in the cells of the organ of Corti. These phalanges contain bundles of microtubules, which can act like scaffolding poles/suspension struts to provide structural support (described in more detail later). At the apical, luminal poles, there are cytoskeletal assemblies that contain actin arranged in filamentous bundles running parallel to the luminal surface of the cell, anchoring to an adherens-like region within the intercellular junction that joins it to the adjacent hair cell (Figure 47.3e). Actin bands that run circumferentially around the neck or cortex of an epithelial cell are present in all epithelial cells and are thought to provide structural support at the points of adhesion between adjacent cells. These cortical actin bands are unusually wide in sensory epithelia of the inner ear (Figure 47.3e), indicating the importance of rigidity at the apical surface of these tissues.[45]

Supporting cells are functionally coupled to each other by substantial numbers of large **gap junctions** (Figures 47.6e and 47.7o).[22, 46–48] Gap junctions are sites of direct cytoplasmic communication between adjacent cells where clusters of pore-forming channel proteins in the membrane of one cell are in direct register with clusters of pore-forming channel proteins in the membrane of its neighbour. When these clusters of proteins dock together, they can form continuous aqueous pores that connect the cytoplasm of the adjacent cells. The protein subunits that form gap junction channels are members of the **connexin** protein family. At least 20 different types, or isoforms, of connexin have been identified. Six connexins form a **hemi-channel** or **connexon**, and the connexons of two adjacent cells align symmetrically to form the communication pathway between the cells. Gap junction channels are clustered in the plane of the membrane to form 'plaques' that can contain up to several thousand connexons. The channels allow the passage of small metabolites (up to 1.2 kDa in size), ions and second messengers, coupling the cells both electrically and chemically. Numerous gap junctions are present at points of contact between adjacent supporting cell bodies and between the head regions of adjacent cells, but there are

no gap junctions associated with hair cells.[22, 47] The large size and number of gap junction plaques between all supporting cells mean that the supporting cell population can be regarded as a functional syncytium, from which hair cells are functionally isolated.[22, 47] In all vertebrate classes from fish to mammals, gap junction plaques in inner ear sensory tissues are typically enormous, among the largest in the whole body, covering several square micrometres (μm^2) in area and containing several thousand channels.[46] One suspected role for supporting cells is thought to be the removal of excess K^+ ions from the intercellular spaces of the sensory epithelium during hair cell repolarization events.[48] Such a mechanism could thereby maintain the low K^+ environment around the body of the hair cell necessary for transduction and sensitivity to stimulation. It has been proposed that the gap junctions provide a means to ferry the K^+ away, preventing local accumulation. Gap junctions in the organ of Corti and in mammalian vestibular sensory epithelia contain two connexin isoforms, Cx26 and Cx30.[46, 48] Mutations in the genes for these connexins have been identified as causes of hereditary sensorineural hearing loss.[49] Those mutations in the gene encoding for Cx26 (*GJB2*) are the most common cause of non-syndromic hereditary deafness. There is increasing evidence that gap junctions with particular connexin composition, in particular Cx26, are important during development of the organ of Corti.[48] However, connexin mutations appear to have much less effect on the vestibular system.

THE VESTIBULAR SYSTEM

The vestibular system can be generally divided into two parts: the **saccule** is anatomically a separate chamber from the **utricle** and the three **semicircular canals** which arise from and terminate in the utricle and run in orthogonal planes – horizontal (lateral), posterior and superior (anterior) (**Figures 47.1a** and **47.2a**). Not only is there anatomical separation; the utricle and semicircular canals are evolutionarily and developmentally separate from the saccule. In the evolutionarily most primitive extant vertebrates (e.g. hag fish), the inner ear is composed of only two semicircular canals that are continuous with a single utricle-like chamber with a macula.[50, 51] During ontogenetic development, the utricle and semicircular canals arise on one side of the embryonic otic vesicle, opposite to that of the saccule which develops close to the site at which the cochlea is defined.[52] There is thus an anatomical and developmental relationship between the saccule and the cochlea, and in fish and some amphibia, the saccule does have an auditory function.[53, 54] This biological relationship may be an underlying factor in the sound-induced vertigo and dizziness characteristic of Tullio syndrome.

Sensory epithelia

The maculae of the utricle and saccule are flat sheets of epithelium that are oriented at right angles to each other (**Figure 47.2a**), the utricle in the anterior–posterior plane, the saccule in the superior–inferior. The utricular macula is approximately U-shaped and the saccular macula, in mammals, is almost S-shaped (**Figure 47.3a,b**). The **cristae ampullares** of the semicircular canals are saddle-shaped epithelial mounds (**Figure 47.3c**) contained within swellings, the ampullae, which open to the utricle at one end. The cell bodies of the nerves that innervate the sensory cells of the vestibular system are collected together in **Scarpa's** or vestibular **ganglion**, which is just external to the medial wall of the inner ear (**Figure 47.2a**).

OTOCONIAL MEMBRANES AND CUPULA

The utricular and saccular maculae are each overlaid by an 'otoconial membrane' which consists of a large number of otoconia (Greek: 'ear dust') (**Figure 47.3g**), crystalline particles composed of calcium carbonate surrounding a proteinaceous core that sit on a honeycomb-like perforated sheet of non-collagenous fibrillar extracellular matrix (**Figure 47.3h,i**). This matrix is composed of proteins unique to the inner ear including otogelin, α- and β-tectorins and ceacam 16 (carcinoembryonic antigen-related cell adhesion molecule 16).[55, 56] In fish, rather than numerous small particles, there is a single, large calcium carbonate particle, the otolith (Greek: 'ear stone'), hence the term 'otolithic organs' is sometimes used (incorrectly) to describe the saccule and utricle of mammals. Hair bundles of the utricular and saccular hair cells appear to align with the perforations in the sheet of extracellular matrix with the longest stereocilia, possibly in contact with the edge of the hole (**Figure 47.3i**). The utricular and saccular maculae detect translational motion of the head in the horizontal and vertical planes. With a linear motion, because of its mass, movement of the otoconial membrane lags in relation to the movement of the epithelium itself, which follows the head movement without any inertia. As a result, the stereocilia are deflected and hair cells stimulated. With a head tilt, the force of gravity acts on the otoconial membrane to produce a relative displacement between the membrane and the tilting surface of the epithelium that deflects the stereocilia. In the semicircular canals, the extracellular structure overlying a crista, known as the **cupula**, is a dense fibrous mass with no otoconia that extends to the roof of the ampulla (**Figure 47.3j**). The principal proteinaceous component is otogelin; neither tectorins nor collagen are are present in the cupula.[55] The longest stereocilia of hair cells of the cristae appear to contact the underside of the cupula. The cristae detect rotational acceleration of the head. When the head rotates, movement of endolymph through the semicircular canals lags behind that of the crista epithelium because of the fluid's inertia. The consequent differential movement displaces the cupula, leading to deflection of the stereocilia.

HAIR BUNDLES AND THEIR ORIENTATIONS

Hair bundles of vestibular hair cells have a stereotypical morphology consisting of stereocilia arranged asymmetrically in a staircase pattern of increasing height in one particular plane, that of activation or sensitivity, and a single kinocilium located behind the tallest stereocilia (**Figures 47.3f**, **47.5a** and **47.6a**). At least four different

arrangements of the stereocilia have been described for the hair bundles on macular hair cells.[57] Although these differences suggest divergent physical and biophysical properties of hair bundles, the functional significance has not been clarified.

In the cristae the orientation of the hair bundles, i.e. the alignment of the staircase pattern which defines morphological and functional polarity, is the same for all the hair cells in an individual crista. In the cristae of the horizontal and superior canals the shortest stereocilia of all hair cells are on the side of the bundle towards the utricle, while in the cristae of the posterior canal the bundles are oriented the opposite way, with the longest stereocilia (and kinocilium) on the side facing the utricle. Because of the uniform orientation of hair bundles across the cristae, a rotation in a particular direction will produce excitatory deflections of all stereociliary bundles of the cristae in one ear and inhibitory deflections of the hair bundles of the cristae in the same semicircular canal in the opposite ear, the integration of signals thereby providing information on the direction of rotation.

In the saccule and utricle there are opposing orientations of the hair bundles across the maculae: all the hair bundles located on one side of a region running across the epithelial sheet are oriented the same way with respect to the periphery, and at 180° to those on the other side of that region (**Figure 47.6a**). In the utricular macula, the shortest stereocilia face the centre (the bundles are oriented 'front-to-front' across the line of polarity reversal) so that excitation of the hair cells occurs with deflections of the stereocilia towards the periphery of the macula, whereas hair bundle orientations in the saccular macula are the reverse of those in the utricle: the longest stereocilia, and excitatory hair bundle deflection, are towards the centre. The line of hair bundle polarity reversal in a macula is located in the middle of the 'striola', a delineated strip, approximately 50–100 µm wide within the body of the macula and shaped to follow its contour.[58] The opposing orientations of the hair bundles, coupled with the asymmetric shape of the maculae and orientation of the saccular and utricular maculae in orthogonal planes, means that as head position changes differing patterns of hair cell excitation are elicited, providing fine-grained information on translational motion.

HAIR CELL TYPES

The basic cellular composition of all vestibular sensory epithelia is essentially the same (**Figure 47.3d**). There are two types of hair cell and these are both surrounded by non-sensory supporting cells. Type 1 hair cells are flask-shaped with a single large afferent nerve ending, a calyx, enclosing the entire basolateral surface of the cell (**Figures 47.3b** and **47.6b**). The endings of efferent nerves (i.e. those that carry signals from the brain to the sensory epithelium) contact the afferent calyx but not the hair cell itself. Type 2 hair cells are cylindrical with several small bouton-like afferent endings that form synapses towards the basal end of the cell (**Figure 47.6c**). In type 2 hair cells the efferent endings contact the hair cell directly. The nuclei of type 2 hair cells are generally located higher (closer to the luminal surface) in the cell than those of type 1s (**Figures 47.3d** and **47.6b,c**) and since the nuclei of the surrounding supporting cells are located beneath the hair cells, cross sections of vestibular sensory epithelia can appear to have three layers of cells (**Figure 47.3d**). There are other morphological features that distinguish the two hair cell types: for example, the stereocilia of type 1 cells are thicker (i.e. they contain more actin filaments) than those of type 2 hair cells. The physiological properties of the two hair cell types, as defined by ion channel expression in the basolateral membrane, are also different.[59] The calcyeal nerve terminals around type 1 hair cells express high levels of a calcium-binding protein, calretinin, which is not expressed in the afferent endings that synapse with type 2 hair cells.[58, 60] Accordingly, immunolabelling for calretinin provides a means for distinguishing and exploring the number and distribution of type 1 hair cells.[61] Use of this and other assays of hair cell morphology combined with dye tracing of the nerves,[62] has shown that the two hair cell types are differentially distributed across the organs. Type 1 cells predominate across the striolar region of the maculae and at the crest of the cristae. Type 2 hair cells are mainly confined to the extrastriolar regions of the maculae and the skirts of the cristae.[58, 60, 62] It is worth noting that the hair cells with a type 1-like innervation pattern are not present in fish or amphibians, rather they appear in vertebrates with necks which initially evolved as terrestrial animals. Thus, type 1 hair cells are likely to be providing information such as detecting rapid and/or smaller incremental head movements that are independent of whole body movements, and necessary for life on land.

PATTERNS OF INNERVATION

The patterns of afferent innervation of the different types of hair cells, often revealed following injection of a tracer dye into a single neurone,[62] are quite complex. An individual afferent neuron usually branches to innervate more than one hair cell. The neurons that innervate hair cells in the striolar region of the maculae and the crest of the crista form calcyeal nerve endings with only a single type 1 hair cell. In the peripheral regions of those organs a few individual afferent nerves form only bouton endings with several type 2s, but the majority of the afferent nerves are 'dimorphic', innervating both type 1 (≥1) and type 2 (typically >1) hair cells.[58, 60, 62] As a result, individual 'dimorphic' afferent fibres carry signals to the brain that result from the integration of convergent inputs from a number of different hair cells. Neurons innervating the striolar regions of the macula and the crest of the cristae do not cross into the extrastriolar regions of maculae or the skirts of the cristae, nor do they cross from one side of the striolar to the other so that the innervations in different regions of the sensory epithelia are anatomically separate. Moreover, there is some evidence from rats that, while afferent neurons from one side of the utricle project to the vestibular nuclei in the brain, those from the opposite side project to the cerebellum.[63] This indicates that there is significant integration and processing of information derived from vestibular sensory periphery that is carried up to higher centres in the brain.

SUPPORTING CELLS

The supporting cells of the vestibular sensory epithelia (Figure 47.6d,e) conform to the general pattern outlined above. They are relatively much less specialized than their counterparts in the organ of Corti and are little different from supporting cells in the sensory epithelia of the inner ear in all other vertebrates. Given that they form the reticular lamina (Figure 47.3e), they play critical roles in the barrier function of the epithelium and are also thought be important in phagocytosing and removing dead or dying hair cells.[64–66]

Ion-transporting epithelia of the vestibular system

The ion-transporting epithelium of the vestibular system is the region of 'dark' cells, so named because in histological sections the cells stain much more intensely (i.e. darker) than any others (Figure 47.8a). Dark cell epithelia are confined to the utricle and semicircular canals; there are no dark cells in the saccule (Figure 47.2a). In the utricle the dark cell epithelium forms a band all around the periphery of the macula separated from the sensory epithelium by transitional cells, a strip of relatively unspecialized cuboidal epithelial cells of as yet undefined function. A band of dark cell epithelium is also located all along the bottom of the skirts of each crista, again separated from the sensory region by a strip of transitional cells. The dark cell is a specialized cuboidal epithelial cell, in which the basolateral membrane is extensively infolded to create a large surface area. These infoldings house numerous large mitochondria likely to be critical for the function of these cells (Figure 47.8a).

Dark cells are crucial to maintaining the ionic concentration of endolymph. Lying underneath the dark cell epithelium is the mesenchyme of the connective tissue, the intercellular spaces of which are part of the perilymphatic compartment (Figure 47.8a). Unusually, there is no basement membrane or permeability barrier between the dark cell epithelium and the connective tissue, so the basolateral surfaces of the dark cells are exposed directly to perilymph. During the ongoing process of MET K^+ is shunted from the endolymphatic to the perilymphatic compartment. The basolateral membranes of the dark cells contain high levels of the Na^+/K^+-ATPase pump,[67] which use ATP to 'pump' two K^+ ions into and at the same time three Na^+ ions out of the cell against their respective ion concentration gradients. The presence of numerous large mitochondria within the basolateral infoldings is likely a specialization necessary for provision of the local energy supply required for this energetically expensive active ion transport. In addition, the dark cells' basolateral membranes contain an Na^+–K^+–Cl^- cotransporter NKCC1 (or SLC12A2).[68] This membrane protein uses energy derived from the Na^+ concentration gradient to cotransport the other two ions into the cell. Entry of Na^+ stimulates activity of Na^+/K^+-ATPase to return Na^+ equilibrium, thereby further enhancing K^+ uptake into the cell. The apical surfaces of the dark cells which face endolymph contain ion channels selective for K^+.[69] K^+ entering the dark cell at the basal side exits through the K^+ channels at the apex, into endolymph.

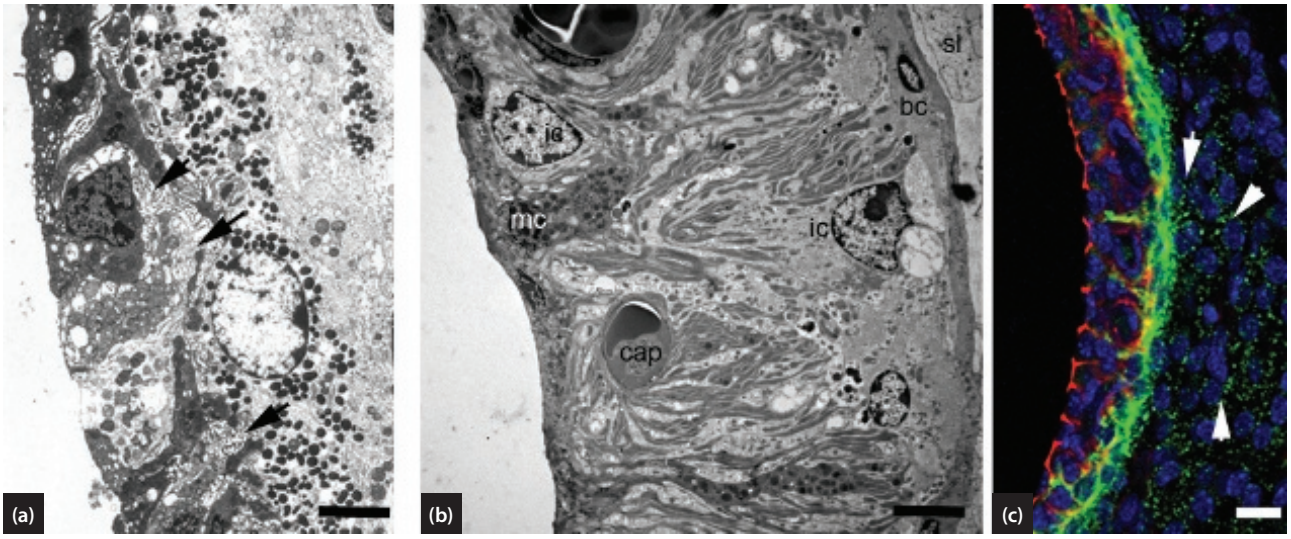

Figure 47.8 Ion-transporting epithelia. (a) Vestibular dark cell layer. The dark cells have numerous basal infoldings (arrows). A layer of pigmented cells containing melanin granules underlies the dark cells with mesenchyme beneath. Scale bar: 5 µm. **(b)** Stria vascularis. mc = marginal cells; ic = intermediate cells; bc = basal cells; cap = capillary; sl = spiral ligament underlying the stria vascularis. Marginal cells line the endolymphatic space and have numerous basal infloldings that extend down to the level of the basal cells. Intermediate cells, which contain melanin pigment granules, are entirely enclosed within the body of the stria. Elongated basal cells in one to two layers separate the stria from the underlying spiral ligament. Capillaries enclosed within the body of the stria are contacted by marginal cell processes and by intermediate cells. Scale bar: 5 µm. **(c)** Stria vascularis. Basal cell layer delineated by intense labelling for connexin 26 (green), indicating numerous gap junction plaques associated with basal cells. Gap junctions are between adjacent basal cells, between basal cells and intermediate cells and basal cells and fibrocytes in the spiral ligament. There are also numerous gap junctions between adjacent fibrocytes in the spiral ligament, indicated by green labelling for Cx26 in puncta (arrows) in tissue below the stria. Scale bar: 20 µm. (Figure courtesy of Dr John Kelly.)

In this way, K^+ ions are transported into endolymph and ion homeostasis in the vestibular system is maintained.

THE COCHLEA

Gross anatomy

The **cochlea** is formed of three parallel canals (or **scalae**, Latin: 'ladders'), coiled in a spiral around a central 'stalk', the **modiolus** (Figure 47.1c). The axons of the central projections of the auditory nerves that innervate the sensory epithelia, and the vessels of the cochlear blood supply, the cochlear artery and cochlear vein, run through the length of the modiolus. There are 2.5 turns in the human cochlea. The number of turns varies between different mammalian species but at present this is not known to have any specific functional significance. The central canal, the **scala media**, is lined by epithelia (part of the membranous labyrinth) and is filled with endolymph. In cross sections of the cochlea, the scala media is bounded by three 'walls' and appears approximately triangular in shape (Figures 47.1c and 47.2b). The sensory epithelium, the **organ of Corti,** running along the **basilar membrane**, forms the 'floor' of the triangle. The primary ion-transporting epithelium, the **stria vascularis**, runs along the lateral side and **Reissner's membrane** forms the 'roof' of the scala media (Figure 47.2b). Above Reissner's membrane is the **scala vestibuli**, and underneath the basilar membrane is the **scala tympani**. These two scalae are filled with perilymph. Reissner's membrane acts as the barrier between endolymph and perilymph in the scala vestibuli. Perilymph from both the scala vestibuli and scala tympani is freely permeable into the intercellular spaces of the spiral ligament that underlies the stria vascularis but, unlike the vestibular system, there is a barrier to direct diffusion of ions from the spiral ligament into the ion-transporting epithelium (see below).

The height and width of all the three scalae decrease systematically from base to apex of the spiral (Figure 47.1c). At the basal end, the scala tympani terminates at the **round window** (Figure 47.1a,b), a flexible membrane formed of two epithelial sheets sandwiching connective tissue, containing collagen and blood vessels.[70, 71] The apical surface of the outer epithelium is exposed to air in the middle ear; that of the inner epithelium is bathed in perilymph. The scala vestibuli at its basal end is continuous with the vestibule and the perilymphatic compartment of the vestibular system. The **oval window**, opening over the vestibule, is covered by a membrane and is filled with the footplate of the stapes. The gap between the border of the stapes footplate and the edge of the oval window is sealed with a ligament. At the apical end of the cochlea, the scala media is closed by epithelial tissue, arising partly by extension of Reissner's membrane, leaving a small opening, the helicotrema, through which the scala vestibuli and scala tympani are connected. Sound-induced movements of the tympanic membrane drive piston-like 'in–out' movements of the stapes footplate displacing incompressible perilymph along the scala vestibuli, through the **helicotrema** and down the scala tympani leading to 'out–in' movements of the round window. As fluid is displaced, the pressure difference across the scala media between the scala vestibuli and scala tympani, produces vibrational movement of the basilar membrane, described by Von Békésy. This 'travelling wave' stimulates the sensory cells housed in the organ of Corti that sits on the vibrating basilar membrane.

Organ of Corti

The mature organ of Corti is a ridge of cells resting on the basilar membrane and overlain by the tectorial membrane (Figure 47.4b,c). The length of the coiled basilar membrane and attendant organ of Corti varies with species; in humans it is about 35 mm long (range, 28–40 mm),[72] ~12 mm in mice, ~20 mm in guinea pigs and ~40 mm in whales. The widths of the basilar membrane and the organ of Corti increase systematically from the base to the apex of the cochlea. The thickness of the basilar membrane and the height (and mass) of the organ of Corti also both increase systematically from base to apex.[73] The consequent changes in the inherent mechanical properties of the basilar membrane, combined with changes in the mass on the membrane, result in sounds of different frequencies producing maximum vibrations at different locations along the cochlea; high frequencies are detected at the basal end and low frequencies at the apex. This frequency-place, or '**tonotopic**' relationship is preserved along the neural pathways in the brain: nerves that innervate the hair cells at the high-frequency, basal end of the cochlea project to a specific place in the cochlear nucleus, and those that innervate hair cells in the apical low-frequency region project to a different but specific place in the cochlear nucleus, i.e. there is a tonotopic map projected onto the cochlear nucleus and this tonotopicity is carried on up the auditory pathway.

There are two hair cell types in the organ of Corti, the **inner** and **outer hair cells** (IHCs and OHCs) (Figure 47.4b,d,e). In most mammals these are regularly arranged into a single row of IHCs on the medial or inner side of the spiral and three, sometimes four, rows of OHCs (Figure 47.4b,d,e) on the lateral or outer side. The human organ of Corti, however, appears less well ordered than the cochleae of lower mammals, with regions containing two ranks of IHC and areas where the rows of OHCs are less clearly definable, less evenly spaced and with occasional discontinuities (Figure 47.4f).[74] Within the body of the organ of Corti are large extracellular spaces (Figure 47.4b,c): the **spaces of Nuel** around the OHCs, and the **tunnel of Corti** between the OHC region. Both of these spaces are created during late stages of developmental maturation of the organ of Corti as a result of morphological specializations of the supporting cells, during which the phalangeal processes between the cell body region and expanded head at the apical (lumenal) end become reduced in width. The spaces are filled with perilymph as the basilar membrane is not a permeability barrier. The actual border and permeability barrier between the perilymph of the scala tympani and endolymph in the scala media is created by the intercellular junctions at the lumenal side of the organ of Corti and lies at the level of the reticular lamina. Mutations in the proteins that

comprise the tight (occluding) junctions in the organ of Corti, result in hearing impairment,[75–77] emphasizing the essential nature of the junctions and the barrier that they form.

BASILAR MEMBRANE

The basilar membrane (BM) is a sheet formed predominantly of extracellular matrix (**Figure 47.4b,c** and **47.7n**). It is composed of filaments within a ground substance, with a discontinuous layer of thin, elongated tympanic border cells on the underside facing the perilymph of the scala tympani.[17] The fibrils of the BM run predominantly radially, and are composed of collagen, mostly collagen type IV α1–α5 chains (COL4A1–COL4A5).[78] In addition, fibronectin[79] and laminin type 11,[80] adhesive-type molecules common to extracellular matrices, are localized to the BM and presumably compose the ground substance in which the collagen fibrils reside. The composition of the BM does not appear to be unique in comparison with basement membranes elsewhere in the body, except for a novel extracellular matrix protein (named 'usherin')[38, 81] that has been identified through the genetic mutation which is associated with Usher syndrome type 2A, in which there is high-frequency hearing loss. Mutations in the genes for the proteins composing the BM might be expected to affect the mechanics of the organ of Corti in response to sound and thereby cause hearing impairment. X-linked Alport syndrome has been attributed to mutations in the *COL4A5* gene. It has been suggested that it is the loss of this protein from the BM that results in the high frequency hearing loss associated with this condition.[82]

TECTORIAL MEMBRANE

The tectorial membrane (TM) is the structured sheet of extracellular matrix material that overlies the organ of Corti (**Figures 47.1b** and **47.4b,g**). At its inner edge it is attached to the interdental cells of the spiral limbus, a bony prominence to the inside of the organ of Corti (**Figure 47.1b**). It appears not to be attached to the surface of the organ of Corti at its outer edge. The longest stereocilia of each OHC are embedded in the underside of the TM (further described below). The TM is not merely a fibrous mass but it is quite highly structured, with a defined shape (**Figure 47.1b**). Its thickness decreases and its radial length increases systematically from base to apex. Over the top surface densely packed fibres are arranged in a network, the 'covernet' (**Figure 47.4g**), that is not unlike the perforated sheet of the otoconial membrane. The outermost tip is also distinguished by a higher density of fibre packing (**Figure 47.4b,g**). On the underside – facing the apical surface of the organ of Corti – there is a thickened ridge known as Hensen's stripe located just lateral to the position of the IHC stereocilia which is thought to contribute to the fluid-coupled deflection of the IHC stereocilia.

The body of the TM is formed of fibre bundles running approximately radially, embedded within a matrix composed of striated sheets formed of fine cross-linked fibrils.[83] The fibre bundles are formed of collagen types II, V and IX,[84, 85] different types to those found in the BM. Associated with the collagen bundles are the glycoproteins otogelin,[86] and α- and β-tectorin[87, 88] and ceacam 16.[89, 90] Otogelin, α- tectorin and β-tectorin are unique and essential to the inner ear, since mutations in the genes that encode for them are associated with non-syndromic hearing loss in humans.[86, 91, 92] Expression of mRNA for otogelin and the tectorins is detected only during development of the cochlea;[93, 94] they are not expressed in the organ of Corti of adults. The cessation of mRNA production indicates that there is no turnover of these key proteins, suggesting that the TM is a lifelong structure produced only during cochlear development. The implication is that damage to the TM (e.g. by disease or noise trauma) would not be repaired and would result in permanent hearing loss.

INNER HAIR CELLS

Rather than being positioned on the flexible BM, the IHCs reside above a thin and inflexible bony extension from the bone that surrounds the modiolus (**Figure 47.2b**). They are roughly flask-shaped (**Figure 47.7a**) and the shape of their hair bundles approximates to a straight line or a shallow 'U'-shape so they appear to form an almost continuous 'fence' along the medial or inner aspect of the organ of Corti (**Figure 47.3d,e**). Unlike the tips of OHC hair bundles, the IHC hair bundles do not appear to contact the TM directly. IHCs are innervated exclusively by **afferent nerve fibres** and 90–95% of all the afferent fibres from the cochlea to the brain arise from IHCs,[95, 96] making them the principal receptor cells that send auditory information to the brain. **Efferent nerve fibres** that terminate in the IHC region arise from the ipsilateral lateral superior olive in the mid-brain. Rather than contacting the IHCs, the efferent fibres contact the afferent fibres that terminate on the IHCs. These **lateral olivocochlear efferent nerve fibres** constitute approximately 20% of the efferent innervation to the organ of Corti.

Each IHC forms synapses with several (up to around 20) different afferent nerve endings that surround its basolateral membrane[97] (**Figure 47.7a,b**) but crucially a single auditory nerve fibre (ANF) innervates only a single IHC. The synapses between an IHC and its innervating afferent nerve endings are specialized **'ribbon' synapses** (**Figure 47.7c,d**). On the pre-synaptic, IHC side of the synapse adjacent to the membrane there is an elongate or rounded structure, the ribbon, surrounded by tethered **secretory vesicles** containing the **neurotransmitter** (glutamate), which release the glutamate into the synaptic gap or cleft when the hair cell is stimulated. The neurotransmitter binds to receptors on the post-synaptic membrane to initiate action potentials in the synapsing ANF. The 'ribbon' specialization provides for a constant pool of neurotransmitter at the site of neurotransmission to allow rapid and sustained release of glutamate and so rapid and sustained firing of the ANFs necessary for audition. Physiological recordings combined with dye tracing of individual ANFs have uncovered different response characteristics within the group of afferent fibres that innervate an individual IHC.[95, 98–101] At least two subpopulations have been identified: afferent fibres with low spontaneous firing rates

(i.e. the numbers of action potentials fired per second in quiet conditions) and high thresholds (i.e. requiring a relatively high sound intensity input to elicit a change in that firing rate); and fibres with high spontaneous rate and low thresholds. This diversity in the firing characteristics of the nerves innervating a single IHC provides a means to enhance the dynamic range of a single IHC that allows it to accurately encode a wide range of sound intensities. There is now increasing evidence that the subpopulations of afferent fibres that innervate an individual IHC are differentially sensitive to the effects of noise and ageing and the loss of a subpopulation of the afferent terminals under these conditions results in what has become known as 'hidden hearing loss'.[101, 102] In this situation, since the IHCs still have some neural connections, the auditory thresholds measured by standard audiological pure tone tests appear normal, but there are deficits in more subtle but critical aspects of audition, for example the ability to discriminate sounds (such as speech) in noise.

OUTER HAIR CELLS

OHCs are located across the most flexible part of the BM (**Figure 47.4b**). They are cylindrical cells with a basally positioned nucleus (**Figures 47.4b** and **47.7e**). Their hair bundles form a characteristic 'W'-shape (**Figure 47.4d,e**) and contact the underside of the overlying TM in which impressions of the longest OHC stereocilia can be seen (**Figure 47.7f**). A fibrous protein, stereocilin, appears to link the tips of the longest stereocilia to the insertion into the TM (**Figure 47.7g**).[103] Mutations in the gene for stereocilin are associated with hearing impairment.[104] Coupling between the longest stereocilia and the TM provides the mechanism by which OHCs are stimulated. The up-and-down movements of the travelling wave that is generated along the BM in response to the sound-induced fluid displacements along the scala vestibuli and scala tympani translate into radial (medial to lateral) movements at the apical surface of the organ of Corti. The TM mass remains static, so there is a relative shearing motion between the reticular lamina (the apical surface of the organ of Corti) and the TM. Since the longest stereocilia of OHCs are embedded in the underside of the TM, this differential movement results in the deflection of the hair bundle along the line of functional polarity resulting in opening and closing the MET channels. Deflection of OHC stereocilia generates a change in membrane potential in the cell, a receptor potential. In the case of the OHCs this generates a motile response (as described below).

OHCs increase in length systematically from the base of the cochlear spiral to the apex.[73, 105] In addition, the longest stereocilia on OHCs also increase in height systematically along the base-to-apex length of the cochlea, in humans increasing from around 2.5 µm in the basal coil to around 7.0 µm at the apex.[106] These systematic, or tonotopic, changes mean that the length of the cell body and height of the stereocilia for a particular OHC are precisely defined for its particular position on the BM. OHCs, in contrast to IHCs, are directly innervated at their basal ends, by several large bouton-like efferent endings (**Figure 47.7e**). About 80% of the efferent cochlear innervation terminates on OHCs.[95, 96] These **medial olivocochlear efferent nerves** that synapse with the OHCs arise primarily from the medial portion of the contralateral superior olive. Afferent nerve fibres that synapse with OHCs, which constitute only 5–10% of the total cochlear afferent innervation,[95, 96] branch considerably within the organ of Corti so that an individual neurone synapses with many OHCs in all three rows. The afferent innervation pattern suggests that OHCs may signal more global, large displacements of the BM, i.e. at high sound pressures, and recent research supports this.[107] The extensive efferent innervation, on the other hand, strongly indicates that OHCs have a modulatory role in the cochlea.

In experiments in which OHC function is disrupted or OHCs are destroyed, in the continued presence of functioning IHCs, there are hearing threshold shifts of 40–60 dB and a loss of fine-tuning of ANF responses (i.e. the sharpness of tuning, whereby an individual nerve fibre is especially sensitive to a specific or **characteristic frequency**).[108] Thus OHCs are critical for the exquisite frequency discrimination of which the cochlea is normally capable. These and other data have suggested the OHCs are the cellular basis of the 'cochlear amplifier'.[109, 110] A particularly unusual feature of OHCs is that they exhibit a unique form of motility. Isolated OHCs maintained in short-term culture undergo fast reversible axial length changes at up to auditory frequencies (at least 20 kHz) when stimulated electrically. It is thought that, *in vivo*, changes in OHC-membrane potential deriving from the normal MET mechanism drive the length changes.[43, 109, 110] Thus motion of the BM induces these motile responses, which are thought to feedback into the BM motion, thereby removing local damping and enhancing the movements. The end result of this cochlear amplification process is to fine-tune and amplify the signal before it reaches the IHCs, which as described do not sit on the flexible BM. Interestingly, as predicted by Thomas Gold in 1948[111, 112] and shown by David Kemp in 1978,[113] the excess energy released by this active process generates sound waves that are emitted from the ear as an **otoacoustic emission** (OAE).[114, 115] These OAEs can be recorded from probe microphones fitted in the external ear canal and they form the basis of the now routine audiological screening test for hearing impairment that can be performed in newborns or adults, and that provides an objective measure of the 'health' of the OHCs.[116–118] The fast motile responses of the OHCs, and the concomitant OAEs, are driven by a motor protein called **prestin,**[119] which is unique to OHCs and which is densely packed all down the lateral plasma membrane of the cell.[120, 121] Mutation or functional absence of the gene encoding prestin causes hearing impairment due to loss of cochlear amplification.[122]

The activity of OHCs upon stimulation is thought to generate a radial flow of endolymph across the surface of the organ of Corti which deflects IHC stereocilia and stimulates IHC responses. In essence, at lower sound pressure levels (below about 60 dB) OHC activity 'drives' IHC responses, but at higher sound pressure levels the larger movements of the organ of Corti produce fluid flow sufficient to deflect IHC stereocilia, and stimulation of the cell, directly.[109]

SUPPORTING CELLS

Several different morphologically recognizable types of supporting cell are present in the mature organ of Corti (Figure 47.3b,c). The **Deiters' cells** that intercalate between OHCs have cell bodies that contact with each other at their basal end and rest on the BM (Figures 47.4b,d,e and 47.7h). Each one forms a cup-shaped enclosure around the very base of an OHC and its nerve endings (Figure 47.7h, i). Deiters' cells extend a thin phalangeal process up through the space of Nuel (Figure 47.7h) so that the entire lateral membrane of each OHC is free from contact with another cell (Figures 47.4b and 47.7e). Contact between the OHC and its surrounding supporting cells is only at the apical junctional complex (Figure 47.7e,j) and at the basal cup around the base of hair cell (Figures 47.4b and 47.7e,h,i). The OHCs and IHCs are separated in the radial plane by the **outer and inner pillar cells** (Figure 47.4b) 'phalangeal cells' that are similar in general morphology to the Deiters' cells, the phalangeal processes of which form the **tunnel of Corti**, the outer pillar cell buttressing against the underside of the head of the inner pillar cell (Figures 47.4b and 47.7l).[123] Unlike OHCs, IHCs are closely surrounded by columnar supporting cells, the inner border cells to the medial side and the phalangeal cells to the lateral side, between the body of the IHC and the inner side of the inner pillar cell (Figures 47.4b,c and 47.7a). Lateral to the outermost (third) row of Deiters' cells are **Hensen's cells** (Figure 47.4b,c and 47.7o) which, in some species contain large lipid droplets that are thought, among other things, to provide additional mass. Additional epithelial cell types including the relatively unspecialized and uncharacterized **Claudius cells** that form the outer skirt of the organ of Corti ridge (Figure 47.4b,c and 47.7o), and lateral to these are the cuboidal epithelial cells of the outer sulcus that extend to the tissues on the lateral wall of the cochlea. In the basal cochlear coils, sitting on the basilar membrane and covered by the Claudius cells are a group of **Boettcher cells** (Figure 47.4c and 47.7p) that have a densely staining cytoplasm and multiple infoldings at their cell–cell interfaces. In most species these cells are absent from the apical coils. The function of these cells is still ill-defined but their morphology suggests some role in maintaining the physiological environment in the cochlea. There is also a suggestion they have a role in the maintenance of the BM.[124]

The Deiters' and pillar cells are thought to provide mechanical support to the organ of Corti that is essential for normal sound-evoked movements of the BM that lead to stimulation of the hair cells. They contain large numbers of microtubules in parallel arrays running from the base to apex of the cell (Figure 47.7k–n).[85, 123, 125] These arrays are some of the largest microtubule bundles in the entire body.[123] The microtubules are packed closely in regular arrays, filling almost the entire phalangeal process (Figure 47.7l,m); they would act like scaffolding poles or suspension struts to provide rigidity. The inner pillar cell lies on the thin bony lip, which extends from the bone covering the modiolus providing a rigid support (Figures 47.4b and 47.7n). The stiffness of the inner pillar cell, anchored on the rigid support provided by the bone and extending to the apical surface, will minimize movement of the reticular lamina on the medial, IHC side of the tunnel of Corti in response to sound-induced basilar motion thereby optimizing sensitivity to deflection of the IHC stereocilia by the fluid motion. In contrast, the rigidity of the outer pillar, anchored to the flexible region of the BM (Figure 47.4b), together with the rigid phalangeal processes of the Deiters' cells, could enable it to act as a stiff rod maximizing transfer of BM motion to movement of the reticular lamina; translation of that movement into the relative shear motion with the TM results in deflection of OHC stereocilia. In this way, pillar cells are crucial elements in the biomechanics that result in detection of sound. Any loss of supporting cell rigidity would, therefore, upset the mechanics by which stereociliary deflection is normally achieved, resulting in loss of hearing acuity. The microtubules of these supporting cells are composed of a form of tubulin that is resistant to depolymerization, which would indicate that the microtubules are long-lived structures,[125] but it has been suggested that changes in the tubulin isoforms may occur with ageing,[126] thereby impacting rigidity and function.

In addition, these cells are thought to play a crucial role in cochlear homeostasis. They take up K^+ from the extracellular spaces around the hair cells[127–129] and ferry it out of the sensory epithelium by an intracellular route through the intercellular coupling provided by the large gap junctions (Figure 47.7q).[48] Removal of K^+ from the spaces around the hair cell bodies is crucial, not only to prevent accumulation of K^+ that would disrupt ionic gradients and thus normal transduction, but also because high extracellular K^+ is toxic to the cells and OHCs are especially sensitive. Consistent with this model, mutations in the genes that encode the K^+-transporting proteins present in the membranes of the Deiters' cells, KCC4 and Kir4.1 (KCNJ10), cause hearing impairment and death of hair cells.[127, 130]

INNERVATION

The afferent ANFs that innervate the inner and outer hair cells arise from two distinct neuronal populations.[95, 96] The majority (90–95%) are myelinated **type 1 neurons** that innervate IHCs. The remaining 5–10% are unmyelinated, thin **type 2 neurons** that innervate OHCs. The cell bodies of both these types of neurons are collected together in the **spiral ganglion** (hence the designation 'spiral ganglion neurones' that is sometimes used) which is enclosed in Rosenthal's canal and located within the bony lip of the modiolar wall just medial and below the organ of Corti itself (Figure 47.2b). The central axonal projections of these bipolar neurons collect together in the modiolus (Figure 47.1c), the number of axons and the width of the nerve (and the modiolus itself) systematically increasing from apex down to the base of the cochlea as the centrally projecting axons from the cell bodies of neurones at successive locations are incorporated. The large bundle of neurons exits the inner ear via the internal auditory meatus as the VIIIth cranial nerve. The peripheral neurites from the cell bodies access the sensory epithelium through a series of holes, the **habenula perforata**, through the thin bone that separates the organ of Corti

from the ganglion and over which the IHCs are located (Figure 47.2b). The type 1 neurons lose their myelination as they reach the habenula, and so are unmyelinated in the organ of Corti as they project directly to the base of the IHCs. The peripheral neurites of the type 2 cells, after crossing through the habenula, turn to run between the bodies of the inner pillar across the floor of the tunnel of Corti, then between the bodies of the outer pillar cells into the region of OHCs. Here they branch, each one sending projections between the Deiters cell bodies to an average of nine (though sometimes many more) OHCs, their terminals mostly synapsing at the very base of the cell.

The innervating efferent neurons have their cell bodies in the mid-brain regions from which they project. The peripheral axons of these neurons also enter the organ of Corti through the habenula perforata. Those projecting from the contralateral medial superior olive in the brain that innervate the OHCs contribute about 80% of the total efferent innervation of the organ of Corti.[95, 96] They pass between the phalangeal processes of adjacent inner pillar cells, cross the tunnel of Corti at a level about the middle of its height, and then pass between phalangeal processes of the outer pillar cells into the OHC region where each individual nerve branches, sending projections to OHCs in each of the three rows. Axons of the efferent nerves arising from the ipsilateral medial superior olive, after passing through the habenula perforata, project directly to the region of the IHCs, branch and form terminals that synapse with the terminals of the type 1 afferent neurons beneath the IHCs.

Ion-transporting epithelia

The **stria vascularis** (SV) is a strip of tissue 150–300 µm wide (depending on location and species) lining the lateral wall of the scala media and running along its entire length (Figures 47.1a and 47.2b). It is responsible for the production and maintenance of both the high endolymphatic K^+ concentration and the EP.[1] The SV encloses a complex capillary network and is composed of three cell types (Figure 47.8b):

- **marginal cells** that line the endolymphatic compartment
- **intermediate cells** in a discontinuous layer enclosed entirely within the body of the epithelium
- **basal cells** that separate the SV from the underlying spiral ligament.

The SV is reputed to have the highest rate of oxidative metabolism (i.e. where oxygen is used to generate energy from carbohydrates) in the entire body, most likely due to the huge energy demand resulting from the mass of active ion transport that takes place in this tissue. The EP provides a source of energy or 'battery' to drive the cochlear amplifier.[131] As would be expected, any loss of EP therefore results in significant hearing impairment.

MARGINAL CELLS

The marginal cells of the SV are primarily involved with the transport of K^+ and are essentially the same as the dark cells of the vestibular system. Their basolateral membranes are extensively infolded, enclosing numerous large mitochondria and they contain high levels of Na^+/K^+-ATPase, both α- and β-isoforms[67, 132] and the $Na^+/K^+/Cl^-$-cotransporter NKCC1 (SLC12A2).[68] NKCC1 is the therapeutic target of action for loop diuretics in the kidney and loop diuretics have rapid, acute ototoxic side effects through an action on the cotransporter in the strial marginal cells[133, 134] inhibiting ion transport, which results in accumulation of ions in the extracellular spaces of the stria and a consequent oedema. The apical membranes of the marginal cells (like the dark cells) contain a K^+ channel which is formed of two subunits, the KCNE1 regulatory protein and the KCNQ1 channel proteins[130, 135] that provide the pathway through which K^+ is secreted into endolymph.[69] Mutations in the *KCNE1* gene disrupt endolymph production, leading to collapse of Reissner's membrane and deafness. In the vestibular system they cause collapse of the epithelia of the roof of the utricle, saccule and ampullae and shaker/waltzer-type behaviours in mice, indicating dysfunction of the vestibular sensory organs.[130, 135] During development, high levels of K^+ are found in cochlear endolymph, and strial marginal cells show high Na^+/K^+ ATPase activity, before an EP can be recorded.[136, 137] These, and other physiological data,[1] indicate that strial marginal cells, like dark cells, are primarily concerned with active transport to maintain the endolymphatic K^+ concentration, but the generation of EP is a separate phenomenon. The absence of any other cell type from the ion-transporting tissue of the vestibular system suggests that the strial intermediate and basal cells play a role in EP generation. During cochlear development the onset and rise in EP coincide with the incorporation of intermediate cells and blood vessels into the body of the stria and the formation of the limiting basal cell layer.[138]

INTERMEDIATE CELLS

The intermediate cells are a type of melanocyte – melanin pigment-containing cells – that arise during development from cells that migrate from the neural crest. They are entirely enclosed within the corpus of the stria, interdigitating with the other two cell types (Figure 47.8b). They contain a variety of enzymes that enable energy production from alternative substrates such as lipids as well as enzymes that detoxify oxidative wastes.[139] In addition, melanin can act as a free radical scavenger. These cellular properties suggest that one role for intermediate cells is to protect the stria under conditions of stress and perhaps also to provide alternative energy sources to maintain activity during periods of reduced blood supply. A population of intermediate cells also sends thin processes to contact the capillaries and express a number of proteins that are found in macrophages, further indicating the role of these cells in protecting the stria from damage. These cells have been termed perivascular macrophage-type melanocytes.[140]

The crucial role of intermediate cells, however, is in the generation and maintenance of EP. In the *viable dominant spotting* mouse mutant, there is a neural crest defect resulting in a highly reduced number or absence of intermediate

cells and no EP is generated,[141] but other than the absence of intermediate cells, the stria appears normal and the marginal cells possess ATPase activity.[132] In wild-type mice, measurement of EP from electrodes inserted into the lateral wall of the cochlea, which pass first through the spiral ligament and then into SV, has shown that under normal conditions a high positive potential is present within the body of SV, i.e. before the electrode actually penetrates into the endolymphatic space, locating the site of EP generation at the intercellular spaces of SV.[142] The intermediate cells are characterized by very high levels of the K^+ transporter protein Kir4.1 in their plasma membranes facing the intercellular spaces and the basolateral infoldings of the marginal cells.[143] Thus EP is considered to be generated by rapid and extensive passage of K^+ via Kir4.1 across the intermediate cell membrane into the intercellular space, followed by immediate uptake of K^+ by marginal cells such that a high positive potential is generated in that space. The basal cell layer provides an insulating seal that prevents dissipation of the potential into the perilymph in the intercellular spaces of the spiral ligament.

BASAL CELLS

The basal cells are flattened and elongated, forming between one and three layers delimiting the basal aspect of SV (**Figure 47.8b**). They arise during development from the mesenchymal cells that also form the spiral ligament. Basal cells closely appose each other and there is extensive sealing of the intercellular spaces between them by tight junctions.[137, 144] This creates an impermeable barrier between the perilymph in the underlying spiral ligament and the body of SV. During development, the initial formation of these tight junctions and the increase in their complexity coincides with onset of EP,[137] suggesting that these junctions are necessary to provide the electrical insulation required for the potential difference to be generated and maintained within the body of SV. Mutations in the gene for the protein claudin 11, which is present in the basal cell tight junctions, cause the loss of EP and so hearing impairment.[145]

Large numbers of gap junctions are also associated with basal cells (**Figure 47.8c**).[46, 144] They are present between adjacent basal cells, between basal and intermediate cells and between basal cells and fibrocytes in the spiral ligament.[46, 144] Thus, basal cells appear to be the central element in a functionally coupled unit or **syncytium**, connected together by intercellular gap junctions, consisting of basal cells, intermediate cells and spiral ligament fibrocytes. Marginal cells are excluded from this syncytium; they do not form gap junctions either with each other or with either basal or intermediate cells[46, 144] and are thus separated, functionally, from each other and from the basal cell/intermediate cell/ligament fibrocyte syncytium.

The gap junction-mediated intercellular communication between basal cells and ligament fibrocytes can provide a pathway for access of ions into SV cells from the ligament that bypasses the tight junctional sealing.[48] Fibrocytes of the spiral ligament possess Na^+/K^+-ATPase activity[67] and thus probably function to take up K^+ from the perilymph in the intercellular spaces of the ligament. The gap junctions between fibrocytes would, therefore, provide an intracellular route for K^+ to those fibrocytes beneath the SV, which are coupled to strial basal cells and which in turn are coupled by gap junctions to the intermediate cells. This gap junctional system, therefore, provides a route for recycling K^+ from endolymph, through hair cells to perilymph in the spaces in the organ of Corti and into supporting cells; out to the intercellular spaces of the spiral ligament and into fibrocytes; then into strial basal cells; into intermediate cells out to the intrastrial spaces and back to endolymph via the marginal cells.[48] The intercellular communication provided by gap junctions may, therefore, be vitally important for the maintenance of EP. During development, the onset and subsequent rise in EP corresponds not only with the formation of the permeability barriers that isolate the SV from the surrounding tissues but also with the initial formation and subsequent increase in size and number of gap junctions associated with basal cells.[137] The gap junctions in the cochlear lateral wall – the SV and spiral ligament – in rodents are all composed of both Cx26 and Cx30,[46, 146] but only functional disruption of Cx30 is associated with loss of EP.[147]

CAPILLARIES

The functional isolation of the SV from the surrounding tissues created by the permeability barriers at the level of the basal cells means there is little or no access of oxygen and nutrients required for the active processes necessary for EP maintenance. These are supplied by the network of intrastrial capillaries that run predominantly longitudinally along the SV (i.e. in an apicobasal direction along the cochlea, so that they are cross-sectioned in sections cut parallel to the modiolus in **Figure 47.8b**) with short interconnecting branches running across the strial thickness. The capillaries are often closely surrounded by extended processes from marginal cells. While allowing passage of oxygen and essential nutrients, the walls of the capillaries form a 'blood labyrinth barrier'[140] that controls exchange between the intrastrial spaces and the blood supply. The capillaries are supplied from branches of the cochlear artery that run from the modiolus through the connective tissue over the roof of the scala vestibuli and further branch into the spiral ligament and SV where the network of capillaries forms. They drain through capillaries that run in the connective tissue beneath the scala tympani to the cochlear vein in the modiolus. The strial capillaries are unfenestrated and the junctions between the endothelial cells that surround the lumen are connected by tight (occluding) junctions that establish a tight seal between the vessel lumen and the intrastrial space.[140] This tight sealing of the capillary lumen from the body of the stria in addition to the tight junctions between marginal cells and the extensive tight junctional sealing between basal cells are crucial to the functional isolation of stria from the surrounding tissues that prevents dissipation of EP as it is generated.

The endothelial cells are surrounded by a basement membrane. Pericytes discontinuously cover the basement membrane extending long, thin processes along the capillary wall. Where these cells are present the basement

membrane thickens to cover them. It has been suggested that macrophage-like melanocytes (the intermediate cell subpopulation), pericytes, BM and endocytes act as a complex to monitor and regulate exchange between the intrastrial spaces and the vessel lumen and maintain the blood-labyrinth barrier.[140] There is increasing evidence that ageing, noise and some genetic mutations may cause disruption of the barrier, leading to dysfunction of the stria, loss of EP and hearing impairment, but further work in this area is needed.

Reissner's membrane

Reissner's membrane is a thin epithelial sheet formed of two cell layers (**Figure 47.2b**).[148–150] A continuous layer of epithelial cells lines the scala media side and, since their apical surfaces face endolymph, they have tight junctions sealing the spaces between adjacent cells. The basal side of the epithelium, in the scala vestibuli, is covered with mesenchymal cells that are bathed in perilymph. The primary role of Reissner's membrane, to maintain the electrical and chemical separation of endolymph and perilymph, is achieved at the level of the tight junctions between the epithelial cells. There is also some evidence that the epithelial cells may have a phagocytic function taking up and then breaking down cell debris released into the endolymphatic compartment. Reissner's membrane also appears to have some elasticity as it can accommodate by swelling outwards into the scala vestibuli quite large increases in endolymph volume – endolymphatic hydrops – such as occurs with ion imbalance that results in water influx into the scala media, before it ruptures (as in Ménière's syndrome).[151, 152] How this is achieved, and whether Reissner's membrane has additional roles, remains to be determined.

FUTURE RESEARCH

- Molecular characterization of the transduction channel and its accessory components.
- Proteostasis (turnover, breakdown and re-synthesis) of hair cell proteins in particular stereociliary components.
- Effects of ageing and stress on tissues, cells and accessory structures other than hair cells, e.g. supporting cells and their microtubule bundles, the tectorial membrane, cells of stria vascularis.
- Detailed structural analysis and determination of the functional and permeability properties of Reissner's membrane and its potential role in clearing debris when cochlear tissues are damaged.
- Understanding of the roles of various glial and glial-like cells in the cochlea.
- The structure and permeability properties of the round-window membrane in relation to delivery of therapeutics to the inner ear fluids.

KEY POINTS

- The cochlea and the vestibular system contain sensory epithelia and ion-transporting epithelia.
- The sensory epithelium of the cochlea is the organ of Corti, a strip of cells coiled in a spiral.
- There are five sensory epithelia in the vestibular system: the utricular macula, saccular macular and 3 cristae, one in each of the three semi-circular canals.
- Sensory epithelia consist of sensory cells – 'hair' cells – and supporting cells, each hair cell separated from its neighbour by intervening supporting cells.
- Hair cells derive their name from the organised bundle of hair-like projections from their apical surface.
- The hair bundle is formed of stereocilia organised in rows of increasing height across the apical surface of the hair cell defining both a morphological and functional polarity.
- In vestibular hair cells, a single true cilium – the kinocilium – is positioned behind the row of longest stereocilia.
- In mature cochlear hair cells there is no kinoclium; the kinoclium is present during cochlear hair cell-development but retracts as the hair cell matures to leave only the basal body.
- There are crosslinks of various types between stereocilia in an individual hair bundle.
- Lateral cross-links produce a cohesive unit of stereocilia in the hair bundle.
- Tip-links are found between the tip of a shorter stereocilium and the adjacent longer stereocilium in the line of functional polarity; these gate the transduction channel at the tip of the shorter stereocilium.
- Each sensory epithelium is overlaid by an acellular extracellular matrix, that provides direct input for the deflection of the stereocilia that stimulates the hair cell.
- There are two types of hair cell in the organ of Corti: inner hair cells and outer hair cells.
- Inner hair cells are the primary receptor cells innervated by 95% of the cochlear afferent nerves that take information to the brain.
- Outer hair cells respond actively to basilar membrane motion to amplify the micromechanics and thus the signal reaching the inner hair cell.
- The cochlea is 'tonotopically' organised; different frequencies are detected at systematically different places along the basilar membrane: high frequencies at the basal end and low frequencies at the apical end.
- There are systematic changes in the basilar membrane and organ of Corti dimensions in line with the systematic tonotopic variation.
- There are two types of hair cell in vestibular sensory epithelia: type 1 hair cells and type 2 hair cells.
- Type 1 hair cells are innervated by a single afferent 'calyceal' nerve ending that enclose the entire baso-lateral surface of the hair cell.
- Type 2 hair cells that are innervated by several afferent nerve bouton endings.
- The stria vascularis is the ion-transporting epithelium of the cochlea.

- The stria vascularis is formed of three cell types and is highly vascularized; it is physiologically and electrically isolated from the rest of the cochlea.
- The stria vascularis generates and maintains the high positive electrical potential of cochlear endolymph – the endocochlear potential – as well as the high potassium ion composition characteristic of endolymphatic fluid.
- The ion-transporting epithelium of the vestibular system is the dark-cell region at the base of each crista and around the utricular macula; there is no dark cell region in the saccule.
- The dark-cell region is a single layer of ion-transporting epithelial cells responsible for maintaining potassium levels in vestibular endolymph, but it is not electrically isolated from the rest of the inner ear tissue, and there is no equivalent of endocochlear potential in the vestibular system.

CHAPTER 48

PHYSIOLOGY OF HEARING

Soumit Dasgupta and Michael Maslin

SEARCH STRATEGY

The data may be updated by a PubMed search using the keywords for 'Fundamentals of sound': soundwaves, measuring sound, decibel scales and acoustic impedance. For 'Applied physiology of Hearing', use the following keywords: pinna, external auditory canal, ossicles, tympanic membrane, cochlea, outer hair cells, inner hair cells, auditory nerve and cochlear efferents.

INTRODUCTION

This chapter consists of two parts. The first (Fundamentals of Sound) will discuss properties of sound and important concepts related to hearing; the second part (Applied Physiology of Hearing) will discuss the applied physiology of the peripheral ear correlated to normal functioning of the ear from the hearing point of view and the aftermath of an affliction by a disease.

FUNDAMENTALS OF SOUND

Michael Maslin

A SOUND WAVE

For something to be a source of sound it must vibrate. Sound is vibratory energy that is transmitted from the source through surrounding media in the form of pressure waves. Sound waves cannot therefore travel through a vacuum; a physical medium is required to convey the vibratory energy. In the context of otolaryngology, the most relevant physical medium is air since most sounds reach the ear by the vibrations of air molecules. Vibratory energy that arrives at, and is detected by, the ear gives rise to hearing. Hence, some understanding of the physical properties of sound is required in order to understand the way in which sound is detected by the ear.

As a starting point one might consider a scenario whereby no force is applied to a region of air. In such a scenario, the air molecules are said to be at ambient (or atmospheric) pressure. When an object in the region vibrates, a force is applied to those air molecules that are in contact with the object, causing their displacement. For example, take the loudspeaker shown in Figure 48.1. As the diaphragm of the loudspeaker moves to the right of its centre position, the air molecules at the surface of the diaphragm are displaced to the right. This movement causes the air molecules to be pushed closer to adjacent air molecules that are further over to the right. Relative to the ambient pressure, a localized pressure increase is produced and this pressure increase is known as compression. Next, when the diaphragm of the loudspeaker moves back through its centre position and over to the left, those air molecules that were displaced to the right are now drawn to the left. When the displaced molecules reach their centre (equilibrium) position, the pressure will momentarily be equal to ambient pressure, but as the molecules move further to the left they are drawn increasingly further apart from their adjacent air molecules. The pressure will now drop below the ambient pressure and this decrease in pressure is called rarefaction. As each molecule vibrates

backwards and forwards around its equilibrium position, alternating regions of compression and rarefaction arise. If these pressure variations can be detected by the ear, they can be described as sound. (It is worth noting that the variations in density of the air molecules shown in Figure 48.1 have been exaggerated for the purposes of illustration. In reality, pressure fluctuations associated with sound are only a small fraction of the overall atmospheric pressure.) Since air is a continuous and elastic medium, the pressure variations will propagate away from the source such that sound generated by the source can be detected in regions of air that are remote. This is known as acoustic radiation.

The air molecules move about their equilibrium position, so there is no permanent displacement of the air. Rather, it is the vibratory pattern (i.e. mechanical disturbance) that is transmitted. Since the air molecules move in the same axis as the sound wave, it is known as a longitudinal wave.

There are two key properties of a sound wave:

- the frequency of the sound wave, which is linked to the perception of pitch
- the intensity of the sound wave, which is linked to the perception of loudness.

Frequency, velocity, period and wavelength of sound

As the air molecules vibrate about the equilibrium, their velocity is greatest as they pass through the equilibrium position and is momentarily zero when at the extreme displacement (where direction of movement reverses). The movement of air molecules from equilibrium to maximum displacement in one direction, back through equilibrium to the maximum displacement in the opposite direction, and back to equilibrium, is one complete cycle of vibration. Frequency (f) is the number of cycles per second (usually expressed in Hertz (Hz) (named in honour of the German physicist Heinrich Rudolf Hertz). The simplest type of sound wave is a sinusoidal (or sine) wave, where the cycles of vibration occur at a single frequency. A concept related to frequency is the period (T), the time required for a vibration to complete one cycle. The higher the frequency, the less time it takes a vibration to complete one cycle. Hence, frequency and period have an inverse relationship which can be expressed as follows:

$$T = 1/f \text{ or } f = 1/T$$

Please note that while the velocity of the displacement of the air molecules relates to the frequency of the sound, there is also the velocity of the sound wave to consider, as it progresses away from the source (i.e. the speed of sound, c). This is not an absolute value. Sound travels more quickly in warm air than in cooler air. Therefore as temperature drops with altitude or in colder climates the speed of sound becomes lower. The velocity of sound waves radiating from a source at sea level is about 344 metres per second (ms^{-1}). Furthermore, at least in air, the velocity is the same irrespective of the frequency of vibrations. The velocity of a sound wave and the frequency of that wave are related by wavelength (λ), which is the distance between corresponding points of displacement in successive cycles (see Figure 48.1). We therefore have four quantities that are related to one another: the frequency, the period, the velocity and the length of a sound wave. The relationship between these quantities is described in the following equations:

$$\text{Wavelength} = \text{velocity} \times \text{period}$$

$$\text{Velocity} = \text{frequency} \times \text{wavelength}$$

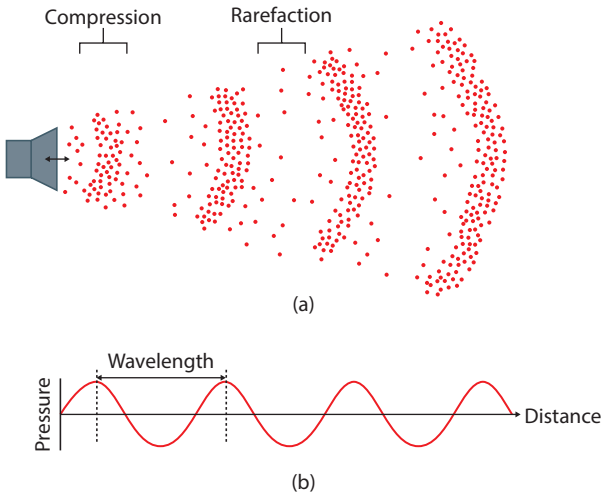

Figure 48.1 **(a)** A schematic of a sound wave propagating away from source via alternating regions of compression and rarefaction of (air) molecules. **(b)** The (air) pressure variations plotted as a function of distance. This example shows pressure varying at a single frequency, to produce a sinusoidal waveform. The distance between two consecutive points on the waveform is the wavelength.

Pressure, impedance, particle velocity and intensity of sound

As we have discussed, as a sound wave radiates from a source, the air pressure fluctuates in cycles of compression and rarefaction as air molecules are displaced about their equilibrium. Let us consider a 'plane progressive' sound wave, i.e. a sound wave with an advancing wavefront that is treated essentially as a flat surface, as it moves unperturbed through a sound field. (In reality a progressive wavefront is almost spherical as it expands from a point source, but at the point of measurement, which might be some distance away, the wavefront will appear flat. Furthermore, there are often objects in a sound field that produce reflections, all of which means that peak pressure and velocity do not necessarily coincide in reality.) The pressure variations about the ambient pressure that occur are directly proportional to the velocity of the particles as they vibrate. That is, the greater the peak particle velocity, the greater the peak pressure of the sound wave. Pressure and particle velocity are therefore said to be in

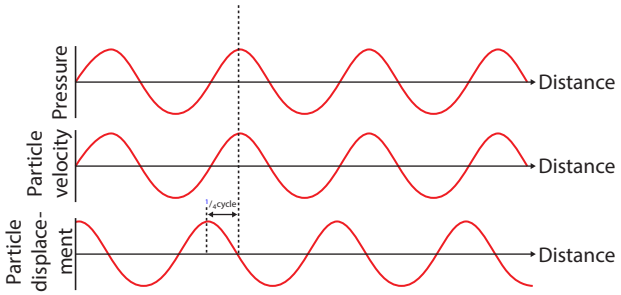

Figure 48.2 The relationship between pressure, velocity and particle displacement. **(a)** Pressure variations plotted as a function of distance. **(b)** Particle velocity plotted as a function of distance. Note that (air) pressure and (air molecule) particle velocity vary in phase with one another. **(c)** Particle displacement plotted as a function of distance, showing a 90° phase lag in relation to particle velocity and pressure variation.

phase, as illustrated by the upper and middle traces shown in Figure 48.2. However, while peak particle velocity and peak pressure are in phase, the displacement of the air molecules shows a one-quarter cycle, or 90-degree, phase lag, illustrated in the lower trace in Figure 48.2.

Phase relates to the temporal relationship between two (or more) oscillatory components that are present simultaneously. In this case, pressure, particle velocity and displacement. One cycle is defined as 360 degrees. If the two components vary together over the cycle, there is no timing difference between then, and they are said to be in phase. However, the second component can lead or lag the first according to its starting point relative to the first, i.e. there is a timing difference. The actual timing difference for a given phase lead or phase lag will depend on the frequencies of the two components, with higher frequencies producing shorter timing differences.

As air molecules become compressed, we also have to consider acoustic impedance, or more specifically characteristic impedance ($\rho_o c$) when referring to a plane progressive wave. The concept of impedance may be illustrated by drawing analogy to electrical circuits, where impedance behaves rather like the resistance to electricity in a circuit. It acts to dissipate energy and so if the sound wave is to radiate out from the source then it must overcome the acoustic impedance of the medium. Impedance depends on the stiffness and density of the medium (in this case air), and so the acoustic impedance at a particular frequency will contribute to defining how much sound pressure is generated by a sound wave. The greater the impedance of air molecules at a given displacement velocity, the lower the sound pressure level. Peak pressure can be related to peak velocity and characteristic impedance (which is independent of frequency), according to the equation:

$$\text{Peak pressure} = \text{characteristic impedance} \times \text{peak velocity}$$

Impedance varies greatly according to the media, especially between gases and liquids. Liquids, being much denser than gases, have a higher acoustic impedance. Therefore, they will convey sounds with much lower intensities for a given pressure variation than if that pressure variation were to occur in a gas.

To continue the analogy drawn with circuits of electrical current, where sound pressure is analogous to voltage (volts) and acoustic impedance is analogous to resistance (ohms), particle velocity is analogous to current (amps), but there is a further component still to consider: power.

The energy of sound and how this is transferred (dissipated) is referred to as the intensity of sound and, in electrical circuitry, this is analogous to power (measured in watts). The more energy that is supplied by the source, the greater the intensity of the sound. Since pressure variation is the means by which sound energy is transmitted, and pressure is force per unit area, then intensity is the power transmitted by the wave through a unit area (watt/metre^2). For a sinusoid, the relationship between intensity, pressure and particle velocity and impedance is expressed using these equations:

$$\text{Intensity} = \frac{\text{Peak pressure}^2}{2 \times \text{impedance}}$$

$$\text{Intensity} = \frac{\text{Peak velocity}^2 \times \text{impedance}}{2}$$

At this point the importance of root mean square (RMS) values becomes apparent. The equations that are shown above relate to the **peak** pressure and **peak** velocity, yet pressure and velocity are continually varying throughout the cycle of vibration hence the intensity of sound will vary throughout the cycle. A solution is therefore to consider the average intensity (kinetic energy) across a complete cycle of vibration. Simple averaging will not suffice, since the mean values will be zero (see Figure 48.3).

One solution is to consider the distance between the most positive peak and the most negative points in the cycle. Alternatively, the square root of the average squared value for pressure (known as RMS pressure and expressed in Pascals or Nm^{-2}) and velocity (known as RMS velocity or ms^{-1}) are perhaps the most common way to overcome this challenge. The equation can now be read as:

$$\text{Average intensity} = \frac{\text{RMS pressure}^2}{2 \times \text{impedance}}$$

$$\text{Average intensity} = \text{RMS velocity}^2 \times \text{impedance}$$

It is also important to note that sound waves spread in all directions, and as the wavefront moves away from the source it spreads over a larger area. Sound intensity

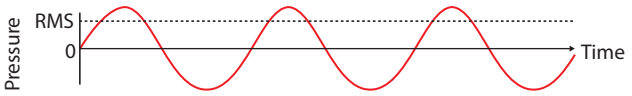

Figure 48.3 A sinusoidal wave. When measuring sound, the time-varying pressure variations would average to zero, which is not representative of the peak pressure. Root mean square (RMS) can be used instead, where RMS pressure = $\frac{1}{\sqrt{2}}$ = ≈ 0.7 of the peak pressure.

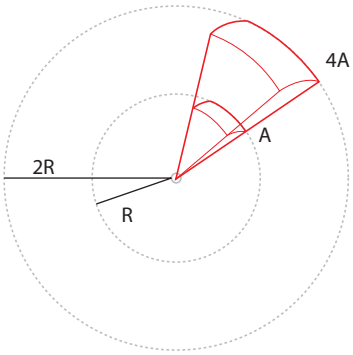

Figure 48.4 Schematic of a point source of sound. Sound waves would spread equally in all directions to produce a spherical wavefront. Due to the expanding area of the wavefront with distance from the source, the energy of the wavefront will progressively attenuate with distance. Sound is attenuated by distance from the source and the amount by which this occurs is given by the inverse square law; intensity falls as the inverse square of the distance. Other factors that influence attenuation with distance in real-world scenarios include, for example, reflections from, and interactions with, obstructions in the sound field, interactions with other sound waves, heat dissipation and net flow of air (wind).

decreases with distance from the source. The total area increases with the square of the distance, so intensity falls as the inverse square of the distance. This relationship is known as the inverse square law, as depicted in Figure 48.4 for a point source of sound in a free field, i.e. with no objects reflecting or blocking the path of the sound.

PERCEPTUAL CORRELATES OF FREQUENCY AND INTENSITY

The two key properties of a sine wave, frequency and intensity, each have a perceptual correlate. The subjective correlate of frequency is pitch and of intensity, loudness.

The bandwidth of human hearing (at least for a young person with normal hearing) is typically from around 0.02–20 kHz. Vibrations of around 20 times per second correspond to a low pitch whereas vibrations of 20 000 times per second correspond to a much higher pitch. Each time the frequency of a sine wave is doubled, the pitch increases by an octave, so human hearing spans around 10 octaves. A sound which has one frequency is known as a 'pure tone' although, in reality, typical sounds are made up from many frequencies and are therefore complex sounds.

As intensity increases above the threshold of hearing, a sound becomes louder. For a 1 kHz sine wave, a young and normal-hearing human listener can detect pressure fluctuations in the air from as little as 0.00002 Pa (the quietest sounds) and increases in pressure become progressively louder to the listener up to as much as 200 Pa (where the threshold of pain is approached). Hence the relationship between the softest audible pressure variation and the maximum tolerable one (known as the dynamic range) is around one million times.

It is important to note that perceived loudness is in fact dependent on both frequency and intensity. The ear is less sensitive to very low frequencies and very high frequencies, and maximally sensitive to frequencies around the 2–4 kHz range. Typically, pure-tone audiometry, as performed in the test battery for diagnosing hearing loss, covers the frequency range 0.25–8 kHz (five octaves) that is most clinically relevant since this corresponds to the frequency range where normal speech occurs. The intensity of pure tones used in pure-tone audiometry is normalized according to the different sensitivities of the ear as a function of frequency in order to plot a pure-tone audiogram. More on this will be described below.

THE INFLUENCE OF A SOUND'S DURATION

In addition to frequency and intensity, a third dimension of sound is its duration. The duration of a sound interacts with frequency and intensity to influence pitch and loudness sensations. For example, a sound must exceed a certain minimum duration before its pitch characteristics become apparent. Below this point, about 200 ms, and the sound will have a click-like sensation regardless of its duration. Similarly, loudness increases as a function of intensity over time, a phenomenon known as temporal integration. Below durations of about 200 ms the sound intensity will need to increase progressively in order to maintain the same sensation of loudness. Therefore, audibility reduces as sounds become briefer below 200 ms (although the perception of duration does not). Paradoxically, despite this reduction in audibility with sound duration, sounds with extremely short duration can become more audible again, at least when close to threshold. We can think of pure-tone sounds used in hearing tests as being comprised of three segments: an onset period when the intensity increases (also known as the rise time), an offset period where the intensity reduces again (also known as the fall time) and between these two extremes there may be a steady period where the sound intensity is maintained. Imagine the steady-state period getting shorter, so that the volume of the pure tone is reducing as the overall duration drops below 200 ms. Eventually, there would be no steady-state period, and so the intensity of the sound would ramp up and immediately down again. Now the only way to make the sound shorter is to reduce the duration of the onset and offset periods themselves. As the onset and offset periods get shorter, the frequency spectrum of the sound becomes progressively broader (the so-called 'spectral splatter'); sound duration and bandwidth are inversely proportional. It is these additional frequencies that may be heard, causing the paradoxical increase in audibility for very short duration signals. Clinically, this is especially relevant in audiological applications where short duration signals are required, such as auditory evoked potential testing. Here, the need for brief stimuli such as a transient click, producing a more synchronous discharge of neural energy (and greater signal strength), must be weighed against the need for frequency-specific analysis of hearing sensitivity (i.e. minimizing spectral splatter) in order to diagnose hearing loss accurately where hearing at some

frequencies is different from others. However, it is also relevant with regards to understanding the way in which normal everyday sounds such as speech, not just audiological test sounds, are heard.

MEASUREMENT OF SOUND

The three dimensions of sound that we have encountered so far (frequency, intensity and duration) can each be described according to principles that have parallels with the way in which sound is detected and processed by the ear (the mechanisms of which will be described in detail later in the chapter). The amplitude of a sound (either in terms of the intensity or resulting pressure fluctuations) can be described by the decibel scale, and the frequency composition of a sound can be shown by spectral analysis of the signal. The influence upon both of these quantities by the duration of the signal will also be described.

The decibel scale

As described, when the energy of a sound wave increases, the pressure fluctuations become greater. A common way to describe the average variation of these quantities is by referring to an increase in the amplitude of the sound.

Given the dynamic range of hearing described above, if sound was routinely described in Pascals (using the most common and practical way to measure sound by observing the electrical output of a pressure-sensitive device or transducer), calculations for the amplitude of sound would soon become cumbersome and unmanageable. To overcome this, a compressed scale which produces a more manageable range of values for describing amplitude is used: the decibel scale. The basic unit of measurement is the bel, named in honour of Alexander Graham Bell, inventor of the telephone. Even this is somewhat large for convenience and so the decibel (dB), one-tenth of a bel, is typically used. Compression of a large-scale dynamic range (either intensity or pressure) to the decibel scale is achieved by finding the logarithm (to the base 10). Importantly, the decibel is not an absolute unit of measurement. It is a ratio. This means that the bel is the logarithm of intensity of sound divided by some agreed reference intensity. Zero dB therefore simply indicates that the measured sound is the same as the reference; it doesn't mean silence. A negative dB value means that the measured sound is less than the reference, and a positive dB value means that the measured sound is greater than the reference. Multiplying the bel by 10 produces the decibel such that a sound's intensity in dB can be calculated using the following equation:

$$\mathrm{dB} = 10\,\mathrm{Log}_{10}\frac{\mathrm{Intensity}_{\mathrm{measured}}}{\mathrm{Intensity}_{\mathrm{reference}}}$$

Sound pressure as measured in Pascals can also be expressed in decibels. This is the logarithm to the base 10 of a measured pressure relative to some agreed reference pressure, multiplied by 20 (to reflect the fact that intensity is related to the square of the pressure). A value very close to the threshold of human hearing for a 1 kHz pure tone at sea level (0.00002 Pa) commonly serves as such a reference pressure, and in this case the scale is referred to as decibel sound pressure level (dB SPL) according to the following equation:

$$\mathrm{dB\,SPL} = 20\,\mathrm{Log}_{10}\frac{\mathrm{Pressure}_{\mathrm{measured}}}{\mathrm{Pressure}_{\mathrm{reference}}}$$

The dB SPL scale is convenient because 0 db SPL is close to the threshold of hearing. The threshold of pain, near the top of the dynamic range of hearing, is 140 dB SPL, i.e. when the pressure in Pascals is multiplied by 10, 20 dB is added to the dB level.

Note that, in addition to convenience of calculation, a second advantage of using a logarithmic scale is that the response of the ear is also logarithmic. This means that loudness is not spaced linearly across the dynamic range, so linear increments in the amplitude of sound do not produce even increments of loudness (e.g. 100 Pa is almost as loud as 200 Pa). However, logarithmic increments in amplitude do produce even increments of loudness; a 1 dB change in amplitude (approximately the minimum detectable change) gives almost the same relative change in loudness across the whole dynamic range.

An important consideration when discussing the relationship between the amplitude and loudness of sound is that the ear is not equally sensitive to sounds of different frequencies, as mentioned earlier. Further complications are that the difference in sensitivity to sounds across frequencies is more pronounced closer to threshold, and less at high SPLs well above threshold. Loudness is also strongly affected by the duration of sounds. That is, sounds of short duration (below approximately 200 ms) will sound less loud than a sound of longer duration with the same sound pressure level. (For further information on the interaction between acoustics and perception, please refer to Moore.[1]) Consequently, this means that, while 0 dB SPL is (close to) the threshold of hearing for a 1 kHz pure tone, the same is not the case for pure tones of other frequencies. Bear in mind also that 'threshold', the quietest sound one can hear, is variable and depends on the way it is defined, the method of measurement and psychological factors such as attention and motivation.

Figure 48.5 shows the threshold, in dB SPL, for a range of pure tones of different frequencies as measured under

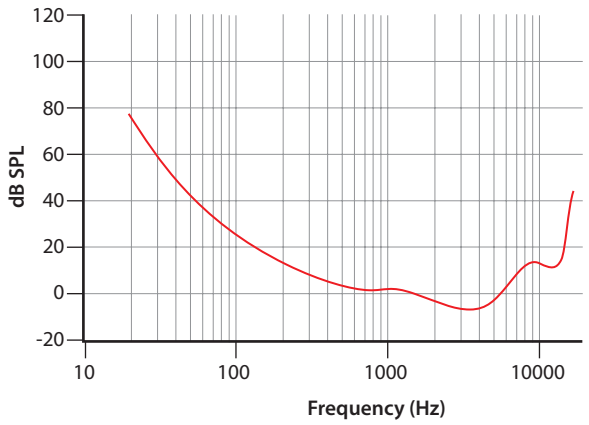

Figure 48.5 Reference threshold of hearing, in dB SPL, based on a group of ontological normal, young adults in binaural listening conditions (ISO 389-7[2]).

binaural free-field listening conditions (ISO 389-7).[2] Hearing sensitivity declines at very low and very high frequencies, and it is not the same even within the central frequencies that comprise the audiometric range. For clinical purposes these differences in hearing sensitivity according to sound frequency present some complications when describing the extent of hearing loss; the same degree of hearing loss across different frequencies produces a different threshold in dB SPL. For example, an individual whose hearing threshold was 40 dB worse than the average threshold at 1 kHz would have a hearing threshold slightly higher than 40 dB SPL. However, if the same individual had a 40 dB reduction in hearing sensitivity at 4 kHz, their hearing threshold would be around 35 dB SPL.

To bypass this complication, audiology uses different reference sound pressures. Perhaps the most important among these is for pure tones in which the reference is the threshold of hearing for normal listeners; this is the decibel hearing level (dB HL). The reference sound pressures for pure tones therefore change in a frequency-specific way to allow a convenient comparison of an individual's hearing thresholds compared to normal, i.e. the amount of hearing loss. The resulting audiogram (see **Figure 48.6**) shows normal hearing (0 dB HL) towards the top of the chart whereas increasing amounts of hearing loss are plotted downwards. For an interesting historical account of the why the audiogram is upside down, the reader is referred to Jerger.[3]

There are other decibel scales used in audiology such as Sensation Level (dB SL), which uses the individual's own threshold of hearing as the reference. For example, a 1 kHz sound presented at 50 dB HL to a patient with a threshold of 10 dB HL would be 40 dB SL. However, to a patient with a threshold of 20 dB HL the same sound would be 30 dB SL. Presentation at the same sensation level may therefore produce different intensities of sound according to alternative scales such as dB HL. Another scale that is in common use is decibel normal Hearing Level (dB nHL). In the strictest sense dB nHL denotes a reference for a sound that is either the mean or the median threshold of hearing for ontologically normal young adults, the same concept as dB HL for pure tones. However, in practice dB nHL usually refers to the level of short-duration sounds as used in auditory evoked potentials. Other important decibel scales in audiology are the peak Sound Pressure Level (pSPL) and peak-to-peak equivalent Sound Pressure Level (ppeSPL). Both of these scales have audiological applications in the measurement of short-duration sounds. Peak sound pressure level is the greatest sound pressure (be it condensation or rarefaction) over the duration of a signal. Peak-to-peak equivalent sound pressure level is the sound pressure level of a long-duration signal (such as a 1 kHz pure tone) that produces the same peak-to-peak sound pressure as a short-duration sound typically used in measuring auditory evoked potentials. The need for these alternative scales arises because, in a similar way in which there is a minimum duration of perception, the ability to measure sound acoustically with a microphone has a lower limit of duration. This limit arises because the measuring device (e.g. a sound level meter) is usually incapable of responding quickly enough to produce an accurate and stable reading of the sound pressure level.

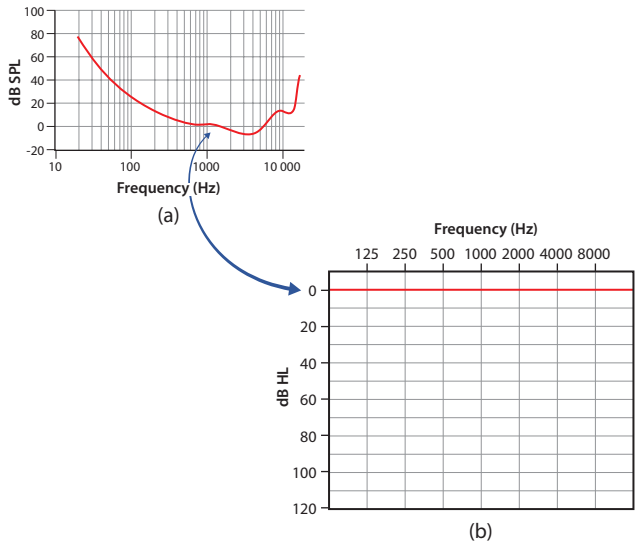

Figure 48.6 Schematic showing the relationship between dB SPL and dB HL. Note that the actual reference equivalent sound pressure levels (RETSPLs) used for audiometric zero in the calibration of audiometers and other diagnostic equipment are specific to transducer type in a specific coupler.

Spectral analysis of sound

So far we have considered sounds in the time domain, where the summed pressure variances as a function of time (or distance) are drawn. It is possible to represent sound in the frequency domain, where the spectral (or frequency) content of the sound is considered irrespective of the temporal relationship between different frequency components. As mentioned earlier, most everyday sounds are complex sounds so, by breaking down such a sound into its individual frequency components one might more easily describe the behaviour of a system in operation (such as the ear in sound detection) and infer the behaviour of that system to more complex sounds. Another reason for considering sounds in the frequency domain is that the ear itself acts as a spectral analyzer. As will be described in more detail later, a filtering action arises within the cochlea that allows sounds of different frequencies to be separated and then transduced into neural energy at different places within the cochlea, known as tonotopicity. Therefore, an understanding of the spectral content of a complex sound can give insight into the way in which that sound will produce activity within the auditory system.

The primary means of decomposition of a complex sound into its constituent frequency components is called Fourier analysis (for a continuous signal), or Fourier transform for any signal (devised by the French mathematician Fourier in the 1820s). A useful starting point is to consider a pure tone, since the spectral content of such a signal will consist of just a single frequency component, as illustrated in **Figure 48.7** for a 0.1 kHz pure tone. **Figure 48.7a** shows the temporal pattern of amplitude fluctuations for the signal (i.e. it is in the time domain); **Figure 48.7b** shows the spectral content of the signal (i.e. it is in the

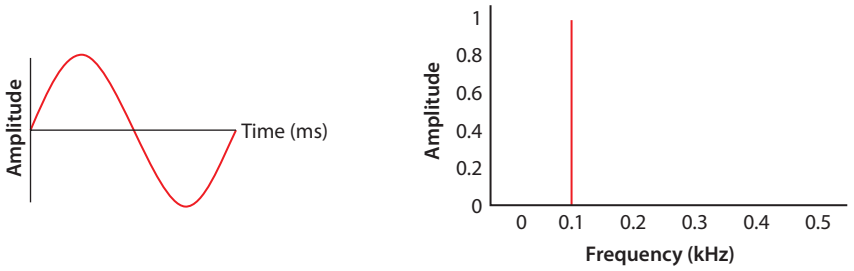

Figure 48.7 A 0.1 kHz sinusoid shown in the time domain (a) and in the frequency domain **(b)**.

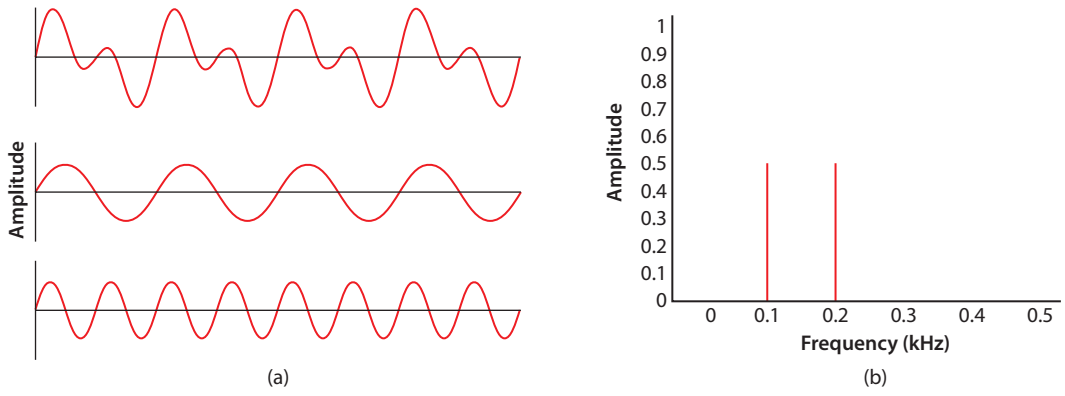

Figure 48.8 (a) The upper row depicts a complex tone in the time domain, comprising 0.1 kHz and 0.2 kHz sinusoids depicted in the middle and lower rows, respectively. The two components are in phase. **(b)** The components of the complex tone are displayed in the frequency domain where the frequencies and amplitudes of the two components are apparent.

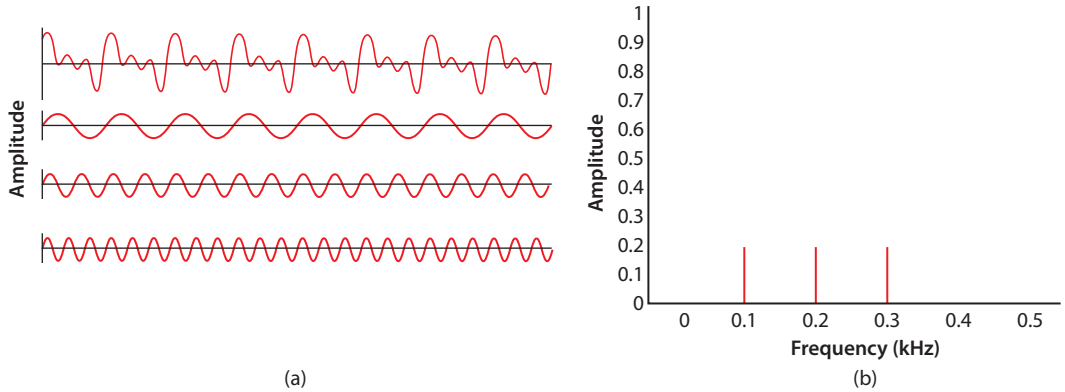

Figure 48.9 (a) The upper row depicts a complex tone in the time domain, comprising three components at 0.1 kHz, 0.2 kHz and 0.3 kHz (second, third and fourth rows, respectively). **(b)** The components of complex tone, displayed in the frequency domain.

frequency domain). Three-dimensional displays may be used to show both amplitude and timing of the different frequency components of a complex sound simultaneously.

A complex tone can be similarly decomposed to produce line spectra at the various different components. For example, the upper trace in Figure 48.8a illustrates a complex tone in the time domain, made up from two components, 0.1 kHz and 0.2 kHz, that are of the same amplitude and both starting from a zero degree phase angle. There are four cycles of the 0.1 kHz component (middle trace), and in the same period eight cycles of the 0.2 kHz component arise (lower trace). Figure 48.8b provides the line spectra corresponding to the complex tone formed by these two components.

In a further example shown in Figure 48.9, a complex sound comprising three pure tones is displayed in the left column (a) (upper trace) with constituent pure tones of 0.1 kHz, 0.2 kHz and 0.3 kHz all at zero degrees phase and of equal amplitude (second, third and fourth traces respectively). The corresponding line spectra are displayed in Figure 48.9b.

The above examples show the effect of adding sinusoids that are in phase. Since sinusoids are periodical sounds, their summation will produce a repeating pattern, the frequency of which (repetition frequency) is known as the fundamental frequency (F_0). In the above examples, 0.1 kHz is the highest common factor between each of the constituent components (i.e. the highest integer that

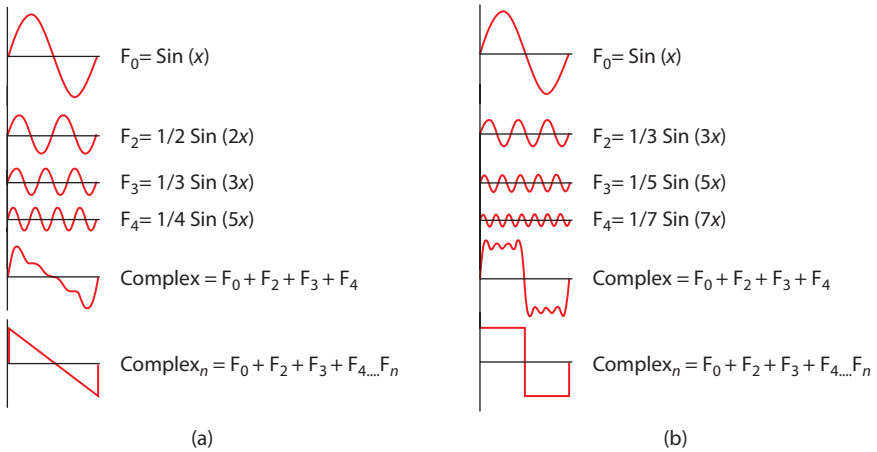

Figure 48.10 **(a)** The upper row shows a sinusoid, beneath which are odd- and even-numbered harmonics which, when added indefinitely, will form a sawtooth wave. **(b)** The same sinusoid with only odd-numbered harmonics added will form a square wave.

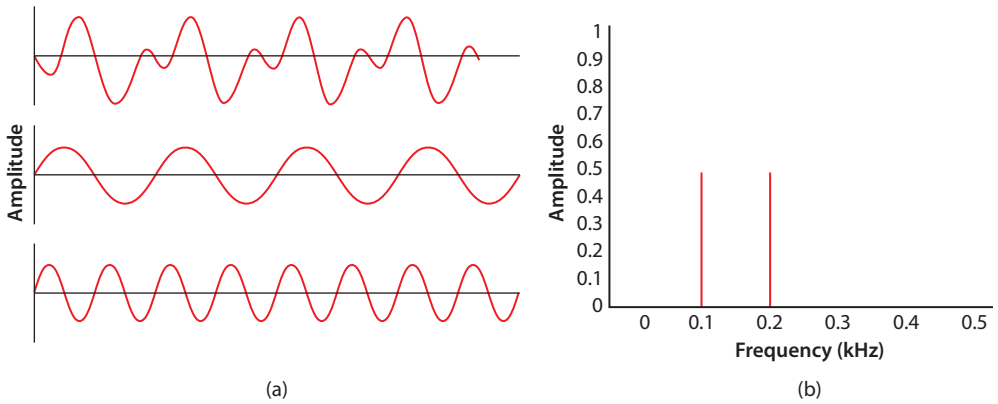

Figure 48.11 **(a)** The upper row depicts a complex tone in the time domain, comprising 0.1 kHz and 0.2 kHz sinusoids depicted in the middle and lower rows, respectively. The 0.2 kHz component has a 90° phase lead over the 0.1 kHz tone. **(b)** The two components are shown in the frequency domain, which does not display the timing relationship between components.

all components will divide into). The period (and therefore the repetition frequency) of the complex periodical sound is equal to the highest common factor. The higher-frequency components, which are exact integer multiples of the fundamental frequency, are known as harmonics.

Continuing the pattern illustrated in Figure 48.9 indefinitely would produce a 'sawtooth' pattern: sine waves with odd and even multiples of the fundamental. However, there are other combinations. For example, a square wave contains only the fundamental and an indefinite number of odd-numbered (or odd-order) harmonics. Sawtooth and square waves are shown in Figure 48.10 a and b respectively.

So far, all of the complex sounds have comprised components of different frequencies, but all with the same phase. Figure 48.11 shows the effect of complex sound that results from combining two pure tones as before, 0.1 kHz and 0.2 kHz of the same amplitude, but this time with a different phase. The 0.2 kHz component has a 90-degree phase lead over the 0.1 kHz component. The result is a different pattern of interaction, resulting in a different complex wave pattern (a) from that shown in Figure 48.8, although both examples have the same fundamental frequency. Note the line spectra (b) are unchanged because the temporal relationship between frequency components is not reflected in the frequency domain. The ear itself is relatively insensitive to phase. What the ear detects are the amplitude and frequency characteristics of the components that made up the complex signal. (The auditory system does respond to phase characteristics of sound, such as phase differences between sounds presented binaurally, and this is achieved by interaural comparisons within the central auditory system. For further information, see the review by Moore.[4])

For a complex sound to be periodic, the sinusoidal components must have a harmonic relationship; each component is an integer multiple of the fundamental. An aperiodic sound is the opposite of this as it does not repeat over time. It is therefore impossible to predict what such a waveform will look like from one moment to the next. While sounds that are (at least nearly) periodic are common in some forums, such as the sounds produced by pitched musical instruments, the majority of sounds in nature are aperiodic and therefore cannot convey pitch. Aperiodic sounds include wind noise, traffic noise and percussive instruments. Spoken speech contains both periodic and aperiodic sounds. The spoken vowel sounds are typically periodic, while consonant sounds are aperiodic.

Since there is no fundamental or harmonic structure, the spectra of aperiodic sounds cannot be a series

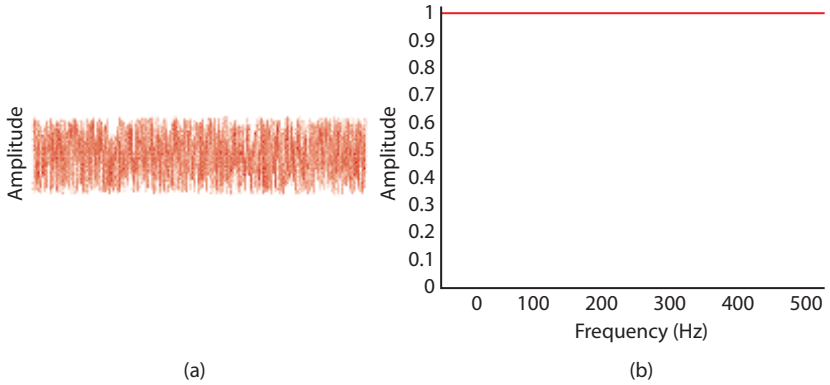

Figure 48.12 A sample of white noise, an aperiodic sound with equal energy at different frequencies, in (a) both the time domain and **(b)** the frequency domain. The relevant frequency range for white noise is 0.02–20 kHz, i.e. the range of human hearing.

of vertical lines. They are a continuous line, with differences in height corresponding to the differences in amplitude across the frequency range of the sound. Perhaps the simplest example is white noise, which is an aperiodic waveform with equal energy in every frequency band (1 Hz wide), as shown in Figure 48.12.

The name 'white noise' is analogous to white light, which has energy in all light wavelengths. Following this convention, different 'colours of noise' typically refer to noise whose energy levels across the spectrum reflect the colour of light with a similar spectrum, such as pink noise (where power density decreases with frequency) and blue noise (where power density increases with frequency).

TRANSMISSION OF SOUND BETWEEN DIFFERENT MEDIA

Earlier we briefly discussed the speed of sound through the medium of air, i.e. the rate at which sound propagates through the air. The speed of the propagation and the extent to which a sound may propagate at all are determined by physical properties of the medium such as the stiffness and density. Air is low density, and low stiffness. This means that vibratory energy from the source is passed from one molecule to the next relatively easily but relatively slowly. As the density of the medium increases, so does the speed of sound. For example, the speed of sound in water is around 1500 metres per second. The speed of sound is calculated using the following equation:

$$c = \sqrt{\frac{\text{Stiffness}\,(K)}{\text{Density}\,(\rho)}}$$

However, as density increases so does the stiffness of the medium. For example, air is far more elastic, and compressible, than fluid. This means that, when an object vibrates in air, the sound waves can propagate relatively 'easily', i.e. small pressures are required to produce a given velocity of movement of the air molecules. However, as the density of the medium and therefore the stiffness increase, such as with a fluid, then the same pressure will produce a smaller velocity of movement. This is the effect of acoustic impedance. The closer the impedances of two media (such as air and fluid), the more acoustical energy will be transmitted between them. The relationship between acoustic impedance (Z) of any substance, sound pressure and velocity of vibration is provided in the following equation:

$$z = \frac{\text{Sound pressure}\,(P)}{\text{Velocity of vibration}\,(\nu)}$$

The effect of different acoustic impedances of media such as air and fluid is relevant because, while sound typically reaches the ear via propagation through air, the physiologically vulnerable structures of the ear within the cochlear are filled with (and bathed in) fluid. Therefore, if the sound waves of a given pressure were to arrive directly at the cochlea from the remote source, the resulting velocity of vibration within the fluid-filled cochlea would fall due to the increased acoustic impedance; most of the energy would instead be reflected back into the air. That this does not happen is a result of the outer and middle ears, which act as an impedance matcher, so that a large proportion of acoustic energy is transmitted into the cochlea. The way in which this happens will be outlined below.

KEY POINTS

- Sound is variations in the pressure of the air (or other medium).
- Key dimensions of a sound wave are its frequency, intensity and duration.
- Each of these three dimensions of a sound can be detected and processed by the cochlea.
- The outer and middle ears match the acoustic impedance of the air in the external environment and the fluid of the cochlea, allowing efficient transmission of sound.

APPLIED PHYSIOLOGY OF HEARING

Soumit Dasgupta

This section looks at the applied physiology of how sounds or acoustic stimuli behave in the ear as well as what happens to the detection of these stimuli in diseases of the ear.

The peripheral ear consists of the pinna, the external auditory meatus and canal, the middle ear with the

tympanic membrane, the ossicles, the middle ear ligaments and the mucosal folds, the ossicles, malleus, incus and stapes, the Eustachian tube opening, the oval and the round windows, and the inner ear with the cochlea and the early part of the auditory nerve. Each component is crucial for normal functioning (i.e. audition) and it follows that any mechanism or process interfering with normal functioning will lead to a decrease in the perception of the auditory signal, generating a hearing loss.

THE PINNA

The pinna is vestigial in man, with non-functional auricular muscles. In lower groups of mammals, especially predators, these muscles are well developed and can move the pinna to localize and concentrate acoustic energy to the external auditory meatus, hence participating in spatial resolution of sound as well as focusing the energy to a relatively smaller area to be incident on the tympanic membrane.

The pinna and the external auditory meatus and the canal develop from similar morphological structures *in utero*. Therefore a dysmorphic pinna might reflect a dysmorphic external auditory canal and middle ear. Simple preauricular tags can indicate an underlying problem further down in the auditory pathway. Indeed, simple pinna deformities may be associated with an inner ear disorder.[5] It has been shown that in Down syndrome 3.5 pinna defects are observed, on average, in each ear as compared to 2.5 defects in the non-Down population; all of these are associated with conductive hearing loss in the former.[6] A pinna deformity is therefore clinically significant and demands an audiovestibular workup and, if necessary, monitoring. Since a pinna deformity may be a part of certain craniofacial syndromes, a genetic workup may be essential.

In terms of acoustic function, although the pinna is vestigial, when coupled with the external auditory meatus and canal, the unit acts to provide frequency specific resonance of sound incident on the ear to make up for the impedance encountered at the air–fluid interface between the cochlea and the middle ear. The applied importance of this is considered below.

The role of the pinna in localization of sound cannot be underestimated.[7] It has been postulated that the unique position of the pinna on the head and its relative size to the craniofacial skeleton transform the incoming sound signal with delay paths dependent on the wavelengths of the acoustic waveform to provide localization clues for the listener to an incoming signal. The head shadow, i.e. the intervening head and the pinna on either side, is an important factor for auditory localization, with interaural time and interaural intensity differences generated by the same acoustic signal impinging on the pinna with different temporal and intensity values at each side.[8]

There are numerous anatomical ridges and convolutions in the pinna. Sound waves from either the horizontal or the vertical direction are reflected from these ridges and enter the ear canal with the original non-reflected incident sound (see below). Then, via the fixed external auditory canal, they are transferred to the eardrum, further modifying the transfer function. The different changes of transfer function from the pinna to the external auditory canal when delivered to the cochlea through the middle ear are encoded accordingly to be finally perceived by the cognitive cortex as directionality of sound or a spatial representation of sound.[9] A pathology in the pinna may therefore interfere with this localization and directionality process.

It is logical to consider the pinna as a funnel to collect sound. As mentioned earlier, however, it can also be a reflector of sound and works best above 1 kHz. Some of the reflected waves enter the canal and may interfere with the original waves if they are out of phase, noted particularly between 7 kHz and 10 kHz where they produce a pinna notch.[10] The frequencies at which the reflected and incident waves boost each other are 2–3 kHz, roughly at frequencies which possess wavelengths of four times the length of the pinna.

The postauricular myogenic response (PAMR) is a measurable compound action potential generated in response to an electrical or acoustic stimulus.[11] The reflex magnitude is a large one and the afferent substrate is the cochlea rather than the vestibular system with the efferent pathway being the facial nerve.[12] The reflex is a bipolar compound action potential with typical latency of 12.5–15 ms and can be elicited by either tone-burst or click stimuli. The reflex is obtained at 20 dB SL and can be detected in 80% of the population.[11] The PAMR has been reported to be inconsistent and variable, with significant test–retest variations. It is also difficult to measure with standard auditory brain stem response (ABR) settings and therefore does not find much clinical use. However, there is evidence that, when measured, it can still be clinically useful to screen for hearing loss, especially in difficult-to-test children,[13] in facial nerve function monitoring for intracranial facial nerve palsies[8] and in auditory neuropathy (AN now called auditory neuropathy spectrum disorder where there is an abnormality in sound conduction and propagation from the inner hair cell synaptic junction all the way up to the brain stem and includes the auditory nerve) where it can be abolished.[14] Given the observation that the acoustic reflex is useful to test for AN in the clinical setting, PAMR can augment suspicion before an ABR for confirmation due to its potential ease of use.

The pinna is an important landmark for taking an impression of the ear, an important step in hearing aid fittings. The antihelix and the concha are anchors for hearing aid retention,[15] and a dysmorphic pinna lacking important landmarks may preclude standard behind-the-ear hearing aid fitting.

The pinna is made of fibrocartilage except at the region of the lobule and an area just above the tragus. These anatomical features provide areas for potential surgical accessibility. The lobule can be used as a fat graft and the supratragal notch can be used in endaural incisions, thereby not injuring the tight cartilage mucoperichondrium of the external auditory canal (see next section).

THE EXTERNAL AUDITORY CANAL

The external auditory canal (EAC) commences at the conchal opening called the external auditory meatus (EAM), includes the ear canal itself and ends at the tympanic membrane lateral surface, which separates it from the middle ear. It is made up of an outer cartilaginous part

and an inner bony part with two constrictions, one at the junction of the distinct anatomical parts and one 5 mm before the tympanic membrane in the bony part. Thus, it can be considered as a tube which is open at one end. The typical length is 25–26 mm in the adult human.

The EAC has acoustic and non-acoustic functions and pathologies of the ear canal will therefore interfere with both of these functions.

Acoustic physiology of the EAC

The most important physiological function of the EAM and the EAC is to 'transfer' the acoustic signal from a sound field to a much smaller area, i.e. the tympanic membrane. The EAC transfer function is a mathematical representation of the output of the external ear in dB SPL plotted against an input of sound in db SPL at different frequencies. The resultant acoustic energy delivery to the tympanic membrane is thus a modified and amplified signal which undergoes resonance amplification and provides directional/localization cues.

The ear canal can be considered as a resonating tube following the quarter-wave principle for resonance; i.e. at a frequency with a wavelength four times the length of the canal, the canal and the pinna together will resonate and vibrate with the incoming signal to augment or magnify the incident acoustic signal given by the equation:

$$f = c/4l.$$

where f is the frequency, c is the speed of sound and I is the length of the canal.[16] The resonant frequency which amplifies the incident sound by 10–20 dB is generally 2.7 kHz with a range of 2–7 kHz.[17] Signals below 1 kHz are generally resonated by the head and the torso whereas frequencies above 3 kHz are augmented by the pinna.

It follows, therefore, that the length of the ear canal plays a significant role in modifying the incident sound signal before its delivery to the tympanic membrane. This amplification is essential to overcome the air–fluid impedance at the oval window.

The EAC and the pinna acting as a unit are also involved in providing monoaural and binaural cues for localization of sound (see 'The pinna' above). The EAC pressure gain and transfer factor changes with directionality of the incident signal especially above its resonant frequency and can be as much as 30 dB in both the horizontal and vertical planes.[18]

The EAC canal is subject to variation in size and may grow from the neonate until the age of 7–9 years.[17] The transfer function may change during this period, with important amplification issues in fitting hearing aids, and must be calibrated accordingly by referring to the normal range. The resonant frequency remains more or less constant from the age of 2 years.[19] However, the resonance amplitude changes at old age.[16] Since prescribed hearing aid function is significantly dependent on external ear canal function, this change of resonance must be taken into account to prevent inappropriate amplification.

In some frequencies the EAC generates a standing wave phenomenon. A standing wave is defined as being created when two sounds of the same frequency travel in opposite directions in the canal (e.g. when the same sound is reflected by the tympanic membrane) and cancel each other out. For sounds of high frequencies, a standing wave may be produced which may interfere with circum or supra aural head phones measured hearing threshold at 8 kHz, which might generate a spurious hearing deficit.[20] Another reason why a spurious threshold may be obtained is because in adults supra aural headphones may collapse the soft cartilaginous part of the external auditory canal. This consideration also becomes important when performing real-ear measurements.

In disorders of the EAC ranging from dysplasia to occlusive pathologies (e.g. wax or tumour), the effect on the external canal resonance gain is real and tangible and some conductive hearing loss (a hearing loss which is caused by any factor interfering with the conduction of sound in the external auditory apparatus i.e., the meatus, canal and pinna and the middle ear) is expected. This hearing loss is usually concentrated around the area of maximum resonance, i.e. at about 2.7 kHz. In cases of occlusive hearing aid moulds, this loss must be incorporated in the prescription.

Morphology of the EAC

The EAC is characterized by its skin and by the production of wax, each of which serves its own functions.

The skin is tightly adherent to the underlying perichondrium without any subcutaneous tissue. It is thicker in the cartilaginous part than in the bony part.[15] Minor trauma to the skin may directly involve the perichondrium, potentially leading to serious infection. A skin breach may damage the mucoperichondrium too, therefore due care must be taken not to damage the skin. Surgical incisions utilize the cartilage-free supratragal notch and the superior wall of the canal which spare the cartilage. Earrings are recommended to be worn in the lobule which is devoid of cartilage.

The migration of dead skin is towards the meatus, i.e. lateral. A blind pocket in the ear canal will trap this skin and prevent its migration, leading to infection and finally to a cholesteatoma if it affects the posterosuperior region of the canal.

The skin of the canal is supplied profusely by nerves. Irritation of the canal may provoke a cough reflex or even a vasovagal spell by stimulating the vagus nerve, which serves the canal by way of the nerve of Arnold. Paraesthesia or anaesthesia of the posterior meatus wall may be a feature of a vestibular schwannoma, which is supplied by the nerve of Arnold.

The canal skin is lined in the outer third by two different types of secretory glands: the sebaceous glands and the modified apocrine ceruminous glands. Sebum and cerumen from the glands mixed with dead skin, dust and shed hair form wax. Therefore wax is a product of secretions from both sebaceous and apocrine glands. It turns brown on oxidation in air. There are two types of wax, dry and wet, which are genetically determined. The functions of ear wax are to lubricate and clean the canal, to act as a vehicle for carrying migrating dead skin from the canal skin in the lateral direction and a protective function due to its bactericidal effects against some bacteria and the antimicrobial effects of the lysozyme, immunoglobulin A (IgA) and fatty acids which it contains.[21]

The ear canal is sometimes called the 'greenhouse of the human body', being warm, dark, humid and moist.[21] It is a perfect culture medium for microbes, especially fungi. The wax provides some protection by trapping these microbes, by virtue of its antimicrobial properties and by providing an acidic milieu. Sodium bicarbonate drops to soften wax in the canal disturb the acidic pH and may lead to infection. It is therefore best to use a neutral agent for this purpose (e.g. olive oil).

Impacted wax generates morbidity. Complete occlusion of the ear canal leads to a hearing loss of 40 dB in addition to possible tinnitus and cough.[21] There is usually a high-frequency shift on lesser occlusions starting from 2 kHz, probably due to the compromise of the resonant gain of the ear canal. Wax may irritate Arnold's nerve to cause a vagal-induced cough reflex, especially during microsuction. Superadded infection may lead to social isolation and even a frank otitis externa.

THE MIDDLE EAR

The middle ear in the human acts as an efficient passive and linear transformer to conduct acoustic energy from the tympanic membrane to the stapes footplate at the oval window and to the cochlea. The middle ear apparatus consists of the tympanic membrane, the ossicular chain of the malleus–incus–stapes complex along with the middle ear muscles. Its fundamental function is to provide critical modifications to the sound energy by providing mechanical advantages to overcome the impedance encountered by the acoustic signal when it is conducted from an air-filled medium (the middle ear cavity) to a fluid-filled medium (the perilymphatic and the endolymphatic fluid in the cochlea). Essentially, therefore, acoustic energy is transferred from a low-impedance, high-velocity medium to a high-impedance, low-velocity medium through this ossicular coupling (**Figure 48.13**). The impedance difference is mainly matched by the ratio of the surface area of the tympanic membrane to the stapes footplate and by the lever action of the ossicles and the membrane. The Eustachian tube links the nasal cavity to the middle ear. This tube supplies air to the middle ear for the air particles to vibrate and also equalize pressure across the tympanic membrane between the EAC and the middle ear.

Middle ear function is assessed by impedance audiometry which measures compliance and pressure of the system by tympanometry, which, in addition, also measures volume of the external auditory canal and the stapedial reflex tests. Tympanometry is essentially a measure of admittance (i.e. the reciprocal of impedance) of the middle ear system. The EAC volume can indirectly verify a tympanic membrane perforation or a patent grommet where the canal volume is higher than the average range of the normal and the stapedial reflex tests provide information about the auditory nerve pathways (see 'The middle ear muscles' below). Middle ear function tests are discussed further in Chapter 51, Psychoacoustic audiometry.

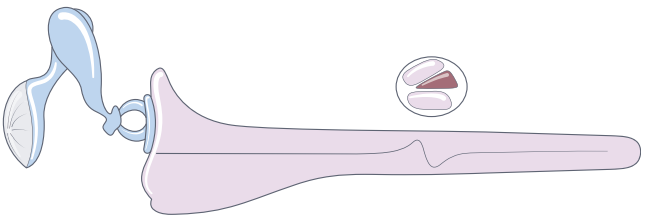

Figure 48.13 Ossicular coupling.

The middle ear space

The middle ear is a closed cavity consisting of the medial surface of the tympanic membrane, the ossicles, the oval window, the Eustachian tube and the middle ear muscles and the ligaments with mucosal folds. The greatest transfer function of the middle ear is at the resonant frequency between 1 and 3 kHz and is determined by the mass and the stiffness of the system. In other words, the middle ear may be considered to be a system with a band pass filtering action.[22] The stiffness or elasticity of the middle ear is determined by the tympanic membrane, the ossicular ligaments and the middle ear cavity compression of the air column while the mass is governed by the ossicles. The stiffness factor limits passage of low-frequency sounds while the opposite is true for the mass factor.

The tympanic membrane

Like the EAC, the middle ear mechanism delivers acoustic energy from a relatively large area of the tympanic membrane to the much smaller area of the stapes footplate. The ratio is about 18:1.[23] This disproportionality contributes to overcoming the acoustic impedance mismatch at the air-fluid interface between the middle and the inner ear. The process begins at the lateral or outer surface of the tympanic membrane which, strictly speaking, is a part of the EAC. The canal side of the membrane exhibits a uniphasic response with little pressure variation and is relatively uniform[24] while the middle ear side is multiphasic with significant pressure variations. This can be explained by the consistency and the structure of the membrane which is non-uniform and provides a multiple integrated multilever mechanical advantage.[25] There is also a destructive interference due to reflection of the sound waves by the membrane, which is important to create a pressure difference across the membrane.

The incident sound from the EAC hits the membrane and sets up a travelling wave, which is mainly collected at the rim of the membrane. This is then conducted to the umbo and coupled to the manubrium of the malleus.[26] At lower frequencies, the membrane transfers all its energy by uniform movement to the malleus; at higher frequencies, the movement is more complex and part of the vibration is shunted by the middle ear.

The reflectance of the membrane is high at the lower frequencies below 1 kHz while it is lowest between 1 kHz and 4 kHz, which means that between these frequencies maximum energy is delivered to the cochlea and the middle ear is most efficient.[27] This range of frequencies happens to be where the middle ear apparatus resonates to the incident stimulus and amplifies the signal to overcome the impedance at the stapes oval window interface.

At higher frequencies up to 15 kHz, the reflectance rises to near total again, which suggests that the middle ear limits sound wave propagation at higher frequencies.[28]

In disorders of the tympanic membrane (e.g. tympanic atelectasis or perforations) the multiple lever action is compromised, leading to a hearing loss, and a myringoplasty cannot restore this feature of the membrane in all cases. A unique case is tympanosclerosis where hearing is preserved in spite of a loss of action of the membrane, presumably because the preferential distribution of the acoustic energy to the oval window from the middle ear is intact due to preservation of some structural integrity.[29] Therefore, structural integrity is crucial for the middle ear transformer mechanism. Note that, when the rim of the membrane is intact (i.e. central perforations), hearing is better preserved than when the margins are affected as energy transfer from the canal to the membrane is via the rim of the membrane.

In perforations, the volume velocity of the sound waves (the volume of vibrating air particles conducting the sound per unit time) is not preferentially distributed to the stapes–oval window interface as normal displacement of the membrane is precluded, but a part of it is absorbed or shunted by the middle ear cavity. Sound transmission may still occur but in a perverted and unnatural way. The main reason for a hearing loss is the reduction in pressure across the tympanic membrane due to this shunt and preclusion of the multilever action.[27] The degree of the loss is proportional to the size of the perforation and inversely proportional to the frequency, i.e. the greatest loss is at lower frequency. This is because reflectance of the membrane, which is an important factor for the pressure difference across the membrane, is lost or diminished at lower frequencies, which does not aid compliance and transfer of energy to the oval window.[30]

The Eustachian tube

The Eustachian tube opens to supply air into the middle ear cavity and is controlled by the muscles in the tube, which are under tonic control and follow the nasal cycle. The tubal opening is best demonstrated at 6–8 kHz, i.e. high-frequency sounds. An evolutionary hypothesis can be proposed to account for this. Since high-frequency sounds are the most important consonant-containing sounds, the middle ear must act in the most efficient way to conduct these sounds, which should be close to its resonant frequency and unaffected by the damping effect of reduced air supply. In other words, maximum air entry from the tube needs to occur at high frequencies to facilitate sound conduction. In Eustachian tube dysfunction where the middle ear cavity is deprived of air, as in early stages of otitis media with effusion (OME), the stiffness of the system is augmented, which leads to a low-frequency hearing loss. With further progression, fluid collection in the middle ear cavity increases the mass of the system, which generates a high-frequency hearing loss.[22] This model may be useful to prognosticate one of the commonest causes of hearing loss in children, i.e. glue ear. It is important to bear in mind that, unlike perforations, which do not affect eventual transmission of sound, OME physically disrupts transmission.

The middle ear cavity

The reflections of the acoustic signal from the walls of the middle ear cavity may contribute to pressure differences across the tympanic membrane[31] and may provide an additional drive to the membrane function.

The transfer function of the middle ear is linear. If stapes velocity which is proportional to acoustic frequency is considered the output of the middle ear mechanism, then it has been shown that there is a peak function at 3 kHz and the shape is that of a shallow band pass cut off.[32] The stapes velocity drives the cochlear fluid movement. Once again, note that the transfer function is most efficient around the resonant frequency range of the middle ear. The cochlear impedance itself makes the middle ear highly damped, which is essentially the impedance the middle ear needs to overcome in order to preserve acoustic stimulus characteristics.

The middle ear mucosal folds

The mucosal folds in the middle ear, which thicken in some instances to form ligaments, divide the middle ear cavity into a superior epitympanum and an inferior mesotympanum and hypotympanum. The ligaments in this epitympanum diaphragm are formed by malleal folds, with the lateral malleoincudal fold posteriorly and the tensor fold anteriorly.[33] The connection between the two is the tympanic isthmus, which is the only conduit for a ventilation stream in the epitympanum from the Eustachian tube, unlike the mesotympanum, which is flooded by air at all times. Congenital defects in the folds, or folds affected by inflammatory processes (e.g. mucosal disease or cholesteatoma), can block the narrow isthmus, leading to loss of air from the epitympanum and provoking further inflammation.[34, 35]

The middle ear muscles

There are two middle ear muscles with function in man: the tensor tympani and the stapedius. They both participate in a reflex contraction, thought in part to protect the delicate sensory epithelium of the cochlea by attenuating high amplitude sounds. Of these, the tensor tympani is less efficient and active than the stapedius, which is the dominant muscle driving the reflex. The muscles are also important for eliciting a prevocalization reflex, i.e. a reflex when someone is about to speak.[36] Given the bony continuity of the human skeleton, vocalization leads to cochlear stimulation via the bony EAC, the ossicles and the skull bones. The middle ear muscles modulate this acoustic signal so that the ear is protected from one's own voice. In the evolutionary sequence, if we consider bats, the acoustic reflexes completely disarticulate the ossicular chain when the bat emits a high-frequency and otherwise very loud echolocating pulse.

The tensor tympani supplied by the Vth nerve has very low electrical activity in response to sound. It attaches to the malleus manubrium and pulls the malleus anteriorly. However, it is active in the following situations: tactile stimulation of the EAC and face, pneumatic pressure on the eyelids, sudden forced opening of closed eyelids or forced closing of the eyelids, swallowing, head movements, anticipation of loud sounds and a startle.[37] It is

interesting that these movements all entail some movement of the bony skull which can stimulate the cochlea. Disorders of the tensor tympani may generate the 'tensor tympani syndrome', which manifests as an audible thump in the ear; the condition is rare.[37]

The stapedius muscle supplied by the VIIth nerve is the dominant muscle in the middle ear and attaches to the stapes neck. Its contraction pulls the annular ligament in the footplate. The stapedius responds primarily to high-intensity low-frequency sounds – about 0.8 kHz[38] –which tend to overpower the high frequencies to preserve high-frequency consonant-containing speech sounds (see below). The middle ear system at lower frequencies therefore generates the maximum impedance to incident sounds. Stapedius contraction is responsible for the stapedial reflex which moves the stapes about 50 microns, increases the stiffness of the ossicular chain and can attenuate the sound transmission to the inner ear by as much as 30 dB.[39]

At the 80–90 dB SL intensity range, the reflex is elicited. However, the stapedius tendon takes about 100–200 ms to contract fully, which implies that it will be unable to protect the cochlea from intense short-impulse noise such as a gunshot, although a noise primer just before the gunshot may address this latent period and may be otoprotective.[37] Although the role of the reflex is controversial, it is thought to serve three important functions:

- Protection of the cochlea to high-intensity sounds to preserve a dynamic range of the auditory system.
- Reduction of output of the middle ear from high-intensity low frequency sounds – these high-intensity low-frequency sounds may mask the high-frequency speech consonant sounds at the base of the cochlea due to the forward propagating cochlear wave (see 'Cochlear travelling wave' below), thereby aiding speech recognition.
- Modulation of self-monitoring of voice and preserving high-definition, high-frequency ambient sounds when one is speaking or by self-generated noise.

The neuronal circuitry of the reflex crosses over to the other side and therefore the reflex can be elicited by both ipsilateral and contralateral stimuli delivered to one ear. As a result, there are several possible response patterns that reflect conductive, sensory and neural hearing losses. The author [SD] believes that the most important utility of measuring the stapedial reflex is to screen for auditory neuropathy spectrum disorder (ANSD) in case of hearing/listening problems with preserved otoacoustic emissions[41] and in cases of spurious hearing losses, for example third windows (see 'The middle ear windows' below) where, in the presence of a significant air–bone gap in pure-tone audiometry (the difference between air conduction and bone conduction thresholds), the reflex may be preserved (the reflex is usually unobtainable in middle ear disease). The reflex may be abolished in brainstem lesions although the response cannot be used to diagnose such a lesion. The reflex itself may be audible, generating an objective tinnitus in the ear which is due to a stapedial tendon myoclonus.

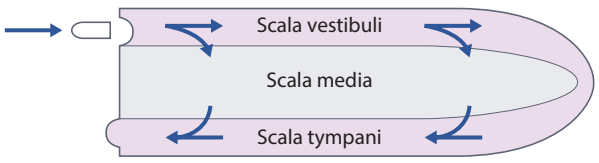

Figure 48.14 The oval window–round window pressure difference for the cochlear travelling wave.

The middle ear windows

The middle ear is characterized by two natural windows or real connections between the middle and the inner ear. The oval window articulates with the stapes footplate while the round window is covered by the secondary tympanic membrane.

The pressure difference between the oval and the round windows is fundamental for the cochlear travelling wave (see below) which drives cochlear function (**Figure 48.14**).[42] Cochlear fluid is not compressible and therefore, to allow a cochlear travelling wave while protecting the sensory epithelia from excessive movement, a mechanism must be present to dissipate part of the mechanical vibration-induced pressure through a channel in the opposite phase. The oval window is the site of the preferential distribution of sound energy although, at higher frequencies, this preference is occasionally shunted by the middle ear cavity.

Disorders of the oval window or in the vicinity (e.g. stapedial or cochlear otosclerosis), congenital absence of the oval window or X-linked gusher syndromes will lead to a loss of this preferential distribution and have a significant effect on auditory sensitivity.

In addition to providing the integrity of the cochlear travelling wave, the round window also participates in absorption and secretion of the perilymph by virtue of a semipermeable membrane.[43] This has opened up possibilities for intratympanic drug delivery through the round window to achieve effective intralabyrinthine concentrations. The round window approach is also used as an alternative to a standard cochleostomy approach for insertion of cochlear implants to minimize operative trauma and subsequent intracochlear fibrosis.[44]

In addition to the two natural windows, virtual third windows may exist for some absorption of the sound from the middle ear thereby affecting the preferential stapes-oval window sound distribution. This includes the vestibular aqueduct and the bony skull itself as well as the ossicular inertia, all of which may shunt away some of the energy, with variable cochlear effect. A pathological third window which can be a real one (perilymph fistula, X-linked gusher i.e., real connection between the inner and middle ear) or a virtual one (dilated vestibular aqueduct or semicircular canal dehiscence i.e. no direct communication between the inner and middle ear) also absorbs or shunts part of this preferential distribution. The cochlea might in part be directly stimulated by the vibrations in the third window itself. Measured air-conduction thresholds therefore decrease and bone-conduction (BC) thresholds increase, generating a spurious conductive hearing loss or 'false' or air–bone gap.[45] The improved BC can also be explained by the fact that the third window generates a pressure drop across the two natural windows. However, it must be noted that third window pathology may directly damage

the cochlear or the vestibular sensory epithelia. As a result, it is very difficult to accurately estimate auditory sensitivity in patients with the disorder and consequently prescriptive fitting of digital amplification which is based on pure-tone thresholds may not give a favourable outcome.

Bone conduction

Apart from being stimulated by the stapes–oval window interface acoustic energy transfer and the round window effect, the cochlea can be directly stimulated by the bony skull composed of canal, ossicles and bony cochlea within which the whole inner ear apparatus is enclosed. Airborne and internally generated sound produces vibrations in the hard bony skull which in turn can lead to endolymphatic movement of the cochlear basilar membrane (BM), bypassing the middle ear and the external ear mechanisms. In addition, there is a non-osseous pathway for stimulation by the acoustic energy which is conducted through the brain and the cerebrospinal fluid (CSF) and transmitted to the cochlea by its fluid channels.[46]

The cochlea is directly stimulated by factors including the sound pressure level in the bony canal vibrating the skull, the ossicular inertia, the cochlear fluids and the cochlear space vibrations.[47] Thus, there are three methods of bone stimulation:[48]

- vibration-induced compression and distortion of the cochlear space consisting of the intralabyrinthine bony skeleton which causes distortion of the BM due to the flexibility of the vestibular aqueduct
- vibration-induced inertia of the ossicles transferring to the bony labyrinth
- particle vibrations leading to vibrations of the EAC, the tympanic bony sulcus and directly transmitted to the cochlea.

The middle ear has a resonant frequency around 1–3 kHz considering both air and bone conduction. If this resonance is reduced or damped by a mechanical problem in the ossicular chain (e.g. adhesion, fixation or sclerosis), the ossicular component of bone conduction as outlined above is jeopardized and generates a drop in the pure-tone thresholds as measured by BC of about 5–10 dB. This classically appears at 2 kHz as Carhart's notch in the BC thresholds in stapedial fixation; however, in any pathology involving the ossicles, a Carhart's effect may be present between 1 kHz and 4 kHz with dips in BC thresholds. Occlusion of the EAC to a significant degree may improve bone-conduction thresholds as the vibrations from the bone travel through the skull and on re-entering the external ear are contained within the canal to directly stimulate the inner ear by the osseotympanic route and do not escape to the outside.

The ossicles

The three ossicles (the malleus, the incus and the stapes) are connected together by synovial joints for transmitting the acoustic stimulus from the tympanic membrane. The geometric length of the malleus is approximately 2.1 times that of the incus and thus the lever action multiplies by 2.1 times; with velocity decreased by a factor of 2.1, the net mechanical advantage or impedance ratio is therefore 4.4. Further, the lever action changes with frequency with its most efficient at 2 kHz.[49]

The malleus and the incus rotate around an anterior–posterior axis of the malleus–incus complex that passes through the centre of gravity of the ossicles.[50] At low frequencies there is relatively less motion between the malleus and the incus; however, at higher frequencies the motion becomes more complex, allowing some slippage between the two to conduct higher-frequency sounds more efficiently.[27] The stapes shows a similar pattern of movement, i.e. simple piston-like movements at low frequencies and more complex spatial movements in higher frequencies along the long and short axes of the footplate.[51]

In ossicular discontinuity, whether congenital or acquired, the ossicular coupling-led preferential distribution of sound to the oval window is lost and the cochlear partition pressure between the round and the oval windows, which drives the cochlear travelling wave, is compromised.[52] The total expected conductive loss is about 60 dB, but much less if there is incomplete discontinuity or when there is a pathological bridge between the ossicles (e.g. a cholesteatoma). In ossicular fixation, such as in chronic adhesive otitis media involving ossicular joints or their ligaments, especially the anterior malleolar ligament, continuity is present but mobility is restricted and leads to a high impedance in the system. This is offset to a certain extent by inbuilt redundancy mechanisms in the middle ear. Thus, the hearing loss which is generated is less than that obtained with ossicular disruption. Otosclerosis is one type of ossicular fixation where the output substrate of the EAC and the middle ear concentrated on the stapes footplate affect forward propagation to the cochlea, thereby generating a significant conductive hearing loss proportional to the mobility of the stapes affected by the disease.

Tympanoplasty and ossicular chain reconstruction surgery attempts to re-establish the broken ossicular bridge either using soft tissue or by synthetic or autologous grafts.

