Recommendation Selective vestibular nerve section aims to abolish vestibular afferent signalling totally and is usually considered as an alternative to intratympanic injection of gentamicin in case of intact hearing or as salvage treatment after intratympanic injection of gentamicin.

There is insufficient evidence to support transtympanic low-pressure therapy (Meniett), endolymphatic sac surgery or tenotomy of the tensor tympani and stapedius muscles' tendons.

KEY POINTS

Diagnosis

- The diagnosis of Ménière's disease can be suspected by acquiring a systematic otovestibular history (including family history and personal drug, trauma, surgery and disease history).
- Potential causes of secondary endolymphatic hydrops need to be excluded.
- Liminal and speech audiometry is essential to support the diagnosis of definite Ménière's disease.
- There is considerable overlap in diagnostic criteria for vestibular migraine, vestibular paroxysmia and chronic subjective dizziness.
- An MRI scan of the cerebellopontine angle after intravenous administration of gadolinium-based contrast agent is the most sensitive imaging method to exclude inner ear malformations, neurovascular conflicts with the vestibulocochlear nerve, cerebellopontine angle and intralabyrinthine lesions (most often the vestibular schwannoma) or white matter lesions of inflammatory or vasculo-ischaemic origin.
- ECoG can demonstrate the electrophysiological substrate of endolymphatic hydrops.
- Delayed MRI after intravenous or intratympanic injection of gadolinium-based contrast agent can visualize endolymphatic hydrops and can provide an *in vivo* surrogate for the histopathologic confirmation of certain Ménière's disease.

Treatment

- Counselling includes a low-salt and caffeine-free diet.
- First-line medical treatment to prevent recurrence of vertigo may include betahistine dihydrochloride 16 mg thrice daily associated with diuretics.
- Salvage treatment in cases of medical treatment failure may include repetitive intratympanic injections of dexamethasone, which enable substantial and long-term vertigo control in 80% of refractory cases without significant hearing loss.
- In refractory or end-stage cases (Tumarkin crises), intratympanic injection of gentamicin (as needed) can be offered.
- Sensorineural hearing loss is a potential complication of this treatment and should be considered in the evaluation of the individual patient.
- Selective vestibular nerve section aims to abolish vestibular afferent signalling totally and is usually considered as an alternative to intratympanic injection of gentamicin in case of intact hearing or as salvage treatment after intratympanic injection of gentamicin.

CHAPTER 64

BENIGN PAROXYSMAL POSITIONAL VERTIGO

Yougan Saman and Doris-Eva Bamiou

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: benign paroxysmal positional vertigo, posterior canal, horizontal canal and anterior canal.

INTRODUCTION

Benign paroxysmal positional vertigo (BPPV) is the commonest presenting cause of vertigo with an estimated lifetime prevalence of 2.4%.[1] In studies of both young adults and the elderly a prevalence of 9% has been described.[2, 3] It has a characteristic history and can easily be diagnosed on examination. Treatment can be performed in the clinic with a good outcome, making it the most rewarding vestibular condition to manage. BPPV may, however, be associated with a reduced quality of life, falls and depression, in which case the term 'benign' may be misleading, particularly when unrecognized and therefore untreated.[2]

The first clinical description of positional vertigo is attributed to Barany in 1921 and in 1952 Dix and Hallpike were the first to clearly describe the provoking maneuvers.[4, 5] Dix and Hallpike coined the term 'benign paroxysmal positional vertigo' in view of the associated benign (non-cancerous) origin and momentary (paroxysmal) bursts of intense vertigo upon head movements (positional).[5] Lanska and Remler provide a concise historical account of the work that has led to our understanding of this condition.[6]

PATHOPHYSIOLOGY

Otoconia are calcium carbonate crystals embedded in the macula of the utricle and saccule. They have a greater density than the surrounding endolymph thus making the macula sensitive to changes in linear acceleration and, importantly, gravity. The semicircular canals, on the other hand, are sensitive to changes in angular acceleration. In BPPV otoconia from the utricle are thought to collect in the semicircular canals, making them abnormally gravity-sensitive. The net result is that changes in head position with respect to gravity result in an abnormal displacement of the cupula and stimulation of the corresponding vestibular afferents. This results in the characteristically abnormal eye movements and vertigo.

There are two theories of how this might occur. **Cupulolithiasis** proposes that degenerative otoconia stick to the cupula making it gravity-sensitive. Post-mortem findings of such deposits in patients who had suffered from BPPV add weight to this theory.[7]

The more recent theory of **canalolithiasis** gained momentum after surgical observations of free-floating debris in the posterior semicircular canal during an occlusion procedure.[8–10] This theory suggests that degenerative

otoconial debris float freely in the endolymph of the semicircular canal. When exposed to gravity, the otoconia fall to the lowest part of the canal, causing a change in endolymph pressure with subsequent displacement of the cupula. The change in pressure is due to a hydrodynamic 'plunger effect' where the otoconial debris act like a piston creating endolymph flow which deforms the cupula. This theory explains the 'latency' (delay in onset) of the nystagmus that is related to the time taken for the otoconial debris to fall and the initial adherence to the membranous canal. In addition, it may also better explain the 'fatiguability' as with repeated movements the otoconial debris may be dispersed or may become trapped in some part of the canal.[8]

While the majority of BPPV cases seem to be more compatible with the theory of canalolithiasis, some cases with atypical features may be explained on the basis of cupulolithiasis. Canalolithiasis may be converted to cupulolithiasis when otoconial debris floating in the canal attach to the cupula.

SYMPTOMS AND NATURAL COURSE OF THE DISEASE

BPPV most commonly arises from the posterior semicircular canal (p-SCC). Much less frequently the horizontal semicircular canal (h-SCC) is involved while the anterior canal (a-SCC) is very rarely affected.[3, 11–15] Honrubia et al.[14] report the prevalence of p-BPPV, h-BPPV and a-BPPV in their clinic as being 93%, 5% and 2% respectively, although other authors report a higher prevalence of about 8–10% for h-BPPV.[3, 16] Using electronystagmography (ENG) to make the diagnosis, Jackson et al. report posterior canal BPPV in 66.9%, horizontal canal in 11.9% and 21.2% with anterior canal.[17] BPPV may also arise from pathology of more than one canal on one or both sides.[3, 15, 18, 19]

The propensity for the accumulation of particles in the posterior canal is postulated to be related to anatomical factors such as the size of the common crus of the posterior and superior semicircular canals, its position below the utricle when supine and its dependent position when both erect and supine. Particles can become trapped in the posterior canal; any debris that may have entered the superior canal is more likely to fall back into the utricle.[20]

In the upright position, the horizontal canal's opening into the utricle is undermost, thus facilitating particle migration out of the canal, while the posterior canal's opening is uppermost. Therefore, the horizontal canal can be easily cleared by natural head movements but the posterior canal is a trap for any particles that have entered it. Similarly, particles may leave the horizontal canal just by the action of the person rolling over in bed whereas particles in the posterior canal will only be shifted backwards and forwards. This may explain the infrequent presentation of h-BPPV.

During manoeuvres, p-BPPV can be converted to either a-BPPV or h-BPPV to p-BPPV and a-BPPV to p-BPPV.[13, 21, 22] Similarly, bilateral apogeotropic h-BPPV may spontaneously convert to bilateral geotropic and is attributed to debris located in the anterior part of the canal sticking to the cupula dislodging and shifting to the posterior part of the canal.[16] Plugging of the horizontal canal presenting with persistent spontaneous nystagmus, vertigo and oscillopsia has also been described.[23]

The hallmark of p-BPPV is vertigo lasting seconds with or without nausea and imbalance on lying down, sitting up from the lying position, or rolling in bed and when extending or flexing the neck. These symptoms can present in clusters with several attacks per day. In between attacks or shortly after successful treatment, patients are either symptom-free or experience a sensation of imbalance. This sensation of imbalance can be described as 'walking on pillows' and may be attributed to the underlying damage of the otolith organs.[24] However, some patients may report atypical symptoms, and it is worthwhile conducting the positional tests in all patients presenting with episodic vertigo.[25] In the majority of cases the BPPV symptoms will subside within a few weeks, but in up to 30% the symptoms may persist for months.[16, 24] Choi et al. report BPPV as recurrent in 12.5% of cases and persistent in 10%.[26]

AETIOLOGY

Hallpike described ear disease in 66 out of 100 BPPV patients, although in only 28 ears was it on the side with the BPPV.[5] No cause has been found in 34–86% of patients.[12, 26–28] These cases have been termed 'primary' or idiopathic BPPV. However, there may also be an association with other pathologies:

- BPPV occurred in 9.8–15.3% of cases following vestibular neuritis.[29–31]
- Otosclerosis may be associated with BPPV in up to 51% of patients and may also occur following stapedectomy.[12, 28, 32, 33]
- Studies have suggested that Ménière's disease may be found in up to 2% of cases but it has been reported to occur in up to 30% of cases.[12, 27, 28] It has been postulated that hydropically induced damage to the maculae or partial obstruction may be responsible.[34]
- Head trauma is one of the most common causes of BPPV in 14.5–18%[12, 28] and can involve more than one canal.[19, 35] The force of the injury may cause the release of otoconia into the endloymph. BPPV can also result following traumatic spinal cord injury in up to 14.5% of cases.[36]
- Patients with positional vertigo may have migrainous vertigo. Migrainous symptoms during the positional episodes, atypical features of positional nystagmus and frequent recurrence of symptoms may differentiate between BPPV and the central positional syndrome due to migraine.[37]
- Otosclerosis and osteopenia are found with greater frequency in females with BPPV, particularly older postmenopausal women.[38–40]

- BPPV also is associated with progressive cochlear or vestibular failure, vertebrobasilar ischaemia and other vestibular disorders.[12, 28]

The common feature of these conditions is that they may lead to dislodgement of otoconia from the utricle, which may invade one or several semicircular canals after days, weeks or months.

In idiopathic BPPV, which becomes more prevalent with advancing age, release of otoconia is probably related to degeneration of the otolith organs. Risk factors that may initiate an acute episode of BPPV include prolonged bedrest, bending forward with the head down, and general anaesthesia, because the supine, head-down and head-reclined position (e.g. during intubation) lower the opening of the posterior canal, thus promoting the penetration of particles.[1]

DIAGNOSIS OF BPPV

Diagnosis of BPPV is made on the basis of typical signs (nystagmus) and symptoms (vertigo and nausea) provoked by specific positional tests. Understanding the characteristic eye movements during these tests will help in making the diagnosis.[41] Our understanding of vestibular eye movements is based on fundamental principles described by Ewald:

- The direction of eye movement is in the plane of the canal or canals that are stimulated.
- In the horizontal canal, endolymph flow towards the ampulla (ampullopetal) results in an excitatory and stronger response than flow away from the ampulla (ampullofugal), which is inhibitory. The opposite holds true for the vertical canals.

For example, the posterior canal and anterior canal pairs are stimulated when performing the Dix–Hallpike test. The patient is seated along the couch, feet up, and the head is turned 45 degrees towards the side being tested, aligning the vertical canals with the sagittal plane. The head is brought down briskly over the end of the couch to lie 30 degrees below the horizontal while maintaining a position 45 degrees to the side being tested. Patients should be counselled prior to the test about dizziness but that they are to try and maintain their eyes open for examination.

The **L**eft **A**nterior and **R**ight **P**osterior canals (**LARP**) are stimulated during the right Dix–Hallpike and the **R**ight **A**nterior and **L**eft **P**osterior (**RALP**) in the left Dix–Hallpike. During the right Dix–Hallpike there is ampullofugal (excitatory) flow in the right posterior canal and ampullopetal (inhibitory) flow in the left anterior. Normally this balances out and there is no nystagmus. However, if there were particles in the posterior canal, the ampullofugal forces would be greater, resulting in a net excitatory effect and eye movement consistent with the plane of the canal. The slow-phase eye movements when excitatory would be towards the right ear or downwards and inwards via the ipsilateral superior oblique muscle and the contralateral inferior rectus muscle. The fast phase would be upwards and outwards or upbeating geotropic-torsional nystagmus. This is best seen by closely watching the scleral vessels. The nystagmus typically reverses when sitting up. A cupulolithiasis type BPPV can also rarely occur and is characterized by nystagmus that occurs without latency and does not fatigue.

The side-lying test is an alternative and has been shown to produce similar results to the Dix–Hallpike.[42] In contrast to the Dix–Hallpike, the head is turned 45 degrees away from the side being tested such that the vertical canals are in the frontal plane. The patient is quickly moved to a supine-lying position with the neck hyperextended 20 degrees. The typical torsional nystagmus is seen beating towards the lowermost ear.

Similarly, the anterior canal during a right Dix–Hallpike or side-lying tests will be inhibited, i.e. flow will be ampullopetal. If particles are present, they will cause an inhibitory effect which will predominate causing the opposite nystagmus to the posterior canal – beating downwards and intorsional in the ipsilateral eye. The straight head-hanging manoeuvre has also been shown to be useful to diagnose a-BPPV where the head is extended backwards to a head-hanging position of the end off the bed from seated to supine.[43]

Horizontal canal BPPV is assessed using the roll test. The head is flexed 30 degrees, bringing the horizontal canal into the axial plane, and is then briskly rolled to one side. The same is repeated to the opposite side. In the majority of cases the nystagmus will be horizontal and geotropic and towards the ear being tested. When turned to the opposite side, the nystagmus will reverse and beat towards the undermost ear again. When a canal is stimulated with an ampullopetal force, the nystagmic response is greater (Ewald's second law), therefore the ear containing the loose particles would generally present with the brisker nystagmus hence helping to make the diagnosis. An apogeotropic nystagmus is also described and is thought to be related to cupulolithiasis.[16] In this situation, when the head is turned to the affected side, the force is ampullofugal hence the nystagmus will beat away (apogeotropic) from the affected ear.

Frenzel glasses can be used to better observe the nystagmus or it can be recorded with electro- or video-oculography. As BPPV can sometimes coexist with other vestibular disorders and the history can sometimes be atypical, many would perform a Dix–Hallpike routinely as part of a vestibular assessment.

Differential diagnosis

Causes of vertigo that need to be distinguished from BPPV include otological and neurological among others.[44] Otolological disorders include Ménière's disease, vestibular neuritis, labyrinthitis, superior canal dehiscence syndrome and post-traumatic vertigo. Neurological disorders include vestibular migraine, vertebrobasilar insufficiency, demyelinating lesions and

CNS lesions. It is important to discriminate BPPV from positional vertigo arising from central pathology. Such pathology may exist in the pontomedullary brainstem or vestibulocerebellum, with lesions often found dorsolateral to the fourth ventricle or in the dorsal vermis.[24, 45] A central lesion should generally be suspected when features different from BPPV are present or when brainstem or cerebellar signs are found. Single characteristics of BPPV such as latency, duration and time course of nystagmus, and fatigability with repeated positioning can also occur in central positional vertigo. However, it is unlikely that a central lesion mimics the entire nystagmus pattern of BPPV. The most reliable criterion to distinguish BPPV from central positioning vertigo is the direction of nystagmus: when the affected canal is optimally stimulated in BPPV by specific head positioning in the canal plane, the nystagmus always beats in the plane which is expected from activation of that particular canal.[45, 46] Thus, in the Dix–Hallpike position, p-BPPV always provokes a combined torsional and vertical component, which is expected from the connections between the p-SCC and specific eye muscles. Likewise, h-BPPV evokes horizontal nystagmus of maximal intensity after specific positioning for the horizontal canal.

In contrast, central positional nystagmus is not attributable to the stimulated canal plane. Purely vertical or torsional nystagmus, verified by examination under Frenzel glasses, should always raise the suspicion of a central lesion as it cannot be explained by stimulation of a single semicircular canal. Central positional nystagmus often persists as long as the precipitating head position is maintained whereas BPPV produces transient nystagmus and vertigo, except for the horizontal cupulolithiasis variant. Moreover, central positional vertigo and nystagmus usually does not fatigue with repetitive positioning. Another feature distinguishing central positional vertigo from BPPV is its monophasic course that makes the diagnosis highly unlikely in a patient with a long-standing history of recurrences and remissions. Rarely, central pathology may mimic typical BPPV except for response to therapeutic positional manoeuvres.[16] In summary, imaging of the posterior fossa is required when:

- nystagmus is atypical for any of the BPPV syndromes
- brainstem or cerebellar signs are present
- positional vertigo does not resolve with repeated therapeutic manoeuvres.

In a patient with central positional vertigo and normal imaging, migrainous vertigo or drug effects (e.g. amiodarone) should be considered.[47, 48] When central positional nystagmus without vertigo occurs as an isolated finding, imaging is often negative and a specific diagnosis cannot be made.

Other causes of dizziness include anxiety disorders and postural hypotension.

TREATMENT OF P-BPPV

Repositioning manoeuvres

EPLEY'S REPOSITIONING MANOEUVRE

The canalith repositioning manoeuvre (CRM) (**Figure 64.1**) has been recommended following evidence-based reviews by the American Academy of Neurology and American Academy of Otolaryngology – Head and Neck Surgery Foundation.[44, 49] A recent Cochrane meta-analysis has found that the CRM on its own is effective in close to 80% of cases.[50]

Epley developed the canalith repositioning procedure (CRP) in 1992 based on the theory of 'canalolithiasis' in order to move the particles from the posterior canal into the utricle via the common crus.[51] It is well tolerated and non-invasive. Patients should be counselled about the procedure and the possibility of vertigo prior to commencement. The affected p-SCC is identified by the Dix–Hallpike manoeuvre and the latency and duration of nystagmus is noted in order to determine the timing of the procedure. The patient is seated longitudinally on the couch facing away from the examiner and brought down with the head turned by 45 degrees to the affected side and extended over the edge of the table, just as in the Dix–Hallpike manoeuvre, and can of course follow on from the Dix–Hallpike. The head is then turned 90 degrees to the opposite side, rotating the body 90 degrees so that the patient is lying on the side, while the head is maintained firmly in place is the next step. The head is then rotated a further 90 degrees so that the patient is looking obliquely downwards. The patient is then asked to swing their legs over the side of the couch in anticipation of the next step which involves the patient being brought to the sitting position with the head turned 45 degrees to the unaffected side. The CRP finishes with the patient in the sitting position and the head turned forward 20 degrees. Epley advocated repeating the manoeuvre until there is no nystagmus or no progress made in the last two cycles. He reported total resolution of symptoms in 90%, and resolution of BPPV but persistence of other symptoms in 10% of patients after the initial CRP treatment. There are several modifications of this manoeuvre involving longer maintenance at each position and gradual position changing with 30-second intervals.[52, 53] A recent Cochrane review suggested limited evidence to support postural restrictions post-treatment, but to remain upright and limit head movement for 24–48 hours appears to offer increased treatment benefit.[50]

A modified Epley's manoeuvre has also been used for self-treatment and its efficacy compared to the efficacy of the Brandt–Daroff exercises. The authors reported a 64% success rate after 1 week in the group of patients that were given the Epley's manoeuvre compared to 23% in those given the Brandt–Daroff exercises. Treatment failures in the Epley's group were attributed either to early discontinuation or to inaccurate performance of the manoeuvre.[54]

Figure 64.1 Epley's repositioning manoeuvre. Left posterior canal BPPV. The patient is sat on the table with the head turned 45° to left side (affected side) **(a)**, and **(b)** brought down rapidly with the head still turned 45° to the affected side and extended over the edge of the table. Note that the neck is well supported. **(c)** The head is then turned 90° to the opposite side (right). **(d)** This is followed by rotating the head and body 90° facing downwards (135° from the supine position). **(e)** The legs are then displaced over the side of the table in anticipation of a return to a seated position, and **(f)** the patient is brought to a sitting position with the head turned forward.

SEMONT'S LIBERATORY MANOEUVRE

Semont, Freyss and Vitte devised what is known as the Semont's liberatory manoeuvre (**Figure 64.2**) that involves laying the patient on the affected side from a seated position, with the face turned upwards 45 degrees away from the affected canal.[55] The patient is quickly swung through the sitting position without pausing to the opposite side with the face now facing downwards by 45 degrees. The head position relative to the shoulder remains unchanged during the manoeuvre and the position should be maintained for 5 minutes. The patient then slowly resumes the sitting position. The authors reported resolution of symptoms in 92% of patients treated once or several times with this manoeuvre.[58] While studies have shown an improvement when this procedure is performed, a superior benefit to CRP has not been conclusively demonstrated according to one review[44] and is possibly not as good as CRP according to another.[49] Some authors, however, maintain that the ease of use makes it a useful option.[56]

BRANDT–DAROFF POSITIONAL EXERCISES

In 1980, Brandt and Daroff proposed a mechanical self-treatment that is based on Schuknecht's hypothesis of cupulolithiasis.[57] This consists of a rapid sequence of lateral head/body tilts. Starting from the sitting position, the patient rapidly moves to the challenging position, i.e. lying on the affected side (nose 45 degrees up)

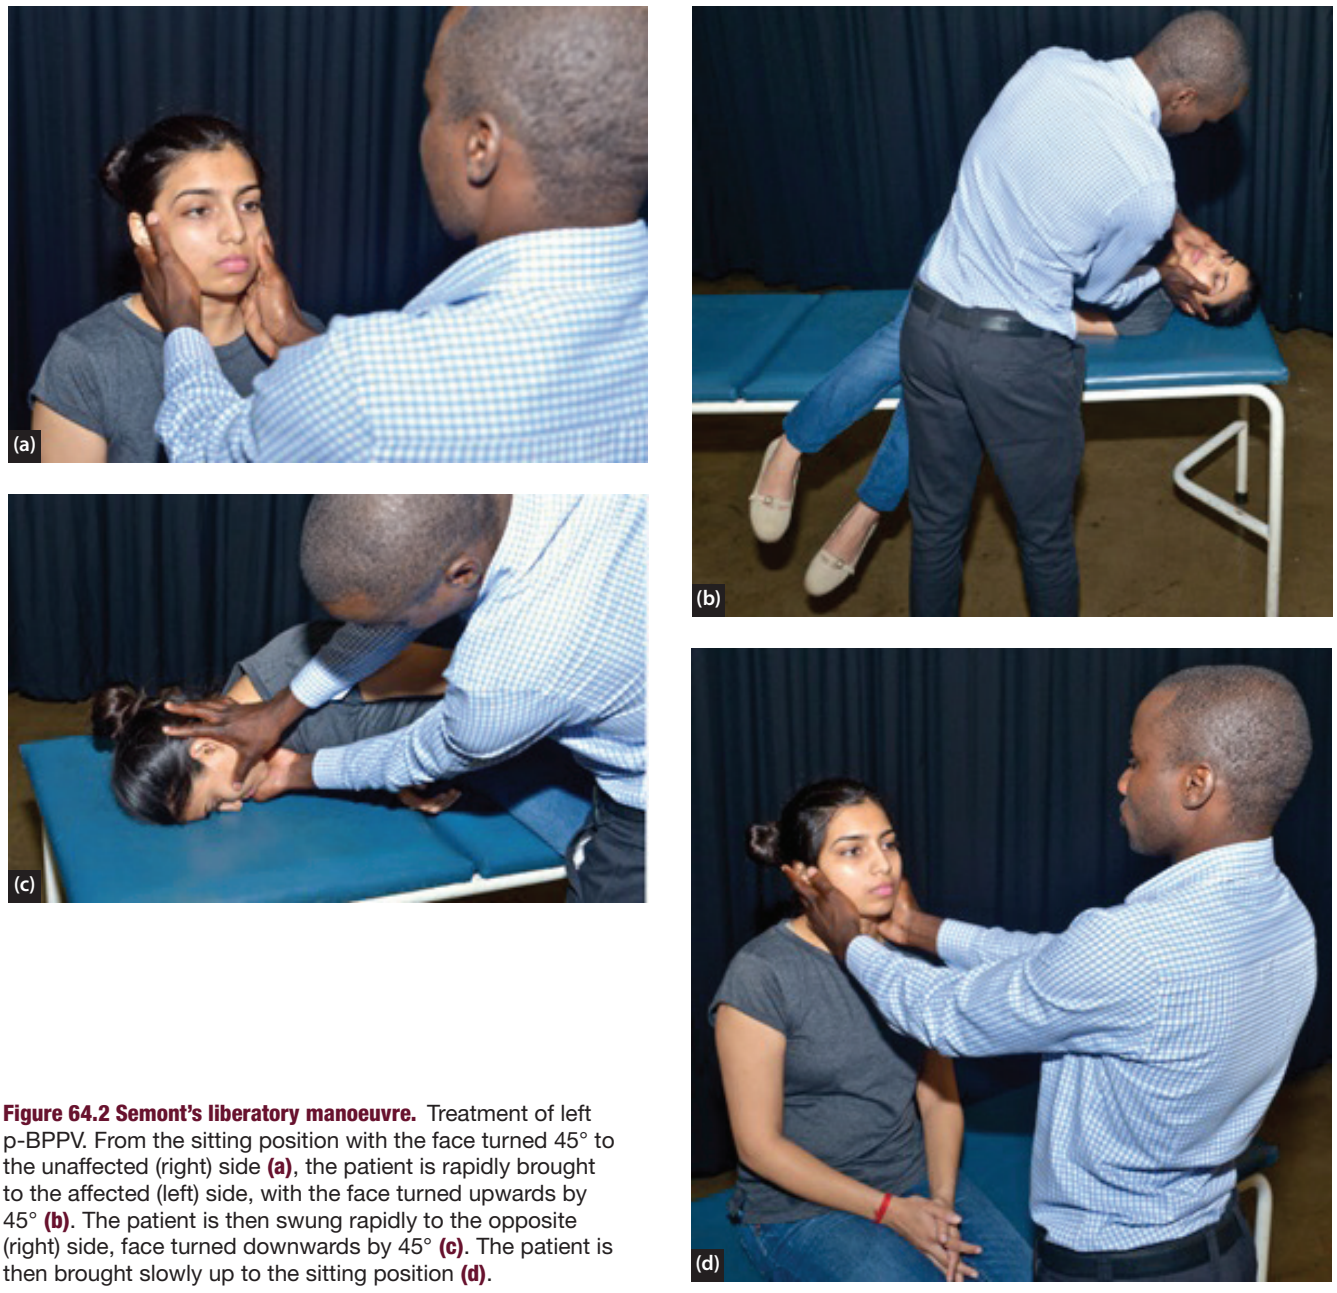

Figure 64.2 Semont's liberatory manoeuvre. Treatment of left p-BPPV. From the sitting position with the face turned 45° to the unaffected (right) side **(a)**, the patient is rapidly brought to the affected (left) side, with the face turned upwards by 45° **(b)**. The patient is then swung rapidly to the opposite (right) side, face turned downwards by 45° **(c)**. The patient is then brought slowly up to the sitting position **(d)**.

and remains in this position for at least 30 seconds or until the vertigo subsides. The patient then sits up for 30 seconds and thereafter assumes the opposite head lateral and nose-up position for 30 seconds before sitting up. This is repeated for 15 minutes three times daily. The authors reported that 66 out of 67 patients experienced complete relief from BPPV within 3–14 days, the exception being one patient who had a a perilymphatic fistula. Clinical experience has shown that response rates are usually lower and a controlled trial showed resolution of BPPV in only 23% after 1 week.[54] Thus, Brandt–Daroff involves dozens of self-induced vertigo attacks before BPPV may eventually disappear. For this reason, they are no longer a first-line treatment of BPPV. A review has shown that Brandt–Daroff exercises are not as effective as CRP.[49]

FACTORS THAT MAY INFLUENCE THE OUTCOME OF REPOSITIONING MANOEUVRES

Reports on whether the application of mastoid oscillation improves the efficacy of the particle-repositioning manoeuvre are contradictory, and in any case, the success rate of the CRP alone is quite high.[58, 59] Some clinicians give post-treatment instructions that include sleeping with two high pillows, wearing a collar and postural restriction for 48 hours after the repositioning manoeuvre. A≈recent Cochrane review has found a lack of evidence to suggest a benefit from mastoid oscillation although a significant but limited benefit may be obtained from postural restriction.[50]

The effect of the duration of symptoms before treatment on CRP success rate is controversial, as some authors report it to be a negative prognostic indicator while others report no correlation.[52, 60, 61] Patients with BPPV due to head trauma tend to improve less with treatment than idiopathic BPPV patients while patients with previous 'vestibular neuronitis' seem to have a better prognosis than patients with BPPV due to other aetiologies.[52, 62]

Studies have assessed the treatment of patients with positional vertigo but no detectable nystagmus on positional testing, i.e. 'subjective' BPPV. In these studies the side to treat was chosen on the basis of the symptoms reported on positional testing.[63–65] Tirelli et al.[63] found that treatment of 43 patients with positional vertigo without positional nystagmus by a modified Epley resulted in a 60% complete recovery rate and a 6% persistence of symptoms compared with a 90% complete recovery rate in 90 patients with typical BPPV. Haynes et al. reported symptomatic improvement with 86% in subjective BPPV after performance of an average of 1.1 Semont's manoeuvres and in 91% of patients with objective BPPV after 1.6 manoeuvres on average.[64] Neither of the studies included a control group with a sham manoeuvre. Weider[65] also reported on 48% of their cohort of 44 patients with symptoms of BPPV with no nystagmus on positional testing. Twelve patients had complete relief following an Epley manoeuvre but patients with long-standing symptoms were less likely to report a good result. It has been suggested that a subgroup of these patients may have otoconial debris in the short arm of the posterior canal.[66] However, other reasons could relate to the fatiguable nature of the nystagmus in BPPV, a mild form that may be suppressed by visual fixation or poor detection without the use of Frenzel glasses.[64]

The CRM has been recommended following evidence-based reviews by the American Academy of Neurology and American Academy of Otolaryngology – Head and Neck Surgery Foundation,[44, 49] and has been found to be effective on its own in nearly 80% of cases. The use of additional interventions such as post-treatment postural restrictions may further increase the treatment benefit but there is limited evidence to support this and only a small increase in treatment efficacy.[50] Hunt et al. did not find added benefit in using mastoid oscillation or additional steps with the Epley manoeuvre. There is no evidence to support the use of medication.[44, 49]

COMPLICATIONS AND ADVERSE REACTIONS

Several patients report gait instability following CRP, possibly due to the new position of the canaliths in the utricle.[67] Complications of CRP include conversion of p-BPPV to a-BPPV or h-BPPV in about 6% of treated patients.[13] In addition, the nystagmus may convert to a rapid form that persists and is unaffected by positional testing, possibly due to canalith jam, and these cases may be treated by the combination of the application of vibration with repositioning manoeuvres.[68]

Both Epley's and Semont's manoeuvres involve some neck strain and may be uncomfortable or impossible to perform in patients with severe cervical problems. The best solution in this situation is to do an Epley's manoeuvre on a couch where the upper half of the body can be lowered by 20–30 degrees, which obviates the need for head reclination. Brandt–Daroff exercises can be an alternative but are sometimes not pursued for long enough by immobile, elderly patients with neck pain.

Recurrence of BPPV increases with length of follow-up and eventually occurs in most patients. It is more likely in patients with secondary causes and should be treated with repeated positional manoeuvres.[26, 69]

Surgical treatment of BPPV

In a series of 5364 BBPV patients over a 20-year period, 53 patients failed to respond to repositioning manoeuvres and underwent p-SCC occlusion surgery.[70] While all were cured of their vertigo, nine patients suffered some degree of permanent hearing loss, ten developed objective balance dysfunction on caloric testing while five complained of subjective imbalance. Two patients later developed h-BPPV in the same ear and eight developed p-BPPV in the opposite ear, with two patients needing bilateral posterior canal occlusion. A number of case series describing the results of posterior canal occlusion can be found in the literature with similar results for control of the BPPV and many reporting the attendant risk of hearing loss and subjective dizziness.[71–77]

Gacek has advocated singular neurectomy via a transcanal approach for patients with chronic disabling vertigo for longer than a year and has reported on his and the results of others over three decades.[78–81] Surgery was performed on 242 patients, with 10 undergoing bilateral procedures. Complete relief (negative Dix–Hallpike) was achieved in 96.8% of cases with nine patients (3.7%) suffering sensorineural hearing loss.[81]

TREATMENT OF H-BPPV

Repositioning manoeuvres

'FORCED PROLONGED POSITION' ON THE HEALTHY SIDE

Vannucchi et al. advised patients with h-BPPV to lie down on the healthy side for 12 hours in order to facilitate gravitation of the debris into the vestibule by maintaining the affected h-SCC uppermost.[21] They reported total recovery within 3 days in 74.3% of cases out of 35 treated patients. They described occasional conversion of h-BPPV to homolateral p-BPPV, which was successfully treated with a Semont's manoeuvre. By contrast, the rate of recovery within 3 days in the group of patients who received no treatment (15 patients) and in those treated by head shaking (24 patients) was 26% and 16% respectively. Obesity and cervical spondylosis were factors that did not permit maintenance of the position for the time required.

270-DEGREE 'BARBECUE' MANOEUVRE

Lempert and Tiel-Wilck report the successful treatment of h-BPPV in two patients by an adaptation of Epley's manoeuvre.[82] This consists of turning the patient's head initially and then the body from the supine position in three 90-degree-step rotations (total 270 degrees) towards the unaffected ear. The body will eventually assume the prone position with the affected ear facing down, following which the patient will sit up. The rotation is performed within half a second and the head positions are maintained for 30–60 seconds.

Nuti et al. reported that, while both the 'barbecue' manoeuvre and the forced prolonged position are effective treatments for h-BPPV, the forced prolonged position may be successful in slightly more cases than the barbecue manoeuvre, which, however, achieves immediate results.[83]

360-DEGREE YAW ROTATION

Baloh et al. initially suggested a 180-degree rotation to the unaffected side with little success and then successfully treated two patients with h-BPPV with a 360-degree yaw rotation performed in 90-degree steps at 30-second intervals.[84] Casani et al. report an 89% success rate in 55 cases with geotropic h-BPPV treated by a combination of the 360-degree yaw rotation and forced prolonged position after one to three attempts.[16]

LIBERATORY MANOEUVRES

De la Meilleure et al. used this manoeuvre in six patients with h-BPPV. From the supine position, the head is lifted by 30 degrees, turned to the affected side and maintained in that position for 5 minutes.[15] The head is then turned quickly 180 degrees to the other side while maintaining 30-degree flexion and held there for 5 minutes. After the manoeuvre, the patient is asked to avoid head shaking and not to lie down for the next 48 hours. A 100% success rate has been reported, but patients may require treatment for bilateral h-SCC or for coexisting p-BPPV. Contraindications for this manoeuvre are cervical spondylosis, vertebrobasilar insufficiency or neck pain during the manoeuvre. The recommendation to perform an abrupt head rotation casts doubt on the safety of this procedure as vertebral artery dissection has been occasionally observed after chiropractic manipulations of a similar type.

Appiani et al. used the liberatory manoeuvre proposed by Asprella et al. for geotropic h-BPPV with a 78% cure rate after the first and 100% cure rate after the second attempt.[85] This manoeuvre begins with the patient seated on the side of the couch. A side-lying position is then quickly assumed on the unaffected side and maintained for 1 minute after the cessation of the nystagmus. The head is then quickly turned 45 degrees downwards and the position maintained for 2 minutes followed by a slow return to the sitting position. A similar manoeuvre, termed a 'modified Semont's', was used by Casani et al. for nine patients with apogeotropic h-BPPV with 55% success rate after two attempts.[16] The only difference between the Appiani manoeuvre and what Casani proposed is a rapid return to the seated position at the end.

A prospective randomized controlled trial for geotropic h-BPPV was conducted in 179 consecutive patients comparing the barbecue rotation, the Gufoni manoeuvre and a sham manoeuvre.[86] The Gufoni manoeuvre for geotropic nystagmus begins with the patient seated in an upright position and rapidly tilted to the unaffected side followed by a swift 45 degree downward turn of the head (nose down). A few minutes later the patient resumes a seated position. For apogeoptrpoic nystagmus the patient lies on the affected side followed by an upward turn of the head.

Outcomes included the resolution of vertigo and positional nystagmus assessed within 1 hour of two applications of each manoeuvre and the percentage resolution at 1-month follow-up. Both on the assessment day and at 1-month follow-up the barbecue rotation and Gufoni manoeuvre showed better responses than the sham manoeuvre, with no significant difference between the two procedures.

In another prospective randomized controlled trial of 157 consecutive patients with apogeotropic h-BPPV the Gufoni, head shaking and a sham manoeuvre were assessed.[87] Outcome measures included the resolution of vertigo and positional nystagmus assessed after a maximum of two applications on the same day, the following day and at 1-month follow-up. The therapeutic manoeuvres were better than the sham on the same day and at 1-month follow-up with no significant difference between the two. The Gufoni manoeuvre did, however, have a higher conversion rate to other types of nystagmus.

A prospective randomized controlled study of 63 patients with geotropic h-BPPV compared the Lempert (270 degree barbecue manoeuvre) manoeuvre with no treatment.[88]

Outcomes include patients' self-reported resolution of vertigo after the resolution of nystagmus and the time course in remission of positional vertigo. No significant difference was found in the time course of remission of positional vertigo between treated and untreated groups.

A prospective cohort was compared with retrospective data assessing prolonged forced position, head shaking and no treatment in patients with geotropic horizontal BPPV.[21] Forced prolonged position on the healthy side was significantly better than head shaking or no treatment at 3-day follow-up.

COMPLICATIONS AND ADVERSE REACTIONS

H-SCC canalolithiasis may convert to cupulolithiasis after a rotation manoeuvre, which, exceptionally, may in turn convert to horizontal canal-plugging by head shaking. The horizontal canal-plugging will be characterized by continuous unidirectional nystagmus that is not affected by positional testing. However, vigorous head shaking or gentle head percussion may unplug the canal.[23]

TREATMENT OF A-BPPV

A 96.7% efficacy has been reported for the modified Epley manoeuvre performed on 30 successive cases with a-BPPV.[89] The modified Epley starts using the Dix–Hallpike with the head turned 45 degrees away from the affected ear and brought to 30 degrees below the horizontal. It is kept in this position for 30 seconds then elevated while maintaining a supine position with the head at 45 degrees for 1 minute. A seated position is then assumed with the chin bent forwards at 30 degrees.

An alternative manoeuvre has been described involving moving from a seated to a head-hanging position with the head 30 degrees below the horizontal. After 30 seconds the head is brought to a chin-to-chest position for 30 seconds and then to a seated position for another 30 seconds. During the manoeuvre otoliths move towards the common crus and utricle. The authors described 84.6% success after a single manoeuvre, with complete resolution in all cases with repeated manoeuvres.[90]

BEST CLINICAL PRACTICE

- ✓ For posterior semicircular canal BPPV the canalith repositioning manoeuvre is safe and effective on its own in close to 80% of cases.
- ✓ Surgical options can be contemplated with long-standing BPPV where there has been no response to repeated appropriate repositioning manoeuvres.
- ✓ Imaging of the posterior fossa is required when:
  - ✓ nystagmus is atypical for any of the BPPV syndromes
  - ✓ brainstem or cerebellar signs are present
  - ✓ positional vertigo does not resolve with repeated therapeutic manoeuvres.

KEY POINTS

- BPPV is the commonest cause of peripheral vertigo.
- If unrecognized or poorly treated BPPV can lead to significant morbidity.
- BPPV results from particles floating in the semicircular canals (canalolithiasis) or attached to the cupula (cupulolithiasis).
- The posterior semicircular canal is most often affected.
- The vertigo typically lasts seconds and is positional.
- The majority of cases are idiopathic.
- The diagnosis is made using positional tests that produce nystagmus and vertigo.
- Repositioning manoeuvres displace the particles back into the vestibule and are successful in the majority of cases.

CHAPTER 65

SUPERIOR SEMICIRCULAR CANAL DEHISCENCE

Harry R.F. Powell and Shakeel R. Saeed

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords superior semicircular canal dehiscence and superior semicircular canal dehiscence syndrome.

HISTORY

The association of vertigo or oscillopsia induced by pressure change or loud sounds, with dehiscence of the superior semicircular canal (SSC) was first described in 1998.[1] Using the scleral coil technique Lloyd Minor's team noted that eye movements evoked by sound or pressure stimuli aligned with the SSC.[2] Dehiscence of otic capsule bone overlying the SSC was identified on computerized tomography (CT). Superior semicircular canal dehiscence (SSCD) syndrome has subsequently become a recognized clinical condition that encompasses a wide variety of vestibular and auditory symptoms.

In 1949 Cawthorne[3] postulated that a 'third window' mechanism accounted for the positive Hennebert sign of labyrinthine fistula. Dehiscence of bone over the SSC and consequent connection with the middle cranial fossa provides a third mobile window into the inner ear in SSCD syndrome (SSCDS). Typical third window symptoms of SSCD occur either as a result of movement at the dehiscence from raised intracranial pressure, or at the oval or round windows from loud sounds or straining (e.g. a Valsalva manoeuvre against closed nostrils forcing air up the Eustachian tube and into the middle ear). Resultant alterations in inner ear fluid dynamics due to the third window cause increased firing of vestibular afferents and transient momentary vertigo.

As familiarity with SSCDS has increased there has been a massive increase in publications in the world literature, particularly in the last 5 years, as clinicians and scientists attempt to unravel the aetiopathogenesis and optimal diagnostic and management strategies for this relatively new condition.

PATHOPHYSIOLOGY

A constellation of symptoms can occur with SSCDS and the severity and spectrum of symptoms varies enormously. The mechanisms for all of them are not yet fully understood. However, the third window symptoms that underpin how the condition was discovered occur in two main ways. Marked inward movement of the stapes (raised middle ear pressure or loud sounds) leads to increased ampullofugal flow of endolymph away from the ampulla of the SSC (on the affected side), which is excitatory and causes tonic upward eye movement and ipsilateral intorsion (rotation of the upper pole of the eye towards the midline). Conversely, inward movement at the dehiscence causes ampullopetal flow towards the ampulla, which is inhibitory and causes tonic downward eye movement and ipsilateral extorsion.[2] The physiological basis for the variability of symptoms and signs between patients is not yet understood.[4] Suggested reasons are differences in the elasticity of the dura over the SSCD, differences in compliance of the round window

membrane, relative patency of the cochlear aqueduct and variance in the size of the dehiscence.[5]

EPIDEMIOLOGY AND AETIOLOGY

A 0.5–0.6% prevalence of SSCD has been observed in histological studies of cadaveric temporal bones.[6, 7] By comparison, reported prevalence from studies reviewing high-resolution temporal bone CT scans was 4–8%.[7–9] This discrepancy is explained by the effect of partial volume averaging in CT, which reduces with higher resolution finer slice collimation. Dehiscence alone is not sufficient to cause the syndrome, and many patients have dehiscence but are asymptomatic.

SSCDS could be congenital, acquired or a combination where a genetic predisposition followed by a secondary event triggers SSCDS. Predominant middle-aged onset and a statistically significant increase in prevalence with increasing age[10] make a pure congenital cause less likely. However, SSCDS has been reported in children[11] and affected siblings,[12] implicating genetic factors. Due to protrusion of the membranous labyrinth into the middle cranial fossa in fetuses, adhesion with the overlying dura has been postulated to prevent entire bone coverage of the SSC in some individuals.[13]

Ossification of the petrous bone over the labyrinth occurs from birth to the age of 3.[6] If the bone is insufficient, the resulting morphological abnormality may predispose certain individuals to SSCDS. Shearing force from a closed head injury, trauma to the temporal bone, slow erosion of thin bone, increased dural elasticity with time or sudden increase in intracranial pressure are all suggested secondary triggers.[14] A cadaveric study concluded that, when only an endosteal layer is present over the SSC, this is susceptible to a second event which could cause dehiscence and hence the SSCDS.[15] A progressive negative balance of labyrinthine osseous metabolism occurring with a congenital thin layer of bone over the SSC has also been suggested.[16] Absence of a single convincing theory suggests a combined or multifactorial aetiopathogenesis is responsible for SSCDS.

CLINICAL MANIFESTATIONS

Patients may present with a variety of signs and symptoms, either exclusive vestibular symptoms, less commonly exclusive auditory symptoms[12] or a combination. One study showed that, when the dehiscence is greater than or equal to 2.5 mm on CT, patients tend to experience combined auditory and vestibular symptoms.[17] Auditory symptoms include hearing difficulty/loss, autophony, pulsatile tinnitus and a description of hearing their eye movements or their footfall. The latter are from abnormal amplification of certain sounds in the body due to increased sensitivity to bone-conducted sound. The hearing loss is an apparent conductive loss with greater air–bone gap (ABG) in the low frequencies due to supranormal bone-conduction thresholds and suspected dissipation through the dehiscence of acoustic energy transmitted by air-conduction mechanisms.[18, 19] There is consensus from some studies that the dehiscence size correlates with the size of the ABG.[20, 21] The autophony of SSCDS usually involves hearing their own voice but not their breathing when compared with patients who have patulous Eustachian tube.[22] The Weber tuning fork test typically lateralizes to the affected side and patients may be able to hear a tuning fork placed on the lateral malleolus of the ankle.[23]

The Tullio phenomenon of vestibular symptoms occurring in response to loud sounds was first noted in patients with otosyphilis and described in 1929. Transient vertigo, imbalance and oscillopsia can all occur with loud sounds or intracranial or middle ear pressure changes in SSCDS and the physiological third window effect is responsible. Generalized imbalance may be a result of fluctuation in the vestibular system that the brain struggles to compensate for. Although a non-specific symptom, generalized imbalance has been shown to improve in patients undergoing surgical treatment for SSCDS.[19, 24]

INVESTIGATIONS

Cross-sectional imaging

High-resolution CT is the gold standard for identification of SSCD. The imaging data are reformatted in the coronal plane as standard (**Figure 65.1a**) but can also be reformatted in the plane of the SSC (Pöschl view) (**Figure 65.1b**) and/or the orthogonal plane (Stenvers view).[25, 26] Due to partial volume, averaging CT results in false-positives and overestimation of dehiscence size as shown in a study comparing CT and surgical findings.[27] To improve specificity and positive predictive value 0.5 mm collimated scans with Pöschl plane reformatting are advised.[28] More recently the senior author and colleagues have been utilizing cone beam CT to give higher-definition imaging and improve sensitivity and specificity.

Using magnetic resonance imaging as an adjunct or instead of CT has been suggested in an attempt to reduce ionizing radiation exposure. Fast imaging employing steady-state acquisition (FIESTA) MRI has been shown conclusively to exclude SSCD, with negative predictive values as high as 100%,[29] but MRI cannot consistently diagnose thin or dehiscent SSCs.[30]

Vestibular evoked myogenic potentials

Vestibular evoked myogenic potentials (VEMPs) are recorded in response to high-intensity narrow-band clicks or tone bursts. In ocular VEMP (oVEMP) testing surface electrodes beneath the eye pick up excitatory responses of the extraocular muscles. Sensitivity and specificity of oVEMPs are reported as greater than 90%[31] and their use has been suggested as a screening tool for SSCDS prior to high-resolution CT and consequent radiation exposure. Cervical VEMPs are short-latency relaxation potentials recorded by surface electrodes placed on the skin over the ipsilateral sternocleidomastoid muscle when it is

Figure 65.1 CT images of dehiscent right superior semicircular canal. **(a)** Coronal, **(b)** oblique coronal reformat in plane of SSC ('Pöschl view').

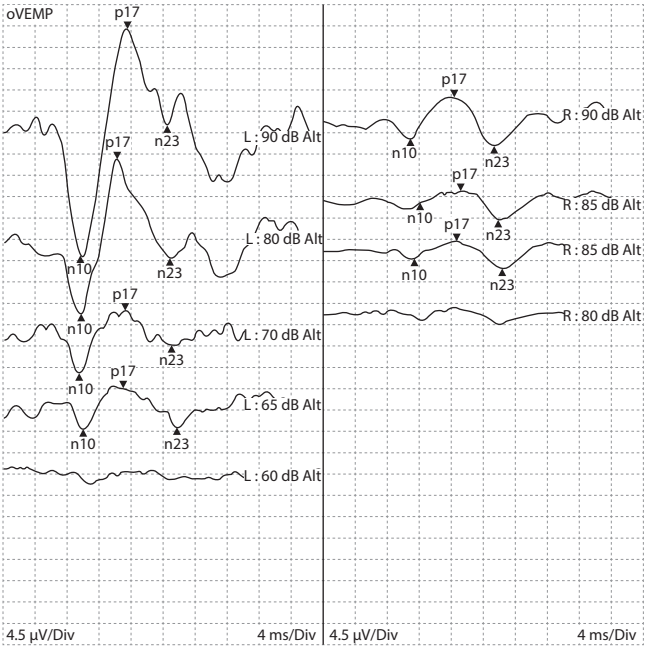

Figure 65.2 Cervical VEMP traces from a patient with left SSCDs. The lowest measurable response (initial inhibition followed by excitation) is at 85 dB on the normal right side. Responses on the left side are present down to 65 dB, which is lower than normal and suggestive of a third window.

tonically contracted (Figure 65.2). Cervical VEMP sensitivity and specificity for diagnosing SSCDS ranges from 80% to 100%.[31] VEMP responses are likely to be from the saccule (cervical) and utricle (ocular).[32–34] It is postulated that the saccule is more sensitive to sound stimuli than normal when there is a third window from SSCD.

Patients with SSCDS have VEMP responses present at lower than normal thresholds for the affected ear in both air conduction and bone conduction.[33] Some studies have also shown larger VEMP amplitudes.[23, 35]

Accurate diagnosis of SSCDS is reliant upon concordant clinical, radiological and electrophysiological findings.

MANAGEMENT

Patients with mild symptoms that are not intrusive or bothersome should be treated conservatively and given advice on avoidance of triggers or stimuli.[19, 36] Ventilation tube insertion has been beneficial for some patients with predominant pressure-related symptoms.[36] This reduces the influence of pressure change in the middle ear cleft but does not deal with the pathology directly.

Surgical management has evolved since 1998. Techniques that address the SSC itself include plugging, capping and resurfacing.[37] Initially, access was through a middle fossa craniotomy.[1] In 2009 the first transmastoid approach to the SSC was described.[38] Round window reinforcement has more recently been proposed in a multicentre series with six surgeons using a permeatal or endaural approach.[24]

If symptoms are disabling or detrimentally affecting a patient's day-to-day life and when those symptoms are predominantly attributable to a diagnosis of SSCDS, surgical management should be offered. The procedure, its risks and alternatives should be explained to enable patient-centred decision-making. In a single-centre series spanning 3.5 years 25/37 patients were offered surgical intervention.[19] The choice of technique or approach is obviously determined by the experience of the surgeon and team.

Middle fossa craniotomy has the advantage of direct visualization of the dehiscence. The disadvantages are the inherent risks of craniotomy and temporal lobe retraction and the necessity for longer inpatient hospital stay. Plugging, capping, resurfacing or combined plugging and resurfacing can all be achieved. The aim of capping and resurfacing is to cover but not occlude the SSC with the intention of inflicting less post-operative dysequilibrium or imbalance. These techniques are also thought to carry lower risk to the cochlea and consequent sensorineural hearing loss than plugging.[39] Bone, cartilage grafts, hydroxyapatite cement or fascia have all been used. A combination of temporalis fascia, bone pâté and/or bone wax have been used for plugging.[37]

An endoscopic middle cranial fossa (MCF) approach has been described.[40] It did enable shorter operative and recovery times but still carries the risks of craniotomy.

The transmastoid (TM) approach has become more common as otologists have become familiar with SSCDS. Kirtane et al.[38] adapted Lorne Parnes' technique for occlusion of the posterior semicircular canal described for benign paroxysmal positional vertigo (BPPV)[41] and applied it to the SSC as TM plugging. The disadvantage or main criticism from sceptics was a lack of direct visualization of the dehiscence. TM resurfacing[19, 39] has subsequently been reported using silicone elastomer sheeting (silastic) or a combination of bone pâté and fibrin sealant (Tisseel) to cover the dehiscence. TM resurfacing requires skeletonization of the labyrinth and exposure of the MCF dura lateral to the SSC. The dura can then be lifted off the MCF floor and the extent of the dehiscent SSC identified with the reflective surface of a round knife (**Figure 65.3**). The TM approach may be less feasible when there is significant 'overhang' of the dura lateral to the SSC or if there is extensive tegmen dehiscence requiring simultaneous reconstruction.[36] Another anatomical variant that poses a particular challenge to TM resurfacing is if the orientation of the dehiscence is such that the exposed canal, particularly the posterior limb, faces obliquely/medially.[19]

Round window (RW) techniques may in future obviate the need for craniotomy or mastoidectomy. Kartush hypothesized that patients previously thought to have perilymph fistula and successfully treated with round and/or oval window patching may actually have had SSCDS.[24] RW occlusion was reported using bone wax and fascia[42] but results were not replicable, heralding adaptation to RW reinforcement techniques utilizing temporalis fascia, tragal cartilage and perichondrium, fat, loose connective tissue, gelatin sponge and/or silastic.[24] Advantages include shorter anaesthetic/operative time and recovery, lower morbidity and none of the risks of intracranial surgery. The temporary nature of reinforcement does permit recurrence of symptoms if and when mobility of the RW recurs and thus the third window effect is re-established.[40] Proponents suggest RW reinforcement as an alternative option for patients with SSCDS in a better- or only-hearing ear, if a patient is not medically fit for general anaesthetic or longer general anaesthetic procedure and if/when the diagnosis is uncertain, to elucidate symptom improvement prior to more definitive surgery.[24]

OUTCOMES AND COMPLICATIONS

A 2015 systematic review and meta-analysis of 150 procedures from 20 studies reported an overall success rate of 94% for four methods of canal repair (plugging, capping, resurfacing or combined plugging and resurfacing), with no statistically significant differences observed between them.[43] The 10/150 procedures where there was no improvement in symptoms were considered failures; the successes include some patients with partial resolution of symptoms. The data analysis recognized a 100% success rate for combined resurfacing and plugging in 19 patients. The review found no significant difference in outcome when comparing the middle fossa approach with the TM approach.[43] Limitations to the meta-analysis include lower numbers of TM procedures and resurfacings compared with numbers of middle fossa approaches and pluggings. This may prove to be a consequence of time and experience as the TM technique shows promise, carries fewer risks and is gaining favour.[19, 44]

For 19 patients undergoing RW reinforcement techniques there was a statistically significant improvement in 8/9 symptoms of SSCDS (the exception being hearing loss).[24] RW reinforcement has distinct advantages but the potential temporary nature of the technique and the lack of intervention with the SSC itself necessitate ongoing/further evaluation in SSCDS. The Superior Semicircular Canal Dehiscence Patient Survey used in the RW study has already been used by other investigators evaluating benefit of interventions for SSCDS[19] but further study is required to assess its validity.

Combined major and minor complication rates have been reported as 12% (13/105) for MCF procedures and 16% (7/45) for TM SSCDS procedures.[43] The observed difference was not statistically significant. There were nine

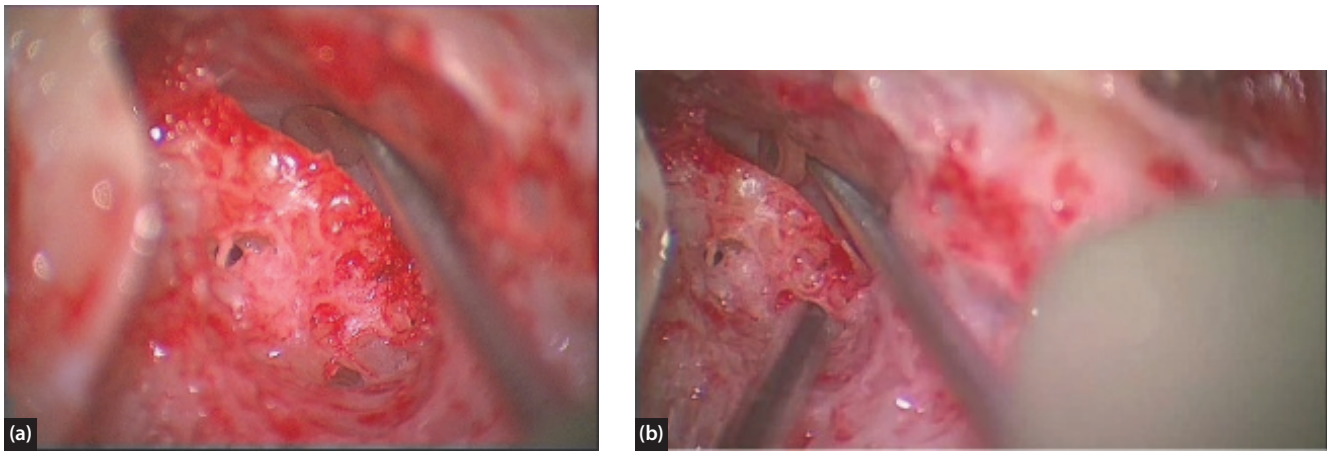

Figure 65.3 Intra-operative images from a left-sided resurfacing procedure. The position of the dehiscent lumen **(a)** and the dehiscent anterior limb **(b)** of the SSC are visualized in the reflective surface of the round knife.

major complications, six permanent total sensorineural hearing losses (four plugging; two resurfacing or capping) and three facial nerve injuries (respective approaches/techniques not reported). The 11 minor complications included transient sensorineural hearing loss, BPPV and transient post-operative dysequilibrium.

Exceptionally delicate surgical plugging technique to minimize the risk of rupture of the membranous labyrinth and consequent permanent sensorineural hearing loss cannot be emphasized enough. The risk of facial nerve injury is suspected to be higher in the MCF approach; however, significant experience of any chosen or preferred surgical technique is essential before attempting surgery for SSCDS.

CONCLUSION

As the experience of clinicians and surgeons treating SSCDS increases, so does the body of world literature to support or refute diagnostic and management strategies. Conservative management is advocated unless symptoms are bothersome. Current surgical interventions show high success and low complication rates. A focus on accurate diagnosis, patient-centred decision-making and a drive to improve the quality of patient care should enable ongoing publication of high-quality evidence. This should underpin future decision-making in all areas of SSCDS management as our experience and understanding of this relatively new condition evolves.

BEST CLINICAL PRACTICE

- ✓ The diagnosis of SSCDS requires a positive triad of history with typical clinical features, high-resolution CT and recording of VEMPs at lower than normal thresholds on the affected side(s).
- ✓ Patients whose SSCDS symptoms are affecting their quality of life should be considered for intervention in light of the severity of their symptoms.
- ✓ With sufficient neuro-otological experience of the surgical techniques, candid discussion of the options enables patient-centred decision-making. It is important to note, however, that in our experience, patients with multiple vestibular pathologies or atypical vestibular symptoms are the ones for whom SSCD surgery has not been curative (although they do report improvement in their SSCD symptoms).

FUTURE RESEARCH

- ➤ To elucidate the aetiopathogenesis of this condition and potentially thus enable development of preventative treatments.
- ➤ Investigate the physiological explanations for those symptoms not yet understood and investigate the causes for variable symptom severity.
- ➤ Robust evaluation of the RW reinforcement techniques.
- ➤ Further meta-analysis of surgical techniques.

KEY POINTS

- There are a huge variety of symptoms associated with SSCDS.
- Some of these are attributable to the third window, some are related to increased sensitivity to bone conducted sounds but for the remainder the pathophysiology is not yet understood.
- Third-window symptoms include transient vertigo, imbalance and/or oscillopsia in response to loud sounds or intracranial or middle ear pressure changes.
- SSC dehiscence alone is not sufficient to cause the syndrome; many patients have dehiscence but are asymptomatic.
- Patients with SSCDS have VEMP responses present at lower than normal thresholds for the affected ear in both bone conduction and air conduction.
- Patients with symptoms that are not intrusive or significantly bothersome should be managed conservatively and advice given regarding avoidance of triggers or stimuli.
- Transmastoid surgery enables shorter hospital stay and does not carry the risks of intracranial surgery when compared to the middle fossa approach.
- The round-window reinforcement technique shows promise; potential advantages are shorter surgical duration and less surgical morbidity with a suspected lower risk of sensorineural hearing loss. For some patients, the technique has only provided temporary relief and it does not deal directly with the SSC.

CHAPTER 66

VESTIBULAR NEURITIS

Charlotte Agrup

SEARCH STRATEGY

Data in this chapter may be updated by searches of Medline, EMBASE classic, EMBASE Ovid, CENTRAL (Cochrane Central Register of Controlled Trials), The Cochrane Ear, Nose and Throat Disorders Group Trials Register and additional sources for published and unpublished trials. Language was restricted to English.

INTRODUCTION

Sudden onset of sustained severe dizziness, nausea, sickness and postural imbalance is the characteristic presentation of vestibular neuritis. The patient will typically complain of vertigo (a subjective sensation of rotation/movement) and symptoms will worsen with change of position and head movements. The severely affected patient will not be able to walk unsupported but will prefer to lie down on their side, often lying on the affected ear. With milder cases the patient feels dizzy and imbalanced with some nausea but may not feel unwell enough to render seeking medical advice.

Even though vestibular neuritis is the preferred nomenclature, labyrinthitis is more commonly used among laymen and also medical professionals. However, if used strictly, labyrinthitis includes cochlear pathology (hearing loss/tinnitus) in addition to the vestibular symptoms. Other terms such as acute idiopathic peripheral vestibular dysfunction and vestibulopathy are occasionally also used.