Middle ear impedance match

The two primary mechanisms to match loss of acoustic energy at the stapes–oval window interface due to change of acoustic transmission from an air to a fluid medium, i.e. the surface area ratio of the tympanic membrane to the stapes footplate and the lever actions of the tympanic membrane and the ossicular levers, are responsible for a pressure gain in the middle ear conducted sound. Ossicular coupling, which is mainly contributory to the pressure gain, is frequency-dependent;[53] between 0.25 and 0.5 kHz it is 20 dB, reaching to 26.6 dB at 1 kHz and then decreasing by about 8.6 dB per octave until near zero above 7 kHz. The cochlear impedance is less at higher frequencies than at lower frequencies.

The effectiveness of impedance matching varies according to sound frequency. At 2 kHz, when the external canal and the middle ear transfer the acoustic energy most efficiently, the average sound pressure loss at the cochlea is 39.5 dB, which is partially compensated for by an external canal gain of 9 dB and a middle ear gain of 26.6 dB for a total gain of

35.6 dB factoring in some loss due to frequency-dependent middle ear function. In humans, at 2.7 kHz (i.e. the resonance of the canal) the sound pressure loss is approximately 35 dB, which is very closely matched by the external and the middle ear transfer function.[54] Note the difference in the impedance match at 2 kHz and at the resonant frequency of 2.7 kHz; the latter is a closer match than the former.

THE COCHLEA

The stapes–oval window interface delivers the mechanical and kinetic energy of the incident acoustic signal to the cochlea. The cochlea is a 2.5-turn coil in humans resembling a snail in the anterior compartment of the bony inner ear labyrinth. Sound introduced to the cochlea undergoes two major processes: a biological and active compression/amplification by the outer hair cells (OHCs) and an electrochemical transduction by the inner hair cells (IHCs), both contained in the scala media of the cochlea. The resulting neural output is a coded and gated signal conveyed by the auditory nerve via the spiral ganglion cells to the brainstem, which preserves frequency information, the amplitude and the phase of the sound by cochlear tonotopicity (frequency specificity), auditory nerve firing rate, phase locking and synchrony.

The cochlea is characterized by amplification to make hearing more sensitive, tuning to make it sharply frequency-selective and compressive non-linearity so that relatively large stimuli are translated to proportionally lesser systematically encoded mechanical functions to maintain integrity.[56] Cochlear mechanisms for the above actions are therefore responsible for the essential functions of the cochlea that include frequency analysis, loudness discrimination, temporal resolution, and the spectral analysis of the incoming signal. This is a highly complex process and interference with any of the component processes will lead to a hearing disorder.

Cochlear OHC function is measured by otoacoustic emissions that include transient emissions in response to a broadband click and distortion product emissions in response to frequency-specific pure tones. It can also be measured by electrocochleography and cochlear microphonics, the latter being incorporated in the software for auditory brainstem response (ABR) testing (see Chapter 9, Hearing tests in children).

Cochlear travelling wave

The mechanical displacement of the stapes–oval window junction is conducted along the cochlea, impinging on the base first and then travelling all the way up to the apex (**Figure 48.15**). In its wake, it causes mechanical movement of the BM which divides the cochlea into two compartments: the scala vestibuli above and the scala tympani below with a small connection between the compartments at the helicotrema in the apex. In addition, there is a third component called the scala media between the scala vestibuli and the scala tympani separated from the scala vestibuli by the Reissner's membrane and the scala tympani by the basement membrane. There are therefore three different travelling waves generated: the wave as a result of the pressure difference of the two compartments, the wave as a result of the mechanical displacement of the BM, and the acoustic energy wave which displaces the cochlear fluids.[56] The displacement wave is by far the most important wave for cochlear function.

The travelling wave propagates aided by the gradual diminution of the thickness and stiffness of the basement membrane from base to apex. As it propagates, it is acted upon by numerous critical oscillators, the characteristic frequency of which is specific to a particular region of the BM. These oscillators move the BM in addition to the travelling wave by expending active energy and are coupled with OHCs in the organ of Corti. The mechanical travelling wave propagates from the base to the apex, so there is a biological need to maintain signal strength at a relatively stable state due to gradual changes in thickness and stiffness of the BM along its length. The oscillators become active when they compress or modify this signal and passive when they allow the signal to pass. There is a critical point at which these may cancel each other out called the Hopf bifurcation.[57] In order to prevent this, the oscillators must possess an autoregulation process or a self-tuning property which, as can be seen later, generates a very important attribute of the cochlea in the form of a cochlear tuning curve.

Given that the critical oscillation function and the compressive function of the OHC (see below) are responsible for tuning the BM in response to an acoustic signal, which is variable along the length of the BM and is spatially represented, it can be inferred that the acoustic output, which is the end result of the BM function, is a non-linear output. In pure tones with frequencies well below the characteristic frequency (see below 'Cochlear tuning curve'), the function is linear and passive. In disease processes, the non-linearity may become linear and can be measured in the growth function of distortion-product otoacoustic emissions. Pathologies such as ototoxicity and possibly age-induced hearing loss will interfere with the non-linear function of the cochlea.

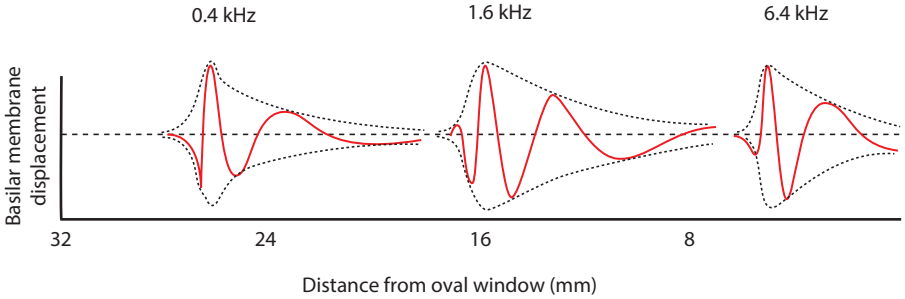

Figure 48.15 The cochlear travelling wave.

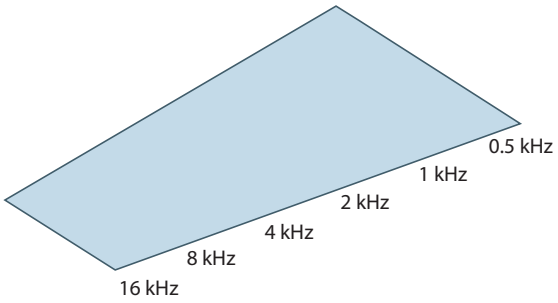

Figure 48.16 Tonotopic representation of the cochlear BM.

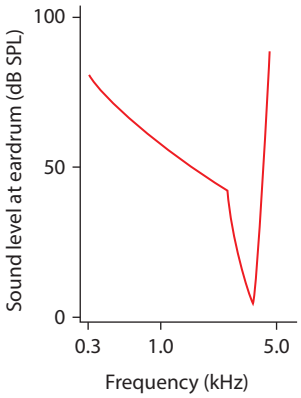

Figure 48.17 The cochlear tuning curve.

Cochlear tuning curve

The cochlear travelling wave in response to an acoustic stimulus reaches a maximum displacement somewhere along the BM following which it starts to dissipate. High-frequency sounds produce peak displacement towards the base of the cochlea whereas the peak moves progressively towards the apex as sound frequency decreases. There is therefore a clear relationship between frequency and displacement in the BM. The frequency at which the maximum displacement occurs is also called the characteristic frequency[58] at a specific place in the BM making it highly frequency-specific or tonotopic (Figure 48.16).

A cochlear tuning curve is the response of the cochlear BM to changing intensities to achieve a maximum amplitude response and is plotted as a function of intensity with frequency (Figure 48.17). A psychophysical tuning curve is the plotting of the amplitude of a narrow band masker required to mask a fixed pure tone as a function of the masker signal.[59]

The human ear has a dynamic range up to 120 dB which inherently dictates that signals of very high intensity must undergo modification at the cochlear level without damaging the cochlea and need to be compressed. The cochlea does this via the OHCs and their non-linear function, and depends on the frequency specificity or the tonotopicity of the BM.

Compression is achieved by the OHCs to generate the tuning curve. For example, a 50 dB SPL tone will result in a 10 dB SPL equivalent change in BM displacement, which inherently implies that the dynamic range is maintained with relatively lesser displacements of the BM.[58] This compression is essential for maintaining the integrity of the BM and increasing its stability in the presence of high-intensity stimuli. For lower-intensity signals, the OHCs amplify the BM response by mechanical elongation/compression of their cell bodies which sharpen the tuning curve; again, this is variable across the response, preserving non-linearity.

Another property of the cochlea is its filtering action. This is indirectly dependent on the tonotopicity. In simplified terms, the characteristic frequency is where other neighbouring frequencies are filtered so as not to interfere with the frequency selectivity i.e., the characteristic frequency is best resolved at a given point in the BM in preference to other frequencies. In other words, these neighbouring frequencies undergo some sort of a filtering action. It has been proposed that this filtering also explains the attribute of perceptual streaming.[59] This is essentially a central auditory function contributed by the ability of the cochlea to discern a rapid sequence of sounds coming from a single or a multiple source (i.e. whether the single sound is an overlap of multiple sounds or whether multiple sounds can be perceived on their own). When the sounds are close together in frequency, fusion may occur and the perception will be of a single sound as the filtering action becomes less in neighbouring frequencies. However, factors other than this overlapping of exciting frequencies may interfere.[59]

The dynamic range is significantly lost and reduced in cochlear pathologies. The tuning curve loses its sharpness and frequency selectivity is compromised along with perceptual streaming. Different pathologies may affect the shape of the tuning curve in different ways: for example, some genetic losses involve the lower-frequency sensitivity while ototoxicity affects the high-frequency sensitivity. Cochlear hearing loss therefore may show some characteristic features, including loss of frequency selectivity leading to difficulties to understand speech and appreciate music, loudness recruitment due to reduced dynamic range and a compromise of perceptual streaming which manifests itself as an inability to perceive or segregate multiple sounds at a given time. (see 'Pathophysiology of cochlear hearing loss' later in the section). These pathologies lead to a perceived hearing loss.

Cochlear fluid

The cochlea contains perilymph in the scala vestibuli and scala tympani. This is an ultrafiltrate of blood plasma and the CSF, rich in sodium and low in potassium and calcium. The scala media or the cochlear partition consists of the endolymph which is actively pumped by the stria vascularis in the scala media. This, in contrast, is rich in potassium, low in sodium and has negligible calcium. The stereocilia of the hair cells are bathed in the endolymph while the hair cell bodies are bathed in perilymph. There is another compartment called the intrastrial space which is the space between the extracellular matrix of the stria vascularis.

The cochlea is supplied by the spiral modiolar artery, which is a branch from the vestibulocochlear artery (VCA) from the anteroinferior cerebellar artery. The VCA is an end artery. The microcirculation of the cochlea, especially the stria vascularis, has certain characteristic features.

The capillary network is arranged in a parallel fashion in the lateral wall of the cochlea; there is an abundance of pericytes and fibrocytes in the network, and the cochlear blood flow is autoregulated by multiple factors which are exquisitely sensitive to changes in the internal environment.[60] These factors include local metabolites such as lactate, nitrous oxide and potassium, the pericytes and the fibrocytes, and the blood vessel smooth muscle cells. Cochlear microcirculation ensures the integrity of the cochlear fluids and there exists a blood–labyrinth barrier which is responsible for ultrafiltration and abundantly supplied with enzymes and protein subunits, for example the Na^+ - K^+ ATP subunit so important for ionic transport. The objective is to deliver energy and provide processes for ionic transport for the cochlear internal milieu. Cochlear microvasculature is affected in a number of disease processes with secondary involvement of cochlear fluid hydrodynamics which in turn lead to impaired cochlear functions. These include noise-induced hearing loss, endolymphatic hydrops and possibly age-induced hearing loss. In addition, the artery is an end artery, which implies that a blockade or obstruction to it (e.g. an embolus) if it persists beyond a certain period of time (about 15–30 minutes[61]) will lead to irreversible damage (ischaemia) to the organ it supplies, which is the cochleovestibular apparatus.[61]

The highly intricate cochlear microvasculature ensures nutrition in the cochlear compartment and also provides the internal environment for cochlear function. The main driving ion for cochlear function as furnished by different cochlear processes is potassium. The way it is recycled is called a potassium cycle, responsible for the endocochlear potential. This potential is the resting potential kept at a constant level in the scala media. From the teleological point of view, potassium is the chosen cation as the other cellular ion, sodium, entails far more cumbersome active transport systems between different media which would crowd up the BM, precluding highly sensitive hair cell function. Potassium, on the other hand, simply utilizes a concentration gradient.[62] However, the role of Na^+ for maintaining the endolymphatic potential cannot be ignored as the Na^+Cl^- ATP cotransporter in the marginal cells and in the fibrocytes of the spiral ligament ensures further potassium efflux and influx by coupling with the potassium.[63] The endocochlear potential results in a dynamic flux of ion transport in the cochlear endolymphatic space in the scala media. The stria vascularis has four cell types:[64] the marginal cells related to the medial scala media, responsible for maintaining a low potassium composition in the intrastrial space by continuous active uptake of the ion from the endolymphatic space; the intermediate cells, which have the marginal cells medially and the basal cells, laterally, are connected to the basal cells by gap junctions regulated by the connexin family genes and where the endocochlear potential is generated; and the basal cells, with the intermediate cells in their medial end and laterally connected to the spiral ligament in the lateral wall of the cochlea by gap junctions as well. potassium from the blood is actively taken up by the fibrocytes of the spiral ligament and pumped to the basal, cells which in turn deliver the ion to the interstitial cells. These cells present the ion to the intrastrial space from where they are taken up by the marginal cells. The scala media receives its ions from the marginal cells. All the active processes are regulated by various enzymatically driven potassium channels and Na–K ATP systems; the end result is maintenance of a high potassium ionic composition in the scala media which is vital for hair cell function by virtue of the endocochlear potential. Some potassium finds its way back by basolateral potassium channels in the perilymph.[65] The whole process is shown schematically in **Figure 48.18**.

Hyperacoustic stimulation depresses the potassium cycle for protecting the cochlea and actually leads to a drop in the endolymphatic potential[66] and stimulation of the P2X by the ATP pathway, which inhibits OHC motility (see below), while beta adrenergic stimulation as a part of sympathetic stimulation swings the cycle to the opposite side.[64]

Genetic mutations in the connexin family or the potassium transport family interfere with maintaining endocochlear potential and therefore sensory epithelia function. Examples include connexin 26/30 hearing loss, the commonest genetic autosomal non-syndromic prelingual genetic hearing loss, and Jervall–Lange–Nielsen syndrome with long QT interval where the *KCNQ1* ionic transport gene in the stria vascularis and cardiac conductive system is deficient.

Cochlear sensory epithelia and supporting cells

The mammalian cochlea is characterized by the presence of two distinct subtypes of sensory epithelia which differ in orientation, morphology and function. The OHCs number about 12 000 in humans; are arranged in three rows;

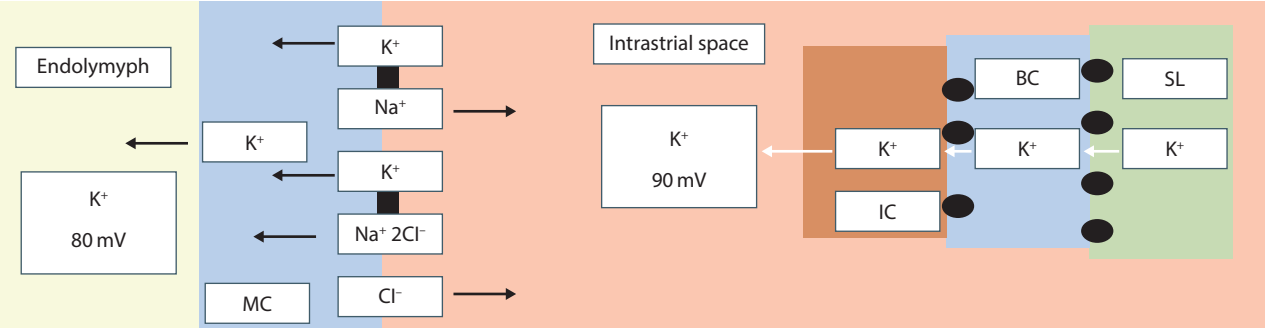

Figure 48.18 Endolymphatic fluid dynamics for generating the endocochlear potential. SL, spiral ligament; BC, basal cells; IC, interstitial cells; MC, marginal cells.

participate in electromotility leading to cochlear tuning, amplification, compression and frequency selectivity; and are innervated by type 2 spiral ganglion afferents and cochlear efferents from the medial olivocochlear bundle. IHCs are arranged in one row; number about 3500 in humans; participate in cochlear transduction of the incoming acoustic signal; largely generate the cochlear afferents to the spiral ganglion type 1 cells from where the auditory nerve commences and also receive efferents from the lateral olivocochlear bundle. Both these cells form the sensory epithelium in the organ of Corti with their apical or stereocilia side bathed in the endolymph of the scala media and their bases bathed in the perilymph of the scala tympani.

Undulations or mechanical vibrations from the BM lead to a shearing force in the tectorial membrane which in turn moves the stereocilia of the hair cells in the endolymph. Following this initial mechanical displacement, the behaviour of the OHCs and the IHCs differ and will be considered separately.

As will become apparent below, cochlear hair cell integrity depends on enzymatically driven functions to maintain structural stability. Thus mutations in the protein-encoding genes are likely to cause a sensory hearing loss.

THE OUTER HAIR CELLS

The OHCs are cylindrical with bundles of stereocilia composed of actin filaments which project at their apical ends in the scala media. BM-led tectorial membrane displacements in response to acoustic stimuli result in movement of these stereocilia in a plane parallel to their plane of orientation: depolarization when the movement is towards the tallest stereocilia and hyperpolarization/repolarization when the movement is towards the smallest stereocilia. Displacement opens up the cation-selective ionic gates responsible for transduction and generation of an action potential. A displacement of just 0.3 nm can displace the stereociliary bundle.

An action potential thus generated happens within 10 ms, which is a graded action potential (AP) mediated through the tip links between adjacent stereocilia which regulate ionic flow in this case potassium from the potassium-rich endolymph. The OHC itself is more negative than the endolymph, which facilitates movement of potassium without any energy expenditure, and it appears that, given the overall metabolic rate of the OHC with its specialized energy-expending function in modulating the acoustic signal, is nature's way of conserving energy. Potassium entry through the transduction channels then generates voltage-gated calcium channels and results in the influx of Ca^{2+} ions in the cells which participate in synaptic transmission and 10% of the depolarizing voltage.[67] The entry of potassium constitutes the depolarization stage. Repolarization occurs in two distinct processes: by the efflux of cell-rich potassium to the potassium-poor perilymph across the concentration gradient through the cation-selective ionic channels in the basolateral portion of the OHC, and by the influx of the Ca^{2+} mentioned above. There is a fine balance between the two and, if this balance is lost (i.e. if there are fundamental problems with either the potassium or the Ca^{2+} delivery or gated controls), then the cochlea OHC loses its tuning curve and therefore part of its function.[68]

The action potential is transmitted to the type 2 spiral ganglion cells, which are essentially non-myelinated and smaller than their IHC counterparts and not as developed. They show reciprocal synapses with their OHC counterpart, i.e. the type 2 cells feed back to the OHC providing a pathway for a closed loop neuronal circuit for bidirectional signalling and reverse transduction.[69] It should be noted that the action potential in the OHCs does not carry auditory information to the auditory nerve. Its job is to provide a motor for altering OHC physical dimensions for further displacement of the BM. The force contributed by this motor is sufficient to drive the acoustic signal through the entire length of the cochlea as an additional travelling wave as well as providing enhanced modulation at a local, site-specific area of the BM[70] (see also 'Cochlear travelling wave'). It also leads to movements of the tectorial membrane itself to open up further ionic gates and augment the AP and amplification process. Note that some type 2 cells are carried through the auditory nerve (only 5%) to synapse at the cochlear nucleus.

The OHC exhibits the special feature of electromotility, which is a highly sensitive attribute as cochlear motility translates frequency specificity and amplification and is responsible for fine-tuning of the acoustic signal. In response to acoustic stimulation of the BM, this motility is driven by two forces: a voltage-dependent mechanotransduction (MET – see last paragraph) that moves the hair bundle with an active movement[68] and a somatic non-linear capacitance prestin-mediated motility[71] which modulates the stiffness of the stereocilia and makes them alter their sizes. Prestin is a crucial component, abundantly located in the lateral membrane of the OHC, which belongs to the SLC26A family and participates in selective anion transport and binder, in this case chloride and carbonate. The action of prestin is voltage-dependent and results in either contraction or elongation of the OHC necessary for augmenting the acoustic signal incident on the BM. Cochlear electromotility is sensitive to frequencies and intensities of the signal.

The OHC in addition receives efferents from the medial olivocochlear bundle in the brainstem which synapse with the spiral ganglion type 2 nerves, offering a regulation of the reverse transduction process.

THE INNER HAIR CELLS

The IHCs are the true sensory end organs for hearing and are responsible for generating the action potential which then is conducted to the type 1 spiral ganglion cells to be delivered to the auditory nerve. The spiral ganglion type 1 nerve endings are myelinated and synapses here are well developed with ribbons and glutamate activity, unlike the OHC synapses.[72] The IHCs are non-actively motile and receive the output from the OHCs through the modified movement of the BM at a given region of the BM.

The IHCs are depolarized as a result of BM movements causing deflection of the stereocilia. The depolarization is mediated by cations potassium and Ca^{2+}, the latter being crucial for synaptic action through chemical neurotransmitters

especially glutamate.[73] The IHC synapses do not exhibit any reciprocal arrangement, unlike the OHC. Ca^{2+} release is mediated by voltage-dependent depolarization mediated by potassium of the IHC apical membrane, i.e. the stereociliary deflections.

Since it delivers the eventual output of cochlear function, the IHC needs to contain all the information amassed so far in the form of coding to the cochlear nerve. There are two types of coding, namely frequency coding and intensity coding.[74] The IHCs phase-lock with the stimulation frequency under 5 kHz while, above this frequency, the frequency-specific depolarization/repolarization is too fast for the IHCs to phase-lock. Intensity coding is by way of an increasing number/rate of action potentials proportional to stimulus intensity (see also 'The auditory nerve').

THE COCHLEAR SUPPORTING CELLS

Increasing evidence is emerging as to the important function served by the cochlear supporting cells (i.e. Hansen cells, Deiters cells, pillar cells, interphalangeal cells and border cells). In addition to providing a scaffold for anchoring the hair cells, these cells also participate in cochlear function and stability.

The supporting cells contribute to the development, differentiation, patterning and synaptogenesis of the hair cell sensory epithelia. From a common precursor, cellular differentiation and their mosaicism dictate variable cell line maturity and feed into each other by the process of autoregulation: if this enzyme-driven process is disrupted, then supporting cell populations might be converted to hair cells and vice versa.[75] Another important function of the supporting cells is that they contribute to the planar cell polarity (PCP) of the hair cells, which essentially is the stable plane of orientation of the basal and apical ends of the hair cells which expose them to the right environment for mechanotransduction. In fact, the supporting cells are abundant, with a PCP regulator which has been shown to regulate the orientation of the stereocilia.[76]

In the mature cochlea, the supporting cells provide the anchor and the platform for tight adherence of the sensory epithelia to the BM at the basal surface and form the reticular lamina at the apical surface where it separates the endolymph from the perilymph and helps maintain the endocochlear potential. They provide proteins for maintaining the extracellular matrix of the BM and thus maintain rigidity and stability of the hair cell population. They further contribute importantly to the homeostatic process by serving four functions:

- By virtue of being endowed with Na^+ gates, they take up Na^+ from the endolymph, ensuring a low concentration of the ion in the scala media.
- They assist in the potassium cycle, especially in the basolateral part of the BM.
- They influence glutamate activity at the hair cell synaptic regions.
- By virtue of their gap junctions (which are regulated by connexin 26), they are involved in the passage of ions and compounds either across the concentration gradient or actively by the ATP mechanism. This ATP-mediated energy-expending process also leads to Ca^{2+} coupling in the hair cells;[75] Deiters cells have an internal Ca^{2+} store which can be readily available in cases of need.[77]

Supporting cells may play a role in the eventual repair and regeneration of the hair cells in response to damage, as they are shown to do particularly in birds.[78] At the moment, mammalian hair cells show no evidence of regeneration although there might be low-level repair in vestibular hair cells.[79]

Curiously, there is nerve innervation of the supporting cells which implies that these cells can generate an action potential. These nerve endings do not synapse with the cochlear efferents or contribute to the formation of the cochlear nerve; they are considered to be a part of the internal neural circuitry which characterizes OHC afferents and participates in OHC non-linear fine-tuning of the acoustic signal through BM activity.[80]

Mutations in genes encoding for supporting cell proteins will lead to cochlear sensory loss. For example, in addition to maintaining gap junctions in the stria vascularis, connexin 26 is also expressed in the supporting cells and a mutation will lead to the loss of structure, stability and integrity of the hair cells through the supporting cell mechanism. *DFNB29*, a cause of autosomal recessive hearing loss, is characterized by a mutation in the gene containing claudin, which is a structural protein of the reticular lamina responsible for tight junctions. A loss of this tightness leads to increased potassium permeability from the scala media to the hair cells, resulting in a drop of the endocochlear potential and loss of function.[81]

Pathophysiology of cochlear hearing loss

Loss of cochlear function for any reason will result in a drop in auditory sensitivity; a drop in complex sound appreciation and analysis due to the loss of frequency selectivity; loss of fine-tuning of the acoustic signal with narrowing of the dynamic range of hearing due the loss of non-linearity, amplification and compressive properties; loss of perceptual streaming due to the loss of frequency selectivity; and loss of temporal pattern of sounds due to the loss of spatial discrimination and the ability of the cochlea to distinguish between closely following frequencies and intensities.

- **Structural abnormality:** A cochlear dysplasia of any kind leads to ill-formed or absent cochlear components. This can follow a congenital maldevelopment, trauma or a space-occupying lesion and will lead to a cochlear hearing loss.
- **Abnormal metabolic activity:** Since ionic transport dictates cochlear function, it follows that a metabolic abnormality (systemic or otherwise) that interferes with cochlear ionic transport as a result of either a genetic syndrome or an acquired condition (e.g. problems with glucose metabolism or thyroid metabolism) will lead to changes in the endolymphatic potential and affect cochlear function.

- **Vascular changes:** Cochlear vascular afflictions (either systemic or local) will lead to a compromise in stria vascularis function; a diminution in cochlear nutrition and hypoxia; sluggish vascular flow or complete obstruction of the cochlear arterial blood flow. Examples include pressure effects due to any cause, noise trauma and ototoxicity, transient ischaemic attacks (TIAs) and hyperviscosity for any reason. Endolymphatic hydrops, i.e. an expansion of the endolymphatic space for any reason including a lack of integrity of the stria vascularis (e.g. Ménière's disease or endolymphatic fluid disturbances such as third window syndromes) will lead to a compromise in function of the stria vascularis.
- **Overloading the BM:** A crowded or loaded BM due to local or systemic causes (e.g. a metabolic syndrome such as diabetes, hyperlipidemias, iron overload, inflammation or autoimmune conditions) will prevent OHC motility and IHC loss of transduction.
- **Infection and inflammation:** An inflammatory involvement in the cochlea leads to the disruption of the biochemical pathway of cochlear function (see below) and the accumulation of toxic lipid-derived substrates which hamper cochlear function.
- **Genetic mutations:** As indicated earlier, a genetic mutation in the genes encoding for numerous proteins involved in cochlear function, from ionic transport to structural proteins, will lead to a cochlear hearing loss. The different genes expressed in the cochlea are given in a seminal publication by Nishio et al.[82] The Hereditary Hearing Loss home page lists genetic hearing losses with phenotypes and genotypes and is updated continually.[83]
- **Biochemical pathway abnormalities:** In response to noise trauma, ototoxicity and due to cumulative wear and tear action in presbycusis, a biochemical cascade for cochlear hair cell integrity loses its balance leading to apoptosis and subsequent cell death. This cascade suggests that, theoretically at least, pharmacological intervention aimed at various steps in the cascade can reverse the process. Figure 48.19 illustrates this.

Otoprotective endogenous compounds play an important role in preserving the delicate cochlear structures and influence the biochemical cascade, although in a rather heterogeneous way. These include heat shock factors (HSFs) and heat shock proteins (HSPs), both abundantly expressed in the cochlea, which can modify the apoptosis response;[84]

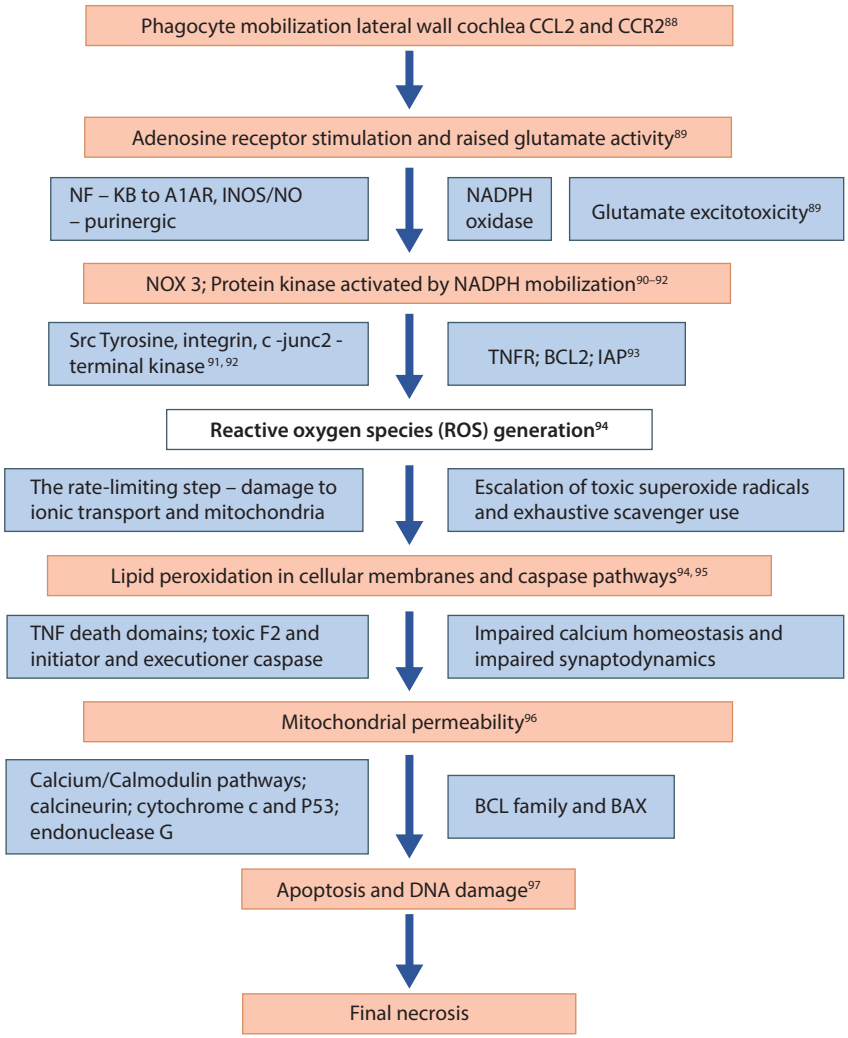

Figure 48.19 Biochemical pathway/enzymatic cascade for hair cell damage.

downregulation of some growth factors;[85] neurotrophin, mainly glial cell-derived neurotrophic factor (GDNF) regulation,[86] to modify the end result of apoptosis for recovery of function and the coenzymes Q9 and Q10.[87]

THE AUDITORY NERVE AND COCHLEAR EFFERENTS

The auditory nerve

The auditory or cochlear nerve, cranial nerve VIII, originates from the joining of the spiral ganglion cells in the cochlea where their cell bodies lie. There are two types of nerve fibres originating from the spiral ganglion cells: type 1, which have large diameters, innervate the IHCs constituting 95% of the nerve fibre population and are myelinated, and type 2 fibres, which are smaller diameter, innervate the OHCs and are unmyelinated. The nerve traverses the internal auditory canal and joins with the vestibular nerve forming the vestibulocochlear nerve. One type 1 fibre innervates one IHC but one IHC may synapse with several nerve fibres. The cochlear nerve fibres terminate at the cochlear nuclear complex located in the medulla of the brainstem.

The synaptic architecture of the hair cells and the spiral ganglions is discussed in detail in 'The cochlea' above. The cochlear nucleus synapses with the cochlear nerve and is represented tonotopically, which implies that frequency encoding by the cochlea is carried up to the central nervous system to be further analyzed.

The action potential of the cochlear nerve in response to acoustic stimulation entails a release of bundle synaptic receptors proportional to the stimulus, which results in spike potentials which are short-lived and attain their peaks quickly. The rates of the spikes vary depending on the intensity and the frequency of the incident sound. Each fibre fires most at a given frequency (called the characteristic frequency) like the spatially represented characteristic frequency in the cochlear BM which facilitates transfer of the tonotopicity to the nerve from the cochlea. For example, fibres from the base of the cochlea will lead to increased firing of the fibres with a high characteristic frequency.

The discharges of the fibres to low-frequency sounds occur at particular times, in other words, there is a phase-locking mechanism which occurs up to 5 kHz.[98] Phase-locking is important to convey temporal information of the incoming signal.[99] A two-tone suppression model is also present in auditory nerve function which dictates that a second stimulus close to the characteristic frequency of the first one will suppress the first, facilitating the representation of complex and multiple stimuli in the nerve which is a non-linear function.[100]

Intensity coding also occurs in the nerve fibres. Nerve fibres possess spontaneous firing activity without sound stimulation. Fibres with high spontaneous firing rates have a low threshold for intensity while fibres with intermediate and low spontaneous firing rates have a high threshold.[101] Stimulus intensity thus influences the firing rate of the nerve fibre: the higher the stimulus intensity, the higher the firing rate, with a saturation point where it plateaus off,[102] which is important for adaptation as explained below. Thus, the fibre codes for intensity as well.

The auditory nerve is the beginning of central processing of the acoustic stimulus delivered from the periphery. This is in the form of auditory nerve adaptation which entails a spike frequency adaptation where the spike in response to a stimulus quickly adapts and reaches a plateau that is more pronounced in high-frequency fibres than the lower ones.[103] Adaptation, which is found in neurons elsewhere, is crucial in the auditory context as it provides vital cues to the brain regarding timing of the signal. Adaptation gets progressively complex and sophisticated in the brainstem and the cortex.

The auditory nerve can be affected by a variety of disease processes which include pressure effects by space-occupying lesions such as a VS; the demyelination processes such as in multiple sclerosis; granulomatous lesions; head trauma; viral illnesses; congenital dysplasias and autoimmune disorders. Essentially, the tuning curve and the phase-locking properties are affected and lead to a failure in encoding time, frequency and intensity information. This is a classical neural deafness. ABRs are a robust way of measuring auditory nerve function and may be used for prognosticating a demyelinating lesion.[104]

The condition auditory neuropathy spectrum disorder (ANSD) deserves special mention. This is defined as a disorder with abnormal auditory brainstem morphology but preserved cochlear OHC function (although measured cochlear OHC function may disappear with time). Structurally, the nerve is unremarkable, especially on imaging, and most likely the damage is at the molecular level precipitated by a few known risk factors such as hypoxia, hyperbilirubinemia and prematurity. Neuropathies such as Charcot–Marie–Tooth and Mohr–Tranebjaerg syndromes or mitochondrial syndromes can cause ASND.[105] Metabolic conditions such as diabetes have a theoretical risk of causing it, especially those which are complicated.[106]

ANSD can be inherited as an autosomal recessive disease, now called *DFNB9* due to the mutation in the gene otoferlin, and presents with profound behavioural neural hearing loss.[107] A second autosomal recessive gene pejvakin has been identified as well which causes ANSD named as *DFNB59*.[108] This may respond to cochlear implants. Previously thought to be a condition involving only the auditory nerves after it has been formed, i.e. beyond the spiral ganglion level, it is now thought to extend to the IHC spiral ganglion synaptic junction and may include the IHC itself. It gets picked up by the newborn hearing screening programme but can affect adults also. The auditory sensitivity as measured by a pure-tone audiogram may be normal but the patient has significant processing problems or the sensitivity might be significantly decreased (e.g. up to severe hearing loss on the PTA). Aiding these patients is difficult as augmenting amplification at the cochlear level may not lead to any benefit in the nerve dysfunction, although it may improve some phase-locking; in addition, providing excessive amplification to a normal cochlea may

be damaging to the cochlea itself. The effect of implantation is also variable; however, theoretically, patients whose condition is limited to the inner ear (the IHCs or the IHC–spiral ganglion synaptic junction) have a better outcome than patients with the problem once the nerve is already formed.

Cochlear efferents

The cochlear efferent system consists of projections from both the lateral olive and the medial olivary complex which synapse mostly with type 1 spiral ganglion cells and type 2 spiral ganglion cells respectively and thus connect to both the IHCs and the OHCs.[109] The efferent fibres are carried by the inferior vestibular nerve and meet at the anastomosis of Oort through the saccular branch of the nerve to join up with the cochlear nerve.[110]

The ratio of efferent to afferent fibres in the OHC is 1:2 whereas those in the IHCs is 1:7,[111] suggesting that the biological amplifiers are the main substrates of efferent function which in turn inherently implies that the signal modulation is primarily a function of the OHC. The medial system innervates both ears while the lateral system supplies only the ipsilateral cochlea. Both project to the different parts of the ventral cochlear nucleus.

The cochlear efferents serve an important function by virtue of their modulation of inhibitory and excitatory neurotransmitter release in the cochlear processes thereby offering cochlear protection from loud noise. The activation of the efferent system modifies frequency-specific gain at the tonotopic BM by acting on the voltage-dependent OHC motility and attempts to linearize the signal with a damping effect.[109] Other functions include fine perception of the acoustic signal for localization, improving the signal-to-noise ratio and supporting adaptation and frequency selectivity. Their function may be compromised in acoustic trauma, ototoxicity, tinnitus and ANSD.[109] The medial olivocochlear bundle function can be measured by contralateral suppression of otoacoustic emissions.

KEY POINTS

- The pinna and EAC participate in localization of sound and, acting as a unit, contribute to add resonance to the incident sound which in turn aids in matching impedance encountered when sound travels from an air-filled medium in the middle ear to a fluid-filled medium in the cochlea.
- The middle ear by its mechanical processes contributes to match the impedance as described above.
- The cochlea receives the oncoming acoustic signal from the middle ear and a cochlear travelling wave is generated which traverses the BM of the cochlea stimulating cochlear OHC function which acts non-linearly as a biological amplifier/compressor and modifies the incident signal.
- The BM of the cochlea is highly frequency specific.
- The IHCs in the cochlea transduce the mechanical or kinetic energy of the OHC influenced cochlear travelling wave to an electric action potential and synapse at the spiral ganglion to form the auditory or cochlear nerve.
- The cochlea participates in frequency resolution, intensity discrimination and temporal ordering of incident sound.
- The auditory nerve phase locks and synchronizes with the IHCs and processing of sounds commence.
- The cochlear efferents originate from the brain to synapse with the cochlear hair cells regulating their function and help in localization and improving signal-noise ratio.

CHAPTER 49

PHYSIOLOGY OF EQUILIBRIUM

Floris L. Wuyts, Leen K. Maes and An Boudewyns

SEARCH STRATEGY

Data in this chapter may be updated a PubMed search using the keywords: vestibular system, vestibulo-ocular reflex (VOR), central pathways of VOR, hair cells and mechanoelectrical transduction.

ROLE OF THE VESTIBULAR SYSTEM

Introduction

Many physiological systems and functions have to be interpreted in view of survival of the species. The main function of the mammalian vestibular system is to generate information to the central nervous system with a fourfold purpose:

1. to ensure gaze stabilization
2. to enable balanced locomotion and body position
3. to provide general orientation of the body with respect to gravity
4. to readjust autonomic functions after body reorientation.

To achieve this, several input systems provide information to the brain, such as visual, vestibular and proprioceptive systems (**Figure 49.1**), but also other clues such as hearing are used, although these are of lesser importance.

Central processing of all this information in the brain leads to distinct outcomes:

- the vestibulo-ocular reflex (VOR) to ensure gaze stabilization
- the vestibulospinal (VSR) and vestibulocollic reflexes (VCR) to ensure maintenance of upright position of body and trunk and head stabilization in space
- orientation and, in higher species, navigation and the perception of self-position with respect to the surroundings and gravity mediated by the vestibular cortex
- autonomic function adjustments after alterations of body orientation.

This list of outcomes is certainly not restricted to these four tasks, since, for example, the vestibular system has recently been shown to influence the circadian rhythm,[1] and there are also connections with cognitive function.[2] Circadian influence is most likely due to direct projection of the vestibular nuclei to the Suprachiasmatic Nucleus (SCN). Hormonal connections are to be studied.

Although visual, vestibular and proprioceptive inputs are constantly processed by the brain, this information is heavily weighted by other factors, such as learning, memory, drugs, ageing, as well as environmental conditions. Additionally, the weight of the different inputs is constantly adjusted depending on the circumstances. It is obvious, for example, that when walking in darkness, balance cannot rely so heavily on vision and so reliance on the somatosensory and vestibular senses is increased. For optimal functioning in daily life, all systems are needed and there is little redundancy in the systems.

Motion decomposition and orientation in the head

Every motion in space can be broken down into three rotational degrees of freedom (yaw, pitch and roll) and three translational degrees of freedom (left–right, up–down, fore–aft). No event in one degree of freedom can

be described by the others, hence every movement is uniquely and appropriately described by a combination of all six degrees of freedom. The anatomical design of the motion sensors in the peripheral vestibular system in the inner ear reflects these six degrees of freedom. The semicircular canals (SCCs) measure predominantly rotations whereas the maculae of the utricle and saccule detect mainly translations.

The orientation of the vestibular system in the head is depicted in Figure 49.2. In a first approximation, one can model the left and right canals as parallel systems, i.e. the right anterior (RA) canal is parallel with the left posterior (LP) canal and both lie in a plane denoted as the RALP plane. Together with the right posterior (RP) canal the left anterior (LA) constitutes the LARP plane. Both horizontal canals are also parallel with each other in the lateral plane. The horizontal canal makes an angle of approximately 30° up with the horizontal axis of the upright head. The angles of the vertical canal are approximately 45° with the sagittal plane of the head. When studied in more detail, however, there exists a great variability of orientation within and between subjects.[3] In addition, the canals themselves are often quite curved, as seen in Figure 49.3.

Movement detection

Basic laws of physics are responsible for the detection of movement or orientation by the vestibular system. The first law of Newton states that 'objects in motion will stay in motion until acted upon by a force'. This force can change either the object's direction or speed. The second law states that a force (F) acting on an object equals mass (m) times acceleration (a) ($F = m \times a$). During daily life, body and head are continuously moving (even during each heartbeat, the head and body are shaking a little), and these movements are always related to forces, i.e. accelerations. These movements are sensed in the vestibular organ by a rigid coupling of sensory epithelium to the bony structure. Thus, a fluid-filled system is attached to the skull and the inertial forces drive the fluid. Motion of the fluid lags behind any motion of the head and this relative displacement is the trigger for movement detection. To limit the movement of the hair cells triggered by the accelerations that drive the head movements, the canal system is designed such that the deflection of the hair cells is proportional to the head velocity.

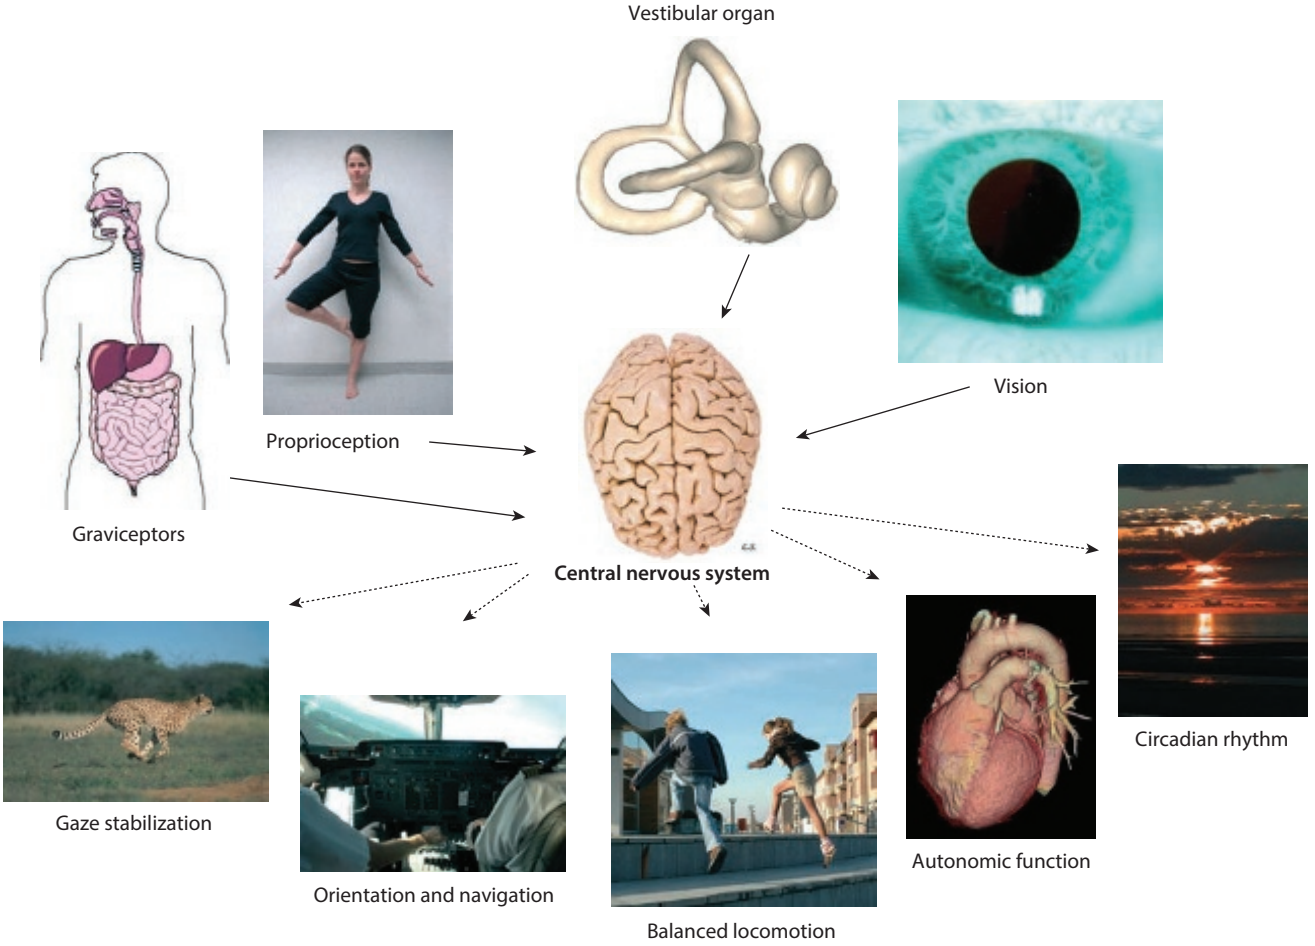

Figure 49.1 Basic input and output scheme of the vestibular system. Main inputs constitute vision, proprioception and information from graviceptors in the body and from the labyrinths. Outputs are gaze stabilization (needed for hunting and food tracking), balanced locomotion, perception of orientation in the surrounding world and autonomic function regulation after altered body position.

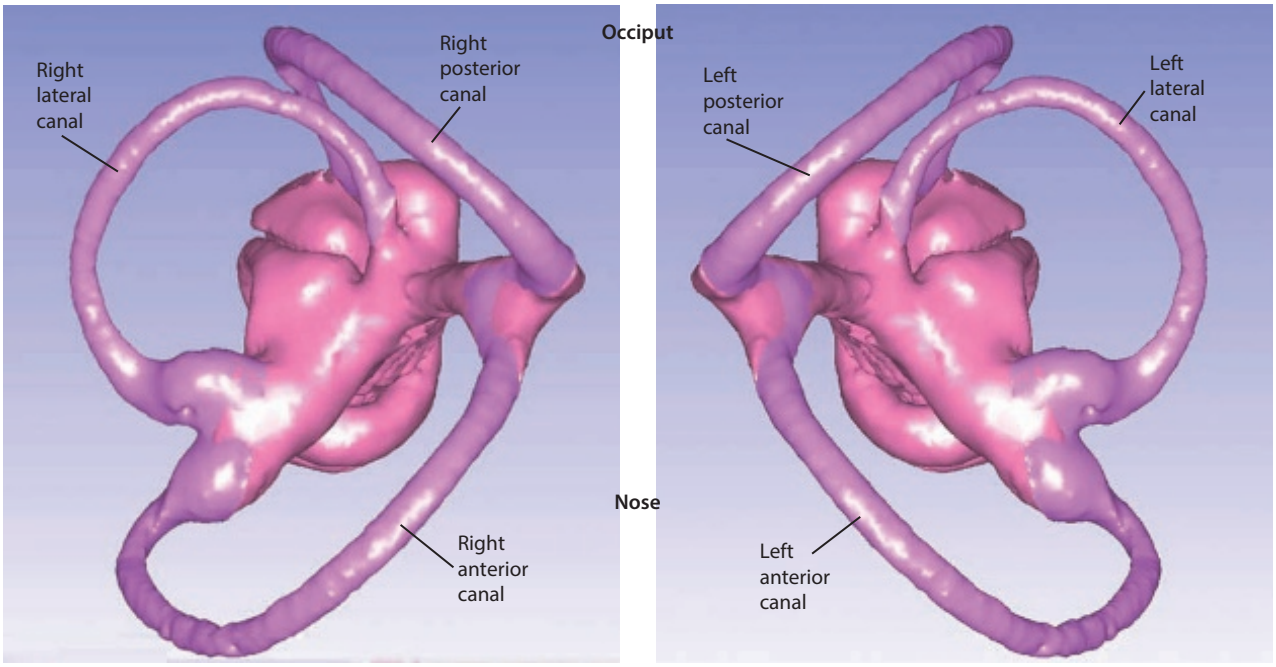

Figure 49.2 Top view of labyrinths as oriented in the human head. The labyrinths are of a gerbil.

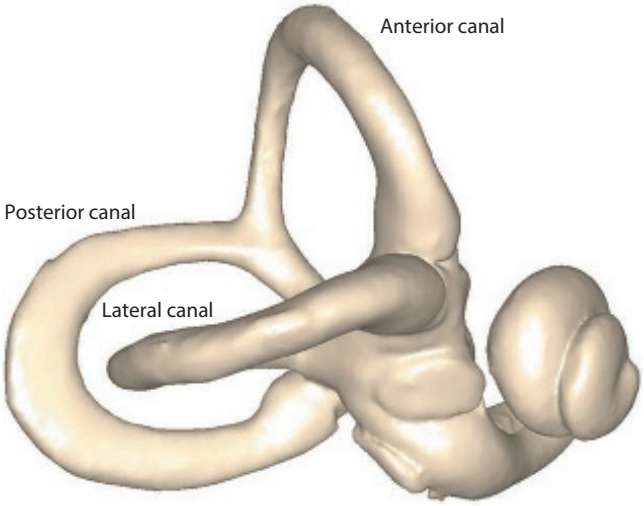

Figure 49.3 Side view of a right human labyrinth (labyrinth filled with resin and bone cut away). The nose is on the right side. The lateral canal makes, in general, an angle of 30° with the horizontal axis of the head.

OTOLITH ORGANS

On Earth, the gravitational force acts on us permanently, hence gravitational acceleration needs to be detected continuously. This is the role of the otolith organs. They additionally detect all linear accelerations. The otolith organs are designed such that they detect the accelerations and send encoded signals to the brain that processes this information. The otolith organs saccule and utricle are relatively orthogonally oriented to each other, with the utricle relatively horizontal and the saccule predominantly vertical (tangential in the head). Consequently, motion in the horizontal plane triggers predominantly the utricle, and vertical movements trigger mainly the saccule. Both organs are, however, quite curved so that any movement is in fact detected by both organs.

Thus, both the saccule and the utricle sense linear accelerations caused by translational movements of the head as well as static tilts of the head. This is enabled by an otolithic membrane, a gelatinous membrane stacked with otoconia (calcium carbonate crystals) characterized by a density about three times higher than that of the surrounding endolymph. Hair cells are embedded at the base of the gelatinous membrane, so that any movement of the membrane results in a deflection of the hair cells, which in turn codes for a signal to the brain. The working of the hair cell is explained under 'Vestibular sensory cells' below.

Einstein's equivalence principle states that no single physical device can distinguish gravity from linear acceleration. This poses a difficulty for the central nervous system, since the otoliths cannot differentiate between linear acceleration and tilt since only the deflection at the base of the hair cells is encoded and sent to the brain. This is illustrated in Figure 49.4. During natural movements (active or passive), the otolith organs sense the sum of all accelerations acting on the head and interpret these signals to initiate postural and eye reflexes mediated by the vestibular nuclei, diverting the appropriate signals either to limb, trunk and neck muscles via the vestibulospinal tract or to eye muscles via the VOR. The interplay of several senses at the same time (visual, vestibular and proprioceptive) enables the central nervous system to cope with the ambiguity of linear accelerations, enabling humans to distinguish tilt from linear translation under normal conditions. In darkness, however, when the system is relying on vestibular cues, Angelaki et al.[4] have shown evidence that an internal model of head orientation exists. This model is presumably constructed in the vestibulocerebellum

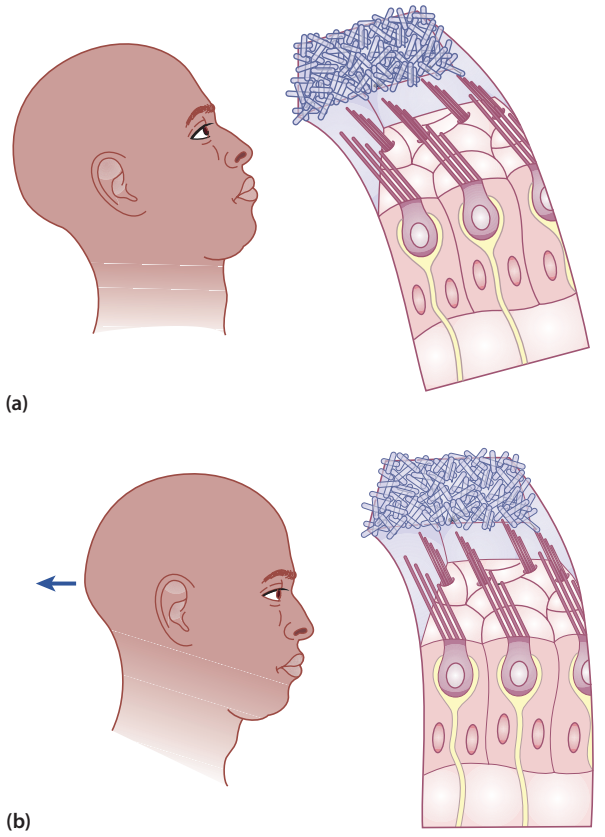

Figure 49.4 Deflection of the otoconial mass causes hair cell depolarization. This deflection is identical when the head is tilted backward **(a)** or when accelerating forward **(b)**.

(floculus and nodulus) and the vestibular nuclei, and it resolves the ambiguous gravitoinertial cues that are measured by the graviceptors, as well as with input from the SCCs. Both sets of information are used to help interpret ambiguous gravitoinertial cues. This implies that the signals from the otoliths and from the canals are not treated separately in the brain, and are continuously combined to optimize the VOR, as can be deduced from the fact that almost all partitions of the vestibular end organs overlap in most of the vestibular nuclei and project to several parts of the vestibulocerebellum.

SEMICIRCULAR CANALS

The moving endolymph in the SCCs is the key trigger for movement detection of the head. Natural movements of mammals consist dominantly of transient rotations, such as during back and forth movements of the head (e.g. nodding), or during walking and running. The SCC system is evolutionarily adapted for these movements. Whereas head accelerations trigger the sensory epithelium, the signal that is transmitted to the brain is proportional with the head velocity. Head accelerations can raise up to several thousands of degrees per second square, while head velocity is limited to several hundreds of degrees per second. Sustained velocity is no longer detected nor perceived after approximately 30 seconds.

Passive forms of motion, such as aeroplanes, merry-go-rounds, cars, rollercoasters or even spaceships, however, generate more intricate movements, and can readily introduce motion sickness since the vestibular apparatus is not adapted to this kind of motion.

The configuration of the SCC allows the movement of the endolymph only in the direction along the cylindrical canalicular cavity. When such a canal is rotated about an axis, three forces act upon the endolymph and cupula in the canal:

- the inertial force, proportional to the mass of the endolymph and cupula
- the elastic restoring force of the cupula that positions the cupula back to the centre position after stimulation
- the viscous forces that act upon the fluid when sliding past the internal wall of the tube. This viscous force is dependent on the speed of relative movement of the endolymph with respect to the wall.

The behaviour of the SCC, referred to as the pendulum model, is governed by the fact that any stimulus (head angular acceleration) provokes a number of reactions within the canal. These include movement of the fluid, determined by its inertial mass, together with its viscous drag along the wall and the restoring force pulling the cupula back to its resting position.

The cupular deflection can be described as a function of the applied stimulus to the head, purely based on physical laws, even without any interference of the central nervous system. The cupular deflection is ultimately the signal that is fed to the brain, because this deflection triggers hair cell depolarization or hyperpolarization. Therefore, it is important to know the specific behaviour of this endolymph–cupular system upon stimulation. Engineers typically approach this kind of system as a transfer function where a given input leads to a specific output. Gain and phase are two quantities that describe very appropriately the behaviour of such a system. Gain expresses the amount of output per input, and phase describes the time difference between output and input.

Given the very small size of the canal ($r \approx 0.15$ mm,[5] the inertial forces that act on the endolymph become very small with respect to the viscous forces that act upon the fluid. Although it is a quite watery substance, endolymph acts as a thick, viscous oil in the small dimensions of the canal. So, rather than being left behind due to its inertia, this fluid is dragged along the walls of the canal, and the relative displacement of the fluid with respect to the wall is of the order of a few microns for very fast head movements. Consequently, the viscous flow 'velocity' of the endolymph becomes proportional to the head's angular 'acceleration'. However, if this holds true for a system, then the flow displacement also becomes proportional to head velocity (after mathematically integrating for time). This is a very important finding, which implies that the message that is sent to the brain, initiated by a deflected cupula which is directly related to the fluid movement, is coding for the head angular velocity (and not its angular acceleration).

The time constant T1, determined by the viscosity and the mass of inertia of the endolymph yields approximately 0.003 s. This means that, when a sudden angular velocity is applied to the head, the cupula reaches 67%, i.e. $(1-e^{-1})$, of its ultimate deflection after just 3 ms. Translated to actual movements, this means that the cupula is deflected almost instantaneously upon movement of the head, signalling the amount of deflection to the brain, which is proportional to the head angular velocity. The design of the SCC enables it to function as an integrator, i.e. inertial force-driven acceleration is reduced to velocity. In normal conditions the head angular accelerations can be very high (in the range of 4–5000 degrees/s^2)[6] so that the time integrator from acceleration to speed limits the deflection of the cupula and presumably prevents it from large excursions that may damage the sensory epithelium.

Many dynamic systems are frequency dependent and yield functionally different kinds of information according to the frequency content of the input stimulus. The frequency region is determined by cut-off frequencies, denoted often by 1/T1 and 1/T2, with T1 and T2 being time constants of the system. Between these frequencies, 0.1–5 Hz, the canal–cupula system is characterized by an appropriate response in amplitude and phase. A gain equal to 1 implies that the output (cupular deflection) matches closely the input (head angular velocity). A phase close to zero indicates an instantaneous reaction. A bode plot (**Figure 49.5**) illustrates this behaviour.

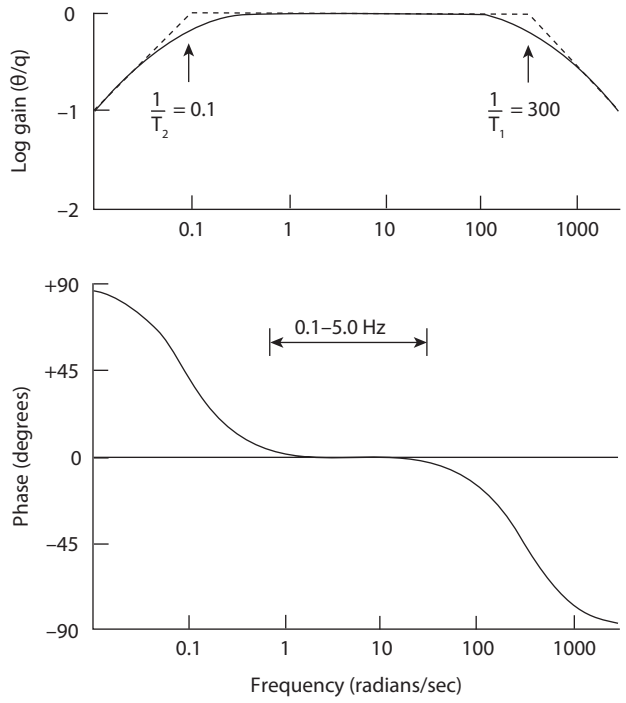

Figure 49.5 Bode plot representing the response of the SCC sinusoidal rotations. The optimal response consists of immediate and appropriate deflection of the cupula what is transmitted to the brain. This optimal situation is characterized by a gain of 1 (log gain = 0) and a phase of zero degrees. Between 0.1 Hz and 5 Hz, this optimal behaviour of the endolymph-filled SCC is achieved in humans, enabling gaze stabilization for these frequencies.

Below or above the frequencies 1/T2 and 1/T1, the gain is reduced and the phase lag is increased. For humans the typical frequencies of natural head movements during walking and running for yaw, pitch and roll are approximately between 0.5 Hz and 5 Hz.[7] Recent work by MacDougall and Moore[8] proves that the 'human resonant frequency for locomotion' is 2.00 Hz ± 0.03 Hz (mean ± s.e.) for vertical head movement, regardless of the activity (e.g. walking, riding a bike uphill, cleaning).

Velocity storage

The above description modelling the deflection angle of the cupula largely explains the behaviour of the vestibular system during laboratory testing, achieved with rotatory chairs. Typical stimulation patterns exist of sinusoidal rotations, usually around 0.05–0.1 Hz, although with more sophisticated equipment higher rotations up to 1 Hz can be achieved. Characteristic for sinusoidal rotations is that the angular velocity and acceleration are varied with sine and cosine functions, respectively. Also used are velocity step tests where a sudden acceleration rotates the subject at a constant velocity and then, after a plateau of constant speed, the chair is suddenly stopped (a ramp test). A variation of this is the test where the speed is gradually increased by applying a constant yet slow acceleration (e.g. 5 degrees/s^2) for 40 seconds to reach a speed of 200 degrees/s, followed by a plateau during which the nystagmus fades away, and then suddenly the chair is stopped.

The SCC system is not designed for sustained rotations, and even rotating at relatively high but constant speeds (> 200 degrees/s) is not sensed by the SCC after approximately 30 seconds. Only the acceleration or deceleration phase is detected. During constant speed rotations, elastic forces pull the cupula again into its centre position. However, after sudden cessation of the rotation (e.g. with a deceleration of 400 degrees/s^2), the endolymph continues to move within the SCC and a nystagmus in the opposite direction becomes evident for another 20–30 seconds. The subject has the impression of being spun around in the opposite direction. After a longer time the nystagmus fades away and may reappear again in the initial direction (post-rotatory nystagmus). Based on mathematical principles and physiological measurements, the time constant during which the cupula repositions itself is determined as approximately 5–7 seconds, which implies that the cupula is almost entirely restored to its central position after 12 seconds. This gradual decrease in cupular deviation results in a decrease in firing rate of the vestibular neurons to the brain, suggesting erroneously a progressively lower head velocity. The fact that the nystagmus outlasts this mechanical phenomenon is due to the so-called 'velocity storage mechanism' (VSM)[9] which is a neurophysiological process, taking place mainly in the nucleus prepositus hypoglossus and the adjacent medial vestibular nucleus. The VSM serves to maintain the VOR at low frequencies (below about 0.02 Hz). The VSM uses principally the peripheral labyrinthine signal and by a process of integration, in the mathematical sense, increases the frequency

response of the VOR, by prolonging the time constant (originally 7 seconds) of the decay of the vestibular nystagmus to approximately 20 seconds. This circuitry is therefore a mechanism that stores neural activity related to head and eye velocity and discharges it over its own time course.

In conditions where visual information of the surrounding rotating world is present during sustained rotations, the optokinetic reflex comes into play and, although slower in response, this takes over the fading performance of the vestibular system. The transition between both reflexes is facilitated by the VSM. Indeed, the VSM not only regulates the dynamics of the VOR but also accounts for optokinetic (after) nystagmus (OKN), i.e. the reflexive eye movements that are induced by a moving background (e.g. while looking outside the window of a moving train). The VSM coordinates these two oculomotor responses that are related to self-motion. Whereas the VOR shows high-frequency behaviour, the OKN reflects low-frequency characteristics. Matching of their time constants in the brain assures smooth transition from the quick-onset vestibular response into the slow-onset optokinetic response. Together, the VOR initially and the OKN subsequently, matched and fine-tuned by the VSM, ensure gaze stabilization.

Interestingly, the time constant of velocity storage is influenced by static inputs from the otoliths. It can be reduced considerably when the head is suddenly tilted (tilt dumping) just after the velocity step, and it is shorter during off-vertical axis rotations.[10–11]

Vestibulo-ocular reflex

The peripheral sensors transmit motion to the brain through frequency encoding. Similar to FM radios, the brain continually receives 'frequency-modulated' signals. A normal resting discharge rate of approximately 90 spikes per second (recorded in the squirrel monkey vestibular nerve)[12] is modulated such that increase of this rate corresponds with an excitation and decrease with inhibition.

The left and right SCCs are oriented in the head such that any movement always induces an antagonistic response in both canals. For example, consider horizontal head movements occurring in the yaw plane. During rightward head rotation, the endolymph in the lateral SCCs on both sides lags behind, bending the cupula of the right SCC towards the vestibulum (ampullo- or utriculopetal) whereas simultaneously the cupula of the left SCC is deflected away from the vestibulum (ampullo- or utriculofugal). A key difference is the polarization of the hair cells. Indeed, since the implantation of the hair cells is opposite for both right and left canals as a mirror image, the deflection on the 'leading' right side induces a movement of the stereocilia towards the kinocilium, whereas on the opposite 'following' ear the movement of the stereocilia is away from the kinocilium. Consequently, the activity of right lateral SCC primary afferent neurons increases, while at the same time the activity of left lateral SCC primary neurons decreases with respect to the normal resting discharge rate. This is called the push–pull principle of the VOR.

The right medial vestibular nucleus in the brainstem receives an increased input from the right lateral SCC primary neurons (no crossing), which excites the activity of type 1 position vestibular pause (PVP) secondary vestibular neurons. These excitatory neurons drive the leftward compensatory eye movements of the VOR, to ensure gaze stabilization. However, commissural disinhibition from the left lateral SCC primary neurons also contributes to the excitation of the PVP neurons. Therefore, both the excitation of the right SCC and the disinhibition of the left SCC are needed for an optimal VOR. In first approximation, the VOR process is a three-arc neuron reflex (first-order vestibular neurons, second-order vestibular neurons and oculomotor plant neurons) as depicted in **Figure 49.6**.

The simplified principle of VOR generation (yaw-plane rotation and horizontal SCC) is as follows:

1. During head rest, hair cells in both SCCs have a resting discharge rate of 90 spikes per second.
2. Head rotation is to the right.
3. Endolymph fluid lags behind, i.e. moves relative to the left within each SCC due to inertia.
4. The cupula bends to the left in each canal.
5. In the (leading) right SCC the stereocilia bend towards the kinocilium.
6. In the (following) left SCC the stereocilia bend away from the kinocilium.
7. The discharge rate increases in the leading right ear (e.g. from 90 to 300 spikes per second).
8. The discharge rate decreases in the following left ear (e.g. from 90 to 20 spikes per second).
9. The vestibular nuclei interpret the difference in discharge rates between left and right SCCs as movement to the right, and therefore trigger the oculomotor nuclei to drive the eyes to the left to maintain gaze stabilization.

Similar to the horizontal canal, a push–pull principle also governs the vertical canal excitatory and inhibitory functions. For example, the left anterior canal is excited while the right posterior canal is inhibited for the same movement. Also, the vertical canals are direction-sensitive, but at this stage ampullopetal movement results in a decreased firing rate. Thus, the ampullar deflection in the vertical canals, corresponding to excitation, is in the opposite direction to the horizontal SCC. For the horizontal canal, excitation is elicited upon ampullopetal endolymph movement (towards the vestibulum–utricle) whereas for both the vertical posterior and anterior SCC ampullopetal flow is inhibitory.

The horizontal canal is involved in pitch movements to only a small extent. The inclination of the vertical canals is more than 90° to the horizontal so that horizontal movements are always detected also by the vertical canals. However, given the antagonistic response of the anterior and posterior SCC on each side, horizontal head movements produce primarily horizontal eye movements.

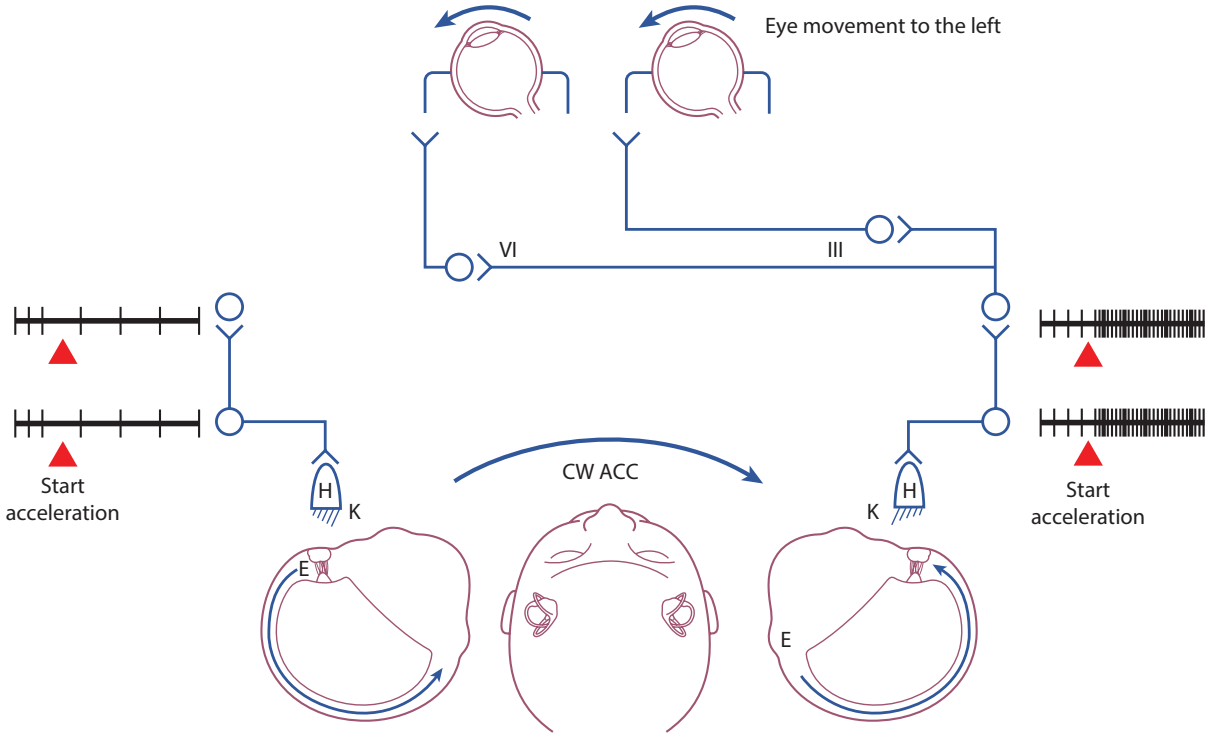

Figure 49.6 Three-arc neuron representation of the VOR. Upon head rotation to the right (CW ACC, clockwise acceleration), the hair cells on the 'leading ear' side are excited and increase their discharge rate, whereas the hair cells on the following ear are inhibited, thereby decreasing the discharge rate. The vestibular nuclei encode the increased discharge rate and redirect the excitation to the ipsilateral ocumolotor nuclei to contract the medial rectus of the right eye, while the contralateral abducens nucleus is triggered generating a contraction of the contralateral lateral rectus. Consequently, the eyes are driven to the left to compensate for the head movement to the right. This is the essence of the VOR. However, only the excitatory pathway is represented here; the actual VOR is much more complex. (E, endolymph; H, hair cell; K, kinocilium; III, oculomotor nucleus; VI, abducens nucleus)

The SCCs and the otolith organs provide the inputs for the VOR. Horizontal VOR compensates for both horizontal rotation and horizontal translation. The former is due to the canal system where the latter due to the utricular system. It is therefore more convenient to use the angular VOR (aVOR) and linear VOR (lVOR). A third type of VOR, the ocular counter-rolling, is provided by the otoliths as a response to, for example, tilting of the head with respect to gravity or a stimulus that results in a shift of the gravito-inertial acceleration (the sum of an acceleration in any direction and gravity).

There are three types of rotationally induced eye movements: horizontal, vertical and torsional. Each of the six pairs of eye muscles must be controlled to produce the desired response. The vertical SCCs and the saccule are responsible for controlling vertical eye movements, whereas the horizontal canals and the utricle control horizontal eye movements. Torsional eye movements are controlled by the vertical SCCs and the utricle.

Stimulation of a single canal results in eye movements that lie in the plane of the canals. To understand the generation of the different eye movements, it is necessary to analyze the stimulation of individual canals and their effect on the eye muscles. Table 49.1 gives an overview of the active and passive eye muscles for each stimulated canal.

TABLE 49.1 Schematic canal stimulation and concomitant eye muscle contraction and relaxation

Canal stimulation	Contracted eye muscle	Relaxed eye muscle
Lateral SCC	Ipsimedial rectus	Ipsilateral rectus
	Contralateral rectus	Contramedial rectus
Anterior SCC	Ipsisuperior rectus	Ipsi-inferior rectus
	Contrainferior oblique	Contrasuperior oblique
Posterior SCC	Ipsisuperior oblique	Ipsi-inferior oblique
	Contrainferior rectus	Contrasuperior rectus

Figures 49.7 to 49.11 represent the effects of single or multiple canal stimulation on the eye muscles and consequently which type of compensatory eye movement is generated.

Figure 49.7 and Figure 49.8 illustrate the stimulation of the anterior and posterior canals. Every stimulation in whichever direction always evokes the push–pull principle. When the head is tilted sidewards (Figure 49.9), a torsional nystagmus is generated, as both posterior and anterior canals are stimulated. When the head is pitched forward (Figure 49.10), both left and right anterior canals are

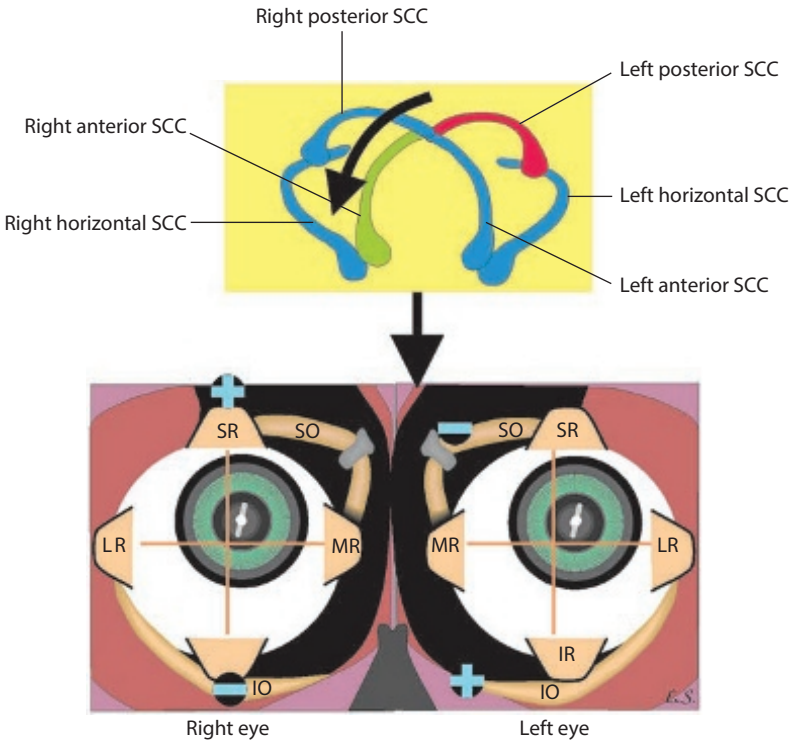

Figure 49.7 Stimulation of the right anterior SCC while the left posterior canal is inhibited occurs during a head movement in the right anterior—left posterior (RALP) SCC plane, i.e. turn the head 45° to the right and move the head downward in that plane. This generates a counterclockwise movement of the eyes (seen from the examiner's view), together with an elevation. The right superior rectus (SR) muscle and the left inferior oblique (IO) muscle are contracted. The right inferior rectus (IR) muscle and the left superior (SO) muscle are inhibited. +, excitation; -, inhibition; LR, lateral rectus muscle; MR, medial rectus muscle. The black arrows show the direction of movement of the head.

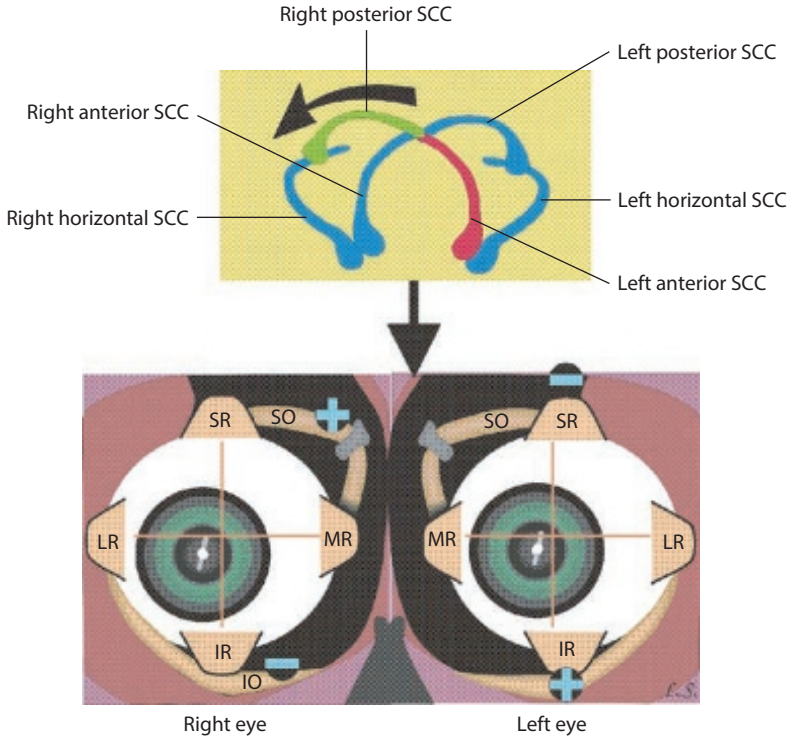

Figure 49.8 Stimulation of the right posterior SCC while the left anterior canal is inhibited occurs during a head movement in the left anterior–right posterior (LARP) SCC plane, i.e. turn the head 45° to the left and move the head upward in that plane. This generates a counterclockwise movement of the eyes (seen from the examiner's view), together with a depression of the eye. The right superior oblique (SO) muscle and left inferior rectus (IR) muscle are contracting, while the right inferior oblique (IO) muscle and the left superior rectus (SR) muscle are relaxing. +, excitation; -, inhibition; LR, lateral rectus muscle; MR, medial rectus muscle. The black arrows show the direction of movement of the head.

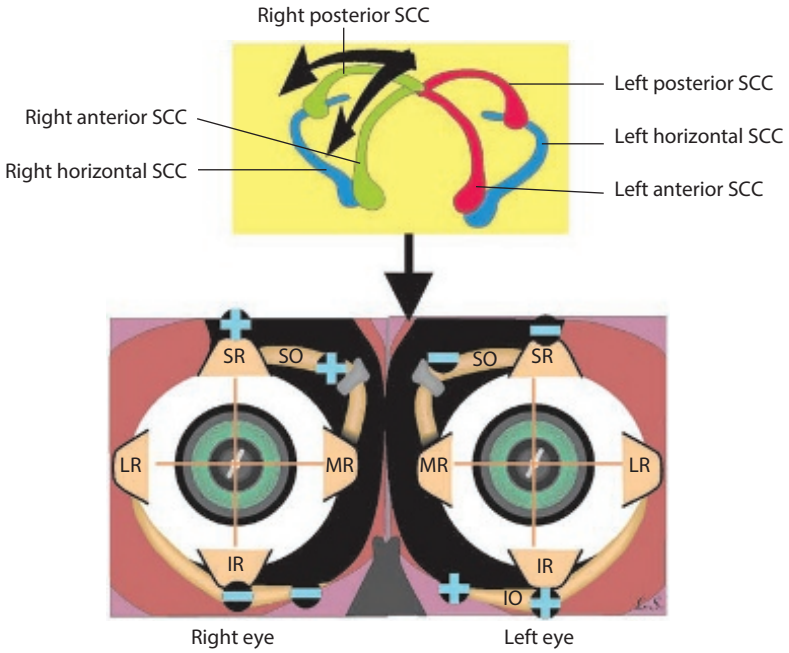

Figure 49.9 Stimulation of the right posterior and right anterior SCCs while the left anterior and left posterior canals are inhibited occurs during a rightward sideways tilting of the head towards the shoulder. This generates a counterclockwise movement of the eyes (seen from the examiner's view). The right superior rectus (SR) muscle and superior oblique (SO) muscle, as well as the left inferior oblique (IO) muscle and inferior rectus (SR) muscle, are contracting while the right inferior rectus (IR) muscle and inferior oblique (IO) muscle and the left superior rectus (SR) muscle and superior oblique (SO) muscle are relaxing. The elevation and depression cancel out and a pure counterclockwise torsional nystagmus is generated. This suggests why during a unilateral lesion, such as a vestibular neuritis that affects the whole peripheral vestibular system, there is never a vertical nystagmus, but only a torsional and a horizontal (not depicted here). Spontaneous vertical nystagmus is therefore almost always due to a central neurological pathology. The black arrows show the direction of movement of the head. LR, lateral rectus muscle; MR, medial rectus muscle.

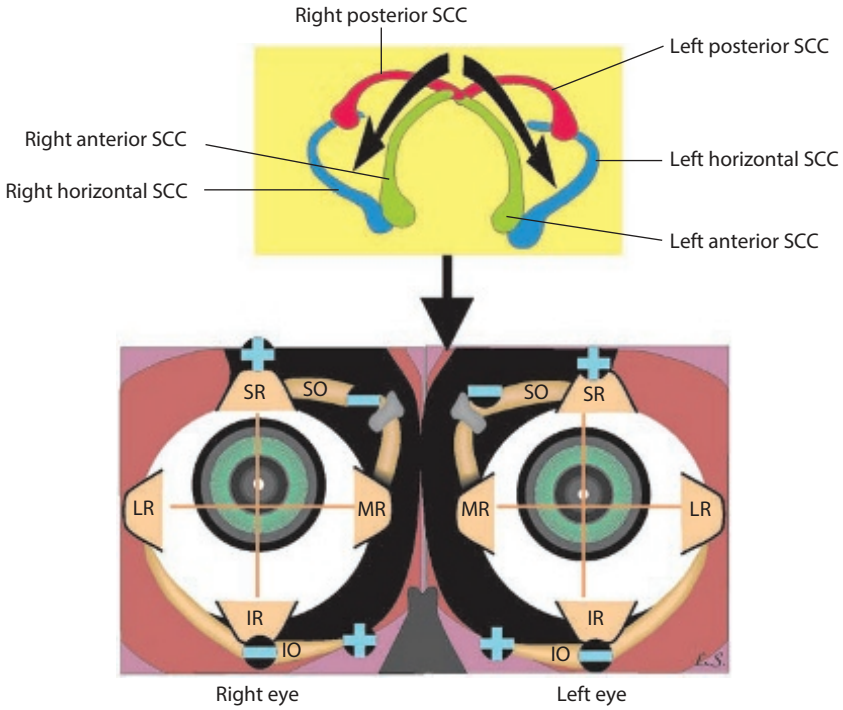

Figure 49.10 Stimulation of the right anterior and left anterior SCCs while the right posterior and left posterior canals are inhibited occurs during a forward bending of the head. This generates an elevation of the eyes or a downbeat nystagmus, depending on the amplitude and speed of bending the head. The right superior rectus (SR) muscle and inferior oblique (IO) muscle, as well as the left inferior oblique (IO) muscle and superior rectus (SR) muscle, are contracting while the right inferior rectus (IR) muscle and superior oblique (SO) muscle and the left superior oblique (SO) muscle and inferior rectus (IR) muscle are relaxing. Given the activity of these muscles, any torsional components are cancelled out. The black arrows show the direction of movement of the head. LR, lateral rectus muscle; MR, medial rectus muscle.

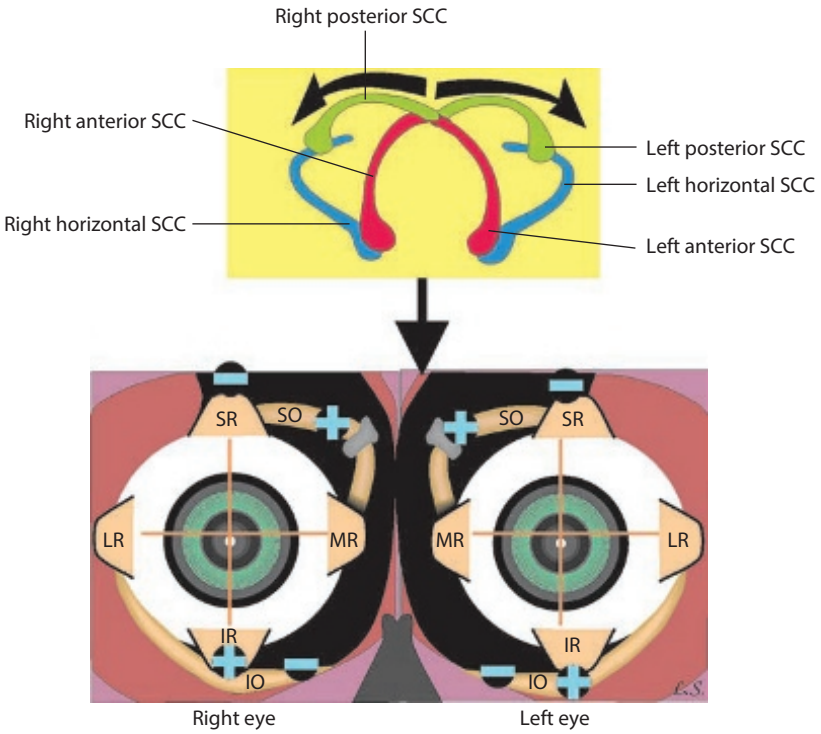

Figure 49.11 Stimulation of the right posterior and left posterior SCCs while the right anterior and left anterior canals are inhibited occurs during a backward bending of the head. This generates a depression of the eyes or an upbeat nystagmus, depending on the amplitude and speed of bending the head backwards. The right inferior rectus (IR) muscle and superior oblique (SO) muscle, as well as the left superior oblique (SO) muscle and inferior rectus (IR) muscle, are contracting while the right superior rectus (SR) muscle and inferior oblique (IO) muscle and the left superior rectus (SR) muscle and inferior oblique (IO) muscle are relaxing. Given the activity of these muscles, any torsional components are cancelled out and a pure vertical nystagmus remains. The black arrows show the direction of movement of the head. LR, lateral rectus muscle; MR, medial rectus muscle.

stimulated, whereas both posterior canals are inhibited. This produces an upward eye movement. Each anterior canal also produces an ocular counter-rolling movement, but as both are in different directions, the counter-rolling is cancelled out. The same applies when the head is tilted backwards (Figure 49.11), but now both posterior canals are stimulated producing a downward compensatory eye movement.

For the horizontal canal stimulation, a more detailed neurological pathway is explained later in this chapter.

Nystagmus

The eye response to a head rotation consists of a combination of a slow phase or drift until the eye reaches the edge of the outer canthus, and a fast phase to reset the eye in its initial position. This pattern repeats itself as long as the head rotation lasts. This saw-tooth pattern is called nystagmus (Figure 49.12). The direction of the nystagmus is defined by the fast reset phase, since that is easiest identified by the clinician. The slow phase, however, represents the actual vestibular output and is quantified. An upward excursion, by convention on electronystagmography or video-nystagmography, represents eye deviation to the right. If the slope of the sawtooth is upward to the right, i.e. a positive slope, this corresponds to a slow drift of the eye to the right, followed by a quick leftward reset saccade, as represented by a steep downward trace. This is defined as a left nystagmus. It is quantified by measurement of the slope of the upward trace, which indicates the speed of the eye movement (degrees/s).

Figure 49.12 Typical pattern of nystagmus to the left. This trace represents the eye movement amplitude in degrees (vertical) as a function of time in seconds (horizontal). Upward deflection denotes rightward eye movement. The trace indicates a series of slow eye deviations to the right (upward) followed by fast beat to the left (downward). This typical behaviour of slow movement followed by a fast reset movement is called nystagmus. Although the slow phase is the vestibular partition of the movement, by convention the nystagmus is called after the direction of the fast beat, since clinically this is more easily discernible. The slope of the slow component represents the velocity that characterizes the VOR.

NYSTAGMUS INDUCED BY ACUTE UNILATERAL DEAFFERENTIATION

The push–pull principle is very convenient to explain the origin of the nystagmus observed during acute peripheral lesions. In the case of an acute unilateral vestibular

deafferentiation (uVD) on, for example, the right side, all three right canals and the otoliths cease spontaneous activity (from 90 spikes per second to zero), while the spontaneous activity of the left SCC remains at 90 spikes per second. Although the head is not moving, the brain perceives an apparent imbalance (R: 0 spikes/second versus L: 90 spikes/second) similar to, for example, when the left system is triggered during head movements towards the left. This tonic imbalance drives the vestibular and, consecutively, the ocular motor nuclei to move the eyes towards the right, as would be appropriate for a head movement towards the healthy side (left).

The brain erroneously interprets the abruptly decreased or absent firing rate of the ipsilateral-affected peripheral system as a relative increase of the contralateral system, resulting in a nystagmus that beats away from the acute lesion.

Additionally, the combination of muscle contraction and relaxation generates not only a pure horizontal nystagmus but also a torsional nystagmus. Indeed, when all the canals are lesioned on the right side, this is interpreted by the brain as a sudden excitation of the contralateral vestibular system, which generates a contraction of the left eye medial rectus, superior rectus and superior oblique muscles. Eye movements may be considered as additive and so, although both superior muscles are on the upper surface of the eye, they have an opposite effect on the eye movement, cancelling any vertical movement. Consider the right eye, activation of the superior rectus results in an elevation, adduction and intorsion, whereas the superior oblique generates a depression, abduction and again an intorsion. When all muscles contract simultaneously, as is the case upon stimulation of all three canals on the same side, the elevation and depression cancel out, as does the abduction and adduction. The torsional movement remains, as well as a horizontal nystagmus due to the contraction of the medial rectus of the left eye (and the lateral rectus of the right eye).

For a left uVD, the torsional nystagmus is counterclockwise (CCW) (from the examiner's perspective) in combination with a horizontal nystagmus beating to the right, whereas a clockwise (CW) and leftward nystagmus is seen for a right-sided uVD. A torsional and horizontal nystagmus is the clinical sign indicating an acute whole labyrinthine deficiency. Conversely, a pure vertical nystagmus is very unlikely to be produced by an acute labyrinthine lesion, and the clinician should in that case firstly consider a central neurological lesion rather than a peripheral vestibular lesion. The sudden onset of this nystagmus is associated with vertigo and disorientation, since the absence of real movement constitutes a conflict between vision, proprioception and the vestibular system.

Vestibulocollic and vestibulospinal reflexes

When they are walking, pigeons move their heads backwards and forwards. This head movement is actually a head nystagmus, meant for gaze stabilization and controlled in an exactly similar manner to the VOR in higher species. In rabbits, however, both eye and head nystagmus are equally present, whereas in the primate eye nystagmus predominates.

The extraocular muscles are the effector organs for the VOR, while the extensor muscles of neck, trunk, arms and limbs are those for the vestibulocollic (VCR) and vestibulospinal reflex (VSR). Similar to the VOR, the same push–pull mechanisms are used for controlling the balance between extensor and flexor muscles.

It is obvious that any change in movement, detected by the vestibular organ, is compensated by a series of contractions and relaxations of several muscles. Since the freedom of motion of the body is much larger than that of the eye, a multitude of muscles are involved in the reaction chain to maintain upright position and stability.

These reflexes are mediated through projections of the vestibular nuclei on to the medial and lateral vestibulospinal tract. These pathways project to the lower limb and neck muscles to maintain an upright position and balanced locomotion. The driving input here is mainly gravity detected by the otolith system. However, proprioceptive and visual information is also necessary to provide the correct body position, given the fact that gravity is only detected in the head, regardless of the position of the trunk and lower body.

Cervico-ocular reflex

In some cases, when the head is fixed but the body is rotated, nystagmus may be observed. This reflex is based on the stimulation of neck receptors, rather than vestibular receptors. However, in humans, this reflex is very unreliable and unpredictable. Only in subjects with, for example, congenital peripheral vestibular loss does this alternative strategy for gaze stabilization become more robust. According to a review by Brandt,[13] the clinical significance of lesions involving the cervico-ocular reflex (COR) are debatable. The fact that voluntary eye movements interfere with the reflex eye movements makes objective measurements very questionable.

Vestibulosympathetic reflex

Moving from a supine to a standing position generates a substantial orthostatic stress on the body, inducing a pooling of blood of approximately 800 mL in the lower limbs and the abdomen. Maintenance of the supply of blood to the brain and other vital organs (orthostatic tolerance) requires the activation of sympathetic outflow in response to such changes in posture, generating increases in heart rate and vascular tone that maintain blood pressure and prevent pooling of blood in the lower body. The otoliths have recently been shown to participate in mediating a vestibulosympathetic reflex that could help maintain orthostatic tolerance when upright.[14–16] The baroreflex is a negative feedback response that buffers short-term changes in blood pressure, with a latency (1.4 s) that, among other factors, depends on the response to pooling of fluid in the legs. The vestibulosympathetic reflex

has a shorter latency (0.4 s) that could provide earlier feed forward excitation to maintain orthostatic tolerance.[14] In addition, recent studies have described an otolith-sympathetic reflex that acts to increase vasoconstriction during nose-up linear acceleration,[14, 16] which may be a short latency mechanism to sustain blood pressure upon standing.

Besides this reflexive sensorimotor control of gaze and balance at the level of the brainstem and cerebellum, the vestibular system is also responsible for the perception of self-motion and sensorimotor control of voluntary movements and balance which are regulated at the cortical/subcortical level. Another important function of the vestibular system is the processing of higher cognitive vestibular functions such as spatial memory, orientation and navigation, where the hippocampus and parahippocampus play an important role.[17]

Vestibular cortex

The insular cortex is a part of the cerebral cortex folded deep within the lateral sulcus and is believed to have a main role in the processing of vestibular signals.[48, 49] Moreover, a predominant role of the right hemisphere in the cortical processing of vestibular afferents has also been proven in the meta-analysis by zu Eulenburg et al.[47] More specifically, zu Eulenburg et al. suggest that operculum parietale 2, a histological defined part of the human parietal operculum in the right hemisphere, is the core region of the human vestibular cortex and possibly processes only vestibular information instead of multisensory input. Recently, changes in the vestibular cortex have been shown in an astronaut returning from space.[50] Space is a unique lab to investigate the effect of unusual physiological stimuli on the human body such as weightlessness. These preliminary findings corroborate the concept of neuroplasticity and may guide further research to find possible causes in the brain of vestibular disorders such as visual vestibular mismatch among others. Until recently, many vestibular dysfunctions were traditionally attributed to peripheral vestibular lesions, but the brain will become more and more important in vestibular physiology.

CENTRAL PROJECTIONS OF THE PERIPHERAL VESTIBULAR SYSTEM

Any movement is detected by several parts of both left and right vestibular organs, and the results converge in the vestibular nuclei after being passed through the ganglion of Scarpa. The different canals and otolith maculae project to different portions of the vestibular nuclei from where they trigger other brain centres so as to maintain gaze stabilization, as well as body stabilization.

Projections to the central nuclei

The vestibular nerve consists of a superior and inferior branch. Afferents coming from the horizontal and anterior canals, as well as from the utricular macula and anterosuperior region of the saccular macula, form the superior vestibular nerve, whereas the inferior vestibular branch contains fibres coming from the posterior canal and the saccular macula. The relative position of these vestibular afferents changes as the vestibular nerve approaches the brain. Fibres coming from the three SCCs are situated at the anterior side of the vestibular nerve, whereas saccular and utricular branches come together at the ventroposterior margin of the vestibular nerve.[18] This knowledge is important for interpreting clinical vestibular tests, i.e. caloric and rotary tests evaluate the horizontal SCCs and thus the superior branch of the vestibular nerve, while the collic vestibular-evoked myogenic potential (cVEMP) test evaluates the saccule and thus the inferior branch.

These vestibular primary afferents mainly project to the vestibular nuclear complex in the pontomedullary region of the brainstem and the cerebellum, with the highest projections to the nodulus and uvula. In the brainstem four classical vestibular nuclei (VN) have been identified: the superior (SVN), lateral (LVN), medial (MVN) and descending vestibular nuclei (DVN). In addition, several small cell groups lie at the periphery of this vestibular complex and also receive vestibular primary afferents. These include, among others, the y-group, the interstitial nucleus of the vestibular nerve (INT8), the parasolitary nucleus (Psol), and the nucleus intercalates.[18–19] Canal and otolith afferents enter the vestibular nuclear complex at the level of the LVN and rostral DVN, and thereafter divide into ascending and descending pathways. The ascending branch mainly projects to the SVN and further on to the cerebellum, whereas the descending branch of all primary vestibular afferents innervates the central region of the vestibular nuclear complex.[18]

Topography within the vestibular complex exists, but it does not conform to the cytoarchitecturally defined boundaries.[19] Several studies have tried to unravel the existence of a topographical map of the single end organ partitions, which confirmed large inconsistencies dependent on the type of test animals and the type of examination technique used.[18, 20–26] This confusion about the topography is not surprising since VN are not simple relay nuclei passing along sensory information to other parts of the brain, but include a mix of complex intrinsic and projection neurons which are responsible for spatial transformation and sensory integration of the incoming head movement signals.[26] In general, it can be concluded that most peripheral systems project to the larger part of all the VN. In early reports[22, 24] common patterns in the central projection of vestibular afferent fibres have been demonstrated, with projections from the canals being prominent in the rostral part of the VN (horizontal and anterior SCC project laterally and posterior SCC medially) whereas otolith fibres terminate more caudally. More recent reports seem to agree more or less on the following findings: the SCCs project to all four VN, with the most heavy projection to the MVN and SVN. Saccular afferents project strongly to the DVN, the INT8, and the y-group, and weakly to the other VN, whereas the utricle mainly projects to the lateral and dorsal portions

of the MVN, the ventral and lateral portions of the SVN and the rostral portion of the DVN.[18, 23, 26]

Besides input from the primary vestibular afferents, non-vestibular systems such as the optokinetic system, the neck-proprioceptive system and the cerebellar Purkinje cells also project to the vestibular nuclear complex,[19] affecting the processing of vestibular signals.

Within the vestibular brainstem nuclei there are commissural projections, which centrally reinforce the differential detection of vestibular signals by commissural inhibition. For signals coming from the SCC, these commissural projections allow push–pull reactions in the VOR, by interconnecting vestibular neurons with bilateral coplanar SCC-related signals. A similar organization exists for the utricular commissural connections, based on spatially aligned bilateral utricular epithelial sectors.[27] This commissural inhibition results in a central amplification which is essential for the detection of small angular and linear head accelerations, and for the prolongation of the dominant time constant of the VOR which is regulated by the VSM.[23, 27–28] In the saccular system this commissural inhibition is present to a lesser extent; however, cross-striolar inhibition enhances here the sensitivity to linear acceleration.[28] This amplification mechanism is based on the fact that neurons in the VN are typically excited monosynaptically by unilateral afferents from the striola of the saccule, whereas they are inhibited disynaptically by afferents from the other side.[28]

From the vestibular nuclear complex, second-order vestibular neurons project to different pathways. These neurons contribute to the control of balance by influencing the discharge of motor and pre-motor neurons. For the **vestibulo-ocular pathways**, the central and dorsal regions of the SVN, the MVN and ventral part of the LVN, as well as the dorsal division of the y-group project heavily to the oculomotor nuclei by means of the medial longitudinal fascicle (MLF) and the ascending tract of Deiters (ATD).[23, 26] The most important **vestibulo-spinal pathways** are the lateral vestibulospinal tract (LVST) and medial vestibulospinal tract (MVST), as well as the lateral and medial reticulospinal tracts (LRST and MRST). Vestibulospinal pathways originate from a wide area in the vestibular nuclear complex including MVN, LVN and DVN.[18] **Vestibulocerebellar pathways** contain neurons coming from all parts of the vestibular nuclear complex, and mainly project to the cerebellar flocculus, paraflocculus, nodulus and uvula.[23] Next, there are also projections found to the nucleus prepositus hypoglossus (NPH), nucleus tractus solitarius, parabrachial nucleus, medullary autonomic centres, the thalamus and even further cortical into the parietoinsular vestibular cortex (PIVC).[18, 23, 29] Most of these projections are beyond the scope of this chapter, but it should be kept in mind that mainly the vestibulocerebellum plays a dominant role in the fine-tuning of the vestibular functions, by adapting and readjusting central vestibular processing if necessary.

A detailed neurological pathway of the horizontal canal stimulation will be explained below.

Two types of neurons have been traced in the MVN, triggered by the lateral SCC input, namely type 1 and type 2 neurons. Their resting discharge rates are approximately 80–90 spikes per seconds. This relatively low resting discharge rate implies that, under specific high accelerations, the discharge rate is blocked to 0 spikes/s. Increased rates, however, can exceed 300 spikes/s. This intrinsic asymmetry is responsible for a limited VOR at higher frequencies when lesions occur. Some type 1 neurons are excitatory (the PVP neurons) and some are inhibitory. Primary vestibular afferents synapse with inhibitory as well as excitatory type 1 neurons (**Figure 49.13**).

Excitatory pathways

Upon head rotation to one side (**Figure 49.14**), denoted as the ipsilateral side, the ampulla of the ipsilateral horizontal canal is stimulated followed by an immediate increase in firing rate of the neurons, proportional to the velocity of the head turn. These signals project mainly on to the ipsilateral MVN, but other parts of the VN are also involved. From there, axons decussate onto the contralateral abducens nucleus which innervates the lateral rectus of the contralateral eye through the VIth nucleus. Additionally, the interneurons of the contralateral abducens nucleus project through the longitudinal medial fasciculus to the ipsilateral medial rectus subnucleus in the oculomotor nucleus (III) that activates the medial rectus muscle of the ipsilateral eye.

There is also an accessory pathway that originates from projections of the ipsilateral horizontal canal ampulla on to the ipsilateral magnocellular part of the MVN (formerly denoted as the ventral lateral vestibular nucleus).[26, 30] From there, increased activity is transmitted via the ATD onto the medial rectus subnucleus of the ipsilateral oculomotor nucleus, activating the medial rectus muscle of the ipsilateral eye. This drives both eyes to rotate towards the side opposite to the direction of the head to stabilize the image on the retina.

It is important to realize that this is not a strict parallel circuit. Although the ipsilateral medial rectus and the contralateral lateral rectus muscles contract simultaneously, the signals coming from the VN neurons are not sent through collateral axons but through different pathways. This separation permits distinct regulation of muscle contraction to combine vergence movements with the VOR, while fixating targets at different distances. Additionally, studies have shown that there is a difference in physiological signals that are conveyed by the abducens internuclear (eye velocity and eye position) and ATD (head velocity) pathways, which suggests that there is a separate control of visuomotor and vestibular functions.[31]

Inhibitory pathways

In addition to the contraction of the appropriate eye muscles (ipsilaterally the medial rectus and contralaterally the lateral rectus), a relaxation of the antagonist eye muscles has to be initiated in the context of the push–pull principle (**Figure 49.15**). This is generated by inhibitory type 1 neurons in the ipsilateral MVN.

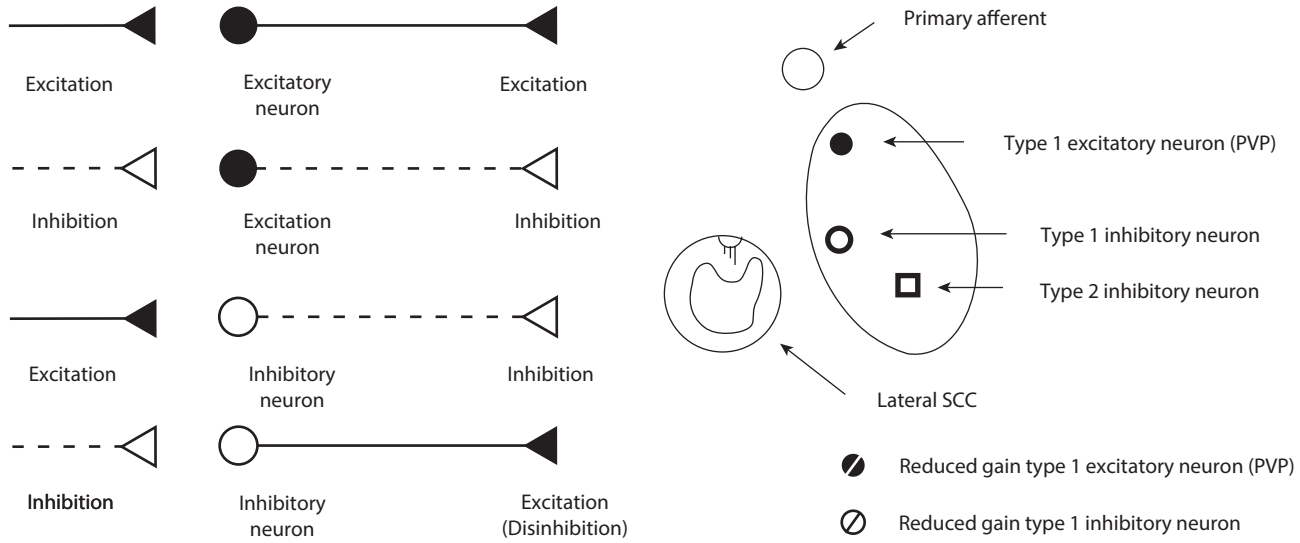

Figure 49.13 Code for excitation and inhibition of vestibular nuclei and oculomotor plants in the brain. Closed symbols represent excitation (full of neurotransmitters). Dashed lines denote inhibitory signal transfer. Solid lines denote excitatory signal transfer. Excitation of an inhibitory neuron will result in further inhibition. Inhibition of an inhibitory neuron results in excitation. This figure provides the key for Figures 49.16, 49.17, 49.18 and 49.19.

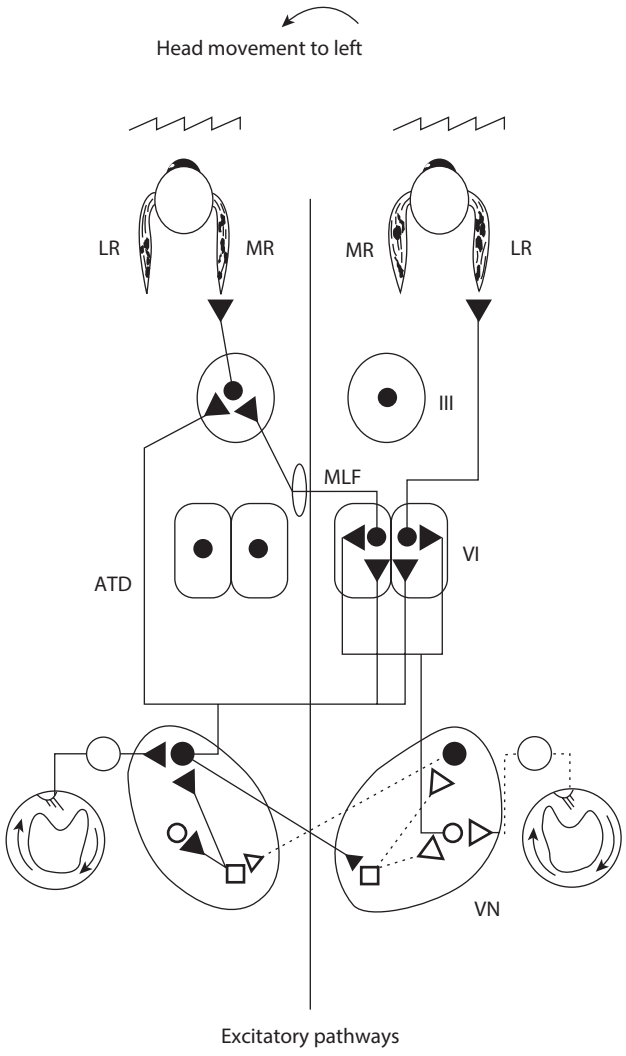

These inhibitory type 1 neurons project onto the ipsilateral abducens neurons and interneurons and, by inhibition, relax the lateral rectus on the ipsilateral eye through the VIth nerve. Likewise, the medial rectus of the contralateral eye is relaxed by inhibition of the contralateral oculomotor neurons where the signals come from the ipsilateral superior vestibular neurons and pass through the MLF.

To enhance this mechanism even further, at the same time the contralateral ampulla is deflected such that the firing rate of the primary afferents is decreased. This inhibits the contralateral MVN, resulting in an opposite effect for the antagonist eye muscles, again optimizing the gaze stabilization during movement.

To summarize, the generation of the VOR is mediated through a combination of signals coming from both labyrinths. During rotation to the ipsilateral side, the ipsilateral horizontal SCC with ampullopetal endolymph movement will transmit an increased firing rate to the central VN, whereas the contralateral SCC will transmit a decreased firing rate to the contralateral VN due to the ampullofugal endolymph movement.

Figure 49.14 During head rotation to the left, a VOR is generated to stabilize the eyes, with the concomitant nystagmus to the left. Stimulation of the horizontal SCCs initiates an excitatory pathway through the ganglion of Scarpa on to the vestibular nuclei. Given the projections of the canals and otolith organs to almost all parts of the vestibular nuclei (VN), we did not subdivide the nuclei into superior, inferior, medial and lateral VN. ATD, ascending tract of Deiters; LR, lateral rectus; MLF, medial longitudinal fascicle; MR, medial rectus; III, oculomotor nucleus; VI, abducens nucleus. See Figure 49.13 for key.

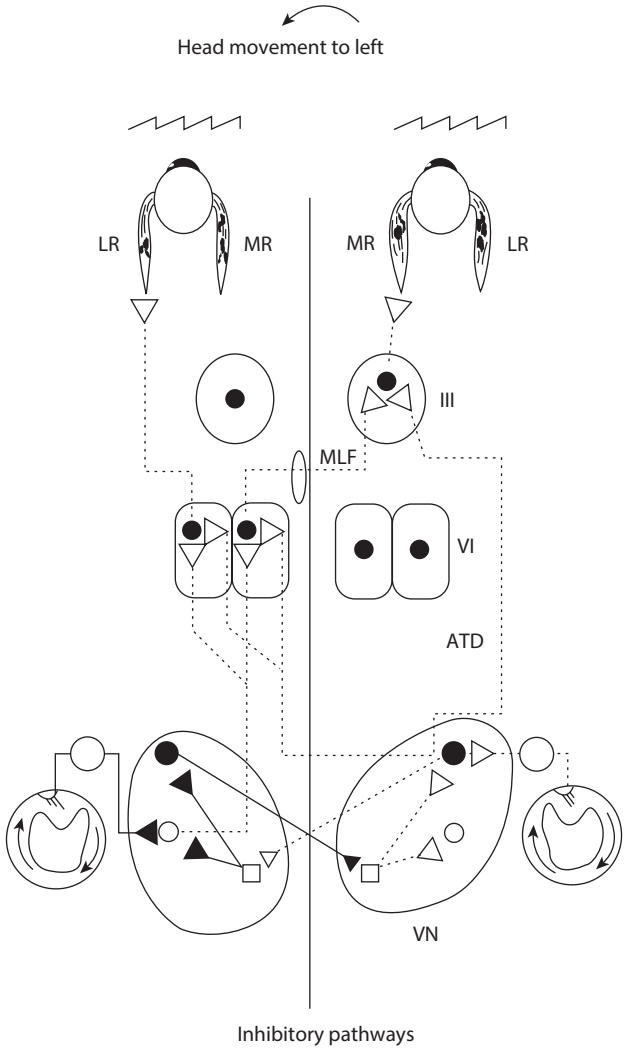

Figure 49.15 During head rotation to the left, a VOR is generated to stabilize the eyes, with the concomitant nystagmus to the left. Stimulation of the horizontal SCCs also initiates an inhibitory pathway. ATD, ascending tract of Deiters; LR, lateral rectus; MLF, medial longitudinal fascicle; MR, medial rectus; III, oculomotor nucleus; VI, abducens nucleus. See Figure 49.13 for key.

Commissural pathways

In the VN, there are also type 2 secondary vestibular neurons, which behave in an exactly opposite manner to type 1 neurons. Activating the inhibitory type 2 neurons silences the neighbouring type 1 neurons. Whereas type 1 neurons increase their discharge rate upon ipsilateral head acceleration, inhibitory type 2 neurons decrease their firing rate. For movement towards the contralateral side, ipsilateral type 1 neurons decrease their firing rate and ipsilateral type 2 neurons increase it.

The VOR-generating mechanism is enhanced in a positive feedback loop by commissural pathways where the excited type 1 neurons in the ipsilateral MVN excite the type 2 neurons on the contralateral side that in turn silence the contralateral type 1 neurons.

Excitation of the ipsilateral type 1 neurons is increased as the silenced type 1 neurons on the contralateral MVN inhibit the ipsilateral type 2 neurons, so that their inhibitory effect is reduced on the ipsilateral type 1 neurons. Therefore, type 1 cells receive direct input from the ipsilateral SCC, as well as indirect input from the contralateral SCC.

The commissural pathway is indicated at the bottom of Figures 49.14 and 49.15. This feedback loop proves to be crucial in the case of unilateral lesions.

Acute peripheral vestibular lesion and central vestibular compensation

As a model for a peripheral lesion, the acute uVD is commonly chosen. After uVD, specific changes occur immediately at the level of type 1 and type 2 neurons in the MVN on the ipsilesioned site. Given the absence of peripheral activity by the SCC afferent neurons, the firing rate of the type 1 neurons decreases.

Due to the decreased inhibitory effect of the ipsilateral type 1 neurons, the contralateral type 2 neurons are less stimulated so their inhibitory effect on the contralateral healthy type 1 neurons is decreased, and thus the healthy type 1 neurons increase their firing rate. This increased type 1 activity on the healthy side in turn activates the inhibitory type 2 neurons on the lesioned side, so that they additionally inhibit the neighbouring type 1 neurons on the lesioned side.

This imbalance generates the typical clinical signs of acute labyrinthine lesions, such as spontaneous nystagmus, i.e. a nystagmus that is present even under static conditions. The direction of the slow phase of the nystagmus is towards the lesioned side, i.e. the fast phase of the nystagmus beats towards the healthy side. The generated nystagmus reflects the situation as if the subject rotates towards the intact side. Indeed, both the absence of the ipsilesioned tonic input from the affected labyrinth and the increased contralesioned activity in the MVN mimic a rotation towards the intact side. This is illustrated in the scheme with acute uVD (Figure 49.16), where a nystagmus is generated by pathways that are very similar to the generation of VOR response upon rotation to the contralateral side. The difference is that no input from the contralateral SCC is present and still a nystagmus is generated. Also the gain of the ipsilesioned type 1 neurons is largely decreased and this will remain that way for a long time.

Stance and gait disturbances, as well as vertigo, are clearly observed in most patients. The postural disturbance often includes head and trunk flexion towards the damaged labyrinth with the head tilted so that the ipsilesioned ear is directed down. The appearance is of the healthy side being pushed towards the damaged side, which lacks the power to counteract the push.

These disturbances also occur under static, immobile conditions. The dynamic alterations yield a dysfunctional VOR, so that gaze stabilization during, for example, locomotion is hampered. Whereas the static symptoms improve within a week, the dynamic disturbances can last much longer, from weeks to years. The static symptoms decrease

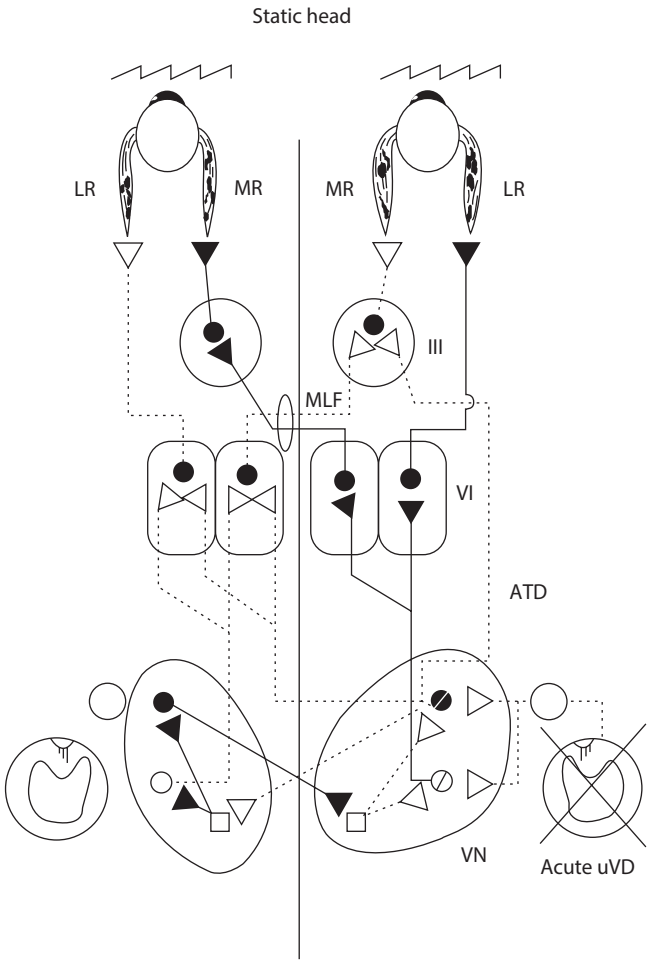

Figure 49.16 Acute stage of a right lesion of the peripheral vestibular system. Only the horizontal pathway is depicted, although a torsional nystagmus can also be observed. No vertical eye movement is seen, since the effect of inhibition of both anterior and posterior canals cancels the vertical eye movements out. Now all excitatory pathways are secondary induced through the commissural pathways and the inhibition of the type 2 inhibitory neurons, generating an excitation. ATD, ascending tract of Deiters; LR, lateral rectus; MLF, medial longitudinal fascicle; MR, medial rectus; III, oculomotor nucleus; VI, abducens nucleus. See Figure 49.13 for key.

over time, as a restoration of the resting discharge rate is affected at the level of the vestibular nuclei. This results in the disappearance of the spontaneous nystagmus: a process called 'vestibular compensation'. In humans, the gain of the VOR is permanently limited to a variable degree, depending on the acceleration of the head movements.

Many VN neurons show convergent input from both canal and otolith systems. The spontaneous activity of otolith afferents arriving in the VN is important for the generation of the oculomotor compensatory responses to SCC stimulation. The consequence of this is that an otolith loss affects not only the lVOR but also the aVOR during angular acceleration. The otoliths are therefore fundamental for the optimal operation of the entire vestibular system.

The imbalance in resting discharge rate between the lesioned vestibular neurons and the healthy vestibular neurons after uVD is the key factor that generates the acute clinical signs of nystagmus and unsteadiness. The short-term restoration of the imbalance of resting activity at the level of the VN results in a recovery of the static clinical symptoms, and the acute spontaneous nystagmus disappears within a week.

Very soon after uVD (within 52 hours), type 1 neurons in the MVN generate a spontaneous firing rate to balance the situation, although this firing rate is not influenced by afferent input from the lesioned side during rotation towards the lesioned side. It is, however, modulated through the ipsilesioned type 2 neurons that receive their input from the intact side type 1 neurons. Therefore, the ipsilesioned type 1 neurons are inhibited when the type 1 neurons on the healthy side are excited during rotation towards the healthy side, and are disinhibited when the contralateral type 1 neurons are inhibited during rotation towards the lesioned side. The responses of the ipsilesioned type 1 neurons are only half of their initial responsiveness, but qualitatively they act in a similar manner as before the lesion. This recovery takes place over a period of weeks to months and parallels the clinical recovery of the patient. The type 1 neurons on the intact side regain a firing rate equal to that before the acute lesion. The sensitivity (gain) decrease of the ipsilesioned neurons explains why the overall VOR gain after a lesion is lower than before the lesion. Even given the commissural network that largely enhances the efficiency of the generation of the appropriate VOR, an optimal VOR is never obtained. At slow accelerations, a relatively normal situation can be obtained, since the VN also receive input from extravestibular systems such as vision and proprioception, and they are not saturated. At higher accelerations, however, even in the physiological range, the intrinsic saturation of the inhibitory neurons (i.e. not being able to inhibit more than to 0 spikes per second), increases the deficiency of the VOR.

Figure 49.17 represents the pathway upon rotation towards a lesioned side. As indicated from the diagram, the only input is the inhibition sensed at the contralateral side. Due to the commissural pathways, a very similar reflex arc is established, generating an appropriate VOR under normal conditions. Nonetheless, the time taken to evoke the appropriate eye movement may be increased, which is demonstrated as an increase in phase during laboratory testing. The clinician may be surprised by the fact that the nystagmus appears symmetrical, i.e. movements to the left and right induce a similar gain (eye velocity/head velocity), but when the phase is too high (>18 degrees), the reaction comes too late, with suboptimal gaze stabilization as a consequence. For the patient, this translates into global unease and unsteadiness, and general fatigue and psychotropic drugs will worsen this.

A clinical bedside test to detect severe unilateral loss of SCC function is the head impulse or head-thrust test, first described by Halmagyi and Curthoys in 1988.[32] The head-thrust test is based on the fact that inhibition of primary and secondary vestibular neurons cannot produce fewer than 0 spikes per second. Excitation can drive the discharge rate from 90 to 300 or more spikes per second. So when the healthy side is excited for a high acceleration

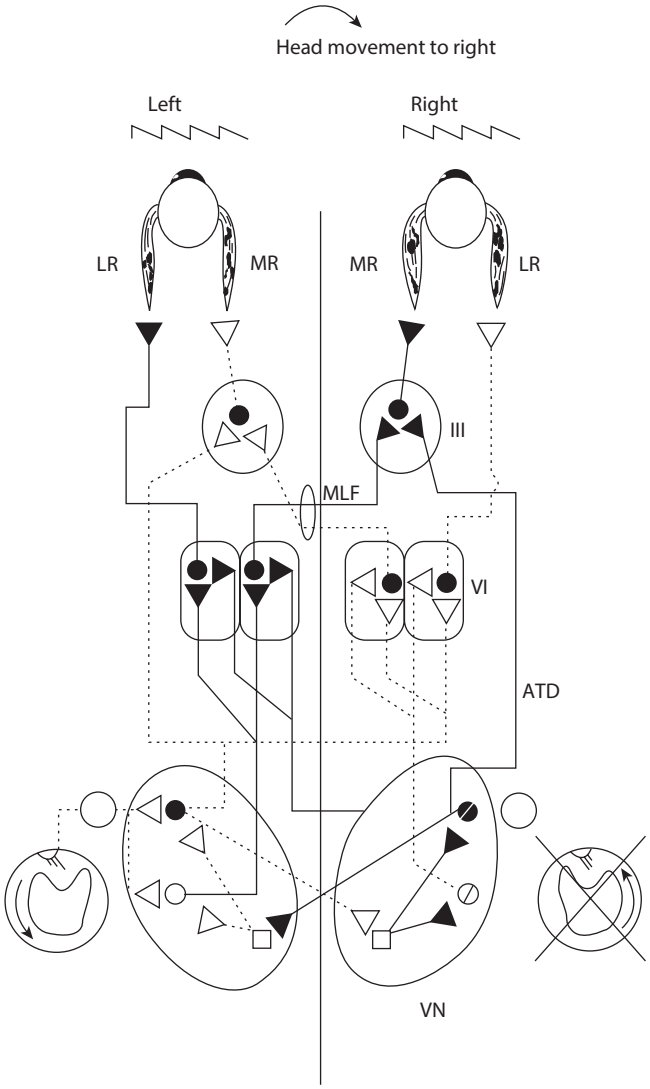

Figure 49.17 Under slow movement, rotating the head towards a stable lesioned side generates conditions for an appropriate nystagmus for gaze stabilization. ATD, ascending tract of Deiters; LR, lateral rectus; MLF, medial longitudinal fascicle; MR, medial rectus; III, oculomotor nucleus; VI, abducens nucleus. See Figure 49.13 for key.

head movement, the healthy side will generate the larger part of the VOR since the disinhibition of the ipsilateral type 1 neurons by the contralateral SCC contributes relatively little to the VOR. When the subjects head is turned to the lesioned side, the VOR is deficient and the eyes move together with the head, so that they no longer fixate. The patient therefore has to make one or more refixation saccades just after the thrust. When the head impulse is imposed in the direction of the healthy side, the VOR is able to maintain the target on the fovea and no refixation saccade is needed. The head-thrust test is positive for the side that causes the refixation saccades upon thrust (**Figure 49.18**). Not only can the lateral SCC be examined, which is in a sense a clinical approximation of the caloric test, but also the other SCC can be investigated. The patient's head has then to be moved in the RALP or LARP planes.

Gaze holding

Not only is it necessary to drive the eyes in the opposite direction to the head movement, but when the head has stopped turning, the eyes should remain in position. This is a complex task as elastic-restoring forces drive the eyes back to their primary position (straight ahead). This gaze-holding system is generated by the neural integrator, which is located in the NPH and the MVN for horizontal eye movements, and in the interstitial nucleus of Cajal (INC) for vertical movements. It is a circuit that integrates the velocity signal over the time the eye movement has occurred and this is mathematically equivalent to a position. In this way, the nuclei that command the eye muscles have input about the position that the eyes have to maintain and receive input mainly from the MVN.

Horizontal or vertical retinal image motion of a target should be held below 5° in order to maintain visual acuity. Torsional movements along the line of sight are much better tolerated. Additionally, it is desirable for optimal vision that the image of the object is directed within 0.5° on the centre of the fovea. This explains the need for an intricate image stabilization system with high gains for horizontal and vertical movement, but much lower gains for torsional movements.

To ensure gaze stabilization during normal movements of head and body, two mechanisms have evolved, namely the VORs and the visually mediated reflexes (optokinetic and smooth pursuit). The first is based on the detection by the labyrinth of the head movements, whereas the latter depends on the ability of the brain to determine the speed of image drift on the retina. Both reflexes work synergistically to maintain gaze stabilization during head movements. The eye movements generated by the VOR have, however, a much smaller latency (<16 ms),[33] whereas the visually mediated reflexes have latencies greater than 70 ms.[34]

During typical head perturbations that occur while walking (1–2 Hz),[8] the main stabilization task is performed by the vestibular system, which explains why patients with a bilateral labyrinthine deficit cannot read street signs when walking. In specific circumstances one system is overridden by the other.

- Watching a tennis match, for example, sitting alongside the court, the head moves from left to right as do the eyes to follow the tennis ball. In this case, the smooth pursuit system is mainly responsible for the image tracking.
- During sustained movements, such as on a merry-go-round, the vestibular system is assisted by the optokinetic system. This is because the vestibular receptors cannot cope with prolonged movements, and the VOR is degraded over time, therefore the optokinetic system takes over to ensure visual stability.