In the adult population, around 40% of all dizziness is caused by a peripheral vestibular pathology (which includes the vestibular end organs of the inner ear and/or the vestibular nerve).[1] Of these peripheral pathologies, 3–23% have been reported to be due to vestibular neuritis.[1] There is only one publication on the prevalence of vestibular neuritis, which reports an occurrence rate of around 3.5 per 100 000.[2] This may well be an underestimate of the true incidence of the condition since no diagnosis is made in a substantial proportion of people who do not seek medical advice.[3] There is no difference in gender prevalence in vestibular neuritis and the typical age of presentation is around 40–50 years old. Although present in the paediatric population, it is much less common, with a suggested prevalence around 1.8% in children presenting with vertigo.[4]

The severe acute symptoms of vestibular neuritis normally last for between 3 and 7 days and are followed by gradual spontaneous resolution. The majority of cases will recover over a period of 6–12 weeks due to the effect of a number of different complex mechanisms collectively called central vestibular compensation.[5] A general rule appears to be that the more vestibular function that is lost during an acute episode of vestibular neuritis the more severe symptoms will be. However, different patients react very differently to symptoms.

PATHOAETIOLOGY

A selective inflammation of the vestibular nerve is the most favourable aetiology. Inflammation of a nerve may cause demyelination and associated loss of function, which can be irreversible. Temporal bone studies have shown evidence of chronic inflammatory changes of the vestibular nerve with diffuse perivascular lymphocytic infiltrates, consistent with post-infectious inflammatory changes.[6] These changes can be seen months to years after the initial acute episode. There is indirect evidence of inflammation of the vestibular nerve but not of inflammation of the

vestibular neurons and therefore vestibular neuritis is the preferred nomenclature, not vestibular neuronitis.

Vestibular neuritis may have a viral cause which is supported in some patients by the history of a preceding or coinciding cold/flu or epidemics of cases, at a workplace or among family members. However, this is not a prerequisite for the diagnosis. Reactivation of a latent virus has been suggested and the presence of herpes simplex virus type 1 (HSV-1) DNA in human vestibular ganglia and nuclei has been shown.[7, 8] Also colocalization of latent HSV-1 and CD8+ T-cells in vestibular ganglia further supports the hypothesis that HSV-1 reactivation is possible and may cause vestibular neuritis.[9, 10] Although HSV-1 is the most favourable viral agent, there is evidence that several other human viruses can cause isolated peripheral vestibular dysfunction, including rubella, cytomegalovirus, Epstein–Barr virus, adenovirus and certain strains of influenza types A and B.[11]

Using magnetic resonance imaging (MRI) an isolated enhancement of the vestibular nerve in connection with vestibular neuritis has been shown, supporting an inflammatory response.[12] Also, a decrease in vestibular nerve cross-sectional area and height in patients with unilateral vestibular neuritis has been shown using constructive interference in steady-state (CISS) parasagittal MRI.[13]

The evidence of viral infection being the aetiology remains indirect and circumstantial[14] and other aetiologies of acute vestibular loss are certainly possible, such as surgical unilateral vestibular deafferentation (i.e. vestibular neurectomy). Head trauma may cause acute vestibular loss and immunological causes have also been suggested.[15, 16] In the patient with vascular disease, particularly the elderly, a vascular aetiology seems likely but is very rarely proved.

CLINICAL PRESENTATION AND DIAGNOSIS

Vestibular neuritis presents with symptoms and clinical signs related to sudden, isolated unilateral vestibular loss. Symptoms typically consist of sudden onset of persistent vertigo (commonly a subjective sensation of rotation) with associated distressing autonomic symptoms such as nausea, vomiting, sweating and pallor. Severe symptoms would normally last for a few days before gradually starting to spontaneously resolve. There should be no associated cochlear symptoms (hearing loss and tinnitus), neurological symptoms or signs of brainstem lesion.

The vestibular nerve has two branches, the superior and inferior nerve. The superior nerve is more commonly affected with vestibular neuritis, which may be explained by its course through a longer and more narrow bony canal making it susceptible to swelling (associated with inflammation) causing entrapment.[17] Accordingly, only approximately 18% of vestibular neuritis affects the inferior nerve.[18, 19] The presentation of symptoms, clinical findings and results of vestibular testing will depend on which branch of the vestibular nerve (i.e. part of the vestibular system) is affected. Superior vestibular neuritis presents with a vestibular lesion that affects the anterior and horizontal semicircular canals and utricular function but spares the posterior semicircular canal function and most of the saccular function. In contrast, inferior vestibular neuritis affects the posterior semicircular canal function and the saccular function. Although vestibular neuritis is mostly unilateral, bilateral sequential involvement has been reported.[20]

Visual vertigo, dizziness provoked by visual environments with repetitive or moving visual patterns, is common with a peripheral vestibular dysfunction.[21] For this reason, this group of patients dislikes visually busy environments (such as traffic, crowds and supermarket aisles) which will induce dizziness/imbalance and a sensation of disorientation. Benign paroxysmal positional vertigo (BPPV) is a common sequel to vestibular neuritis and will develop in the affected ear in 10–15% of cases.[20] However, in a study of patients with inferior vestibular neuritis, none showed BPPV as a sequel. Anxiety disorders and panic episodes are very common in association with vertigo/imbalance. It is likely that, in some patients, vestibular dysfunction may play an important role in the aetiology of these disorders[22] and often anxiety and panic episodes may be the main presenting symptoms associated with the vestibular neuritis.

Diagnostic criteria for vestibular neuritis have been suggested by Coats (**Box 66.1**)[23] but there are no generally agreed specific criteria. History, clinical examination and vestibular tests are the basis for diagnosing vestibular neuritis and a clear, detailed history provides a big step towards a certain correct diagnosis.

The most characteristic clinical finding with sudden unilateral loss of vestibular function is the spontaneous peripheral vestibular nystagmus (**Box 66.2**). An acute loss of peripheral vestibular function results in a slow vestibular-induced drift of the eyes in the same direction as the lesion. This drift is interrupted by rapid saccadic eye movements in the opposite direction, towards the healthy ear. This combination of slow and fast eye movements constitutes the spontaneous peripheral vestibular nystagmus. The nystagmus is horizontal with a torsional component, its direction is defined by the fast phase and it is described as first-, second- and third-degree nystagmus. In acute severe cases, the nystagmus is initially present with optic fixation but, in milder cases and during recovery, there will be no visible nystagmus with optic fixation and it is not until the optic fixation have been removed that the nystagmus will be present. Of note is that, when only the

BOX 66.1 Modified diagnostic criteria for vestibular neuritis suggested by Coats[23]

Acute onset of non-recurrent vertigo often accompanied by nausea and vomiting
Absence of cochlear symptoms (hearing loss/tinnitus) or signs of central nervous involvement
Commonly unilateral partial or complete peripheral vestibular lesion
Complete subsidence of symptoms within 6 months

BOX 66.2 Characteristics of the spontaneous peripheral vestibular nystagmus

- Unidirectional
- Horizontal
- Conjugate
- Temporary
- Enhanced by removal of optic fixation
- Obeys Alexander's law

BOX 66.3 Characteristic clinical examination findings with acute vestibular neuritis

- Horizontal–torsional spontaneous nystagmus, beating away from the side of the lesion, more vigorous without optic fixation
- Headthrust test positive on the same side as the lesion
- Gait test and Unterberger test show deviation to the side of the lesion
- Romberg test shows marked increase of sway

inferior vestibular nerve is affected, spontaneous nystagmus is rare. It is also important to note that other types and directions of nystagmus (i.e. purely torsional, vertical or dysconjugate nystagmus) indicate a central pathology and should prompt further investigations.

Clinical examination

A detailed medical examination including neuro-otological examination, general neurological examination and examination of the cardiovascular system is essential and confirms diagnosis. The neuro-otological examination should include examination of the external ear and otoscopy, in addition to assessment of vestibulo-ocular and vestibulospinal function.

Examination of eye movements is a must and should include the cover test (looking for strabismus), the full range of eye movements and gaze testing (looking for nystagmus with central gaze, 30-degree left gaze and 30-degree right gaze, preferably with and without optic fixation). With the left and right gaze testing it is important that the angle does not exceed 30 degrees since a larger angle can induce physiological end-point nystagmus (beating in the same direction as the gaze). In the majority of patients the spontaneous nystagmus will subside within 48 hours and the nystagmus with optic fixation disappears within 1–2 weeks. However, with removal of the optic fixation (e.g. by using Frenzel glasses or videonystagmography (VNG) goggles) the spontaneous nystagmus may be observed for as long as 5–10 years.

The **headthrust test** is a simple bedside test of the horizontal vestibulo-ocular reflex and is positive for the side that causes the corrective saccades, indicating a vestibular dysfunction on the same side. A **Hallpike test** to exclude positional vertigo should always be performed, in the non-acute stage, since it is not unusual for BPPV to follow after the acute vestibular neuritis. Clinical tests assessing vestibulospinal function are non-specific and often insensitive. However, tests of stance and gait provide an indication of the extent of the patient's disability and interaction of vestibulospinal activities with other systems. A tendency to sway on the **Romberg test** may suggest peripheral vestibular pathology and a marked increase in sway has been demonstrated in elderly patients with a unilateral vestibular hypofunction.[24] Also with the **gait test** (5 m walk with the eyes open and then with eyes closed) a deviation towards the side of the peripheral vestibular lesion is commonly seen. The **Unterberger test** has been shown to have poor sensitivity and specificity.[25] However, with a peripheral vestibular dysfunction the patient may also deviate to the side of the lesion during this test.

Characteristic test findings are summarized in **Box 66.3**.

Diagnostic vestibular testing

The use of diagnostic vestibular testing confirms diagnosis. These testing facilities are only available at specialist centres and consist of the caloric test, videonystagmography/electronystagmography (VNG/ENG), cervical and ocular vestibular-evoked myogenic potential (c- and oVEMP), subjective visual vertical and horizontal and video head impulse test (VHIT). A detailed explanation of these different tests is beyond the scope of this chapter and they will therefore be discussed only briefly where they have particular relevance to vestibular neuritis.

The **caloric test** is the gold standard for diagnosing unilateral peripheral dysfunction, with a reduced or absent response on the affected side. In the study by Sekitani et al. 50% of patients with vestibular neuritis, investigated with the caloric test, were shown to have a partial canal paresis.[2] Of note is that, when only the inferior nerve is affected, the caloric test, which depends largely on the horizontal canal function, is normal. The **VNG/ENG recordings** of eye movements allow a more detailed evaluation compared to the clinical examination, in addition to providing a record of the eye movements. A number of the standard battery of eye movement recordings help to identify a unilateral vestibular dysfunction, for example the gaze testing with identification of the typical peripheral nystagmus, but also central neurological pathologies can be identified (typically cerebellar lesions).[26] The **rotatory chair** (used in combination with VNG or ENG) is the gold standard for diagnosis of bilateral vestibular loss. The standard test battery can also identify a peripheral vestibular asymmetry.[26]

The oVEMP and cVEMP can determine which branch is affected in an episode of vestibular neuritis (the superior or inferior vestibular nerve). Studies have shown that, when the superior nerve is affected, oVEMP is abnormal and cVEMP is normal (reduced or absent n10 amplitude at the eye contralateral to the lesion and large asymmetry ratio with oVEMPs as opposed to normal amplitude and asymmetry ratio with cVEMPs). Contrarily, when the inferior vestibular nerve is affected, the oVEMP is normal and the cVEMP is abnormal (increased asymmetry ratio and reduced or absent amplitude response).[27, 28]

Subjective visual vertical and horizontal are quick to perform and both show a deviation to the side of the lesion with vestibular neuritis.[29] The VHIT is a relatively new development and it has been suggested that video recording of the head impulse test improves the sensitivity of this test.[30] An abnormal VHIT has been shown to be associated with a vestibular loss of more than 62.5% identified with the caloric test. On the other hand, with a caloric deficit of less than 40%, the VHIT is normal.[31]

RECOVERY AND RESOLUTION

As mentioned above, the majority of patients with vestibular neuritis recover fully without intervention within 6–12 weeks. This process may be partly related to restoration of peripheral vestibular function[32] and partly to development of vestibular compensatory mechanisms which involve brainstem, cerebellar, cortical and spinal functions.[5, 33] The recovery does not follow a linear pattern but symptoms will often fluctuate. However, a ground rule is that reoccurring symptoms will not be as severe as symptoms appearing during the initial vestibular insult.

Vertigo is experienced when there is an asymmetric resting activity between the two vestibular nuclei (localized in the brainstem). Neural recordings in animals recovering from a unilateral peripheral vestibular lesion show that central compensation depends on an increased spontaneous neural activity in the ipsilesional vestibular nucleus and a decreased spontaneous neural activity in the contralesional nucleus, thereby rebalancing activity of the left and right vestibular nuclei.[34, 35] Some of resolution of symptoms can be related to recovery of peripheral vestibular function and 50–70% of patients have been shown to have a complete recovery of peripheral vestibular function assessed by using the caloric test.[36, 37] In line with this, around 20% of patients have been shown to remain symptomatic following surgical unilateral vestibular deafferentation, limiting peripheral vestibular recovery.[38] However, there is a lack of correlation between recovery of clinical symptoms and caloric recovery: where there has been no restoration of peripheral function some patients feel well recovered but up to 20% of patients experience continued symptoms despite normalization of caloric testing.[39] Hence, there are other factors than recovery of peripheral vestibular function that are significant for patient recovery.[40]

Patients who are able to compensate fully for the vestibular loss will mostly remain asymptomatic and unaware they are balancing using mainly one ear rather than two; they will feel subjectively 'back to normal'. In some patients, especially the elderly and those with additional central nervous system disorders, the compensation is often not as effective. This will lead to chronic peripheral vestibular dysfunction (with a persistent sensation of imbalance) or recurrent episodes of decompensation (with recurrent episodes of imbalance). Complaints about sensations of floating, rocking, lightheadedness, disorientation and/or depersonalization are frequent with decompensation.

The recurrence rate of vestibular neuritis is very low and may involve the other side. In a study by Huppert et al. only 1.9% of patients developed a second vestibular neuritis within 39 months after the first episode.[20] The patient would typically have only one episode of sudden-onset vertigo and any recurrent episodes that occur could be explained by episodes of temporary decompensation. However, with recurrent symptoms, other aetiologies must be considered, such as migrainous vertigo, BPPV and Ménière's disease.

MANAGEMENT AND TREATMENT

Symptomatic treatment with antiemetic medication during the acute stage is often required, and antihistamines, anticholinergic agents and antidopaminergic agents are the most commonly used drugs. Fluid replacement may be necessary in particularly severe cases. Most antiemetics are vestibular sedatives and will suppress the stimulus of sensory mismatch which is required for habituation and compensation. It is therefore important that they are only used during the acute stage since prolonged use has been shown to prevent development of vestibular compensation. Accordingly, regular vestibular sedatives are not indicated in patients with chronic dizziness and should preferably not be given for longer than 3 days, following which they should be used only as an emergency medication on an as-required basis.

Vestibular neuritis may cause adverse effects on quality of life, affecting activities such as driving, employment and loss of confidence in everyday living. An important part of management is to advise the patient clearly of the benign nature of the condition and to reassure patients their symptoms will settle. Also inform patients of the fluctuant nature of the recovery process and the common prevalence of decompensation. Advice on safety is important and may be required with regards to driving, workplace and increased risk of falls.

There is at present no clear consensus with regards to specific treatments for vestibular neuritis. Benefit of treatment with oral corticosteroids, in the acute stage of vestibular neuritis, has been suggested.[41] There are some published studies comparing the effectiveness of oral corticosteroids (methylprednisolone) with placebo,[42] but the studies are small and of low methodological quality. This Cochrane review[42] showed an overall significant effect of corticosteroids compared with placebo medication on complete caloric recovery at 1 month. On the other hand, there was no significant effect on complete caloric recovery at 12 months or on the extent of caloric recovery at either 1 month or 12 months. In addition, there was no significant difference between corticosteroids and placebo medication in the symptomatic recovery (using the Dizziness Handicap Inventory score) at 1, 3, 6 and 12 months. Accordingly, there is currently insufficient evidence to support treatment of patients with acute

vestibular neuritis with corticosteroids, particularly considering the risk of adverse side effects.

Despite the suggested possible viral aetiology of vestibular neuritis, no benefit of antiviral treatment in the acute stage has been shown.[41]

Vestibular rehabilitation is a safe and effective treatment for unilateral vestibular dysfunction and is required in some patients to enable recovery and development of effective compensation.[43] The central nervous system needs the stimulus of sensory mismatch for habituation and compensation and controlled studies have indicated that vestibular exercises can accelerate balance recovery and development of compensatory mechanisms.[33] Whether more frequent exercise leads to faster recovery is not known.

The vestibular rehabilitation should be started when the acute stage of nausea and vomiting has passed. It is thought that vestibular compensation develops more quickly and more effectively if the person is active as soon as possible.[44] Vestibular rehabilitation could partly consist of the Cawthorne–Cooksey exercises as well as gait retraining.[44] Although there is insufficient evidence to discriminate effectiveness between different forms of vestibular rehabilitation, more customized vestibular exercises are most probably of benefit with additional visual exercises to manage the visual vertigo.

Cognitive behavioural therapy may be required in the group of patients in which anxiety and panic disorders are the main presenting symptoms associated with the vestibular neuritis.

BEST CLINICAL PRACTICE

- A detailed medical history and examination including neuro-otological examination, general neurological examination and examination of the cardiovascular system is essential and confirms diagnosis.
- With recurrent episodes of vertigo other aetiologies must be considered such as vestibular migraine, benign paroxysmal positional vertigo and Ménière's disease.
- Sudden onset severe vertigo presenting with associated hearing loss, headache and/or neurological symptoms indicate other pathology than vestibular neuritis and require prompt further investigations.
- An important part of management is explanation and reassurance about the benign nature of the condition.
- The majority of patients with vestibular neuritis recover fully spontaneously within 6-12 weeks due to central vestibular compensation. However, in the elderly patient the compensation is often not as effective.
- Vestibular rehabilitation is a safe and effective treatment in patients who do not recover fully.
- Most symptomatic treatments (antiemetic medications) are vestibular sedatives and should only be used during the acute phase, preferably no longer than 3 days.

FUTURE RESEARCH

- ➤ Further research to clarify the pathogenesis of vestibular neuritis is essential for the development of effective specific treatment modalities.
- ➤ Development of specific diagnostic criteria for vestibular neuritis is imperative for research into evidence based specific treatments.
- ➤ Better understanding of development of vestibular compensatory mechanisms will enable improved guidelines for individualized and more effective rehabilitation of vestibular neuritis.

KEY POINTS

- Vestibular neuritis typically presents with one acute episode of sudden-onset vertigo and, if recurrent episodes occur, other aetiologies must be considered.
- The typical peripheral nystagmus is horizontal and increases when the optic fixation is removed.
- The presence of auditory or neurological symptoms indicates a different diagnosis.
- Symptomatic treatment during the acute stage may be required but should preferably not be given for longer than 3 days and is not indicated in patients with chronic dizziness.
- If the patient has atypical symptoms, consider referral to a balance specialist.

CHAPTER 67

VESTIBULAR MIGRAINE

Louisa Murdin and Linda M. Luxon

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: vestibular migraine, migraine and migrainous vertigo.

CLASSIFICATION AND DEFINITIONS

Migraine is common. Almost everyone will either have experienced the condition personally or have friends, family or other acquaintances who are sufferers. The disorder has long been recognized from antiquity as a 'sick headache' or similar description. However, the understanding of the spectrum of migraine manifestations, pathophysiology and management options has increased rapidly over the last 20 years. The story of the concept of 'vestibular migraine' is a part of this fast expansion of understanding.

Migraine is defined by the International Headache Society International Classification of Headache Disorders (ICHD), most recently ICHD-3 beta (**Box 76.1**).[1] Of note, there is no objective diagnostic test and the diagnosis rests with the patient's subjective description of the symptoms, as well as the clinician's assessment that no other disorder better accounts for the clinical presentation. This can be supported to some extent by behavioural observation, especially in those unable to provide a history, such as young children.

The definition is intended to be workable for clinicians, and also to be of use to those executing clinical trials and other research into headache disorders. In addition to the features tabulated in **Box 76.1** there are many other characteristics of migraine that may be encountered in clinical practice. These include other sensory aversions such as osmophobia, motion sickness, sensitivity to alcohol in the form of hangover headaches, and family history. The latter, however, is of limited diagnostic utility given the frequency with which migraine occurs in the general population.

Migraine is primarily and most commonly an episodic disorder. In some cases symptoms it can become chronic. Even in those individuals whose phenotype has evolved to a chronic form, symptoms are usually fluctuating. Even in chronic migraine, careful history taking will elicit an initial period of episodic symptoms.

In about 30% of patients there is experience of aura (**Box 67.2**), comprising fully reversible focal neurological symptoms. These are characteristically followed by a migraine headache, although some individuals experience aura without headache.

Vertigo is mentioned three times in relation to migraine in this classification system. Firstly, it relates to benign paroxysmal vertigo of childhood, a condition of vertigo without headache that occurs in younger children and is thought to be a migraine precursor. Secondly, vertigo can be part of the aura of basilar-type migraine. The key feature of vertigo in basilar-type migraine is that the vertigo is thought to form part of a posterior circulation aura. To identify this with confidence it should conform to the timing definitions for an aura as laid out in **Box 67.3**. In addition, there should be other identifiable posterior circulation symptoms such as dysarthria, tinnitus, reduced hearing, diplopia, visual symptoms simultaneously in both temporal and nasal fields of both eyes, ataxia, decreased level of consciousness or simultaneously bilateral paraesthesias.

However, in neuro-otology and dizziness clinics, the majority of patients who describe dizziness and

BOX 67.1 Migraine headache as defined by ICHD-3 beta (2013)

A. At least five attacks
B. Headache 4–72 hours' duration
C. At least two of:
   - unilateral
   - pulsating
   - moderate/severe
   - aggravation by routine physical activity
D. During headache at least one of:
   - nausea and/or vomiting or
   - photo- and phonophobia
E. Not attributed to another disorder

BOX 67.2 Definition of aura

Fully reversible symptoms:
- sensory, visual, speech disturbance
- at least two of:
  - homonymous visual symptoms and/or unilateral sensory symptoms
  - at least one aura symptom develops gradually over ≥5 minutes and/or different aura symptoms occur in succession over ≥5 minutes
  - each symptom lasts between ≥5 minutes and ≤60 minutes
- migraine headache begins during the aura or follows aura within 60 minutes

BOX 67.3 Migraine with brainstem aura (formerly basilar-type migraine)

A. At least two attacks fulfilling criteria B–D
B. Aura consisting of visual, sensory and/or speech/language symptoms, each fully reversible, but no motor or retinal symptoms
C. At least two of the following brainstem symptoms:
   - dysarthria
   - vertigo
   - tinnitus
   - hypacusis
   - diplopia
   - ataxia
   - decreased level of consciousness
D. At least two of the following four characteristics:
   - at least one aura symptom spreads gradually over 5 minutes, and/or two or more symptoms occur in succession
   - each individual aura symptom lasts 5-60 minutes
   - at least one aura symptom is unilateral
   - the aura is accompanied, or followed within 60 minutes, by headache
E. Not attributed to another disorder

BOX 67.4 Vestibular migraine

A. At least five episodes with vestibular symptoms of moderate or severe intensity lasting 5 minutes to 72 hours
B. History of migraine according to IHS classification
C. Migraine feature with >50% of attacks:
   - headache with two of unilateral, throb, moderate–severe, aggravation by movement
   - photo- and phonophobia
   - visual aura
D. Not better accounted for by another disorder

vertigo in association with migraine headaches and other migrainous phenomena, do not meet strict criteria for aura.[2] This led to the proposal by Neuhauser in 2001 to define an entity they called **migrainous vertigo**. This definition was updated in 2012 in a joint statement by the International Headache Society and the Barany Society and termed **vestibular migraine** (VM) (**Box 76.4**, also in the Appendix section of ICHD-3 beta),[1] which is the third type of migrainous disorder mentioned in the classification system. The validity of the diagnosis has been supported by long-term follow-up studies in which its stability has been demonstrated over a period of up to 9 years.[4]

To be confident of the diagnosis of VM, note that criterion B in **Box 67.4** must be fulfilled, i.e. the patient must have a history of typical migraine, although this does not necessarily need to be highly active at the time of presentation. There is also a definition of **probable vestibular migraine**, in which criteria A and E are fulfilled but only one of B or C. **Definite vestibular migraine** was found to be a highly stable and valid diagnosis over 10 years or so in a longitudinal study, with probable VM unsurprisingly much less so.[5] Note also that migraine may be a risk factor for incomplete compensation from an acute vestibular episode, the pathophysiological basis for which is as yet incompletely understood.[6]

Other terms are encountered in the literature such as migraine-related dizziness, migrainous vestibulopathy and vertiginous migraine, but these have not found widespread international acceptance or standardized definitions.

EPIDEMIOLOGY

There has been only one large population-based epidemiological study of VM in the community.[7] In this study, which took place in Germany, the lifetime prevalence was estimated at 0.98%, two-thirds of participants with VM had consulted a doctor but only 20% of these were diagnosed correctly. Age-adjusted health-related quality of life scores (SF-8 Health Survey) were consistently lower in participants with VM compared to dizziness-free controls. As for migraine, there is female preponderance. It may be more common in women in mid-life, with 1 year prevalence of 5%.[8] This would make it one of the most common causes of episodic vertigo, more common than disease (population lifetime prevalence estimated at 0.12%[9] to 0.5%,[10] although less common than benign paroxysmal positional vertigo.

There are epidemiological associations between migraine and a number of vestibular disorders, including Ménière's disease,[11] benign paroxysmal positional vertigo,[12] episodic ataxia type II[13] and motion sickness.[14]

BOX 67.5 Six-fold relationship between migraine and vestibular symptoms

1. Benign paroxysmal vertigo of childhood (migraine precursor)
2. Migraine with brainstem aura (formerly basilar-type)
3. Vestibular migraine
4. Epidemiological and clinical associate of other vestibular disorders (e.g. Ménière's disease, benign paroxysmal positional vertigo, episodic ataxia type II, motion sickness)
5. Risk factor for slow compensation from acute vestibular event
6. Secondary vestibular migraine (underlying episodic vestibular disorder triggers migraine episodes)

BOX 67.6 Pitfalls in diagnosis

Many patients deny a history of migraine when first asked about headaches so, if VM is suspected, it is worth enquiring specifically about the experience of headache, including any that the patient describes as a 'normal' headache.

While it is increasingly recognized that vestibular symptoms can result from migrainous processes, it is also known that vestibular stimulation can act as a trigger for migraine headaches.[16] This means that some patients with vestibular symptoms and migraine have an underlying vestibular disorder that is triggering migraine headaches. To reduce headache frequency in these patients, the underlying vestibular disorder must be addressed.

While primary migraine is one of the commonest headache disorders, it should be recognized that there are many other causes of both primary and secondary headache. These should be delineated and managed appropriately.

Various mechanisms have been proposed for these associations including inner ear vasospasm,[15] overlapping pathophysiologies[11] and a secondary triggering effect of vestibular disorders on episodes of headache.[16] This latter mechanism distinguishes primary VM, in which vestibular symptoms are attributable to migrainous processes, from secondary VM, in which symptoms of migraine are triggered by a vestibular disorder that causes episodic vertigo (**Box 67.5**).

Migraine is also known to be associated with poor recovery from acute vestibular disorders, although the mechanism of this effect is not entirely clear.[17]

In summary, the current state of knowledge suggests that there are therefore six ways in which vestibular symptoms and migraine can coexist (see **Box 67.5**).

PATHOLOGY AND GENETICS

Theories about the pathology of VM derive from theories of pathogenesis of migraine. Migraine is considered a disorder of sensory modulation, involving both neural and vascular tissue.[18] Many theories of migraine pathogenesis centre on the 'trigeminovascular reflex', with aminergic brainstem nuclei activating trigeminal afferents responsible for the pain of migraine headache that is a central characteristic of the disorder.

Migraine is well recognized as a familial disorder and there are documented pedigrees of families with VM.[19] Rare forms of migraine where there are associated neuro-otological findings have a simple Mendelian inheritance with specified identified mutations (familial hemiplegic migraine Types 1–4 with mutations in *CACNA1A*, *ATP1A* and *SCN1A* and the episodic ataxias Types 1–7 with mutations in *KCNA1* and *CACNA1A*). These data suggest that migraine and its neurological manifestations are mostly likely ionopathies. However, a single genetic mutation for common forms of migraine, including VM, remains elusive, despite extensive work in this area. Genome-wide association studies have identified several candidate variations for common migraine, but the pathological significance of these is yet to be confirmed.[20–22]

Cortical spreading waves of depression of Leao are thought to be analogous to the aura symptoms of migraine.[23] Such a phenomenon affecting brainstem structures such as the vestibular nuclei has been proposed to account for some types of episodes of migraine-associated vertigo.[24] However, this theory does not account for all the clinically observed features of VM, including the time course of attacks that commonly last for several hours or days.

Another possible source for the vestibular symptoms of VM is ion channels within the inner ear. These are critical for neuronal excitation as calcium enters the neurons and potassium exits it into the endolymph. Serotonin, known to have an important role in the modulation of migraine headache, influences neurovascular homeostasis within the mouse inner ear.[25]

Yet another suggested theory is the possibility of vasospasm of the vestibular branches of internal auditory artery causing the ischaemia of the labyrinth and then resulting in cochleovestibular dysfunction experienced in migraine-associated vertigo.[26]

CLINICAL ASSESSMENT

Potential pitfalls in diagnosis to be aware of are given in **Box 67.6**.

History

The key feature of the history is the presence of episodic vestibular symptoms. In some patients with chronic symptoms the symptoms can be present constantly but are subject to fluctuation. Episodes can be of variable duration. Much discussion has taken place over whether very short-lived episodes (less than 5 minutes) can be classified as VM. There is no doubt that such episodes are frequently reported by individuals who otherwise have clear-cut VM, but on current criteria the diagnosis may not be made in those with exclusively short-lived episodes.

Figure 67.1 Everyday situations of work and leisure. (Images courtesy of artur34/arrbrey/Nathan Greenwood FreeDigitalPhotos.net.)

Headache need not necessarily be a prominent feature of the presentation, but it is useful for distinguishing VM from other causes of episodic vertigo.

Photo- and phonophobia are key diagnostic symptoms that should be specifically and carefully enquired about, since they are easily missed.[27] Sensitivity to self and visual motion are frequently associated, and can persist between acute episodes (the 'interictal period'). This can result in avoidance of everyday situations at work and at leisure, such as supermarkets, transportation systems and leisure activities (**Figure 67.1**).

Family history is often sought and can help in some settings but the statistical yield of such enquiry is low due to the high prevalence of migraine in the general population. A history of motion sickness may be of use since migraine and motion sickness are strongly linked.[14]

Other aspects of the history should be directed to symptoms that may be suggestive of an alternative diagnosis, such as the unilateral auditory symptoms of Ménière's disease. Similarly, consider in the history both other causes of primary headache (e.g. tension-type) and less common but potentially serious secondary causes of headache such as intracranial space-occupying lesion, meningitis, subarachnoid haemorrhage, temporal arteritis, primary angle-closure glaucoma, idiopathic intracranial hypertension and carbon monoxide poisoning.

Examination

The physical examination of patients with VM in the interictal period is usually normal. However, some patients report significant visual motion intolerance that can be detected during eye movement examination. One study of patients with VM in the acute setting found a range of eye movement abnormalities including positional nystagmus,, spontaneous nystagmus, mixed and central type patterns.[28] The presence of interictal eye movement abnormalities should alert the examiner to consider the possibility of either a different disorder altogether (e.g. episodic ataxia type 2) or an underlying neurological disorder causing migraine via secondary effects. **Figure 67.2** shows the MRI scan of a patient who presented with frequent headaches and episodic vertigo but was found to have a meningioma in the cerebellopontine angle that was thought to be contributory.

Neuro-otological investigations

Pure-tone audiometry is usually normal in VM, but it can also be helpful in differentiating VM from Ménière's disease in which low-frequency unilateral hearing loss may be detected. A directional preponderance may be

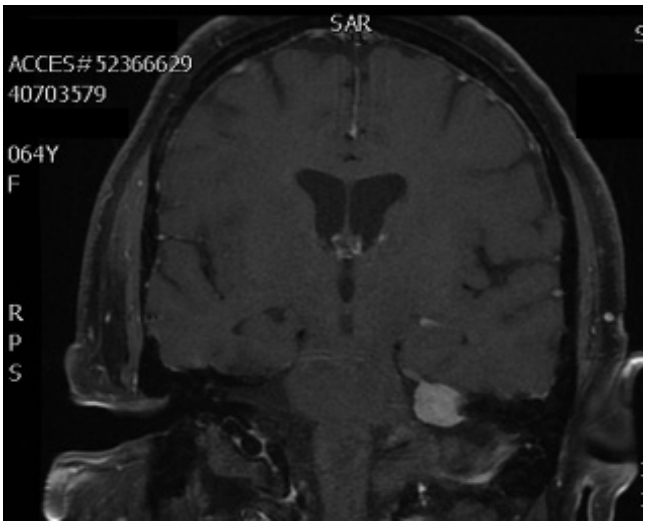

Figure 67.2 MRI scan of a patient who presented with frequent headaches and episodic vertigo but was found to have a meningioma in the cerebellopontine angle.

seen on rotation testing in around half of cases, abnormal posturography is present in around one-third and a canal paresis on caloric testing in around a quarter.[29] Vestibular-evoked myogenic potential (VEMP) abnormalities are likewise non-specific and variable.[30]

Other investigations

MRI scanning can be helpful in selected cases to look for secondary neurological disorders. In cases where the history is typical and examination findings normal, MRI scanning may not be required.

MANAGEMENT

The most important aspect of management after the correct diagnosis is a clear explanation to the patient about the nature of the condition. This is essential since the condition is frequently present over long periods and patients need to become expert in self-management of the disorder. Because migraine is usually thought of as primarily a headache disorder, careful discussion about how migraine may be responsible for vestibular symptoms is often required. The evidence base for management of VM is generally weak, and recommendations are generally made on the basis of what is known about management of other kinds of migraine.

Lifestyle

In some cases, trigger factors for migraine are clearly identifiable. These may be dietary, although there is no convincing evidence that large-scale exclusion diets are beneficial. Keeping regular sleep, exercise and meal times is advisable. In some cases patients can take action to avoid triggers, but this is not always possible (e.g. external stressors).

Drugs

ACUTE RELIEF

Migraine headache should be managed along standard lines with analgesics or migraine-specific relief medicines such as the 5HT1B/D agonists ('triptans'), taking care to avoid analgesic-overuse headache. Further up-to-date guidelines can be consulted.[31, 32] Acute symptoms of vertigo can be managed with vestibular sedatives such as prochlorperazine, cyclizine or cinnarizine. These drugs are not suitable for long-term administration. Nausea can also be relieved by vestibular suppressants; domperidone can also be used for this purpose.

PREVENTIVES

When symptoms of headache and vertigo together are sufficiently intrusive to justify the risk of adverse effects, migraine prophylactic agents can be considered. This judgement is made on an individual basis by each patient. These include propranolol, topiramate and many others. Medication can be selected according to comorbidities and individual preferences with regards to adverse effect profiles.[31, 32]

Physiotherapy

Vestibular rehabilitation can be used to manage symptoms of VM, especially head and visual motion intolerance, and associated underlying fixed vestibular deficits. Progress can be slower than in other conditions. Vestibular rehabilitation can also be associated with an increase in headache frequency, which may justify a decrease in the threshold for starting prophylactic agents.

Psychological

VM can be associated with secondary psychological effects that can be considered on neurochemical, neuroanatomical and neuropsychosocial levels. Patients with VM have higher rates of psychological symptoms than many other vestibular disorders.[33] The interaction of migraine, anxiety and vestibular symptoms is sufficiently common for the concept of migraine anxiety-related dizziness (MARD) to have been proposed.[34] Secondary psychological disorders such as anxiety and depression should be recognized and treated appropriately by medical and/or psychological means as indicated.

Other treatments

There is some evidence that acupuncture is of benefit when combined with other treatments.[35] Riboflavin, coenzyme Q10 and magnesium are all nutritional supplements with low-level evidence of efficacy in migraine.

Some of the pitfalls in effective management are given in **Box 67.7**.

BOX 67.7 Pitfalls in management

It is important to ensure patients have had adequate trials of medications before labelling them ineffective. Starting doses of drugs may not be adequate for therapeutic purposes. Patients should be supported to increase doses where appropriate.

Patients with VM can have a high rate of dropout from physiotherapy programmes due to increases in associated symptoms. The threshold for starting migraine prophylactics may need to be lowered in these patients.

Patients with unidentified and untreated secondary psychological disorders have a poorer prognosis. Consider such factors in individuals who are failing to make expected progress.

FUTURE RESEARCH

- Further work on the pathophysiology of VM is required to delineate ways in which it might be similar to or differ from other migraine subtypes.
- Genetic studies are likely to advance knowledge about pathophysiology through novel technologies such as exome sequencing.
- The evidence base for clinical trials is currently very weak, although some clinical trials have been registered and are proceeding at the time of writing.
- Due to the nature of the condition, including its episodic and unpredictable prognosis, multicentre trials are likely to be required to show adequate power.

KEY POINTS

- Vestibular migraine is a subtype of migraine in which vestibular symptoms predominate.
- Diagnosis is made predominantly on the history.
- Objective vestibular tests are usually normal although peripheral or central abnormalities can be seen in some cases.
- Management options include lifestyle modifications, medication, and physiotherapy, depending on symptom severity and frequency.

CHAPTER 68

VESTIBULAR REHABILITATION

Marousa Pavlou

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: vestibular rehabilitation, balance re-training, adaptation and novel techniques.

INTRODUCTION

Customized vestibular rehabilitation (VR) incorporating appropriate movements and sensory exposure is currently the standard of care for patients with peripheral vestibular disorders. Approximately 50–80% of individuals completing a customized programme achieve significant subjective symptom, dynamic visual acuity, gait and postural stability improvements.[1–5] A direct relationship has also been demonstrated between VR treatment outcome and improvements in psychological state[5, 6] and quality of life,[7–9] while specialized adjuncts to VR, such as exposure to visual motion stimuli, have been shown to significantly improve symptoms of visually induced dizziness,[5, 6, 10] which refers to symptoms of dizziness, disorientation and/or unsteadiness provoked or exacerbated in situations involving visual–vestibular conflict (e.g. walking down supermarket aisles) or intense visual motion (e.g. watching wide-screen movies).

However, despite a strong body of evidence supporting the use of VR for the management of peripheral vestibular disorders, referrals to VR remain low. A qualitative study evaluating clinicians' (neurologists, primary care, otolaryngologists) perspectives regarding the factors which influenced their management of people with vestibular disorders found that they were often unaware of the concept of VR and wanted to learn more to improve the healthcare delivery of their patients.[11] The main aim of this chapter is to provide an overview of VR including: (i) the physiologic basis, (ii) customized VR techniques including novel and supplementary techniques, (iii) factors that may affect outcome, and (iv) its efficacy for peripheral and central vestibular disorders.

NEUROPHYSIOLOGICAL BASIS FOR VESTIBULAR REHABILITATION

Habituation, adaptation, substitution and/or sensory reweighting comprise the neurophysiological basis for vestibular compensation and the improvements noted following a VR programme, with recent findings showing structural changes in grey matter volume in certain brain areas after people with vestibular neuritis have recovered functionally.[12]

Habituation is a decrease in the magnitude of the response to repetitive sensory stimuli.[13] Initial VR programmes such as the Cawthorne–Cooksey[14, 15] exercises are a type of habituation and involve repeating the provoking movement at regular intervals until symptoms are no longer experienced. However, although components of this exercises programme may still be used today, the evidence advocates customized VR programmes which focus on an individual's deficits and incorporate exercises based on multiple neurophysiological components.[2, 4, 16–18]

The vestibulo-ocular reflex (VOR) is responsible for our ability to maintain fixation on a target during head movement. The VOR functions to stabilize images on the retina during head movement by producing compensatory eye movements, simultaneously and at the same rate, in the direction opposite to head movement. Therefore the

'gain' of the VOR (eye velocity/head velocity) should be equal to 1.0. In people with a peripheral vestibular disorder, the VOR gain can be reduced, resulting in retinal image slip with visual blurring during head rotations.[19] Retinal image slip provides an error signal which generates VOR response changes that decrease (i.e. improve) the gaze error.[20–22] Adaptation exercises[23] (see 'Vestibular rehabilitation interventions' below) incorporating gaze fixation and head movements are prescribed to simulate retinal slip to promote VOR improvement with a reduction in blurring of the visual image during head movement. Recently it has been reported that, in addition to retinal slip, saccadic substitution and specifically compensatory saccades (the substitution of a saccade in the direction of the deficient VOR)[24] also contribute to improvements in VOR gain with a decrease in gaze instability.[25] The use of compensatory saccades appears to be related to the severity of vestibular hypofunction.[25]

Sensory reweighting is the central nervous system's ability to adapt its relative reliance on a specific sensory modality for orientation depending on environmental conditions, task demands and/or pathology.[6] Therefore, if a sensory input is reduced, absent or unreliable, other sensory inputs are centrally upregulated or weighted-up. For instance, in the dark or in the presence of unstable visual surroundings, when visuopostural responses are unavailable or unreliable respectively, the efficiency of vestibulo-proprioceptive responses increases whereas visuopostural responses are downregulated.[26] Similarly, a patient with uni- or bilateral vestibular failure will develop increased postural responses to visual motion stimulation.[27] It is thought that, by performing exercises in environments with altered sensory information, VR is able to affect a person's use of sensory information or sensory reweighting.[28]

Optokinetic stimulation can induce adaptation of specific vestibular parameters including VOR reflex gain in primates, healthy individuals and chronic peripheral vestibular patients.[16, 20, 29] Regarding patients' symptoms, post-rotational vestibular sensation duration also reduces in healthy subjects with exposure to repetitive, vestibular or optokinetic stimulation.[30] Short-term repeated exposure to visuovestibular exercises has been found to induce adaptive changes, decreasing (improving) the magnitude of visual dependency in healthy controls.[31] It is believed that improvements noted in visually induced dizziness following a programme of VR incorporating exposure to optokinetic stimulation is due to a decreased over-reliance on visual input for perceptual and postural responses. The underlying mechanism is likely to relate to motion-induced changes in neuronal excitability in visual motion cortical areas (V5/MT).[32, 33] PET and fMRI studies involving small or large-field optokinetic stimulation without additional vestibular stimulation note activation in cortical areas related to visual motion processing and eye movement control, and deactivation of parietoinsular vestibular cortices indicating a reciprocally inhibitory visual–vestibular interaction.[34–36] Similarly, when multisensory vestibular cortex areas are stimulated, bilateral deactivation is noted in visual and somatosensory cortex areas.[34, 37] It is suggested these interactions have a functional significance and indicate a sensory reweighting process, with greater weight given to the more reliable input thus suppressing the possible mismatch between contrasting sensory information.[36] Recurring exposure to conflicting visual input is also believed to promote reduced visual reliance and foster a more effective use of vestibulo-proprioceptive cues through sensory reweighting.[38] Overall, however, the mechanisms mediating sensory reweighting in postural control remain poorly understood.[39]

VESTIBULAR REHABILITATION INTERVENTIONS

Clinical assessment

A thorough assessment is required prior to the onset of VR. Vestibular function tests to assess for accuracy and normalcy[40] can be evaluated bedside by examination of spontaneous, gaze-evoked and positional nystagmus, dynamic visual acuity and headthrust tests.[41, 42] The recently developed Vestibular/Ocular Motor Screening test, which includes five domains (smooth pursuit, horizontal and vertical saccades, near point of convergence distance, horizontal VOR and visual motion sensitivity), is reported as a brief, sensitive vestibular/ocular screen for people with sport-related concussions that can be performed by physiotherapists.[43, 44]

The patient history will provide information regarding symptom severity, frequency, duration and triggers as well as falls history. Several validated questionnaires can aid in quantifying this information including the Vertigo Symptom Scale,[45] Dizziness Handicap Inventory,[46] Situational Characteristic Questionnaire[27, 47] and Activities-specific Balance Confidence Scale.[48, 49] A physiotherapist will also perform objective and subjective tests to identify functional deficits in people with a vestibular disorder, including the completion of questionnaires regarding perceived handicap due to their symptoms, objective static and dynamic balance tests (i.e. the modified Clinical Test of Sensory Integration and Balance (CTSIB),[50, 51] dynamic computerized posturography) and gait measures (i.e. gait speed, Functional Gait Assessment[52]).[40] Muscle strength, range of movement and sensation will be assessed and the eye, head and body movements or positions and challenging environments (e.g. visually 'busy' or unstable surroundings, irregular or compliant surfaces) which provoke symptoms will be identified in order to design an appropriate exercise programme.

Treatment goals are devised to address each person's individual subjective (i.e. dizziness, giddiness, nausea) and objective symptoms (postural and gait instability, falls). These goals often include:

- improve functional balance, gait and ability to perform daily activities
- decrease falls risk
- decrease symptom severity
- improve VOR function
- improve sensory integration and reweighting ability
- patient education.

VR should be based on the eye, head and postural exercises that provoke a patient's symptoms. Adaptation exercises (Figure 68.1)[23] incorporating gaze fixation and head movements and postural exercises are prescribed to promote recovery of VOR and vestibulo-spinal reflex function. Gaze fixation exercises are practised with varying target distances (i.e. 2 m, 1 m, 0.5 m) since VOR gain varies with target distance (closer targets require higher gains).[53] Fixation exercises are given to patients with oscillopsia and/or decreased VOR gain, most often seen in peripheral vestibular disorders.

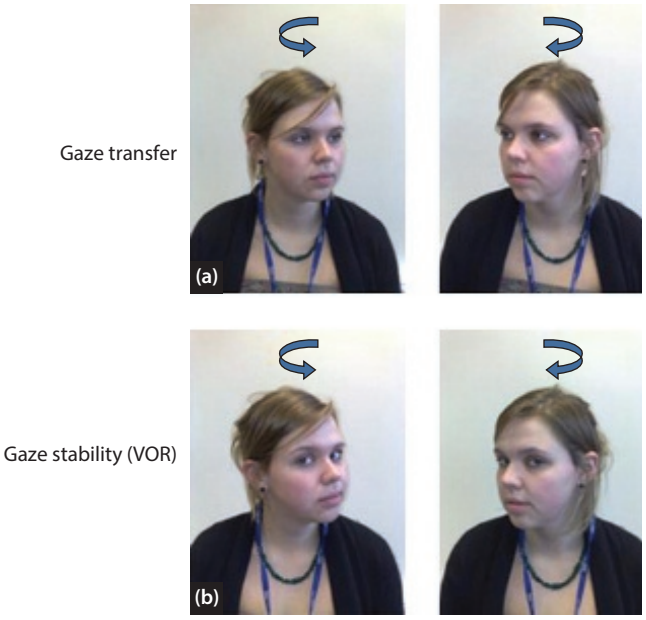

Figure 68.1 Gaze transfer and adaptation exercises[54] included within a vestibular rehabilitation programme. During 'gaze transfer' **(a)** the normal head and eye movement required for transferring gaze from one object to another is practised. The exercise can initially be practised without head movements with objects placed approximately 40 cm apart at eye level. During adaptation exercises **(b)** the vestibulo-ocular reflex (VOR) is being stimulated. This is responsible for maintaining a steady gaze on a fixated object with progressively faster head movements.

Saccades can support higher speed functional eye movements in people with bilateral vestibular hypofunction in whom the VOR gain is extremely reduced or absent.[40] Patients are asked to practise saccadic or gaze transfer exercises whereby they quickly shift their gaze between two horizontal or vertical targets. As the VR programme progresses, the complexity and difficulty of exercises should increase and therefore exercises will be practised in sitting, standing and walking on level ground or compliant surfaces (e.g. foam). Table 68.1 includes examples of commonly prescribed exercises, which can also be viewed online.[42]

Many people with a vestibular disorder will experience some level of balance and gait dysfunction. Exercises which focus on retraining postural alignment and movement strategies may need to be incorporated whereby patients learn to maintain an upright posture during progressively more difficult tasks including eyes closed and standing on compliant surfaces, with progressively reduced feedback about position.[55] The goal when retraining movement strategies is to develop those successful in moving the centre of gravity relative to a stationary base of support (ankle or hip strategy) and changing the base of support relative to the centre of gravity (stepping strategy). Retraining a coordinated ankle or hip strategy involves practising voluntary anterioposterior and lateral sway, without taking a step. Facilitating a hip strategy involves faster and larger displacements than an ankle strategy and may include activities such as tandem or single leg stance.

TABLE 68.1 Examples of commonly prescribed exercises in vestibular rehabilitation

Type of exercise	Examples
Head exercises (performed with eyes open and eyes closed)	Bend head backwards and forwards Turn head from side to side
Eye movement exercises	Head stationary follow movement of finger left and right/up and down Head movement to look back and forth between two vertical or horizontal targets
Visual fixation exercises	Perform head exercises while fixating stationary target Perform head exercises while fixating moving target
Positioning exercises (performed with eyes open and closed)	While seated, bend down to touch the floor While seated, turn to look over shoulder to left and then right Bend down with head turned first to one side and then the other Lying down, roll from one side to the other Sit up from lying supine and on each side
Postural exercises (performed with eyes open; eyes closed under supervision)	Practise static stance with feet as close together as possible Practise standing on one leg, and heel-to-toe Repeat head and fixation exercises while standing and then walking Practise walking in circles, pivot turns, up slopes, up stairs, around obstacles Stand and walk in environments with altered surface and/or visual conditions with and without head and fixation exercises Aerobic exercises, e.g. alternate touching the fingers to the toes, trunk bends and rotation

Retraining externally induced postural responses involves pushes or pulls of various amplitudes, speed and direction applied at the hips or shoulders, or the use of moving surfaces. Stepping can be practised by shifting the patient's weight to one side and then quickly bringing the centre of gravity back towards the unweighted leg, or in response to large anterioposterior or lateral perturbations. Multidirectional stepping, and stepping over a visual target or obstacle can also be practised.[55]

When the ability to select appropriate sensory input for postural stability is disrupted, exercises focus on asking patients to maintain balance in situations where the availability and accuracy of one or more sensory inputs is varied.[56] Sensory strategy retraining aims to help people with a vestibular disorder learn to effectively select appropriate sensory information for balance in various environments. Treatment focuses on maintaining balance during progressively more difficult static and dynamic balance and gait exercises while the availability and accuracy of sensory input are systematically varied. People who overrely on somatosensory cues for orientation (i.e. difficulty when walking on uneven surfaces, changing between different types of floor surface) practise tasks while sitting, standing or walking on surfaces with disrupted somatosensory cues such as compliant foam, moving platforms or tilt boards. For people with a visual dependency this involves exercises where visual input is incorrect, conflicting or absent, in order to learn to rely more on proprioceptive and available vestibular cues.[38] Guerraz et al.[27] suggested that rehabilitation programmes promoting desensitization and increased tolerance to visual stimuli through exposure to visual motion (i.e. optokinetic stimulation) would be specifically beneficial for patients with visual vertigo (VV). Advanced techniques in VR incorporate exposure to optokinetic stimuli[5] (**Figure 68.2**) or virtual reality[57] (**Figure 68.3**) environments. When the optokinetic stimulation has been incorporated into both the treatment session and the home programme, improvements have been noted in postural and gait stability, visually induced dizziness and psychological state, including depression and anxiety.[5] Easily accessible and economical computer games, YouTube videos or a DVD including visual stimulation recorded from the clinical equipment (i.e. optokinetic test in neuro-otology departments)[58] can also be used. Regardless of the type of optokinetic or virtual reality stimulus employed, exposure should be gradual and progressive.

People with a vestibular disorder may complain of poor concentration and memory impairment and a cognitive–vestibular function interaction has been highlighted in this population.[59] People with a vestibular disorder appear to have decreased attentional resources available when simultaneously performing a cognitive and posture or gait task (i.e. dual tasking) with priority given to maintaining the motor task to the detriment of performance on the cognitive task.[60, 61] Postural studies in standing, though, show varying results with regards to the effect of an additional cognitive task on postural sway, with some reporting that

Figure 68.3 Four aisles from a virtual reality supermarket,[57] showing a progression in visual complexity.

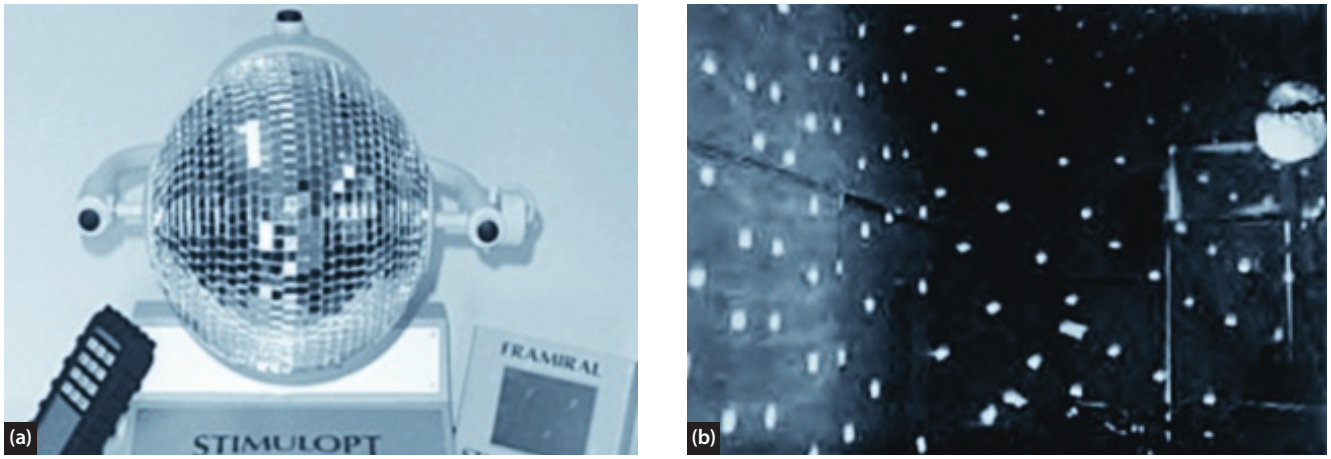

Figure 68.2 Apparatus used for full-field optokinetic stimulation-based intervention.[5] **(a)** A photo of the visual environment rotator apparatus (Stimulopt, Framiral, France). **(b)** Participants are asked to stare ahead while the apparatus rotates in different directions and at differing speeds. Participants practise exercises in sitting, standing and walking either towards and away from the stimulus or alongside it with or without vertical or horizontal head movements.

sway increases (i.e. worse),[62] decreases (i.e. improved)[63] or no change.[61] The disparate findings may be due to variations in task difficulty as well as the ability to isolate obvious sensory mismatches so they do not draw on attentional resources.[64] More recent studies investigating gait performance while performing a simultaneous cognitive task (dual-task) consistently show a significantly decreased gait speed[65, 66] and greater ataxia and deviation from a linear path[65] in this population when dual-tasking. Although no studies have specifically assessed the impact of incorporating dual task training within a VR programme, findings in older adults with increased falls risk show an increase in dual-task gait speed after training[67] and clinicians often include dual-task training into VR programmes when a functional deficit is noted in this area. Dual-task training involves practising progressive balance exercises (e.g. tandem standing or walking with or without upper limb activities) while simultaneously performing a secondary task such as counting backwards by 3s, recounting daily activities.[68] During training patients are asked either to constantly maintain attention on both tasks or to focus attention on one of them.[69]

Motor, sensory and cognitive strategy retraining should occur in parallel rather than sequentially. General characteristics of VR include specificity, repetition, progression, and patient education, for example explaining that initially symptoms may worsen, and improvement may be uneven. Patients should be aware that, even after symptoms have largely resolved, a temporary reoccurrence may occur during periods of stress, fatigue or illness. Patients should be advised to stop exercising and seek advice if they experience neck pain, loss of consciousness or vision, sensations of numbness, weakness or tingling in the face or limbs, or increased migraine frequency.

Novel and supplementary techniques

Various authors have discussed the potential benefit of virtual reality as a therapeutic protocol to improve postural and gait stability, VOR gain and subjective symptoms.[68–70] Two studies using a limited field-of-view head-mounted device noted improvements in VOR gain and symptoms in patients with a peripheral vestibular disorder.[69, 71] Two randomized controlled trials comparing customized VR versus virtual reality-based VR reported no significant pre–post treatment between-group differences in gait speed, functional gait performance, computerized dynamic posturography or subjective symptoms despite one study using a full-field immersive virtual environment consisting of a grocery store model[56] while in the other the low-cost Nintendo Wii Fit Plus® was employed (**Figure 68.4**).[72] The lack of difference in findings between the customized vestibular rehabilitation exercises versus virtual reality based rehabilitation in the two aforementioned studies[56, 72] may be due to the fact that both small- and large-field optokinetic stimulation shows similar reciprocally inhibitory visual–vestibular interactions, indicating that sensory reweighting occurs independently of visual field size and other factors including frequency,

Figure 68.4 A patient practising a balance exercise using the Nintendo Wii Fit Plus® system.[73]

velocity, texture, stimulus area and position within the visual field.[34–36, 73] Pavlou et al.[5] reported that this may explain why significant improvements were noted for both full and limited field-of-view optokinetic stimulation without significant between-group differences in their study. However, it should be noted that virtual reality systems may provide a more enjoyable rehabilitation method to re-train balance.[72]

Sessoms et al.,[74] however, reported that 12 sessions virtual reality exposure without additional VR provided greater benefit in gait speed and weight shift in people with traumatic brain injury (TBI) and vestibular dysfunction compared to virtual reality (6 sessions) plus VR (6 sessions). It is important to note that balance and vestibular exercises were practised during exposure to the virtual reality environment, thus providing multidimensional tasking. This provides a form of VR that is more demanding and may possibly be more appropriate than traditional techniques for people requiring more challenging tasks and who are required to operate at a higher level of performance in their profession (athletes, military servicemen).[75]

Current literature therefore suggests that virtual reality is beneficial and may offer a more enjoyable exercise method, particularly with regards to the Nintendo Wii® system.[73] Further work is needed, however, to identify the specific role of virtual reality within VR, particularly with regard to the patient groups for whom it is most suitable and to the optimal virtual reality format.

FACTORS AFFECTING OUTCOME

The relationship between psychological and dizziness symptoms is well documented as is the significant correlation between depression and anxiety in people with vestibular dysfunction.[82, 83] People who experience higher levels of somatic anxiety report greater handicap[84] and show a delay in recovery.[85] Every effort should be made to identify and act on these negative factors, referring the patient for counselling and/or adding psychopharmacological medication as appropriate. Studies combining VR with explicit cognitive behavioural therapy demonstrate improvements in patients' ability to cope, function, subjective symptoms and satisfaction with care.[86, 87] However, the clear additional effect of combining cognitive behaviour therapy with VR remains unknown.

People with peripheral or central vestibular disorders may experience visuomotor symptoms, such as oscillopsia or diplopia, which are capable of disrupting recovery and rehabilitation. Rehabilitation specialists should enquire directly about such symptoms. It has recently been reported that binocular vision abnormalities may affect the improvement of visually induced dizziness symptom improvement and these findings may have important implications for the management of subjects with refractory vestibular symptoms.[88] Clinicians need to be aware of the possible negative effect of this type of binocular abnormality on visually induced dizziness treatment outcome in order to manage their own and the patient's expectations from treatment.

Patients with vestibular migraine can adhere to and benefit from VR.[5, 89, 90] However, Bronstein and Pavlou[55] reported that, in their experience of treating patients with migraine-associated dizziness, an initial exercise programme including fewer exercises (i.e. three maximum) is better tolerated and adhered to. The exercises should be practised only once daily initially and gradually increased to twice daily. As symptoms and tolerance improve the number and total duration of daily exercises progressively increases. It is important for improvement to be noted with exercises such as those in **Table 68.1** before progressing to the inclusion of optokinetic stimuli.

Other factors that may impact on VR treatment outcome are listed in **Box 68.1**.

BOX 68.1 Factors that may delay vestibular compensation (adapted from Bronstein and Pavlou)[56]

- Fluctuating vestibular disorder (i.e. Ménière's disease)
- Migraine
- Additional disorder:
  - CNS
  - Peripheral nerve
  - Cervical spine
  - Visual (reduced visual acuity, modified optics (e.g. cataract operation), strabismus, diplopia)
- Age
- Lack of mobility (orthopaedic problem, forced bedrest, psychological/fear)
- Medication (antivertiginous drugs)
- Psychosocial
- Visually induced dizziness

EFFICACY OF VESTIBULAR REHABILITATION

VR, in the form of appropriate movements and sensory exposure, is currently the standard of care for patients with peripheral vestibular disorders regardless of age and symptom duration.[2, 4, 5, 91] Customized VR programmes provide greater benefit than generic ones (Cawthorne–Cooksey).[2, 4, 5, 91, 92] A recent Cochrane review and other systematic reviews have validated the safety and effectiveness of VR for the management of unilateral vestibular dysfunction.[93, 94]

People with bilateral vestibular hypofunction have an increased falls risk[95] and in one study a significant percentage of participants reported that they had to alter or change their professional activities and/or required the presence of another person due to the level of disability they experienced.[96] However, a number of studies have reported significant improvements in gaze, postural and gait stability, balance confidence, subjective symptoms and perceived handicap from dizziness in people with bilateral vestibular hypofunction,[1, 4, 97] with a systematic review stating that there is moderate strength evidence to support VR for improvements in gaze and postural stability but further work is need to identify its benefit for International Classification of Functioning, Disability and Health (ICF)–Participation outcome measures.[98]

In people with Ménierè's disease, management has been challenging due to recurring vertigo episodes. Long-term management may include dietary changes (low salt), medications (betahistine, steroids) and/or ablative therapy (e.g. intratympanic gentamicin administered to the affected ear).[99] Specifally for VR, significant improvements in postural stability, subjective symptoms and quality of life have been noted with customized VR physical exercises[2] or incorporating balance exercises with exposure to a virtual reality platform.[100] In the study by Garcia et al.,[100] participants in both the control and treatment groups had been given dietary recommendations and prescribed 48 mg/day of betahistine, however improvements were only noted in the treatment group.[100]

Some studies report similar responses for patients with peripheral, central and mixed pathology, but others claim poorer outcomes for the latter two groups. Differing results may be due to individual study variations regarding treatment duration (patients with central deficits are expected to require a longer duration for improvement), extent and location of central deficit (cerebellar dysfunction appears to reduce the effect of rehabilitation) and any additional cognitive or neuromuscular deficits.[101] Cerebellar and vascular disease, migraine and traumatic brain injuries (including concussion) are examples of central vestibular disorders associated with dizziness.

Current evidence suggests that VR can improve dizziness, gait and postural stability after mild traumatic brain injury (or concussion).[102, 103] In people with persistent neck pain, headaches and/or dizziness following a sports-related concussion, the time to return to sport is reduced following a programme of VR combined with cervical exercises.[104] McCulloch et al.[105] published clinical guidelines for rehabilitation providers regarding progressive return to activity after military mild traumatic brain injury and VR was recommended for those experiencing persistent dizziness and/or balance symptoms.

As stated above, people with vestibular migraine benefit significantly from a VR programme.[88, 106, 107] Patients with vestibular migraine or migraine history and a peripheral vestibular disorder can also tolerate and benefit from customized VR incorporating optokinetic exposure; surprisingly, migraineurs report significantly greater improvements for visually induced dizziness compared to non-migraineurs.[5] It has been suggested medication may help control visually induced dizziness symptoms in migraineurs, enabling them to better tolerate the exercises and thus leading to greater improvement.[89] However, Vitkovic et al.[107] reported that a 6-month VR programme without optokinetic exposure showed similar improvements in both participants with vestibular migraine and those with vestibular symptoms without migraine and, for the former, improvements were noted regardless of medication regime, although medication was not controlled for.

FUTURE RESEARCH

Further work is needed regarding:

- optimum interventions
- treatment duration
- long-term outcome
- the efficacy and potential benefit of novel techniques, i.e. virtual reality.

KEY POINTS

- VR is the mainstay of treatment for people with peripheral vestibular disorder.
- Evidence is emerging for its benefit in people with central vestibular disorders, particularly mild traumatic brain injury.
- VR should be informed by assessment and individually designed based on each person's impairments.

CHAPTER 69

AUDITORY NEUROPATHY SPECTRUM DISORDER AND RETROCOCHLEAR DISORDERS IN ADULTS AND CHILDREN

Rosalyn A. Davies and Raj Nandi

SEARCH STRATEGY

Data in this chapter may be updated by Medline and PubMed searches using the keywords 'auditory neuropathy', 'auditory neuropathy spectrum disorders', 'retrocochlear hearing loss' and 'auditory dyssynchrony'.

AUDITORY NEUROPATHY SPECTRUM DISORDER

Auditory neuropathy spectrum disorder (ANSD) is a specific form of hearing impairment when the patient can hear the sound of speech but has difficulties understanding the words. In infants, this problem understanding speech leads to difficulties developing speech. ANSD is caused by pathology in the inner hair cells of the cochlea or the auditory nerve and its synapses (i.e. 'neural' hearing loss). One of the major features of ANSD is that testing frequently shows pure-tone audiometric thresholds that are relatively well preserved but speech thresholds that are markedly impaired. It is in this context that the acoustic brainstem-evoked response (ABR) is performed and often found to be delayed or absent. Thus the concept of auditory dyssynchrony has arisen, i.e. the loudness of sound is relatively well perceived but the synchronization of acoustic signals is not adequate to evoke an ABR, or to elicit the stapedius reflex, or to suppress the contralateral otoacoustic emissions (OAEs). Because this synchronization requires the integrity of the VIIIth nerve, these causes of hearing loss were first described in the literature as 'auditory neuropathy' then 'auditory neuropathy/dyssynchrony', but since 2008 have been referred to as 'auditory neuropathy spectrum disorder' (ANSD).

The hearing difficulty in ANSD is typified by a characteristic pattern of abnormalities on audiological testing:

- normal to raised pure-tone auditory thresholds
- poor speech discrimination
- delayed, or absent, ABRs
- normal OAEs and cochlear microphonics.

There are many causes of ANSD and it is only with recent developments in assessing the function of cochlear receptor elements (inner and outer hair cells) that a finer definition of ANSD and a more accurate classification of aetiological factors have been possible.

Historical perspective

INCONSISTENT MEASURES OF HEARING

The term 'auditory neuropathy' arose as a way of grouping together those hearing disorders where observations of inconsistent measures of hearing are made, i.e. where hearing sensitivity is better than might be expected from the ABRs. The first publications presenting these paradoxical findings of absent ABR and behavioural audiometry[1–4] described children who responded behaviourally to moderate- or low-intensity sounds but had absent ABR.

PRESENCE OF OTOACOUSTIC EMISSIONS AND COCHLEAR MICROPHONICS

The first report of a further inconsistent test abnormality which helped to define both the concept and the diagnosis of neural synchrony disorder, came in 1991.[5] An 11-year-old boy was described with the characteristic findings of absent event-related potentials and acoustic reflexes with poor performance on temporally based psychoacoustic tests, but who had present click-evoked OAEs and cochlear microphonics. These latter two findings strongly pointed to normal preneural hearing. Further papers confirmed the presence of OAEs[6,7] in similar patients. One of these studies describes four infants in a special care baby unit who failed the ABR test but passed the click-evoked OAE screen. These infants were found in a series of 100 neonates admitted to the ITU. By following the infants, they observed that two out of the four showed normalization or reversal of the ABR abnormalities, but the other two retained their abnormal ABR. They concluded that, in instances where either no response or early waveforms only were obtained, ABR was insufficient as the sole evaluator of hearing sensitivity. They recommended concomitant use of behavioural audiometry with ABR and OAEs, and the importance of follow-up to guard against inappropriate diagnoses of cochlear hearing loss (see below).

SEQUENCE OF NAMES USED TO IDENTIFY THE DISORDER

'Auditory neuropathy' (AN) was first used as a clinical term by Starr and others in 1996[8] to describe patients whose hearing impairment was attributed to 'neuropathy of the auditory nerve'. Their hearing dysfunction was characterized by absent or disordered ABR in the presence of normal, even robust, preneural responses evidenced by the recording of normal OAEs or cochlear microphonics (CMs) in the same patients. The concept of 'auditory neuropathy/dyssynchrony' (first coined in 2001[9]) has challenged thinking about the physiology of hearing, and has provided a model for examining the role of neural synchrony of the VIIIth nerve and brainstem, and its impact on auditory perception. In 2008, after extensive review,[10] the term auditory neuropathy spectrum disorder was first adopted as a way of describing the heterogeneous and multifaceted nature of this disorder and the different ways ANSD affects patients, with symptoms ranging from very mild to very severe.

Further study has permitted the characterization of this group of disorders, and better assessment of these patients. These cases are now recognized as relatively common (5–12% of those previously considered to have severe to profound hearing loss in paediatric populations,[11,12] with an estimated 1 in 7000 of neonates, assessed by universal newborn hearing screening,[13] showed abnormal VIIIth nerve function) and probably represent a heterogeneous group where the common feature is disordered temporal processing (i.e. synchronization of sound). Progressive AN is reported in association with age-related degenerative changes, toxic effects of noise, mitochondrial, genetic and autoimmune disorders, etc.[14] The first large series[15] identified 49 cases from 543 patients who had either no ABR response or absent waves III and V. In seven patients, the audiometric data ranged from normal hearing to moderate impairment, i.e. 14% had better hearing sensitivity than might have been expected from their ABR, which was completely absent in these cases. Each of these seven patients also had abnormal acoustic reflex findings. Although the range of deficits as identified on medical, behavioural and electrophysiological testing was variable, there were many common features, including perinatal insults such as perinatal asphyxia, hyperbilirubinaemia or head injury. Tests of psycholinguistic abilities revealed significantly worse performance in auditory as compared to visual tasks, and speech discrimination testing revealed worse scores than would have been predicted from the patient's hearing thresholds in the majority.

Causes of auditory neuropathy

In classifying the causes of auditory neuropathy, **Table 69.1** identifies those aetiologies that are genetic or acquired congenitally, and **Table 69.2** identifies those that are acquired postnatally, including causes of retrocochlear hearing loss.[16] It should be remembered that some of the genetic causes only present with hearing impairment in adulthood, and so the tables do not differentiate 'paediatric' from 'adult' hearing disorders. The evidence for these aetiologies to be included in the tables is given by the references cited in the tables. The majority of the references are individual, or a series of, case reports with audiological, electrophysiological, imaging and in some papers histopathological evidence for a nerve VIII or brainstem cause of hearing impairment.

Starr[52] suggests an aetiological classification of AN that distinguishes between presynaptic and postsynaptic lesions. He suggests the following 'groupings' of AN:

- **Type I postsynaptic AN:** plus vestibular and peripheral neuropathies, e.g. Charcot–Marie–Tooth disease
- **Type I postsynaptic AN:** plus optic nerve disorders accompanying nuclear and mitochondrial mutations, e.g. Leber's optic atrophy, Wolfram syndrome (or 'DIDMOAD')
- **Type II presynaptic AN:** inner hair cell and neurotransmitter disorder, e.g. AN seen in otoferlin and *GJB6* mutations
- **AN unspecified:** affected sites unknown.

However, there is evidence to suggest that AN associated with specific gene mutations may change or progress to involve both pre- and postsynaptic locations. For example, patients with mutant *OPA1* gene show demyelination and axonal loss in advanced stages of disease and patients carrying the *DIAPH3* mutation show progressive deterioration of hearing thresholds from moderate to profound with gradual disappearance of OAEs.[53] Various types of genetic

TABLE 69.1 Genetic and congenital causes of auditory neuropathy

Genetic causes		
Non-syndromal	Non-syndromal recessive auditory neuropathy due to mutations in the otoferlin gene,[1, 17, 18] mutations in the pejvakin (*DFNB59*) gene[19] and in the connexin 26 gene[30] Non-syndromal autosomal dominant auditory neuropathy due to mutations in the *AUNA1* and *PCDH9* genes[20] Non-syndromal X-linked recessive auditory neuropathy due to the *AUNX1* gene[20]	
	Delayed maturation of auditory pathways[2]	
Syndromal	Degenerative conditions, with peripheral neuropathy	Hereditary sensory–motor neuropathy (HSMN), i.e. Charcot–Marie–Tooth[21]
		Friedreich's ataxia[22, 23]
		Roma (gypsy) families[24]
		Refsum disease[20]
	Degenerative conditions, without peripheral neuropathy	Usher syndrome[25]
		Mitochondrial myopathies: • MELAS[10] • chronic progressive external ophthalmoplegia[26, 27] • Mohr–Tranebjaerg syndrome 'deafness/dystonia peptide'[28]
Congenital causes		
Toxic/metabolic		Perinatal risk factors:[11, 29] • asphyxia • respiratory distress syndrome • low birthweight • cerebral palsy • hyperbilirubinaemia

TABLE 69.2 Acquired causes of auditory neuropathy and retrocochlear hearing loss

Acquired causes		
Infection	Viral	Herpes zoster/herpes simplex: • Ramsay Hunt[31, 32] • Bell's palsy[32]
		CMV[33]
		HIV/AIDS[34]
	Bacterial, fungal/ spirochaetal	Basal meningitis:[35, 36] • pneumococcal • meningococcal • haemophilus • tuberculosis • cryptococcosis • coccidiomycosis
		Syphilis
		Borrelia[37]
Immune-mediated	Post-infective	Guillain–Barré
	Vasculitic/ granulomatous	SLE, rheumatoid arthritis, sarcoid, Behçet's
Demyelination	Multiple sclerosis:[38, 39, 50–51] • VIIIth nerve • brainstem	

(Continued)

TABLE 69.2 ***(Continued)*** Acquired causes of auditory neuropathy and retrocochlear hearing loss

Acquired causes	
Neoplasia/ neoplasia-related	Vestibular schwannoma[40] Meningioma Cerebellopontine angle lesion
	Carcinomatosis[41]
	Radiotherapy
Metabolic/toxic	Uraemia[42]
	Paget's disease[43]
	Organic mercury[44]
	Cisplatin[45]
	Haemosiderosis[46]
Vascular	?Migraine[47]
	Posterior inferior cerebellar artery syndrome (PICA)
	Macrovascular:[48, 49] • posterior fossa aneurysms • AV malformations • vascular loops

mutations in AN result in different pathological changes in the auditory system as discussed by Manchaiah et al.[20] For example, the *AUNA1* gene is associated with changes in the distal auditory nerve, including dendrites and inner hair cells, the *OTOF* gene is associated with changes

mostly within the inner hair cells, the *AUNX1* gene results in demyelination and axonal loss of the auditory fibre, the pejvakin/*DFNB59* mutation is responsible for pathology in neural cell bodies in the auditory pathway from the spiral ganglion to the inferior colliculus causing degraded neural function, the *MPZ* mutation is associated with loss of auditory nerve fibres and ganglion cells and the *GJB2* mutation causes impairment of inner hair cells/synapses and/or auditory nerve terminals.[30]

Clinical presentation

Perhaps one of the more helpful ways of understanding the complaints of patients with AN is to consider the description given in an early account of patients with this disorder.[54] The case is of a young girl called 'Eve', who was identified at the age of 8 years because she had difficulty following her teacher's instructions at school and did not improve when placed in the front row of the class. She had measures of pure-tone hearing and ABR that were inconsistent with each other. Her evoked responses, both middle latency and cortical, were absent and tests of auditory processing were especially affected, but her hearing thresholds suggested better hearing than these would imply. Her comments prior to implantation were recorded as follows:

'seeking
so
desperately
to
underSTAND

The calls, the bangs, the thumps, the beats…

HEARING
FEELING

but never *TRULY* comprehending'

The common clinical features of patients with AN are that their hearing difficulties are worse with speech than with simple environmental sound, and using the telephone causes particular difficulty. Patients complain that they can identify the speech sounds and the language used, but they cannot understand the words. Their difficulties are always more marked in noisy environments when there are competing signals. The effect of an AN can be thought of as causing a 'time-smear' of sound. The severity of the hearing impairment may be variable (see **Figure 69.3**) and can range from transient, intermittent, to stable and deteriorating.

Pathophysiology

AN shows some features similar to other peripheral neuropathies. The latter have: (i) elevated thresholds for sensation; (ii) altered perception (paresthesia); (iii) rapid adaptation to stimuli; (iv) absent or hypoactive deep tendon reflexes. By comparison, patients with AN have varying degrees of elevation in pure-tone thresholds[55] (see (i) above); have altered perception of hearing (see (ii) above); exhibit absent acoustic middle ear reflexes (see (iii) above); have disordered or absent auditory nerve conduction (see (iv) above).

PHYSIOLOGY

In the physiology of audition, sound energy is transduced to electrical stimuli in the cochlea and transmitted via the auditory nerve. The inner hair cells in the organ of Corti (see **Figure 69.1**) are responsible for this transduction process as has been shown by Russell and Sellick[56] who first demonstrated the importance of the inner hair cells in this process. The afferent auditory nerve consists of 95% type I myelinated nerve fibres (with many type I nerve fibres innervating one inner hair cell), and 5% type II nerve fibres (each type II nerve fibre innervating many outer hair cells (OHCs)). The cell bodies of both these types of bipolar neurons lie in the spiral ganglion. The arrangement of type I neurons in relation to inner hair cells is conducive to synchronous neural impulses whereas the arrangement of type II neurons is not.[57] Thus these respective neural anatomical arrangements have implications in relation to the diagnosis of AN, where it is proposed that the afferent neural pathway is involved (**Figure 69.1**).

The auditory nerve is a myelinated cranial nerve, with the myelin in the distal portion of the nerve being derived from Schwann cells (which are responsible for myelination of peripheral nerves), while that more proximally is derived from the oligodendroglia (cells supplying myelin in the central nervous system). The change between the two different types of myelin occurs as the auditory nerve exits the internal auditory meatus at the porus acousticus. Neuropathies affecting the auditory nerve are considered to be due to either demyelination (see below) or axonal degeneration.

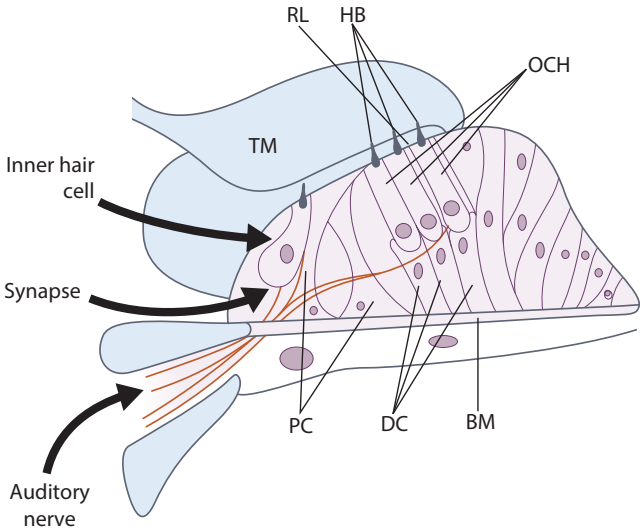

Figure 69.1 Diagram depicting proposed sites of lesion in auditory neuropathy. BM, basilar membrane; DC, Deiter's cells; HB, Habenula perforata; OHC – outer hair cell; PC, Pillar cells; RL, Reticular lamina; TM, tectorial membrane.

A combination of the two can also occur. The two functional consequences of these processes are a disruption of temporal synchrony of the auditory neural signals due to demyelination and a reduction of amplitude of neural signals because of axonal loss respectively. It is proposed that loss of neural synchrony (as can happen with demyelination) causes auditory nerve signals to be out of phase with the acoustic stimulus such that an averaged auditory brainstem response is not detected. Furthermore, dyssynchrony causes temporal tasks of audition to be disrupted (as tested by gap detection, localization and low-frequency pitch discrimination).[57, 58] Additionally, axonal loss results in reduced auditory neural input and therefore is also implicated in the absence of ABR recording, the loss of acoustic middle ear reflexes and disruption of temporal processes.

Demyelinating pathology results in the loss of the normal, rapid, 'saltatory' conduction of action potentials from one node of Ranvier to the next along the nerve fibre. This results initially in a conduction block where action potentials diminish to such an extent that the onward propagation of the neural impulse is halted. Over time the voltage-sensitive sodium channels (which are normally concentrated at the nodes of Ranvier) diffuse into the axon shorn of myelin, allowing for slow propagation of action potentials and hence slow neural impulses. Further, demyelination has been shown to cause increased sensitivity of nerve fibres to temperature increases, explaining cases of temperature-sensitive auditory neuropathy.[57] Finally, demyelination causes ephaptic transmission or 'cross-talk' between adjacent nerves that has the potential to interfere with synchronous auditory signals essential for understanding complex sounds such as speech.

Site(s) of lesion

It is now generally agreed that the term 'auditory neuropathy' encompasses heterogeneous conditions where the site of lesion may occur anywhere along the auditory pathways from the inner hair cells (IHCs) of the cochlea distally, through to the auditory brainstem pathways centrally (the afferent auditory pathway) (**Figure 69.1**). There is evidence accumulating to indicate at least three different sites of dysfunction:

- electromechanical transduction at the IHCs (including synaptic transmission)
- axons, cell bodies and myelin sheaths
- efferent influences through the olivocochlear feedback pathways.

ELECTROMECHANICAL TRANSDUCTION AT THE INNER HAIR CELLS

IHC disorders have been studied in animals[60] and have shown that anoxia and toxic agents (e.g. cisplatin) selectively impair IHC function, effectively removing the transduction process, including the release of neurotransmitters. Using the chinchilla animal model, scattered IHC loss (replicating the effects of sustained hypoxia) was induced, and OAEs, ABR thresholds and single unit tuning curves recorded at the inferior colliculus in the midbrain were measured. IHC damage correlated with ABR signal changes, but it was noted that individual inferior colliculus neurons had relatively normal thresholds across the frequencies, despite the loss of IHCs. This suggested that the number of active neural elements was reduced to the point that the remotely recorded compound action potential was reduced in amplitude. The single unit data was interpreted as implying that low threshold information was nonetheless reaching the central auditory system, and hence the dissociation of ABR and inferior colliculus neural thresholds. Extrapolating, it was suggested that patients with scattered IHC loss would have a reduced number of 'information channels', and therefore the speech information transferred to the brain would depend on the amount of redundancy in the system. However, studies of adult temporal bones have not shown isolated IHC loss.[61] [Level 1 evidence]

An excess of neurotransmitters, i.e. an infusion of synaptic agonists, has been shown to cause attenuation of auditory nerve activity.[57] A disorder affecting the synapse between the IHCs and the dendrites of the auditory nerve could account for many of the electrophysiological features of an auditory neuropathy. The disorder could be pre- or postsynaptic, affecting the release of neurotransmitters from the IHCs or their receptor sites on the dendritic cells. In neonates with an abnormal ABR release of neurotransmitters is deficient from ribbon synapses due to deficient ion vesicle turnover and acquired excitotoxic effects of noise damage on these synapses with subsequent neural degeneration.

The effect of stimulus rate on the ABR may be a useful tool in investigating synaptic dysfunction. In healthy controls, an increase in stimulus repetition rate results in an increase in the latency and decrease in the amplitude of wave I. Electrocochleography (ECoG) has also been used to identify presynaptic versus postsynaptic lesions in auditory neuropathy. Prolonged summating potential (SP) latencies indicated a presynaptic lesion whereas a normal latency SP often followed by a negative 'dendritic potential' (DP) was associated with a postsynaptic lesion. Electrically evoked auditory brainstem response (EABR) measured following cochlear implantation showed a normal EABR waveform in patients with prolonged SP on ECoG (presynaptic lesion) while EABR waveforms were either absent or of poor morphology in patients whose SP on ECoG had a normal latency with evidence of DP (postsynaptic lesion) (**Figure 69.2**).[62]

AXONS, CELL BODIES AND MYELIN SHEATHS

There are 30 000 auditory nerve fibres, most of which have diameters of approximately 3 µm. Type I nerve fibres, which innervate IHC, make up 95% of the afferent fibres, with 10–30 neurons innervating each IHC. Type II nerve fibres make up the remaining 5%, each one making contact with many outer hair cells (OHCs) (see above). These nerve fibres are myelinated bipolar neurons with their cell bodies in the spiral ganglion.

Distinguishing whether a neuropathy is principally demyelinating or axonal in type is primarily determined

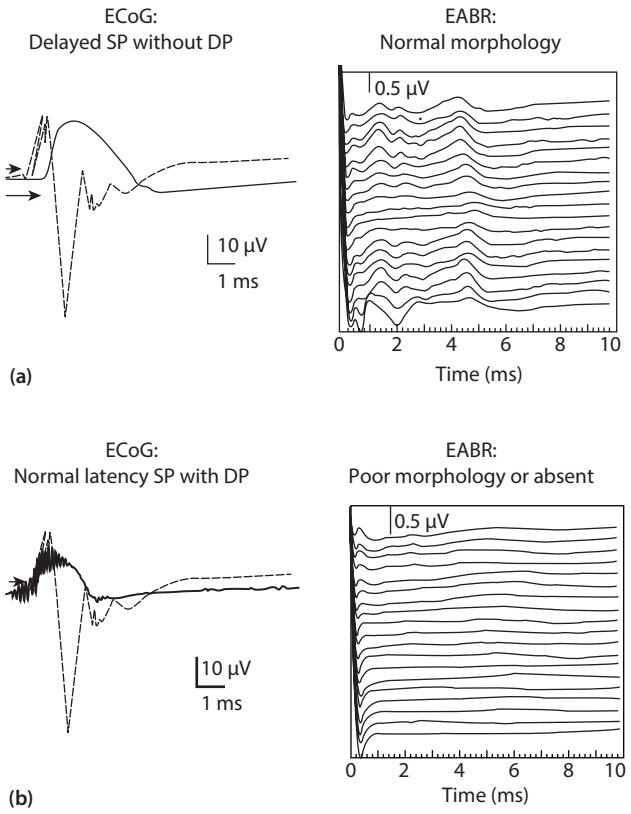

Figure 69.2 Precochlear implantation ECoG waveforms compared with postcochlear implantation EABR showing correlation between **(a)** delayed SP and normal EABR (presynaptic lesion) and **(b)** normal latency SP with DP and absent or poor morphology EABR (postsynaptic lesion). Redrawn with permission.[60]

histologically following biopsy, clearly not a procedure applicable to the auditory nerve. In the circumstances, electrodiagnostic studies (nerve conduction studies) can provide a functional categorization for the type of neuropathy. A patient with late-onset HSMN, beginning at age 40, and presenting with a hearing loss 10 years later, came to autopsy at the age of 77 years. Histopathological examination of both auditory and sural nerves showed a significant loss of nerve fibres more extensive in the sural nerve than in the auditory nerve. Photomicrographs of a section of the patient's auditory nerve and an age-matched control showed an extensive loss of large nerve fibres in the former. This woman's neuropathy was inherited in an autosomal dominant fashion, with genetic analysis of the affected members of the pedigree showing a duplication disorder on the *MPZ* gene of chromosome 1. The *MPZ* gene (myelin protein zero) was the first gene associated with auditory neuropathy in patients with Charcot–Marie–Tooth disease (CMT). The *MPZ* gene codes for a protein required for myelin formation and adhesion. Preserved cochlear hair cells were found on postmortem examination of a patient with CMT together with decreased spiral ganglion cells and degeneration of the residual axons. The proximal auditory nerve showed axonal loss and incomplete myelination at the entrance to the brainstem. [Level 1 evidence]

EFFERENT INFLUENCES THROUGH OLIVOCOCHLEAR FEEDBACK

Auditory efferent fibres travel from the olivocochlear bundle in the midbrain through the VIIIth nerve to the cochlea. Studies of the effects of the efferent pathway have demonstrated a reduction in the compound action potential (CAP) following electrical stimulation of the olivocochlear bundle in humans.[63–65] The contralateral pathway involves only crossed afferent fibres and is believed to mediate the suppression of OAEs in the presence of noise.[65] The ipsilateral pathway to the OHCs, however, involves crossing of both the efferent and afferent fibres. The suppression of OAEs in the presence of noise is known as the medial olivocochlear reflex, and has been studied in detail[65–67] showing the greatest suppressive effect in the 8–18 ms time period in the lower frequencies with low-intensity stimuli and with binaural noise (using a forward masking paradigm).

Two patients with AN, followed for some time, showed robust OAEs but, in both, contralateral noise failed to suppress their OAEs.[66] Three 'foil' subjects were chosen as controls: one with a similar audiogram to patient 1, one with a Bell's palsy and absent stapedius reflex thresholds (i.e. absent middle ear muscle reflexes), and one with bilateral temporal lobe disease. Testing of the 'foil' subjects showed that isolated normal hearing at 2 kHz, absent middle ear reflexes and conscious cortical awareness of sound did not contribute directly to the lack of efferent suppression.

Their suggestions to explain this included:

- deficiency of synchronous activation of type I afferent fibres (originating at the base of the IHCs), so they cannot activate efferent feedback
- restriction to only using type II afferent neurones (originating at or near the OHCs) to support normal zones of pure-tone sensitivity.

Discharge of primary neurons, synchronized by a primary deficit in the efferent system, has largely been discounted following studies on patients with unilateral auditory neuropathy,[67] where the function of the efferent system on the side with the profound hearing loss has been demonstrated to be functional (i.e. OAEs on this side can be partially suppressed by noise to the good ear). The efferent system requires input from the afferent system to be activated. The two patients above show the effects of disconnecting the afferent system from efferent stimulation and revealing this disconnection by leaving the patients with an absence of both static (middle-ear mediated) and dynamic (medial olivocochlear system mediated) efferent suppression.

Test battery

- Baseline audiometric tests
  - Pure-tone audiogram
  - Tympanogram
  - Stapedius reflex thresholds

- Electrophysiological tests
  - ABRs
  - ECoG
  - CMs
  - OAEs, both with and without contralateral suppression
  - Middle latency responses (MLRs)
  - P300
- Behavioural auditory tests
  - Speech recognition tests
  - Temporal pattern tests:
  - frequency pattern tests
  - temporal gap detection

Figure 69.3 shows a range of test results from a 7-year-old male patient with auditory neuropathy.

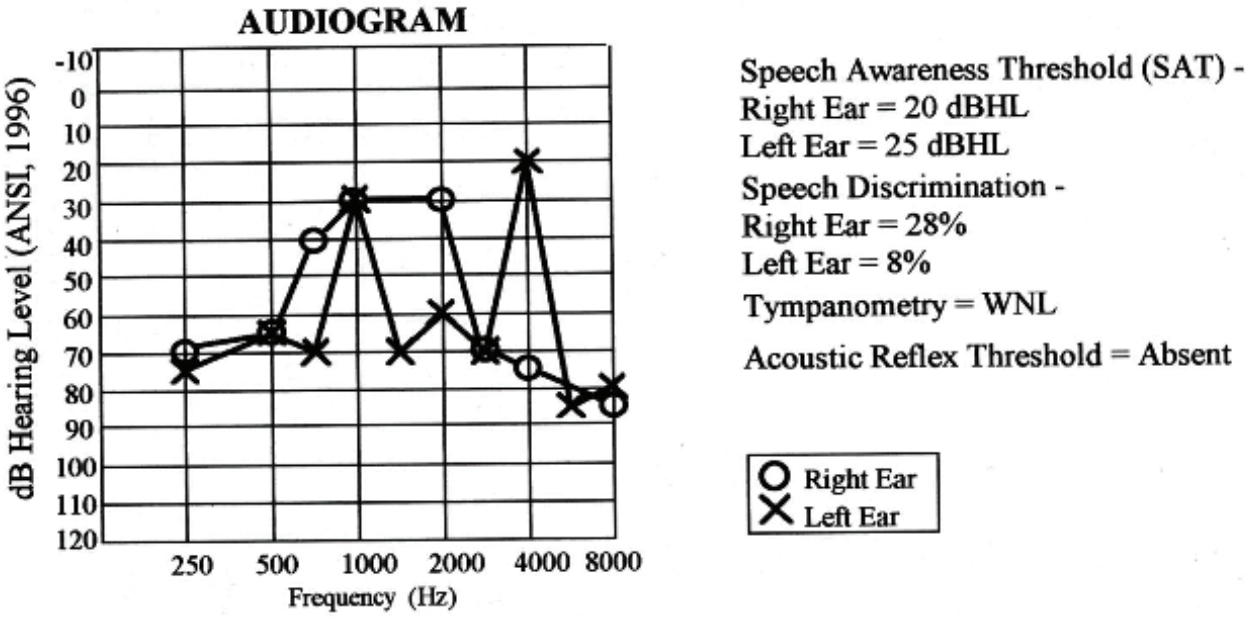

Figure 69.3 **(a)** Audiogram, **(b)** transient-evoked otoacoustic emissions and **(c)** auditory brainstem responses from a 7-year-old male patient with auditory neuropathy. Reproduced with permission.[55]

ACOUSTIC BRAINSTEM EVOKED RESPONSES

Acoustic brainstem evoked responses (ABRs) are detected by scalp electrodes and are a far-field reflection of electrical activity generated by the VIIIth nerve and brainstem auditory pathways in response to acoustic stimuli. Waves I and II are thought to come from generator sites in the distal and proximal sections of the VIIIth nerve, respectively, and III, IV and V from generator sites within the brainstem auditory pathways.[68] It has been proposed that the absent ABR of the patient with AN can be explained by the altered temporal synchrony of the auditory brainstem pathway, suggesting that, in these patients, auditory nerve and brainstem discharges are not precisely time-locked to the acoustic signal, so that short duration components (i.e. of 1 ms) are cancelled in the averaging process, rendering them indistinguishable from background electrical levels.

PURE-TONE AUDIOMETRY

Pure-tone audiometric thresholds show varying configurations of hearing thresholds (**Figure 69.4**) and variable degrees of hearing impairment (**Figure 69.5**).

Otoacoustic emissions (OAEs), first described in 1978,[64] are low-intensity sounds generated by the active movement of the OHCs of the cochlea. They are a marker of cochlear function and are left intact after section of the auditory nerve.[69] These acoustic echoes are evoked by stimulation with transients (clicks) at 80–86 dB sound pressure, and, typically, responses to 260 stimuli are captured over a time frame of the first 20 ms after stimulus application. These transient evoked otoacoustic emissions (TEOAEs) are present if the response amplitude, after subtraction of background noise, is 4 dB or more, and the waveform is reproducible in at least three octave bands. Measurement of distortion product otoacoustic emissions (DPOAEs) allows specific testing of a restricted region of OHCs, giving more frequency-specific information than TEOAEs. This is achieved by stimulation with two continuous tones of different frequencies (f1 and f2) that evoke DPOAEs that are largest at the 2f1–f2 frequency.

From the first papers describing TOAEs in these patients[8, 64] it was evident from the clearly recognizable waveforms that the hearing disorder was not due to significant dysfunction of the cochlear OHCs. On the occasions when these patients were monitored over a period of time, some started to lose their DPOAEs from small regions of the cochlea and this was attributed to a lack of trophic factors on the OHCs due to the auditory nerve disorder. Another study that describes the results of OAE testing in 17 children thought to have AN failed to show OAEs in either ear in more than half of their patients (8/17, with intersubject variation in behavioural hearing thresholds varying from 10 dB to 120 dB). However, in this latter report, how the authors felt confident to diagnose auditory neuropathy is questioned.

Contralateral suppression of OAEs can occur if noise (set at a level 5 dB louder than the click) presented to the contralateral ear fails to reduce the TEOAEs by 1 dB or more. This may occur if either the afferent pathway from the contralateral ear or the efferent pathway on the recorded side (via the olivocochlear bundle in the brainstem and carried with the inferior vestibular division of the VIIIth nerve) is dysfunctional.

Two studies have reported the lack of contralateral suppression of OAEs in patients with AN.[66, 70] The second of these describes the absence of contralateral suppression of OAEs in all eight of the patients tested from their series of ten. This is consistent with VIIIth nerve pathology occurring in either the contralateral afferent or the ipsilateral efferent pathway.

Cochlear microphonics (CMs) are an electrophysiological response generated in the cochlea to acoustic signals.[71] They represent the early components of the ABR and are small in size and susceptible to contamination by electroacoustic artefact. They can be better determined by reversing the click phase, at 5–25 ms, from condensation to rarefaction. They occur in the 0.7–1 ms window post-stimulus and show similar waveform characteristics to the stimulus itself[72] (the endocochlear potential of +80 mV is not measurable in humans). Transtympanic electrocochleograms indicate that the phase reversal to the click occurs at the level of the

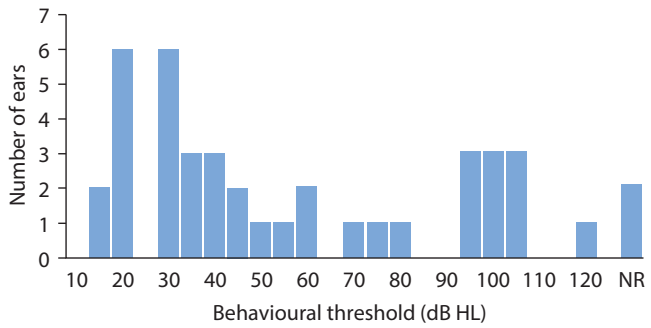

Figure 69.4 The distribution of behavioural thresholds (three-frequency average) for 38 years with auditory neuropathy. Reproduced with permission.[15]

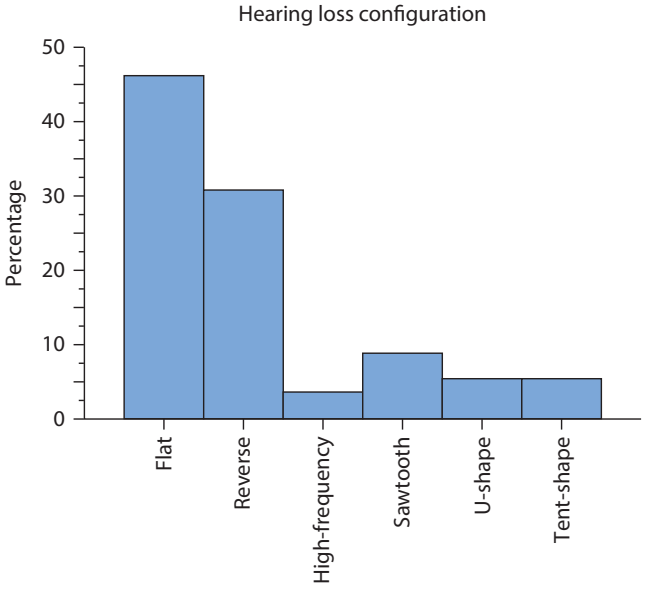

Figure 69.5 Hearing loss configuration (audiogram shape) distribution from a database of 59 patients with auditory neuropathy. Reproduced with permission.[95]

cochlea itself, and therefore the presence of CMs is indicative of a preneural response to sound.

Where investigation of the neural response is the primary aim, alternating polarity clicks are used in the recordings of the ABR because they cancel the cochlear potential and overwrite the CAP. This generates a 'microphonic-free' ABR leaving only the desired summating and action potentials, as evidence of a neural response. Thus, OAEs are preneural phenomena that reflect the integrity of the OHCs of the cochlea, whereas ABRs and the summating and CAP of the ECoG are tests of neural synchrony. The common stimulus to all these phenomena is the broad-spectrum 100 µs pulse.

The enhancement and detection of CMs was studied in five infants who had paradoxical results to hearing testing in a series of 60 deaf children.[73] By performing latency–intensity ABR studies using condensation and rarefaction clicks through insert earphones, intact preneural responses to sound with the characteristics described in **Table 69.3** were identified. It was suggested that, if diagnosticians do not have access to OAEs, patients with AN can be detected by comparison of ABR responses to condensation and rarefaction clicks at 100 µs (**Figure 69.6**).

Insert earphones are recommended[64] for recording ABRs to enable the separation of the stimulus artefact from cochlear potentials. The response of two opposite polarity clicks can be compared, with search for phase reversals and lack of shifts in latency with intensity changes. Adding the positive and negative polarity traces may uncover small residual neural events.

STEADY-STATE POTENTIALS

Sixty patients have been tested using steady-state potentials (SSEPs) to study the evoked potentials in the frequency domain rather than in the temporal domain, on the basis that the SSEP threshold might be more resistant to the effects of neural dyssynchrony. The study conclusion, however, was that SSEPs at a high rate had little or no predictive value for hearing thresholds in children with auditory neuropathy.

Tympanometry and stapedius reflex thresholds from 500 to 4000 Hz are also used in the test battery, as activation of the middle ear muscles (i.e. stapedius) by high-intensity sound is dependent on the integrity of the VIIIth nerve. The latter were absent in all ten patients in one study of auditory neuropathy,[8] irrespective of the pure tone threshold.

Speech recognition tests have been an essential item of the test battery for recognizing AN. Speech intelligibility is affected out of proportion to that expected if the pure-tone loss were entirely of cochlear origin. Speech intelligibility scores, tested at comfortable hearing level, are reduced disproportionately to the extent of the pure-tone impairment.[74] These scores are calculated from the average audiogram thresholds at 1, 2 and 4 kHz and, if the score falls below predicted values, the hearing impairment is likely to be retrocochlear in nature. Expected sentence recognition scores are calculated using the PTA to find the number of audible cues available to the patient and dividing by the total number of audible cues in the speech spectrum.

PSYCHOPHYSICAL

Further transmission of neural impulses via the auditory nerve to the brainstem is followed by auditory projections to higher centres where perceptual registration and cognitive elaboration takes place (see Chapter 48, Physiology of hearing). Psychophysical measures can also be used to assess patients with AN. They include the following tests which may be required to distinguish central auditory processing disorders from retrocochlear hearing disorders:

- monaural low redundancy speech tests, i.e. speech stimuli, presented to one ear
- dichotic/binaural interaction tests, i.e. stimuli presented to both ears, the task requiring the patient to attend to

TABLE 69.3 Comparison of the response characteristics of cochlear microphonics, compound action potentials and otoacoustic emissions (reproduced with permission)[73]

Response	Source	Measured by	Response to stimulus polarity inversion	Response to intensity decrease
Cochlear microphonic	Primarily from outer hair cells	Far-field or near-field electrical recordings using signal averaging and common-mode rejection	Inverts and follows the polarity of the stimulus; is not forward maskable and does not change in latency during simultaneous masking	No latency shift
Compound action potential (CAP)	Primary afferent neurons in primarily the basal turn of the cochlea	Far-field or near-field electrical recordings using signal averaging; comprises wave I of the ABR and the CAP of the ECoG	Does *not* invert, but shifts in latency by about one-half period of the stimulus; reductions in size and increase in latency occur during simultaneous masking in the same ear	Increase in latency at roughly 0.3 ms per 10 dB decrease in intensity
Otoacoustic emissions (OAEs)	Outer hair cells, with response size in humans probably mediated by the middle ear, transfer function	Sensitive microphones and amplifiers in response to clicks or tone pairs in the 2f1–f2 paradigm	Invert in polarity	No obvious change in latency with change in intensity

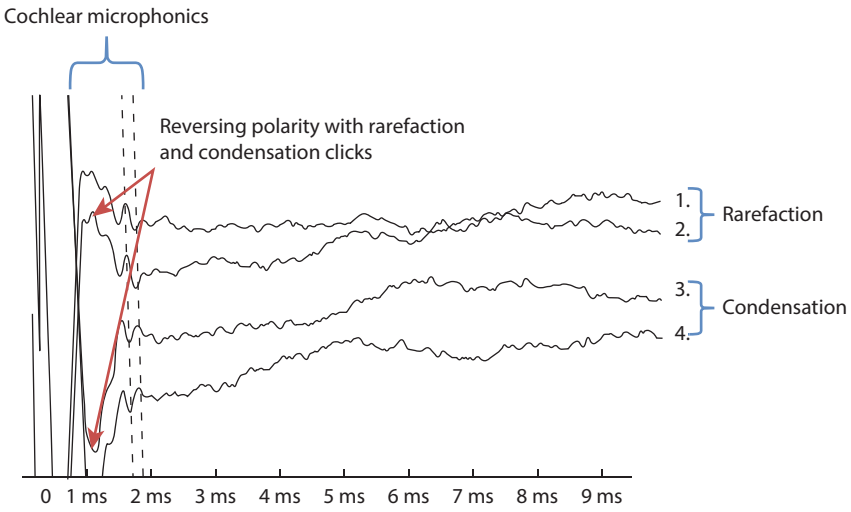

Figure 69.6 Acoustic brainstem evoked response to condensation (Con) versus rarefaction (Rar) polarity clicks. Note the complete biphasic inversion of elements even beyond 2 milliseconds. Reproduced with permission.[72]

one ear only, or both at the same time e.g. competing sentence tests
- temporal tests, i.e. sequencing tasks (e.g. the temporal gap detection test with a silent period embedded in a noise burst)
- modulation transfer function tests, i.e. fluctuations in levels of steady-state noise.

Further details are presented later in the chapter under 'Differential diagnosis'.

KEY POINTS

Criteria for diagnosis of auditory neuropathy

Evidence for preneural response to sound

- Normal otoacoustic emissions (OAEs)*
- Normal cochlear microphonic (CM)*

Evidence for abnormal neural synchrony

- Absent or severely abnormal acoustic brainstem auditory evoked responses**
- [Absent contralateral suppression of OAEs]
- [Absent middle ear reflexes]

plus

- Pure-tone thresholds ranging anywhere from normal to severely impaired

Diagnosis requires simultaneous presence of a pre-neural response to sound * *plus* abnormal neural synchrony **

PAEDIATRIC AUDITORY NEUROPATHY SPECTRUM DISORDER

Prevalence of disorder

A rigorous study[15] has been reported of 20 subjects fulfilling the criterion for AN, 12 of whom were identified from the Victorian Hearing Screening Programme for children considered at risk of hearing loss, and 8 of whom were identified by parental concern or failure to develop speech and language normally. An incidence of AN as 2.09% of those who failed ABR screening (n = 39), and 0.23% of those children at risk for hearing loss (n = 5199), i.e. 2/1000, was reported. A review of published literature which looked at prevalence of AN in the well-baby population and the false negative rate of OAE based on newborn hearing screening programmes showed that prevalence of AN in children in population hearing screening was between 0.006% (SD 0.006) and 0.03% (SD 0.02). The false negative rate, however, due to children with AN not detected through newborn hearing screening programmes using only OAEs is between 4% and 17%.[75]

Table 69.4 summarizes the results of the larger studies of paediatric populations assessed for AN.

From the studies in Table 69.4, it can be seen that the prevalence of AN in the population of children with permanent hearing loss is 5.1–15.38%, i.e. approximately 1 in 10. This compares with 1 in a 100 of those suspected of hearing loss (0.5–1.29%), or 2 in a 1000 of the 'at risk' population (0.23%).

Comorbidities such as developmental and learning delays, attention deficit disorder (ADD), attention deficit hyperactivity disorder (ADHD), autism spectrum disorders, visual problems, blindness, cerebral palsy, motor disorders, apraxia, inner ear malformation, seizures and various syndromes are reported in up to 54% of children with AN. These can have an adverse influence on the child's speech and language development in addition to the underlying AN. In 2008 the Guidelines Development Conference on the Identification and Management of Infants with AN, meeting in Lake Como, Italy, considered the many aspects of AN, including comorbidities, and proposed the term 'auditory neuropathy spectrum disorder' in an attempt to encompass the heterogeneous nature of the condition.[10]

Causes of paediatric auditory neuropathy

PERINATAL RISK FACTORS

The first report of perinatal risk factors in babies who failed the ABR test but passed the click-evoked OAE

TABLE 69.4 Prevalence of disorder in neonates/children

Authors	Study population	Number with absent ABRs	Those fulfilling criteria for AN	% of study population with AN
Kraus et al. 1984[4]	543 with suspected hearing loss	49 with absent ABRs	7 with no worse than moderate hearing loss (14.3% of those with absent ABRs)	1.29% of those with suspected hearing loss
Davis and Hirsh 1979[1]	200 clinic population		1	0.5% of clinic population
Berlin et al. 1994[12]	60 children diagnosed as 'deaf'		5 with absent ABRs and present OAEs	12% of deaf children
Rance et al. 1999[15]	5199 with increased risk of hearing loss	37 with absent ABRs	12 subjects with absent ABRs and present CMs	0.23% of those at risk of hearing loss
Madden et al. 2002[11]	428 children with sensorineural hearing loss (SNHL)		22 with CMs/OAEs but absent ABRs	5.1% of children with permanent hearing loss
Foerst et al. 2006[76]	5190 children with hearing concerns and risk factors for hearing loss, of whom 3415 were tested with ABR and TEOAEs	379 with elevated or absent ABRs	32 with OAEs present but absent ABRs	0.94% of children at risk of hearing loss
Talaat et al. 2009[77]	112 children aged 6–32 months, with severe to profound hearing loss		15 with absent ABRs and OAEs present	13.4% of children with permanent hearing loss
Kirkim et al. 2008[78]	23 786 babies had universal newborn hearing screen; 2236 were referred for further tests	65 with absent or elevated ABRs	10 with absent or elevated ABRs and clear OAEs	15.38% of children with hearing loss, and 0.044% of babies undergoing universal newborn hearing screen

screen came in 1996. Four out of 100 fulfilled these criteria: one had periventricular leukomalacia, two were low birthweight and one was very low birthweight; three were diagnosed with having a respiratory distress syndrome; two received ampicillin and gentamicin; and three had hyperbilirubinaemia necessitating either exchange transfusion or phototherapy. Two out of these four normalized or reversed their ABR abnormality. Although these observations did not prove causality in any of the cases, the findings did imply that perinatal factors were likely to be involved, with some factors possibly causing temporary abnormalities only.

In an extensive report of neonates with AN[15] neonatal risk factors were documented and details of bilirubin levels recorded. Increased bilirubin (>350 µmol/L) was identified in 50% (Table 69.5).

Perinatal risk factors for AN were also analyzed in a retrospective study[11] of 22 patients with present OAEs and CMs but absent ABRs. These patients were identified from 428 children with permanent hearing loss in a paediatric otology clinic. Sixty-eight per cent of the children with AN had a complicated perinatal course, with hyperbilirubinaemia in 50%, prematurity in 45%, ototoxicity in 41%, neonatal ventilator dependency in 36% and/or cerebral palsy in 9%. In 36% a possible genetic link was identified, although this was apparently of a non-syndromic type as no other anomalies, particularly peripheral neuropathy, were identified. Following these children for an average of 32 months, 50% showed an improvement, not accounted for by normal development, within 1–15 months, and those with hyperbilirubinaemia

TABLE 69.5 Hearing loss risk factors in subjects with auditory neuropathy (reproduced with permission).[15] Figures in brackets represent the bilirubin level in micromoles/litre, except where otherwise indicated

Child	Risk factor	Other disabilities	Gestation
1	Jaundice (1010)		37
2	Jaundice (792)		36
3	Jaundice (467)		39
4	Jaundice (420)		40
5	Jaundice (380)		41
6	Jaundice (353)/hypoxia	Cerebral palsy	34
7	Hydrocephalus/hypoxia		33
8	LBW (900 g)/hypoxia		25
9	Parental concern	Cerebral palsy	40
10	Unilateral middle ear malformation	Unilateral facial palsy	39
11	Neonatal meningitis		39
12	Parental concern		41
13	Jaundice (540)		40
14	Jaundice (470)/hypoxia		32
15	Jaundice (420)		41
16	Jaundice (390)/hypoxia		31
17	None	Cerebral palsy	40
18	None		39
19	None		39
20	None		39

were more likely to improve than those without hyperbilirubinaemia ($p < 0.04$ at 2 kHz). Prematurity and perinatal anoxia were shown to predispose to bilirubin encephalopathy, with the risk for kernicterus and permanent sequelae being much higher at serum bilirubin levels thought to be safe for term babies.[6] 'Finer tools' such as ABR and other event-related potentials, have been recommended for use alongside biochemical measures to predict the risk of kernicterus and its sequelae. Children with hyperbilirubinaemia would thus appear to represent a unique subpopulation of patients with AN and require surveillance electrophysiologically as well as behaviourally.[79]

As children treated in neonatal intensive care units are found to have higher incidence of AN, the Joint Commission on Infant Hearing (JCIH, 2007) have recommended that infants treated in neonatal intensive care have their hearing tested using auditory brainstem response audiometry.[80]

KEY POINTS

Perinatal factors implicated in auditory neuropathy spectrum disorder

- Prematurity
- Perinatal anoxia/respiratory distress syndrome
- Low birthweight
- Hyperbilirubinaemia (>350 µmol/L)*
- Ototoxicity
- Cerebral palsy
- Neonatal ventilator dependency

* This level may be lower in preterm babies.

GENETIC

Non-syndromic recessive hearing loss is thought to account for approximately 40% of all cases of childhood hearing loss. Where that hearing loss has been demonstrated to have the characteristics of AN, genetic causes of the disorder have, until recently, only been associated with syndromic hearing loss, i.e. CMT[21] and Friedreich's ataxia.[22, 23] However, mutations in the otoferlin (*OTOF*) gene have been demonstrated to be associated with non-syndromic recessive auditory neuropathy (NSRAN).[17] The causative gene in four families was sought using a genome-wide linkage study and a critical region on chromosome 2p23 was identified that contained the *OTOF* locus. Out of eight alleles, four *OTOF* mutations were observed in the NSRAN families: a frameshift, a splice site and 2 missense mutations. These patients have been helped by cochlear implants but not by hearing aids. Thus, finding the genetic cause of this NSRAN has implications not only for aetiological diagnosis in newborn screening but also for prognosis and habilitation. Otoferlin is expressed in the IHCs in the region where afferent synaptic contacts are located.[17]

More recently, mutations in the pejvakin (*DFNB59*) gene, located on chromosome 2q31.1-q31.3 were identified in four families with AN. Pejvakin is a protein found in the cell bodies of neurons in the afferent auditory pathway and is thought to cause neural dysfunction.[19] Mutations to connexin 26 (*GJB2*) genes have also been implicated in auditory neuropathy. In a study reported in 2008, three children with hearing loss but preserved OAEs underwent transtympanic ECoG that showed normal CMs but abnormal neural responses.[30] [Level 1 evidence]

IMPACT ON NEONATAL HEARING SCREENING PROGRAMMES

Importantly, the association of a screening ABR fail and an OAE pass raises questions about whether OAE should be universally employed as the only initial screening tool for hearing loss infants in special care baby units.

Various protocols have been recommended for neonatal hearing screening.[6, 63, 73] One ABR intensity series protocol requires an estimate of threshold immediately if the infant fails an initial 60 dB nHL or 30 dB nHL test in either ear,[61] advising that records should be kept of threshold estimates and indicators of site of lesion (i.e. cochlear or neural). As ABR is also insufficient as the sole evaluator of hearing sensitivity, particularly if no response or early waveforms only are obtained, some[6, 63] recommend OAE testing at the same time as the ABR threshold series. Ideally, a system that can collect ABRs and OAEs simultaneously from the same sleeping infant is recommended. The importance of follow-up with the concomitant use of behavioural audiometry with ABR cannot be underestimated to guard against inappropriate diagnoses of cochlear hearing loss or reversible ABR abnormalities.[10, 63, 73]

KEY POINTS

Neonatal hearing screening programmes

- Checks of ABR and/or CMs should be considered in **high-risk newborns** who undergo OAE testing as their primary screening tool.
- Clinicians and audiologsts should include **auditory neuropathy spectrum disorder** in their differential diagnosis of SNHL in children.
- Patients with **hyperbilirubinaemia** should be seen as a distinct subset of those patients fulfilling the criteria for AN, particularly because they tend to show a distinct audiological improvement during the first year of life.

ADULT NEUROLOGICAL AUDITORY NEUROPATHY AND BRAINSTEM HEARING LOSS

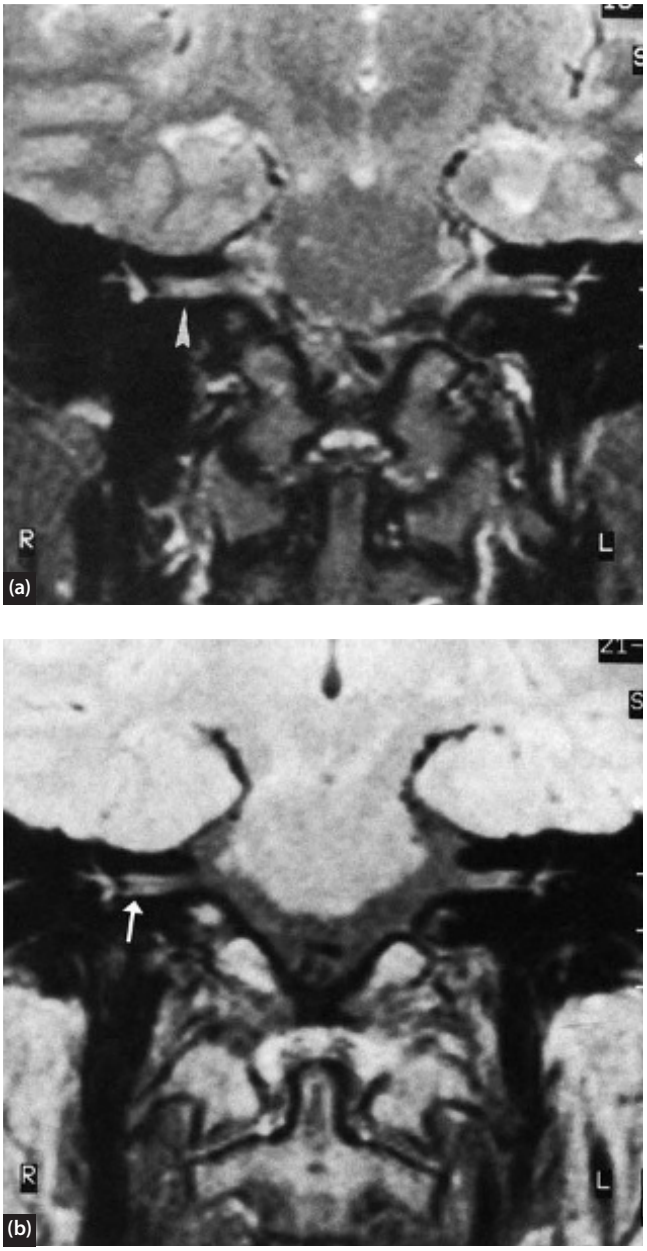
Neurological causes of AN and retrocochlear hearing loss include those with first-order cochlear neuronal degeneration (i.e. VIIIth nerve lesions) and those with pathology of the second-order cochlear neurons within the brainstem.

Multiple sclerosis

Multiple sclerosis (MS) is a disorder characterized by multiple areas of demyelination in the central nervous

system, and the clinical diagnosis rests upon the demonstration of two or more such lesions. Acoustic brainstem evoked response audiometry has been used for nearly 40 years in patients presenting with a single lesion suggestive of MS, to detect other sites of demyelination. In the first study in this area, wave V was the most consistently abnormal wave in patients with MS.[50] A correlation was demonstrated between this ABR abnormality and clinical evidence of a brainstem lesion due to MS in 79% of patients, but there was also an ABR abnormality in 51% of those patients without clinical signs of MS related to the brainstem. However, the presentation of MS with acute hearing loss is rare, and reported in only 1–3.5% of patients.[81, 82] Demyelinating lesions have been identified in the VIIIth nerve;[83, 84] in the nerve root entry zone/cochlear nucleus;[52, 85] and in the pons.[38] Conversely, an MRI study of 354 patients with sudden hearing loss, tinnitus and vertigo identified abnormalities in 12 (34.5%), only 2 of whom showed focal hyperintensities that were subsequently found to be the first evidence of MS.[86]

MRI and electrophysiological correlates have been reported as evidence for demyelination in the VIIIth nerve:[39] a small hyperintense lesion along the cochlear nerve which decreased in size and disappeared with steroid treatment (**Figure 69.7a, b**), and, in parallel, a return to normal of the ABR (**Figure 69.7c**). Wave I was initially undetectable, then delayed and finally normal, with invariably normal interpeak latencies throughout the time



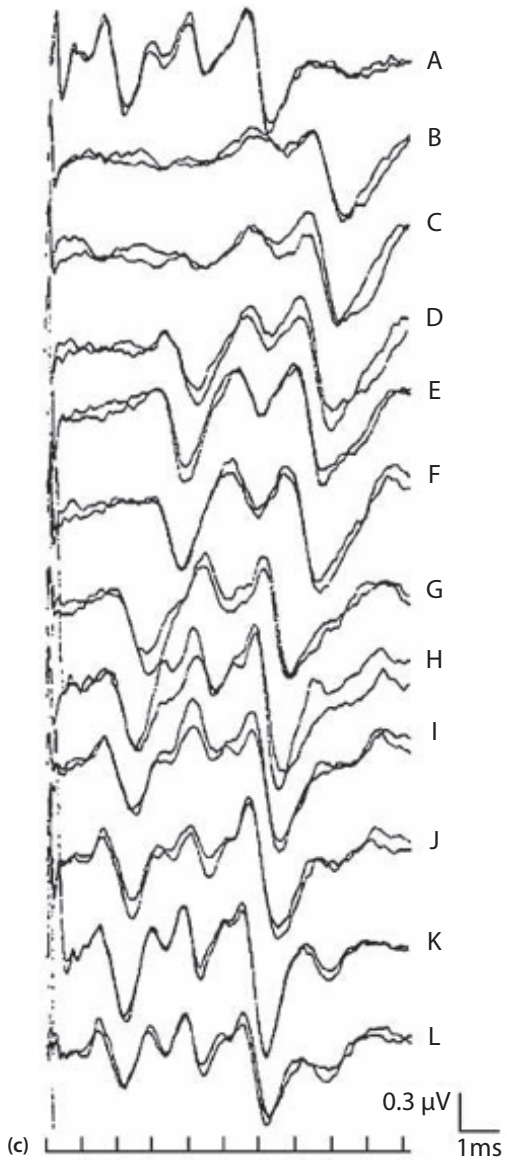


Figure 69.7 **(a)** Coronal T2-weighted MRI: mild enlargement of the right VIIIth nerve inside the internal auditory canal, and punctate area of hyperintense signal (arrow). **(b)** Coronal T2-weighted MRI: no lesion seen along the right VIIIth cranial nerve. **(c)** ABR recordings (rarefaction clicks, 65 dB SL intensity, 22.1 Hz frequency, Cz–A2 electrodes) before (A), and after (B–L), right sudden hearing loss. Reproduced with permission.[37]

frame of the recordings. The ABR abnormalities are likely to have been related to the sudden hearing loss because the ABR had been normal in previous testing, and then improved in parallel to the clinical recovery.