There are also, however, specific systems designed to shift gaze so that new objects of interest can be placed on the fovea. The main functional classes are summarized in **Table 49.2**.[35]

Figure 49.18 Head impulse test for horizontal canals. Hold the subject's head slightly turned to one side ((a) and (c)), and ask them to maintain fixation on a target behind you. Then, turn the head briskly to the opposite side. If the gaze is still focused on the target (as in **(b)**), then the SCC on the side towards which the head was turned (in this picture to the right) is functioning properly, generating compensatory eye movements upon excitation. However, when the eyes rotate together with the head and are no longer focused on the target, the SCC on the side towards which the head was turned is not functioning properly **(d)**. The off-target eye movement is quickly followed by a refixation saccade, so that the target is in sight again. Since this happens quickly, careful observation and handling by the investigator is required to notice abnormalities. When posterior and anterior canals need to be investigated, brisk head movements need to be made in the right anterior–left posterior (RALP) and left anterior–right posterior (LARP) planes while observing the gaze stabilization.

VESTIBULAR SENSORY CELLS

Each response of the peripheral vestibular system starts at the level of the sensory epithelium located in the SCCs and the otolith system. This section describes the functional anatomy of the peripheral vestibular system and its physiological properties related to the processing of vestibular stimuli.

The vestibular sensory epithelium is formed mainly of hair cells, which are very similar to those located in the cochlea. Two types of hair cells (I and II) can be distinguished. Type I hair cells are amphora-shaped, have a spherical nucleus and are surrounded by a chalice-like afferent nerve ending. Efferent nerve buds impinge on the afferent nerve chalice. Type II hair cells are more cylindrical, contain a cylindrical nucleus and have bud-shaped

TABLE 49.2 Functional classes of human eye movements

Class of eye movement	Main function
Vestibular	Gaze stabilization, i.e. holds images of the surrounding world steady on the retina during transient head movements (0.5–5 Hz) (see **Box 49.1**)
Visual fixation	Holds the image of a stationary object on the fovea
Optokinetic	Holds the image of the surrounding world steady on the retina during sustained head movement
Smooth pursuit	Holds the image of a small slow-moving target on the fovea
Nystagmus quick phase	Resets the eyes during sustained head movement and directs gaze towards the oncoming visual scene
Saccades	Bring images of objects of interest onto the fovea
Vergence	Moves the eyes in opposite directions to place targets simultaneously on both foveas

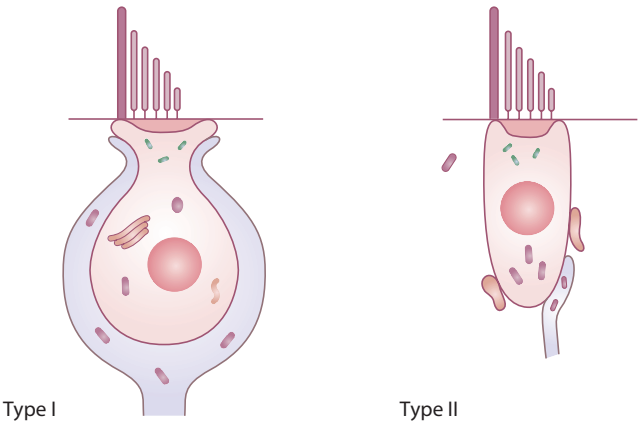

Figure 49.19 **(a)** Type I and **(b)** type II hair cells of the vestibular system.

afferent and efferent nerve endings located at the distal end of the cell. The apex of the hair cells is bathed in endolymph and is surrounded by non-sensory, supporting cells and dark cells (**Figure 49.19**).

The cell's hair bundle serves as the receptor for mechanical stimuli and is located at the apical end of the cell. Each bundle consists of 20–300 stereocilia and a single kinocilium. Hair bundle length varies: from 40–120 µm in vestibular hair cells to 0.5–30 µm in auditory hair cells.[36]

The sterocilia are rigid tubes of plasma membrane with a cytoskeleton of actin filaments, cross-linked by fibrin. They are arranged in a hexagonal pattern and vary in length across the surface of the cell, with the shortest stereocilia at one end and the tallest at the other end of the apical membrane, adjacent to the kinocilium. Consequently, the hair bundle looks like a staircase. The ion channels involved in mechanoelectrical transduction are located in

BOX 49.1 Gaze stabilization and the VOR

Shake your index finger at arm's length left and right, with increasing speed. As soon as you shake it at a frequency above 1 Hz, the eyes are not capable of following the movement and you see a blurred image of your finger. Next, shake your head while you fixate your finger, held stable at arm's length. You'll notice that the image remains sharp even at higher accelerations of your head. Up to frequencies of 5–6 Hz of head movements, many people are able to maintain a clear image of the target. This is the effect of a properly working VOR.

the stereocilia and each stereocilium possesses only one or a few transduction channels.[37]

Stereocilia are connected to each other by tip links, fibrillary strands running obliquely from the distal end of one stereocilium to the side of the longest adjacent stereocilium. The tip links are connected to the molecular gate of the transduction channels and the tension in the tip links controls the opening or closing of the transduction channels. The hair cell bundle is stiffer along its axis of mirror symmetry.[38] This increased stiffness is accounted for by the tip links. The upper end of each tip link is anchored to the stereocilium at a particular structure, known as the 'insertional plate' or 'insertional plaque', an oval disc that joins the plasmalemma of the stereocilium to its actin core (**Figure 49.20**).

The kinocilium is located at the tall edge of the bundle. The kinocilium is a true cilium consisting of an axoneme (nine paired microtubules and sometimes an additional central pair of microtubules). The role of the kinocilium is the transmission of stimulus forces to the stereocilia, but this appears not to be essential for mechanotransduction.

Hair cells are organized differently depending on their location in the SCCs or the otolith organs. Hair cells in the SCCs are located at the crista ampullaris, an elevated sensory area within the ampulla of the SCC. The tips of the cilia are embedded in a gelatinous cupula attached to the membranous labyrinth and functioning like a diaphragm (**Figure 49.21**). Hair cells in the SCCs are sensitive to changes in angular velocity and the output of the sensory cells is proportional to the angular displacement of the cupula, not to its velocity of motion.[39] Displacement amplitude of the cupula due to endolymph flow was found not to exceed 1 µm or 35° in the natural situation.[40] Larger displacement of the cupula is restrained by cupular attachments to supporting cells. As the hair cells located at the crista are all oriented in the same direction, they are all excited or inhibited by endolymph flow in the same direction. Hair cells in the horizontal SCC are excited by flow of endolymph towards the utricle (utriculopetal), whereas hair cells in the vertical SCCs are excited by endolymph flow in the opposite direction (utriculofugal). This organization is the basis of Ewald's first law which states that head and eye movements always take place in the plane of the canal being stimulated and in the direction of endolymph flow.[41]

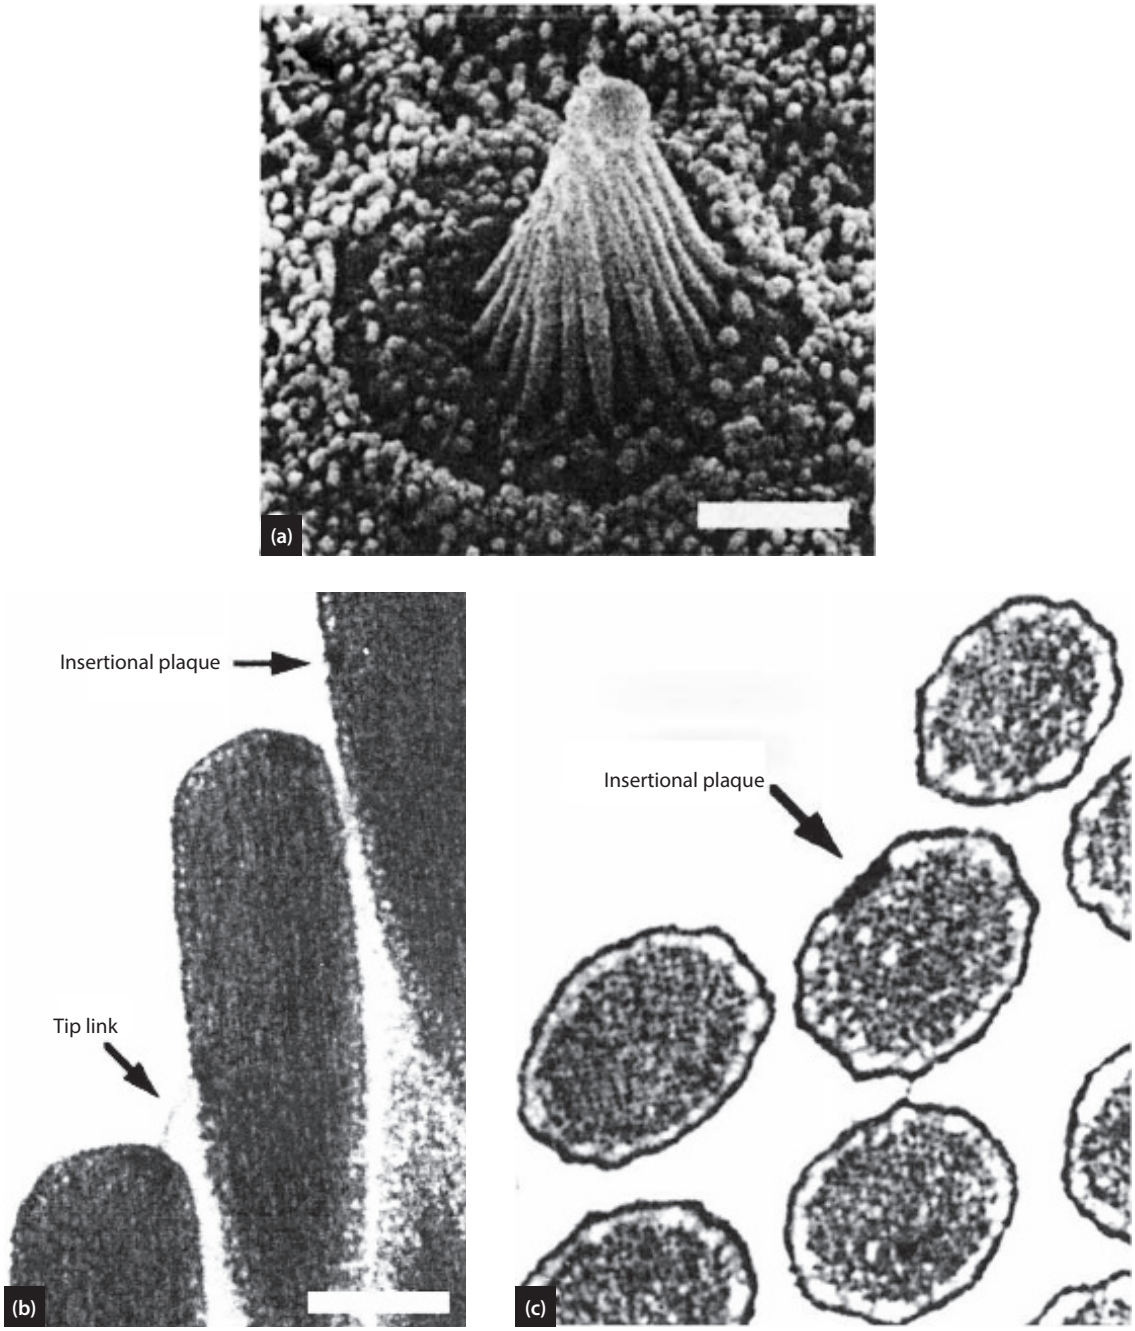

Figure 49.20 The hair cell's transduction apparatus. (a) The hair bundle comprises about 20–300 stereocilia and a single kinocilium surmounted by a bulbous swelling. The stereocilia monotonically increase in length across the mirror-symmetrical bundle. The bar in this scanning electron micrograph of a bullfrog's saccular hair cell represents 2 µm. **(b)** A tip link, a fibre about 160 nm in length and 3 nm in diameter connects the end of each stereocilium to the side of the longest adjacent process. A link often appears to comprise two or more strands, and it may splay into a pair of filaments near its upper termination at the osmiophilic insertional plate. A tip link's lower end is secured to the density capping a stereocilium. Each link is thought to be attached to the molecular gate of one or a few ion channels. **(c)** A section across several stereocilia reveals in one the insertional plaque at which a tip link's upper insertion occurs. The plaque, which interconnects the plasmalemma and the outermost tier of microfilaments in the stereociliary core, is about 50 nm high, 70 nm across and 20 nm thick. Transmission electron micrograph **(b)** is from a bullfrog; **(c)** is from a leopard frog. Scale bar: 200 nm in both. (Reprinted from Hudspeth and Gillespie.[45] Copyright 1994 with permission from Elsevier.)

In the utricle and saccule, hair cells are located in a structure known as the 'macula'. The utricular macula lies on the floor of the utricle and the saccular macula is usually in a vertical plane, on the posterior wall of the saccule. The hair cells of the utricle and saccule are embedded in a gelatinous layer impregnated with crystals of $CaCO_3$ called otoliths or otoconia. A filamentous network, the so-called subcupular meshwork, connects the lower surface of the otoconial membrane to the supporting cells of the sensory epithelium (Figure 49.22).

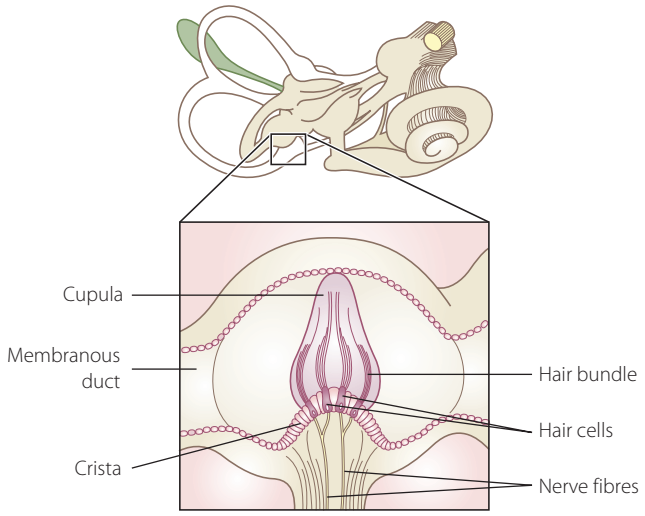

Figure 49.21 Organization of hair cells in the SCC. Hair cells are located at the crista ampullaris. The tips of the hair cells are embedded in the cupula.

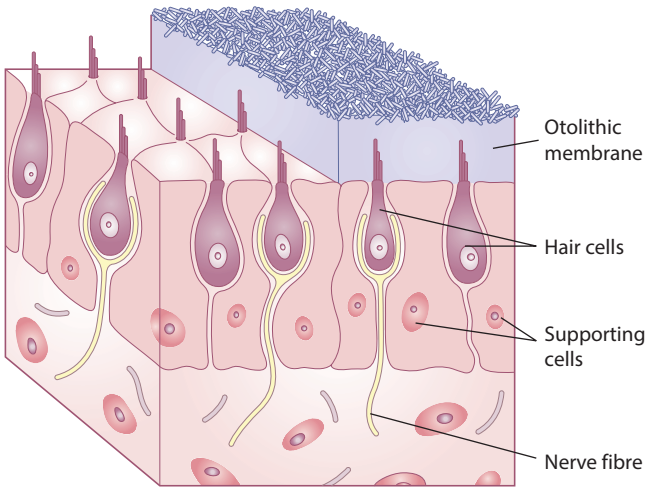

Figure 49.22 Hair cells of the otolith organs are located at the macula. The tips of these hair cells are embedded in the otolithic membrane (a gelatinous mass covered with calcium carbonate crystals, the so-called otoliths or otoconia).

Utricular hair cells are oriented in the shape of a fan with a medial group of cells pointing in an anterior–lateral–posterior direction and a lateral group of cells pointing in the opposite direction. Saccular hair cells can be divided into two parts with opposing orientation (a ventral group and a dorsal group), separated from each other by a virtual central line (the striola). Responses originating from hair cells located at opposite sides of the striola are coordinated in the central vestibular system, thus generating a common excitatory or inhibitory input. The otolith organs are sensitive to linear acceleration or changes in gravitational forces.

The endolymph surrounding the apical pole of the hair cells is characterized by a positive endolymphatic potential which plays an essential role in the transduction process. It was found that the endolymphatic potential in the vestibular part of the labyrinth (the endovestibular potential) is much lower (1–10 mV) in comparison to the endolymphatic potential in the cochlea (the endocochlear potential with values of 80 mV).[42] A more detailed analysis has shown that the ampullar and utricular endolymphatic potentials are respectively generated within the ampulla and utricle and independent of the endocochlear potential. By contrast, the endolymphatic potential of the saccule (with values of 4 mV) depends upon the integrity of the first turn of the cochlea. It is assumed that the presence of an utriculoendolymphatic valve between the saccule and the cochlear duct on one side and the ampullae and utricle on the other side might account for these differences in endolymphatic potential.[42]

Mechanotransduction

Hair cell function can be described in terms of a biological strain gauge; mechanical stimulation opens ion channels (transduction channels) in the cell membrane.[37] Displacement of the stereocilia towards the kinocilium stretches the tip links, which increases the ion permeability of the channel, resulting in an influx of cations (mainly K^+ and Ca^{2+}), thus depolarizing the hair cell. Displacement of the stereocilia away from the kinocilium shortens the tip links. This results in closure of the transduction channels and hyperpolarization of the cell. In a steady state condition, 10–20% of the transduction channels are open. Hair bundle displacement in the positive direction opens transduction channels. Channel opening decreases the stiffness of the hair bundle, which in turn promotes further movement in a positive direction, thus resulting in a positive feedback mechanism. This mechanism is known as 'gating compliance', an intrinsic property of direct mechanoelectrical transduction that enhances hair cell sensitivity.[43] The hair bundle's compliance is similar to other biological systems characterized by a non-linear stress/strain behaviour, i.e. stiffness increases when more tension is exerted on the system.

Adaptation

The extreme sensitivity of hair cells calls for a mechanism to prevent saturation of the mechanotransductor response from large and sustained stimuli (longer than 25 ms). Since mechanotransduction is a direct and fast process without intervening second messenger molecules, a unique mechanism has been developed, known as 'adaptation'. During adaptation, the transducer's sensitivity is maintained but the position at which the hair bundle displays maximal sensitivity changes from the resting position towards that at which the bundle is displaced with sustained stimulation. The stimulus/response relationship of the hair cells shifts in the direction of the applied stimulus and causes a return of the channel open probability to its resting value.[44] In this respect, adaptation in hair cells is completely different from the desensitization process encountered in other cell types. If a second stimulus is imposed during the adaptation process, the cell responds again.[45] In the primary vestibular afferents, adaptation manifests itself as a decay in spike rate during sustained head movement.

During sustained angular head velocity, deflection of the cupula decays so slowly that it does not affect afferent responses in the physiological range of human head movements (0.1–5 Hz). There is no adaptation of otolith movement during linear acceleration.[46]

Adaptation in vestibular hair cells may have at least four different purposes:[43]

- It avoids saturation of hair cell responsiveness by large or sustained stimuli.
- It allows a cell to detect small stimuli in the presence of an enormous background input.
- It places the hair cell bundle in a sensitive region of its operating domain.
- It contributes to high-pass filtering because hair cells with very fast adaptation responses are insensitive to low-frequency stimuli. Cells in the same receptor organ may have different adaptation responses, accounting for differences in frequency responsiveness.

Frequency selectivity

The length of the hair bundle varies from cell to cell in the same receptor organ. Hair cells responding to low-frequency acoustic vibration and acceleration stimuli bear relatively long bundles whereas receptors for the highest-frequency stimuli have the shortest bundles. Shatz et al. suggested that hair bundle length might be related to frequency selectivity and that longer hair bundles, such as those encountered in the vestibular hair cells, contribute to the low-frequency selectivity in the vestibular organs.[36]

FUTURE RESEARCH

- ➤ The development and implementation of vestibular implants, similar to cochlear implants in the past decades.
- ➤ Study of the vestibular cortex and regions of interest relevant for the vestibular system by application of advanced MRI scan methods such as e.g. diffusion tensor imaging (DTI), resting state functional MRI (rsfMRI) and voxel and surface based morphometry (VBM and SBM).
- ➤ The efferent vestibular system and its regulatory characteristics.
- ➤ Study of functional dizziness and its physiological correlates.

KEY POINTS

- The vestibular system ensures gaze stabilization, postural control, balanced locomotion and autonomic function readjustment.
- The geometry of the SCCs is such that head velocity is measured and used for the generation of VOR.
- The optimal efficiency of the SCC is obtained for frequencies of 0.1–5 Hz.
- The typical head frequencies for human behaviour peak around 2 Hz.
- The VOR is essentially a three-arc neuronal reflex, but the central pathways of the VOR generation use multiple inputs from both ipsilateral and contralateral vestibular afferents, through commissural fibres.
- The push–pull principle states that, upon head rotation to one side, the discharge rate in the hair cells in the leading ear increases while it decreases in the following ear. This imbalance generates the appropriate nystagmus for gaze stabilization upon rotation.
- After an acute unilateral vestibular lesion, a spontaneous nystagmus is generated due to the imbalance in discharge rate of the peripheral organs, similar to that induced during head rotation to one side.
- An acute spontaneous vertical nystagmus is more commonly due to a central nervous system disorder than to a peripheral vestibular disorder.
- Conflict between sensory inputs often leads to motion sickness.
- The head-thrust test is a bedside test that investigates directly the efficiency of the VOR.

ACKNOWLEDGEMENTS

The authors would like to thank Ann Boudewyns for her contribution on hair cell physiology, Luc Sanspoux for his drawings; Stefan Gea for the 3D cochlear images; Gwen Vanuffelen, Gitte Leijnen, Charlotte and Maxim-Hadriaan for modelling for the photographic images.

CHAPTER 50

PERCEPTION OF SOUNDS AT THE AUDITORY CORTEX

Frank E. Musiek and Jane A. Baran

SEARCH STRATEGY

The data in this chapter maybe updated by a search using the keywords: auditory cortex, auditory pathways, tonotopic maps, cortical mapping, and auditory field maps.

INTRODUCTION

In discussing the auditory cortex (AC) and what it does, one must realize there is probably much more about this structure that is unknown than known. That said, to adequately cover what is known about the AC would require books and not just a single chapter. So in an attempt to provide some meaningful information about the AC we will follow a course that provides glimpses of what this central auditory nervous system (CANS) structure is and does.

The first part of the chapter will discuss the anatomy of the AC, touching on some of the basic principles and findings. Questions to be addressed include: What is the extent of the AC and how do we define it? How is it connected to other parts of the auditory system and brain? Are the ACs in each hemisphere highly similar or different?

The second major area of discussion in the chapter addresses some of the functions of the AC. How does the AC represent the various parameters of sound? How does it respond to sound and how do we measure these responses? The physiology of the AC provides us with much of the meaning that we garner from both simple and complex stimuli – do we know how this happens?

The final section of the chapter will relate information on what happens when the AC is compromised in some way. Some classic animal ablation studies are reviewed and cryoloop cooling will be introduced. Also discussed will be lesion studies in humans. This particular discussion will be clinically oriented. The studies that look at humans with damage to the AC can provide us with some very practical and highly relevant views of what the AC can or cannot do in regard to hearing and related processes.

Many of the questions that have just been posed cannot be answered fully, but hopefully they will provide the reader with some direction and guidance regarding the organization and contents of this chapter. Throughout the chapter, we will stress basic elements of understanding and build upon them as much as the scope of this chapter will allow.

The orientation of the chapter will be one that necessarily utilizes some of the traditional literature for establishing a foundation of knowledge. However, whenever possible we will touch upon some of the newer studies that are garnering attention. Certainly, there has been an explosion of knowledge about the brain recently and, along with this, there have been many advances in our understanding of the structure and function of the AC. We hope that this mixture of information provides a worthwhile learning experience for the reader.

GROSS ANATOMY OF THE AUDITORY CORTEX

It is difficult to fully define the extent of the human AC, mainly because there is considerable variability among the findings in many of the studies on the anatomy of the AC. These variances are reflected in imaging studies, electrophysiological reports and investigations of human cadaver brains.[1,2] Also it is difficult to discern what constitutes primary versus secondary or associative AC.[1] Given these kinds of limitation, this chapter will provide our best deductions regarding the anatomical definition of the AC in humans.

Defining the auditory cortex

Two approaches to defining the AC will be rendered here: one will be what we term the 'traditional approach' and the other the 'core–belt approach'. In the traditional view the primary AC is generally considered to be limited to Heschl's gyrus, which is positioned on the superior temporal plane of the superior temporal gyrus (**Figures 50.1** and **50.2**). This gyrus runs in an anterior–lateral to posterior–medial direction. Heschl's anterior segment is located in the posterior third of the superior temporal gyrus. It is bordered anteriorly by the planum polare and posteriorly by the planum temporale. The medial border is formed by the insular sulcus and the insula. There often are one or two gyri in this auditory structure, but three or more have been reported, although this is quite rare. Depending on the stimulus, recording technique and other variables, additional areas in the vicinity of Heschl's gyrus can be found to respond rather vigorously to sound, making one consider anatomical areas such as the planum temporale, the supramarginal gyrus, the inferior central gyri, the frontal lobule, and the posterior part of the planum polare as part of the AC, and if not a part of the AC itself, at least a 'highly responsive auditory area' in the vicinity of the AC. This roughly defined region is strikingly similar to the auditory areas defined in the classic paper by Celesia based upon recordings from humans[3] – though Celesia[3] and others[2] confine the AC to the planum polare, Heschl's gyrus and the planum temporale. Although there are differing views as to the extent of what may be considered the AC and the auditorily responsive area(s) around it, most would agree that the anatomical region just defined would provide some insight into the general location and extent of the AC in humans.

The core–belt approach to defining the AC has gained popularity recently (**Figure 50.3**). This increased interest is based primarily on non-human primate studies and the subsequent extrapolations of the results of these studies to humans.[2] In non-human primates the AC has a central or 'core' designation, which receives inputs from the medial geniculate body (MGB), mostly from the ventral division of this CANS structure. The core, if adapted from the non-human primate to the human, is estimated to take up about one-half or more of Heschl's gyrus.[2] The 'core' constitutes the primary auditory reception area and is immediately surrounded by a 'belt' region, which then is surrounded by a 'parabelt' area. The concept that is promulgated here is that, at this level, neural activity originates at the core and then spreads to the belt and parabelt

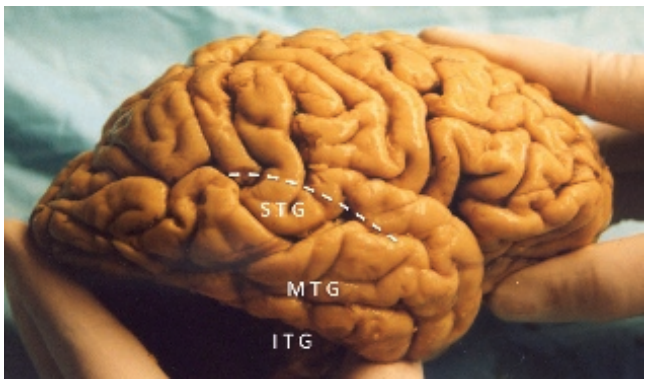

Figure 50.1 Right lateral view of the human brain with focus on the temporal lobe. The white arc signifies the course of the Sylvian fissure. The superior (STG), middle (MTG) and inferior (ITG) temporal gyri are indicated.

Figure 50.2 View looking down on the left superior temporal plane. The orientation of the numeration is from posterior to anterior. Key: 1 = planum temporale, 2 = Heschl's gyrus, 3 = planum polare, 4 = insula.

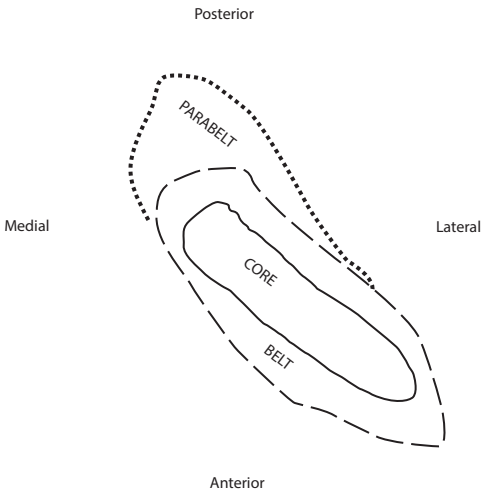

Figure 50.3 Sketch depicting the authors' interpretation of the core–belt anatomy of the auditory cortex. The drawing is aligned at a similar angle as seen in Figure 50.2 with Heschl's gyrus on the superior temporal plane. The core covers most of Heschl's gyrus with the belt and parabelt extending to parts of the planum polare and planum temporale.

regions as part of processing and neural connectivity of the CANS. Beyond the parabelt region there is neural communication with other parts of the brain in a rather non-modular fashion.[4, 5]

The core–belt arrangement makes sense in many ways and certainly there is good evidence that it exists in the non-human primate. However, the existence of a similar anatomical arrangement in humans remains an unsettled argument. Some evidence does exist from imaging data in humans, but it is not convincing to the present authors' interpretation. Moreover, even if there is a core–belt arrangement in humans, a question remains as to what form it may take; i.e. is it highly similar to that which is seen in the non-human primate, or does it vary considerably from the non-human primate model?

Projections to the auditory cortex

Heschl's gyrus receives projections from other cortical areas of the brain, but the present discussion will focus on the inputs that ascend from the thalamus. Neurons arising from the MGB project to the AC via the internal capsule. Specifically, the ventral division of the MGB is the main input to the AC. The dorsal division of this CANS structure also sends fibres to the AC, though not to the extent of the ventral division.[1] In referring to the core–belt model, the core receives input from the ventral MGB and the belt areas receive inputs from the other areas of the MGB.[6]

Projections from the auditory cortex

There are intrahemispheric, interhemispheric and efferent output projections (either direct or indirect) from the AC. Heschl's gyrus has immediate connections within this structure and then connections outside the structure. The key intrahemispheric connection is input to the arcuate fasciculus, which has fibres that connect to the insula and the frontal lobe (Broca's area).[4] The core–belt model has proposed connections from the core to the belt and parabelt regions in the superior temporal gyrus, which is similar to the Heschl's gyrus connections mentioned above.[1, 2, 6] Efferent connections originate in the AC regions and project to the inferior colliculus and MGB forming a loop that feeds back to the AC. The interhemispheric connections leave the AC and likely course around the lateral ventricles and across the midline via callosal fibres. These connections are mostly to similar loci in each hemisphere (i.e. homolateral connections), but some callosal fibres connect to different neural substrate in the opposite hemisphere (i.e. heterolateral connections).[7] Of course, the AC has connections to other parts of the brain as well, making its neural network more of a non-modular than a modular one.[5]

Asymmetries of the auditory cortex

The classic study of Geschwind and Levitsky[8] alerted us to the concept of anatomical differences between the left and right sides of the planum temporale (see **Figure 50.2**). This study and many subsequent studies have shown that in normal brains the left planum temporale is significantly larger than its right-sided counterpart. There is also anatomical evidence that is definitely slanted towards the Sylvian fissure being longer and more horizontal on the left than the right side of the brain.[2, 9] In regard to Heschl's gyrus there is also evidence supporting a left-sided size advantage, but this is not without some exceptions that point to both left and right Heschl's being similar in size.[1, 2, 10, 11] The existence of asymmetries for the core–belt orientation is, at least for the present authors, difficult to glean from the literature and requires more investigation before a definitive determination of the existence of any asymmetries (or lack thereof) can be rendered. This lack of information regarding asymmetries in the core–belt areas is due in part to the lack of understanding of the borders of the core–belt designation as it applies to humans.

It is important when discussing asymmetries of the AC that variations in the contour of the Sylvian fissure be considered. Rubens'[12] classic article brought attention to the concept that approximately the last third of the Sylvian fissure can course horizontally, or it can ascend or descend. Most Sylvian fissures run essentially a horizontal course, but in many instances this fissure ascends – often termed an ascending ramus (**Figure 50.4**). An ascending ramus has been shown to alter the morphology of a number of auditory structures, including Heschl's gyrus, the planum temporale, the angular gyrus and the supramarginal gyrus.[13] This altered morphology obviously has an influence on anatomical interpretations of imaging, lesion and evoked potential studies, rendering interpretations of the structures on the posterior third of the superior temporal gyrus and adjacent regions complex and controversial. Structural asymmetries may well exist if one hemisphere has an ascending ramus and the other does not. However, the impact of brains that have ascending rami compared to brains that do not is not fully understood at this time, but it is anticipated that with more investigation the effects will likely be found to be considerable.

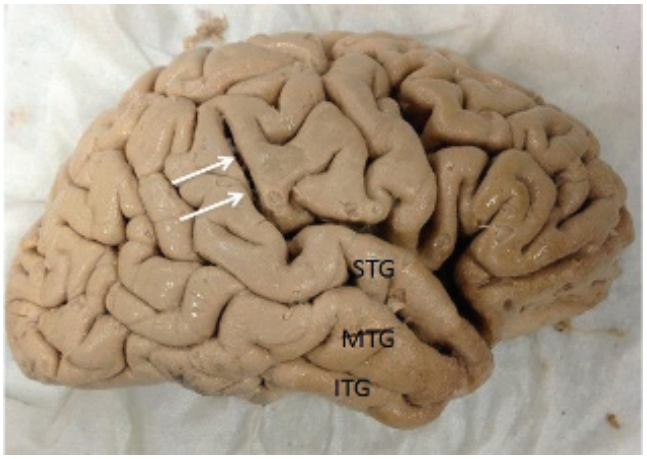

Figure 50.4 Right lateral view of a human brain with the arrows pointing to an obvious ascending ramus. Key: STG = superior temporal gyrus, MTG = middle temporal gyrus, ITG = inferior temporal gyrus.

Vascular anatomy relevant to the auditory cortex

A familiarity with the vascular anatomy of the AC is essential to understanding both its function and dysfunction (Figure 50.5). The key vessel for the AC is the middle cerebral artery (MCA). As shown by Waddington and Ring[14] and related by Musiek and Baran,[1] the MCA is derived from the internal carotid artery deep within the cerebrum. The MCA essentially runs along the Sylvian fissure before sending branches to the frontal, temporal and parietal regions of the brain. The length and morphology of the MCA proper varies greatly before it changes into branches and the MCA can no longer be discerned. Key auditory branches originating from the MCA include two or three temporal branches that infuse the temporal lobe (anterior to posterior) as well as the angular gyrus, and provide the vascular supply for the posterior temporal lobe, the supramarginal gyrus and the angular gyrus. These major arteries then give rise to smaller branches and even arterioles that penetrate the auditory regions.

AUDITORY CORTEX PHYSIOLOGY

The discussion of the physiology or function of the AC will initially focus on the manner in which this structure codes intensity, frequency and temporal information. Much of the available information in this area is a result of animal recordings where the intensity, frequency and/or temporal characteristics of an acoustic stimulus are varied and the effects are measured intracranially. Human physiological data, on the other hand, are generally obtained using functional imaging, evoked potentials, and psychoacoustic paradigms using non-invasive procedures, and although these non-invasive procedures do provide some insights to the physiology of the AC, they do not offer the spatiotemporal resolution that intracranial recordings afford.

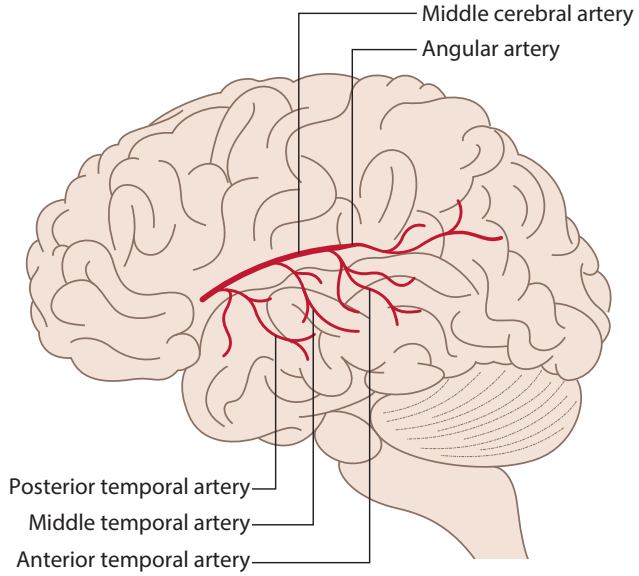

Figure 50.5 Sketch of the key arteries for the auditory cortex and immediate areas around it.

Intensity representation at the auditory cortex

Intensity in the AC is coded in three major ways. One is that as the intensity of the stimulus is increased neurons increase their firing rates.[15] Though this concept is often true, there are some exceptions that are indeed interesting and insightful. It is true that many AC fibres do increase their firing rates in a monotonic fashion, but some neurons will show a different firing pattern, i.e. they will 'roll over'. These neurons increase their firing rates with increases in stimulus intensity up to a certain level and then they actually decrease their firing rates as stimulus intensity increases further, yielding what are called non-monotonic intensity functions. The range of intensities for which there is continuous increase in a neuron's firing rate and the level at which the neuron 'rolls over' varies greatly across neurons.

A second way in which intensity is coded is related to the number of fibres that respond to a stimulus.[16] Generally, as the stimulus intensity increases, more neurons will respond, resulting in a larger neural response area. This increase in the number of neurons firing has been documented in imaging, fMRI and evoked potential studies in humans.[16] In general, as intensity increases, the response area for functional imaging responses becomes larger. Also, with increases in intensity, auditory evoked potentials (AEPs) will become larger in amplitude, likely reflecting changes not only in the number of neurons firing but also their firing rates.[16, 17]

The third way that the AC codes intensity is a complex interaction between excitatory and inhibitory neurons in the cerebrum. For example, a neuron could be non-linear in its amplitude representation and could be inhibited or enhanced in its response to a sound stimulus by activity in other neurons in and around its cortical field.[1, 18]

Changes in the latency of the neural response can also be noted if responses from the AC are recorded for a stimulus that systematically increases in intensity. In such cases, the latency of the neural response will often decrease. Though some of this shortened latency can be attributed to the travelling wave time in the cochlea, this cochlear phenomenon cannot account for all of the decrease in latency. Therefore, it appears that the neurons that respond to higher intensities may be favoured in some way to allow faster neural conduction times. This can be demonstrated by the decrease in late cortical potentials generated from the AC.[16, 17]

As has been discussed above, the AC employs a number of different neuronal mechanisms to process and code intensity information. It is likely that these mechanisms interact in various ways to provide the neural response that forms the foundation for the perception of loudness as well as changes in loudness.

Frequency representation at the auditory cortex

The representation of frequency at the AC depends on whether one is ascribing to the traditional or core–belt view. Early animal studies seemed to indicate that low

frequencies were located rostrolaterally and high frequencies were found in a caudomedial location in the AC. This, at least for present purposes, is referred to as the classic view. This view gained momentum with the functional imaging study performed by Lauter et al.[19] for which results in humans were found to be similar to those in earlier studies conducted in other animals. More recent functional imaging work with humans supported the Lauter et al. findings.[20, 21] However, it has become clear that there was variability surrounding these studies:[21] these studies in general would use only a few frequencies to map the tonotopic representation of the AC and this limitation could have lead to an overinterpretation, if not a complete misinterpretation, of the tonotopic contour in the human AC. For example, the classic investigation by Lauter et al.[19] used only two acoustic stimuli (500 Hz and 4000 Hz). The 500 Hz stimulus resulted in AC activity that was lateral and caudal to that evoked by the 4000 Hz tone. Therefore, these responses, though likely accurate for the specific frequencies studied, may or may not paint a valid picture of the complete tonotopic organization of the human AC as only two frequencies were tested. Certainly, a number of assumptions must be made in studies like those of Lauter et al. to allow an accurate interpretation of frequency contour of the human AC. It seems clear that the frequency arrangement described earlier is what is seen in non-human primates, as more comprehensive mappings of frequency representations in non-human primate studies have been completed. However, this does not mean that this same tonotopic arrangement occurs in humans and caution is recommended before applying non-human primate findings to humans. Moerel et al.[2] tried to reconcile the varying views on the tonotopic arrangement within the human AC. These investigators relate that perhaps the tonotopic arrangement may stretch from the planum polare to the planum temporale with a more general high–low–high representation. This varies from the more concentrated (less area) that has been postulated. This frequency representation has the core area segmented into three regions, each having its own frequency display. The anterior and the posterior segments have a low to high frequency representation coursing medially and maybe slightly posteriorly. The middle segment has essentially the opposite representation.[22]

It seems that perhaps many issues emerge in understanding what the tonotopic arrangement really is in humans, but two will be offered here. One is the adoption of the non-human primate tonotopic findings for human models. The other is the lack of specificity of the frequency representation in the human, and even (to a lesser degree) the non-human primate. These issues, among others, make the clear identification and definition of frequency maps within the human AC an unresolved issue.

Coding of temporal information at the auditory cortex

Frequency-modulated (FM) and amplitude-modulated (AM) signals are often used to gain insight to temporal processing capabilities, and in this case the AC. A basic concept of interest and import is that many neurons in the AC respond to changes in an acoustic signal over time, and a good example of this is the response of cortical neurons to AM and FM signals. Perhaps one of the most insightful concepts in regard to how the AC responds to acoustic signal modulations is that some neurons will only respond to modulated signals and not to steady-state signals.[23] It has long been suggested that modulated tones create more activity in the cortex than steady-state tones. A glimpse of this kind of AC activity was related by Whitfield and Evans[24] over 50 years ago. Notable is research showing that FM modulation depth discrimination thresholds are strikingly better than those derived with static tones.[25] Extending this concept, this could be one reason why complex acoustic stimuli such as FM and AM signals are more appropriate than traditional pure-tone stimuli for evaluating dysfunction of the AC clinically.

Modulation rates of AM and FM signals are an important consideration when reviewing the topic of temporal processing within the AC. Although there is variability in findings as well as in opinions, it appears that lower modulation rates seem to favour activity from the AC as opposed to higher modulation rates, which align better with brainstem and auditory nerve activity. It has been suggested that AM rates of less than 50 Hz are optimal for involving the AC, whereas rates above 50 Hz better suit brainstem neurons and the AC becomes less involved.[26] However, it must be understood that there is considerable overlap of cortical and subcortical neurons in regard to their responses to both high and low modulation rates but that, as modulation rates decrease, the neurons that respond best to the stimuli ascend in their location from the low brainstem to the AC.[23]

Another factor related to AC temporal processing of AM and FM signals is phase locking, which of course is related to overall responses to various modulation rates as just discussed. For AC neurons, phase locking is best for lower rates (again below 50 Hz), but in unsedated animals some phase locking for frequencies of over 100 Hz has been shown.[23, 27]

As recently reviewed,[28] the sweep of FM signals (low to high to low) appears to have a laterality factor in regard to AC activity. For slow sweeps, the right AC seems to respond better than the left, while just the opposite is true for fast sweeps. More fundamentally, however, is the key concept that there are neurons in each AC that are specifically sensitive not only to FM signals but to the direction of the sweep of these signals.[28] These kinds of functions would likely be related to the manner in which the AC processes speech stimuli as speech is represented by rapid changes in its underlying acoustic representation(s).

Gap detection procedures also have been used to measure temporal acuity of the AC as well as other areas of the auditory pathway. As in other regions of the CANS, neurons within the AC synchronize to the offset and onset of the lead and trailing segments within the stimuli. In addition, there is suppression of activity during the silent interval – although some spontaneous activity remains.[29] Accuracy for gap detection perception requires that the neuron array, whether in the cortex or elsewhere, follows the acoustic pattern in the stimulus (**Figure 50.6**).

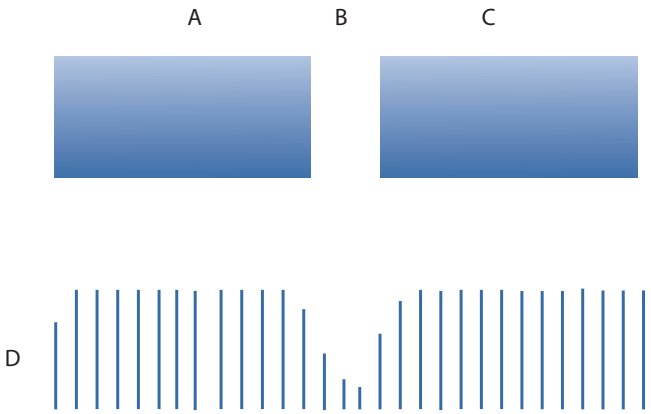

Figure 50.6 Depiction of a gap-in-noise stimulus array. Key: A = lead white noise, B = gap, C = trailing white noise, and D = predicted neural response (firing rate).

That is, when the lead element is 'on', cortical neurons are firing, and when the stimulus stops, the neurons must synchronously shut down quickly (i.e. reduce their activity to their spontaneous firing rate) and then synchronously initiate increased firing rates again when the stimulus (trail element) returns. The available research appears to indicate that the termination of the gap physiologically is of more import than the onset of the gap.[30]

Localization

The AC plays an important role in spatial hearing, which has been shown to underlie two major auditory functions: the ability to identify the location or the source of a sound, and auditory scene analysis or the ability to separate sounds based on their locations.[31–33] Research findings in both other animals[34] and humans[35] have demonstrated that the accurate localization of a sound source is affected if the AC is compromised. In humans, sound localization in the horizontal plan is largely dependent on the neural processing of interaural time differences (ITDs) and interaural intensity level differences (ILDs). Research findings have demonstrated that the perceived location of low-frequency sounds is largely mediated by processing of ITDs, while perception of high-frequency sounds is more heavily weighted on the processing of ILDs.[36,37] The time and intensity differences in these binaural cues are represented by excitatory and inhibitory responses in the cells of the AC.[38] Within the AC, there are two main types of cells, including excitation–excitation (EE) cells and excitation–inhibition (EI) cells. EE cell responses are excitatory to stimulation at each ear, whereas EI cells usually present an excitatory response at the contralateral ear and an inhibitory response at the ipsilateral ear.[38] The identification of the elevation of a sound source is based primarily on monaural spectral cues, although some weak binaural cues may be available due to small head asymmetries that often exist in individual listeners.[33]

Non-human primate studies have suggested the existence of a number of distinct subregions within the AC that are responsible for processing distinct sound properties. For example, a number of investigations have revealed that the tonotopic organization representing frequency that is first seen in the cochlea is maintained in some topographic fashion up to and including the belt regions of the AC.[33] However, investigations of the AC in humans have not yielded consistent findings and, as a result, the existence of similar topographic fields and/or representations in the human AC has not been established.[1,33]

Although the existence of clear frequencies maps within the human AC have not been established, results of fMRI testing in humans have provided evidence for two broad processing areas in humans, an anterior 'what' and a posterior 'where' area.[33] The posterior auditory 'where' pathway in humans is involved in the processing of spatial information and encompasses two non-primary AC areas, the planum temporale and the posterior superior temporal gyrus. These posterior non-primary AC areas have been shown to be strongly activated by horizontal sound direction changes, distance changes and sound movement. However, they are also activated by a wide variety of other stimulus features (e.g. frequency and phonetic stimuli), which suggests that the processing of acoustic information in these areas is not limited to purely spatial information (see 'Complex sounds (speech)' below).[33,39]

Research studies in humans have shown that unilateral lesions interfered with the localization of sound in the contralateral hemisphere of space, suggesting that each cortex preferentially processes acoustic signals on the contralateral side.[40] However, there appear to be some differences between the right and left ACs in their responses to sounds. For example, Spierer et al. found that lesions in the right hemisphere typically affected the localization of sound sources originating from both the ipsilateral and contralateral hemifields, whereas left hemisphere lesions were limited to contralateral sound sources.[40,41] They also found that the deficits noted among their subjects tended to be more severe following right hemisphere compromise than left hemisphere damage, and that greater deficits were noted for the processing of ITD than ILD cues. Based upon their findings, these researchers have proposed that the right hemisphere plays a dominant (but not an exclusive) role in the processing of spatial location, and it has an integrative role in representing sound localization.[41]

The processing of acoustic cues for moving sound sources is different from the processing of acoustic cues for stationary sources,[15] with the available evidence implicating the presence of separate processing mechanisms for stationary and moving sounds. The existence of direction-specific motion sensitive neurons in the non-primary areas of the AC (planum temporale and the posterior superior temporal gyrus) has been suggested in a number of studies.[33,42,43] However, it is not clear if the neural responses to moving acoustic targets are the result of activation of unique 'motion'-sensitive neurons, or whether the perception of auditory movement is based upon the sampling of discrete locations in space as the target moves.[33]

Complex sounds (speech)

In humans, research has documented that a variety of speech sounds activate areas immediately anterior to

Heschl's gyrus in both hemispheres,[44] while others have shown that speech stimuli (syllables and words) activate cortical areas both immediately anterior and posterior to Heschl's gyrus in the left hemisphere.[45] These findings (i.e. that speech stimuli activate areas both anterior and posterior to Heschl's gyrus) are consistent with more recent theories that posit a 'where' area in the non-primary AC as has been discussed above, as well as a 'what' area, which incorporates the anterolateral Heschl's gyrus, the anterior superior temporal gyrus and the posterior planum polare.[39] Recent auditory evoked response findings have suggested that these two processing mechanisms occur in parallel with activation of the 'where' processing pathway, occurring slightly ahead of the activation of the 'what' processing mechanism, which may enable the brain to employ top-down spatial information to assist with the processing of speech sound identity cues.[39]

Dichotic listening studies have shed some light on how the AC processes dichotic stimuli. In 1999, Hugdahl et al. in a positron emission tomography study using dichotic CVs as stimuli found activation in the mid to posterior segment of the superior temporal gyrus, with the most noticeable activation levels occurring around Heschl's gyrus in both hemispheres.[46] However, when the activation patterns of the two hemispheres were compared, the extent of the activation in the left hemisphere was greater than that noted for the right hemisphere, a pattern that is consistent with behavioural findings for dichotic speech materials. In addition, the activation area in the AC appeared to extend beyond the 'core' and possibly even the 'belt' areas. Finally, results from fMRI and magnetoencephalography (MEG) studies have shown that directing attention to one ear or the other during dichotic listening to speech stimuli influences the amount of activation in the primary AC, with increased activity noted in the hemisphere contralateral to the attended ear.[47, 48]

Auditory evoked potentials

AEPs reveal stimulus-related responses that can be measured both near and far field. These responses can tell us, at least to some degree, about the functional integrity of the AC. Of course, the AEPs that are most relevant to AC function are those for which the generator sites are in the AC.

Perhaps the earliest of AEPs that are generated by the AC is the middle latency response (MLR) (**Figure 50.7**).[49]

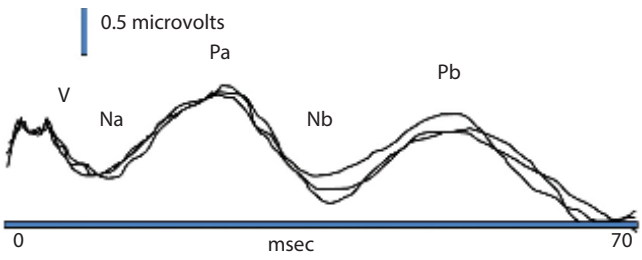

Figure 50.7 Sketch of a normal middle latency response (MLR). V = wave V of the auditory brainstem response (ABR) and Na, Pa, Nb, Pb are the wave components of the MLR.

The MLR is considered a thalamocortical potential, meaning that it is likely generated by the thalamocortical pathway. However, the main wave component of the MLR is the Pa wave, which most would agree is generated by the AC. The Pa wave has a latency of approximately 30 msec in adults for stimuli such as tone bursts and clicks presented at moderately intense levels. It appears to be generated by the medial aspect of Heschl's gyrus.[50]

The N1 and P2 potentials are often considered late and/or cortical AEPs. The N1 and P2 waves occur at about 100 and 200 msec after the onset of the stimulus in adults. The origin of N1 is Heschl's gyrus and possibly the planum temporale.[51] The P2 response also is generated by or in the area of Heschl's gyrus.[51, 52] The N1 appears to demonstrate laterality differences, with earlier latencies and greater amplitudes typically noted for the responses arising from the contralateral hemisphere, and with the right hemisphere showing greater lateralized activity (i.e. greater amplitude) than the left.[53] The P2 component may have laterality differences as well, but this has been debatable for a long time. Hine and Debener[53] relate that, if laterality differences exist for the P2, they are not as great as those noted for the N1. Even as far back as 1977 reports indicated that there was little agreement on laterality differences for AEPs.[54] Lesion effects on AEPs will be discussed in the next section of this chapter, which will provide additional information on AC function.

THE DISORDERED AUDITORY CORTEX

There is a long and respected history of learning about the function of the AC by measuring the effects of damage to it. This approach to learning about the AC can take a variety of forms. In this chapter we will focus on various ablation studies, and a new technique called cryoloop cooling as well as clinically based studies of various disorders of the human AC.

Ablation studies

Ablating the AC in mammals in most cases is related to some depression in performance on auditory tasks. Though cortical damage is generally not associated with changes in tonal thresholds, this may not be entirely true. One of the key investigations was performed on monkeys with bilateral AC ablations.[55] Immediately after these ablations the animals, at least in some cases, were unable to respond to simple stimuli but over a period of time ranging from months to years their detection thresholds improved in some cases to essentially normal levels.

Sound localization is dependent on good AC function. The early work by Neff in the late 1940s indicated that with cortical ablations animals could discriminate left-from right-sided sounds but could not locate these sounds in space with any degree of accuracy.[56] Later work showed that, if one AC was damaged, deficits of localization were often noted in the opposite auditory field.[57] Like most structures along the auditory pathway, damage to the AC compromises consistent and accurate sound localization.

Diamond and Neff[58] performed a series of bilateral AC ablations on cats. They initially measured the animals' intensity and frequency discrimination abilities before surgery and then reassessed these abilities post-surgery. The cats were able to relearn discriminations to near their pre-surgical performance levels. However, when the cats were tested on the discrimination of tone patterns, they did not regain pre-ablation performance levels. Since Diamond and Neff's studies in the late 1950s and early 1960s their findings on intensity and frequency discrimination have been both supported and disputed.[1] It has been shown that, after AC ablation, intensity discrimination suffers, especially for detecting decreases in intensity. Also, after AC ablations, non-human primates cannot distinguish a tone at given frequency from one that is changing in frequency.[55] This finding was consistent with animal research that demonstrated that, after AC ablations, gerbils were not able to accurately discriminate FM tones, while discrimination of steady-state tones was largely unaffected.[59] The findings of impaired pattern perception following AC ablation have been well accepted. In fact, these findings on auditory pattern discrimination influenced the development of two popular clinical tests of central auditory function (frequency pattern sequences and auditory duration patterns).

Cryoloop cooling

A relatively new technique termed cryoloop cooling presents some advantages over ablation procedures and other techniques that create permanent lesions.[60] Lesion effect studies often provide valuable clinical information in regard to disordered auditory systems. Cryoloop cooling involves passing cooled methanol through specially designed tubing directly into the brain. This tubing can be inserted for short-term study or implanted for long-term investigation of the physiology of the AC or other areas of the brain. The cooling has been shown to deactivate areas of the brain in a rather discrete manner, rendering the underlying neural circuitry inactive. However, the cooled area of the brain can then be allowed to warm and resume normal function. This capability provides the investigator with a research design that permits a measure of normal function, impaired function and then a return to normal function. It also allows the animal to retain a healthy system. Recent work with the cryoloop cooling procedure has shed light on a number of functions and dysfunctions of the auditory system, including the underlying mechanisms for localization[61] and effects of impairment in one auditory field on an adjacent field,[62] as well other processes.

Clinical studies

Clinical and clinically relevant studies have provided a significant amount of information on AC function and dysfunction in the human. One of the key findings reported in the mid 1950s was that simple high redundancy stimuli such as pure tones were not highly sensitive to AC damage, but more complex stimuli such as altered (distorted) speech materials were.[63] Low redundancy speech stimuli such as filtered speech, compressed speech, speech stimuli presented in noise and especially dichotic speech often revealed deficits for the ear contralateral to the damaged AC.[64] In addition, deficits in auditory pattern perception have been noted in individuals who suffered damage to the AC, though interestingly many of these patients with unilateral damage revealed deficits in both ears.[65]

Though not as commonly used clinically, studies employing AEPs on patients with AC lesions have often shown deficits. Principally, middle and late potentials (MLR, N1, P2 and P3) have been shown to be compromised in patients with AC pathology.[49] In humans, lesions of the AC can result in extended latencies and reduced amplitudes of cortically generated AEPs. However, in general it appears that changes in amplitudes of AEPs may be a more sensitive index for detecting dysfunction than changes in latency. Key in utilizing AEPs in AC lesion studies are multichannel recordings. Electrodes placed over the auditory areas and midline will allow comparisons of responses between the two hemispheres. Also, each ear can be, and should be, tested independently to allow ear comparisons. These types of comparisons can reveal differences which, if present, can document CANS dysfunction.

KEY POINTS

- The precise anatomical extent of the auditory cortex (AC) is uncertain.
- The auditory cortex codes intensity, frequency and temporal information from acoustic stimuli.
- The key vessel for the AC is the middle cerebral artery (MCA).
- The AC plays an important role in the ability to identify the location or the source of a sound.
- Auditory evoked potentials (AEPs) are clinically useful and can tell us about the functional integrity of the AC.

CHAPTER 51

PSYCHOACOUSTIC AUDIOMETRY

Josephine E. Marriage and Marina Salorio-Corbetto

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: pure-tone audiometry, audiogram, hearing loss, hearing thresholds, degree of hearing loss, type of hearing loss, speech audiometry.

INTRODUCTION

What the mind perceives as sound is not directly equivalent to the physical stimulus that reaches the ear. Psychoacoustics is the science that studies the transformation of the physical signal of sound into a mental percept. In other words, Psychoacoustics studies auditory perception. Psychoacoustic audiometry requires that a person is able to cooperate by giving a suitable response to the auditory stimuli being presented. In general, the methods described in this chapter will relate to adults and children older than approximately 5 years of age. Younger children require adjustments to the test protocol and to the type of response required, depending on age and abilities. These will not be covered here.

Psychoacoustic methods are valuable in clinical practice as their outcomes can give a first indication of the site of a lesion in the auditory system (i.e. external or middle ear, cochlea, or higher levels of the auditory system). Also, these methods provide a basic measure of the impact of ear pathology on communication.

AUDITORY DEVELOPMENT AND DECLINE OVER A LIFETIME

The auditory system in humans is permanently scanning and interpreting sound signals in the environment, moment by moment. The anatomical structures of the ears begin to develop around day 22 of gestation.[1] By weeks 25–30 of gestation, the outer, middle and inner ears are structurally developed, and the auditory system has experience of speech and other physiological sounds.[2] The fetus is capable of auditory learning while still *in utero*, as has been shown in fetuses as young as 33 weeks' gestational age.[3] There is evidence of auditory plasticity elicited by maternal voice and heartbeat before the full period of gestation is completed.[4] Near term, the fetus learns to recognize its mother's voice or a particular melody and is able to discriminate between these sounds after birth.[5]

Input from the peripheral auditory system shapes and drives the development of the central auditory system from the first years of life. Auditory deprivation arising from unidentified hearing loss can result in delays in linguistic,[6] social[7] and cognitive[7] development. The human auditory system continues to develop the capacity to receive, interpret, and respond to complex sound stimuli such as language and music over the first decade of life and well into the teenage years.[8] In later years, the auditory system starts to decline. 'Presbyacusis' (derived from the Greek words *presbys,* meaning 'elder', and *akusis,* meaning 'hearing') describes age-related changes to the auditory system. Four predominant pathological types of presbyacusis have been described: sensory, strial, neural and cochlear-conductive.[9] An individual may have more

than one type of presbyacusis, with age-related changes affecting both the peripheral and central auditory systems. Typically, changes to the periphery are seen in elevated pure-tone thresholds[10] and absent or reduced otoacoustic emissions (OAEs),[11] with decreased speech recognition scores, while changes to the central auditory pathways are demonstrated by even poorer speech recognition scores[12] and low scores on gap-detection tests,[13] which may indicate abnormal temporal processing. In other words, as the threshold for detecting a sound deteriorates with age, it may be paralleled by the reduced ability to discriminate and categorize complex sounds. In other cases, the hearing thresholds may be normal or near-normal, but suprathreshold abilities, such as the ability to use the information about the rapid time changes in sound (temporal fine structure), and some top-down cognitive processes involved in speech processing may deteriorate, which is reflected by poor speech intelligibility in noise.[14]

USEFUL DEFINITIONS

Sound level: Sound levels are measured in decibels (dB). Decibels are used to express the magnitude of a sound relative to a reference. The number of decibels is 10 times the logarithm of the ratio of two intensities, or 20 times the logarithm of the ratio of two amplitudes or pressures. The reference commonly used for sound in the air is 20 µPa, as this is close to the average absolute threshold for 1000 Hz (see Chapter 48, Physiology of hearing). This is defined as 0 dB SPL (sound pressure level). Decibels are a convenient unit, as the human dynamic range of hearing is very wide. The ratio between the intensity of the softest detectable sound and that of the loudest tolerable sound one can hear is vast, being in the order of 1 000 000 000 000:1, which corresponds to 120 dB.[15]

Frequency: The frequency of a sound is the number of times the wave is repeated within 1 second.[15] Each repetition is known as a cycle, and one cycle per second corresponds to 1 Hertz (Hz), which is the standard unit used to specify frequency (see Chapter 48, Physiology of hearing).

Absolute threshold: The level at which a person reliably just detects a signal in the absence of any other sounds is referred to as the **absolute threshold** for that sound. If the sound level were to be increased even slightly, the person would always hear the sound; if the sound level were to be decreased, the sound would be generally inaudible. The absolute threshold is the 'lowest sound pressure level or vibratory force level at which, under specified conditions, a person gives a predetermined percentage of correct detection responses on repeated trials'.[16] In audiology, the absolute threshold is also referred to as the **hearing threshold**. Measuring the absolute threshold for pure tones at different frequencies is standard practice in clinical settings. This is known as 'pure-tone audiometry' (PTA), and it aims to quantify the degree of hearing loss.

Minimal audibility curve: The human ear does not have equal sensitivity for pure tones across frequencies. For example, a pure-tone signal of 100 Hz is just detectable to the normal-hearing person when delivered to the ear via headphones at a level of about 35 dB SPL. However, a 4500 Hz pure-tone signal at a level of about 12 dB SPL will be just audible to a normal-hearing person. Figure 51.1 shows the minimal audibility curve for normal-hearing listeners. The dashed line shows thresholds measured monaurally, usually delivering the sound by headphones. The sound pressure levels at thresholds were measured with a probe microphone placed closed to the eardrum. A threshold measured in these conditions is called the minimum audible pressure (MAP). The solid line shows thresholds measured bilaterally, by delivering the sound through a loudspeaker in an anechoic chamber. The sound pressure levels are thresholds measured in the sound field, at the point where the centre of the head of the listener was placed, after the listener has left the room. A threshold measured in such conditions is called the minimum audible field (MAF). MAP thresholds are about 2 dB higher than MAF thresholds, since the latter are binaural and the former monaural. The MAP and MAF curves also differ in shape, particularly at around 3000–4000 Hz and around 8–9 kHz.[15] This is due to the effect of the head, the pinna, and the ear canal when thresholds are measured in the sound field. Remember that the conditions of measurement for these curves are different. The maximal sensitivity is around 2000–5000 Hz as this is the range where the least sound pressure is required to just detect a sound at threshold. Between 500 Hz and

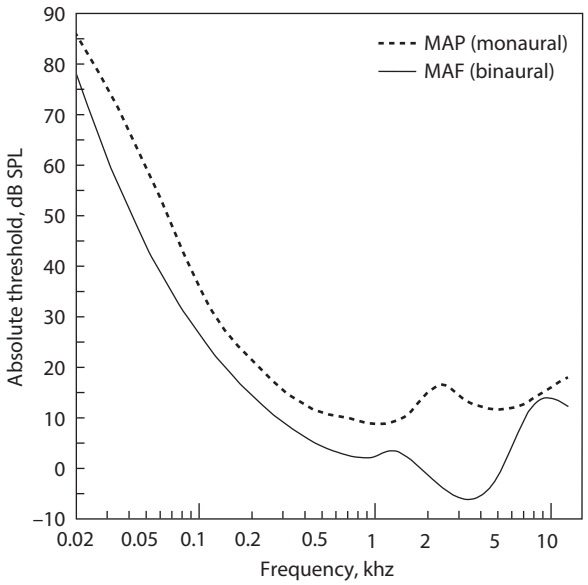

Figure 51.1 The solid line shows the MAF estimates for binaural listening as published in the standard ISO 389-7:1996. The dashed line shows the MAP estimates for monaural listening. Figure courtesy of Brian C.J. Moore. Published in *An introduction to the psychology of hearing*, 6th ed. Emerald Group, 2012.[15]

5000 Hz the variation in sensitivity is less than 10 dB and this is the frequency range that encompasses most speech sounds. Outside this range, hearing becomes increasingly less sensitive. This is partly due to the characteristics of the transmission of vibrations by the middle ear to the cochlea.[17] It is generally agreed that the range of human hearing for typically hearing young adults falls between 20 Hz and 20 000 Hz.

Upper level limit of hearing: The upper limit of hearing before pain and possible damage to the auditory system is in the region of 120–130 dB SPL; the upper limit of comfort for most people is well below this, however, in the region of 100 dB SPL.

PSYCHOACOUSTIC CORRELATES OF SOUND PRESSURE LEVEL AND FREQUENCY

Loudness and sound pressure level: It is generally understood that the higher the level of a sound is, the louder it will sound. In other words, loudness is the subjective psychoacoustic correlate of sound pressure level, although there are additional factors that can influence loudness. Loudness is the term used for the attribute of sensation by which a listener can order sounds on a scale going from quiet to loud,[15] whereas the measured level of a sound is based on the physical properties of the signal. The relationship between loudness and sound level is not straightforward. Two sounds of different frequencies can have different sound pressure levels but lead to the same loudness level. For example, a 40 dB SPL 1000 Hz pure tone may be judged to have the same loudness as a 250 Hz pure tone presented at 50 dB SPL. The unit used to quantify loudness levels is the **phon**. The phon is referenced to a particular level of a 1000 Hz pure tone against which the loudness of all other tones is matched. The 250 Hz tone would therefore have a loudness level of 40 phon. Figure 51.2 shows the equal loudness contours and the lower dashed curve represents the hearing threshold. The shape of the loudness contours changes with increasing level, with contours becoming flatter at high input levels.

The healthy auditory system is able to operate in a very wide range of sound levels, as described above. There are several mechanisms that may be involved in supporting the wide dynamic range of human hearing: the compressive behaviour of the basilar membrane, changes in the firing rate of the auditory nerve, the spread of excitation on the basilar membrane, and the information provided by phase-locking of the responses of the auditory nerve.[15] Although describing these mechanisms and discussing their contribution is beyond the scope of this chapter, they are mentioned here because one of the most common manifestations of cochlear damage in ENT clinics is **loudness recruitment**. Loudness recruitment occurs when the dynamic range of hearing is narrower than normal.

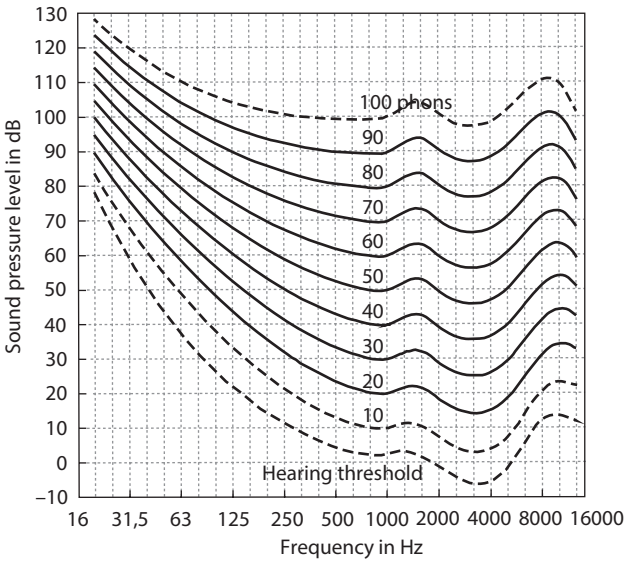

Figure 51.2 Graph showing the equal loudness contours and the lower dashed curve representing the hearing threshold. Figure courtesy of Brian C.J. Moore. Published in *An introduction to the psychology of hearing*, 6th ed. Emerald Group, 2012.[15]

In other words, the range between the sound level that is just detectable and the maximum comfortable level is less than for normal-hearing people.

Pitch and frequency: Pitch is an 'attribute of the auditory sensation in terms of which sounds may be ordered on a scale extending from low to high'.[18] Periodic sounds have pitches, as pitch is related to the repetition rate of the sound. For pure tones, the repetition rate of a sound is given by its frequency. Thus, pitch and frequency are closely related for pure tones. As stated above, frequencies are objectively measured using units of Hertz (Hz). Pitch cannot be measured directly because it is a subjective quality. Pitch is coded in the auditory system using both a place code (given by the distribution of activity across the auditory neurons) and a temporal code (given by the temporal patterns of firing within and across neurons). The relative importance of these codes for a given sound may depend on its frequency range and other characteristics.[15]

The thresholds for sounds of different frequencies are measured in PTA. The frequencies of the tones presented to the patient during audiometric testing are measured at octave intervals, i.e. their frequencies increase by a factor of 2 from tone to tone: 250, 500, 1000, 2000, 4000 and 8000 Hz. Sometimes semi-octave frequencies are tested too, as will be explained later. It should be noticed that pitch perception, as many other suprathreshold abilities, is not explored during PTA. The detection of a sound does not imply the perception of all the qualities of that sound. For example, two patients with identical pure-tone audiograms may have completely different outcomes for speech perception. Similarly, it is not uncommon to find patients who have rather good hearing thresholds but relatively

poor sound discrimination or even speech perception. From a clinical point of view, it is important not to dismiss any functional problems described by the patient solely based on a normal or near-normal audiogram.

PURE-TONE AUDIOMETRY

The purpose of PTA is to determine the hearing thresholds for pure tones, which are sinusoidal signals with a single defined frequency, amplitude and phase (see Chapter 48, Physiology of hearing). While pure tones are rare in nature, they are easily characterized, which makes them suitable for quantitative tests of hearing sensitivity. Pure tones can be considered as the basic components for all periodic sounds generated by the human larynx and many tones from musical instruments, thus having validity for hearing assessment in addition to convenience of use.

There are international and national standards that specify the characteristics and calibration of the equipment used to carry out PTA (e.g. IEC 60645-1:2017[19] and BS EN 60645-1:2017[20]), as well as the characteristics of the test room and the procedure followed for identifying thresholds (ISO 8253-1:2010[21]). These specify the types of signal used, the way in which they are presented and their duration, the type of response expected from the patient, and the presentation mode (air conduction (AC) or bone conduction (BC), as will be explained later). It is crucial to follow these conventions in order to obtain valid, comparable results across sessions and clinicians. Local professional societies usually publish their own guidelines for the procedures, which in turn are in line with the current standards (e.g. American Speech–Language–Hearing Association,[22] British Society of Audiology[23]).

Equipment for pure-tone audiometry

The principal equipment for deriving the clinical audiogram is the audiometer. There are four different levels of complexity of functions and options, classified as: screening, clinical, diagnostic, and more recently, via computer-integrated software applications.[19, 20] **Figure 51.3** shows a clinical audiometer. All types of audiometer generate pure tones at specified levels for standard test frequencies. In addition, there are narrow and broad bands of noise for use in clinical testing, as discussed later. The option of being able to present pure tones as modulated warble tones or pulses can help listeners detect signals in the presence of tinnitus. Warble tones are also crucial for getting around standing-wave artefacts particular to a given booth in the sound field. Some audiometers include options for higher-frequency hearing assessment up to 16 000–20 000 Hz, used, for example, for monitoring the effect of ototoxic drugs on high-frequency hearing thresholds.[24]

The calibration of test equipment is required at least annually and perhaps twice-yearly in some situations. Calibration may drift over time so that the gradual change in signal output is not apparent without systematic daily checks and measurement routines as specified in ISO 8253-1:2010.[21] Changes in the transducer type – for example, between headphone sets, or from headphones to insert earphones – require different calibration settings to be stored within the audiometer. The audiometer, transducers and response buttons (used by the patient to indicate that they hear the stimuli) need to be clean, functioning consistently, and used with the correct calibrated equipment.

Figure 51.3 A clinical audiometer.

Transducers: air-conduction and bone-conduction measurements

When performing PTA, the tester fits the transducers to the patient, and the patient is instructed not to move or hold the transducers. The examiner should check for any discomfort caused by the transducers.

The use of AC and BC transducers seeks to separate the conductive (outer and middle ear) and sensory (cochlear) components of hearing loss. Signals presented from headphones or insert earphones are transmitted by AC. In BC testing, a bone vibrator is positioned on the mastoid behind the pinna, or sometimes on the forehead, with a known force so that mechanical vibrations are coupled to the skull bone to stimulate the cochlea through bone transmission. The sensitivity for detecting these mechanical vibrations depends largely on the inner ear function, with reduced influence of the outer and middle ears. Thus, comparison of results obtained by AC and BC often allows the separation of conductive and sensorineural components of hearing loss. There are, however, caveats in this simple model which have useful diagnostic indications, as described later in this chapter.

AIR-CONDUCTION TRANSDUCERS

The most common headphone type is the Telephonics TDH-39, 49 or 50 headphone, which is a **supra-aural** headphone. These rest on the surface of the pinna, without enclosing the pinna in their cups. Supra-aural headphones can fail to achieve good coupling with the ear. Thus, air

leaks can occur, and the hearing thresholds below 500 Hz may be overestimated as a consequence.[25]

An alternative type is the **circum-aural** headphone, which encloses the pinna in its cups. These are designed to give a close fit to the outer ear to prevent leakage of the test signal or ambient noise from the test environment, and reduce the amount of physiological noise in the ear.[25] Examples include Sennheiser HDA-200 headphones, which have noise-excluding muffs and can be used for high-frequency audiometry (i.e. 8000–20 000 Hz). However, circum-aural headphones, as well as supra-aural headphones, are less reliable at high frequencies due to wave effects in the cavity defined by the headphone and the ear canal, which in turn depend on the positioning of the headphone.[25]

A third type of AC transducers are **insert earphones** (e.g. Etymotic Research EAR-Tone 3A). These consist of two probes (right and left) covered by a disposable foam tip that is placed in the ear canals for testing. Insert earphones give improved attenuation of ambient noise relative to supra-aural headphones, along with reduced likelihood of infection transmission as inserts are single use,[26] and the positioning of the insert reduces the likelihood of the ear canal becoming collapsed in soft or elderly ears.[26] They also reduce the amount of physiological noise in the ear and the occurrence of air leaks even further than circum-aural headphones, and reduce the wave effects associated with the other types.[25] In addition, they are more convenient when testing patients with profound loss at the low frequencies, for whom responses are given to vibrotactile stimulation. Insert earphones reduce vibrotactile stimulation when delivering high-level low-frequency tones.[27] They also have a higher 'interaural attenuation' compared to supra- and circum-aural headphones.[25, 26]

Interaural attenuation (or transcranial transmission loss) is the attenuation of sound delivered by a transducer to one ear as it reaches the opposite ear. While supra-aural headphones typically have 40 dB interaural attenuation, Etymotic Research ER3 or ER5 insert earphones inserted deeply have at least 75 dB interaural attenuation at frequencies below 1000 Hz, and about 50 dB interaural attenuation at frequencies above 1000 Hz.[28] This is relevant when testing the AC hearing thresholds of persons with asymmetric hearing or with bilateral conductive hearing loss, and it will be addressed later in this chapter. However, insert earphones are not recommended when there is excessive earwax in the ear canal, or when obstructions and abnormalities affect the ear canal or in the event of ear infection.[23]

The correct position for supra- or circum-aural headphones is to have the sound opening of the headphone aligned with the ear canal entrance. For insert earphones, the correct position is to have the outer end of the foam tip flush with the ear canal entrance. It is important to use an appropriate-size tip for the earphones. **Figure 51.4** shows the correct placement of supra- and circum-aural transducers. **Figure 51.5** shows correct insert positioning.

Calibration standards are different for supra-aural headphones (ISO 389-1:2017[16]), insert earphones ISO 389-2:1994[29]) and circum-aural earphones (ISO 389-8 2004[30]).

BONE-CONDUCTION TRANSDUCERS

The most commonly used BC transducer for clinical audiometry is the Radioear B-71. The transducer is held at one end of a rigid vertical headband. The opposite end has no transducer attached and serves only as support. When placed correctly, the headband holds the BC transducer against the skull with a given static force. The BC transducer is placed first on the mastoid prominence of the worse-hearing ear.[23] The transducer must be placed so that it is as close as possible to the pinna, without touching it and avoiding the hair (see **Figure 51.6**).

The Radioear B-71 is prone to distortion below 500 Hz[31] and limited above 6000 Hz.[32] Thus, testing is generally done for frequencies between 500 Hz and 4000 Hz. For 3000 Hz and 4000 Hz, especially when testing at relatively high-level, the Radioear B-71 produces airborne sounds. In order to prevent the patient from responding to these, an earplug can be used in the test ear when testing the BC threshold in this ear. It is important to record the use of an earplug during testing on the audiogram form as this causes an occlusion effect. Airborne sounds are reduced when placing the BC transducer on the forehead. However, corrections should be made to the calibration in this case.[23] Recently, it was proposed to adjust the reference equivalent force threshold level (REFTL), especially for 4000 Hz, to reduce observed false air–bone gaps at this frequency.[33] Calibration for BC transducers is specified in the standard ISO 389-3:2016.[34]

Environment for clinical testing

The acceptable level of ambient noise in the test environment is specified by standard ISO 8253-1:2010.[21] It is generally accepted that the ambient noise should not exceed 35 dB(A). Additionally, the examiner should be aware that transient noise (i.e. coughing, furniture noise following movement, etc.) can also affect the test results.

It is crucial that the examiner can see the face of the patient at all times. This helps to detect situations when the patient is confused, or has lost their focus on the task, or feels that the test sounds are unpleasant. It is equally important that the patient is not able to see or hear the examiner manipulating the audiometer controls. Usually, the patient sits in a soundproof booth during the test, and the examiner controls the audiometer from outside the booth (**Figure 51.7**). Soundproof booths used for clinical testing have silent fans, light and a double-glass window or a closed-circuit TV system through which the examiner can see the patient and the patient can see the face of the examiner. The examiner and the patient should be able to talk to one another when needed, thus an intercom system is available in most clinical audiometers.

Audiometric procedure for clinical assessment

BEFORE THE TEST

The following is based mainly on the recommendations of the British Society of Audiology.[23] The examiner relies

Figure 51.4 Correct position of the supra-aural headphones **(a,b)** and circum-aural headphones **(c,d)**.

on the patient's responses for the accuracy of the test and therefore establishes at the beginning of the test that the patient understands what they are expected to do and that they feel comfortable in the test environment. Several factors about the patient, including age, hearing deficit, language skills and communication problems (whether or not related to their hearing problem), should be taken into account. Important communication difficulties must be recorded as they are likely to affect the outcomes of the test. If the test is carried out in a soundproof booth, claustrophobia will constrain testing for some patients. In this case, the environment should be modified (e.g. by

Figure 51.5 Insert earphones. (a) Correct position of earphones. **(b)** View of the inside of the ear canal in an ear model. This illustrates the depth of the transducer into the ear canal when the foam is placed flush with the entrance of the ear canal, as shown in (a).

Figure 51.6 Correct placement of the bone-conduction transducer. Note that the transducer is not touching the hair or pinna.

not closing the door of the booth) to avoid subjecting the patient to undue anxiety, and any modifications to the test procedure should be noted in the outcome form or audiogram.

Typically, the patients are asked about two situations that can interfere with the detection of the test tones:

- **Exposure to loud sounds in the last 24 hours:** In this case, it may be necessary to retest the patient as loud sounds could temporarily shift the hearing threshold.
- **Tinnitus:** In this case, the patient must be asked to ignore their tinnitus as much as possible. The clinician may decide to use warble tone signals to make it easier for the patient to distinguish between their tinnitus and the test stimuli. Frequencies where there was variation in thresholds and any modification in the protocol to measure the thresholds should be recorded.

Patients are also asked whether they have better hearing in one ear, as in this case testing should start in that ear.

It is essential that the PTA is preceded by otoscopic examination, and that the findings are noted on the audiogram. Hearing thresholds will be affected by the presence of occluding earwax so, if occluding earwax is detected, the patient should have earwax removal first. If it is determined that the ear canals are likely to collapse during the test, this should be noted in the audiogram, and insert earphones should be used if possible.

Before carrying out the test, instructions are given to the patient about what they are expected to do during the test. While the wording can be varied, the essential points of the instructions should be kept constant in order to be able to compare test results across sessions and/or examiners. The British Society of Audiology proposes the following instructions to the patient:

> *'I am going to test your hearing by measuring the quietest sounds that you can hear. As soon as you hear the sound (tone), press the button. Keep it pressed for as long as you hear the sound (tone), no matter which ear you hear it in. Release the button as soon as you no longer hear the sound (tone). Whatever the sound and no matter how faint the sound, press the button as soon as you think you hear it, and release it as soon as you think it stops.'*[23]

A printed version of these instructions may be useful. The patients should be asked whether they understood the instructions, and should be told to sit quietly during the test, and that they may interrupt the test in the event of discomfort.

The patient responds by pressing a button or perhaps raising a finger, in the way indicated in the instructions. Every time the button is pressed a light indicator is lit on the audiometer panel, so that the examiner knows that the patient has responded.

MEASURING THE HEARING THRESHOLDS

As discussed above, the procedure for PTA is specified by the relevant standards.[21] For AC audiometry, the test is started in the better ear, and the threshold for each of the pure tones is measured before moving to the next pure-tone test frequency. Traditionally, the order of the pure tones presented to the patient is: 1000 Hz, 2000 Hz, 4000 Hz, 8000 Hz, 500 Hz and 250 Hz. Inter-octave frequencies can be tested if there is a difference of 20 dB hearing loss or more between contiguous frequencies. The threshold at 1000 Hz is then retested for the ear tested first only. If the test–retest difference is within 5 dB, the best hearing threshold is noted. If the test–retest difference is greater than 5 dB, it is necessary to check that the patient understands the procedure, the transducers are still in place, and the response button works properly, together with other possible sources of variation. After testing the first ear, testing is carried out in the other ear. Retesting of the hearing threshold at 1000 Hz is not required for the second ear if there was no significant test–retest difference for the first ear.

Testing is preceded by a familiarization trial. Details of the step-by-step procedures for familiarization and testing are shown in **Figures 51.8** and **51.9**. Each test signal is introduced at an easily audible level, and then systematically attenuated, or reduced in volume, in 10 dB steps until the signal is inaudible. When the patient does not respond, the signal is increased in steps of 5 dB until the signal becomes audible and the patient responds. This can be described as a 'bracketing technique' and it is also called the '10 dB down, 5 dB-up technique'.

The bracketing technique used to determine the hearing threshold is schematized in **Figure 51.9**. This technique is used until two corresponding ascending thresholds have been derived, with the listener responding for the full duration of the signal. The duration of the signal is varied between 1 and 3 seconds. At very short durations, there is a trade-off between time and intensity, with the hearing threshold being higher for shorter sounds. This occurs for sounds shorter than about 200 msec. It is therefore convention that signal durations shorter than 500 msec are not used during the measurement of the audiogram. Duration is usually varied between 1 and 3 seconds.[23] The onset and offset of the pure-tone signal is the most salient feature for detection when listening close to threshold. For accurate assessment of hearing thresholds, the listener is required to respond by pressing the button, or perhaps raising a finger, for the full duration of the perceived signal rather than just at the onset. Effective audiometry requires unpredictable silent gaps (lasting 1–5 seconds) between signal presentations, as rhythmic presentation leads the patient to respond at regular times, even if they did not hear the signal. It is generally accepted that the threshold of hearing is defined as the stimulus level giving rise to 50% or more correct detection responses, or a minimum of two out of two, three or four ascending presentations.[23]

Testing is carried out by AC first and then, if necessary, by BC. Test frequencies for BC are those in the range 500–4000 Hz, with no retest at 1000 Hz required. The mechanism for transmission of sound through BC conduction is more complex than for AC. However, comparison of results for AC and BC generally provides evidence for

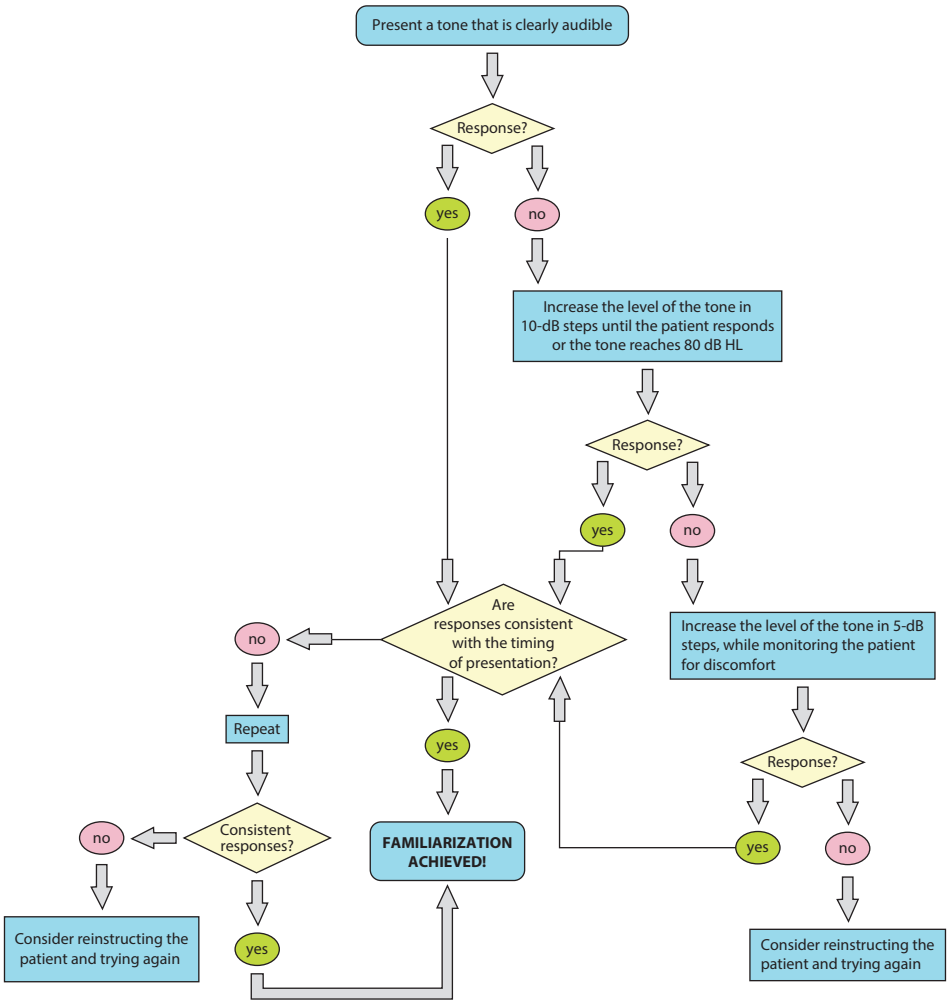

Figure 51.8 Procedure to achieve the familiarization of the patient with the task.

conductive and sensorineural components of hearing loss, although BC thresholds can be increased in the absence of sensorineural loss

The AC pure-tone audiogram is the basic test used to express the degree of hearing loss. BC thresholds provide important information for differentiating between conductive and sensorineural disorders. An equal extent of hearing loss for AC and BC generally indicates a sensorineural lesion whereas a larger loss by AC than BC, referred to as an air–bone gap (ABG), often indicates a conductive lesion. The ABG at a single frequency needs to be at least 15 dB in order to be considered clinically significant, particularly at 4000 Hz where there is a recognized artefact in the BC threshold norms.[33] As mentioned above, it should be noted that BC thresholds can occasionally be increased due to pathology affecting the middle ear and not the cochlea. An example is the hearing loss due to otitis media with effusion. Although in most cases BC thresholds are normal, these can be slightly elevated, especially at lower frequencies. According to Huizing[35] this can occur because: a) The round window is being pressed by a fluid; b) the stiffness of the middle ear is increased by the negative air pressure; c) the resistance of the mass of the middle ear may be increased by the presence of fluid and

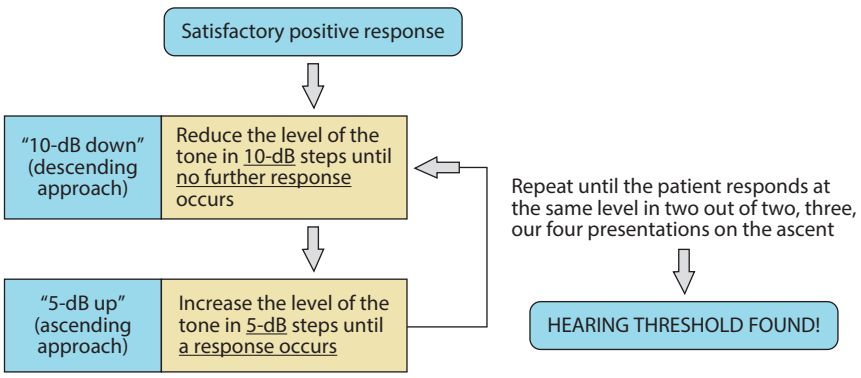

Figure 51.9 Method to measure threshold.

the swelling of the mucosa (which can improve or worsen BC thresholds depending on its point of action on the ossicular chain). Another example is the 'Carhart notch' (originally thought to be present more often at 2000 Hz),[36] described as an increased BC threshold that improves after surgical treatment in cases of otosclerosis.[37]

MASKING

In order to accurately measure hearing in each ear, signals are presented directly to the right and left ears. In the case of poorer hearing in one ear, when a signal is delivered to that ear at a sufficiently high level, it may be perceived in the contralateral ear. This is known as **transcranial transmission** or **cross-hearing**, and it is related to the concept of interaural attenuation introduced in 'Air-conduction transducers' above. If the hearing threshold of the non-test ear is equal to or lower than the level of the stimulus minus the interaural attenuation, then the stimulus may be detected by the non-test ear. Using conservative estimates of interaural attenuation, it is recommended to present a continuous masking noise (or masker) to the non-test ear to prevent cross-hearing of the test tone whenever there is an interaural difference of 40 dB or more when using supra- or circum-aural headphones, or 55 dB or more when using insert earphones.[23] As BC signals are transmitted to both cochleae, regardless of the side on which the transducer is placed, it is necessary to deliver masking noise to the non-test ear to prevent the test signal being detected in that ear. Calibration for the narrow-band noise signals used for clinical masking are specified in the standard ISO 389-4:1994.[39] Masking noises used in clinical masking are calibrated in dB 'effective masking level' (dB EML). Presenting the masking noise at a given EML will raise the threshold for a pure tone of the same frequency as the geometric centre frequency of the noise to that level.[23] For example, if the threshold for a pure tone of a given frequency were taken when presenting (to the same ear) a noise centred at the same frequency and whose level was 50 dB EML, the masked threshold would shift from 0 to 50 dB HL.[23, 28]

A procedure for plateau-seeking for clinical masking is specified in ISO 8253-1:2010.[21] The masking noise is presented continuously to the non-test ear and is introduced first at a level where it is just audible. It is increased in steps of 10 dB and the threshold for the pure tone signal is re-evaluated. When the masking noise level can be increased by three 10 dB steps without changing the detection level of the test tone, this constitutes the masking plateau (See **Figure 51.10**). This is interpreted as the true hearing threshold of the poorer test ear. This method is known as the 'plateau-seeking' method.

There are constraints in the use of clinical masking: sometimes the masking plateau cannot be reached because the level of the masking noise is so high that it reaches the test ear by cross-hearing and it shifts the measured hearing thresholds. This is called 'cross masking', and is likely to occur when testing listeners with a large bilateral conductive hearing loss. Use of an insert earphone reduces the likelihood of cross masking in addition to the necessity for clinical masking. Additionally, special masking techniques may be required in these cases.

Although the plateau-seeking method is the standard procedure for clinical masking, clinicians sometimes use abbreviated procedures in which an initial masking noise level is used, and subsequent increments of this level, if necessary, are adaptively varied depending on the threshold shift in the presence of the masking noise (e.g. see Yacullo).[28] Such procedures have the advantage of using lower masking noise levels in most cases, and the disadvantage of not producing a masking noise level–threshold function. Masking noise level–threshold functions (usually called 'masking functions') can be useful to detect cases of central masking (a usually 5 dB threshold shift that occurs when the tone is presented together with a contralateral masking noise and may be related to central processes)[28] or cases of cross-masking. The clinician should use their judgement to determine which type of procedure is most suitable in each case.

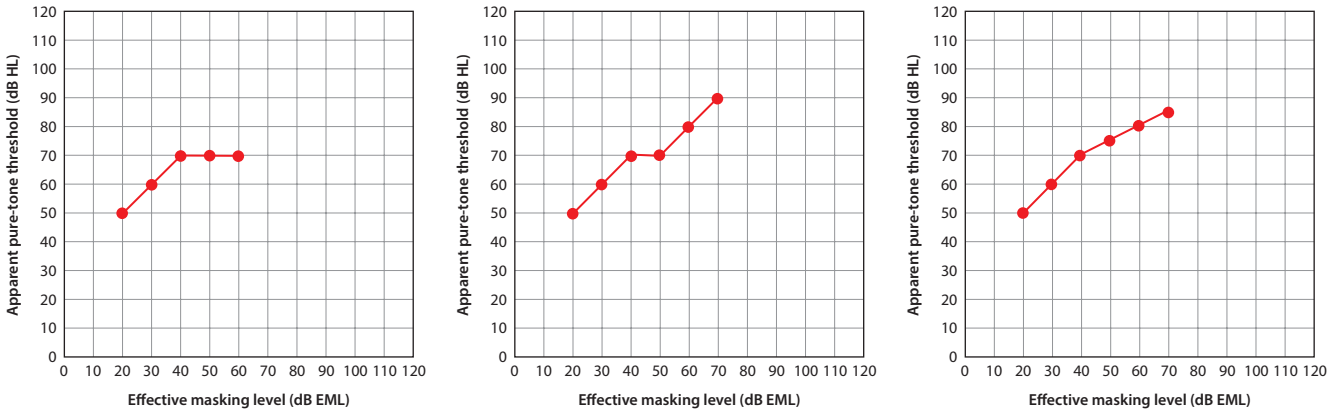

Figure 51.10 Examples of masking functions. The left panel shows a typical shape of the curve when a plateau is reached and the masked threshold is found. In this example, the threshold is 70 dB HL, as this is the level where the plateau is found. The central panel shows an example of cross-masking. Here the plateau is short, consisting only of two points. This is followed by a second 1 dB per dB slope. The right panel shows an example of central masking, where the slope of the function is less than 1 dB per dB. In this example a 5-dB increase of the hearing threshold follows a 10-dB increase in the masking noise, so the slope is 0.5 dB per dB.

TABLE 51.1 Rules or indicators for the use of clinical masking

'Rule'	Situation	What to do
1	The not-masked AC thresholds differ by 40 dB or more when using supra- or circum-aural headphones, or by 55 dB when using insert earphones.	Retest the AC threshold of the worse ear masking the contralateral ear.
2	The not-masked BC threshold of one ear is better than the AC threshold of either ear by 10 dB or more.	Retest the BC threshold of the ear with the worse AC threshold masking the contralateral ear. Use clinical judgement. Is it critical to diagnosis to apply this rule (e.g. when there are only small BC thresholds)? If the masked BC threshold has changed little (i.e. up to 10 dB), it may be necessary to retest the BC threshold of the ear with better AC thresholds masking the contralateral ear.
3	Rule 1 was not applicable, but the BC threshold of one ear (ear A) is 40 dB (for supra- or circum-aural headphones) or 55 dB (for insertion earphones) better than the not-masked AC threshold for the other ear (ear B).	Retest the AC threshold of ear B masking ear A.

Although interaural attenuation varies across individuals, there are some rules or 'indicators' for the use of clinical masking during audiometric testing. These rules are based on typical values of interaural attenuation. Table 51.1 summarizes the rules for the use of clinical masking as recommended by the British Society of Audiology,[23] for AC and BC testing. In clinical practice, there are often cases where it is difficult to obtain accurate masked thresholds.

It is fundamentally important for ENT doctors to have reliably masked audiometric information for discussion and decision-making of surgical options.

DURATION OF TESTING

The total time for testing should be managed with care to avoid fatigue and its subsequent impact on test results. It is recommended that the subject should have a short break if the test exceeds 20 minutes.[23]

INTERPRETING RESULTS

Test–retest difference

The test–retest difference in hearing levels measured on two different occasions is accepted as +/–5 dB without necessarily indicating a real change in hearing levels. If assessing average change in threshold across two or three frequencies, a difference of 10 dB is more likely to be significant.[38] The test–retest accuracy for absolute thresholds derived with BC transducers is poorer than that for AC transducers.[38]

Variability in responses

Variability in hearing thresholds can be influenced by multiple factors including:

- **subject variables**, including physiological noise or tinnitus, attention state, fatigue and motivation, and precise wording of instructions to the subject
- **method of assessment**, including the duration and variation in the intervals between signal presentations, subject positioning in test booth, ambient noise levels in the test environment, method of response (e.g. pressing a button or lifting a hand)
- **type and placement of signal transducer**, including removal of earrings and glasses when needed; relatively small changes in placement over the earphone in relation to the ear canal can affect the sound pressure at the eardrum
- **calibration of test equipment**, monitoring and maintenance of all parts including transducers, plugs and connectors.

Screening audiometry

There are procedures for screening audiometry, for example the one described in ISO 8253-1:2010.[21] The outcomes are either a 'pass' or a 'fail' rather than defined audiometric thresholds. Industrial or occupational hearing screening is often provided using automated audiometry and is not within the remit of this chapter.

The pure-tone audiogram

The results of PTA are plotted on the pure-tone audiogram, which is a graphic representation used to characterize hearing detection thresholds in each ear for clinical assessment.

The pure-tone audiogram is a graph where the *x*-axis shows the frequency of sounds in Hertz and the *y*-axis shows the sound level expressed in decibels hearing level (dBHL), where 0 dBHL represents the average threshold for otologically normal young individuals at each frequency. Thresholds in the minimal audibility curve (see Figure 51.1) are expressed in dBSPL (decibel sound pressure level). As mentioned above, the minimum sound pressure level required for the hearing threshold of a sound varies with frequency. Therefore, if the mean normal-hearing thresholds were plotted in dBSPL, a curve would be obtained. In contrast, in a pure-tone audiogram, the average normal-hearing thresholds across frequency lie on a straight line, as they are expressed in dBHL. Another difference between the graph in Figure 51.1 and

a pure-tone audiogram is that the levels in the *y*-axis are ascending from bottom to top in the former, but they are descending from bottom to top in the latter. Levels are shown in the pure-tone audiogram from –10 to 120 dB HL. Negative numbers mean that the measured thresholds are better than the average.

The *x*-axis, which is logarithmic, represents frequency in the range 125–8000 Hz, thereby covering the frequencies important for understanding speech and the frequencies of many environmental sounds. For example, 250 Hz is close in frequency to middle C on the piano keyboard.

Assessment is performed at each frequency across octave spaces, typically at 250, 500, 1000, 2000, 4000 and 8000 Hz. Inter-octave frequencies (e.g. 750, 1500, 3000 and 6000 Hz) may be included in steeply sloping hearing loss configurations or when the desired frequency resolution is greater (e.g. for the fitting of hearing aids). It is recommended to use forms with an aspect ratio of 20 dB : 1 octave to facilitate the visual reading of the audiometric curve. It is important to register the date of the test, the name of the examiner, the audiometer and transducers used and the date of the last calibration.

Figure 51.11 shows an audiogram chart. Note that the test results for each ear and transducer have different symbols. Outcomes for the right ear are usually plotted in red, and those for the left ear are usually plotted in blue. AC symbols are open circles for the right ear and crosses for the left ear. The thresholds are joined by continuous straight lines. In the UK, BC thresholds are either an open triangle for unmasked thresholds or a square bracket for masked thresholds (see below). BC thresholds are usually joined by broken straight lines. Conventions may vary slightly between countries. It is important to use conventional symbols in order to facilitate the interpretation of test results across institutions.

Figure 51.12 shows a simplified representation of the levels and frequencies of the sounds of speech and of environmental sources on the audiogram. Graphs of this type are used for counselling purposes, and the area where the speech sounds are represented is colloquially known as 'the speech banana'. Although the perception of these sounds should not be thought of as an 'all-or-nothing' event, merely reliant on the audibility at a given frequency/level, it is useful to see where conversational and environmental sounds fall on the audiogram plot. It should be noted that the audiogram is mainly focused on the range of frequencies that are important to understand speech.

Interpreting the pure-tone audiogram

QUANTIFYING THE EFFECT OF HEARING LOSS

Traditionally, hearing loss is characterized by its degree: mild, moderate, severe and profound. These degrees are defined as ranges where the average hearing threshold falls. An example of these categories is the classifications of the British Society of Audiology (2011),[23] which is based on the average of the hearing thresholds for 250, 500, 1000, 2000 and 4000 Hz, and describes four categories:

- Mild: 21–40 dB
- Moderate: 41–70 dB
- Severe: 71–95 dB
- Profound: 96 dB and above.

Classifications based on the average hearing loss originated from the need to have an easy way of describing cases among professionals or from professional to patient.[40] However, they do not describe the implications of hearing loss accurately for several reasons. First, hearing loss often affects hearing thresholds unevenly across frequencies. Examples are shown in Figure 51.13. The hearing losses shown for 'Example 1' and 'Example 2' have the same pure-tone average (60 dB HL) but the audiogram configuration (i.e. the shape of the audiogram, given by the difference in hearing thresholds across frequency) differs considerably across the two. The functional consequences of each hearing loss will vary significantly. These examples, most common in clinical practice, illustrate how inadequate the classification of hearing loss by degree based on hearing thresholds is.

It is also worth mentioning that even individuals with the same degree and configuration of hearing loss may have very different outcomes in real-life communication. The impact of hearing loss cannot be appreciated based purely on the audiogram, as characterization of the degree of hearing loss based purely on the hearing threshold does not account for suprathreshold deficits, such as in the mechanisms for frequency selectivity, temporal resolution and integration, etc. Thus, the degree of hearing loss defined by the hearing threshold does not adequately reflect the impact of hearing loss on auditory perception, communication and quality of life. In addition, other factors that can have an influence on the functional implications of hearing loss, such as the existence of other sensory deficits, use of hearing aids, lip-reading abilities, cognitive abilities and family support, among others, are not considered.

FUNCTIONAL IMPACT OF HEARING LOSS ON SPEECH COMMUNICATION

In terms of the functional effect of hearing loss categories, it can be seen that what is categorized as mild hearing loss may reduce half of the audible information in conversational-level speech, or even more for quiet speech or when at a distance. Thus, 'mild' is a misnomer in this context: the communicational impact of mild hearing loss is not mild but significant. For example, a person of school or university age will have trouble following teachers or lecturers, and persons of working age may struggle at company meetings. A moderate loss may make distant speech inaudible and degrade the quieter parts of conversational speech even at close range. A severe hearing loss makes speech inaudible even at close range, though the person may be able to hear some of her own vocalizations. A profound hearing loss prevents a listener from hearing his/her own speech or that of others at all without hearing-aid or cochlear implant use.

TYPES OF HEARING LOSS

As already mentioned, hearing loss can be broadly divided into four types: conductive, sensorineural, mixed or auditory neuropathy (see Figure 51.14).

Conductive and mixed hearing loss

A hearing loss is classified as 'conductive' when there is a difference of more than 10 dB between AC and BC thresholds at any frequency, which, as mentioned in 'Measuring the hearing thresholds' above, is considered a significant ABG. BC thresholds are generally at normal-hearing levels (equal or better than 20 dB HL) in cases of conductive hearing loss. If the BC thresholds are raised above 20 dB HL and there is a significant ABG, this is referred to as a 'mixed' hearing loss. Conductive hearing loss occurs due to the disruption of the transmission mechanisms of

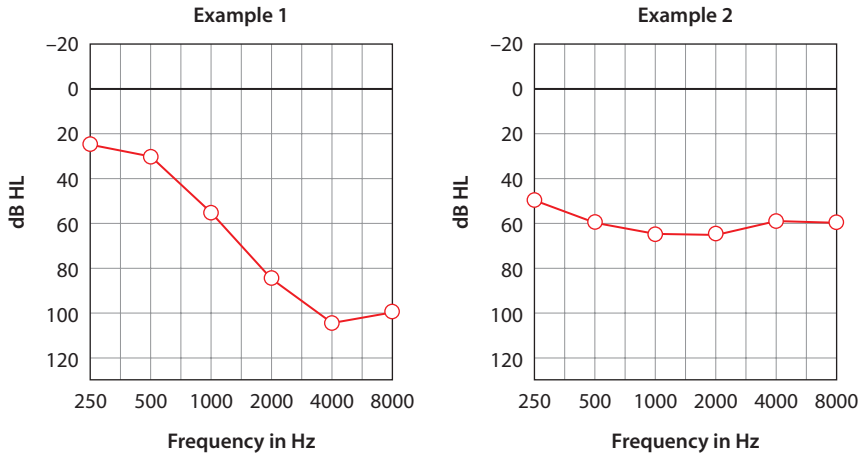

Figure 51.13 The hearing losses shown in the two right-ear examples have the same pure-tone average up to 4000 Hz (60 dB HL). However, the audiogram configuration (i.e. the shape of the audiogram, given by the hearing loss across frequency) is very different for the two ears. The functional consequences of each hearing loss will vary considerably.

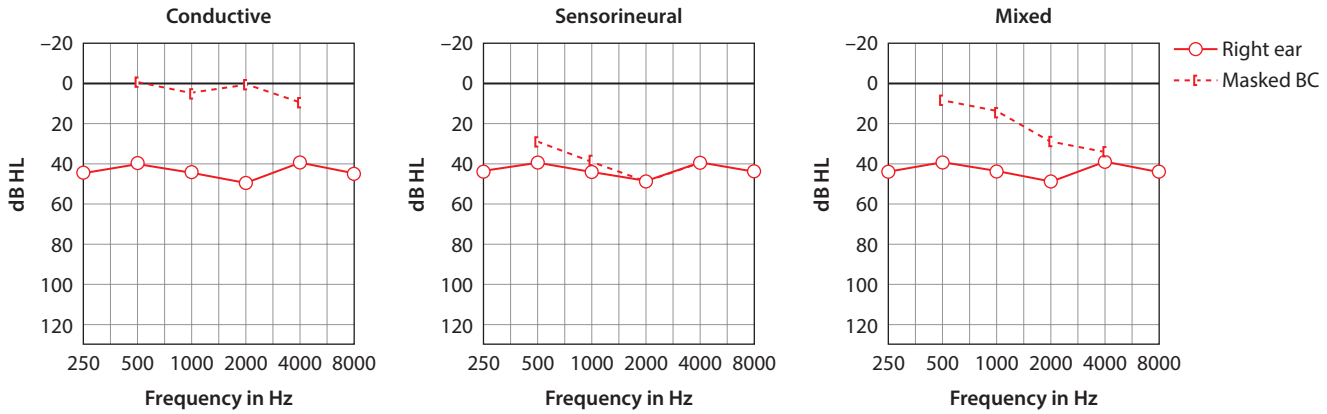

Figure 51.14 Types of hearing loss. **(a)** A conductive hearing loss, where the BC thresholds are normal, the AC thresholds are increased and there is significant ABG. **(b)** A sensorineural loss, where both BC and AC thresholds are increased and there is no significant ABG. **(c)** A mixed hearing loss, where the AC thresholds are increased, at least some of the BC thresholds are increased too and there is significant ABG.

the external and/or middle ear. For example, abnormalities of the tympanic membrane or the ossicles, or presence of fluid in the middle ear, lead to conductive hearing loss. Conductive hearing loss causes reduction in hearing sensitivity that may vary across frequency, but most aspects of sound perception remain generally unaffected as long as the signal is fully audible. This means that conductive hearing loss can be well compensated for by hearing-aid amplification. The maximum possible extent of conductive hearing loss is traditionally deemed to be 60 dB HL. However, all sounds are attenuated (reduced) equally by the extent of the hearing loss, regardless of their input level, so overall auditory deprivation from conductive hearing loss may be greater than for an equivalent level of sensorineural hearing loss with loudness recruitment.

The fluctuating nature of conductive hearing loss means that children with this type of hearing loss may have inconsistent perception of sound patterns and consequently reduced opportunities for recognizing familiar patterns of sound.[41] With the relatively high incidence of middle ear pathology in children, conductive hearing loss is very common and can also overlie cochlear-based sensorineural hearing loss, giving rise to a 'mixed loss'. Medical and surgical treatments are available for many cases of conductive hearing loss, sometimes with the possibility of hearing restoration. When there is a permanent conductive or mixed hearing loss, hearing aids stimulating via AC or BC and BC hearing implants are treatment options.

Sensorineural hearing loss and auditory neuropathy

Sensorineural hearing loss (SNHL) refers to impairment in the cochlea and/or the immediate (primary) nerve connections. The extent of SNHL can range from minimal to total and is usually permanent. The inclusion of 'neural' in 'sensorineural' only refers to the nerve connections from the inner hair cells to the auditory nerve (CN VIII). This is therefore different from auditory neuropathy spectrum disorder (ANSD) in which neural firing may be diminished or out of synchrony across nerve fibres, causing fluctuations and distortion in speech information.

SNHL is shown on the audiogram by both AC and BC thresholds being within 10 dB of each other. Recall that there is an artefact in the standards for BC thresholds at 4000 Hz which means that a discrepancy of 15 dB between AC and BC thresholds is often seen but does not indicate a conductive hearing loss.[33] Be aware that in moderate-to-profound hearing loss some low-frequency BC signals may be felt as vibration, giving the impression of an apparent mixed hearing loss at the low frequencies. The thresholds at which individuals can feel the bone conductor vibration can be as low as 25 dB at 250 Hz, 55 dB at 500 Hz and 70 dB at 1000 Hz.[23]

Options for medical or surgical interventions are very limited in cochlear-based mild or moderate impairment. Most cases of SNHL are treated with hearing aids or hearing implants.

Example audiograms for the different types of hearing loss are illustrated in **Figure 51.14**.

WHAT THE AUDIOGRAM DOES NOT SHOW

Sources of distortion in cochlear hearing loss

Although the measurement of hearing thresholds is the most commonly used method of characterizing hearing status in clinical settings, there are many changes in sound perception that can occur and are not apparent on the audiogram.

These other features of impaired auditory perception may combine to cause reduced clarity of hearing for complex sounds, particularly in understanding speech in noisy listening environments. The interested reader is referred to Moore[42] for a comprehensive analysis of the perceptual effects of cochlear hearing loss. Below is a brief description of the perceptual deficits most commonly associated with cochlear hearing loss.

Loudness recruitment: As stated above, this refers to the reduced dynamic range of hearing between the hearing threshold and the upper limit of loudness tolerance for the listener. A feature of cochlear hearing loss is that loudness grows faster with increasing sound level than for normal hearing. Therefore the dynamic range over which a person

with hearing loss can hear becomes narrower compared to that of a person with normal hearing. In other words, if a person had a hearing threshold of 60 dB HL and a loudness discomfort level of 90 dB HL, their dynamic range of hearing would be 30 dB. This would be about one-third of the dynamic range of someone with normal hearing (when measured in dB) and creates difficulties in providing amplification to make more low-level sounds audible while preventing amplified sounds from being uncomfortably loud. The 'active mechanism' of the outer hair cells (OHCs) on the basilar membrane is believed to be involved in the normally wide dynamic range of hearing. By virtue of this mechanism, the response of the basilar membrane increases in a compressive manner with increasing input level for a wide range of sounds levels between moderate and perhaps very high levels. This means that, for example, a 10 dB increase in sound level leads to only a 2.5 dB increase in the response of the basilar membrane.[43] Damage to the active mechanism in hearing loss cases leads to a reduction or loss of cochlear compression and thus to a narrower dynamic range. Loudness recruitment is addressed by the use of amplitude compression in current hearing-aid design.[42]

Loss of frequency selectivity: Frequency selectivity is the ability of the hearing system to separate out the individual frequency components of a complex sound.[15] Damage to the OHCs in the cochlea leads to a reduction in the sharpness of the basilar membrane response to a narrow-band sound. When the active mechanism of the OHCs becomes damaged, perhaps through noise exposure and/or ageing, the ability to separate the frequency components of complex sounds is degraded. The loss of frequency selectivity makes hearing-impaired people more susceptible to masking.[42] This leads to problems in understanding speech, particularly in a background noise, even when the noise does not have the same spectrum as the speech.[43] The perception of timbre, which allows the listener to distinguish between sounds of the same loudness and pitch (e.g. the same note played by two different musical instruments), is also affected when frequency selectivity is impaired. A reduced ability to perceive differences in timbre can lead to poorer vowel discrimination.[42]

Loss of ability to use temporal fine structure (TFS) information: A complex sound reaching the ear is separated in the cochlea into a series of narrow-band signals. These signals can be characterized by their envelope (the slow changes in the amplitude of sound over time) and their TFS (the rapid changes in the amplitude of sounds, with rate close to the centre frequency of the band). Deficits in TFS perception may result from loss of auditory neurons or loss of synapses between inner hair cells (IHCs) and neurons. These aspects are represented in the timing of neural spikes. TFS information is relevant for pitch perception. Deficits in pitch perception can lead to problems in the identification of the prosodic aspects of speech (i.e. to distinguish a question from a statement), the identification of a speaker, and the discrimination of speech sounds.[42] In addition, impaired TFS perception may reduce the ability for listening in the dips of a fluctuating masker, for example, when listening to a talker in the presence of a competing background talker, and to 'hear out' a target speaker in the presence of a competing talker based on differences in fundamental frequency (the fundamental tone produced by the vibration of the vocal folds).[42, 44] Deficits in the processing of TFS information may also lead to reduced sound localization abilities.[44]

Loss of temporal resolution: Temporal resolution refers to the ability to detect changes in auditory stimuli over time, particularly in their envelope.[15] Temporal resolution may be compromised in cochlear hearing loss due to the partial or complete loss of the compressive mechanism of the basilar membrane. When cochlear compression is reduced or lost, sounds that have fluctuations in their envelope may seem to have even greater fluctuations. This may make it difficult to detect gaps in those sounds.[42] This is relevant to speech perception as one feature of consonants such as /p/, /b/ and /t/ is the presence or absence of a gap between the burst of the consonant and the start of voicing of the following vowel, and this feature is one of the cues for the discrimination of these consonants. Another consequence of a loss of temporal resolution is an increased threshold for detecting a sound preceded by another more intense sound. In speech perception, this can make low-level consonants preceded by more intense vowels more difficult to hear.[42]

Cochlear dead regions: A dead region in the cochlea is a place on the basilar membrane where the IHCs or synapses are not functional or function very poorly.[45] When a signal excites only a region with such IHC damage, such signal would theoretically be inaudible. However, if the sound level is increased, the area of excitation along the basilar membrane spreads to a non-dead region, and the signal may become audible. If a person has a dead region at 4000 Hz, they may hear sounds with a frequency of 4000 Hz using IHCs placed at a neighbouring point along the basilar membrane, tuned to a different frequency. This is known as 'off-frequency listening'.[45] The pure-tone audiogram might show a detection threshold for 4000 Hz, but this would not reflect encoding of the signal by the correct part of the cochlear hearing mechanism. The recognition of speech cues falling well within extensive dead regions is limited.[46–48]

In summary, SNHL is associated with changes in the individual experience of loudness perception, frequency selectivity, pitch perception and speech recognition, especially when listening in noise. It is therefore important to recognize that people with similar pure-tone audiograms may have very different experiences of hearing in everyday life and they may receive very different help from hearing-aid amplification.

Human speech is a great deal more complex than the simple pure-tone signals that are used to define the lowest level of detection across frequencies on the audiogram. The distortions that occur with SNHL are not assessed by the pure-tone audiogram, and are often not acknowledged by professionals working in hearing loss.

Improved hearing for speech is, however, the primary motivation of the patient looking for ENT intervention for hearing impairment.

SPEECH AUDIOMETRY

In the past speech audiometry was an important component of the diagnostic test battery for distinguishing peripheral from central causes of hearing loss, particularly acoustic neuroma. This role has been superseded by imaging techniques.

Speech audiometry is now mainly used for assessing rehabilitation outcomes from both hearing aids and cochlear implants. There are also specialist test applications developed for auditory processing disorders which may have central auditory components.

Speech intelligibility

SPEECH INTELLIGIBILITY INDEX

The speech spectrum for conversational speech can be represented on the audiogram as a shaded area covering the frequencies range 125–8000 Hz and the level range from 20 to 60 dB, as previously shown in **Figure 51.12.** Some of the acoustic information to detect consonants has levels lower than 20 dB, requiring hearing levels below 20 dB in order to hear all the speech sounds. A way of predicting the impact of hearing loss on speech intelligibility is to consider the proportion of speech information that is audible to the patient given their hearing deficit on the audiogram. The Speech Intelligibility Index (SII)[49] is calculated as the product of a band–importance function (the contribution of a frequency band to the intelligibility of speech) and a band–audibility function summed across all the frequency bands. Additionally, the SII takes into account the known sources of distortion in cochlear hearing loss and the impact of these on speech understanding for the listener. However, predictions of the SII for listeners with hearing loss are not always accurate, particularly when hearing loss is greater than 55 dB.[50] It is important to understand that no method of amplification can offset the sources of cochlear distortion or provide 'normal hearing'; it can only improve the audibility of sounds. Additionally, there is usually a period of relearning the new sound patterns of speech through amplification, derived from a consistent period of hearing-aid use over several weeks or longer.[51]

HEARING LOSS AND SPEECH INTELLIGIBILITY

Normal-hearing listeners use multiple cues to understand speech. For sustained vowels, the main cues are the formant patterns (the frequencies of the resonances of the vocal tract, added to the fundamental tone produced by the larynx).[52] For vowels in conversational speech, duration and temporal pattern of the direction of the change of the formant frequencies into and out of the syllable nucleus are more relevant.[52] For consonants, there are several possible cues that can be used for identification. These vary across consonant groups. Because of the redundant nature of speech, there is usually more than one cue available at a given time. In general, features such as the gross spectral shape of a sound and the relationship with the spectral shape of the next sound, the rate of spectral or amplitude change, the presence or absence of periodicity, the presence or absence of a silent gap, the delay in the start of voicing after this silent gap, the formant transitions and envelope cues (given by the relative slow changes in amplitude over time) have all been shown to provide important information.[15] Detecting these features requires the auditory system to perform temporal and spectral analyses of the speech signal. These analyses are disrupted by the perceptual deficits associated with SNHL, and this has an impact on the ability to understand speech in quiet and in noise. The interested reader is referred to Revoile[53] for a review of the use of cues for speech intelligibility by persons with hearing loss. It is extremely common in the clinic to find patients with SNHL who have trouble understanding speech, particularly in situations where the talker they want to hear is not the only speaker, and there are other talkers in the background. This is known as the 'cocktail party problem',[54] and it is an issue to some extent even with the use of hearing aids or hearing implants.

Speech testing in clinical audiometry

Hearing loss impacts greatly on speech understanding in everyday situations in ways that cannot be represented simply by the ability to detect pure tones. This role is fulfilled by the use of speech testing both in identifying the cause of hearing loss and, more importantly, in the potential for improved ease of speech understanding through surgery or applied technology. Speech audiometry methods are specified in the standard ISO 8253-3:2012.[55] They are an important component of hearing assessment which cannot be represented by simpler psychoacoustic testing or assessing the hearing-aid output levels to estimate the audibility of amplified speech. In addition, an important diagnostic and often underutilized role of speech testing is in identifying non-organic or feigned hearing loss, either in isolation or as an overlay to a true physiological hearing deficit.

Historically, speech testing used single words presented at different levels in a defined procedure called 'speech audiometry' to derive an individual's performance-intensity (PI) function. Different features of the PI function were used to infer diagnostic indications. Features such as the optimal discrimination score (ODS) and the corresponding half peak measure were used to characterize and differentiate potential central causes from peripheral hearing loss.[12, 56]

There are a number of terms still used when testing with speech material from these earlier roles. **Speech discrimination** implies an ability to hear a difference between a set of alternative response options. **Speech intelligibility** and **speech recognition** are used interchangeably now,

rather than in the defined circumstances of their original use (as a measure of fidelity of a transmission system, and as defined by the PI function in speech audiometry, respectively).

HEADPHONE OR SOUND-FIELD TESTING

As part of the diagnostic process of hearing assessment, speech material may be presented to each ear through the use of headphones or insert earphones. When the test material is used to assess benefit for speech understanding from use of hearing devices, speech is presented in the sound field, thereby being processed by the hearing aid or hearing implant before being delivered to the patient's ears. As with any ear-specific testing, clinical masking may need to be delivered to the non-test ear to prevent cross-hearing in the non-test ear. When measuring the threshold for speech, contralateral masking is used when the speech presentation level in dB HL exceeds BC thresholds in the better-hearing ear by 40 dB or more at two frequencies. The noise masker used for speech audiometry is a 'speech-shaped noise'. This means that it is the result of having filtered white noise to match the long-term average speech spectrum.

CALIBRATION OF SPEECH TEST MATERIAL

Recorded speech materials should be used for testing, as this increases control of the testing conditions and quality of the stimuli. The recorded speech materials include calibration signals. When testing in the sound field (presenting the stimuli via a loudspeaker), the calibration signal is usually a narrow band of noise or a frequency-modulated tone at 1000 Hz, as defined in ISO 8253-3:2012.[55] The level of this calibration signal is equal to the level of the speech signal derived with a specified frequency- and time-weighting and is expressed as the equivalent sound pressure level, L_{eq} with A-weighting. The silent pauses between words or test items are discarded in the measurement of the equivalent sound pressure level. When speech testing is in the sound field, the calibration method is typically performed using a sound level meter and defined in dB A. Presentation levels need to be checked in the calibration position (corresponding to the position of the listener's head) – on a regular basis.

When speech testing is performed with headphones, the speech signals are usually calibrated by playing the calibration sound (usually a 1000-Hz pure tone) and adjusting the audiometer and so that the VU-meter displays the desired value, usually 0. In computer-based audiometers instructions for calibration vary depending on the options of each device. The presentation level of speech through headphones is typically expressed in dB HL.

EQUIPMENT FOR SPEECH TESTING

The level of presentation of speech is typically controlled through a two-channelled clinical audiometer or computer-based audiometer software. In sound-field audiometry the loudspeaker is typically placed at a distance of 1 m from the listener and at the same height as the head. Competing noise may be presented either from the same loudspeaker or from a pair of loudspeakers located on either side, at a recommended azimuth (i.e. angle relative to the head of the listener) of +/– 45 degrees, 90 degrees or 180 degrees depending on the functional testing required. Multi-speaker configurations can also be used.

SPEECH MATERIAL

The simplest and most commonly used speech material in clinical audiology is lists of monosyllable, real words made up of three speech sounds, or 'phonemes', usually a consonant, a vowel and a consonant, for example 'hat'. Most languages have enough monosyllabic, familiar vocabulary items to develop lists of words in which each list has a similar number of types of phonemes in approximately the same proportion as these speech sounds occur within the given language. Some languages have a small number of monosyllabic words available and use two- or three-syllable words (e.g. Spanish, Finnish, and Arabic).

PRESENTATION METHOD

The typical way that speech tests are delivered is through prerecorded material played from a computer or CD and passed through the audiometer so that the level of presentation can be controlled. As with PTA, the method of presentation, calibration and the acoustic characteristics of the test room need to be specified and consistent for valid and comparable results.

The acoustic characteristics of a test room fulfilling a quasi-free sound field considered adequate for clinical speech testing is specified in ISO 8253-3:2012[55] but the requirements of ambient noise levels are less restrictive than for PTA since the speech signal is presented at suprathreshold levels.

OPEN-SET AND CLOSED-SET TESTING

Responses are typically made by the patient repeating the word they identified. This is referred to as 'open-set testing' as there is no constraint on the options that the patient has in the response that they make. The tester records their response or the number of speech sounds they correctly identified from the target word. For example, response 'cat' for test item 'hat' gives a score of two out of three, although there are many variations on scoring methods for different languages. For open-set speech material to be valid the test material must be novel to the listener. Repeated use of the same material, whether made up of single words or sentence material, in open-set testing makes results invalid due to learning effects. There are therefore practical constraints from the number of speech tests available for patients requiring ongoing speech recognition assessment, such as those with hearing aids, cochlear or brainstem implants.

An alternative method of presenting closed-set speech material gives the listener a selection of items from which to choose a response. This may be from a list of options on a computer screen, a written list of words or a constrained

range of options, for example by repeating spoken numbers between 1 and 100. The benefit of closed-set testing is that one can analyze the individual speech sound confusions that were made between the target word and the response and therefore derive confusion matrices, which can be crucial when adjusting hearing-aid features or fine-tuning cochlear-implant maps for instance. Scoring of responses in closed-set testing does not require clear articulation by the patient, and results can be scored by the computer in many cases.

There are many different types of material that can be used to assess speech detection, discrimination and recognition. In order to assess the functional benefit of a particular hearing aid for an individual, open-set sentences presented in quiet and in different types of noise may be required. For assessing the discrimination potential of a cochlear-implant recipient, one may use closed-set nonsense syllables (such as /aka/, /ubu/, and /isi/) to evaluate consonant discrimination while keeping the vowel context consistent. For assessing whether the frequency-lowering feature in a hearing aid is helpful (a feature intended to increase the access to high-frequency information for people with high-frequency hearing loss), one could use a single word final-s test in closed-set testing; for example, a plural detection test, where the pictures of a 'brick' and a selection of 'bricks' are presented as alternative response options, are used to indicate whether detection of the sound /s/ is improved with the frequency-lowering feature activated.[57, 58]

RESPONSE MEASURES

The speech reception threshold (SRT) is defined as the lowest speech presentation level at which the individual is able to correctly identify 50% of the items.[59] For a given individual, the outcome depends on the type of speech material that is used. In general, the more familiar and meaningful the information that is audible to the listener, the lower the minimum presentation level that is required for them to identify the test item. Thus, meaningful sentences will be correctly identified at lower presentation levels than single words. Familiar single words will be identified at lower levels than nonsense syllables. Cognitive resources are employed when performing intelligibility tasks,[60] especially when not all of the speech cues have been audible or there are competing speakers in the background. In other words, listeners use cognitive resources such as memory and attention to focus on the target speaker and fill in the gaps of missing information. In practice this tends to conspire against patients with high cognitive ability fulfilling criteria for cochlear implantation on the basis of their sentence recognition score, as they are very efficient in working out the spoken message in spite of their poor auditory abilities. However, the increased demand for cognitive resources often leads to fatigue and therefore has an impact on quality of life.

Different types of speech material are shown in Table 51.2. For each of the types of speech material used there is a different level of linguistic and acoustic redundancy and the opportunity for the cognitive and linguistic function of the listener to influence scores, independent of hearing status. Any single test material is a compromise between validity in terms of representing real-life listening experience (e.g. sentences in noise) and repeatability of results in defining audibility (e.g. by using nonsense words in quiet).

The difference in two scores that infers a significant change in the two test conditions is related to the number of test items in the list. The PI function can be quite steep. For example, for normal-hearing listeners, an increase in presentation level from 20 dB to 25 dB may lead to a 20% increase in the score for word recognition.[12] The more the steepness of the slope of the function increases, the more predictable speech material is. Thus, the level at which speech is presented and the consistency in calibrating this level in test sessions is critical in deriving useful comparative information across test sessions and conditions.

SPEECH-IN-NOISE TESTING

Measures of speech recognition in competing noise give a better representation of cochlear distortion and the potential benefit from hearing aids than speech in quiet, which aims to characterize performance in optimal listening environments. Speech-in-noise testing is generally carried out using sentences presented in a specific type of noise, by scoring the number of keywords correct. In adaptive scoring algorithms the signal-to-noise ratio (SNR) is varied (by changing the level of the speech or the noise) depending on how many of the keywords are correctly identified. Typically, tests are performed to find the SRT in noise. This is the SNR required to identify 50% of the test items correctly. An outcome of 5 dB SNR

TABLE 51.2 Different types of speech material commonly used in clinical practice

Speech material	Detection	Discrimination	Recognition	Speech in noise	Clinical uses
Phoneme	Ling six-sound test (/m/ /a/ /u/ /i/ /s/ /sh/)[61]	Repetition of Ling sound	Identification of item containing the Ling sound, e.g. snake for /s/		Setting sensitivity, e.g. hearing-aid gain, cochlear-implant map
Word	Plurals test[57]	AB words lists[62]	McCormick toy test[63]	Adaptive McCormick toy test[64]	Evaluation of frequency-lowering hearing aids, indication or assessment of assistive technology
Sentence		ASL[65] BKB[66]	GASP[67]	HINT[68]	Assessment of hearing aids, cochlear implants and remote mics

means that the speech needs to be presented at 5 dB above the level of the noise for the individual to identify 50% of words correctly. Similarly, an SRT equal to −5 dB SNR, means that the noise level was 5 dB above the speech level and still the words were recognizable 50% of the times. In a clinical setting, the speech-in-noise measure gives an indication of distortion in the hearing mechanism, regardless of hearing level on the audiogram. Aside from the auditory factors involved, the value of the SRT depends on the characteristics of the background noise[69] (e.g. steady noise, competing talker, multi-talker babble), reverberation,[56, 70] as well as linguistic[71] and cognitive factors.[60]

It can be seen from this short section on clinical testing with speech materials that this is an area of rapid development, largely driven by changes in hearing-aid technology and hearing implants and the new testing that is necessary for evaluating individual hearing potential.