This was the most caudal site of a demyelinating lesion in MS reported to that date, and the authors felt that the lesion could still be accounted for as an abnormality of central myelin as the transition zone from glia to Schwann cells is quite distal in the VIIIth cranial nerve. Transtympanic ECoG[84] has also been used to demonstrate a disturbance of synchronization at the level of the first-order cochlear neurons in a patient known to have MS who developed sudden hearing loss. Investigation identified enhanced latency of the CP, a normal CM and SP, but absent ABRs, showing this hearing loss to have the characteristics of an AN. MRI has allowed the progression of demyelinating lesions of the ventral cochlear nucleus near the entry zone of the VIIIth nerve to be documented in MS patients with sudden hearing loss[52, 86] and also in MS patients with hearing loss who have pontine lesions.[39]

Extrinsic and intrinsic tumours of the cerebellopontine angle

There are a number of tumours of the cerebellopontine angle (CPA) which can present with retrocochlear hearing loss: cerebellar medulloblastoma, neurinoma, meningioma, cholesteatoma, ependymoma, jugular glomus tumour and metastasis. Imaging will generally identify these tumours and, in the case of metastases, CSF lumbar puncture for cytological examination, or serological search for antineuronal antibodies (anti-ro, anti-la, anti-RNP, anti-Jo-1, anti-SCL-70) will lead to the diagnosis. Cerebellar medulloblastomas are particularly common in childhood (25% of all intracranial neoplasia) where they tend to be midline, but in adulthood they tend to be located laterally and can present as CPA lesions. In a study comparing AN and neural deafness in acoustic neuromas, the following similarities in auditory tests were reported: presence of tone decay, normal distortion product OAEs and CMs and poor speech perception which was out of proportion to the pure-tone audiometry configuration. However, ABR abnormalities were different. In patients with acoustic neuromas only wave I of the ABR was seen with following waves absent, whereas in patients with AN ABR was absent or, when present, abnormal wave I was seen.[87]

Auditory neuropathy plus peripheral neuropathy

In a series of 70 cases of AN,[88] no aetiology was identifiable in 40% of affected individuals. The AN was typically bilateral and affected men and women equally. In general, ANs have been considered to be an infrequent associate of peripheral neuropathies but, where they do occur, other cranial neuropathies (i.e. optic, trigeminal and facial neuropathies) occur more frequently. However, a peripheral neuropathy was identified in 18/70 (26%) of the cases cited above following clinical assessment of deep tendon reflexes at the ankle, vibration sense at 128 Hz in the foot and investigations with nerve conduction studies plus sural/peroneal nerve biopsy. Hereditary sensory–motor neuropathy (HSMN) was found in 9 out of 70 of the patients, with 3 families providing all 9 of these cases. Several different genetic disorders may present with HSMN, and one Roma family from Slovenia[24] was shown to have a mutation on chromosome 8q24. In these patients, the peripheral neuropathy occurred first, and sural nerve biopsy demonstrated a mixed axonal and degenerative neuropathy, with hearing loss only developing later. These cases also had bilateral vestibular failure, presumably on the basis of VIIIth nerve involvement, and demonstrated a recessive mode of inheritance. [Level 1 evidence]

NERVE CONDUCTION STUDIES

This investigation allows the detection of a peripheral neuropathy and its characterization as a demyelinating or axonal type neuropathy. A demyelinated nerve fibre has a much reduced membrane resistance and increased capacitance to current draining through the axonal membrane and the action potential falls off much more rapidly than in a normal nerve fibre because of the reduced membrane resistance. The action potential cannot reach any excitable region of the axon with sufficient amplitude to regenerate itself. The result of this is a slowing of conduction velocity, and a widening of the whole nerve action potential as multiple axons become affected by the demyelinating process (**Figure 69.8**). Demyelinated axons also have an impaired capacity to transmit trains of impulses. Such high discharge rates would typically be seen in response to intense acoustic stimuli, contributing to the appreciation of loudness and mediating reflex activation of middle ear muscles and olivocochlear reflexes, explaining the absence of stapedius reflexes and loss of contralateral suppression of OAEs in patients with AN.

Two patients with AN who have a temperature-sensitive hearing loss have been reported. Demyelinated axons may also demonstrate 'cross-talk' (ephaptic transmission) between fibres, with one active fibre initiating impulses in an adjacent fibre, possibly accounting in the auditory system for distortion in the coding complex of speech. However, in an axonal neuropathy, there is no conduction delay and therefore relative preservation of velocity but reduced size of the nerve action potential due to the reduced number of functioning axons. This becomes more evident the greater the distance from the cell body, with the longest fibres most susceptible to pathology. This is likely to affect the low frequencies on the audiogram as the longest cochlear fibres extend to the apex of the cochlea.

The neuropathy associated with CMT type I is characteristically demyelinating, and that of CMT type 2 is axonal. The axonal neuropathy theoretically should not

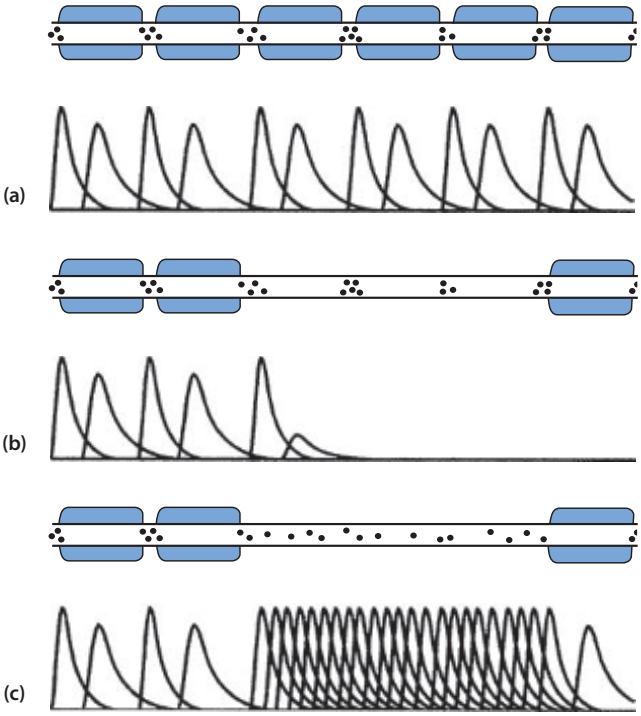

Figure 69.8 A diagrammatic representation of what happens when a nerve fibre becomes demyelinated. The blue regions are the myelin sheath. The dark dots are the voltage-sensitive sodium channels that are concentrated at the nodes of Ranvier. Three conditions are shown: **(a)** normal, **(b)** conduction block and **(c)** demyelination with slowing. The action potential is represented stroboscopically as it is conducted along the axon. The trace in (c) shows what happens when the sodium channels diffuse into the bare axon. The action potential can now regenerate itself, but this occurs over much shorter distances than when the axon was myelinated and the conduction velocity is therefore very slow. Redrawn with permission.[53]

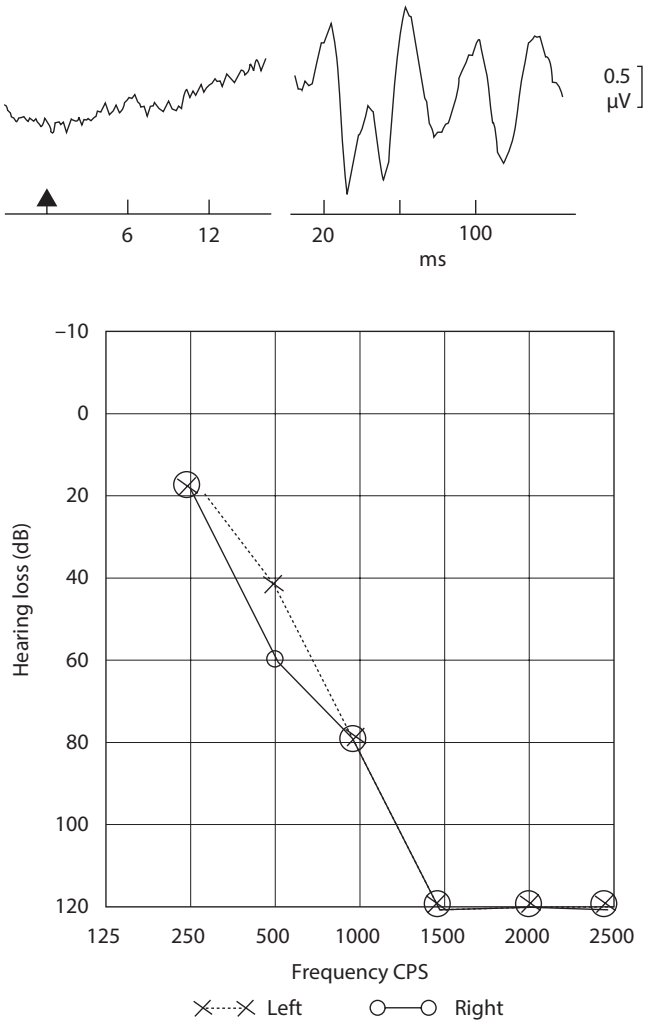

Figure 69.9 Pure-tone audiometry and acoustic evoked responses in a patient with congenital myotonia administered with high-dose quinine. Reproduced with permission of Dr Peter Rudge, The National Hospital for Neurology and Neurosurgery, London).

affect neural synchrony in the VIIIth nerve. However, as the axon and its myelin sheath are so closely related, one cannot exist without the other, and an axonal neuropathy is often accompanied by signs of secondary demyelination, which would then impact on neural synchrony, as above. Delmaghani et al. have described an autosomal recessive type of auditory neuropathy due to pejvakin, a protein within cell bodies of neurons of the afferent auditory pathway which causes neural dysfunction in the auditory nerve. *DFNB59* encodes pejvakin.[19]

DIFFERENTIAL DIAGNOSIS

Sharply sloping high-frequency hearing loss of cochlear origin

Quinine at a high dose is known to selectively destroy the OHCs of the cochlea. The pure-tone audiogram in Figure 69.9 shows a sharply sloping SNHL, induced by quinine in a patient with congenital myotonia. The acoustically evoked responses from the same ear are also shown, illustrating that in the time frame 0–12 ms, there are no reproducible waveforms (i.e. no ABR) whereas the MLRs are identifiable.

Distinction of auditory neuropathy from brainstem neuropathy

In a patient with normal preneural function but abnormal ABRs, only a full battery of tests as above can begin to distinguish a primary cochlear neuron lesion from a secondary cochlear neuron lesion. This would include other tests of neural synchrony such as stapedius reflex thresholds, in addition to ABRs, and, if the former are present, this might suggest a lesion higher in the brainstem than the pathways required to activate the facial nerve nucleus and cause contraction of the stapedius muscle bilaterally. Similarly, the type of ABR abnormality, specifically the pattern of abnormal or lost wave latencies, may give a relative clue as to site of lesion although, as in the case of MS, these patterns of abnormality have less localizing value than might be expected.

Central auditory processing disorders

With the advent of clinically available central auditory function tests, it has become possible to distinguish central auditory processing disorders (CAPDs) from other causes of deficits/delay in some children with language, reading and/or spelling difficulties. A 'bottom-up' approach to understanding these difficulties better now includes use of the behavioural central auditory tests.[89, 90]

- monaural low redundancy speech tests, i.e. speech stimuli, presented to one ear, that are:
  - degraded in frequency content
  - embedded in competing signals (multispeaker babble).
- dichotic/binaural interaction tests, i.e. stimuli presented to both ears, the task requiring the patient to attend to one ear only, or both at the same time:
  - dichotic digits
  - competing sentence tests.
- temporal tests, i.e. sequencing tasks:
  - frequency pattern test
  - temporal gap detection.

These are in addition to baseline audiometric tests and electrophysiological tests such as ABRs, MLRs, P300 and mismatch negativity. The characteristic abnormality of speech perception disproportionately poorer than the degree of hearing loss, plus abnormal ABRs in the presence of OAEs/CMs but absent stapedius reflex thresholds and absent contralateral suppression of OAEs, will distinguish patients with AN from those with CAPD.[91]

KEY POINTS

Differential diagnosis of auditory neural spectrum disorder

- Sharply sloping high-frequency hearing loss of cochlear origin.
- Distinction of auditory neuropathy from brainstem neuropathy.
- Central auditory processing disorders/language acquisition disorders.

AMPLIFICATION AND HABILITATION/ REHABILITATION STRATEGIES

Patients whose test results fulfil the criteria for AN represent a heterogeneous group. Not only is the site of lesion likely to vary, from the IHCs and synaptic connections within the cochlea to axonal degeneration and demyelination of the first- or second-order cochlear neurons, but also loudness sensitivity varies, as demonstrated by pure-tone audiometric thresholds. Degraded speech perception inconsistent with pure-tone sensitivity remains the common feature.

Early language intervention

For those children with auditory neural dyssynchrony, the onsets of plosive consonants and transitions, which make speech intelligible, would appear to be lost, preventing these children from categorizing or sequencing sounds. This makes early language intervention critical. A phoneme-based language therapy seems reasonable as it includes other tools for communication as well as audition. 'Cued speech' has been advanced as an adjunct to aural rehabilitation, as a way of 'eavesdropping' on family conversations, as it allows children to 'hear English phonemes and English grammar with their eyes'. It is a method whereby cues to vowel and consonant sounds that are difficult to perceive from lip-reading can be given by synchronous hand-shapes presented alongside either the mouth or pharynx of the speaker. These cues will give syntax and phonological structure to language and are more easily learned by parents. However, cued speech cannot aid in the phonological representation of language for children who are deaf or hard of hearing.

Total communication

Total communication uses spoken language and elements of sign language to link the different communication systems. Recognizing that each child with AN has a vast array of needs and that, for the individual, acquisition of language will also affect acquisition of culture, use of a system such as total communication to link aural–oral and manual communication systems would seem to have much to recommend it in a prelingual child.

Will hearing aids help?

Various studies have examined the benefits of hearing aids,[4, 15, 92] and shown variable results. In the earliest of these studies, three out of four patients fitted with hearing aids reportedly derived little benefit from amplification. In a later study, of 15/20 patients prescribed hearing aids, 8 were developmentally mature enough for speech perception threshold levels to be assessed, and 4 showed significantly increased aided threshold levels. Anecdotal reporting in the remaining 7 children suggests that 4 of these had benefited from hearing aids. The main concern regarding the use of hearing aids in patients with AN is that they can cause significant noise exposure and permanent threshold shift (up to as much as 20 dB HL) in children with SNHL.[93] It has been observed that TEOAEs may deteriorate in some children with AN after hearing aid use.[92, 93] Thus, the use of an algorithmic approach to hearing aid fitting and real-ear measures to verify parameters of the hearing aid needs to be calculated in much the same way as for the risk–benefit analysis for children with SNHL (**Table 69.6**).

Gap detection and modulation transfer function are abnormal in AN patients, and it has been hypothesized that these patients have 'a (time) smeared internal representation of a physical stimulus'.[55] A speech-processing type of hearing aid with a high-frequency emphasis to enhance high-frequency transient speech sounds (i.e. consonants) has been recommended. Also the use of directional microphones and personal FM systems to improve

TABLE 69.6 Breakdown of otoacoustic emission status by hearing aid status (reproduced with permission[54])

	OAE present		OAE absent		OAE once present now absent		All patients	
Hearing aid status		%		%		%		%
User	5	16	4	80	3	50	12	30

Total	31	100	5	100	6	100	42	100

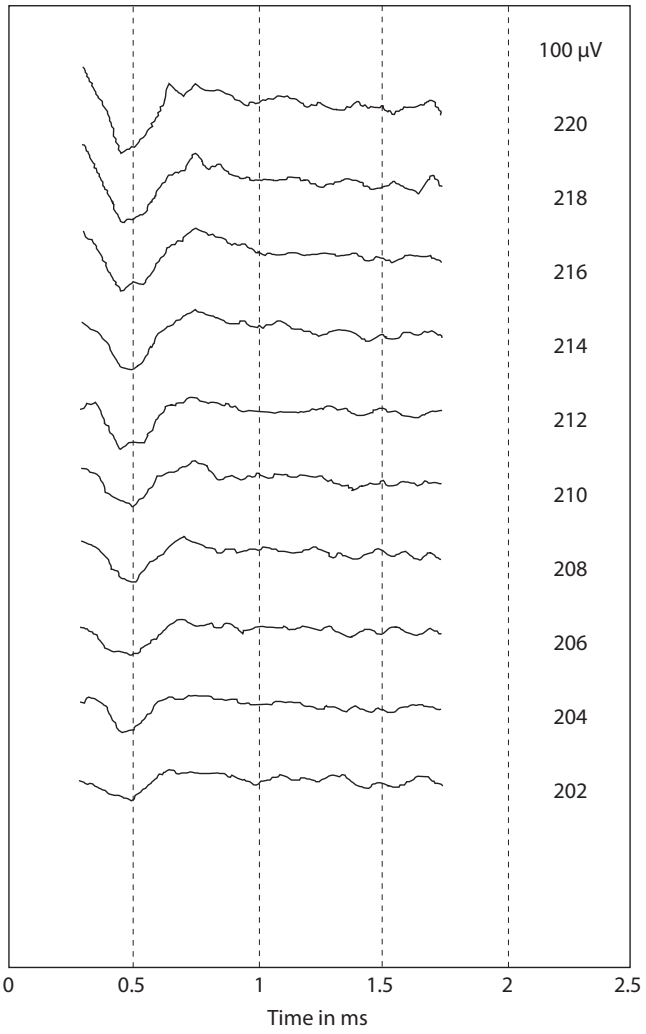
the signal-to-noise ratio in those patients with pronounced difficulties with speech in background noise has been proposed.[94]

Use of cochlear implants

The question arises as to whether cochlear amplification could be predicted to be of value and, if so, which patients would be likely to show a benefit. Theoretically, the patient with axonal degeneration/demyelination of the VIIIth nerve might not benefit from cochlear implantation (CI). However, electrical stimulation has been shown to produce synchronous ABRs in the presence of peripheral auditory nerve demyelination.[78] The potential benefits to these patients would be that CI provided consistent neural firing and the stimulus itself might promote neural survival and restore temporal activity. The disadvantages of CI would be not only the risk of surgery and anaesthesia, but also the chance that the electrode insertion might damage the cochlea itself and destroy residual hearing. Thus, proceeding to CI would need to be made with a thorough assessment and careful counselling of the child's family.

Studies published demonstrate the benefit of CI in children with AN. One child who wore aids from the age of 21 months for 2 years, and who was then fitted with a cochlear implant, was reported as receiving no benefit.[15] Six children with AN in whom CI was performed have also been reported.[95] Four of these children represented two sets of siblings, and all had undergone a trial period of powerful behind-the-ear-aid use. Five out of the six benefited significantly from implantation, as judged at the 1-year evaluation period using developmentally appropriate speech perception testing, with and without visual cues. Three of these children were considered to have adequate language and communication skills to attend mainstream school, having started their education in oral preschool for children with hearing loss. One child, however, showed no benefit from his CI. His understanding at 1 year post CI relied entirely on context, routines, gestures and lip-reading. There were no clear reasons why this particular child should have failed to benefit from CI.

Neural response telemetry (NRT) was used to assess neural synchrony and temporal coding post-CI (**Figure 69.10**). NRT uses a subtraction technique to remove the ECAP from the stimulus artefact using a forward masking paradigm.[95] The presence of the ECAP is interpreted as



NRT : Child C
Recording parameters:
Stimulating electrode 10
Recording electrode 12
Averages = 100

Probe:
Current level = variable
Pulse width = 25 µs/phase
Rate = 80 Hz

Masker:
Current level = fixed (220 units)
Pulse width = 25 µs/phase
Advance = 500 µs

Figure 69.10 Electrical compound action potential recording for 'Child C'. Reproduced with permission.[94]

indicating that electrical stimulation has restored some degree of synchrony and temporal encoding at the level of the cochlear nerve. These authors conclude that CI should be performed only after a trial of conventional amplification and that each decision to implant must be based on the individual circumstances. Children in the Sydney Cochlear Implant programme who had bilateral profound hearing loss were studied to examine the efficacy of CI. The study included 54 children and 15 of them were found to have cochlear nerve anomalies. Cochlear implant outcomes in terms of open-set speech discrimination were found to be poor in this group. Implant evoked electric auditory brainstem response (EABR) was uniformly poor in this cohort of children whereas children with normal cochlear nerves and AN had better open-set speech discrimination.[95]

In another study of 140 patients with a diagnosis of ANSD, over 40% were born pre-maturely and 38% had abnormal pre-operative MRI findings of the brain and inner ear. Thirty-seven per cent of these patients received cochlear implants, and 50% of those implanted demonstrated open-set speech perception abilities after implantation. None of those with cochlear nerve deficiency in the implanted ear achieved open-set speech perception abilities. Structural integrity of the cochlear nerve is therefore integral to achieving good outcomes following CI.[96]

BEST CLINICAL PRACTICE

- ✓ Suspect AN in patients whose pure-tone audiograms are normal or show a mild to moderate loss but who exhibit poor speech discrimination or delayed speech.
- ✓ Request electrophysiological tests of hearing including measurements of OAEs and ABR audiometry (preferably with measurement of CMs) to confirm diagnosis.

FUTURE RESEARCH

- ➤ Clear test protocols need to be developed for newborn hearing screening programmes to ensure that:
  - ➤ cases of AN are not missed (i.e. if only OAEs are performed)
  - ➤ those who have absent ABRs are not assumed to be profoundly deaf and amplified inappropriately (i.e. if OAEs are not performed).
- ➤ Test protocols for site-of-lesion diagnosis in patients with retrocochlear hearing disorders are needed, to distinguish:
  - ➤ first-order cochlear nerve lesions
  - ➤ second-order cochlear nerve lesions
  - ➤ central auditory processing disorders.
- ➤ Research is needed into the identification of predictors of stable AN vs progressive AN vs reversible AN vs maturational delay.
- ➤ Further work is needed in the following areas:
  - ➤ the relationship of pathophysiology to signs and symptoms
  - ➤ perceptual effects of AN
  - ➤ prospective case-controlled studies of hearing aid use versus CI
  - ➤ the identification of factors predicting the benefit from one type of hearing prosthesis over another
  - ➤ AN as a marker for neurodegenerative conditions.

KEY POINTS

- Auditory Neuropathy Spectrum Disorder (ANSD) is characterized by electrophysiological evidence of normal or near normal cochlear function (normal OAEs or cochlear microphonics) and abnormal auditory nerve signal transduction (abnormal ABR).
- Hearing may be normal or show mild to severe loss on pure tone audiometry.
- Speech discrimination is poor and language development may be delayed.
- Aetiologies are genetic or acquired.

CHAPTER 70

UNDERSTANDING TINNITUS: A PSYCHOLOGICAL PERSPECTIVE

Laurence McKenna, Elizabeth Marks and David J. Scott

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: tinnitus, hyperacusis, psychology, cognitive and CBT.

INTRODUCTION

Affecting 10–15% of the population at any one time,[1] tinnitus is one of the most common persistent physical symptoms to affect humankind. Most individuals habituate to tinnitus with just 5% of the population reporting mild to moderate disturbance and 1–2% reporting severe and chronic disturbance attributed to tinnitus.[2, 3] The challenge for tinnitus researchers and practitioners is to understand why such variability exists and to develop effective interventions for those who suffer.

Medicine has traditionally focused upon the psychophysical characteristics of tinnitus. This 'linear' model fails to account for findings that acoustic characteristics of tinnitus are poorly related to its severity or treatment outcome,[4, 5] and that psychological treatments can lead to broad improvements in psychosocial measures, even when tinnitus loudness does not change.[6] More modern perspectives take into account the complex moderating and mediating factors in the experience of tinnitus; these are principally psychological and social in nature and interact with the underlying psycho-physiological changes.[7] To this end, a biopsychosocial model[8] provides a useful framework for understanding tinnitus.[9]

The biopsychosocial model of health and illness

The biopsychosocial model places health and illness within the context of the psychological and social influences affecting an individual, together with their biology. This approach offers a theoretical foundation for a multidisciplinary approach to tinnitus management. It explains how psychosocial factors influence the individual's behaviour in response to tinnitus (i.e. illness behaviour),[10] which in turn affects their health and well-being. This model implicitly indicates the influence of the doctor–patient relationships on treatment outcome. The clinician is thus responsible for minimizing unintentional iatrogenic harm and supporting patients' compliance with treatment recommendations. The focus of treatment is on a multidisciplinary approach that enables patients to manage tinnitus and its impact upon their life themselves, rather than being 'cured' of it.

Admittedly, few studies directly explore a biopsychosocial approach to tinnitus. However, there are convincing similarities between chronic pain and chronic tinnitus.[11, 12] In particular, both are linked to changes in the CNS after being triggered by peripheral changes, and both are associated with anxiety, depression, insomnia and reinforce each other within a vicious circle. A biopsychosocial approach to tinnitus would thus be a fruitful avenue for research.

PSYCHOSOCIAL FACTORS IN TINNITUS

Patients disturbed by tinnitus most commonly complain of emotional distress, insomnia and problems with sustained concentration and cognitive functioning. Over time, these difficulties have broader consequences, disrupting other aspects of daily life such as sleep.[13] There may also be

predisposing or precipitating psychosocial factors that make tinnitus-related distress a more probable outcome, such as personality traits, emotional state, psychiatric illness and cognitive style.

Personality factors

It is possible that stable personality characteristics can affect how an individual reacts to tinnitus and thus influence the degree of distress they experience. Studies have supported the idea that specific personality traits are associated with tinnitus severity, in particular, traits of perfectionism,[14] life satisfaction[15] and anxiety sensitivity[16, 17] have been found to relate to increased tinnitus severity. Optimism is negatively associated with tinnitus distress.[15] Erlandsson and Persson[18] found that 50% of a subgroup of more distressed tinnitus patients were diagnosed as suffering from a personality disorder.

Establishing a causal relationship between personality variables and tinnitus distress is challenging. These studies assume such traits were present through most of the person's life, and that anxious or depressed dispositions are not the product of tinnitus. Anxious traits identified in people soon after the onset of tinnitus have been found to predict greater tinnitus distress 6 months later.[19] These observations suggest that, when tinnitus arises in people who are already emotionally strained, it is more likely to lead to distress. Another study[20] examined the relationship between type D personality (a generally gloomy view of life and social inhibition), tinnitus distress and quality of life and found that the impact of type D personality on tinnitus severity was in part mediated by the presence of anxiety and depression. Additional evidence supports the idea that the relationship between personality variables and distress is not direct but is mediated by cognitive variables such as dysfunctional thoughts,[21] particularly catastrophization,[22] and tinnitus-specific illness perceptions.[23]

Cognitive variables related to tinnitus

The process of targeting illness perceptions begins right from the emergence of the illness and will be affected by the approach taken by healthcare professionals. In tinnitus, as in all illness, it is important for the whole care of a patient to be directed towards enhancing more helpful illness perceptions.

As well as general disposition, an individual's style of thinking about tinnitus is important in determining the nature of their experience of tinnitus. The psychological perspective suggests that distress arises because tinnitus is interpreted in a threatening way. The most common themes in the thinking of distressed tinnitus patients reflect despair, persecution, hopelessness, loss of enjoyment, a desire for peace and quiet, and beliefs that others do not understand.[24] Higher tinnitus distress is associated with more reported unhelpful thoughts about tinnitus.[24–26] Beliefs that tinnitus will lead to dreadful consequences (i.e. thoughts that overstate the impact of tinnitus, minimize the ability to cope and which involve rumination or excessive worry) appear to be particularly important. These kinds of catastrophic thoughts are associated with fear, which increases attention towards the tinnitus and reduces quality of life.[9] Catastrophic thinking has been observed to be associated with high subjective tinnitus loudness, poorer coping, depressive symptoms and with more frequent medical visits.[22] Catastrophization in the early stages of the tinnitus experience appears to have a pivotal role in determining the long-term distress, since patients quickly become caught in a vicious cycle of anxious and depressed thoughts about tinnitus, intensifying the intrusiveness, increasing distress and prompting frequent help-seeking behaviours, which in turn may maintain unhelpful illness beliefs.

The perception of an illness is known to influence coping behaviours and outcomes in chronic illness,[27–29] and, if interventions are to be helpful, they should address specific illness perceptions. Although research into illness perceptions in tinnitus is limited, one study reported on significant relationships between depression and anxiety and the perception of tinnitus in terms of the symptoms attributed to it and perceived consequences.[30] It has also been observed that an internal locus of control in tinnitus (i.e. the perception that you can control what happens to you rather than being affected solely by external factors) is associated with habituation, reduced psychological distress and reduced severity.[31–33]

With the perception of tinnitus determining its severity and related distress, psychological factors are clearly central to the tinnitus experience. This has direct implications for a clinician, as illness perceptions are influenced by historical, social and cultural context. Clinicians have a responsibility to remain aware of their contribution to this psychosocial context, as clinical contact will directly influence how a patient learns to perceive their tinnitus. Patients will benefit from a hopeful but realistic assessment of tinnitus, so it would be worth avoiding a purely biological focus on tinnitus, as this would suggest that there is 'nothing to be done'. Instead, offering a viewpoint that takes psychosocial factors into account will enable the patient to see potential areas of adaptability, leading to more helpful illness perceptions and thus possibly reducing distress.

Emotional consequences: Anxiety and depression in tinnitus

Patients with tinnitus report higher rates of psychiatric problems compared to the general population. In the late 1980s the use of formal psychiatric assessment tools demonstrated that 63% of a tinnitus sample could be classified as psychiatrically disturbed and that 78% had experienced one or more major depressive episodes in their lifetime, compared to 21% of a control group.[34] Since then other researchers have reported similar figures using both formal assessment[16, 26, 30, 35, 36–38] and self-report tools for measuring anxiety and depression.[39–42]

Psychological distress in tinnitus patients can clearly be a reaction to the tinnitus, but emotional disorders can also act as a trigger for tinnitus.[43] Goebel and Floetzinger[44]

found that, in 64% of tinnitus patients classified as suffering from a psychiatric disorder, the disorder preceded the onset of tinnitus. Clinical observations show that the more distressed the patient becomes the more problematic the tinnitus. Studies point to a link between problematic tinnitus and depression,[44, 45] with indications that the severity of tinnitus relates to the severity of the depression.[36] Stress is also thought to aggravate tinnitus, with evidence that a high workload and difficult shift-work patterns contribute to tinnitus distress.[46] An interaction between tinnitus distress and poor psychological state has been noted by others,[34] who found that depressed tinnitus patients reported more psychological and somatic complaints than those who were not depressed. Since the non-depressed group did not report more problems than the control group, the authors concluded that the problems reported by tinnitus patients were more closely related to the depression than to the tinnitus.

There is a risk of circularity of argument here, since anxiety symptoms often form part of tinnitus severity measures.[47] However, even when this is taken into account, tinnitus patients report greater than average cognitive anxiety (worry and negative self-talk) and somatic anxiety (rapid heart rate and shortness of breath), which continues after treatment.[30] There is also evidence that depressed and anxious patients report more tinnitus distress and severity,[14, 32, 48, 49] and that anxiety at onset predicts tinnitus distress 6 months later.[19] The interaction between tinnitus and psychological state is implicated by the relationship between post-traumatic stress disorder (PTSD) and tinnitus,[50] where it is likely that the symptoms of PTSD and tinnitus are mutually aggravating. The impression created by the literature is of a diathesis–stress interaction taking place in which the diathesis is the vulnerability to distress, and tinnitus level is the stress.[51]

Tinnitus and suicide

Of those individuals with tinnitus who do commit suicide, it seems that psychological and demographic factors play a more important role than tinnitus itself.[52–55] Jacobson and McCaslin[56] conclude 'it is not tinnitus per se that results in suicide but concomitant psychiatric conditions that amplify the effects of tinnitus on the individual patient'. Lewis et al.[53] found 40% of suicides occurred within a year of tinnitus onset and about 50% within 2 years. Psychological features known to increase the risk of suicide include hopelessness, helplessness, fear and anger. If patients are provided with messages about their tinnitus that evoke such psychological states, then their vulnerability to suicide is likely to increase.

Behavioural responses to tinnitus

Studies of the coping strategies used by tinnitus patients suggest that both avoidant coping strategies[34, 57, 58] and active coping styles[16] are associated with worse tinnitus. Hesser and Andersson[17] found that behavioural avoidance in an effort to reduce or stop tinnitus was a significant mediator in the relationship between anxiety sensitivity and tinnitus distress and tinnitus handicap. Kleinstäuber et al.[59] reported that tinnitus-related fear-avoidance behaviour is highly correlated with anxiety and depressive symptoms and plays an important role in predicting tinnitus handicap. Fear-avoidance behaviour serves to maintain catastrophic thinking. Thus, habituation may be enhanced by a middle-way that involves acceptance and engagement with *life* rather than employing strategies that involve either avoidance or attempts to *defeat* tinnitus.

Concentration/attention problems

Many tinnitus patients complain of difficulties in concentration or attention that they attribute to tinnitus. Research suggests a relationship between tinnitus and inefficiency in cognitive processing. Initial theories suggested that cognitive difficulties are a result of emotional distress,[26, 60] but such studies did not directly assess attention problems, and do not account for the fact that observed difficulties in cognitive functioning were not explained by differences in emotional state.[61–64] Other theories claim that attentional resources are depleted as the individual attends to the tinnitus, and related experiences.[65, 66] It has been argued that tinnitus acts as a competing stimulus that attracts attention away from other things.[67, 68]

Sleep

Sleep disturbance is one of the commonest tinnitus complaints with as many as 71% of tinnitus patients reporting problems sleeping.[69] It is particularly prevalent among children with tinnitus[70–71] and is the main reason why parents seek help for their child. An epidemiological study found poor sleep was reported by 14% of men and 28% of women in an older adult population with tinnitus.[72]

Sleep problems tend to be associated with more distressing tinnitus,[73-77] although direction of causality is unclear. Insomnia is not an inevitable consequence of tinnitus,[78] so tinnitus is probably not a specific sleep antagonist. A premorbid sleep disturbance may create an opportunity to focus upon tinnitus, thus emphasizing a lack of sleep.[79] It may be the anxiety associated with the tinnitus rather than the tinnitus per se that causes sleep problems, as seen in the cognitive behavioural model of tinnitus.[80, 81]

Family and relationships

The way a patient responds to tinnitus may act as a stressor within personal relationships. Emotional distress or avoidance of situations as a result of tinnitus can adversely affect relationships. It is important to consider how the social environment influences tinnitus. For example, the way in which people perceive the negative attitudes of others (e.g. people will treat me differently or get annoyed with me) is associated with severity and reduced quality of life.[82] Other people's responses to the patient can also have an impact by affecting their level of disability. As might be expected, punitive responses and poor marital cohesion tend to result in demoralization,

particularly in the context of depression.[83] Perhaps more surprisingly, solicitous responses by spouses can also have a detrimental effect, with enquiries about tinnitus increasing distress.[84] It is thought that both punitive and rewarding responses to tinnitus impede habituation.[83] Helpful responses to tinnitus should thus be supportive, acknowledging the distress, without encouraging further distress-related behaviour. This approach would seem to be relevant to all social contexts including the clinical one.

TREATMENTS FOR TINNITUS

Cognitive behavioural therapy

The main psychological therapy used in the management of tinnitus is cognitive behavioural therapy (CBT). CBT is an effective psychological treatment for a range of psychiatric disorders.[85, 86] It can bring benefits to individuals with long-term physical health conditions and somatoform disorders,[87, 89] insomnia[89] and tinnitus.[90]

CBT MODEL AND RATIONALE

CBT seeks to change *overly* negative thoughts and beliefs about tinnitus (and other issues causing distress), thus breaking unhelpful feedback cycles, reducing distress and improving habituation. Many of the negative thoughts that people hold about tinnitus are accurate: 'I have tinnitus,' 'I will never have silence.' However, they may also be troubled by thoughts that are inaccurate or unhelpful and which can increase tinnitus-related distress: 'Tinnitus will drive me mad' or 'This is affecting me so much I must be a weak person.' Thoughts tend to become more 'distorted' as stress levels increase and mood deteriorates. In CBT, the patient is helped to recognize the link between thoughts, mood and behaviour and to identify and challenged 'distorted' or unhelpful thoughts. The patient can then generate alternative, realistic and helpful thoughts.

Behaviour is also targeted because the actions taken by a person to reduce tinnitus tend to keep them focused upon tinnitus, reduces their quality of life and maintains their distress, by preventing the opportunity to test out and disprove negative (and often distorted) cognitions. Avoidance behaviours play a particularly important role in inhibiting habituation or even sensitizing a person to tinnitus or hyperacusis-related information. In therapy, unhelpful behaviours are identified and support for change is provided,[7] for example through exposure to noisy and quiet environments. Baguley and colleagues[1] outline a standard CBT package. CBT is time-limited (six to ten weekly sessions) and teaches skills that will enable the person to become their own 'therapist'. Homework assignments reinforce the skills learnt in therapy sessions. After therapy ends, a follow-up session can be offered to maintain progress. CBT for tinnitus can also be successfully delivered on a group basis.[91]

EVIDENCE BASE FOR COGNITIVE BEHAVIOURAL THERAPY

CBT is a well-validated treatment for tinnitus[90, 92] and a number of meta-analyses describe the beneficial effects of CBT on tinnitus-related distress. Andersson and Lyttkens[93] analyzed 24 studies (n = 700) of psychological therapy; this showed strong to moderate effect sizes on tinnitus annoyance post-treatment and at follow-up. CBT (Cohen's d = 1.1) was more effective than other psychological treatments (Cohen's d = 0.30) on ratings of annoyance in controlled studies. Smaller effect sizes were obtained for measures of negative affect and sleep problems. Effects upon tinnitus loudness were weaker and disappeared at follow-up. The largest meta-analysis to date[90] looked at 15 randomized controlled trials (n = 1091) and found CBT to have a significant positive impact on tinnitus-related distress (effect sizes ranging from 0.44 to 0.7) as well as a significant positive effect on mood. The benefits of CBT remained significant at follow-up.

Cochrane reviews of CBT for tinnitus[6, 94] have used tinnitus loudness as a primary outcome and tinnitus severity (a global measure of distress or quality of life) and depression as secondary outcomes. They found no effect of CBT upon tinnitus loudness but tinnitus-related distress improved with effect sizes ranging from 0.64 to 0.91. This review found a mild but significant impact on depression when compared with a waiting list control (effect size = 0.37). Since CBT is not designed to change tinnitus loudness, it is perhaps not the most appropriate primary outcome indicator, particularly as many CBT studies do not even measure it.

Self help and the internet

CBT equips patients with skills that ultimately should allow them to cope with difficulties on their own. As such, interest has grown in CBT-based self-help treatments that involve minimal therapist contact.[96] Bibliotherapy (self-help books or manuals) offers significant benefits, enhanced by minimal therapist support but attrition rates are higher[96, 97] and effect sizes smaller than in regular CBT.[6, 90, 93] Internet-based CBT delivers self-help via a computer programme, with therapist support provided over email. Outcomes are superior to self-help manuals in relieving tinnitus distress and depression,[98–100] with reports of benefits equal to those found in regular CBT,[100] although attrition rates can again be high.[101]

'Third wave' therapeutic approaches

'Third wave' approaches refer to CBT that has been developed and extended by increasing the emphasis upon accepting unwanted thoughts and feelings.[103] Suffering is regarded as a normal part of life, and attempts to resist or change suffering can potentially perpetuate distress. There are two overlapping strands: acceptance and commitment therapy (ACT) and mindfulness-based therapies such as mindfulness-based cognitive therapy (MBCT). ACT has been shown to reduce tinnitus distress,[103] with

effects equivalent to conventional CBT[104] and that surpass tinnitus retraining therapy.[105] ACT has been delivered effectively via the internet,[106] and a comparison of internet-delivered CBT and ACT found that acceptance mediated therapeutic change in both approaches. Mindfulness in the form of MBCT was originally developed as a treatment for recurrent depression[107] for which it is now a NICE recommended treatment.[108] More recently, MBCT has been developed for tinnitus and a randomized-controlled trial has found MBCT to be superior to applied relaxation in reducing tinnitus-related distress.[109] Further trials are under way.

HYPERACUSIS

Hyperacusis has been studied much less than tinnitus. Nonetheless, the evidence that does exist suggests that the two symptoms share many psychological characteristics and processes. As in tinnitus, patients with hyperacusis often report elevated levels of emotional and psychological distress, particularly anxiety.[110] Reports that 56% of patients with hyperacusis have at least one psychiatric disorder[111] is comparable to tinnitus patients. However, hyperacusis may exacerbate distress further, as tinnitus patients who report comorbid hyperacusis also report increased levels of psychiatric disorder compared to patients with only tinnitus.[44] The association between hyperacusis and emotional distress clearly points towards a need to improve our understanding of the psychological factors maintaining hyperacusis.

Behavioural responses in hyperacusis are characterized by avoidance and safety behaviours (avoiding noise and using ear protection).[110] Such behaviour is comparable to the fear-avoidance found in tinnitus and pain.[60] As in tinnitus, hyperacusis has important social implications. If patients react to noise with avoidance, their capacity to engage in normal daily activities and effective interpersonal functioning will be inhibited. However, here and in many other aspects of hyperacusis the research evidence is sparse, so the conclusions that can be drawn are limited.[110]

With such limited evidence, there is understandably little consensus about treatment strategies for hyperacusis. If we consider the presentation of hyperacusis in the clinic, two forms of intervention are indicated. The first is that of desensitization to sound.[111] This involves the use of white noise generators with sound levels gradually increased over time. There is, however, no evidence on the efficacy of this treatment. Weaknesses in extant studies of sound therapy for hyperacusis are present due to the reliance upon loudness discomfort levels (LDLs) as a subjective and unreliable measure and the paucity of peer reviewed studies.[110] To assess the value of LDLs as an outcome measure, well-controlled outcome studies are required.

The second main treatment approach involves talking therapies to reduce the distress that accompanies hyperacusis. Given the observation that anxiety is the predominant comorbid psychiatric presentation for patients with hyperacusis, CBT may be an effective treatment strategy.[112] A randomized-controlled trial of six sessions of CBT for hyperacusis, using psychoeducation, applied relaxation, exposure to sound and behavioural activation to reduce avoidance of noise, found improvement in LDLs and depression.[113] This is the first RCT into CBT for hyperacusis so further studies are needed before firm conclusions can be made.

SUMMARY

The experience of tinnitus involves the complex interaction of biological, psychological and social processes; this interplay is likely to be of relevance to hyperacusis as well. Psychological distress, particularly anxiety and depression, are common experiences among tinnitus and hyperacusis patients. Negative thoughts (particularly catastrophic thoughts), avoidant behaviour and emotional distress also act as provocations for tinnitus and hyperacusis-related problems. These processes are particularly important in determining the overall experience.

While a biological solution may still be the holy grail of tinnitus treatment, currently psychological treatments appear to offer the most effective remedy for patients. A psychological approach is unlikely to make tinnitus (or hyperacusis) disappear, but it can lead to a significant reduction in distress, and enable people to return to living a more 'normal' and meaningful life. The consultation with the clinician is a critical part of the experience of tinnitus (and probably hyperacusis) as it shapes the social context of tinnitus and can have a profound impact upon psychological processing. The clinical environment will shape the thoughts, behaviours and emotions of patients and their significant others, and therefore provides an important opportunity for therapeutic benefit, or a risk of iatrogenic harm. It is incumbent on the clinician to be aware of the multiple mechanisms at work in tinnitus and of the effective therapeutic strategies that can support them.

FUTURE RESEARCH

- More research is needed into a biopsychosocial approach to tinnitus.
- Mindfulness-based cognitive therapy has been shown to be superior to applied relaxation in reducing tinnitus-related distress. Further trials are needed.
- We need to improve our understanding of the psychological factors maintaining hyperacusis.
- Cognitive behavioural therapy for hyperacusis has shown improvement in loudness discomfort levels and depression. Further studies are needed before firm conclusions can be made.

KEY POINTS

- The experience of tinnitus is as much a psychological as a biological process.
- Cognitive factors, particularly catastrophic thinking, are leading determinants of tinnitus-related stress. The influence of personality type seems to be mediated by cognitive processes and emotional state.
- The clinical encounter can influence the patient's thinking for better but care is needed as an overly biological approach can contribute to negative thinking.
- Behavioural processes, particular avoidance and escape behaviours maintain and exacerbate distress.
- CBT and acceptance based psychological therapies can reduce tinnitus related distress.
- A number of psychological processes are common to both tinnitus and hyperacusis.

CHAPTER 71

AUDITORY PROCESSING DISORDERS ACROSS THE AGE SPAN

Doris-Eva Bamiou and Cristina Ferraz B. Murphy

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: auditory processing disorder, aging, children, cognition, language, diagnosis and management.

PREVALENCE AND DEFINITION

Approximately 5% of children and 1–10% of adults who present to audiology departments with complaints of significant listening difficulties in noise or in group conversations have normal pure-tone thresholds.[1, 2] In a proportion of these patients, their listening symptoms are attributed to functional deficits in sound processing within the extended central auditory nervous system.[3] This clinical presentation is categorized as auditory processing disorder (APD, category H93.25 in ICD-10).[4] This clinical presentation has attracted considerable debate that is summarized to some extent in several consensus statements from professional audiological organizations.[5–9] However, there is no international consensus on what constitutes APD as yet, nor is there explicit agreement on diagnostic criteria for this clinical entity.

AETIOLOGY ACROSS THE AGE SPAN

In children, as well as in adults, APD may be diagnosed in the background of neurological disease such as brain tumours, stroke, trauma, prematurity or low birthweight, epilepsy and brain infections or demyelinating conditions.[10] In some cases, APD may also be the first or even the only feature of neurological disease, both in children[11] and in adults[12] (see also **Figure 16.1** from Bamiou and Iliadou)[13], highlighting the need for clinicians to maintain a high clinical index of suspicion and to investigate for neurological causes. APD may also overlap with several developmental disorders such as language impairment (LI), dyslexia and attention-deficit and hyperactivity disorder (ADHD) and in such cases the clinician should carefully consider whether the clinical presentation is due to deficits in higher-order language or cognitive domains rather than to the deficits within the auditory modality.[14–17] Clinical comparisons of children with APD versus children with specific LI and/or dyslexia find broadly similar profiles in these children.[13, 15, 18] This has led to speculation that these language-based disorders may be different labels or parts of the spectrum of the same developmental disorder.[3, 15] Another subtype of APD is the 'spatial processing disorder' (SPD).[19] SPD is attributed to the presence of a prolonged history of chronic otitis media in childhood which gives rise to deficits in binaural auditory processing due to the prolonged or fluctuating auditory deprivation. SPD is thought to be present in 6% in a population with high incidence of chronic otitis media and in up to 15% in children referred for speech-in-noise difficulties.[19, 20] In adults, APD may be a feature of psychiatric presentations such as schizophrenia and some subtypes of dementia, or of central presbycusis, which is a multifactorial condition characterized by senescence-related and/or disease-related brain changes.[21–23]

THE DIAGNOSTIC APPROACH

The diagnostic process includes history taking, including patient/teacher/parent questionnaires, followed by targeted medical examination. Children and adults with APD have difficulties with speech in noise, auditory attention, localization of sound and other auditory difficulties.[24–26] The history should establish the patient's and/or carer's main concerns and related symptoms, and the symptom onset and progression. Children may experience difficulties in the classroom and psychosocial difficulties that may persist well into adulthood.[27, 28] Key symptoms and difficulties are summarized in **Box 71.1**. History should also include medical history (to ascertain risk factors/other impacting factors), as well as early developmental, educational and professional history of the individual, and family history for related disorders (hearing, auditory processing, other developmental, neurological disorders). This part of the evaluation will also include questionnaires, which are used to collect as much information as possible for the clinical presentation.[15, 25, 26, 29]

The initial information collected during the medical interview will guide the choice of appropriate audiological tests, which should include a thorough assessment of peripheral auditory function as well as tests of auditory processing, both speech and non-speech. The American Speech-Language-Hearing Association (ASHA) technical report proposes that, in addition to pure-tone audiometry and speech-in-quiet tests, a central auditory processing battery should include tests for auditory discrimination, temporal processing and patterning, dichotic speech, monaural low-redundancy speech, binaural interaction, and electroacoustic and electrophysiological measures (see **Table 71.1**).[5, 6] The rationale behind this proposal (which is still followed by most audiology clinics worldwide) is that one needs to check thoroughly cochlear and auditory nerve integrity and subsequently different domains of central auditory processing. However, with a few exceptions for tests developed in recent years, clinically available tests are affected by a range of higher-order factors.[30]

Assessments of other domains such as language and cognition are of paramount importance in order to provide a clearer understanding of the patient's communication profile and needs while other medical

BOX 71.1 Key symptoms and difficulties of auditory processing disorder

Difficulties understanding speech: In background noise, acoustically challenging/complex acoustic environments, when speech quality is degraded
Difficulties discriminating speech: Difficulties repeating or recalling similar-sounding words
Sound localization/streaming difficulties: Difficulties identifying the source of a sound; with separation of auditory foreground from auditory background
Auditory attention/memory difficulties: Difficulties recalling instructions; difficulties concentrating in noise
Hyperacusis: With or without a diagnosis of autism spectrum disorder
Need for multisensory cues: For example, seeking visual/facial cues to better understand
Disproportionate educational/cognitive/language difficulties:

- In the presence of normal audiometry and no other developmental disorders OR
- In the presence of normal audiometry and other diagnosed developmental disorders (specific LI attention deficit disorder; autism; dyslexia) and (i) DESPITE implementation of appropriate interventions or (ii) when other specialists or the educational environment seek further advice/assessment on management of the auditory aspect of this presentation

TABLE 71.1 An APD test battery[6]

AP domain	Test assesses	Test examples
Auditory discrimination	Ability to differentiate similar acoustic stimuli that differ in frequency, intensity and/or temporal parameters	Difference limens for frequency, intensity and duration; psychophysical tuning curves; phoneme discrimination
Auditory temporal processing	Ability to analyze acoustic events over time	Pattern tests; gap detection in noise; fusion discrimination, integration; forward and backward masking
Dichotic listening	Ability to separate (i.e. binaural separation) or integrate (i.e. binaural integration) disparate auditory stimuli presented to each ear simultaneously	Dichotic consonant–vowels, digits, words, sentences
Low-redundancy speech recognition (monaural)	Recognition of degraded speech stimuli presented to one ear at a time	Filtered, time-altered, intensity altered, speech-in-noise or speech-in-competition
Binaural interaction	Binaural processes dependent on intensity or time differences of acoustic stimuli	Masking level difference, localization, lateralization, fused-image tracking Listening in spatialized noise
Other tests		
Electroacoustic measures	Otoacoustic emissions, acoustic reflex thresholds and acoustic reflex decay	
Electrophysiological measures	Auditory brainstem response (consider middle latency response, cortical event-related potentials and other responses)	

investigations ought to be considered as required, and additional information gathered (e.g. school observation).[5, 6] It is also useful to establish how the individual and their family perceive and explain their communication-related difficulties, any previous related assessments conducted and any remedial action taken or strategies implemented.

The diagnostic decision-making will synthesize this information in order to interpret reported symptoms in the light of test/assessment results and other contextual factors. However, it must be noted that professionals in the audiology field use different diagnostic criteria for APD and a recent review by Wilson and Arnott revealed nine different diagnostic criteria with a diagnostic yield of 7.3% up to 96% for APD.[31]

CONFOUNDING FACTORS AFFECTING APD TEST PERFORMANCE ACROSS THE AGE SPAN

Throughout the age span different confounding factors might affect APD test performance and hence the aetiology and diagnosis of APD.

In children, the extent to which non-sensory factors, such as working memory and attention skills, might affect negatively the performance on APD tests is still under debate.[32, 33] This is because some non-auditory cortical areas, which are also involved in the neural processing of sound, such as inferior prefrontal cortex and the posterior temporoparietal areas, are still in development until the age of 10 years.[32] Thus, it is discussed whether the variability in the APD performance reflects the maturation aspects of cognitive skills rather than some specific auditory processing skill impairment. Additionally, some auditory processing tests include highly cognitively demanding tasks, especially those including verbal response, such as dichotic digit or frequency pattern test.[33] Thus, maturation aspects of cognitive skills (late or incomplete maturation) combined with highly cognitively demanding tasks might lead to confounding results and difficulties in interpretation. To minimize the cognitive influence, the use of intratest comparison measures, such as right ear advantage index and humming-label differential,[34] are taken into consideration. Additionally, the need for cross-modality testing is also discussed.[35, 36]

In middle-aged and elderly individuals, age-related hearing loss as well as age-related cognitive decline might also lead to difficulties in interpretation of APD performance.[37–41] Age-related cognitive decline is a well-known confounding factor for auditory processing performance, particularly because of the cognitive–sensory interaction that is observed with ageing.[42, 43] Research has also demonstrated that some tests are more susceptible to hearing loss effects, especially tests involving understanding speech. This is because the broadband nature of speech signals requires reasonable audibility over at least 4000 Hz for discrimination.[23, 44]

Given the increasing recognition of the influence of many confounding factors affecting auditory processing test performance, the appropriate selection of tests as well as their careful interpretation must be taken into consideration on APD diagnosis. Assessment of elderly subjects' cognitive skills, such as working memory, would be useful before interpreting their performance on auditory processing tests. In addition, both the degree and configuration of the hearing loss must also be taken into consideration, especially when considering results of auditory processing tests involving verbal stimuli. For children, further studies should focus on the development of clinical auditory processing tests with low cognitive demand to reduce the impact of non-sensory factors on APD performance.

MANAGEMENT STRATEGIES

The goal for APD rehabilitation is to improve the functional deficits of individuals with specific impairments that are impacting on their communication and overall well-being. In order to achieve maximum functional benefit, a multidisciplinary team approach should be employed.[45] Generally, a comprehensive management programme for APD should focus on the following three areas:[45, 46]

- to remediate the disorder by means of techniques that aim to harness the brain's ability for change (i.e. neuroplasticity) in order to enhance neuroauditory function (e.g. auditory training)
- to improve access to auditory information by changing the environment (e.g. signal enhancement strategies, including frequency modulation systems/remote microphone hearing aids and teacher/speaker based adaptations)
- to improve listening and learning skills by teaching children and adults various compensatory strategies to overcome their residual functional difficulties (e.g. metacognitive and metalinguistic training).

Auditory training

Auditory training (AT) aims to capitalize on the brain's ability for structural and functional reorganization in response to sensory input across the lifespan. This brain 'plasticity' may involve the activation of inactive neuronal connections and/or the formation of more efficient synaptic connections within the brain; such changes are often associated with behavioural changes.[47, 48] AT involves listening exercises that aim to improve auditory system function and to achieve successful auditory learning, i.e. a relatively permanent improvement of perception and behaviour.[49, 50] AT studies in normal adults indicate that learning is better when the listener works hard enough for attention to be taxed.[51] It is also important to train with a wide variety of materials and situations since studies indicate that learning may not generalize to untrained material.[52] AT can be categorized as formal or informal. Informal AT can be a school- or home-based programme

as well as therapy conducted by a speech and language therapist or audiologist in the clinic, and it involves predominantly language-based tasks that tap into multiple processes concurrently. Examples of informal AT are discriminating similar-sounding notes on a keyboard for training temporal patterning skills phoneme discrimination exercises for training auditory discrimination skills and listening to lyrics of songs for training speech-in-noise ability.[45, 48] Formal AT is typically conducted in a controlled setting, such as a clinic or a lab, by audiological professionals, or at home, by means of CDs/web-accessed services. Formal AT uses acoustically controlled training paradigms with the ability to specify and precisely alter the stimuli.[53] Formal AT employs a variety of auditory tasks including tonal and speech stimuli.

There are several commercially available computer-based AT programs in the English language, for both adults and children (see **Table 71.2** for some key examples). Post-training improvements are reported on a range of auditory and non-auditory measures for a broad range of paediatric populations with disorders that overlap APD, in APD populations as well as in adults.[49, 54–58] However, it remains unknown which program works best (compared to others) and what the optimum dosage and long-term benefits are.

Signal enhancement strategies

Signal enhancement strategies include environmental modifications, to reduce the synergistic deleterious effects of noise and reverberation of the acoustic environment on the target speech (or other acoustic) signal, and assistive listening devices such as remote microphone hearing aids (RMHAs). (For a list of environmental modifications that can be applied in school classrooms or elsewhere, please see BSA APD document, page 55[7] – discussion of these is beyond the scope of this chapter.) RMHAs are personal listening devices that bypass high-level classroom noise and transmit clearer speech to the child's ears. RMHA use may improve speech understanding by 53%.[59]

Studies of children with abnormal speech-in-noise performance due to abnormal auditory processing show improved speech reception even without FM (after 5 months FM use), improved observer-rated listening and behaviours as well as improvements in higher-order processing such as working memory after 12 weeks and spelling after 6 weeks.[27, 54, 60, 61] Importantly, some behavioural improvements in phonological processing have been shown to correlate with improved consistency of electrophysiological neural response to complex sounds (after 1 year of RMHA use), indicating that such interventions may have positive effects on brain plasticity.[62] There are a couple of studies in adults with auditory perceptual problems, in the presence of auditory neural pathology within a diagnosis of Friedreich's ataxia and another study in adults with multiple sclerosis.[63, 64] The study by Rance et al. on Friedreich's ataxia patients that included both children and adults reported a mean 18% improvement in communication and 20% improvement in speech-in-noise intelligibility with FM versus without FM in a hearing disability questionnaire that assessed listening in the patient's everyday situations after 6 weeks' use. Lewis et al. similarly reported good benefit in their adults with multiple sclerosis, indicating that this technology can be applicable for a wide range of APD presentations across the age spectrum.[64]

Compensatory strategies

Compensatory strategies are taught in order to help overcome dysfunction and maximize the use of auditory information.[45] These strategies may include, for example, 'active listening' where the individual is taught how to taking responsibility for their own listening, strategies that aim to enhance memory (e.g. auditory memory enhancement or auditory directives training) or attention (e.g. auditory vigilance strategies), and linguistic and metacognitive strategies.

TABLE 71.2 Computer-based AT programs for adults and children: key examples

AT for children	Description
FastForWord (Scientific Learning Corporation, USA)	This is an adaptive intervention program that employs acoustically modified non-speech and speech sounds (e.g. elongated tones, slower-rate speech sounds) and is designed to train temporal processing, speech perception and language comprehension skills.
Earobics (Houghton Mifflin Harcourt)	The activities aim to improve sound awareness, discrimination of sound in noise and quiet, sequencing sound, associating sound with letters, understanding of complex directions with and without background noise, and memory for sounds and words, and include items to strengthen reading, spelling and comprehension.
LisN & Learn (NAL, Australia)	This aims to improve listening in noise for children diagnosed with spatial processing disorder (SPD). It involves word identification from a target sentence that appears to emanate from 0° azimuth while background noise (looped children's stories) comes from either + or - 90° simultaneously.
Adult AT	
'Listening and Communication Enhancement' –LACE (Neuroton)	This is marketed as top-down intervention for speech-in-noise difficulties and includes degraded speech tasks, cognitive tasks and interactive communication strategies screens.
Brain Fitness Program for auditory processing (Posit Science)	This includes six adaptive exercises which aim to enhance the fidelity in auditory sensory input and language representations. It is specifically designed for older adults.

Curriculum modifications (such as preteaching new material, giving breaks to the student during the day) are also widely used. These are not formally validated in controlled studies, but there is good consensus that such strategies are of considerable benefit.[4]

AUDITORY TRAINING BENEFITS ON AUDITORY PROCESSING AND TOP-DOWN SKILLS: GENERALIZATION OF LEARNING

It is well established that AT improves auditory trained tasks. However, the extent to which auditory learning transfers to top-down skills such as language and reading skills remains unclear. This topic is important due to the co-occurrence of APD with other learning difficulties such as dyslexia, phonological disorder and ADHD. Some studies have demonstrated learning generalization following non-linguistic AT to measures of language, including reading, speech perception and phonological awareness.[65–67] Others reported on-task learning but no generalization to higher-level measures of language skills.[52, 68]

According to Mossbridge et al., generalization of learning can only occur if the neural circuits modified during training also influence the untrained task performance.[69] In general, during perceptual training such as AT training, several abilities are trained simultaneously (e.g. linguistic, cognitive and perceptual skills), thereby hindering investigation into how factors related to the training may affect the extent of generalization. Despite that, there is considerable evidence that the characteristics of the trained tasks might influence the transfer and specificity of learning.[51] The involvement of complex cognitive skills in AT for children, for instance, might act as a limiting process in the generalization of sensory learning due to the non-maturation of cognitive functions until adulthood.[32] Another important factor is the time course of training. Halliday et al.,[52] for instance, delivered AT for 6 hours and discussed if this length of time was sufficient to observe learning transfer, given that previous research reported successful transfer in training of more than 10 hours.[70, 71] Murphy et al. delivered non-linguistic AT for 9 hours and, as Halliday et al., found no generalization of learning.[68] Given the conflicting findings, further studies should investigate the extent to which different lengths of the same training affects learning followed training.

CONCLUSION

Despite the considerable research addressing APD aetiology and the development of several clinically available tests, APD diagnosis is not straightforward and it must be carried out taking into account all possible confounding factors affecting the test performance across the age span. A multidisciplinary approach aimed at the differential diagnosis between APD and other disorders with similar profiles is essential. Currently, several different management strategies are available to rehabilitate APD but well-designed studies are still needed to determine the extent of learning generalization and overall real-life benefits for the affected individual following the training as well as what is the best training method for the different populations with APD.

KEY POINTS

- Despite the lack of international consensus on diagnostic criteria and management of auditory processing disorder (APD), it is well-accepted that children and adults may experience significant listening difficulties in the presence of normal pure-tone audiograms, which might be categorized as APD.
- Different confounding factors such as memory, attention and hearing loss, may interfere on auditory processing test performance across the age span; as a consequence, an appropriate selection of tests as well as their careful interpretation must be taken into consideration on APD diagnosis.
- A multidisciplinary team approach should be employed for APD rehabilitation taking into account varied strategies such as auditory training, signal enhancement and compensatory strategies.

SEARCH STRATEGY

Data in this chapter may be updated based on searches of relevant textbooks, PubMed and other online search tools using the keywords: chronic dizziness, unexplained dizziness, functional dizziness, psychogenic dizziness, phobic positional vertigo, space and motion discomfort, chronic subjective dizziness, alone and in combination with psychopathology, anxiety, stress, depressive disorder and psychiatric.