OBJECTIVE TESTS OF AUDITORY FUNCTION

Decades ago special tests with pure tones, usually termed 'suprathreshold audiometry', were used to distinguish cochlear and retrocochlear hearing loss. The most popular tests were the Short Increment Sensitivity Index (SISI) test[72] and the tone decay test (TDT).[73] The SISI test is based on the detection of an intensity increment superimposed upon a pure tone. Traditionally, the outcomes of the SISI test have been considered indicative of cochlear pathology if the person was able to detect a critical number of 1 dB increments in a continuous pure tone presented at 20 dB above the threshold. The TDT is based on the phenomenon of adaptation. The TDT outcomes have been interpreted as suggestive of retrocochlear pathology if the person is unable to perceive a pure tone presented at 10 dB above the threshold over 60 seconds, requiring several 5 dB increments of the sound level to maintain perception over this interval. However, some persons with cochlear hearing loss present pathological adaptation and therefore score positive in the TDT probably due to dysfunction of the IHCs/neurons.[74] In addition, some individuals with retrocochlear pathology such as acoustic neuroma score positive in the SISI test and/or negative in the TDT.[75] The consistency of outcomes of the special tests varies within groups classified by audiogram shape (e.g. flat loss, high-frequency hearing loss, low-frequency hearing loss) and with tumour size (smaller tumours leading to greater inconsistencies).[75]

Nowadays, image studies and objective tests have replaced these special tests in the differential diagnosis of cochlear and retrocochlear hearing loss. The most popular objective audiology tests used for topographic diagnosis are briefly introduced below.

Measuring middle ear function

A test-battery approach is used to assess middle ear function and hearing threshold levels. Tympanometry is used to assess middle ear function and the mobility of the eardrum. This test confirms the presence of middle ear effusion when tympanometry shows a flat compliance trace. Additional testing through the use of tympanometry includes measurement of the acoustic stapedial reflex, elicited by brief pure tones or noise bursts. The lowest intensity of sound that triggers the reflex is the acoustic reflex threshold (ART), and this can give an objective measure of loudness recruitment in addition to the subjective uncomfortable loudness level, which can be subjectively measured following the PTA.[76] An absent or abnormal stapedial reflex with normal middle ear pressure is characteristic in cases of otosclerosis.[77] The stapedial reflex threshold and decay have been used in the assessment of cases of acoustic neuroma.[75] However, it emerged in the last decades that its sensitivity is relatively low compared to PTA asymmetry and, most importantly, because of the high levels required in these cases, it poses a hazard on residual hearing.[78] The stapedial reflex can be electrically evoked in users of cochlear implants in order to obtain information about their dynamic ranges.[79] These tests are covered in Chapter 48, Physiology of hearing.

Otoacoustic emissions

Otoacoustic emissions (OAEs) are low-level sounds that are recordable in the external auditory meatus and reflect the active mechanism of the OHCs in the cochlea.[80] These are absent if there is damage to the OHCs. OAEs are an important part of the evolving test battery, particularly when screening for hearing loss in early life. It is advised that the measurement of OAEs is combined with tympanometry, especially in screening cases where the OAEs are absent. The reason for this is that middle ear problems can interfere with the recording of OAEs. Thus, clinicians may misinterpret the absence of OAEs as indicative of sensorineural loss if they are unaware of the existence of middle ear pathology.[81] These tests are covered in Chapter 48, Physiology of hearing.

Electrophysiological tests including ABR

Auditory brainstem response (ABR) testing measures the nervous system activity around the primary auditory pathway which can be affected by tumours of the eighth nerve and neural demyelination. The normal result is a waveform with multiple peaks (known as waves I, II, III, IV and V) that are generated by neurons at different levels of the auditory system from the distal portion of the eighth nerve to the midbrain. The ABR is a test of neural synchrony but is also used to estimate hearing sensitivity, particularly in predicting hearing thresholds in infants.[82, 83] Aside from the analysis of the morphology of the response, the observation of response parameters such as the wave I–V interpeak latency and the interaural latency difference of wave V and others are useful in the functional assessment of the auditory nerve.[84, 85] Electrophysiological tests can be electrically evoked in users of cochlear implants.[86] These tests are discussed in Chapter 48, Physiology of hearing.

FUTURE RESEARCH

- Methods that involve machine learning have been developed to automate audiometric testing and decrease its duration. This approach tends to minimize the number of trials used while achieving outcomes that are close to conventional PTA and some additional information, as testing is not limited to the standard frequency intervals. For example, in the implementation developed by Schlittenlacher et al.,[87] the frequency and level of each signal after the initial stimulus are selected based on the responses to all previous trials in order to maximally decrease the uncertainty of the outcome.
- Systems have been developed lately that perform audiometry with a computer and a special headset composed of insert earphones enclosed by circum-aural cups. These systems monitor background noise and do not require a soundproof booth.[88] This has potential for use in caring for persons unable to attend a clinic, or in surveillance audiology, where workers exposed to noise are screened for hearing loss.
- Internet-based systems have been developed to perform PTA remotely. This is known as 'teleaudiometry'.[89] Some of these systems allow for the storage of results in a 'cloud' format, making them available to the user from any device. They also have potential for the analysis of the large datasets collected.
- Smartphone and tablet apps have emerged recently to perform PTA with domestic headphones. However, the reliability of these systems is usually low.[90]
- Psychoacoustic tests have been developed that test for the dysfunction of the IHCs by detecting and characterizing 'dead regions' in the cochlea.[91, 92] Other tests assess the ability to use temporal fine structure information.[93, 94] Although these tests have been available for some time, most of them are not implemented in clinical equipment. They can be carried out easily with a computer and good-quality sound card and headphones, but it is expected that clinical use will increase once they are integrated in the test batteries included in audiometers.
- Speech audiometry is being complemented with objective measurements of listening effort such as pupillometry[95–97] or EEG[95, 98] in order to increase the sensitivity of the test battery when comparing different hearing devices or evaluating technology features (i.e. algorithms for noise reduction). It is expected that new clinical tools will be developed based on these findings.
- Speech recognition systems are being developed in order to replicate the speech recognition issues associated with ageing. Such systems could assist audiologists, reducing the time needed to optimize hearing-aid selection and fitting.[99]

KEY POINTS

- PTA is often the first functional test of hearing performed in the clinic. It provides basic information about the type and degree of hearing loss.
- However, performance in PTA relies on sound detection and therefore the PTA outcomes do not quantify or characterize other deficits that have a significant impact on communication.
- PTA and speech audiometry must be carried out following standardized procedures, equipment and environment, and the outcomes must be recorded in forms following conventions to facilitate the circulation of clinical information among health professionals.
- Speech audiometry is essential in the assessment of the impact of hearing loss on communication, particularly when assessing candidacy for or the outcome of hearing aids, hearing implants or assistive listening devices. The test battery in speech audiometry is rapidly evolving to adjust to the technological changes of hearing aids and hearing implants, and new measures are emerging that assess listening effort in order to achieve greater sensitivity.

ACKNOWLEDGEMENTS

We would like to thank Brian C.J. Moore and Joanna Lemanska for providing images used in the chapter. We also thank Brian C.J. Moore for his helpful comments and advice for the section 'What the audiogram does not show', and Thomas H. Stainsby for his helpful comments on an earlier version of our manuscript.

CHAPTER 52

EVOKED MEASUREMENT OF AUDITORY SENSITIVITY

Jeffrey Weihing and Nicholas Leahy

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: auditory evoked potentials, auditory brainstem response, middle latency response and auditory late response.

INTRODUCTION

Excitation of auditory neurons by an acoustic stimulus presented at the ear results in electrical activity that can be recorded at the scalp using electrodes. Though small in amplitude, this electrical response can be isolated from the background electroencephalogram (EEG) by averaging the auditory electrical activity across many successive presentations of an acoustic stimulus. This averaged auditory electrical response, or auditory evoked potential (AEP), can be used to infer the relative health of various peripheral and central auditory regions. For instance, a reduction in amplitude of the evoked potential or prolongation of its latency may indicate an inability of the auditory neurons to respond efficiently to the stimulus, or it may reflect a reduced ability of the cochlea to respond to the sound and stimulate the auditory neurons. In either case, the AEP would reflect auditory pathology.

There are several obligatory AEPs that are used by audiologists in the diagnosis of hearing disorders. These potentials include the auditory brainstem response (ABR), middle latency response (MLR), and auditory late response (ALR). Historically, much of the clinical interest in AEPs has focused on the ABR. Initially used as a diagnostic measure in the detection of acoustic neuromas, applications of the ABR have expanded to include assessment of cochlear hearing sensitivity (i.e. threshold ABR). Part of the utility of the threshold ABR is a result of this AEP being relatively unaffected by sleep or sedation. Thus, patients who are difficult to test or who are too young to have their thresholds assessed by behavioural audiometry can often have their hearing thresholds quantified using the threshold ABR.

Neural generators for the remaining obligatory AEPs, the MLR and ALR, are situated superior to the ABR generators. Like the ABR, these measures have also been used to identify neurologic dysfunction and/or to establish hearing threshold. Since the MLR and ALR both include cortical contributions, they provide a more comprehensive view of the ability of the central auditory nervous system (CANS) to respond to sound. They are limited, however, by the requirement that the patient remain awake during the procedure. In addition to the diagnosis of neurologic dysfunction and establishing threshold, some of these later AEPs have also been used in the assessment of central auditory processing disorder (CAPD). CAPD occurs as a result of CANS dysfunction and is thought to interfere with the processing of speech when in complex listening situations.

The present chapter will provide a discussion of these three AEPs as they relate to clinical audiology. Given the broad application of the ABR in current audiology practice, the majority of this discussion will centre on this AEP and how it can be used to establish threshold and diagnose neurological issues. However, some consideration will also be given towards the end of the chapter to the MLR and ALR. These latter potentials complement the ABR in many clinical situations and can be used to test some aspects of auditory function that are not assessed by the ABR alone.

EVOKED POTENTIAL BASICS

There are several principles that apply to all of the AEPs discussed in this chapter that we will consider here briefly. AEPs are a reflection of synchronous activity in auditory neural generators resulting from the presentation of an auditory stimulus. Activity in these generators creates an electrical field that has a positive and a negative pole. To measure this activity at the scalp, at least three electrodes must be placed: an inverting, non-inverting and ground electrode. **Figure 52.1** shows electrodes placed on the scalp for acquisition of different AEPs following the 10–20 system.[1] For the ABR, the non-inverting electrode is placed at Fz and the inverting electrode is placed at either A1 (for left-ear stimulation) or A2 (for right-ear stimulation). The ground electrode is also placed on the forehead some distance below Fz. For the MLR and ALR, the location sites for the inverting and ground electrodes are similar to the ABR. However, for the non-inverting electrode, these potentials may utilize Cz or a combination of C3 and C4 instead of Fz.

There are many sources of noise that can interfere with the acquisition of AEPs. These sources may be acoustic, electric or biological in nature. In order to partly reduce the negative influence of these noise sources, AEPs are acquired through a process called physiological averaging. In averaging, the auditory system's electrical responses to many presentations of a stimulus are averaged together. Averaging will tend to enhance the AEP while reducing the effect of noise.[2] This occurs in part because noise is mostly random in its occurrence while AEPs occur at a predictable latency post-stimulus onset.[2] A common exception to this rule is 60 Hz electrical line noise, which can cause sinusoidal-type interference with the evoked potential. This line noise can sometimes be reduced by using special filters, changing stimulus rates or instituting improved grounding precautions.

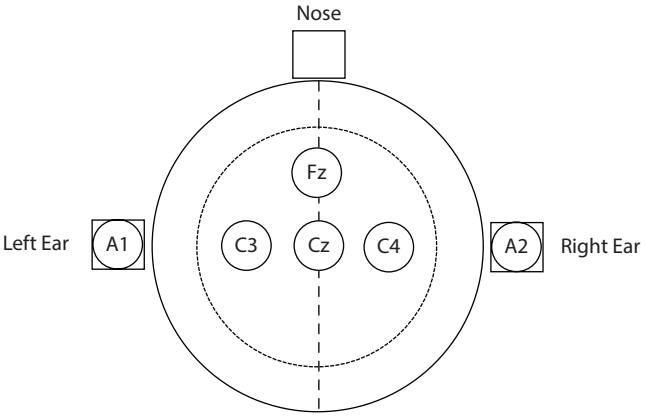

Figure 52.1 Electrode locations following the 10–20 system. The image is a superior view of the top of the scalp. A1 and A2 are located on the earlobes or mastoids. Fz is located on the high forehead and Cz is located at the centre of the scalp. C3 and C4 are located to the left and right of Cz, respectively. A ground electrode (not pictured here) is placed some distance below Fz on the forehead.

AEPs are commonly evoked with a click stimulus, which is a 100 microsecond (msec) rarefaction or condensation square wave pulse. The very rapid acoustic wave front of a click yields an abrupt stimulus onset. As the ABR is a stimulus-onset response, the abrupt onset provided by a click will frequently evoke well-formed ABRs. Spectral energy of the click measured acoustically at the ear canal is broadband but tends to be greatest in the 2000–4000 Hz range.[3] AEPs can be evoked to other stimuli, including tone bursts. Tone bursts are sinusoidal and, relative to a click, can be longer in duration with a more gradual onset and offset. The longest duration tone bursts can be used for the MLR and ALR, while the ABR makes use of shorter duration tone bursts. The spectrum of tone bursts varies by the duration of the stimulus, with longer stimulus durations showing less splatter of spectral energy into bands around the centre frequency.[4]

Stimulus intensity level for AEPs is expressed as dB normal hearing level, or dB nHL. This dB unit uses the average behavioural hearing threshold for normal hearing individuals as its reference. As an example: if calibrating a click stimulus, one would obtain an average behavioural threshold to the click in a sample of normal hearing individuals. This threshold would correspond to 0 dB nHL. Subsequently, any given dB nHL presentation level used in the clinic would reflect how much higher or lower the presentation level was relative to the average behavioural hearing threshold for normal-hearing individuals. If an 80 dB nHL presentation level was used, this would indicate that the level was 80 dB above the average normal behavioural threshold to the stimulus. Sometimes AEP equipment is not calibrated in dB nHL for all stimuli. In such cases, the clinic should make sure to establish their own behavioural calibration so a correction factor can be applied to the presentation level on the equipment display.

DIAGNOSTIC AUDITORY BRAINSTEM RESPONSE

Overview

The ABR is a response to stimulus onset and arises from the auditory nerve and low brainstem. It was first reported by Jewett and Williston,[5] who identified a complex occurring under 10 msec post-onset of an auditory stimulus that was comprised primarily of five potentials. These potentials, or waves, are labelled consecutively from I to V, with the earliest wave occurring near 1.5 msec and the latest around 5.5 msec in the normal auditory system. The waves were subsequently correlated with various neural generators of the peripheral and central auditory system.[6–8] Wave I reflects a neural response which originates from the distal end of the auditory nerve, wave II from the proximal end of this nerve, wave III from the cochlear nucleus, wave IV from superior olivary complex and lateral lemniscus, and wave V from the lateral lemniscus and possibly the inferior colliculus. Frequently, waves IV and V will present as a complex, with wave IV at the peak and wave V as a smaller shoulder to this peak occurring

later in latency. A negativity follows wave V that in many cases is the SN10 wave. The SN10 is a low-frequency negative potential that is most readily apparent when using low frequency stimuli.[9, 10] The negativity following wave V for other stimuli most likely receives some contribution from this potential. The SN10 is thought to arise from the inferior colliculus.[9] **Figure 52.2** shows an ABR with the major peaks identified.

The ABR initially emerged as a tool for diagnosis of retrocochlear pathology, such as acoustic neuromas.[11] More recently, it has found application as an estimate of hearing sensitivity for difficult-to-test patients. The current section discusses uses of the ABR as a diagnostic tool to detect lesions of the auditory nerve and central auditory system. The section that immediately follows this discussion of diagnostic ABRs considers applying the ABR to obtaining electrophysiological thresholds.

Description of diagnostic protocol

Many stimulus and recording parameters can be used in acquisition of the ABR. Subtle changes in these parameters can affect the quality of the electrophysiological response. Presented below is a description of recommended parameter values. The ABR is evoked separately from the left and right ears using these settings.

- **Stimulus:** A 100 msec click stimulus is most commonly used for assessment of retrocochlear function using the ABR. Tone-burst stimuli are sometimes used because they can be less influenced by peripheral hearing loss effects.[12] A tone-burst waveform envelope of 2-cycle onset, 0-cycle plateau, and 2-cycle offset is used. Stimuli are administered through insert earphones for diagnostic ABR testing.
- **Presentation level:** The presentation level of the ABR stimulus varies between 80 dB nHL and 100 dB nHL. If there are not concerns that hearing loss will affect the ABR indices, then 80 dB nHL is an appropriate level to use.

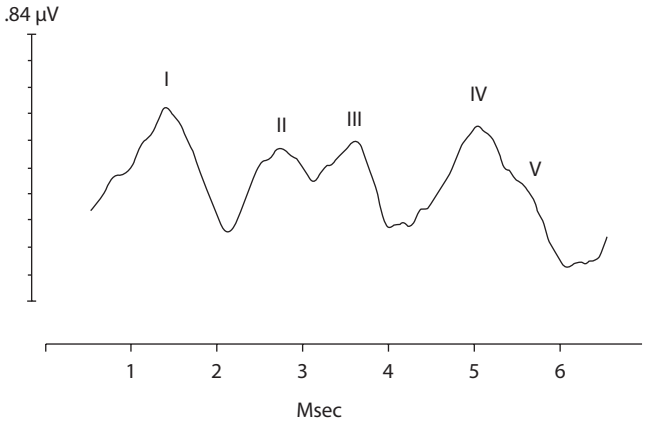

Figure 52.2 ABR with the first five peaks identified.

- **Polarity:** A rarefaction click stimulus will yield slightly earlier latencies than a condensation click.[13] As most normative values utilize a rarefaction click, it is recommended that this polarity by applied in diagnostic ABR protocols. If a tone-burst stimulus is being used, then alternating polarity should be applied.
- **Time window:** The recording time window refers to the duration over which the auditory system's response is recorded following presentation of a stimulus. A recording time window of 10–15 msec is recommended to ensure full view of the ABR response.
- **Filters:** The electrical activity recorded from the scalp is generally filtered out both above and below the frequency range of the ABR response. In adults, ABR electrical energy at the scalp is primarily in the 100–3000 Hz range, and therefore the filter is designed to pass energy in this range only. An exception to this is when the ABR is evoked to 500 Hz tone bursts, which requires the use of a lower high-pass filter setting around 30 Hz. Additionally, in infants the morphology of the ABR can sometimes be improved by using a lower high-pass setting.[14] If electrical artefact is encountered and cannot be resolved by other means, a notch filter option is available in most AEP units. This filter will reduce the amplitude of energy around 60 Hz. This filter should be used only sparingly as it can sometimes negatively affect the ABR morphology.
- **Stimulus rate:** Neurons contributing to the ABR have relatively short refractory periods and, for this reason, the response is acquired at a relatively high stimulus rate of 20–30 clicks per second. A non-integer rate, such as 17.7 clicks per second, should be used to avoid the time locking of periodic noise sources. For fast-rate ABRs, the stimulus rate is increased to 77.7 clicks per second.
- **Number of trials:** As mentioned previously, averaging the ABR across many trials will enhance the AEP and reduce noise. At least 2000–3000 trials per recording are recommended. Another viable option is to acquire a response until a predetermined signal-to-noise ratio has been reached, at which point testing can be stopped.[15] This method can help to reduce test time.
- **Replications:** Clinical analysis of ABRs requires some comment on whether the response was replicable. A replicable response is one that appears morphologically similar across two waveforms. After completing 2000–3000 trials, the ABR is acquired a second time to ensure reliability of the response. If there is concern regarding the consistency of the response, a third waveform may sometimes be acquired.

Diagnostic ABR analysis

The presence of retrocochlear lesions, including unilateral acoustic neuromas, can affect characteristics of the ABR waves, such as latency and amplitude. For instance, the neuroma can prolong the time it takes click energy to reach a particular neural generator, thus delaying the latency of the wave that arises from that generator. Likewise, a neuroma can negatively affect the synchrony of neural firing

and reduce the number of neurons being recruited for the response. In this scenario, amplitude of the wave may also be reduced. Measures of the ABR waves are discussed below and normative values are provided in Table 52.1.

Latency in the context of ABR measurement is defined either as the absolute latency of the wave, which indicates the time it takes for the wave to occur post-stimulus onset, or as the interwave latency difference, which indicates the time it takes for the neural energy to be conducted from one neural generator to the next. Interwave latency differences are calculated as the difference between the absolute latencies of two ABR peaks. This measurement is identified by the waves used in the calculation. Typical interwave latency differences are the I–III, III–V and I–V intervals.

Both absolute and interwave latency measurements can be abnormally delayed by lesions that directly involve the ABR neural generators. Absolute latencies can also be delayed by lesions occurring earlier in the auditory pathway. For instance, an acoustic neuroma can delay the latency of wave V even though the lesion is occurring in the vicinity of where wave II is generated. In addition, interwave latencies can be prolonged by lesions occurring between the two neural generators contributing to the latency measurement. A lesion between the neural generators of waves III and V will increase the latency of the III–V interval even though the generators responsible for III and V may not be directly compromised by the lesion.

Both absolute and interwave intervals have been shown to be sensitive and specific to the diagnosis of retrocochlear dysfunction, particularly in the application of acoustic neuroma detection. Musiek et al.[16] showed that all three interwave intervals had 100% specificity for this type of lesion. They varied, however, in their sensitivity, with the I–III interval showing the largest sensitivity value of approximately 90%, followed by the I–V interval with around 75% sensitivity, and then the III–V interval with the lowest sensitivity of 45%. If one considers just the I–III and III–V intervals, then 100% of the patients with acoustic neuromas in the study failed at least one of these measures and high specificity was still maintained.

TABLE 52.1 Normal limits for diagnostic ABR indices

Index	Normative value (msec)
Absolute latency of wave V	<6.2
Interwave latency I–III	<2.5
Interwave latency III–V	<2.4
Interwave latency I–V	<4.4
Inter-ear latency difference	<0.5
Fast rate shift	<1.0

Source: Values reflect adult cut-offs for ideal test efficiency based on clinical decision analysis and are obtained from Dartmouth Hitchock Medical Center normative data (Musiek). Protocol was click stimulus, monaural presentation of stimuli, presentation level 80 dB nHL, presentation rate of 17.7 clicks per second for slow rate and 77.7 clicks per second for fast rate, a 10 msec time window with 2000 accepted trials, and an online filter of 100–3000 Hz with recordings made from Fz.

Two additional latency measures that can be calculated are the inter-ear latency difference (ILD) and the fast-rate latency shift (e.g. fast-rate ABR). The ILD reflects the difference between the left ear wave V latency and the right ear wave V latency. As acoustic neuromas commonly present unilaterally, the affected side will often show an extended latency relative to the unaffected side. This leads to a larger ILD value for patients with the disorder. Sensitivity and specificity for ILD are 90% or greater.[17]

The fast-rate latency shift quantifies the degree to which the latency of wave V will shift when the click stimulus is presented at higher repetition rates. Presentation of the stimulus at these higher rates can lead to longer latency and smaller amplitude ABR waves even in the normal auditory system. This is a consequence of the stimulus rate more closely approximating the refractory period of the neurons that contribute to the ABR. In the disordered auditory system, increasing the repetition rate can lead to even longer extensions in wave latency and/or the absence of waves.[18] Normal limits on this measure are calculated as follows:[19]

[Normal wave V latency at standard repetition rates] + [0.1 msec for every 10 clicks/second increase in repetition rate] + 0.2

Therefore, if the normal latency is 6.1 msec and the repetition rate is increased from 20 clicks/second to 70 clicks/second, we would expect the new normal limit to be 6.1 + [0.1 × 5] + 0.2, or 6.8 msec. If the latency of wave V is beyond this value when the stimulus rate is 70 clicks/second, it would be considered an abnormal shift in latency.

Amplitude characteristics of the ABR are also sometimes examined to determine the presence of retrocochlear pathology. Amplitude is measured as the wave V to wave I (V/I) ratio. The amplitude of both peaks is measured from wave peak to the nearest negativity that follows the wave. The ratio is computed by dividing the wave V amplitude by the amplitude of wave I, and values less than 1.00 indicate that wave V amplitude is below that of wave I. While the specificity of this measure is relatively high (92%), the sensitivity is low enough to limit the diagnostic utility of this measure (44%).[20] As a result, amplitude is not used as commonly as latency measurements in the diagnosis of retrocochlear pathology.

Related to wave amplitude is the concept of examining wave presence or absence as an indicator of acoustic neuroma. This index does not appear always to be a reliable indicator. For instance, the percentage of patients with known acoustic neuromas who lack a wave I, III or V is 41%, 85% and 33% respectively.[21] Therefore, while the absence of a wave might be cause for follow-up testing, a high number of patients with neuromas will demonstrate the ABR waves.

Middle ear/cochlear hearing loss and test interpretation

Middle ear or cochlear hearing loss can negatively affect the latency and amplitude of the ABR peaks and can

sometimes complicate interpretation of the diagnostic ABR results. These hearing losses can prolong the latency and reduce the amplitudes of ABR waves. In such situations it is not always clear if these abnormal results are obtained because of the middle ear/cochlear hearing loss or because of a retrocochlear lesion.

There are several ways in which hearing loss can be addressed in the diagnosis of acoustic neuromas using ABR. First, if the degree of hearing loss is symmetrical, then the ILD can be used.[17] This is because the wave V latency shift being caused by the decrease in hearing sensitivity should be relatively equal in each ear. Second, interwave intervals can be used instead of absolute latencies to determine dysfunction as hearing loss would be expected to shift all waves relatively equally.[16] This approach can sometimes be limited if one or more waves cannot be visualized due to the severity of the hearing loss, particularly in the case of cochlear hearing loss. Finally, the Selters–Brackmann method yields an adjustment to the expected normal maximum latency of wave V based on the degree of sensorineural hearing loss at 4000 Hz. The new normal limit based on this method is computed as:

[Normal wave V latency] + [0.1 msec for every 10 dB of hearing loss above 50 dB HL at 4000 Hz].

Thus, if someone had a 70 dB HL loss at 4000 Hz, we would expect the new normal limit to be 6.1 + [0.1 × 2], or 6.3 msec. This modification yields reasonably good test efficiency.[22]

Diagnostic accuracy of ABR vs MRI

There has been much consideration in recent years over the diagnostic utility of the ABR when compared to magnetic resonance imaging (MRI). This arises from the observation that MRI has improved detection of acoustic neuromas when compared to ABR.[23] While this has led to the implication that all patients suspected of acoustic neuromas should be referred for MRI,[24] others have advocated for the continued use of the ABR in testing for the disorder. The value of the ABR in this capacity arises from both its very high diagnostic efficiency (e.g. sensitivity and specificity) and its reduced cost relative to MRI.[25, 26] Mangham[27] has suggested determining referral for ABR versus MRI based on the degree of average interaural hearing asymmetry at the octave frequencies of 1000–8000 Hz. If the average asymmetry is 20 dB HL or greater, patients should be referred for MRI, while average asymmetries less than 20 dB HL would warrant referral for an ABR. Using this approach they report about 2% less sensitivity than if all patients had received a diagnosis based on MRI. The cost saving was approximately US$25 000 per tumour diagnosed.

An alternative approach to acquiring ABRs has been proposed which improves the sensitivity of the test to small acoustic neuromas. The stacked derived-band ABR (or stacked ABR) utilizes the presentation of ipsilateral noise during the ABR procedure to derive responses from specific tonotopic regions of the auditory nerve.[28] This approach is based on the observation that standard click ABRs may miss dysfunction in certain frequency regions of the auditory nerve due to the spectral properties of the unmasked click stimulus. By introducing ipsilateral masking noise with different low-pass cut-offs, these various frequency regions can be assessed more directly. This approach has been shown to detect small tumours that are missed by conventional ABR.[28]

It has also been suggested that sensitivity of the ABR to small acoustic neuromas may be improved by comparing patients' ABR click threshold to their behavioural click threshold.[29] The trend witnessed in cases of acoustic neuroma is that ABR threshold tends to be poorer than behavioural threshold. Results in the study showed that patients with acoustic neuromas show approximately a 40 dB mean difference between these thresholds in the affected ear, while unaffected ears tend to yield a much smaller mean difference of 15 dB. Applying an abnormal criteria of >30 dB difference between the thresholds yielded excellent sensitivity and specificity.[29]

THRESHOLD AUDITORY BRAINSTEM RESPONSE

Overview

The ABR is commonly used in the electrophysiological assessment of hearing thresholds. ABR testing can be utilized to estimate hearing sensitivity in many cases where reliable behavioural audiometric results cannot be obtained. The test is commonly used in paediatric populations who are too young for reliable visual reinforcement audiometry or who otherwise would not condition to audiometric tasks. Acquisition of the ABR in this context allows for an estimate of hearing sensitivity that would not otherwise be obtainable.

It should be noted that the morphology of the ABR at threshold levels is different from the suprathreshold response. As the level of the stimulus is decreased, the latency of the ABR waves increases while the amplitudes decrease.[30] This occurs because fewer neurons are recruited at less intense stimulus levels and neuron firing occurs less synchronously. Earlier ABR waves (e.g. wave I) are more affected by these changes in intensity than later waves (e.g. wave V). For this reason it is not uncommon for the ABR to show only a wave V and SN10 at threshold. It is based on detection of these two peaks that ABR threshold estimates are generally made.

Description of threshold protocol

The equipment parameter settings for the threshold ABR are nearly identical to those used for the diagnostic ABR described above. As the lower stimulus levels used in the threshold ABR will increase the latency of the ABR peaks, a slightly longer time window is used, between 15 msec and 25 msec. In addition, unlike diagnostic ABRs, there tends to be a greater variety of stimuli used when completing a threshold ABR protocol. The click provides a good estimation of hearing at 2000–4000 Hz in many

clinical groups[31, 32] and tends to yield a robust ABR waveform. Since the click only assesses this 2000–4000 Hz range, it is recommended that tone bursts also be used in the assessment of hearing threshold via ABR.[31, 33] To this end, low (e.g. 500 Hz) and mid-frequency (e.g. 1000 Hz) stimuli are added to the protocol to provide a more complete evaluation of the patient's hearing. In cases where hearing thresholds demonstrate a sloping configuration for the 500 Hz, 1000 Hz and click threshold, acquisition of responses to 4000 Hz can sometimes provide a better estimate of the severity of a high-frequency loss.[31]

A typical threshold ABR evaluation will begin with assessment of the click ABR at suprathreshold levels (e.g. 70 dB nHL). There are several reasons why the acquisition of the suprathreshold response is advantageous to the clinician. First, except in cases of substantial hearing loss, this provides a well-formed template response to which subsequent click ABR responses can be compared. Second, this suprathreshold ABR should be evoked to condensation and rarefaction clicks to also test for auditory neuropathy (see below). Finally, though the patient was referred for a threshold ABR evaluation, there may be reasons to investigate the integrity of the auditory nerve and/or brainstem in a diagnostic manner, such as in cases of Chiari malformation or neurofibromatosis type 2. Acquiring a suprathreshold response will allow for this evaluation of retrocochlear pathology.

Once the suprathreshold ABR has been established, threshold can be determined for each of the frequencies being evaluated in the ABR protocol. Threshold may be defined as the lowest level at which wave V and SN10 are present. Alternatively, some clinics will only test down to a minimal hearing level (e.g. 15 dB nHL), as a detectable threshold at this level establishes that hearing is normal.

There are several ways in which threshold can be assessed. A modified Hughson–Westlake procedure[34] can be used in a fashion similar to what is done in pure-tone behavioural audiometry. However, it is sometimes more convenient and less time-consuming to test for a response at a minimal normal hearing level first. If a replicable response is not obtained, the presentation level can be increased in 5–10 dB steps until wave V is reliably evoked.

ABR testing must be undertaken when the patient is completely relaxed or asleep in order to minimize recording artefact generated by muscle movement. For newborn infants, ABR testing can be completed without sedation. Sleep deprivation, along with feeding just prior to the appointment, can increase the likelihood of a sufficient period of relaxation or sleep during the test. However, time to complete testing is often limited and testing may be interrupted or terminated early when the patient awakes. Multiple follow-up appointments may sometimes be necessary to obtain complete results in newborns.

An ABR utilizing sedation is often necessary for difficult-to-test patients. ABR can be performed under sedation or anaesthesia without degradation in response morphology. While sedation is generally used as a last resort, it can be valuable in providing the uninterrupted time necessary to perform a thorough audiological examination.

Correlation between AEP and behavioural threshold

The goal of performing the threshold ABR is ultimately to comment on the patient's hearing sensitivity. While the correlation between ABR threshold and behavioural hearing sensitivity is less than perfect, there tends to be a strong relationship between the two measures. ABR thresholds to clicks show a high degree of correspondence with some behavioural thresholds. The strongest correlation is seen between the ABR click threshold and the pure-tone average of 2000 Hz and 4000 Hz, with 89% shared variance.[31] The mean difference between the click ABR threshold and this pure-tone average threshold is approximately 1 dB, with the largest differences being in the vicinity of 35 dB.[31] Other studies have confirmed this high correlation between click ABR thresholds and the pure-tone average of 2000 Hz and 4000 Hz, with 81% shared variance, a mean ABR–behavioural threshold difference of 4 dB and a modal difference of 0 dB.[32]

ABR thresholds to tone bursts also show a relatively high level of association with their respective behavioural thresholds. The 500 Hz and 1000 Hz ABR thresholds share between 86% and 89% of their variance with behavioural measures.[31] The mean difference between the 1000 Hz ABR threshold and the corresponding behavioural threshold is approximately 1 dB, with the largest differences being in the vicinity of 30 dB.[31] In this regard, prediction of threshold at these frequencies using the ABR is as accurate as using the click threshold to predict the average of 2000 Hz and 4000 Hz.

Contralateral masking, conductive hearing loss and asymmetrical hearing

Certain clinical situations may require the use of a contralateral masking stimulus to eliminate the contribution of the non-test ear from the ABR. Testing the poorer ear of a unilaterally deaf subject has been shown to evoke a response from the contralateral ear that can be successfully eliminated with sufficient masking.[35] The presence of contralateral masking does not appear to influence the ipsilateral waveform.[35, 36] For air-conduction testing, the interaural attenuation for using ER-3A earphones and a click stimulus is approximately 70 dB.[37] Since click presentation levels will generally not much exceed 90–100 dB nHL, using a contralateral masking level of 50 dB nHL will eliminate most crossover. A white noise masker is typically provided with commercial ABR units.

Special consideration must be given to administration and interpretation of the threshold ABR in cases of conductive hearing loss and asymmetrical hearing. In cases where unilateral conductive hearing loss is suspected, the degree of hearing loss being contributed by the conductive component can sometimes be determined by obtaining bone-conduction ABR thresholds. Bone-conduction stimuli are elicited in an approach similar to that taken when obtaining behavioural thresholds, with placing a bone vibrator onto the mastoid. The contralateral non-test

ear will require masking during bone-conduction threshold assessment of the test ear.

There are several potential limitations to bone-conduction testing with ABR. First, responses evoked using this type of transducer tends to be more susceptible to stimulus artefact and this can decrease the ABR morphology and detectability. Alternating polarity stimuli must therefore be utilized to minimize the effect. Second, as artefact is sometimes high even at mid-intensity levels, the maximum intensity level at which ABRs can be reliably elicited by bone conduction (i.e. the equipment limits) is often lower than that obtained by air conduction. Finally, the spectrum of the stimulus is different when conducted through earphones as compared to the bone oscillator.[38] While this would imply that it is difficult to equate air- and bone-conduction thresholds, it has been noted that, at least in normal hearing individuals, air- and bone-conducted ABR threshold testing yields similar ABR results despite these spectral differences.[39]

Another approach to determining whether a conductive hearing loss is contributing to an ABR threshold shift is to use a latency–intensity function.[40] The latency of wave V is inversely related to stimulus intensity. Plotting wave V latency as a function of stimulus intensity generates a predictable curve in normal hearing subjects, with wave V latency increasing as stimulus intensity decreases. Conductive hearing impairment causes a latency shift in the curve that is relatively equal at all intensities and which yields no change to the slope of the curve.[41] Conversely, sensorineural hearing loss can cause a greater deviation from normal latency for stimuli closer to threshold and this can contribute to an increase in the slope of the latency–intensity curve.[41] In this way, the latency–intensity function can sometimes be used to discriminate conductive from sensorineural hearing loss.

As with behavioural audiometry, the presence of bilateral conductive hearing loss can pose a masking dilemma for the clinician. Assessment of cochlear hearing using the bone oscillator requires contralateral masking in order to prevent the contralateral cochlea from responding. However, when the masking level in the contralateral ear is raised to an intensity level that exceeds the degree of conductive impairment on that side, the masking signal can cross over to the cochlea in the test ear. This can elevate the bone-conduction threshold in the test ear, with subsequent increases in contralateral masking level further elevating this threshold. This phenomenon creates a situation in which bone conduction thresholds cannot be assessed by standard methods.

Jerger and Tillman's[42] sensorineural acuity level (SAL) technique has been advocated as an approach to measuring ABR bone-conduction thresholds in these cases of bilateral conductive hearing loss.[43] The rationale behind this method is to apply masking via a bone oscillator placed on the forehead and then quantify the degree of air-conduction threshold shift as a function of the masker level. In sensorineural hearing loss, the bone-conducted masker is less effective at shifting air-conduction thresholds since some or all of the masker energy will be below cochlear threshold. In cases of conductive loss, the masking noise is more effective at shifting air-conduction thresholds because the cochlea is unaffected by the conductive pathology. Therefore, the degree of air-conduction threshold shift that presents when a bone-conducted masking signal is introduced can assist in discriminating conductive from sensorineural hearing losses.

Central maturation

Morphology of the ABR changes with age from the perinatal period through the first years of life. The ABR response to high-intensity stimuli emerges at 28–32 weeks conceptual age.[44, 45] A repeatable three-peaked response is present by 35 weeks conceptual age. The ABR gradually becomes better defined with a full five-peaked response emerging in the first months of life. The ABR is similar in morphology to an adult response by 1–3 years of age.[45]

Maturation effects are also seen in ABR latency measures. All components of the ABR show a rapid reduction in latency during the first weeks of life, with wave I of the ABR reaching adult latency by 8–10 weeks postpartum.[40, 45] Waves III and V continue a gradual decrease in latency over the next several years, reaching adult latency by 2–3 years of age.[40, 45]

Perhaps of greater relevance to the clinician interpreting threshold ABRs is the effect of central maturation on threshold detectability. Studies have shown that, in some cases, ABR thresholds are initially elevated in newborns and show a gradual reduction over the first 6 months of life.[46–49] The degree of threshold elevation from suspected immaturity ranges from a few dB to as much as 25 dB. Often the greatest elevation in threshold occurs for higher-frequency stimuli such as 4000 Hz, whereas lower-frequency stimuli such as 500 Hz are more similar to adult levels at birth.[46, 48] ABR thresholds are also more variable in infants and this variability decreases with age.[46, 47]

Due to this trend of elevated thresholds and greater threshold variability in infants, the possibility of overtreatment may present itself when mild–moderate hearing loss is identified with the ABR at a young age. A conservative approach that includes close audiological monitoring through infancy may be warranted in cases where central immaturity is suspected. Follow-up electrophysiological testing or behavioural audiometry can be used to confirm the presence of hearing loss.

Auditory neuropathy

Auditory neuropathy is a condition that is characterized by normal cochlear responses on otoacoustic emissions and/or cochlear microphonic testing, but absent or abnormal suprathreshold ABRs.[50] Hearing loss can occur with the disorder and the site of dysfunction is localized to auditory structures beyond the outer hair cells through the auditory nerve.[51] There is a variety of risk factors associated with the disorder, including hypoxia, prematurity and hyperbilirubinaemia. There may also be genetic causes of the disorder.[51]

The patient is evaluated for the disorder as part of the threshold ABR protocol to eliminate neuropathy as a cause

of their listening difficulties. The disorder is assessed by comparing the presence/absence of the cochlear microphonic to the morphology of the ABR. The cochlear microphonic is an electrical potential that mimics the acoustic properties of the stimulus. It starts at near zero latency and, in some cases of neuropathy, it can also contribute to peaks later in the recording time window. If the cochlear microphonic is present but the ABR is otherwise compromised, auditory neuropathy would be suspected.

To evaluate the AEP for the presence of a cochlear microphonic, the ABR is evoked to a rarefaction and condensation click at suprathreshold levels. The cochlear microphonic will appear as peaks in the ABR waveform that invert in amplitude when the polarity of the stimulus is switched from rarefaction to condensation. Observation of the inversion in these peaks is typically consistent with detection of the cochlear microphonic.

One pitfall to be wary of when evoking the cochlear microphonic is not to misinterpret stimulus artefact as the microphonic response. Stimulus artefact arises from the transducer and is not a physiological potential. This artefact, when present, will show similar morphology to the cochlear microphonic and will sometimes overlap this AEP in time. Artefact will also invert its amplitude with changes in stimulus polarity. At stimulus levels of 80 dB nHL or greater there is an increased risk of stimulus artefact being present in the waveform.[52]

Alternatives to the conventional threshold ABR protocol

AUDITORY STEADY-STATE RESPONSE

The auditory steady-state response (ASSR) is sometimes used to predict hearing thresholds in difficult-to-test populations. Unlike the ABR, the procedure uses a continuous tonal stimulus instead of frequent repetition of a transient stimulus (e.g. click or tone burst). A carrier frequency is presented which is amplitude-modulated at a given modulation rate and depth. If the sound is detected by the cochlea and stimulates the auditory system, the neural generators underlying the ASSR will respond at a rate equal to the modulation rate of the stimulus. When neural firing is detected at this rate, the response is said to be 'phase-locked'.[53] A phase-locked response indicates that the auditory system has responded to the carrier frequency and this information can be used to establish threshold.

A potential advantage of this approach is that multiple frequencies can be assessed simultaneously as long as their carrier frequencies utilize different modulation rates.[53] Another benefit is related to the analysis of the ASSR. While ABR analysis involves the subjective interpretation by a clinician to identify response peaks, the ASSR can be analyzed using statistical methods that are applied and interpreted automatically.[53] This removes some of the subjectivity inherent to the process of obtaining an electrophysiological threshold.

The accuracy of the ASSR in predicting behavioural thresholds is similar to that of the tone-burst threshold ABR.[53, 54] There is some evidence that ASSR may be less likely to underestimate hearing loss in patients with steeply sloping audiometric configurations than is the ABR.[54] The ASSR may also be negatively affected by state of arousal[55, 56] and this could potentially limit its clinical application. This is particularly problematic for difficult-to-test populations where the ABR may be acquired while the patient is asleep or sedated.

ABR CHIRP STIMULUS

The chirp stimulus was developed to achieve greater neural synchrony by compensating for the travel time of the cochlear wave.[57] When a traditional click stimulus is presented, higher-frequency regions of the basilar membrane near the base of the cochlea are stimulated before the lower-frequency regions nearer the apex. This time delay causes different portions of the basilar membrane to respond in succession rather than synchronously. Conversely, chirps are acoustically designed to compensate for the tonotopic arrangement of the cochlea. This is accomplished by using a tone that increases in frequency throughout its duration, so that low-frequency cycles occur earlier than high-frequency cycles. Therefore, low-frequency energy enters the cochlea first and, by the time it reaches the apex, the higher-frequency energy is stimulating the base of the cochlea. The chirp creates a situation in which all regions of the basilar membrane are likely to be stimulated simultaneously. A potential benefit of the higher neural synchrony provided by chirp stimuli includes a larger response that is more easily detectable at lower intensity levels.[58]

MIDDLE LATENCY RESPONSE

Overview

The middle latency response (MLR) was first reported by Geisler and colleagues.[59] It is an AEP that is both larger in amplitude and later in latency than the ABR. It has multiple neural generators in the thalamocortical system, which includes the medial geniculate body, thalamocortical connections, auditory cortex and reticular formation.[60] The MLR comprises four separate potentials, a negativity occurring in the latency range of 12–21 msec (Na), a positivity that occurs between 21 msec and 40 msec (Pa), a negativity that follows Pa (Nb), and a second positivity that follows Nb in the latency range of 50 msec (Pb). MLR indices include the latency of the potentials, as well as the peak-to-peak amplitude (i.e. Na–Pa or Nb–Pb voltage difference). The Na and Pa amplitudes are the only two measured with any regularity in the clinic. This is a result of Pb being more difficult to evoke.[61] **Figure 52.3** shows an MLR with the Na–Pa peaks recorded and identified.

Historically, the MLR was pursued as a measure of hearing sensitivity. Relative to the ABR, this AEP provided an advantage in this regard since its larger amplitude made it more detectable near threshold.[62, 63] This application was limited, however, by the discovery that

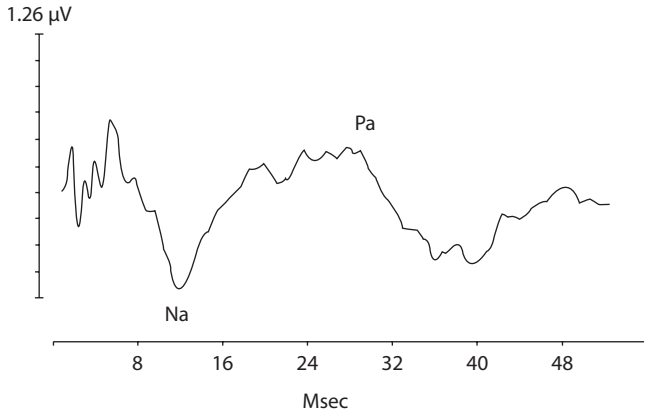

Figure 52.3 MLR with Na–Pa identified. The waves present at less than 8 msec are the ABR.

characteristics of the MLR morphology were negatively affected by degree of wakefulness.[64] Acquiring the MLR during sleep can lead to a reduction in peak amplitude or a complete absence of the complex. This posed a limitation for the use of this potential in the objective assessment of hearing sensitivity as the testing is frequently performed when the patient is asleep or sedated.

Presently, there are two primary applications of the MLR in the clinic: detection of neurological dysfunction of the CANS and diagnosis of CAPD. In regards to the former, patients with lesions that include the generator sites of the MLR will often show abnormalities on this measure. Lesions in the vicinity of the primary auditory cortex can give rise to changes in the morphology of Pa, frequently when measured over the affected hemisphere.[65, 66] Conversely, damage to the midbrain appears to affect the characteristics of the Na peak.[67] MLR abnormalities appear to be more common overall with brainstem lesions than with cortical lesions and this may be because large brainstem lesions are more likely to denervate thalamic projection nuclei.[68]

Applications of the MLR have also been reported in the diagnosis of CAPDs. CAPD refers to dysfunction of the CANS that contributes to significant listening difficulties, particularly when in the presence of background noise.[69] In addition to neurological dysfunction, it has been attributed to ageing-related changes to the CANS in older adults[70, 71] and CANS immaturity in younger populations.[72–74] There exists some controversy related to diagnosing the disorder by using tests that require patients to make a behavioural response (e.g. repeat back what they hear or press a button). For instance, it has been speculated that these types of tests may be susceptible to cognitive issues.[75] In this regard, using the MLR to evaluate for CAPD may be advantageous because no patient response is required and cognitive demands may be reduced as a result.

Description of MLR protocol

The MLR is evoked in a manner similar to the ABR, but there are several key differences. Figure 52.1 shows the electrode montage for recording this potential. Note that the response can be assessed using Cz as the non-inverting site (one-channel recording), or a combination of C3 and C4 can be used as the non-inverting electrodes (two-channel recording). The MLR settings are further characterized below, and differences from the ABR protocol are highlighted.

- **Stimulus:** A click stimulus is used to evoke the MLR for clinical purposes. Tone bursts can also be used and, due to the longer time window and slower stimulus presentation rate, a larger number of cycles can be included in these stimuli when compared to the ABR. Use of low- and mid-frequency tone bursts in this manner may be advantageous when evoking the MLR from patients with high-frequency hearing loss.
- **Presentation level:** The presentation level used for evoking the MLR is 70 dB nHL. This can be increased if there are concerns about sufficient audibility, although postauricular muscle artefact (PMA, see below) may be more likely to be evoked at these higher levels.
- **Polarity:** Rarefaction or condensation clicks may be used to evoke the MLR. If tone bursts are used, the polarity should alternate.
- **Time window:** Stimulation of the neural generators responsible for the MLR occurs only after the ABR neural generators have responded. For this reason, the latencies of the MLR peaks are later than the ABR peaks and a longer time window is needed. If only Na and Pa are being assessed, then a 50 msec time window is usually sufficient. For Nb and Pb, the time window should be extended to 75 msec.
- **Filters:** The frequency range of the MLR is lower than the ABR, extending down to 30 Hz.[76] For this reason a bandpass filter from 30–1500 Hz is used during acquisition of the MLR. Post-acquisition, an offline filter with a bandwidth of 30–300 Hz can be applied to assist in smoothing the MLR peaks. A 60 Hz notch filter should not be applied when acquiring the MLR as a filtering at this frequency could reduce a large proportion of MLR energy.
- **Stimulus rate:** Neurons contributing to the MLR have longer refractory periods than those that contribute to the ABR. For this reason, a slower stimulus rate of 9.7 clicks per second is used to evoke the MLR.
- **Number of trials:** Relative to the ABR, a fewer number of trials need to be averaged together to measure the MLR. Approximately 800–1000 trials are collected in the MLR average.
- **Replications:** As with the ABR, the MLR average is acquired at least twice to confirm response reliability.

MLR analysis

Although the latency and peak-to-peak Na–Pa amplitude of the MLR can be analyzed to determine dysfunction, these measures tend to have high between-subject variability in normal listeners.[77, 78] If normal variability on a

clinical measure is too high, it becomes difficult to establish practical normative values. One way in which MLR between-subject variability can be reduced is to compare MLR amplitude between ears (left vs right) or electrodes (C3 vs C4). Therefore, instead of examining the amplitude at either ear or either electrode individually, the difference between the two ears or two electrodes is calculated and this difference is used to determine normalcy. Sources of individual variation that are common to both ears or electrodes will be subtracted out of the index by computing this difference, and this will decrease between-subject variability on the MLR.[71, 79] In addition, amplitude measures of the MLR tend to be more sensitive to dysfunction than latency measures,[80] so differences in amplitude are used instead of latency.

Between-ear and between-electrode amplitude differences are referred to as ear effects and electrode effects, respectively.[80] They are computed as the absolute value of the difference between the two amplitude measures, or |Left ear Na–Pa amplitude - Right ear amplitude| for ear effects and |C3 amplitude - C4 amplitude| for electrode effects.[79, 80] For patients with neurological lesions, normalizing the difference by dividing by the smallest amplitude can improve the sensitivity of the index.[80] Normative values for ear and electrode effects are included in Table 52.2.

One pitfall to be aware of when interpreting the MLR is to not misinterpret PAM artefact as the MLR. PAM artefact is a myogenic response that can be evoked by the MLR stimulus.[81] The latency of PAM artefact is approximately 10–15 msec and, given its much larger amplitude relative to the MLR, the presence of this myogenic activity makes the MLR difficult to measure accurately. It has been suggested that the presence of PAM artefact is related to the direction of gaze and neck tension.[82] If the artefact is encountered, it can sometimes be reduced by having patients stare directly straight ahead at a picture on the sound booth wall and/or reclining them in a chair so as to relax the neck.

TABLE 52.2 Normal limits for MLR indices

Index	Normative value (μV)
7–8 years (AD)	Ear effect: <0.49 Electrode effect: <0.15
9–10 years (AD)	Ear effect: <0.43 Electrode effect: <0.17
11–12 years (AD)	Ear effect: <0.27 Electrode effect: <0.19
13–14 years (AD)	Ear effect: <0.24 Electrode effect: <0.20
15–16 years (AD)	Ear effect: <0.35 Electrode effect: <0.22
Adult (N)	Ear effect and electrode effect: <20% to 50%

Source: Values reflect upper limit of 95% confidence interval in normal hearing participant and are obtained from Musiek et al.[79] and Weihing et al.[78] Protocol was as follows: click stimulus, monaural presentation of stimuli, presentation level 60–70 dB nHL, presentation rate of 9.8 clicks per second, a 72 msec time window with 1000 accepted trials, and an online/offline filter of 20–1500/20–200 Hz with recordings made from the C3 and C4 electrodes.

AUDITORY LATE RESPONSE

Overview

The auditory late response (ALR), or long latency response, is an AEP that is primarily cortical in origin and was first reported by Pauline Davis.[83] The neural generator system contributing to the ALR is broad but receives important contributions from the Sylvian fissure and the superior aspect of the temporal lobe including Heschl's gyrus.[84–86] A total of six or more neural generators may contribute to the response.[86] The peaks most commonly measured in the ALR are the N1 and P2. The N1 is a negativity that can be observed between 60 and 170 msec, while the P2 is a positivity that is seen between 115 and 290 msec. Amplitude of the ALR waves is larger than the ABR or MLR wave amplitudes. Figure 52.4 shows an ALR with the N1–P2 peaks recorded and identified.

The ALR can be used clinically to diagnose lesions of the CANS. Patients with lesions of the temporal lobe have been shown to demonstrate prolonged ALR latencies, reduced amplitudes and/or absent potentials.[87] The ALR can also be used in the assessment of hearing sensitivity and in auditory rehabilitation applications.[88–92] Stimuli of relatively long duration can be used to evoke the response due to the very slow stimulus repetition rate and long time window of the ALR (see below). This allows for an increased number of cycles in pure-tone stimuli, which may yield better frequency specificity of

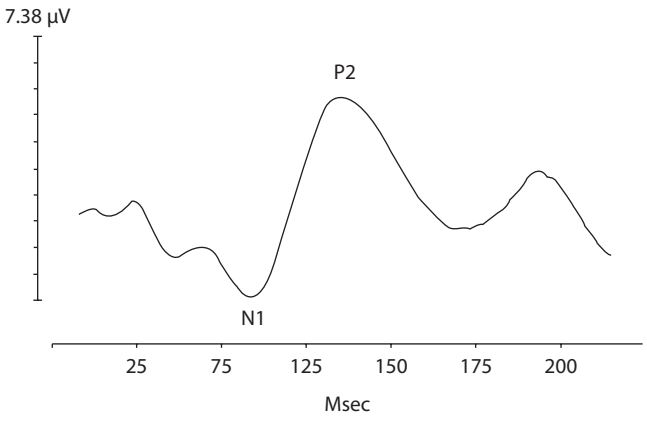

Figure 52.4 ALR with N1–P2 identified.

the evoked response in adults.[88] The ability to use longer stimuli also allows for the inclusion of more complex sounds, such as speech, in the ALR paradigm.[89] The ALR has also been used in rehabilitation contexts for demonstrating that amplification makes sounds audible in infants[90] and to show outcomes from auditory training.[91, 92]

Similar to the MLR, the ALR morphology is affected by sleeping and this can limit its utility as a threshold measure in difficult to test populations.[92, 93] In addition, the amplitude and latency characteristics of the response are affected by whether the auditory stimulus is attended to or not.[94] This may be the result of ALR arising from generator sources that respond to multiple modalities and/or that are responsible for mediating attention.[85, 95, 96]

Description of ALR protocol

Due to the many novel applications for which the ALR is used it is not possible to discuss all configurations the clinician may encounter when attempting to measure this response. However, we present below a minimal protocol that can be used to evoke an N1–P2 to address basic clinical questions. Note that, while the ALR protocol shares similarities with the ABR and MLR protocols, differences exist because of the later latency of the ALR peaks and the longer refractory periods of the cortical neurons. Recording sites include some combination of Cz, C3 and C4, as the N1 and P2 amplitudes are sufficiently large in these regions.[97] The ALR settings are further characterized below, and differences from other AEP protocols are highlighted.

- **Stimulus:** Although a click stimulus can be used to evoke the ALR, the much longer time window and slower stimulus rate allows for long duration tones and complex stimuli to be used in the task. For example, consonant–vowel syllables are frequently used to assess the response of the CANS to speech stimuli.[87, 98]
- **Presentation level:** A presentation of level of 70–80 dB nHL is sufficient for evoking the ALR if there are no concerns about audibility.
- **Polarity:** Rarefaction or condensation clicks may be used to evoke the ALR. If tone bursts or complex stimuli are used, the polarity should alternate.
- **Time window:** The latencies of the ALR peaks are later than the ABR and MLR peaks. For this reason, a much longer time window of 300–400 msec is utilized to acquire the N1–P2.
- **Filters:** The frequency range of the ALR is considerably lower than the ABR and MLR, from 1–30 Hz.[99] A bandpass filter in this range is applied online.
- **Stimulus rate:** ALRs are evoked using a slow rate of 1.1 stimuli/second due to the longer refractory periods of cortical neurons. Given the slow rate of presentation, there is sometimes concern that eye blinks will become time-locked with the AEP unit. To prevent this, an electrode should be placed at the outer canthus to reject trials on which eye blinks occur.
- **Number of trials:** Relative to the ABR and MLR, fewer trials need to be averaged together to measure the ALR. Approximately 100–200 trials are collected in the ALR average.
- **Replications:** As with the other AEPs, the ALR average is acquired at least twice to confirm response reliability.

TABLE 52.3 Normal limits for ALR indices

Index	N1	P2
Amplitude (μV) (male)	<-2.28	>2.99
Amplitude (μV) (female)	<-2.73	>3.83
Latency (msec) (male)	<109.24	<170.53
Latency (msec) (female)	<102.23	<163.35

Source: Values reflect upper or lower limit of 95% confidence interval in young adult normal hearing participants and are calculated based on data from Swink and Stuart.[100] Protocol was as follows: ~750 Hz tone burst with a 10.5–49–10.5 envelope and a duration of 70 msec, binaural presentation of stimuli, presentation level 75 dB peak SPL, presentation rate of 1.1 tones per second, a 500 msec time window with 150 accepted trials, and an online filter of 1–30 Hz with recordings made from the Cz electrode. Amplitude was measured from pre-stimulus baseline.

ALR analysis

ALR indices include the latency of the potentials, as well as a single peak-to-peak amplitude (i.e. N1–P2 voltage difference). Alternatively, N1 and P2 amplitudes are sometimes measured relative to the baseline voltage of the response. In these cases a separate amplitude measure is obtained for the two peaks (see Table 52.3 for example normative values). In neurological cases, ear and electrode effects are not calculated even though the ALR recorded over the affected hemisphere is more likely to show dysfunction.[87]

SUMMARY

The present chapter described basic approaches to acquiring AEPs in clinical populations. Perhaps the most relevant of these AEPs is the ABR, which can be used diagnostically to assess retrocochlear function or as a threshold measure in difficult-to-test populations. The resistance of the ABR to sleep effects and its high reliability make it a valuable tool in this regard. In addition to the ABR, protocols and characteristics of the MLR and ALR were also considered. These potentials assess regions more superior in the CANS and their acquisition provides a more comprehensive description of hearing health in this regard. The MLR has been used in the diagnosis of CAPD, while the ALR has a found a broad range of applications that include assessment of neurological function, validation of hearing aid fittings and quantifying neural benefits from auditory training.

KEY POINTS

- AEP can be used to infer the relative health of various peripheral and central auditory regions.
- Patients who are difficult to test or who are too young to have their thresholds assessed by behavioural audiometry can often have their hearing thresholds quantified using the threshold ABR.
- AEPs are commonly evoked with a click stimulus.
- ABR is a response to stimulus onset and arises from the auditory nerve and low brainstem.
- Auditory neuropathy is a condition that is characterized by normal cochlear responses on otoacoustic emissions and/or cochlear microphonic testing, but absent or abnormal suprathreshold ABRs.

CHAPTER 53

PREVENTION OF HEARING LOSS

Shankar Rangan and Veronica Kennedy

SEARCH STRATEGY

Data in this chapter may be updated by Medline and PubMed searches using the keywords: hearing loss, deafness, epidemiology, prevention, infection, vaccination, cytomegalovirus, measles, mumps, meningitis, ototoxicity, barotrauma and noise trauma. Epidemiological data from the World Health Organization have been used. Material from previous editions of this textbook on the same chapter has also been used.

EPIDEMIOLOGY

Hearing loss is a very common worldwide problem affecting all age groups and leading to marked disability and handicap. The World Health Organization (WHO) lists hearing loss in the 20 leading causes of burden of disease and as a most common cause of disability globally.[1]

In 2012, the WHO estimated that there are 360 million people worldwide with a disabling hearing loss, which is 5.3% of the world's population.[2] Of these, 91% are adults and 9% children. The prevalence of disabling hearing loss is greatest in South Asia, Asia Pacific and Sub-Saharan Africa both for children and for adults over the age of 65. The prevalence of hearing loss increases with age: in children it is 1.7%, 7% in individuals over the age of 15, and in adults over the age of 65 it is almost one in three. However, a noteworthy point is that half of all cases of hearing loss can be avoided through primary prevention.[3]

In the UK the incidence of children born with a permanent hearing impairment is about 1 in 1000, but this figure nearly doubles in early childhood.[4] In 2011 there were approximately 10 million people in the UK with some form of hearing loss.[5]

DISABLING HEARING LOSS AND ITS PREVENTION

Disabling hearing loss refers to hearing loss greater than 40 dB in the better ear in adults (15 years or older) and greater than 30 dB in the better-hearing ear in children (0–14 years).[3] The majority of people with a disabling hearing loss live in the developing countries.

For any disease or disability, there are three levels of prevention:[6]

- **Primary prevention:** This is prevention of pathology by reduction in the causative factors leading to that pathology.
- **Secondary prevention:** This is prevention or limitation of disability and handicap in those individuals with an impairment. This can be by screening for affected individuals prior to clinical presentation and, when possible, providing treatment to prevent progression of pathology and impairment.
- **Tertiary prevention:** This is prevention or limitation of handicap by early management of the disability.

The three levels of prevention of hearing loss are further subclassified in **Box 53.1**.

PRIMARY PREVENTION OF HEARING LOSS

The effects of primary prevention have markedly altered the profile of the aetiology of hearing loss in the developed countries. The incidence of hearing loss due to chronic suppurative otitis media has fallen dramatically. However, this still remains a leading cause in the developing countries.

BOX 53.1 Subclassification of the three levels of prevention of hearing loss[6]

1. Primary preventable causes of hearing loss
   - Genetic
     - Genetic counselling
   - Infective (congenital or acquired)
     - Immunization
     - Early treatment
     - Avoidance and education
   - Traumatic (noise, physical trauma and barotrauma)
     - Avoidance
     - Early treatment
   - Ototoxic medications
     - Avoidance
     - Monitoring
     - Treatment
   - Prevention of deafness by improving lifestyle to prevent other diseases
2. Secondary prevention
   - Screening
   - Treatment
3. Tertiary prevention
   - Early rehabilitation of hearing loss

Prevention of disease in the developing countries still lags far behind and ongoing efforts to promote uptake of preventive measures is essential. The WHO has developed a programme for the prevention of deafness and hearing impairment (PDH) and has produced guidelines on the prevention of hearing impairment from ototoxic drugs, chronic otitis media and noise-induced hearing loss.[7]

Genetic hearing loss

Around 60% of prelingual deafness is genetic. Of this, about 70% is non-syndromic. Between 75% and 80% of non-syndromic hearing impairment is autosomal recessive, 10–15% is autosomal dominant, and the rest are X-linked, mitochondrial or chromosomal.[8] The most common cause of genetic deafness is mutations in the gap junction beta 2 gene (*GJB2*), located on chromosome 13q and encoding the protein connexin 26.[9, 10] One particular mutation, 35 delG, is the commonest[11, 12] and has been reported to account for more than 80% of the *GJB2* mutation in the Caucasian population.[13]

PREVENTION OF GENETIC HEARING LOSS

Genetic counselling

Identifying the genetic profile of the hearing loss is the first step before any genetic counselling can be given to the individual and the family members. The genetic counsellor can inform a family about the risks of any child being born with a hearing impairment. This is especially applicable when they already have a child with hearing loss. The parents can then make an informed choice whether to have more children. Prenatal counselling would also enable early intervention and provision of support for a child with deafness, thus minimizing the impact of the hearing loss.

Role of consanguinity

With almost three-quarters of genetic hearing loss being autosomal recessive, the role of consanguinity assumes very important proportions. The prevalence of parental consanguinity has been found to be significantly higher in hearing-impaired children than in those with normal hearing. A decline in the prevalence of hearing impairment has been found with restriction of consanguineous marriages.[14] Improved education of the community about the risks involved with consanguinity should help to some extent to prevent deafness.

Infective causes of hearing loss

The role of primary prevention is quite significant and effective in the field of prevention of infective causes of hearing loss. This is true for both congenital and acquired infective causes. In the developing world, the focus on preventing hearing loss due to chronic suppurative otitis media remains as important as ever.

Where possible, the aim should be to prevent hearing loss due to infective causes. This can be through vaccinations, or, the adoption of measures which will prevent the development of chronic suppurative otitis media. If this is not possible, infection should be treated early to minimize the impact of hearing loss.

PREVENTION OF INFECTIVE CAUSES OF HEARING LOSS

Although infective causes of hearing loss may be congenital or acquired, the methods of prevention are the same for both. These include immunization, early treatment, and education and avoidance.

Rubella (or German measles) is a generally mild viral infection occurring mostly in children and young adults. Rubella infection during pregnancy can cause congenital rubella syndrome (CRS) with the classical triad of symptoms of sensorineural hearing loss (SNHL), ophthalmic abnormalities and congenital cardiac defects. There is no effective treatment for rubella, but the disease can be prevented by vaccination. Vaccines have been developed since 1969 and the immunization programmes have nearly eradicated CRS from most developed countries. However, the disease can still be a problem in developing countries. In 2014, the WHO estimated that there were 110 000 babies born worldwide with CRS.[15]

Hearing loss is a known complication following measles. The hearing loss can be sensorineural or conductive or mixed.[6] Prior to widespread vaccination for measles, it was reported to account for 5–10 % of cases of profound SNHL in the US.[16] Atrophy of the stria vascularis and loss of the organ of Corti after measles infection have been proposed to be the cause of SNHL.[17] Encephalitis is a rare complication of measles that can lead to profound SNHL. Measles is also associated with a high incidence of otitis media, which can also lead to hearing loss.[18] In addition, measles virus has been implicated in the aetiopathogenesis of otosclerosis.[19] Immunization against measles

may therefore play a role in reducing the incidence of otosclerosis.

Mumps is a systemic viral illness typically causing symptoms of fever, malaise, myalgia, headache and swelling of one or both parotid glands. Complications of mumps may include SNHL, orchitis, meningitis, encephalitis and pancreatitis. The incidence of SNHL after mumps has been estimated to be 0.5–5 per 100 000, but it has been reported to be as high as 1 in 1000 in Japan where mumps vaccination is optional.[20] The hearing loss is mostly unilateral but can also be bilateral. With the introduction of the Mumps, Measles and Rubella (MMR) vaccination, the incidence of mumps, and thereby hearing loss due to mumps, has reduced significantly.[21]

Effective immunization against mumps, measles, rubella and meningitis has led to a reduction in the incidence of hearing loss due to these conditions. The MMR vaccine was first licensed by the US government in 1971. In the UK it has been available for children between the ages of 1 and 2 years since 1988.[22] After the introduction of the MMR vaccine, the spread of measles was effectively halted in the mid 1990s. However, following adverse publicity, linking it with autism and Crohn's disease, there was a reduction in the uptake of the vaccination. Vaccine uptake levels in UK fell to 80% in 2003 and 2004 from levels of 92% in 1995.[23] This led to an increase in the incidence of these diseases, with 1370 cases of measles reported in England and Wales in 2008.[24] From November 2012 to July 2013, Wales experienced the largest outbreak of measles, with 1202 cases notified.[24] There has been a similar increase in mumps cases. The suggested association between MMR and autism has been proven to be baseless:[25] Public Health England investigated possible links between the MMR vaccine and autism and Crohn's and determined there was no evidence for this.

Meningitis remains the most common cause of acquired severe to profound SNHL in childhood.[26] Likewise, deafness is the most common long-term neurological sequela of the disease.[27] The hearing loss after meningitis can be unstable, with the deterioration occurring many years after the disease.[28] Another important consideration following meningitis is the development of labyrinthitis ossificans in which there is new bone formation within the lumen of the otic capsule. Ossification of the labyrinth can develop within a few days of meningitis.[29] This can make cochlear implantation difficult.[30] Early diagnosis of deafness after meningitis is therefore important. Of the various organisms causing bacterial meningitis, *Streptococcus pneumoniae* is associated with more profound hearing loss.[31] Various vaccinations against meningitis are available. These include the pneumococcal vaccine for *Streptococcus pneumoniae*, meningitis C vaccine for the serogroup C of *Neisseria meningitidis* and vaccination against *Haemophilus influenzae* type B. Quadrivalent vaccines effective against serogroups A, C, W-135 and Y of *Neisseria meningitidis* are also available. By protecting against mumps, measles and rubella, the MMR vaccine also protects against meningitis, which can arise as a complication of these diseases. Vaccination against serogroup B of *Neisseria meningitidis* has also become available, although it is still not available widely. Pneumococcal vaccines also have a role in the prevention of hearing loss arising due to otitis media: use of the 13-valent pneumococcal vaccine has been shown to reduce the incidence of pneumococcal otitis media in childhood.[32]

The use of adjuvant corticosteroid therapy in acute bacterial meningitis due to *Haemophilus influenzae* has been shown to reduce the incidence and severity of SNHL.[33] Its role in preventing hearing loss resulting from meningitis caused by other organisms is less well defined.

Cytomegalovirus (CMV) is the most common cause of congenital infections in humans.[34] Congenital CMV (cCMV) is being increasingly recognized as a leading cause of non-hereditary congenital SNHL,[35, 36] and it has been estimated to be the cause of congenital SNHL in 20–30% of cases.[37] The hearing loss associated with cCMV may be detectable at birth or can be of delayed onset.[38] It could be the only symptom in an otherwise asymptomatic baby. The hearing loss can be progressive. Fowler et al. reported a progression of hearing loss in 50% and fluctuation in around 23% of children with SNHL due to cCMV infection.[39] CMV is a ubiquitous infection and in adults causes mild flu-like symptoms. However, when a pregnant woman acquires the disease for the first time or develops a primary CMV infection, the risk of vertical transmission to the foetus is estimated to be around 30–40%.[40] Only about 13% of children with cCMV exhibit obvious symptoms at birth.[41] These may include permanent neurological sequelae including sensorineural deafness, blindness, seizures and learning disability. Treatment of cCMV with antiviral medications started within 1 month of life,[42] with 6-week therapy of intravenous ganciclovir[43] or 6-month therapy with oral valganciclovir,[44] has been shown to improve the audiological outcome. Recent evidence seems to suggest 6 months of oral valganciclovir produces better outcomes in the long term.[45]

Health education forms an important part of primary prevention for many diseases. Awareness about cCMV infection among the general public is still quite low. Providing health education materials to pregnant women has been shown to increase their knowledge about the infection and may reduce its incidence.[46] CMV is transmitted in body fluids including saliva and urine. It is a very common infection in toddlers and preschool children and exposure to saliva and urine of small children is the commonest cause of CMV spread to pregnant women. Simple hygiene measures adopted by pregnant women, such as avoiding kissing young children on the mouth or cheek, careful hand washing after contact with any bodily fluids and not sharing cutlery or drinks and food, can help to reduce the risks of pregnant women getting CMV.[47]

Toxoplasmosis is an infection caused by the parasitic protozoan *Toxoplasma gondii*. Cats are important vectors in the transmission of the infection. They can become infected by eating infected rodents, birds or other small animals. They then pass the parasite in their faeces. Handling cat litter can spread the infection. It can also be contracted by eating uncooked meat. *Toxoplasma* infection

during pregnancy is often asymptomatic or may present as mild flu-like symptoms. Congenitally infected infants are mostly asymptomatic at birth, but long-term studies have shown that up to 85% may develop sequelae including sensorineural deafness, chorioretinitis, developmental delay and microcephaly.[48] The incidence of *Toxoplasma*-associated hearing loss has been estimated to be in the range of 0–26%.[49] Careful hygiene during pregnancy, avoiding handling cat litter and eating only well-cooked meat can prevent toxoplasmosis during pregnancy. In children with congenital toxoplasmosis who received antiparasitic therapy initiated within 2.5 months of age, the prevalence of SNHL was 0%. The prevalence was 28% in children who did not receive any treatment.[49] However, there is no randomized controlled trial evaluating the benefits of treatment. The optimum duration of treatment is not clear and there are concerns about the adverse effects of treatment in the newborn period. In the UK, routine screening for *Toxoplasma* during pregnancy is not carried out as there is no clear evidence that prenatal treatment reduces maternal to foetal transmission of the infection.

Exposure to tobacco smoke is a known cause of increased ear infections in children, and parental education regarding the effects of passive smoking is vital to reduce the incidence of ear infections in children.[50] Inadequate treatment of acute otitis media, delay in seeking medical treatment, poor housing conditions, poor hygiene and nutrition, unhygienic ear cleaning and swimming in infected ponds and pools are some of the factors leading to chronic suppurative otitis media (CSOM) in developing countries.[51] Public education about the impact of the disease, and improvement in hygiene, nutrition and housing conditions will reduce the global burden of deafness due to CSOM.

Traumatic causes of hearing loss

Traumatic causes of hearing loss include acoustic trauma, noise-induced hearing loss (NIHL), direct physical trauma and barotrauma.

PREVENTION OF TRAUMATIC CAUSES OF HEARING LOSS

Noise

It has been estimated that worldwide about 16% of disabling hearing loss in adults is occupational noise-induced.[52] The risk of developing NIHL is proportional to the duration of noise exposure. Although most developed countries have legislation in place to prevent NIHL, it still remains one of the commonest health problems and one of the most common occupational diseases. Non-occupational noise exposure, such as that resulting from leisure activities, including music, power tools and motor sports, and also daily exposure to noise due to environmental conditions, can lead to NIHL. The formation of free radicals reactive oxygen species (ROS) and reactive nitrogen species (RNS) seems to be the molecular basis for NIHL and ototoxicity. Excessive noise exposure leads to the formation of these free radicals; they trigger cell death pathways through necrosis and apoptosis, resulting in loss of hair cells and neurons, which results in the hearing loss.[53] Apart from using adequate protection to prevent exposure to noise, the role of several antioxidants and therapeutic agents has been studied in the prevention of NIHL in mainly animal models but also in some human studies. These include glutathione,[54] *N*-acetylcysteine,[53] transforming growth factor (TGF)-β1 inhibitor,[55] alpha lipoic acid[56] and hydrogen sulphide[57] among other agents. The topic of NIHL is covered more extensively in Chapter 57 Noise-induced hearing loss and related conditions.

Acoustic shock is another phenomenon which can cause SNHL. This happens when there is exposure to a short-duration, high-frequency and high-intensity sound through a telephone headset. Use of telecommunications with an acoustic limiter reduces the risk of hearing loss associated with acoustic shock.[58]

Physical trauma

Hearing loss can be due to physical trauma to the ear such as temporal bone injuries. The trauma may also be self-inflicted or iatrogenic. A recent study found that, in adults, cotton swabs, first-aid products, hearing aids and other ear-specific accessories were common aural foreign bodies.[59] Public education about the risks of ear cleaning with buds or other materials has to be ongoing.

Iatrogenic trauma includes inexpert attempts at syringing or removal of foreign bodies. In some developing countries 'ear cleaning' services are offered by street vendors which may cause serious damage to the ear. Increasing public awareness about the risks associated with these actions is vital. Iatrogenic trauma can also be caused during ear surgery. Ensuring adequate and appropriate training is given to surgical trainees is necessary to reduce this. Radiotherapy to the head and neck for tumours can cause conductive hearing loss due to middle ear effusion or sensorineural deafness due to cochlear damage. This can be prevented by careful modulation of radiation fields to limit exposure of the cochlea.[60]

Barotrauma

Barotrauma results when there is failure to equalize the pressure between an air-containing space and the surrounding environment. Barotrauma to the ear is most commonly caused by pressure changes encountered in flying and scuba diving. It can result in damage to the middle or the inner ear. Middle ear barotraumas results when there is failure of equalization of pressure between the middle ear and the atmospheric air pressure. This occurs when the Eustachian tube function is compromised.

Inner ear barotrauma is encountered in divers when they force a Valsalva manoeuvre to try to equalize the middle ear pressure and the resultant increase in pressure causes inner ear damage by either the **implosive** or the **explosive** route. In the implosive route, if the forced Valsalva opens the Eustachian tube, there is a significant increase in the middle ear pressure which can cause either

rupture of the round window membrane or disruption of the stapes footplate. If the Eustachian tube remains closed, the increase in intracranial pressure can be transmitted along a patent cochlear duct or the internal auditory meatus, causing disruption of the round window or the stapes footplate. With either route, perilymphatic leak or intracochlear membrane damage may result in SNHL. Decompression sickness in divers occurs when dissolved gas, usually nitrogen, comes out of solution on ascent and forms bubbles in soft tissues and blood vessels, causing various symptoms including sensorineural deafness.

Preventive measures for barotrauma as a result of air travel would include avoidance of flying during or immediately after an upper respiratory tract infection. Frequent swallowing, for example by sucking sweets or sipping drinks during ascent and descent, helps equalization of pressure in the Eustachian tube. Similarly for divers, avoidance of diving during an upper respiratory tract infection is important. Proper training in equalizing pressure plays a major role in preventing barotrauma. Manoeuvres to equalize pressure include the Valsalva (blowing against closed nose and mouth) and Toynbee (holding the nose and swallowing simultaneously). Decompression sickness can be prevented by strictly following existing guidelines on decompression times relating to time and depth of dive.

Ototoxic medications

A wide variety of drugs may have ototoxic effects. Ototoxic medications include aminoglycosides, antimalarials (e.g. quinine), aspirin, anticancer drugs (e.g. cisplatin), diuretics (e.g. ethacrynate and furosemide) and industrial solvents (e.g. toluene). As in the case of NIHL, ototoxic medications may lead to the formation of free radicals which trigger cell death pathways through necrosis and apoptosis, resulting in hearing loss. Ototoxic hearing loss may be prevented by minimizing and controlling the exposure to these medications. There does not seem to be a safe dose with relation to vestibulotoxic effects.

There is a known genetic predisposition to ototoxicity. Individuals with the mitochondrial mutation *A1555G* develop a hearing loss with aminoglycoside exposure which often progresses after the use of aminoglycoside at therapeutic doses has ceased.[61] However, the prevalence of deafness in individuals with the *A1555G* mutation is likely to be high even in the absence of aminoglycoside exposure.[62] Screening individuals due to receive aminoglycoside treatment may lead to prevention of hearing loss from this cause.[63] Similar to NIHL, antioxidants may have a role in preventing ototoxic hearing loss. Aspirin has been shown to attenuate the ototoxic effects of gentamicin.[64] Ototoxicity is discussed in greater detail in Chapter 59 Ototoxicity.

Perinatal factors

The role of preventable perinatal factors in developing SNHL has reduced in the developed countries with better obstetric care, but it can still be a major concern in developing countries. Reduction in morbidity due to hazardous levels of hyperbilirubinaemia has been achieved in developing countries through a variety of preventive measures including better antenatal care, monitoring of serum bilirubin in infants, exchange transfusion, phototherapy and anti-D immunization. Use of other antibiotics and careful monitoring of aminoglycoside levels can prevent incidence of ototoxicity in the perinatal period. Paradoxically, in developed countries, improved neonatal care now enables several very preterm infants to survive and as a result of their extreme prematurity they may have long-term neurodevelopmental sequelae including SNHL. The major preventable perinatal factors which can cause SNHL include hypoxia, hyperbilirubinaemia and aminoglycoside toxicity. Although birth asphyxia is associated with SNHL,[65] it is thought that it is a combination of risk factors which leads to SNHL.[66] Severe neonatal hyperbilirubinaemia is associated with a higher incidence of SNHL.[67] Hyperbilirubinaemia may also be associated with auditory neuropathy spectrum disorders.[68]

Prevention of deafness by improving lifestyle to prevent other diseases

Smoking, obesity and poor gylcaemic control are well-known risk factors for cardiovascular diseases which in turn may increase the risk of hearing impairment.[69] Ongoing public education, especially in developing countries, about the risks of smoking and benefits of healthier diet with regular exercise would help in the prevention of hearing loss by reducing the risk of cardiovascular diseases. Hypertension is also associated with hearing loss. Optimizing blood pressure control should also, therefore, reduce the risk of hearing loss.[70]

SECONDARY PREVENTION OF HEARING LOSS

Screening

Increasing evidence that early identification of deafness and early intervention will result in significantly better outcome for language development[71, 72] led to the development of the Newborn Hearing Screening programme. The World Health Organization[73] recommended that the policy of universal neonatal hearing screening should be adopted in all countries with available rehabilitation services and that this should be extended to other countries and communities as rehabilitation services are established. This has been implemented in several developed countries in the world. Implementing it can be quite a challenge in developing countries due to factors including non-availability of expensive screening equipment and trained personnel to do the screening. In many developing countries, the majority of births may take place away from maternity hospitals so, typically, screening will not be performed by skilled staff and screening equipment will not be available in such settings.[74] In countries which

have adopted universal newborn hearing screening, the age of identification of hearing loss has reduced dramatically. In England, the median age at identification of permanent hearing impairment has come down from 18 months before the implementation of the screening to 10 weeks, with 90% of cases being identified before 6 months of age.[75] In many developing countries, family suspicion remains the main mode of diagnosing childhood hearing impairment.

Hearing loss undiagnosed at birth or during the first few years of life adversely affects speech and language development, academic progress and social and emotional development. In countries without universal newborn hearing screening programmes, a significant number of children with permanent childhood hearing impairment (PCHI) are not diagnosed until well into childhood. Milder hearing loss or unilateral hearing loss may not be identified until 6 years of age. Identification and rehabilitation of PCHI during the first few months of life will result in a significantly better outcome for speech and language development, school performance and social and emotional development.[73]

School screening is an effective method of identification of children with hearing loss. Even in countries with universal newborn hearing screening, school screening identifies those children who may have developed a hearing loss later in life, have a progressive hearing loss or have missed hearing screening at birth.

Regular hearing screening of those at risk of developing NIHL is mandatory in several industries. Early identification and cessation of the noise exposure will prevent the hearing loss from progressing.

Treatment

Early identification of hearing loss and its cause can enable commencement of appropriate treatment in several situations. For instance, in the case of NIHL and ototoxicity, once the hearing loss is diagnosed, cessation of exposure to the noxious agent will usually prevent the hearing loss from progressing. Several agents have also been shown to be effective in improving NIHL and hearing loss due to ototoxicity (see above). Early diagnosis of cCMV as a cause of hearing loss in the neonatal period and treatment with antiviral medication has been shown to prevent the progression of the associated hearing loss.

Hearing loss due to middle ear disease can be very effectively prevented by early identification of the disease and appropriate management. This is all the more important in developing countries where CSOM is still a leading cause of hearing disability.

TERTIARY PREVENTION OF HEARING LOSS

Tertiary prevention involves early rehabilitation of hearing loss. Provision of appropriate amplification is the first step, but ongoing support is equally important. In the case of children, educational support specially tailored for the hearing-impaired child is essential. The use of assistive listening devices, such as hearing loop systems, FM systems and personal amplifiers, are invaluable tools in the management of an individual with hearing loss. The provision of appropriate amplification is an ongoing challenge in the developing world. The WHO has made several efforts at improving the availability of high-quality hearing devices in low- and middle-income countries, where in many cases charitable institutions play a major role in providing hearing aids.[76] The financial aspects of cochlear implantation may be a significant limiting factor in its availability in the developing world. To overcome this, some developing countries produce their own indigenous cochlear implants.[77] However, continuing support for cochlear-implanted children, which is so vital for its success, may not be available. Efforts to improve education and support for the family of a hearing-impaired child or older person across the world must continue.

CONCLUSION

Hearing loss is a leading disability worldwide but there are several preventable causes of hearing loss. Health education and improving awareness about the role of preventive medicine should be an ongoing endeavour by health professionals worldwide to reduce the impact of disabling hearing loss. Although major advances have taken place over the years in preventing deafness, there is still much more work to be done. This chapter gives a broad overview of the various preventable causes of hearing loss. For more exhaustive knowledge the reader is directed to the references listed.

FUTURE RESEARCH

- More clinical trials in humans need to be carried out to establish firmly the role of various therapeutic agents in the prevention of NIHL and ototoxicity.
- Gene therapy has been shown to have a role in preserving inner hair cells exposed to ototoxic agents in animals. Gene transfer and stem cell therapy for the cochlea may become a possible way of treating SNHL, but much more research has to be carried out in this area before it can have any clinical benefits.

KEY POINTS

- The World Health Organization (WHO) lists hearing loss as one of the 20 leading causes of burden of disease and as a most common cause of disability globally.
- Around half of all cases of hearing loss can be avoided through primary prevention.
- The incidence of hearing loss due to chronic suppurative otitis media (CSOM) has fallen dramatically in developed countries but still remains a leading cause in developing countries.
- CMV is the most common cause of congenital infections in humans, and congenital CMV (cCMV) is a leading cause of non-hereditary congenital sensorineural hearing loss (SNHL), which can be progressive.
- Treatment of cCMV started within the first month of life can prevent progression of hearing loss.
- About 16% of disabling hearing loss in adults is occupational noise-induced.
- Formation of the free radicals reactive oxygen species (ROS) and reactive nitrogen species (RNS) seem to be the molecular basis for noise-induced hearing loss (NIHL) and ototoxicity.
- Several antioxidants and other therapeutic agents may have a role in the prevention of NIHL and ototoxicity.
- In babies early identification of deafness and early intervention will result in significantly better outcome for language development.

CHAPTER 54

HEARING AIDS

Harvey Dillon

SEARCH STRATEGY

The developments and research described in this chapter are in part based on a PubMed search using the keywords 'hearing aid'. To a small degree, they are also based on technical reports provided by manufacturers and on otherwise unpublished measurements and calculations by the author.

INTRODUCTION

Hearing aids partially overcome the deficits associated with a hearing loss. For a sensorineural hearing loss, there are several deficits to be overcome. Some sounds are inaudible. Other sounds can be detected because part of their spectra is audible, but may not be correctly identified because other parts of their spectra (typically the high-frequency parts) remain inaudible. The range of levels between the weakest sound that can be heard and the most intense sound that can be tolerated is less for a person with sensorineural hearing loss than for a normal-hearing person.

To compensate for this, hearing aids have to amplify weak sounds more than they amplify intense sounds. In addition, sensorineural impairment diminishes the ability of a person to detect and analyze energy at one frequency in the presence of energy at other frequencies.

Similarly, a hearing-impaired person has decreased ability to hear a signal that rapidly follows, or is rapidly followed by, a different signal. Hearing-impaired people are also less able to separate sounds on the basis of the direction from which they arrive. This decreased resolution (frequency, temporal and spatial) means that noise, or even other parts of the speech spectrum, will mask speech more than would be the case for a normal-hearing person.

The physiological origins of sensorineural hearing loss include loss of inner hair cell and outer hair cell function, reduced electrical potential within the cochlea and changes to the mechanical properties of the cochlea. The resulting auditory deficits mean that a person with a sensorineural hearing impairment needs a signal-to-noise ratio (SNR) greater than normal in order to communicate effectively, even when sounds have been amplified by a hearing aid. In contrast, a conductive impairment simply attenuates sound as it passes through the middle ear, so the amplification provided by hearing aids comes close to restoring hearing to normal.

To understand how hearing aids work, the physical characteristics of signals must be understood. These characteristics include the rate at which sound fluctuates (frequency), the time taken for a repetitive fluctuation to repeat (period), the distance over which its waveform repeats (wavelength), the way sound bends around obstacles (diffraction), the strength of a sound wave (pressure and sound pressure level), the break-up of a complex

sound into pure-tone components at different frequencies (spectrum), or into several frequency bands (octave, one-third octave or critical bands), and the degree to which a body of air vibrates when it is exposed to vibrating sound pressure (velocity and impedance).

The amplifiers inside hearing aids can be classified as linear or non-linear. For sounds of a given frequency, linear amplifiers amplify by the same amount regardless of the level of the signal or what other sounds are simultaneously present. By contrast, the amplification provided by a non-linear amplifier varies with the amplitude of the signal input to the amplifier. The degree of amplification can be represented as a graph of gain versus frequency (gain–frequency response), or as a graph of output level versus input level (I–O curve). The highest level produced by a hearing aid is known as the saturation sound pressure level (SSPL). The SSPL is usually estimated by measuring the output sound pressure level (OSPL) for a 90 dB SPL input (OSPL90).

The sound output by a hearing aid can be measured in the ear canal of an individual patient, or in a small coupler or ear simulator that has a volume similar to that of a real ear.

Hearing aids are described according to where they are worn. In order of decreasing size these categories are: body, spectacle, behind-the-ear (BTE), in-the-ear (ITE), in-the-canal (ITC) and completely-in-canal (CIC). For behind-the-ear hearing aids, further categorization is needed to distinguish between styles where the hearing aid receiver (the output transducer) is within the hearing aid case (receiver-in-the-aid, RITA) or within the ear canal (receiver-in-the-ear, RITE).

Decreasing size has been a constant trend during the history of the hearing aid. This history can be divided into six eras: acoustic, carbon, vacuum, transistor, digital and wireless. The last of these eras, which we are just entering, promises to hold advances at least as significant as in the eras that preceded it.

HEARING AID COMPONENTS

Hearing aids are best understood as a collection of functional building blocks. The manner in which a signal passes through these blocks in any particular hearing aid is indicated in a block diagram. The first block encountered by an acoustic signal is a microphone, which converts sound to electricity. Modern miniature electret microphones provide a very high sound quality, with only very minor imperfections associated with internal noise and sensitivity to vibration. Directional microphones, which have two entry ports, are more sensitive to frontal sound than to sound arriving from other directions. These enable hearing aids to improve the SNR by several decibels (depending on acoustic conditions) relative to omnidirectional microphones, and hence they can improve the intelligibility of speech in noise. Dual-microphone hearing aids can be switched automatically or by the user to be either directional, or omnidirectional, as required in different listening situations.

The small signals produced by microphones are made more powerful by the hearing aid amplifier. All amplifiers will distort the signal, by peak clipping it, if they attempt to amplify the signal to too high a level. Excessive distortion decreases the quality and intelligibility of sounds. To avoid distortion, and to decrease the dynamic range of sound, compression amplifiers are used in most hearing aids. These amplifiers decrease their gain as the level of the signal put into them increases, in much the same way that a person will turn down a volume control when the level becomes too high.

Amplifiers can represent sound in an analogue or a digital manner. The signals within analogue amplifiers have waveforms that mimic the acoustic waveforms they represent. Digital systems represent signals as a string of numbers. Performing arithmetic on the string of numbers alters the size and nature of the signals these numbers represent. Fully digital circuits may be constructed so that they process sounds in ways specific to each device, or may be able to perform any arithmetic operation, in which case the type of processing they do depends on the software that is loaded into them.

Filtering a signal is a common way in which hearing aids alter sound. Filters can be used to change the relative amplitude of the low-, mid- and high-frequency components in a signal. When the filters are made with variable, controllable characteristics, they function as tone controls operated by the user or the clinician. Filters can also be used to break the signal into different frequency ranges, so that different types of amplification can be used in each range, as required by the hearing loss of the hearing-impaired person.

Receivers are miniature headphones that use electromagnetism to convert the amplified, modified electrical signals back into sound. Their frequency response is characterized by multiple peaks and troughs, which are partly caused by resonances within the receivers, and partly caused by acoustic resonances within the tubing that connects a receiver to the ear canal. Inserting an acoustic resistor, called a damper, inside the receiver or tubing will smooth these peaks and troughs. A damper absorbs energy at the frequencies corresponding to the peaks, and this improves sound quality and listening comfort.

There are several other ways to put signals into hearing aids. A telecoil senses magnetic signals and converts them to a voltage. A radio receiver senses electromagnetic waves and converts them to a voltage. A direct audio input connector enables an electrical audio signal to be plugged straight into the hearing aid.

Users operate hearing aids via electromechanical switches on the case of the hearing aid or via a remote control. The hearing aid performs all its functions by taking electrical power from a battery. These batteries come in a range of physical sizes and capacities, depending on the power needed by each hearing aid and the space available.

HEARING AID SYSTEMS

Components can be combined into hearing aids in an extremely customized manner, such that individual components are selected for each patient and are located in

the position that best suits each ear. At the other extreme are modular aids, including some ITC hearing aids, and all BTE hearing aids, which are prefabricated in a totally standard manner. Many hearing aids fall somewhere between these extremes.

Increasingly, the hearing aids on each side of the head communicate with each other by wireless transmission so that their amplification characteristics (directionality, noise reduction processing, compression characteristics and input source) can remain coordinated as the environment changes or as the user varies a control. In some cases, the complete audio signal is transferred from one side of the head to the other, which enables a telephone signal to be heard in both ears and will enable superdirectional microphones to be developed.

Hearing aid amplification characteristics are programmed from a computer, via a suitable wired or wireless interface, to suit the hearing capabilities of each user. Often, more than one program is put into the hearing aid so that different amplification characteristics can be selected, automatically by the hearing aid or manually by the user, in different listening conditions.

The most effective way to make speech more intelligible is to put the microphone near the lips of the person talking. This markedly decreases noise and reverberation but requires a means of transmitting the signal from the microphone to the hearing aid wearer some distance away. Methods to do this currently include:

- magnetic induction from a loop of wire to a small telecoil inside the hearing aid
- radio transmission of a frequency-modulated or digitally modulated electromagnetic wave
- infrared transmission of an amplitude-modulated electromagnetic wave
- acoustic transmission of an amplified sound wave.

Each of these systems has strengths and weaknesses compared to the others. The first three offer a very large potential increase in SNR, and hence intelligibility. It can, however, be a challenge to adjust the hearing aid and wireless system together so that both the wireless system and the hearing aid individually provide maximum benefit to the wearer without the wireless input and microphone input signals interfering with each other. Increasingly, wireless receivers are being built into hearing aids, considerably improving cosmetic appearance and convenience. A major application of these systems is to make teachers more easily understood in classrooms, but they can be used by children and adults in other situations as well.

Wireless reception is also enabling hearing aids to conveniently accept electrical signals from a range of audio devices, including televisions, MP3 players, computers and mobile phones. In many cases, this connection requires an intermediary wireless relay device, as the current consumption of the ubiquitous Bluetooth receivers and transmitters precludes them from being directly built into hearing aids. While there have been problems with mobile phones causing interference in hearing aids, this problem is decreasing due to improvements in hearing aid design and changes in the mobile phone transmission system. Use of a mobile phone via hearing aids is now often trouble-free. There is the potential for hearing aids to become the audio portal to the world, and possibly not just for hearing-impaired people.

Assistive listening devices enable hearing aid wearers to receive sounds other than just by the amplification provided in a self-contained hearing aid. Assistive listening devices include the transmitter/receiver pairs already described for remotely sensing and sending speech or music, and devices that alter sound at its source (such as a telephone amplifier). Other types of assistive listening devices enable the aid wearer to detect alerting sounds (e.g. the doorbell, a telephone ring, a smoke alarm). Some do this by transmitting the sounds wirelessly to the hearing aids; others convert sound to other sensory modalities (such as flashing lights or vibrating shakers).

The long-established distribution and fitting system for hearing aids is being somewhat challenged by over-the-counter hearing aids, and their more modern cousin, hearing aids sold over the internet, and even by disposable hearing aids.

ELECTROACOUSTIC PERFORMANCE AND MEASUREMENT

The performance of hearing aids is most conveniently measured when the hearing aid is connected to a coupler. A coupler is a small cavity that connects the hearing aid sound outlet to a measurement microphone. Unfortunately, the standard 2 cc coupler is larger than the average adult ear canal with a hearing aid in place, so the hearing aid generates lower SPL in this coupler than in the average ear. This difference is called the real-ear-to-coupler difference (RECD), a quantity that is worth measuring in infants because they have ear canals considerably different from the average adult. A more complex measurement device, which better simulates the acoustic properties of the average adult ear canal, is called an ear simulator.

Test boxes provide a convenient way to get sound into the hearing aid in a controlled manner. These sounds can be pure tones that sweep in frequency, or can be complex, broadband sounds that, like speech, contain many frequencies simultaneously. Broadband sounds are necessary to perform meaningful measurements on many non-linear hearing aids. Increasingly, it is necessary for the test sound to approximate the spectral and temporal properties of speech so that the various signal processing algorithms in the hearing aid alter the gain in a manner representative of actual use. The measurements most commonly performed using test sounds are curves of gain or output versus frequency at different input levels, and curves of output versus input at different frequencies. The curve of output versus frequency when measured with a 90 dB SPL pure tone input level is usually taken to represent the highest levels that a hearing aid can create. Some other test box measurements that are less commonly performed are measures of distortion, internal noise and response to

magnetic fields. These measurements are used to check that the hearing aid is operating in accordance with its specifications.

Test box measurements are but a means to an end. That end is the performance of the hearing aid in an individual patient's ear. This performance can be directly measured using a soft, thin probe-tube inserted in the ear canal. Real-ear performance can be expressed as real-ear aided response (REAR; the level of sound in the patient's ear canal), real-ear aided gain (REAG; the level of sound in the ear canal minus the input level of sound near the patient) or as real-ear insertion gain (REIG; the level of sound in the ear canal when aided minus the level in the same place when no hearing aid is worn). Each of these measures requires the probe to be carefully located, but the requirements for probe placement are a little less critical for REIG than for REAG or REAR.

Both types of real-ear gain are different from coupler gain, partly because of the RECD already mentioned, and partly because the input to the hearing aid microphone is affected by sound diffraction patterns around the head and ear. The changes in SPL caused by diffraction are referred to as microphone location effects. Insertion gain is further different from coupler gain because resonance effects in the unaided ear form a baseline for the insertion gain measurement. This baseline, referred to as the real-ear unaided gain, provides the link between the REAG and the REIG.

Many factors can lead to incorrect measurement of real-ear gain. These include incorrect positioning of the probe, squashing of the probe, blockage of the probe by cerumen, background noise and hearing aid saturation. Fortunately, there are some simple checks one can do to verify measurement accuracy.

Feedback oscillation is a major problem in hearing aids. It happens when the amplification from the microphone to the receiver is greater than the attenuation of sound leaking from the output back to the input. Clinicians must be able to diagnose the source of excess leakage. Other problems that often have simple solutions include no sound output, weak output, distorted output and excessive noise.

HEARING AID EARMOULDS, EARSHELLS AND COUPLING SYSTEMS

An earmould or earshell is moulded to fit an individual's ear and retains the hearing aid in the ear. Premoulded canal fittings, available in a range of standard sizes and shapes, are an alternative way to connect the hearing aid to the ear canal. Whether custom-moulded or preformed, the ear fitting retains the sound bore, which is a sound path from the receiver to the ear canal. In many cases the fitting provides a second sound path, referred to as a vent, between the air outside the head and inside the ear canal. Where no vent exists, as in high-gain hearing aids, the fitting is said to be occluding. Where the cross section of the ear canal remains largely unfilled for its entire length, the hearing aid is said to be an open fitting, or an open-canal fitting. The three functions of an ear fitting are thus physical retention, transmission of amplified sound to the ear canal, and control of the direct sound path between the ear canal and the air outside the head.

There is a wide variety of physical styles of both earmoulds and earshells. These styles vary in the extent of the concha and canal that they fill. These variations affect the appearance, acoustic performance, comfort and security of retention of the hearing aid.

One unwanted consequence of a hearing aid can be an occlusion effect, in which the aid wearer's own voice is excessively amplified by bone-conducted sound. For many hearing aid fittings, vent selection is a careful juggle between choosing a vent that is big enough to avoid an unacceptable occlusion effect, but not so big that it causes feedback oscillations or limits the ability to achieve sufficient low-frequency gain and maximum output. For patients with mild or moderate hearing loss, the choice will often be an extremely open fitting comprising a BTE connected to thin tubing, or a wire connection for an ITE style, terminating in a preformed, flexible, perforated, dome-shaped canal fitting.

For any ear fitting with a vent or other direct path to the outside air, the speech range of frequencies can be subdivided into the vent-transmitted frequency range, the amplified frequency range and the mixed frequency range that is intermediate to these. Hearing aids perform very differently in each of these ranges.

The shape of the sound bore that connects the receiver to the ear canal affects the high-frequency gain and output of hearing aids. Sound bores that widen as they progress inwards (horns) increase the high-frequency output. Conversely, those that narrow (constrictions), whether by design or as a consequence of poor construction technique, decrease the high-frequency output. Horns have to exceed a certain length if they are to be effective within the frequency range of the hearing aid.

Dampers are used within the sound bore to smooth peaks in the gain–frequency response. Careful choice of the placement and resistance of the damper can also control the mid-frequency slope of the response.

The key to a well-fitting earmould is an accurate ear impression. This requires an appropriate material (medium viscosity silicone is good for most purposes), a canal block positioned sufficiently deeply in the canal and smooth injection of the impression material.

Tighter earmoulds or shells that reduce leakage of sound from the ear canal can be achieved by a variety of techniques. These techniques include taking an impression with the patient's jaw open, patting down the impression material before it sets, using viscous impression material and building up the impression in the patient's ear.

Earmoulds are made from a variety of materials. The most important difference between materials is hardness. Soft materials provide a better seal to the ear, but they deteriorate more rapidly, can be more difficult to insert and are more difficult to modify and repair. Earmoulds and earshells are routinely constructed by computer-aided

manufacture in which lasers guide the 'printing' of plastic based on a scanned image of the ear impression.

COMPRESSION SYSTEMS IN HEARING AIDS

The major role of compression is to decrease the range of sound levels in the environment to better match the dynamic range of a hearing-impaired person. The compressor that achieves this reduction may be most active at low, mid or high sound levels. More commonly, it will vary its gain across a wide range of sound levels, in which case it is known as a wide dynamic range compressor. Compressors can be designed to react to a change in input levels within a few thousandths of a second, or their response can be made so gradual that they take many tens of seconds to react fully. These different compression speeds are best suited to different types of people.

The degree to which a compressor finally reacts as input level changes is best depicted on an input–output diagram or on an input–gain diagram. The compression threshold, which is the input level above which the compressor causes the gain to vary, is clearly visible on such diagrams. The compression ratio, which describes the variation in output level that corresponds to any variation in input level, is related to the slope of the lines on these diagrams.

Simple compression systems can be classified as input-controlled, which means that the compressor is controlled by a signal prior to the hearing aid's volume control, or as output-controlled, which means that the compressor is controlled by a signal subsequent to the volume control. This classification is irrelevant for hearing aids with no volume control and inadequate for hearing aids with multiple, sequential compressors.

Compression systems have been used in hearing aids to achieve the following more specific aims, each of which requires different compression parameters. Output-controlled compression limiting can prevent the hearing aid ever causing loudness discomfort or the signal being peak clipped. Fast-acting compression with a low compression threshold can be used to increase the audibility of the softer syllables of speech, whereas slow-acting compression will leave the relative intensities unchanged but will alter the overall level of a speech signal. Compression applied with a medium compression threshold will make hearing aids more comfortable to wear in noisy places, without any of the advantages or disadvantages that occur when lower level sounds are compressed. Multichannel compression can be used to enable a hearing-impaired person to perceive sounds with the same loudness that would be perceived by a normal-hearing person listening to the same sounds. Alternatively, it can be used to maximize intelligibility, while making the overall loudness of sounds (rather than the loudness at each frequency) normal. Compression can be used to decrease the disturbing effects of background noise by reducing gain most in those frequency regions where the SNR is poorest. Gain reduction of this type increases listening comfort and with some unusual noises may also increase intelligibility. Finally, compression can be applied by using the combination of compression parameters that patients are believed to prefer, irrespective of whether there is a theoretical rationale guiding the application. Although these rationales are different, they have various aspects in common. Furthermore, many of them can be combined within a single hearing aid.

Despite the complexity, the benefits of compression can be summarized simply, but accurately, as follows. Compression can make low-level speech more intelligible, by increasing gain and hence audibility. Compression can make high-level sounds more comfortable and less distorted. In mid-level environments, compression offers little advantage relative to a well-fitted linear aid. Once the input level varies from this, of course, the advantages of compression become evident. Its major disadvantages are a greater likelihood of feedback oscillation and excessive amplification of unwanted lower level background noises.

DIRECTIONAL MICROPHONES AND ARRAYS

Other than the use of a remote microphone located near the source, directional microphones (which work by sensing sound at two or more locations in space) are the most effective way to improve intelligibility in noisy environments.

Directivity is most commonly achieved in hearing aids with first-order subtractive directional microphones, in which the output of one omnidirectional microphone is delayed and subtracted from the output of the other. This internal delay, relative to the physical spacing between the two microphone sound ports, largely determines the polar sensitivity pattern of these microphones. The head itself also affects the polar pattern.

These subtractive directional microphones inherently cause a low-frequency cut in the frequency response, for which the hearing aid signal processing often compensates by a low-boost characteristic, but which also causes greater internal noise in the hearing aid. Split-band directivity, which combines a directional response for the high frequencies with an omnidirectional response for the low frequencies, avoids this problem but, of course, provides no noise reduction for the low frequencies. Irrespective of the frequency range over which the microphone is directional, the complete hearing aid fitting will have directivity only over the frequency range for which the gain of the amplified sound path exceeds that of the vent sound path. In open fittings, this will likely be only half the speech frequency range. Whether achieved by split-band processing or by the acoustics of an open fitting, the resulting pattern of high-frequency directivity and low-frequency omnidirectional processing simulates the directivity pattern of normal hearing.

Additive directional arrays create directivity by adding together the output of two or more omnidirectional microphones. They do not create additional internal noise. To be effective, however, the microphones have to be separated by distances larger than a quarter of the

sound's wavelength. They are therefore less suitable for hearing aids, but are suitable for accessories such as handheld microphones.

These simple fixed subtractive and additive arrays have a fixed pattern of sensitivity versus direction of the incoming sound. Adaptive arrays, by contrast, have directional patterns that vary depending on the location, relative to the aid wearer, of background noises. Adaptive arrays automatically alter the way they combine the signals picked up by two or more microphones so as to have minimum sensitivity for sounds coming from the direction of dominant nearby noise sources. The multiple microphones that provide the input signals can be mounted on one side of the head or on both sides of the head.

The most sophisticated directional microphone arrays apply complex, frequency-dependent, adaptive weights to the outputs of each omnidirectional microphone before combining them. Like all directional microphone arrays, complex adaptive arrays work most effectively in situations where there is a low level of reverberant sound.

Directional microphones are effective when either the target speech or the dominant (rearward) noise source(s) are closer to the aid wearer than the room's critical distance (at which the reverberant and direct sound fields have equal intensity). In the special case of a close frontal talker and many distant noise sources, the improvement in SNR will approximate the directivity index of the hearing aid averaged across frequency.

The disadvantages of directional microphones include insensitivity to wanted sounds from the sides or rear, increased internal noise if used in quiet places, reduced localization accuracy if the two hearing aids act in an uncoordinated manner, and increased sensitivity to wind noise. These disadvantages can be minimized by intelligent switching (automatically or manually) between directional and omnidirectional modes, on the basis of noise levels and apparent SNR at the output of the omni and directional microphones.

All hearing aid wearers are candidates for directional microphones because all hearing aid wearers need a better SNR than people with normal hearing. Adaptive directional arrays that combine (via a wireless link or a cable) the outputs of microphones on both sides of the head produce a superdirectional response that should enable people with mild hearing loss to hear better than people with normal hearing in many social situations.

ADVANCED SIGNAL PROCESSING SCHEMES

Adaptive noise-reduction schemes, such as Wiener Filtering and Spectral Subtraction, progressively decrease the gain within each frequency region as the SNR deteriorates. Although they generally improve sound comfort and the overall SNR, these schemes do not change the SNR in any narrow frequency band. Consequently, they do not generally improve intelligibility. Other types of noise reduction include wind noise reduction, achieved by a low-frequency cut, and transient or impulsive noise reduction, achieved by limiting the rate at which the waveform changes.

Feedback oscillation can be made less likely by several electronic means. One simple technique is to decrease the gain only for those frequencies and input levels at which oscillation is likely. A second technique is to modify the phase response of the hearing aid so that the phase shift needed for oscillation does not occur at any frequency for which there is enough gain to cause feedback oscillation. A third technique involves adding a controlled internal negative feedback path that continuously adapts to maintain the gain and phase response needed to cancel the accidental leakage around the earmould or shell. A final technique involves making the output frequency different from the input frequency. Often, a combination of these techniques is used.

High-frequency components of speech can be made more audible by lowering their frequency. This can be achieved by transposition: moving sections of the spectrum to lower frequencies and superimposing them on the spectrum already in the lower frequency range. Alternatively, frequency compression is used to compress a wide frequency range into a narrower (and lower) one. While both frequency transposition and frequency compression can guarantee audibility of high-frequency sounds, they do not necessarily guarantee better intelligibility, as the speech components shifted down in frequency may interfere with perception of the speech components that were originally dominant in this lower frequency range. The range of possible frequency-lowering methods, frequency transformation maps and gain characteristics is large. Finding the best combination is made more difficult by the time it takes people to adapt to a highly altered spectrum and by our present uncertainty over how best to evaluate success.

There are various theoretically appealing methods for enhancing features of speech that have been tried in research experiments. These include exaggerating the peaks and troughs in the spectrum of a speech sound, increasing the amount of amplification whenever a consonant occurs, increasing the amplitude at the onset of sounds, lengthening and shortening the duration of particular sounds, simplifying speech down to a few rapidly changing pure tones, and resynthesizing clean speech based on the output of an automated speech recognizer. On the evidence available so far, however, none of these techniques will produce a worthwhile increase in intelligibility compared to conventional amplification, so there is as yet little motivation to include the processing within commercial hearing aids.

Various other signal processing algorithms have already been implemented in commercial hearing aids, or could readily be implemented. Reverberant energy that does not overlap other speech sounds can be removed, giving a crisper sound quality. Hearing aids can automatically categorize the listening environment they are in, and select amplification characteristics that have been preprogrammed into the hearing aid for each type of environment. Their data-logging systems can record how often each environment is encountered, and how the user

adjusts the hearing aids in each environment. Trainable hearing aids can learn from the adjustments the aid wearer makes, and infer how the aid wearer likes the hearing aid to be adjusted as the acoustics of the listening situation vary. Fine-tuning is therefore carried out by the hearing aid and the client together, rather than by the clinician. Active occlusion reduction processing enables a hearing aid to sound like an open-canal hearing aid, despite the ear canal being completely blocked. In addition to cancelling the occlusion-induced sound, active occlusion reduction cancels the vent-transmitted sound, enabling directional microphones to work over the entire frequency range, increasing their efficacy.

ASSESSING CANDIDACY FOR HEARING AIDS

Although the decision to try hearing aids is ultimately made by the patient, many patients will be in doubt as to whether they should acquire hearing aids and so will look to the clinician for a recommendation. This recommendation must take into account many factors other than pure-tone thresholds.

Initial motivation to obtain hearing aids has been shown to be a key determinant of whether patients continue to use them. This motivation reflects the balance of all the advantages a patient expects hearing aids will provide offset by all the expected disadvantages, irrespective of whether all these positive and negative expectations are realistic. The advantages expected by the patient are affected by the degree of disability they feel they have. Disability includes how much difficulty the person has hearing in various situations, referred to as activity limitation, and the extent to which a person is unable to participate in activities because of the hearing loss, referred to as participation restriction. The advantages and disadvantages expected by the patient are affected by what the patient has been told about hearing aids by others. Disadvantages potentially include the impact on a patient's self-image of wearing hearing aids. The clinician must attempt to discover a patient's expectations and modify those that are unrealistically low or unrealistically high. Although hearing aids help in quiet and in noise, they help much more in quiet, so hearing aids are more likely to be valued and used if the patient needs help hearing in quiet places.

When a clinician encounters a hearing-impaired patient who does not want hearing aids, the clinician should find out whether this is because the patient is not aware of the loss and/or the difficulty that he has compared to others, or because the patient, although acknowledging the loss, does not wish to wear hearing aids. If the latter is true, the patient's reasons should also be discovered.

Difficulty managing a hearing aid can greatly affect use, so the clinician must consider likely manipulation difficulties when determining candidacy and aid type. People with tinnitus often find that hearing aid use diminishes their problems, so tinnitus positively affects candidacy. The presence of central processing disorders and extreme old age can both affect candidacy, but not in a manner sufficiently predictable to affect the clinician's recommendation. People who are not worried that hearing aids will stigmatize them are more likely to acquire them, and people who more readily accept the presence of noise while listening to speech are more likely to use them. Several personality characteristics also make hearing aid acquisition, use and/or benefit more likely.

People with a severe to profound hearing loss are likely to receive more benefit from cochlear implants than from hearing aids. The most useful indicator of which device will be better for them is the speech score they receive for well-fitted hearing aids after some years of becoming accustomed to them. For infants, this is not possible so the decision to implant has to be based primarily on aided or unaided hearing thresholds (as well as requiring no medical or psychological contraindications). Cochlear implants and hearing aids generally provide complementary cues, whether they are worn in the same ear, or in opposite ears.

Vibrotactile or electrotactile aids are a worthwhile alternative for those with too much hearing loss to receive useful auditory stimulation from hearing aids but who do not wish to receive a cochlear implant, or for whom a cochlear implant is not suitable on medical or psychological grounds. Training in integrating the tactile information with visual information is essential.

Hearing aids should not be withheld just because speech scores obtained under headphones fall below some arbitrarily determined criterion. There are, however, several audiological/medical indications that should cause hearing aid fitting to be delayed until the cause of the problems has been resolved.

A clinician therefore has to consider a large number of factors that may affect candidacy for hearing aids, none of which has such a strong effect that the remaining factors can be ignored.

PRESCRIBING HEARING AID AMPLIFICATION

Amplification can be prescribed using a formula that links some characteristics of a person to the target amplification characteristics. Prescription formulae most commonly used are based on hearing thresholds, but some are based on suprathreshold loudness judgements.

Popular procedures for linear hearing aids include prescription of gain and output (POGO), National Acoustic Laboratories (NAL) and desired sensation level (DSL). For all of these, gain can be prescribed based on hearing thresholds alone. These formulae all contain variations of the half-gain rule (in which gain equals half of hearing loss, in dB), but the variations are so different that the resulting prescriptions differ greatly, especially for people with a sloping hearing loss.

For non-linear hearing aids, all available prescription procedures include some aspect of normalizing the loudness of suprathreshold sounds. Procedures such as loudness growth in octave bands (LGOB), International Hearing Aid Fitting Forum (IHAFF), DSL[i/o] curvilinear, the Cambridge method for loudness restoration (CAMREST)

and FIG6 aim to normalize loudness at all frequencies, at least for sounds with levels above the compression threshold of the hearing aid. Other procedures vary from loudness normalization in some way. ScalAdapt decreases the loudness of low-frequency sounds; CAM2 and NAL-NL2 normalize only the overall loudness. CAM2 aims to equalize the contributions that different frequency regions make to loudness, whereas NAL-NL2 aims for the sensation levels across frequency that will maximize calculated speech intelligibility. As each of the formulae has been revised, their prescriptions have become more similar to each other, but marked differences still occur.

There are some issues related to prescription that are not yet resolved, although there is considerable information available about each issue. How much do patients' preferences and performance with hearing aids change following weeks, months or years of experience with amplified sound? How loud (a perception, not a physical quantity) do patients like sound to be? Should tests of dead regions in the cochlea routinely be conducted? How severe does hearing loss need to be before it is considered unaidable? As signal level decreases, down to how low a level should gain keep increasing? How accurately must prescription targets be met? What is the best combination of fast and slow compression?

Maximum output (OSPL90) has to be prescribed so that loudness discomfort is prevented, but so that enough loudness can be obtained without the hearing aid becoming excessively saturated. In many procedures, the target OSPL90 is assumed to just equal the loudness discomfort level (LDL), in others it is predicted from threshold, in which case it may fall above or below an individual patient's LDL as measured in the clinic. For patients with mild to severe hearing loss, an acceptable sound quality is more likely if compression limiting controls maximum output than if peak clipping controls maximum output. Many patients with a profound loss, however, will benefit from the additional SPL that is achievable with a peak clipper.

People with conductive and mixed hearing loss require greater gain and OSPL90 than people with sensorineural loss of the same degree. For a variety of reasons, the gain needed to compensate for a conductive loss seems to be less than the amount of attenuation that the conductive loss causes in the middle ear. Consequently, the same is true of OSPL90.

Multimemory hearing aids can have a different prescription for each memory. These alternatives can be prescribed as variations from the baseline response prescribed for the first memory. The variations are designed to optimize specific listening criteria or for listening to different types of signals, such as music. People who wear their hearing aids in many environments, have more than 55 dB high-frequency hearing loss and require more than 0 dB low-frequency gain are most likely to benefit from multiple memories.

Neither gain nor OSPL90 should be any higher than is necessary for a patient. Otherwise, a hearing aid may increase hearing loss because of the resulting high-level exposure to sound. The risk of temporary or permanent noise-induced loss is greatest for patients with a profound loss and can be minimized by using non-linear amplification.

SELECTING, ADJUSTING AND VERIFYING HEARING AIDS

The first decision to be made when a clinician and patient select a hearing aid is whether a CIC, ITC, ITE, BTE–RITE, BTE–RITA (with standard tubing and earmould, or thin tube and earmould or instant-fit dome), spectacle, body, or a subvariety of any of these would be most suitable. For each style there are advantages relating to ease of insertion, ease of control manipulation, visibility, amount of gain, sensitivity to wind noise, directivity, reliability, telephone compatibility, ease of cleaning, avoidance of occlusion and feedback, ability to assess and fit in the same appointment, and cost. The weight given to each factor will vary greatly from patient to patient.

The need for specific features, such as a volume control, a telecoil and switch, a direct audio input and a directional microphone, must be determined on an individual basis. These needs will also influence the style of hearing aid selected. BTEs have more advantages than the other styles for a majority of patients.

Next, signal-processing options appropriate to the needs of the patient must be selected. Compression limiting is a more appropriate form of limiting than peak clipping if it can provide a high enough maximum output. In addition to compression limiting, a low compression ratio, active over a wide range of input levels, is appropriate for most patients. This low-ratio compression will provide advantages whether it is single- or multichannel, and whether it is fast- or slow-acting. Multichannel compression will provide greater speech intelligibility and/or comfort for patients with moderately or steeply sloping hearing loss, and the multichannel structure facilitates other features such as adaptive noise suppression and feedback suppression. The comfort advantages of adaptive noise reduction are greatest for patients who wear their hearing aids in a range of environments and who also require amplification across a wide range of frequencies. These same considerations apply to multimemory hearing aids, the only difference being that the patient, rather than the hearing aid, chooses the response variations. Feedback cancellation is most beneficial for patients with a severe or profound hearing loss, patients with a severe loss in the high frequencies but near-normal hearing in the low frequencies, any patients fitted with open canal devices, and any patient who wishes to use the telephone without using telecoil input. This combination makes it useful for nearly every client. Frequency lowering is advantageous for some patients though it is not yet possible to predict which patients will benefit. Trainability enables patients to take responsibility for fine-tuning their hearing aids.

Hearing aid fitting software provides a first approximation to the prescribed gain–frequency response target. The software must appropriately allow for the

acoustic configuration of the earmould shell or dome fitting. The approximation can be made even more accurate by incorporating the individual patient's RECD in the prescription. This increased accuracy in the precalculation is probably only worthwhile for hearing aids intended for infants, where measurement of the final real-ear gain is difficult.

Any signal-processing scheme that requires adjustment for each patient must also be supported by an appropriate prescription method. Measurement of real-ear gain is necessary unless the hearing aid has been adjusted in the coupler using the individual's (or at least an age-appropriate) RECD.

Because it is not possible to prescribe OSPL90 with complete precision, the suitability of maximum output should be subjectively evaluated before the patient leaves the clinic. A variety of intense sounds should be presented to the patient to ensure that the hearing aid does not make sounds uncomfortably loud. Maximum output must, however, be great enough for the patient to experience intense sounds as being loud. This can be assessed by presenting speech signals at a high level and asking the patient to report their loudness.

PROBLEM SOLVING AND FINE-TUNING

Many hearing aid fittings need to be fine-tuned, either electronically or physically, after the patient has had a week or two to try the hearing aids. When a patient has trouble managing hearing aids (inserting, removing, using the controls, changing the battery), reinstructing the patient may solve the problem. If not, the hearing aid should be physically modified or, if necessary, a different style chosen. Physical modification will also be necessary when a patient is suffering discomfort from the earmould, shell or case, or when the hearing aid works its way out of the ear.

Feedback oscillation has several potential solutions: reducing gain at selected frequencies; reducing the vent size; making a tighter earmould or shell; or changing the hearing aid to one that has more effective feedback cancelling and management algorithms.

Complaints about the patient's own-voice quality are particularly common. The most common cause is physical blocking of the ear canal, so the best cure is to add a vent, or increase the size of an existing vent, including using an open-fitting. Where feedback oscillation precludes that, the earmould or shell can be remade with the canal stalk extended down to the bony canal, preferably using a soft material. Own-voice problems are sometimes caused, and cured, by electronic variation of the gain–frequency response for high-level sounds.

Complaints about the tonal quality of amplified sounds are fixed by changing the balance of low-, mid- and high-frequency gain. The hard part is knowing when to ask the patient to persevere with a gain–frequency response in the expectation that it will eventually become the preferred response and confer maximum benefit to the patient.

When a patient complains about the clarity or loudness of speech, or the loudness of background noise, he/she must be questioned particularly carefully so that the acoustic characteristics of the sounds causing the problems can be identified. The clinician's first aim is to identify whether it is the gain for low or high frequencies, and the gain for low, mid or high levels, that should be adjusted. Only then can the appropriate hearing aid controls be adjusted.

In those cases where it is not clear which control should be adjusted, or by how much it should be adjusted, a systematic fine-tuning can be performed using one of two general methods. The first of these is paired comparisons, in which the patient is asked to choose between two amplification characteristics presented in quick succession. Multiple characteristics can be compared by arranging them in pairs. Paired comparisons can be used to adaptively fine-tune a hearing aid control if the settings compared in each trial are based on the patient's preference in the preceding trial.

The second general method for fine-tuning relies on the patient making an absolute rating of sound quality. The best amplification characteristic (out of those compared) is simply the characteristic that is given the highest rating by the patient. The absolute rating method can also be used to adaptively alter a chosen hearing aid control. This is achieved by deciding on a target rating (e.g. just right) and adjusting a control in the direction indicated by the patient's rating (e.g. too shrill or too dull).

The paired comparisons and absolute rating methods are best carried out while the patient listens to continuous discourse speech material, or other sounds they are complaining about. Depending on the complaint being investigated, this can be supplemented with recordings of commonly encountered background noises. The paired comparisons method is more sensitive when the differences between the conditions are small. Fine-tuning is usually carried out only for patients dissatisfied with the prescribed response, but it can be used for all patients if desired.

PATIENT EDUCATION AND COUNSELLING FOR HEARING AID WEARERS

People with a hearing impairment benefit from patient education and may benefit from communication training and counselling. These activities may be aimed at giving patients information about their hearing loss, developing skills needed to operate and care for their new hearing aids, improving listening skills, or changing patients' beliefs, feelings and behaviour relating to their hearing and communication. Providing appropriate education and counselling increases the likelihood that hearing aids will be fully used and that residual communication difficulties will be minimized.

It is difficult to help patients understand the variety of hearing aid styles and performance features that may be suitable for them. The benefits and cost implications of

each (including ongoing service costs, warranty and trial periods) have to be presented in a suitably simple manner.

Once they start using their hearing aids, first-time hearing aid users experience a new world of amplified sound and may benefit from guidance about how to gradually increase their range of listening experiences. The aim is to provide them with the best experiences first and to avoid having them become overwhelmed by sound. Patients need to know that their brains may take some time to adapt to hearing parts of speech and other sounds around them that they have not heard for some time.

A major part of educating the new hearing aid user has nothing to do with hearing aids! A wide range of hearing tactics and strategies can help the hearing-impaired person understand more in difficult listening situations. The first group of hearing strategies requires the listener to look carefully at the talker and the surroundings. The second group requires the listener to alter the communication pattern in some way. The final group requires the listener to manipulate the environment to remove or minimize sources of difficulty. Patients will benefit if family members and/or other frequent conversation partners participate in education sessions on these topics.

Patients will more easily appreciate and learn this material if it can be taught in a patient-centred, individual problem-solving method, rather than as a set of rules disconnected from their everyday lives. Communication training comprises training in the use of these hearing strategies, plus practice in listening to speech (synthetic training) or to the basic sounds from which speech is built (analytic training), especially in difficult listening conditions. Increasingly, communication training is being provided in packages that patients can use on their computer or DVD at home. Patients should be advised about protecting their remaining hearing and be made aware of where they can obtain support (from peer groups or other professionals) beyond that which the clinician can provide.

Hearing aids do not provide an adequate solution to all hearing problems, so patients must be made aware of other assistive listening devices that may help them. Clinicians should be aware that different people learn in different ways. Consequently, the same material should be taught in different ways to different patients, and clinicians should develop the flexibility needed to accomplish this.

Clinicians must be flexible regarding how and when they present information and carry out other procedures. It is, nonetheless, useful to have in mind a standard programme from which variations can be made as required.

ASSESSING THE OUTCOMES OF HEARING REHABILITATION

Clients and clinicians both benefit when the outcomes of the rehabilitation process (i.e. changes in the patients' lives) are measured in some way. Systematic measurement of outcomes can help clinicians learn which of their practices, procedures and devices are achieving the intended aims. Some measures can also help determine how the rehabilitation programme for individual patients should be structured and when it should be ended.

Outcome assessment can be based on an objective speech recognition test (the results of which depend hugely on the measurement conditions) or on a subjective self-report and/or the report of a significant other person. Speech test scores show the increase in the ability to understand speech in specific situations, whereas self-report measures more generally reflect the patient's views about the impact of rehabilitation.

Many self-report measures have subscales so that outcomes can be separately assessed for different listening environments. Outcome measures can assess the domains of benefit, defined as a reduction in disability (comprising activity limitation and participation restriction), device usage, listening effort, quality of life or the satisfaction that the patient feels.

Self-report measures that assess benefit can be grouped into various classes. First, patients can be asked to make a direct assessment of the benefit of rehabilitation. Alternatively, patients' views of their disability can be assessed both before and after the rehabilitation programme. The change in score provides a measure of the effects of rehabilitation. Measures obtained both before and after rehabilitation provide a more complete view of disability status and change. These difference measures probably assess change less accurately than those that directly assess benefit because they involve subtracting two scores.

The second way in which self-report measures differ from each other is the extent to which the items are the same for all patients or are determined individually for each patient. Results can more easily be compared across patients if a standard set of items is used for all patients. When the items are individually selected for each patient, however, the questionnaires become shorter and can more easily be incorporated within interviews with the patient. They are also more relevant to each patient.

There are thus four types of self-report measures: standard questionnaires that directly assess benefit (e.g. Hearing Aid Performance Inventory (HAPI); standard questionnaires that compare disability before and after rehabilitation (e.g. Hearing Handicap Inventory for the Elderly (HHIE); Abbreviated Profile of Hearing Aid Benefit (APHAB)); individualized questionnaires that directly assess benefit (e.g. Client Oriented Scale of Improvement (COSI)); and individualized questionnaires that compare disability before and after rehabilitation (e.g. Goal Attainment Scaling (GAS)).