INTRODUCTION

Psychogenic, somatoform or functional dizziness refers to dizziness in the absence of objective organic pathology or an alternative diagnosis that is able to explain its presence. It is a common problem: 20% of primary care patients seek help for dizziness during their lifetime,[1–4] it is chronic in 30% of these[3] and 10% with chronic dizziness are functionally impaired.[2] Typically, patients are initially referred to cardiology, neurology and specialist vestibular clinics but in 30% of cases investigations and diagnosis are unable to account for the symptoms.[5]

'Psychogenic dizziness' is, however, a 'catch-all' diagnosis that is steeped in misunderstanding. Recent concepts of phobic positional vertigo, space and motion discomfort and chronic subjective dizziness have done much to clarify a syndrome of unexplained chronic dizziness. This has aided a disabled and sadly often disregarded patient group in terms of understanding and ultimately treatment. The common thread running through these three descriptive concepts is the presentation of dizziness with a predominance of anxiety and disordered affect that must be appropriately managed for an optimal outcome.[6]

Here we focus on the importance of neuropsychiatric contributions to these disorders and their treatment from a primarily psychopharmacological but also psychotherapeutic perspective.

NOMENCLATURE

Agoraphobia

In the 19th century, Karl Westphal described a disorder defined by debilitating dizziness, spatial disorientation and anxiety when exposed to open spaces: agoraphobia. Agoraphobia subsequently became a syndrome defined more by a phobic response to situational exposure and heightened anxiety with or without panic attacks, rather than by dizziness per se.

It was not until the 1950s that the concept of psychogenic dizziness as a clinical entity re-emerged. Since then, various approaches to reaching this diagnosis have been described.[7–9] The core premise to all of these proposed diagnostic strategies was the presence of dizziness without true vertigo, typically occurring in anxious individuals, replicated by hyperventilation and combined with the presence of psychiatric symptoms preceding the onset of dizziness. There are assumptions here that are problematic: that anxious individuals do not suffer from vestibular disorders and that individuals with vestibular disorders do not suffer from anxiety. This is obviously not so.

Phobic positional vertigo

In the mid-1980s, Brandt and Dieterich defined phobic positional vertigo (PPV): postural dizziness with a

subjective sense of disturbed posture and unsteadiness, which could be precipitated by complex and motion-rich environmental and situational stimuli. Similar to the concept of psychogenic dizziness, Brandt and Dieterich noted a prominence of anxiety-related symptoms, obsessive–compulsive personality traits and biological or vegetative symptoms, more typical of disorders of affect.[10] Precipitants for the disorder were noted as vestibular disorders and stress. They reported that PPV was the second most common cause of dizziness presenting to their practice and the most common in younger adults.[10]

Longitudinal studies have demonstrated that, as a diagnostic entity, PPV is a stable construct,[11] still being clinically identifiable in patients followed up 5–15 years later. As such, PPV demonstrates a chronicity with a fluctuating course of improvement and exacerbation of symptoms but without full remission.[11] Long-term follow-up also determined that the high incidence of major depressive and anxiety disorders in this cohort of patients was chiefly responsible for the significant disability and poor prognosis of the disorder.[10] The involvement of these neuropsychiatric disorders in disability and poor prognosis is something well recognized today in a variety of different clinical conditions. In PPV, this was so much the case that it has been debated as to whether PPV was in fact a vestibular or a psychiatric disorder. However, in spite of the strong link between anxiety, panic and major depressive disorder, PPV was argued to be a distinct pathology closely linked to these syndromes, rather than occurring as a direct sequela of them.[10, 11]

PPV was, therefore, a stable, reliable and inclusive diagnosis. However, in spite of its diagnostic stability, treatment studies of PPV were disappointing (involving a mixture of reassurance, behavioural desensitization through increasing exposure and serotonergic antidepressants). Longer-term studies have demonstrated some improvement in symptoms but rarely resolution, with almost half of all patients relapsing in the subsequent 12 months, once or repeatedly.[11]

Space and motion discomfort

Space and motion discomfort (SMD)[12] unified the previously described situationally specific syndromes characterized by anxiety and phobic symptoms combined with dizziness, such as street neurosis,[13] space phobia[14] and motorist vestibular disorientation syndrome.[15] SMD refers to the physical symptoms that arise when the sensory information necessary for normal spatial orientation is inadequate or conflicting. In SMD, visual and proprioceptive input is thought to compensate for defective vestibular sensory input, with consequent visual or proprioceptive dependence and heightened sensitivity to these inputs.

SMD describes discomfort that includes dizziness, imbalance or anxiety in situations characterized by certain spatial or motion characteristics. The avoidance of these symptoms leads to the avoidance of the situations likely to precipitate them and, ultimately, to increasingly phobic and disabling behaviour.

SMD therefore refers to situationally specific vestibular symptoms occurring with anxiety and ultimately resulting in phobic avoidance. A questionnaire measure for SMD has been successful in identifying vestibular dysfunction across five groups (panic disorder, agoraphobia with panic disorder, other anxiety disorders, major depressive disorder and healthy controls), with the highest frequency of vestibular dysfunction and SMD being in patients with agoraphobia with panic disorder.[16] In support of this, most studies, although not all, have found a high incidence of abnormalities on vestibular function tests in panic disorder, especially those with agoraphobia.[17] SMD is therefore common in anxiety disorders and its presence predicts vestibular dysfunction. Jacob et al. have subsequently suggested that the absence of panic disorder or acrophobia (a fear of heights) reduces the probability of peripheral vestibular dysfunction and that, where this dysfunction is present, it is likely to complicate the phenomenology of anxiety disorders.[18]

Psychiatric dizziness

Furman and Jacob[17] proposed the more narrow definition of 'psychiatric dizziness', namely dizziness occurring 'exclusively in combination with other symptoms as part of a recognized psychiatric symptom cluster and this symptom cluster is not itself related to vestibular dysfunction'. That is to say that dizziness occurring with panic attacks was 'psychiatric' but that dizziness occurring between panic attacks was not. The caveat made by the proponents here was that this diagnosis did not exclude the possibility of 'functional' or 'psychogenic' overlay, whereby non-psychiatric dizziness is exacerbated by the presence of psychopathology through 'amplification of somatic sensations'. They noted that this was most common in those disorders where hypochondriacal concerns were prominent (anxiety and panic disorders, major depressive disorder and somatoform disorders) as well as those with particular personality traits, citing those found by Brandt in his PPV sample (predominantly obsessive–compulsive).[10] Based upon their definition of 'psychiatric dizziness', Furman and Jacob[17] suggested that PPV was a reflection of vestibulopathy with 'psychogenic overlay' and that its aetiology in this regard was related to a predominance of particular personality trait clusters.

Chronic subjective dizziness

In the early 2000s, Staab and Ruckenstein[19–21] noted that what was previously described as psychogenic dizziness lacked diagnostic specificity as it was also present in migraine, mild traumatic brain injury and dysautonomias. Staab et al. further refined these concepts, removing emphasis from the presence of psychiatric phenomena and presenting the new diagnostic formulation of chronic subjective dizziness (CSD). Staab et al. concede that anxiety is responsible for most of the morbidity of somatoform dizziness but explain that it was not included as a core symptom in order to avoid the assumption that the syndrome is psychiatric alone.[5]

CSD consists of three central components, namely chronic subjective dizziness (of 3 months or more),

hypersensitivity to motion stimuli (including one's own movement) and difficulty or exacerbation of symptoms with complex visual tasks (e.g. reading, writing, using a computer). Three subtypes were described:[19]

- **Neurotological:** This group had a current or past history of transient illnesses (e.g. neuronitis, adverse drug reaction) or intermittent phenomena (e.g. migraine, Ménière's) that triggered secondary anxiety disorders that were predominantly phobic.
- **Psychogenic:** These patients exhibited primary anxiety disorders that resulted in dizziness, with panic disorder being the most frequent cause.
- **Interactive:** This group included those patients with a neurotological complaint that exacerbated a pre-existing anxiety disorder (most often generalized anxiety disorder).

Notwithstanding these subdivisions and the absence of anxiety as a core defining symptom, as a group, patients diagnosed with CSD are nearly all diagnosed with either psychiatric or neurological disorders.[20] Staab's group reported 59.7% of CSD patients demonstrating either primary or secondary anxiety. Others have suggested that this is higher, with one group reporting a clinic sample in which almost 80% were diagnosed with anxiety.[22]

CSD has been met with more consistent psychopharmacological treatment responses than PPV,[21] although psychotherapy has been less successful[23] and without long-term improvement beyond 6 months.[24, 25]

Persistent postural-perceptual dizziness

A further diagnostic category has been divined in a consensus document recently published: persistent postural-perceptual dizziness (PPPD),[26] which is expected to be added to the international classification of vestibular disorders (ICVD).

The diagnostic criteria include dizziness, unsteadiness, or non-spinning vertigo that are present pervasively over three months or more and which are exacerbated by upright posture, active or passive movement, and exposure to moving or complex visual stimuli.[26] This novel nomenclature represents a synthesis of the terms that have gone before over the past three decades. Within this context, PPPD allows for chronic vestibular symptoms that can be precipitated by other conditions that disrupt balance or cause vertiginous symptoms including dizziness. This takes into account peripheral or central vestibular disorders as well as other general medical and neuropsychiatric comorbidity, whilst emphasizing that it is not a psychiatric but a functional disorder, similar to the ideas underpinning CSD. Although yet to be fully pathophysiologically defined, it is thought to arise from an abnormality in function, including multi-sensory information processing, integration of spatial orientation and threat assessment. This brings pathophysiological concepts of functional vestibular disorders in line with the current neurophysiological understanding of other functional syndromes in which this has been demonstrated.[27] A problem similar to that found in the other functional syndromes also penetrates PPPD, namely the heterogeneity of pathoaetiology, presentation, response to treatment and so prognosis. Subtypes of PPPD are therefore proposed to exist. There is an argument that necessarily arises here – namely is there a single PPPD or a number of subtypes?[26] This too is a debate that has raged in the world of functional syndromes and which has been widely reported (for example the debate between Professors White and Wessely regarding 'lumping' and 'splitting'[28]).

The opinion of the authors of this chapter is that the assumption that subtypes exist, differing physiologically but giving rise to the same or similar phenotypes, matches clinical experience better than does the assumption that all similar presentations are the same. As noted above, this allies the concept of PPPD with other functional syndromes.[27] Such subtypes are yet to be explored fully and until defined are likely to impact upon studies of treatment strategies and responses to them. Any future research involving management strategies will need to take this into account as otherwise, results will need to be interpreted with caution in a similar manner to the interpretation of those studies performed to date, involving a variety of different historical diagnostic terms and criteria.

The importance of anxiety in chronic dizziness

The presence of personality traits that predispose to a state of anxiety (**Table 72.1**) along with varying degrees of clinically significant anxiety and avoidance behaviour have been consistent in the diagnostic formulations of unexplained chronic dizziness. Although the nomenclature has changed and with it the emphasis on these factors, they remain of fundamental importance.

Anxiety and major depressive disorders are common in patients with CSD but do not occur in all cases. The prevalence is, nevertheless, high: 60% of patients with CSD have clinically detectable and significant levels of anxiety, while 45% of patients with CSD have a major depressive disorder. This constitutes 75% of the CSD sample[10, 29] and is higher than in other vestibular disorders,[30–32] although these differences are not sufficient to differentiate between CSD and 'organic' vestibular disorders alone.

More recent studies using the CSD criteria have suggested that high trait anxiety (see **Table 72.1**) or a pre-existing anxiety disorder may predispose an individual to CSD and high state anxiety during an episode of vestibular dysfunction may act as a precipitant, while concurrent psychopathology contributes to disability in those with CSD.[33–36] However, this is perhaps an oversimplification since predisposition to high trait anxiety and anxiety disorders (personal history, personality traits and family history of anxiety disorders) also seems relevant as it is in these predisposed individuals that CSD is typically more chronic.[34] This would not come as a surprise to a liaison psychiatrist, seasoned in the diagnosis of functional somatic syndromes affecting other body systems, because this pattern of vulnerability is the same, so much

TABLE 72.1 Definitions

Trait anxiety	Refers to the general level of anxiety and stress that an individual characteristically experiences as a trait related to their personality. Trait anxiety is relatively stable. Higher levels of trait anxiety would typically be found in a characteristically anxious individual.
State anxiety	Refers to the emotional response experienced in the context of particular situations or events and so is a measure of anxiety that fluctuates with context. Threatening situations, including those experienced on a day-to-day basis, will result in raised levels of state anxiety. State anxiety is not a stable phenomenon and measures will vary depending on context.
Agoraphobia	A situationally specific anxiety disorder. Anxiety typically arises in public and crowded spaces, although it may be a lack of obvious exit or escape that precipitates the anxiety. Subgroups exist, determined by whether panic disorder is present or absent, although panic attacks are frequently present and some suggest that agoraphobia itself is a complication of these. ICD considers agoraphobia in terms of being with or without panic disorder, while DSM works in terms of panic disorder with or without agoraphobia.
Panic disorder	An anxiety disorder, the hallmark of which is panic attacks. These episodes are severe and associated with physical symptoms and disability. In ICD, the disorder is graded as moderate (one attack per week over 4 weeks) or severe (four per week over a 4-week period). DSM does not grade the disorder in the same way, referring instead to recurrent attacks and at least a month of persistent rumination over their recurrence and a behaviour change that accompanies this.
Conversion disorder	The presence of unfeigned neurological symptoms affecting voluntary motor or sensory function in the absence of an accompanying neurological diagnosis to explain them. The onset of symptoms is typically associated with a significant psychosocial stressor. In ICD, conversion disorders are referred to as dissociative disorders.
Malingering	The intentional production or feigning of physical or psychological symptoms or disabilities motivated by external stresses or incentives.
Factitious disorder	The consistent and repeated feigning of symptoms in the absence of a confirmed physical or mental disorder, disease or disability. The motivation for this behaviour is almost always obscure and presumably internal, and the condition is best interpreted as a disorder of illness behaviour and the sick role. Specifically, the unconscious desire appears to be to fill the sick role – to be a patient. Individuals with this pattern of behaviour usually show signs of a number of other marked abnormalities of personality and relationships.

so that a debate as to whether they are in fact representative of a single functional somatic syndrome has ensued.[37]

Ultimately the importance of recognizing and treating anxiety is not down to nomenclature and diagnostic criteria alone: the effect of anxiety on the disability suffered from a comorbid diagnosis[38] and its impact on suicide risk[39] are significant.

DIFFERENTIAL DIAGNOSIS

Although chronic dizziness frequently occurs in combination with clinically significant anxiety, there are additional considerations in the case of the patient who presents with chronic vestibular symptoms, negative investigation results and/or a significantly poorer response to treatment than expected.

The differential diagnosis in this instance should include conversion disorder[40] and, more rarely, malingering[41] and factitious disorder.[42] These are identifiable through a careful clinical history and by tracking the clinical course of the presentation and its response to treatment. The differences between these clinical syndromes are summarized in **Table 72.2**.

It is important to ensure that these differential diagnoses are taken into consideration on a secondary basis, i.e. other diagnostic and treatment avenues must be considered first. Care must be taken here and the diagnosis of conversion disorder should be made by a psychiatrist. The diagnoses of factitious disorder and malingering are potentially harmful to a patient's subsequent medical care and should be made with caution and, in the instance of factitious disorder, must include the early involvement of a psychiatrist.

NEUROANATOMICAL MODEL

The association between anxiety and mood disorders and chronic dizziness can also be found in and potentially explained by the overlap in neural correlates. Animal studies suggest that vestibular deafferentation is associated with increased anxiety-related behaviour,[43–45] while highly anxious strains of mice perform more poorly on tests of balance,[46, 47] with performance improving on administration of benzodiazepines[46] or SSRIs.[47]

In human models, the parabrachial nucleus is important in balance and dizziness with dense reciprocal connections with vestibular nuclei.[48] The parabrachial nucleus is also of importance in the experience of anxiety and related symptoms, including panic.[49–52] It has reciprocal connections with the amygdala, infralimbic cortex, hypothalamus and, via midline structures, the insula.[53–55] Functional neuroimaging studies involving caloric stimulation have also implicated the insula and hippocampus.[56, 57] Insula has been implicated in numerous interoceptive phenomena,[58] including pain,[59] as well as emotional processing.[60] Reciprocal connectivity between insula and amygdala, which is also vital in emotional, anxiety and stress responses,[49, 51, 52] forms a network of both functional and structural connectivity that is strongly associated with both state and trait anxiety.[61]

TABLE 72.2 Clinical differentiation between CSD, conversion disorder, factitious disorder and malingering

	CSD	Conversion disorder[40]	Factitious disorder[42]	Malingering[41]
History	>3 months subjective imbalance or dizziness Hypersensitivity to motion, including one's own or the environment's Exacerbation with complex and motion-rich stimuli	Subjective report of dizziness Difficulties with standing or moving Presence of other neurological complaints such as sensory loss, typically not fitting an anatomical pattern Onset of symptoms may coincide with a readily identifiable stressor Involves 'primary gain' (an unconscious internal motivator)	Subjective reports of dizziness May be accompanied by other varied symptoms History often inconsistent when taken on more than one occasion Falsified names and dates of birth may be used Recurrent presentations at multiple and often geographically diverse hospitals may be discovered May be a history of medical training or employment in an allied field Primary motivation is to be 'the patient'	Subjective reports of dizziness May be accompanied by other varied symptoms History often inconsistent when taken on more than one occasion Involves secondary gain (an external motivator that may or may not be unconscious, e.g. avoiding having to work)
Neurological examination	Normal	Symptoms are inconsistent with clinical signs and do not match anatomical pattern Symptoms may vary with distraction	Symptoms are inconsistent with clinical signs and do not match anatomical pattern Symptoms may vary with distraction	Symptoms are inconsistent with clinical signs and do not match anatomical pattern Symptoms may vary with distraction
Neurological and vestibular investigations	Non-diagnostic (normal or minor abnormalities that do not explain the clinical picture)	Normal May be minor incidental abnormalities that do not explain the clinical picture	Normal May be minor incidental abnormalities that do not explain the clinical picture	Normal May be minor incidental abnormalities that do not explain the clinical picture
Management	SSRIs SNRIs CBT VBRT	CBT Abreaction[96] Longer-term psychotherapy Hypnosis SSRIs or other antidepressants may be useful in treating an underlying depressive or anxiety disorder	Views on management strategies vary The more complex and chronic factitious disorder is often difficult to provide an intervention for Approaches include confrontation, non-confrontation and, in certain circumstances, compulsory detention through mental health legislation Underlying psychopathology must also be adequately treated	Confrontation is rarely successful and more indirect approaches that allow the patient to save face are more advisable The success of management approaches is inversely related to the rewards that are motivating the malingering

CSD, chronic subjective dizziness; SSRIs, selective serotonin reuptake inhibitors; SNRIs – serotonin–noradrenaline (norepinephrine) reuptake inhibitors; CBT – cognitive behavioural therapy; VBRT – vestibular balance rehabilitation therapy.

Connectivity between amygdala and hippocampus is well established and is also of known importance in stress-related responses, which in turn may serve to strengthen this network.[62] The effect of anxiety, mediated by the optimization of autonomic responses through cortisol release, is to switch the amygdala 'on' while switching 'off' the hippocampus. This serves to promote the learning of fear-related information (amygdala) and ensuring that resources are not wasted on more complex aspects of memory and learning (hippocampus). The strength of the 'learning' that occurs during heightened anxiety helps to explain why fear- and anxiety-related memories and associated behaviours are typically the hardest to extinguish. In turn, this might explain why the adequate recognition and management of anxiety is of vital consideration in the morbidity, chronicity and disability of chronic dizziness.

Functional connectivity between the vestibular nuclei and hippocampus is also of importance. Animal models have suggested that this connectivity is a potential link between vestibular lesions and the cognitive deficits seen in patients affected by them,[63, 64] with long-term non-spatial memory deficits arising in rats after bilateral (but not unilateral) vestibulectomy.[65] A small case control series has provided support for this in humans, with hippocampal down-regulation in patients with bilateral vestibular lesions as compared to healthy controls, suggesting that functional hippocampal deficits occur as a consequence of a chronic lack of vestibular input.[66] It has been proposed that anxiety disorders arising in the context of vestibular disorders occur as an indirect consequence of these cognitive deficits.[43] However, research in this area is contradictory[67] and, given that the dorsal raphe nucleus innervates limbic structures, including amygdala, in addition to vestibular nuclei,[48, 68] it is possible that affective aberrations directly influence vestibular networks, while the contribution of the vestibular system to autonomic control[69, 70] may explain how vestibular dysfunction gives rise to anxiety.[71] This interaction between networks, affective tone modulating vestibular function versus vestibular function affecting autonomic tone, has the potential to explain why vestibular complaints are common in psychiatric disorders and why psychopathology is common in vestibulopathy.

NEUROCHEMICAL MODEL

Studies examining the management of disorders such as CSD have predominantly focused on the use of medications that increase monoaminergic (serotonin, noradrenaline and dopamine) neurotransmission (see below). The monaoamines are considered central in the pathophysiology of anxiety and panic disorders.[49, 51, 72–74] Serotonin receptors are present in the vestibular ganglion,[75] with direct serotonergic innervation from the dorsal raphe nucleus (DRN – the largest serotonergic nucleus)[76] and collaterals projecting to amygdala.[68] Serotonergic activity in the vestibular nuclei has an effect on the responsivity of motion-sensitive neural pathways,[77] although the vestibular nuclei also receive non-serotonergic innervation from DRN, including gamma-aminobutyric acid (GABA) and neuropeptides. The locus coeruleus (the principal site for noradrenaline synthesis in the brain) innervates the vestibular nuclei and the cerebellum, in addition to connectivity with limbic areas such as orbitofrontal and anterior cingulate cortices, hippocampus and hypothalamus.[78, 79] These connections may be implicated in SMD and postural sway in patients with anxiety disorders.[18] It has been proposed that these monoaminergic inputs to the vestibular system mediate the effects of anxiety and the responsivity of these systems to novel stimuli.[80]

COGNITIVE BEHAVIOURAL MODEL

The cognitive behavioural models for PPV and CSD are similar and rely on an understanding of behavioural conditioning.[10, 21]

Vestibular symptoms result in strong physiological responses, often with anxiety. Anxiety, especially panic, results in strong physiological responses and physical manifestations that can include vestibular symptoms. These responses result in similar subjective experiences (e.g. lightheadedness, the room spinning, change in heart and respiratory rate). The two of these working in tandem result in a powerful conditioning response and anxiety in particular is a powerful reinforcer of behaviour. Hypervigilence for feared symptoms, particularly in given situations where they might be expected, means that this conditioning is able to sensitize responses to subsequent motion stimuli that may resemble or herald the onset of actual vestibular symptoms, which in turn further reinforces a sensitized response. Both anxiety and vestibular symptoms are unpleasant and the two major behavioural responses to these experiences are exaggerated rescue responses (reaching for something to stabilize the perceived motion) and avoidance. Avoidance is a powerful behavioural reinforcer and in this instance its effects are reciprocal – it reinforces itself. The feared consequences of symptoms that result in such strongly conditioning physiological responses, whether vestibular or anxiety in origin, also lead to the development of cognitive distortions such as catastrophization, lending greater weight to the worst perceived outcome.

It is the potent reinforcing effects of avoidance and associated cognitive distortions that are thought to lead to greater chronicity in such disorders and, as a consequence, greater disability, similar to the pattern seen in agoraphobia.

Cognitive behavioural therapy is aimed at psychoeducation to improve understanding of the origin of symptoms, the reattribution of the misinterpretation of anxiety-related symptoms in order to reduce catastrophization, the development of coping skills through the use of relaxation techniques, which in turn enables gradual exposure to both internal (such as through the use of hyperventilation to recreate symptoms) or external (exposure to environments associated with vestibular symptoms) phenomena. The approaches applied in vestibular rehabilitation are similar to those central to CBT but focus more on the behavioural elements, aiming for a reduction in pathological avoidance as a route to habituation to aversive stimuli.

TREATMENT STRATEGIES

Psychopharmacology

To date, no large-scale randomized controlled trials have been performed in cohorts of patients diagnosed with chronic dizziness with and without psychiatric morbidity. There is some variation in the diagnoses used to recruit to these trials on account of the timing in the historical changes in nomenclature detailed above. Uncontrolled trials indicate that selective serotonin reuptake inhibitors (SSRIs)[81–84] and serotonin–noradrenaline (norepinephrine) reuptake inhibitors (SNRIs)[85] may be of benefit for chronic dizziness in the presence of anxiety and major depressive disorders and that this benefit is independent of improvement in psychopathology.[86] However, in being from uncontrolled studies, these results should be interpreted with caution. Staab and Ruckenstein[86] examined the response of the three subtypes of CSD to SSRIs. They report that the otogenic and psychogenic subtypes demonstrated 'more complete' responses than did the interactive. This is likely to be a reflection of the fact that this subtype is likely to exhibit greater chronicity and treatment resistance requiring higher doses, longer treatment course, pharmacological augmentation perhaps in addition to subsequent psychological interventions.

There is sufficient evidence for the use of SSRIs in this group of patients, although further work is necessary; in particular, larger randomized and controlled trials and long-term follow-up studies are still lacking. Studies to date would advise starting at a lower dose than would be ordinarily used in the treatment of anxiety and affective disorders, with a gradual titration to the lower end of this treatment range. The major caveat here is that presence of anxiety symptoms typically requires higher doses than mood disorders do, and a longer course of treatment. A dosage limitation in this regard would provide a false ceiling and an unfair disadvantage to many patients. Another important factor to note is the potential for a dizziness to appear independently of the underlying diagnosis and as a consequence of the SSRIs. This may be in the form of a side effect but may also occur as part of the withdrawal phenomena associated with members of this family with longer half-lives (e.g. paroxetine and fluoxetine).

Psychotherapy

Psychotherapy, specifically cognitive behavioural therapy, has been examined in a number of trials looking at PPV or CSD.[24, 25, 87] In an uncontrolled trial in 41 patients, Edelman et al.[87] suggest that CBT is effective in improving scores of dizziness, avoidance behaviour and disability with high effect sizes after only three sessions but without effect on anxiety or mood-related symptoms. The response after so few sessions is surprising and may explain the lack of efficacy against psychopathology (between six and eight sessions are standard here) but this was conducted in relatively small cohorts of patients and was uncontrolled. The important question that is obviously begged by this potentially positive data after such a brief intervention is whether this clinical response is sustained. No details were provided on follow-up in this initial study but the same group reported that the effects were sustained at 6 months in a subsequent report.[25] This is promising, given that earlier groups suggest that at 12 months after an initial intervention no benefits are sustained.[24]

Vestibular balance rehabilitation therapy

Vestibular balance rehabilitation therapy (VBRT)[88] aims to facilitate the process of compensation and involves a habituation programme that ultimately encourages the 'avoidance of avoidance'. VBRT therefore also engages the behavioural component of the CBT model and is in this way similar in principle to graded exercise therapy in chronic pain syndromes such as fibromyalgia and chronic fatigue syndrome. VBRT is effective against hypersensitivity to motion, improves confidence with balance and reduces avoidance behaviour.[89] Early forays into the combination of VBRT and CBT have yielded mixed results from small randomized trials, with positive results in terms of disability but without effect on the core symptoms of vertigo, anxiety or depression.[90, 91] This is perhaps not surprising with respect to symptoms of vertigo, as exposure to the activity that provokes symptoms is core to the process of compensation (part of the goal of VBRT); the patient needs to experience the symptoms in order for these subsequently to diminish.[91]

AN APPROACH

The assessment and management of patients with complaints such as chronic dizziness is complicated by assumptions that are potentially made with ease. The first is that the discovery of psychopathology may lead to the assumption that this alone explains the presentation, preventing appropriate investigation being sought.[92] On the flip side of the coin, the discovery of 'organic' pathology may result in a lack of appropriate assessment and treatment of psychopathology,[93] with the ensuing negative effects on chronicity and disability. It is also a problem that those initially referred to 'organic' clinics are often reluctant to accept input from a psychiatrist,[94] as a consequence of both stigma and a fear that their disabling problem is being accounted for by 'just being in their head'.

The best practice in this regard is the early involvement of a psychiatrist. Ideally, this should be one who specializes in this area and is familiar with the practice of vestibular medicine. Even more optimal is the psychiatrist who is embedded in the outpatient department with vestibular specialists and is seen as being part of not just the same team but the same process. The advantage of this in terms of the patient's appraisal is that being seen by the psychiatrist is not in any way remote from being seen by the vestibular specialist. The advantage to the clinicians is that investigation can continue from both medical disciplines concurrently, contributing to a complete and ideally seamless clinical picture and subsequent management. We have

reported on the success of such practices from an inpatient perspective with another group of disorders that are met with very similar conflicts.[95]

CONCLUSIONS

Chronic dizziness is commonly associated with psychiatric morbidity, most frequently in the form of anxiety. The presence of anxiety adds to both chronicity and disability, irrespective of whether it is primary or secondary in nature. The early involvement of an appropriately experienced psychiatrist in the comanagement of this patient group for the detection and early management of such comorbidities is vital and need not delay ongoing vestibular investigations, which can be pursued in parallel.

BEST CLINICAL PRACTICE

Psychopathology should be an early consideration in the assessment of patients and, when present, should be actively treated as part of the overall diagnosis and management strategy. Optimally, this should be performed in conjunction with a psychiatrist working in tandem with vestibular specialists, rather than in a remote clinical environment.

FUTURE RESEARCH

- ➤ Rigorously designed randomized and placebo-controlled trials should form the mainstay of future research at this juncture, unified by the use of current nomenclature to define diagnostic groups.
- ➤ Such trials might explore the efficacy of the SSRIs, the SNRIs, CBT and VBRT independently, as comparisons and in combination with one another as well as in isolation.
- ➤ Further to this, the new concept of 'Persistent postural-perceptual dizziness' will require careful exploration for diagnostic reliability and stability and the identification of subgroups that may otherwise hamper the interpretation of results of studies into both pharmacological and non-pharmacological interventions.

KEY POINTS

- Psychopathology commonly coexists with chronic vestibular disorders.
- Typically this is in the form of disorders of anxiety and affect.
- Concurrent psychopathology is a source of chronicity, disability and suicide risk.

CHAPTER 73

CLINICAL EXAMINATION OF THE EARS AND HEARING

George G. Browning and Peter-John Wormald

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search focusing on reviews using the keywords: examination and ear/otology/otoscopy, otoscopy, wax, cerumen, syringing and ear, tests/clinical and hearing, tuning fork, Rinne, Weber and Bing tests.

PINNA

The external ear or pinna is constructed of a cartilage skeleton covered by skin and soft tissue. The cartilage forms an outer helix and an inner antihelix. These structures surround the conchal bowl which is shielded anteriorly by the tragus (Figure 73.1). In humans the physiological purpose of the pinna is to collect high-frequency sounds which are thereby amplified in the external auditory canal. These normal features of the pinna are assessed as part of the initial examination of the external ear.

It is necessary to identify external surgical scars used for access, which are most commonly endaural (Figure 73.2) or post-auricular (Figure 73.3). These scars can be thin and may be difficult to see but, if present, alert the otoscopist to the potential for surgical abnormalities, especially in the attic, such as open mastoid cavities. Other scars to harvest graft material such as tragal cartilage and temporalis fascia are also worth identifying.

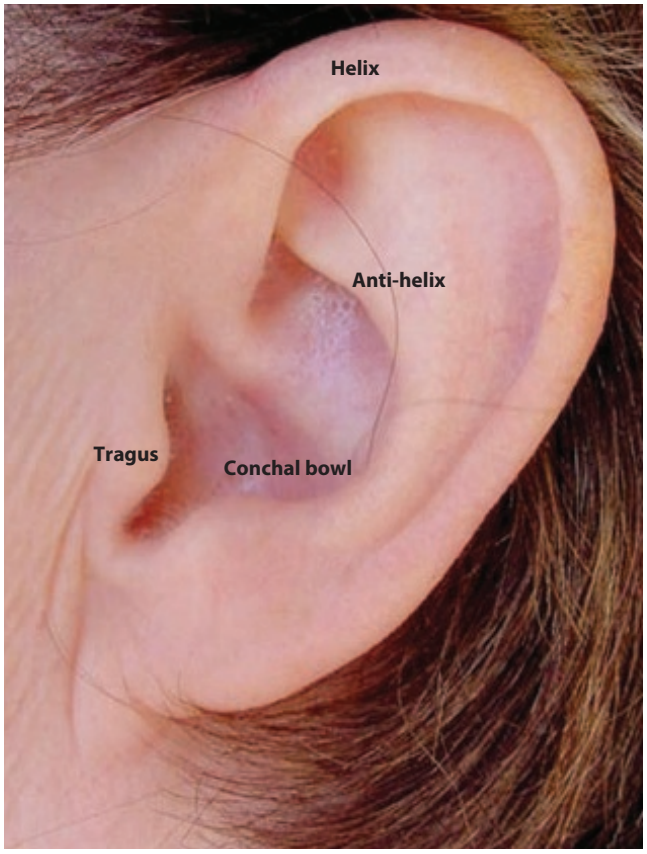

Figure 73.1 Anatomy of the ear (pinna).

EXAMINATION OF THE EXTERNAL AUDITORY CANAL

The external canal consists of a cartilaginous outer third and a bony inner two-thirds. It is angled and needs to be straightened before examination is attempted. This is done by gently pulling the pinna posterosuperiorly (Figure 73.4). This aligns the cartilaginous canal with the bony canal and should allow visualization of the

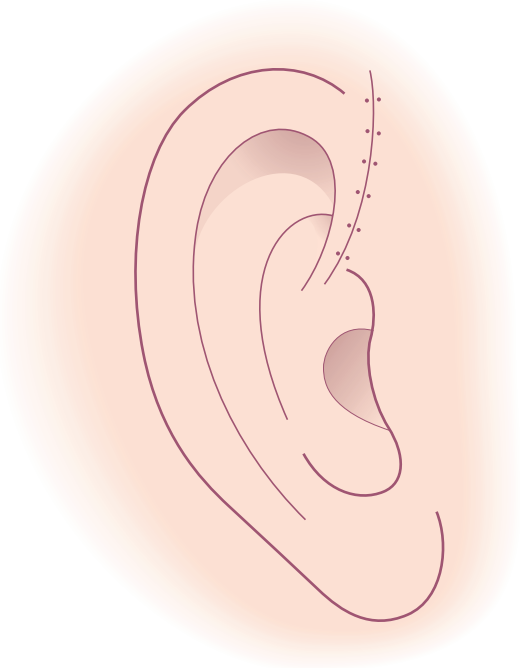

Figure 73.2 Endaural incision (right ear).

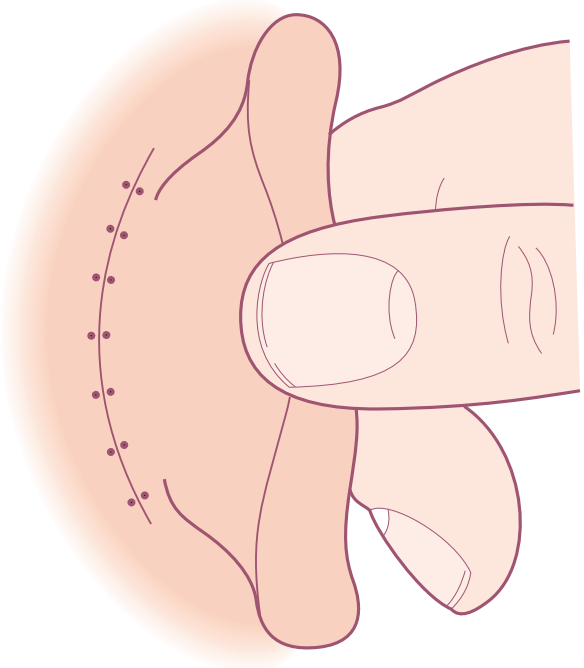

Figure 73.3 Post-auricular incision (right ear).

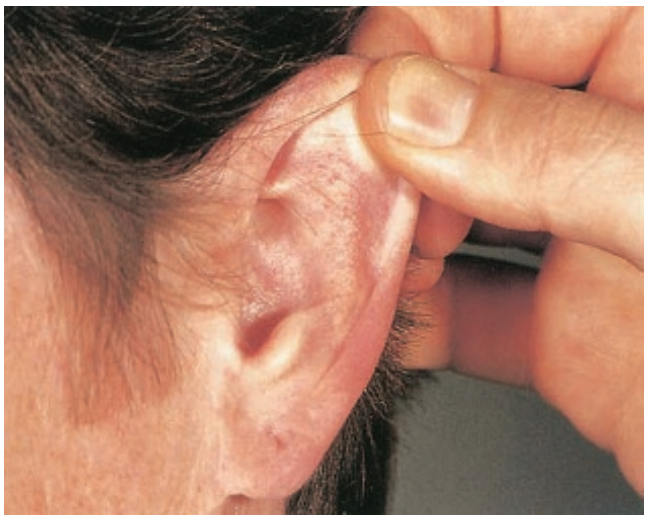

Figure 73.4 Positioning of ear for otoscopy.

entire canal and tympanic membrane. The temperomandibular joint creates an anterior bulge in the deep external canal that may obscure the anterior inferior tympanic membrane. A high proportion of adults and children will have visually occlusive wax plugs, where the tympanic membrane cannot be seen in its entirety. In clinical practice, visually obstructive wax is more common in those who wear a hearing aid. Patient indications for wax removal are the feeling that the ear is blocked, perhaps associated with impaired hearing. Clinical indications for removal are if the patient has otological symptoms that require the external auditory canal and tympanic membrane to be assessed, such as ear discharge, otalgia and hearing loss.

WAX PRODUCTION

Wax is produced by the hair-bearing skin of the external auditory canal. Wax is a combination of desquamated skin and cerumen formed by glands in the base of the hair follicles. Hairs are present in the outer third of the external canal. Most external canals are self-cleaning with the desquamated skin migrating up to the hair follicles where it is separated from the dermis and mixes with the cerumen to form wax. The wax migrates down the hair and migrates out of the ear canal (Figure 73.5). The most common finding is partial occlusion of the canal (Figure 73.6). In the majority of patients this will be an incidental, symptomless finding. In those with otological symptoms, wax

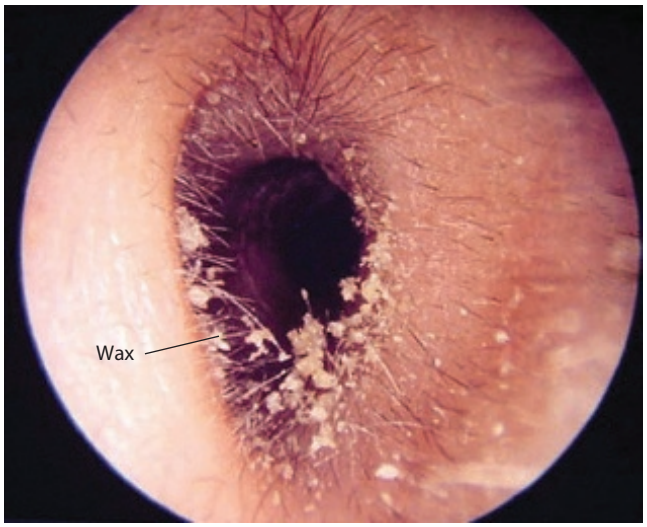

Figure 73.5 Wax on the tips of external canal hairs.

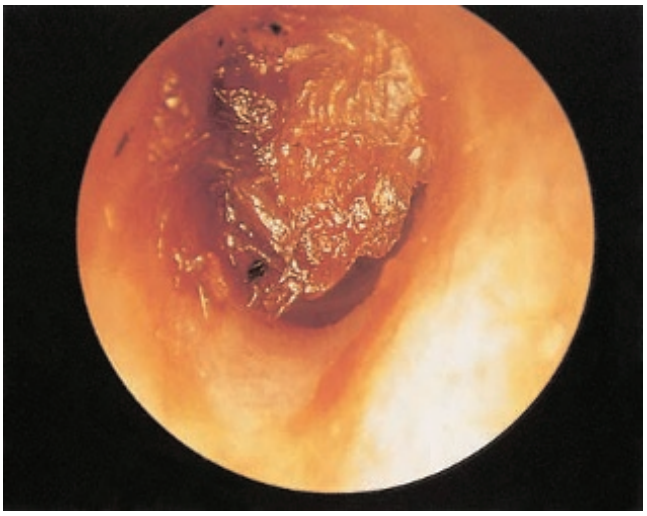

Figure 73.6 Wax totally obscuring view of right tympanic membrane. Associated hearing impairment is unlikely.

will need to be removed to enable the canal and tympanic membrane to be assessed. It is relatively uncommon for wax to cause a hearing impairment. It requires the wax to be impacted deep in the canal by the use of cotton buds or an ear mould for it to act like 'ear defenders' that are used to limit noise exposure.

Wax is amenable to removal by non-specialists by water syringing most commonly using a pressure-controlled irrigator. Specialists prefer to remove wax under direct vision with the aid of a headlight, microscope or endoscope, often via a speculum with ear wax hooks, Jobson Horne probes or suction irrigation.

WAX SOFTENING

In primary care settings various wax softening agents including olive oil, sodium bicarbonate and commercial agents such as Cerumol are frequently used to aid wax or ease of wax removal. Such substances are effective[1] but there is no evidence to support the use of one agent rather than another. Adverse effects are not common but can include skin irritation. In secondary care their previous use requires to be noted if there is inflammation of the skin of the ear canal.

EAR TOILET

In primary care ear toilet is mainly confined to clearance of wax. In secondary care, though removal of wax is the predominant reason, debris including pus, dried pus and blood will also require to be removed to aid assessment and management. Performing toilet under direct vision, especially if this is magnified with a microscope or endoscope, greatly aids the process of clearing out difficult areas including the attic and open mastoid cavities. Patients will tolerate extensive toilet better if they are in a relaxed position on a reclining chair or couch. They should be informed as to what to expect, especially the noise of suction or irrigation of water. The latter on occasions can cause a short episode of vertigo especially if the irrigation fluid is not at body temperature.

Syringing

Syringing to remove visually obstructing wax or wax considered potentially to be causing a mild hearing impairment is now most frequently performed by suitably trained, paramedical staff (**Figure 73.7**). As this is most often not performed under direct vision and the otoscopic diagnostic skills of the operator will be limited, there are usually firm contraindications to syringing. So ears with a discharge or previous ear surgery are not permitted. These contraindications do not apply to specialists in secondary care settings.

In the UK, various Health Boards have produced guidelines readily available online with titles such as *Ear irrigations: guidelines for Community Nursing*. That by Derby City Primary Care Trust can be recommended.[2]

Microscopic/endoscopic suction toilet

Ear toilet with magnification is popular among specialists as it allows the external canal and tympanic membrane to be magnified while wax, pus or debris is removed using a suction cannula or other instrument. The magnification afforded by the microscope or endoscope allows the ear to be cleaned with great precision and with minimal patient discomfort. Irrigation of troublesome areas with a small syringe filled with water often aids the process. Because such toilet is performed under direct vision, adverse effects including trauma to the ear canal or tympanic membrane/middle ear are uncommon. Haemorrhage, if it occurs, can be easily controlled.

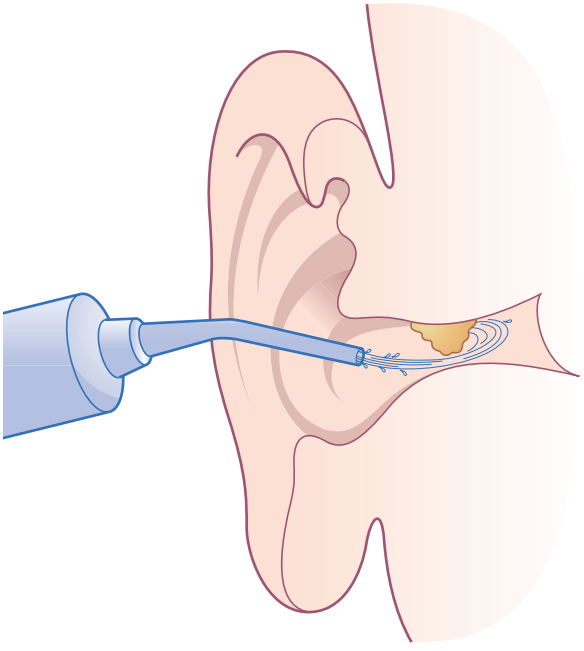

Figure 73.7 Wax syringing. The water bypasses the wax and is reflected by the tympanic membrane to expel the ear wax.

Mopping the ear canal

A mop can be used to remove discharge or debris from the ear canal for management purposes of otitis externa and active chronic otitis media, as well as allowing visualization of the underlying canal and tympanic membrane. Mopping can be performed without the aid of equipment such as suction which is the main alternative method. It can also be performed, after adequate instruction, by paramedical staff and patient carers.

A mop is made by winding a thinned-out piece of cotton wool around the end of an orange stick. Care should be taken to ensure that the stick extends only halfway into the cotton wool (Figure 73.8) and that the mop is about the same diameter as the stick. The protrusion of cotton wool beyond the end of the stick will ensure that, if the mop touches either the deep canal skin or the tympanic membrane, no damage will occur or pain be felt.

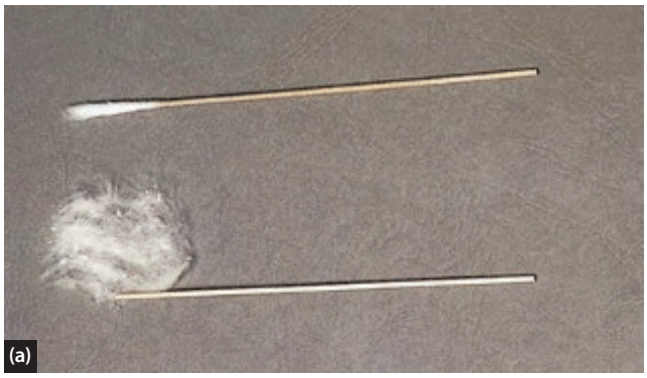
OTOSCOPY

With an otoscope

The first decision when performing otoscopy with an otoscope (auriscope) is to choose the most appropriate size of speculum (Figure 73.9). A narrow speculum limits the visible canal and/or tympanic membrane. The otoscope then has to be moved around and all the subsequent images mentally pieced together like pieces of a jigsaw until the overall picture is established (Figure 73.10). The larger the speculum, the less reconstruction will be needed by the examiner.

With an endoscope

Endoscopy with a short 4 mm diameter straight-view rigid scope has the advantage of not requiring a speculum. It is therefore perhaps more able to be angled to see the different areas including the attic and open mastoid cavities. If attached to a camera, both the patient and others can view the ear, allowing permanent photographic records to be kept electronically. Condensation of the lens is the main drawback. This can be mitigated to some extent by wiping the lens with an alcohol swab.



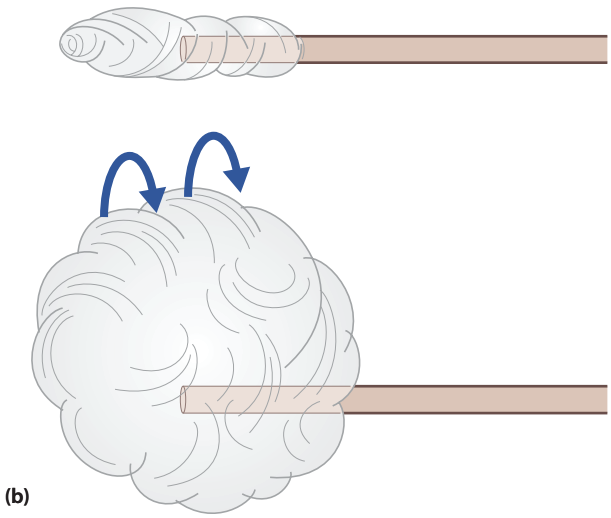


Figure 73.8 (a,b) Method of making a cotton bud.

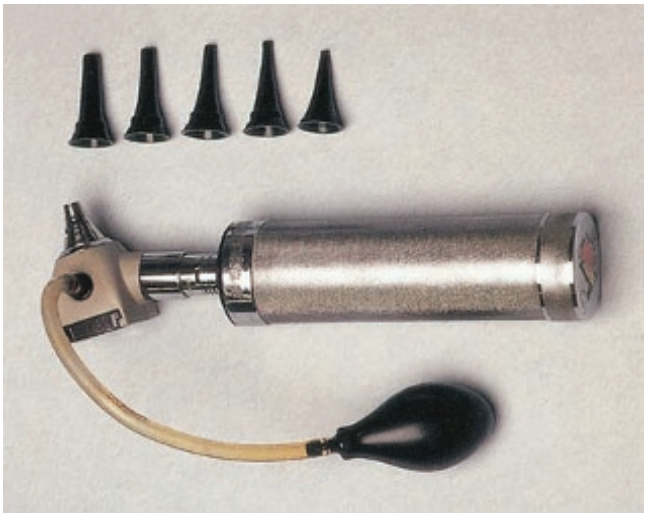

Figure 73.9 Closed pneumatic otoscope.

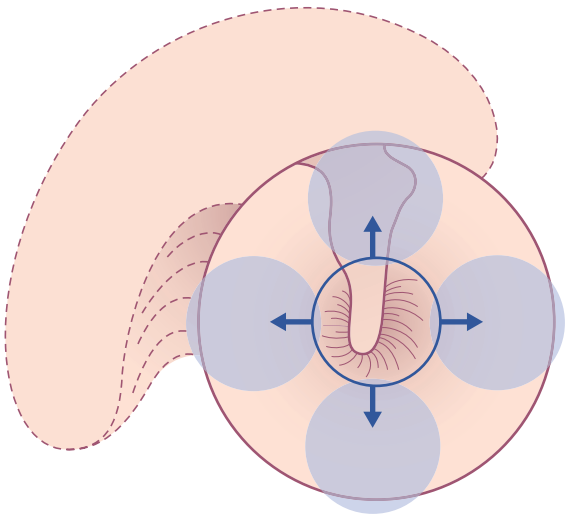

Figure 73.10 A wide view of the attic is obtained by multiple views via a speculum.

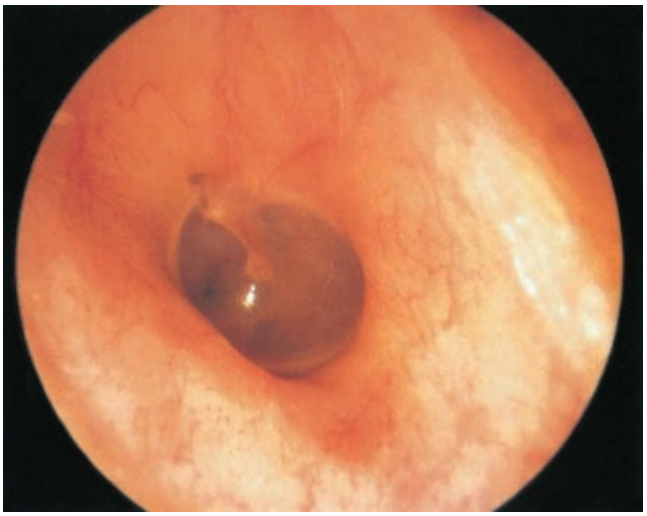

Figure 73.11 Normal skin in the left external auditory canal.

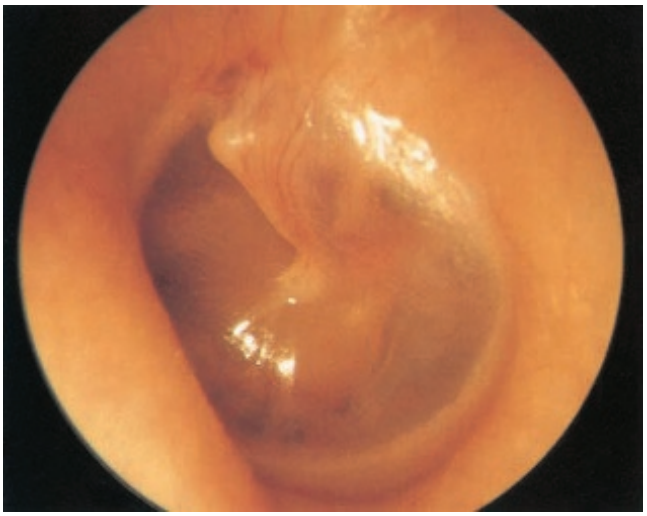

Figure 73.12 Normal left tympanic membrane. The anterior pars tensa is not entirely visible due to anterior canal bulge of the temporomandibular joint.

Normal external canal

The outer third of the normal external canal has hair-bearing skin which is relatively thick as it contains the ceruminous glands. At the junction of the cartilaginous and bony canal, the skin thins without glands and covers the underlying bony canal (Figure 73.11). This allows the bony prominence formed by the impression of the temperomandibular joint to be clearly seen anteriorly. This prominence allows photographs of tympanic membranes to be identified as either a left or a right ear as the prominence is always anterior (Figure 73.12). In some photographs taken through a Hopkins rod, the bony prominence may not be obvious.

Structured otoscopy

With the increased availability of texts on the pathology of the external canal and tympanic membrane,[3, 4] otoscopy is becoming easier for practitioners to learn. If a structured approach to otoscopy is taught, diagnostic skills improve and disease patterns are more easily recognized and appropriately dealt with.[5] The most recognizable feature in most ears is the handle of malleus and this should be the first structure sought (Figure 73.13). The umbo and lateral process should be identified and the adjacent tympanic membrane visualized (Figure 73.13). The tympanic membrane can be divided into the pars tensa and the pars flaccida (Figure 73.14). The examiner should then decide if the pars tensa is intact and, if this is the case, whether it is in its normal position. Clues as to its normal position should be sought in identifying the angle of the handle of the malleus. Foreshortening indicates retraction of the tympanic membrane medially as does lipping around the annulus creating a 'neoannulus' (Figure 73.15). Loss of the light reflex, while less important, may be caused by retraction, inflammation or scarring of the tympanic membrane (Figure 73.16). The tympanic membrane is normally a grey, slightly translucent colour. Hyaline degeneration of the fibrous layer sometimes associated with calcium deposition occurs as a consequence of previous episodes of middle-ear inflammation. This increases the whiteness of the tympanic membrane and can be a diffuse thickening

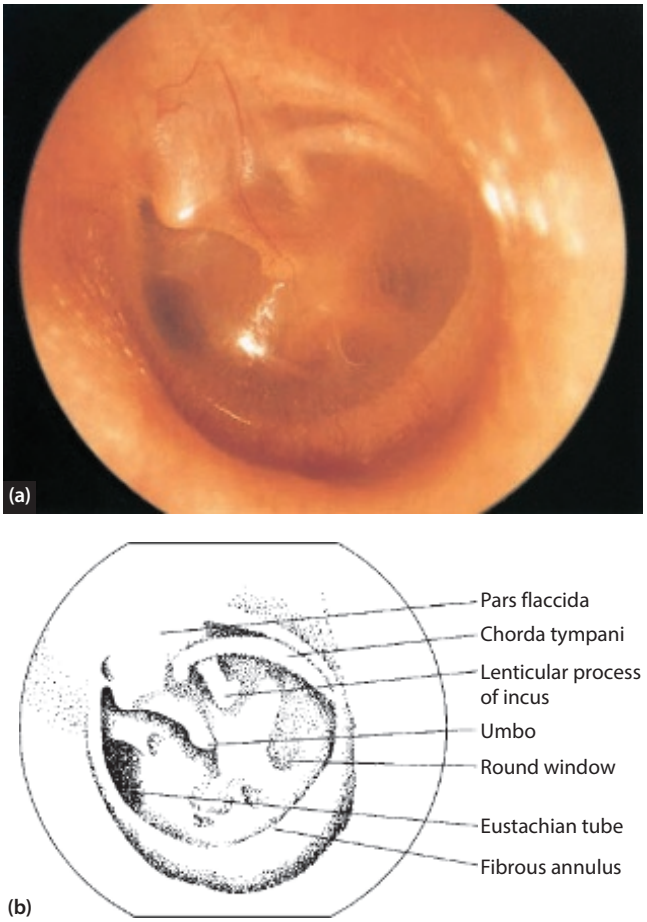

Figure 73.13 (a) Normal left tympanic membrane. **(b)** Important middle-ear anatomy structures often identified behind the tympanic membrane.

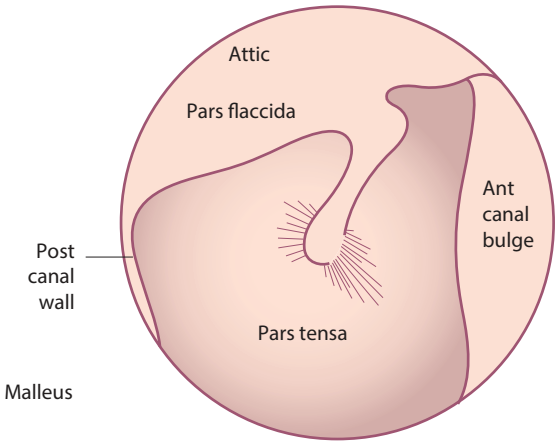

Figure 73.14 Diagram of the ear indicating the pars tensa and pars flaccida. Redrawn with permission from Browning, *Updated ENT.* 3rd ed. London: Hodder and Stoughton; 1994, p. 2.[6]

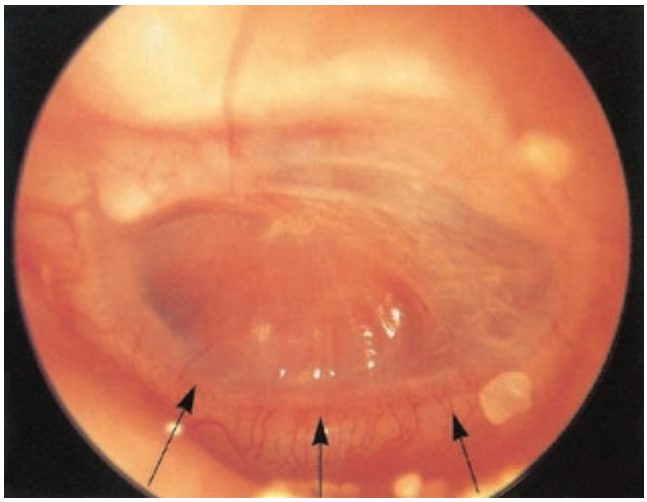

Figure 73.15 Severely retracted position of the malleus handle in otitis media with effusion (left ear). As retraction develops, a neoannular fold may form (arrows).

Figure 73.16 Tympanosclerotic plaques, extending from posterior to inferior. Remainder of the tympanic membrane scarred (right ear).

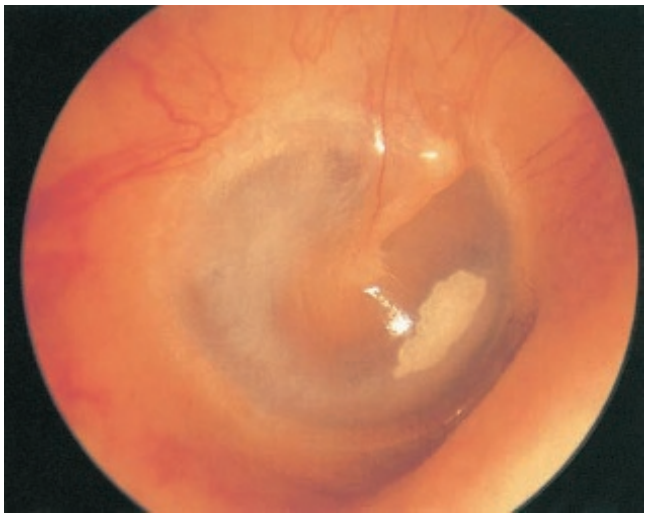

Figure 73.17 Chalk patch on the anterior pars tensa (right ear).

of the tympanic membrane or isolated tympanosclerotic plaques (Figure 73.17). Previous grommet insertion produces a rather characteristic crescent-shaped deposition of calcium in 32% (CI 30.6,32.8) of patients (Figure 73.18).[7] Tympanosclerosis may also fixate the middle ear ossicles with a resultant conductive impairment. If the tympanic membrane is perforated posteriorly, the ossicular chain may be visible. In Figure 73.19 the malleus handle, long process of the incus and stapes are all seen through a subtotal perforation in an ear with active, mucosal chronic otitis media.

Changes in the tympanic membrane and ossicles as a result of ageing

The tympanic membrane may lose its translucency and become less transparent with age. It had also been thought

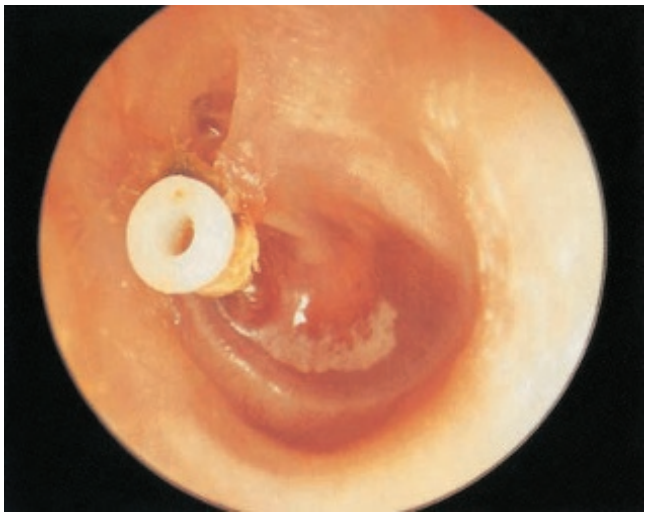

Figure 73.18 Extruded ventilating tube with otoscopic recurrence of middle ear fluid. Left ear retracted and yellow.

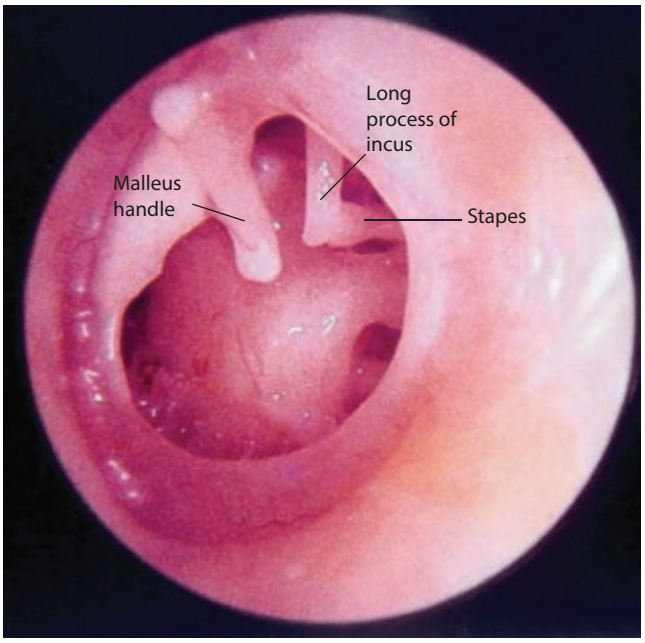

Figure 73.19 Perforated tympanic membrane with visible ossicular chain.

that the ossicular chain increased in stiffness with age. However, Holte[8] showed that there was no change in the middle ear resonance, admittance or tympanometry width with increasing age. The less translucent tympanic membranes seen with increasing age are likely to be as a consequence of episodes of middle ear inflation rather than directly related to ageing.

CLINICAL ASSESSMENT OF HEARING

It is useful before clinically assessing the hearing to have some idea of how impaired the patient is overall. If communication is difficult without hearing aids, this would suggest a bilateral severe or profound hearing impairment. If they find it difficult to hear conversation when out of sight of the speaker, they will have a bilateral mild to moderate impairment. The history from the patient and from any attending partner or friend as to what situations cause difficulty is also helpful. More often it is the attendant person who gives a truer record of the overall disability. One should be particularly wary if an individual is adamant that they have no hearing impairment.[9] Ascertaining whether the patient has a better hearing ear helps direct the clinical assessment, rather than being 'correct' in many instances.

Questionnaire assessment

Several questionnaires are available for ascertaining the degree, if any, of an individual's hearing impairment. These have been primarily designed as screening instruments[10] and are not sufficiently specific to determine the requirement for audiometry in secondary care. Individual questions from these questionnaires that ascertain the circumstances in which the patient finds hearing difficult can, of course, guide subsequent management.

Free-field speech testing

This is the main method of clinically assessing an individual's hearing[11] and is applicable to both adults and older children.[12] Its main value is in primary care when audiometric facilities are not available as a screening test for a hearing impairment. In secondary care its value is also as a screening test to determine whether an audiometric assessment is required. In addition, the test is such that it can assess the relative severity of a hearing impairment in each ear, which is sufficiently reliable to guide management. It can also be useful to demonstrate to the patient or parent of a child the presence/lack of a hearing loss.

GENERAL TECHNIQUE

The examiner explains to the patient that a combination of letters and numbers are going to be whispered or spoken and the patient's task is to try to repeat them. A number–letter combination is chosen as this has a reasonable mix of consonants that allows a relatively broad range of frequencies to be tested. For less experienced testers to have a list of these to read from allows a more consistent voice level to be produced. The examiner then positions themselves behind the patient so that the subject cannot lip-read and in a loud voice confirms that they understand the task by saying very recognizable numbers such as '99'. The next step depends on whether the patient is being screened to detect a hearing impairment or each ear is being screened separately for a hearing impairment.

SCREENING TECHNIQUE

When the tester is standing behind the subject at arm's length from their head and the subject cannot repeat more than 50% of the number–letter combinations spoken in a whispered voice, they will have a hearing impairment of at least 30 dB HL in both ears (Table 73.1).[13] The main variable to ensure control for is the level of the whispered voice. Some suggest that fully exhaling before whispering gives more consistent voice levels. It must also be remembered that testing has to be in a quiet environment.

If each ear requires to be tested, the non-test ear requires to be masked as sound attenuation across the skull from

TABLE 73.1 Sensitivity and specificity of a hearing impairment being detected by an individual's inability to hear a whispered voice at 60 cm (reproduced from Browning et al.[13] with permission)

PTA	Impairment (db HL)	Percentage	
		Sensitivity	Specificity
PTA over 0.5, 1 and 2 kHz	≤25	86	94
	≤30	95	90
	≤35	100	84
PTA over 0.5, 1 and 2, 4 kHz	≤25	91	96
	≤30	96	91
	≤35	98	86

one side to the other ear is in the region of 15 dB. Adequate masking is achieved most easily by the examiner closing the ear canal in the non-test ear by pressing the tragus over the canal with a finger. The tragus is then rubbed to produce a continuous masking noise that is in the region of 40 dBA. The examiner then positions themselves at full arm's length on the test-ear side of the patient which is approximately 60 cm from the test ear. The number–letter combinations are again whispered and the subject is asked to repeat them. If they cannot do this on more than 50% of occasions, the hearing level in that ear will be 30 dB HL or poorer.

While this test is not as accurate as pure-tone audiometry it will give the examiner a reasonable idea of the hearing, especially in the low frequencies (speech frequencies). The free-field speech test will in most cases (90–100 %) detect a hearing loss of greater than 30 dB with a false-positive rate of 13–30%.[13]

In primary care such voice testing can be sufficiently sensitive and specific to discriminate those requiring onward referral for audiometric testing.[12, 14]

DETERMINING THE DEGREE OF IMPAIRMENT IN EACH EAR

In secondary care the above 'by ear' screening method can be extended to determine the likely level of the impairment if the subject is not able to repeat what is said in a whispered voice. This requires the examiner to move their head in position from arm's length (60 cm) to 15 cm from the ear and repeat the test again in a whispered voice. If the subject can do this, that ear has a mild impairment (Table 73.2).[13] If they are unable to do it, the voice level is raised to a conversational level and the test repeated at arm's length. If the subject is able to do this, they will have a moderate hearing impairment and the conversational voice is then tested at 15 cm. If unable to repeat this, the subject has a severe impairment or poorer. If the test is to be taken any further, tragal rubbing will provide insufficient masking and a Barany box will be required.

The main variable between tests and testers is the reproducibility of the voice levels. Examiners should frequently compare their results with the audiogram to ensure that their conversational voice level and whisper levels are giving consistent results.

TABLE 73.2 Comparison of free-field voice thresholds and pure-tone average (PTA) over 0.5, 1, 2 and 4 kHz (after Swan and Browning)[14]

Voice level	Distance (cm)	Loudness (dBA)	PTA mean percentiles	
			5th	95th
Whisper	60	12	–	27
	15	34	20	47
Conversation	60	48	38	60
	15	56	48	67
Loud	60	76	67	87

Tuning fork tests

Tuning fork tests have a potential role in ears with a normal tympanic membrane to distinguish between a conductive and a sensorineural hearing impairment when accurate pure-tone audiometry, with both air and bone conduction, is not available. In these circumstances, if they suggest a conductive hearing impairment, then otosclerosis is the most likely diagnosis. Tuning fork tests have relatively little value if otoscopically the ear is abnormal with otitis media with effusion and acute or chronic otitis media where, by definition, there must be a conductive defect. What one requires to know in these ears is the magnitude of the conductive defect and pure-tone audiometry is the only method of doing this by measuring the air–bone gap.

The most commonly used forks are the 256 Hz and 512 Hz forks, as these give more reliable responses than the 1024 Hz fork.[14, 15] Tuning forks are activated by striking them lightly against the elbow. The sound generated should not be audible until the fork is brought close to the ear. Striking them against a solid object may produce harmonics that distort the pure-tone generated by the fork and result in an unreliable test. A correctly activated tuning fork held up to the ear generates about 70 dBA, while one activated by pushing the tines together and letting go can generate slightly higher levels (89–90 dBA).

In theory, masking should always be applied to the non-test ear, especially for bone conduction. However, such masking cannot be done by bone conduction as this would affect both ears. Consequently, it has to be done by air conduction and a Barany box is used because it generates sufficient noise. Other methods of masking (tragal rubbing and paper) produce an insufficient volume of noise to adequately mask the tuning fork.[13, 15]

RINNE TEST

The standard **loudness comparison method** of performing the Rinne test compares the relative loudness of air conduction against bone conduction. In ears with normal hearing or a pure sensorineural hearing impairment, the tuning fork will sound louder opposite the ear canal (air conduction) than when placed on the mastoid bone behind the ear (bone conduction). Therefore, with the tuning fork activated, the patient is asked to say which of the following sounds louder: the fork placed within 2 cm of the external auditory canal or placed firmly on the flat bone of the mastoid behind the pinna. To aid bone contact with the tuning fork base it is advisable to hold the patient's head with the other hand to prevent it from moving.

The alternative method of performing the Rinne test is the **threshold comparison method**. Here, the activated fork is held opposite the external canal until it is no longer heard. It is then placed on the mastoid bone. If the sound is heard again, then bone conduction is better than air conduction and there is a conductive impairment. This method of performing the Rinne is not as reliable as the relative loudness comparison method (Figure 73.20).[13, 16]

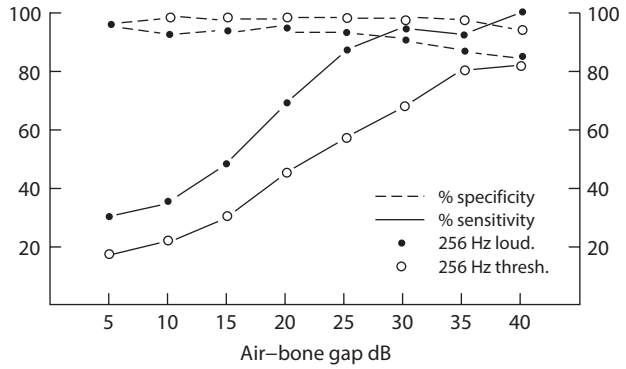

Figure 73.20 A comparison of the sensitivity and specificity of the 256 Hz fork using a loudness comparison method against the 512 Hz fork using a threshold method, in detecting air–bone gaps of various magnitudes. Redrawn with permission from Browning et al. Clinical role of informal tests of hearing. *J Laryngol Otol* 1989; **103**: 7–11.[13]

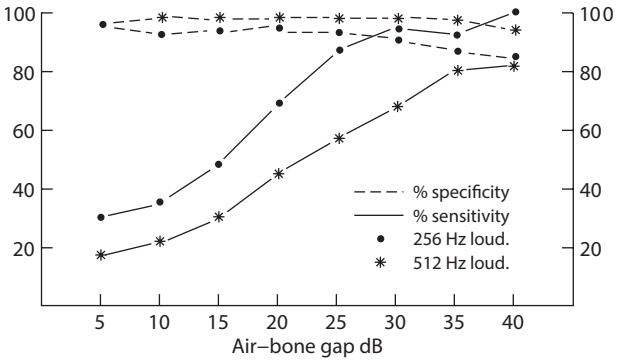

Figure 73.21 A comparison of the sensitivity and specificity of the 256 Hz against the same forks in detecting air–bone gaps of various magnitudes, but using the loudness comparison method. Redrawn with permission from Browning et al. Clinical role of informal tests of hearing. *J Laryngol Otol* 1989; **103**: 7–11.[13]

In practice, masking of the non-test ear only requires to be done when testing a poorer-hearing ear (determined by voice testing) and the bone conduction is louder than the air conduction. A false-positive Rinne could result in these circumstances by the bone conduction being heard by the better-hearing ear.

Although many clinicians use a 516 Hz tuning fork, the 256 Hz fork gives superior sensitivities and specificities (Figure 73.21). The 256 Hz Rinne tuning fork test will detect a conductive defect above 30 dB in 90% of patients (Table 73.3). Between 20 and 30 dB, the sensitivity will fall to 70% and between 10 and 20 dB it will be less than 50%.[13, 15–20] The specificity of the test is high above 30 dB conductive defect but falls as the air–bone gap narrows. The false-positive and false-negative rates again depend on the air–bone gap (Figure 73.20).[13] The false-positive rate in normal patients is 20%.[13, 15–20]

Table 73.4 shows the results with a 512 Hz fork in greater detail. Using the loudness comparison method, it shows there is a third type of response of no difference in loudness (ac = bc). This makes the test uninterpretable in up to 10% of patients with an air–bone gap of 11–40 dB at 512 Hz.

TABLE 73.3 Size of air–bone gap (dB) which would be correctly identified by Rinne test on various percentages of occasions

Fork	Study	Confidence limits		
		50%	75%	>90%
256 Hz	Crowley & Kaufmann (1966)[17]	25 dB		30 dB
	Gelfand (1977)[20]		40 dB	
	Browning et al. (1989)[13]	15 dB	20 dB	30 dB
512 Hz	Crowley & Kaufmann (1966)[17]	25 dB		30 dB
	Wilson & Woods (1975)[18]			40 dB
	Gelfand (1977)[20]		40 dB	
	Golabek & Stephens (1979)[19]	19 dB		
	Browning et al. (1989)[13]	20 dB	25 dB	40 dB

BING TEST

The Bing test is based on the principle that, if there is a conductive hearing loss, occlusion of the external auditory canal will not augment the sound of the tuning fork in the test ear. This is what would happen in those with normal hearing or a pure sensorineural hearing loss. The test is performed by placing the activated tuning fork on the mastoid bone and then occluding the external auditory canal with a finger. If the patient reports that this makes the bone-conduction sound louder, there is unlikely to be a conductive impairment. However, if it remains the same, then a conductive impairment is likely.

The sensitivity and specificity of this test are low as it frequently suggests a conductive hearing loss in patients with normal hearing.[18] The reliability of the Bing test correctly identifying an ear with a conductive deafness is only slightly better than chance (57–66%).[18] Today it is used less frequently than the Rinne to identify a conductive impairment in ears with a normal tympanic membrane as its sensitivity is less although its specificity is similar.[21]

WEBER TEST

The Weber tuning fork test is only applicable if a patient has unilateral or asymmetrical hearing. The test is based on a tuning fork placed centrally on the skull being heard

TABLE 73.4 Comparison of the Rinne test results with a 512 Hz tuning fork against the air–bone gap at 0.5 Hz using a loudness comparison (after Browning and Swan)[16]

Air–bone gap (dB)	Percentage ears		
	AC > BC	AC = BC	BC > AC
0–10	97	1	2
10–20	61	11	19
21–30	32	8	60
31–40	42	8	49
40+	10	0	90

AC – air conduction; BC – bone conduction.

louder in an ear with a conductive impairment or in an ear with better sensorineural thresholds. This distinction is only possible if the examiner has performed a clinical test of hearing previously and knows which ear is the better-hearing ear.

The test is performed by placing an activated tuning fork over the forehead, on the bridge of the nose or over the incisor teeth. The tuning fork can also be placed in the midline over the vertex of the skull. The patient is asked to identify in which ear the sound is heard or alternatively in which ear the sound is louder. If it is heard in the better-hearing ear, then the poorer ear has a sensorineural impairment. If it is heard in the poorer ear, then it has a conductive impairment.

Unfortunately, the Weber test has a low sensitivity and specificity and is marginally better than chance.[15, 19, 22] It is still in use but this test should not be relied upon, as the chance of accurately and reliably identifying conductive and sensorineural deafness is only 33%.[22]

OVERALL ROLE OF TUNING FORK TESTS

With the general availability of pure-tone audiometry, the distinction between a conductive and a sensorineural hearing impairment should generally be made on a comparison of the air- and bone-conduction thresholds, masked where appropriate. The air–bone gap will also give a measure of the magnitude of any conductive defect, which is essential when assessing the potential role of surgery to improve the hearing. Tuning fork tests should be held in reserve for otoscopically normal ears where satisfactory audiometry is not available to diagnose otosclerosis and should always be interpreted in the light of their generally low sensitivity and specificity.[23]

BEST CLINICAL PRACTICE

- ✓ Wax or pus that obstructs the view of the tympanic membrane is most easily removed by non-specialists by syringing.
- ✓ Wax softeners to aid syringing are of 'benefit' but there is no evidence to support a specific softener. [Grade A]
- ✓ Specialists will frequently use suction with microscopic vision to clear the canal.
- ✓ In otoscopy, the speculum should be as large as practicable.
- ✓ Free-field speech tests with a whispered voice at 60 cm from the ear can be used when audiometry is not available to detect those with a hearing impairment.
- ✓ Tuning fork tests are insufficiently reliable to make a distinction on their own between a conductive and a sensorineural hearing impairment. They are not recommended except when reliable audiometry is unavailable to test an ear that is otoscopically normal, mainly to diagnose otosclerosis. [Grade A]
- ✓ If the middle ear is otoscopically abnormal, there will be an element of a conductive hearing impairment to any hearing loss. In this situation tuning fork tests have minimal added value.

KEY POINTS

- Wax is a normal phenomenon.
- Wax only needs to be removed if it causes deafness or if the patient has symptoms related to the ear and the tympanic membrane cannot be visualized.
- The features of a normal tympanic membrane need to be recognized.
- Structured otoscopy provides a tool to evaluating normal from abnormal.
- Clinical assessment of hearing is useful in the primary care setting as a screening tool for hearing loss.
- The Rinne tuning fork test can distinguish between a conductive and sensineural hearing loss but the Weber tuning fork test has little clinical value.

CHAPTER 74

FURUNCULOSIS

Malcolm P. Hilton

SEARCH STRATEGY

Data in this chapter may be updated by a search using the keywords: furuncle; ear, external and infection; otitis externa; ear, external and *Staphylococcus aureus*; alone and in combination.

DEFINITION

Furunculosis is a localized form of otitis externa resulting from infection of a single hair follicle. Hair follicles are only present in the lateral (cartilaginous) segment of the external auditory canal. Furunculosis is therefore confined to the lateral canal.

Bacterial invasion of a single hair follicle results initially in a well-circumscribed deep skin infection. As the infection progresses, a pustule forms and this progresses to local abscess formation, often with considerable associated cellulitis and oedema. Bacteria attach initially to the cells of the stratum corneum and proliferate around the ostium of the hair follicle. There is deeper invasion of the hair follicle between the inner and outer root sheath.[1]

DIAGNOSIS

Histology is the reference standard for diagnosis (**Figure 74.1**) but is never obtained in routine clinical practice. Symptoms do not usually discriminate furunculosis from severe diffuse otitis externa. The affected ear is extremely painful, feels blocked and exudes a scanty serosanguinous discharge. The pinna and tragus are tender on palpation. Otoscopic examination may be difficult if the external auditory canal is severely oedematous but usually establishes the diagnosis. Characteristically, the oedema and inflammation are restricted to the lateral segment of the canal, with relative sparing of the medial canal and an unaffected tympanic membrane. If the infection is advanced, the abscess may be seen to be pointing into the canal or have discharged already. If the oedema and secondary cellulitis spread to the post-auricular crease, the condition may be mistaken for acute mastoiditis as the pinna is protruded and swollen. Even very gentle movement of the pinna by the examiner causes pain and tenderness in furunculosis but it is typically painless in mastoiditis. Differentiation can be difficult and there are no good studies to examine the sensitivity and specificity of these clinical findings.[2]

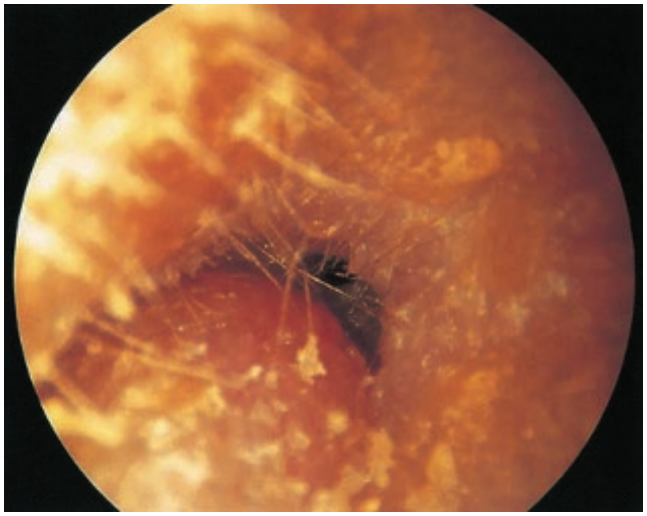

Figure 74.1 Furuncle of the right external auditory canal. Localized rather than generalized oedema of otitis externa. Reproduced with permission from Wormald and Browning, *Otoscopy: a structured approach.* London: Hodder Arnold; 1996.[3]

Samples for bacteriological culture may guide therapy but do not contribute to the diagnosis of the disease.

AETIOLOGY AND EPIDEMIOLOGY

Staphylococcus aureus (*S. aureus*) is the most common organism causing furunculosis. Uncontrolled case series suggest that pathogenic strains of *S. aureus* responsible for furunculosis (at all body sites; not restricted to otological furunculosis) are of different phage types from *S. aureus* causing other skin infections such as impetigo and scalded skin syndrome.[4] The *S. aureus* frequently express genes for Panton–Valentine leucocidin (PVL).[5] *In vitro* evidence demonstrates that leucocidal toxins commonly isolated from pathogenic strains of *S. aureus* trigger lysis of phagocytic cells and may have an important role in cutaneous infection.[6] Sporadic cases of furunculosis happen when pathogenic organisms are introduced into the canal in the context of other local risk factors (e.g. heat, humidity, trauma, maceration).

Recurrent furunculosis presents as repeated episodes of infection at multiple sites. Colonization of the external nares and, less commonly, the perineum with the pathogenic strain of *S. aureus* is also a contributing factor in many cases of generalized recurrent furunculosis.[7, 8] Several conditions appear to be associated with recurrent furunculosis including hypogammaglobulinaemia, diabetes mellitus and dysphagocytosis.

OUTCOMES

If untreated, the infection usually progresses to a localized abscess, which then discharges into the external ear canal. Providing there is adequate drainage, the infection will resolve spontaneously. The infection can also spread towards the deeper tissues, where it may cause a diffuse soft-tissue infection spreading to the pinna, post-auricular skin and parotid gland.

Repeated infection can cause permanent scarring and fibrosis of the external canal with subsequent meatal stenosis. Ultimately, this may also predispose to chronic diffuse otitis externa.

MANAGEMENT OPTIONS

Furunculosis of the external canal is exquisitely painful and appropriate analgesics should be offered to all patients. No evidence exists that compares the efficacy of different analgesics. A recent systematic review of treatment for otitis externa specifically excluded furunculosis from consideration.[9]

Treatment choices include:

- oral or systemic antistaphylococcal antibiotics (penicillinase-resistant penicillin, macrolide, cephalosporin, clindamycin or quinolone)
- topical treatment (antibiotics, astringents, hygroscopic dehydrating agents)
- incision and drainage.

No evidence can be presented on the resolution rate for any individual treatment strategy or to compare the efficacy of different treatment strategies. Oral antibiotic treatment is recommended in the early stages of the disease. Severe spreading soft-tissue infection should be treated with intravenous antibiotic therapy. Abscess formation is an indication for formal drainage. After the abscess has discharged, surgically or spontaneously, topical treatment is preferable. Topical antibiotics active against staphylococcus are usually prescribed. Insertion of a wick into the ear canal facilitates treatment in the presence of severe canal oedema and narrowing. Alternative topical agents are available. Glycerol and ichthammol solution has a specific antistaphylococcal action[10, 11] and is hygroscopic, thus causing dehydration of the canal tissue. Aluminium acetate solution is an astringent as well as a hygroscopic agent.

For patients suffering generalized recurrent furunculosis who are carriers of pathogenic strains of *S. aureus*, each episode of furunculosis is treated on clinical merit but additional therapy should be considered. Options include:

- eradication therapy with nasal mupirocin
- eradication therapy with oral flucloxacillin or azithromycin for 14 days
- bacterial interference therapy: deliberately implanting a non-pathogenic strain of *S. aureus* (strain 502A is the most popular) to recolonize the nares and skin.

All treatments appear to show more rapid and effective resolution of colonization and subsequent infections compared with controls although there is a high spontaneous resolution rate of 75% over 2 years for untreated patients.[12, 13] It has been reported that correction of specific biochemical abnormalities (e.g. hypoferraemia, low serum zinc) may lead to a marked reduction in the frequency of infections.

BEST CLINICAL PRACTICE

- ✓ Furunculosis may be difficult to distinguish from simple but severe otitis externa.
- ✓ Optimum treatment combines specific antistaphylococcus antibiotics, either systemic, topical or in combination, along with topical treatment to reduce the oedema and swelling of the external auditory meatus.
- ✓ Strong analgesia is indicated.
- ✓ Incision and drainage is indicated when an abscess has formed.
- ✓ Eradication of nasal carriage of *S. aureus* should be considered in patients with recurrent furunculosis.

FUTURE RESEARCH

Comparative studies are needed of topical antibiotic/steroid drops (e.g. gentamicin with hydrocortisone) versus glycerol/ichthammol and/or aluminium acetate solution.

KEY POINTS

- Furunculosis is localized otitis externa.
- It is caused by staphylococcal infection of a single hair follicle.
- Oral antibiotics are the treatment of choice before abscess formation.
- Formal incision and drainage are recommended if an abscess forms.
- Severe associated soft-tissue infection or cellulitis is an indication for systemic antibiotic therapy.

CHAPTER 75

MYRINGITIS

Samuel A.C. MacKeith

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: granular myringitis, chronic myringitis, myringitis granulosa, acute myringitis, bullous myringitis and myringitis bullosa haemorrhagica.

INTRODUCTION

Myringitis is, simply, inflammation of the tympanic membrane. It commonly occurs as part of either acute bullous myringitis or granular myringitis (which is usually described as a chronic disorder). These two terms represent two distinct clinical entities and are therefore considered separately in this chapter.

ACUTE BULLOUS MYRINGITIS

DEFINITION

Bullous myringitis (BM) is an acute inflammatory condition affecting the tympanic membrane (TM) characterized by the presence of bullae or vesicles on the surface of the TM. The bullae may be single or multiple, may affect a segment or the whole of the TM and may even spread on to the adjacent ear canal.[1–4]

PATHOLOGY

The bullae are believed to develop between the middle fibrous and outer squamous layer of the TM due to extravasation of serous fluid or blood, although this has never been confirmed histologically.[4, 5]

AETIOLOGY

The exact aetiology remains unclear. The long-held belief that BM was pathognomonic for mycoplasma pneumonia has been largely dispelled.[3, 6] Most of the evidence suggests the underlying pathogens to be similar to those seen in acute otitis media (AOM), namely bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, beta-haemolytic streptococci, *Moraxella catarralis* and respiratory viruses such as rhinovirus, enterovirus, respiratory syncytial virus, influenza A and parainfluenza virus.[2–5] Interestingly, *Streptococcus neumoniae* is consistently noted as the predominant bacterial pathogen

in BM. In most large case series published, BM is diagnosed with concurrent AOM in almost all (97%) cases.[1] This, in conjunction with the comparable aetiological pathogens, supports the theory that BM may simply represent a severe variant of AOM.[3] In contradiction with this theory is the fact that BM is known to occur (albeit less commonly) in isolation or with external ear canal disease where the pathogenesis may be different. What seems apparent is that the aetiology of BM (as with AOM) is a complex interaction of viral and bacterial pathogens in a susceptible host producing a severe acute inflammatory reaction affecting the TM.

EPIDEMIOLOGY

Although the true incidence is unknown, BM has been reported as occurring in 5.7% of children under 2 years of age in a 1-year follow-up period and in the same cohort to occur in 1 in every 20 episodes of AOM.[1] It is more common during the winter and, though it may occur at any age, it is most prevalent in the age group 2–8 years. This differs from AOM, which is more common in children under 2 years of age.[7, 8]

PRESENTATION

Diagnosis of this condition is clinical. Typically, patients present with sudden-onset severe otalgia, usually unilateral and often in association with an upper respiratory tract infection.[1, 2, 4] In most patients the pain is thought to last only 1–2 days[9] although discomfort may persist for longer, even after rupture of the bulla. A cohort of 2028 children under 2 years of age compared the symptoms of 86 diagnoses of BM (of which 97% had concomitant AOM) with the symptoms of AOM alone. They found symptoms to be more severe in BM, with higher rates of earache (58% vs 29%), fever (62% vs 41%) and excessive crying (80% vs 65%), again suggesting BM to be a severe variant of AOM.

Otoscopy reveals bullae on the TM (**Figures 75.1** and **75.2**). Rupture of the bulla may be associated with scanty serosanguinous otorrhoea, which is usually short-lived due to the absence of a TM perforation. In view of the high incidence of associated middle-ear effusion, conductive hearing loss is very common. However, mixed or sensorineural hearing loss is also well documented.

Sensorineural hearing loss

The prevalence of a sensorineural component to the hearing loss has been reported to occur in 15–66% of cases.[7, 8, 11–14] According to these series, complete recovery of hearing is seen in 57–100% of cases, regardless of treatment. Comparison of these studies is difficult due to significant heterogeneity regarding audiological criteria, follow-up and treatment. A further criticism is that none had pre-existing audiological data, meaning that sensorineural hearing loss (SNHL) which did not improve may in fact be long-standing. In addition, all these reports are in adults. We therefore do not know the patterns of hearing loss in the paediatric population in which this disease is predominant.

The pathogenesis of SNHL in BM is unknown but stapedial reflexes and auditory brainstem responses have implicated the cochlea as the site of the lesion.[8, 15]

Figure 75.1 A large single bulla arising from the posterior aspect of the left tympanic membrane.

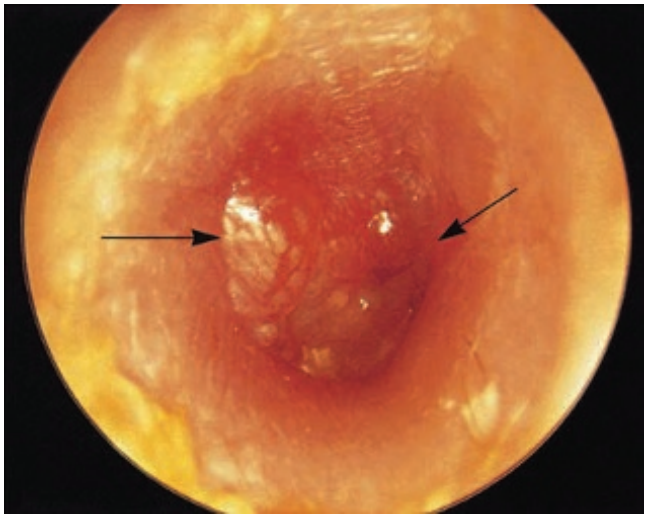

Figure 75.2 Multiple bullae on a tympanic membrane. Reproduced with permission from Wormald and Browning. *Otoscopy: a structured approach.* London: Hodder Arnold; 1996.[10]

Vertigo

Other than in the earliest reports, the presence of vertigo as part of BM has received little attention. However, in 2004 a prospective study showed 7 of 13 patients with BM (54%) reported vertigo at presentation.[13] Of the 13, 11 had abnormal electronystagmography, including 4 who did not complain of vertigo. In this cohort, a sensorineural component of hearing loss was seen in 82%. Again, the aetiology is unknown.

TREATMENT

There is no consensus, nor good evidence, to inform best practice in BM. In the majority of cases it is a self-limiting disease with spontaneous resolution of symptoms. The large case series in paediatric populations, demonstrating comparable aetiology with AOM and suggesting a possible common disease process, has supported the practice of management as for AOM.[2, 3, 9] Symptomatic treatments described include analgesia, warm compresses and incision of bullae. The third of these is of unproven benefit and may have a risk of secondary infection. The use of topical local anaesthetics has also been described.[16]

The frequent finding of inner ear involvement identified in adult case series is associated with more aggressive medical treatment, usually with broad-spectrum oral antibiotics.[4] In addition, the management of sudden-onset SNHL in association with BM has been treated by some authors with high-dose oral steroids as they would for isolated sudden-onset SNHL. Eliashar et al. treated all BM patients with an SNHL component with admission, oral steroids and carbogen, with complete recovery of hearing in 86%.[13] Drendel et al. reported 13 cases of BM with a SNHL component to their hearing loss, nine received steroids, of which five made a complete recovery and four only a partial recovery.[14] The four patients with a SNHL component who did not receive steroids all made a complete recovery.

Only one study has compared systemic antibiotics alone versus systemic antibiotics and steroids.[17] This did not demonstrate improved hearing outcomes with the addition of steroids. However, given the small sample size (23 patients), this may be subject to type 2 error. Therefore, currently there is insufficient evidence to determine the effectiveness of steroids as a treatment of SNHL in BM.

GRANULAR MYRINGITIS

DEFINITION

Granular myringitis (GM) can be defined as a chronic inflammatory disorder characterized by de-epithelialization of the outer (squamous) layer of the tympanic membrane (TM) and replacement with granulation tissue, all in the absence of middle ear disease.[18, 19]

PATHOLOGY

Histology has demonstrated oedematous granulation tissue with capillaries and diffuse infiltration of chronic inflammatory cells.[20]

AETIOLOGY

Aetiology is unknown but it has been suggested that non-specific injury to the lamina propria, such as trauma or infection, may impair epithelialization and promote granulation tissue formation.[20] This theory may be supported by the high incidence of myringitis following myringoplasty (5.5%) and the fact that in some series of GM nearly all patients had had prior otological surgery (93%).[18, 21]

The common finding of positive cultures from affected ears (*Pseudomonas aeruginosa*, *Staphylococcus aureus* (including MRSA), *Corynebacterium*, *Proteus mirabilis*, fungal species), in addition to the success of antimicrobial treatment, implicates the contribution of infection to the aetiology.[20, 22, 23]

PRESENTATION

Clinically this condition may be defined as persistent inflammation confined to the squamous layer of the TM for at least 12 weeks.[21]

Most patients present with persistent or recurrent painless otorrhoea, which may be malodorous.[18] In one study 70% of these patients had had symptoms for more than 1 year.[22] Other symptoms include intrameatal itch or fullness, mild conductive hearing loss and rarely otalgia. Some patients may be asymptomatic.

Following microsuction of otorrhoea, examination reveals granulation tissue/polyp replacing normal squamous epithelium on a sometimes thickened TM. Granulation can be localized to part of the TM (focal/segmental) or diffuse (**Figures 75.3** and **75.4**).[18, 19] The segmental type is more common, with the posterosuperior segment of the eardrum most frequently affected.[24] It may also involve the skin of the adjacent medial ear canal.

It is important to differentiate GM from other causes of chronic otorrhoea. Furthermore, most definitions of GM exclude patients with perforation or cholesteatoma.

Figure 75.3 Focal areas of granular inflammation affecting the anteroinferior and posteroinferior aspects of the left tympanic membrane with active inflammation and pus.

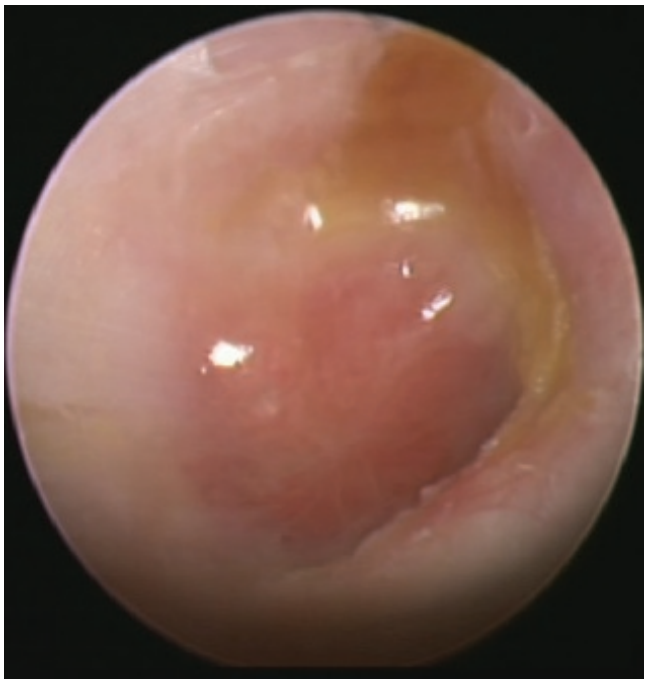

Figure 75.4 Diffuse granular myringitis affecting the entire right tympanic membrane.

INVESTIGATIONS

A swab should be taken for microscopy, culture and sensitivities to guide any antimicrobial treatment. Pure-tone audiometry and tympanometry may help to identify associated hearing loss or middle ear pathology. Occasionally, CT temporal bone may help exclude underlying middle ear/mastoid disease. Some published series include normal type A tympanogram and a normal CT as essential diagnostic criteria in GM.

Biopsy to exclude malignancy should be considered if there are concerning features such as significant otalgia or non-resolution despite treatment.

COMPLICATIONS

The natural history of this condition is difficult to determine as patients may be asymptomatic despite continued myringitis. However, we know that many patients have symptoms persisting for years.[18] This long-standing chronic inflammation of the TM and medial ear canal wall skin, in association with proliferating granulation tissue, can lead to fibrosis, scarring and stenosis of the medial ear canal with lateralization of the eardrum.[25] Although these sequelae may resolve any otorrhoea, there is likely to be a significant resultant conductive hearing loss.

MANAGEMENT

Most would agree that meticulous microscopic cleaning/debridement in combination with topical antibiotic or antiseptic agents forms the mainstay of initial management. Treatment is often more prolonged than for other types of otitis and recurrence is relatively common. A plethora of published treatment strategies exist. These can broadly be grouped into:

- topical antibiotic and antifungals, often with a steroid/anti-inflammatory agent
- topical antiseptic agents: acetic acid, aluminium acetate, phenol, hydrogen peroxide
- debulking of granulations with cold steel (curettage/cupped forceps), silver nitrate cautery or laser debridement/resurfacing
- surgical excision with grafting (onlay skin graft, temporalis fascia/perichondrium underlay technique).

A systematic review published in 2008 found 46 potentially relevant studies of which only two met the inclusion criteria.[19] The two non-randomized studies included in the review are summarized in Table 75.1.

This review concluded that, although there is insufficient evidence to support any particular management strategy, 'conventional topical antibiotic and steroid drops appear less efficacious that other treatment modalities'. In addition, dilute vinegar solution is an effective simple alternative to topical antibiotic drops.[23, 24]

Subsequent to this review, further published case series have shown good results with antiseptic topical preparations, CO_2 laser resurfacing as well as more aggressive surgical excision with overlay myringoplasty.[22, 26, 27] In addition, there has been a double-blind randomized controlled trial which compared topical 5-fluorouracil to placebo (petroleum jelly).[28] Unfortunately, as this is not a commonly used preparation and has not been compared

TABLE 75.1 Summary of the two studies included in the 2008 review of management options

Study	Design/Level of evidence	Sample size	Intervention group	Control group	Follow-up	Outcome
Jung et al. (2002)[23]	2b	30	Topical vinegar (acetic acid pH 2.43)	Topical ofloxacin	>6 months	Faster symptom resolution and reduced recurrence with topical vinegar
El-Seifi and Fouad (2000)[24]	2c	74	Surgical excision of granulation tissue with tragal cartilage underlay graft	Topical acetic acid with antibiotic/steroid drops	>6 months (average 6.25 years)	Reduced recurrence with surgery compared with topical treatment

with other more commonly used treatment modalities, it is of limited clinical utility.

In summary, there is a wide range of potential treatment modalities which have been found to be effective, but unfortunately all have reported problems with recalcitrant or recurrent cases. More recently, published studies are demonstrating the benefits of antiseptic agents in preference to antibiotic drops. Many clinicians may use more than one strategy, reserving more aggressive surgical management for recalcitrant cases as there may be a higher rate of subsequent perforation with these techniques.

FUTURE RESEARCH

- ➤ Further research is required to identify optimal treatment of BM especially when complicated by SNHL.
- ➤ Given the association of GM following otological surgery, research to identify operative risk factors for development may help reduce the incidence.
- ➤ Quality randomized controlled trials are required to compare the topical treatments most commonly used in GM.

KEY POINTS

- Bullous myringitis represents an acute severe inflammatory reaction affecting the TM.
- Aetiological pathogens in BM are similar to those in AOM.
- Inner ear involvement with SNHL (and vertigo) is not uncommon in BM and usually resolves spontaneously.
- As BM is usually a self-limiting disease, the mainstay of treatment is symptomatic. The optimal management of associated hearing loss, however, remains to be elucidated.
- Granular myringitis is a chronic condition usually presenting with otorrhoea.
- In GM, de-epithelialization of the outer layer of the TM and replacement with granulation tissue occurs in the absence of middle ear disease.
- Treatment of GM usually involves topical antimicrobial or antiseptics often for prolonged periods.
- More aggressive physical debulking or surgical excision and grafting is usually reserved for recalcitrant cases of GM.

CHAPTER 76

KERATOSIS OBTURANS, PRIMARY AUDITORY CANAL CHOLESTEATOMA AND BENIGN NECROTIZING OTITIS EXTERNA

Tristram H.J. Lesser

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: keratitis obturans, wax keratosis, external auditory canal cholesteatoma, external auditory meatus cholesteatoma, external ear cholesteatoma, osteomyelitis of the ear, benign otitis externa, benign necrotizing otitis externa, osteonecrosis and ear canal necrosis, tympanic bone and epithelial migration of the ear. This was supplemented by obtaining all the references quoted in the papers. Sixty-six papers were considered after removing non-relevant papers and repeats. The only evidence found was in observational studies and from expert opinions.

DEFINITIONS

Keratosis obturans (KO) is a different clinical and pathological entity from primary auditory canal cholesteatoma (ACC) and benign necrotizing otitis externa (BNOE) (Table 76.1). There is a less clear distinction between ACC and BNOE. While ACC and BNOE are different diseases, they may have similar aetiologies and are not separated from each other by an identified abnormality. Whereas KO, is separated by having a specific deficit of the epithelial migration.[1,2]

The 1980s saw the definition of the difference between KO and ACC, and articles before then on KO contained some cases that were probably primary ACC and vice versa. More recent articles on necrotizing otitis externa (NOE) and ACC still contain cases that could be NOE or ACC in the same series and this may represent a clinical and pathological overlap.

Keratosis obturans is the accumulation of a large plug of desquamated keratin in the external auditory meatus.

Primary auditory canal cholesteatoma is the invasion of squamous epithelium into a localized area of bony erosion with or without bony necrosis.

Benign necrotizing otitis externa is the formation of an avascular bony sequestrum of the inferior tympanic bone with secondary inflammation of the overlying soft tissue and skin.

PATHOLOGY

In KO, a geometrically patterned keratin plug within the lumen of an expanded external auditory canal is seen (Figure 76.1). The keratin squames are shed from the complete circumference of the deep ear canal forming a lamina (onion skin) arrangement.

In primary ACC, the keratin is derived primarily from a sac that involves the bone of the ear canal with bony fragments within it and random keratin in the lumen of the ear canal. Keratin is found deep to the bone fragments.[3]

In BNOE the necrotic sequestrum of bone appears to involve the superficial cortical layer primarily.[4] Histology of the bone reveals dead lamellar bone with inflammatory

TABLE 76.1 Differential diagnosis of non-neoplastic conditions eroding the bony external auditory canal, with their clinical characteristics

	Keratosis obturans	Auditory canal cholesteatoma	Benign necrotizing otitis externa	'Malignant' necrotizing otitis externa
Aetiology	Abnormal epithelial migration	Abnormal bone leading to epithelial migration into bone	Avascular bone leading to inflammation of overlying skin	Immunocompromised Patient with necrotic bone in ear canal
Symptoms and findings	Severe otalgia Conductive hearing loss Lung or sinus disease Younger Occasionally bilateral	Otalgia mild No hearing loss Itchiness Older Usually unilateral Blocked feeling	Chronic painless infected otorrhoea Partial response to previous treatment Localized exposed bone in canal 3–10 mm diameter Dehiscent skin	Severe penetrating pain Cranial nerve palsy Diabetic/renal failure or otherwise immunosuppressed Raised inflammatory markers
Pathology	Keratin plug Tympanic membrane thickened Widened deep canal Hyperaemia of skin canal with granulations	Keratin in random pattern Tympanic membrane normal Localized osteitis/erosion of ear canal usually posterioinferior Sequestration of bone	Chronic inflammation with no associated keratin and no cholesteatoma deep to sequestrum Commensals on bacteriology	Chronic inflamation *Pseudomonas aeruginosa*
Treatment	Remove plug Treat granulations Occasionally biopsy	Surgically remove cholesteatoma graft with cartilage and fascia Biopsy	Conservative initially Surgical removal of sequestrum	Treat cause of immunosuppression High-dose antibiotics Long-term antibiotics Surgical debridement
Differential diagnosis	Wax impaction with infection Otitis externa Neoplasm	Necrotizing otitis externa Neoplasm	Auditory canal cholesteatoma Neoplasm Malignant otitis externa	Malignant neoplasm

Note: Modified from Shire JR, Donegan JO. Cholesteatoma of the external auditory canal and keratosis obturans. *Am J Otol* 1986; **7**: 361–4, by kind permission of Lippincott, Williams & Wilkins.[2]

Note the deficient area of skin, and bony sequestrum. **(c)** Canal cholesteatoma. A sac of canal skin invades bone. **(d)** Keratosis obturans. The bony canal is 'ballooned' out.

cells filling the marrow spaces.[5] There are limited chronic inflammatory changes of the adjacent skin and subcutaneous tissue.

BACTERIOLOGY

In all three conditions skin flora and a wide range of bacteria may be cultured: *Proteus mirabilis*, *Staphylococcus epidermidis*, *Klebsiella pneumoniae* and betahaemolytic streptococci are found, but generally no *Pseudomonas* species. *Staphylococcus aureus* is the most frequent isolate.

AETIOLOGY

It is thought that KO is due to abnormal epithelial migration of the ear canal skin.[6] One case report found that the epithelium moved in an anterior direction across the whole drum. Another case that was not typical of KO but had a need for repeated aural cleaning had a grossly abnormal migratory pathway. The movement of the surface epithelium of the pars flaccida was reversed such that it migrated downwards to the pars tensa and then moved inferiorly across the whole drum.[7]

A condition called 'keratosis tympanicum' has been described with similar abnormal epithelial migration

associated with unilateral tinnitus.[8] It is not certain that these two diseases are related or that all cases presenting with KO are the same disease.

It has been suggested that there may be two types of KO. One is of an inflammatory nature which occurs secondary to an acute problem, such as a viral infection, causing inflammation of the ear canal which temporarily alters the epithelial migration. This is cured by removal. The second or the silent type is a disease that persists and is caused by abnormal separation of the keratin that continues even after the first removal and will need subsequent removals.[6]

The aetiology of external ACC is uncertain, but in some of the series primary ACC is post-traumatic or post-surgical (e.g. stapedectomy cases). It has been postulated that a piece of exposed bone of the primary auditory canal becomes infected and sequests, the epithelium migrates into this bony abnormality and the cholesteatoma is formed. Primary ACC is distinguished from cholesteatoma that arises secondary to a previous ear canal insult. Many authorities believe that idiopathic external ACC results from a reduced migratory capacity of the canal epithelium, which leads to 'keratinization *in situ*'.[9–15] This view has been challenged, however, by a study which showed no difference in the rate of epithelial migration between normal ears and those affected by external ACC.[16]

In some cases the occurrence of external ACC has been linked to branchial arch anomalies, which result in the retention of epithelial masses and lead to cholesteatoma formation in the floor of the external auditory canal.[17]

The cause of the necrotic bone in BNOE is unknown.[18] Theories relating to vascular insufficiency began with Goufas in 1954.[19] It is often stated that the tympanic bone is particularly susceptible to osteonecrosis because of its 'relatively poor blood supply'. The microangiopathy of diabetes has been advanced but there is only a little evidence that BNOE is more common in diabetics, as opposed to the 'malignant' form. Small arterial emboli have been suggested. Repeated local trauma, for example ear bud abuse, picking of the ear or the use of hearing aids, is a popular theory.[20] Bharadwaj et al. suggested association with respiratory tract inflammatory conditions is difficult to support. Bottari proposed 'neurotrophic disturbances'.[18, 21]

The overlap between ACC and BNOE if it exists is uncertain and has yet to be defined fully.[22]

The aetiology of BNOE may have some similarity with 'malignant' NOE.[23] As the tympanic plate appears to have a relatively poor blood supply, the additional microangiopathy in diabetes, as mentioned above, may predispose it to avascular necrosis and the formation of bony sequestra. The high sugar content of the bone may encourage *Pseudomonas* to grow. A similar pathogenesis is found in radionecrosis of the tympanic bone with a slowly progressive obliterative endarteritis.[24] Although diabetics may have a slightly higher incidence of BNOE as well as 'malignant' NOE, the pathogenesis of the avascular necrosis of the tympanic bone is not clear.[25]

CLINICAL SYMPTOMS

The clinical symptoms are different in KO and ACC/BNOE.

KO occurs more commonly in younger patients. It classically presents with acute severe otalgia and a conductive hearing impairment. Infrequently, the disease is bilateral. There may be an associated bronchiectasis or sinusitis.[26, 27] Many of the patients in the historical papers had a condition called 'wax keratosis', which is thought to be becoming less common as the associated lung disease and sinusitis are now better controlled. These are historical papers that may not agree with the current clinical presentation of KO.

ACC and BNOE have a similar set of clinical findings. The most common presentation is chronic otorrhoea with dull pain or itching. It is not associated with hearing impairment. Bilateral cases account for around 1 in 6–12 cases.[28, 29] A review of published case series concluded that the most common presenting symptoms of idiopathic external ACC are unilateral otorrhoea with mild to moderate otalgia.[12] A minority of patients complained of unilateral hearing loss, or were asymptomatic with the cholesteatoma being discovered on routine otoscopy performed for a separate indication.

INVESTIGATION

The primary investigation of these patients is microscopic examination of the ear either in the clinic or under general anaesthetic. In KO, the ear canal can become grossly widened or ballooned such that the tympanic membrane is left standing out in relief in a widened ear canal (**Figure 76.2**). In ACC the cholesteatoma is able to be suctioned (**Figure 76.3**) and has fragments of bone within it, and there may be some granulation tissue which needs biopsy. In BNOE the covering on the floor of the ear canal is deficient with granulations around the edges of the epithelial defect, yellow necrotic bone in the bare area with small necrotic fragments (**Figure 76.4**).[30]

Computed tomography of the temporal bones has become accepted as the gold standard for staging and preoperative planning in external auditory canal destructive disease.[32] This method allows accurate evaluation of the extent of local bone erosion and involvement of adjacent structures. Should surgery be contemplated for BNOE, a CT scan may be indicated in order to identify the extent of bone necrosis.

If gross infection is present, a pus swab may be taken. If *Pseudomonas* is cultured, the diagnosis should be queried in favour of 'malignant' NOE. If prominent inflammatory or granulation tissue coexists, chronic 'granulomatous' conditions including syphilis and tuberculosis should be excluded.

Audiometry should be normal or show a mild conductive hearing impairment in ACC and BNOE but will show a marked conductive hearing loss in KO.

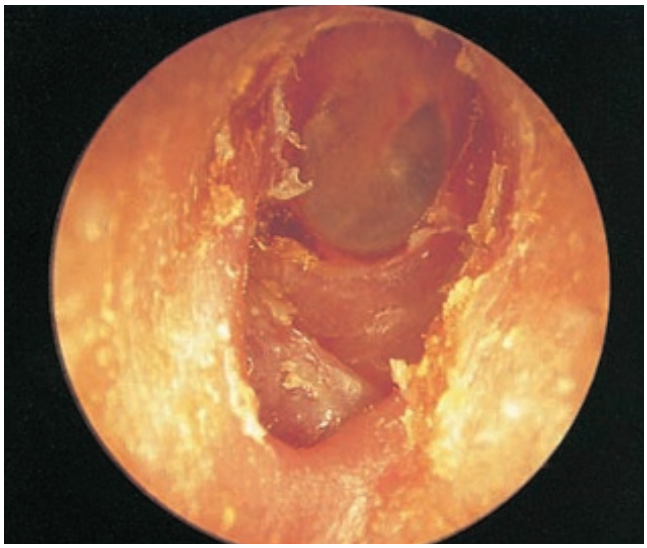

Figure 76.2 Keratisis obturans. The keratoma has been removed from the right ear with KO and shows expansion of the bony canal just lateral to the tympanic membrane. Reprinted with permission from Wormald and Browning. *Otoscopy: a structured approach.* London: Hodder Arnold; 1996.[31]

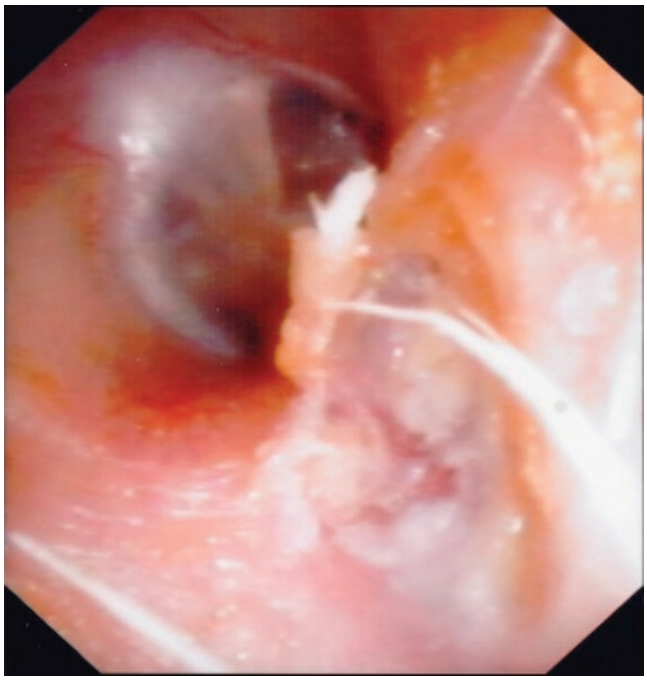

Figure 76.3 Cholesteatoma of the auditory canal after suction.

Figure 76.4 Typical appearance of benign necrotizing otitis externa. An area of denuded necrotic bone is visible in the floor of the bony external auditory canal.

BIOPSY

Histological examination of any granulation tissue is required to exclude malignancy, as the differential diagnosis will include carcinoma of the ear canal, 'malignant' NOE and benign neoplasm that has secondary infection in the external auditory canal.

EPIDEMIOLOGY

The frequency of primary ACC has been estimated as one in 1000 new otological cases and for every case of primary ACC there are four or five cases of KO.[33] BNOE is probably the most common of the three diseases.

NATURAL HISTORY AND COMPLICATIONS

Little is known of the natural history of these diseases. Sporadic reports demonstrate that normal ear canals can suddenly develop these conditions; for instance, KO can occur in either previously normal ears or in ears that have had plugs of keratin needing removal beforehand. KO can cause extensive bony erosion, including automastoidectomy.[7] There are no reports of intracranial complications from this disease. In ACC erosion through the anterior wall of the canal may affect the temporomandibular joint and rarely, in advanced cases, extension into the posterior fossa has been reported with resulting intracranial abscess.[34]

EXTERNAL AUDITORY CANAL CHOLESTEATOMA STAGING

There are two staging systems for ACC but none for the other two diseases.

Nairn et al. external ACC staging is based on the proposal that there is a preclinical disease. Stages I and II will not usually present as the disease of ACC.[15]

Nairn et al. staging:[15]

I	Epithelial hyperplasia
IIa/b	Periostitis hyperplasia with erythema (a), or denuded but not eroded bone (b)
III	Canal wall erosion and bony sequestrum
IV	Invasion into adjacent structures

Subclasses of disease stage IV include: mastoid (M), skull base and sigmoid sinus (S). temporomandibular joint (J), and facial nerve canal (F).

Seung-Ho Shin et al. clinical and radiological staging:[32]

I	Limited to the external auditory canal
II	Invades the tympanic membrane as well as ear canal
III	Creates a defect of the EAC and involves the cortex of mastoid bone
VI	Involves areas beyond the temporal bone (**Figure 76.5**)

This classification also includes treatment suggestions, as follows:

I	with local care or canaloplasty
II	with canaloplasty + tympanoplasty
III	with the above and mastoidectomy and canal wall reconstruction
IV	with removal of cholesteatoma using various techniques.

MANAGEMENT OPTIONS

The pain and deafness associated with KO mean that it is necessary to remove it, often under general anaesthetic. Canaloplasty has been suggested for recurrent KO with good results.[29] For ACC, conservative treatment is used where the extent of the cholesteatoma erosion can be seen (**Figure 76.6**). When this is not possible, patients are treated with excision of necrotic bone and cholesteatoma via the mastoid and repair of the defect using temporalis fascia.[35] The only other treatment suggested is a canal wall-up procedure with repair of the defect, but no long-term follow-up is available of such patients.

In BNOE conservative management consists of removing the bony sequestrum once it separates spontaneously,

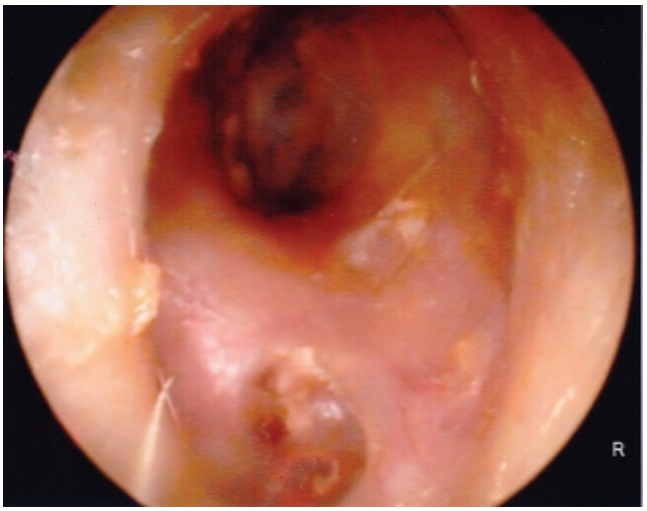

Figure 76.6 Healing cholesteatoma of the ear canal after conservative treatment.

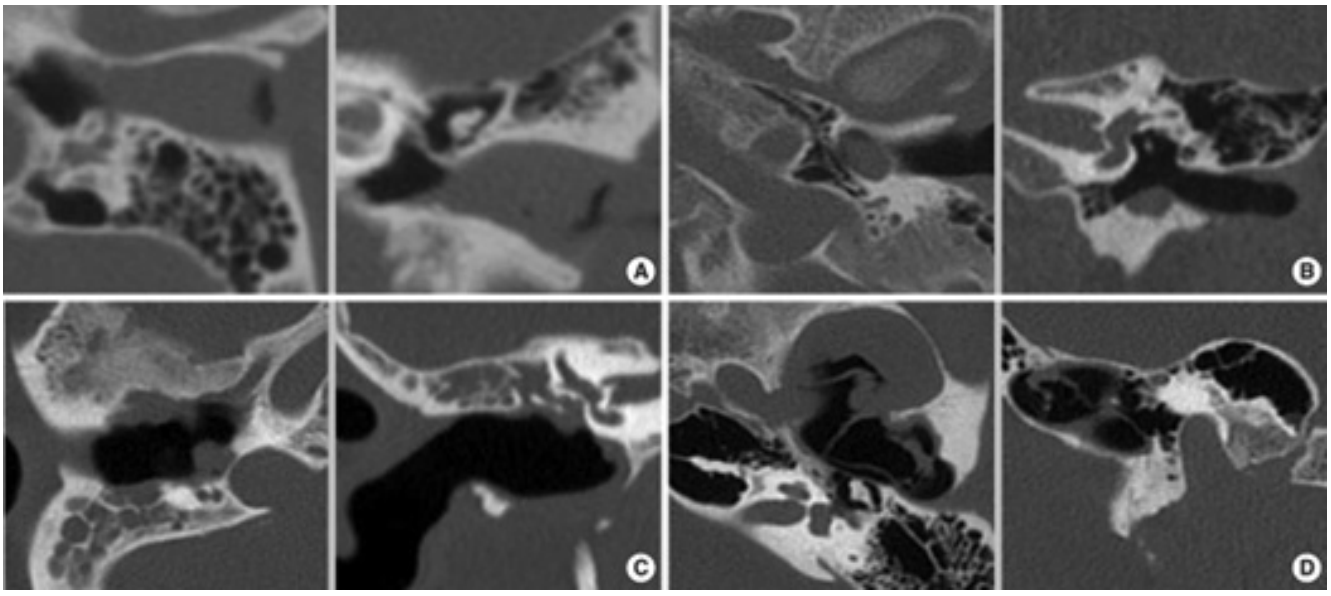

Figure 76.5 Radiology of the stages of ACC: A = I; B = II; C = III; D = VI. Reproduced from Shin et al. Classification of external auditory canal cholesteatoma by computed tomography. *Clin Otorhinolaryngol* 2010: **3**: 24–6.[32]

with local toilet and local treatment to control any infection. An oral antibiotic may be used.[22] Speculation based on a series of eight patients is that younger patients (less than 60 years) are more likely to respond to conservative management. Separation of the sequestrum, followed by epithelial growth to cover the bony defect, as encouraged by conservative management, is the most likely outcome.[21]

A more aggressive surgical approach has been advocated, with early surgical removal of the sequestrum down to healthy bone.[5, 25] Adjunctive hyperbaric oxygen may be considered when there is progression despite intensive local and systemic treatment and when there is necrosis beyond the tympanic plate.[4]

Treatments for these conditions are reported to be effective.

BEST CLINICAL PRACTICE

- ✓ Microscopic examination should be carried out in the clinic or under general anaesthetic.
- ✓ CT scan should be used for primary ACC.
- ✓ Biopsy should be undertaken to exclude carcinoma.
- ✓ Removal of the plug of keratin should be carried out in KO.
- ✓ Surgical removal and repair should be performed in primary ACC.
- ✓ Conservative treatment of BNOE is usually adequate providing 'malignant' otitis externa has been ruled out.
- ✓ Osteoradionecrosis, chronic inflammatory conditions and benign tumours should be excluded.
- ✓ These conditions may all resolve spontaneously or with local toilet and care.