Self-report measures also commonly assess hearing aid usage (which can now also be measured objectively with data logging) and are the only viable way to assess satisfaction. Some measures contain questions that address only one domain (benefit, use or satisfaction) whereas others address more than one domain. One comprehensive questionnaire, the Glasgow Hearing Aid Benefit Profile (GHABP), addresses all three dimensions, contains standard and individualized measures, and assesses benefit both directly and by comparing disability before and after rehabilitation. A very simple and widely used

questionnaire that assesses several domains with a single question each is the International Outcomes Inventory for Hearing Aids (IOI-HA).

Some questionnaires are designed to assess problems experienced with the hearing aid, although freedom from problems with the hearing aid is more properly viewed as a means to an end rather than a life-changing outcome.

While outcomes can be assessed any time after hearing aid fitting, the extent of benefit does not appear to stabilize until about 6 weeks after fitting. Hearing loss is associated with a decrease in many aspects of quality of life (such as increased depression) and use of hearing aids is associated with general improvements in health and quality of life. Causal relationships between these quantities are difficult to establish, however. Generic measures of health outcome are not efficient means by which a clinician can assess the outcomes of rehabilitation.

BINAURAL AND BILATERAL CONSIDERATIONS IN HEARING AID FITTING

Sensing sounds in two ears (binaural hearing) makes it possible for a person to locate the source of sounds and increases speech intelligibility in noisy situations. Wearing two hearing aids (a bilateral fitting) instead of one hearing aid (a unilateral fitting) increases the range of sound levels for which binaural hearing is possible. Bilateral fitting is thus more important when hearing loss is severe than when it is mild or moderate.

Accurate horizontal localization is possible because sounds reaching the two ears differ in level and in arrival time, and hence in phase. These cues are also present, but altered, when people wear hearing aids. Most hearing-impaired people, once they become used to the effect of their hearing aids on these cues, can localize sounds accurately to the left and right in the horizontal plane. Vertical localization and front–back localization, which are based on very high-frequency cues created by the pinna, are extremely adversely affected by hearing loss and are not significantly improved by hearing aids.

When speech and noise arrive from different directions, head diffraction causes the SNR to be greater at one ear than at the other. Further, the auditory system can combine the different mixtures of speech and noise arriving at each ear to effectively remove some of the noise. This ability is known as binaural squelch. Even presenting identical sounds to the two ears provides a small improvement in speech intelligibility over listening with one ear, a phenomenon known as binaural redundancy.

Wearing a second hearing aid will improve speech intelligibility in noise whenever it causes speech to become audible in the previously unaided ear. Achieving audibility of speech in both ears is a prerequisite to attending to the ear with the better SNR, and to benefiting from binaural squelch and binaural redundancy. Bilateral fitting of hearing aids has several other advantages. These include improved sound quality, suppression of tinnitus in both ears and greater convenience if one hearing aid breaks down or when one battery dies. A bilateral fitting may help prevent a problem sometimes associated with unilateral fittings: a unilateral fitting can lead to decreased speech processing ability in the unaided ear if this ear is deprived of auditory stimulation for too long, a phenomenon referred to as late-onset auditory deprivation.

The advantages of bilateral fittings also apply to patients with asymmetrical hearing thresholds. If such patients must receive a unilateral fitting, it may be generally advisable to fit the ear with thresholds closest to about 60 dB HL.

Bilateral fittings also have disadvantages: they cost more, are more susceptible to wind noise and are more difficult for some elderly people to manage. Also, some people regard two hearing aids as an indication of severe hearing loss and do not wish to be perceived in this way. For some people, binaural interference causes speech identification ability to be better when unilaterally aided than when bilaterally aided. The causes of this interference may lie in differences between the two cochleae, differences between the two hemispheres of the cortex or distortions in transfer of information from one hemisphere of the cortex to the other.

Because of the variability associated with speech intelligibility testing, conditions have to be chosen carefully to reliably demonstrate bilateral advantage or detect binaural interference on an individual patient. To best demonstrate bilateral advantage, loudspeaker positions for speech and noise should be chosen to maximize the effects of head diffraction and binaural squelch. To best detect binaural interference, speech and noise should emanate from a single, frontal loudspeaker, so that the effects of head diffraction and binaural squelch are minimized. In either case, speech tests with steep performance–intensity functions should be used. A method for predicting whether individual patients will benefit more from a unilateral or bilateral fitting is urgently needed.

SPECIAL HEARING AID ISSUES FOR CHILDREN

When a child is born with a hearing loss, early provision of hearing aids is essential if he or she is to learn to speak and listen with the greatest possible proficiency. Hearing aids should be provided by 6 months of age. If cochlear implants are a better option, these should be implanted by 12 months of age. Children with bilateral loss should receive bilateral hearing aids. There is some uncertainty over optimal treatment for children with unilateral loss, mild loss or auditory neuropathy.

For the hearing aids to be optimally adjusted, frequency-specific hearing thresholds must be determined separately for each ear. No matter what type of transducer is used, the small size of a baby's ear complicates the interpretation of hearing threshold. This difficulty is overcome either by expressing threshold in decibels sound pressure level (dB SPL) in the ear canal, or by expressing it as equivalent adult hearing threshold in decibels hearing level (dB HL).

BTE hearing aids are most likely to be provided, in conjunction with soft earmoulds, until the child is at least 8 years old (and possibly much older). The hearing aid should contain features that will enable the child to receive the best possible signal. This is likely to include an audio input socket and/or telecoil and/or internal wireless receiver, so that there is some means to receive wireless transmission. Ideally, the wireless device should be able to automatically attenuate the local microphone whenever the person wearing the transmitter talks.

To communicate effectively, normal-hearing children learning language need a better SNR than do adults. They also understand speech less well than adults at very low sensation levels. These observations may lie behind the empirical finding that hearing-impaired children prefer more gain than adults with the same hearing loss. Compared to adults, they almost certainly do not need any more real-ear gain for high-level sounds, they probably prefer more gain for medium level sounds, and they almost certainly need more gain for low-level sounds.

There is an even greater need for wide dynamic range compression in hearing aids for children too young to manipulate the volume control than there is for adults. Similarly, infants have an even greater need than adults for directional microphones and adaptive noise-reduction systems. These algorithms also have potential disadvantages but they should be provided if the clinician has confidence in the automated manner in which the hearing aid selects them.

To achieve a certain real-ear gain, young children need less coupler gain than do adults, because children have smaller ear canals. An efficient way to allow for small ear canals is to measure RECD before prescribing the hearing aid, and to calculate the coupler gain that will result in the target REAG. A faster but less accurate way is to use age-appropriate values of RECD.

The maximum output that has been prescribed should be evaluated by observing the child when intense sounds are made and, for those over approximately 6 years of age, by assessing the loudness of these sounds.

Hearing aid fittings can be evaluated by speech testing (for those over 3 years of age), paired-comparison preference testing (for those over 6 years of age), and subjective reporting by the child, the parents or the teachers, whether informally or using systematic methods such as Parents' Evaluation of Aural/Oral Performance of Children (PEACH) and Meaningful Auditory Integration Scale (MAIS). The audibility of speech can be estimated by calculating the articulation index (also known as the speech intelligibility index (SII)) or assessed by measuring the presence, latency and perhaps morphology of the cortical responses elicited by speech sounds. The availability of speech to the child can be indirectly assessed by measuring the child's language development.

Effective amplification for young children is not possible without the support and understanding of parents. The audiologist must therefore inform and support the parents in a variety of ways. One way to provide ongoing habilitation is to base the service activities around goals determined jointly by the audiologist and the parents (and by the child when old enough). Information provided to parents includes safety aspects of amplification and hearing loss. Hazards include battery, earmould or hearing aid ingestion, excessive exposure to noise, physical impact and failure to detect warning signals if amplification is not functioning correctly.

CROS, BONE-CONDUCTION AND IMPLANTED HEARING AIDS

In the CROS (contralateral routing of signals) family of hearing aids, hearing aid components on opposite sides of the head are wirelessly linked. Basic CROS aids are most suitable for people with unilateral loss. CROS aids consists of a microphone on the side of the head with a deaf ear, combined with an amplifier, receiver and open earmould or shell on the side with a normal-hearing ear. Adding a microphone to the side of the better ear converts it to a BICROS hearing aid, which is suitable for patients with loss in both ears. A transcranial CROS has all the components in one ear, but sends a signal across the head by bone conduction. CROS hearing aids must be carefully fitted to ensure the aid wearer receives, in a single cochlea, an appropriate balance of sounds reaching the two sides of the head.

Bone-conduction hearing aids output a mechanical vibration instead of an airborne sound wave. They are most suited to people who, for medical or anatomical reasons, cannot wear a hearing aid that occludes the ear in any way, or for those who have a large conductive loss in either ear. For patients with normal external and middle ears, bone-conduction hearing aids cannot stimulate the cochlea as effectively as do air-conduction hearing aids because of the relative inefficiency of the bone conduction pathway. For patients with maximal conductive hearing losses, whether or not there is also a sensorineural loss, bone-conduction hearing aids can stimulate the cochlea as strongly as air-conduction hearing aids. Prescriptions for air-conduction hearing aids can be converted into bone-conduction prescriptions by using available standards for the thresholds of hearing for air- and bone-conducted sound. Bone-conduction output is specified in terms of output force level instead of OSPL and in terms of acoustomechanical sensitivity instead of gain.

Disadvantages of non-implanted bone-conduction hearing aids include their wearing comfort and the limited sensation level they can provide. A commonly used form of bone-conduction hearing aid is the bone-anchored hearing aid, in which the vibrations are transmitted to the skull via an embedded titanium screw, thereby increasing stimulation of the cochlea by about 15 dB compared to a bone conductor applied to the skin. Bone-anchored hearing aids have been used successfully for patients with unilateral or bilateral conductive or mixed loss. They are also routinely being fitted to people with unilateral sensorineural loss, referred

to as single-sided sensorineural deafness. The output levels they can achieve make them suitable for people with cochlear loss up to about 45 dB HL for head-worn devices and up to about 60 dB HL for body-worn devices. Bone-anchored hearing aids can provide greater cochlear stimulation than air conduction hearing aids for patients with air-bone gaps greater than about 30 dB.

A variety of other middle-ear implants have been researched, and several have been approved for routine use. Middle-ear implants may have only the output transducers surgically implanted or may be combined with implanted microphones and batteries to form completely implanted hearing aids. Four types of output transducers have been used: magnets enclosed by a coil that rely on the inertial mass of the magnet, magnets mounted on the middle ear chain driven by a remote coil, and piezoelectric or electromagnetic stimulators anchored to the mastoid bone and vibrating the middle ear chain. Three types of microphones have been used: external microphones, microphones implanted under the skin on the scalp or in the ear canal, and transducers that are driven by the vibration of the middle ear chain.

Several implanted hearing aids are now commercially available. For some clients, particularly those with mixed hearing loss, middle ear implants may have advantages related to freedom from occlusion, amplification gain and bandwidth, stimulation level and invisibility of the device. Fully implanted devices have additional advantages arising from there being no external parts. Candidacy criteria are still developing.

FUTURE RESEARCH

- Research is needed to better understand the barriers preventing many people with hearing loss from seeking rehabilitation through acquiring and wearing hearing aids. Equally important, psychological research is needed to find effective ways to overcome those barriers and so reduce the time that hearing loss adversely affects quality of life. Related to this, knowledge is needed on the minimal degree of hearing loss at which hearing aids become effective, and how this minimal aidable loss is also determined by the cognitive, psychological, psychoacoustic and lifestyle characteristics of each patient.
- At the other end of the hearing loss spectrum, prediction tools that take account of individual characteristics are needed to indicate which patients are likely to function better were they to receive one or more cochlear implants, rather than continue to wear hearing aids. Fully implantable hearing aids require a method of implanting microphones that enables them to achieve the same sensitivity and low internal noise levels that hearing aids mounted outside the head currently achieve.

KEY POINTS

- Hearing aids have become sophisticated devices, the amplification characteristics of which are adjustable to optimize listening over a wide range of hearing loss configurations and degrees.
- Digital signal processing has largely solved the previous major problem of feedback oscillation (whistling) even when the hearing aid is fitted to the ear with an acoustically open connection. Such open fittings leave the patient's own voice sounding more natural.
- Although nothing can reverse the reduced precision of signal analysis that inevitably accompanies sensorineural loss, hearing aids can restore audibility, and in many listening situations can improve the signal-to-noise ratio of the signal delivered to the ear, so that good speech understanding occurs despite the reduced analysis ability of the damaged auditory system.
- Wireless technology is increasingly being built into hearing aids, and in situations where a remote microphone can be positioned near the talker or source, speech understanding in noise can be superior to that enjoyed by someone with normal hearing.
- Compared to the number of people with significant hearing loss, hearing aids are an under-utilized solution. This applies even in developed countries, but much more so in the developing world.

ACKNOWLEDGEMENT

The material in this chapter is a slightly edited version of synopses of each of the chapters in the chapter author's book *Hearing aids*.[1] The reader is referred to that book, which is comprehensively referenced and elaborates on all the information covered in this chapter.

CHAPTER

55

BEYOND HEARING AIDS: AN OVERVIEW OF ADULT AUDIOLOGICAL REHABILITATION

Lucy Handscomb

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: aural rehabilitation, hearing therapy, hearing assistance technology and language service professionals.

INTRODUCTION

Hearing aids are often seen as the mainstay of adult audiological rehabilitation, and their benefits are undeniable. However, they are far from being a panacea. While some patients attend hearing services seeking hearing aids and are satisfied with the help they provide, others have needs which cannot be met by amplification alone. This chapter gives an overview of approaches to aural rehabilitation other than hearing aid fitting and provides guidelines about when they may be needed.

NON-TECHNOLOGICAL REHABILITATION

Hearing therapy

Hearing therapists provide one-to-one support to people with hearing loss and related problems (particularly tinnitus). The term aural rehabilitation specialist may also be used, and in some countries this kind of service is provided by clinical psychologists. Hearing therapy involves counselling and supporting patients as they adjust to living with hearing loss. For many people, the experience of losing hearing goes far beyond the frustration of mishearing speech, although this in itself is a significant problem. Hearing loss can necessitate changes in lifestyle, both at work and at leisure. It can change the way one interacts with others, making conversation effortful and tiring, and profoundly alter one's sense of identity.[1] An in-depth interview study found that people felt their hearing loss held them back in life, made them feel 'left out' and caused considerable emotional distress.[2] Personal relationships are also negatively affected, with couples in particular feeling that hearing loss places a strain on their interactions.[3, 4] People who are having difficulty adjusting to life with hearing loss may well benefit from an opportunity to discuss their feelings and explore ways of coping, whether or not they are also fitted with hearing aids (or cochlear implants). A group in particular need of urgent referral to rehabilitation services are those who develop sudden hearing loss, who often report feelings of utter bewilderment and confusion. In a medical emergency, it is easy for emotional needs to be neglected, but timely emotional support is just as important as prompt medical treatment.

Specialist rehabilitative support can also be beneficial to people who feel ambivalent about using hearing aids. There are many reasons why people feel unsure about using amplification including perceived stigma and lack of confidence.[5, 6] An opportunity to spend time discussing one's ambivalence in a supportive environment is likely to be more cost-effective than fitting hearing aids that are likely to remain unused.

A hearing therapy appointment is likely to consist of counselling and joint goal-setting, using a collaborative approach between patient and therapist. Hearing assistance technology may also be demonstrated (see 'Types

of technology' below). Most patients are seen for several appointments over a period of weeks or months as they develop and practise new coping strategies.

Access to specialist aural rehabilitation services is usually via ENT and may require a referral form or letter.

Aural rehab groups and lip reading classes

Some audiology clinics offer rehabilitation through an aural rehab group. As well as being cost-effective for clinics, groups have the advantage of bringing people with hearing loss together to share experiences and ideas and to support each other. Many encourage the participation of partners too. There are many different group formats, but typically participants meet weekly for five or six sessions of around 2 hours each. Groups usually follow a problem-solving format, with a facilitator encouraging participants to generate ideas themselves about how to manage difficult communication situations and then to role-play them with each other. A review of research into aural rehab groups found fairly consistent evidence that they are effective in reducing the amount of restriction people feel in relation to their hearing loss (as measured on self-report scales) and in improving use of communication strategies.[7] The author also points out that participants' comments after attending a group are overwhelmingly positive; people enjoy group sessions and perceive them to be very worthwhile.

Outside the healthcare system a number of groups and classes exist for people with hearing loss. Perhaps the most popular are lip-reading classes, often held in community centres and adult education colleges. These are usually run by trained lip-reading teachers and involve a mixture of lip-reading exercises and communication tips. Although effects of class attendance on lip-reading ability are equivocal, qualitative research indicates that people value their classes very highly.[8] Hard-of-hearing groups or clubs are also available in some areas which offer peer support and an opportunity to take part in social activities without being restricted by hearing problems.

The UK charity Hearing Link offers week-long residential rehabilitation courses for adults with acquired profound hearing loss and their families. Such courses are hugely beneficial to families struggling to adjust to the far-reaching changes that profound deafness brings. Referral from a medical professional – such as an ENT doctor – is normally required in order to secure funding to attend a course.

Auditory training

Auditory training attempts to improve speech discrimination in people with hearing loss by presenting a variety of listening tasks involving phonemes, words and sentences. Exercises such as listening in background noise or attending to sound in one ear and not the other might be included. Traditionally, auditory training was conducted one-to-one in clinics, but now a number of computer-based auditory training programs are available, enabling users to practise regularly at home with minimal intervention from clinicians. A systematic review of 13 computerized auditory training studies found firm evidence that performance on auditory training tasks improves significantly with practice.[9] Some (but not all) studies also showed generalization of learning to untrained tasks, which of course has more real-world benefit. The authors of the review conclude that better-quality evidence is needed, but computerized auditory training is already an increasingly popular option for motivated individuals who are willing to put in the practice time required.

The voluntary sector

A great deal of support for people with hearing loss and related problems (such as tinnitus and balance disorders) is provided by charities and voluntary organizations. Charities are very often an invaluable source of information; many produce fact sheets about a range of hearing-related topics and some have telephone and email helplines available. Regular magazines for members can help people with hearing loss feel better informed and connected to others with similar problems. There are also several forums available via the internet and social media through which people can share information and offer support. These are perhaps particularly helpful to younger people with hearing loss, who may otherwise feel rather isolated.

TECHNOLOGY OTHER THAN HEARING AIDS AND COCHLEAR IMPLANTS

The need for additional technology

While both hearing aids and cochlear implants are capable of providing great benefit, there are situations in which many users find them inadequate. In spite of recent advances in digital signal processing, interference from background noise is still a primary cause of dissatisfaction among hearing aid users and, in some cases, a reason for giving up with hearing aids altogether.[10, 11] Distance can also cause difficulties; many hearing aid users complain that, while they hear well in their own living room, they struggle to understand a speaker in a large church or hall. The two problems of intrusive background noise and distance are combined when, for example, fellow students cough and shuffle in a lecture theatre. Telephone use can also be problematic, particularly as many people experience interference when a mobile phone is placed close to their hearing aid. People with more severe hearing loss may find television unclear, even when using hearing aids, and disputes over TV volume have been found to be among the most frequent sources of irritation when one half of a couple has hearing loss.[12] Moreover, there are situations in which most people take their hearing aids or speech processors off (particularly while bathing or in bed) but still need to be aware of signals such as smoke alarms or alarm clocks. Additional technology goes some

way towards solving all of these difficulties but, as will be discussed, its use is not widespread.

Types of technology

Additional technology can broadly be divided into two categories: assistive listening devices (ALDs), which are designed to improve audibility, and alerting devices, which use visual or tactile signals as a substitute for sound. Collectively they are sometimes known as hearing assistance technology (HAT).

Connectivity

There are three ways in which hearing aids or speech processors can be linked with audio equipment and ALDs.

- **Telecoil:** A telecoil is a small receiver fitted as standard in most behind-the-ear (BTE) and many in-the-ear (ITE) hearing aids. When active, it picks up signals from an electromagnetic field created by an induction loop, which itself can be linked to a range of amplifiers and audio devices. The telecoil can be switched on and off by the hearing aid user, but it first needs to be activated by the person fitting the hearing aid. Switching the telecoil on normally disables the hearing aid microphone, thus reducing background noise substantially. A neckloop can be plugged directly into a standard headphone socket, essentially allowing hearing aids to function as headphones.
- **Direct audio input:** Some BTE hearing aids can have a small electric cable plugged into them either directly or via an adapter which clips onto the bottom of the hearing aid; this is sometimes known as a 'shoe' or 'boot.' The other end of the cable can be plugged into a standard headphone socket, enabling the user to receive the sound directly into the hearing aid without interference from surrounding noise.
- **Bluetooth:** In recent years a number of Bluetooth-compatible hearing aids have become available. Most of these require an intermediary device called a streamer (worn round the neck) to enable the hearing aid to pick up signals from paired Bluetooth-enabled devices such as smart phones and tablets. At the time of writing, some hearing aids which use Bluetooth technology without the need for a streamer are also available.

All of the options above enable users to connect their hearing aids directly to a range of standard audio devices and also to specialized ALDs.

Personal listening equipment

A number of devices exist which are designed to improve sound quality, increase amplification and reduce interference from background noise when listening to live speech, television, radio or music. All of the devices described below allow people direct control of the volume of sound going through their hearing aids, meaning that companions without hearing aids can listen alongside them comfortably.

FM SYSTEMS

These consist of a receiver connected to the user's hearing aids by means of direct audio input or a neckloop, and a transmitter (with an in-built microphone) which can be placed close to any sound source or clipped onto a speaker's clothing. The transmitter converts sound into a radio signal which is then picked up by the receiver. When linked to the FM system, hearing aids will only pick up signals from the receiver and not extraneous noise. FM systems are particularly valuable in classrooms and lecture theatres, where the speaker tends to be at a distance from the listener and may be moving about, and they are often used by hearing-impaired children in school. The sound quality is excellent.

LOOP SYSTEMS

A less expensive option than an FM system for those purchasing equipment privately is a portable loop system. At their most basic, these consist of a neckloop, an amplifier 'box' with volume control and a hardwired microphone which can be placed close to any sound source. Wireless microphones are also available. Portable loops tend to perform less well at a distance than FM systems but are useful in domestic environments and when travelling. Listening to a driver or travelling companion in a car or bus via the amplifier and neckloop cuts out interference from engine and road noise.

A convenient option for TV listening is a room loop. An amplifier is connected to the television (usually by means of a SCART lead) and a loop wire emerging from it is fixed to the skirting board around the room. Once installed, the user only needs to switch the amplifier on and activate the telecoil in the hearing aids in order to be able to listen through the loop from anywhere in the room.

INFRARED SYSTEMS

Sound can be converted to an infrared signal which is then transmitted wirelessly to a receiver worn by the hearing aid user with a neckloop attached. This is another neat and convenient option for TV watching, but it has the disadvantage that the signal can easily be interrupted if the user moves around.

STREAMERS

As well as giving access to Bluetooth, streamers can be used with compatible hearing aids as portable amplifiers with wireless microphones or plugged into personal music players. An additional adapter is needed in order for a streamer to be used as a TV listener.

Using personal listening equipment without hearing aids

Many personal amplifiers and FM systems can be used with headphones as an alternative to neckloops or direct

audio input. These make them accessible to non-hearing aid users and to people who need or prefer to be without their hearing aids temporarily, perhaps due to an ear infection.

An inexpensive personal amplifier with headphones can be particularly helpful as a communication device in hospital. Many hearing-impaired patients on a ward will not have their hearing aids in, either because they were left behind during an emergency admission or because they are uncomfortable to wear in bed. This sometimes results in confidential and sensitive information being spoken at high volume by hospital staff and being clearly audible to all those around. Speaking to the patient via a simple amplifier with headphones slipped over the ears can make all the difference to confidentiality and dignity.

ALDs in public places

Commercial loop systems have been installed in many public buildings such as theatres, cinemas, meeting halls and places of worship. Loops can also be found at reception desks, ticket counters, banks, post offices and in taxis. Where a public loop system has been installed, the user only needs to switch their hearing aid to telecoil to be able to benefit from clearer sound. The presence of a loop system is normally indicated by an ear symbol with the letter T (for telecoil).

Some theatres use infrared listeners instead of a loop system and will loan receivers to hearing-impaired customers at the box office.

Telephones

LANDLINES

Many conventional telephones available from mainstream suppliers have a small inductive coupler fitted into the receiver, which enables the hearing aid user to listen via the telecoil and thereby reduce ambient noise. If this does not provide adequate volume, a range of portable amplifiers is available, which either strap onto the receiver or can be connected to a corded phone between the handset and the base.

A wide range of telephones, both corded and cordless, is available with amplifiers built in, some of which are very powerful. Many have tone control as well, which can improve clarity. A selection of additional features are also available, such as large buttons for people with visual impairment, extra receivers to allow another person to assist with the conversation and adapted handsets which can be held against the mastoid bone to allow hearing via bone conduction.

Adapters can be bought to enable landlines to be heard via a streamer.

MOBILE PHONES

For many years the majority of hearing aid users found it impossible to use a mobile phone with a hearing aid, due to an unacceptably high level of interference. While interference continues to be an issue, more recently manufacturers have taken the needs of their hearing-impaired customers into account and a universal rating scheme has been introduced (although its use is not compulsory). Mobile phones can be given a rating of 1 (poor) to 4 (excellent) depending on how well they perform with hearing aids set to microphone (M) or telecoil (T). The very best mobile phone for hearing aid users would be rated M4/T4.

Even better clarity can still be obtained by the use of a mobile phone-compatible neckloop or a Bluetooth streamer (discussed above). These enable the phone to be held right away from the hearing aid and have the added advantage of making the ringtone audible in the hearing aid itself.

Some older people may be put off by additional gadgetry but want to use a mobile phone for security. A range of basic mobile phones is available with amplified speech and large buttons but with a minimum of extra features.

TEXTPHONES

People with severe or profound hearing loss can communicate using a textphone – sometimes known as a Minicom – which can send and receive typed messages over a phone line. Two people with textphones can communicate directly with each other or a textphone user can communicate with a conventional phone user via an operator. This system predates the internet and has been a lifeline to many, but its use is now in decline owing to the multiple methods of mainstream text communication available via computers and smart phones.

Alerting devices

STAND-ALONE EQUIPMENT

There are many quite simple and inexpensive devices which can be used to alert people with hearing loss to telephone ringers, door bells, alarm clocks, smoke alarms and baby monitors. Most use a loud sound accompanied by a flashing light. Some devices can be supplied with a vibrating pad which can be placed under the pillow to wake the user at night.

PAGERS

A practical option for many people is a pager, which can be linked to several devices at once. Normally, a small unit clipped onto clothing or worn on the wrist will vibrate when any device it is linked to makes a sound, and a small light indicates which device has been activated. Larger vibrating units can be supplied for night-time.

WIRED-INSYSTEMS

It is possible for an electrician to connect doorbells and telephones to the house lights so that they flash on and off in response to sound. However, this is a less popular option now that pagers are widespread.

HEARING DOGS

People with severe or profound hearing loss can apply to have a hearing dog. Such dogs are specially trained to alert their owners and lead them to the source of the sound when the doorbell, phone or other device is activated. They are also taught a 'danger' signal in response to a smoke alarm. Like other assistance dogs, hearing dogs wear a special coat and can accompany their owners in public places. Many deaf people feel more confident with a hearing dog by their side.

Research into HAT use and benefit

There is a paucity of research into the use of HAT and its benefits. However, when ALD users have been asked about their impressions, responses have been largely positive. An internet survey of 356 ALD users reported that the majority rated their ability to understand speech as 'better' or 'much better' when using a personal listening device as compared to when using their hearing aids or cochlear implants alone.[13] Ratings were particularly high for listening through an ALD when part of an audience. A qualitative interview study conducted by the charity Action on Hearing Loss also cites several very positive comments about the clarity of listening via a loop system.[14] FM systems have been subject to more rigorous investigation than other technology and a consistent finding is that their performance is superior to hearing aids alone when listening to speech in noise.[15–17] A smaller-scale study also showed use of a more basic listening device with headphones to result in fewer communication breakdowns in informal discussion.[18]

Despite these benefits, it appears that the use of any type HAT is not very widespread. A large survey of almost 3000 Australian adults aged 49 and over found that 11% owned hearing aids but only a quarter of these had used any kind of ALD over the past year.[19] The most commonly used type of ALD was a telephone amplifier, while only a tiny proportion had used a personal listening device. A survey of around 500 adults over 65 in the US found that only 5% of those with hearing loss used any kind of ALD, as compared to 26% who used hearing aids (notably, of those who did use ALD, all but two reported high levels of satisfaction).[20] In the UK, the aforementioned study conducted by Action on Hearing Loss found that only a few interviewees had ever used HAT of any kind. This study gives lack of awareness as a principle reason for non-use of HAT; most people simply did not know that technology other than hearing aids was available. A similar theme emerged from an earlier qualitative study in Canada.[21] Other potential barriers to HAT use which were identified by this study were concerns over adapting to new technology and lack of confidence. Previous research has found that ALDs may be rejected because of the extra effort required to set them up.[15] For personal listening systems particularly, a further possible barrier is that people may feel awkward about asking others to speak through a microphone on their behalf.

Chisolm et al. noted that, in previous trials of FM systems, most participants have not continued to use their devices afterwards despite clear benefits to hearing.[17] These authors tried a different approach, offering intensive support with FM systems over five visits which included discussion and role-play of difficult listening situations in addition to instructions for use. They found that 30 out of 36 of their participants were continuing to use their FM system a year later. Further research in this area is needed, but it seems that successful use of ALDs could potentially be increased by seeing them as an integral part of aural rehabilitation rather than an 'add-on'.

LANGUAGE SERVICE PROFESSIONALS

In certain situations where communication is difficult, a person with severe or profound hearing loss may find that even additional equipment is inadequate. In such cases, communication support is available from specially trained people known as a language service professional (LSP). LSPs are most often used to enable participation in meetings, conferences and training courses. They can also provide support in court rooms and at medical appointments. Different types of LSP are listed below.

- **Sign language interpreter:** Interpreters translate what is being said into sign language in real time and also 'voice over' what a deaf person is signing. Interpreting usually happens live but is sometimes provided by video link. Hands-on interpreters are available to deaf–blind people and 'relay' interpreting is possible for deaf people who use sign language from another country.
- **Lip speaker:** Lip speakers repeat exactly what a speaker is saying but without voice. They use clear lip patterns and always face the front to enable people to lip-read.
- **Speech-to-text:** A speech-to-text operator either types an instant summary of what is being said or converts speech to text verbatim using a special keyboard, with text appearing on a screen. Increasingly, this service is being provided over the internet, making it more widely available.
- **Notetaker:** A notetaker's role is to support a deaf student by taking lecture notes on their behalf, thus enabling them to look up and lip-read the lecturer.

OBTAINING HAT AND ACCESSING LSP

Unlike hearing aids, HAT is not provided by the UK National Health Service. Devices can often be purchased from private hearing aid dispensers or directly from the companies which supply them by mail order or online. However, some equipment and services are available free of charge to the user.

Domestic equipment

In the UK, equipment for home use by both adults and children can usually be supplied by the local social services. A referral can be made by the audiology department or an individual can refer themselves (or their child). Normally, an assessment of needs will be arranged before equipment is supplied. The range of equipment provided by social services is generally quite limited, but a major advantage is that help with set-up is available and faulty devices can be replaced.

The UK fire service offers domestic fire safety assessments on request. It is able to provide smoke alarms with flashing lights and vibrating pads free of charge to individuals with hearing loss.

Equipment for work

It is an employer's responsibility to supply additional equipment or support necessary for an employee with hearing loss to perform his role. This might be an amplified telephone, a loop system for meetings or a speech-to-text operator for a training course. In the UK, help with funding can be applied for through the government's Access to Work scheme.

Equipment for education

In the UK, FM systems for school children with hearing loss are provided by the Local Education Authority. In higher and further education, students with hearing loss can apply for a Disabled Students Allowance. A certain amount of money is allocated per year, depending on the level of disability, and the student is able to spend this on either equipment, communication support or a combination of both.

CONCLUSION

The consequences of hearing loss are far-reaching. Many people with hearing loss could benefit from a range of rehabilitation services, either as an alternative or as a supplement to hearing aids or cochlear implants. While it is not the responsibility of ENT doctors to provide such services, it is important to be aware of what is available in the local area and to be able to make appropriate referrals and recommendations.

KEY POINTS

- Hearing therapists provide one-to-one support to people with hearing loss and related problems (particularly tinnitus).
- In a medical emergency, it is easy for emotional needs to be neglected, but timely emotional support is just as important as prompt medical treatment.
- Auditory training attempts to improve speech discrimination in people with hearing loss by presenting a variety of listening tasks involving phonemes, words and sentences.
- A telecoil is a small receiver fitted as standard in most BTE and many ITE hearing aids. When active, it picks up signals from an electromagnetic field created by an induction loop, which itself can be linked to a range of amplifiers and audio devices.
- In recent years a number of Bluetooth-compatible hearing aids have become available.
- FM systems are particularly valuable in classrooms and lecture theatres, where the speaker tends to be at a distance from the listener and may be moving about, and they are often used by hearing-impaired children at school.
- There are many quite simple and inexpensive devices which can be used to alert people with hearing loss to telephone ringers, door bells, alarm clocks, smoke alarms and baby monitors.

CHAPTER 56

AGE-RELATED SENSORINEURAL HEARING IMPAIRMENT

Linnea Cheung, David M. Baguley and Andrew McCombe

SEARCH STRATEGY

Data in this chapter may be updated by Medline searches using the keywords: age-related hearing loss, presbyacusis and presbycusis. The search strategy included the keywords diagnosis and management for sourcing the relevant subsections. Some references have been hand-sourced from the authors' personal collections on this subject.

DEFINITION, BACKGROUND AND PATHOPHYSIOLOGY

DEFINITION

Age-related hearing loss may be defined as a progressive bilateral sensorineural hearing loss of mid to late adult onset, where underlying causes have been excluded. Strictly speaking, age-related hearing loss is a diagnosis which excludes hearing loss caused by primary factors including loud noise exposure, intrinsic otological disease (e.g. otosclerosis, chronic otitis media and Ménière's disease), head injury, ototoxic drug therapies and underlying medical conditions (e.g. atherosclerosis, diabetes, hypertension, Paget's disease of bone, myxoedema). 'Age-related hearing loss' is used interchangeably with 'age-associated hearing loss' and these are now terms in widespread use, replacing 'presbyacusis' (presbycusis in US spelling). Presbyacusis was originally derived from 'presbyacusia', used to describe a loss of high-frequency hearing acuity in the elderly observed when tested with tuned whistles designed by Sir Francis Galton for testing hearing.[1, 2] Age-related hearing loss is associated, in the majority of cases, with an audiogram that reveals greatest hearing loss at higher frequencies. Indeed, the definition of age-related hearing loss is also somewhat arbitrary; there is no agreed age above which an individual suffers from age-related hearing loss and below which one does not.

BACKGROUND

It would appear that auditory acuity is at its best in the late teenage years and into one's early twenties.[3] From then on there is a progressive decline,[4] which is greater for men[5] and for manual workers.[6]

It has generally been believed that at the extremes of life, there is relatively little progression of hearing loss, with most deterioration taking place in between. However, as the number of people surviving to extreme old age increases, there are emergent indications that the rate of progression of hearing loss in the 10th decade increases.[7]

Whilst the rate of deterioration tends to increase with age, the timing of onset is variable, with the greatest variability in the middle years (40–60 years). It appears that once a certain amount of hearing loss has occurred (approximately 75–80 dB HL), further progression is very slow,[8] particularly in the higher frequencies.[9] The variability of onset in the middle years can be explained by the concept of accelerated ageing.[10] In all likelihood this represents some form of hereditary/genetic degenerative process[11, 12] or some alternative process causing a sensorineural hearing loss. Table 56.1 summarizes the causes of sensorineural hearing loss.

TABLE 56.1 Causes of sensorineural hearing loss, shown in order of prevalence and with approximate values where available

Cause	Prevalence (%)
Age	Ultimately 100?
Noise	<5
Idiopathic	5–30
Ear infections	
Ménière's disease	
Head injury	> 0.004
Ototoxicity	
Non-syndromic genetic	0.7 (probably greater)
Syndromic genetic	0.3
Systemic illness (e.g. meningitis, renal failure, diabetes)	
Others (e.g. autoimmune, otosclerosis, acoustic neuroma)	

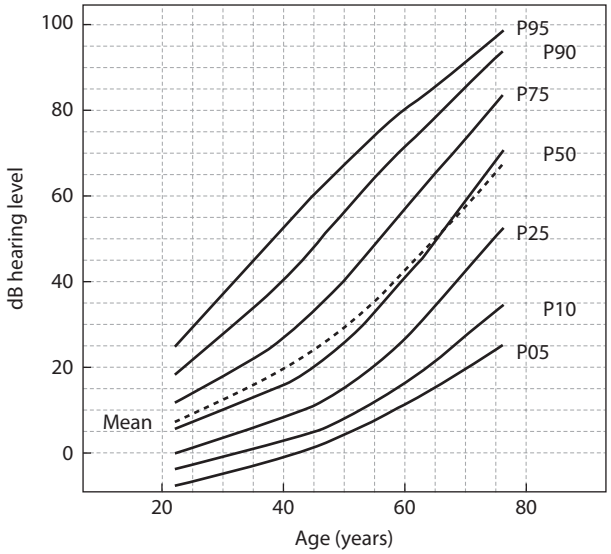

Figure 56.1 Hearing threshold and population percentiles for better ear at 8 kHz. Redrawn from Davis[14] with permission from Whurr Publishers, London.

TABLE 56.2 Prevalence of hearing impairment with age

Age group (years)	Prevalence (%)
18–30	2
31–40	5
41–50	10
51–60	17
61–71	30
71–80	53

Average threshold >30 dB HL; all causes; both ear average. Reproduced with permission from Davis A. *Hearing in adults.* London: Whurr Publishers; 1995.[14]

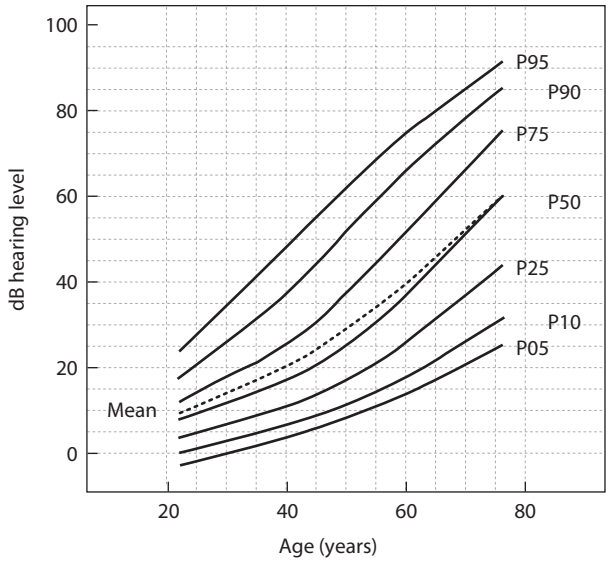

Figure 56.2 Hearing threshold and population percentiles for 4, 6 and 8 kHz average (better ear). Redrawn from Davis[13] with permission from Whurr Publishers, London.

It is probable that all these processes affect the cochlea in remarkably similar fashion but with a unique temporal course both in terms of onset and progression.[13] Almost invariably, databases displaying age-related, average hearing thresholds for either screened or unscreened populations show a marked increase in the rate of progression of the hearing loss once into the sixth decade. This is demonstrated in Table 56.2 and Figures 56.1 and 56.2.

It is, therefore, reasonable (although somewhat arbitrary) to attribute high-tone hearing loss in an individual over the age of 50 to age-related changes (in the absence of any alternative explanation). Under the age of 50 an alternative diagnosis should be considered. In the absence of any other clear diagnosis (e.g. noise, family history, ototoxic medication, systemic illness), it is reasonable to describe the loss as 'a non-syndromic, genetic, degenerative hearing loss'. With genetic mapping continuing apace, mutations and/or genetic explanations are becoming increasingly documented.[12, 13]

In addition, the problems and consequences of age-related hearing loss are compounded in the elderly as a result of additional degenerative processes in the central nervous system. This can result in a relative loss in neuronal plasticity, a loss of cognitive abilities and other sensory modalities, in particular, sight. The diagnosis of age-related hearing loss is, therefore, made on clinical grounds on the basis of a recognizable constellation of features.

Relatively recent research[15–17] tells us that age-related hearing loss impacts on psychological well-being as well as physical ability. Decreasing hearing acuity correlates with an increased incidence of falls,[18] depression[19] and dementia[20] in the elderly.[21] The feelings of imprisonment and anxiety that result from social isolation lead to reduced higher cognitive functioning which can in turn increase the economic and societal burden of age-related hearing loss.[22] It is therefore ever more important as the life expectancy of our population increases to make the diagnosis and offer treatment early.

PATHOPHYSIOLOGY

External and middle ear

Involvement of the middle ear in age-related hearing loss was suggested by Toynbee.[23] Several age-related changes occur in both the outer and middle ear (Table 56.3),[24] however these do not significantly contribute to resultant hearing loss.[25]

Inner ear

Schuknecht et al. hypothetically divided the age-related changes in the cochlea associated with hearing loss into six distinct types based on their histopathological studies.[26–28] Although this classification is deduced from a relatively small sample (n = 21), other authors[24, 29–31] have correlated clinical results with pathological findings leading to the consensus that this represents useful distinctions in the pathological substrate of age-related hearing loss.

Table 56.4 summarizes the different types and their pathological defining features known to date. The neural type of histopathology was believed to be the most common,[24] though a longitudinal study[31] has indicated that metabolic, and mixed sensory-metabolic phenotypes increase with increasing age.

TABLE 56.3 Summary of age-related changes in the outer and middle ear

Outer ear	Middle ear
Increased cerumen production	Stiffening, thinning, loss of vascularity of tympanic membrane
Reduced epithelial migration	Arthritic changes and ossification in ossicles and ossicular joints
Increased hair growth	Degeneration of middle ear muscles
Potential collapse of ear canal	Calcification of cartilaginous support of Eustachian tube
Enlargement of pinna	

TABLE 56.4 Histological subtypes of age-related hearing loss and the known defining features to date

Type	Defining features
Sensory	Loss of hair cells and sustentacular cells[32] at the basal end of the organ of Corti (Figures 56.3 and 56.4)
Neural	Degeneration of cochlear nerve neurons Cochlear ganglion cell loss
Vascular or metabolic	Atrophy of the cochlear stria vascularis Loss of strial tissue in the cochlea[33] primarily in the apical and middle turns of the cochlea[24]
Mechanical or cochlear conductive	Stiffened cochlear basilar membrane An increase in the number of fibrillar layers of the basilar membrane[6]
Intermediate	Submicroscopic changes of the cochlear duct[28] Possible changes in intracellular organelles involved in cell metabolism, decrease in synapse numbers and changes in endolymph composition[24, 25]
Mixed	A combination of the other five subtypes

The various histological types have been correlated with audiogram patterns in post-mortem studies:[26] sensory and neural histopathological types are associated with the common high-frequency loss pattern, with associated poor auditory discrimination abilities. In contrast, the strial type has been associated with a 'flat' audiogram and good discrimination abilities also seen in age-related hearing loss. It is not possible, however, to determine the site of pathology from audiometric data alone.[24] Given that the Schuknecht classifications are essentially hypothetical, it is not yet known whether these different histopathology patterns reflect the existence of a number of different underlying mechanisms for age-related hearing loss. Whilst cochlear hair cell loss has been the main focus of research into the pathophysiology of ARHL, the auditory neuroscience community have become interested in a precursive state wherein degeneration of cochlear synapses precedes hair cell loss and threshold elevation.[34] Whilst there is presently more evidence for this in animal models than humans, it does raise the possibility of novel potential therapies.[35]

Central nervous system

Age-related degenerative change in the central nervous system was suggested as a contributory factor in age-related hearing loss by Hinchcliffe.[36] Such change in the auditory system is relatively subtle[25] and highly variable;[24] a significant consequence is reduced plasticity, which in part accounts for the marked acclimatization period required for the elderly to obtain maximum benefit from hearing rehabilitation by amplification.[37, 38]

Central auditory processing abilities decline with age, and decrements in tests of temporal fine structure and word recognition and discrimination have been reported.[39, 40] Over recent years, there has been a strong association demonstrated between age-related hearing loss and cognitive impairment including dementia and depression.[21, 41] Although a causal relationship has not been proven, it is suggested that behavioural mechanisms such as the social isolation resulting from the chronic hearing loss results in reduced activation of the central auditory pathways leading to decreased cognitive performance.[19]

Animal models of age-related hearing loss, specifically inbred mice, have shed some light on mechanisms and pathological changes with age[33] and, in particular, upon metabolic mechanisms of age-related hearing loss. These include recent research into the possible roles of mitochondrial DNA mutations and reactive oxygen species.[42] It is hoped that such studies will lead to the development of targeted therapies applicable to humans although this prospect still remains distant.

GENETICS

The genetics of congenital, childhood and early-adult onset forms of deafness have been intensively studied and many of the responsible genes have been identified. However, the genetics of age-related deafness in humans are much more poorly defined and no associated genes or loci have been identified. The available data do, however, implicate genetic

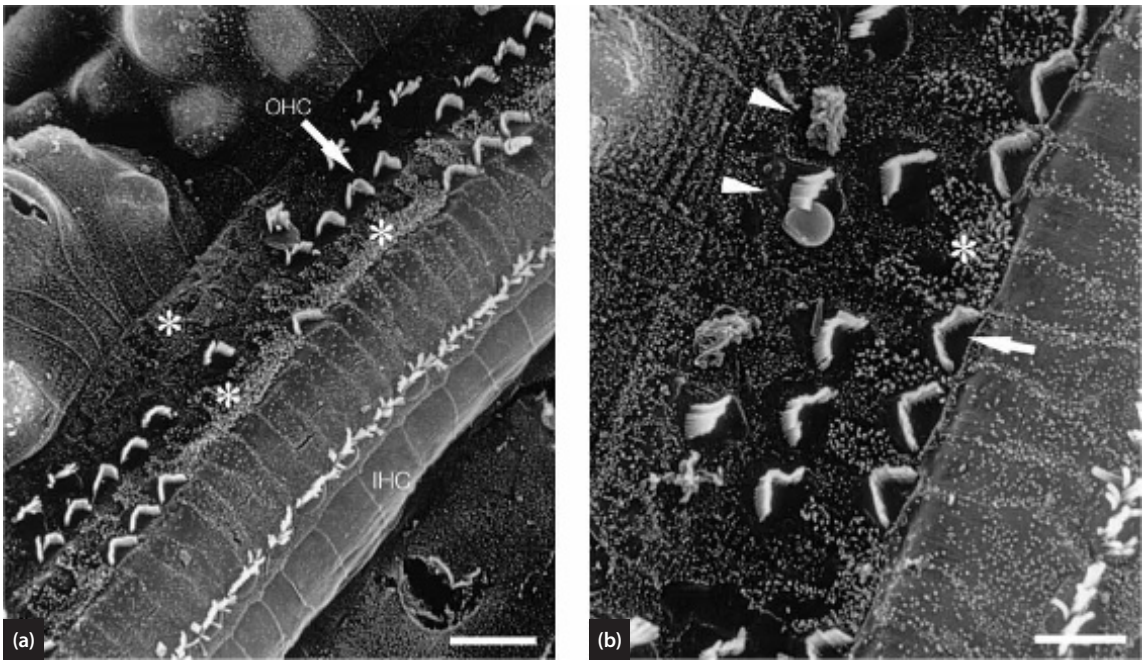

Figure 56.3 Scanning electron micrographs showing typical examples of the aged mammalian organ of Corti from a guinea pig. (a) The outer hair cell (OHC) rows show substantial patches where hair cells are probably missing (*) and in the process of degenerating, although the inner hair cells (IHC) are relatively undamaged. Scale bar: 20 µm. **(b)** Detail of the OHC region showing different levels of damage to the hair bundles of OHCs (arrowheads) including complete loss (*). The underlying hair cell is probably missing. Scale bar: 10 µm. Courtesy of Dr D.N. Furness, Mackay Institute of Communication and Neuroscience, Keele University.

Scale bar: 10 µm. **(b)** Detail of the extrusion of an outer hair cell apex. The hair bundle itself is relatively intact. Scale bar: 2 µm. Courtesy of Dr D.N. Furness, MacKay Institute of Communication and Neuroscience, Keele University.

factors in causing age-related hearing loss. Standard methods for determining the genetic component of a condition involve twin studies, examining concordance rates in monozygotic versus dizygotic twins, and family-based case-control studies. Two studies assessing the contribution of genetic factors to age-related audiology thresholds and hearing loss are available. A Swedish twin study examined audiometric hearing thresholds in 557 male twin pairs aged 36–80 years, identified from the Swedish Twin Registry. Similarity in audiogram thresholds was consistently greater for monozygotic versus dizygotic twins in all age ranges, but particularly so in the youngest group. These findings were interpreted as showing that genetic and environmental factors are important sources of variation in hearing at all ages, with genetic factors being particularly important for younger men.[43]

A family-based case-control study examined members of the US Framingham Heart Study and Framingham Offspring Study cohorts. It compared aggregation of audiometric hearing threshold in spouse pairs versus sibling or parent–child pairs. It also examined the aggregation of hearing level in pairs where one member had age-related deafness, with either a sensory or a strial audiogram pattern. Significant aggregation of hearing thresholds was found in parent–child and sibling pairs, but not in spouse pairs. Parent–child and sibling aggregations in hearing threshold were also found when pairs including a member with a sensory or strial deafness phenotype were analyzed separately. Heritability (the proportion of population variance attributable to genetic variation) was estimated for the sensory age-related deafness phenotype at 35–55% and for the strial phenotype at 25–42%. All of the aggregations were stronger in women than in men.[44] A genome-wide linkage screen, carried out on the Framingham study population, failed to map any age-related hearing loss gene conclusively, perhaps because the test population lacked the power to do so.[45]

Genetic studies of mice have made an important contribution to the field of deafness and conclusively indicate that genetic factors can be important in age-related hearing loss.[12, 46] Many different inbred mouse strains show accelerated age-related hearing loss and in at least ten of these the gene involved is *ahl*, which maps to mouse chromosome 10.[47, 48] This gene is inherited in a recessive pattern. This same gene is also implicated in susceptibility to noise-induced hearing loss and to aminoglycoside-induced hearing loss.[49, 50] A mitochondrial genome variant that interacts with and modifies this locus has been identified.[51] A more recent study indicates that the *ahl* gene is the mouse orthologue of cadherin 23, a human deafness gene associated with non-syndromic hearing loss and Usher syndrome.[52] At least two other mouse age-related hearing loss loci, designated ahl2 and ahl3, exist,[53] with alh2 mapped to mouse chromosome 5.[54] Finally, it has been suggested that mitochondrial genome mutations or variations, either inherited or acquired with age, may contribute to age-related hearing loss in humans.[42, 55] The available evidence indicates that genetic factors are important in age-related hearing loss and in the determination of age-related hearing thresholds. The strength of the genetic effect in and the mode(s) of inheritance of the age-related deafness clinical phenotype are not yet clear, and much work is needed to identify the genes involved.

RISK FACTORS

Risk factors implicated in primary age related hearing loss (i.e. where underlying causes have been excluded) are not clear. Epidemiological studies have suggested two main categories of modifiable factors that may contribute to the development of age-related hearing loss: environmental factors (noise exposure,[56–58] cigarette smoking and alcohol use[59]) and health comorbidities (hypertension,[60] blood hyperviscosity[61] and cardiovascular and cerebrovascular disease[42]). Studies have failed to illustrate consistent associations of these factors with the development of age-related hearing loss in contrast to those considered non-modifiable factors such as increasing age, male gender and possible genetic predisposition. It is likely that these and other factors have complex interactions with each other and age-related hearing loss, but more work is needed to determine the associations between these factors.

DIAGNOSIS AND MANAGEMENT

HISTORY

Typically, the patient will describe a slow and insidious hearing problem. Often, the first symptom is difficulty in hearing conversation, particularly in the presence of background or competing sound. Normally, the description involves a lack of clarity rather than a loss of volume. The symptoms have often been present for many years and are frequently more of a problem to the rest of the family. Sometimes, tinnitus may be the presenting feature. These symptoms are, of course, no different from any other sensorineural hearing loss. As the hearing loss progresses, so the nature of the complaint may change. Patients may complain of a more obvious hearing problem and frequently having to ask others to repeat themselves. The television is often louder than is comfortable for other members of the household. These problems can all lead to significant domestic distress.

As the hearing loss worsens, a complaint of deafness becomes more apparent and recruitment may be described.[62] Recruitment is the abnormal growth in the perception of loudness by an individual with a hearing loss[63] and is exemplified by the line: ‘Speak up! No, don’t shout, I’m not deaf!’

Tinnitus is a frequent accompanying symptom (30–50%) and not uncommonly may be the most troublesome.[64] There is a strong and well-demonstrated correlation between worsening hearing thresholds and the presence of tinnitus.[65] The prevalence of troublesome tinnitus rises from 5% in the under-thirties to 16% in the over-sixties.[66]

Even if not particularly severe, the hearing loss may lead to social isolation, and depression may ensue.[19] This should be specifically asked for, especially in the elderly who often have less opportunity for social contact.[67] A positive family history of hearing loss in old age may often be encountered.

The frequency of falls increases with worsening hearing thresholds in old age.[16, 18] This can compound problems with social isolation and reduced overall mobility, and should be addressed with involvement of relevant allied

healthcare professionals and specialists as required. Given this relationship, recurrent falls in an individual may prompt earlier screening and enquiry into hearing loss.[22]

When making the diagnosis, it is important to be aware of other significant causes of sensorineural hearing loss.[68] Significant head injury, meningitis, serious systemic illness, often involving previous aminoglycoside treatment, and a strong family history of early hearing loss (indicating a non-syndromic hereditary/genetic degenerative hearing loss) should all be enquired for.

EXAMINATION

The patient will be older, normally at least in their fifties, to display some of the early symptoms. Typically, otological examination will be normal. However, evidence of either active or quiescent otitis media does not preclude the diagnosis. Age-related hearing loss occurs in all individuals to varying degrees and so appropriate allowance for coexistent pathologies will need to be made.

Investigations

Unfortunately, there is no specific test for age-related hearing loss. The first and often only investigation required is a pure-tone audiogram. Various audiometric patterns have been described and classified but the relevance of these is still debatable. Some argue that they indicate damage to different parts of the cochlea or auditory nerve. Most commonly, though, the audiogram shows a hearing loss which tends to be worse at the higher frequencies. Often in the early stages of the condition, the only finding will be a mild high-frequency hearing loss. As the condition advances there tends to be progressive loss of the middle (1 and 2 kHz) and even low (250 and 500 Hz) frequencies.[9]

If sufficient asymmetry exists, a magnetic resonance scan may be required to exclude an acoustic neuroma. No definite evidence exists on this issue but a difference of more than 10 dB averaged over the frequencies 0.5, 1, 2 and 4 kHz or 20 dB or more at any single frequency would be reasonably pragmatic indications. Scanning in the presence of unilateral tinnitus has been suggested. The presence of any associated middle-ear pathology will require further investigation on its own merits, as the diagnosis of age-related hearing loss in this group of individuals is only possible once all other reasonable causes of hearing asymmetry are excluded.

DIAGNOSIS

In an individual over the age of 60, with normal examination findings and a symmetrical (often predominantly high-tone) hearing loss, a diagnosis of age-related hearing loss is fairly secure. Diagnostic difficulties may arise if the patient is younger than expected or the condition seems to be progressing more quickly than expected. Here, there is often an overlap with the increasingly recognized and described, heterogeneous group of genetically determined, progressive, degenerative hearing losses. More often in this group there will be a family history of early age-related hearing loss. Whether this actually matters in terms of management of these patients remains a moot point.

MANAGEMENT

The management and rehabilitation of age-associated hearing loss (AAHL) can be directed to three broad areas: psychological and practical (both non-specific) and sensory (specific).

Non-specific management

Unfortunately, there is no way to return hearing thresholds to their pre-elevation levels of acuity. It is beneficial to give advice regarding the optimization of an individual's acoustic environment. This involves the reduction of background noise (as far as possible), face-to-face conversation to maximize exposure to non-verbal communication cues and an explanation of the problem, to allow the legitimization of their hearing loss.

Involvement of allied health professionals and general practitioners can offer psychological counselling and support in cases of severe hearing loss, especially in the presence of other comorbidities. This will help the patient to acknowledge their problem, which is often one of the first steps on the road to rehabilitation.

Practical measures for individuals with a more severe hearing loss include wireless headphones for use with their television, volume-controllable telephones and louder doorbells, often with an alternative alerting system such as a flashing light or vibrating pager system. Hearing dogs can take on such a role as well as providing a valuable source of companionship in the elderly. Lip-reading classes can be extremely valuable. As the hearing loss becomes more severe, a hearing aid or cochlear implant can take on an increasingly beneficial role.

Specific management

Systematic review has demonstrated that hearing aids are of benefit, even in cases of mild or moderate hearing loss,[69] and the benefits include improved health-related quality of life as well as listening abilities.

Binaural hearing has been shown[70, 71] to produce an approximate additional 10 dB signal to noise ratio advantage. Not surprisingly, then, a recent National Institute for Health and Clinical Excellence (NICE) report has suggested that there is significant benefit to patients in being fitted with binaural hearing aids.[72] The evidence suggests that digital aids are a substantial improvement upon the now obsolete analogue devices,[73] and there is very good evidence of the importance of follow-up and rehabilitative support after fitting to ensure maximum benefit and hearing aid use. Furthermore, success with hearing aid use in older adults has been shown to be greater in those where use is supported by their family members and in those with a positive attitude towards the technology.[74] Tinnitus should also be managed as part of the overall care package. Modern neurophysiological methods, such as tinnitus retraining therapy, utilize a combination of cognitive, directive counselling and sound therapy, including

hearing aids and/or white-noise generators, and success rates are reported in the region of 60–70%.[75] Anecdotal[76] evidence suggests open-fit hearing aids are particularly effective in this situation, and the reduction in the occlusion effect encourages usage and compliance for all indications.

The presence of comorbidities that affect cognition (dementia, for example), can significantly impact on an individual's ability and readiness to adapt to the use of hearing aids.[22, 77] In these situations, cooperation is required from caregivers and family members to support ear and hearing aid hygiene and assist with insertion of hearing aids. Early recognition of the need and thus early administration of hearing aids is likely to improve the time which is required for the individual to recognize speech and grasp the benefits of hearing aid technology.[77] This may reduce development of the psychosocial comorbidities that can occur with hearing loss.[22] And finally, whether cause or effect, there is a lower prevalence of depression and dementia symptoms in hearing aid users when compared with a similar elderly group of non-aided persons[78] with researchers increasingly undertaking trials of hearing treatment and support to reduce cognitive decline.[79]

BEST CLINICAL PRACTICE

- ✓ Make a thorough assessment of the patient to establish the level of hearing loss and consequent disability.
- ✓ Early recognition of hearing loss in the elderly may help to prevent the development of several psychosocial comorbidities.
- ✓ Treatment should include binaural digital hearing aids and appropriate audiological rehabilitative support, which may comprise assistive devices and lip-reading classes as well as advice and guidance regarding hearing aid usage.

FUTURE RESEARCH

- ➤ It is naive to believe that one can stave off the effects of ageing forever. However, progress in unravelling the genetics of ageing, and age-related hearing loss in particular, means that with advances in gene therapy we may be able to delay its arrival.
- ➤ Introduction of genes that programme for hair cell longevity or at least avoid early hair cell death, may be possible.[80]
- ➤ An increased understanding of cochlear physiology and molecular biology means that drug therapy may be able to slow the progress of symptoms. An example might be drugs or chemicals that could stimulate a genetic cascade for hair cell regeneration.
- ➤ Finally, where the hearing loss is unavoidable, continuing advances in electronics will hopefully allow better performance from hearing aids. In particular, the perennial thorn of signal detection in background noise might be ameliorated, perhaps by 'smart' programming.

KEY POINTS

- Age-related hearing loss is almost invariably inevitable.
- It occurs from the sixth decade onwards.
- It is usually symmetrical.
- The effects extend far beyond simple hearing loss.

CHAPTER 57

NOISE-INDUCED HEARING LOSS AND RELATED CONDITIONS

Andrew McCombe and David M. Baguley

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: noise-induced hearing loss, diagnosis and management including prevention. Unfortunately, this produced a high yield but of relatively poor quality or narrow focus, thus most of the references have been hand-sourced from our personal collections on this subject. Also used are the references from the course 'Medicolegal aspects of noise-induced hearing loss' now run at the University of Southampton, and other references found during the course of our ongoing clinical and medicolegal practices.

DEFINITION

The term noise-induced hearing loss (NIHL) refers to a reduction in auditory acuity as a consequence of excessive noise exposure. This situation may be temporary and is described as temporary threshold shift (TTS) (although a strict definition regarding duration is not available), or permanent and described as permanent threshold shift (PTS). PTS may occur following repeated noise exposures, or following a single episode; the term 'acoustic trauma' has been used to describe the situation where a single exposure to an intense sound leads to an immediate hearing loss.[1, 2] The use of these terms does not carry any implication about the nature of the noise exposure (occupational or leisure) or about the noise itself (intensity, frequency, duration).

This chapter will also cover the other common adverse consequences of excessive noise exposure, which include tinnitus, hyperacusis (see also Chapter 61, Tinnitus and hyperacusis) and the relatively new condition of 'acoustic shock'.

AETIOLOGY

By its very definition NIHL is caused by exposure to noise. The sources of such noise are common and various, recreational or occupational. Many examples can be given, but of particular concern in younger people is the use of personal music devices, and regular attendances at clubs and concerts. Gunfire exposure, motor-racing and power tools for DIY are all potential culprits for an older age group.[3]

However, worldwide, occupational noise exposure represents one of the most prevalent, potentially preventable, sources of health impairment. Recent reports suggest that, outside Europe and North America, up to 25% of adult males of working age have evidence of occupational NIHL. This seems to be a particular problem in those countries moving from agriculture to a stronger manufacturing base for their developing economies.[4]

Like all biological insults, the effects on any individual from exposure to excessive noise levels are extremely variable and relatively unpredictable, especially at moderate exposure levels.[5] However, there is no doubt that, with increasing exposure to excessive noise levels, noise damage becomes inevitable. It is generally agreed that, for the human ear, sound levels below 80 dB(A) are unlikely to cause hearing damage, no matter how long one is exposed to them. Sounds of 130 dB(A) or greater will cause hearing damage after even short time periods in almost all exposed individuals. Between these two extremes the 'safe' period of exposure decreases as the sound level increases. In this

regard, noise can be thought of as a toxin, which exhibits its toxic effects in proportion to the total 'dose'. To try to quantify this relationship, the concept of the 'noise imission level' (NIL) was developed by Burns and Robinson.[6]

It is given by the equation:

$$\text{NIL} = \text{Lepd} + 10\log_{10}T$$

where Lepd is the daily noise exposure in dB(A) and T is the time of exposure in years.

So, as an example, a 20-year career with exposure to 85 dB(A) would produce an NIL of 85 + 13 = 98.

They also described the 'equal energy principle'. In essence, this states that if exposure to 85 dB(A) is safe for an 8-hour working day, then a doubling of sound intensity to 88 dB(A) effectively doubles the 'dose', and so is safe for only half that time, i.e. 4 hours. This principle may well hold for continuous noise exposure but is less certain for the more common situation of intermittent exposure.

PATHOPHYSIOLOGY

Although the tympanic membrane and ossicles may be damaged or disrupted in very high-impulse noise, such as an explosion, it is generally the cochlea that is the predominant site for the pathological manifestations of noise damage.

Pathological change associated with NIHL is the source of considerable scientific enquiry and some controversy, and hypotheses regarding mechanisms abound.[7] To this end, there has been great sacrifice by a variety of animals, in particular the cat, guinea pig and chinchilla! The majority of studies consider cochlear function, particularly metabolic and structural changes.[8] Recovery from TTS is thought to imply a role for metabolic mechanisms, and the persistence of PTS, for structural change mechanisms; there is also some experimental evidence in this regard.[9]

Metabolic mechanisms

Acoustic overstimulation could potentially lead to the excessive release of neurotransmitters associated with the transduction function of the cochlea. The possibility that excessive glutamate release may contribute to NIHL has been proposed, based in part upon experimental evidence that the administration of glutamate receptor antagonists may reduce TTS.[10, 11]

There is substantial experimental evidence from animal studies for change in cochlear blood flow associated with acoustic stimulation.[8, 12] Specifically, there are indications that stimulation with sound of moderate intensity increases cochlear blood flow, and with sound of high intensity decreases cochlear blood flow (this being a potential mechanism for cochlear dysfunction associated with noise exposure).[8] The mechanisms of these phenomena are unclear but may reflect metabolic demand. It should also be noted that there is some evidence that NIHL and cochlear hypoxia precede changes in cochlear blood flow.[13]

Other metabolic cochlear mechanisms that are the focus of experimental investigation include outer hair cell (OHC) plasma membrane fluidity, the role of glucocorticoid receptors and oxidative stress.[14–17] Such mechanisms are not mutually exclusive, and there is a consensus that NIHL is a multifactorial and complex situation.

Structural mechanisms

Changes to the micromechanical structures within the cochlea have been reported as possible mechanisms of NIHL. The suggestion has been made that depolymerization of actin filaments in stereocilia may be a substrate of TTS. Additionally, changes to non-sensory elements of the cochlea, such as swelling of the stria vascularis, afferent nerve endings and supporting cells, have been noted.[18]

Apoptosis and necrosis

There is evidence that both apoptosis (programmed cell death) and necrosis play a role in NIHL[9, 19, 20] and OHC are particularly vulnerable in this regard.[21] The progression of OHC death well after the cessation of noise has implicated apoptotic mechanisms.[22] Apoptotic changes in chinchilla OHC (specifically nuclear condensation and cell body shrinkage) have been detected 5 minutes after exposure to impulse noise, whereas necrotic change (nuclear swelling) appeared 30 minutes following exposure.[20] A present focus for research is the role of caspases (a family of cysteine-dependent aspartate-specific proteases) in cochlear hair cell apoptosis.[23]

The evidence above regarding metabolic and structural change in the organ of Corti following noise exposure is indicative of necrotic mechanisms being involved. It has been demonstrated, however, that the relationship between NIHL and hair cell dysfunction is complex. Specifically, it appears that in the rat, high-frequency hair cells die rapidly after noise injury, but that low-frequency hair cells may survive but without auditory function. This finding may account for the common observation that the relationship between hearing thresholds and hair cell damage is not direct.[24]

Synaptopathy

The adverse effects of excessive noise are not limited to the cochlear hair cells. There is a growing body of evidence that the synaptic connections between the inner hair cells (IHCs) and spiral ganglion cells may be especially vulnerable to noise insults (and indeed to ageing), and that this may occur even when the hair cells themselves remain intact.[21, 25] This latter scenario has been given the name 'hidden hearing loss', as audiometric thresholds would be unchanged, but those affected demonstrate difficulties with hearing in background noise.

Predisposing factors

A potential genetic basis for susceptibility to NIHL has been considered but, while this is well established in

animals, in humans it remains elusive.[26] Experimental evidence gleaned from studies with mice has implicated the *Ahl* gene[27, 28] and there are several strains of knockout mice (both homo- and heterozygous) that are more susceptible to NIHL than their littermates that are wild-type.[26]

A clinical interaction between NIHL and age-related hearing loss has been reported and supported by further data.[29–31] The suggestion is that, as individuals with NIHL age, the effect of ageing upon thresholds affected by NIHL is slowed but for adjacent frequencies is accelerated. Mechanisms underlying this observation are presently unclear. The observation that populations in minimally industrialized areas of the world (specifically the Sudanese desert) experience not only no NIHL but also no age-related deterioration of hearing is of interest, but this needs corroborating, and with some urgency while such populations exist.[21, 32]

Other factors demonstrated to have an association with susceptibility to NIHL in humans include smoking and certain disease states such as diabetes and cardiovascular disease.[33–36] Hood et al. noted a greater extent of TTS in individuals with blue eye colour, and an association with PTS has also been demonstrated.[37–39]

A further suggestion has been that recreational drug use causes greater risk of NIHL and tinnitus although it should be recognized that intoxicated individuals may take more risks with intense sound.[40] The combination of exposure to ototoxic agents and noise has been shown to be synergistic in animal models and the potential existence of a common pathway for cochlear ototoxicity and NIHL has been suggested.[41–43] A similar situation has been proposed in humans with regard to industrial solvents, and this warrants investigation.[44, 45] Henderson et al. noted that the individual variability in human susceptibility to NIHL was so great that the situation is complex, and much further research, both animal and human, is needed to substantiate fully the effect of other factors on it.[43]

DIAGNOSIS

Unfortunately, there is no specific test available to make the diagnosis of NIHL. Furthermore, there are two different settings in which a clinician may be required to make such a diagnosis: in the clinical setting and in a medicolegal context. Although the degree of accuracy required is quite different, it is surprising how often the course through the former (which often comes first) can influence the course in the latter. It is therefore most important that as accurate a diagnostic process as possible is pursued in the clinical setting in order to avoid later inconsistencies and reversals in the medicolegal process. At the very least, an acknowledgement of the areas of uncertainty is required.[46]

Of some help, though, in the latter setting is the requirement to make the diagnosis 'on the balance of probabilities' – or simply more likely than not!

There are additional problems with which the clinician must grapple when diagnosing NIHL. There is the enormous biological variability and individual susceptibility to the effects of noise, as well as the insidious nature of the progress of NIHL. In practical terms, this means that, often, by the time an individual presents with symptoms, the noise exposure will have ceased and, in all likelihood, there will be a contribution from the ubiquitous age-related degenerative process.[47, 48]

Historically, the diagnosis of NIHL has been fairly straightforward. Typically, an individual would present with a hearing loss, confirmed by audiometry, and a career of exposure to, relatively undisputed, excessive noise. The diagnostic process would include separating the effects of ageing from the effects of noise. This process would be accomplished by reference to one or more of the many standardized reference tables detailing hearing thresholds with age for typical screened and unscreened populations (e.g. the NPL tables, among others).[49–52] Removal of an 'average' value for age-related hearing loss leaves an assumed NIHL.

The choice of appropriate control group here is obviously important. Comparison of the subject with a highly screened control group, and their better hearing thresholds, may suggest a significant hearing loss due to noise, while a less highly screened control group (with poorer thresholds) may suggest near-normal hearing for an individual of that age.

Much has changed in recent years: heavy manufacturing industry has almost completely disappeared from the UK, and machinery performance and design have improved, as have hearing protection programmes. This has all led to a workforce that enjoys far less in the way of very high levels of excessive noise exposure. Consequently, there have been far fewer claims based on just a hearing loss; more often now claims will also focus on the often-associated symptoms of tinnitus and hyperacusis.

Furthermore, new industries and processes have arisen such as call centres and covert surveillance. These have brought novel and unique problems and patterns of exposure, culminating in a new condition: 'acoustic shock'.[53–55]

Finally, there have been the problems, alluded to earlier, of recreational noise exposure in a younger population, and an increasing recognition of early degenerative hearing processes and other adventitious hearing losses.[56] This latter point has led to a renewal of the debate regarding the most appropriate control group for comparison.[57] The screening of the control group effectively removes all other otological pathology, such as ear disease, head injuries, positive family history of hearing loss, alternative noise exposure and so on. The net result is a group with better hearing thresholds than a so-called 'typical population' group where far less screening has taken place. This distinction is exemplified by databases A and B for the corresponding groups in ISO 1999.[46, 51]

For practical purposes it is probably best to start from a diagnostic assumption that, in a possible case of NIHL, the individual will have a hearing loss composed of three parts: an age-related component, a noise-induced component and, finally, a third, idiopathic degenerative component. The clinician's task is to separate and calculate the relative contribution (if any) from the three sources.

In the end the diagnosis is based on a combination of the clinical picture that emerges from the patient or claimant and the audiometric findings and, in a large part, is influenced by the experience of the examining clinician.

History

The patient or claimant is far more likely to be male than female, usually in middle age, but sometimes older. They may be younger, especially if the complaint is more about tinnitus (with or without hyperacusis) than deafness. Women more frequently present with acoustic shock.

Inevitably, there will be a history of hearing difficulties. Typically, in the early stages, especially as the OHC are first affected by noise damage, a history of hearing difficulties in the presence of background noise is encountered. Normally, the description involves a lack of clarity rather than a loss of volume. Difficulty with the television being louder than is comfortable for the rest of the family is frequently reported. Telephone conversations may become more difficult. The symptoms will often have been slowly progressing for many years.

Tinnitus is a common accompanying symptom of NIHL and often occurs early in the course of the condition. In fact, post-exposure tinnitus is a useful symptom when making the diagnosis, especially if reported unsolicited. The main effects of tinnitus tend to be on sleep, mood and concentration. Impact in these areas should be detailed and any medical attendance for it noted. This will help in grading its severity.[58]

Hyperacusis is found in 40% of tinnitus sufferers and is becoming an increasingly volunteered accompanying symptom in NIHL. Its presence should be recorded. The instrument to determine severity that is in most common use worldwide is the Hyperacusis Questionnaire, though some issues with the factor structure have been identified.[59, 60]

As the hearing loss progresses, so the nature of the complaint may change. Patients may complain of a more obvious hearing problem and frequently having to ask others to repeat themselves. With further progression, a clear complaint of hearing loss occurs.

NIHL is found far more often in men and produces particular difficulties in social functioning. There is often a history of social withdrawal although this will rarely be volunteered. There is often increasing reliance on the spouse for social and family interaction and this can lead to marital stress. There may be embarrassment, loss of confidence, anxiety and frank depression.[61]

It is important to be aware of other significant causes of sensorineural hearing loss when making the diagnosis. Significant head injury, meningitis, serious systemic illness, often involving previous aminoglycoside treatment, and a strong family history of early hearing loss (indicating a non-syndromic hereditary/genetic degenerative hearing loss) should all be enquired for.

It is axiomatic that, for a diagnosis of NIHL to be made, there must be a history of noise exposure. In the clinical setting it is important to establish that there has been sufficient noise exposure to cause NIHL. In the medicolegal setting it is essential to be thorough about this. It is important to detail all the potential sources of noise exposure and assess typical noise levels and duration of exposure.[62] If one is not familiar with the suspect machinery or device, get the claimant to describe and explain it. A useful yardstick of background noise levels is the ability to hold some type of conversation in its environment (Table 57.1).

For gunfire noise exposure, the type of weapons used and number of rounds fired are important questions; heavy artillery is particularly damaging. Provision and type of hearing protection should be known, although this by no means guarantees protection.[63] Post-exposure tinnitus is a useful surrogate for the presence of a TTS.[64]

If the total noise exposure has come from a variety of sources, it is important to document the contribution from each carefully and thoroughly (including recreational exposure).

The problem of acoustic shock is very different and is thought to be more of an acute stress reaction. It is found typically in call-centre workers who are under some pressure to process high volumes of calls in a defined time period. The sound comes through their headsets and may be the result of a technical malfunction, or a malicious act by the individual on the other end of the phone line. The sound is unexpected and is perceived as both loud and unpleasant by the affected individual, although when measured it may be less than classically damaging sound levels of 85 dB(A) or above. Objective hearing loss is rarely a feature but multiple symptoms and high levels of psychological distress are often described. Common symptoms are summarized in Table 57.2. Theories exist that the problem represents a combination of an excessive 'startle' response, and/or a form of post-traumatic stress disorder.[54] In addition, there is a view that myoclonic activity of the tensor tympani muscle is involved.[50] The degree of psychological distress is often enough to

TABLE 57.1 Typical background noise levels based on communication ability

	Distance from speaker to listener		
Voice level	**4ft**	**2ft**	**At ear**
Loud voice	93 dB(A)		
Shout	99 dB(A)	105 dB(A)	
Impossible to hear			Over 110 dB(A)

TABLE 57.2 Common otological symptoms of acoustic shock (derived from Westcott[55])

Symptom	Occurrence (%)
Hyperacusis	84
Otalgia	81
Tinnitus	50
Imbalance	48
Hearing loss	18

force the individual to leave the job where the exposure occurred.

Examination

Typically, otological examination will be normal. However, evidence of either active or quiescent otitis media does not preclude the diagnosis. Age-related hearing loss happens in all individuals in varying degrees and so appropriate allowance for this and any other coexistent pathologies will need to be made.

Investigations

The cornerstone of investigation is a pure-tone audiogram, with both air and bone conduction to identify any conductive hearing loss. The usual clinical frequencies should be tested as well as 3 kHz and 6 kHz. The classical audiometric pattern is of a high-tone hearing loss with a notched appearance centred on 4 kHz or 6 kHz, with some recovery at 8 kHz. However, the classic notch is often absent or not obvious, particularly in the presence of significant age-associated hearing loss or other causes of hearing loss. Furthermore, the presence of a significant notch at 4 kHz on its own is not evidence of NIHL. There are numerous case reports and population surveys of 4 kHz notches in individuals with no history of noise exposure.[65–67]

Significant audiometric loss at frequencies below 2 kHz is extremely uncommon in NIHL. If present, it should raise suspicion of some other pathological process affecting the cochlea.

Some authors have suggested an analytical approach to the shape of the audiogram as an aid to predicting the likelihood of NIHL.[48, 68] This analysis merely helps to increase the confidence in making a diagnosis of NIHL. Lutman et al. have more recently produced a follow-up paper to their original guidelines which attempts to provide quantification of the noise-induced component of any high-tone hearing loss.[69]

Since 2007, and the judgement in a group action by textile workers in Nottinghamshire,[70] there has been a much greater reliance on the Coles, Lutman and Buffin (CLB) guidelines;[48] in fact, many solicitors will not proceed with a claimant's case if their audiogram does not meet the relevant criteria. This is helpful and does provide a degree of certainty and clarity, but a lack of conformity does not exclude the diagnosis. Nor does it help in cases where non-hearing loss symptoms dominate.

Tympanometry is helpful to confirm normal middle ear functioning. A conductive hearing loss is not due to noise exposure and can even provide some protection to the cochlea by virtue of the sound attenuation.

In those individuals in whom a significant non-organic component (feigned thresholds) is suspected, cortically evoked response audiometry, or otoacoustic emissions (OAE), may be required to provide a more objective measure of hearing thresholds.

In cases with significant asymmetry, a magnetic resonance imaging (MRI) scan may be required to exclude an acoustic neuroma. Significant asymmetry is unusual in NIHL but can be found in certain military personnel due to the 'shadow effect' from the head with shoulder-borne weapons. More than 10 dB at the same frequency is uncommon and will indicate the need for MRI scanning.[71]

Tinnitus pitch and intensity matching are often performed. Although they may help to describe the tinnitus, there is little evidence that they have a role in the assessment of tinnitus severity.[72]

Loudness discomfort levels are a useful measure of the presence of hyperacusis. They can also be used to monitor the effects of treatment.

There is some evidence of changes in OAEs and decreased, contralateral, OAE suppression with early noise damage, although these findings are still a long way from regular and reliable clinical application.[73–75] They may yet help in the diagnosis of noise-induced tinnitus without measurable hearing loss.[76]

At the present time there is no practical means of determining the extent of synaptopathy in an individual exposed to noise and research in this regard is underway internationally.[21]

Diagnosis and report writing

Diagnosis is simple in an individual with a clear and prolonged history of unprotected exposure to excessive noise, no evidence of any other otological pathology and an audiogram showing good preservation of mid and low frequencies but a significant high-tone hearing loss with classical notching at 4–6 kHz.

However, in practice, such a case is relatively rare. Most commonly, one is faced with an older patient who has developed symptoms as a result of the combined effects of ageing and NIHL. There will be a history of excessive noise but in many cases this will not be overwhelmingly impressive or, alternatively, hearing protection may have been provided. The audiogram will show a sensorineural hearing loss, often with loss of the middle frequencies too. In this situation it is necessary to tease out the effects of ageing, balance the remaining hearing loss against the described noise exposure and try to make a judgement based on one's experience of NIHL as to whether all of this remaining loss can be attributed to the noise. If not, a third idiopathic, degenerative process has to be invoked to explain the discrepancy.[48, 55, 69]

Help for this task comes from both the 'Black Book' and the NPL tables. The NPL tables are particularly useful as they describe average noise imission levels (NILs) for various hearing losses. Where there is a significant discrepancy between the required NIL for a hearing loss and the noise exposure supposedly responsible, the presence of an additional degenerative process becomes more likely.[77] The 'Black Book' provides disability values for various hearing losses and for typical age-related changes.[62]

A medical report requires all of these points to be addressed. A value should be attached to the noise-induced portion, and any other components, of the total hearing loss. In addition, the writer should make some effort to

calculate the relative contribution to the NIHL from each noise source, if there is more than one.

Tinnitus, if present, should be graded for severity and, again, the various contributions to its aetiology should be apportioned. Guidance for severity grading has been published.[60] By and large, the courts tend to accept the premise that the cause of any tinnitus (and hyperacusis) is the same as the cause of any coexisting hearing loss, and in the same relative proportions if there are multiple contributions, such as age and noise, among others. Tinnitus following noise exposure without apparent hearing loss is a little more controversial.[78] Obviously, this does not apply if the onset of tinnitus followed closely from a specific incident, such as an episode of acute acoustic trauma, a head injury or following a known ototoxic medication. In these cases the specific incident in question is more likely, on the balance of probabilities, to have been the cause.

The report should also include a section on prognosis in respect to both hearing loss and tinnitus. In particular, comment should be made regarding the need (either current or predicted) for any hearing aids or rehabilitative treatment, and, if possible, some indication of their costs.

With the relatively recent changes in the civil justice system leading to the production of the Civil Procedure Rules in 1999, it is important that an expert does not comment outside his field of expertise and, where there is a range of opinion on a point or subject, it is acknowledged and commented upon.[79]

MANAGEMENT, INCLUDING MEDICOLEGAL

Prevention

From a clinical perspective, once a diagnosis is made, further noise exposure should be reduced as far as possible. This may be by avoiding the excessive noise altogether or, if this is not possible, by the use of ear protection in the form of earplugs or earmuffs. Changes to working practices might also be suggested. In the occupational setting, legislation exists to enforce this.

Employers have a statutory duty under the Health and Safety Act 1974 to minimize risks to employees, including risks from excessive noise exposure.[80] The 1989 Noise at Work Regulations described two action levels for daily, personal noise exposure: a first action level at 85 dB(A) and a second at 90 dB(A). In addition, there was a peak action level of 140 dB.[81, 82] These were replaced in 2006 by the European Control of Noise at Work Regulations 2005, where each action level is 5 dB lower, respectively.[83, 84]

In summary, at the first action level, an employer should conduct a noise survey, embark on a programme of employee education and provide appropriate hearing protection. The use of this hearing protection is at the discretion of the employee until the second or peak action level is reached, when it becomes compulsory. The employer is required to identify those areas where hearing protection use is required. Regular hearing tests should be offered to employees where and when a potential risk is recognized.

The main thrust of the regulations, though, is to reduce noise exposure 'as far as reasonably practicable' by reduction of noise at source (or time of exposure), with hearing protection very much the last solution. This reduction may be by means of engineering (quieter machines) or acoustic (sound-isolating) solutions.

PERSONAL HEARING PROTECTION

There is evidence that the use of hearing protection reduces the risk of NIHL from noise in both recreational and occupational contexts.[83, 84] As regards hearing protection, the choice is between earplugs, earmuffs and active noise reduction. The choice will often depend on the performance of the protector and the environment in which it will be used. Earplugs may be personally moulded or 'off the shelf', and are made from silicone rubber, acrylics or closed cell foam. They are relatively cheap and particularly useful when other protective devices (e.g. helmets or goggles) must also be worn. The best earplug can perform as well as the best earmuff in terms of sound attenuation but they are harder to fit correctly.[85] It is well established that the real-world performance of ear protectors is significantly poorer than the laboratory scores, largely as a result of inadequate or incorrect fitting. Therefore, earmuffs are generally a more reliable form of ear protector. In a real-world setting, earplugs can be assumed to give approximately 10–15 dB of sound attenuation and earmuffs at least 15 dB.[86]

Active noise reduction is an electronic method of sound attenuation. It uses electronics to provide sound, inside a set of earmuffs that is 180 degrees out of phase with the ambient sound. This effectively cancels out the background noise. This is a very effective form of sound attenuation, particularly for lower frequencies (around 1000 Hz), but the electronics required are expensive. Its most frequent use is in military and aircraft settings where additional communication devices are required and it can be incorporated into the headset.[87]

Unfortunately, given the known variation in susceptibility to noise damage, adherence to all the regulations does not guarantee protection for all employees.

Non-specific management

Unfortunately, there is no way to replace the hearing that has been lost. In those individuals with a mild high-tone hearing loss, hearing aids may provide benefit, but this can be meagre.[88] The best that can be done in this situation is to give advice regarding the optimization of their acoustic environment. This involves the reduction of background noise (as far as possible), face-to-face conversation to maximize exposure to non-verbal communication cues and an explanation of the problem, to allow the legitimization of their hearing loss.

In more severe hearing loss, directed rehabilitation programmes including psychological counselling, can help the patient to understand and acknowledge their problem. This acceptance is one of the first and, most crucial, steps on the road to successful rehabilitation. Inclusion of, and support for, the individual's partner should also be provided as part of such a programme.[89]

Practical measures for individuals with a more severe hearing loss include infrared headphones for use with television, volume-controllable telephones and louder doorbells, often with an alternative alerting system such as a flashing light or vibrating pager system. Lip-reading classes can be extremely valuable.

Specific management

As the hearing loss becomes more severe, a hearing aid takes on an increasingly beneficial role. There is solid evidence of a significant benefit to the patient in being fitted with binaural digital hearing aids.[88] There is also good evidence of the importance of follow-up and rehabilitative support after fitting to ensure maximum benefit and hearing aid use.[90]

Tinnitus should be managed as part of the overall care package. Modern neurophysiological methods (such as tinnitus retraining therapy) utilize a combination of cognitive, directive counselling and sound therapy (including hearing aids and/or white-noise generators) and report useful success rates in the region of 60–70% in terms of improvement in the perception of tinnitus and its severity.[91] Hyperacusis responds well to similar treatment methods.

Acoustic shock really requires psychological treatment as much as anything else. Many sufferers are unable to continue that occupation. Tinnitus is a frequent symptom and standard tinnitus treatment strategies do seem helpful for this and a number of the other auditory symptoms.

Pursuing a claim

In the clinical setting, once a diagnosis of NIHL is made, the patient may well ask advice about pursuing a claim for damages. There are two options.

If the individual has worked for 10 years or more in one of the prescribed occupations, they may be entitled to statutory DSS compensation, available since 1974.[92] The hearing loss is calculated on the basis of the average hearing levels at 1 kHz, 2 kHz and 3 kHz.

$$[(4 \times \text{better ear} + 1 \times \text{worst ear}), \text{ divided by } 5]$$

The entry point is 50 dB HL, which equates to a 20% disability. The disability payments are relatively modest. For illustration, in 2016 a 20% disability attracted a payment of £33.60 per week and complete deafness (100% disability) £168. There are many who think this entry point is too high; it equates to an approximate 38% disability in the 'Black Book'.[62] A similar scheme has operated for the military pension scheme since 1987.

The second and more common option is to pursue a civil claim, where the burden of proof is on the claimant. For such a case to succeed, the claimant must demonstrate 'on the balance of probabilities' (i.e. more likely than not) that:

- there has been exposure to excessive noise levels
- the hearing loss has been a consequence of that exposure
- there was a foreseeable risk of injury from the exposure
- the case was brought in time (3 years from the time of awareness).

The claimant must retain a solicitor to coordinate the case. Such a solicitor can normally be found through the employee's union or work federation, or through the Citizens Advice Bureau.

FUTURE RESEARCH

- While the dangers of hearing loss associated with noise exposure have been known for many years, there remains much to discover about pathological mechanisms of NIHL, genetic susceptibility and the influence of other factors. Animal studies will be of assistance in building the knowledge base, as will human population studies.
- Sound conditioning protects against the adverse effects of future sound exposure.[93] Understanding the physiological and biochemical explanation for this may allow drug therapy to protect against or possibly reverse the effects of excessive noise exposure. Current areas of interest include the intratympanic administration of corticosteroids, and the use of antioxidant medication.[26]
- Explanation and understanding of these phenomena may also be helped by further research based on our knowledge that certain individuals naturally have 'tough' ears when it comes to noise exposure.
- Advances in our understanding of hair cell regeneration may allow treatment to encourage this to take place in the noise-damaged cochlea.

KEY POINTS

- In noise-induced hearing loss (NIHL) cases there are usually three components to the hearing loss: age, noise and an idiopathic component.
- The diagnosis is clinical and requires sufficient noise exposure and the presence of a hearing loss greater than expected from age alone.
- Tinnitus and hyperacusis are frequent accompanying symptoms and nowadays often present without any evidence of a hearing loss or only a modest hearing loss.
- Treatment is essentially preventative and involves personal hearing protection (earplugs or earmuffs) or reduction of noise levels at source.
- This is a diagnosis that frequently enters the legal arena.

CHAPTER 58

AUTOSOMAL DOMINANT NON-SYNDROMIC SENSORINEURAL HEARING LOSS

Polona Le Quesne Stabej and Maria Bitner-Glindzicz

SEARCH STRATEGY

The data in this chapter may be updated by a search on NCBI PubMed, OMIM and the Hereditary Hearing Loss website at http://hereditaryhearingloss.org[1] using the keywords: autosomal dominant non-syndromic sensorineural hearing loss, next generation sequencing, hearing loss gene panel and DFNA.

INTRODUCTION

Hearing loss which is the result of damage to the hair cells within the inner ear, the vestibulocochlear nerve or central processing centres of the brain is called sensorineural hearing loss (SNHL). When SNHL occurs without any additional manifestations in at least one other body system, it is called 'non-syndromic' SNHL. This accounts for approximately 70% of all genetic SNHL cases, the other 30% being part of a syndrome in which clinical features form a recognizable association. According to mode of inheritance, non-syndromic SNHL can be autosomal dominant (AD) (15% of non-syndromic SNHL cases), recessive (80%), X-linked or mitochondrial.[2] Deafness is a highly heterogeneous disorder with genes encoding a plethora of different proteins involved in numerous pathways.

CLINICAL FEATURES OF AD NON-SYNDROMIC SNHL

Clinical evaluation of a patient with hearing loss includes involvement of a multidisciplinary team with audiologist, otolaryngologist, clinical geneticist and other specialists where appropriate. When environmental and syndromic causes of hearing loss have been excluded as far as possible, the hearing loss can be considered to be non-syndromic, until proven otherwise. If family history is available, a non-syndromic AD form of SNHL is recognized by the observation that several generations are affected; in a singleton case, probably due to *de novo* mutation, or reduced penetrance, the inheritance pattern is often not apparent.[2] To date, loci for more than 60 genes have been mapped (which means that the detailed chromosomal position has been localized), but only just over half of these genes have been identified.[1] Unlike the situation in which *GJB2* accounts for a significant proportion of cases recessive hearing loss, there is no single major gene accounting for a large proportion of dominantly inherited cases. Therefore genetic heterogeneity, relative clinical homogeneity (see 'History of AD non-syndromic SNHL gene discovery') and the fact that AD non-syndromic SNHL accounts for a minority of all genetic hearing losses means that genetic testing to achieve a molecular diagnosis has proved challenging and expensive until recently.

Clinically, AD SNHL is usually postlingual and progressive in contrast to non-syndromic autosomal recessive SNHL which is usually prelingual and more or less stable.[2, 3] There are some notable exceptions: mutations in some genes may cause prelingual or early childhood-onset hearing impairment such as those in *TECTA* (DFNA8/12) (**Figure 58.1**) and the recently described *CD164,* which may give rise to prelingual moderate to severe hearing loss with a distinctive mid-frequency 'U-shaped' pattern; *SIX1* (DFNA23), which may also cause prelingual high-frequency hearing loss associated with unilateral or bilateral ear pits; and *CRYM*, which may cause a downsloping, progressive hearing loss. Genes which cause onset of hearing loss in the first decade

include *WFS1* (DFNA6/14/38) (Figure 58.2), which can cause low-frequency progressive hearing loss (<2 kHz), *MYO6* (DFNA22), *HOMER2*, *OSBPL2* (DFNA67) (Figure 58.3), which causes a steeply sloping ('ski-slope') mild to profound progressive hearing loss, and *TMC1* (DFNA36), which can cause a high-frequency rapidly progressive hearing loss. However, even within a single family, age of onset of hearing loss, progression and even audiometric configuration can vary between individuals, making distinction between genetic causes difficult.

So, although some non-syndromic AD SNHL loci are associated with particular audiometric patterns or clinical presentations, such as mutations in *COCH*, also giving rise to prominent vestibular symptoms, a sufficiently distinctive, unique audiogram or clinical picture to confidently enable clinical diagnosis is unusual. This has spurred the development of 'AudioGene', an online automated tool which automatically analyzes audiometric data to predict the likely underlying genetic causes of hearing loss. It has been shown to have some success in predicting the gene/locus responsible for deafness based on audiogram,[4] particularly for *KCNQ4* mutations which cause a pattern of mainly high-frequency hearing loss and which has been found to be a relatively common form of dominantly inherited hearing loss.[5,6] Audioprofiles for many other loci have now been compiled and are available for use to try to predict the gene or locus involved based purely on audiometric pattern and progression. The currently known AD genes for SNHL are outlined in Table 58.1, together with age of onset and audiometric description.

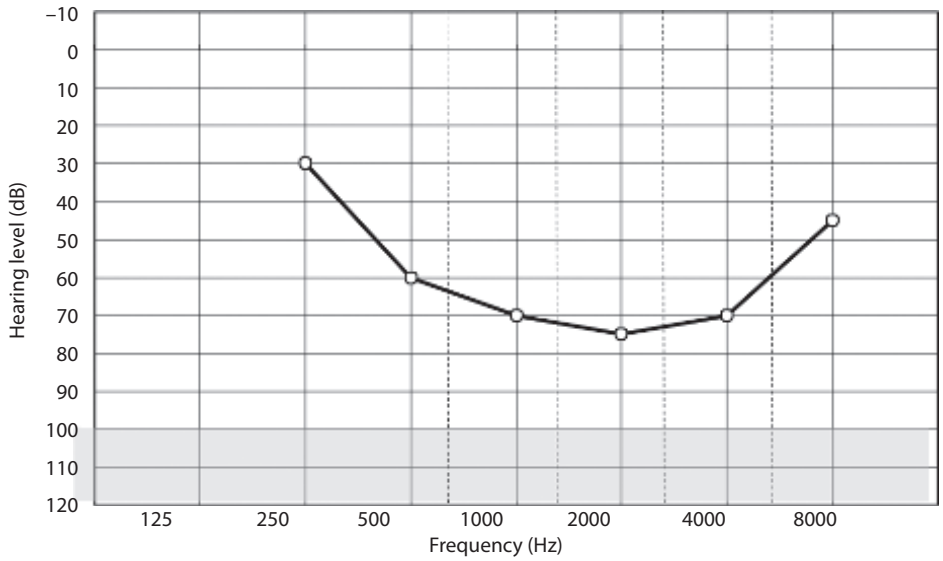

Figure 58.1 'U-shaped' or 'cookie-bite' audiogram typical of hearing loss caused by *TECTA* mutations.

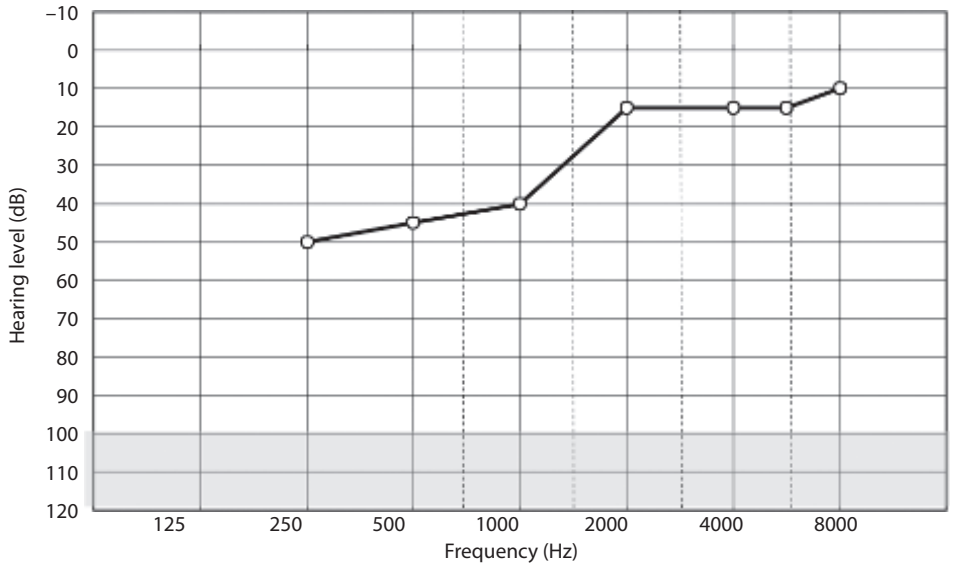

Figure 58.2 Low-frequency hearing loss seen with *WFS1* mutations.

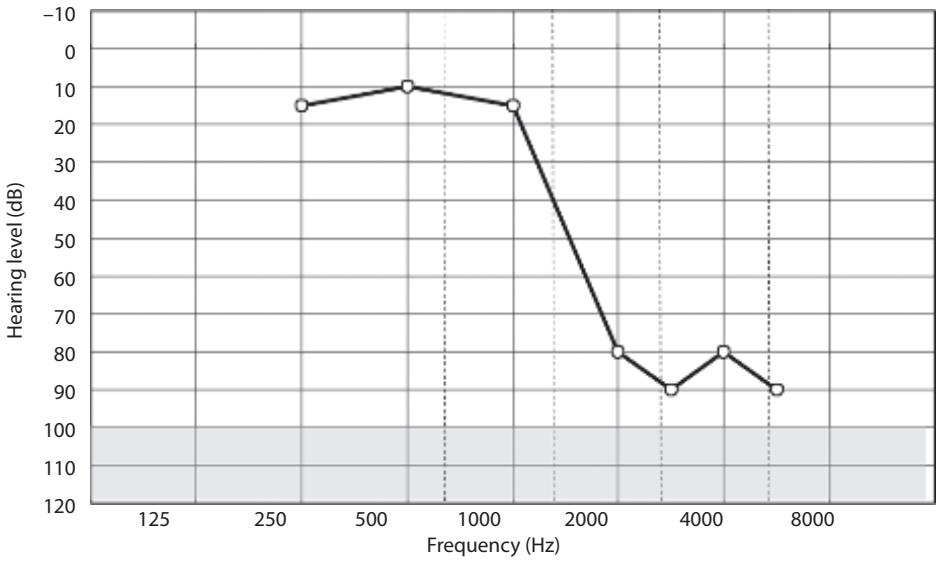

Figure 58.3 Steeply sloping, 'ski-slope' high-frequency hearing loss seen with OSBPL2 mutations.

HISTORY OF AD NON-SYNDROMIC SNHL GENE DISCOVERY

Non-syndromic AD SNHL can be identified by a multigenerational family history and is genetically heterogeneous with no single gene accounting for a high proportion of cases; there are currently 37 genes and 67 loci with yet unidentified genes listed on the Hereditary Hearing Loss website (see **Table 58.1**)[1] This extreme genetic heterogeneity makes genetic diagnosis of AD SNHL very difficult.

Box 58.1 defines the most important terms related to research in this area.

In 1992 the first AD SNHL locus (DFNA1) was mapped to chromosome 5q31 using linkage analysis in large multigenerational Costa Rican kindred. Five years later, in 1997, using laborious positional cloning as the human DNA sequence was not yet available, a splice mutation leading to a 4bp insertion in the mRNA and frameshift causing a truncating variant in *DIAPH1* gene was identified as the cause of AD SNHL in this family.[7, 8] Recently it has been shown that this leads to a constitutive activation of the encoded protein DIA1 by loss of autoinhibition.[9] In the same year, it was shown that an in-frame 9-bp deletion in *MYO7A* and a truncating mutation in *GJB2* were responsible for deafness in two families previously linked to DFNA11 and DFNA3A loci, respectively. Both genes were cloned after linkage analysis pointed to the two genes which were already known to cause autosomal recessive deafness.[10–12] Linkage analysis followed by positional cloning and sequencing of candidate genes further led to identification of *GJB3*, *DFNA5*, *COCH*, *POU4F3*, *TECTA*, *KCNQ4*, *TECTA*, *COL11A2* (see **Table 58.1** for full list).[13–19] Gene identification processes preceding the release of the human genome draft sequence in 2001[20] heavily relied on linkage analysis of large multigenerational families, bacterial artificial chromosome (BAC)-mediated cloning as well as singling out of candidate genes based on previous knowledge of gene function, mouse models or expression studies. In cases where no family members other than the proband were available, making linkage analysis impossible, a candidate gene approach was pursued (see **Box 58.1**). Examples of gene identification using the candidate gene approach are *GJB6*, *CRYM* and *MYH14* genes, which were selected as candidate genes based on expression in the cochlea and vestibule, and data from existing mouse models coupled with the knowledge that genes from the same family have been previously shown to cause deafness. However, due to extreme heterogeneity of SNHL, sequencing of candidate genes in large groups of patients had a low yield, identifying deafness-causing variants in only 1/198 deaf families for *GJB6*, in 2/192 families for *CRYM* and in 4/300 families for *MYH14*.[21–23] While the release of the human genome draft sequence in 2001 made targeted sequencing of candidate genes more straightforward, this approach is heavily biased as it relies on *a priori* knowledge of gene function and is therefore unlikely to reveal a novel deafness-causing gene or a novel pathway.

Since completion of the human genome (accomplished by Sanger sequencing), a demand for faster and cheaper methods led to the development of high-throughput sequencing called next generation sequencing (NGS) or massive parallel sequencing (MPS). On NGS platforms, millions of DNA fragments are sequenced simultaneously, enabling sequencing of the entire genome in a day.[24] This led to the development of the whole exome and genome sequencing techniques which have been successfully implemented in gene identification studies (see **Box 58.1**).[25] Exome sequencing is a robust, unbiased approach in which all protein-coding parts of the genome are amplified, sequenced and analyzed. Loci previously linked to AD deafness in families, containing hundreds of genes, could now be rapidly sequenced. Additionally, small families in whom linkage analysis was not feasible, could now be screened using whole exome sequencing (WES). The technique transformed genetic analysis and was soon applied in AD SNHL studies. Zheng et al. used a combination of linkage analysis and WES (with the analysis

TABLE 58.1 Autosomal dominant genes causing non-syndromic hearing loss (adapted from Hereditary Hearing Loss)[1]

Locus	Gene	Gene function	Onset (years)	Pattern of hearing loss	Reference(s)
DFNA1	*DIAPH*	Profilin ligand and target of Rho that regulates polymerization of actin, the major component of the cytoskeleton of hair cells of the inner ear	Postlingual (10)*	Low-frequency, rapidly progressive	8
DFNA2A	*KCNQ4*	Potassium channel; regulation of electrical signalling and the ionic composition of biological fluids	Postlingual (10–30)	Higher frequencies more affected, progressive	18
DFNA2B	*GJB3***	Gap junction protein, connexin 31; building blocks of GAP junctions; mediate diffusion of ions and metabolites between the cytoplasm of adjacent cells	Postlingual (20–40)	Higher frequencies more affected, progressive (one family described)	14
DFNA3A	*GJB2***	Gap junction protein, connexin 26; building blocks of GAP junctions; mediate diffusion of ions and metabolites between the cytoplasm of adjacent cells	Postlingual (6–20)	Higher frequencies more affected, or flat	12
DFNA3B	*GJB6**	Gap junction protein, connexin 30; building blocks of GAP junctions ; mediate diffusion of ions and metabolites between the cytoplasm of adjacent cells	Prelingual (age not mentioned)	High-frequency, progressive (one family described)	21
DFNA4	*MYH14***	Non-muscle myosin heavy chain IIC; ATP-dependent molecular motor which interacts with cytoskeletal actin	Postlingual (1st or 2nd decade)	Higher frequencies more affected, or flat	23
DFNA4B	*CEACAM16*	Carcinoembryonic antigen-related cell adhesion molecule 16 (CEACAM16) is an adhesion protein	Postlingual (early adolescence)	Higher frequencies more affected, or flat	26
DFNA5	*DFNA5*	*DFNA5* (*ICERE-1*); function unknown; it might be involved in apoptosis	Postlingual (5–50)*	Higher frequencies more affected, progressive	13
DFNA6/ 14/38	*WFS1*	Wolframin; transmembrane protein	Prelingual (5–15)	Low-frequency, gradually progressive	37, 38
DFNA8/12	*TECTA*	Alpha tectorin; structural component of tectorial membrane	Prelingual	Mid-frequency or high-frequency	17
DFNA9	*COCH*	Cochlin; extracellular matrix protein	Postlingual (16–52)	Higher frequencies more affected, gradually progressive	15
DFNA10	*EYA4*	Eye absent 4; transcriptional activator that interacts with members of other protein families to regulate early developmental event	Postlingual (20–60)	Flat, gradually progressive	39, 40
DFNA11	*MYO7A*	Myosin 7A; motor molecules that move along actin filaments	Postlingual* (before12)	Higher frequencies more affected, or flat, gradually progressive	10
DFNA13	*COL11A2*	Collagen, type XI, alpha-2; its association with type II collagen, which is known to be present in the tectorial membrane, led us to hypothesize that type XI collagen is essential for appropriate spacing of type II collagen within this structure	Postlingual (20–40)	Mid-frequency or flat, slowly progressive	19
DFNA15	*POU4F3*	Transcription facctor	Postlingual (18–30)	Higher frequencies more affected, progressive	16

(*Continued*)

TABLE 58.1 (*Continued*) Autosomal dominant genes causing non-syndromic hearing loss (adapted from Hereditary Hearing Loss)[1]

Locus	Gene	Gene function	Onset (years)	Pattern of hearing loss	Reference(s)
DFNA17	*MYH9*	Myosin heavy chain 9; non-muscle-myosin heavy-chain gene; localizes in the organ of Corti, the subcentral region of the spiral ligament, and the Reissner's membrane; contributes to cytoarchitecture	Postlingual (10)	Higher frequencies more affected, progressive	41
DFNA20/26	*ACTG1*	γ-actin gene; predominant actin isoform in the auditory hair cell; protein of the cytoskeleton	Postlingual* (7–30)	High-frequency, gently sloping, progressive	42, 43
DFNA22	*MYO6*	Myosin 6; unconventional motor molecule	Postlingual* (8–10)	Higher frequencies more affected, or flat, progressive	44
DFNA23	*SIX1***	Members of the SIX gene family encode proteins that are characterized by a divergent DNA-binding homeodomain and an upstream SIX domain, which may be involved both in determining DNA-binding specificity and in mediating protein–protein interactions	Prelingual (1–20)	High-frequency, sloping (one family)	45
DFNA25	*SLC17A8*	Vesicular glutamate transporter-3 (VGLUT3); VGLUT3 is essential for auditory coding at the IHC synapse	Postlingual (20 and older)	High-frequency, sloping, progressive	46
DFNA28	*GRHL2*	Grainyhead-like transcription factor	Postlingual (7 and older)	Flat, gently downsloping	47
DFNA36	*TMC1*	Transmembrane cochlear-expressed protein 1	Postlingual* (5–10)	High-frequency, rapidly progressive	48
DFNA39	*DSPP***	Dentin sialophosphoprotein	Postlingual (20–30)	High-frequency, progressive	49
DFNA41	*P2RX2*	Encodes the P2X2 receptor; in the inner ear, P2X2 receptors are thought to regulate sound transduction and auditory neurotransmission	Postlingual* (2nd decade)	Gently downsloping or flat, progressive	27
DFNA44	*CCDC50*	Encodes Ymer, an effector of epidermal growth factor (EGF)-mediated cell signalling that is ubiquitously expressed in different organs and has been suggested to inhibit downregulation of the EGF receptor	Postlingual (6–10)	Low- and mid-frequency, progressive (one family)	50
DFNA50	*MIRN96*	MicroRNAs (miRNAs) bind to complementary sites in their target mRNAs to mediate post-transcriptional repression, with the specificity of target recognition being crucially dependent on the miRNA seed region	Postlingual (12 onwards)	Flat, progressive	33
DFNA51	*TJP2 FAM189A2*	Tight junction protein; it is suggested that TJP2- and GSK-3β-mediate increase susceptibility to apoptosis of cells of the inner ear	Postlingual (4th decade)	High-frequency, progressive	31
DFNA56	*TNC*	Tenascin C; a member of the extracellular matrix (ECM); it is present in the basilar membrane (BM) and the osseous spiral lamina of the cochlea; it plays an important role in cochlear development	Postlingual (8–30	Low-frequency, ascending, progressive	28

(*Continued*)

TABLE 58.1 (*Continued*) Autosomal dominant genes causing non-syndromic hearing loss (adapted from Hereditary Hearing Loss)[1]

Locus	Gene	Gene function	Onset (years)	Pattern of hearing loss	Reference(s)
DFNA64	*SMAC/DIABLO*	Mitochondrial proapoptotic protein that is released from mitochondria during apoptosis and counters the inhibitory activities of inhibitor of apoptosis proteins	Postlingual (12–30)	Flat, progressive	51
DFNA65	*TBC1D24*	TBC1 domain family, member 24; GTPase-activating protein expressed in the cochlea;	Postlingual (3rd decade)	Gently downsloping, progressive	29, 52
DFNA66	*CD164*	Transmembrane sialomucin involved in cell migration and adhesion	Prelingual and postlingual (0–20)	Flat or mid-frequency, stable or progressive	53
DFNA67	*OSBPL2*	Oxysterol binding protein-like 2; possibly plays a role for the maintenance of hair cells' cytoskeleton	Postlingual* (10–30; possibly as early as 2)	Mild to profound, steeply sloping	30, 54
	HOMER2	Possibly has a role in cytoplasmic Ca^{2+} control	Postlingual* (*1st decade)	High-frequency, progressive	56
	CRYM	Mu-crystallin (CRYM; also known as 'NADP-regulated thyroid hormone-binding protein')	Prelingual (19 months)	Downsloping, progressive	22
DFNA70	*MCM2*	Nuclear protein important in cell cycle (onset of DNA replication and cell division)	Postlingual (earliest 13 years)	Mild to profound, slowly progressive, involving high frequencies or all frequencies	55
AUNA1	*DIAPH3*	Diaphanous-related formin 3; these proteins remodel the cytoskeleton by nucleating and elongating non-branched actin filaments, and they can also bind and stabilize microtubules	Postlingual (average 18.6)	Auditory neuropathy, moderate to profound, high-frequency, progressive (one family)	57
	KITLG	KIT receptor ligand	Prelingual	Unilateral or asymmetrical, Mild to profound	56
	DMXL2	Alpha subunit of rabconnectin protein complex that concentrates on synaptic vesicles	Postlingual (onset 2nd decade)	Mild to moderate, slowly progressive to severe to profound by 6th decade	22

*Onset can be in first decade; ** may also cause syndromic features in some families; reported in only one family.

BOX 58.1 Glossary of terms

Hereditary Hearing Loss website:[1] an important resource providing up-to-date information on mapped genes and loci associated with deafness as well as expression patterns of deafness genes
Linkage analysis: testing of DNA sequence variants that are near or within a gene of interest to track within a family the inheritance of a disease-causing mutation in a given gene; a prerequisite for linkage analysis is availability of a clinically well-characterized multigenerational family
Bacterial artificial chromosome (BAC): an engineered DNA molecule used to clone DNA sequences in bacterial cells (for example *Escherichia coli*)
Candidate gene approach: genetic analysis focused on the selection of genes that have previously been related to the disease in some way; it requires *a priori* knowledge of the gene's function, expression profile or pathway
Single nucleotide variant (SNV): a variation occurring in the genome when a single nucleotide in the genome is altered
Copy number variation (CNV): when the number of copies of a particular gene varies from one individual to the next
Whole exome sequencing (WES): a technique for sequencing all the protein-coding genes in the genome (known as the exome)
Whole genome sequencing (WGS): a technique that determines the complete genome sequence of an organism
Genetic heterogeneity: a term describing a single phenotype being caused by multiple genes and/or different variants in the same gene

focusing on the linked DFNA4 interval) to successfully identify a novel deafness gene *CEACAM16*.[26] Using similar approaches multiple novel genes followed: *P2RX2*, *TNC*, *TBC1D24*, *OSPBL2*.[27–30] However, in an Israeli family in whom AD deafness was linked to chromosome 9p13.3–q21.13, sequencing of all 121 genes in the linked region did not identify any potentially pathogenic variants because sequencing at that time was not able to detect quantitative variants such as duplications and heterozygous deletions. Using array comparative genomic

hybridization (a technique that can detect duplications and deletions in the genome), the cause of AD SNHL was found to be an inverted duplication spanning the *TJP* gene locus,[31] although new NGS technologies now offer sensitive tools for detection of genomic variants such as copy number variations (CNVs).[32]

Adding to the complexity of the molecular basis of SNHL is the discovery of a mutation in miR-96, a gene encoding micro RNA (miRNA) that binds to complementary sites in target mRNAs and mediates post-transcriptional repression.[33] It is therefore possible that other miRNAs may have a role in hearing and hearing loss. See **Table 58.1** for all non-syndromic AD SNHL genes.

Despite tremendous progress in sequencing techniques as well as exome sequencing becoming more and more cost-effective, the sequence produced by NGS is still imperfect. Certain regions are not well covered, particularly the 5′ regions of genes, or poorly assembled due to repetitive regions, and similarities in sequences of genes from the same family may be difficult to analyze. Therefore, although the process of sequencing the whole exome or genome is relatively fast, the downstream analysis requires a lot of time and expertise from bioinformaticians, genome analysts, molecular biologists and clinicians. While techniques will gradually improve and we will be able to produce an accurate sequence of the whole genome, the main challenge in the future will be interpretation of the variants, from single nucleotide variants (SNVs), insertions/deletion to CNVs. The whole exome sequence of one individual on average identifies between 70 000 and 90 000 SNVs; of them just over 21 000 SNVs are detected in coding regions.[34] The present and future challenge is how to reliably single out the disease-causing variant, which is especially difficult for novel genes with unclear functions. Current diagnostic yield with whole exome sequence technology is only ~25–30%; however, this is still higher than the diagnostic yield of other genomic assays such as karyotyping (<5%) and array comparative genomic hybridization (~15–20%). Currently, variants that cause Mendelian phenotypes have been identified in ~2937 human genes of the approximately 19 000 protein-coding genes predicted to exist in the human genome.[35] In the coming years, a huge number of additional variations in the genome will be produced by NGS and integration of this data will lead to better understanding of individual gene functions and identification of pathways leading to disease, which will result in improved diagnostic yield.

FUNCTIONS OF GENES INVOLVED IN NON-SYNDROMIC SNHL

Non-syndromic AD SNHL genes encode a variety of proteins essential for inner-ear function. Broadly, the non-syndromic AD deafness-coding genes with known function can be divided into four categories (adapted from Hilgert).[36]

1. Hair bundle morphogenesis (genes important for the development, structure and function of stereocilia in the hair cells):
   - proteins of the cytoskeleton: *ACTG1*
   - motor proteins: *MYO6*, *MYO7A*, *MYH9*.
2. Ion homeostasis (genes important in the recycling and transport of ions within the fluid-filled cochlea, often requiring energy):
   - connexins: *GJB2*, *GJB3*, *GJB6*
   - ion channels: *KCNQ4*, *SLC26A4*, *WFS1*.
3. Transcription factors (genes encoding proteins which are important for controlling expression of other genes, particularly during development): *EYA4*, *GRHL2*, *POU4F3*.
4. Extracellular matrix proteins (specialized structural molecules): *TECTA*, *COCH*, *COL11A2*.

CONCLUSIONS

Variants in 38 genes are currently known to cause non-syndromic AD SNHL; 21 loci are still awaiting gene identification together with numerous novel genes yet to be discovered. New sequencing technologies capable of sequencing the whole genome in a cost-effective manner are now, albeit still imperfect, in full flow and will lead to molecular diagnosis in many non-syndromic AD SNHL affected families. Due to high genetic heterogeneity, non-syndromic AD SNHL causing variants are individually rare or private, but collectively they play an important role in the pathogenesis of hearing loss.

Molecular genetic diagnosis is of critical importance for management of deafness, since it enables early and accurate clinical diagnosis, better prediction of the course of disease, early intervention essential for language and cognitive development, genetic counselling, as well as potential development of molecular treatments. As the whole genome sequence analysis is gradually making its way from research towards the diagnostic domain, clinicians must be aware of the genetic component of deafness and of the genetic tests and techniques available for molecular diagnosis.

BEST CLINICAL PRACTICE

- ✓ Always take a thorough history and ask about factors which may suggest a syndrome. History should include a 3 generation family history (or more if there is more significant information).
- ✓ Examine the patient to exclude obvious syndrome diagnoses (skin, pigmentation, facial appearance, general appearance).
- ✓ Request information (audiometry details) on other affected family members to look for similarity, or audiometric patterns in younger family members before progression.
- ✓ Investigate with visual acuity and dilated fundoscopy.
- ✓ Biochemical, immune and genetic testing where indicated by history/family history.

FUTURE RESEARCH

- Although the use of constantly evolving hearing loss panels has improved the molecular diagnosis of highly heterogeneous AD non-syndromic SNHL, the diagnostic yield is still limited as many SNHL genes are yet to be discovered.
- The identification of novel hearing loss causing genes has increased exponentially in the past few years; we are now faced with the challenge of accurate and consistent interpretation of novel variants and verification of these using functional studies.
- There is a need for clear guidelines and levels of evidence on inclusion of novel genes in hearing loss gene panels.
- Adequate guidelines and procedures should be set for genetic testing of children with hearing loss identified through newborn hearing screening to enable timely and sensitive clinical and molecular diagnosis.
- Affordable and timely molecular diagnosis will be important to ensure that novel genetic treatments can be offered to appropriate patients; novel therapies for dominant and recessive forms of hearing loss have proven successful in mice, and clinical trials in humans requires identification of suitable participants.[60–63]
- Finally, the rapidly changing landscape of SNHL genetic testing requires appropriate levels of genomic focused educational programs for genetic counsellors and clinicians who are the key to translation of the latest research findings into clinics.

KEY POINTS

- AD SNHL is characterized by marked genetic heterogeneity with most variants being private (e.g. disease-causing in a single family).
- It is usually, but not exclusively, postlingual and progressive.
- Linkage analysis coupled with whole genome/exome sequence analysis is a powerful tool enabling identification of novel pathogenic variants and discovery of novel genes and pathways in AD SNHL.
- Molecular diagnosis enables us to predict the progress of deafness and has important implications for early diagnosis, management of deafness and accurate genetic counselling for families.

CHAPTER 59

OTOTOXICITY

Andrew Forge

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: ototoxicity, inner ear, hearing impairment, hearing loss, deafness, cochlea, aminoglycoside (and individual aminoglycoside), *cis*-platinum, salicylate, quinine, (loop) diuretics (or individual diuretics) and organic/industrial solvents (or individual solvents).

INTRODUCTION

The term ototoxicity is used to refer to the process by which a number of therapeutically useful drugs, certain environmental agents such as industrial solvents, and bacterial toxins cause damage to the peripheral end-organs of hearing and balance. This definition excludes agents which cause hearing impairment or balance dysfunction through primary action on the respective neural pathways and centres.

MODES OF ENTRY OF OTOTOXIC AGENTS TO THE INNER EAR

The complete enclosure of the inner ear structures within the temporal bone means that they are not exposed directly to potentially damaging environmental agents. Access to the perilymphatic compartment of the inner ear via the cochlear aqueduct from the cerebrospinal fluid (CSF) is possible and this may be a route of entry for bacterial toxins, such as those associated with meningitis. However, the cochlear aqueduct is not patent in many individuals and tends to close as an individual ages.[1] Access to perilymph is also possible from the middle ear cavity via the membrane covering the round window at the base of the cochlea and that filling the oval window over the vestibule. The permeability properties that determine what will and will not cross these membranes into the inner ear are not known. After entry into the perilymphatic compartment of the inner ear from the middle ear an agent would have access to the basal end of the cochlea and to the vestibular system. Subsequent drug distribution is somewhat complicated, influenced by a relatively slow diffusion rate away from the site of entry and localized clearance rates (e.g. along the cochlear aqueduct).[2–5] Nevertheless, if entry to perilymph is gained, because the basilar membrane is freely permeable, then there is direct access to the lateral membranes of the hair cells, to their synaptic regions and to the nerve fibres.

Potentially, bacterial toxins associated with middle ear infections as well as ototoxic drugs may enter the inner ear across the round window. There is evidence that some children who have had otitis media with effusion (OME) may develop extended high-frequency hearing loss, i.e. with a normal audiogram down to about 8 kHz but with significant threshold shifts at higher frequencies.[6, 7] This has been linked to what has become known as 'listening difficulties' that may underlie behavioural problems.[8] Temporal bones from patients who have had OME show loss of both inner and outer hair cells in the most basal regions of the cochlea[9, 10] and it is thought that this is caused by bacterial endotoxins released in the middle ear effusion crossing the round window membrane to access the basal coils of the cochlea. Ototoxic drugs may also reach the perilymph from the middle ear. In particular, the entry of aminoglycoside antibiotics applied to the middle ear cavity across the round and oval window membranes into the perilymphatic spaces of the inner ear is used as a clinical procedure to ablate hair cells in the vestibular system in cases of severe balance dysfunction

such as that resulting from unilateral Ménière's disease.[11] This approach is also a potential means for introducing therapeutics.[12]

Predominantly, however, ototoxic agents reach the inner ear through the blood supply but there are restrictions on the entry of agents to the fluids of the inner ear. Perilymph is not simply an ultrafiltrate of blood plasma, nor does it derive from CSF. The composition of perilymph is different both from CSF and from blood plasma and the composition of perilymph in scala vestibuli differs from that in scala tympani.[13] This indicates that perilymph is produced and circulated locally and that there is a so-called 'blood–perilymph barrier'. Glucose entry, for example, requires facilitated diffusion through glucose transporters.[13, 14] This may limit access of potentially damaging agents to the perilymphatic compartment. However, relatively little is known about the characteristics of this blood–perilymph barrier and how substances can cross it. Entry to endolymph in the internal compartment of the inner ear is even more restricted and endolymph composition is tightly controlled.[13] The principal boundaries between endolymph and perilymph, formed by selectively permeable membranes and tight junctions between adjacent cells, in the cochlea appear to be Reissner's membrane, at the level of the basal cells in the stria vascularis, and the network formed by the apical surfaces of the hair cells and adjacent supporting cells in the organ of Corti at the reticular lamina. In the vestibular system they are at the level of the tight junctions between hair and supporting cells in the sensory patches and between the epithelial cells that surround the endolymphatic, luminal spaces including the dark cells of the utricle and semicircular canals, the roofs of the utricle and saccule and the semicircular canals themselves. If an agent were to penetrate these boundaries, it would have access to the hair-bearing (apical) ends of the hair cells.

EFFECTS AND ACTIONS OF OTOTOXIC DRUGS

A diverse range of therapeutically useful drugs and some environmental agents have been reported to be ototoxic (Table 59.1). For some of these chemicals the evidence for ototoxicity is limited (see below); sometimes it derives from individual case reports, where other confounding factors may have contributed to the observed effect, and there are no confirmatory experimental studies in animals. The occurrence and extent of ototoxicity is to some extent dependent upon the dosing regime (or exposure conditions) but are compounded by the status of the patient receiving the drug and multiple drug regimes. Stress produced by infection may increase sensitivity as may malnourishment; the effects of aminoglycosides are more pronounced in nutritionally deprived animals.[15, 16] Drug interactions can also result in much greater damage than would be expected from single drug regimes. A number of ototoxic agents, including aminoglycosides, polypeptide antibiotics and anti-neoplastics, are also nephrotoxic so that possible damage to the kidney may result in reduced drug clearance and higher serum levels potentially increasing the risk to the inner ear. In addition, certain genetic factors may predispose to ototoxin-related damage (see below).[17] Individuals under similar conditions and with similar drug-dosing regimes differ in their sensitivity to ototoxic side effects. For these reasons it is not always possible to predict a likely effect following administration of a potentially ototoxic drug.

In Table 59.1 ototoxic drugs have been classified based on their therapeutic use, but perhaps a more useful classification derives from the sites and modes of action, which also provides a basis for illustrating the selective action of these different agents upon the inner ear. On this basis, ototoxins can be divided into three broad groups. The

TABLE 59.1 Compounds known to be or implicated in ototoxicity

Classification	Compounds
Aminoglycoside antibiotics	Amikacin, dibekacin, dihydrostreptomycin, framycetin, gentamicin, kanamycin, neomycin, netilmicin, ribostamycin, sisomicin, streptomycin, tobramycin
Macrolide antibiotics	Erythromycin, azithromycin, clarithromycin
Other antibiotics	Ampicillin, capreomycin, chloramphenicol, colistin (polymyxin E), minocycline, polymyxin B, rifampicin, vancomycin, viomycin
Antitumour agents	**Cisplatin (*cis*-platinum)** carboplatin Antinomycin, bleomycin, nitrogen mustards (e.g. mustine), misonidazole
Anti-inflammatory agents	**Salicylate** (aspirin) Fenoprofen, ibuprofen, indomethacin, naproxen, phenylbutazone,
Antimalarials	**Quinine**, **chloroquine**
Loop diuretics	Bumetanide, ethacrynic acid, frusemide (furosemide), piretanide
Iron chelators	Desferrioxamine
Beta-blockers	Practolol, propranolol
Contraceptives	Medroxyprogesterone
Industrial chemicals	**Trimethyltin**, **toluene**, **trichloroethylene**, **styrene**, **xylene**

first, exemplified by the 'loop' diuretics and erythromycin, have acute effects in the stria vascularis resulting in temporary hearing loss (temporary 'threshold shift' (TTS)). Agents in the second group, which includes salicylate and quinine, predominantly produce temporary impairment of hair cell function (TTS), often accompanied by tinnitus. These symptoms are completely relieved upon withdrawal of the drug. The third, and most significant, group of ototoxic agents cause death of the hair cells and permanent hearing loss (permanent threshold shifts (PTS)) and vestibular dysfunction. Aminoglycoside antibiotics and cisplatin (*cis*-platinum), as well as organic solvents, fall into this category. In mammals, the functional deficits resulting from the hair cell losses caused by these agents are permanent because, unlike the sensory epithelia in the inner ear in birds and other non-mammalian vertebrates,[18–21] the organ of Corti does not spontaneously regenerate hair cells to replace those lost, although the mammalian vestibular organs possess some capacity to regenerate hair cells.[22–27]

Agents affecting the ion-transporting epithelia

Those agents whose primary site of action is on the ion-transporting epithelia, the stria vascularis (SV) in the cochlea and the vestibular dark cells, adversely affect endolymph composition and, in the case of the SV, the endocochlear potential (EP). Such agents, including the loop diuretics, generally cause acute, completely reversible affects after a single drug administration,[28] although some cases of permanent deafness have been attributed to diuretic.[29] The SV has one the highest rates of oxidative metabolism in the body,[13] with oxygen delivered from the intraepithelial blood supply so agents that induce anoxia or ischaemia will affect strial activity. Aminoglycoside antibiotics and cisplatin[30, 31] may induce permanent strial pathologies although this does not necessarily correlate with effects on EP.

All **loop diuretics**, that is those diuretics whose principal site of action is in the ascending limb of the loop of Henle, including **ethacrynic (etacrynic) acid**, **furosemide (frusemide)**, **bumetanide** and **piretanide**, produce a transient hearing loss across most of the frequency range. This usually occurs following intravenous administration of large doses. The effects are rapid in onset, within minutes or hours, and persist for some hours but are usually completely resolved within a day if the drug is discontinued. Repeated diuretic administration does not appear to cause permanent damage to the inner ear. However, a single dose of diuretic when administered closely with a single dose of an ototoxin such as aminoglycoside or cisplatin which has the potential to cause hair cell loss only after chronic repeated treatment, results in rapid devastatingly extensive hearing loss and hair cell death (see below).

Histological studies of the temporal bones from patients who have died while on diuretic treatment[32, 33] have shown extensive oedema and swelling of the SV. Experimental studies in animals have confirmed the SV as the principle site of action and that diuretics produce a rapid, reversible decline in EP, falling from the usual +80 mV to negative values as low as around -40 mV, the K^+ diffusion potential.[34, 35] The rate of decline and the level of suppression are dependent upon the dose of drug administered.[28] The EP then recovers over a period of a few hours but takes several hours to return to normal levels after a single administration. In parallel with the decline in EP an extensive oedema occurs; the extracellular spaces become grossly enlarged (**Figure 59.1**) and strial thickness can almost double. This oedema is also reversible, resolving within about 2–4 hours, prior to complete recovery of EP.[35] The decline in EP correlates with threshold shifts in sound-evoked responses[36] and depression of otoacoustic emissions, a finding that provides evidence that EP is the power that drives the active mechanical responses of the organ of Corti in response to sound.[37] This illustrates the importance of EP maintenance to the cochlear

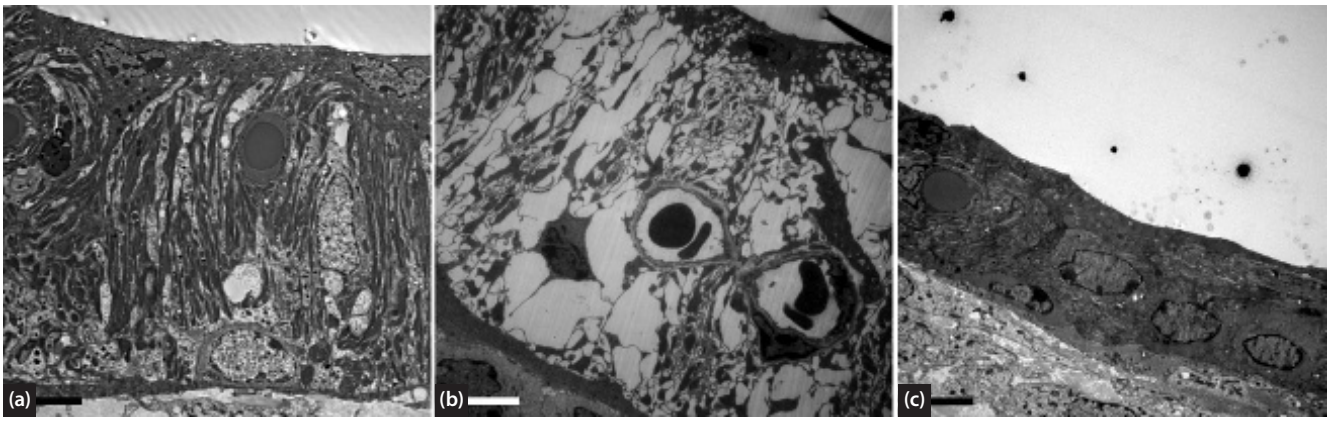

Figure 59.1 Effects of ototoxins on the stria vascularis (SV). Panels (a), (b) and (c) are all at the same magnification. (a) Cross section of the normal SV. **(b)** Effects of diuretic on the SV. There is significant oedema – enlarged extracellular spaces that are confined within the body of the tissue – and an increase in depth. The relative positioning of all the cellular elements of which the SV is composed is unaltered. **(c)** Atrophy of SV 12 weeks following chronic aminoglycoside treatment of the animal. The depth of the SV is significantly reduced. Scale bars on all panels: 5 µm.

amplification mechanism and why damage to the SV will cause hearing impairment.

The rapid onset of their effects suggests that diuretics gain direct access to their site of action through entry from the strial vasculature into the extracellular spaces of the SV and thus to the plasma membranes of all strial cell types including the basolateral membranes of the marginal cells. The development of oedema suggests that diuretics inhibit the ion-transporting processes: ions accumulating in the extracellular spaces would be confined by the tight junction sealing between basal cells, those between marginal cells and those between capillary endothelial cells, resulting in osmotic uptake of fluid. In the kidney, diuretics act on a Na/K/Cl cotransporter. The same cotransporter, NKCC1, localizes to the basolateral membrane both of vestibular dark cells and of marginal cell of the SV[38] and has been shown to be a target of the diuretics in the SV and vestibular dark cells.[39, 40] It is currently thought, therefore, that the diuretics reversibly inhibit the action of the electroneutral NKCC1 cotransporter, in the basolateral membranes of strial marginal cells and vestibular dark cells leading to inhibition of ion transport. In the cochlea, the generation of EP is thereby inhibited and along its entire length such that the consequent hearing impairment resulting from reduction of cochlear amplification is across almost the entire frequency range. (There is no equivalent of EP in the vestibular system so the effects are less pronounced.)

Na^+/K^+-ATPase is also present at high concentration on the basolateral membrane of marginal cells.[41, 42] Inhibition of this might have a similar effect as inhibition of the cotransporter. **Potassium cyanide**, along with its other actions in the body, causes TTS with a symptomatology similar to that of loop diuretics, thought to result from inhibition of marginal cell Na^+/K^+-ATPase.[43] **Macrolide antibiotics** such as **erythromycin** also produce effects similar to those of diuretics: generally transient threshold shifts[44] of the order of about 50 dB maximum across all frequencies[45] following high-dose intravenous administration; rapid, dose-dependent decline in EP in experimental animals;[46] an action on the basolateral side of the marginal cells affecting ion transport by these cells shown in isolated tissues maintained *in vitro*;[47] and, consistent with inhibition of ion transport in the SV, sections of temporal bone from patients who have died during a course of erythromycin therapy have shown extensive oedema of the SV.[45] However, the precise site of action of the macrolides in the SV has not yet been identified.

Agents causing reversible effects on hair cells

Salicylates and **quinine** cause TTSs across most of the detectable frequency range, and tinnitus. Dizziness is reported as a symptom of the use of either of these drugs, but there have been no experimental studies of their possible effects on the vestibular system. The ototoxic effects of these agents are generally reversible when treatment ceases; salicylates are rarely associated with permanent hearing loss.[48] Although it has been reported that excessive doses of quinine or chloroquine may result in permanent deafness,[49] quinine-induced ototoxicity is also usually completely reversible both in healthy volunteers and in patients with malaria.[50]

Salicylates produce threshold shifts across all frequencies simultaneously, indicating effects along the entire cochlear spiral. The shifts are usually no more than 40–60 dB and almost equal across the frequency range or somewhat greater at higher frequencies. These symptoms are completely reversible within 1–3 days following withdrawal of the drug and usually develop only at the high dosage levels used in treating rheumatoid arthritis, 2–5 g/day.[48] Salicylate enters perilymph rapidly after systemic administration, peak levels in perilymph being reached 1–2 hours after injection. The concentration in perilymph is linearly related to the serum concentration,[51, 52] and deterioration of auditory and neural thresholds is linearly related to perilymph salicylate concentration. Thus, the degree of threshold shift is quantitatively related to salicylate plasma concentration. These findings indicate that salicylate penetrates the blood–perilymph barrier readily.

Experimental studies in animals have shown that salicylate causes threshold shifts only at low stimulus intensities; responses to stimuli above about 60 dB appear to be unaffected. The tuning of responses of individual nerves to their characteristic frequency also is lost.[53, 54] In addition, otoacoustic emissions, are reversibly suppressed in humans[55, 56] and animals.[53, 54] These findings suggest effects of salicylate on OHCs and inhibition of the activity that produces signal amplification in the cochlea. EP is unaffected following salicylate administration[54, 57] and effects of salicylates on cochlear vasculature and thereby activity of the SV in generating EP are not considered to be a significant factor in their ototoxicity. Rather, OHCs appear to be the primary target of salicylate following its entry into the perilymph and access to a site of action on the basolateral membrane. Salicylates inhibit electrically driven motile responses of isolated OHCs.[58, 59] It is these responses that *in vivo* are thought to underlie the cochlear amplification mechanism.[60, 61] Investigation of basilar membrane mechanical responses to sound stimulation during salicylate perfusion *in vivo*[62] have confirmed direct effects on OHCs that adversely influence their active responses and thus, auditory sensitivity. The fast motile responses of OHC are driven by the 'motor' protein prestin, which is unique to OHC and is packed into its basolateral plasma membrane.[63] There is evidence that reversible interactions with anions produce conformational changes in prestin that result in the reversible electrically driven changes in OHC length.[64] Salicylate, an anion, appears able to interact with prestin and block this electromotility.[64]

Likewise, **quinine**, at therapeutic doses of 200–300 mg per day, can cause threshold shifts at all frequencies, effects which are usually entirely reversible, disappearing upon withdrawal of the drug.[50] As with salicylate, quinine enters perilymph rapidly,[65] reaching perilymph

concentrations directly related to serum concentrations and direct perfusion of quinine into the perilymphatic space revealed threshold shifts in a number of sound-evoked responses the magnitude of which are related to perilymphatic concentration of the drug between 10 µM and 100 µM.[66] However, unlike salicylate, quinine affects cochlear responses across all stimulus intensities, not just the lower ones, indicating a site(s) of action different from salicylate and not confined to the cochlear amplifier. It has been reported that at the lowest concentrations at which effects can be detected, around 0.05 mM, quinine does not affect OHC responses, such as OAEs, but produces a reversible elevation in threshold for the compound action potential (CAP), which derives from stimulation of inner hair cells (IHCs), without affecting neural tuning.[67, 68] Tuning derives from the activity of OHCs that produces amplification. This suggests that the initial site of action of quinine may be on the IHC, synaptic transmission at the base of IHCs, or/and upon the spiral ganglion neurons themselves, with OHCs affected only at higher concentrations. An effect of quinine at the hair cell synapse could also explain vertigo as the ready entry of the drug into perilymph would enable it to gain access to the basolateral membranes of vestibular hair cells. It has been found that quinine and its derivatives such as chloroquinine block nicotinic acetylcholine receptors (nAChR) composed of α9α10 subunits,[69] which are the predominant acetylcholine receptor subunit composition of hair cells in both chicks and mammals.[70, 71] Acetylcholine is the predominant efferent neurotransmitter in the cochlea. Efferent fibres synapse with the afferent neurones of IHC just below the hair cell body and modulate the responses of those afferents to stimulation, and they synapse directly with OHC whose activity is regulated by the efferent system. Thus, the effects of quinine may result from its action at these efferent synapses.

The ototoxic effects of salicylate and quinine thus derive from an ability to cross the blood–perilymph barrier freely, illustrated by the rapid onset of responses, so they may become distributed throughout perilymph along the entire cochlea, indicated by effects across the entire frequency range, and consequently gaining access to the basolateral membranes of hair cells and to the neurons and their synapses with the hair cells. Since the particular activities of OHC in producing signal amplification are associated with specializations along the basolateral wall, these will become vulnerable, as with salicylate. The characteristics of the symptomatology of the hearing impairment produced by salicylate and quinine thus provide an immediate insight into the likely routes of entry and potential sites of action of the ototoxins.

Agents that cause permanent hearing loss and balance disorders

The third group of agents are those whose administration causes permanent hearing impairment and/or balance dysfunction as a result of death of the hair cells. The ototoxicity of most of these agents usually develops only after repeated systemic administration; a single systemic application does not generally affect hearing or balance.

AMINOGLYCOSIDE ANTIBIOTICS

The aminoglycoside antibiotics constitute the clinically most important group of ototoxic agents. They are toxic to hair cells in all inner ear sensory patches in all vertebrate classes as well as neuromasts of the lateral line systems of fish and aquatic amphibia. Indeed, the nematocyst cells in marine and aquatic invertebrates, which are mechanotransducing cells thought to be evolutionarily related to vertebrate hair cells, are also affected by aminoglycoside.[72] Although all aminoglycosides are potentially both cochleotoxic and vestibulotoxic, the different aminoglycosides exhibit differences in their toxic potential and organ preference. Assessment of the degree and time course of functional impairment following cochlear perfusion with different aminoglycosides[73] and analysis of the extent of damage to cultured explants of the murine organ of Corti directly exposed to different aminoglycosides[74] have established similar rank orders of cochleotoxic potency for different aminoglycosides. These have indicated that neomycin is the most toxic, gentamicin, kanamycin and tobramycin less so, and amikacin and netilmicin least toxic, but such differential toxicity may not apply in a clinical setting. Streptomycin and gentamicin are considered more vestibulotoxic than cochleotoxic to humans, whereas amikacin and neomycin are primarily cochleotoxic in the human inner ear. The reasons for such preferences are not known, but it is not related to any site-specific uptake mechanism or drug levels in the tissues.[75] There are also species differences in susceptibility to the different aminoglycosides of which dihydrostreptomycin provides the most striking example.[76, 77] In early clinical use dihydrostreptomycin proved to be markedly toxic to the human cochlea. However, in the macaque monkey treated with large doses of dihydrostreptomycin for a prolonged period, there was only a very modest shift in auditory threshold at the highest frequency tested, and less than 10% of the hair cells were absent at the basal end of the cochlea.[77] In contrast, the patas monkey was affected in a manner similar to humans and appeared to be the only laboratory animal whose cochlea was sensitive to the toxic action of dihydrostreptomycin.

The effects of aminoglycosides usually become manifest only after days or weeks of parenteral treatment. Single systemic administrations are not normally damaging to the inner ear, but topical application of a single dose of the drug to the middle ear cavity can almost immediately initiate the progressive damage observed after chronic systemic treatment.[24, 78] The severity of the effects increases progressively with time, continuing after drug administration has been stopped; insidiously, in some cases, hearing impairment may not even begin until after treatment has ceased. The initial effect in the cochlea is a hearing loss confined to the high frequencies,[79] indicating hair cell damage in the most basal region of the cochlea. The hearing loss then continues progressively to include

successively lower frequencies, indicating a spread of the damage to hair cells apicalwards along the organ of Corti spiral and involving frequencies in the human speech range and thus ultimately to cause a permanent communication disability. A bilateral loss of 20 dB at two or more adjacent test frequencies is accepted as a hearing impairment.[80] However, most clinical audiometry usually covers the frequency range only from about 8 kHz downwards, whereas in the average person the high-frequency limit is about 16–18 kHz, so that the initial ototoxic effects of the drug will be missed unless high-frequency audiometry is used. Vestibular damage from systemic aminoglycoside administration results in severe unsteadiness that becomes worse in the dark. Perception of unreal movement, usually elicited by head motion, can also occur. Objective clinical assessment is, however, difficult and limited.[80]

Location and nature of lesions

Aminoglycoside-induced hair cell death occurs in a distinct pattern. In the organ of Corti, in line with the pattern of hearing loss, hair cells in the basal (high-frequency) coil are affected first, damage spreading progressively apicalwards with time and with increasing dosage. Outer hair cells are more sensitive than inner hair cells (**Figure 59.2**). IHCs do not usually appear to die until all the OHCs in their immediate vicinity and may persist for months after there has been complete loss of all OHCs.[81] The delay before IHCs are affected may suggest that their loss is a secondary event that occurs as a consequence of OHC loss and unrelated to the initial ototoxic events.[81]

There is also significant progressive loss of spiral ganglion neurons, the afferent nerves that innervate hair cells. This appears to progress following death of IHCs[76, 82] and has been ascribed to a loss of the neurotrophic factors NT-3 and BDNF derived from the IHCs that are necessary for neuronal survival[83, 84] together with loss of continuing stimulation normally provided by IHC activity. Perfusion of neurotrophic factors into the cochlea following aminoglycoside administration has been shown to ameliorate loss of the auditory neurons.[85] This has been suggested as a means to preserve cochlear innervation to enhance the efficacy of cochlear implants.[86, 87] However, recent work on the effects of noise and ageing has indicated that loss of a subpopulation of afferent terminals from IHCs may precede any overt hair cell loss.[88] This may be the basis of some more subtle forms of hearing impairment, such as difficulties in detecting speech in noise, when auditory thresholds as recorded by routine testing procedures are unaffected. The loss of the terminals is thought to occur by excess release of the neurotransmitter glutamate from the IHCs at synapses with afferent terminals causing excitotoxic damage to the nerve. However, it is not yet known if this occurs with aminoglycoside-induced injury.

In the vestibular system aminoglycoside-induced hair cell loss is seen initially in the central regions of the epithelia, i.e. at the crests of the saddle-shaped cristae and across the 'striola' along the middle of utricular and saccular maculae. HC loss then spreads progressively towards the peripheries.[89] There is also differential susceptibility among the vestibular organs; in an individual subject, cristae show greater HC loss than the utricle which in turn

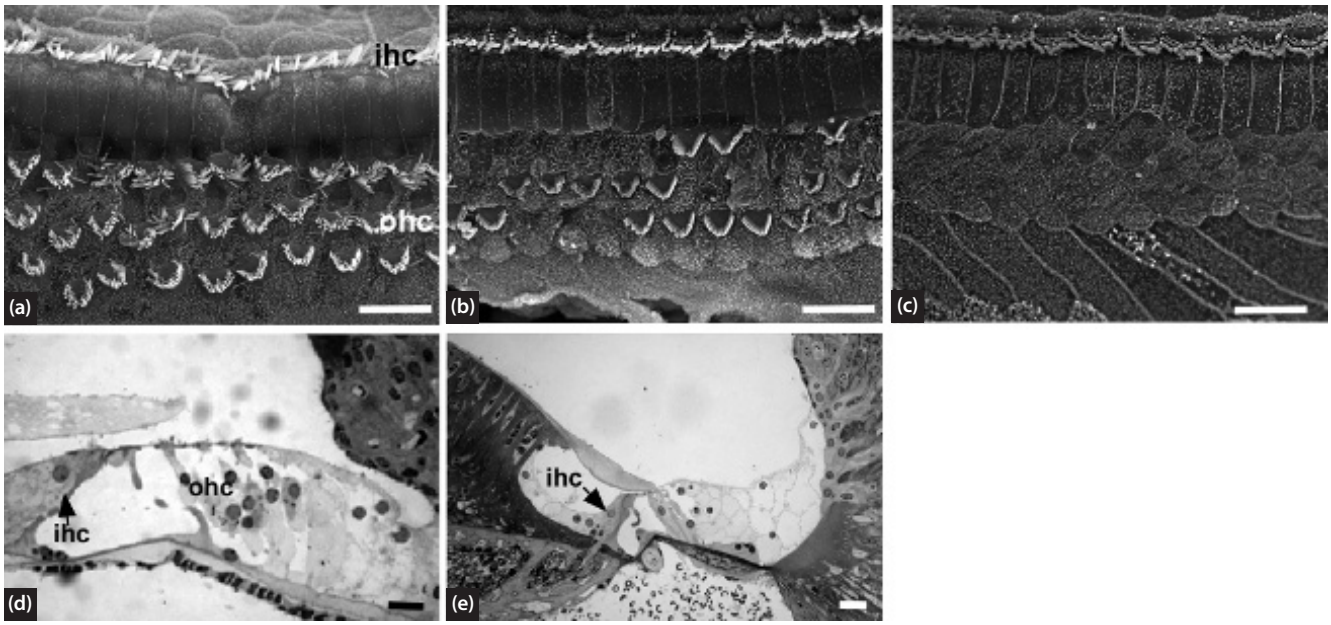

Figure 59.2 Effects of aminoglycoside in the organ of Corti. **(a,b,c)** Scanning electron microscopy of the apical surface of mouse organ of Corti in the apical coil: **(a)**, middle coil **(b)** and basal coil **(c)** after aminoglycoside treatment of animals. In the apical coil all inner hair cells (ihc) and almost all outer hair cells (ohc) are present. In the middle coil there is significant loss of ohc. In the basal coil, 6 weeks after the end of the treatment, all ohc are lost but almost all ihc are still present. **(d,e)** Sections of the organ of Corti of a mouse following chronic aminoglycoside treatment: **(d)** apical coil – all ohc as well as ihc are present; **(e)** basal coil – there are no ohc but ihc are present. Scale bars in all images: 10 µm.

shows more extensive damage than the saccule.[82] This differential susceptibility conforms to a differential uptake of aminoglycoside between the two hair cell types; immunohistochemistry has shown preferential uptake of gentamicin into the type 1 hair cells.[90] The type 1 hair cells predominate on those regions where damage is initiated and are thought to be more susceptible to aminoglycoside-induced damage than the type 2 vestibular hair cells.

The death of each hair cell is accompanied by expansion of the supporting cells around them to close the lesion and effect tissue repair (**Figure 59.2**).[27, 91–94] Supporting cells are not usually affected by aminoglycosides (or other ototoxins). Following the initial lesion closure by expansion of the supporting cells, reorganization of the sensory epithelium may continue for some time after hair cell loss and ultimately the crest of cells that normally constitutes the organ of Corti can become replaced by an apparently simple cuboidal-like epithelium across the basilar membrane.[95] In the organ of Corti lost hair cells are not replaced, but there is some evidence for regeneration of hair cells in the mammalian utricle,[23–26] including that of humans.[27] The extent to which this occurs is limited and only a proportion of the lost hair cells may be replaced by new ones.[24, 27] In birds and other non-mammalian vertebrates regeneration of hair cells is extensive and can lead to complete recovery of damaged sensory epithelia.[18, 21, 96] The replacement hair cells derive from the supporting cell population through initiation of cell division among the supporting cells and/or through direct non-mitotic transdifferentiation, or 'phenotypic conversion' of supporting cells into hair cells.[21, 22, 26, 97] Enhancing the phenotypic conversion mechanism is the basis of some attempts to develop therapies to induce hair cell regeneration in the mammalian inner ear.

Pharmacokinetics and mechanisms of toxicity

There is a linear relationship between serum concentration of aminoglycoside and the perilymph concentration,[2, 98] but aminoglycosides enter perilymph relatively slowly, the peak concentration after extravascular injection to guinea pigs occurring much later in perilymph (about 4 hours) than in serum (about 15–30 minutes). However, clearance from perilymph is delayed and the drug persists in the inner ear for some time. The half-life of aminoglycoside in the inner ear has been estimated as more than 30 days.[99] The peak level reached in perilymph after multiple dosing has been reported to be approximately 50–250 μM,[2, 99–101] but following systemic administration appears in greater amounts in the scala tympani of the apical turn than in the basal coil.[2] Aminoglycosides also enter endolymph, but only after a prolonged period following entry into perilymph. While this has been interpreted to suggest that aminoglycosides enter endolymph from perilymph,[99] some other evidence has suggested that they are taken up quite rapidly into marginal cells of the SV directly from the strial vasculature.[102] Once inside marginal cells there is the potential to enter endolymph directly. Whether there is a similar route into endolymph in the vestibular system, perhaps via dark cells, has not been tested. Nevertheless, persistence in perilymph and delayed entry to endolymph may account for the delayed effects of aminoglycosides. The delayed responses and the progressive effects may result from slowly increasing endolymphatic concentrations of the drug to critical levels that can cause damage. Several pieces of evidence from a range of experimental models suggest that aminoglycosides affect hair cells through access from their endolymphatic (apical) surface.

The susceptibility of all hair cell types in all vertebrate classes emphasizes that hair cells are specific targets of the aminoglycosides, and studies using radioactively or fluorescently labelled aminoglycosides administered to animals have shown that the drug is indeed taken up specifically into hair cells in the mammalian cochlea.[103, 104] The common feature of all hair cells is the transduction apparatus at their apical poles and it is apparent from a range of experimental studies in a variety of animal models that one of the major routes of entry for aminoglycosides into hair cells is through the mechanotransduction channels at the tips of the stereocilia.[105–107] In fact, aminoglycosides are one of the few known blockers of the hair cell transduction channel. Mutations in genes that encode proteins known to be involved in regulating opening of the transduction channels, such as myosin 7a, prevent entry of aminoglycosides into the hair cells and the hair cells are protected from lethal injury.[108] This demonstrates that entry of aminoglycoside into the hair cell is necessary to cause the cell death. Blocking entry would prevent aminoglycoside-induced hair cell death and one current line of research is to determine modifications of the aminoglycoside molecule that retain antimicrobial activity but are unable to enter the transduction channel.[109] Entry via the transduction channels could provide one explanation for the base-to-apex gradient in hair cell death along the cochlea: the probability of the open state of the transduction channels in OHCs in the basal coil is 50%, but the open state probabilities decrease towards the cochlear apex.[110] However, other/additional factors may also underlie the differential sensitivity to aminoglycosides of hair cells along the cochlear spiral.

Although entry into the cell is necessary for aminoglycosides to trigger hair cell death, it is not sufficient. Following systemic administration, gentamicin can remain inside hair cells for as long as 11 months without injury ensuing.[111] This implies that the cell death occurs only after some critical concentration of the drug has been reached inside the cell. Aminoglycosides cause death of hair cells by inducing apoptosis,[81, 91, 92, 112, 113] a programmed cell death pathway in which particular enzymes called caspases play the crucial roles. Gentamicin-induced hair cell death can be prevented by pan-caspase inhibitors.[112, 114, 115] A number of different cellular stress-activated biochemical pathways that lead to apoptosis have been identified as being triggered following aminoglycoside treatment[116–119] and offer potential therapeutic targets of intervention for preventing aminoglycoside-induced hair cell death.[120, 121]

One significant initiator of programmed cell death leading to apoptosis is generation of reactive free radicals.[122, 123]

Every cell in the body produces reactive oxygen species (ROS) as part of normal metabolism through enzymatic reactions and the oxidative respiratory mechanisms in mitochondria. Naturally produced ROS are normally removed as substrates or act as messengers in other biochemical reactions or they are neutralized by inherent cellular scavengers such as glutathione or specific enzymatic neutralizing systems such as superoxide dismutases. However, adverse conditions lead to overproduction and/or insufficient scavenging of ROS. The resultant oxidative stress upsets homeostatic redox balance, leading to damage to cellular components, proteins and lipids in particular, through oxidation/reduction reactions and can trigger cell death pathways.

There is evidence that hair cells may be vulnerable to oxidative stress. In strips of organ of Corti isolated from the cochlea and maintained in short-term culture, even without exposure to aminoglycosides, OHCs from the basal coil die much more quickly than those in apical coils. The survival of basal coil OHCs can, however, be enhanced by addition to the maintenance medium of free radical scavengers, including n-acetyl cysteine, salicylate and glutathione.[124] This indicates that in the cochlea, basal coil hair cells are more susceptible to oxidative damage than those at the apex. Effects of aminoglycosides that lead to the release of free radicals to levels in excess of cellular mechanisms to detoxify them has been considered one potential route through which aminoglycoside-induced hair cell death is triggered and a number of mechanisms of how this might occur have been proposed.[75, 120, 121] Following the discovery that mutations in mitochondrial genes that encode for mitochondrial rRNAs are associated with enhanced susceptibility to aminoglycoside-induced hearing loss (see below), a number of studies now suggest that aminoglycosides may damage mitochondria leading to production of ROS to lethal levels and release of pro-apoptotic factors from the mitochondria.[120, 121] Mitochondria are derived during evolution from bacteria and they contain their own distinct set of genes, separate from the genes encoded by the cell's nuclear DNA. These genes encode some of the mitochondrial proteins and the ribosomal- (r-)RNAs necessary for their translation. Bacterial r-RNAs are the target for aminoglycosides as antibiotics. Damage to mitochondria releases not only ROS but also a number of factors normally resident within mitochondria that regulate the cascade of reactions leading to apoptosis.

Suppressing the generation or enhancing the scavenging of ROS have therefore been proposed as potential therapeutic interventions for protecting hair cells from the lethal damage caused by aminoglycosides.[120, 125] However, the direct evidence that aminoglycosides trigger generation of ROS in hair cells *in situ* in the mature organ of Corti is limited. Nevertheless, in an experimental study the aminoglycoside apramycin, which has potent antibacterial activity and is used in veterinary medicine, was found to cause less hearing impairment and hair cell loss *in vivo* than other aminoglycosides and in explant cultures of the organ of Corti from neonatal mice generation of ROS was reduced in comparison with gentamicin.[126] The studies with apramycin are part of a further current line of investigation: to design aminoglycoside molecules with antimicrobial activity but which do not activate cell death pathways inside hair cells.

Effects of aminoglycosides on the stria vascularis

Although hair cells are the primary site of aminoglycoside action, the drugs are taken up quite rapidly into marginal cells in the SV.[127] A decrease in the volume of the SV (strial atrophy) has been observed in human temporal bones obtained within 2 weeks of aminoglycoside treatment.[128] In experimental studies in animals immediately following the end of a course of aminoglycoside treatment alterations to the stria can be seen at the same time as the earliest effects in the organ of Corti are apparent.[129] The subsequent decrease in the thickness of the stria is due to effects almost exclusively on marginal cells.[30] Some cells are lost by a process which shows morphological attributes of apoptosis, but the majority of marginal cells remain but with much reduced volume. Such alteration might be expected to affect EP and the ionic profile of endolymph, but EP appears to be maintained at close to normal levels for up to 4 weeks after the end of aminoglycoside treatment but is reduced by more than half 12 weeks after treatment when there is significant decrease in strial thickness (see **Figure 59.1**).[130] Interestingly, the changes to the stria and coincident relatively small decreases in EP that occur with aminoglycosides are similar to those seen with ageing in a gerbil model.[131] Here there is significant thinning of the stria but EP is little affected until the stria is less than one-third its normal volume when there is a catastrophic loss of EP. These results might suggest that there is significant redundancy in the stria; EP and organ of Corti activity can be maintained even when there has been considerable strial injury. Thus, it maybe that the stria can sustain injury for some time without a noticeable effect on auditory function, but in this 'compromised' state it might be less able to resist further insults. Consequently, a sudden loss of auditory function might ensue in conditions which would otherwise not be expected to cause hearing loss.

Confounding factors and genetics

The degree of vestibular or auditory impairment with aminoglycosides may depend upon the drug itself, the unit or total dose, the route and period of administration and the patient's age or pathological state; for example, the risk is substantially increased by impaired renal function.[132] The situation is further complicated in that the aminoglycosides, to varying degrees, are nephrotoxic. Genetic factors also play a role.[17] A predisposition to aminoglycoside ototoxicity is conferred by mutations in the gene that encodes 12s ribosomal RNA of mitochondria. The 'A1555G' missense mutation (an adenosine to guanosine substitution at base position 1555),[133, 134] a thymidine to cytosine mutation at 1095,[135] cytosine to thymidine missense at 1494,[136] and a cytosine insertion at position 961, all appear to confer particular sensitivity to aminoglycoside. In some

cases profound hearing loss may occur after only a single parenteral injection rather than the usual situation where hearing loss occurs only after several repeated administrations. The presence of these mutations in the mitochondrial chromosome has been identified through maternal inheritance patterns. The prevalence of A1555G mutation has been estimated as 0.19% in children in the UK[17] but is greater in Chinese, Arab-Israeli, Japanese and North American families[137, 138] and may be as high as 1% in these populations. A carrier rate of 17% of those developing aminoglycoside-induced hearing loss been estimated. However, the mutations appear to affect only the cochlea's sensitivity to aminoglycoside; there is no enhanced effect on the vestibular system, and no other organ of the system is affected. The reasons why only cochlear hair cells are affected or how the mutation enhances susceptibility are currently not known.

Aminoglycosides may also present a problem for those with tuberculosis and for cystic fibrosis patients. These antibiotics were first developed for use against tuberculosis and are still part of combination drug therapy against it. However, it has been estimated that as many as 80% of patients receiving aminoglycosides chronically to treat tuberculosis develop ototoxic side effects. There is also a significant incidence of hearing loss in cystic fibrosis patients who receive continuous treatment with aminoglycosides to combat pneumonia.[139–141] A further consideration is that aminoglycoside antibiotics can cross the placenta. Thus there is a potential to cause deafness in the foetus. Studies of development in animals have suggested a 'critical period' in development, when sensitivity to the ototoxic agent is greatest at around the time of the onset of auditory function during development. The existence and timing of a critical period in humans has not been identified but, based on anatomical findings comparing development of the human inner ear with that of experimental animals, it has been estimated that a critical period for the human cochlea maybe present in about weeks 18–20 of gestation. An ototoxic action of aminoglycosides during intrauterine life of human embryos has been reported.[141]

Interactions

Noise and aminoglycosides. Both epidemiological studies of the incidence of hearing loss in man and experimental studies in animals have indicated that noise exposure in conjunction with aminoglycoside may cause more extensive damage than with either agent alone.[143] Indeed, exposures under conditions in which neither noise nor the aminoglycoside alone would be expected to cause damage can result in marked auditory impairment and hair cell loss when the two agents are presented together. Animals reared in a sound-attenuated room do not take up gentamicin as extensively as animals raised in the environment of a normal animal facility.[144] This could result from increased uptake through the transduction channel; in the presence of sound stimulation, more transduction channels will be in the open state more frequently thereby enabling increased entry of the aminoglycoside than would be the case in a quiet environment. With increased sound exposure this effect will be enhanced. Thus, with exposure to noise, aminoglycoside uptake to a 'critical' level necessary to cause hair cell death would be reached more quickly. High sound pressure levels also lead to the generation of a variety of free radical species,[145, 146] which would exacerbate the effects of aminoglycoside-induced cellular stress.

Loop diuretics and aminoglycosides. Clinical experience and animal studies have also shown that coadministration of a single dose of loop diuretic with a single systemic administration of aminoglycoside, neither of which alone would cause hair cell loss, produces significant cochlear damage.[147] All aminoglycoside antibiotics have been found to interact with loop diuretics.[147] Administration of an intravenous dose of ethacrynic acid, frusemide or bumetanide shortly before a single, non-ototoxic dose of kanamycin rapidly produces depression of cochlear function which is permanent and associated with extensive hair cell destruction.[148, 149] A similar protocol applied to mice, subcutaneous injection of kanamycin followed after about 40–60 minutes with a single intraperitoneal injection of bumetanide causes almost complete loss of almost all OHCs within 48 hours of injections.[81] The SV is also affected, becoming progressively thinner through loss of marginal cells. The effects of the interaction are generally confined to the cochlea; no significant loss of hair cells is apparent in the vestibular system which appears to remain unaffected even at prolonged periods of time after all OHC have been lost from the organ of Corti.[81, 150]

The loop diuretics markedly increase the penetration of aminoglycosides into endolymph[151] and enhance uptake of gentamicin into cochlear hair cells.[81, 127] The potentiation of cochleotoxicity following systemic adminstration of both agents therefore likely arises because the diuretic enhances uptake of the aminoglycoside from the systemic circulation into endolymph. It is perhaps noteworthy that the interaction is only manifest when the time between administration of the two agents is relatively short, the diuretic administered no more than 1 hour before or 2 hours after the aminoglycoside[147] and that the vestibular system is not affected following the combined administration of single doses of these drugs. The timescale covers the time over which the EP is significantly reduced. The reduction in EP to negative values from the normally high positive potential may encourage entry of the cationic aminoglycoside into endolymph. Since there is no equivalent of EP in the vestibular system and diuretic does not cause a reduction of the positive diffusion potential of the vestibular endolymph, such enhancement of aminoglycoside uptake into vestibular hair cells would not occur.

CISPLATIN

Sites of action and nature of effects

Cisplatin (*cis*-dichlorodiammine platinum II [*cis*-DDP] or *cis*-platinum) is used to treat various tumours of soft tissue. Like the aminoglycosides, it is nephrotoxic as well as ototoxic.[120, 152–154] It has been estimated that the current clinical protocols for its use result in at least 60% of patients

suffering some degree of hearing impairment. Hearing loss often progresses after completion of drug therapy, which may in part be related to prolonged retention of platinum in the body; significantly higher levels of platinum than normal were detected in ex-patients at least 6 years, and in some reports longer, after the completion of *cis*-DPP therapy.[154, 155] Cisplatin induces a progressive loss of hair cells, the extent of which correlates with the dose of drug administered.[156] This occurs following repeated injections of relatively low drug doses (1 mg/kg daily) administered by intramuscular, intraperitoneal or subcutaneous routes, and after a single intravenous high dose (10–12 mg/kg).[31, 157, 158] The pattern of hair cell damage in the cochlea also resembles that of the aminoglycosides; hair cells in the basal coil of the cochlea are preferentially affected with damage spreading progressively apicalwards.[157, 158] As with aminoglycosides, the IHCs appear to be relatively resistant to damage following cisplatin administration.[159, 160] These histopathological findings correlate with assessment of auditory function in both animals and patients which shows an initial high-frequency hearing loss measured by auditory brainstem response (ABR), and suppression of otoacoustic emissions indicating an effect on OHCs.[161, 162] However, auditory neural threshold is increased to a greater extent than OAE, suggesting cisplatin may have direct effects upon the spiral ganglion cells themselves.[163] Since IHCs appear to be intact, these discrepancies suggest an effect at the level of the auditory nerve. Detachment of the myelin sheaths from type 1 spiral ganglion cells (those that innervate IHCs) has been observed and appears to progressively increase in extent in parallel with loss of OHCs. This suggests that the injuries at the two sites are separate phenomena.

Effects in the SV are also apparent. Cisplatin causes a decline in EP within 1 day of single intravenous high dose and it may become completely lost, though with lower repeated doses the effects take longer and appear less severe.[31, 164] Ultimately, strial atrophy develops several days or weeks after the end of the chronic treatment, which appears to be due primarily to apoptotic death of the marginal cells.[165, 166] That this was apparent in all turns of the cochlea when hair cell death was confined to the basal turns, as well as the fact that differing dosing regimes may influence which tissue is most affected,[167] suggests that effects in the stria and in the organ of Corti are independent of each other.

Cisplatin, therefore, appears to have effects at multiple sites in the cochlea: outer hair cells, spiral ganglion neurons, and the SV and perhaps also fibrocytes of the spiral ligament.[168] Furthermore, although not reported as extensively, cisplatin also causes vestibular dysfunction and loss of hair cells from vestibular sensory organs in patients.[169, 170] Experimental studies in a number of different animal models have confirmed HC loss from the vestibular organs in a manner similar to that resulting from aminoglycosides.[171, 172]

Mechanisms of action

Platinum can be detected in hair cells, spiral ganglion neurons and at particularly high levels in SV following repeated systemic administration of cisplatin.[173] Transport proteins megalin (LRP2), the organic cation transporter OCT2 (also known as SLC22A2) and the copper uptake transporter Ctr1 (SLC31A1) are thought to play roles in cellular entry of cisplatin. Ctr1 has been localized to hair cells, the SV and spiral ganglion cells in mice.[120, 153] Variations in the gene encoding megalin and that of Ctr1[174] have been associated with the severity of cisplatin ototoxicity, but the small size of the populations assessed requires caution in interpreting these results.[17] The uptake of the drug to strial marginal cells would assist potential entry into endolymph and this may be a crucial factor for access to hair cells.[153, 154, 159] A rapid deterioration in the auditory nerve response threshold is produced when cisplatin is present in the scala media at concentrations of about 5 mM, but no effect is apparent with perilymphatic perfusion at drug concentrations of less than 3 mM.[175] This suggests that one possible site of the drug action is at the apical end of the hair cells. Cisplatin has been shown to be able to block transduction currents in isolated hair cells from chicken,[176] and functional mechanotransduction channels have been shown to be required for uptake of fluorescently labelled cisplatin into hair cells in neuromasts of zebra-fish lateral line (a model system for screening for ototoxic drugs).[177] Thus, it is possible that, like aminoglycosides, cisplatin gains entry to endolymph from the SV, and an affinity for the hair cell transduction channel may underlie its specific action upon hair cells, but there is no conclusive evidence for this.

Once inside a cell cisplatin leads to cross-linking of nuclear DNA, which in proliferating cells, such as those of tumours, inhibits DNA synthesis, induces cell cycle arrest, suppresses transcription and ultimately leads to apoptosis. The majority of cells in the inner ear into which cisplatin enters are, however, non-proliferative. Nevertheless, damage to DNA is likely to occur which will activate DNA repair mechanisms. Polymorphisms in genes for two DNA repair enzymes, ERCC2 and XPC, have been associated as risk factors for cisplatin-induced hearing loss,[120, 152, 153] but the mechanisms underlying such risk are not clear. Cisplatin also binds to several other molecules, perhaps most significantly to sulphhydryl-containing molecules such as metallothineins and glutathione that scavenge free radicals and thereby it negatively affects redox balance. The binding to glutathione upsets the turnover and cisplatin ototoxicity correlates with a decrease in cochlear glutathione and significant decrease in the activity of glutathione peroxidise and glutathione reductase in cochlear tissues.[178] In addition, variants in the glutathione-5-transferase gene show a significant association with cisplatin ototoxicity.[17] Hearing loss in children receiving cisplatin has also been associated with genetic variants in two genes that encode enzymes in the methionine pathway that is involved in maintaining glutathione levels, thiopurine-5-methyltransferase (TPMT) and catechol-O-methyltransferase (COMT).[17, 179] Interference with antioxidant systems in the cochlea would lead to accumulation of free radicals and the consequent death of the hair cells though cisplatin may additionally cause generation of excess ROS,[120] possibly though effects in mitochondria.[153] However, there is evidence that agents

such as d-methionine and 4-methylbenzoic acid, which enable maintenance of glutathione levels or preserve the activity of associated enzyme systems, may be effective in preventing the ototoxic effects of cisplatin *in vivo* and clinical trials have been initiated.[152, 167, 180]

Interactions

Noise and cisplatin. There is some evidence, primarily from experimental studies in animals, that noise exposures above about 70 dB concurrent with cisplatin administration can induce hearing impairments and hair cell loss much greater than those expected from either the noise exposure conditions or cisplatin dosing regime alone.[181] In addition, cisplatin treatment appears to increase susceptibility to noise-induced hearing impairment and hair cell loss at prolonged periods after the end of cisplatin treatment.[182] Increased susceptibility to hearing loss in patients who have received cisplatin even some years prior to noise exposure has also been reported.[183] This may be a reflection of the long persistence of platinum in the body and might suggest prolonged suppression of antioxidant mechanisms. It argues for cautioning patients who have received cisplatin and perhaps long-term audiological follow-up.

Diuretics and cisplatin. Like aminoglycosides, a single dose of a loop diuretic administered shortly before or shortly after a single administration of cisplatin leads to extensive and quite rapid hearing loss and death of outer hair cells.[159, 184, 185] The underlying reason for this is likely to be similar to that with aminoglycoside–diuretic combination, the decline in EP enhancing uptake of the cisplatin into endolymph.

ORGANIC SOLVENTS

Exposure to high concentrations of organic solvents induce acute, reversible narcosis and neurotoxicity, but the possibility of ototoxic damage was initially recognized from the unusually high number of workers in the chemical industry who showed a hearing loss, and from case reports of hearing deficits in solvent abusers.[186] The effects of solvents may be exacerbated by concurrent exposure to high noise levels, or the converse, i.e. noise-induced hearing loss becoming more pronounced with concomitant exposure to certain solvents presenting a significant occupational hazard.[187, 188] Vestibular dysfunction may also follow from exposure to organic solvents but this may result from specific effects on vestibulo-oculomotor pathways in the vestibulocerebellum rather than from effects in the inner ear.[188] This would be classified as neurotoxicity rather than ototoxicity for the definitions used in this chapter.

A number of different aromatic solvents have been implicated in ototoxicity,[186] and in a comparative study conducted in rats of 21 different solvents 8 were identified as ototoxic: toluene, p-xylene, ethylbenzene, n-propylbenzene, styrene, ά-methylstyrene, *trans*-β-methylstyrene and allylbenzene.[189] Trichlroethylene has also been reported to be ototoxic.[190, 191] The features of the ototoxicity caused by all these agent are similar and are exemplified by the effects of toluene following exposure by inhalation in rats.[192] ABR and behavioural audiometry revealed auditory deficits after repeated exposures to high doses for periods of 2–16 weeks. Similar results were subsequently obtained after subcutaneous administration. Concomitant with the permanent hearing loss that results, OHCs are lost.[192, 193] Suppression of otoacoutic emissions by toluene confirms the OHCs as a site of injury *in vivo*.[194] However, unlike the ototoxins discussed above, the characteristic features of damage caused by toluene are:

- It is the mid-frequency ranges of hearing that are affected rather than the high frequencies,[190, 194] which coincides with HC loss in the middle and apical turns of the organ of Corti.[193–195]
- There is a distinct spread of damage from the third (outermost) row of OHCs inwards to involve subsequently the second and maybe the first row of OHCs. Additionally, the supporting cells, especially the third (outermost) row of Deiters cells, are affected.[193]

These features are characteristic effects of all the solvents implicated in ototoxicity.[189–191, 196, 197] The cell bodies of the afferent neurones may also be a target of trichloroethylene.[191] However, there are species differences in ototoxic susceptibility to solvents. While rats have proved to be sensitive, organic solvents do not cause damage in the inner ears of guinea pigs[198, 199] or chinchillas.[200] This obviously raises questions about the use of particular species of animals as models for the likely conditions in humans. However, it has been argued that the way solvents are distributed and metabolized in rats is similar to the human and thus that these animals are an appropriate model.[196]

Since organic solvents are minimally water-soluble their distribution in the inner ear is unlikely to be determined by entry into the fluid spaces. It is their distribution in the tissue that is significant. The pattern of damage across the organ of Corti, from outside to in, has suggested that the solvents reach the inner ear from the vasculature of the SV or the spiral prominence region just below it and then pass through the tissues to the organ of Corti.[196, 201] The cuboidal cells of the outer sulcus and the epithelial cells that connect the epithelia of the lateral wall to the organ of Corti along the basilar membrane may be a major transport route.[201] Upon reaching the organ of Corti, the supporting cells of the organ of Corti, the Hensen's cells that form the outer ridge of the sensory epithelium and the Deiters' cells that surround the hair cells, may then become injured. Deiters' cells, in particular those in the outermost row, have been reported to be the most vulnerable cells in the organ of Corti following styrene administration.[197, 202] The supporting cells are involved in the reuptake of K^+ from around the hair cells, and damage to these cells may therefore result in excessive K^+ levels around the OHC that would lead to their death. The effects of the solvents may be upon the membranes of the supporting cells and of the hair cells themselves. Loss of membrane integrity and cell swelling, perhaps as a consequence of membrane damage,

have been described as early events in the progression of damage in the organ of Corti. Whether the cell death is principally apoptotic[202] or necrotic[196] is contentious, but it has been reported that the death of Deiters' cells, unlike that of hair cells, is not prevented by antioxidants, suggesting that different mechanisms of cell death operate in the two cell types.[197]

Why damage is initiated in the middle frequency region of the cochlea is not clear. It may be of significance that the SV in the middle and apical cochlear turns is affected by trimethyltin,[203] perhaps indicating some characteristic of the vascular pathways and blood flow that may influence solvent distribution.

OTHER OTOTOXIC AGENTS

Good evidence for the ototoxicity of many of the other drugs listed in **Table 59.1** is relatively sparse. Vancomycin has been reported to cause transient hearing loss and/or tinnitus but many of these clinical reports derive from cases in which it has been used in combination with other potentially ototoxic drugs. The few experimental studies which have been performed suggest no loss of hair cells or permanent hearing impairment from systemic administration of polypeptide antibiotics even at very high doses.[204] Viomycin has been reported to be predominantly vestibulotoxic following chronic treatment regimes,[205, 206] and animal studies have confirmed that, after repeated systemic injections of relatively high doses, viomycin causes hair cell death in the vestibular sensory organs in a pattern similar to that seen with aminoglycosides.[207] Chloramphenicol has been shown to cause irreversible hearing loss following infusion into the middle ear cavity in animals,[208] presumably gaining access to the perilymph following uptake across the round window membrane, but clinical reports of hearing loss following use of chloramphenicol are rare. Polymyxin B when perfused through the perilymphatic spaces caused an almost immediate decline in cochlear microphonic (CM) potential followed shortly after by a decline in EP, suggesting separate effects on both the organ of Corti and the SV.[209] However, the rarity of clinical reports in which an ototoxic effect can be attributed directly to polymyxin B suggests the use of this antibiotic does not present a significant risk to the inner ear. Desferrioxamine (deferoxamine mesylate (DFO)) binds iron and is used in patients with β-thalassaemia to remove excess iron from the serum. In cultured explants of inner ear sensory epithelia DFO attenuates aminoglycoside-induced hair cell loss.[112] However, repeated high-dose systemic administration of DFO to patients has been reported to cause high-frequency hearing loss in about 20–40% of those receiving long-term therapy.[210–212] On the other hand, other clinical studies failed to identify a direct ototoxic effect of DFO[213, 214] and experimental studies with a mammalian model (chinchilla) could find no effects on cochlear physiology following long-term systemic treatment.[215] The reasons for these apparent discrepancies have not been resolved. Differences between experimental models may derive from the differences in susceptibility between species, known to be the case for aminoglycosides (above), and differing treatment regimes and/or patient groups may account for differences in clinical reports.[211, 216]

The reports of ototoxicity following the use of other agents listed in **Table 59.1** are often anecdotal and there are no rigorous, well-controlled clinical studies or experimental studies in animal models to confirm and define the ototoxic effects.

FUTURE RESEARCH

- Identification of the cellular stress mechanisms that lead to hair-cell death.
- Therapeutic interventions to inhibit stress-activated pathways or cell-death pathways.

KEY POINTS

- Ototoxic agents may affect hair cells directly; or ion-transporting epithelia and cochlear homeostasis; or both.
- Agents that affect stria vascularis (e.g. loop diuretics) cause temporary hearing impairment across all frequencies through inhibition of endocochlear potential.
- Agents such as salicylate and quinine that gain rapid access to perilymph, cause reversible hearing loss across all frequencies.
- Aminoglycoside antibiotics and *cis*-platinum cause permanent hearing loss that spreads progressively from high to low frequencies following chronic treatment regimes.
- Aminoglycosides and *cis*-platinum also cause vestibular dysfunction.
- Aminoglycosides and *cis*-platinum cause hair-cell death resulting in permanent hearing loss (and balance dysfunction).
- Hair-cell death follows entry of drug into endolymph and then into hair cells across the luminal surface of the cell probably via the transduction channels.
- One factor underlying hair-cell death may be production of excess free-radicals to toxic levels following aminoglycoside or *cis*-platinum challenges.
- Aminoglycosides and *cis*-platinum may cause atrophy of the stria vascularis. *Cis*-platinum may also have direct damaging effects on spiral ganglion neurones.
- Organic solvents (e.g. toluene, xylene, styrene) also cause hair-cell death and permanent hearing loss.
- Pattern of hair cell and hearing loss with organic solvents different from aminoglycosides and *cis*-platinum: lower middle cochlear turn and mid-range frequencies first affected, damage spreading progressively to lower and higher frequencies (apically and basally respectively along the cochlea).
- Various interactions – aminoglycosides with loop diuretics or with noise; *cis*-platinum with loop diuretic or noise; organic solvents with noise – produced greater damage and functional impairment than either agent alone.

CHAPTER 60

IDIOPATHIC SUDDEN SENSORINEURAL HEARING LOSS

Tony Narula and Catherine Rennie

SEARCH STRATEGY

The data in this chapter are based on searches in Medline, Embase and CENTRAL for randomized controlled trials in idiopathic sudden sensorineural hearing loss (ISSNHL). The Cochrane ENT Disorders Group's specialist register of controlled trials was also searched for additional references to randomized controlled trials in ISSNHL. Keywords used were sensorineural hearing loss (SNHL), sudden sensorineural hearing loss (SSNHL), idiopathic sudden hearing loss (ISHL), idiopathic sudden sensorineural hearing loss (ISSNHL), randomized controlled trials, controlled clinical trial and random allocation.

INTRODUCTION

Sudden sensorineural hearing loss (SSNHL) is an otological emergency for which a definitive aetiology and treatment remains controversial, but prompt recognition and management have been shown to improve hearing outcomes and quality of life. The estimated annual incidence is 5–30 per 100 000 persons[1–4] and 99% of cases are unilateral.[5]

The definition is a hearing loss of 30 dB or more, over at least three contiguous audiometric frequencies, that develops over 72 hours or less.[1,2,6] There is a long list of possible causes, but the vast majority of cases are idiopathic. The aetiology is identified in less than 5–10% of cases. Factors including autoimmunity, vascular insult and viral infection have been postulated in the pathogenesis. The low incidence and high spontaneous recovery rate of between 32% and 65%[2,7,8] have made the validation of empirical treatments difficult. In the literature there are large numbers of case series regarding treatments but a relative lack of large randomized controlled trials assessing interventions, as a result of which there has been a wide variation in management of SSNHL to date. The recent development of evidence based clinical practice guidelines for SSNHL[6] should begin to address the heterogeneity in clinical practice. Steroid treatment (either systemic or via transtympanic injection) or hyperbaric oxygen treatments are advocated, but many other treatment regimes have been explored.

SSNHL often affects healthy individuals and is a frightening symptom that prompts the individual to seek urgent medical attention. There is a wide age distribution with an average of 50–60 years and no sex preference.[9] Early recognition and prompt management of SSNHL may improve hearing recovery and the quality of life of the individual.

DEFINITION

SSNHL was described in the literature by De Kleyn in 1944.[10] The following definition is currently accepted in the literature and in clinical practice:

- Sudden hearing loss is defined as the rapid onset, occurring over a 72-hour period, of a subjective sensation of hearing impairment on one or both ears.
- The audiometric criteria of a 30 dB sensorineural loss in at least three consecutive frequencies can be difficult to show clinically as premorbid audiometry is rarely available. Therefore the hearing loss is defined in relation to the contralateral side.
- Idiopathic sudden sensorineural hearing loss is defined as SSNHL with no identifiable cause in spite of thorough investigation.

Clinicians must decide the degree of certainty they are comfortable with when making a decision that the hearing loss is 'new'. There are four levels of 'certainty' about the 'newness' of the hearing loss in the affected ear:

1. Very certain: patient had previous audiometric evaluation.
2. Certain: patient had no prior otologic history and feels his or her premorbid hearing was normal bilaterally.
3. Fairly certain: patient had a long-standing hearing problem and reports that the current episode of SSNHL is subjectively poorer.
4. Uncertain: the clinician feels there was some pre-existing hearing loss, but the hearing loss was never documented.[11]

It is important to differentiate between SSNHL and other causes of SNHL so that early diagnosis and management can be instigated. The possible identifiable causes of SNHL can be divided into the following categories: infectious, traumatic, neoplastic, autoimmune, toxic, circulatory, neurologic and metabolic (**Box 60.1**). The most pressing of these are acoustic neuroma, stroke and malignancy.[12] Despite the long list of possible causes the vast majority of cases are idiopathic.

CAUSES OF IDIOPATHIC SUDDEN SENSORINEURAL HEARING LOSS

Several factors have been postulated as central to the aetiology of idiopathic sudden sensorineural hearing loss (ISSNHL). Possible causes include labyrinthine viral infection, vascular insult, intracochlear membrane rupture and autoimmune inner-ear disease.

Viral

Viruses, particularly the herpes family, can cause SNHL in acute infection and it is possible that reactivation of the latent virus could cause SSNHL.[13–15] However, the serological evidence for a viral aetiology in SSNHL is conflicting. Wilson et al. found patients with SSNHL to have a statistically significant increase in seroconversion for cytomegalovirus (CMV), influenza B, mumps, rubella or varicella zoster, and 63% of 122 patients had evidence of seroconversion.[16] In contrast, Xenellis et al. showed seroconversion in only 27% of 262 patients with SSNHL for Epstein–Barr virus (EBV), herpes simplex virus (HSV) I and II or CMV.[17] In a smaller study of 48 patients Gross et al. reported positive serology for EBV in 6% and enterovirus in 2%.[18] Mentel et al. studied 55 patients with SSNHL for serconversion to enterovirus, HSV and varicella zoster virus (VZV). They found seroconversion rates of 40% to enterovirus but no evidence of HSV or VZV seroconversion.[19] More recently a large Taiwanese population-based study investigated the frequency and risk for SSNHL following a recent herpes zoster attack in the general population. The results showed that SSNHL is a rare event in the 2 months following an attack of herpes zoster, and the risk of developing SSNHL is not increased among people who have had a recent herpes zoster infection compared with a matching population.[20]

BOX 60.1 Possible causes of sensorineural hearing loss

Infectious	Traumatic	Neoplastic	Autoimmune
Meningococcal meningitis Encephalitis Herpes virus (simplex, zoster, varicella, cytomegalovirus) Mumps Measles Human immunodeficiency virus Lyme disease Rubella Syphilis Toxoplasmosis	Barotrauma Perilymph fistula Intense noise exposure Inner ear decompression sickness Temporal bone fracture Ear surgery (stapedectomy)	Cerebellopontine angle tumours, e.g. acoustic neuroma meningioma Leukaemia Myeloma	Wegener's granulomatosis Rheumatoid arthritis Sjögren's syndrome Polyarteritis nodosa Relapsing polychondritis Lupus erythematosus Ulcerative colitis Cogan's syndrome Antiphospholipid syndrome Sarcoid Autoimmune inner-ear disease (AIED)
Toxic	**Circulatory**	**Neurologic**	**Metabolic**
Aminoglycoside antibiotics Loop diuretics NSAIDs Salicylates Platinum-based chemotherapeutic agents General anaesthesia	Vascular disease/alteration of microcirculation Vascular disease associated with mitochondriopathy Vertebrobasilar insufficiency Red blood cell deformability Sickle-cell disease Cardiopulmonary bypass	Multiple sclerosis Focal pontine ischemia Migraine	Hyperlipidaemia Thyrotoxicosis Diabetes

Examination of temporal bones reveals histopathological evidence which is consistent with viral infection in patients with SSNHL.[21,22] There was shown to be greater loss of neurons in the apical spiral ganglion compared to the basal region without corresponding loss of hair cells and dendrites. This suggests a viral cause since other conditions such as hypoxia, acoustic trauma, presbyacusis and hereditary conditions would result in changes at the basal region. Animal studies experimentally inducing a vascular cause of hearing loss have resulted in cochlear fibrosis and inner ear ossification, which has not been seen in the temporal bone studies of SSNHL patients.[23] Animal experiments have demonstrated viral penetration of the inner ear,[24] and the isolation of virus and viral antigens in perilymph of affected patients provides further evidence for the viral aetiology.

Many similarities have been drawn between SSNHL and Bell's palsy, both neurological conditions with a sudden onset and their symptoms that can be improved with steroid treatment. However, in Bell's palsy a viral aetiology has been demonstrated following the identification of virus in the endoneural fluid of the facial nerve in effected patients.[25] Although a viral aetiology has been hypothesized in SSNHL, the epidemiological, serological and histopathological evidence is inconclusive.

Vascular

The cochlea is supplied by an end artery, and hence is susceptible to damage by vascular occlusion, making a vascular cause for ISSNHL a popular theory. Many treatments to date have been recommended because they are thought to improve cochlear blood flow. Changes in blood viscosity could lead to cochlear ischaemia and hearing loss. However, patients with ISSNHL are no more likely than the general population to have a hyperviscosity disorder.

Ballesteros et al. evaluated 99 patients with SSNHL for thrombophilic genetic polymorphisms and coagulation studies associated with vascular disorders but did not find a significant difference between patients and controls.[26] However, Capaccio et al. investigated 100 patients with SSNHL for five prothrombotic genetic polymorphisms and found a statistically significant association between the incidence of these polymorphisms in the patient group when compared to the control population.[27] In another study by Capaccio ten patients with SSNHL and previously documented cardiovascular disease were found to have a significantly higher number of thrombophilic allelic mutations when compared to the previous 100 SSNHL patients with no history of cardiovascular disease. Einer et al. reviewed a number of haemostatic parameters in 32 SSNHL patients compared to controls.[28] They concluded that, although isolated aberrations in the haemostatic pathway were observed, these were not of decisive importance for the pathogenesis of sudden deafness.

Isolated case series have reported that patients with sickle-cell anaemia and Waldenstrom macroglobulinaemia have a higher risk of SSNHL, but this is usually reversible with treatment.[29,30] Strokes involving the anterior inferior cerebellar artery are associated with auditory and vestibular symptoms, but also cerebellar symptoms. The risk of stroke is also said to be higher in the SSNHL population.[31] In addition, SSNHL following cardiopulmonary bypass has also been reported.[32] Many of these are small studies, however, and there is a lack of experimental, histological and clinical evidence to support this theory.

Intracochlear membrane rupture

Rupture of the intracochlear membrane was proposed as a cause of sudden hearing loss but the evidence is only coincidental and studies looking at temporal bones of patients with SSNHL found no evidence of Reissner or basilar membrane rupture.[21]

Autoimmune

Historically the inner ear has been regarded as an immunoprivileged site, separated by the blood labyrinthine barrier. However, we now know that immunoglobulins (predominantly IgG) are found in the perilymph at a fraction of their serum concentrations.[33] The endolymphatic sac is thought to be the likely site for immune processing due to the presence of lymphocytes in the perisaccular tissues.[34]

SNHL has been reported in many systemic autoimmune disorders such as Wegener's granulomatosis,[35] rheumatoid arthritis,[36] polyarteritis nodosum,[37] Sjögren's syndrome,[38] Cogan's syndrome,[39] systemic lupus erythematosus,[40] ulcerative colitis[41] and relapsing polychondritis.[42] This provides some evidence that autoimmunity can damage the inner ear although it does not address organ-specific disease and an audiological investigation of patients suffering well-characterized systemic lupus erythematosus (SLE) found no significantly worse hearing than age, sex and socioeconomically matched controls.[43]

In 1979 McCabe described autoimmune inner-ear disease (AIED) a rapidly progressive bilateral SNHL that responded to steroid therapy. The cause is thought to be antibodies or immune cells that damage the inner ear and there are several theories as to how these may arise.[44]

Yoo et al. reported that rodents injected with type II collagen developed new-onset SNHL and pathologic cochlear changes that appear to be immune-mediated.[45,46] However, a more recent study found the incidence of anti type II collagen antibodies to be very low and disputed it as a cause of AIED.[47]

Harris and Sharp used bovine inner-ear extract as antigen in Western blot assays and detected antibody to a 68 kDa antigen in 35% of patients with progressive SNHL.[48] This is now known to represent the ubiquitous rather than inner ear-specific highly inducible heat shock protein 70 (hsp70).[49] Although hsp70 antibodies are elevated in autoimmune SNHL, they are not thought to be the underlying cause of hearing loss.[50] The frequency of antibodies against hsp70 is not different in patients and controls and therefore it is not useful in the diagnosis of AIED.[51] The presence of antibodies to hsp70 found

in AIED patients has been correlated to responsiveness to steroid treatment.[52] The sensitivity and specificity of anti-hsp70 for the diagnosis of AIED was 42% and 90% respectively, and their positive predictive value 91%.[53] Further research is required to understand the aetiology of AIED fully and to develop diagnostic tests.[54]

Damage to the inner ear results in the release of cytokines, which trigger immune reactions. TNF-alpha, IL-1A, NFkB and IkBa have all been found in the cochlea.[55]

Activation of cochlear nuclear factor kappa B (NFKB) has been proposed as a mechanism of SSNHL as it would account for clinical and histological observations, but there is no direct evidence.[23]

The inner ear may share common antigens with potentially harmful substances and T-cells and antibodies may damage the inner ear when trying to fight these antigens. COCH5B2 has been proposed as a target antigen.[56]

The basic problem with any autoimmune theory for ISSNHL is that one would expect an immune condition to affect both ears and ISSNHL is usually unilateral.

Ménière's disease

The first presentation of Ménière's disease may be as SSNHL and therefore it is important to consider in the differential diagnosis. The classic triad of Ménière's is episodic vertigo, tinnitus and deafness. The aetiology is unknown and theories include autoimmune activation and labyrinthine ischaemia. Patients develop endolymphatic hydrops, which results in the classical symptoms. The audiogram classically shows a low-frequency hearing loss.

While there have been a number of proposed aetiological theories, it is possible that they are not mutually exclusive; for example, a viral insult can cause direct neural injury, direct vascular structure injury or direct injury to erythrocytes, leading to secondary microvascular insufficiency. Viruses can also lead to inflammation resulting in vascular insufficiency. Autoimmune disease can lead to vasculitis through antiendothelial cell antibodies.

CLINICAL ASSESSMENT

History

The aim in evaluating any patient with SSNHL is to identify any treatable causes.

It is important to cover the following key points in the history:

- The onset of the hearing loss. Patients with SSNHL often first notice their hearing loss on awakening in the morning and a better prognosis is associated with a short history.
- Sudden onset of blockage or fullness warrants prompt investigation. SSNHL often presents as a full or blocked ear. As this is a common and non-specific symptom it can be underestimated by both patients and clinicians, thus leading to a delay in evaluation and treatment.
- The premorbid hearing level. SSNHL can be either a new loss or an incremental deterioration in an ear with a pre-existing loss. Conditions such as Ménière's disease can cause sudden fluctuations in hearing.
- A poorer prognosis is associated with increasingly profound hearing loss.
- Is the loss unilateral or bilateral? Unilateral loss is commoner but autoimmune disease and ototoxicity are more likely to be bilateral.
- Associated symptoms such as tinnitus, vertigo, dizziness and aural fullness should be asked about and may point to a diagnosis of endolympatic hydrops. Vertigo is present in 30–40% of cases of SSNHL[57, 58] and is a poor prognostic indicator.
- SSNHL is frequently associated with tinnitus, which can cause significant anxiety and depression for patients. It is therefore important to recognize the psychological response to the sudden loss of hearing.
- Any history of trauma, straining, diving, flying and intense noise exposure should be noted. Patients should be questioned about previous or concurrent viral infections.
- A past medical history of other diseases associated with sudden hearing loss should be explored as SSNHL can rarely be the first presentation of a systemic disease.
- Any history of previous ear surgery should be noted.
- A full drug history should be elicited to rule out ototoxicity.

Examination

A complete examination of the head and neck should be carried out on all patients with SSNHL. Otoscopy should be performed to exclude middle ear effusions, infections, cholesteatoma and wax impaction. Tuning fork tests should be performed to distinguish a conductive hearing loss (CHL) from a SNHL.[59, 60] A fistula test may help identify a perilymph fistula. A thorough neurological examination of cranial nerves and cerebellar signs is essential.

Investigations

Audiometry must be performed and may give an indication of prognosis, as a downward sloping audiogram is associated with a poorer outcome.

An MRI scan with gadolinium enhancement should be performed to exclude an acoustic neuroma but is also useful in evaluating multiple sclerosis and cerebrovascular accidents. Around 10–20% of patients with acoustic neuromas will report a sudden decrease in their hearing at some point in their history.[61] However, the incidence of vestibular schwannoma in patients who present with SNHL is considerably lower but still noteworthy. Several studies have demonstrated a relatively high prevalence of cerebellopontine angle tumours in SNHL patients ranging from 2.7% to 10.2% of patients who are evaluated with MRI.[12, 62–66] When an MRI is contraindicated (i.e. pacemakers, other metallic implants, claustrophobia), a fine-cut CT of the temporal bones with contrast may be used.

Other investigations to rule out identifiable causes should be focused by the history. Bloods including FBC, ESR, urea and electrolytes, lipid profile, glucose, thyroid function tests, clotting screen, VDRL, serology for Lyme disease and autoantibodies (antinuclear antibodies, anti-cardiolipin antibodies, lupus anticoagulant, antineutrophil cytoplasmic antibodies) may be requested if clinically indicated. The American Academy of Otolaryngology – Head and Neck Surgery guideline makes a strong recommendation against routine laboratory testing.[6]

PROGNOSIS

Four factors have been shown to affect recovery from ISSNHL:[67]

- time since onset – the earlier the presentation the better the prognosis
- age – there is a worse prognosis in the over 60s
- vertigo – a poor prognostic indicator
- audiogram – patients with profound hearing loss and a downward-sloping audiogram have a poorer prognosis.

It is important to reassure patients that around 50% of cases have spontaneous recovery with no treatment. Due to the lack of evidence for any single treatment the risks and benefits of each treatment should be discussed with the patient to enable them to reach an informed decision about their care. Patients should be followed up to monitor for delayed symptoms, and audiograms should be repeated. Evidence shows that improvement rate in the first 2 weeks may predict long-term outcome.[68, 69]

Long-term follow-up is recommended as some patients will have an underlying cause identified that is not evident at initial presentation.[62] Also patients with limited or no hearing recovery or persistent tinnitus will require ongoing support from the audiological and psychological services.[70]

Unilateral SNHL has a significant impact on patients' quality of life.[71] So too does SSNHL and perhaps more so, especially if dizziness and significant tinnitus are suddenly present.[72–74]

TREATMENT

The high spontaneous recovery rate for ISSNHL and its low incidence make validation of empirical treatment difficult. Many treatment regimens have been proposed (Table 60.1).

TABLE 60.1 Proposed treatment regimes for ISSNHL

Treatment	Examples
Anti-inflammatory/ immunosuppression	Steroids[2, 75] Prostacyclin[76]
Antiviral agents	Acyclovir[77, 78] Valcyclovir[79]
Vasodilators 5% carbon dioxide with 95% oxygen (Carbogen)[75,80]	Papaverine[80] Pentoxifylline[81–83]
Volume expanders/haemodilutors	Hydroxyethyl starch[82, 84] Dextran[80, 82, 85]
Calcium antagonists	Nifedipine[86]
Other agents and procedures	Iron[87] Vitamins[86, 88] Procaine[85] Hyperbaric oxygen[89, 90] Gingko biloba[81] Zinc[91] Co-enzyme Q10[92]

Steroids

SYSTEMIC STEROIDS

Steroid therapy is widely used as the standard treatment for SSNHL, although systematic reviews and meta-analyses have revealed no evidence of benefit of steroids over placebo.[7, 93–95] The evidence for steroids comes from Wilson et al. who found that steroids had a significant effect on the recovery of hearing in patients with hearing loss of 40–90 dB.[2] Moskowitz et al. confirmed Wilson's findings in 1984.[96] However, the methodology of these studies has been criticized.[93] Cinamon et al. compared treatment with prednisolone, placebo, carbogen and room air inhalations and found no significant differences between the four groups.[75] Nosrati-Zarenoe et al. performed a prospective randomized, triple-blind, placebo-controlled trial comparing oral steroids to placebo in 103 patients. Prednisolone or placebo was given at 60 mg/day for 3 days then 10 mg less each day until day 8. The results showed no significant difference in hearing improvement.[97]

A more recent meta-analysis of various medical treatments, including corticosteroids, showed a slight but not statistically significant improvement with medical therapy compared to placebo.[98]

Risk vs benefit of oral corticosteroid therapy

In view of the limited evidence to support steroid therapy in the treatment of ISSNHL, clinicians must weigh up the risks and benefits of the treatment for an individual patient. Although the evidence for corticosteroids is limited, it is one of the few treatments with demonstrated efficacy.[2, 77, 96, 99–104] In view of the significant devastating impact of a severe to profound SSNHL on an often otherwise healthy patient, the treatment should be considered.

Spontaneous improvement in hearing is most likely to occur during the first 2 weeks;[8] late recovery has been reported but is rare. Early corticosteroid treatment within the first 2 weeks is associated with the greatest hearing recovery, with minimal benefit after 4–6 weeks.[57, 103, 105–107]

Dose

The best treatment outcomes are associated with a single dose of oral prednisolone of 1 mg/kg/day, up to a maximum of 60 mg daily, for 10–14 days.[6] This is based on

the maximum adrenal output of hydrocortisone (cortisol), which is 200–300 mg/day during stress. Prednisolone is 4 times, methylprednisolone is 5 times, and dexamethasone is 25 times more powerful than hydrocortisone. A dose of 60 mg prednisolone is equivalent to 48 mg methylprednisolone and 10 mg dexamethasone.

Complications of systemic steroid treatment

Systemic corticosteroids have a wide range of potential side effects as they affect many organ systems. They can suppress the hypothalamic–pituitary–adrenal function causing Cushing's syndrome.[108] Possible side effects of corticosteroid use are given in **Box 60.2**.

In view of the associated side effects and limited evidence for efficacy, systemic corticosteroids may not be an appropriate treatment for patients with increased risk of complications. For example, these will include those with insulin-dependent or poorly controlled diabetes, labile hypertension, tuberculosis, peptic ulcer disease and prior psychiatric reactions to corticosteroids.[109] The severe side effects are typically associated with long-term high-dose usage and adverse events are rare with the short 10- to 14-day course of steroids recommended for SSNHL.

Super high-dose steroid therapy has shown greater hearing recovery than standard dose treatment but further research is required.[110] Caution should be taken when prescribing very high-dose steroids to reduce the risk of serious complications.

INTRATYMPANIC CORTICOSTEROIDS

Intratympanic (IT) steroid therapy is gaining popularity as a treatment for SSNHL, particularly in refractory cases or those in which systemic steroids may be hazardous, but again evidence is lacking.[100, 111–113] There have been many small studies, often with very small numbers, but many are retrospective, without controls, and the steroid dosage, delivery method and frequency of injection have varied considerably, making it difficult to assess and compare outcomes. The main advantage of IT treatment is the reduction in systemic corticosteroid side effects. IT steroids very rarely cause changes in serum glucose levels in patients with diabetes.[114] They may also be given to patients with cataracts, myasthenia gravis and glaucoma.[115]

BOX 60.2 Possible side effects of corticosteroid use

Possible side effects with short-term use	Severe but rare side effects
Gastritis	Pancreatitis
Increased blood sugar	Bleeding
Increased hunger	Cataracts
Behaviour changes, insomnia, irritability	Myopathy
Weight gain, salt and water retention	Avascular necrosis of humeral and femoral heads
High blood pressure	Diabetes
	Osteoporosis
	Opportunistic infections[108]

IT injection is associated with higher inner ear steroid levels[116, 117] so many authors have explored its use in the treatment of SSNHL. An early prospective study using IT steroids in patients with profound ISSNHL found only 3 of 25 patients had hearing improvement.[118] However, another study combining a high-dose prednisolone taper with IT steroids resulted in partial or complete hearing recovery in 14 out of 16 patients.[119] Three separate randomized controlled trials comparing IT + oral steroids with oral steroids alone found that the addition of IT steroids did not show a significant benefit when compared to corticosteroids alone, although there was a trend towards greater improvement with the combination therapy.[120–122] Filipo et al. investigated IT steroids as the sole initial treatment in SSNHL and showed improvement in 31 out of 34 patients.[123] The same author went on to compare IT steroid with IT saline in a randomized controlled trial and found a significant improvement in hearing in the steroid group compared to the control.[124] Dispenza et al. compared IT with oral steroids and found no significant difference between the two groups.[125] Lim et al. compared the efficacy of three different steroid treatments: IT, IT + oral steroids, and oral steroids alone. Their results showed similar hearing recovery rates in all three groups.[126] The efficacy of simultaneous versus subsequent IT steroid with oral steroids has also been studied. The results showed that the administration of simultaneous IT steroid with oral steroid did not confer additional hearing gain or earlier recovery rate over those that had subsequent treatment with IT steroid.[127] A systematic review concluded that IT steroids can be a valuable solution for patients with ISSNHL who either cannot tolerate systemic steroid therapy or are refractory to it.[114, 128, 129]

Choice of steroid and dose

The most frequently administered IT steroids are dexamethasone and solumedrol (methyl prednisolone sodium succinate). The research shows a wide variation in the concentration given. Most studies quote doses of 10–24 mg/mL dexamethasone and 30–40 mg/mL solumedrol. Higher concentrations may have better outcomes.

Use of facilitator

Improved transport across the round window membrane has been demonstrated in laboratory studies with the addition of facilitator agents such as histamine and hyaluronic acid.[130, 131]

Frequency and injection technique

Studies vary widely in the frequency of IT steroid injection, from self-administration several times a day by the patient across a grommet, to clinician administered on consecutive days, to weekly. A variety of methods of administration have been reported, via a spinal needle on a syringe, through a grommet or myringotomy, via a MicroWick or microcatheter,[132] hydrogel applications, and nanoparticles. Transtympanic needle or grommets are the most frequently used.[133] IT steroids have been used as

the primary treatment, in combination with other therapies and as salvage treatment.

Complications of IT steroids

Even though IT steroids are widely used in clinical practice they are associated with an inconsistent clinical response.[134] This is due to the wide variability in diffusion across the round window membrane leading to unpredictable intracochlear bioavailability. This variability is further exacerbated by any inflammation or scar tissue in the round window niche.[135, 136] Adverse effects with IT steroids are infrequent but include pain, transient dizziness, infection, persistent tympanic membrane perforation, possible vasovagal episode during injection, and the need for repeat visits. The main risk appears to be a persistent tympanic membrane perforation at the injection site.

The largest randomized controlled trial comparing oral versus IT steroid therapy for ISSNHL was conducted at 16 centres and recruited 250 patients.[137] All patients were recruited within 14 days of onset of their SSNHL and followed up for 6 months. The first group, of 121 patients, received 60 mg/day of oral prednisone for 14 days with a 5-day taper; the other 129 patients received four doses over 14 days of 40 mg/mL of methylprednisolone injected into the middle ear. The results showed that, for initial therapy of SSNHL, promptly administered and equivalently dosed oral and IT steroid appeared to be equally effective, with hearing improvement seen in more than 75% of treated patients. Since the results for the two groups were equivalent, decisions on the choice of treatment for an individual should be based upon the risk of potential side effects and cost. Side effects were reported by 88% of the oral group, such as elevated blood sugar, increased thirst, and sleep or appetite changes, and 90% of the IT group, such as transient pain at the injection site and brief caloric vertigo. These were the anticipated manageable side effects, most of which were resolved within 1–2 weeks.

HYPERBARIC OXYGEN

Impairment of vascular supply and the resulting cochlear ischaemia is one of the proposed aetiologies for SSNHL. Hyperbaric oxygen therapy (HBOT) delivers 100% oxygen to a patient at a pressure greater than 1 atmosphere. This results in an increase in tissue oxygenation as well as potentiating the response to infection and ischaemia.[138]

HBOT has been used in the treatment of SSNHL since the 1960s.[90] Since then, numerous studies have investigated the use of HBOT in SSNHL, although very few have been prospective randomized controlled trials. The most recent Cochrane review included seven identified randomized controlled trials, published between 1985 and 2004.[139–145] The criterion used for determining significant benefit was a 50% improvement in hearing. Although the chance of a 50% improvement was not significantly increased following HBOT, the chance of a 25% increase was and the number needed to treat (NNT) to achieve one extra good outcome was five. For people with early presentation of ISSNHL, the application of HBOT significantly improved hearing loss, but the clinical significance of the level of improvement is not debatable. The data also suggested that improvement may be related to the severity of the hearing loss on presentation. However, further evidence is required from future randomized controlled trials.

A more recent prospective randomized control of HBOT for SSNHL[146] compared HBOT + oral steroid with oral steroid alone. Success was defined as hearing regained completely (>50 dB improvement) or moderately (10–50 dB improvement). The results showed no significant difference between the two groups and therefore did not support the addition of HBOT to oral steroids. HBOT has also been used in combination with IT steroids.[147] When HBOT + IT steroid was compared to HBOT + i.v. steroid, the overall success rate was higher in the IT steroid group but the result was not statistically significant.

Complications of HBOT

Complications are rare but include damage to ears, sinuses and lungs from pressure changes; temporary worsening of short-sightedness; claustrophobia; and oxygen poisoning. No significant adverse events were reported in the studies reviewed. In a large study (782 patients) looking at HBOT for a variety of indications, the most frequent complication was difficultly equalizing pressure in the middle ear, which occurred in 17% of patients.[148] Rates of Eustachian tube dysfunction of up to 45% have been reported in other studies of HBOT for a variety of indications.[149] Although the reported rates of Eustachian tube dysfunction are lower in patients undergoing HBOT for SSNHL, this may be a result of concurrent steroid treatment.[150] Another common complication of HBOT is claustrophobia while undergoing treatment.[148, 150]

Disadvantages of HBOT

HBOT is an expensive and time-consuming intervention that is not readily available. Therapy typically involves multiple sessions of 1–2 hours over days to weeks. Typical treatments have consisted of between five and ten sessions.

The evidence supports possible benefit of HBOT as an adjuvant treatment in cases of acute SSNHL when used within 3 months of the onset of the hearing loss, with potentially more benefit noted in cases of severe to profound loss.[6]

OTHER THERAPIES

Michel and Matthias compared intravenous prostacylin therapy with saline and found no significant difference between the groups.[76]

Acyclovir has been used for the treatment of SSNHL both alone and in conjunction with steroids but neither shows any significant improvement in hearing. Valcyclovir, although better bioavailability has also been used in conjunction with steroids but again offers no improvement above controls.[77–79]

Agents thought to increase cochlear blood flow, papaverine, pentoxifylline, hydroxyethyl starch, dextran, nifedipine and ginkgo biloba show no difference between active treatment and controls.[80–86]

Kronenberg et al. compared intravenous procaine, dextran and placebo and found no significant differences in outcomes.[85]

SALVAGE TREATMENT

For patients who are refractory to systemic steroid therapy, salvage therapy has become popular. Both IT steroid and HBOT have been investigated as salvage treatments.

There is now a large body of research investigating the use of IT steroid therapy in this setting, including numerous case series, a number of randomized controlled trials and a meta-analysis.[100, 112, 113, 116–118, 132, 151–155] The methodology in many of these studies has been criticized, however the majority do show improved hearing outcomes after IT steroid therapy with reported improvement rates ranging from 8% to 100%.[100, 122, 128, 129, 156–160]

The meta-analysis identified 184 studies of which five met the inclusion criteria and were analyzed.[112, 155, 161–163] There was a statistically significant greater improvement in hearing on pure-tone audiometry in patients who received salvage IT steroids than in those who did not.[154]

Side effects of IT steroids for salvage therapy were reported by four of the five studies. Minor side effects included transient dizziness, ear pain, and tinnitus. Of the 203 patients in these studies, three developed tympanic membrane perforation. Of the three, one healed spontaneously, one was treated successfully with a paper patch, and one required a myringoplasty (in this patient a round window catheter was used). No infective complications occurred.

The main limitation of this meta-analysis is the small number of trials involved. Although all the studies included were randomized controlled trials, only one was blinded and placebo-controlled. The subgroup analysis found that dexamethasone rather than methylprednisolone, administered via injections rather than a round window catheter, tended to demonstrate better outcomes. However, in view of the limitations of the analysis, further work is required to demonstrate this conclusively. While this meta-analysis showed a statistically significant improvement in hearing, the degree of clinical significance is questionable, as the improvement in audiological thresholds may not confer an improvement in usable hearing to the patient.

HBOT has also been successfully used in the treatment of refractory SSNHL.[152, 164–166] Recent studies have compared HBOT with IT steroids and with combined treatment of IT steroids + HBOT. Yang et al. found that IT steroid, HBOT and combination therapy all offered some benefit in hearing improvement but the largest gain in word recognition score (WRS) and recovery in hearing, especially in the lower frequencies, was seen with combination therapy.[153] However, the numbers in these studies was small.

OUTCOMES ASSESSMENT

In order to assess and compare outcomes there need to be standardized outcome measures. Unfortunately, for a long time there were no widely accepted standards, however 2006 guidelines from AAOHNS proposed recommendations for outcomes assessment.[167]

All patients diagnosed with ISSNHL need follow-up audiological assessment; this may reveal other aetiologies, as ISSNHL could be the first presentation of another condition. Also it will identify which patients have ongoing hearing loss and those who may benefit from hearing rehabilitation. Audiological assessment is important in determining the benefit of any given treatment and to identify those who may be suitable for salvage therapy.

Yeo et al. evaluated the long-term results for a 3 month retrospective series of 156 patients diagnosed with ISSNHL.[168] Of 121 patients who recovered over the 3 months of follow-up, 45.5% showed a delayed recovery after the end of 10-day course of therapy. Of these 55 patients, 78.2% recovered within 1 month, 5.5% recovered within 1–2 months, 12.7% recovered in 2–3 months, and 3.6% recovered later than 3 months after discharge. Only one patient showed any recovery beyond 6 months. In view of these results 6 months has been given as a reasonable follow-up period.

In patients with permanent hearing loss early discussion regarding rehabilitation options can reduce patient anxiety. Ideally, these discussions should take place when a hearing loss is first identified, as temporary aiding during treatment may be beneficial.

In order to assess the benefit of treatments for ISSNHL the audiological assessment should compare the pure-tone audiometry (PTA), speech recognition threshold (SRT) and/or WRS at each appointment following diagnosis. The evidence from this comes from a meta-analysis that reviewed 20 studies investigating a variety of treatments for ISSNHL. Although the treatments were diverse, the majority of studies used PTA, and/or WRS to monitor the effectiveness of treatment leading to recovery of hearing.[7]

Definition of recovery and improvement

In one of the early studies on SSNHL Wilson et al.[2] defined recovery as follows:

- **Complete:** if the follow-up PTA (dB HL) or SRT (dB HL) improved to within 10 dB of pre-sudden hearing loss hearing levels.
- **Partial:** if the follow-up PTA (dB HL) or SRT (dB HL) improved to within 50% of pre-sudden hearing loss hearing levels.
- **No recovery:** if the follow-up PTA (dB HL) or SRT (dB HL) was less than 50% of recovery of pre-sudden hearing loss hearing levels.

American Academy recommendations for outcomes assessment

The American Academy of Otolaryngology–Head and Neck Surgery (AAOHNS) makes the following recommendations for outcomes assessment:[6]

1. Unless a previous asymmetry of hearing was known or suspected, the unaffected ear should be used as the standard against which recovery should be compared;

2. a complete recovery requires return to within 10 dB HL of the unaffected ear and recovery of WRSs to within 5% to 10% of the unaffected ear;
3. partial recovery should be defined in two ways based on whether or not the degree of initial hearing loss after the event of SSNHL rendered the ear non-serviceable (based on the AAO-HNSF definition); and
4. anything less than a 10 dB HL improvement should be classified as no recovery.

Associated symptoms of tinnitus, sensation of fullness, vertigo, or nausea following treatment should also be recorded.

The problems with these strategies are that:

- although improvement in pure-tone threshold may be statistically significant, it may not be clinically significant
- there is often no pre-existing audiology.

Smyth and Patterson developed the 'Belfast Rule of Thumb' based on analysis of the relationship between the patient's perceived subjective benefit and post-operative audiometric changes. Although designed to look at hearing outcomes following surgery, it can equally be applied to determine the benefit to patients following treatment for ISSNHL. In order for the hearing gain to be appreciated by the patient, the hearing in the affected ear must be brought to 30 dB or better or to within 15 dB of the contralateral ear.[169]

CONCLUSION

The aetiology and treatment of SSNHL remains controversial. Current research supports several possible aetiologies and, although a variety of treatment options have been investigated, there is no clearly optimum management. Early steroid treatment, either systemic or intratympanic, is advocated, and HBOT may be useful within the first 3 months. There is, however, still a need for high-quality evidence and further research to determine the optimal management.

BEST CLINICAL PRACTICE

✓ Patients presenting with SSNHL should be investigated thoroughly.
✓ When it has been determined that a patient has probable or certain ISSNHL, the diagnostic uncertainty and management options should be discussed with the patient.
✓ The physician should use their expertise in evaluating the risks and benefits of any specific treatment in the light of the patient's individual medical status.

FUTURE RESEARCH

➤ The variability in diffusion across the round window membrane has led to a number of studies looking at:
  ➤ the dose-dependent sensitivity of different hair cell types
  ➤ pharmaceutical and surgical approaches to alter the permeability of the round window membrane
  ➤ delayed drug release formulations to provide precise delivery of therapeutic agents into the inner ear.[170]
➤ The recent development of delayed-release gels placed on the round window membrane has the potential for continuous drug release[171] although they are still affected by the variable permeability of the membrane.[172] Microperforations in the round window membrane have been shown to be an effective means of increasing diffusion across the round window membrane.[173]
➤ The American Academy guidelines have highlighted the following areas in which further research is required:
  1. Investigation of the effectiveness of corticosteroid treatment vs a placebo.
  2. Further investigation of the benefit of HBOT. Current evidence looks promising; however, this is an expensive therapy and is not universally available. Standardised treatment protocols are needed.
  3. Develop standardised outcome criteria to aid the comparison of clinical studies.
  4. Further study the use of IT steroids as salvage therapy, particularly the optimal drugs, dosage, concentrations, and administration schedules for IT therapy.
  5. Develop criteria to determine at what level of hearing recovery IT steroids would be offered as salvage.
  6. Determine the percentage of patients who gain serviceable hearing as a result of treatment.
  7. Investigate the use of "combined therapy" (i.e. oral and IT steroids) in patients with ISSNHL.
  8. Develop long-term follow-up protocols for patients with ISSNHL.
  9. Evaluate therapies using standardised definitions and treatment protocols across studies.

KEY POINTS

- SSNHL is defined as a hearing loss of 30 dB or more, over at least three contiguous audiometric frequencies, that develops over 72 hours or less.
- The aetiology and treatment of SSNHL remain controversial, but prompt recognition and management have been shown to improve hearing outcomes and quality of life.
- Many alternative treatment strategies have been proposed.
- Steroid treatment (either systemic or via transtympanic injection) or hyperbaric oxygen treatments are advocated.

CHAPTER 61

TINNITUS AND HYPERACUSIS

Don McFerran and John Phillips

SEARCH STRATEGY

Data in this chapter may be updated by searches of Medline, EMBASE, the Cochrane Library and Clinical Evidence *BMJ* using the keywords tinnitus and hyperacusis, focusing on pathophysiology, diagnosis and treatment. The data are supplemented by hand searches of specialized books and proceedings from relevant meetings where tinnitus was the main subject. The evidence in this chapter covers all evidence levels.

INTRODUCTION

It is unusual to read any authoritative text or publication about tinnitus without the obligatory introductory paragraph that educates the reader of the etymology of the word 'tinnitus', usually quoting its classical derivation and citing Dennis McFadden's description of the term.[1] It is true that the word tinnitus originates from the Latin word *tinnire* (to ring) and McFadden's description of tinnitus as 'the conscious expression of a sound that originates in an involuntary manner in the head of its owner, or may appear to him to do so' is appropriate. However, there is a lot more to these standard definitions than are worthy of further explanation. In the 1950s, Heller and Bergman studied the descriptions of 180 subjects (80 with reportedly normal hearing and 100 with hearing impairment) who were interviewed regarding sounds that they perceived when introduced into a soundproof booth. Despite many subjects describing a 'ring', this was only one of 39 descriptions reported.[2] In reality, the sound perceived by the patient does not have to be ringing, does not have to be a continuous sound, and in some cases can even represent complex sounds such as musical tunes. As an interesting footnote to one of the most commonly cited tinnitus publications, McFadden was the chairman of a working group set up in the US by the Committee on Hearing, Bioacoustics, and Biomechanics (CHABA) and in his preface to the group's report wrote: 'A number of my friends have noted that tinnitus is an unlikely topic for me to be reviewing and critiquing, and I am the first to agree. I do not consider myself to be an expert on tinnitus: I have never done research on the topic, nor have I ever seen a tinnitus patient.'

Tinnitus has been one of the bugbears of humanity for as long as medical records have been kept: ancient Babylonian clay tablets from more than 600 years BC contain multiple references to tinnitus together with instructions on how to treat the condition using incantations and charms.[3] **Hyperacusis** has a much shorter written history: one of the earliest mentions of the word was in 1881 in a book entitled *Imperfect hearing and the hygiene of the ear*, written by Laurence Turnbull, an American physician.[4] Although often considered as independent entities, there is no denying that an association exists between both of these symptoms, although this does not rule out a link with a common disorder, rather than one being the cause of the other.

Tinnitus and hyperacusis are both fascinating symptoms which, contrary to popular belief, are becoming much better understood with respect to their underlying causes and associations, and their ability to be successfully treated. As we observe advances in our understanding as the result of animal studies, the use of sophisticated imaging techniques, and developments in pharmacology

and psychology, more and more patients are benefiting. In this chapter we will provide an evidence-based overview of tinnitus and hyperacusis, from both a clinical and a research perspective. The psychological aspects of tinnitus will be discussed in Chapter 70, Understanding tinnitus: A psychological perspective, so only a brief summary of this management modality will be provided.

TINNITUS

DEFINITIONS AND CLASSIFICATION

The definition produced by McFadden and described above is still useful, though it would include the hallucinations of mental illness and exclude tinnitus that is perceived outside the body. Other attempts at a definition have included the sensation of hearing a sound in the absence of an external stimulus or a sound sensation in the absence of an external or internal acoustical source or electric stimulation.[5] While perhaps an improvement on the McFadden definition, these would still include auditory hallucinations of mental illness as a form of tinnitus and the latter definition would exclude some types of pulsatile tinnitus where there is an intracorporeal sound source. A completely unambiguous definition has yet to be published.

Many classifications systems have been historically used to define tinnitus, based either on the proposed underlying cause or on the associated symptoms.[6] For consistency we have divided tinnitus into pulsatile and non-pulsatile. Pulsatile tinnitus is considered to be either synchronous or non-synchronous, depending on whether the sound is in synchrony with the patient's arterial pulse. Throughout this chapter non-pulsatile, synchronous pulsatile and non-synchronous pulsatile tinnitus will be considered separately.

Tinnitus can also be divided into subjective or objective forms: in the former, only the patient is aware of the sound sensation: in the latter, the sound can be perceived by others, either unaided, using a stethoscope or a microphone and amplifier. The majority of people with tinnitus report subjective non-pulsatile tinnitus with no specific associated pathological process other than age-associated hearing loss: this is often referred to as subjective idiopathic tinnitus. As described above, the sound perceived in this type of tinnitus can take virtually any form. Mostly, the sounds reported are simple sounds: whistling, humming, ringing or tones. More complex sounds are sometimes described including voices or music. When such complex sounds are present, they are generally indistinct and do not carry specific meaning, unlike the auditory hallucinations of mental illness.

NON-PULSATILE TINNITUS

Epidemiology

The largest investigation into the epidemiology of tinnitus was carried out as part of a UK, Medical Research Council, Institute of Hearing, study of hearing (n = 48 313).[7] This study discovered that the prevalence of persistent spontaneous tinnitus in the adult population was 10.1%, defining persistent spontaneous tinnitus as tinnitus that arose spontaneously, not as a response to sound stimulus, and lasted for periods of 5 minutes or more at a time. Of those surveyed, 5% described their tinnitus as moderately or severely annoying and 0.5% reported that it had a severe effect on their ability to lead a normal life. Studies in other countries have produced broadly similar figures: prevalence figures in Italy have been reported as 14.5% of the population,[8] in the US as 14.9%[9] and in Sweden as 15.8%.[10] Until recently most tinnitus epidemiology studies were limited to Western populations but a few studies have emerged from other countries in the last few years. An overall figure of 5.2% was reported from Egypt, rising to 17.7% in patients over 60 years of age.[11] In Japan, 18.6% of people aged over 65 described tinnitus[12] and in a similarly aged population sample in Nigeria the figure was 14.1%.[13]

Very few incidence or longitudinal studies have been carried out. One of the few published longitudinal studies was undertaken in a community in Beaver Dam, Wisconsin, US. As part of this study, participants aged between 48 and 92 years who did not have tinnitus at baseline were studied over a 10-year period. At the 5-year time-point, the cumulative incidence of new cases of tinnitus was 5.7%;[14] at 10 years the figure was 12.7%.[15] The prevalence of tinnitus in the population at baseline was 8.2% and it is noteworthy that these people tended to show improvement rather than worsening of their tinnitus during the study.

The prevalence of tinnitus seems similar in men and women though there are some differences in the way that the sexes perceive the symptom: women are more likely than men to perceive their tinnitus as a complex sound.[16,17] Presence of a hearing loss increases the likelihood of an individual experiencing tinnitus and, in particular, a high-frequency hearing deficit is a good predictor of tinnitus. Previous noise exposure is also a good predictor: Davis found a prevalence of tinnitus of 7.5% in adults who gave a history of little or no noise exposure but 20.7% in those with high exposure.[18]

Tinnitus is perceived in both ears or in the middle of the head by approximately half of sufferers. A few people perceive it as an external sensation. The remainder have unilateral tinnitus, with left-sided tinnitus slightly more common than right-sided. The reason for this left-sided preponderance is unknown and cannot be explained by asymmetrical hearing loss.[19] The location of tinnitus is not necessarily a fixed entity: it is not unusual for someone to report that they initially thought the sound percept was an external sound due to a faulty electrical item in their home. It was only when the sound sensation was audible in a different location with no electrical appliances present that they realized they had tinnitus and the perception then became internal. Similarly, a number of people who present with unilateral tinnitus subsequently report that the symptom has become bilateral.

Several studies have demonstrated that the prevalence of tinnitus increases with age.[20, 21] This is likely to represent the known association of tinnitus with hearing loss although, interestingly, the tinnitus prevalence does not rise as steeply as that of hearing loss and some studies have shown tinnitus prevalence reaching a plateau around the age of 70 and, in some cases, even diminishing thereafter.[7] There is some evidence that older people are more annoyed by their tinnitus than younger people.[7] It is popularly assumed that tinnitus is a condition of adulthood. Tinnitus does, however, present in children, with prevalence figures not dissimilar to those in adults. This is discussed in more detail later in this chapter. Although tinnitus experience is common in childhood, relatively few seem to find the experience troublesome. Furthermore, it is unusual to see an adult with tinnitus who reports that they have had the problem since childhood, suggesting that children must, by and large, habituate to the symptom.

Various risk factors for the development of tinnitus have been suggested. These include socioeconomic class, smoking, alcohol consumption and other health issues such as previous head injuries, cardiovascular disease and hypertension.[7] Specific otological conditions including Ménière's disease, otosclerosis and vestibular schwannoma are associated with an increased risk of tinnitus: such cases are sometimes referred to as cases of 'syndromic tinnitus'. Numerous drugs have been cited as possible triggers for the development of tinnitus. In most cases the risk is low and the association has not been examined with any great degree of scientific rigor – it is probable that in many cases the link is either idiosyncratic or coincidental. A few drugs do have a more definite link with tinnitus and these include salicylates, quinine, aminoglycoside antibiotics, and some antineoplastic agents, particularly the platinum-based drugs. It has been suggested in a recent study that tinnitus development may have a small genetic predisposition.[22] There have been suggestions that certain personality types such as type D personality are associated with the development of tinnitus.[23] Most studies, however, have suggested that tinnitus patients have a normal gamut of personality types.[24]

Although many patients report that they feel that tinnitus is affected by dietary factors, there has been very little research in this area. A recent publication described a cross-sectional study of 171 722 adults aged 40–69 years who had agreed to participate in the UK Biobank scheme.[25] The authors subdivided tinnitus into persistent, transient and bothersome subtypes and investigated the association of the subtypes with reported consumption of common food groups. An increased report of persistent tinnitus was associated with fruit, vegetable and bread consumption and dairy avoidance. Reduced reporting of persistent tinnitus was associated with consumption of fish and caffeinated coffee and avoidance of eggs. Transient tinnitus reports increased with dairy avoidance and decreased with caffeinated coffee and brown bread consumption. Bothersome tinnitus reports decreased with consumption of wholemeal, wholegrain bread. Although the authors of this study controlled for as many other factors as possible, they highlighted several potential shortcomings in their study and stressed that these results only show evidence of an association between certain foods and tinnitus; they do not imply a causal link.

Two other studies have investigated the relationship between caffeine and tinnitus. The first of these studied the effect of caffeine abstinence on tinnitus and concluded that caffeine has no effect on tinnitus severity.[26] The second study followed 65 085 women aged 30–44 years at baseline over an 18-year period.[27] During the course of the study 5289 participants developed tinnitus; higher caffeine consumption was associated with lower risk of developing tinnitus.

In addition to risk factors, tinnitus has several comorbidities. Depression and anxiety are not infrequently seen with tinnitus and in many instances it is impossible to determine whether these neuroses have precipitated the emergence of tinnitus or vice versa.[28] Temporomandibular joint dysfunction has also been reported as a comorbidity.[29] The tinnitus community is split as to whether this is a causal association or simple coincidence. Disorders of sound tolerance are commonly seen in association with tinnitus: 40% of people with tinnitus report some degree of hyperacusis[30] and, when this association is reversed, 86% of people reporting hyperacusis also report tinnitus.[31] Disorders of sound tolerance are discussed in more detail later in this chapter.

Pathophysiology

The most prevalent presentation of tinnitus in the general population is that of a subjective non-pulsatile sound. Although, in this form, the link between high-frequency hearing loss and tinnitus might be taken as evidence for a cochlear origin for tinnitus, most modern research underscores the importance of central auditory pathways in both the development and maintenance of distressing tinnitus.[32–34] Traditionally, it was considered that tinnitus can exist in the presence of a perfectly functioning auditory periphery but recently the definition of normal hearing has been disputed as many cochlear hair cells may be damaged before an apparent hearing loss is demonstrated using conventional pure-tone audiometry; furthermore, there is evidence that patients with tinnitus may demonstrate hearing loss at frequencies much higher than conventionally tested using standard methods.[35]

Conversely, tinnitus can exist even if the auditory periphery has been completely destroyed or after the neural connections between ear and brain have been severed, as can be seen following some forms of vestibular schwannoma surgery.[36] In addition, damage to the auditory system does not automatically induce tinnitus: although noise-induced hearing loss increases the likelihood of someone reporting tinnitus, the majority of people with cochlear damage secondary to noise exposure do not have significant tinnitus. These observations have been drawn together in a concept that makes a distinction between the location, within either the peripheral or central auditory system, at which an initial tinnitus signal is generated and the subsequent central auditory mechanism by which this signal is misconstrued as a sound with the potential to become

a clinical problem. The point at which the initial signal generation occurs has been dubbed the **ignition site** and the ensuing central mechanisms have been entitled **promotion**.[37] Pathological events which create an ignition site do not inevitably generate tinnitus – the central promotion must also be present. This theory has clinical relevance in that, if tinnitus distress is maintained by central auditory pathways, it may be futile trying to correct peripheral auditory pathology.

While the exact mechanism behind tinnitus ignition is not fully understood, it is now considered that any pathology that can potentially damage the auditory pathways has the potential to result in tinnitus. The following text outlines some of the pathophysiological mechanisms that have been suggested as giving rise to tinnitus, but this list is far from exhaustive and many other hypotheses have been proposed. Likewise, these theories are not mutually exclusive.

PERIPHERAL MECHANISMS

Discordant damage of cochlear hair cells

Outer hair cells have been shown to be more susceptible than inner hair cells to damage by certain agents including noise and aminoglycoside antibiotics. It has been suggested that, in areas where outer hair cells have been damaged but inner hair cells remain, the tectorial membrane is no longer supported by the outer hair cells and can sag onto the inner hair cells, causing them to depolarize.[38]

Calcium channel dysfunction

Calcium is fundamental to several functions of cochlear hair cells and some drugs that are known to cause tinnitus, including salicylates and quinine, affect intracellular calcium levels. Noise also affects the concentration of intracellular calcium. It has therefore been suggested that calcium flux may be implicated in tinnitus generation.[38]

Glutamate receptors

Glutamate is the main excitatory neurotransmitter in the auditory system and several subgroups of glutamate receptor exist. AMPA receptors are the main receptors found on the auditory nerve fibres under the inner hair cells and are responsible for the fast transmission of information from the cochlea to the brain.[39] However, glutamate in large quantities is toxic to nerve fibres. This effect, which can be observed following significant noise exposure, is mediated by AMPA.[40] Another subgroup of glutamate receptors, NMDA receptors are also present in auditory nerve fibres though their function is still a matter of some speculation. It has been observed that pharmacological blockade of NMDA receptors can be protective against both salicylate-induced[41] and noise-induced tinnitus in animal models.[42] Although the evidence that glutamate receptors are directly implicated in the causation of tinnitus is at best circumstantial, they do offer a potential site for therapeutic intervention and this continues to be an active research area.

CENTRAL MECHANISMS

Increased spontaneous firing

There is always a certain degree of electrical activity in the auditory system even when there is no sound input to the ear. Damage to the ear results in reduced activity in the auditory nerve which in turn downregulates inhibitory processes in higher auditory centres, thereby potentially generating increased spontaneous activity in the auditory cortex that could be perceived as tinnitus.[43]

Increased central neural synchrony

Spontaneous neural activity in the auditory cortex is normally random and, when this activity becomes synchronized, this is the signal that a sound is present. If the peripheral auditory system is damaged, spontaneous cortical activity tends to become more synchronized and there is speculation that this can give rise to tinnitus.[44]

Reorganization of the cortical auditory map

The auditory system is tonotopically organized from cochlea to cortex: structures within the auditory system that deal with adjacent sound frequencies are situated beside each other. When the peripheral auditory system is damaged, one change seen in the auditory cortex is that neurons that received inputs from parts of the cochlea that have been damaged tune in to the nearest adjacent frequency input that is still active. This results in over-representation of frequencies adjacent to areas of damage and increased neural activity at those frequencies.[45] It has been suggested that this produces tinnitus.

TINNITUS MODELS

Rather than becoming fixated on the neurobiology of tinnitus, many clinicians prefer to view the functional basis for the symptom. Many psychological and neurophysiological models for tinnitus exist, some of which form the basis for contemporary tinnitus therapies. In 1984 Hallam et al. suggested that tinnitus was caused by 'some neurophysiological disturbance in the auditory system at any point between periphery and cortex'.[46] They went on to suggest that normally the central auditory system should habituate to this activity. However, in certain situations such as high autonomic arousal this process does not happen and the tinnitus activity can become intrusive. Treatment modalities that arose from this concept included the use of relaxation therapy to reduce autonomic activity and cognitive behavioural therapy to help change the emotional significance of the tinnitus.[47] Psychological models of tinnitus and psychological management strategies are discussed in greater detail in Chapter 70, Understanding tinnitus: A psychological perspective. In 1990 Jastreboff published what has become known as the 'neurophysiological model' of tinnitus, drawing together all the available knowledge at the time and suggesting that, in addition to events within the classical auditory system, tinnitus involved altered activity within the limbic system, reticular system and autonomic nervous system.[38] This model was then

used to produce a clinical application that became known as 'tinnitus retraining therapy' (TRT).[48, 49]

TINNITUS MODULATION

Over the last two decades it has become apparent that tinnitus can be influenced by stimuli from outside the auditory system: many patients with tinnitus can modulate their symptom by touching their face,[50, 51] clenching their teeth[52] or changing their gaze.[53] Although this was initially dismissed as a rare curio, it has become apparent that this phenomenon is quite common, highlighting the importance of links between the auditory system and other somatosensory pathways. Furthermore, this interesting phenomenon is currently being employed to form the basis of a novel form of tinnitus therapy.[54]

Investigation

BASIC AUDIOMETRY

Specific forms of tinnitus, such as tinnitus in the presence of Ménière's disease, may require specialist investigations. However, it is well accepted that all patients with tinnitus, in addition to having a thorough history and examination performed, require, as a bare minimum, a pure-tune audiogram. Many people with tinnitus complain that their ear or ears feel blocked and tympanometry is therefore often valuable.

TINNITUS-SPECIFIC AUDIOLOGICAL MEASUREMENTS

A number of specific tinnitus tests are available, but their reliability is variable, even when assessed using contemporary research methods.[55] Tests include the assessment of loudness discomfort levels, tinnitus pitch matching, tinnitus loudness matching and minimal masking levels.

IMAGING

Patients with unilateral tinnitus, an asymmetrical sensorineural hearing loss or associated neurological symptoms or signs require imaging to exclude the presence of a retrocochlear pathology such as a vestibular schwannoma. The modality of choice is MRI and there are now sufficient MRI options that even the claustrophobic, obese and those unable to lie flat should be able to undergo MRI scanning. The presence of non-compatible medical devices such as pacemakers or the presence of metal foreign bodies may still preclude MRI, in which case CT may be utilized.

TINNITUS QUESTIONNAIRES

Tinnitus questionnaires are an essential tool for research[56] and also have a role in the assessment of patients during routine clinical practice: their use has been recommended in the UK by the Department of Health's good practice guide.[57] There are a plethora of questionnaires available and there is no clear winner. Examples include the Tinnitus Handicap Questionnaire,[58] the Tinnitus Handicap Inventory (THI),[59] The Mini Tinnitus Questionnaire[60] and the Tinnitus Functional Index.[61] A survey of audiology departments in 2012 showed that the THI was the most popular tinnitus questionnaire used in the UK.[62] However, this study was conducted prior to the release of the Tinnitus Functional Index, which is claimed to have several advantages over its older competitors.

OTHER QUESTIONNAIRES

Because of the comorbidity of psychological conditions such as anxiety and depression with tinnitus, it is often helpful to use a mental health questionnaire such as the Hospital Anxiety Depression Scale (HADS).[63] Similarly, sleep disturbance is commonly reported in patients with tinnitus and it may be advantageous to use a sleep assessment tool such as the Insomnia Severity Index.[64]

VISUAL ANALOGUE SCALES

Visual analogue scores are considered useful, particularly in the research setting, when assessing specific components or consequences of tinnitus. Scores are usually formulated by putting a mark on a straight line, the ends of which represent the extremes of the parameter being assessed.

Mainstream treatments

To date a whole host of medicinal, device and psychological treatments for tinnitus have been proposed. The evidence base to support these treatments is poor at best, mainly due to a paucity of well-designed randomized controlled trials (RCTs). The scientific community has often been criticized for relying too heavily on the gold standard double-blinded RCT, but for conditions such as tinnitus, where many treatments may work via a placebo effect,[65] and there being a general natural improvement in symptoms with time, it is difficult to consider any other method of scientific evaluation as fit for purpose.

EXPLANATION AND REASSURANCE

An explanation of the condition and reassurance is a key initial step in the management of any patient with tinnitus. Often, the process of education and information giving is not the only treatment provided but, when provided in a formal setting, a number of RCTs are supportive of this modality.[66–68] A common report of patients seen in specialist tinnitus clinics is that clinicians who they have previously consulted have offered a very pessimistic view of tinnitus outcome. Reports such as 'the doctor told me that I would have it forever and nothing can be done' are all too common. This negative counselling is damaging for patients with tinnitus and should always be avoided.[69]

HEARING AIDS

As there is an association between tinnitus and hearing loss, it would make sense that providing hearing amplification would in part ameliorate a patient's symptoms. The literature lends some support for this[70, 71] but a recent

robust appraisal of the literature concluded that there was limited support from well-designed trials.[72] Hearing amplification may amplify external sounds and mask tinnitus, but indirect effects, such as improving communication, may reduce stress and anxiety that may be exacerbating the patient's symptoms.

Hearing aids first featured as a method of tinnitus management in the 1940s.[73] Currently, when supplemented with education and advice, hearing amplification is considered to be the primary intervention for a patient with tinnitus and aid-able hearing.[62] A large best practice consensus document has recently been published that recommends the provision of hearing aids in tinnitus patients even if they would normally be regarded as marginal hearing aid candidates.[74] A Delphi review of the use of hearing aids in the management of tinnitus, however, showed that, although there is some consensus among professionals, there is also still considerable disagreement.[75] Despite this lack of consistent good quality evidence, many clinicians encourage patients who have a hearing loss in addition to their tinnitus to try appropriate hearing aids even if they feel that amplification is not yet required for the hearing loss.

SOUND THERAPIES

Sound therapy can be used as part of TRT or as a standalone treatment. It is possible to use sound to completely or partly suppress, or mask, tinnitus in 95% of tinnitus patients in a clinic setting using specialist equipment, with 92% experiencing complete masking.[76] Translating this into practical treatment is less successful. Also, it has been suggested that complete masking is counterproductive as it may prevent habituation to the tinnitus signal. Proponents of TRT suggest that sound therapy is important but not used as masking. Instead, it is advocated that sound should be used at very low levels at a point where the added sound is just below the perceived level of the tinnitus.[77] Sound therapy at this so-called mixing or blending point is supposed to facilitate the habituation process, although there is conflicting evidence to the efficacy of this approach.[78, 79] There are three methods of providing wearable sound therapy: patients may wear hearing aids that produce masking by amplifying ambient sound (as discussed above), small ear level devices that generate wide-band sound (known as tinnitus maskers, sound generators, white noise generators or wide-band sound generators) or combination devices that blend the functions of the first two types of device. Whether such devices deliver masking or sound therapy at a mixing point simply reflects the output level that is set on the device. An alternative to donning a wearable device is to use an appliance that produces sound in the patient's immediate environment. This is referred to as environmental sound enrichment and can be delivered by devices such as electric fans, wind chimes, water features, prerecorded compact discs and electronic environmental sound generators. Sound from the latter two devices can be fed to a loudspeaker fitted into or under a pillow, allowing the patient to hear the sound while preparing for sleep without impinging on his/her partner. There are numerous programmes for computers and apps for smartphones that can be used to produce environmental sound enrichment.[80]

NOVEL SOUND THERAPIES

Several devices deliver forms of sound therapy that claim to specifically target tinnitus rather than simply offering masking or distraction.[81] Some purport to do this using sound on its own whereas others deliver sound stimulation while simultaneously stimulating other sensory systems.

Neuromonics®

Neuromonics® is a device that uses music modified to compensate for any hearing loss that the patient may have. The music has a large dynamic range with peaks and troughs with the intention that tinnitus is audible in the troughs. The sound therapy is accompanied by education and counselling and it is claimed that gradual exposure to the tinnitus during the troughs aids habituation. Several studies have been undertaken, mostly by the team that developed the device [82] and scientific rigour has been questioned.[83] An RCT compared Neuromonics® against ear-level sound generators and concluded that they had a similar effect on tinnitus.[84]

Serenade®

Work undertaken on a patient with profound hearing loss and tinnitus who had undergone cochlear implantation showed that certain stimulation paradigms were effective in ameliorating the tinnitus.[85] Extrapolating from this work, an acoustic stimulation regime was developed using temporally patterned sound altered to account both for any hearing loss and the pitch of the patient's tinnitus. This sound therapy is delivered via a device called Serenade® and the sounds have been dubbed S Tones.[86] There is now some evidence that S Tones may have a modest benefit compared to wide-band sound.[87]

Noise cancellation

Noise cancellation has been investigated as a possible tinnitus therapy. One device, Phase-Out, matches a therapeutic tone to the patient's tinnitus tone and then phase shifts the therapeutic tone by 6 degrees every 30 seconds. The suggestion made by the developer is that the therapeutic sound cancels the tinnitus for one-third of the total time.[88] Although some supportive research was published,[89] more scientifically robust research showed no benefit.[90]

Acoustic CR neuromodulation

One of the theories regarding the pathophysiology of tinnitus is that it is due to increased neural synchrony in the central auditory system (see above). It was suggested that a specific form of sound stimulation could be used to disrupt this pathological synchrony: four tones are delivered via headphones, two above and two below the dominant frequency of the patient's tinnitus. The technology is known

as Acoustic CR (Co-ordinated Reset) Neuromodulation and initial research looked promising.[91, 92] An RCT was planned.[93] This research was undertaken but the results were not published owing to deviations from the trial protocol. Following a freedom-of-information request by a UK tinnitus charity, a limited disclosure of the results was published online.[94] This stated that the end-of-study report did not report a significant difference in the primary outcome measure (global Tinnitus Handicap Questionnaire scores) between the treatment group and the placebo group.

Sound therapy with vagal nerve stimulation

Another theory regarding the pathophysiology of tinnitus is that of cortical map reorganization (see 'Central mechanisms' above) in which damage to the ear causes plastic changes within the central auditory system. Animal studies have suggested that direct electrical stimulation of the nucleus basalis in the forebrain in conjunction with stimulation of the sensory organ could reverse such changes. Clearly, this is too invasive to become a mainstream treatment but animal experiments have shown that stimulation of the vagus nerve paired with sound stimulation could potentially achieve the same effect.[95] Small-scale studies to stimulate the vagus nerve both by electrodes implanted against the nerve in the left side of the neck[96] and by the transcutaneous route[97] have been undertaken. As yet, however, there is insufficient evidence to reach meaningful conclusions and further work is required.

Mute button

Another therapy that utilizes crossover between the auditory system and other somatosensory pathways is Mute Button. This pairs acoustic stimulation with electrical stimulation of trigeminal nerve fibres in the anterior tongue. To date this treatment modality is only available in the Republic of Ireland and scientific evidence is limited to conference proceedings.

ULTRASOUND

Ultrasound has also been used to treat tinnitus: high-frequency sound is applied by a bone-conduction transducer. The rationale of this approach is that the ultrasound should stimulate the cochlea without interfering with the patient's hearing for sounds occurring in the normal auditory spectrum. An initial study reported optimistic results but this was not repeated.[98]

COMBINATION TREATMENT MODALITIES

Following publication of his neurophysiological model in 1990,[38] Jastreboff went on to generate a clinical management strategy that combined directive counselling and sound therapy to counteract the pathological positive feedback process and promote habituation to the tinnitus.[48] This process was subsequently titled tinnitus retraining therapy (TRT)[49] and the technique has been extensively discussed in a book which outlines a rigorous protocol.[99] However, the neurophysiological model, from which it is derived, can be interpreted differently and many tinnitus practitioners apply the clinical extrapolates of the model in a less rigorous fashion. A Cochrane systematic review has considered the evidence for the administration of TRT.[100] The initial findings were that, based on a single, low-quality RCT, TRT is much more effective as a treatment for patients with tinnitus than tinnitus masking.[101]

COGNITIVE BEHAVIOURAL THERAPY

The use of psychological techniques such as cognitive behavioural therapy (CBT) in the UK is hugely hampered by a lack of psychologists with appropriate tinnitus training. A Swedish group has investigated delivering CBT via the internet and initial results suggest that this may be a useful approach.[102] A Cochrane systematic review has considered the evidence for the administration of CBT and it was concluded that CBT resulted in no significant difference in tinnitus loudness, but CBT did result in a significant improvement in both depression scores and in quality of life scores.[103] A recent systematic review concluded that both CBT and TRT were effective treatments for tinnitus and neither was demonstrably superior.[104]

OTHER PSYCHOLOGICAL TREATMENTS

More modern psychological treatment modalities have recently been explored for efficacy in the management of tinnitus: these include mindfulness meditation[105] and acceptance and commitment therapy (ACT).[106] Initial reports appear optimistic. Psychological treatments are discussed in more detail in Chapter 70, Understanding tinnitus: A psychological perspective.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

Many forms of complementary medicine are promoted as being beneficial for tinnitus patients. A list of some of the more commonly used modalities is shown in **Box 61.1**. Many of these therapies involve much contact between the

BOX 61.1 Some of the complementary medicine therapies and exercise regimes that have been used in the management of tinnitus

Acupuncture	Hypnotherapy
Alexander technique	Massage
Aromatherapy	Meditation
Black cohosh	Osteopathy
Chiropractic	Reflexology
Craniosacral therapy	Reiki
Herbal medicine	St John's wort
Ginkgo biloba	Shiatsu
Homeopathy	Tai Chi
Ear candles	Yoga

therapist and patient and promote a sense of relaxation. It might therefore be expected that these therapies could help tinnitus patients, at least in a non-specific way.

Relaxation techniques have been studied as a specific therapy to treat tinnitus and three RCTs have been performed to assess their effectiveness.[107–109] These studies supported the efficacy of relaxation therapy for tinnitus intrusiveness but there was mixed evidence for its efficacy for depressive symptoms, and there was no evidence for an effect on anxiety.

In 2000 Park et al. systematically reviewed the efficacy of acupuncture as a treatment for tinnitus.[110] This review identified only six randomized trials: two unblinded trials and four blinded trials. The two unblinded trials demonstrated a positive effect of acupuncture treatment for tinnitus, whereas the four patient-blinded, sham-controlled studies demonstrated no significant difference between treatment with acupuncture and placebo.

There have been some claims that chiropractic manipulation benefits tinnitus patients, but there have been no scientific studies to substantiate any positive effect in comparison to placebo.

A note of caution must be sounded regarding the use of ear candles in the management of tinnitus. Not only has no benefit been demonstrated but in a few instances damage to the ear has resulted as a consequence of their use.[111]

Several exercise regimes such as Tai Chi and yoga have been promoted as helping patients with tinnitus. In these cases, no claim is made that the exercises treat the tinnitus directly but rather that the techniques promote relaxation and combat stress.

Ginkgo biloba has attracted more interest for the treatment of tinnitus than any other complementary therapy. The efficacy of ginkgo has had mixed support. A number of large double-blinded, placebo-controlled trials have been undertaken reaching different conclusions. In 2001 Drew and Davies failed to demonstrate a significant effect in treating tinnitus using ginkgo doses of 150 mg.[112] A double-blinded, placebo-controlled trial and meta-analysis of randomized trials recently concluded that ginkgo did not benefit patients with tinnitus.[113] Despite these reports it must be noted that the success of other studies has been based on much higher doses of up to a daily total of 480 mg of ginkgo extract.[114] Further supporting the role of ginkgo is a controlled study demonstrating a statistically significant reduction in tinnitus using an animal model.[115] Systematic appraisal of the role of ginkgo has been performed by way of a Cochrane review, which found no reliable evidence supporting its use as many of the studies performed have been flawed in one way or another.[116]

ELECTROMAGNETIC STIMULATION

Direct electrical stimulation of the ear has been shown to suppress tinnitus but delivering this stimulation is invasive and risks damage to the inner ear.[117] Partly because of this tantalizing glimpse of a tinnitus suppressant, other ways of delivering electrical and magnetic energy to the cochlea or central auditory system have been investigated. High-powered rare earth magnets have been placed in the ear canal but an RCT failed to show any benefit despite initial positive reports.[118] Electromagnetism has also been investigated: initial trials gave mixed results,[119] but the use of refined methods of delivery have promoted further interest in this area. Electromagnetism has been used in conjunction with functional imaging such as PET scanning or fMRI: pathologically active areas of brain are identified and electromagnetic therapy is then directed to this area.[120, 121] Repetitive transcranial magnetic stimulation (rTMS) can be delivered at a variety of different frequencies and in some circumstances employing complex wave administration.[122] A recent Cochrane systematic review has considered the evidence for the administration of rTMS and concluded that there is very limited support for the use of low-frequency rTMS for the treatment of patients with tinnitus.[123] When considering the impact of tinnitus on patients' quality of life, there was support from a single study with a low risk of bias based on a single outcome measure at a single point in time.

SYSTEMIC DRUG TREATMENTS

Although drug therapy should be relatively easy to investigate, much of the published information is of poor quality. The use of inert placebos, inadequate outcome measures and high drop-out rates are common in drug trials. Moreover, most trials have failed to make a distinction between helping concomitant psychological illness and direct effect on tinnitus. Tinnitus drug trials are often carried out on small groups of patients and consequently lack the power to detect small effects.

Psychoactive drugs have been used in the management of tinnitus, partly because tinnitus patients score highly for symptoms of psychological distress[28] and partly because many of the receptors that psychoactive drugs act upon are also found within central auditory pathways. While there is a role for such drugs in the treatment of any psychological or psychiatric disease that accompanies tinnitus, the situation with respect to the tinnitus itself is less clear. There are four reasonably well-constructed RCTs which investigated the use of tricyclic antidepressant drugs.[124–127] These all reported slight improvement in tinnitus but these conclusions may be attributable to methodological flaws, so no major conclusions can be drawn. A well-constructed trial of a selective serotonin reuptake inhibitor, paroxetine, showed no advantage over placebo for the majority of criteria investigated.[128] Benzodiazepines have been widely used in the management of tinnitus and some work has suggested that this group of drugs may have a direct effect on tinnitus.[129] Unfortunately, this research can be criticized for using an inert placebo and, in any case, the propensity for benzodiazepines to induce dependence restricts their usage.

Antiepileptic[130, 131] and antispasmodic[132] drugs have both been investigated for potential activity against tinnitus but the results have been disappointing. Likewise the use of vasodilators[133] and diuretics[134] has proved unhelpful. Betahistine is frequently administered to patients with idiopathic tinnitus: there is no scientific rationale for this action. In 2006 a group in China reported an improvement

in tinnitus loudness when subjects received betahistine as compared with subjects that received a control drug.[135] However, only a small number of subjects were studied and there have been no further studies published since to corroborate the original study authors' findings.

Local anaesthetic agents have offered one glimmer of hope for a possible pharmacological solution to tinnitus. Following a serendipitous discovery when procaine caused temporary abatement of tinnitus in a patient undergoing nasal surgery,[136] several trials have confirmed that intravenous injections of some ester and amide local anaesthetic agents cause short-term reduction of tinnitus. A double-blind, placebo-controlled, crossover trial investigated 16 patients who had post-operative tinnitus following translabyrinthine resection of a vestibular schwannoma.[137] Bolus intravenous injection of lidocaine produced significant short-term tinnitus suppression despite the fact that the auditory nerve had been divided during the surgical procedure. Although the trial can be criticized for using an inert placebo, the observations suggest that, at least within this group, the antitinnitus effect of the local anaesthetic agent was central rather than peripheral. Previous attempts to find a less hazardous and orally active agent that has the same beneficial effects as these local anaesthetics have failed.[138]

Two small-scale trials have shown that the hormone melatonin helps patients who have sleep disorders associated with tinnitus.[139, 140] As many patients with tinnitus do have sleep disorders,[141] this merits further investigation.

Tinnitus, like idiopathic sudden sensorineural hearing loss, has been thought to arise from a lack of oxygen secondary to vascular insufficiency. For this reason interest has been shown in the application of hyperbaric oxygen therapy to increase the supply of oxygen to the ear and brain to reduce the severity of hearing loss and tinnitus. A critical assessment of the role of hyperbaric oxygen therapy has been performed by way of a Cochrane review and no clear value could be demonstrated.[142]

As glutamate is the main excitatory neurotransmitter in the auditory system, there has been considerable interest in studying a variety of antagonist drugs, including memantine,[143] flutirpine[144] and neremexane[145] but no demonstrable benefits have been shown.

There have been sporadic reports of the successful use of drugs to treat specific subtypes of tinnitus. For example, it has been suggested that the antiepileptic drug carbamazepine can be effective in treating a variant of tinnitus that presents with an intermittent staccato quality, described as sounding like a typewriter or popping corn.[146] However, this report is from a small uncontrolled case series and better scientific evidence in the form of an RCT would be required before such therapy could be recommended.

REGIONAL DRUG TREATMENTS

Botulinum toxin has been shown to be beneficial through non-paralytic effects for conditions such as neuropathic pain and migraine. With respect to migraine, botulinum toxin is thought not only to block acetylcholine but also to inhibit the release of other neurotransmitters and neuropeptides involved in the autonomic pathway. Botulinum toxin A has been trialled in a small study of 26 tinnitus patients with the drug injected into soft tissues around the ear.[147] Benefit was demonstrated in the treatment arm as compared to the control arm but, due to the small number of patients recruited, no statistical significance was demonstrated.

INTRATYMPANIC DRUG TREATMENTS

The idea that drugs could have a therapeutic effect following instillation into the middle ear cavity has a long pedigree: work in the 19th century investigated the application of volatile vapours into the middle ear using Eustachian tube catheters.[148] Direct injection through the tympanic membrane was first utilized as a potential treatment for otosclerosis.[149] After initial enthusiasm this route of drug administration underwent a period when it was rarely used, but following the successful experience of using transtympanic administration of aminoglycosides in the treatment of Ménière's disease, the use of intratympanic therapies is once again being investigated for patients with subjective idiopathic tinnitus. It has been theorized that transtympanic administration allows direct labyrinthine drug absorption which may offer improved labyrinthine metabolism and hence reduction of tinnitus in those patients who have tinnitus in association with cochlear pathology. This mode of administration may appear to fly in the face of most modern theories of tinnitus pathophysiology, which suggest that the long-term problems of tinnitus occur in the central rather than peripheral auditory system. Events within the ear such as sudden sensorineural hearing loss, acute noise trauma or acute otitis media can trigger tinnitus and it has been suggested that there is a small therapeutic time window between the pathological event in the ear in these cases and the development of permanent changes in the central auditory system that produce troublesome tinnitus. It is therefore hypothesized that, in patients with sudden onset of tinnitus, there might be a short period when intratympanic treatments could be efficacious. Furthermore, it has been observed that some treatments that improve hearing, such as stapedectomy in otosclerosis, generally help any associated tinnitus. Extrapolating from this, intratympanic therapies that could potentially improve hearing could therefore also potentially be beneficial with any associated tinnitus.

Various agents, including steroids,[150] local anaesthetic agents,[151] anticholinergic drugs,[152] glutamate antagonists[153] and antioxidant compounds[153] have been delivered into the middle ear, either by single transtympanic injections, through perforations and grommets, or via an implanted micropump.[154] Most of the trials in this area are small observational studies. The solitary placebo-controlled trial in this field demonstrated no advantage of intratympanic dexamethasone over placebo.[155]

Although there has been no demonstrable benefit from using systemic glutamate antagonists in the management of tinnitus, interest in this class of drugs continues.

Some glutamate antagonists are too toxic to consider for regular systemic usage and consequently there has been interest in the intratympanic administration of these drugs. Recently there have been some encouraging results from preliminary studies investigating the use of esketamine, the S(+) enantiomer of ketamine, for acute 'inner-ear' tinnitus.[156] This compound acts as a non-competitive antagonist of the N-methyl-D-aspartate (NMDA) subgroup of glutamate receptors. At the time of writing, larger-scale multinational trials are being conducted to decide whether the acute administration of this drug will prove to be a viable treatment in the future. Similarly, clinical trials are shortly expected to start for a sustained-release formulation of another NMDA antagonist, gacyclidine.