FUTURE RESEARCH

- ➤ The true incidence of these diseases is not known.
- ➤ The clinical courses are not well defined.
- ➤ Further work needs to be undertaken to determine the aetiologies of these diseases and any relationship to abnormal epithelial migration and vascular insufficiency.
- ➤ The relationship between ACC and BNOE is uncertain.
- ➤ The relationship and possible shared aetiology between BNOE and malignant NOE is likewise uncertain.
- ➤ The rarity of the conditions makes level 1 or 2 evidence for treatment difficult to obtain.

KEY POINTS

- Primary ACC, KO and BNOE are different diseases.
- KO occurs in younger patients, presents with pain, may be associated with sinusitis or bronchitis, may be associated with disordered epithelial migration, either temporary or permanent, and is treated with removal of the keratin plug.
- Primary ACC is more common in the elderly, may be traumatic, presents with otorrhoea and itching and minimal hearing loss, and is treated with permeatal or mastoid surgery to remove the disease.
- BNOE is probably more common and has similar clinical presentation to ACC but may need less radical treatment.

CHAPTER 77

ACQUIRED ATRESIA OF THE EXTERNAL EAR

Jonathan P. Harcourt

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: external ear, external ear canal, acquired and atresia.

DEFINITION

Atresia is defined as the absence of or closure of a passage of the body. This covers both congenital and acquired lesions. Tos[1] defines acquired atresia of the external ear as 'intraluminal sequelae of either intraluminal or extraluminal processes of varying aetiology, resulting in a blind sac in the external acoustic meatus'.

Atresias may be solid or membranous.

- **Solid atresia** consists of a continuous block of fibrous or fibrous and bony material which is continuous with the structure of the tympanic membrane and is of variable extent. The face of the solid atresia may be blunt or tapering, producing a funnel-shaped medial aspect to the lumen of the ear canal (Figures 77.1 and 77.2).
- **Membranous atresia** is typified by fibrous tissue that has a covering of ear canal skin on both sides, thus separating the ear canal into a medial and lateral segment (Figure 77.3). The medial part inevitably collects keratin from desquamation of the skin; this may become an erosive process and thus be defined as an external canal cholesteatoma.

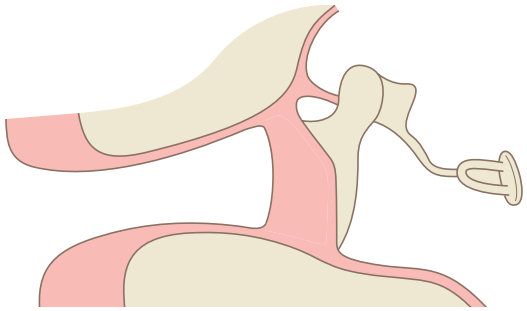

Figure 77.1 Solid atresia, obliterating the medial aspect of the bony external ear canal.

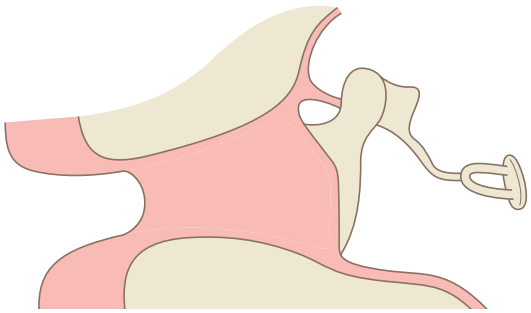

Figure 77.2 Extensive funnel-shaped solid atresia.

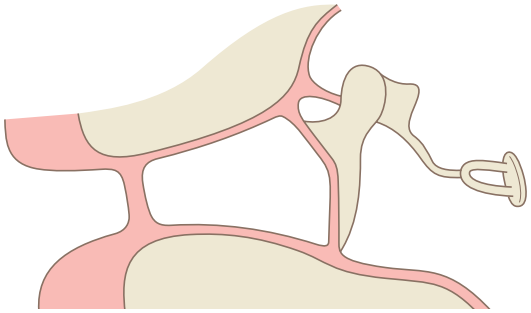

Figure 77.3 Membranous atresia in lateral external ear canal.

DIAGNOSIS

The clinical diagnosis of acquired atresia is supported by the use of CT scanning which gives a very detailed image of the bony and soft-tissue structure of the external ear. Figures 77.4 and 77.5 show examples of medial and mid-canal atresias. It particularly helps in the differentiation of solid and membranous atresia. This is an important distinction as there may be a substantial divergence of management between these two entities. Solid atresia is a safe form of ear disease, whose surgical treatment is very challenging. Membranous atresia will inevitably produce associated cholesteatoma and therefore erosion of local structure. Surgical outcome is superior to solid atresia.

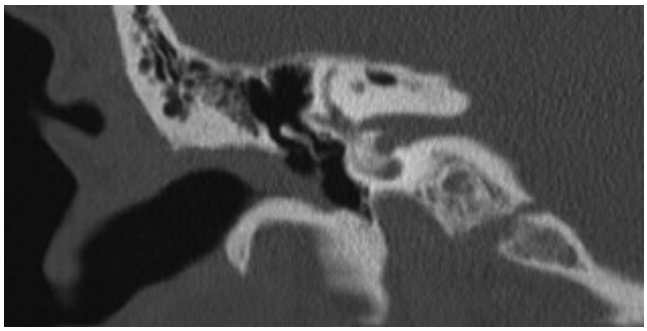

Figure 77.4 Coronal CT of right external ear canal showing medial atresia.

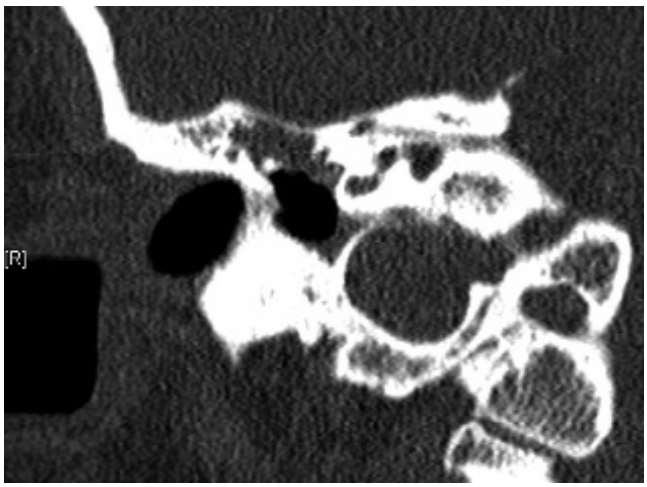

Figure 77.5 Coronal CT scan of right external ear canal showing lateral predominantly membranous atresia. The patient had undergone previous surgery for chronic otitis media.

AETIOLOGY

Acquired atresia may be caused by the following processes:[2]

- **Inflammation**, which may be as a result of :
  - otitis externa
  - psoriasis, eczema and other dermatological conditions
  - active chronic otitis media
- **Trauma**, by various mechanisms:
  - open injury, especially gunshot wounds
  - closed fracture of the tympanic plate, particularly associated with frontal facial injuries when the mandibular condyle is forced backwards through the anterior wall of the external ear canal
- **Burns**, which may be thermal, chemical, electrical or post-irradiation in nature
- **Surgery**. Any operation involving a meatal approach (tympanoplasty, etc.) has a remote risk of solid atresia but particularly with on-lay techniques. Meatal surgery (removal of an osteoma) may also precipitate membranous atresia in the lateral canal.

Pathogenesis

The pathogenesis of solid and membranous types differs.

SOLID ATRESIA

In cases associated with otitis externa or media the key development is of granular medial otitis externa with granulations of the tympanic membrane that persist for many months in spite of treatment. The granulations become fibrotic and the eardrum becomes thickened as the medial meatal mass is re-epithelialized. This process can be repeated again and again. If it is associated with active chronic otitis media, the granulations appear around the tympanic membrane perforations and eventually lead to closure of the defect before the process extends laterally as described above.

MEMBRANOUS ATRESIA

This originates in the lateral meatus as a web formation[2] which is precipitated by a circular irritation from inflammation, trauma or burns and ulceration of the skin around the entire circumference of the external ear canal. The web-like stenosis forms after fibrosis and re-epithelialization as with solid atresias. Repeated attacks or one massive injury such as a tympanic plate fracture leads to a complete atresia.

EPIDEMIOLOGY

Becker and Tos[3] estimated an annual incidence of 0.5 per 100 000 based on clinical presentation of cases over 26 years in a centralized otology practice in Denmark. The vast majority of cases were solid fibrous atresias and only a few were membranous, making the incidence of typical membranous atresias 20 times smaller than that of the solid form.

NATURAL HISTORY AND COMPLICATIONS

Once solid atresia has formed, though there may be further episodes of medial granulating otitis externa, fibrosis and re-epithelialization, overall there is a change from a 'wet' to a 'dry' phase. In the latter situation the principle

complaint is of conductive hearing loss and this is generally a stable situation. Membranous atresia is associated with medial cholesteatoma, which can potentially produce local erosion and complications. This is usually of a broad slow erosive nature, similar to keratosis obturans.

MANAGEMENT OPTIONS

Medical

During the wet phase, the medial granulations can be removed by aspiration and cauterization with silver nitrate or trichloroacetic acid and the ear packed with ribbon gauze or a wick. This local treatment may turn the ear dry and prevent further progression of the atresia.[4]

The conductive hearing loss (if bilateral) may be managed by an air-conduction hearing aid though the presence of a mould in the external ear canal can aggravate the process and lead to the ear becoming or persisting in an active state. A bone-anchored hearing aid is an alternative when a conventional air conduction device is not tolerated.

Surgical

FIBROUS ATRESIA

The principle of surgery for fibrous atresia is to remove the fibrous tissue by elevating it from the ear canal bone, the fibrous annulus and lamina propria of the tympanic membrane (Figure 77.6a). In most cases access is adequate via a speculum inserted into the external ear canal, though an endaural or retroauricular approach may be utilized. A circumferential incision is made lateral to the blunt face of the atretic plate and a plane of dissection developed between the bone of the ear canal and the canal skin, followed by the atretic plate and finally lateral to the fibrous annulus and lamina propria of the tympanic membrane (Figure 77.6b). The epithelial defect is repaired by a fine split-skin graft (SSG) which may be laid in single or multiple pieces (Figure 77.6c). A silastic disc or tube may be inserted to stabilize the epithelial surface and finally the ear canal is packed with ribbon gauze soaked in antiseptic. The ear canal requires regular suction toilet and may need repacking to prevent medial granulation and early recurrence of the atresia. This is also prevented by careful removal of all fibrous tissue with exposure of the entire circumference of the fibrous annulus. This allows stable long-term results.[3]

MEMBRANOUS ATRESIA

Similar to fibrous atresia, membranous atresia can be approached trans-canal using an ear speculum. This is satisfactory for a small atretic plate (Figure 77.7a) but, if the fibrous lesion is very thick, a retroauricular approach may be superior, allowing preservation of the lateral and medial epithelial coverings to aid repair of the ear canal skin. In the trans-canal approach the fibrous plate is excised via a circumferential incision just lateral to its margin. The whole lesion is excised with sacrifice of the minimum

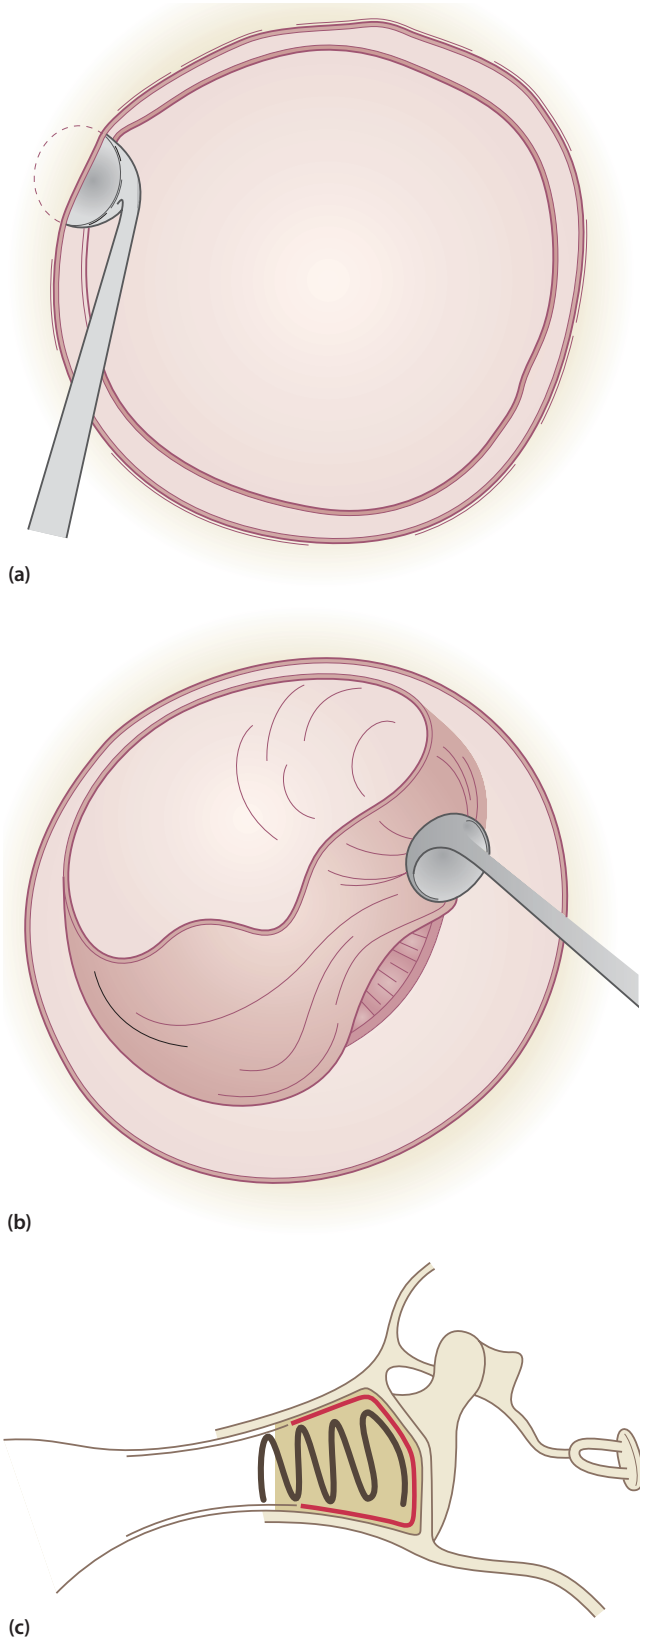

Figure 77.6 Surgery for solid atresia. **(a)** Circumferential canal incision lateral to fundus. **(b)** Dissection of the fibrous plate continues down to the lamina propria and the plate is excised. **(c)** Split-skin graft is applied to the bare medial bony canal wall and over the fibrous annulus and lamina propria and the canal is packed with ribbon gauze.

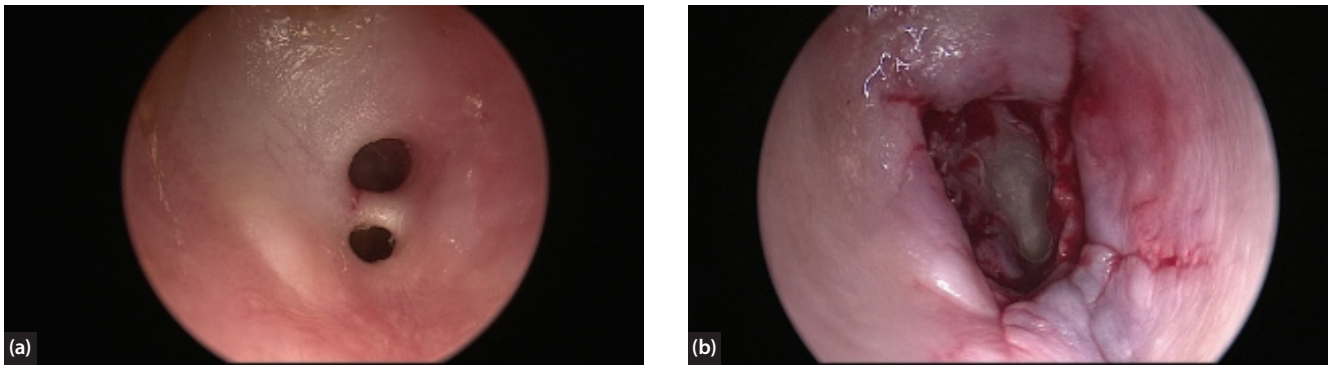

Figure 77.7 Surgery for membranous lateral atresia. (a) Predominantly membranous atresia with two small defects. **(b)** Lateral and medial flaps interleave to aid post-operative epithelialization.

of surrounding epithelium. Silastic sheets are overlaid, holding the lateral and medial skin edges against the bone of the ear canal. With thicker plates the retroauricular approach provides access to lift off the outer skin, remove the atretic plate and dissect it away from the medial skin covering. This aids the final reconstruction, providing skin flaps which can be turned to cover the bare canal bone at the site of the membranous atresia (**Figure 77.7b**).

Atresia surgery combined with tympanoplasty

As the underlying condition of atresia, particularly the solid form, is associated with middle-ear disease, such as chronic otitis media, it is not surprising that Becker and Tos[3] found that in 40% of their surgical cases there was an associated middle ear problem such as an ossicular discontinuity or tympanosclerosis. A tympanotomy may be combined with atresia surgery, especially in solid cases where the delicate fibrous layer of the tympanic membrane can be lifted to examine the ossicular chain and give access for reconstruction.

OUTCOMES

There are few published large series of long-term results in surgery for ear canal atresia. This is of particular relevance to this form of surgery because recurrence may be a late development, as the processes that drive the condition, such as otitis externa, may persist. The principal outcome measure is residual conductive hearing loss as the aim of surgery is to provide an open and stable ear canal with a relatively thin and mobile tympanic membrane.

Becker and Tos[3] published a series of 53 ear cases with follow-up of up to 27 years (average >10 years), Herdman and Wright[5] of 9 cases with about 5 years' follow-up and Magliulo[6] of 41 ears with 5 years' follow-up in the majority. The recurrence rates were 11%[3], 33%[5] and 36%.[6] The residual air–bone gap was less than 20 dB in 90%[3] in the Danish series but there was a recurrence of about a third of a clinically significant air–bone gap in the latter report.[6]

These results suggest that surgery can offer stable long-term results with good hearing in the majority but long-term recurrence is a significant risk.

BEST CLINICAL PRACTICE

- ✓ During the wet phase, the ear should be managed with regular suction toilet and local medical treatment to attempt to render the ear dry.
- ✓ Hearing loss may be managed with air-conduction or bone-anchored hearing aids.
- ✓ Atresia (particularly membranous) can be complicated by cholesteatoma and cases should undergo CT scanning.
- ✓ Surgery to relieve conductive hearing loss is possible and in expert hands may lead to stable long-term results.

KEY POINTS

- External ear canal atresia may be solid or membranous.
- It is caused by local irritation by inflammation or trauma.
- Assessment should include CT scanning of the temporal bone.
- It may be complicated by ear canal cholesteatoma.
- If in a wet phase, local treatment may render it dry.
- Auditory rehabilitation with air- or bone-conduction hearing aids should be considered.
- Ear canal surgery to relieve the conductive element and deal with any medial cholesteatoma is effective and stable in expert hands over the long term.

CHAPTER 78

OTITIS EXTERNA AND OTOMYCOSIS

A. Simon Carney

SEARCH STRATEGY

Data in this chapter may be updated by a Medline (Ovid) search using the keywords: otitis externa, external otitis, external auditory canal and limiting the search to human, English language, full papers.

OTITIS EXTERNA

DEFINITION

Otitis externa is a generalized condition of the skin of the external auditory canal. It is characterized by oedema and erythema associated with itch, pain and discharge.

CLASSIFICATION

There is no universally accepted classification for otitis externa and it has been put into many subcategories in the past. In fact, most of these (e.g. eczematous otitis externa) are actually just predisposing factors (Table 78.1).

PATHOLOGY

The clinical course of diffuse otitis externa is extremely variable but has been divided into the following stages:[1]

Stage 1: Pre-inflammatory
Stage 2: Acute inflammatory (mild, moderate or severe)
Stage 3: Chronic inflammatory

TABLE 78.1 Predisposing factors for otitis externa

Type	Factor
Anatomical	Narrow external auditory meatus (EAM) (hereditary, iatrogenic, exostoses, trauma, etc.) Obstruction of normal meatus (kerratosis obturans, wax, foreign body, hearing aid, in-ear head phones, hirsute canal, etc.)
Dermatological	Eczema, sebhorrhoeic dermatitis, psoriasis
Allergic	Atopy, non-atopic allergy, exposure to topical medications
Physiological	Humid environment, immunocompromisation
Traumatic	Skin maceration (bathing or irrigation), ear probing, laceration, radiotherapy, ear candling
Microbiological	Active chronic otitis media, exposure to *P. aeruginosa* or fungi

In stage 1, the protective lipid/acid balance (normal pH 4–5) of the ear is lost and the stratum corneum becomes oedematous, blocking off the sebaceous and apocrine glands and producing aural fullness and itching.

With further oedema and scratching, there is disruption of the epithelial layer and invasion of resident or introduced organisms. This results in stage 2, with

a progressively thickening exudate, further oedema, obliteration of the lumen (mild: little or no obliteration; moderate: sub-total obliteration; severe: complete obliteration) and increasing pain. In the severe stages, auricular changes and cervical lymphadenopathy are often seen. After 6 months, by definition, chronic otitis externa occurs. Stage 3 is characterized by thickening of the external canal skin and this is covered in Chapter 77, Acquired atresia of the external ear.

DIAGNOSIS

Otitis externa is a clinical diagnosis based on the following symptoms and signs: pain, itch, oedema and erythema of the external auditory canal with purulent otorrhoea and debris in the meatus (**Figure 78.1**). An active chronic otitis media may be identifiable in some cases. There are no studies evaluating the accuracy of clinical diagnosis in otitis externa.[2]

EPIDEMIOLOGY

Otitis externa is estimated to have a prevalence of 0.4% per year, affecting approximately 10% of the population during their lifetime.[3]

AETIOLOGY

Any condition or situation that disturbs the lipid/acid balance of the ear will predispose an individual to otitis externa.[4] These conditions can be classified as in **Table 78.1**.

Water and moisture are thought to cause a change from a predominantly Gram-positive skin flora to a Gram-negative one. As the ear becomes inflamed, healthy cerumen (with its bactericidal properties) is rapidly removed from the ear and is no longer produced.

Secondary bacterial infection

Secondary bacterial infection is a major feature of the disease. The bacteriology of otitis externa has not changed significantly over the last few decades[5] and most patients will culture multiple organisms (**Table 78.2**). Case reports of methicillin-resistant *Staphylococcus aureus* (MRSA) in otitis externa do not appear to show it to be a management problem unless systemic involvement occurs[6] as most cases settle with topical treatment, whether the bacteria is sensitive to the topical antibiotic or not.[5] There is some evidence that the *Pseudomonas aeruginosa* strains in ear disease are different from those found elsewhere in the human body. These strains may have special adherence properties that allow the bacteria to enhance their pathogenicity.[4, 7]

Bathing

Current opinion would suggest that, although water is a well-established risk factor for the development of otitis externa, bacterial contamination is not required for the development of the condition[5] although bathing in freshwater lakes containing *Pseudomonas* contributed to a large outbreak of the condition in the Netherlands, whereas bathing in rivers, swimming pools or the sea were not shown to be risk factors.[9]

TABLE 78.2 The microbiology of otitis externa (from Agius et al.[8] and Anonymous[5])

Bacteria	Percentage
Pseudomonas spp.	50–65
Other Gram-negative organisms	25–35
Staphylococcus aureus	15–30
Streptococcus spp.	9–15

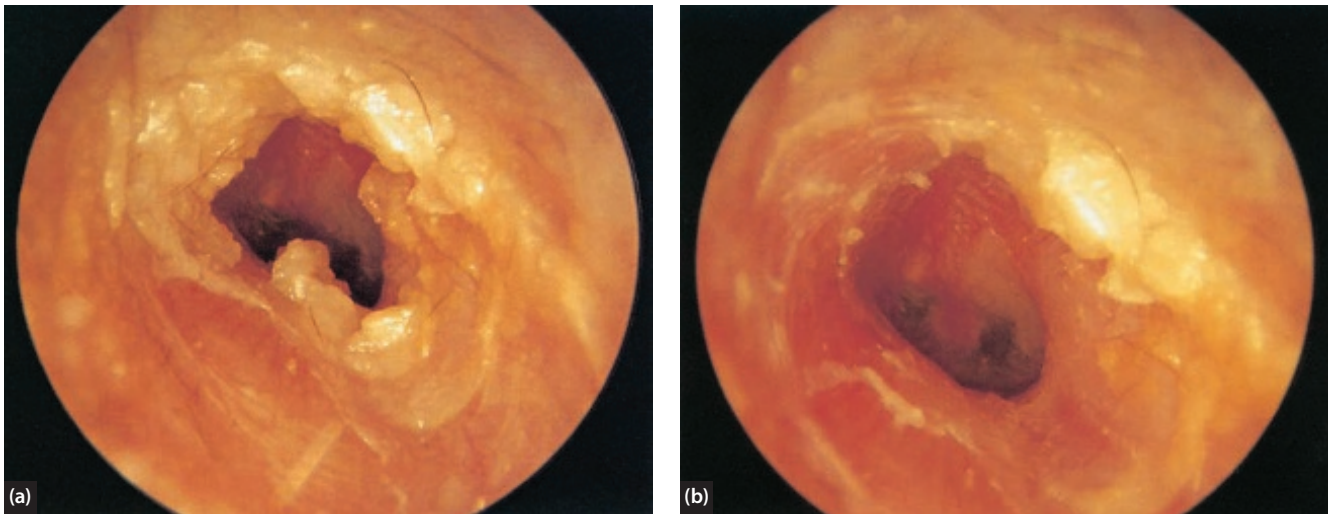

Figure 78.1 Acute otitis externa. (a) Debris inflammation in the left external auditory meatus. **(b)** After removal of the debris the swollen oedematous canal skin of the otitis externa can be seen.

Irritant/allergic reactions

Treatment of otitis externa is often with topical medications. Around 40–58% of patients have been shown to be sensitive to ingredients in topical agents on patch testing although clinical reactions may only develop in half that figure.[10, 11] There is increasing evidence that steroids may also sensitize the ear and steroid-only drops can still be a major exacerbating factor in some patients. This hypersensitivity can be through both atopic and non-atopic 'allergic' mechanisms and may or may not involve IgE.[12] In cases of resistant otitis externa, a patient should be investigated for topical hypersensitivity to possible therapeutic agents.

OUTCOMES AND COMPLICATIONS

If untreated, mild attacks of otitis externa often spontaneously resolve as the epithelial barrier becomes reestablished, the piloapocrine units produce normal secretions and the pH of the canal returns to normal. If the inflammation progresses faster than repair, increasing pain, otorrhoea and oedema of the canal occurs and the patient's condition will deteriorate. Due to the rich lymphatic drainage of the area, lymphadenopathy often occurs and soft-tissue infection can progress rapidly. This can lead to perichondritis, chondritis, cellulitis, parotitis and/or erysipelas. In the immunocompromised host, malignant otitis externa (periostitis/osteomyelitis of the skull base) can develop with significant associated morbidity and mortality.[3]

MANAGEMENT OPTIONS

The principles of treatment of otitis externa are as follows:

- thorough and regular aural toilet
- topical medication to the external auditory canal, with or without a wick
- analgesia
- treatment of regional and/or systemic complications with systemic antibiotics
- prevention of aetiological factors that could lead to exacerbation or recurrence.

Expert opinion is divided on the role of routine swabbing of the ear in otitis externa. Most otolaryngologists tend to reserve microbiological investigation for resistant or high-risk cases.[5]

Toilet remains the most effective single treatment for otitis externa. Although one primary care review claims irrigation of the ear canal is effective for the removal of debris,[2] expert opinion is generally against this and most specialists will perform aural toilet with or without microscopic assistance. There have been case reports of severe complications as a result of irrigation.[13] As microscopic toilet is not readily available to most general practitioners, patients are often treated with antibiotic/steroid medication in the form of drops or sprays without prior toilet. Aural medication commonly causes stinging or burning which may decrease compliance[14] and topical sensitivity is a common feature, especially in resistant or recurrent cases. There is no evidence for the efficacy of systemic antibiotic therapy for uncomplicated diffuse otitis externa.[15]

The use of a wick such as 1 cm ribbon gauze or a Pope otowick is often used to hold medication in the EAM. Glycerol and ichthammol (90% : 10%) used to be commonly used with an aural wick for moderate and severe cases of otitis externa, although it is now difficult to source. It has proven dehydrating and anti-inflammatory properties and antibacterial activity against *Streptoccocus* and *Staphylococcus* but poor activity against *Pseudomonas*.[16, 17] The dehydrating effect reduces canal oedema and also helps reduce pain but oral analgesia is usually necessary in moderate or severe cases. Non-steroidal anti-inflammatories, if not contraindicated, are excellent analgesics for otitis externa.

In patients who are prone to recurrent attacks, avoidance of water penetration into the ear is a major management issue. Cotton wool with petroleum jelly (e.g. Vaseline) will work well in the bath or shower and custom-made ear moulds can be made. Neoprene head bandages are a useful adjunct with the above for children in swimming pools. The use of alcohol ear drops or proprietary preparations (e.g. ear calm) after swimming will help remove any water that has penetrated into the canal. Blow-dryers (note: not on 'hot' setting) can also help remove moisture from the EAM.[5, 18]

Where dermatological conditions exist, multidisciplinary input is often required and tar preparations may be required. Any topical agent should be suspected as an exacerbating factor for eczema around the EAM.

In a small minority of patients who have recurrent attacks of otitis externa exacerbated by conventional hearing aids, insertion of a bone-anchored hearing aid can result in a spectacular and gratifying resolution of the condition.[19]

EFFECT OF MANAGEMENT ON OUTCOMES AND COMPARISON BETWEEN MANAGEMENTS

Randomized trials comparing interventions for the treatment of otitis externa are few in number. Scientific design of trials is difficult as the disease is heterogeneous in presentation, has a high rate of resolution with little or no intervention, endpoints are difficult to ascertain and often subjective and compliance with medication is known to be poor.[20]

A consensus panel convened by the American Academy of Otolaryngology – Head and Neck Surgery found no evidence for the use of systemic treatment in the absence of known risk factors or systemic signs and/or symptoms.[21] Although the choice of antibiotic used is controversial and toilet was not performed, in one randomized trial, addition of clotrimoxazole to Kenacomb ointment provided no benefit over the ointment alone.[22] The best available evidence shows little or no difference between the various topical agents, once thorough toilet has been performed,[2] although these studies are usually of low statistical power.

Likewise, toilet and topical hydrocortisone with an acidification agent (acetic acid) gives equivalent results to combination antibiotic/steroid preparations[23] and an acidification agent alone (aluminium acetate) produces similar outcomes to antibiotic (gentamicin) alone.[24] An early study compared steroid/aminoglycoside drops to placebo alone, showing a significant benefit with topical therapy at 10 days ($p < 0.001$).[25] Likewise, budesonide drops have been shown to produce better clinical outcomes than placebo.[26] Addition of any form of topical agent does seem to be better than toilet alone.[27] The sensitivity of the bacteria to the antibiotic in topical medication does not seem to influence outcomes. The fluoroquinolones ciprofloxacin and ofloxacin have been shown to be as effective as combination steroid–aminoglycoside drops[5, 28] and have the attraction of being non-ototoxic.[29] They are expensive but only need to be given twice daily, which has an advantage for compliance, especially in paediatric populations.[5] It is worth noting that many fluoroquinolone preparations still contain potentially ototoxic preservatives, although the question of ototoxicity is perhaps less relevant for otitis externa unless there is perforation of the tympanic membrane. The issue of topical ototoxicity is discussed at greater depth in Chapter 83, Chronic otitis media.

There is some evidence that spray-based medication systems provide better drug delivery to the meatus[30] although this remains controversial. In two studies from the same authors demonstrating improved outcomes from spray when compared to drops, one was non-blinded.[31, 32] It is also worth noting that the sprays used in these trials ('Otomize') also contained acetic acid, in contrast to the antibiotic/steroid drops.

TABLE 78.3 Randomized controlled trials in otitis externa

Treatment vs placebo	Trials	Result
Aural toilet	None	
Acetic acid	None	
Aluminium acetate	None	
Antibiotic, oral	None	
Antibiotic, topical	None	
Antibiotic and steroid, topical	Ref 25	80% vs 20% benefit
Antifungal, topical	None	
Ichthamol and glycerol	None	
Steroid, topical	Ref 26	Benefit
Tar	None	
Method of administration		
Drops vs spray	None	
Drops vs pack	None	
Drops vs wick	None	
Drops vs ointment	Ref 38	No difference
Wick vs gauze	Ref 36	No difference
Comparison of different treatments		
Multiple trials	The majority show no difference but are mostly underpowered.	

Self-administered powder was shown to cure otitis externa in 74% of patients when compared to drops (53%) in a randomized, non-blinded trial from Israel[33] and there may prove to be benefits from using sprays or powder, although more research is needed before firm conclusions can be drawn on this.

Compliance with medication has been shown to rise from 25% to over 90% if the medication is administered by a third party[20] and only 40% of self-medicating patients were able to get within 25% of the correct dose after 3 days of treatment.[34] Insertion of a Pope wick can cause trauma to the EAM[35] and there is only limited evidence of any enhanced efficacy for wicks over drops alone[5] although many experts find these useful in tight ear canals. In a randomized trial involving 94 patients, there was no difference in resolution rates when wicks were compared to medicated ribbon gauze.[36]

The results of randomized controlled trials comparing treatments for otitis externa are summarized in Table 78.3 and have now also been the subject of other systematic reviews.[37]

OTOMYCOSIS

Otomycosis (or fungal otitis externa) accounts for approximately 10% of all cases.[3] It is more common in hot, humid climates and is often secondary to prolonged treatment with topical antibiotics. Diabetes and other causes of immunocompromise also predispose to the condition. The diagnosis must be considered in patients with otitis externa who fail to respond to topical antibiotic/steroid drops.

Aspergillus accounts for 80–90% of cases with *Candida* being responsible for the remaining 10–20%.[3] Other fungi are rarely involved.

The commonest finding is a black, grey, green, yellow or white discharge with debris that is often said to resemble wet newspaper. Occasionally, debris is seen with visible fungal hyphae (Figure 78.2). Treatment is similar to that for diffuse

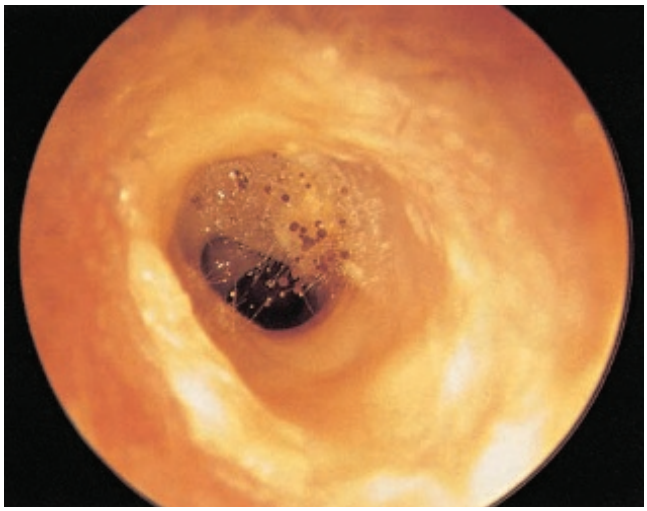

Figure 78.2 Otomycosis with *Aspergillis niger*.

otitis externa, namely toilet and removal of the debris but topical antifungal drops (e.g. clotrimazole or flumethasone with clioquinol) are usually used to expedite recovery.

In cases of resistant otomycosis, it is essential to exclude fungal infection elsewhere in the body. The 'foot and ear'[39] dermatophytid (i.d.) reaction can occur from a fungal infection in a remote location. Immunotherapy with dermatophyte (*Trichophyton*, *Oidiomycetes* and *Epidermophyton*: TOE) extracts and dust mite is the treatment of choice in this condition.[40]

Rarely, fungi can cause invasive otitis externa, especially in immunocompromised patients. Aggressive systemic antifungal therapy is required in these patients[41] who often have a high mortality from the condition.[42]

BEST CLINICAL PRACTICE

- ✓ Addition of any form of topical agent is better than toilet alone. [Grade A]
- ✓ Topical combination antibiotic/steroid drops or spray (with or without the addition of acetic acid) would be regarded as best practice for first-line treatment, given the current evidence. [Grade A]
- ✓ Regular toilet remains the most effective single treatment for otitis externa.
- ✓ Water avoidance is essential in the acute phase and to prevent recurrence. Consider hypersensitivity to topical medication in resistant cases.
- ✓ Think of otomycosis and treat with topical antifungal agents, especially if topical antibiotics have been previously used. Bone-anchored hearing aids can provide excellent results in chronic disease.

FUTURE RESEARCH

- ➤ More powerful prospective randomized controlled trials are necessary to compare different interventions for otitis externa.
- ➤ Accepted grading systems and outcome measures for interventions for otitis externa would greatly facilitate research in this area.

KEY POINTS

- Otitis externa occurs because the protective lipid/acid balance of the ear is lost.
- It affects up to 10% of the population in their lifetime.
- Up to 25% of patients may be clinically hypersensitive to topical medication.

CHAPTER 79

PERICHONDRITIS OF THE EXTERNAL EAR

James W. Loock

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keyword perichondritis. This was augmented by references from these articles. No level 1 or 2 evidence was identified.

DEFINITION

The term correctly refers to infection or inflammation involving the perichondrium of the external ear: auricle and external auditory canal. However, it is commonly used to describe a continuum of conditions of the external ear, from erysipelas (infection of the overlying skin), through cellulitis (infection of the soft tissue) and true perichondritis to chondritis (infection involving the cartilage itself).

Classification and staging

See the definition above. A useful practical classification might be:

- erysipelas of the external ear
- cellulitis of the external ear
- perichondritis
- chondritis.

Prasad et al.[1] suggest a simple and logical staging of perichondritis/chondritis as:

Stage 1: early perichondritis without fluctuant abscess
Stage 2: perichondritis with fluctuant abscess
Stage 3: perichondritis with fluctuant abscess and cartilage destruction.

AETIOLOGY

The thin skin, minimal subcutaneous tissue and vulnerable anatomical position make conchal cartilage particularly susceptible to trauma with subsequent infection. Perichondritis usually happens secondary to trauma. Such trauma may include laceration of the auricle, surgery to the external ear, frostbite, burns, chemical injury, infection of a haematoma of the pinna, aspiration or incision of a haematoma and, in recent years, 'high' piercing of the (cartilaginous) portion of the auricle for the insertion of earrings.[2] Superficial infections of the skin (erysipelas) or subcutaneous tissue (cellulitis) of the external auditory meatus or pinna may spread deeply to involve the perichondium (perichondritis) or cartilage (chondritis).

In an analysis of 36 patients the organisms most commonly isolated were *Pseudomonas aeruginosa* (69%), polymicrobial (22%), *Streptococcus* spp. (22%) and *Staphylococcus aureus* (20%).[3] However, this may represent a selected subgroup of severe cases as in most (milder) cases no culture is taken. Other organisms cultured include Gram-negatives (*Proteus*, *Enterococcus* and *Escherichia coli*).

PATHOLOGY

Hyperplasia of the dermal layers, thickened subcutaneous tissue, intense infiltration with polymorphonuclear

leukocytes, thickening of the perichondium and destruction of the cartilage by phagocytes is described.[4]

DIAGNOSIS

The presentation is with a dull pain increasing in severity and the classical signs of inflammation involving the cartilaginous pinna (**Figure 79.1**). The lobule, which contains no cartilage, is spared. The severity of the pain and swelling of the pinna are indicators for true perichondritis as opposed to the more superficial conditions of erysipelas and cellulitis. The diagnosis is clinical and special investigations are not routinely required. A background history of underlying trauma to the external ear should be sought.

Differential diagnosis

Relapsing polychondritis may present with similar signs of inflammation, involving the pinna and fever, but it is differentiated on the basis of the systemic nature of the condition. This manifests in the involvement of cartilaginous structures at multiple sites, possibly ocular conditions (scleritis, iritis and keratitis) and, occasionally, vasculitis. See also Volume 1, Chapter 18, Connective tissue diseases: ENT complications.

Rare cases of extranodal non-Hodgkin lymphoma of the pinna, both with[5] and without[6] the presence of human immunodeficiency virus, have been reported to present similarly to perichondritis.

OUTCOMES

If untreated, a subperichondrial abscess may develop, leading to avascular necrosis of the underlying cartilage and marked deformity of the pinna. The infection may spread to the cartilage itself. Rare reported complications of perichondritis include fatal septicaemia secondary to streptococcal infection, subacute bacterial endocarditis and necrotizing fasciitis of the neck.

Figure 79.1 Perichondritis of the left ear. There is an associated subperichondrial abscess in this case.

MANAGEMENT OPTIONS

Prevention

Acute perichondritis should be prevented by careful placement of ear piercings away from the cartilaginous pinna. Surgery in and around the ear should avoid trauma to cartilage and tight head bandages. Haematomas of the auricle should be drained promptly and using careful aseptic techniques. The meticulous management of burn injuries to the ears should include the use of prophylactic antibiotics against Gram-negative bacteria and diligent local care including daily dressings and the removal of eschars and crusts.

First-line management

The mildest forms (cellulitis and Prasad stage 1) are adequately managed by the use of topical and oral antibiotics. Prompt treatment with a broad-spectrum antibiotic at a high dose, possibly intravenously, should be designed to cover common organisms and, in particular, *P. aeruginosa*.

The presence of subperichondrial abscess as evidenced by fluctuation requires drainage, but only when definite fluctuation is present, as premature invasive intervention may result in further spread of the infection. If pus is obtained, a pus swab should be sent for culture and sensitivity; however, pending the result, intravenous antibiotic treatment should not be delayed. Standard drainage would be by incision; Pattanaik[7] reports success with a procedure involving aspiration, syringing the cavity two or three times with streptomycin solution, and then refilling the cavity with a premixed solution of streptomycin, triamcinolone and hyaluronidase.

Resistant cases

Non-response to the above treatment, accompanied by persistent pain, suppuration and extensive signs of inflammation, necessitates further intervention.

Various authors advocate aggressive excision of necrosed cartilage including the overlying skin and subcutaneous tissue.[8, 9] However, it is difficult to decide how much cartilage to excise, and repeated debridement may be required. Furthermore, this procedure usually results in deformity, especially if the peripheral cartilagenous framework has to be removed. In severe cases, where the entire area is involved, these authors advocate total chondrectomy via an incision in the helical margin, the ear being split in bivalve fashion, the necrotic cartilage resected, and a layer of fine mesh gauze placed between the flaps and changed daily.

An alternative is a system of continuous drainage and irrigation with an antibiotic and steroid solution in order to preserve the structure and form of the auricle.[10–12] Fenestrated polyethylene tubes are placed in subperiosteal tunnels on either side of the cartilage, and aminoglycoside/cortisone solution used to irrigate these twice daily. The authors report good results and minimal deformity.

The principle of preservation of the perichondrium is supported by experimental work on rabbit ears (animal evidence), which showed that new cartilage formed when the subperichondrial space was preserved.[13] These results could however not be reproduced in monkey auricles (animal evidence).[14]

Other forms of management

The difficulty of delivering adequate antibiotic levels to devascularized cartilage, particularly in burn injuries, led to the investigation of iontophoresis (electromotive drug administration) as a means of effective local antibiotic delivery without systemic absorption. This technique creates an electric field to drive medication (antibiotics in this case) through the skin to deliver high-tissue concentration. This form of treatment is rarely used despite compelling animal and human clinical evidence. A number of authors have demonstrated experimentally the effectiveness of iontophoresis in delivering high levels of penicillin and gentamicin, respectively, to burn-injured rat and rabbit ears (animal evidence).[15–18]

In perichondritis resistant to antibiotic treatment alone, low-dose radiation has been successfully used, based on the lethal effect of such radiation, on three or four sessions of approximately 0.8 Gy of radiation over a period of 2 days.[19]

Ultraviolet radiation has been employed; however, the side effects can be significant and the efficacy of this form of treatment has subsequently been questioned.[20]

Effect on outcomes

All the above case series report resolution of the condition using the therapy they advocate. Aggressive surgery, while it may at times be necessary, may aggravate the ultimate deformity.

BEST CLINICAL PRACTICE

The available clinical literature constitutes Grade D recommendations. Consequently, recommendations must be guarded but the following would seem logical.

- ✓ Consider broad-spectrum (including antipseudomonas) antibiotic prophylaxis in severely traumatized or burnt pinnas.
- ✓ Make early use of local and systemic broad-spectrum, anti-pseudomonal antibiotic if perichondritis is suspected.
- ✓ Fluctuation indicative of pus collection requires drainage with or without irrigation and/or an indwelling drain.
- ✓ In resistant cases, add effective local antibiotic delivery by irrigation or iontophoresis.
- ✓ If further surgery is needed for excision of necrotic cartilage, preserve the perichondrium and a cartilage framework wherever possible.

FUTURE RESEARCH

- ➤ The relative rarity of this condition and the need to individualize management mitigate against level 1 and 2 evidence.
- ➤ Burns units are best placed to provide data.

KEY POINTS

- Trauma, including piercing, may contribute to perichondritis of the pinna.
- Pseudomonas is the commonest organism, but the infection may be polymicrobial.
- Cartilage necrosis and deformity may result.
- First-line management is in the form of (anti-pseudomonal) antibiotics.
- Severity, pus collection, and failure to respond may call for surgical or other forms of treatment.

CHAPTER 80

EXOSTOSIS OF THE EXTERNAL AUDITORY CANAL

Philip J. Robinson and Sophie J. Hollis

SEARCH STRATEGY

Data in this chapter may be updated by Medline and PubMed searches, both using the keywords ear and exostosis.

DEFINITION

An exostosis (Figure 80.1) of the external auditory canal (EAC) is a benign growth of periosteal bone, which forms a smooth, sessile, hemispherical swelling in the deep part of the meatus, adjacent to the tympanic membrane. Exostoses are usually multiple, occurring in a group of three, and are bilateral. They may arise from the anterior and posterior walls of the EAC. They are usually found as an incidental finding during the examination of an asymptomatic patient. Internal auditory canal (IAC) exostoses have been described, but these are rare clinical entities.[1]

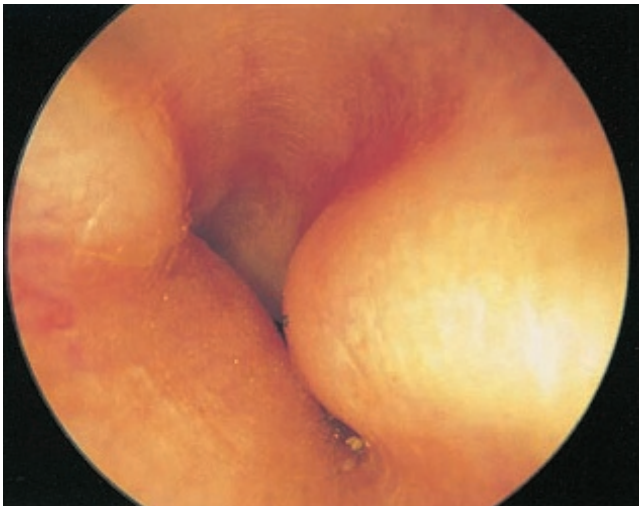

Figure 80.1 Multiple exostosis of the right external auditory canal. One exostosis is anterior and two are posterior.

PATHOLOGY

Histopathological studies of exostoses are few, as a result of the lack of suitable specimens available from the drilling method of surgical excision. However, Graham[2] described exostoses as broad-based, dense and composed of lamellated bone, covered with periosteum and its overlying squamous epithelium with an internal structure formed by concentric, dense layers of subperiosteal bone with abundant osteocytes. A lack of fibrovascular channels and the features mentioned here were proposed as a histopathological method of differentiating exostoses from the other bony swelling seen in the ear canal, an osteoma. However, a later histopathological study[3] demonstrated a considerable overlap of histological features between the two clinical entities.

AETIOLOGY AND EPIDEMIOLOGY

The relationship between cold water exposure and exostoses is now widely accepted. Exostoses are common among water sports enthusiasts, with a prevalence as high as 73.5% in a surfing population.[4] The incidence rises with length of exposure to cold water, from 55.3% for individuals who had surfed for 10 years or less to 90.9% for individuals who had surfed for longer than 20 years.

In a study of two similar groups of Japanese divers, exostoses were significantly more common and more severe in the group working in the cold water area and again showed a significant increase in incidence as the diving career progressed.[5]

Laterality of exostoses is also thought to be related to the cooling effect of wind direction in those who surf. A Californian study proposed that surfers spent most of their time in the water facing west, waiting for waves, which corresponded with the right ear being exposed to more evaporative cooling. Accordingly, the study showed that severe exostoses were twice as likely to be found in the right ear.[6]

An anthropological study of over 1000 prehistoric crania from northern Chile demonstrated a significantly higher prevalence (30.7%) in the coastal area, compared with 2.3% in the valley area and 0% in the highland population, which may be a consequence of habitual fishing in the cold waters of the Pacific ocean.[7] Fowler and Osman,[8] working with guinea pigs, were able to demonstrate the formation of new bone on the inner surface of the tympanic bulla following irrigation of the external canal with cold water. Harrison[9] carried out similar experiments with guinea pigs and found histological evidence of new bone formation in the deep meatus.

The formation of exostoses may represent a rudimentary, evolutionary response to protect the middle ear against immersion in cold water. In the hooded seal (*Cystophora cristata*), there is a broad-based exostosis in the floor of the EAC, lateral to the tympanic membrane, which helps to obstruct the EAC. In addition to cavernous tissue in the middle ear, this feature allows the seal to dive to depths of greater than 1000 m, where it stays for close to 1 hour at pressures of 100 atm, without damage to the middle ear or tympanic membrane.[10]

DIAGNOSIS

The diagnosis of exostoses (**Figures 80.1** and **80.2**) is usually made clinically from the characteristic otoscopic appearances of multiple and usually bilateral sessile, hemispherical, bony swellings arising deep in the EAC, adjacent to the tympanic membrane. It is usually straightforward to differentiate them from an osteoma, which is generally a unilateral, solitary, discrete, pedunculated mass, arising from the lateral part of the bony EAC.[11]

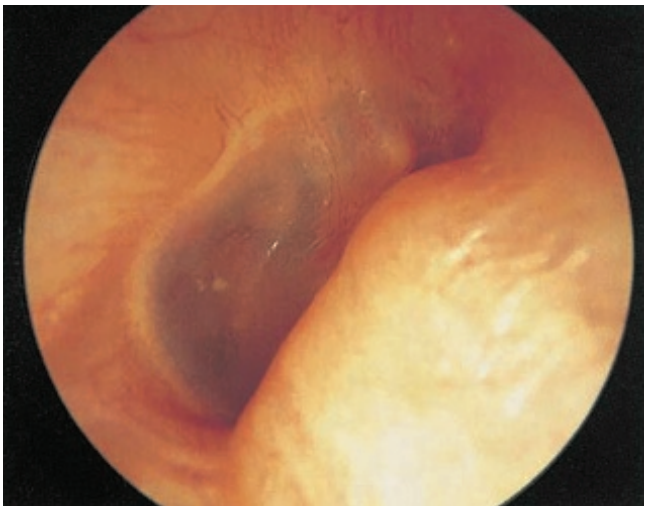

Figure 80.2 Single anterior exostosis of the right external auditory canal.

Exostoses are generally an incidental finding and asymptomatic when small. However, when the exostoses enlarge to cause a stenosis of greater than 80% of the canal lumen, there may be a history of recurrent otitis externa, chronic infection, wax and debris accumulation and conductive hearing loss. As noted above, exostoses are common among water sports enthusiasts.

In the presence of a tight stenosis of the deep ear canal, a high-resolution computed tomography (CT) scan will help differentiate large exostoses from other causes of stenosis, such as chronic otitis externa. A scan will also demonstrate complications, such as a canal cholesteatoma, developing medial to the exostoses.[12]

OUTCOMES AND NATURAL HISTORY

The incidence of exostoses and their size increases with duration of exposure to cold water. In a population of surfers, 44.7% of those who had surfed for 10 years or less had normal ear canals and only 6% had severely obstructed ear canals. In comparison, in the group that had surfed for greater than 20 years, only 9.1% had normal ear canals and 16.2% were severely affected.[4]

There are no longitudinal studies of individuals with exostoses, but it seems unlikely that there would be any significant growth in the absence of continued water exposure.

In most cases, exostoses are an incidental finding and symptoms are rare, with mild to moderate stenosis only. However, with greater than 80% canal stenosis, debris may accumulate medial to the obstruction, leading to recurrent episodes of otitis externa, conductive hearing loss and occasionally a canal cholesteatoma.

MANAGEMENT OPTIONS

In the majority of cases, no treatment is required as the patient is asymptomatic. However, general advice about avoidance of cold water should be given, with a recommendation to use earplugs or a wetsuit hood for water sports.

Hearing loss due to debris collection, or otitis externa, can be managed medically, by meticulous aural toilet using a microscope and suction. Topical application of steroid, antibiotic, antifungal or combination ear drops, may be necessary to treat inflammation or infection.[13]

Surgery

Surgery to remove the exostoses and enlarge the meatus by a meatoplasty procedure is indicated for cases refractory to medical treatment, causing recurrent or persisting otitis externa, frequent cerumen obstruction causing hearing loss and cases where wider access is required for middle-ear surgery.

Surgery is carried out, via a postaural, endaural or permeatal approach, with very careful elevation and preservation of the skin overlying the exostoses. The bone of the exostoses is removed by high-speed drill, using both cutting and diamond burrs. Great care is necessary to avoid damaging the tympanic membrane and facial nerve.

COMPLICATIONS OF SURGERY

Sheehy[11] has recommended a postaural approach in all cases of diffuse exostoses of the EAC, because of the incidence of complications and recurrence of the lesions in patients operated on transmeatally. Of the transmeatal group 25% required revision procedures (6 of 24) compared to 0/55 in the postaural group.

In some series of cases, the permeatal approach seems to be favoured, particularly in the hands of an experienced surgeon,[14] although House and Wilkinson[15] conclude from a series of more than 400 ears that the postaural approach results in complications being kept to a minimum.

Complications of surgery can include infection, tympanic membrane perforation, facial palsy, hearing loss from damage to the ossicular chain or inner ear, exposure of the temporomandibular joint with chronic pain or subluxation and early or late soft-tissue stenosis of the ear canal.

BEST CLINICAL PRACTICE

- ✓ Most exostoses are asymptomatic and are incidental findings. These are best managed by advice to minimize exposure to cold water by using swim plugs or a wetsuit hood for water sports.
- ✓ Recurrent episodes of otitis externa or cerumen impaction may be associated with exostoses and should be managed medically in the first instance with microsuction and antibiotic ear drops.
- ✓ Cases of severe exostoses may require meticulous surgical removal via a postaural approach using a high-speed drill.

FUTURE RESEARCH

- ➤ There are currently inadequate histological data.
- ➤ Further studies are required to establish the true natural history of untreated exostoses.

KEY POINTS

- Exostoses are common in water sports enthusiasts.
- Exostoses are usually an incidental finding and require no treatment.
- There is evidence that prolonged exposure to cold water in the EAC leads to increasing size and incidence of exostoses.
- Exostoses causing greater than 80% stenosis may lead to recurrent episodes of otitis externa, hearing loss and, occasionally, canal cholesteatoma.
- Treatment is usually unnecessary in small exostoses, but advice to avoid further cold water exposure may be appropriate.
- Meticulous medical management will often control the symptoms but, in cases refractory to medical treatment, excision of the exostoses may sometimes be necessary.

CHAPTER 81

OSTEORADIONECROSIS OF THE TEMPORAL BONE

James W. Loock

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: osteonecrosis/osteoradionecrosis and temporal bone/petrous temporal bone/ear. Most of the evidence is level 3 or 4 and is based upon the more frequent mandibular form of the disease.

DEFINITION

Osteoradionecrosis of the temporal bone is defined as exposure and necrosis of a variable portion of previously irradiated petrous temporal bone which fails to heal over a period of 3 months.

INCIDENCE, AETIOLOGY AND PATHOGENESIS

Because of its density, bone absorbs a greater proportion of radiation than soft tissues. Osteoradionecrosis and chondroradionecrosis may occur in various sites in the head and neck following high-dose radiotherapy, despite the relative radioresistance of bone and cartilage.[1] Osteoradionecrosis of the mandible (see Volume 3, Chapter 19, Principles and practice of radiotherapy in head and neck cancer) occurs far more frequently than in the petrous temporal bone. Chondronecrosis of the larynx, and osteonecrosis of the maxilla and nasal bone, nasopharynx/skull base, zygoma, palate,[2] clavicle and hyoid[3] have all been described.

Osteoradionecrosis of the petrous temporal bone occurs as a result of high-dose radiotherapy administered to and around the petrous temporal bone for malignancies of the parotid gland, external auditory canal, middle ear, maxilla, nasopharynx[4] and pituitary.

The radiation causes inhibition of mitosis and the capacity for tissue repair, and a vasculitis leading to obliteration of blood vessels and avascular necrosis.[5, 6] Marx et al.[7, 8] characterized the tissue as hypoxic, hypocellular and hypovascular.

The compact, rather than cancellous, nature of the petrous temporal bone, and poor blood supply of the tympanic ring, may increase susceptibility.

Radiotherapeutic techniques which have been developed to reduce the risk of osteoradionecrosis include increased energy of the beam (megavoltage versus kilovoltage) which reduces the dose to bone, the use of multiple fields to contain dose distribution, intensity-modulated radiotherapy, and the use of heavy charged particles (Hadron therapy) where the dose-distribution avoids exit dose.

The occurrence of osteoradionecrosis may be increased in patients with microvascular disease (atherosclerotics and diabetics), and as a result of trauma after radiotherapy – classically dental extractions in the case of the mandible. High local doses of brachytherapy may give an increased incidence.

PATHOLOGY

The tissues affected include bone, overlying subcutaneous tissues and skin. Auricular cartilage is seldom affected due to the low superficial radiotherapy dose received in all but irradiation of skin tumours.

The histological changes in bone include death of osteocytes and osteoblasts resulting in empty lacunae,

preponderance of osteoclasts, demineralization, osteolysis, loss of marrow substance, reparative fibrosis and often secondary infection.[6, 9] Soft-tissue histological changes include epithelial hyperplasia, atrophy of dermal structures, dermal fibrosis and soft-tissue necrosis with replacement by fibrosis.[9]

Macroscopically, there is loss of skin and soft tissue exposing bone, bony sequestration and frequently the complication of secondary infection. Of the parts of the temporal bone, the tympanic ring appears particularly susceptible.[9]

The effects of radiation on the middle and inner ears and hearing are not discussed here. The reader is referred to the publications of Borsanyi et al.,[10] Anteunis et al.,[11] Gyorkey and Pollock[12] and Jereczek-Fossa et al.[13]

DIAGNOSIS, CLINICAL PICTURE, NATURAL HISTORY AND OUTCOMES

The time interval between radiotherapy and clinically evident osteoradionecrosis can vary considerably – from less than 12 months to 23 years.[14]

Ramsden et al.[14] usefully divided cases into localized and diffuse (extensive) forms. The localized form presents mild otalgia and otorrhoea, with small areas of exposed bone in the external auditory canal (**Figure 81.1**). It generally occurs when the petrous bone was in the periphery of the irradiated field. Computed tomography (CT) scanning should show not more than small areas of sequestration. This type can heal if managed conservatively, with resolution occurring typically over 1–4 years, after spontaneous separation of the sequestrum.

The diffuse or extensive form occurs generally when irradiation is directed at the petrous temporal bone, and has more severe symptoms of pain and otorrhoea (**Figure 81.2**). CT imaging may show widespread bony destruction. Erosion of the facial canal and extension to the inner ear can occur, as well as intracranial complications, brain abscesses, meningitis and death. Radical surgical debridement and repair is often necessary to prevent complications and effect healing.

There are no studies analyzing the reliability of CT scanning in indicating the extent of bony non-viability.

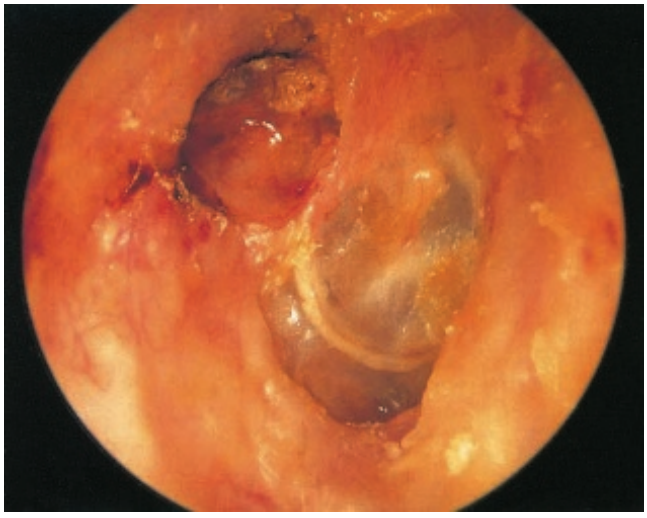

Figure 81.1 Radionecrosis of the right ear. In this ear, there is a bony defect of the posterior canal wall, a bone sequestrum having been extruded. Reprinted from Wormald and Browning, *Otoscopy: a structured approach.* London: Hodder Arnold; 1996.[15]

Figure 81.2 Osteoradionecrosis of the right petrous temporal bone. There was extensive bony destruction, multiple small sequestra, granulation tissue and superinfection.