DIETARY SUPPLEMENTS

A large number of vitamins, minerals and other dietary supplements have been given to tinnitus patients in an effort to alleviate the condition. Some of the agents used are listed in **Table 61.1** although this is far from an exhaustive list.

There is some evidence that some of these compounds listed in **Table 61.1**, particularly the B vitamins, can help to defend the cochlea against noise trauma.[157] Indeed, some of the compounds on the list are being investigated for effectiveness in protecting people who are exposed to noise from developing tinnitus (see 'Prevention' below). However, there is no convincing evidence that they have any effect against established idiopathic tinnitus. The human cochlea has the body's greatest concentration of zinc. Some studies have demonstrated a significant decrease in zinc levels in some patients suffering from tinnitus and rectifying this deficiency has been shown to decrease tinnitus significantly.[158] Paaske et al., however, demonstrated little correlation between hypozincaemia and tinnitus[159] and no significant improvement in tinnitus with zinc supplementation. A randomized double-blind, placebo-controlled trial of the use of zinc in a population of tinnitus patients aged 60 or over showed no benefit with regards to their tinnitus.[160]

TABLE 61.1 Some of the dietary supplements that have been used in the management of tinnitus

Name of supplement	Class of supplement
Arginine	Amino acid
Beta carotene	Vitamin precursor
Calcium	Mineral
Club moss	Herbal
Coffee (unroasted)	Herbal
Cornus	Fruit
Folic acid	Vitamin
Foxglove	Herbal
Garlic	Herbal
Hydergine	Herbal
Ipriflavone	Bioflavonoid
Ligustrum	Herbal
Magnesium	Mineral
Manganese	Mineral
Melatonin	Hormone
Mullein	Herbal
N-acetylcysteine (NAC)	Antioxidant
Omega-3	Fish oil
Peruvian bark	Herbal
Plumbago	Herbal
Potassium	Mineral
Pulsatilla	Herbal
Salicyclic acid	Herbal
Selenium	Mineral
Sulphite of quinine	Herbal
Vegetable charcoal	Herbal
Vinpocetine and vincamine	Herbal
Vitamin A	Vitamin
Vitamin B1 (Thiamine)	Vitamin
Vitamin B3 (Niacin)	Vitamin
Vitmain B6 (Pyridoxine)	Vitamin
Vitamin B12	Vitamin
Vitamin C	Vitamin
Vitamin E	Vitamin
Wobezym	Enzyme formula
Zinc	Mineral

LASERS

Lasers have been used successfully in the management of some forms of chronic pain but the exact mechanism for this benefit remains contentious. Low-power lasers have been used in the treatment of tinnitus, applied either transmeatally or to the mastoid process. Although some workers have reported good results from such treatment,[161, 162] two well-constructed trials found no benefit above that derived from placebo.[163, 164]

SURGERY

Surgery has a definite role in the management of tinnitus associated with certain conditions such as otosclerosis when stapedectomy is reported as improving or eradicating tinnitus in 80–88.3% of cases.[165, 166] When tinnitus is associated with profound hearing loss, tinnitus suppression has been demonstrated as a secondary benefit of cochlear implantation. Improvement of tinnitus occurs in up to 86% of implanted patients and, interestingly, in up to 67% the benefit applies to the contralateral ear as well as the implanted ear.[167] There is no good evidence to support cochlear implantation for the sole purpose of tinnitus suppression and it would be ethically difficult to propose cochlear implantation for someone with significant residual hearing. The use of cochlear implantation with regard to the management of tinnitus in conjunction with single-sided deafness is discussed in 'Single sided deafness' below.

Destructive surgical procedures including VIIIth nerve neurectomy or selective cochlear neurectomy have been tried but there is no trial using good scientific methodologies such as validated outcome measures. Surgical treatments of Ménière's disease are generally aimed at control of vertigo and few trials have explored the effect on tinnitus. A Cochrane review of surgical treatments for Ménière's disease identified two studies that had commented on tinnitus outcome, both employing endolymphatic sac decompression. In both studies endolymphatic sac decompression showed no advantage over the control treatment with regard to tinnitus.[168]

PREVENTION

Cochlear damage caused by exposure to agents including noise, ototoxic agents and cytotoxic drugs is recognized as a trigger for tinnitus. Clearly, the best way to avoid damage from these agents is to avoid exposure to them: this is not always possible or practical. At a cellular level, the inner ear damage is generally mediated by a process of apoptosis[169] and this cascade has the potential to be therapeutically blocked. Driven in part by a need to protect military personnel from noise during combat,[170] several studies are researching the use of antioxidants including D-methionine (D-met),[171] ebselen[172] or a combination of beta carotene, vitamin C, vitamin E and magnesium (ACE Mg).[173] Stem-cell and gene therapies are also being investigated.[169]

PULSATILE TINNITUS

Pulsatile tinnitus is a form of tinnitus whereby the perception of sound is not that of a continuous form. The perceived sound takes on the form of a pulsation, clicking or fluttering. Pulsatile tinnitus is worthy of consideration as a specific subtype of tinnitus because the management of pulsatile tinnitus is different from that of the typical tonal tinnitus that patients report. Pulsatile tinnitus is classified as either synchronous or non-synchronous, depending on whether the tinnitus takes on the characteristics of a pulsation in synchrony with the patient's heart.

Synchronous pulsatile tinnitus

PATHOPHYSIOLOGY

Synchronous pulsatile tinnitus may present as the direct result of abnormal vascular anatomy in the vicinity of the peripheral auditory system. Systemic aberrations of the circulation, such as a hyperdynamic circulation, have also been implicated in the development of synchronous pulsatile tinnitus. Processes that result in altered arousal, altered selective attention, hearing loss, or altered cochlear blood flow or trauma may result in increased central auditory gain.[48] It has been proposed that, once this process has ceased, the increased gain will cause the subject to become more aware of their own physiological vascular pulsations. Table 61.2 summarizes the different pathological causes of synchronous pulsatile tinnitus.

TABLE 61.2 Pathological causes of pulsatile tinnitus

Type of pathology		Specific pathology
Vascular	Arterial	Atherosclerotic carotid artery disease[174] Arteriovenous fistula[175] Arteriovenous malformation[176] Intracranial aneurysm[175] Fibromuscular dysplasia of the carotid artery[177] Dissection of the carotid artery[178] Vascular anomalies of the ear[179] Vascular compression of the VIIIth nerve[180]
	Venous	Jugular bulb abnormalities[181] Dural venous sinus stenosis[182] Abnormal condylar or mastoid emissary veins[183] Idiopathic tinnitus, venous hum, essential tinnitus[184, 185]
Microvascular		Glomus tumour[186] Paget's disease[187] Cholesterol granuloma of middle ear[188] Meningioma of middle ear[189] Cavernous haemangioma[190] Histiocytosis X[191]
Circulatory		Increased cardiac output (anaemia, thyrotoxicosis, pregnancy)[192] Aortic murmurs[188]
Perceptual		Conductive hearing loss[193] Cochlear trauma[193]
Other		Benign intracranial hypertension[194–197] Superior semicircular canal dehiscence syndrome[198]

Whereas, traditionally, pulsatile tinnitus has been considered to be always a consequence of a primary vascular abnormality, over the last decade there has been a greater consideration of other primary causes. Intracranial hypertension is particularly gaining increased attention as a cause of pulsatile tinnitus.[196, 197] Idiopathic intracranial hypertension, or pseudotumor cerebri, is one cause of intracranial hypertension; this condition tends to occur more often in young, overweight women. Superior semicircular canal dehiscence syndrome is more usually featured in the medical literature as a cause of dizziness, however the emergence of this condition as a presentation of pulsatile tinnitus is beginning to gain acceptance.[198]

INVESTIGATION

Simple blood tests are considered helpful to exclude anaemia and thyrotoxicosis. In the absence of an obvious cause, synchronous pulsatile tinnitus requires imaging. Over the years there has been much debate regarding the ideal imaging modality. If otoscopy reveals a retrotympanic mass, a contrast-enhanced computed tomography (CT) of the temporal bone, brain and scalp is indicated.[199] If atherosclerotic carotid artery disease is suspected, duplex carotid ultrasonography can be helpful. Otherwise, the

advantages and disadvantages of magnetic resonance angiography (MRA) over contrast-enhanced CT has not been satisfactorily resolved. The gold standard mode of imaging the vascular system of the temporal bone, brain and scalp is via formal angiographic imaging, but this is not without risk, so this is often reserved for severe, recalcitrant cases where less invasive techniques have not revealed an obvious pathology. If idiopathic intracranial hypertension is suspected, an ophthalmological assessment, lumbar puncture, measurement of intracranial pressure and diagnostic reduction of intracranial pressure by draining off some cerebrospinal fluid may be required.

TREATMENT

Supportive

When no obvious cause is identified, providing reassurance that there is no untoward pathology present is often an important aspect of treatment. These patients may benefit from CBT or TRT to address the coexisting emotional effects of their tinnitus. Anecdotally, sound therapies can be used as for subjective idiopathic tinnitus though there is no evidence base to support this management.

Surgery

Surgery can play an important role in the management of pulsatile tinnitus,[195] depending on the causative pathology. Treatments may include decompressive and destructive procedures. Modern imaging techniques, and in particular MRI, have shown that vascular loops are commonly in close proximity to the cochlear nerves of patients with tinnitus. It has been suggested that laterally placed loops generate pulsatile tinnitus whereas vessels adjacent to the medial half of the nerve generate non-pulsatile tinnitus.[200] However, the prevalence of such loops in people who do not have tinnitus is unknown. Microvascular decompression of vascular loops in tinnitus patients has been used with very variable results, ranging from 40% improvement[201] to 77%.[202] The highly invasive nature of this surgery precludes its use in all but the most exceptional cases.

Non-synchronous pulsatile tinnitus

Tinnitus may manifest itself as a train of rhythmical clicks or a buzzing or fluttering noise or sensation that is not synchronous with the pulse. These sounds are often related to myoclonic activity resulting in repetitive contractions of the middle ear muscles, but other muscles within the head and neck region can be affected. Currently there is no evidence to suggest that the middle ear is part of a systematic myoclonic disorder. Within the middle ear, contraction of the tensor tympani and/or stapedius muscle are often proposed to be the cause of either a clicking or buzzing noise respectively; however, whether the associated tinnitus is the direct result of muscle contraction noise, vibration of the tympanic membrane or movement of the ossicular chain remains unknown.[203] The palatal muscles can also develop myoclonic contraction and this can produce sound that is audible to others. The clicking sound of palatal myoclonus is usually irregular with a frequency of one to two clicks per second. Involuntary palatal movements may be seen, either simply by inspecting the palate transorally or by visualizing the upper surface transnasally using a fibreoptic endoscope. Palatal myoclonus exists in two forms: symptomatic palatal myoclonus, which may be associated with lesions of the brainstem; and essential palatal myoclonus, which is usually idiopathic. It is generally essential palatal myoclonus that is associated with pulsatile tinnitus.

INVESTIGATION

The role of specialist testing for the assessment of middle ear or palatal myoclonus is unclear. While middle ear myoclonus can be diagnosed based on history and impedance changes on long-time-based tympanometry, an accurate differentiation between myoclonus of the tensor tympani and the stapedius muscle is not possible.[203] It is, however, important to differentiate a middle ear myoclonus from a palatal myoclonus. Palatal myoclonus usually produces an objective rhythmic sound that is associated with an involuntary movement of the soft palate and/or suprahyoid muscles. As palatal myoclonus has been associated with lesions in the central nervous system, MRI is recommended to exclude a pathology with the triangle of Guillain–Mollaret.[204]

TREATMENT

In cases of middle ear myoclonus, despite evidence to support the division of the middle ear tendons, a period of conservative treatment is recommended in the first instance. Pharmacological solutions that have been explored have included the use of benzodiazepines,[205] orphenadrine,[206, 207] carbamazepine,[208] piracetam[206] and botulinum toxin.[209]

Other reported supportive treatments include relaxation therapy,[210] psychotherapy,[211] tinnitus masking[212] and biofeedback,[212] although outcomes have been variable. In persistent cases, the surgical division of the middle ear tendons has been reported to be a definitive procedure: it is recommended that in these cases both tendons are divided as it is not possible to reliably identify the muscle which is responsible for the symptoms.

ALLIED CONDITIONS

Musical hallucination

As discussed earlier in this chapter, the sound perception of tinnitus can take virtually any form. A small number of patients report that they can hear music when none is present, usually describing short excerpts of music that they were familiar with in their youth. Although many feel that the music sensation is within their own head, some perceive it as an external sound. This may lead them to falsely accuse neighbours of playing the music, either unthinkingly or maliciously. The condition is more common in women, the elderly and those with significant

hearing impairment.[213] The association with hearing loss has led to the hypothesis that musical hallucination is caused by deafferentiation, in which reduced input to the central auditory system causes increased gain within the associative auditory cortex.[214] This results in the brain misinterpreting background neuronal activity as music. The difference between this and the 'earworm' or tune stuck in the head that we all get from time to time is that people with musical hallucination are convinced that the sound is real. It is important to ensure that the patient is not describing the auditory hallucinations of mental illness; if there is any doubt, a psychiatric opinion should be sought. Musical hallucination can rarely be associated with epilepsy so a neurological opinion is prudent. There is no substantial evidence base for the management of musical hallucination but addressing any associated hearing loss is anecdotally helpful.

Acoustic shock

Over the last quarter of a century a cluster of symptoms has been observed among call-centre operatives who are exposed to sudden unexpected sounds through their headsets or telephone handsets. This has become known as acoustic shock syndrome, acoustic shock injury or simply acoustic shock.[215–217] The symptoms of acoustic shock can be divided into immediate and delayed. Pain is the most common immediate symptom, with 81% of those affected describing otalgia, 11% describing neck or jaw pain and 7% describing facial pain. Tinnitus occurs in approximately half of these patients, and balance disorders are also common. Hearing loss is reported less frequently and, when it does occur, it is usually temporary. Delayed symptoms include hypervigilance, anxiety, sleep disorders, hyperacusis and a feeling of aural fullness. Examination is normally unremarkable and audiometry usually shows normal symmetrical hearing or an age appropriate sensorineural hearing loss. If there is any additional audiometric loss it is often of an atypical pattern and does not have the typical characteristics of noise induced hearing loss.

The sounds that cause acoustic shock have been analyzed and do not need to be excessively loud to trigger the symptoms. One study identified sounds with intensity in the range 56–100 dB whereas another reported sounds in the range 82–120 dB.[215, 218] One common feature of the causative sounds was that they had short rise times. It is not clear whether exposure to similar sounds when not wearing headsets can generate acoustic shock. Certainly there are anecdotal reports of other abrupt sounds generating similar symptom complexes. Sounds that are generated close to the ear seem more likely to cause these symptoms than distant sounds. The pathophysiology of acoustic shock remains obscure. Cochlear and central auditory system mechanisms have been suggested but the most popular current hypothesis is that acoustic shock represents tonic contraction of the middle ear muscles – tonic tensor tympani syndrome.[216, 219, 220] The management of acoustic shock is also uncertain. Many people with acoustic shock feel that they are being disbelieved or accused of malingering: supplying a diagnosis and offering general reassurance can be helpful in this respect. If the patient has persistent tinnitus and hyperacusis, these symptoms can be treated using the standard audiological or psychological techniques that are discussed elsewhere in this chapter. The question of whether someone who has experienced a significant acoustic shock can remain in call-centre employment is complex and as yet there is no consensus regarding the best course of action.

Low-frequency noise complaint

Low-frequency noise complaint is an unusual condition in which people report distress caused by the perception of intrusive low-frequency sound.[221, 222] This can result in major disruption of normal activities and is often associated with sleep disturbance. People with low-frequency noise complaint report sounds such as humming, rumbling or machinery noise. They generally feel that the sound is a real external sound, contrasting with standard tinnitus in which the person feels that the sound is within their own ears or head. Consequently, it is common for environmental health officers to be called in to investigate, but low-frequency sound levels are usually at or below hearing threshold. The UK and US press have been interested in this condition, christening the phenomenon 'The Hum' and referring to sufferers as 'Hummers'. There is no strong evidence base regarding either the pathophysiology or the management of this condition. In some cases there may be a real external sound source: dealing with this is the duty of environmental health teams. If there is no external source, which is the usual situation, techniques used for spontaneous idiopathic tinnitus can be utilized, including psychological treatments such as CBT[223] or audiological treatments using counselling and sound therapy.[224] Many people with low-frequency noise complaint are reluctant to embrace such therapeutic approaches because they remain convinced that their symptoms are generated by an external sound and do not represent a form of tinnitus.

Exploding head syndrome

Exploding head syndrome is a parasomnia phenomenon characterized by the perception of a sudden loud noise in the head or ears that occurs during a transition of sleep stages. Because there is an auditory hallucination some patients may be referred to tinnitus clinics though referral to sleep clinics or neurologists also occurs. Exploding head syndrome is generally hypnagogic, occurring at the interface from wakefulness to sleep, but can be hypnopompic, presenting at the onset of wakefulness. The range of sounds reported is large and includes sounds such as explosions, banging, roaring, voices yelling, a bell ringing or the thunder crack accompanying lightning. The auditory hallucination is accompanied by visual sensations in approximately 10% of cases, with sufferers describing experiences such as a brief vivid flash of light.[225] Other sensory experiences may be reported including a feeling of heat or an electrical sensation.[226, 227] The phenomenon is generally painless and has no serious medical sequelae

though understandably it may generate feelings of shock and fear. Tachycardia and palpitations have been reported after an episode. Historically exploding head syndrome has been said to be a rare,[228] to be more common in women than men[229] and to be more common in those over 50.[225] However, a study of 211 undergraduate students suggested that the condition may be more common than previously thought, may occur in younger people and may have no gender imbalance.[230] The natural history of the condition seems unpredictable from evidence derived from the available case reports, with some people reporting a single episode whereas others experience multiple events per night; the problem can be persistent over many years or can spontaneously remit.

Clinically, it is important to exclude other conditions such as nocturnal epilepsy or subarachnoid haemorrhage. If the patient describes significant pain, an alternative diagnosis should be sought. Once the diagnosis has been established, education and reassurance are reported to help. Various pharmacological agents have been assessed including tricyclic antidepressants,[226] anticonvulsants[231] and calcium-channel blockers.[232] However, drug studies have been small-scale and uncontrolled and further research is clearly required.

SPECIAL POPULATIONS

Tinnitus in children and adolescents

Tinnitus is not as rare in children as was once thought. In children with normal hearing, the prevalence of tinnitus can vary from 12% to 36%.[233] Tinnitus in children, like adults, is more common if there is hearing loss.[234–238] Tinnitus has been demonstrated to commonly occur in children with otitis media.[239, 240] Tinnitus in children, as compared to adults, presents itself in a different manner and, while many of the basic principles of tinnitus management still stand, a different approach is required when dealing with children. In 2015, the British Society of Audiology (BSA) published practice guidance on the management of tinnitus in children. Developed through the Paediatric Audiology Interest Group (PAIG) of the BSA by national specialists in paediatric tinnitus, the project was supported by the British Tinnitus Association and the guidance is available from the BSA website.[241]

Military personnel

The association between tinnitus and noise exposure is well known and military personnel experience both chronic noise exposure and sudden extreme noise exposure. Military personnel in the UK are legally protected during training, but in a combat situation the use of hearing protection may not be viable and noise exposure may be particular high. Indeed, noise levels can become so high that, even when wearing hearing protection, military personnel may be exposed to levels of sound that exceed safe limits.[170] In addition, service personnel may be exposed to ototoxic chemicals during their military service.[242] It is therefore perhaps not surprising that tinnitus is now reportedly the number one disability among US veterans.[243] Post-traumatic stress is high among service personnel and seems particularly high among those with concomitant tinnitus: a study of military veterans showed that 34% of those who attended a tinnitus clinic also fulfilled the diagnostic criteria for post-traumatic stress disorder.[244] Traumatic brain injury is also more common among military veterans and this may affect the central auditory system.[245] Management of tinnitus in this population is therefore often complex and may require a multidisciplinary approach.

Single-sided deafness

Acquired unilateral profound hearing loss is a relatively common clinical problem. A study in 2006 estimated that the incidence may be up to 8000 new adult cases per annum in the UK.[246] In a study of 21 patients with single-sided deafness, two-thirds reported tinnitus and in 29% the tinnitus was severe.[247] Various therapeutic interventions have been explored in these patients, including the use of contralateral routing of signal (CROS) hearing aids, bone-anchored hearing aids, bone-conduction hearing implants and cochlear implants. There is little evidence to support the effect of the first three of these options but there are several studies that have investigated cochlear implantation and a systematic review has suggested that tinnitus is generally lessened, at least during the period when the implant is activated.[248]

DISORDERS OF SOUND TOLERANCE

DEFINITIONS AND CLASSIFICATION

Hyperacusis is a word that is used to denote a specific disorder of loudness perception but is also frequently used as a blanket term to describe all forms of decreased sound tolerance. Originally, disorders of sound tolerance were divided into hyperacusis, defined as a dislike of loud sounds, and phonophobia, defined as a fear of particular sounds and loudness recruitment, which is a specific experience that is associated with cochlear hearing loss and specifically with dysfunction of the outer hair cells of the organ of Corti.[249]

Jastreboff and Jastreboff[250, 251] recognized that many of their patients reported dislike of particular sounds but their emotional response did not constitute fear. They therefore employed the services of a Cambridge University classicist, Guy Lee, who devised a new word, misophonia, which they defined as a strong dislike of specific sounds. This new classification has not garnered universal support and a recent publication from an international working group has proposed an alternative set of definitions for decreased sound tolerance comprising loudness hyperacusis, annoyance hyperacusis, fear hyperacusis and pain hyperacusis.[252] With this definition, loudness hyperacusis and pain hyperacusis approximate to the previous definition of hyperacusis, annoyance hyperacusis to misophonia

and fear hyperacusis to phonophobia. To further complicate the terminology of disorders of sound tolerance, the neurological community describes phonophobia as part of the symptom complex experienced during migraine attacks. Such patients generally report a general dislike of sounds which would probably equate better to the audiological definition of hyperacusis, rather than phonophobia. Clearly, this field is ready for rationalization and reorganization.

In the following section hyperacusis is discussed as a specific symptom, and misophonia and phonophobia will be considered later.

HYPERACUSIS

Definitions

Definitive descriptions depict hyperacusis as an 'unusual tolerance to ordinary environmental sounds'[253] and as 'consistently exaggerated or inappropriate responses to sounds that are neither threatening nor uncomfortably loud to a typical person'.[254] In simple terms, hyperacusis is dislike of sounds above a certain intensity.

Epidemiology

There is a paucity of data to define the prevalence of hyperacusis. The available population surveys have suggested a prevalence of between 8% and 15%.[255, 256] The relation between tinnitus and hyperacusis has long been recognized and it has been suggested that hyperacusis may be a precursor state for tinnitus. Approximately 40% of patients who present with tinnitus also complain of hyperacusis.[30, 257] Of those whose primary complaint is hyperacusis, up to 86% report tinnitus.[31]

Pathophysiology

Hyperacusis and tinnitus often present together, and often in combination with hearing loss. This had led to speculation regarding a common underlying aetiology.[258, 259] Nelson and Chen have suggested that increased perception of sound intensity in the auditory cortex (hyperacusis) together with the perception of phantom sounds (tinnitus) results from a common trigger (hearing loss). A number of conditions have specifically been associated with hyperacusis.[258, 259] Some of these conditions, such as Bell's palsy and Ramsay Hunt syndrome, are associated with facial nerve dysfunction. However, since it is likely that in these cases the mechanism is due to an increased perception of sound intensity, secondary to an inefficient or absent stapedial reflex, some have considered that the resulting 'sound sensitivity' cannot truly be defined as hyperacusis.[260] Williams syndrome is a disorder characterized by deficits in conceptual reasoning, problem solving, motor control, arithmetical ability and special cognition[261] and hyperacusis has been reported to feature in 90% of individuals with this syndrome.[254] As Williams syndrome is associated with an underlying dysfunction of 5-hydroxytryptamine (5-HT), some have considered that the effects of 5-HT in other conditions, including migraine, depression and post-traumatic stress disorder, may lead to the increased auditory gain that may be responsible for hyperacusis.[262] Many other mechanisms have been suggested to underpin the neurophysiology of sound perception, with Jastreboff and Hazell proposing the central auditory system as playing the key role in setting auditory gain and perpetuating the perception of increased loudness.[48]

Investigation

Hyperacusis questionnaires are available but their sensitivity to treatment responses limit their usefulness as an assessment tool.[263, 264] Some clinicians recommend the measurement of loudness discomfort levels (LDLs) to confirm the diagnosis and quantify the problem whereas others suggest that the test is unreliable, risks alienating the patient and making the problem worse and has limited value with regard to planning. Certainly, if LDL testing is proposed in a patient with hyperacusis, they should be thoroughly counselled beforehand and offered an opportunity to decline the investigation. Stapedial reflex testing should be avoided in patients with hyperacusis because the procedure involves a loud test tone that many hyperacusis patients find unpleasant or painful.

Treatment

The usual response to an increased perception of loudness is for the patient to use a variety of types of ear protection in the form of ear plugs or ear defenders. This will often have the opposite to the desired effect by further increasing central auditory gain and exacerbating the patient's distress: there is evidence that sound deprivation worsens sound tolerance whereas enhancement of the acoustic background improves tolerance.[265] Although TRT was introduced primarily for the treatment of tinnitus, with minor modifications, TRT has been advocated for hyperacusis, with several studies demonstrating improvements in loudness tolerance.[266, 267] Psychological treatments have been used in the management of hyperacusis and there is evidence to suggest that CBT is efficacious.[268] Although there are anecdotal reports that other psychological modalities such as mindfulness meditation and ACT are being used in the treatment of hyperacusis, there is as yet no supportive literature.

MISOPHONIA

Definitions

As discussed under 'Definitions and classification' above, the term misophonia was created in 2001 to define a group of patients who dislike particular sounds irrespective of the level of the sound.[250, 251] The neologism literally means strong dislike or hatred of sound. Within the

classification system, phonophobia was retained as a subsection of misophonia when fear is the dominant evoked emotion.

In the late 1990s North American audiologist Marsha Johnson[269] recognized a group of patients who demonstrated negative emotions to a range of specific sounds generated by other humans, often repetitive sounds and often produced by oral or pharyngeal action. Causative sounds included those of lip smacking, throat clearing, chewing or breathing. Typical emotions included anger, disgust or anxiety and patients often demonstrated avoidance behaviour. This was termed selective sound sensitivity syndrome. Other terms including soft sound sensitivity syndrome or 4S have also been used.

The word misophonia has not been universally accepted by otologists and audiologists but patient support groups and mental health professionals have adopted it much more readily and it has gradually become synonymous with selective sound sensitivity syndrome. There have been multiple reports of patients with misophonia associated with psychiatric conditions including obsessive–compulsive disorder,[270–272] eating disorders[272, 273] and Tourette syndrome,[274] which has led some clinicians to suggest that misophonia should be reclassified as a specific psychiatric condition.[272] The authors who developed the new word, misophonia, have opposed this proposed reclassification, stating that mental health issues are rare in their series of patients with misophonia. They go on to suggest that the other authors must be reporting patients with psychiatric conditions who have coincidental comorbid misophonia.[275] It seems likely that further debate in this field will ensue.

Epidemiology

Demographic details of misophonia are slowly emerging. Case reports and small series of patients have been reported from Europe,[272, 273, 276] North America,[277] South America[271] and Australia.[274] To date there is no gender difference but, because the number of subjects is small, this observation may be premature. The onset of the problem is generally peripubertal with the largest study (n = 157) demonstrating a mean age of onset of 12 years.[278] There is a dearth of information regarding the prevalence and incidence. Jastreboff and Jastreboff used figures regarding the prevalence of tinnitus and the comorbidity of tinnitus and misophonia to extrapolate a population prevalence figure of 3.2%.[275] However, a study performed in a group of psychology undergraduate students has suggested that the prevalence might be much higher: 23.4% of participants reported that they were sometimes sensitive to specific sounds and 19.9% felt that this has had an impact on their lives.[279]

Clinical features

Sounds that trigger misophonia are generally sounds produced by other humans and in many cases the sound is produced by a specific person, often another family member.[270–272] The most common causative sounds are orally generated including eating, breathing, whistling, gum chewing and lip smacking. Other repetitive sounds, such as fingernail clipping or clicking the top of a pen, may trigger the symptom.[272] Environmental sounds such as wind, rain or waves do not generally trigger misophonia. Sounds produced by the person with misophonia generally do not elicit a misophonia response even if the sound is very similar to their normal triggers. Anger, disgust or irritation are the most frequently described emotions,[278] followed by anxiety or panic. Most people with misophonia will display avoidance behaviour, trying to stay away from the trigger sound or sounds. A few will confront the person producing the sound but actual aggression seems uncommon.[274, 277] A few patients are reported to have developed tics as a response to their trigger sound and a few have developed coping strategies such as mimicking the causative sound.

Investigation

There is a general lack of data regarding the audiological status of patients with misophonia. One study investigated 20 patients with misophonia and 14 controls, using a form of evoked-response audiometry.[280] The results of this study suggested that patients with misophonia could have an underlying central auditory processing problem. A recent study compared six patients with misophonia and five controls when exposed to a range of sounds which included sounds such as birdsong, that are generally regarded as pleasant, and other sounds, such as fingernails on a blackboard, that are usually perceived as unpleasant.[270] Skin conductance measurements were obtained: both groups found similar stimuli to be unpleasant but the reaction demonstrated by the people with misophonia was greater than the reaction in the control group.

Various questionnaire tools for assessing misophonia have or are being developed. These include the Amsterdam Misophonia Scale,[272] the Misophonia Questionnaire,[279] the Misophonia Assessment Questionnaire,[281] the Misophonia Coping Response Survey[281] and the Misophonia Trigger Survey.[281] These tools have yet to enter widespread usage.

Pathophysiology

Various suggestions regarding the pathophysiology of misophonia have been made. These include abnormal activation of the limbic and autonomic nervous systems,[282] psychological conditioning to repetitive events,[272] a generalized hyper-reactivity condition, a defect in serotonin and dopamine utilization in the limbic system and basal ganglia, or a variant of synaesthesia.[270, 283] There is no robust scientific evidence behind any of these hypotheses and the mechanism must still be regarded as unclear. Moller has pointed out that, as the problem is linked to specific sounds, it is likely that the anatomical location of the problem is downstream from initial sound processing areas and may be situated in the inferior part of the temporal lobe where the nature of sounds or 'what' information is processed.[284]

Treatment

The management of misophonia is still a matter of conjecture.[285] Multidisciplinary team management has been suggested[286, 287] and, as both otological and mental health assessment may be required, this approach seems logical. Structural brain pathology has not been reported with misophonia so there is a low requirement to undertake brain imaging. Anecdotally, reassurance and education directed to both the patient and family may be helpful. The presence of an associated specific psychological problem may dictate a specific mental health pathway. CBT has been reported as effective in a single case.[269] Sound therapy can be used to desensitize patients: Jastreboff and Jastreboff suggest a treatment strategy based on TRT using a combination of counselling and sound therapy.[275] Allowing the affected person to wear headphones when in the presence of their misophonia trigger has also been suggested.[286] There is no pharmacological treatment yet identified, though drugs may have a role in the management of associated conditions such as anxiety.

BEST CLINICAL PRACTICE

- ✓ All patients with tinnitus should undergo a basic audiological assessment. Further investigation should be undertaken in the following groups: those with pulsatile tinnitus; unilateral tinnitus; tinnitus in association with asymmetric hearing loss; tinnitus in association with significant vertigo; tinnitus in association with neurological symptoms and/or signs.
- ✓ Comorbidities are common, particularly anxiety, depression and disorders of sound tolerance (hyperacusis). Insomnia is also common in tinnitus patients. These factors should be considered during the history-taking process.
- ✓ Although there is currently no drug treatment for subjective idiopathic tinnitus, drugs may have a role in the management of comorbid conditions such as anxiety and depression.
- ✓ Patients are often given negative counselling, being told that nothing can be done for tinnitus. While a cure for tinnitus remains elusive, there are many helpful management strategies, particularly sound based therapies, counselling and psychological therapies. Surveys have shown that many patients with tinnitus are investigated in secondary care but are never offered any therapeutic intervention. Negativity should be avoided, and patients should be referred onward to audiology, hearing therapy or mental health services as appropriate.
- ✓ When tinnitus is associated with hearing loss it is usually helpful to try and correct this loss, surgically if appropriate, or via the use of hearing aids.

FUTURE RESEARCH

Despite major advances in our understanding of tinnitus, many major questions remain unanswered. In particular, we do not fully understand the fundamental mechanisms behind the development of tinnitus in many groups of patients. There is no reliable method to consistently measure tinnitus, and a universally effective drug treatment does not currently exist. However, as we gain more understanding about this intriguing condition, basic research has introduced many different routes to allow the investigation of the pathophysiology, diagnosis and treatment of many of the different presentations of this condition. Furthermore, tinnitus and its allied conditions have become a focus of attention within many different disciplines outside the traditional domains of ENT and audiology. A number of major research organizations are currently investing significant amounts of money to research this condition. The goal for many is to identify a 'cure', but during this journey tinnitus research has benefited our understanding of how the auditory system and the brain perceive and process sound in ways that we might never have considered.

KEY POINTS

- Tinnitus is common: prevalence in the UK population is estimated at approximately 1 in 10. For about 1 in 200, tinnitus has a severe effect on the activities of daily living.
- Epidemiological studies suggest that most people with tinnitus go through a process of habituation and the impact of the symptom gradually lessens with time.
- Tinnitus is more common in people with a hearing loss but the degree of hearing impairment correlates poorly with tinnitus severity. About 1 in 10 people presenting with tinnitus have a normal audiogram. Tinnitus can exist after division of the auditory nerve.
- Modern models suggest that tinnitus is due to increased awareness of spontaneous electrical activity in the auditory system. Although changes in the auditory periphery can trigger tinnitus, the processes that cause the symptom to perpetuate and become distressing occur in the central auditory pathways and in associated brain regions, particularly the limbic system.
- Tinnitus is rarely a harbinger of serious pathology, but careful clinical assessment is recommended.
- A blocked sensation in the ears is common among tinnitus patients though generally there is no evidence of Eustachian tube dysfunction.
- Interventions that improve hearing are often helpful and various audiological and psychological management strategies for tinnitus have been developed.
- Disorders of sound tolerance are common but terminology is confused, pathophysiology is unclear and many questions remain regarding management.

CHAPTER 62

EVALUATION OF BALANCE

Adolfo M. Bronstein

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: vestibular, eye movements, balance, clinical tests, dizziness and vertigo.

SYMPTOMS IN BALANCE DISORDERS

Patients with disorders of balance are common, not only in otolaryngology clinics but also in neurology, general practice, internal medicine and geriatrics. It can be estimated that dizziness, vertigo and unsteadiness accounts for one-fifth of referrals to ENT and neurology clinics. This is not surprising since approximately one-quarter of people experience dizziness at some time in their life and in 80% of cases this is severe enough to see a doctor.[1] The rise in ageing population worldwide is likely to increase these percentages since dizziness occurs in almost 50% of people over the age of 75 years.[2]

There have been many developments in the field of balance and vestibular testing but, as in other branches of medicine, nothing replaces a good clinical history. The techniques used and ranges of normality adopted by different vestibular laboratories can be very disparate and so 'positive', 'objective' vestibular findings must be taken strictly within the appropriate clinical context. Reciprocally, some clinical histories are so typical that the absence of corroborative findings on a single visit to the clinic should not make the clinician rule out a diagnosis: for example, a patient with brief vertigo on turning over in bed, so typical of benign paroxysmal positional vertigo (BPPV), but negative positional testing on his first visit.

The symptoms that patients with balance or vestibular disorders may report are vertigo, dizziness, nausea, motion intolerance, unsteadiness and oscillopsia. Associated anxiety and depression are also extremely common. It is of vital importance, in all balance symptoms, to identify triggers provoking the symptoms, such as position, movements or visual or acoustic triggers. It is equally important to determine if the symptom is acute, episodic or chronic, and whether it occurs alone or in association with other symptoms (e.g. audiological, visual or neurological).

Vertigo and dizziness

Vertigo, when defined as an illusion of either oneself or the environment rotating, is a reliable symptom. It indicates involvement of the angular motion sensing system, i.e. the semicircular canals and their central projections. However, such involvement can occur from the labyrinth up to the vestibular cortex so that the site of the lesion will have to be presumed by additional symptoms (**Table 62.1**). Of particular value are hearing loss or tinnitus, usually indicating labyrinthine or VIII nerve involvement, and brainstem symptoms such as frank diplopia, facial numbness/weakness and dysarthria. Acute vertigo is terrifying and disabling and its duration can be a good guide to diagnosis. In BPPV it is usually less than a minute; in migraine-associated vertigo (= vestibular migraine) it can be from minutes to many hours; in Ménière's disease a few hours; and in acute vestibular neuritis and consolidated brainstem stroke a few days.

Illusions that one is moving linearly, such as falling vertically downwards or linear vertigo, can arise from disorders of the otolith system but it is extremely difficult to confirm selective otolith lesions and thus the clinical value of linear vertigo as a symptom is less well established.[3, 4] There is no evidence to classify postural symptoms, such

TABLE 62.1 Additional symptoms helpful in the topographical diagnosis of balance disorders

Site of lesion	Symptom	Comment
Peripheral (labyrinth or VIII nerve)	Tinnitus	
	Hearing loss	
Special cases		
Labyrinthine	Ear fullness	Ménière's disease
CP angle	V, VI, VII cranial nerves	Extracanalicular growth
VII + VIII neuritis	Ext auditory canal vesicles + VII	Ramsay Hunt syndrome
Brainstem	Diplopia (III, IV, VI or skew deviation)	
	Facial numbness (V)	
	Difficulty swallowing, choking (IX, X)	
	Slurred speech (XII, cerebellum)	
	Uni-bilateral numbness, weakness, ataxia (long tracts, cerebellum)	
	Unilateral deafness (+ ataxia)	AICA infarct
Cerebral hemisphere	Unilateral weakness, numbness	
	Hemianopia (parieto-occipital lobe)	MCA/PCA
	Blindness (both occipital lobes)	Both PCAs
	Loss of consciousness	
	Syncope, cardiac arhythmia	Common
	Epilepsy	Rare (in vertigo)

AICA, anterior inferior cerebellar artery; MCA, middle cerebral artery; PCA, posterior cerebral artery.

as lateropulsion or retropulsion, as specifically otolith-related. Despite traditional emphasis on defining symptoms precisely, patients may find it difficult to describe clearly and experienced clinicians know that dedicated efforts to distinguish vertigo from dizziness in individual patients does not always pay off. Dizziness and giddiness are common terms employed by vestibular patients to describe their problems. There is no good definition for these terms. One should encourage the patient to describe what they mean by dizziness and/or to compare it to situations that they may have experienced. Body language is also important as many patients wave a hand round and round when describing their dizziness, implying actual rotational vertigo. When the dizziness is non-rotational, it is less certain that the problem lies in the vestibular system. Descriptions such as rocking or swimming sensations, light-headedness, walking on cotton wool, feeling detached, can also be vestibular. However, one often needs independent evidence to reach this conclusion. Such evidence may be difficult to find on vestibular testing, such as a significant caloric canal paresis, or a preceding history of rotational vertigo. There are numerous non-primarily vestibular causes of dizziness and light-headedness, including anaemias, drug toxicity and psychological dizziness to name just a few (Table 62.2).

TABLE 62.2 Some non-vestibular causes of dizziness

Type	Possible causes
Endocrine	Hypoglycaemia Adrenal failure Pheochromocytoma
Cardiovascular	Vasovagal syncope Orthostatic hypotension Embolic disease Cardiac dysrhythmias
Haematological	Hyperviscosity syndromes Anaemias
Psychological	Anxiety Phobias Panic attacks

Some patients indicate clearly that they have no 'head' sensations. They are unsteady, off balance or clumsy on their feet, 'not dizzy in the head'. They feel fine if seated or lying down. In such cases it is useful to ask if relatives or friends have made any comments about the patient's balance. If there is an objective, visible balance problem, this is more likely to be a neurological gait disorder, with patients just perceiving their own objective dysequilibrium. If these patients trip over or are pushed over in a crowd, they can stumble or fall. The lesion may lie anywhere in the somatosensory motor chain (peripheral nerves, spinal cord, cerebellum or cerebrum) and the clinician should enquire about symptoms represented at these various levels in the neuraxis, such as weakness, numbness, incoordination, tremor, sphincters, memory and other cortical functions. Enquiries as to the presence of falls as a result of poor postural balance should be actively made, particularly in the elderly patient. If present, prevention of further falls becomes an urgent matter. Fall-related complications in the elderly are a major killer and public health problem.[2]

Motion intolerance

Anyone who has ever been motion sick will understand that patients with vestibular disorders dislike movement. In the acute phase of Ménière's disease or vestibular neuritis the picture is dramatic. The patient is bedridden and terrified of even going to the toilet; any movement brings more vertigo, nausea and vomiting. Symptoms gradually settle over time. A patient with vestibular neuritis may have strong rotational vertigo and nausea for 3 days, followed by dizziness for 3 weeks and by light-headedness for 3 months. In these latter stages, however, patients tend to avoid head movements or looking at moving visual scenes. Unfortunately, in some patients, light-headedness, dizziness and motion intolerance can last for many months or years, for reasons that are not completely understood.

A complex interrelation between lack of effective vestibular compensation, idiosyncratic perceptual style, migraine and anxiety may be at play.[5]

Oscillopsia

The intolerance to visual motion mentioned in the previous paragraph is sometimes called visual vertigo, visually induced dizziness, space and motion discomfort, visuovestibular mismatch or simply 'the supermarket syndrome'.[6] This should not be confused with oscillopsia, which is the movement or oscillation of the visual surroundings.[7] Oscillopsia is described by patients as jumpy, jerky, bobbing, wobbly or sometimes just blurred vision. In the balance disorder patients, always consider the possibility that a patient's complaint of blurred vision or difficulty in focusing might be oscillopsia.

The critical question to ask a patient with oscillopsia is 'when': when does it happen?[7, 8] Is the oscillopsia present during movement, or only triggered or present in certain head positions, or unrelated to movements (Table 62.3)? Oscillopsia during head movements (e.g. while walking, driving, shaking the head) is due to a defective vestibulo-ocular reflex (VOR), typically bilateral vestibular lesions as encountered after meningitis, gentamicin ototoxicity or idiopathic. Oscillopsia present in certain head positions (e.g. lying but not seated or vice versa) is likely to reflect a positional nystagmus, usually of a central CNS origin. Oscillopsia unrelated to head movement can be continuous, in which case the patient is likely to have an acquired CNS nystagmus (e.g. acquired pendular nystagmus, downbeat nystagmus (DBN), torsional nystagmus) or just be paroxysmal, i.e. in attacks. Paroxysmal oscillopsia can be spontaneous, as in paroxysmal nystagmus and ocular oscillations of central origin, vestibular paroxysmia or, more commonly, voluntary nystagmus. Some patients with idiopathic bilateral loss of vestibular function present with paroxysmal oscillopsia.[9] Triggered paroxysmal oscillopsia is rare; the most common being the Tullio phenomenon,[10, 11] as in the superior canal dehiscence syndrome,[12] where patients report jumpy vision and lateropulsion in response to loud sounds or Valsalva manoeuvres.

TABLE 62.3 Causes of oscillopsia

When?	Syndrome	Examples
During head movements	Absent VOR	Ototoxicity, idiopathic, post-meningitic
Triggered by head movements	Positional nystagmus	Positional DBN
Unrelated to head movements		
Continuous	CNS nystagmus	DBN, pendular nystagmus
Paroxysmal	Paroxysmal eye oscillation	Voluntary nystagmus Progressive vestibular failure, vestibular paroxysmia

DBN, downbeat nystagmus.
Modified from Bronstein.[7]

Vertigo presentations

The first thing to ascertain is whether the patient's problem is a single vertigo episode (acute vertigo), recurrent (or episodic) vertigo or chronic dizziness. Once this is established the key to diagnosis lies in identifying triggering factors and associated symptoms. Tables 62.4, 62.5 and 62.6 summarize this topic.

SINGLE ACUTE EPISODE OF VERTIGO

An acute single spontaneous episode of rotational or 'true' vertigo can be encountered in acute vestibular neuritis (or neuronitis), which has no hearing symptoms, a vascular or inflammatory disorder of the labyrinth (labyrinthitis), usually with hearing loss, and a brainstem stroke, usually with other CNS symptoms. In all

TABLE 62.4 Vertigo presentations: single vertigo episode

Hearing	Possible cause
Hearing spared	Vestibular neuritis (or neuronitis or viral labyrinthitis or neurolabyrinthitis)
	Head injury
Hearing involved	Head injury
	Labyrinthine fistula
	Viral infection (mumps, Ramsay Hunt)
	Vascular disorder (labyrinthine stroke)

Modified from Bronstein and Lempert.[8]

TABLE 62.5 Vertigo presentations: episodic or recurrent vertigo: accompanying features

Accompanying feature	Possible cause
Positional	BPPV (on lying or turning in bed) Orthostatic hypotension (on standing)
Paroxysmal	Vestibular paroxysms
Migraine	Vestibular and basilar migraine
Hearing disorder	Ménière's syndrome or hydrops
Ataxia	Episodic ataxias
Brainstem symptoms	Transient ischaemic attacks (TIA)
Autonomic-anxiety-avoidance	Panic attacks
Faintness	Heart disease, vasovagal syncope
No accompanying features	Benign recurrent vertigo (BRV)*

* Benign recurrent vertigo,[13] recurrent peripheral vestibular disorder or vestibular Ménière's disease are names given to describe patients with recurrent peripheral vertigo which does not fall into any other category such as Ménière's disease or migraine.
Modified from Bronstein and Lempert.[8]

TABLE 62.6 Vertigo presentations: symptom triggers in patients with episodic vertigo

Trigger	Possible cause
Lying down, turning over in bed	BPPV
Standing up	Orthostatic hypotension
Neck movements	Any vestibular disorder
Pressure changes	Fistulas
Loud sounds	Tullio phenomenon
Alcohol, exercise	Episodic ataxias

Modified from Bronstein and Lempert.[8]

these conditions the vertigo is usually severe and prolonged, inevitably leading to autonomic symptoms, such as nausea, vomiting, pallor, sweating and malaise. It must be borne in mind that any vertigo is more tolerable when the head is kept still. Only provocation, not exacerbation, of vertigo by movements or positions of the head should be labelled as positional vertigo. The clinician should actively ask for additional hearing or CNS symptoms, such as slurred speech, facial or limb numbness or weakness, diplopia and swallowing problems. Intense vertigo can be so overwhelming that some patients may not volunteer other symptoms (Table 62.4). In recent years the distinction between peripheral and central acute vertigo has become a hot topic because of new available therapies for stroke, mainly thrombolysis. Given that the window of treatment opportunity is only a few hours, various 'red flags' have been described (see Box 62.1).

The presence of recent or concurrent general illnesses should be sought. In vestibular neuritis, patients can report a recent upper respiratory tract infection. Mumps can affect both the cochlear and vestibular labyrinth. Patients with herpes zoster oticus or Ramsay Hunt syndrome can have a peripheral facial palsy and show herpetic vesicles in the outer ear canal. The presence of risk factors such as smoking, hypertension, obesity or diabetes can suggest a vascular aetiology.

RECURRENT OR EPISODIC VERTIGO

The presence of triggers becomes critically important for diagnosis in the patient with recurrent vertigo or dizziness. Certain triggering by head movements, such as looking up, lying down or turning over in bed, are highly suggestive of BPPV. Incorrectly, clinicians often jump to the conclusion that dizziness related to neck movements (inevitably associated with head movements!) indicates cervical or vertebrobasilar vertigo before excluding a much more likely vestibular disorder.[15] Triggering by loud sounds or Valsalva manoeuvres suggests the Tullio phenomenon, often due to superior canal dehiscence or labyrinthine fistula. In some patients with migraine-associated vertigo, food or sleep deprivation or certain foods (chocolate, cheese, red wine) may be triggers. Orthostatic hypotension induces light-headedness, dizziness and even true rotational vertigo,[16] on standing up suddenly or after being standing up for a long time, particularly in the heat or motionless. Exercise, alcohol or stress can trigger an attack in patients with episodic ataxias or channelopathies, which usually includes vertigo (see Tables 62.5 and 62.6).[17]

BOX 62.1 'Red flags' for acute brain imaging in acute vertigo

Modified from Seemungal and Bronstein[14]

- Acute unilateral deafness
- Acute (occipital) headache
- Any central symptoms or signs
- A negative (normal) head-impulse test

Associated symptoms, such as aural fullness, tinnitus and hearing loss, may suggest Ménière's syndrome. Associated brainstem symptoms can indicate vertebrobasilar transient ischaemic attacks (TIA) whereas palpitations, breathlessness or loss of consciousness would suggest a cardiac arrhythmia. Patients with panic attacks can also report dizziness, palpitations, fear of dying and breathlessness but the social triggers and the ensuing avoidance behaviour are highly suggestive of this diagnosis – the three 'As', autonomic, anxiety and avoidance. Patients with presyncopal dizziness can report sensations of feeling hot or cold, clammy and sweaty, greying out of vision and bilateral tinnitus. The presence of frank ataxia may indicate paroxysmal ataxia (e.g. episodic ataxia type 1 or 2, spinocerebellar degeneration type 6 or other channelopathies). The presence of migrainous symptoms, such as visual aura, throbbing headaches, nausea, photophonophobia, must be enquired;[18] migrainous vertigo can precede, overlap, follow or occur independently of a migraine headache.

CHRONIC DIZZINESS

The majority of patients with a single acute vertigo attack recover fully and the majority of patients with recurrent vertigo are free of symptoms between attacks, but not all. Since vertigo and dizziness are so prevalent in the community, this small proportion of patients with long-term dizziness makes up enough absolute numbers to fill up specialized clinics.

There is no simple explanation as to why some patients do not fully recover from a single attack or episodic vertigo. The actual vestibular loss is unlikely to be the reason since patients with vestibular schwannomas rarely suffer from any troublesome dizziness. Hence, a slow rate of progression as opposed to an acute onset may play a part. Failure of the compensatory mechanisms is also often invoked and this may be due to a variety of factors. This evidence cannot be fully reviewed here but aggravating or limiting factors include:

- fluctuating vestibular lesion, as in hydrops, which poses a challenge to the central compensatory processes
- an idiosynchratic trend in some subjects to rely excessively on visual cues, or 'visual dependence', which perpetuates intolerance to visual motion (visual vertigo or supermarket syndrome)

BOX 62.2 Factors interfering with vestibular compensation

Fluctuating vestibular disorder
Additional disorder:
- CNS
- Peripheral nerve
- Cervical spine
- Visual

Lack of mobility
Drugs
Visual dependence ('visual vertigo')
Psychosocial

CNS, central nervous system.

- psychological factors, including pre-existing or reactive anxiety, depression or phobias
- excessive bedrest and lack of physical activity, sometimes prescribed by doctors unaware of the importance of motion exposure as a promoter of vestibular compensation
- excessive use of psychotropic and antivertiginous medication
- concomitant visual or neurological disorders (**Box 62.2**).

In the elderly, there are usually many of these factors operating simultaneously.

Finally, the otologist should bear in mind the possibility that the sense of unsteadiness reported by the patient may be due to a general medical disorder or to neurological or psychogenic gait disorders (**Box 62.3**). The latter, particularly in the form of an overcautious gait, can be triggered in the elderly by a fall or an episode of vertigo, so full investigation is warranted. Pain during locomotion (e.g. hip arthritis) will also aggravate any gait disorder.

BOX 62.3 Chronic dizziness – mental checklist

Is it oscillopsia rather than dizziness?...See Table 62.3
Is it a gait disorder?.....See Tables 62.10 and 62.11
Is it a general medical disorder?.....See Table 62.2

EXAMINATION OF THE PATIENT WITH A BALANCE DISORDER

One of the disappointing aspects of balance disorders is that both the ENT and neurological examination are often entirely negative, except perhaps in the acute phase. This should not bias clinicians into thinking that it is not worth thoroughly examining the patient; much money, time and suffering can be spared by carrying out a Hallpike manoeuvre instead of organizing a head scan in a patient with BPPV!

A standard neuro-otological assessment should include auroscopy, eye movement, positional manoeuvres and posture and gait examination. Auroscopy is covered in Chapter 73, Clinical examination of the ears and hearing.

Eye movements

CLINICAL EXAMINATION OF EYE MOVEMENTS

The vestibular system provides a powerful input to the oculomotor system so eye movements must be examined in detail. In a patient suspected to have a peripheral vestibular disorder (labyrinth and VIII nerve) one can consider that the examination has two broad aims.

1. One is to search for direct ocular signs indicative of a peripheral vestibular disorder, typically nystagmus, BPPV or a positive head thrust test (see under 'Head-impulse test' below).
2. The other is to exclude CNS lesions by making sure that non-vestibularly mediated eye movements are normal.

The oculomotor examination should include:

- search for spontaneous and gaze-evoked nystagmus
- convergence
- smooth pursuit
- saccades
- vestibulo-ocular reflexes
- positional manoeuvres.

General updated reviews of eye movement assessment are available.[19, 20]

If the patient reports diplopia, or if at any point during the examination the two eyes appear disconjugate, a formal examination of the individual cranial nerves III, IV and VI is mandatory. This usually requires a separate eye cover test in the six cardinal positions of gaze to identify the weak individual muscle or group of muscles (right – horizontal, up and down; left – horizontal, up and down). Before embarking on a complex examination with which the ENT surgeon may not feel completely at ease, it is useful to confirm with the patient whether he was aware of the presence of an old squint, weak/lazy eye or congenital nystagmus. If there is an infantile squint, the ocular examination is more difficult to interpret.

SPONTANEOUS NYSTAGMUS

The search for spontaneous nystagmus begins in the primary, straight-ahead position of the eyes. In the presence of nystagmus, ascertain the waveform – essentially sawtooth or jerk nystagmus (in which case you should identify the direction of beat) or pendular nystagmus, which has no fast-phase or beating direction (**Figure 62.1**). Since spontaneous nystagmus often enhances by convergence, it is convenient to examine convergence at the same time, by slowly moving an object in and out along the visual axis. Absence of convergence occurs in midbrain lesions but one must remember that reduced/absent convergence is extremely common in normal people above the age of 60 years of age.

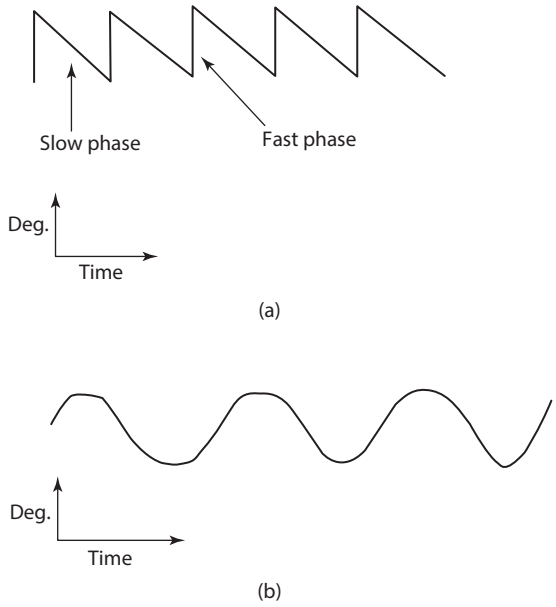

Figure 62.1 (a) Nystagmus waveforms, jerk or saw-tooth; and **(b)** pendular nystagmus. The former can be peripheral or central but the latter is only of central origin but usually non-acute.

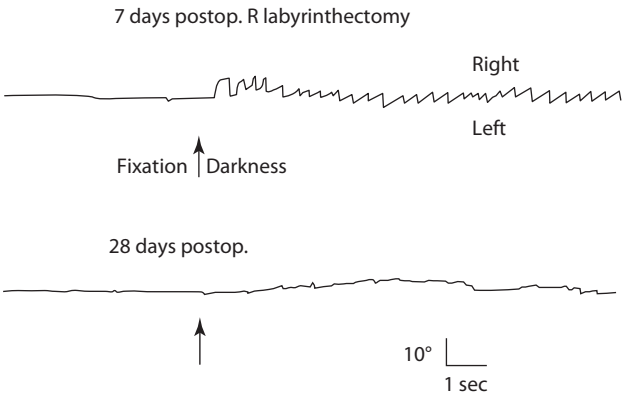

Figure 62.2 Acute and compensated peripheral vestibular nystagmus. Note that at 1 week after labyrinthectomy the nystagmus in the light was negligible but increased notably in the dark. At 1 month follow-up vestibular compensation had effectively reduced the nystagmus in the dark. Also note the rectilinear slow phase velocity of the nystagmus, in agreement with its peripheral origin.

While in primary gaze, one should undertake a cover test, particularly in patients with difficult-to-interpret eye signs. The cover test is usually part of the examination to assess diplopia and ocular alignment, but what we suggest here is a simplified version of the test, looking for the presence of latent nystagmus. Latent nystagmus is a common congenital oculomotor disorder.[3, 4] Typically, these patients have no nystagmus during binocular viewing but, on covering one eye, the uncovered eye beats horizontally away from the covered eye (both eyes beat but one can only see the uncovered one). It can be observed on covering one or the two (one at a time) eyes. The value of discovering latent nystagmus, which is essentially asymptomatic, lies in the fact that this condition is often associated with congenital squints, nystagmus, square wave jerks, abnormal pursuit or optokinetic nystagmus. Thus, finding latent nystagmus in a patient with an abnormal, 'central-looking' oculomotor examination strongly suggests that the findings are congenital rather than relevant to a recent complain of vertigo or loss of balance.

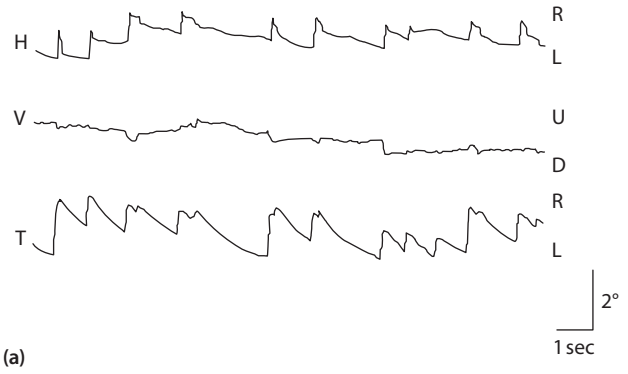
When examining nystagmus as well as other eye movements, patients have to be clearly instructed to look at a predetermined object and the eyes should be well illuminated. The presence of spontaneous nystagmus in primary gaze immediately raises the question of whether it is caused by a central or peripheral lesion. If the patient is in the middle of an acute vertigo attack, with severe unsteadiness and nausea, it can be peripheral or central, but if the patient comes as a routine ambulatory patient and does not look acutely ill, the nystagmus is more likely to be of central origin. In practice, a nystagmus of peripheral vestibular origin, observable by the naked eye in primary gaze, can only come from an acute, massive vestibular imbalance, as in vestibular neuritis, Ménière's attack, recent labyrinthine surgery or trauma (Figure 62.2). The nystagmus is essentially horizontal, with a minor torsional (rotatory) component. The fast phase beats contralesionally but can beat ipsilesionally in the acute irritative phase of a Ménière's attack.

Can a nystagmus like this result from a central lesion? Yes, in particular lesions in the VIII nerve root entry zone, vestibular nuclei or cerebellum but, almost invariably, there are additional brainstem symptoms and signs. Any other nystagmus is almost certainly of central origin. These differ from a peripheral vestibular nystagmus in waveform (e.g. pendular, a quasi-sinusoidal oscillation of the eye without distinction between slow and fast phases – Figure 62.1),[21] or beat plane (e.g. vertical up or downbeat or torsional nystagmus – Figure 62.3).[22] A large, horizontal nystagmus in a patient with no significant vestibular or neurological symptoms should always raise the possibility of congenital nystagmus.[23]

GAZE-EVOKED NYSTAGMUS

Soon after the acute stage of a peripheral vestibular lesion, the nystagmus is not visible in primary gaze but only on deviation of gaze to the opposite side of the lesion, i.e. in the direction of the fast phase. A useful classification for the severity of the nystagmus, based on this observation, has stood the test of time. First-degree nystagmus is a nystagmus only visible on gaze deviation in the direction of the fast phase, second-degree when present in primary gaze, and third-degree when it is also visible when the eyes are deviated in the opposite direction to that of the fast phase. A second- or third-degree nystagmus will enhance on gaze deviation in the direction of the fast phase (Alexander's law; Figure 62.4). However, the severity scale and Alexander's law apply mostly to peripheral vestibular nystagmus. For instance, DBN in primary gaze, which is always of central origin, often does not enhance on looking down but on looking sideways.

Nystagmus on gaze deviation can also indicate a central lesion. This is what is frequently called 'gaze paretic'



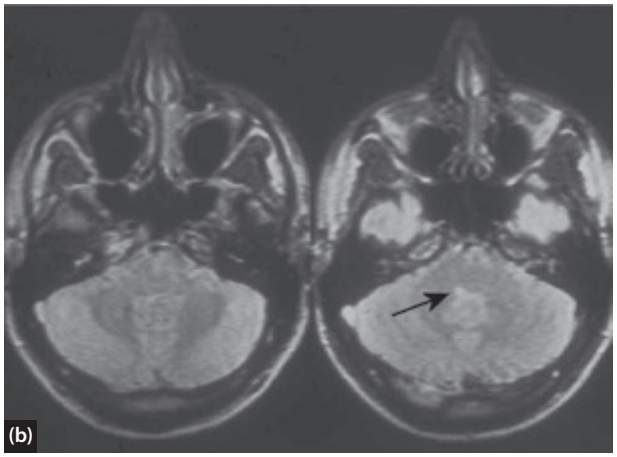


Figure 62.3 (a) Three-dimensional scleral search coiled oculography in a patient with a small demyelinating left-sided brainstem lesion, as shown on MRI **(b)** (arrow). The presence of a clinically observable torsional component in the spontaneous right beating nystagmus indicated that the lesion was central rather than peripheral. H, V and T are horizontal, vertical and torsional eye recordings. Left side of the brain is on the left side of the scan.

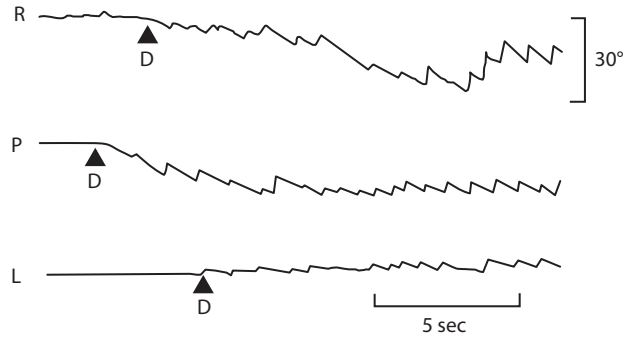

Figure 62.4 The effect of fixation and gaze deviation (L, left; P, primary; and R, right positions) on peripheral vestibular nystagmus. Horizontal EOG recordings begin in the light and continue in the dark (D). Note the increase of the nystagmus with gaze deviation in the direction of the fast phase (Alexander's law). Reproduced by kind permission of P. Rudge.

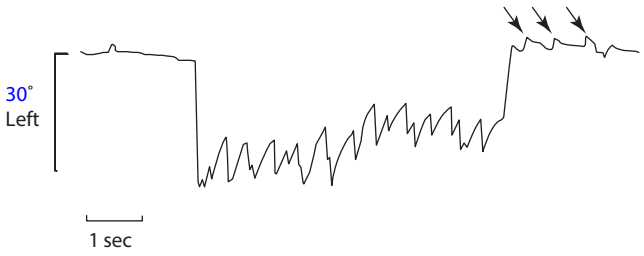

Figure 62.5 Left-beating gaze paretic and rebound nystagmus (arrows) in a cerebellar lesion. Note the exponentially decreasing slow phase velocity (slope) of the nystagmus. Reproduced by kind permission of P. Rudge.

nystagmus, not to be confused with the broader term 'gaze-evoked' nystagmus. A subacute peripheral vestibular lesion can have a gaze-evoked nystagmus, i.e. a second-degree nystagmus as discussed above. Instead, the term gaze paretic implies that the patient has difficulty in holding gaze in an eccentric position in the orbit. The eyes drift in centripetally with a slow phase which progressively decreases in velocity, until a new saccade refixates the eccentric target (Figure 62.5). This nystagmus, usually of larger amplitude than vestibular nystagmus, is due to damage to the gaze-holding mechanisms mediated by ipsilateral brainstem and cerebellar structures. An example of vestibular and gaze paretic nystagmus present in the same patient is Brun's nystagmus due to a large extracanalicular vestibular schwannoma. The vestibular nystagmus beats, as expected in any destructive vestibular lesion, in the opposite direction of the tumour. The coarser nystagmus, evoked by looking in the same direction of the tumour, is gaze paretic, due to cerebellar–brainstem compression (Figure 62.6). Gaze paretic nystagmus can be present in all directions of gaze in the same patient, typically in symmetrical processes such as cerebellar degenerations.

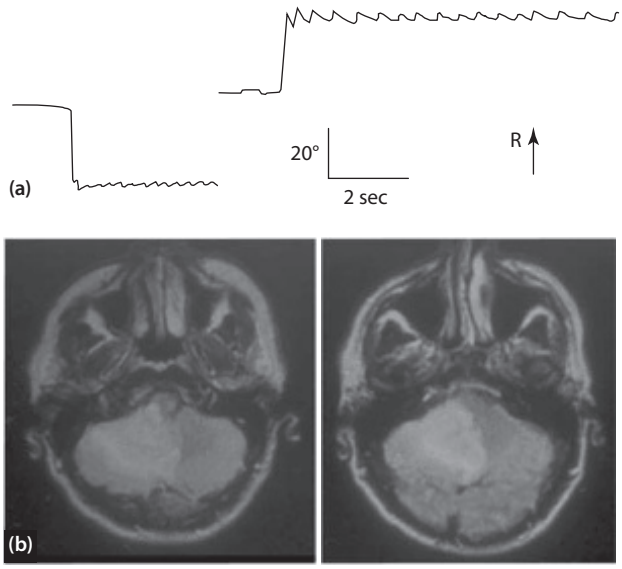

Figure 62.6 Brun's nystagmus due to a right-sided pontine glioma; **(a)** vestibular nystagmus on left gaze; **(b)** a larger gaze paretic nystagmus. Typically, large vestibular schwannomas compressing the brainstem produce this nystagmus combination.

SMOOTH PURSUIT EYE MOVEMENTS

When tracking an object with our eyes, we use a combination of fast (saccades) and slow-phase eye movements. Strictly speaking, only the latter should be considered smooth pursuit. When the target moves slowly (<10–15 degrees per second) the eye is capable of following it almost exclusively with smooth pursuit movements. The pursuit system is velocity limited so that, when targets move at velocities of 40–50 degrees per second or faster, the proportion of tracking carried out by saccades increases progressively. Clinically speaking, pursuit looks abnormal, or 'broken up', when the observer detects too much saccadic tracking; this gives a cogwheel, jerky appearance to the pursuit movements (**Figure 62.7**). The message for the clinician is: move the target slowly, otherwise everybody shows 'broken pursuit'.

Investigation of pursuit eye movements is a vital component of the neuro-otological examination. There may be occasional exceptions but, in principle, the presence of normal pursuit rules out a central vestibular disorder and, vice versa, a patient with balance symptoms and unequivocally broken pursuit movements almost certainly has a neurological rather than a labyrinthine disorder. In order for the clinician to reach these conclusions confidently, the examination has to be technically correct.

- Since pursuit movements are visually guided, rule number one is that the patient should be able to see the target correctly. Any object can be a target, not only the examiner's finger or pen. In patients who are too young, too old or with attentional problems, a substantial, solid target such as a key, a toy, a mobile phone or a credit card can increase performance. Make sure that in elderly subjects, with presbiopia and age-related convergence insufficiency, the object is presented at a comfortable viewing distance. Sometimes, the examination must be conducted with the patient wearing his/her own glasses.
- Rule number two is that the target has to be moved at a slow speed, taking 4–5 seconds to travel from right to left and vice versa (i.e. approximately 0.1 Hz). One cycle is usually not enough since many patients do not understand the task and tend to jump their eyes ahead of the target; the patient should be encouraged to 'glue your eyes to the target'. Pursuit should be investigated in the horizontal and vertical planes.

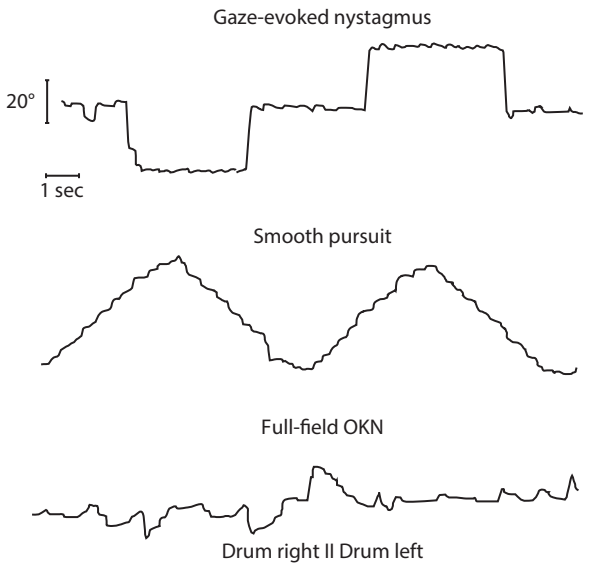

Figure 62.7 Cerebellar degeneration producing gaze-evoked nystagmus, broken ('cogwheel') pursuit and almost complete absence of optokinetic nystagmus.

It is easy to identify asymmetric pursuit, with excessive 'catch-up' saccades in one direction only. When pursuit is broken, say, to the right, the lesion is likely to be in the ipsilateral (right) cerebellum or parietal lobe. Brainstem lesions can have more complex effects (e.g. if they involve the vestibular nuclei which can generate nystagmus) but often are ispilateral too.[20, 24] Small asymmetries in the horizontal plane, if consistent, are significant. Asymmetries in the vertical plane are less useful since they occur in many normal subjects.

Global or pandirectional abnormalities of pursuit are somewhat more difficult to interpret. The reason lies in the fact that pursuit pathways are long, complex and multisynaptic, including visual pathways, parietal and frontal cortex, vestibular nuclei and cerebellar flocculus. This makes them vulnerable to trivial sources of mild diffuse CNS dysfunction, including ageing, psychotropic drugs and alcohol. The influence of age on pursuit is considerable, so one must be careful in diagnosing bilaterally abnormal pursuit in an elderly patient. During examination of pursuit or searching for spontaneous nystagmus, one may discover a limitation, or paresis, of gaze; this will be discussed under 'Saccadic eye movements' below.

SACCADIC EYE MOVEMENTS

Saccades are fast movements of the eyes (200–500 degrees per second) which allow us to shift gaze from one object of interest to another. Unlike smooth pursuit movements, that do require a visible moving target, saccades can be generated at will or command without a specifically defined target. These refixations occur incessantly so that gross saccadic defects are often detected while interrogating the patient. It should be said at the outset that just saying that a patient has abnormal saccades is not sufficient to make a topographic diagnosis; there are three independent properties of saccades to be clinically assessed: velocity (normal, slow or absent saccades, i.e. a gaze palsy), accuracy (normo-, hypo- or hypermetric) and binocular conjugacy (conjugate or dysconjugate, e.g. as in internuclear ophthalmoplegia).

With practice, all three aspects of saccadic function can be assessed in the clinic. Initially, however, it may be useful for the clinician in training to cross-validate subtle clinical findings with ocular movement recordings. One can gain some insight of saccadic velocity by simply asking the patient to look right, left, up and down. If one wishes to assess accuracy at the same time, however, a visible target should be provided, usually the examiner's

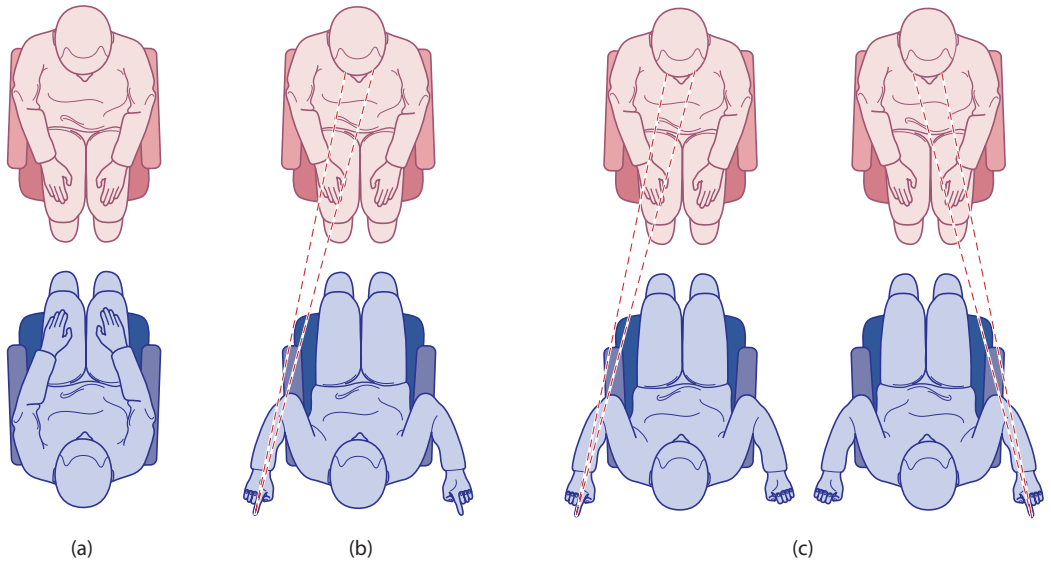

Figure 62.8 Different techniques for eliciting saccades during clinical examination: **(a)** on command; **(b)** self-paced; **(c)** visually elicited (to flicking fingers). During routine neuro-otological examination it does not matter which of these procedures, or combinations of procedures, is used. However, patients with cortical or basal ganglia disorder can show selective deficits with some but not other techniques. Redrawn with permission from Stell and Bronstein.[25]

finger placed 20–30 degrees to the right–left of primary gaze, for horizontal saccades, or up–down for vertical saccadic assessment. The patient can be instructed to look at the target when, for instance, the right or left finger flicks or when the hand opens up (Figure 62.8). It is customary, however, to reinforce the visual stimulus with a simultaneous verbal command such as 'right', 'left' (making sure to be directionally congruent with the patient's point of view) or 'pen', 'finger'. Subtypes of saccades (e.g. self-paced saccades, anti-saccades) can be elicited with more complex instructions and these can be selectively abnormal in frontobasal ganglia disorders, but these will not be reviewed here.[25, 26]

Saccadic velocity

A purely slowed-down saccade takes longer to travel from one target to another, but the movement is a unity, not fragmented. Saccadic slowing is the intermediate stage between normal velocity saccades and an absence of saccades (complete gaze palsy or paralysis). Neurodegenerative disorders involving the saccadic system reduce velocity from say 500 degrees per second to 100 degrees per second (taking up to 3–4 seconds longer than normal) before the patient becomes completely unable to transfer gaze at will or command (Figures 62.9 and 62.10).

Saccadic accuracy

Saccadic amplitude is normally slightly smaller than target amplitude; for example, for targets 30 degrees apart, the eye initial saccade is 27 degrees. In such cases the subject makes additional, smaller corrective saccades towards the target. Whereas one or two small corrective saccades can occur in normal subjects (usually bilateral in such cases), the presence of three or more corrective saccades is considered saccadic hypometria. Severely hypometric saccades look fragmented, often called 'multiple-step' saccades.

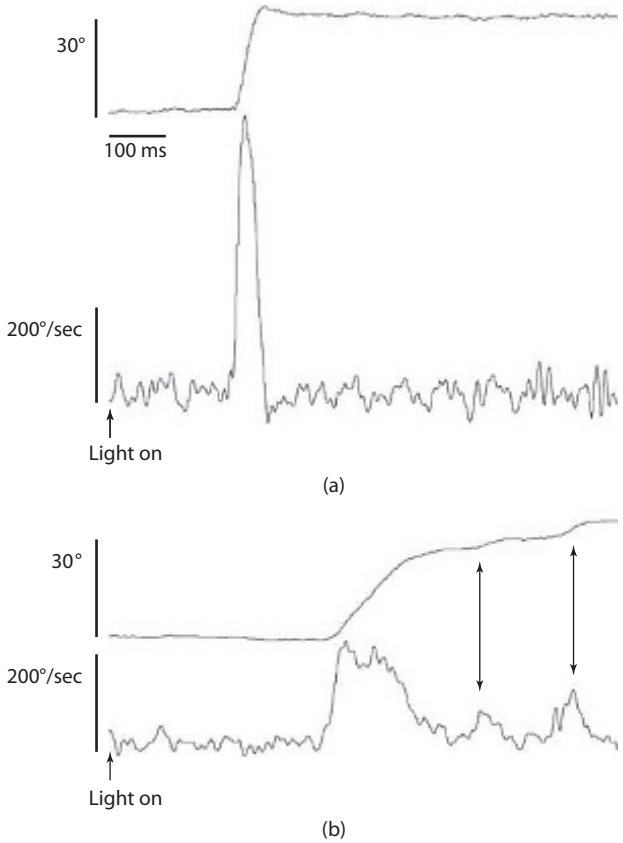

Figure 62.9 Examples of a normal saccade **(a)** and **(b)** a slow and hypometric saccade in a patient with a demyelinating brainstem lesion. Both the position (deg) and velocity (deg/second) traces are shown. The arrows point at two small corrective saccades.

In contrast, if the initial saccade is too large and travels past the target, the patient makes corrective saccades in the opposite direction of the initial saccade. This is saccadic hypermetria, a reliable cerebellar sign (anterior lobe)

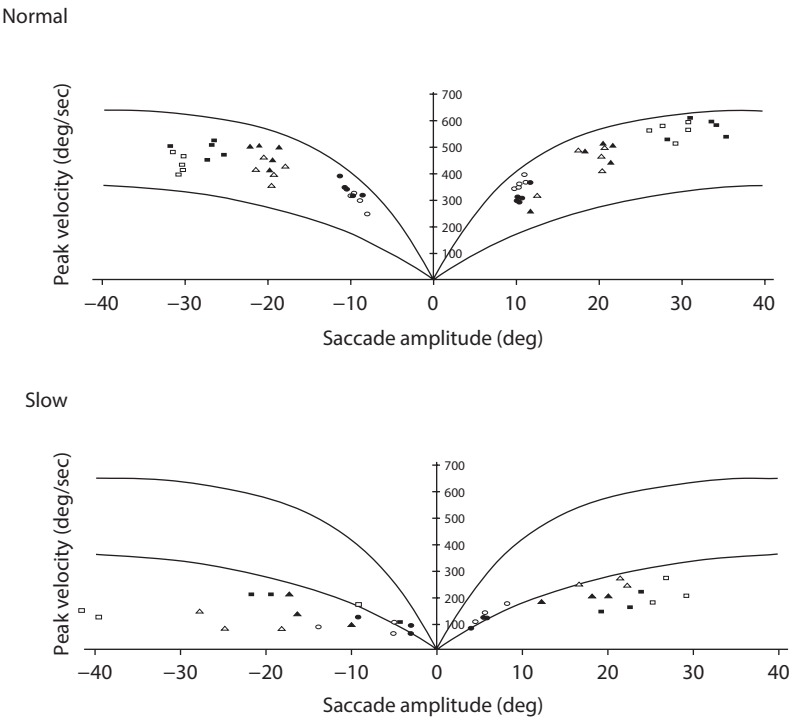

Figure 62.10 'Main sequence', obtained by plotting amplitude versus velocity of saccades in the normal and brainstem-lesioned subjects shown in Figure 62.9. The continuous 'butterfly' lines indicate the range of normality.

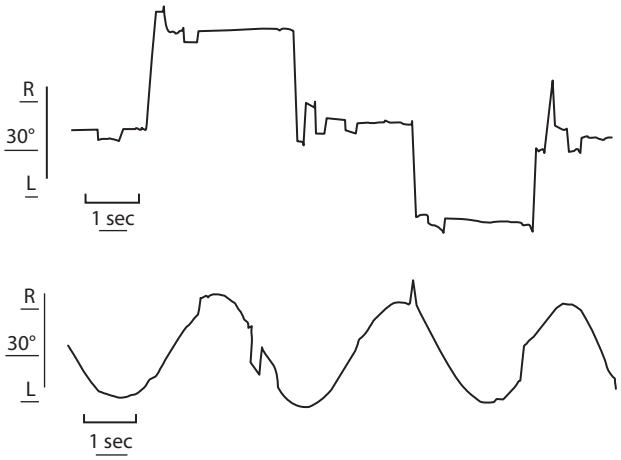

Figure 62.11 Eye movements in a patient with predominantly dorsal vermis cerebellar disease. Note the hypermetric saccades in spite of relatively normal smooth pursuit movements.

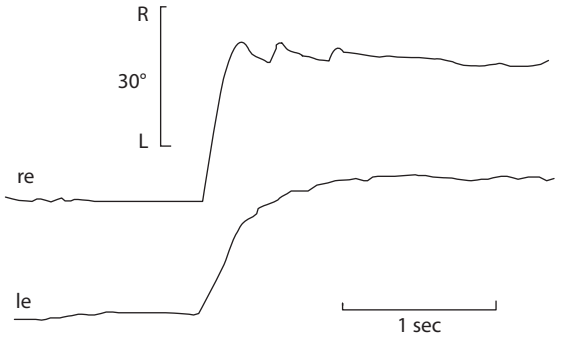

Figure 62.12 Separate eye EOG recording in a patient with a left internuclear ophthalmoplegia. Note the slower movement of the left eye to the right (adduction) and the right-beating nystagmus in the right (abducting) eye.

(Figure 62.11). The corrective saccade itself can be hypermetric so that the eye progressively homes in onto the target. The appearance and meaning is similar to abnormal past pointing during a 'finger–nose' test in an ataxic patient. By contrast, saccadic hypometria is much less specific and can be due to lesions in the cortex, basal ganglia, brainstem, cerebellum and oculomotor nucleus, nerve, muscle or metabolic (see Figure 62.9).

Saccadic conjugacy

When examining saccadic conjugacy (i.e. the two eyes should travel at the same speed), one should first make sure that there is no individual III, IV or VI nerve palsy (i.e. nuclear or infranuclear deficit). A common source of saccadic disconjugacy in the horizontal plane is, however, not nuclear but internuclear. This is the internuclear ophthalmoplegia (INO) in which the abducting eye saccades are fast and large whereas saccades in the adducting eye are slow and small. INOs are due to lesions of the medial longitudinal fasciculus (MLF) which connect abducens interneurons of the VI nucleus with medial rectus motoneurons in the contralateral III nucleus. Abducens interneurons cross the midline immediately to form the ascending MLF on the other side of the brainstem. Thus, a right INO means that right-eye adduction during gaze to the left is slow, hypometric or incomplete due to a right MLF lesion. Since innervation to the eyes is yoked, the attempt of the CNS to overcome the limitation in adduction makes saccades in the abducting eye to be larger (hypermetric). This sequence of overshoots in the abducting eye leads to the characteristic monocular, 'ataxic nystagmus' in INO (Figure 62.12).

Other essential 'supranuclear' clinical neuroanatomy concepts on saccades now follow.[24]

- The more important cortical areas for the generation of saccades are the frontal eye fields. At cortical level, saccadic control is contralateral, so that a left cortical lesion causes abnormal hypometric saccades towards the right.
- From these frontal (and also parietal) areas, pathways originate that reach the contralateral reticular formation of the brainstem, directly and indirectly.
- There are three important reticular saccadic areas.
  - A small central region in the pontomedullary junction (nucleus raphe interpositus (RIP)) which is the gateway for all saccadic movements; small lesions in this area can produce absence or slowness of saccades and quick phases of nystagmus in all directions.
  - The paramedian pontine reticular formation (PPRF) which generates the high frequency neuronal burst required to accelerate the eyes; this area is responsible for ipsilateral horizontal saccadic velocity so that a right side pontine lesion produces absence or slowness of saccades towards the right.
  - The midbrain reticular formation, in particular the rostral interstitial nucleus of the medial longitudinal fasciculus (RIMLF) responsible for the generation of vertical saccades. Lesions in this area can cause selective up, down or complete vertical saccadic gaze palsy or slowing, according to location and extension.
- Another area of importance for the accuracy (not velocity) of saccades is the anterior lobe of the cerebellum; lesions here can produce hyper- or sometimes hypometric saccades. Saccadic hypermetria strongly indicates cerebellar dysfunction but, in contrast, hypometria is not specific.

OPTOKINETIC NYSTAGMUS

The optokinetic nystagmus (OKN) system in man is not a truly separate oculomotor system but it will be briefly described here due to its historical and clinical value in neuro-otology. When a repetitive visual pattern moves in front of our eyes, such as a large curtain or traffic, our eyes follow one object with a smooth slow-phase movement. From time to time the eyes are reset in the orbit by a fast or quick component. This sequence of slow ipsidirectional and fast contradirectional eye movements constitute a visually or optokinetically elicited nystagmus. Its function is to complement the normal vestibular nystagmus during prolonged or slow head rotations. In animals, particularly those with poorly developed foveas, it is a peripheral retinal reflex. However, in man, particularly when OKN is elicited with a small handheld drum, the main contribution to the slow phase movement comes from the foveally driven smooth pursuit system. For these reasons, it is said that if smooth pursuit and saccades have been properly examined, what one can learn from observation of OKN is very little. Nevertheless, the alternating and repetitive nature of the nystagmus makes it sometimes easier to visualize some abnormalities; for example, a small asymmetry of pursuit may be easier to appreciate as an asymmetry of OKN.

OKN is usually investigated with a small hand-held striped drum (**Figure 62.13**). As in smooth pursuit assessment, the patient should be able to see the drum clearly; distance may have to be adjusted to age (presbiopia) and refractive defect of the patient. Subjects should be instructed to glance at the surface of the drum. If this fails to elicit nystagmus, one can try to ask the patient to follow or count the stripes as they pass by. The natural trend in the inexperienced examiner is to rotate the drum too fast, sometimes even letting the drum spin freely in front of a mesmerized patient. One or even half a stripe per second (for stripes of approximately 2–3 cm width) is what is required – if in doubt move it slower! If there is no drum available, OKN can be assessed with an open magazine or newspaper moved slowly in one direction and then the other. If what you want is to see nystagmus, the patient should be strictly instructed to look straight ahead; otherwise patients just follow a single word or image with smooth pursuit movements.

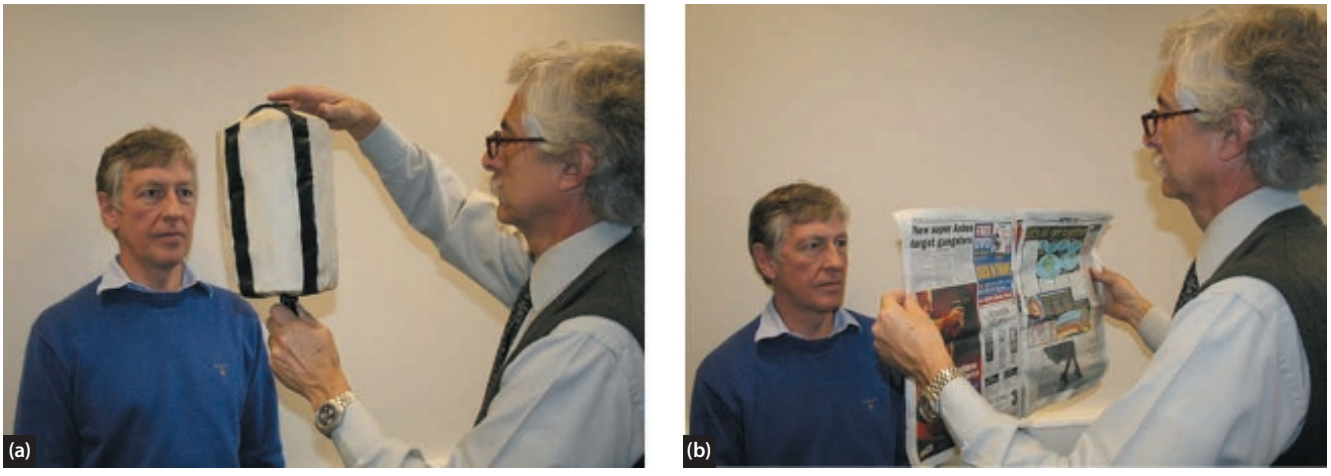

Figure 62.13 OKN elicited with **(a)** a small drum or **(b)** a newspaper. Rotation of the drum or movement of the large target object should be slow. The patient is usually instructed to look straight ahead, rather than follow the stripes or print.

The essential clinical neuroanatomy of OKN is that of pursuit, for the slow phase, and saccades, for the quick phase, but the clinician must be aware of the following practical points.

- The direction of OKN is defined by that of the fast phase. A directional preponderance of OKN to the right (elicited by drum rotation to the left) thus means that right-beating OKN is more active, better formed than left-beating OKN. Be aware that this usually means that slow-phase, smooth pursuit to the right is at fault.
- OKN assessment can be more useful than that of its pursuit-saccades constituents in cortical or subcortical lesions, due to the fact that a cerebral hemisphere is responsible for generating fast phases (saccades) contralaterally but slow phases ipsilaterally. Thus, a directional preponderance to the right of OKN observed in a right cortical lesion is due both to poor leftwards saccades and rightwards smooth pursuit. This functional coupling of slow and fast, oppositely directed eye movements is preserved in many brainstem areas so that, typically, a right brainstem lesion induces a left directional preponderance of OKN (e.g. by affecting the ipsilateral vestibular nuclei and ipsilateral PPRF saccade generators) (**Figure 62.14**). A right cerebellar lesion, with its massive loss of ipsilateral smooth-pursuit movements, usually generates a right directional preponderance of OKN.

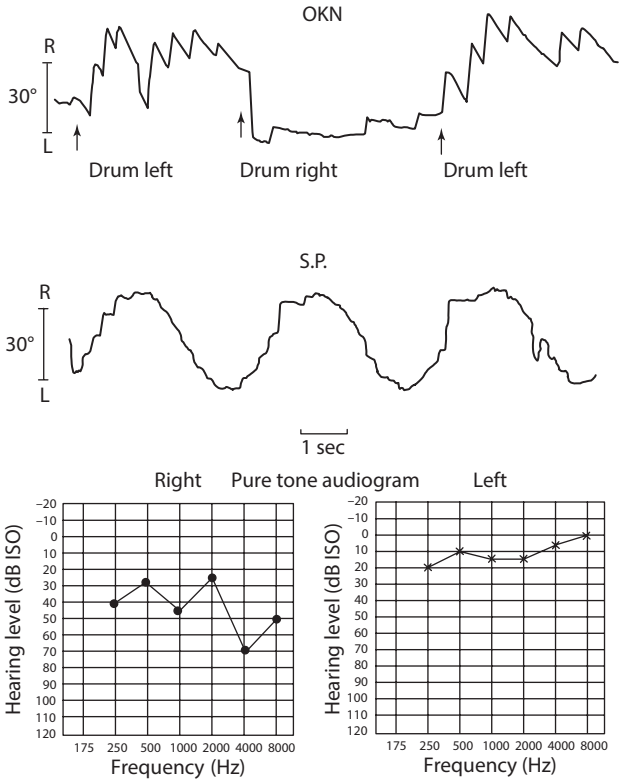

Figure 62.14 OKN asymmetry in a patient with an infiltrating brainstem tumour in the area of the right cerebellopontine angle.

- In disorders with selective or preferential saccadic problems (e.g. gaze palsies as in progressive supranuclear palsy) all one sees during OKN stimulation is the slow phase pursuit. Quick components of nystagmus are slow and scarce. This leads to the 'deviation of the eyes in the direction of the slow component of nystagmus' as described by Dix et al.[26] On reversing drum rotation direction, the eyes passively follow the drum, which is a useful sign in progressive supranuclear palsy.
- Peripheral (labyrinth and VIII nerve) lesions, unless acute and massive with clinically visible spontaneous nystagmus, leave OKN unaffected. A slight directional preponderance, concordant with the peripheral vestibular nystagmus, is all that can be observed in a peripheral disorder.

VESTIBULAR OCULAR REFLEXES

The vestibulo-ocular reflex serves a very specific function: to stabilize gaze in space during head movements. The VOR is what allows us to see clearly when we walk, run or turn our heads. It does so by generating slow-phase eye movements of equal velocity, but opposite in direction, to head movement. This is achieved by a three-neuron, short latency, reflex: a Scarpa ganglion neuron, a vestibular nucleus neuron and an oculomotor nuclear neuron (III, IV or VI).

For many years, clinicians relied almost exclusively on laboratory examination of the VOR, namely caloric or rotational tests. In the last 20–30 years, thanks to our increased understanding of the physiological basis of the vestibulo-ocular system and our improved skills in observing eye movements, we can now assess the VOR in the clinic room. Unilateral and bilateral loss of vestibular function can, in many cases, be identified clinically, but will be easier the more severe and the more acute the lesion is. In contrast, a unilateral, partial, long-standing, peripheral vestibular disorder cannot be detected clinically and a caloric test is required.

The clinical manoeuvres available rely on either:

- a slow doll's head manoeuvre, assessed by (i) direct observation of the eyes, (ii) measurements of visual acuity or (iii) ophthalmoscopy, or
- a fast version of the doll's head, the 'head-impulse' or 'head thrust' test (**Figure 62.15**).

THE DOLL'S HEAD (DOLL'S EYE) MANOEUVRE

This manoeuvre requires the patient sitting in front of the examiner, close enough to be able to observe the patient's eyes carefully. The patient is instructed to continuously fixate a feature of the examiner face (nose or bridge of nose), or an object across the room. The examiner then oscillates the patient's head from side to side, at a frequency of approximately 1 Hz. In the absence of VOR, the patient's eye movements will not be smooth but will be interrupted by 'catch-up' saccades towards the fixation target. This occurs because, at frequencies of 0.5–1 Hz, a head oscillation of ±30 degrees will generate peak head velocities of between 94 and 188 degrees per second, i.e. too high for the pursuit or cervico-ocular

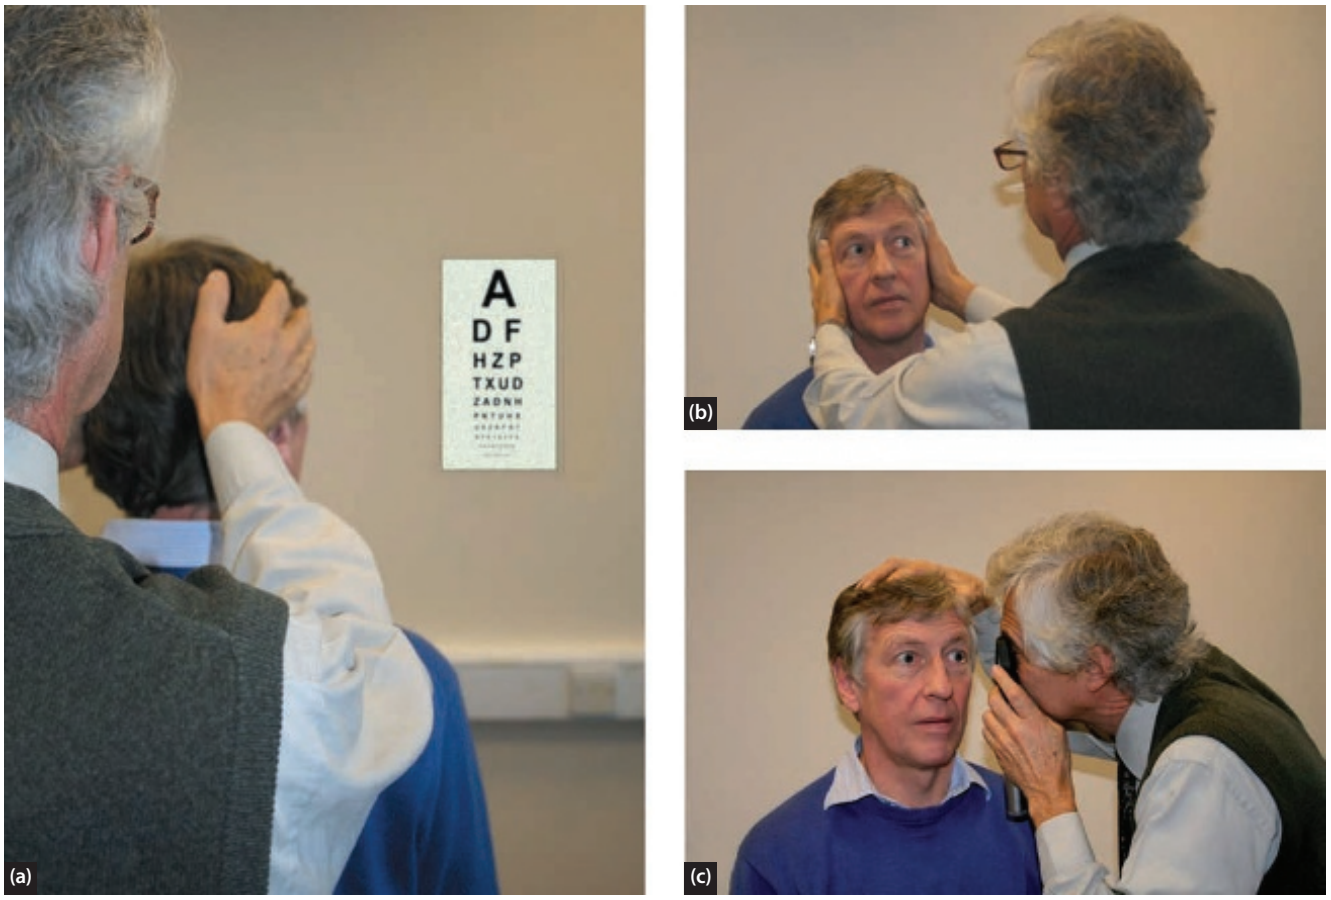

Figure 62.15 Techniques for assessing the VOR in the clinic. The general principle is that the examiner moves the patient's head, with two hands **(a)** and **(b)** or with one hand as in **(c)**. **(a)** Dynamic visual acuity. Two measurements of visual acuity are taken, one with the head stationary and one with the head oscillating at approximately 1 Hz. Reductions in visual acuity of two or more lines indicate bilateral abnormality of the VOR. **(b)** The examiner observes the patient's eye movements during either slow (doll's head) or fast, sudden head turns (head-impulse test). The presence of catch-up saccades towards a target (usually the examiner's nose) during a head turn indicates severe failure of the horizontal semicircular canal in the direction of the head turn. **(c)** The head is turned during ophthalmoscopy while the viewing eye maintains fixation on a distant object. If the optic disc remains absolutely steady, the VOR is functioning well. If the disc appears jerky during head (nose) turns in one direction, the ipsilateral horizontal semicircular canal is likely to be significantly impaired.

reflex to compensate.[27] As slow-phase eye movements are unable to keep up with the target, catch-up saccades are put in – and these can be easily observed if you are close enough. In patients with bilateral, complete or severe (>90%) loss of vestibular function (e.g. gentamicin ototoxicity, meningitis or idiopathic[9]), the manoeuvre is positive.

DYNAMIC VISUAL ACUITY

A similar movement of the head can be used to investigate the VOR while reading a visual acuity chart. A baseline, binocular visual acuity measurement is noted, for the sake of argument 6/6. Standing behind the patient, the examiner oscillates the patient's head at approximately 1 Hz while a new visual acuity measurement is taken. A normal subject's visual acuity does not change with respect to the baseline reading or it can deteriorate by one line, say, down to 6/9. A loss of two lines in visual acuity must be treated as suspicious and when three lines or more are lost, the results are frankly abnormal, i.e. indicative that the patient's VOR is grossly reduced. False positives may occur if the patient has a spontaneous nystagmus (e.g. a downbeating nystagmus) which is exacerbated by head movement and/or lateral gaze. However, this nystagmus should have been observed during conventional examination of the eye movements. False negatives occur if the patient himself oscillates the head, since they often 'cleverly' stop the head movement and get a snap of the visual acuity chart. In controlled conditions, a correlation between the degree of caloric response loss and dynamic visual acuity decrement was found.[28]

Although examination of the patient's eye during the doll's head manoeuvre can in some cases detect a unilateral vestibular lesion, this is detected more efficiently with the head-impulse test (see below). The reading or dynamic visual acuity test, as used clinically, cannot be applied to unilateral lesions.

OPHTHALMOSCOPY

A procedure first proposed by Zee[29] promotes the use of ophthalmoscopy for the assessment of vestibular disorders.

As the ophthalmoscope is a powerful magnifying glass, nystagmus of small amplitude can also be detected easily. However, as funduscopy is not routinely carried out by otolaryngologists, the reader is referred to the original reference and a recent brief review.[30, 31]

HEAD-IMPULSE TEST (OR HEAD THRUST TEST)

The value of VOR examination as described in the preceding sections is limited by the fact that they are all carried out with relatively low head velocities. The VOR is only really irreplaceable at high velocities and accelerations of the head. Pursuit, optokinetic or cervical mechanisms cannot fully take over from the VOR during brisk head movements. For this reason, Halmagyi and Curthoys have popularized the examination of the doll's head manoeuvre with discrete, sudden, brisk and unpredictable head turns, so that the VOR deficit is more apparent.[32, 33] In essence, the patient is seated with the examiner at close range so that the eyes can be observed carefully. The patient is instructed to fixate a target, preferably across the room (e.g. the video-camera lens if you wish to document the findings) or on the examiner's face. The head is turned in discrete steps of ±10–15 degrees, briskly, by the examiner thus producing head velocities of several hundred degrees per second. A fast right head (nose) turn will make a patient with right-sided vestibular loss introduce one or more catch-up saccades towards the target, i.e. towards the left. These catch-up saccades can be easily identified by a trained observer. The test is clearly useful for identifying acute unilateral peripheral vestibular deficits, for instance in patients with vestibular neuritis (neuronitis, labyrinthitis). In patients with chronic, compensated, incomplete unilateral lesions the test is often negative or inconclusive. A study comparing caloric testing versus the head-impulse test shows that the overall sensitivity of the head-impulse test is 34%.[34] This means that, when taking into account all patients with canal paresis, the sensitivity is low. However, specificity is high (100%) and all patients with a canal paresis ≥87% had a positive head-impulse test.[34] In the acute scenario the head-impulse test is extremely useful as it helps to confirm that an acute vestibular syndrome is of likely peripheral origin (abnormal result in vestibular neuritis). Although many small brainstem or cerebellar strokes show a normal head-impulse test, vascular lesions involving the labyrinthine artery (a branch of the anterior inferior cerebellar artery (AICA)) will also infarct the labyrinth hence producing vertigo, unilateral deafness and an abnormal head-impulse test when tuning the head towards the lesion. Combining the head-impulse test with other central oculomotor abnormalities indicative of a central lesion (skew eye deviation, bidirectional nystagmus) is, in experienced hands, more sensitive than diffusion-weighted image (DWI) MRI for the diagnosis of acute vertebra–basilar stroke (the HINTS for stroke protocol – head impulse, nystagmus characteristics, test for skew).[35, 36] Although HINTS is a nice protocol backed up by good research, clinicians should not forget many other hints or red flags suggestive of stroke (see **Box 62.2** above).

With practice it is possible to investigate clinically all six semicircular canals by moving the head obliquely in the planes of the vertical canals (LARP plane: left anterior–right posterior and RALP plane: right anterior–left posterior) (**Figure 62.16**).[37]

To feel fully confident with the head-impulse test one should be conversant with the oculomotor clinical examination and, like any other clinical manoeuvre, be shown how to do it – at least once. In some patients with spontaneous nystagmus or square-wave jerks the head-impulse test maybe inconclusive (i.e. it may be difficult to know whether you have seen the little saccade you are looking for, or just another square wave jerk). As with all other clinical procedures for VOR examination, the head-impulse test does not replace caloric testing. Quantitative versions of the test (video head-impulse test or VHIT) are now on the market and are useful (see vestibular testing below) but, despite pressure from the commercial manufacturers, they have not replaced the caloric test and perhaps they never will.

VESTIBULO-OCULAR REFLEX SUPPRESSION

When a subject rotates the head in the environment, his eyes adopt a pattern of alternating slow and fast phases, a physiological vestibular nystagmus (VOR). In a normally lit room this is aided by OKN. A property of the human brain, and other higher mammals, is the ability to suppress the VOR. This is executed by the vestibulo-ocular reflex suppression (VORS) system, closely related or identical to pursuit mechanisms and pathways. Abnormalities in VORS are thus indicative of central dysfunction, as discussed already for smooth pursuit.

Clinical examination of VORS is easy, both clinically and during oculography (**Figure 62.17**). The general principle is to oscillate the patient while he/she fixates a head-fixed target. Any obvious breakthrough nystagmus indicates poor suppression. In the clinic, this can be achieved by asking the patient to clasp the hands together in front of him and put the thumbs up as a target (**Figure 62.17b**); the patient can then oscillate side to side *en bloc*, by himself if standing up, or the examiner can oscillate the patient's swivel chair if sitting down. Alternatively, the patient can bite on a tongue depressor or ruler with his teeth, and fixate on the other end of the ruler or on an object attached to it while moving the head side to side (**Figure 62.17a**). As with pursuit, the oscillation should be slow, say 2–5 seconds from right to left, and vice versa (0.10–0.25 Hz) and one should have a good view of the patient's eyes.

Patients with peripheral vestibular lesions have normal VORS, or even 'super-normal' VORS as they are trained at suppressing their own spontaneous vestibular nystagmus. In central lesions, the abnormality of pursuit and VORS usually goes hand in hand, i.e. a patient with a right cerebellar lesion will show abnormal rightwards pursuit and abnormal VORS, with visible nystagmus breaking through, when oscillating the head towards the right.

Figure 62.16 Head movements required during the head-impulse test to investigate the horizontal canals (top, a–c) and the vertical canals (bottom, d–f). In the position shown in the figure the compensatory eye movement required during the head movement is horizontal (top) or vertical (bottom). Reproduced with permission from Bronstein and Lempert[8] and Bronstein et al.[37]

Figure 62.17 Clinical assessment of VOR suppression. The principle of the examination is that the patient fixates a head-fixed target during either **(b)** whole-body oscillation (his own thumbs) or **(a)** head oscillation (ruler or tongue depressor with an object on top, in the example shown the ear piece of an auriscope taped to the tongue depressor).

POSITIONAL MANOEUVRES

One of the most common causes of vertigo is BPPV, accounting for one-quarter of all patients with dizziness and vertigo. Positional manoeuvres are a vital component of the examination in the balance-disordered patient, particularly in light of the efficient treatments available for BPPV.

Positional manoeuvres must be conducted in all patients with vertigo or dizziness, particularly if provoked by head–neck movements or positions. Typical symptoms are vertigo on looking up, bending over, lying down and turning over in bed. If a patient is dizzy on standing up from the sitting position, the likelihood of the symptoms being primarily vestibular in origin is less. The latter challenges vascular orthostatic mechanisms but there is no reorientation of the head with respect to gravity.

The purpose of conducting a positional manoeuvre is to attempt to elicit vertigo, but vertigo is unpleasant. The patient should be made aware that despite modern technology this is the only way to make a diagnosis of a perfectly treatable condition such as BPPV. During the positional manoeuvre, and regardless of whether there is vertigo or not, the examiner should carefully observe the patient's eyes. In order to fulfil this purpose the following practical measures can be taken.

- Patients should be warned beforehand that, even if they feel vertiginous, they should look straight ahead at one point on the examiner's face (i.e. the nose or bridge of the nose). If the eyes are not in primary gaze or wandering around, the observation of the nystagmus is more difficult.
- At least one eye of the patient can be easily helped to stay wide open by one of the free hands of the examiner, as shown in Figure 62.18.
- Keep the patient in the head-down position for a few seconds. Some patients with BPPV show extremely long latencies, occasionally up to 20–30 seconds. If the suspicion of BPPV is strong, one should wait this long. In most cases, 10–15 seconds is sufficient, indeed most cases of BPPV have latencies of less than 5 seconds.

Figure 62.18 Positional manoeuvres. Examination technique for a right-sided, posterior canal BPPV. **(a,b)** The Hallpike manoeuvre, in which the head (face) is turned approximately 45° to the right. This is done so that the rotation, down to the head-hanging position, takes place in the plane of the right posterior canal. Note how the examiner's right hand can contribute to open the patient's eye widely. **(c,d)** 'Variant' Hallpike manoeuvre, starting from a sitting position. Note that the head reaches a similar final position, despite not actually being off the couch; this manoeuvre is useful if the couch is placed in between walls or cupboards.

There are no excuses for not doing a positional manoeuvre. However, two of the most commonly excuses heard are 'The couch in my room is placed awkwardly to do a Hallpike, I just cannot get the patient's head to hang off the couch' and 'We have not got Frenzel glasses in our clinic.' Wrong! A positional manoeuvre can be done with a couch in any position and Frenzel glasses are definitely not required for any positional nystagmus. **Figure 62.18a** and **b** show the conventional Hallpike manoeuvre with the head in the classical hanging position and a recommended alternative to the procedure when, for instance, the couch is placed between walls or cupboards (**Figure 62.18c** and **d**). Examination of these pictures shows that the final head position achieved is very similar. As to the use of Frenzel glasses, it must be remembered that all the classical descriptions of BPPV by Dix and Hallpike were carried out without Frenzel glasses. Presumably, the rationale for using Frenzel glasses is that, when the patient is able to fixate, the nystagmus can be potentially suppressed. However, the vast majority of patients either have or do not have BPPV. If they have BPPV, the nystagmus is extremely strong and so the patient is unable to suppress it with visual fixation. Furthermore, a critical component in the most common form of BPPV, posterior canal BPPV, is torsional (rotatory) nystagmus. The ability to suppress torsional nystagmus by visual fixation is less than nystagmus in other planes.[38] It is theoretically possible that Frenzel glasses could help in a patient with a mild form of BPPV. In practice, there seems to be no increase in diagnostic efficacy but controlled studies are lacking.

What can we expect to see during a Hallpike or variant Hallpike manoeuvre? The most common form of positional nystagmus is BPPV of the posterior canal. During a left-ear-down head hanging position one triggers a left posterior canal BPPV, with the main component of the nystagmus being torsional (or rotatory) beating clockwise from the observer point of view. This means that the upper pole of the patient's eye beats towards the patient's left shoulder. Technically speaking, it is left-beating torsional nystagmus, as expected from activation of the left posterior canal. A secondary upbeating component of nystagmus is often observed which is synchronous with the torsional beat. The nystagmus is often accompanied by intense vertigo and by the patient's attempt to close the eyes or to sit up – which the doctor will have hopefully instructed him/her in advance to resist. The characteristics of posterior canal BPPV are the presence of latency, as mentioned above, adaptation and fatigability. Adaptation refers to the decline and eventual disappearance of the nystagmus within a minute or so, usually less. Fatigability refers to the fact that on repeated positioning, the nystagmus and the vertigo are less with time. The patient can be reassured that usually the intensity of the symptoms will be less as we repeat the manoeuvre. Currently, one rarely repeats the manoeuvre to assess fatigability as it is advisable to proceed straight to repositioning treatment (see Chapter 64, Benign paroxysmal positional vertigo).

The positional manoeuvre should be conducted on both sides, particularly if no nystagmus is observed on the first side. On confirmation of the diagnosis, most specialists proceed to treatment with Epley or Semont manoeuvres. Partly because of fears that a new Hallpike after an Epley or Semont manoeuvre could undo the benefits of the treatment, many doctors do not do the Hallpike manoeuvre on the other side if BPPV has been diagnosed and treated on one side. If all symptoms resolve in the first session, that is end of story. If symptoms persist, the Hallpike manoeuvre will have to be carried out on a separate session on both sides. If the patient knows that a particular ear down provokes the vertigo, it is sensible to do the healthy side down first to increase patient confidence and so be able to examine both sides in the same session.

Several other types of nystagmus can be observed during the Hallpike manoeuvre, which are not posterior canal BPPV. In principle, a purely vertical nystagmus, be it up- or downbeating nystagmus, should be considered of central origin. Our review of 50 consecutive cases of positionally induced downbeating nystagmus we found that three-quarters of patients had independent evidence of neurological disease.[39] In the remaining quarter of patients the most likely diagnosis was anterior canal BPPV. Ideally, in anterior canal BPPV, one should see a torsional component added to the positional downbeating nystagmus. Of interest, the right/left specificity to trigger anterior canal BPPV seems less than for posterior canal BPPV.

A purely horizontal nystagmus can also be observed during a Hallpike manoeuvre. In a patient with a recent history of peripheral type positional vertigo, the diagnosis is almost certainly horizontal canal BPPV. As in posterior canal BPPV, it is usually due to canalolithiasis (free-floating particles in the lumen of the canal) and occasionally to cupulolithiasis (particles become adhesive to the cupula).[40] Horizontal canal BPPV produces intense nystagmus and vertigo and this happens when the head is turned both to the side of the lesion and to the opposite direction. The nystagmus usually beats in the direction of the face turn. The intensity of the nystagmus is stronger in the direction of the abnormal side, i.e. stronger right-beating nystagmus with the right ear down suggests right horizontal canal BPPV. Horizontal canal BPPV is a much more self-limiting condition than other canal BPPV and can disappear spontaneously in a few days.

When a patient gives a positive typical history of BPPV and no nystagmus can be elicited in the Hallpike or similar manoeuvres for posterior canal BPPV, other manoeuvres should be investigated. For horizontal canal BPPV the optimal plane of rotation should be in the plane of the canal. This can be achieved with the head end of the couch raised 20–30 degrees above the horizontal, followed by a full head turn about the longitudinal axis of the body in each direction. It can be estimated that the Hallpike (i.e. posterior canal) manoeuvre may not identify 20% of horizontal canal BPPVs. In other words, one in five patients with horizontal canal BPPV will require the specific horizontal canal manoeuvre for diagnosis.

For anterior canal BPPV, the left head-hanging Hallpike position should provoke a right anterior canal BPPV and vice versa. This is due to the coplanar orientation of the left posterior canal with the right anterior canal and

vice versa. However, a crucial factor in provoking anterior canal BPPV seems to be placing the head as low down as possible and this may be best achieved by taking the patient in one movement from the sitting upright position to the straight back, head hanging position.[39]

In summary, many positional manoeuvres exist and BPPV can come from any of the three semicircular canals. Bilateral cases, often post-traumatic, also exist. At least the Hallpike manoeuvre, or variant, for posterior canal BPPV must be carried out in all patients with head–neck movement or position triggered vertigo. If negative, the horizontal and straight back manoeuvre should be applied but the hit rate may be low. A typical nystagmus for posterior canal BPPV, with normal CNS examination, needs no imaging procedures. Successive failures to treatment should prompt imaging. Even in the absence of nystagmus, more than 80% of patients with a typical history improve with particle repositioning manoeuvres for posterior canal BPPV.[41] Observation of any other positional nystagmus, particularly if it lasts for longer than a month, should undergo detailed MRI investigation of the posterior fossa. Further details about examination and treatment of positional vertigo can be found in Chapter 64, Benign paroxysmal positional vertigo.

Laboratory assessment of eye movements

Not all patients with a suspected vestibular disorder, peripheral or central, require eye movement recordings (oculography); only a minority do. Not even patients requiring a caloric test may need eye movement recordings (see 'Caloric tests' below). In a research, academic or tertiary referral environment, vestibular and eye movement tests are conducted for a variety of reasons and not necessarily diagnosis. These are perfectly valid reasons such as research, training of medical and paramedical personnel and patient reassurance.

From the strictly clinical point of view, oculography is required firstly for formal vestibular testing, as this is usually conducted in the dark (Table 62.7). Otherwise, visual input may suppress spontaneous vestibular nystagmus and override abnormalities in rotational responses. Oculography is also required to elucidate the nystagmus waveform in some patients with spontaneous nystagmus, particularly when there is doubt if the nystagmus is acquired or congenital. Oculography is required when clinical examination of eye movements leaves doubts on the presence of a potentially significant abnormality such as INO or slow saccades.

The clinician must bear in mind, however, that routine oculographic examination, as carried out in most vestibular laboratories, will fail to answer these questions unless they are specifically formulated. This is no different to other special medical investigations.

Vestibular conditions that can be diagnosed clinically or with other laboratory investigations (audiograms, head scans) do not necessitate ocular recordings. Examples are BPPV, Ménière's disease and vestibular schwannomas. Formal vestibular testing in such cases is variably indicated according to the presence of complications, poor response to treatment, presurgical evaluation, evaluation of the 'healthy' labyrinth, or need for objective measurements on follow-up.

TABLE 62.7 Indications for oculography: eye movement recordings to investigate imbalance

Clinical problem	Recording/action
Assessment of eye movements in the dark	Is there vestibular nystagmus?
	Vestibular function (e.g. rotational test)
Nystagmus waveform	Vestibular versus gaze paretic?
	Acquired versus congenital?
Confirmation of subtle abnormalities of diagnostic value (e.g. abnormal pursuit, subclinical? INO?)	
Quantification	Research and follow-up

OCULOGRAPHY TECHNIQUES

There are many techniques available and they all offer advantages and disadvantages. The two techniques usually available in ENT or audiology departments are electro-oculography (EOG) and video-oculography (VOG). These two techniques are relatively easy to set up, inexpensive, non-invasive and have a range of signal linearity of approximately ±20–30 degrees, capable of coping with the large eye movements encountered during vestibular tests in the dark. The main disadvantages are poor spatial (EOG) and temporal (VOG) resolution, but in the clinical vestibular setting these two techniques are the ones to be recommended (note that EOG and electronystagmography (ENG), are synonymous). An increasingly popular use of VOG is as part of the video head-impulse test (VHIT).

Infrared oculography and the scleral search coil technique may be found in specialized departments with an interest in eye movement disorders. Infrared oculography has a small range of linearity which is not suitable for the large movements observed during vestibular testing. The search coil system has the single but major disadvantage of being a semi-invasive procedure as it requires wearing a copper wire coil embedded in a plastic contact lens.

EOG or ENG

In this technique, surface electrodes, usually disposable, are glued around the orbit. Pairs of electrodes record the difference in potential between the cornea and the retina and, since the corneal region is positive and the retina negative, the eye becomes a dipole. Two electrodes placed at each side of the orbit, right–left for horizontal movements or above–below the orbit for vertical movements, will detect movement of this dipole. The usual configuration of electrodes for conventional vestibular testing is two electrodes, one at each external canthus ('bitemporal recording'). This gives a better signal-to-noise ratio because the recording taken is of an ideal 'cyclopean' eye. If the patient has clearly disconjugate eye movements or if the question is whether this patient has got an INO, then simultaneous separate

eye horizontal recordings are needed. Vertical eye recordings are taken only occasionally in the vestibular scenario; there are not many instances when they are required, and they are often dogged by blink artefacts. If the question is whether the patient has a vertical nystagmus, ophthalmoscopy, Frenzel glasses or video techniques are often more reliable. Major disadvantages are that EOG cannot record torsional eye movements and that many other biological potentials can be picked up with periocular electrodes as artefacts, such as electroencephalography or electromyography. The presence of drifts in the recording and low voltage potential in some ocular diseases indicates that EOG, although popular, is far from ideal.

VOG

Small video cameras can be mounted on goggles to obtain good quality images of the eye. Infrared cameras work in darkness and these images can be used to directly observe the presence of nystagmus in the absence of visual fixation (videonystagmoscopy). If the images are further processed, on- or offline, so that traces or measurements are obtained, the technique is called VOG. The main limitation of this technique as compared to EOG/ENG is temporal resolution. This depends on the sampling video rate, usually 50 Hz, i.e. a video image taken every 20 ms; the velocity of a saccade, which only lasts 50–100 ms, may not be reliably measured. Other types of eye movements, all much slower than saccades, can be confidently recorded but eyelid artefacts and occasional difficulties with the eye-tracking software are also troublesome. Most commercial VOG systems are two-dimensional (2D) (horizontal and vertical) but the more sophisticated are 3D and this offers the unique advantage of being able to non-invasively record torsional eye movements.

Routine EOG or VOG

Oculography can be carried out very selectively, for instance to see if a patient has normal or abnormal rotational responses, but often a battery of investigations are grouped in a 'routine' ENG or VOG. There are many variations to this routine but it essentially involves a search for spontaneous and gaze-evoked nystagmus, visually guided eye movements (pursuit, optokinetic and, if requested, separate eye saccadic velocities) and a vestibular test, namely caloric or rotational stimulation. Mostly, the analysis of the eye movement trace is carried out automatically or semi-automatically by computer; automatic artefact rejection is often suboptimal. The analysis is often collated by a technician who then produces a report to the physician or surgeon. There are therefore a number of possible weak links in the chain which can potentially mislead the clinician. I have seen many untenable diagnoses of 'central vestibular disorder' on the basis of artefactual ENG or poor-quality interpretation.

Since it makes no difference whether an abnormality is detected by direct clinical observation or by oculography, the various possible findings and their interpretation have already been discussed above. Herewith we will concentrate on any added value or new aspects of the examination that can be provided only by oculography.

SPONTANEOUS AND GAZE-EVOKED NYSTAGMUS

A spontaneous nystagmus present in primary gaze or evoked by eccentric gaze can have many different meanings. Features helpful to the differential diagnosis are the effect of visual fixation and waveform characteristics, to be discussed below. The plane (horizontal, vertical, torsional) of the nystagmus is also a critical feature but it is best decided on clinical grounds, unless high-performance 3D oculography is used. With the head upright, horizontal or horizontotorsional nystagmus can be peripheral or central but any other direction, namely torsional (unless in the Hallpike position) or vertical, in principle indicates CNS disorder. The reader is referred to specialized references for neurological nystagmus.[21, 22, 42]

Visual suppression

Nystagmus of peripheral vestibular origin is suppressed, sometimes completely abolished, by visual fixation. Thus, peripheral vestibular nystagmus increases in size and slow phase velocity in the absence of visual fixation, that is, in the dark or with Frenzel glasses (**Figure 62.4**). In contrast, central lesions usually damage pathways involved in the suppression of nystagmus (VOR suppression) and so the nystagmus enhances little, not at all or even diminishes in the dark. Thus the effect of darkness on nystagmus is an extremely useful aid to the differential between labyrinthine and neurological nystagmus (**Table 62.8**). This can also be carried out by direct inspection of the eyes behind Frenzel glasses or with modern commercial video cameras which have a standard inbuilt infrared lens ('handycams'). The search for nystagmus must be done in the primary position of the eyes and on gaze deviation right and left by 20 or 30 degrees. There are no hard rules but a nystagmus which is less than 2–3 degrees per second on gaze deviation in the dark is not significant. Significant nystagmus is not only induced by vestibular or CNS lesions but also by neuropharmacological agents and alcohol.

Nystagmus waveform

There are two basic types of waveforms. Saw-tooth or jerk nystagmus, intercalating a fast and a slow phase (see the examples in **Figures 62.2**, **62.3**, **62.4** and **62.5**), and pendular nystagmus, a quasi-sinusoidal waveform with no distinct fast phases (**Figure 62.19**). Jerk nystagmus can be peripheral or central; pendular nystagmus is always central, but not always ominous as it may be congenital or secondary to severe visual loss.

Due to the ability of the normal CNS to suppress nystagmus, the rule of thumb is any large amplitude nystagmus recorded in the light, particularly if it does not enhance in the dark, is of central origin. The exception could be an acutely ill vestibular patient (vestibular neuritis, attack of Ménière's disease). It is not appropriate to review the many types of neurological nystagmus in a general chapter

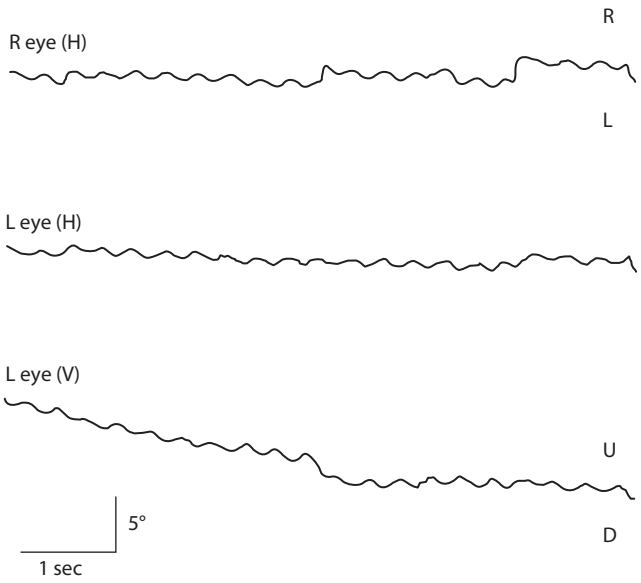

Figure 62.19 Pendular nystagmus in a patient with multiple sclerosis. The presence of simultaneous horizontal and vertical components, in this case in the left eye, produces complex movement trajectories (elliptical, 'banana'-shaped, circular). With kind permission from M. Gresty.

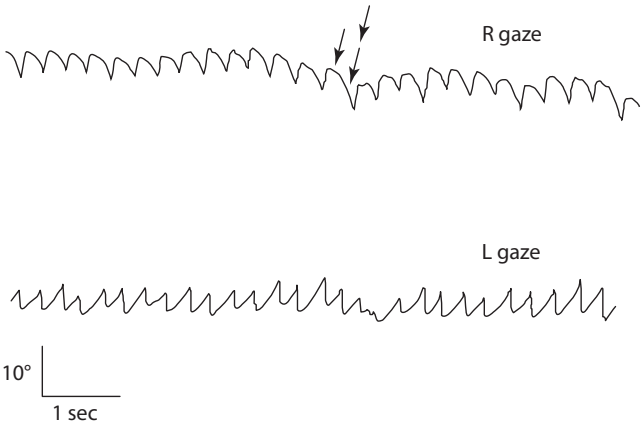

Figure 62.20 Exponentially increasing slow phase velocity in a patient with congenital nystagmus (CN).

TABLE 62.8 Differential diagnosis between central and peripheral nystagmus

Characteristic	Peripheral	Central
Plane	Hor or Hor > Tors	Any
Amplitude	Acute ++	++/+++
	Chronic +/–	++/+++
Fixation removal*	Appears/enhances	Variable (can diminish)
Waveform†	Rectilinear (jerky)	Exponential (jerky)
		Pendular

* By oculography, Frenzel glasses or fundoscopy in the dark.
† By oculography.
Hor, horizontal; Tors, torsional.

on the assessment of balance but it is worth mentioning some useful steps for the differential, peripheral versus central and acquired versus congenital nystagmus.

As mentioned under 'Clinical examination of eye movements' above, jerk nystagmus can be of peripheral or central origin. A jerk nystagmus of peripheral vestibular origin has a typically linear slow phase (Figure 62.4). Linear means that the velocity of the slow phase is constant and it is so because the magnitude of the velocity at rest is a direct measure of the vestibular tonus asymmetry. CNS lesions can also create a vestibular imbalance but they usually involve in addition central integrating mechanisms. This makes the slow phase of nystagmus to be non-linear, particularly during eccentric gaze, typically with an exponentially decreasing slow phase in velocity (Figure 62.5). A jerk nystagmus with a slow-phase velocity exponentially increasing (Figure 62.20), however, strongly suggests the diagnosis of congenital nystagmus, although some exceptions have been reported.[43] The diagnosis of pendular nystagmus is usually easy by simple clinical inspection and confirmed with recordings but establishing whether it is acquired or congenital is not possible on simple oculographic criteria. Patients with acquired pendular nystagmus usually have clinically severe vascular or demyelinating brainstem disease whereas patients with congenital pendular nystagmus have congenital or infantile visual loss and defects.

By way of summary (Table 62.8), a typical peripheral vestibular nystagmus is small in the light but increases amplitude in the dark and shows linear slow-phase velocity in the horizontal (or horizontotorsional) plane. It normally follows Alexander's law of increasing in magnitude when looking in the direction of the fast phase. Additional findings can be a caloric canal paresis (see under 'Caloric tests' below) or a positive head-impulse test contralateral to the beat direction of the fast phase, as in vestibular neuritis. Also, there should be no oculographic evidence of CNS lesion, namely visually guided eye movements should be normal.

VISUALLY GUIDED EYE MOVEMENTS

The clinical significance of abnormalities of pursuit, OKN, saccades and VOR suppression is the same whether documented clinically or by oculography. Recording very slow saccades or broken pursuits that have been definitely observed by the naked eye will not add anything to the diagnosis. Recording of mild abnormalities for confirmation of a questionable clinical abnormality is reasonable and, in addition, may provide a baseline for future comparisons on follow-up.

Saccades

Technical variations are unlimited but nowadays most oculography systems are computer-controlled. The target for saccades (or pursuit) can be projected, generated by rows of light emitting diodes (LED) or directly viewed on a computer screen. Unless specified, recordings are usually only conducted in the horizontal plane. For saccades, the target jumps to different locations and the latency (reaction time), velocity and accuracy of the saccade

is measured. Saccadic latency is a less important parameter for balance assessment. Since there is a fairly fixed relationship between the amplitude and the peak velocity of saccades (called the 'main sequence'), the results are often presented as an amplitude-velocity plot, with or without an exponential curve fitted (see **Figures 62.9** and **62.10**). The significance of slow and inaccurate saccades has been discussed above under 'Clinical examination of eye movements'.

Smooth pursuit

For smooth pursuit, the target slowly oscillates with a triangular or sinusoidal trajectory. Usually a range of frequencies and/or velocities are explored. Results are often expressed as 'gain', the ratio between peak velocity of the eye and peak target velocity. At low frequencies and velocities, say 0.10 Hz, peak target velocity 10 degrees per second, normal gain is close to unity. As frequency/velocity increases, gain values drop. In neurological patients, gain at a single frequency are lower than control, and the drop out occurs early. As discussed under 'Clinical examination of eye movements' above, abnormalities can be uni- or bilateral. The possibility that poor pursuit performance is just due to simple attentional factors is higher during laboratory than during clinical assessment, when the clinician can encourage and observe the patient directly. During all oculography procedures audiologists and technicians need to be trained to keep an eye on the patient's alertness, to recognize artefacts due to drowsiness and to urge patients to stay awake and cooperative.

Optokinetic nystagmus, particularly as elicited in the clinic with a small drum, is just a combination of pursuit and saccades. Large vestibular laboratories add a full-field encircling drum, covered in vertical black and white stripes, for OKN investigation, which is a more powerful stimulus. Whereas a peripheral vestibular asymmetry can occasionally bias small drum OKN, full-field OKN is never affected by a peripheral disorder (**Figure 62.21**).[44] As with all other visually driven eye movements, abnormalities are indicative of central disorder and can be uni- or bilateral (see under 'Clinical examination of eye movements' above). Although one often refers to asymmetries of OKN as directional preponderance (DP) of nystagmus, what matters is on which side the slow-phase velocity is subnormal. Thus, a left DP of OKN is due to the fact that the leftwards slow phase is subnormal; as a consistency check, the vast majority of patients should also have abnormal pursuit and VOR suppression during leftwards motion.

VESTIBULO-OCULAR REFLEX

In practice, there are three ways of assessing the VOR: clinically as discussed above, with caloric irrigation or with rotational stimuli. Electrical (galvanic) stimulation of the VOR has historical and experimental value. This will not be discussed here except to say that galvanic stimulation excites the VIII nerve afferents directly and this was occasionally used to distinguish if a caloric unresponsive ear was due to an VIII nerve lesion (absent galvanic response) or a labyrinthine lesion (present galvanic response).[45]

CALORIC TESTS

The principle of the caloric test is that changes in temperature in the external auditory canal influence the level of activity of the vestibular labyrinth. The caloric test is still the main test available to any clinician to assess individual-ear vestibular function whereas rotational tests stimulate both labyrinths simultaneously.

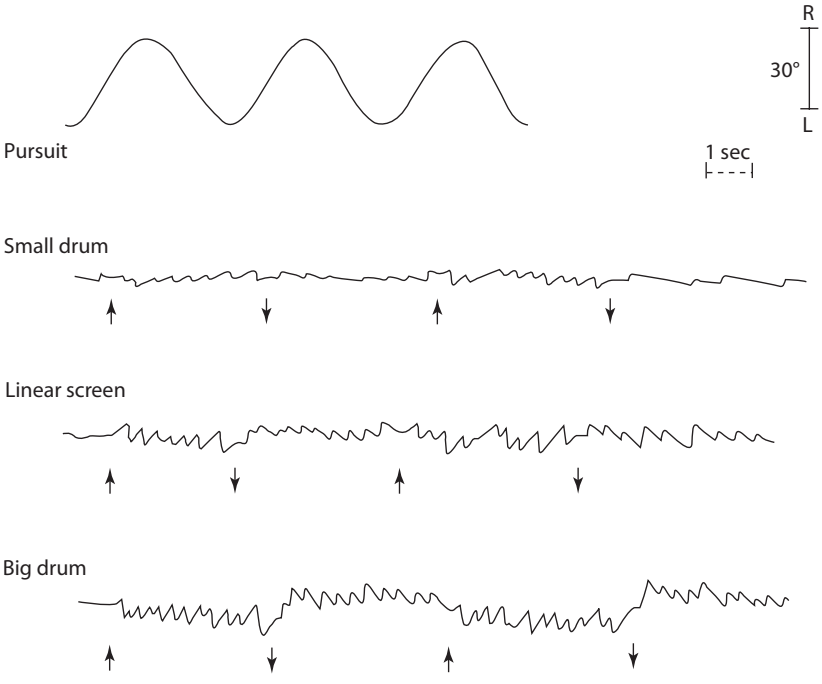

Figure 62.21 Pursuit and OKN in a patient with a right-sided acute peripheral vestibular lesion. Pursuit and big drum OKN are normal but minor directional preponderances (DPs) with the small drum can be observed in the acute phase (in this case to the left). Arrows represent drum or screen motion direction reversal. Reproduced with permission from Mossman et al.[44]

The disadvantages are that some patients cannot tolerate the caloric test (because of local discomfort or induced vertigo) and that disease or anatomical variability in the middle and external ear can preclude irrigation or interfere with the results.

To some extent, the mechanism of the caloric response is still debated. In order to obtain a satisfactory nystagmic response, the subject has to lie down with the head raised 30 degrees above horizontal. This places the horizontal semicircular canal in an approximately vertical position; the more lateral position of this canal leaves it more accessible to external temperature changes. The mechanism commonly invoked as responsible for the caloric nystagmic response is that the thermal change induces convection currents in the horizontal canal (when placed vertically) and thus cupular deflection. This hypothesis is strongly supported by the fact that, if the position of the subject during a caloric test is inverted (supine to prone), then the direction of the nystagmus reverses.[46] This is expected because the direction of the convection current will be reversed (note, convection currents occur in a gravitational field). However, the finding that a caloric response can be partly obtained in minimal gravity conditions, such as in the Space Lab mission, indicates that a direct thermal effect on the end organ is also present.[47]

Irrigation of the external auditory canal can be carried out with water or air. In the conventional procedure, two temperatures are used, one above and one below body temperature. Water irrigation at 30 °C and 44 °C (37 ± 7 °C) is the standard technique. In the original description by Fitzgerald and Hallpike,[48] the procedure follows the order left cold, right cold, left warm, right warm, for standardization purposes, with each irrigation lasting 40 seconds,[49] but this order is not essential. Temperature in the temporal bone has to be minimally stable before the next irrigation, so at least 5 minutes since the end of the previous irrigation has to be allowed for. Air irrigation offers the main advantage that it can be used in patients with eardrum perforations, but responses appear to be less consistent than with water. Technical modifications have improved this,[49] but insufficient patient data are available. If the surgeon needs to know whether there is any vestibular function at all in a perforated ear, then the answer is an air caloric test. For routine balance function assessment, water irrigation is preferred.

In the conventional testing position described above, cold irrigation induces horizontal nystagmus beating in the opposite direction of irrigation, and ipsilaterally during warm irrigation (cold-opposite-warm-same (COWS)). In this way, left cold and right warm irrigation induce right-beating nystagmus, and vice versa. Recording of the nystagmic response is usually carried out with EOG or VOG, often as part of a 'routine' computerized assessment. Measurements are taken of the velocity of the slow-phase component of the nystagmus and these are often displayed as a function of time. However, the original description by Fitzgerald and Hallpike is based on direct clinical measurement of the duration of the response and this technique is perfectly acceptable.

There are five main abnormalities of the caloric response.

1. Bilateral absence of caloric nystagmus, as in aminoglycoside ototoxicity or postmeningitis (see **Table 62.9**).
2. Unilateral canal paresis, a reduced/absent response from one ear, as in unilateral vestibular schwannoma or vestibular neuritis.[48, 50] Canal pareses can also be caused by a brainstem lesion in the VIII nerve root entry zone or vestibular nuclei but usually there will be other CNS symptoms or signs.[51]
3. DP, essentially an asymmetry in the VOR.[52] A right DP indicates that right-beating nystagmus is stronger, i.e. longer duration or faster slow-phase velocity according to the technique used, than left-beating nystagmus. A typical example is a patient with a, say, left vestibular neuritis. Initially the picture will be dominated by the complete left canal paresis and the spontaneous right-beating nystagmus. With time, all there may be left over is a right DP. Even if the caloric canal paresis does not recover at all, irrigation of the healthy right ear can show longer/stronger responses during warm irrigation (rightwards nystagmus) than cold irrigation (leftwards responses). Unfortunately, the finding of a DP in isolation is not specific and can be due to lesions ranging from the labyrinth to the cortex.[53, 54] One of the many possible visual representations used for canal paresis and DP is shown in **Figure 62.22**.
4. Abnormal VOR suppression. During caloric testing, VOR suppression is investigated in two possible ways.
   - With the conventional Fitzgerald and Hallpike technique the duration of the patient's nystagmus is directly timed in the presence of optic fixation. Once the nystagmic response has finished in the light the patient's eyes should be examined with either Frenzel glasses or an infrared viewer. In normal subjects or patients with peripheral vestibular disorders the caloric nystagmus then re-emerges. The duration of this nystagmus in the absence of optic fixation should be measured and the value compared to that obtained in the light.[56] Typically, a caloric nystagmic response in the light will last 80–160 seconds and this would be extended by 20–60 seconds without fixation. Values of less than 20 seconds may indicate loss of VOR suppression but this should be corroborated with clinical

TABLE 62.9 Causes of bilateral caloric hypofunction

Cause	Percentage (%)
Neurological (cerebellar degenerations, postmeningitis, neuropathies)	25
Ototoxic (usually gentamicin)	25
Miscellaneous (e.g. autoimmune, Ménière's, head trauma)	25
Idiopathic	25

Modified and simplified from Rinne et al.[9]

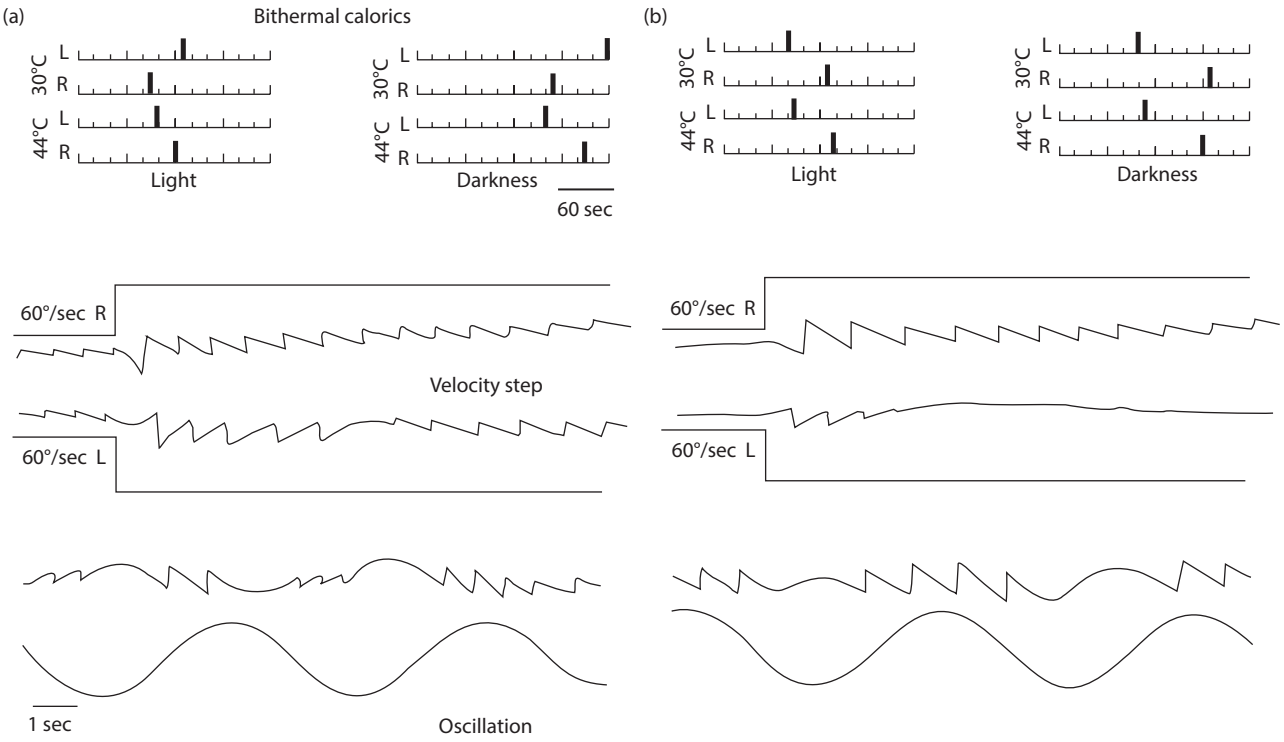

Figure 62.22 Caloric and rotational nystagmic patterns. (a) Right DP; **(b)** left canal paresis. Idealized recordings. Redrawn with permission from Bronstein et al.[55]

or rotational assessment of VOR suppression. It should be noted that subjects regularly exposed to intense vestibular stimulation may show little or no visible nystagmic response in the light but the response will be of normal magnitude without visual fixation. This can be observed in ballet dancers, acrobats, jet-fighter pilots and some patients with peripheral vestibular disorders with repetitive vertigo attacks.[57]

- VOR suppression is more often assessed by providing a fixation light for a period of 10–20 seconds in the middle of the caloric response. This requires ocular recordings and the results are expressed as the absolute or relative amount of reduction in slow phase velocity brought about by fixation. Results will depend, to some extent, at which point in time the fixation target is presented, but usually a reduction of approximately 50% is expected. With any technique, lack of VOR suppression indicates the presence of a central disorder of eye movement control, usually correlated with pursuit disorder, often of cerebellar/brainstem origin.[58]

5. Perverted nystagmus. This is the name given to the phenomenon whereby, instead of the expected caloric-induced horizontal nystagmus, one observes nystagmus in other planes, for example DBN (note, a minor torsional component added to the main horizontal nystagmus can be accepted as normal). If the caloric test is carried out pretty 'blindly', for instance with EOG in the dark, perverted nystagmus may be missed. However, perverted nystagmus rarely occurs in isolation, as it indicates posterior fossa disease, and other cerebellar or brainstem ocular signs should be seen.

ROTATIONAL TESTS

Most rotating chairs are motorized and computer-controlled so that velocity and rotational waveform can be delivered accurately. The patient's head should be comfortably immobilized, otherwise his own head movements interfere with the test and unwanted side effects, such as nausea, may develop. There are many velocity profiles used but here we will describe two of the more commonly used, velocity steps and sinusoidal oscillation (Figure 62.22). The more recently developed video head-impulse test will be described after the traditional rotational examination.

Velocity step or 'impulsive' rotational test

The stimulus consists of a sudden increase in chair velocity, say from 0 to 60 or 90 degrees per second. The time taken to reach this velocity, i.e. acceleration time, is of the order of 1–3 seconds.[48] Testing is conducted either in total darkness or with light-tight goggles. This elicits per-rotational nystagmus which slowly decays and eventually stops (if it does not stop the subject inadvertently may not be in total darkness). Full chair velocity is maintained for 60–90 seconds, or until any rotationally induced nystagmus disappears. At this point the chair is suddenly stopped and a similar nystagmic response, in the opposite direction, occurs (post-rotational nystagmus). The whole sequence

is then repeated in the opposite direction. Clockwise or rightwards rotation induces right-beating nystagmus (following the principle that the function of the VOR is to generate a slow-phase velocity in the opposite direction of head rotation); the stopping response is in this case a left-beating nystagmus.

As mentioned above, the nystagmus is of maximal intensity immediately after acceleration ('starting') or deceleration ('stopping') and then gradually (exponentially) decays. One can obtain time measurements of the response, such as duration of the nystagmus or time constant of decay of the slow phase velocity. In addition, the peak velocity of the slow phase component should be measured, which can be expressed as 'gain', the ratio between eye velocity and chair velocity. As with caloric testing, one assesses the overall level of activity and right–left response symmetry (DP) but normal values depend on stimulus parameters and laboratories.

I should like to mention that it is possible to obtain a semi-quantitative velocity-step assessment with an office swivel chair, to deliver rotation, and Frenzel glasses, to remove fixation. In this case, nystagmus duration is directly timed during the 'stopping response'. Stimulus velocity can be reasonably controlled by the examiner walking the chair round at a constant rate; for example, four steps per cycle (revolution) will deliver approximately 90 degrees per second and this should be maintained for 40–60 seconds and then suddenly stopped. Beware that you will be as dizzy as your patient, so plan your actions carefully!

Notice that, during rotation with the head in the normal upright position, or slightly tilted forwards to keep the lateral semicircular canals in the horizontal plane, the nystagmus will be almost exclusively horizontal. If the head were to be tilted backwards as much as possible, (e.g. the patient's face pointing up), the vertical semicircular canals (anterior and posterior) will now be placed in the plane of rotation. On stopping the chair the nystagmus observed is mostly torsional and so, timing its duration, assesses the function of the vertical canals *en bloc* (right and left, superior and inferior canals). Placing the head obliquely down to the left stimulates the left anterior–right posterior (LARP plane) semicircular canals; rotating with the head obliquely down to the right stimulates the right anterior–left posterior (RALP plane) canals. In order to fully assess vertical canal function accurately, however, one requires sophisticated 3D oculography and precision positioning of the head in a 3D rotating device.[59] The 3D VHIT can assess high acceleration function of all six canals with relatively simple and inexpensive technology (see below). However, it is not clear how much vertical canal testing adds to the day-to-day diagnosis and management of vestibular patients.

In summary, the 'impulsive' rotational test has been successful in practice since Barany's days. It has the advantage that it can be administered in a relatively short period of time, it is reproducible and is less affected by the patient's mental status than sinusoidal testing.

Sinusoidal rotation

In this test the velocity of the chair is sinusoidally modulated (**Figure 62.22**, bottom). Usually, a range of frequencies are used from approximately 0.05 Hz to 1 Hz, while the peak velocity of the stimulus is kept constant. This arrangement has the effect that acceleration increases progressively. A problem with this test is that a gentle oscillation in the dark is soporific and too predictable. Patients can be drowsy, giving responses difficult to interpret, or produce responses which are influenced by prediction and therefore look more normal than they really are. In order to avoid these complications, stimuli combining sinusoids of various frequencies in a random or pseudo-random fashion have been developed; these are effective but complicated software is required.

The results are usually expressed as gain (slow-phase eye velocity/chair velocity) and phase (the difference in degrees between maxima and minima of the chair and eye velocity waveforms), both plotted as a function of stimulus frequency. As in other vestibular tests, one examines the overall strength of the vestibular response, in this case as gain, and degree of asymmetry both as gain and phase. Unfortunately, variability is large from subject to subject and within the same subject due to concentration and mental set, both in health and disease.

The gain of the VOR in the light is, as mentioned earlier, close to unity. The test is normally conducted in the dark where normal gains at middle frequencies are between 0.4 and 0.8 but these values are only indicative; normal data should be collected under strict conditions, including mental tasks (e.g. mental arithmetic or imaginary targets). Indicative values of asymmetry should be larger than 20–30%, the lower gain and larger phase error occurring during the hemicycle with rotation towards the side of the vestibular lesion.

Although frequently used in research, in the clinic the sinusoidal test has problems with result variability and the time required for appropriate testing. An advantage is that it is an easy and reliable way of assessing VOR suppression by comparing gain values in the dark and those obtained during rotation with a chair-fixed target.

Interpretation of rotational results

Regardless of the technique, there are three main abnormalities of rotational responses.

1. Bilateral reduction or absence of response, as in bilateral vestibular failure, for instance due to ototoxicity, postmeningitis and idiopathic.[9]
2. Asymmetry, or DP, which if considerable (say >30%) is a valuable indicator of vestibular system disorder but, unfortunately, not a good localizing sign per se. However, an isolated DP is often the only 'objective' finding in a balance disorder patient. In the absence of any central vestibular or oculomotor disorder, it is supporting evidence in favour of a peripheral vestibular disorder but specificity and sensitivity data are lacking.

3. Loss of VOR suppression, investigated by providing a chair-fixed target during part of the rotation, indicative of central disorder (see 'Vestibulo-ocular reflex suppression' above).

VIDEO HEAD-IMPULSE TEST

In the last few years, computerized, video-based versions of the head-impulse test have appeared in the market. The physiological principle has been explained above but a head motion sensor and a VOG system records the head and eye velocity response. This makes detection of the corrective 'catch-up' saccades described above (see 'Vestibulo-ocular reflex' and 'Head-impulse test' above) easier, more objective and quantitative; the gain of the vestibulo-ocular response (peak eye velocity/peak head velocity) is also measured (Figure 62.23). At the same time, like with any automated analysis system, the possibility of recording and wrongly measuring undesirable artefacts such as blinks also increases. Therefore, the clinician should carefully compare his/her own findings during the clinical head-impulse test (HIT) with the results of the VHIT. As with other vestibular tests, the VHIT can detect uni- and bilateral loss of vestibular function (both by a low gain and by the presence of catch-up saccades). In contrast to conventional rotational tests, the side of the hypofunction can be reliably detected with VHIT but the level of agreement with the 'gold standard' caloric test is not great, particularly in chronic, compensated lesions. In many cases, particularly if there is clinical –VHIT discrepancy, a caloric test is warranted. Discrepancies will not always be due to technical problems though. The VHIT tests the VOR at high frequencies/accelerations of the head (a head impulse lasts 0.5 seconds = 2 Hz) whereas a caloric response lasting 2 minutes can be converted thus: 1/120 seconds = 0.008 Hz! Hence selective or preferential

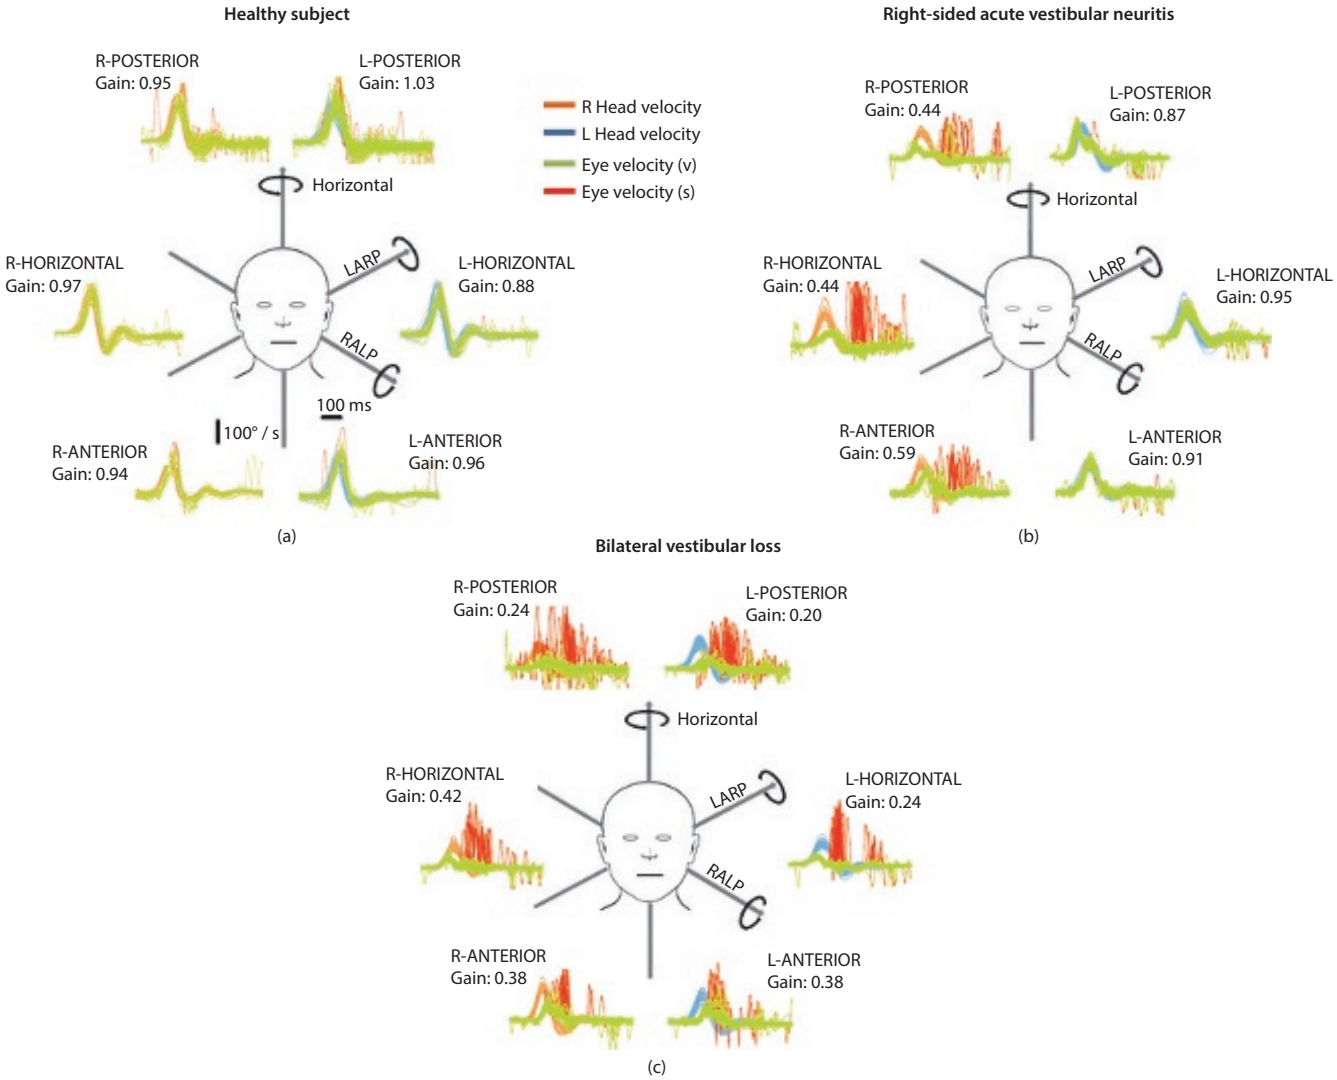

Figure 62.23 **(a)** A normal healthy subject, with gain values close to unity for all six canals and no 'catch-up' saccades. **(b)** A patient with neuritis of the right superior and inferior vestibular nerve showing reduced gain (close to 0.5) and many catch-up saccades (spiky traces). **(c)** Results in a patient with bilateral vestibular failure, showing low gains (0.2–0.4) in all six canals. Reproduced from Bronstein et al.,[37] with permission.

involvement of the high- or low-frequency VOR would produce selective abnormality in one but not the other test.

Several factors have contributed to the success of the VHIT, despite the fact that both the clinical HIT[60] and the VHIT are relatively new tool in diagnosis.[61] In contrast to rotating devices, VHIT systems are relatively cheap and take much less space than rotating chairs. Testing time is also shorter than a routine EOG/VOG rotational or caloric assessment and, usually, better tolerated by the patient even if all six canals are being assessed. Finally, the timing is also right. Acute vertigo has become 'fashionable' again given the need to separate acute vertigo due to vestibular neuritis from posterior fossa stroke, which requires thrombolytic treatment within 3–4 hours of vertigo onset. As mentioned already, in this scenario the clinical or video HIT can be critical in separating a unilateral peripheral vestibular deficit (likely vestibular neuritis – no thrombolysis needed) from brainstem–cerebellar ischemic stroke (thrombolysis often provided). Despite this success, most users and scientists using VHIT devices with no conflict of interest do not believe that this new development has replaced or will replace caloric testing in the near future.

Examination of postural balance

The investigation of postural balance is influenced by the clinician's own background. More research using posturography comes from ENT or audiology departments than from neurology ones,[30, 31] which could mean that ORL specialists see more dizzy patients than other specialists. It could also mean that neurologists tend to rely on their own clinical assessment of posture and gait, which is understandable since almost all neurological diseases impair gait and posture. Regardless of the clinician's background, the value of direct clinical observation of gait and posture in patients with unsteadiness cannot be overemphasized. I will first summarize the clinical examination of posture and gait and then address the contribution of posturography.

CLINICAL EXAMINATION OF BALANCE, POSTURE AND GAIT

Gait unsteadiness is associated with a wide range of disorders.[55] If it has never been associated with vertigo, dizziness, oscillopsia or hearing disorder, it is unlikely to be due to vestibular disease.[62] It is important to realize, however, that patients with mild gait disorders often describe their problem as dizziness and therefore do turn up in ENT and neuro-otology clinics.

It is usually possible to establish a topographical diagnosis (site of lesion) in a gait disorder on the basis of clinical observation of gait and a neurological examination (Tables 62.10 and 62.11).[63–65]

It is beyond the scope of this chapter to describe the many diseases with gait disorder. However, the aspects required when examining a patient with gait unsteadiness listed in Table 62.11 will be reviewed.

TABLE 62.10 Topographical classification of gait abnormalities

Level of abnormality	Topographical classification
Lower levels	Peripheral lesions: mono/polyneuropathies, root lesions and myopathies Vestibular and visual lesions
Medium levels	Spinal and brainstem lesions
Higher levels	Cerebellar syndromes
	Subcortical disorders (basal ganglia and internal capsule): Parkinson's disease, orthostatic tremor, choreas and corticospinal tract lesions
Highest levels	Frontal lesions of the cerebral cortex, white matter in the semioval centre and periventricular area (vascular, degenerative diseases, demyelinating, tumours and hydrocephalus) Cautious gait and psychogenic gait disorders

Modified from Dominguez and Bronstein,[63] Nutt et al.,[64] Marsden and Thompson.[65]

TABLE 62.11 Examination of posture and gait

Aspect	Examination
Posture	Head and neck Trunk Stance and Romberg test Postural reflexes
Walking	Step initiation Stepping pattern Associated trunk and arm movements Eyes closed walking
Neurological and relevant skeletal examination	

Modified from Dominguez and Bronstein.[63]

Posture

Observation of head and trunk posture can provide immediate useful information. There are abnormal tilts or rotations in dystonia, flexed posture in Parkinson's disease, hyperextension in progressive supranuclear palsy (PSP) and titubation in cerebellar disease. In lesions of the vestibular nuclei, as in the lateral medullary (Wallenberg) syndrome, there can be an ipsilesional ear-down head tilt, together with a skew eye deviation (ipsilesional lower eye) and ipsilesional body pulsion.

Observation of stance will reveal a broadening of the base of support in diffuse vascular disease, frontal lesions, cerebellar lesions, sensory ataxia, acute or bilateral vestibular lesions and patients with a cautious gait. Lateropulsion can be seen in acute unilateral peripheral vestibular lesions and in lateralized brainstem–cerebellar lesions. Midline brainstem–cerebellar lesions can show retropulsion. Minor degrees of unsteadiness can be brought about by asking the patient to put the feet together or in the heel-to-toe position. A 'bouncy' stance, with head-trunk oscillations about 2–3 Hz, may be observed in ataxic or ataxic–spastic disorders, typically in

multiple sclerosis. A shaky 'tremulous' stance, with higher-frequency oscillations, can be seen in some patients with Parkinson's disease and orthostatic tremor.

The Romberg test, originally described for patients with tabes dorsalis, is positive in patients with dorsal column or severe afferent polyneuropathy. A positive Romberg means that the patient shows a tendency to actually fall, unlike normal subjects and almost all patients with balance problems who show a small to moderate increase in body sway on eye closure. Only in the acute phase of a peripheral vestibular disorder will the Romberg test be positive, usually with an ipsilesional fall. In a patient with either cerebellar degeneration or polyneuropathy, a high level of unsteadiness on eye closure may indicate the presence of additional bilateral vestibular failure.[9] This syndrome has been named CANVAS (cerebellar atrophy, neuropathy, vestibular arreflexia syndrome).[66] Patients with anterior lobe cerebellar degeneration may show the characteristic trunk oscillation or titubation only on eye closure; when mild, this may just be visible as a tremor of the ankle extensors ('dancing tendons'). On a practical note, anyone who can stand on either foot unaided, with eyes closed, is unlikely to have any objective and organic postural balance problem.

Postural reflexes are an important part of the balance examination, particularly when the patient's dizziness cannot be explained in vestibular terms. They are examined by gently pushing and pulling the upper trunk. This can be carried out by standing behind the patient so he/she cannot anticipate the precise timing and direction of the push (forwards or backwards) to the shoulders. In akinetic syndromes, these responses may be completely absent – such as in Parkinson's disease, PSP and small vessel white matter disease with or without parkinsonism – patients falling rigidly like a log. A few shuffling steps backwards (retropulsion) or forwards can be seen in the early stages. In cerebellar syndromes, particularly anterior lobe disease, the trunk pushes may unmask a trunk titubation, observable as a 'trunk rebound' in response to the push. In the elderly, with fear of falling or a cautious gait, trunk pushes trigger a startle, panic-like response. Vestibular patients may be unsteady but the overall pattern of the response is preserved.

Walking

Step initiation can be impaired in frontal lesions, including the gait ignition failure syndrome[64, 65] and as part of the akinesia in the Parkinsonian syndromes. Initiation of gait is hesitant, the feet appearing to be stuck to the ground ('magnetic feet'; 'slipping clutch' phenomenon).

The steady-state stepping pattern may be less disturbed in patients with difficulty in step initiation, once they are off. In akinetic-rigid, Parkinsonian syndromes steps are often shallow, short and slow but with preserved rhythm. In contrast, cerebellar patients show irregular rhythm, variable length, oscillations and a wide base, giving a lurching, 'drunken' appearance to their walking. Patients with severe loss of sensory information from the lower limbs (sensory ataxia) lift the feet high and place them on the ground under intense visual control; in dorsal column lesions the heels strike the ground first (tabetic gait), in cases with ankle extensor weakness (foot drop) the toes make contact first (steppage). In spasticity, the knee-extensor and ankle-flexor hypertonus leads to the characteristic slow gait with circumduction movements of the leg during the swing phase.

The normal associated movements of the arms while walking are lost in Parkinson's disease. Unilateral loss of arm swing can be a useful early sign in Parkinson's disease and hemiparesis. The arms of patients with a cautious gait reach out as if expecting to fall and step with apparently unnecessary care, giving the appearance of 'walking on ice'. Although a cautious gait can be part of a psychogenic gait disorder, it can be triggered by a vestibular, vascular or falling episode. Sometimes this is the only finding in elderly patients.

Walking with eyes closed in a straight line can reveal a previously unsuspected degree of unsteadiness or a cautious gait in patients with bilateral loss of vestibular function. In somatosensory ataxia this task is often impossible. In unilateral vestibular lesions, particularly in the acute stage, patients veer in the same direction as the lesion. A paradoxical improvement while walking fast has been reported in acute vestibular lesions.[67] In the Unterberger test, instead of walking along, the patient is asked to walk on the spot with the eyes closed. In unilateral vestibular lesions the patient turns towards the hypoactive side. It is helpful to ask the patient to keep the arms and index fingers pointing forwards towards the examiner's index fingers; this allows a more precise assessment of the degree and consistency of turning (**Figure 62.24**).

Figure 62.24 The 'stepping on the spot' or Unterberger test. Lining up of the examiner and patient's fingers is useful to document mild abnormalities when the patient steps with the eyes closed. Repetition of the test, for consistency, is essential.

Summary of the relevant neurological examination

We present a summary of the neurological examination relevant to balance and gait disorders, in the hope that it may guide the non-neurologist who suspects a neurological cause for unsteadiness or gait disorder. Weakness of the legs can be documented by asking the patient to push against the examiner's hands with different muscle groups or by asking the patient to stand/walk on tiptoes or heels, crouch and rise. Identification of weakness of the ankle extensors is paramount as these muscles are responsible for toe clearance during the swing phase of the gait cycle. Lower-limb weakness is a major contributor to the gait disorder in muscle, root and peripheral nerve disease, motorneurone and corticospinal tract disease; the tendon jerks will be exaggerated in pyramidal tract disease and depressed or absent in all the others; extensor cutaneous plantar responses (Babinski sign) can be found in pyramidal lesions.

Normal somatosensory function is needed for voluntary placing of the feet while walking, as well as for the proprioceptive reflexes controlling upright posture. At least pinprick, tuning fork and joint position sense must be examined in the lower limbs. If large fibres carrying proprioceptive input are involved, the ankle and sometimes patella jerks will be absent and the Romberg test will be positive.

Gait disorders due to neurological involvement at medium or high levels (see **Table 62.10**) will have associated clinical neurological features. In spinal cord compression or lesions there is often sphincter dysfunction and sensory disturbances in the limbs. At brainstem level, cranial nerve involvement including central vestibular and ocular–motor disorders; at cerebellar level, trunk titubation, intentional tremor, abnormal eye movements including nystagmus; at basal ganglia level, Parkinsonian features (including tremor, cogwheel rigidity, hypomimia, bradikinesia, loss of postural reflexes) dystonic limb or neck posturing and choreoathetosis.

It is important to keep in mind the unabated weight of the clinical neurological examination in the assessment of balance and gait disorders. Observation of gait, postural reflexes and the Romberg test followed, if appropriate, by a quick examination of lower limb power, coordination, reflexes and tuning fork are likely to help more than posturography. Normal CT and MRI scans are extremely valuable but do not exclude neurological disease (e.g. Parkinson's disease) and posturography findings usually lack topographical and aetiological specificity. Functional (psychogenic) disorders can only be diagnosed on the basis of an inconsistent or theatrical gait pattern, in a patient with essentially normal findings. Finally, particularly in the elderly, examination of the skeletal and cardiovascular examination or referral may hold the key to the cause of balance or dizzy symptoms. Cardiovascular syncope is a major cause for unexplained dizzy spells and falls in the elderly, regardless of whether the patient reports loss of consciousness or not.[68, 69]

Posturography

Strictly speaking, posturography is any means of recording postural activity, not only sway or force platforms which are indeed the most convenient way. In fact, 'sway' platforms do not actually measure body sway but foot torque (Nm), conveniently expressed as movement of the centre of foot pressure (cm). For standard clinical purposes, platform signals alone are acceptable but research questions often require additional recordings such as photoelectrical or electromagnetic recordings of head sway, accelerometry of head or trunk motion and EMG signals from the lower limbs. If the patient just stands quietly on the platform, with eyes open or closed, the procedure is called static posturography. When additional balance perturbations or stimuli are added (e.g. moving platform, visual stimuli, muscle vibration), it is called dynamic posturography.

Three general questions can be asked in this area.

1. Has posturography advanced the knowledge of how the postural systems work?
2. Has posturography taught us how posture is impaired in certain patient groups?
3. Does posturography help in the management of an individual patient complaining of a balance problem?

The answer to the first two questions is certainly yes, but opinions are divided as to the third.

Posturography has been useful in defining the contribution of the different sensory-motor components in postural control. The first attempts to generate a comprehensive system approach to postural control were led by Nashner and coworkers.[70–73] They suggested that postural balance is maintained on the basis of a limited repertoire of centrally generated muscle synergies. During slight perturbations to balance, the body behaves essentially as an inverted pendulum, pivoting around the ankle joints. Muscular responses are organized in a distal-to-proximal manner, with activation of distal muscles such as tibialis anterior and soleus occurring earlier than proximal ones; this is the 'ankle strategy'. Larger perturbations to balance, or lesser possibility of response such as when standing on a narrow beam, leads to movements around the hip joints and earlier activation of proximal muscles, such as abdominal, paraspinalis, quadriceps and hamstrings; this was called the 'hip strategy'.

The posturography system designed by Nashner consists of a support platform and a visual surround which can be moved angularly about an approximate inter-ankle axis. This setting allows for the ankle and visual information available to the subject to be, at least partly, neutralized by means of coupling the visual surround or the support surface to the AP sway movements of the subject. This set-up formed the basis of the commercial product 'Equitest', a computerized dynamic posturography (CDP) system, in particular, a testing protocol known as the sensory organization test. If patients with vestibular deficits are allowed to stand freely on this system, they show little

or no difficulty if the platform is stationary, with normal visual information (e.g. stable surrounds) or with eyes closed. When either or both the platform and visual surround are sway coupled, patients have poor balance performance.[74, 75] When presented in a historical context, the findings in vestibular patients seem trivial. Clinicians have known for decades that vestibular patients are usually normal in static conditions and that the way to unveil their unsteadiness is to examine them with eyes closed under conditions of reduced proprioceptive accuracy (e.g. on a mattress – reviewed in Martin).[76]

POSTUROGRAPHY IN PERIPHERAL VESTIBULAR DISORDERS

Clinical observation of patients with severe acute, unilateral vestibular disorders (e.g. vestibular neuritis) shows that they tend to fall towards the side of the lesion on eye closure – i.e. in the direction of the slow phase of nystagmus.[77] This can be documented by posturography but with little practical clinical benefit for the individual patient. In the compensated state, static posturography with eyes open or closed is usually normal. CDP shows increased sway, in conditions in which the support surface, the visual surroundings or both simultaneously are unstable (sway referenced). In some early series, 100% of patients have been reported abnormal when both visual surround and support surface are sway referenced,[75] in others this figure drops to around 50%.[78] In a small but carefully controlled series, ten patients with severe unilateral caloric reduction were abnormal when tested in the acute stage only under unstable support/visual surroundings.[79] Within 2 weeks, all patients regained total normality in all test conditions. The reasons for these discrepancies are not clear but the inability to confirm the earlier optimistic reports is one of the reasons underlying the current disaffection with the technique.

What clinicians want to know is what the added value of posturography is, in comparison with traditional testing of the vestibular system. A comparison between posturography and the caloric test showed that the caloric test correlates better with a history of vertigo and that CDP can show abnormalities in patients with normal caloric function.[80] This finding can be interpreted essentially in two ways: either posturography is capable of detecting abnormalities that caloric tests cannot (which it can – think of a spinal cord lesion or Parkinson's disease as a cause of unsteadiness) or posturography can give false positive results. There is no simple solution to this problem and, as outlined above, the clinician's beliefs, training background and interests will influence his decision.

A similar problem arises when comparing CDP with inexpensive alternatives. To a large extent, the sophistication of the commercially available CDP systems comes from the fact that the support surface and the visual surround can be moved. Clinical observation of a subject's balance while standing on rubber foam (which makes lower limb proprioceptive input inaccurate) and with either optically reversing goggles or a Chinese lamp (dome) on their head (which makes visual input unreliable) makes a reasonable, inexpensive approximation to CDP. This is sometimes called the 'clinical test of sensory integration and balance' or simply the 'foam and dome' test (**Figure 62.25**). A study compared CDP with its clinical counterpart and found an excellent correlation between the two sets of results.[81] This is good news to clinicians, particularly in rehabilitation, who may want to assess postural control thoroughly but are not prepared to make a large investment. Another comparison between results in moving-platform posturography and clinical analysis of posture with subjects standing on foam also reported significant correlation, with sensitivity and specificity of 90% and above.[82] Surprisingly, static posturography has been reported to have a good predictive value to help in identifying elderly subjects at risk of falls.[83]

Bilateral vestibular lesions are easily diagnosed clinically and with conventional laboratory tests – an audiogram is a much more helpful test by comparison. Posturography in these patients has limited value in diagnosis but studies have been of interest in defining the contribution of the vestibular system to postural control. Static posturography is normal in most patients with bilateral vestibular failure.[84, 85] It has been known for more than 70 years[76, 86, 87] that a sudden tilt, particularly if the patient is on a mattress and blindfolded, throws these patients off balance. This observation has been confirmed with dynamic posturography, including the fact that rotation of the base of support is more effective than translation in unmasking the postural deficit.[88, 89] Although patients tend to use more hip strategy,[89] latencies and muscle synergies are not essentially different from normal. EMG amplitudes in lower limb musculature are reduced by more than 50% during platform tilts and this may explain why they actually fall.[90–92] If the postural responses to movements of the support surface are indeed centrally patterned, these findings indicate that vestibular input is essential for adequate gain setting of early muscular components operating at 80–120 ms.[92] The alternative explanation that independent vestibulospinal or vestibuloreticulospinal pathways mediates the observed effects is equally possible and compatible with known latencies following direct vestibular activation.[93, 94] Answering this question is difficult with whole-body postural responses, as investigated by posturography. However, isolated motion stimuli to the head showed delayed neck responses[95] in bilateral vestibular patients, indicating that short latency vestibulocollic responses (about 25 ms) have a specific role in righting the head during sudden perturbations.[93]

POSTUROGRAPHY IN NEUROLOGICAL DISORDERS

As already emphasized, it would be naive to think that a posturography assessment could screen for a neurological deficit. Even if results were abnormal, the topographical and etiological specificity of the finding would be very low.

Patients with peripheral neuropathy have increased sway and this correlates with the loss of vibration sense in the lower limbs.[96–99]

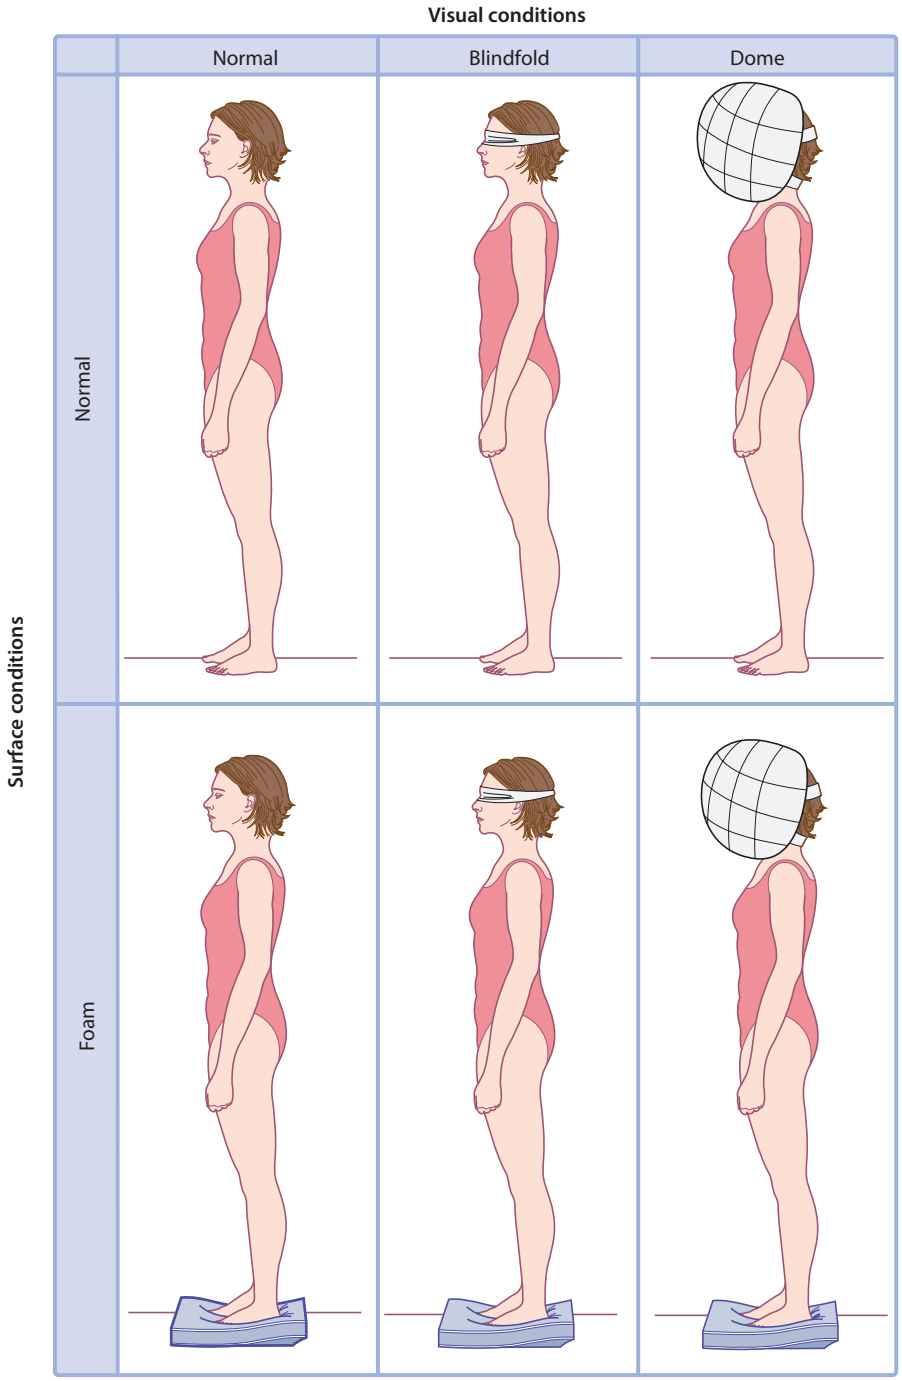

Figure 62.25 The 'foam and dome' test. The six testing conditions (visual 3 × support 2) correspond approximately to those of computerized dynamic posturography (CDP) as in the Equitest. Redrawn with permission from Pavlou et al. in Bronstein et al.[55]

The balance disorder in cerebellar disease is due to loss of muscle coordination,[100] central modulation of vestibular and somatosensory mechanisms,[101] neural adaptation to vestibular loss[102] and recalibration and learning processes.[103] On the basis of comparisons between lateral versus anteroposterior sway, eyes closed versus eyes open (EC/EO or Romberg quotient) and the frequencies of sway involved, four cerebellar sway patterns can be identified.[104] Perhaps the single most useful finding is the presence of a body tremor at approximately 3 Hz in patients with anterior lobe degeneration, either alcohol-induced or degenerative. In clinical practice, however, this tremor can be detected clinically and the value of posturography in its diagnosis has been questioned.[105]

The commonest basal ganglia disorder is Parkinson's disease and approximately one-third of patients report falls.[106] Falls, however, are not common in the early phases of conventional, idiopathic Parkinson's disease, in contrast to other 'parkinsonisms' such as PSP (Steele–Richardson–Olszewski syndrome).[107] Despite the

significant contribution made by posturography to the understanding of the postural disorder in Parkinson's disease,[108–112] there is very little room for the technique in the management of patients. Of possible diagnostic interest is the fact that in some patients the tremor is recorded by the platform,[108] in which case frequency analysis will show a peak of tremor activity at frequencies between 4 and 6 Hz, well beyond those of body sway (<1–2 Hz). Other conditions with unsteadiness and high-frequency peaks in posturography recordings include some cerebellar ataxias, with a 3 Hz tremor discussed before,[104, 113] and orthostatic tremor.[114, 115] Orthostatic tremor is a relatively rare disorder, usually misdiagnosed as a psychogenic balance problem, but platform recordings can easily identify the pathognomonic high-frequency tremor, typically at 16 Hz (**Figure 62.26**). During platform fore–aft motion postural reflexes are elicited and the stepping responses in parkinsonian patients are usually abnormal (hypometric and multiple stepped)[116] but, again, for the clinician the simple trunk pulls described above are equally useful.

PSYCHOPHYSIOLOGICAL UNSTEADINESS

Some patients report dizziness in surroundings with intense visual motion or repetitive visual patterns, such as driving, supermarkets, crowds, disco lights or ironing striped shirts. We use the term 'visual vertigo' or visually induced dizziness to describe these patients, when there is clinical and/or laboratory evidence of a vestibular lesion without clinically obvious psychiatric disorder.[117] Such patients are 'visually dependent', in that they rely excessively on visual cues for spatial orientation and postural control. Visual motion or optokinetic stimuli makes them selectively unsteady,[5] particularly if the vestibular disorder is central or if there is additional strabismus.[117] Posturographic and perceptual measures of visual dependence are correlated, albeit weakly, and this is important because identification of visual dependence helps in the selection of appropriate vestibular rehabilitation. This may also be identified with CDP, or its clinical version, the 'foam and dome' test, during testing conditions with sway-referenced visual surroundings. However, simple questionnaires[118] are equally useful to identify visually susceptible patients who are likely to benefit from additional optokinetic stimulation during vestibular rehabilitation.

PSYCHOLOGICAL UNSTEADINESS

The relationship between psychological disorders and balance is extremely complex. Anxiety can create dizziness and vice versa and there is no easy solution to this common 'chicken and egg' clinical dilemma.

Both vestibular[119] and anxiety patients[118] show increased sway in response to visual motion. Patients with panic and agoraphobia also show excessive sensitivity to platform or visual surround motion.[120] It has also been reported that posturography can identify inconsistent and incoherent responses in patients with non-organic dizziness.[121–123] An increase in sway frequencies of up to 8 Hz has also been reported in some patients with psychogenic unsteadiness.[124]

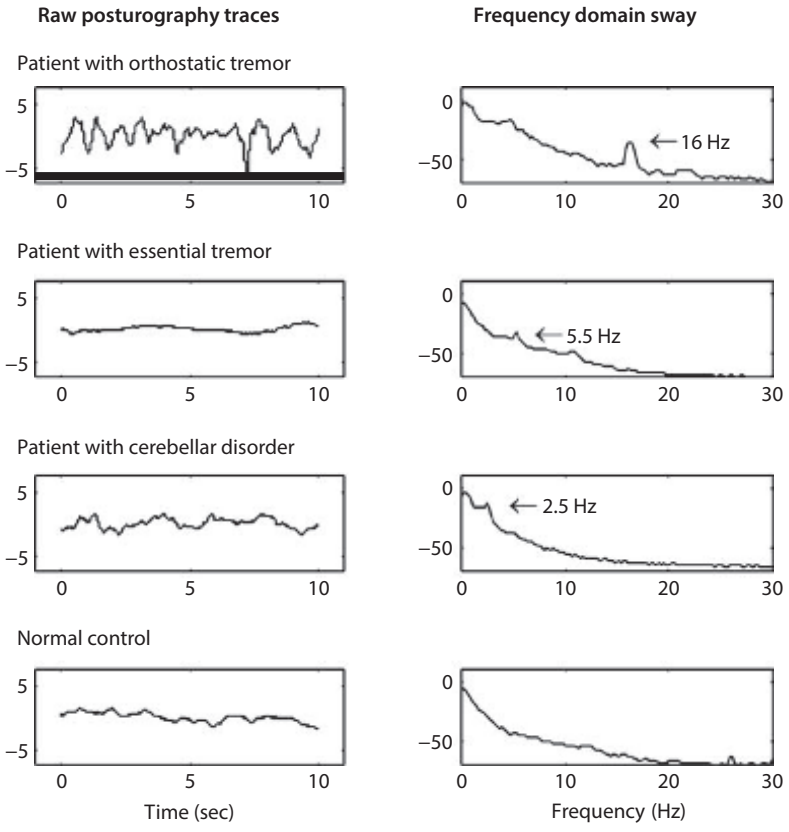

Figure 62.26 Fast Fourier analysis of posturography platform signals in patients with tremolous or 'shaky' stance. Reproduced with permission from Yarrow et al.,[115] with permission from Elsevier.

However, clinicians should rely on a constellation of negative findings (neurological, vestibular and imaging) and positive malingering or conversive (functional) features, as well as an appropriate psychological profile before making such a diagnosis.[125]

SUMMARY OF POSTUROGRAPHY

In summary, there is debate as to the clinical usefulness of posturography for the day-to-day management of patients.[126–129] A report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology remains a good and objective introduction to the topic for non-subspecialized clinicians.[130] The specialist panel concluded in 1993 that dynamic posturography had a promising role in the assessment of balance disorders patients. The ensuing discussion 25 years later testifies that such potential has not been fully developed. I am only able to make only one definite diagnosis with posturography, orthostatic tremor, but this is a rare condition. Similarly good specificity is also seen with the 3 Hz body postural tremor in certain cerebellar lesions, but the tremor is also observed clinically.[105]

The rationale behind clinical posturography is that it tests postural control as a whole, with the various sensory inputs interacting in physiological ways and mimicking potential real-life challenges to upright balance. This is its strength and its weakness at the same time, the latter because of its lack of topographic specificity. The findings of a meta-analysis of posturography indicates that its overall sensitivity and specificity is of the order of 50%.[131] As expected, the diagnostic power was enhanced if patients with CNS lesions were included in the studies surveyed, but this is of little consolation since there are much better ways of diagnosing CNS disease than posturography. It is often said that posturography can be useful for rehabilitation, and indeed posturography has been instrumental in proving the value of vestibular rehabilitation.[132, 133] However, the daily problem in neuro-otology is the patient who is not objectively unsteady, but still reports off-balance sensations and dizziness. Whether posturography has anything to add to simple questionnaire assessment of symptoms remains an open question.

OTOLITH AND PERCEPTUAL ASSESSMENT

Otolith and perceptual assessment tests will be discussed briefly because they are currently evolving and are rarely available as a routine test in clinical departments. We will briefly describe linear acceleration tests of otolith function but vestibulo-evoked myogenic potential (VEMPs, ocular and cervical) are thought to be of otolithic origin and so they will be mentioned in this section as well. Perceptual tests of vestibular function, with an emphasis on the procedure known as the subjective visual vertical (SVV), will follow.

Otolith testing

LINEAR ACCELERATION TESTS

The otoliths are selectively stimulated by linear acceleration, including gravity.[134] Due to their morphology and curved trajectory of the polarization vectors of the hair cells, both the utricular and saccular maculae are sensitive to multiple axes of linear acceleration. The predominantly horizontal orientation of the utricules, however, makes them mostly sensitive to accelerations in this plane (i.e. right–left, fore–aft) or tilt away from this plane. The predominantly (para) sagittal orientation of the sacculi makes them more sensitive to sagittal plane tilt (pitch tilt) and acceleration (e.g. fore–aft, rostrocaudal). One should remember that linear acceleration is also generated during rotatory motion (centrifugal and tangential acceleration) and this has been recently exploited in the field of otolith testing. Here, I will present the general principles of otolith testing and the reader interested in any individual technique should pursue the original references.

Otolith testing is technically challenging. The generation of pure linear acceleration of sufficient magnitude (>0.2 g) under controlled conditions requires motorized sleds running on precision tracks (**Figure 62.27c**). Although a linear acceleration version of the head-impulse test, the clinical head heave test can provide information on the utricular–ocular reflex,[135] but this has not been validated against quantitative techniques.

Centrifugal and tangential accelerations can be generated with rotating devices but these have to be powerful and sturdy to carry the weight of a human subject placed eccentrically from the rotational axis. Perhaps the simpler way to obtain tangential acceleration of the head and stimulate otolith–ocular reflexes is to make the subject lean forwards onto an eccentric chin- or headrest, while seated on a conventional rotating chair (head-eccentric rotation).[136, 137] Following this principle, one can also rotate a person around an earth-vertical axis passing through one of the labyrinths, thus creating a centred labyrinth and an eccentric labyrinth. Only the latter is subjected to tangential and centrifugal acceleration and this test is the only test capable of providing information on each individual utricle (eccentric centrifugation).[138, 139]

Another way of obtaining controlled stimulation of the otolith is to rotate the subject about an axis which is tilted (off-vertical axis rotation (OVAR)) or orthogonal ('barbeque-spit rotation') with respect to the gravitational vector; in these tests the stimulus is provided by the continuous reorientation of the head with respect to gravity.[140, 141] It is important to note that, whenever the linear acceleration is generated by rotation, the otolith response is assessed either by subtracting the component due to angular motion (e.g. subtracting head-eccentric response from head-centred response, in the head-eccentric test) or by waiting until the angular VOR has ceased (e.g. in OVAR or BBQ rotation). Finally, a simple way of stimulating the otoliths is head tilt with respect to gravity. This can be refined with

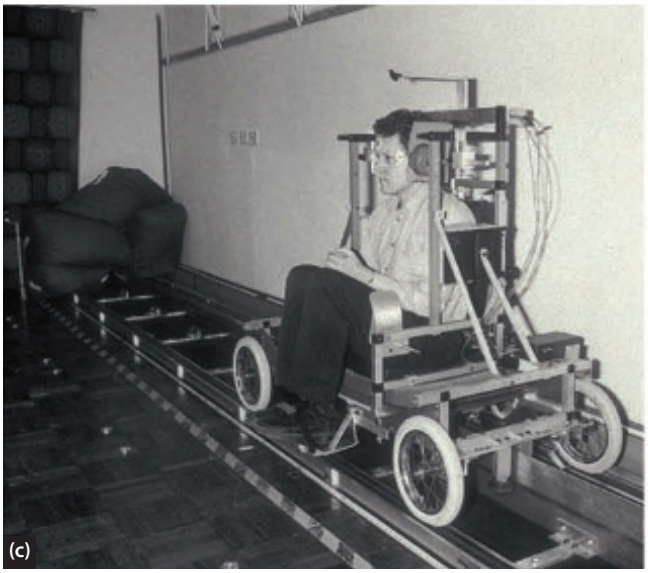

Figure 62.27 Otolith testing devices I. (a,b) Ocular counter-rolling measured by 3D VOG during body tilt. **(c)** Oculography (in this case conventional horizontal EOG) during lateral linear acceleration.

precision gimbals systems (**Figures 62.27a** and **b**).[142] A summary of the stimulation techniques for otolith assessment is presented in **Figures 62.27**, **62.28** and **62.29**.

What can be measured to assess otolith function? The more common measure is the slow-phase eye movement response, called linear or translational VOR or, more generally, otolith–ocular reflexes.[143] Recording of eye movements during otolith testing also poses technical problems. The forces involved usually generate more movement artefact than during conventional rotational or caloric procedures. In addition, the relatively small size of the otolith–ocular response, coupled with the fact that an important component of the otolith response is ocular torsion (not recorded by EOG or conventional VOG), often requires 3D oculography (VOG or search-coil technique).[138] Another response, which can be measured during linear acceleration, particularly in centrifugal tests,[144] is the SVV which largely follows ocular torsional position (see 'Subjective visual vertical' below).[145]

Difficulties in testing the otoliths are not only technical. The orientation of the hair cells is such that a single utricle (or sacculus) is capable of sensing linear accelerations in all directions. Thus, deficits due to unilateral otolith lesions are usually only acute and transient. For instance, the horizontal otolith–ocular reflex in response to interaural linear acceleration remains abnormally asymmetric for

Figure 62.28 Otolith testing devices II. These techniques can be used with relatively minor modifications of a conventional rotating chair. Comparison of **(a)** head-centred and **(b)** head-eccentric horizontal eye movements, during horizontal rotation. [136, 137] Otolith stimulation is provided by the tangential acceleration present during head-eccentric oscillation. **(c)** Off-vertical axis rotation (OVAR). Otolith stimulation is due to head reorientation with respect to gravity during rotation.

only approximately 4 weeks after a unilateral vestibular nerve section.[143] Torsional and visual vertical deficits may be unmasked during eccentric centrifugation.[138, 144]

In summary, there are many tests of otolith function and most have been validated in patients with acute vestibular lesions (spontaneous or surgical). Such lesions are not selective and destroy not only the otoliths but large parts of the vestibular labyrinth. In such circumstances there is little clinical doubt that a patient has sustained unilateral vestibular damage and so documenting otolith involvement in such cases is just a research exercise. The challenge of devising a test of otolith function in a patient who lacks independent evidence of vestibular lesion still remains. Currently, there is no validated test to confirm that a patient has a selective otolith lesion. Claims that the SVV is a selective test of otolith function[3, 146] have not been scientifically

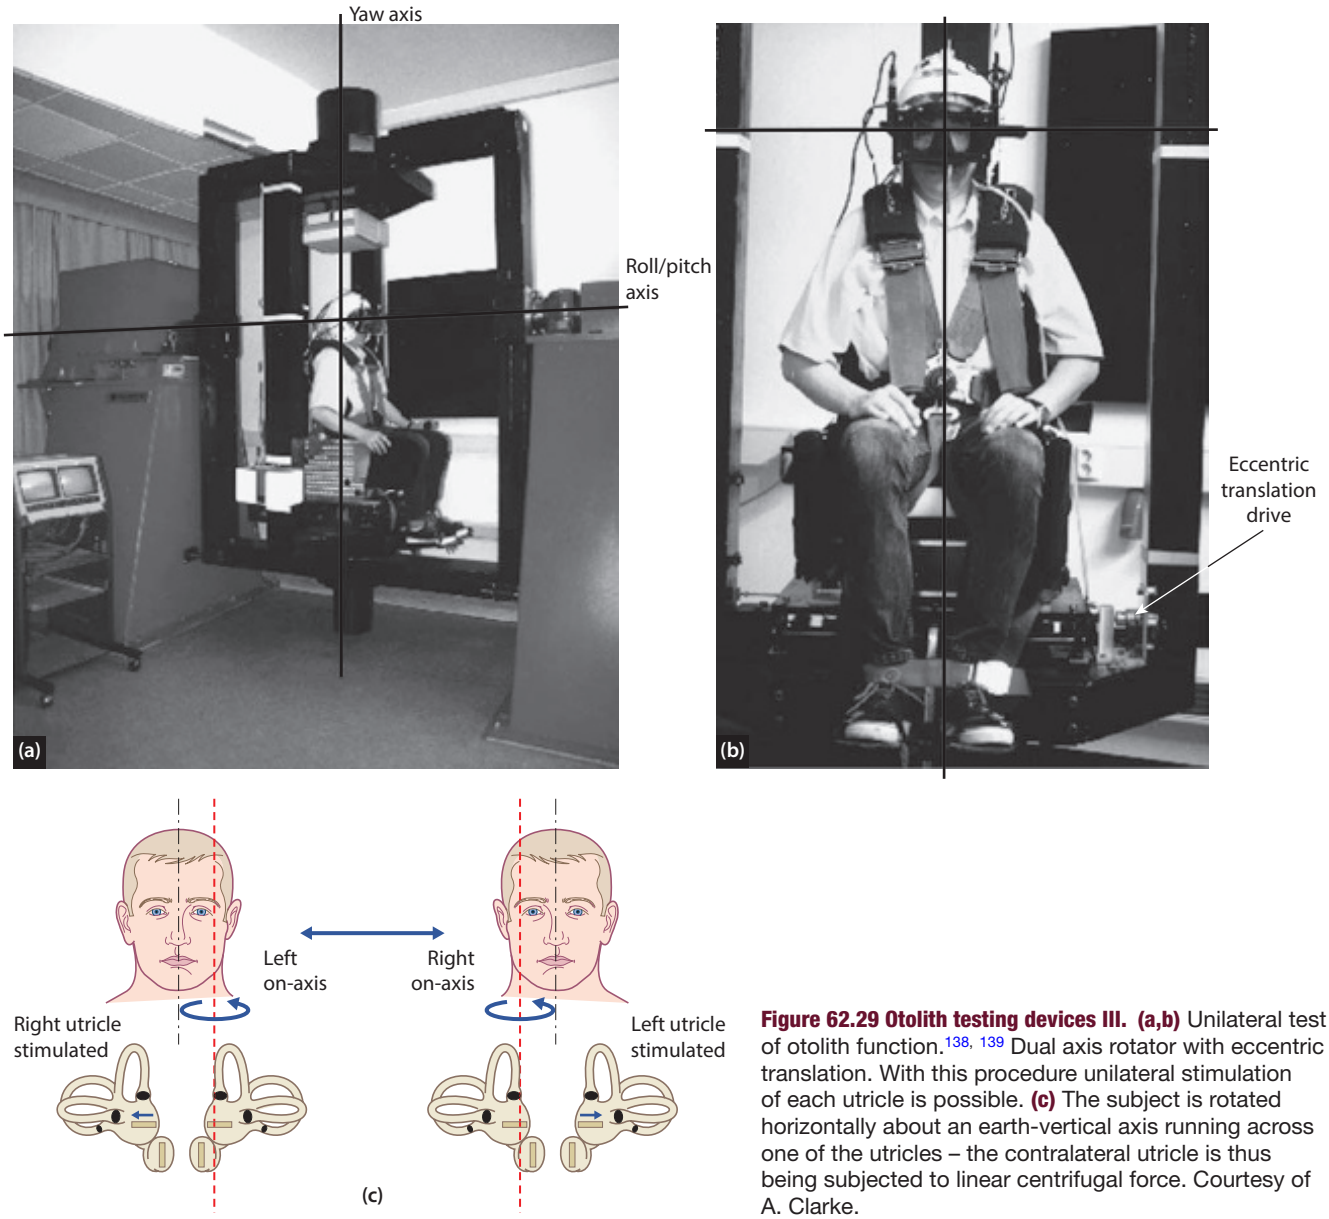

Figure 62.29 Otolith testing devices III. (a,b) Unilateral test of otolith function.[138, 139] Dual axis rotator with eccentric translation. With this procedure unilateral stimulation of each utricle is possible. **(c)** The subject is rotated horizontally about an earth-vertical axis running across one of the utricles – the contralateral utricle is thus being subjected to linear centrifugal force. Courtesy of A. Clarke.

validated. Furthermore, this view has been seriously challenged on the basis of clear experimental evidence showing that vertical semicircular canal input also induces tilt of the visual vertical.[147]

VESTIBULAR-EVOKED MYOGENIC POTENTIALS

Loud sounds can activate the vestibular labyrinth. If these sounds are brief in duration (clicks), the total amount of energy delivered to the ear is small and the procedure harmless. Using averaging techniques similar to those in brainstem auditory evoked potentials, an electromyographic (EMG) potential can be identified from neck muscles.[148, 149] The response is a sound-evoked vestibulocollic (or vestibulospinal) reflex and this is often called the cervical vestibular-evoked myogenic potential (cVEMP). The technique can be easily set up in any clinical neurophysiology or audiology department with access to calibrated sound generators, averaging equipment and surface recording electrodes and several devices are available commercially.

A useful feature of this procedure is that it can investigate each ear separately. The main response is an ipsilateral positive deflection at 13 ms (P13) and a negative deflection at approximately 23 ms (N23). Conductive deafness, by obstructing the clicks reaching the labyrinth, interfere or abolish the reponse, so auralscopy and a pure-tone audiogram are necessary if the response is absent. However, as expected from a genuine vestibular response, vestibular-sparing, sensorineural deafness does not interfere per se with the cEVMP. All available evidence indicates that the main inner ear structure activated by sound is the sacculus, so cEVMP can be considered an otolith test.[150]

Clinical applications of this test are developing. The main practical diagnostic use is for the diagnosis of the superior semicircular canal dehiscence syndrome, or more generally

the Tullio phenomenon.[149] These patients have lower threshold, higher amplitude potentials from the symptomatic ear only, even when the radiological abnormality is bilateral. (It is worth noting that, although useful, this test is not essential for diagnosis as, in most of these patients, one can usually see torsional nystagmus by naked eye or video-techniques in response to loud sounds or Valsalva manoeuvres.) The mechanism as to why a presumed saccular potential has abnormally high sensitivity in a superior semicircular canal syndrome is not exactly understood.

Clinical evidence suggests that the afferent fibres of this reflex travel in the inferior vestibular nerve. Patients with acute vestibular neuritis and absent caloric and cEVMP do not develop secondary BPPV.[151] This suggests that the absent cEVMP indicates loss of inferior vestibular nerve afferents which carry the macular fibres from the posterior semicircular canal; a deafferented posterior canal cannot produce symptoms of BPPV. Halmagyi et al. reported two patients with acute vertigo, normal lateral semicircular canal function but selective loss of posterior semicircular canal function as shown by absent cEVMP[53] suggestive of selective inferior nerve vestibular neuritis.

More recently, short-latency ocular EMG potentials recorded with periorbital surface electrodes in response to air-conducted sound and bone vibration have been elicited, which have been called ocular VEMPs (oVEMPs).[152] They are thought to represent a crossed excitatory utriculo-ocular response, hence a functional test of the superior vestibular nerve (as opposed to cVEMPs – inferior nerve). Ocular VEMPs can also be enhanced and show low thresholds in patients with superior canal dehiscence[153] but overall their clinical applicability has not yet gained wide support.[154]

Ideally, one would like to think that absent VEMPs would imply a selective, probably otolithic abnormality in a given patient with a vestibular-sounding history of dizziness but normal clinical and laboratory examination. Unfortunately, this does not seem to be the case and the meaning of an isolated VEMP abnormality is unclear, particularly in patients older than 40 years of age.[155] In patients with acoustic neuromas, however, an abnormal VEMP can occasionally be the only vestibular finding.[156]

PERCEPTUAL AND SUBJECTIVE VERTICAL TESTING

Perceptual tests of vestibular function were in use well before oculography came along with the advancement of electronics in the 1950s. Perceptual tests have underwent a revival in the last 20 years once the vestibular community realized that vestibulo-ocular test results often do not correlate well with patients' symptoms. The VOR is a simple reflex but a patient is a complex human being. It was therefore felt that assessment of how a patient perceives vestibular sensation may be more clinically relevant than oculography. Although the principle is sound, perceptual tests do not replace, but rather complement, eye movement tests, as oculography provides a more objective measure of vestibular function. In patients with long-standing blindness or eye movement disorders such as congenital nystagmus or chronic external ophthalmoplegia, perceptual tests are the only vestibular tests possible.

The simplest perceptual test is to ask the patient to compare subjectively the quality and intensity of the vestibular sensation for right and left stimuli. The stimuli can be the ones used in routine vestibular tests. Extremely useful information can be gained from simply asking a patient with a large congenital nystagmus or a complete ophthalmoplegia if they experience vertigo from caloric irrigation on both ears. The information can be improved by timing the duration of the vertigo or asking the patient to consider the subjectively better ear as 100%, and then estimate how much the other ear's vertigo is reduced. No formal normative data are available for this test but I personally give weight when a patient says that one ear is down 50% or more. (Note that most patients wrongly believe that the 'sick' ear is the one producing more, not less, vertigo!) In the appropriate clinical context this information can help in the diagnosis of a dizzy patient, specifically when they suffer from pre-existing visual or oculomotor disorders.

Even in patients undergoing conventional eye movement tests of vestibular function, enquiring about the quality of the sensation experienced during the caloric or rotational test can be extremely useful. One must not forget that a fundamental problem in the clinic is finding out if a patient's complaint of dizziness is of vestibular origin or not. In this scenario, a patient's equating the calorically elicited sensation to that of his own dizzy spells brings in considerable support for a diagnosis of vestibular disorder and, vice versa, when a patient says that his own dizziness does not resemble at all the caloric-induced vertigo.

Before the advent of EOG, the main quantitative vestibular perceptual test was cupulometry.[157] This test consists of measuring the duration of the postrotational sensation to a range of velocities, so that the sensitivity and time constant of decay of the sensation could be measured. The procedure could also be conducted with direct observation of the nystagmus with Frenzel glasses. In either case, the procedure took far too long to complete, was tiring for the subject and is no longer in use.

We have developed specific quantitative perceptual testing protocols, measuring either perceived displacement or velocity, to investigate vestibular function in patients with congenital nystagmus,[158] external ophthalmoplegia[159] or in selective semicircular canal lesions.[160] A useful aspect of these perceptual tests is that they can be conducted with the head placed in different positions, thus providing potentially useful information on vertical canal function.

SUBJECTIVE VISUAL VERTICAL

Intuitively, the perception of verticality must relate to the otoliths since these are linear acceleration/gravity sensors. However, one can easily conclude that one is lying sideways by the unambiguous asymmetry in pressure/contact cues between the two sides of the body, and/or by seeing that all buildings or trees appear to be tilted to our eyes. These examples illustrate that the perception of verticality is mediated not only by vestibular but also by proprioceptive and visual inputs.

In the clinical setting, the test of verticality more commonly used is the subjective visual vertical (SVV). The technique is easy, low cost, simple and reliable; examples include a system simply based on a bucket[161] and a laptop-based system with free download.[162] Essentially, a subject sits in front of an adjustable straight luminous line (**Figure 62.30**). The line may be viewed either in the dark or against a verticality cue-free background (e.g. all white or covered in dots). The subject's task is to set the line to what he/she thinks is real (gravitational) vertical. Normal subjects are quite accurate, all settings being within 1–2 degrees of real vertical.[163] The line can be either remotely controlled by the subject or an assistant adjusts the line according to the subject's instructions.

Initial excitement with this test was justified as vestibular lesions produce definite abnormalities of the SVV. Acute unilateral peripheral vestibular lesions produce tilt of the subject's SVV settings ipsilaterally.[141] Initially, in the acute stage, the tilt is of the order of 8–10 degrees but gradually disappears within a few months as compensation develops.[145]

Vestibular brainstem lesions cause larger and longer-lasting SVV tilts.[164, 165] Lesions involving the vestibular nuclei create ipsilateral SVV tilt (usually with an ocular-tilt reaction or skew eye deviation with the lower eye ipsilesional). Lesions in the upper brainstem induce contralateral SVV tilts and skew deviations with the upper eye ipsilesional, indicating a central vestibular pathway decussation at pontine level. Initially, these findings were thought to represent a global disruption of verticality perception due to an otholitic asymmetry. However, brainstem lesion patients with large tilts of the SVV usually show normal perception of verticality to other modalities, such as the haptic or tactile vertical or the perception of whole-body verticality (subjective postural vertical).[166, 167] Furthermore, 3D oculography has demonstrated an almost one-to-one correlation between torsional eye position measurements and SVV tilts.[145] Therefore, all evidence indicates that, for most, the tilt of the SVV is secondary to torsional VOR bias (i.e. ocular tilt), not a primary perceptual defect.

So long as the ocular torsional tilt (and usually associated skew) were due to an otolith–ocular pathway asymmetry, the SVV would still be useful as a simple test of otolith function. However, experimental studies have shown that sustained ocular torsion, skew deviation and SVV tilts can all be induced by pure stimulation of the vertical semicircular canals.[6, 147, 168] To summarize, SVV tilts of labyrinthine or brainstem origin can be taken to indicate an imbalance in the torsional ocular system. Claims of any specificity to otolith function (peripheral or central) are not tenable but a combined otolith–vertical canal effect is more likely.

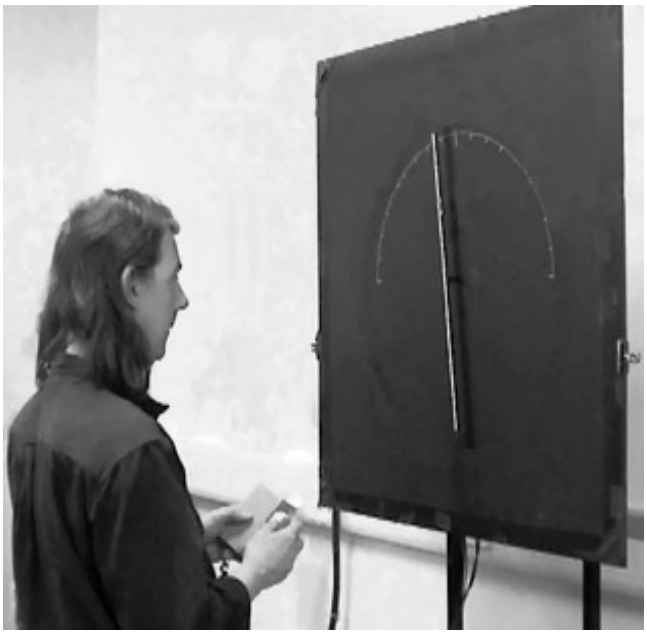

Figure 62.30 Measurement of the subjective visual vertical (SVV).

Hemisphere lesions can also induce tilts of the SVV but the magnitude is smaller; when the tilt is large, this is due to involvement of mesodiencephalic subcortical areas.[164, 165] The polarity is also variable. Interpretation of a cortical tilt is further confounded by the fact that proprioceptive input can also influence the SVV.[169] It is safer at this stage to consider any SVV tilt of cortical origin as due to disruption of central multisensory integration rather than to involvement of central vestibular pathways.[170] An extreme example of cortically induced tilt of all modalities of verticality perception (visual and postural) is seen in some stroke patients who develop the 'pusher syndrome'.[171] These patients 'push' themselves in the direction of their hemiparesis in order to align their body with the perceived tilted gravitational vector complicating the rehabilitation process. The subjective postural vertical can be measured with whole-body tilt devices of the type shown in **Figure 62.27a** and **b**[166] but this is only carried out for research purposes.

FUTURE RESEARCH

- Despite the fact that vertigo, dizziness and imbalance can comprise up to a fifth of all ENT and neurology patients, the problem is not taken seriously. This situation will get worse as population age increases, and further research in the area of dizziness in the elderly is required.
- Very few clinicians make the effort to cross the border between ENT and neurology, and more interdisciplinary centres are required.
- Few attempts are being made at classifying vestibular disorders on the basis of scientific evidence but the Bárány Society is currently attempting this.
- Further research is needed into laboratory diagnostic tools; studies comparing diagnostic efficiency are lacking. Pressures from equipment manufacturers on clinicians with little time for serious thoughts on the subject complicate matters further.
- More vertigo specialists in emergency departments are also needed to differentiate benign causes of vertigo from posterior circulation stroke, which often requires thrombolytic treatment acutely.
- Neuro-otologists should educate their peers, showing that understanding dizziness is not difficult and does not necessarily involve complex laboratory testing but good clinical skills.

KEY POINTS

- History taking remains the main approach for diagnosis of a patient with balance disorder.
- Rotational vertigo indicates semicircular canal system involvement, but the lesion can lie anywhere between the labyrinth and the cortex.
- Dizziness, giddiness and off-balance feelings can also indicate vestibular disease but care needs to be exercised as they may reflect a general medical condition, oscillopsia, gait disorder or psychological problems.
- Establish if there are additional aural or neurological symptoms and whether the vertigo/dizziness is acute, episodic or chronic.
- In patients with episodic vertigo always consider migraine.
- ENT and neurological examination is important but peripheral vestibular patients may only have signs in the acute phase of a disorder.
- Think 'stroke' in patients with acute vertigo. If the nystagmus is horizontal and unidirectional, there are no central symptoms/signs or deafness and the head-impulse test is positive, it is likely to be vestibular neuritis.
- So, you are interested in neuro-otology? If you are an ENT person, persuade a neurologist to work with you. If you are a neurologist persuade an ENT person. Both ENT and neurologists have to persuade an enthusiastic audiologist and/or physiotherapist to join the team.
- Cervical vertigo, if it exists, and vertebrobasilar insufficiency are grossly overdiagnosed. Always consider that dizziness on head–neck movements may be due to a vestibular disorder and do a Hallpike manoeuvre.
- Careful eye movement examination has two main aims: (i) detect any nystagmus, (ii) rule out CNS disease, since central vestibular disorders show additional abnormalities of pursuit, VOR suppression or saccades.
- Only a minority of patients require formal oculography for diagnosis.
- Caloric testing is cheap, efficient and examines one ear at a time. You do not need oculography to carry out caloric tests. The video head-impulse test (VHIT) is useful to detect canal paresis but it does not replace the caloric examination.
- Clinical assessment of posture and gait is a vital part of the examination. It is cheaper and better than posturography.
- There is no simple and clinically reliable way of testing the otolith system.
- Vestibular-evoked myogenic potentials (VEMPs) test otolith function but paradoxically they are most useful to detect superior canal dehiscence, a semicircular canal abnormality.

CHAPTER 63

MÉNIÈRE'S DISEASE

Vincent W.F.M. Van Rompaey

SEARCH STRATEGY

Data in this chapter may be updated by a search on Medline and the Cochrane Database of Systematic Reviews using the keywords Ménière's disease and endolymphatic hydrops.

INTRODUCTION

Ménière's disease is an idiopathic inner ear disorder characterized by recurrent spontaneous vertigo accompanied by fluctuating or progressive sensorineural hearing loss, tinnitus and aural fullness in the affected ear.[1] Of all audiovestibular symptoms, the vertigo episodes are experienced as the most incapacitating.[2]

The histopathological correlate is highly linked to endolymphatic hydrops, a finding which is not pathognomonic to Ménière's disease, but more likely a marker for overall disordered inner-ear homeostasis. Ménière's disease is, by definition, the idiopathic type of endolymphatic hydrops. A clear differentiation is made with the secondary type presenting a similar clustering of symptoms (which is called Ménière's syndrome) caused by, for example, syphilis, trauma, autoimmune disorders. Because Ménière's disease is an idiopathic condition lacking a gold standard for diagnosis, the search for an evidence base is difficult. Diagnostic criteria have been published but are based on expert opinion.

Ménière's disease affects the quality of life significantly and generally is treated with counselling on dietary restrictions, drug therapy and surgical interventions to prevent recurrence of vertigo. Hearing loss is treated by means of hearing aids, bone-conduction implants in cases of unilateral deafness and cochlear implantation in cases of bilateral profound hearing loss.

This review gives an overview of the current state of knowledge about Ménière's disease with a specific focus on management of vertigo, hearing loss and tinnitus.

EPIDEMIOLOGY

Incidence and prevalence

The exact incidence and prevalence of Ménière's disease are unknown and in fact difficult to demonstrate in any population because of inherent difficulties to diagnose this condition after exclusion of all other possible causes. First-line physicians tend to overdiagnose Ménière's disease in patients with chronic vertigo (with or without recurrent vertigo or any additional symptoms). In a secondary or tertiary referral balance clinic it is difficult to establish the exact catchment area. In a study on a Finnish population by Kotimäki et al.,[3] a prevalence of 43.2 per 100 000 persons and an incidence of 4.3 definite Ménière's disease per 100 000 persons per year was reported (1992–1996).

Age

The age of onset is more commonly reported in the second to sixth decade of life. Only 1–7% of Ménière's disease cases are seen in the paediatric population.[3] Surprisingly, 9% of all patients experience the start of Ménière's disease at the age of 65 or more, with a higher incidence of drop attacks.[4]

Sex

There is no difference in the female-to-male ratio.[3]

Sporadic and familial

While Ménière's disease is sporadic in the majority of cases, an estimated 5–15% of cases are familial.[5] Several candidate genes have been proposed for Ménière's disease, including *AQP2*, *KCNE1*, *KCNE3*, *HCFC1*, *COCH*, *ADD*, *HSPA1A*, *PTPTN22* and *IL1*. Many of them are linked to inner ear ion and water transportation. *AQP2* is one of the aquaporin water channel genes,[6] *KCNE1* and *KCNE3* are potassium channel genes[7] and *ADD1* is linked to a sodium–potassium pump activity regulator.[3] *COCH* is linked to cochlin protein production, which is part of the extracellular matrix of the inner ear.[8] *COCH* gene is also known as *DFNA9* and leads to progressive non-syndromic deafness and bilateral vestibular areflexia.[9] *HCFC1* is associated with the host cell factor C1 which has been involved in cell cycle control and transcriptional regulation during herpes simplex virus infection.[10] *HSPA1A* is related to single nucleotide polymorphisms of the heat-shock protein 70 gene,[11] *PTPN22* encodes a lymphoid protein phosphatase[12] and the interleukin-1 gene (*IL1*).[13] A higher prevalence of autoimmune diseases and longer spells of vertigo have been reported in patients affected by a familial form of Ménière's disease.[14, 15] The familial form is more prone to present bilaterally during a lifetime.[16]

PATHOPHYSIOLOGY

Endolymphatic hydrops

The cause of Ménière's disease is unknown. Hallpike and Cairns suggested the relationship with endolymphatic hydrops in 1938.[17] This finding was independently reported by Yamakawa in 1938.[18] However, this theory remains controversial although endolymphatic hydrops was observed in all temporal bones studied in deceased patients with Ménière's disease.[19] Foster and Breeze provide a critical review on temporal bone histopathology.[20] Clinical data supporting the theory of endolymphatic hydrops is based on electrocochleography and delayed magnetic resonance imaging after intratympanic or intravenous administration of gadolinium-based contrast agents. A large summating potential has been observed in 50–70% of patients with Ménière's disease, which can be reduced with administration of hyperosmotic substances.[8] Based on animal studies and clinical studies using cone-beam computed tomography, anatomical variations in the temporal bone could be identified that may predispose for blockage of the endolymphatic canal or foreign protein deposition in the perilymph, both of which have been observed to cause endolymphatic hydrops.[13, 21] Endolymphatic hydrops, however, is not pathognomonic to Ménière's disease. Endolymphatic hydrops was observed in a significant number of temporal bones from patients with hearing loss, without the classical symptoms of Ménière's disease.[22] Delayed MRI after intratympanic injection of gadolinium-based contrast agent in unilateral Ménière's disease reveals bilateral endolymphatic hydrops quite frequently.[23] Additionally, the use of diuretics does not unequivocally lead to an improvement of symptoms and/or hydrops. Membrane ruptures have been suggested to cause the acute episodes of vertigo. However, Merchant et al. observed clear histologic examples of membrane ruptures in patients without a history of vertigo, which contradicts this theory.[22] Based on a large human temporal bone study, Merchant et al. suggested that the endolymphatic hydrops observed in Ménière's disease might be a marker for disordered inner ear homeostasis in which a yet unknown factor produces both the clinical symptoms of Ménière's syndrome and endolymphatic hydrops.[22] Potential etiological or precipitating conditions include genetic variations, infection, vascular risk factors, diet, allergy, autonomic, endocrine and autoimmune factors.

Autoimmune factor

In approximately 1 in 3 patients with Ménière's disease there seems to be an autoimmune factor. Several theories were suggested, including cross-reactions between similar antigens, innocent bystander damage due to cytokine release, acquired intolerance to inner ear antigens (covert from the immunological system and exposed by trauma or infection), genetic factors (extended major histocompatibility complex haplotype).[24–26]

Viral factor

A viral etiology has been suggested as well, most often involving the herpes simplex virus. Viral structures have been observed by means of transmission electron microscopy in the vestibular ganglion cells of one Ménière's disease patient, which supports this theory albeit one case.[27] Vertigo control in 91% of Ménière's disease patients by means of acyclovir treatment also supports the potential viral etiology.[27]

Allergic factor

An association with allergy has been observed by Derebery. Vertigo control (Class A and B) was achieved in 47.9% (n = 137) accepting allergy treatment.[28] Potential mechanisms include the endolymphatic sac targeted by the allergic reaction, deposition of circulating immune complexes in the fenestrated blood vessels of the endolymphatic sac and stria vascularis and viral antigen-allergic interaction with T-cell homing to the endolymphatic sac.[29]

Vascular factor

It has been observed that endolymphatic hydrops impairs blood flow autoregulation.[30] The combination of endolymphatic hydrops and venous obstruction has shown to induce vertigo attacks similar to Ménière's disease in an animal model.[31]

DIAGNOSIS

Diagnostic criteria for Ménière's disease

The most recent guidelines for the diagnosis in patients with Ménière's disease were issued in 2015 by the Classification Committee of the Bárány Society, The Japan Society for Equilibrium Research, the European Academy of Otology and Neurotology (EAONO), the Equilibrium

TABLE 63.1 Diagnostic criteria for Ménière's disease (other causes excluded)

Diagnosis	Criteria
Definite Ménière's disease	≥ Two definitive spontaneous episodes of vertigo lasting 20 minutes to 12 hours + Audiometrically documented low- to medium-frequency sensorineural hearing loss in the affected ear on at least one occasion before, during or after one of the episodes of vertigo + Fluctuating aural symptoms (hearing, tinnitus or fullness) in the affected ear
Probable Ménière's disease	≥ Two episodes of vertigo or dizziness, each lasting 20 minutes to 24 hours + Fluctuating aural symptoms (hearing, tinnitus or fullness) in the reported ear

Committee of the American Academy of Otolaryngology–Head and Neck Surgery (AAO–HNS) and the Korean Balance Society.[32] According to these guidelines, the diagnosis of Ménière's disease in a vertigo patient is based on clinical symptoms and exclusion of identifiable other etiologies, rendering Ménière's disease idiopathic. They provide 2 degrees of certitude: definite and probable Ménière's disease. The definition of each of these categories can be found in Table 63.1. In the most recent 2015 guidelines, diagnostic criteria were suggested without providing minimal outcome criteria for use in daily practice in the absence of a gold standard test. Therefore, minimal outcome reporting is still based on the 1995 criteria issued by the AAO–HNS.[1]

A typical attack of Ménière's disease can be defined by the direction of the spontaneous nystagmus.[33] In the irritative phase the nystagmus will beat towards the affected ear in a horizontal or horizontal–torsional direction, a finding which usually lasts less than 1 hour. In the paretic phase, the nystagmus will beat away from the affected ear and last hours to days. In the recovery phase the nystagmus again beats towards the affected side because peripheral vestibular function recovers.

Particularly in the later stages of Ménière's disease, drop attacks (also known as Tumarkin crises) can develop. These may be related to acute otolythic dysfunction. The patient suddenly drops to the ground (without losing consciousness) without associated vertigo.

For the record, 'low-frequency sensorineural hearing loss' is defined as: increases in pure-tone thresholds for bone-conducted sound that are higher (i.e. worse) in the affected ear than the contralateral ear by at least 30 dBHL at each of two contiguous frequencies below 2 kHz. In cases of bilateral low-frequency sensorineural hearing loss, the absolute thresholds for bone-conducted sound must be 35 dBHL or higher at each of two contiguous frequencies below 2000 Hz. If multiple audiograms are available, demonstration of recovery of low-frequency sensorineural hearing loss at some point in time further supports the diagnosis of Ménière's disease. Bilateral synchronous sensorineural hearing loss (symmetric or asymmetric) can occur in some patients.

Figure 63.1 demonstrates the hallmark low-frequency sensorineural hearing loss and its recovery after low-sodium diet.

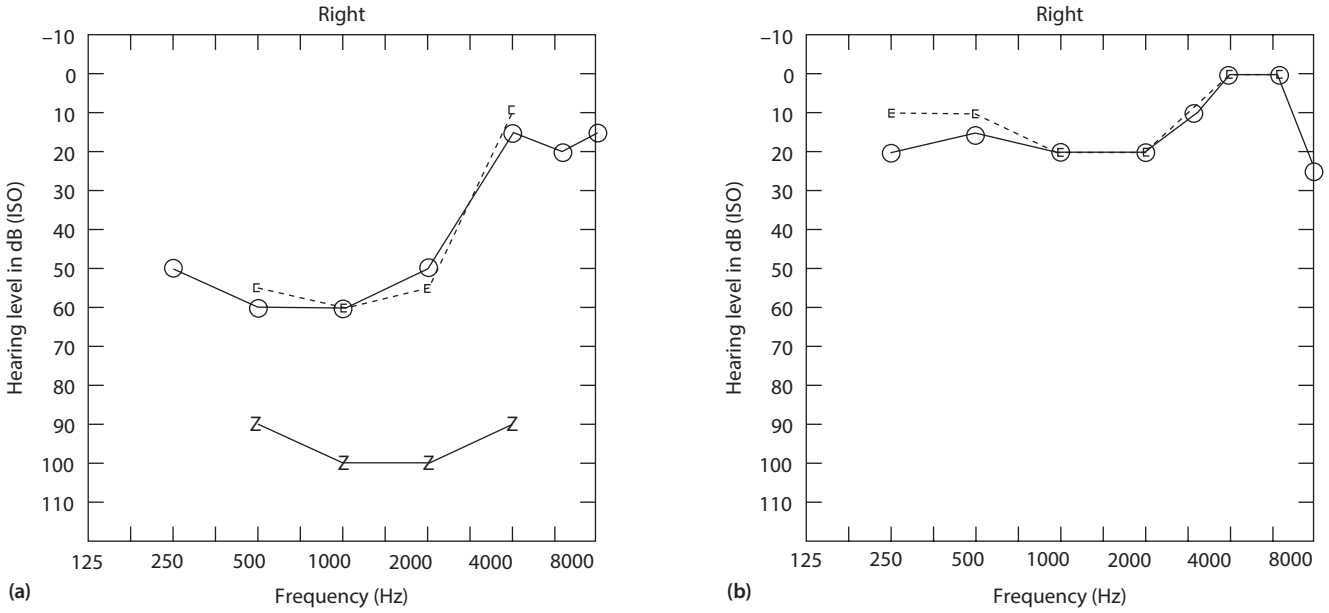

Figure 63.1 Audiogram in Ménière's disease. This patient, a 14-year-old female, began to have attacks of acute spontaneous vertigo with right-sided aural fullness and then tinnitus. **(a)** Audiogram on presentation shows a 60 dB low-frequency hearing loss with normal acoustic reflexes (Z), indicating a fully recruiting cochlear hearing loss. **(b)** Audiogram after 4 months of treatment with a rigorous low-sodium diet shows normal pure-tone thresholds.

The 2015 guidelines define Ménière's disease as an idiopathic syndrome of endolymphatic hydrops and therefore other causes have to be excluded. The following conditions are explicitly mentioned: transient ischemic attack, vestibular migraine, vestibular paroxysmia, recurrent unilateral vestibulopathy, vestibular schwannoma and endolymphatic sac tumour. The 1995 guidelines also mention trauma or surgery, infection (syphilis) and inflammatory disorders (Cogan's syndrome) as potential causes of endolymphatic hydrops and refer to the work of Schuknecht and Gulya for further causes.[34] The latter article additionally reveals the 'embryopathic symptomatic endolymphatic hydrops', related to inner ear malformations, and the 'acquired symptomatic endolymphatic hydrops' (also known as 'delayed hydrops'), related to trauma and inflammation caused by viruses, bacteria or spirochaetes. The case of a patient with bacterial meningitis and subsequent labyrinthitis was given to demonstrate the presence of 'delayed hydrops'. This report was published in the early 1980s and is limited by the contemporary state of the art where, for example, only polytomography was available as imaging tool. According to the 2015 guidelines the term 'delayed hydrops' should be avoided in favour of 'delayed Ménière's disease' in cases of sensorineural hearing loss antedating the vertigo spells.

To exclude these Ménière-like diseases any diagnostic technique available to the clinician should be used: for example, full clinical examination of the head and neck region (including vestibular examination), liminal and speech audiometry, tympanometry, multidetector computed tomography (CT scan) of the temporal bone (with or without intravenous injection of iodine-containing contrast), MRI of the posterior fossa (with intravenous injection of gadolinium), blood analysis (haematology, thyroid, biochemical and genetic testing). The posterior fossa MRI with intravenous administration of gadolinium is the most sensitive examination to exclude cerebellopontine angle and inner ear pathology (in the absence of any contraindications to MRI).

Since the diagnosis of Ménière's disease is based on a syndrome of idiopathic endolymphatic hydrops, it is good practice to challenge the diagnosis during follow-up of the patient. Simultaneously, these patients can report vertigo unrelated to their Ménière's disease, which needs careful examination and separate treatment. In the differential diagnosis of Ménière's disease, vestibular migraine, vestibular paroxysmia and chronic subjective dizziness have to be considered. These conditions can also coexist with Ménière's disease and need to be treated separately.[35] Unfortunately, since all of these conditions are idiopathic, their diagnosis relies on expert opinion-based criteria.[36] Diagnostic criteria for vestibular migraine,[37] vestibular paroxysmia[38] and chronic subjective dizziness[39] can be found respectively in **Tables 63.2**, **63.3** and **63.4** to enable direct comparison.

Diagnostic tools to detect endolymphatic hydrops

Evidence supplementary to the diagnostic criteria (which are in fact based only on history and audiometry) can be provided with electrocochleography (ECoG) or cochlear hydrops analysis masking procedure (CHAMP). More recently the use of delayed MRI after intratympanic injection of gadolinium has enabled the clinician to demonstrate endolymphatic hydrops *in vivo*.

ELECTROCOCHLEOGRAPHY

Electrocochleography records sound-evoked electrical activity near the cochlea by means of transtympanic or extratympanic measurement. This technique is not routinely available and was therefore not included as a minimal outcome criterion of the 1995 Committee guidelines. ECoG is assumed to measure endolymphatic hydrops by evaluating the amplitude ratio of the action potential (AP) and the summating potential (SP). The SP amplitude is increased by displacement of the basilar membrane towards the scala tympani. **Figure 63.2** demonstrates ECoG findings in the same patient as in **Figure 63.1**. Diagnostic SP/AP-ratio thresholds were suggested by Wuyts et al. by performing a meta-analysis of published results.[40] These thresholds differ between extratympanic and transtympanic electrodes and are presented in **Table 63.5**.

Diagnostic SP amplitude thresholds were also suggested when using tone-burst stimuli. These suggestions are not based on a meta-analysis because of insufficient data, but reflect the proposal of the Prosper Ménière Society's

TABLE 63.2 Diagnostic criteria for vestibular migraine

Diagnosis	Criteria
Vestibular migraine	A. At least five episodes with vestibular symptoms of moderate to severe intensity, lasting 5 minutes to 72 hours B. Current or previous history of migraine with or without aura according to the International Classification of Headache Disorders (ICHD) C. One or more migraine features symptoms with at least 50% of the vestibular episodes: (1) headache with at least two of the following characteristics: one-sided location, pulsating quality, moderate or severe pain intensity, aggravation by routine physical activity (2) photophobia and phonophobia (3) visual aura D. Not better accounted for by another vestibular or ICHD diagnosis
Probable vestibular migraine	A. At least five episodes with vestibular symptoms of moderate or severe intensity, lasting 5 minutes to 72 hours B. Only one of the criteria B and C for vestibular migraine is fulfilled (migraine history *or* migraine features during the episode) C. Not better accounted for by another vestibular or ICHD diagnosis

TABLE 63.3 Diagnostic criteria for vestibular paroxysmia

Diagnosis	Criteria
Definite vestibular paroxysmia	Patients suffered from a minimum of five vertigo attacks and fulfilled one criterion of each category (A)–(E): A. *Vertigo attacks:* Vertigo attacks (rotatory as well as to and fro vertigo) with short duration (seconds to minutes), which ceased spontaneously B. *Vertigo triggers:* Attacks occurred while in rest, were induced by a specific head and/or body position, or by a specific change of head and/or body position C. *Accompanying symptoms:* Attacks were accompanied by at least one of the following additional symptoms: unsteadiness of stance and/or gait, lateralized tinnitus, decreased hearing function or subjective sensory irritations, such as a feeling of pressure within or around one ear D. *Additional criteria:* The diagnostic procedures in addition to the anamnestic aspects revealed a neurovascular compression of the eighth cranial nerve on MRI scans including CISS sequences, a hyperventilation-induced nystagmus, a detectable progress of vestibular deficit over the course of disease, or patients responded positively to treatment E. *Exclusion:* Any other possible pathology or disease explaining the symptoms had to be excluded
Probable vestibular paroxysmia	Patients suffered from a minimum of five vertigo attacks and fulfilled criterion (A) and additionally at least three criteria out of the categories (B)–(E)

TABLE 63.4 Diagnostic criteria for chronic subjective dizziness

Diagnosis	Criteria
Chronic subjective dizziness	1. *Subjective unsteadiness or dizziness*: Persistent (≥3 months) sensations of unsteadiness or non-vertiginous dizziness that are present on most days. These symptoms may be described as: • rocking, swaying, or wobbling that is usually not apparent to others • a feeling that the floor is moving or wavy • light-headed, foggy or cloudy in the head • heavy-headed or full in the head • spinning 'inside the head' without a perception of movement of the visual surround • a feeling of dissociation from the environment
	2. *Hypersensitivity to motion*: Chronic (≥3 months) hypersensitivity to one's own motion, which is not direction-specific, and to the movement of objects in the environment
	3. *Visual dizziness (also known as visual vertigo)*: Exacerbation of symptoms in settings with complex visual stimuli, such as displays in grocery stores or shopping malls, or when performing precision visual tasks (e.g. reading or working on a computer).

International Standard.[41,42] SP amplitude is typically measured at 10 msec after stimulus start. Unfortunately, no studies were available on extratympanic ECoG through tone-burst stimuli.[40]

COCHLEAR HYDROPS ANALYSIS MASKING PROCEDURE (CHAMP)

The hypothesis of CHAMP is that endolymphatic hydrops causes changes in the response properties of the basilar membrane, i.e. travelling wave velocity is faster by basilar membrane stiffening in endolymphatic hydrops. These changes lead to impaired high-pass noise masking of auditory brainstem response (ABR) to clicks in stacked ABR. Unfortunately, different groups have reported conflicting results.[43–46] These results are potentially due to the different standards and diagnostic thresholds used. Therefore, the CHAMP cannot be used (yet) to prove or disprove the diagnosis of endolymphatic hydrops in Ménière's disease patients.

DELAYED MRI AFTER INTRATYMPANIC OR INTRAVENOUS INJECTION OF GADLINIUM

Since 'certain' Ménière's disease involves the histopathologic confirmation of endolymphatic hydrops, this level of certitude is only reached post-mortem and clinically irrelevant to the patient. Electrophysiological testing (such as ECoG or CHAMP) is based on measuring sound-evoked electrical responses and therefore quite circumstantial evidence for endolymphatic hydrops. The intratympanic injection of gadolinium-based contrast agent (hereafter called gadolinium) provides a potential *in vivo* biomarker to evaluate the perilymphatic and endolymphatic spaces separately. Gadolinium loads into the perilymphatic space without entering the endolymph in healthy inner ears.[47]

Normative values have been established in healthy volunteers.[48,49] Based on the study on normal individuals by Nakashima et al.,[49] the upper limit for enlargement of the endolymphatic space of the vestibule should be set at 33%. This new technique for visualizing endolymphatic hydrops demonstrated, surprisingly, that Ménière's disease is essentially a bilateral condition. Bilateral endolymphatic was observed in 79% of patients with unilateral definite Ménière's disease. Pyykkö et al. also argued that Ménière's disease rather is a continuum from monosymptomatic patients with endolymphatic hydrops to the full-blown patient profile of definite Ménière's disease.[23] This technique certainly is promising and might be helpful as a biomarker to confirm endolymphatic hydrops in cases

where clinical suspicion is present. Gadolinium can be administered intravenously 4 hours before MRI or intratympanically 24 hours before MRI. We remind the clinician that the intratympanic use of gadolinium is strictly off-label.

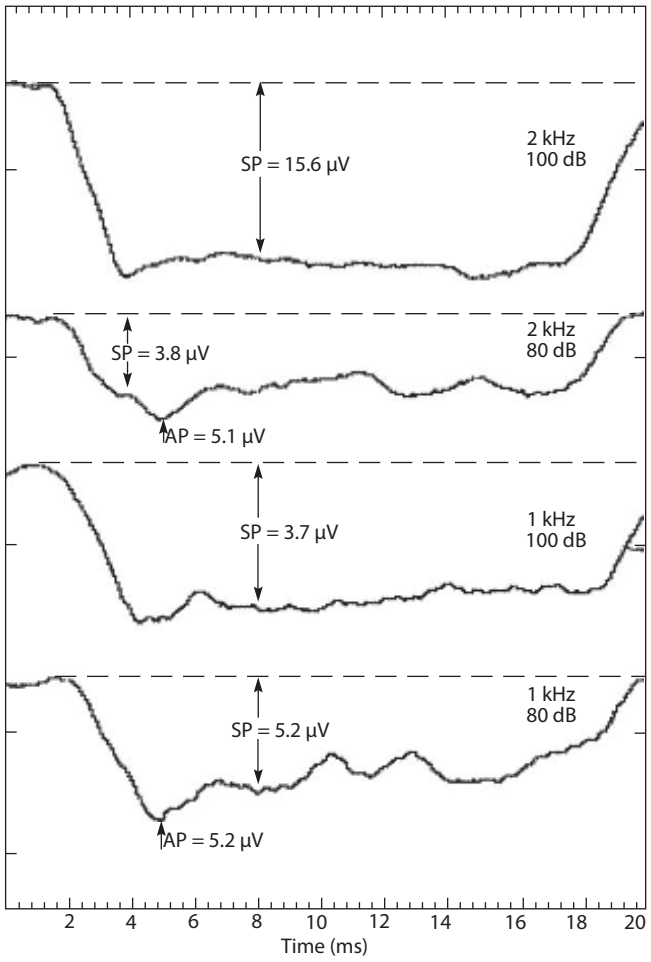

Figure 63.2 Electrocochleogram (ECoG) in Ménière's disease. Transtympanic ECoG of the patient whose audiogram is shown in Figure 63.1, showing large negative summating potentials (SP) in response to 16 ms, 1 kHz and 2 kHz tone-bursts at 80 and 100 dB nHL. The mean absolute negative SP levels in patients with definite Ménière's disease, who have subjective thresholds below 40 dB nHL, are as follows: 2 kHz, 100 dB 46 mV; 2 kHz, 80 dB 44 mV; 1 kHz, 100 dB 44 mV. These results show that tone burst ECoG responses are more likely to be abnormal in patients with Ménière's disease than are click-evoked responses.[75] Figure courtesy of W. Gibson, Sydney, Australia.

TABLE 63.5 Electrocochleography SP/AP ratio and SP thresholds

	Stimulus	Thresholds	
		Extratympanic	Transtympanic
SP/AP ratio	Click	>0.42	>0.35
SP	Tone-bursts	–	<–2 µV (<–3 µV at 1 kHz)

OUTCOME REPORTING

Vertigo

DEFINITION

The definitive spell of Ménière's disease is described as spontaneous rotational vertigo (i.e. the sensation of motion when no motion is occurring relative to Earth's gravity) lasting at least 20 minutes. The severity of vertigo is reported as prostrating or incapacitating by the patient. This spell might be followed by a period of disequilibrium, a sensation present for up to several days. The definitive spell is usually accompanied by nausea and/or vomiting. Consciousness is not lost during or after the spell. While examining the patient during the definitive spell, horizontal nystagmus (with or without torsional component) is always present.

FREQUENCY OF VERTIGO

The frequency of vertigo should be evaluated over a period of 6 months. The average number of definite spells per month lasting at least 20 minutes is used in the reporting index as shown in Table 63.6. Any treatment can only be evaluated 2 years after treatment started. At that follow-up visit, the frequency of vertigo over the last 6 months has to be reported. Class F is the category of Ménière's disease patients who require 'secondary treatment' due to disability from vertigo (e.g. vestibular nerve section).

SEVERITY OF VERTIGO

The AAO–HNS Committee released an update in the AAO–HNS Bulletin of April 2014. Its main consideration was that in the 1995 guidelines outcome reporting was based totally on frequency of vertigo, while information on the severity of vertigo spells would be more appropriate. Table 63.7 includes five categories ranging from 'no vertigo' to 'extreme attack'.

FUNCTIONAL LEVEL

It has been reported that Ménière's disease symptoms are highly intrusive in comparison to other conditions.

TABLE 63.6 Summary of reporting guidelines

Numerical value	Class
0	A (complete control of spells)
1–40	B
41–80	C
81–120	D
>120	E
Secondary treatment initiated due to disability from vertigo	F

Numerical value = $(X/Y) \times 100$, rounded to the nearest whole number, where X is the average number of definitive spells per month for the 6 months 18–24 months after therapy and Y is the average number of definitive spells per month for the 6 months before therapy.

TABLE 63.7 Severity of vertigo

Scale	Category	Definition
0	No vertigo	No vertigo
1	Mild attack	Brief episode of vertigo lasting less than 20 minutes and/or vague sense of disequilibrium lasting less than 2 hours
2	Moderate attack	Vertigo lasting 20–60 minutes and/or disequilibrium lasting greater than 2 hours with reduction in daily activities from 0% to 50%
3	Severe attack	Vertigo lasting more than 1 hour with or without accompanying nausea and vomiting, with or without lingering disequilibrium lasting greater than 2 hours with reduction in daily activities of 50–100%
4	Extreme attack	Vertigo lasting more than 1 hour with nausea and vomiting and persistent lingering severe disequilibrium requiring bedrest the entire day

Only fibromyalgia, human immunodeficiency virus (HIV) infection, anxiety disorders and chronic fatigue syndrome/myalgic encephalomyelitis are more intrusive, as reported by Arroll et al.[50] Functional level, commonly related to work or active recreational pursuits, is mainly related to the intrusiveness of the vertigo spells. The six categories are shown in **Box 63.1**.

DIZZINESS HANDICAP INVENTORY

The Dizziness Handicap Inventory (DHI) has gained widespread acceptance as a useful instrument to evaluate the handicap resulting from vertigo and achieves a responsiveness superior to other patient-reported outcome measures.[51] It has been used frequently as an outcome measure in clinical trials to document the effect of medical, surgical and rehabilitative interventions.[52]

MÉNIÈRE'S DISEASE OUTCOME QUESTIONNAIRE

In 2004, Kato et al. published an 18-item multiple-choice questionnaire for evaluating quality of life in patients with Ménière's disease before and after endolymphatic sac surgery: the Ménière's Disease Outcome Questionnaire (MDOQ). This questionnaire includes three domains: physical, emotional and social well-being. It was designed as a retrospective survey enabling patients to evaluate their symptoms after surgery and not requiring baseline analysis. This feature makes the MDOQ easy to use but it also reflects its main limitation: the retrospective and post-hoc evaluation.[53]

ELECTRONYSTAGMOGRAPHY

Electronystagmography cannot confirm the diagnosis itself, but reflects the residual horizontal semicircular canal response to caloric stimulation. In patients with Ménière's disease, these results can vary quite significantly. In case of treatments that aim for destruction of labyrinthine function (such as intratympanic injection of gentamicin or a vestibular nerve section), electronystagmography can measure residual function and evaluate the treatment's effectiveness to destroy vestibular function. However, the absence of caloric response does not invariably predict long-term vertigo control.[54]

Hearing loss

Hearing loss is essential in the diagnosis of certain, definite and probable Ménière's disease. If no hearing loss was documented, the patient can only be allocated

BOX 63.1 Functional level scale

Regarding my current state of overall function, not just during attacks (check the ONE that best applies):	
1. My dizziness has no effect on my activities at all.	
2. When I am dizzy I have to stop what I am doing for a while, but it soon passes and I can resume activities. I continue to work, drive, and engage in any activity I choose without restriction. I have not changed any plans or activities to accommodate my dizziness.	
3. When I am dizzy, I have to stop what I am doing for a while, but it does pass and I can resume activities. I continue to work, drive, and engage in most activities I choose, but I have had to change some plans and make some allowance for my dizziness.	
4. I am able to work, drive, travel, take care of a family, or engage in most essential activities, but I must exert a great deal of effort to do so. I must constantly make adjustments in my activities and budget my energies. I am barely making it.	
5. I am unable to work, drive, or take care of a family. I am unable to do most of the active things that I used to. Even essential activities must be limited. I am disabled.	
6. I have been disabled for 1 year or longer and/or I receive compensation (money) because of my dizziness or balance problem.	

TABLE 63.8 Staging of definite and certain Ménière's disease

Stage	Pure-tone average of 0.5–1–2–3 kHz (dB)
1	≤25
2	26–40
3	41–70
4	>70

to the possible Ménière's disease group (in the presence of other qualifying symptoms). The 1995 Committee guidelines combine the use of pure-tone audiometry and word recognition scores in order to evaluate hearing loss. However, they only use the pure-tone average of 0.5, 1, 2 and 3 kHz for staging of certain and definite Ménière's disease. The proposed staging system can be found in Table 63.8. This pure-tone average should be calculated on the worst audiogram during the 6 months before the start of treatment. The staging system cannot be used in probable and possible Ménière's disease according to the 1995 Committee guidelines. Once the patient is allocated, the stage cannot be changed. No suggestion was made to incorporate word recognition in staging, but a positive change of 15% in speech discrimination was considered clinically significant.

Tinnitus and aural fullness

According to the 1995 Committee guidelines, the evaluation of tinnitus and aural fullness is at the discretion of the clinician.

TINNITUS FUNCTIONAL INDEX

For evaluation of tinnitus severity, several self-reporting questionnaires have been developed and are currently in use. However, many questionnaires were not designed to maximize responsiveness (i.e. to measure positive or negative change after treatment). For this reason an expert panel based in the US and New Zealand developed the Tinnitus Functional Index (TFI).[55] In this study, a 13-point reduction was considered a clinically meaningful reduction of TFI scores.

VISUAL ANALOGUE SCALE

The visual analogue scale has been in use for reporting complaints that are difficult to quantify. Using the visual analogue scale, the patient has to indicate a value between 0 (no symptoms) and 10 (maximal intensity). The visual analogue scale can also be used for evaluation of average and maximal tinnitus loudness.[56]

MANAGEMENT

Based on the levels of recommendation produced by the Oxford Centre for Evidence-based Medicine we will discuss all different aspects in the management of Ménière's disease patients.

Diagnosis

The diagnosis of Ménière's disease can be suspected by acquiring a systematic otovestibular history (including family history and personal drug, trauma, surgery and disease history) while excluding all other potential causes of the Ménière's syndrome due to secondary endolymphatic hydrops, as required by the 2015 guidelines (recommendation grade D). Liminal and speech audiometry is essential to support the diagnosis of definite Ménière's disease. The clinician should be aware that there is considerable overlap in diagnostic criteria for vestibular migraine, vestibular paroxysmia and chronic subjective dizziness. It is uncommon but possible that more than one condition can be diagnosed and requires separate treatment.

There are no studies on how to exclude other potential causes of endolymphatic hydrops, which is left at the discretion of the clinician. A blood sample can be taken to evaluate thyroid and immunological status if thyroid disease or autoimmune diseases are suspected. Genetic analysis is not routine practice in every balance clinic. *COCH*-mutations can be screened in unaffected family members to provide information on individual prognosis. An MRI scan of the cerebellopontine angle can be performed after intravenous administration of gadolinium-based contrast agent to exclude inner ear malformations, neurovascular conflicts with the vestibulocochlear nerve, cerebellopontine angle and intralabyrinthine lesions (most often the vestibular schwannoma) or white matter lesions of inflammatory or vasculoischaemic origin. ECoG can demonstrate the electrophysiological substrate of endolymphatic hydrops. Delayed MRI after intravenous or intratympanic injection of gadolinium-based contrast agent can visualize endolymphatic hydrops and can provide an *in vivo* surrogate for the histopathologic confirmation of certain Ménière's disease.

Hygienic measures

DIETARY RESTRICTIONS

Dietary restrictions on sodium and caffeine are traditionally advised by clinicians to prevent the development of endolymphatic hydrops.[57] However, this hypothesis was only recently confirmed by means of a retrospective study.[58] Luxford et al. demonstrated that implementation of a low-sodium and caffeine-free diet had a statistically significant effect on functional level in Ménière's disease patients. Those patients who were compliant longer than 6 months had larger improvement in vertigo frequency and functional level. The latter group of patients also had a higher rate of class A/B vertigo outcome.

Recommendation Counselling may include a low-salt and caffeine-free diet.

Medication

DIURETICS

Diuretics, including hydrochlorothiazide, acetazolamide or a combination of hydrochlorothiazide and triamterene, are still the first-line medical therapy for Ménière's disease patients in many clinics. Their therapeutic mechanism is to reduce endolymphatic volume and pressure.[57] Osmotic diuretics, such as oral urea powder twice a week, are rarely used as a 'salvage oral therapy' to reduce endolymphatic hydrops. Thirwall and Kundu published a 2006 Cochrane analysis on the use of diuretics in patients with Ménière's disease. This analysis was assessed as up-to-date in 2009. Unfortunately, there was insufficient good evidence of the effect of diuretics on vertigo, hearing loss, tinnitus or aural fullness in clearly defined Ménière's disease.[59] Diuretics, however, can cause electrolyte disturbances and potentially interact with patient-specific drugs and conditions.

BETAHISTINE DIHYDROCHLORIDE

Betahistine dihydrochloride (hereafter called betahistine) is an oral preparation of a histamine precursor marketed in Europe as a specific treatment for patients with Ménière's disease. Betahistine is an analogue of histamine with weak agonist properties at histamine H1 receptors and more potent antagonistic effects at histamine H3 receptors.[60, 61] James and Burton published a 2001 Cochrane analysis on the use of betahistine in patients with Ménière's disease.[62] This analysis was assessed as up-to-date in 2010. Unfortunately, according to this analysis there was insufficient evidence to identify whether betahistine has any effect on vertigo control in patients with Ménière's disease. Six trials involving 162 patients were included. No trial met the highest quality standard set by the review because of inadequate diagnostic criteria or methods, and none assessed the effect of betahistine on vertigo adequately. Most trials reported some form of vertigo control. However, these results may have been caused by bias in the study design. Another, more recent, meta-analysis (performed by an employee of pharmaceutical company Abbott, commercializing Betaserc) demonstrated an overall beneficial effect of betahistine.[63] This study was not restricted to Ménière's disease and also includes 'vestibular vertigo', which might induce bias. Additionally, this meta-analysis introduces internal unpublished (Duphar) reports on placebo-controlled clinical studies with betahistine, which is a controversial issue (bypassing the challenge of peer review). High-dosage betahistine dihydrochloride (up to 480 mg or 30 tablets each day) has been reported in a case series to be effective in patients with Ménière's disease who do not respond sufficiently to lower dosages.[64]

Recommendation First-line medical treatment to prevent recurrence of vertigo may include betahistine dihydrochloride 16 mg thrice daily and/or diuretics. Betahistine has a limited side effect profile while diuretics can cause electrolyte disturbances, potentially interact with patient-specific drugs and conditions.

Transtympanic and intratympanic therapies

TRANSTYMPANIC LOW-PRESSURE THERAPY (MENIETT)

This therapy was established after reports of subjective improvement of acute vertigo attacks when pressure changes were induced in a pressure chamber.[65, 66] Based on these reports, the Meniett device was conceived, producing a repetitive 0.6-second pulse of low pressure (ranging from 0 to 20 cm H_2O) transmitted through a ventilation tube.[67] The treatment consists of three to four cycles of a 5-minute treatment sequence. A recent Cochrane review had to conclude that there is no evidence to demonstrate the effectiveness of positive low-pressure therapy.[68]

INTRATYMPANIC INJECTION OF CORTICOSTEROIDS

The suggested therapeutic mechanism of corticosteroids is inner ear homeostasis via transmembrane water transporters, the aquaporins.[69] Based on a 2011 Cochrane analysis by Phillips and Westerberg, one randomized placebo-controlled trial was identified comparing intratympanic injection of dexamethasone to saline solution.[70] This trial demonstrated a statistically significant improvement of vertigo frequency and severity measured 24 months after treatment start. Substantial vertigo control (Class A and B) was achieved in 11 patients (100%) of treatment group versus 4 patients (57%) in the control group.[71, 72] Therefore the authors of the Cochrane analysis concluded that limited evidence is available to support the effectiveness of intratympanic steroids in patients with Ménière's disease. An important aspect is that patients were only included if failing a combination of dietary restrictions and medical therapy with vasodilator and diuretics for 6 months.

INTRATYMPANIC INJECTION OF GENTAMICIN

Aminoglycosides are infamous for their vestibulotoxicity after intravenous use. There are several pathways that might cause this effect including excitotoxicity through N–methyl–D–aspartate (NMDA) receptor binding[72] and production of reactive oxygen species[74] which can be influenced by the antioxidant N-acetylcysteine.[74] Schuknecht first reported on intratympanic therapy with aminoglycosides as early as 1956.[75, 76] Based on a 2011 Cochrane analysis by Pullens et al., two randomized placebo-controlled trials were identified demonstrating the beneficial effect of intratympanic injection of gentamicin on vertigo control in Ménière's disease patients.[77] A meta-analysis was deemed impossible due to clinical heterogeneity. Huon et al.[78] did perform a meta-analysis which was published in 2012 confirming the beneficial effect of intratympanic gentamicin on vertigo control: 87.5% Class A and B. Sensorineural hearing loss was reported in 0–38.7% of cases. After the publication of these two articles another randomized controlled trial was published in 2012

comparing intratympanic gentamicin with dexamethasone.[79] Because different injection schedules were used, this trial could not be blinded. In the intratympanic gentamicin group substantial vertigo control (Class A and B) was achieved in 30 patients (93.5%) at 2-year follow-up. In the intratympanic dexamethasone group, substantial vertigo control was achieved in 17 patients (61%).[79]

Noteworthy is that intratympanic injection of gentamicin has demonstrated its effectiveness in patients with Ménière's disease experiencing drop attacks (Tumarkin crisis).[80]

Recommendation Salvage treatment in case of medical treatment failure may include repetitive intratympanic injections of dexamethasone (recommendation grade A), which enable substantial and long-term vertigo control in 80% of refractory cases without significant hearing loss. In refractory cases after intratympanic injection of dexamethasone, intratympanic injection of gentamicin (as-needed) can be offered (recommendation grade A). This treatment is based on the vestibulotoxic effect of gentamicin and aims to destroy vestibular hair cell function (therefore also called partial chemolabyrinthectomy). The typical Ménière's disease vertigo attacks are not detected and do not provoke nystagmus. Consequently, the patient does not experience vertigo any more but may develop some imbalance or visual vestibular mismatch.

Intratympanic injection of gentamicin may also be indicated in 'end-stage' patients who develop drop attacks/Tumarkin crises.

Sensorineural hearing loss is a potential complication of this treatment and should be considered in the evaluation of the individual patient.

Surgery

ENDOLYMPHATIC SAC SURGERY

Based on a 2010 Cochrane analysis by Pullens et al. (updated in 2013) only one surgical modality was studied in randomized controlled trials, i.e. endolymphatic sac surgery. Neither of the two studies reported any beneficial effect over grommet insertion or mastoidectomy,[80] therefore the authors concluded that there is insufficient evidence to support endolymphatic sac surgery in Ménière's disease. A more recent systematic review and meta-analysis of available clinical studies (although lacking a control population) supported the use of endolymphatic sac surgery in Ménière's disease patients refractory to medical treatment.[81] Different surgical approaches to the endolymphatic sac were compared including endolymphatic sac decompression and mastoid shunting. Sood et al. calculated a respective average of 79.3% and 76.4% vertigo control (Class A and B) at 12 months (short-term) and 81.6% and 75.7% at 24 months (long-term). Average hearing preservation rates (within 10 dB of pre-operative thresholds) were respectively 72.8% and 71.4% at 12 months and 71.6% and 69.3% at 24 months. These numbers, however, might reflect natural Ménière's disease progression since control groups are lacking.[82]

TENOTOMY OF THE TENSOR TYMPANI AND STPEDIAL MUSCLE TENDONS

Conflicting results have been reported on tenotomy of the tensor tympani and stapedial muscles' tendons.[52, 83–85] The suggested mechanism of action in Ménière's disease patients is that the tympanic membrane is pushed laterally by increased cochlear pressure against the ossicular chain. By sectioning the tensor tympani muscle this effect is (partially) alleviated.[86] Positive results were only reported in one centre that published several case series.[83–85] Randomization of patients undergoing intratympanic injection of gentamicin into one group who had simultaneous tenotomy and another group without tenotomy could not reveal any statistically significant differences.[52]

SELECTIVE VESTIBULAR NERVE SECTION

Surgical section of the vestibular nerve while preserving the facial and cochlear nerve can be used as an alternative to intratympanic injection of gentamicin to produce vestibular areflexia. Several case series were reported, but only three case-control studies were published reporting a similar outcome as intratympanic injection of gentamicin.[87–89] Hillman et al.[88] reported 90% substantial vertigo control (Class A and B) in the selective vestibular nerve section group, while 66% was observed in the intratympanic injection of gentamicin group, which favours the selective vestibular nerve section group on a statistically significant level. These results might have been provoked by the relatively low dosage of gentamicin (26.7 mg/mL) the authors used and the short irrigation time of 10 minutes in the supine position. Hearing preservation rates were 72% in the selective vestibular nerve section group and 52% in the intratympanic injection of gentamicin group. Statistically significant differences were reported favouring selective vestibular nerve section. However, pre-operative hearing was also better in the selective vestibular nerve section at a statistically significant level. Colletti et al.[89] reported substantial vertigo control (Class A and B) in 95.8% of selective vestibular nerve section cases and 75% of intratympanic injection of gentamicin cases. Schmerber et al.[90] observed recurrence of disabling vertigo in 7% of selective vestibular nerve section cases and 11.4% of intratympanic injection of gentamicin cases, while respective numbers of 74% and 85.7% hearing preservation were reported. The hearing preservation rate in intratympanic injection of gentamicin cases might have been biased by the specific inclusion of cases with pure-tone averages over 40 dB (only Class C and D hearing cases). All the studies mentioned above have significant limitations including their retrospective nature, selection bias, etc. A proper systematic review (and meta-analysis of raw data if possible) of selective vestibular nerve section is currently lacking. Randomized controlled trials using sham procedures are impossible due to ethical reasons in this type of surgical procedure and preclude the establishment of level 1 evidence. The conception of a delayed-start study design would enable randomization and increase the level of evidence.[91]