MANAGEMENT OPTIONS

Prevention

The likelihood of osteoradionecrosis should be reduced by careful planning of the radiotherapy, by the scheduling of any surgical intervention prior to radiotherapy, and by waiting for full wound healing before irradiation. A relatively large case series has suggested that, when treatment for parotid neoplasms requires mastoidectomy, a situation in which the risk for radionecrosis is high, subtotal petrosectomy with mastoid obliteration and oversewing of the external ear canal should be performed *ab initio* as a better option than simple mastoiodectomy.[16]

Treatment

In an established case, the first step should be to exclude an underlying recurrence of malignancy. Thereafter, the severity of the problem guides management.

LOCALIZED NECROSIS

Cases, which just leave an area of exposed dead bone in the floor of the external auditory canal can successfully be managed conservatively, with toilet careful removal of

sequestra, local antibiotics and analgesics, although healing may take up to 4 years. Hill et al.,[17] and subsequently Metselaar et al.,[18] describe the use of a local rotational flap from postauricular skin to cover small exposed areas of bone in the external auditory canal.

DIFFUSE NECROSIS

Conservative management is inadequate for severe diffuse necrosis of the temporal bone. However, the poorly vascularized irradiated field is less than ideal for surgery. In Ramsden et al.[14] and Thornley et al. series,[19] radical surgical debridement alone required revision in half the cases.

For this reason, subsequent authors[20] recommend bringing in a vascularized soft-tissue flap at the time of debridement, as well as radical mastoidectomy or subtotal petrosectomy until healthy vascularized bone is reached. Careful placement of incisions is required in order to optimize blood supply.

The use of hyperbaric oxygen in radiation-injured tissue and osteoradionecrosis is controversial. There is a paucity of evidence in relation specifically to the petrous temporal bone but extrapolation from related literature suggests it might be helpful. In a randomized controlled trial, Marx reported four to five times reduced tissue-related complications in a series of 160 heavily irradiated head and neck patients receiving combined treatment with hyperbaric oxygen in support of debridement and surgical repair.[21] Two reviews have concluded that the available trials constitute a modest level of evidence but suggest an improved outcome with hyperbaric oxygen therapy for late radiation injury in tissues of the head and neck (*inter alia*).[22, 23]

BEST CLINICAL PRACTICE

- ✓ Radiotherapy should be carefully planned to avoid osteoradionecrosis.
- ✓ In making the diagnosis, underlying recurrent malignant disease should be excluded.
- ✓ Mild localized forms of osteoradionecrosis are best managed conservatively.
- ✓ Severe diffuse forms require aggressive surgical debridement to healthy tissue and covering with well-vascularized soft tissue.
- ✓ Hyperbaric oxygen is an adjunct worth considering in severe forms.

FUTURE RESEARCH

- ➤ The prevalence of temporal bone osteoradionecrosis is unknown but is likely to be falling because of improved radiotherapeutic techniques.
- ➤ The value of imaging in assessing the extent of osteoradionecrosis warrants study.
- ➤ The rarity of the condition makes evidence in support of management options difficult.

KEY POINTS

- Radiotherapy to and around the petrous temporal bone may cause osteoradionecrosis.
- This may occur months to years after the radiotherapy.
- Careful planning of surgery and radiotherapy can prevent this complication.
- Underlying malignancy should be excluded.
- Mild cases can be managed by local care.
- Extensive osteoradionecrosis may require radical debridement and vascularized flaps.

CHAPTER 82

ACUTE OTITIS MEDIA AND OTITIS MEDIA WITH EFFUSION IN ADULTS

Anil Banerjee

SEARCH STRATEGY

Data in this chapter may be updated by PubMed searches using the keywords mentioned here. The first search used the keywords acute otitis media and adults, limited to human. The second search used the keywords otitis media with effusion, adults, limited to humans. These were assessed for relevance and quality. Further articles were identified from citations and other publications.

Acute otitis media and otitis media with effusion are often temporally related due to pathology also seen in childhood. They are also encountered due to specific adult-related aetiologies.

ACUTE OTITIS MEDIA IN ADULTS

DEFINITION

'Acute otitis media' (AOM) translates as acute middle ear inflammation. It is generally seen in infective conditions with the causative organism being viral or bacterial. It is a relatively common childhood condition and is seen less often in adults.

PREVALENCE AND INCIDENCE

An international multicentre primary care setting study recorded the total number of patients seen with symptoms consistent with a diagnosis of AOM (n = 3224). Sixteen per cent of the total number was over the age of 15.[1] This condition is therefore not as uncommon in the adult population as was previously thought. It remains, however, predominantly a disease of childhood and more specifically infancy.

A separate study calculated the relative risk of getting AOM to be about 200 times higher during the first 2 years of life than as an adult.[2]

AETIOLOGY

Bacterial infection accounts for the majority of adult AOM cases presenting to ENT doctors (Table 82.1). The organisms found are similar to those in paediatric cases.

TABLE 82.1 Bacteriology of middle ear aspirates from adults with acute otitis media (reprinted from Celin et al.)[3]

Bacterium	Percentage*
Haemophilis influenzae	26
Streptococcus pneumoniae	21
Moraxella catarrhalis	3
Streptococcus aureus	3
Other bacterium	26
No growth	26

* This includes multiple growths (n = 36).

DIAGNOSIS

History

Unlike presentation in the paediatric population, the affected adult can usually describe symptoms in detail and seek treatment of his or her own volition. Despite this, some may still delay treatment until a fulminating middle ear infection results in perforation of the tympanic membrane. The pain experienced together with the resultant mucopurulent otorrhoea should be distinguished from bullous myringitis, which produces a similar history of hearing loss and increasing otalgia but ends in a bloody otorrhoea secondary to bursting of blood blisters on the tympanic membrane. The two conditions occasionally occur together.

In those cases of AOM presenting before perforation occurs, hearing loss, tinnitus and otalgia are the cardinal symptoms.

Secondary symptoms include balance disturbance, general malaise, pyrexia and headache.

Examination

Otoscopy may be challenging as the bulging red tympanic membrane may prove difficult to focus on until the examiner realizes the drum is more lateral than is usually the case and withdraws the otoscope slightly to allow the drum to appear in focus. If the tympanic membrane has already perforated, it will have reverted to its usual anatomical position and the perforation may be visible. Pus may be seen in the external auditory meatus and on the tympanic membrane. Microsuction is often required to allow adequate inspection of the perforated drum.

Confusion can arise between a normal tympanic membrane with a profusion of blood vessels radiating from the umbo and a case of AOM. The most reliable otoscopic indicator of AOM has been found to be tympanic membrane bulging.[4] The diagnosis should therefore be made on a combination of history and otoscopy. Pure-tone audiometry is usually only performed if the diagnosis of AOM has been missed, but it typically shows a significant conductive hearing loss in the affected ear.

MANAGEMENT

Most cases will resolve spontaneously and only analgesia is required.

Although antibiotics are often given for this condition, there is no evidence to suggest efficacy in the adult population. Extrapolation from a Cochrane Database review of antibiotics for AOM in childhood suggests that treatment may reduce pain and the incidence of tympanic membrane perforation but this remains untested by clinical research in an adult population.[5] Studies have been bedevilled by diagnostic uncertainty. Definitive diagnosis of otitis media involves tympanocentesis and this is almost never done so that many cases of otalgia are characterized as otitis media in both adults and children.

Approximately 10% have a perforation with otorrhoea at presentation.[1] Adults with AOM are at higher risk of intracranial complications than adults with chronic otitis media.[6] While all complications of AOM are rare, acute mastoiditis, labyrinthitis, sigmoid sinus involvement and intracranial abscesses have been described as the commonest. Facial palsy accounts for 30% of these complications.[7] Full recovery of the facial nerve is the expected outcome in most cases.[8] Unlike childhood disease, meningitis in adults is an uncommon complication.

OTITIS MEDIA WITH EFFUSION IN ADULTS

DEFINITION

Otitis media with effusion (OME) describes a collection of fluid in the middle ear often extending into the mastoid air cells. This may be secondary to a severe upper respiratory tract infection (URTI). It may also follow on from, or precede, AOM. Most episodes of OME in adults will resolve untreated, but in some cases they may persist for months or longer. In adult cases it is important to ensure that other pathology has not been missed. Patients will often describe hearing loss, crackling or popping of the ears, tinnitus and sometimes balance disturbance.

PREVALENCE AND INCIDENCE

For those with both a paediatric and adult ENT practice it is well known that adults make up a very small proportion of the overall number of OME patients seen. Robinson described a prevalence of 0.6% over the age of 15.[9]

AETIOLOGY

Infection

Most adults report a URTI preceding an episode of OME.[10] Sinus infections often occur in affected individuals.[11–13] As in childhood, OME can follow on from AOM or precede it.

Liederman et al. reported that, when cultures of effusions were matched with polymerase chain reaction (PCR) detection, the organisms found were the same as in childhood disease. PCR detected *Streptococcus pneumoniae* and *Haemophilus influenzae* in 15 of 19 samples. Other organisms found were *Moraxella catarrhalis* and adenovirus.[14] Fungi have been found in the middle ear fluid of 100% of individuals with OME (n = 12) when effusions were collected and stained. Whether they also exist in the middle ear cavities of normal individuals is unknown.[15]

HIV has been reported as predisposing to a high rate of middle ear problems. In a study of 155 HIV-positive adults 18% were identified as having chronic middle ear disease – most with effusion.[16]

Allergy

The evidence for allergy as a causative factor in OME is mainly reported in paediatric studies. In a large Norwegian study, the authors found surgery for otitis media to be more common in subjects who reported an allergy.[17] Pelikan reported 71 of a group of 87 adults having positive responses to nasal allergen challenges, and 119 of the 131 positive challenges resulted in Eustachian tube dysfunction leading to significant audiometric changes. He concluded that nasal allergy can lead to Eustachian tube dysfunction.[18]

Barotrauma

Barotrauma from air flights, typically during descent, is a common cause of OME in adults, particularly when travelling with a URTI. Spontaneous resolution within a few days of landing is the usual course of events but, if this fails to occur, medical evaluation is required. There are no reliable data on the incidence of glue ear in adults following air travel.

Hyperbaric oxygen treatment can also cause OME although in most cases this will resolve without the need for ventilation tube insertion.[19]

Eustachian tube obstruction

In the paediatric population adenoidal hypertrophy or inflammation is a common cause of poor Eustachian tube function. Although this is not the case in adults, a middle ear effusion can be due to an obstructing tumour of the Eustachian tube.

A skull base tumour such as a meningioma can obstruct the upper part of the Eustachian tube leading to a middle ear effusion.[20] Although still rare, a more common cause for Eustachian tube obstruction is a tumour of the nasopharynx occluding the lower end of the tube.

Radiotherapy of the skull base can lead to impaired Eustachian tube function and induce long-term OME, in one or both ears. A retrospective study of 81 patients with nasopharyngeal carcinoma found 52% of patients had an effusion at presentation and 26% developed an effusion after radiotherapy.[21]

Eustachian tube dysfunction may also be caused by reflux. In one study, 40% of effusions taken from adults were positive for *Helicobacter pylori* (HP) by PCR assay. Of these, seven grew HP when cultured and had a positive urease test.[22] Sone et al. found that in 24 adults with high pepsinogen levels in unilateral middle ear effusions a low-frequency audiometric bone-conduction threshold elevation was present in the affected ear when compared with the healthy ear and matched controls. This led them to postulate that this may be a diagnostic sign of high pepsinogen level effusions. Unfortunately, the authors did not have sufficient data after resolution of effusions to evaluate whether this was a temporary or permanent audiometric finding.[23]

Miscellaneous

Cerebrospinal fluid in the middle ear secondary to a skull-base defect may be mistaken for OME. Ventilation tube insertion can lead to persistent otorrhoea and a route for intracranial infection.

Prolonged endotracheal intubation is a risk factor for post-operative OME. The condition has also been described in approximately 20% of patients undergoing head and neck surgery.[24]

Rare conditions producing OME include amyloidosis[25] of the nasopharynx, Wegener's granulomatosis[26] (now called vaculitis), multiple myeloma,[27] cystic fibrosis,[28] polyarteritis nodosa[29] and immune deficiency syndrome. Nasal polyposis can also be associated with OME. A history of previous surgical treatment for nasal polyps or Samter's triad (a chronic condition of asthma, recurrent sinus disease with nasal polyps, and a sensitivity to aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs)) is associated with an increased risk of synchronous OME.[30]

PRESENTATION

The majority of adults seeking treatment do so because of hearing loss. The condition is bilateral in between 42% and 69% of those affected.[9, 10, 12] In a case-control study[12] symptoms in OME sufferers were:

- hearing loss: 97%
- aural fullness: 77%
- pulsatile or crackling tinnitus: 60%.

Balance disturbances are also sometimes reported.

Subjects frequently have predisposing factors which include smoking, childhood ear infections and nasal symptoms. A recent URTI, AOM and/or barotrauma is often a feature.

Unilateral OME in adults, unexplained by past history, should always be treated with suspicion.

EXAMINATION

Features on otoscopy described in childhood disease apply equally to adult disease. The tympanic membrane is usually retracted with an abnormal light reflex and the membrane may appear dull or a fluid level may be seen.

It is important to examine not only with otoscopy but also with flexible fibre-optic nasopharyngolaryngoscopy and/or a 0 degree Hopkins rigid nasendoscope. The nose and nasopharynx should be inspected. Evidence of rhinosinusitis will direct treatment. Postnasal space lesions will require imaging and biopsy while simultaneously dealing with the aural symptoms.

INVESTIGATIONS

Audiology

A pure-tone audiogram will show the level of impaired hearing function and typically reveal a conductive hearing loss. Experienced clinicians will usually make

the diagnosis of OME from tympanic membrane appearance and tympanometry is often not necessary. However, tympanometry does have a high correlation with MRI evidence of middle ear effusion[31] and may be used for diagnosis and monitoring of OME. Pre-operative tympanometry has also been shown to have a high correlation with myringotomy findings when gas displacement of fluid is controlled for.[32]

Myringotomy

The presence of fluid at surgery confirms the condition of OME but the absence of fluid does not necessarily refute it. Although the displacement of middle ear fluid by anaesthetic gases is thought to be minimal or absent, MRI scans have shown fluid in the mastoid air cells but not in the mesotympanum.[31] Immediate pre-operative tympanometry has been compared with tympanometry once a general anaesthetic was applied. In a group of 93 patients 30% of tympanograms were found to change under general anaesthetic. A type B pre-operative tympanogram was found to be predictive of a middle ear effusion in 92%.[33]

MANAGEMENT

There are four management options in adults: (i) non-medical treatment, (ii) medical treatment, (iii) hearing aids, and (iv) surgical treatment.

Non-medical treatment

Using a Toynbee manoeuvre or Valsalva technique can be beneficial. It is particularly useful in the perennial sniffer who needs to be educated against continuing this practice and encouraged instead to increase middle ear pressures. The Valsalva technique should be performed several times a day and the patient warned that the first time air enters the middle ear space may be uncomfortable and noisy. This tends to become less dramatic as the middle ear space is gradually aerated with continued application. In children, or in adults who fail to clear their effusions using the Toynbee or Valsalava techniques, mechanical devices such as the Otovent™ balloon and Ear Popper™ can be employed to achieve the same effect.

Medical management

Nasal decongestants such as xylometazoline are widely advocated for OME in adults but there is little evidence to indicate that they alter the natural course of the disease, which is to resolve without treatment in most cases.

Most research into antibiotic use for OME has been in the paediatric population. No large studies of adults were identified in the literature searches. Using a combination of both culture techniques and confocal laser scanning microscopy, a study of middle ear effusions in children found approximately 92% to contain live bacteria. A high proportion showed biofilm morphology. This strengthens the evidence for bacteria in the aetiology of OME in children but requires further investigation in the adult population.[34]

There has been no strong evidence to indicate that N-acetyl cysteine is a reliable form of therapy for OME in adults. Although in theory a mucolytic would appear to hold promise as an alternative form of treatment, laboratory studies show that the concentration of the drug reaching the mesotympanum together with the time it remains there would be critical in determining efficacy.[35] These variables remain difficult to control in a clinical setting.

Eosinophilic otitis media (EOM) has been defined as an intractable otitis media characterized by a highly viscous effusion containing eosinophils and high levels of immunoglobulin E. A pilot study found that long-term anti-IgE therapy produced significant benefits in patients. Larger clinical trials are awaited.[36]

Hearing aids

Hearing aids are highly effective for any conductive hearing loss depending upon the underlying sensorineural function, and should be offered as a form of treatment for hearing loss in adults with long-term OME.

Surgical treatment

Several studies have shown evidence for the short-term efficacy of ventilation tube insertion in adult OME. Unfortunately, once tubes extrude, the condition may return. Sade and Fuchs found that, in 50 adult ears treated with ventilation tube insertion, the majority reverted to the disease state within 3 months of tube extrusion.[37] Similar results have been reported in a more recent study.[38] The problems of infected ventilation tubes and chronic otorrhoea have led some authors to caution against the insertion of ventilation tubes (VTs) in patients treated for nasopharyngeal carcinoma.[21]

Different types of tube design and material are used depending upon the surgeon's intentions but all have a risk of long-term perforation. Recently, the subannular tube has been advocated as a method of reducing this risk.[39]

LASER MYRINGOTOMY

The use of a laser to produce fenestration of the tympanic membrane produces a short-term solution. A mean of 15–22 days for a functioning myringotomy has been reported.[40, 41]

MASTOID VENTS

Mastoid vents bypassing the need to perforate the tympanic membrane have been shown to have good long-term efficacy in chronic OME patients with significant atelectasis. In a multicentre trial of 23 subjects, 20 of the 23 vents were

still patent after 18 months and 18 of the 23 patients had improved hearing.[42]

LASER EUSTACHIAN TUBOPLASTY

Eustachian tuboplasty using a laser has been found to confer significant benefit on a small group of patients with OME when reviewed after a year. Practised as an outpatient technique under local anaesthetic, the authors reported it to be safe and well tolerated.[43]

BALLOON DILATATION OF THE EUSTACHIAN TUBES

Dilatation of the Eustachian tubes has been proposed as a treatment by some authors.[45] A recent meta analysis of studies to date which included 1155 patients in total concluded that the treatment offers short-term benefit in the majority of cases and medium to longer term benefit in a smaller number of patients.[45] There remains a need for large placebo controlled trials.

BEST CLINICAL PRACTICE

- ✓ Acute otitis media is diagnosed on symptom history and otoscopy. Pure-tone audiometry and tympanometry are not required.
- ✓ Otitis media with effusion in adults is uncommon. Treatment options, as described, should be discussed with the patient together with the attendant risks and benefits.

KEY POINTS

- Although relatively uncommon, AOM in adults is usually bacterial and is typically caused by the same organisms found in the paediatric form of the condition.
- Vascularity of the normal tympanic membrane should not be confused with the bulging red tympanic membrane seen in AOM.
- An unexplained middle ear effusion in an adult requires endoscopic visualization of the Eustachian tube entrance in order to exclude an obstructing lesion.
- Balloon dilatation of the Eustachian tubes may be an alternative treatment to ventilation tube insertion in adult OME.

CHAPTER 83

CHRONIC OTITIS MEDIA

George G. Browning, Justin Weir, Gerard Kelly and Iain R.C. Swan

SEARCH STRATEGY

A PubMed search was carried out using the search terms cholesteatoma, middle ear/ or mastoiditis/ or otitis media, suppurative/ or tympanic membrane perforation; randomized controlled trial; controlled clinical trial; randomized controlled trials/ random allocation/ double-blind method/ single-blind method. Comparative study/ exp evaluation studies/ follow-up studies/ prospective studies. Placebos/random. Limited to animal; limited to human; animal and human. An additional search for inactive squamous COM used the search terms: tympanic membrane and/or retraction.

DEFINITION

George G. Browning

The diagnosis of chronic otitis media (COM) implies a permanent abnormality of the pars tensa or flaccida, most likely a result of earlier acute otitis media, negative middle ear pressure or otitis media with effusion. COM equates with the classic term chronic 'suppurative' otitis media (CSOM) that is no longer advocated as COM is not necessarily a result of 'the gathering of pus'. However, the distinction remains between **active COM**, where there is inflammation and the production of pus, and **inactive COM**, where this is not the case though there is the potential for the ear to become active at some time. A third clinical entity is **healed COM** where there are permanent abnormalities of the pars tensa, but the ear does not have the propensity to become active because the pars tensa is intact and there are no significant retractions of the pars tensa or flaccida. 'Healed COM' can also be the end result of successful surgery. The differences are summarized in Table 83.1.

Our current ability to accurately assess an individual's ear, particularly with magnification, has made redundant the earlier, mainly anatomical, distinction between 'tubotympanic' and 'atticoantral' disease. The terms 'safe' and

'unsafe' are incorrect and misleading as complications can occur from any ear with active COM irrespective of its pathology.

PATHOLOGY

Justin Weir

INTRODUCTION

It is widely believed that COM often starts with episodes of acute otitis media (AOM) or otitis media with effusion (OME) in childhood. OME may lead to thinning of the tympanic membrane, hearing loss and delayed speech development, and it can impact on the child's educational development.[1] COM can be characterized histopathologically by middle ear pathology such as granulation tissue, cholesterol granulomas or cholesteatoma formation.[2]

Active COM is chronic inflammation of the middle ear and mastoid mucosa, with recurrent discharge (at least 2 weeks) through a chronic perforation of the tympanic membrane.[3] The World Health Organization (WHO) estimated that 65–330 million people worldwide are affected by CSOM, of whom 50% suffer from hearing impairment and approximately 28 000 deaths per annum are attributable to the complications of OM. Some of these figures have been confirmed by Monasta et al.[4] who recorded a CSOM incidence of 31 million cases globally. The highest incidence occurs in the first year of life (15.4 per thousand) and Oceania is the geographical area with the highest incidence (9.37 per thousand). They also found that OM-related hearing impairment has a prevalence of 30.8 per 10 000, and that 21 000 people died annually from complications of otitis media.

MOLECULAR PATHOLOGY

OM and COM are complex multifactorial diseases with no single genetic defect, which makes detection of those genes responsible for the disease process difficult to ascertain. Furthermore, it is likely that the multifactorial nature of this disease is in part due to innate immunity (toll-like receptors, cytokines, surfactant), adaptive immunity (immunoglobulins), non-specific immunity (epithelial barriers and mucin production), inflammatory regulation and craniofacial abnormalities. Towards the end of the last century several authors showed a genetic component to both AOM and OME.[5–7]

The exact molecular pathways by which persistent inflammation occurs are now beginning to be unravelled. OM is frequently caused by bacteria, which enter via the Eustachian tube, though sterile OM is not uncommon and the initiation of inflammation in this scenario is unclear. A number of murine models of OM have been developed[8] to resolve this conundrum and, in particular, two non-syndromic mouse models of COM have analyzed the heterozygous *Jeff*[9, 10] and *Junbo*[11] mutant mice.

Jeff carries a mutation in the F-box only protein 11 gene (*Fbxo11*) and *Junbo* a mutation on the zinc finger domain at the ecotropic virus integration site 1 (*Evi1*) gene. Both mutant models demonstrate hypoxia and hypoxia-inducible factor (HIF) mediated responses (more so in *Junbo* than *Jeff*).[12] HIF signalling is regulated at the transcriptional level by interactions with the master regulator of inflammation – nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) – and at the translational level by cytokines, which are glycoproteins produced by inflammatory cells and epithelial cells, such as interleukin-1 (IL-1β) and tumour necrosis factor alpha (TNF-α or TNFA) which induces the acute phase of the inflammatory response and releases other cytokines.[13, 14] Indeed, both IL-1β and TNF-α act synergistically and have similar functions in activating neutrophils, promoting fibroblast proliferation and stimulating prostaglandin and leukotrienes, all of which are important in the pathogenesis of OM.[15] NF-κB can be activated by a range of factors, other cytokines, including bacterial lipopolysaccharides, viral pathogens and growth factors.[16]

The downstream HIF signalling protein vascular endothelial growth factor (VEGF) has been shown to play a role in OME[17] and the link between HIF and VEGF was further investigated and confirmed by Cheeseman et al.[12] Essentially, hypoxia drives inflammation by activation of NF-κB, IL-1β and TNF-α and also increases angiogenesis,

TABLE 83.1 Classification of COM and synonyms used in this chapter

COM classification	Synonyms	Otoscopic findings
Healed COM	Tympanosclerosis; healed perforation	Thinning and/or local or generalized opacification of the pars tensa without perforation or retraction
Inactive (mucosal) COM	Perforation	Permanent perforation of the pars tensa but the middle ear mucosa is not inflamed
Inactive (squamous) COM	Retraction	Retraction of the pars flaccida or pars tensa (usually posterosuperior) which has the potential to become active with retained debris
Active (mucosal) COM		Permanent defect of the pars tensa with an inflamed middle ear mucosa which produces mucopus that may discharge
Active (squamous) COM	Cholesteatoma	Retraction of the pars flaccida or tensa that has retained squamous epithelial debris and is associated with inflammation and the production of pus, often from the adjacent mucosa

COM, chronic otitis media.

vascular permeability and recruitment of neutrophils through activation of VEGF. The introduction of tympanostomy tubes (grommets) alters the oxygen tension and this might be an important mechanism in the downregulation of HIF signalling.

The recruitment of inflammatory cells, whether neutrophils, mast cells, lymphocytes, plasma cells or monocytes/macrophages, is integral to the initiation and subsequent chronicity of OM.[15] Once inflammation is initiated, there is an accumulation of fluid and inflammatory cells in the middle ear cavity, causing conductive deafness and rarely secondary cochlear dysfunction through diffusion of cytokines through the round window.[18] Moreover, cytokines, such as TNF-α and IL-8, induce upregulation of mucin genes within the middle ear and the altered viscosity impairs mucociliary clearance.[15, 19] Both TNF-α and IL-8 can increase inducible nitric oxide synthase (iNOS) in the middle ear mucosa and nitric oxide stimulates mucin production.[20]

Fbxo11 and *Evi1* also interact with the transforming growth factor beta (TGF-β or TGFB) signalling pathway in mice[21] and in humans.[22] Tateossian et al.[23] identified a further link between TGF-β and COME in mutant TGF-β-induced factor homeobox 1 (*Tgif1*) mice, highlighting the importance of the TGF-β signalling pathway and its effects on the responses to hypoxia in the chronically inflamed middle ear. There is considerable crosstalk between TGF-β and HIF-1α pathways as both SMAD-3 (which is one of the many mediators of the TGF-β pathway) and HIF-1α are coactivators of VEGF expression.[24] Furthermore, TGF-β /SMAD signalling leads to downregulation of p38 by including MAPK phosphatase-1 and the subsequent suppression of the mucin protein MUC5AC,[25] resulting in the impaired mucociliary defence. Conversely, NTHi strongly induced upregulation of MUC5AC via activation of the Toll-like receptor 2-MyD88-dependent p38 pathway in a middle ear epithelial cell line.[25] In addition, *MUC5AC* rather than *MUC5B* or *MUC2* was shown to be associated with OME,[26] though this has been challenged by Preciado et al.[27] who showed that MUC5B is the predominant mucin in middle ear effusions from children with OME. However, Kerschner et al.[28] showed that the *MUC5AC* gene was upregulated by more than 150 times in OME samples compared with controls. Either way, the upregulation of mucins, whether by microbial pathogens, cytokines, growth factors, cigarette smoke[29] or gastric acid,[30] results in overproduction of mucin within the middle ear and the subsequent conductive deafness.

Toll-like receptors (TLR) are a group of pattern-recognition receptors that are involved in the innate immune system against microbial pathogens. In particular, Toll-like receptor 4 (*Tlr4*) responds to and recognizes the lipopolysaccharide (LPS) of Gram-negative bacteria such as nontypeable *Haemophilus influenzae* (NTHi), *Streptococcus pneumoniae* and *Klebseilla oxytoca*.[31] Thus, a lack of *Tlr4* results in a poor response to Gram-negative bacteria. The innate immune system is the first line of defence against invading pathogens and has been widely studied in OM.[32, 33] Several studies have shown that TNF-α is important in the regulation of inflammation in the middle ear. Downregulation of TNF-α results in the formation of mucosal polyps,[34] the lack of activation of TLRs and downstream proteins such as CC chemokine ligand 3 (CCL3) and the subsequent lack of recruitment of inflammatory cells.

The human homologues *FBXO11* and *TLR4* of the mouse genes *Fbxo11* and *Tlr4* have been investigated in genetic association studies of human OM. The Minnesota OME/rOM Family Study cohort looked at 142 families with 248 children diagnosed with recurrent or chronic OM.[35] They were genotyped using 13 single-nucleotide polymorphisms (SNPs) across the *FBXO11* gene[36] and a significant association with univariate but not multivariate analysis was found. However, in the larger Western Australian Family Study of Otitis Media, Rye et al.[22] found a significant association with two *FBXO11* polymorphisms on both univariate and multivariate analyses. Interestingly, *EVI1* was not associated with OM in three independent predominantly Caucasian cohorts,[22, 37] suggesting that this gene does not exert the same effect on OM susceptibility in humans as it does in mice.

In a Dutch population of 348 children aged less than 7 years with two or more episodes of AOM, Emonts et al.[38] found that there was a significant association at the *TLR4* D299G polymorphism with 'otitis-prone' (four or more episodes of AOM in the preceding year) when compared to 'non-otitis-prone' children (two to three episodes of AOM in the preceding year).

Genome-wide linkage studies have identified OM susceptibility loci at several regions of linkage on chromosomes 3p25, 10q22, 10q26, 17q12 and 19q13.[35, 39, 40] To date, the susceptibility genes underlying these linkage regions have not been mapped, though Casselbrant et al.[39] proposed a cluster of chemokine genes on 17q12 and several surfactant protein genes near 10q26, while Daly et al.[35] proposed *ADAM8* gene (a disintegrin and metalloproteinase domain), an allergy-associated gene, as a possible candidate for 10q22 linkage peak and Chen et al.[40] suggested potential candidate genes at 19q such as *ZNF71*, an endothelial zinc finger gene induced by TNF-α, and *ZNF304*, which activates lymphocytes.[41] Other candidate genes included members of the inflammasome protein complex which are key regulators of the innate immune response to harmful exogenous or endogenous stimuli.

In summary, the genetic studies, whether from mouse to human or vice versa, have highlighted the importance of regulating the pro-inflammatory and anti-inflammatory effects of pathogens. No doubt the next-generation sequencing methods such as exome sequencing and whole-genome sequencing will help to identify the candidate genes and clarify the molecular pathogenesis of this disease.[8]

EOSINOPHILIC OTITIS MEDIA

Eosinophilic otitis media is a relatively new subgroup of OM/COM which was first described in Japan.[42] It occurs mainly in patients with bronchial asthma who have T–helper type 2 dominant predisposition, and a patulous Eustachian tube which allows entry of

antigenic material into the middle ear resulting in an eosinophilic dominant inflammatory infiltrate.[43] IL-5 is one of the key cytokines in this entity as it has a direct chemotactic effect on eosinophil recruitment. In COM there can be either a simple perforation with a thick yellow viscous effusion or a proliferation of granulation tissue extending into the external ear canal which can often be intractable.

PATHOLOGY OF SUBTYPES OF CHRONIC OTITIS MEDIA

Inactive mucosal COM (dry perforation)

WHO includes inactive mucosal COM (dry perforation) under CSOM.

There is permanent perforation of the pars tensa but the middle ear and mastoid are not inflamed (Figure 83.1). The mucocutaneous junction is usually located at the margin of perforation which can extend up to the fibrous annulus.

Active mucosal COM (perforation with otorrhoea, CSOM)

There is chronic inflammation within the mucosa of the middle ear and mastoid with varying degrees of oedema, submucosal fibrosis, hypervascularity and an inflammatory infiltrate including lymphocytes, plasma cells and histiocytes (Figure 83.2). There is also an increase in the number of goblet cells and basal cell hyperplasia in the middle ear epithelium.[44] Granulation tissue can occur (Figure 83.3) and this is often clinically described as 'aural polyps' which have protruded through the perforated tympanic membrane. Some areas with active COM (both mucosal and cholesteatomatous subtypes) demonstrate focal areas of cholesterol granuloma formation, which microscopically consists of a giant cell reaction surrounding cholesterol clefts (Figure 83.4).

Chronic inflammation can affect the whole of the middle ear cleft including the mastoid antrum and some surgeons believe it is important when a perforation is repaired that the whole of the infected mucosa and granulation tissue from the mastoid and middle ear space is removed in order to control the disease. There is, however, no good evidence that this is necessary and many surgeons only close the perforation even in active disease (see role of adjuvant mastoidectomy in the discussion of management below).

Active mucosal COM is often associated with destruction of the ossicular chain.[45] The affected ossicles typically show areas of hyperaemia with proliferation of capillaries and prominent granulation tissue (Figure 83.5). The long process of the incus, stapes crura, body of incus and manubrium are involved in decreasing order of frequency. Bone resorption or destruction occurs by osteoclast activity. There are a number of bone-modelling molecules/proteins such as receptor activator NF-κB (RANK) and RANK ligand (RANKL) that are expressed in COM which can activate osteoclasts, whereas osteoprotegerin acts as an antagonist to RANKL.[46, 47] Kuczkowski et al.[45] also investigated the expression of TNF-α, IL-1α, IL-6 and IL-10 (an immunosuppressive regulator of acute inflammation) in COM with cholesteatoma formation and bone destruction and found a significant correlation with TNF-α, IL-1α and IL-6. IL-10 is a key anti-inflammatory cytokine and inhibits the production of TNF-α, IL-1, IL-6 and IL-8 as well as inhibiting macrophages and the production of oxygen radicals by neutrophils.[48]

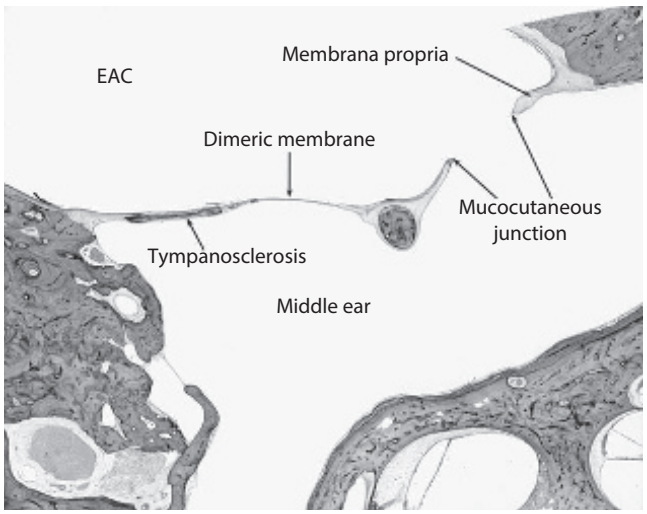

Figure 83.1 Axial temporal bone section from a 43-year-old man. There is a dry perforation of the anterior part of the pars tensa. The mucocutaneous junction is located at the margins of the perforation. The drum remnant anterior to the perforation shows fibrous thickening affecting its middle layer, the membrana propria. There is also a dimeric membrane and tympanosclerosis in the posterior part of the tympanic membrane. EAC, external auditory canal. (*Magnification ×13.*)

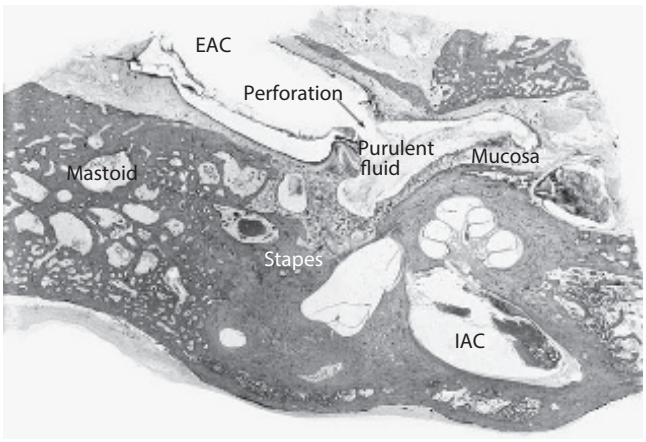

Figure 83.2 Axial temporal bone section from a 77-year-old woman with active mucosal COM. There is a perforation of the pars tensa anterior to the manubrium. The middle ear mucosa is markedly thickened with hypervascularity and active chronic inflammation. There is purulent fluid in the tympanic cavity that is draining through the perforation. The mastoid air cells also show chronic inflammation. EAC, external auditory canal. IAC, internal auditory canal. (*Magnification ×4.*)

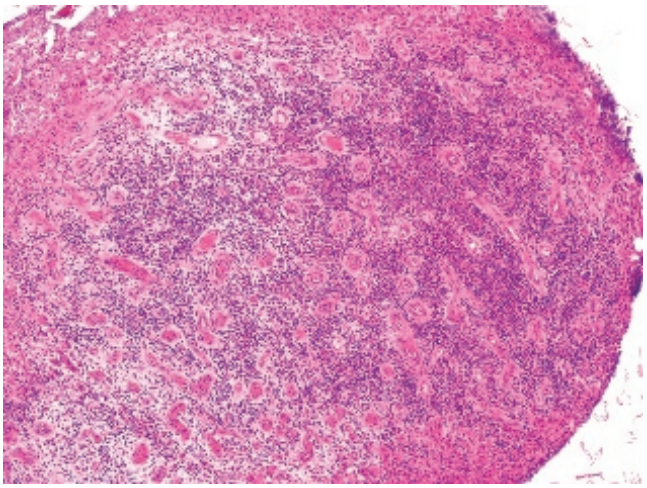

Figure 83.3 Granulation tissue consisting of numerous blood vessels and an inflammatory infiltrate of neutrophils, lymphocytes and plasma cells. (*Magnification ×100.*)

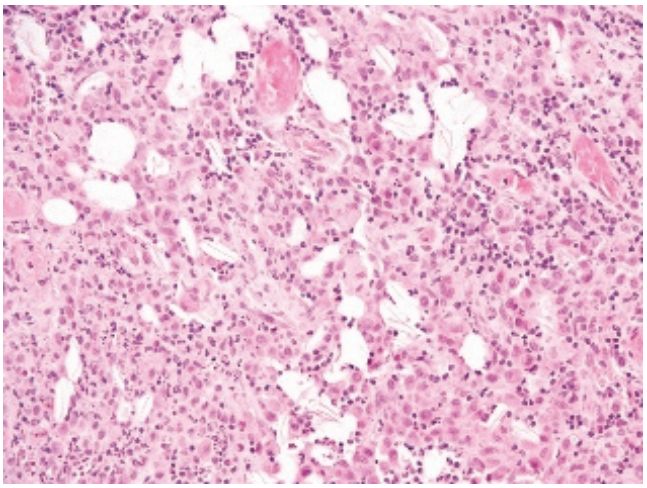

Figure 83.4 Cholesterol clefts (++) surrounding flakes of keratin. Around the cholesterol clefts are numerous macrophages as well as the smaller lymphocytes and neutrophils. (*Magnification ×200.*)

It most likely contributes to the elimination of middle ear inflammation and provides a negative feedback mechanism to the pro-inflammatory effects of TNF-α.

Bacteria also play a role in the bone destruction seen in COM and infected cholesteatoma. Nason et al.[49] showed that *Pseudomonas aeruginosa* LPS (the main antigenic component of the bacterial cell wall) stimulates RANKL-primed precursor osteoclasts into bone-resorbing osteoclasts by an autocrine/paracrine mechanism involving at least 11 cytokines including TNF-α, IL-1α, IL-1β, IL-9 and IL-10, granulocyte-colony stimulating factor (G-CSF), monocyte chemotactic protein-1 (MCP-1) and macrophage inflammatory protein (MIP-1α) among others.

Inactive squamous epithelial COM (retraction, atelectasis and epidermization)

Negative static middle ear pressure can result in retraction (atelectasis) of the tympanic membrane. A 'retraction pocket' consists of an invagination into the middle ear space of part of the tympanic membrane and this may be **fixed**, when it is adherent to the structures in the middle ear, or **free**, when it can move medially and laterally depending on the state of inflation of the middle ear. 'Epidermization' is a more advanced type of retraction and refers to replacement of the middle ear mucosa by keratinizing squamous epithelium without retention of keratin debris.[50]

Active squamous epithelial COM (acquired cholesteatoma)

Cholesteatoma is a benign keratinizing epithelial-lined cystic structure found in the middle ear and mastoid (Figure 83.6). It can cause destruction of the local structures – ossicular chain and otic capsule, thereby

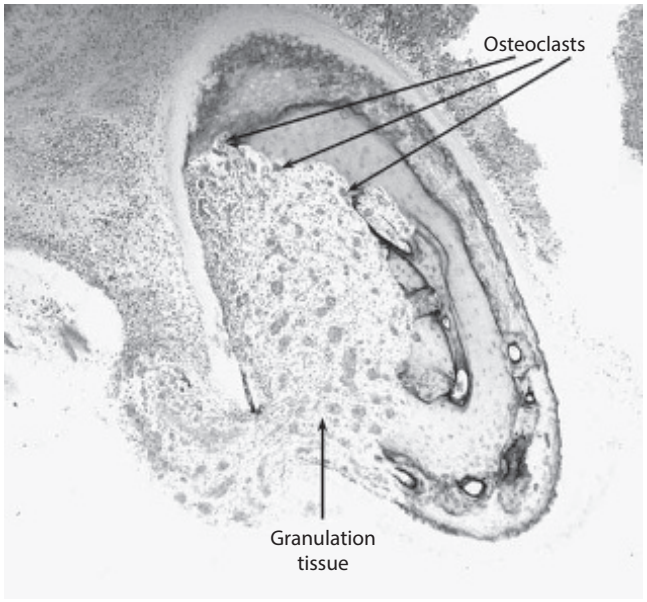

Figure 83.5 High-power view of cross-section of manubrium from a 23-year-old woman with active mucosal COM, showing resorptive osteitis with replacement by granulation tissue. (*Magnification ×81.*)

leading to complications such as hearing loss, vestibular dysfunction, facial paralysis and intracranial disease or infection. The term 'cholesteatoma' was first coined by the German physiologist Johannes Muller in 1838.[51]

The annual incidence of cholesteatoma was found to be approximately 3 per 100 000 in children and 9.2 per 100 000 in an adult Caucasian population in Northern Europe.[52, 53] There is variability of prevalence across racial types, however, with Inuit Eskimos having a significantly lower rate, of 5 per 100 000.[54] Moreover, an Australian study of Aboriginal children and adults reported a low incidence of cholesteatoma (1–3%) compared to higher rates of COM (25–45%), suggesting that the anatomical location of the perforation may have a bearing on the development of a cholesteatoma.[55]

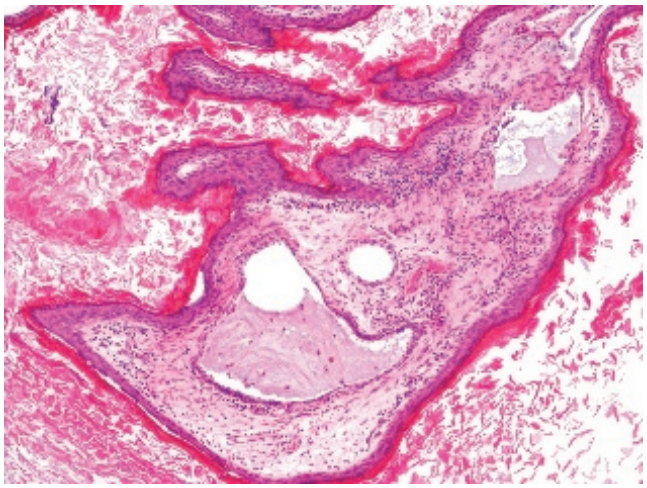

Figure 83.6 Cholesteatoma consisting of keratinizing squamous epithelium. In the submucosa there are a few dilated glands (+) containing mucus. (*Magnification ×100.*)

The pathogenesis of cholesteatoma is due either to the retraction of Shrapnell's membrane (pars flaccida) or the posterior superior quadrant of the pars tensa, or to retraction of the entire pars tensa[56, 57] – the so-called 'retraction pocket theory' first described by Bezold in 1890.[58] This was developed by Sudhoff and Tos[59] who proposed a combined retraction and proliferation model. Key to this theory is Eustachian tube dysfunction which leads to retraction of the pars flaccida into the epitympanum, and subsequent cholesteatoma formation.[60, 61]

A number of other theories relating to the pathogenesis of cholesteatoma, in addition to the retraction pocket theory, have been proposed:[56]

- **basal cell hyperplasia:** proliferation of papillary cones in the basal layer of the squamous epithelium of the pars tensa or flaccida
- **immigration:** based on the ingrowth of squamous epithelium through a pre-existing perforation
- **metaplasia:** of colonies of epithelial cells in the middle ear from cuboidal to keratinizing squamous epithelium.

Cholesteatoma can also be classified according to its topology. Thus, attic cholesteatoma is a mixture of retraction and papillary proliferation as proposed by Sudhoff and Tos,[59] whereas sinus cholesteatoma is a posterosuperior retraction or perforation of the pars tensa extending to the tympanic sinus, posterior tympanum and beyond. Tensa cholesteatoma is retraction and adhesion of the entire pars tensa and may involve the tympanic orifice of the Eustachian tube. On occasions it may result in an acquired epidermal remnant behind the intact tympanic membrane. The pathogenesis of such a remnant remains elusive, but it is thought to develop either from a resolved retraction of the pars tensa, where residual squamous epithelium remains in the middle ear cavity, or from an ingrowth of meatal squamous epithelium.[59, 60] Of note, those individuals who have a perforation of the tympanic membrane rarely have a cholesteatoma on the posterior superior quadrant of the pars tensa or in the pars flaccida.[1]

Recently, Yamamoto-Fukuda et al.[62] performed an elegant study using a hybrid gerbil model to demonstrate that the epithelial cells in cholesteatoma are derived from the tympanic membrane and not from the epithelial cells within the middle ear or epithelium from the external auditory canal. Indeed, the molecular pathology of cholesteatoma has been investigated by a number of authors. Using DNA chip analysis, 282 genes were found to be differentially expressed in comparison to the control samples[63] and Klenke et al.[64] identified 3558 new cholesteatoma-related transcripts. Of those, 811 were upregulated and 334 downregulated more than twofold. The genes involved are found in a number of different biological processes including signal transduction, cell growth, cell communication, metabolism, transport and the immune response. Hamajima et al.[65] determined the role of inhibitor of DNA-binding (Id1) in the proliferation of cholesteatoma keratinocytes. They found that Id1, a protein that leads to cell immortalization, induces up regulation of NF-κB/cyclin D1/keratin 10 in the keratinocytes. The authors concluded that Id1 contributed to the thickening of the middle ear mucosa, cell cycle progression and removal of cell cycle inhibition.

The role of keratinocyte proliferation has also been described in animal models of cholesteatoma[66] and in humans the proliferation rate of cholesteatoma in comparison to external auditory skin has been investigated and been shown to be 2.3 times higher.[67] More detailed studies on keratinocyte proliferation including the *p53* tumour suppressor gene, c-jun and c-myc protein were all found to be upregulated in cholesteatoma.[56, 68, 69] This is coupled with the increased apoptotic rate of cholesteatoma leading to the accumulation of keratinous debris.[70, 71]

Others, such as Huisman et al.[72] have explored the function of TGF-β in cholesteatoma from 12 patients. They ascertained that, while TGF-β is not upregulated in the keratinocytes, it is upregulated in the stroma. They concluded that cholesteatoma behaves as a chronic wound healing process. Further support for this argument has been provided by Lee et al.[73] who demonstrated an increased expression of some pattern recognition receptors (PRRs) mRNA including those encoding for TLRs, TLR-2, -3, -4, -6, -7 and -10, and nucleotide-binding oligomerization domain-containing protein 2 (NOD-2). PRRs, which recognize conserved microbial structures, activate the innate immune system and the activation of TLRs lead to the mobilization of cytokines, chemokines and interferons as well as proteases, defensins, collectins, lysozyme and lactoferrin.[74] Furthermore, downstream mediators of inflammation such as IL-1 and IL-8 were also upregulated. Indeed, TLRs can induce NF-κB as well as TNF-α.[75]

The interplay between the epithelium of cholesteatoma and the surrounding stroma is key to understanding its destructive effects. There are defects in the regulation of epidermal growth factor receptor (EGFR) system,[76]

as well as IL-1 and TGF-α[77] – all important factors in the inflammatory process. Furthermore, TGF-α has been shown to upregulate matrix metalloproteinase-9 (MMP-9),[78] which has been demonstrated to cause bone destruction.[79]

The inflammatory nature of cholesteatoma has gained credence and some authors believe that inflammation rather than retraction is the precursor event required for acquired cholesteatoma formation:[80] when a perforation has occurred, the normal epithelial migration on the external aspect of the tympanic membrane is altered, resulting in a proliferation of squamous epithelium through the perforation into the middle ear cavity. If infection intervenes, migration ceases and squamous hyperplasia with the resultant keratin formation commences, leading eventually to the formation of a cholesteatoma.[60] However, as noted, perforations per se are not often associated with cholesteatoma and it may well be that there are different pathological processes involved in the formation of cholesteatoma secondary to perforated tympanic membranes compared to cholesteatoma derived from an intact tympanic membrane.

In the rare instances of cholesteatoma occurring behind an intact tympanic membrane it has been shown that the cholesteatoma is derived from the tympanic membrane.[62] Whether it is due to a hyperproliferation of squamous epithelium which forms protrusions into the tympanic cavity and, with repeated bouts of chronic inflammation, these turn into cholesteatoma,[72, 81] or whether there is a proliferation of squamous cones or papillary ingrowths from the epidermal basal layer within the retraction pockets[57] remains to be determined.

Healed chronic otitis media

Jensen et al.[82] observed a 39% spontaneous healing rate among a long-term population-based cohort of Greenlanders. Of those healed ears, circular atrophy indicating a healed perforation was the commonest finding. The presence of circular atrophy can lead to a higher risk of reperforation from further episodes of AOM or barotraumas. De Beer et al.[83] followed up 358 subjects from a birth cohort with and without OM histories and/or ventilation tube insertion. They found that at 8 and 18 years of age the prevalence of abnormalities (tympanosclerosis, atrophy, atelectasis, pars tensa retraction pockets and pars flaccida retraction) fell from 92% to 46%. By 18 years of age, many of the tympanic membrane abnormalities had completely resolved, though the prevalence of tympanosclerosis remained high in those treated with tubes.

In OME the tympanic membrane can be damaged by matrix metalloproteinases within the effusion.[84] Tympanosclerosis develops in the lamina propria between the epidermis and mucosal epithelium. It consists of hyaline deposits of acellular material visible as white plaques and white nodular deposits. Pathologically, these hyaline deposits are composed of thickened collagen fibres I, II and III admixed with calcium phosphate deposits[50] and over time osseous metaplasia can occur. Tympanosclerosis surrounding the ossicles in the epitympanum and the stapes superstructure or footplate in the oval window causes varying degrees of immobility of the ossicular chain and it is a well-recognized adverse factor in tympanoplasty (**Figure 83.7**).

PATHOLOGY OF COMPLICATIONS OF CHRONIC OTITIS MEDIA

Routes of spread of infection

The prevalence rates for the extracranial and intracranial complications of COM have been reported as ranging between 0.69% and 5%.[85–87] The most common extracranial complication remains a mastoid abscess. In cases with both extra- and intracranial complications, cholesteatoma was frequently found in the middle ear and mastoid cavity. Facial nerve paralysis can complicate OM in the absence

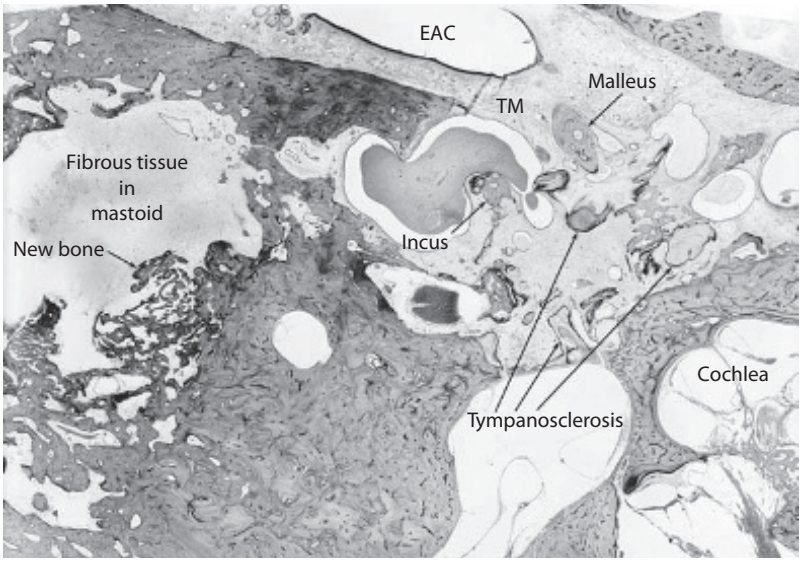

Figure 83.7 Axial temporal bone section from a 77-year-old man with healed COM. The tympanic membrane (TM) is markedly thickened due to proliferation of fibrous tissue. The middle ear and mastoid spaces have been overrun by fibrosis and cyst formation ('fibrocystic sclerosis'), as well as deposition of new bone ('fibro-osseous sclerosis'). There are extensive deposits of tympanosclerosis within the middle ear. It is very difficult to restore hearing by tympanoplasty surgery in such cases of end stage pathology. EAC, external auditory canal. (*Magnification ×9.*)

of cholesteatoma. Patients with COM and cholesteatoma were more likely to develop complications than those with just COM.[86] The most frequently isolated pathogen from ear swabs was *Proteus mirabilis* in 33.3% of cases.

Ibrahim et al.[88] analyzed the incidence of meningitis secondary to suppurative OM in adults. They found that acute and chronic suppurative OM accounted for 13% and 3% of cases of meningitis respectively and calculated that the incidence of otogenic meningitis was 0.42 per 100 000 per year.

Labyrinthine fistula

Labyrinthine fistula can be caused by active mucosal COM or cholesteatoma. The lateral semicircular canal is the most commonly affected site and the reported incidence of fistula formation is 4–13% of all cases.[89] Histologically, cholesteatoma matrix or granulation tissue becomes apposed to the endosteum of the inner ear or directly to the membranous labyrinth. In many fistulae reactive inner ear changes are absent thus a protective walling off phenomena appears to occur (**Figure 83.8**). The margins of some labyrinthine fistulae show evidence of new bone formation and this probably explains the clinical observation that many fistulae show spontaneous bony closure after removal of the offending cholesteatoma or granulation tissue.

Labyrinthitis

Labyrinthitis, whether serous or suppurative, can cause sensorineural hearing loss by affecting various cochlear structures including the hair cells, spiral ganglion cells and striae vascularis. Adams[90] demonstrated that the type I fibrocytes within the spiral ligament expressed NF-κB, which may alter the function of the ion channels within the spiral ligament, resulting in hearing impairment. Suppression of cochlear NF-κB activity by steroids before antibiotic treatment may suggest a role for steroid therapy in recovering from sensorineural hearing loss although there is no evidence for their efficacy in clinical practice.

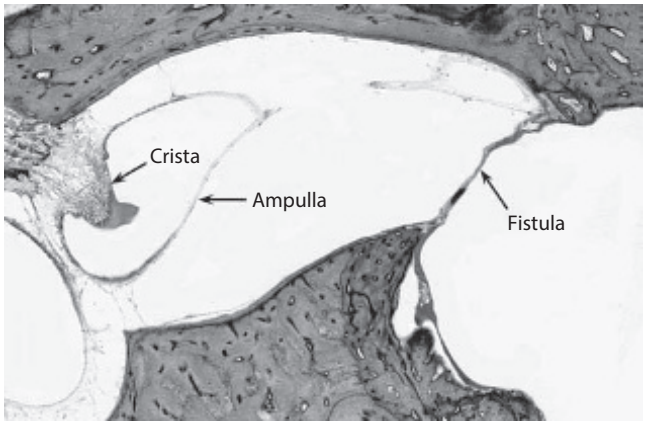

Figure 83.8 High-power view of temporal bone section from a 76-year-old woman with active mucosal COM that resulted in resorption of bone over the lateral semicircular canal with resulting fistula. Only the endosteum separates the perilymphatic space from the middle ear space. Note the absence of reactive inner ear change at or adjacent to the fistula site. (*Magnification ×34.*)

Facial nerve paralysis

The frequency of facial nerve paralysis ranges from 0.16% to 2.62%.[87, 91, 92] Granulation tissue and/or cholesteatoma may cause facial nerve paralysis with a dehiscent or eroded bony facial canal.[92] The nerve and surrounding vascular plexus can become inflamed and swollen and result in degeneration of the axonal fibres. Of note is the fact that the prognosis of the paralysis is worse in COM than in paralysis from trauma, Bell's palsy or AOM.[92]

Otogenic intracranial complications

Although death from intracranial complications of COM has decreased in the developed world,[93] it still remains problematic in developing countries,[94] where Dubey et al. reported a mortality rate of 31.2% in their series. Intracranial complications include meningitis, otitic hydrocephalus, lateral sinus thrombosis, cavernous sinus thrombosis and intracranial sepsis (e.g. extradural, epidural, subdural, perisigmoid sinus and cerebral abscess formation).[87, 91, 95] The routes of infection are via osteitis of the mastoid or temporo-occipital bone, resulting in thrombophlebitis of the venules with or without bone erosion, or by thrombosis of the sigmoid sinus by infected cholesteatoma.[94]

Hearing loss

COM can produce inflammatory changes at the round window and inflammation in the adjacent scala tympani.[96] This can rarely result in loss of both inner and outer hair cells in the basal turn as well as a reduction in the area of the stria vascularis leading to sensorineural hearing loss. The pathogenesis of the inner ear inflammation has been linked to the spiral ligament fibrocytes (see 'Labyrinthitis' above) which release chemokines in response to the middle ear pathogens, in particular monocyte chemoattractant protein-1 (MCP-1/CCL2).[97] Using the C3H/HeJ mouse model which lacks the gene for TLR4, MacArthur et al.[98] observed disruption of inner ear ion and water transport functions as well as alteration in tissue remodelling genes. As many of these channels and transporters are located on the lateral wall of the cochlea, both endolymph production and maintenance are at risk when COM occurs.

AETIOLOGY AND EPIDEMIOLOGY

Gerard Kelly

PREVALENCE OF CHRONIC OTITIS MEDIA

The prevalence of adult middle ear disease in the British population was obtained from the UK National Study

of Hearing,[99] a prospective clinical study of a randomly selected UK population (Table 83.2). An otoscopic diagnosis was made in over 2000 individuals. The overall prevalence of healed, inactive and active COM was 11.9%, 2.6% and 1.5% respectively. The prevalence of active and inactive COM was 4.1%, with 3.1% of individuals having unilateral and 1.0% bilateral disease.

The UK National Study of Hearing[99] also examined the relationship between COM and age, sex and socioeconomic group. There was no sex difference in the prevalence of COM.

Individuals in the age group 41–80 years were twice as likely to have COM as those in the age group 18–40 years. COM has a higher prevalence in lower socioeconomic groups, with manual workers having twice the prevalence of non-manual workers.

Unfortunately, in this study, it was not possible to separate patients with COM into those with mucosal and those with squamous disease. Surgical data is all that is available to give the relative frequencies of mucosal and squamous disease.

Alho et al.[100] reported the rates of surgery in the general population in 1992. The surgery rates were 13 per 100 000 for inactive COM, 7 per 100 000 for active mucosal disease and 4 per 100 000 for active squamous disease. These figures clearly underestimate the true incidence of this disease in the population as not all patients with COM will be seen by a physician or undergo surgery. A similar study[101] identified an incidence of chronic squamous otitis media to be 9.2 per 100 000, with a bilateral incidence of 4.4% within this subgroup. This study showed no socioeconomic difference in incidence; however, unlike the UK National Study of Hearing, these individuals were not randomly selected but presented with ear symptoms and therefore the sample may have been biased with patients in higher socioeconomic groups being more inclined to seek medical intervention.

AETIOLOGY OF CHRONIC OTITIS MEDIA IN GENERAL

Acute otitis media and otitis media with effusion

Both childhood AOM and OME can cause long-term changes of the tympanic membrane.[102] Histological degeneration of the tympanic membrane occurs in the outer and inner fibrous layers of the lamina propria and in the submucosal layer.[103] These changes may reduce the elastic properties of the tympanic membrane making it more susceptible to chronic perforation or retraction. Cases of adults acquiring COM are not uncommon but, again, this could be the result of adult episodes of AOM.

Why some individuals progress from AOM to COM is not clear but the risk factors for this occurring are likely to include some of those for AOM and OME. What is required is for one of the cohorts of children that have been studied for OM to be followed up into adulthood. Unfortunately, none has yet been reported. An alternative is to study a group of adults with COM and record risk factors in comparison to a group of adults that do not have COM. In this type of study a multifactorial analysis would be required. The only study in this category was the

TABLE 83.2 Population prevalence (%) of adult chronic otitis media.[99] The 95% confidence intervals are in parentheses

	Healed otitis media	Inactive chronic otitis media	Active chronic otitis media
Overall	11.9 (10.2, 13.6)	2.6 (1.8, 3.4)	1.5 (1.1, 1.9)
Age (years)			
18–40	10.1 (8.6, 14.4)	2.5 (1.0, 4.0)	0.9 (0.2, 1.6)
41–60	11.5 (9.3, 13.7)	2.1 (1.2, 3.0)	2.1 (1.3, 2.9)
61–80	16.2 (12.8, 19.6)	2.7 (1.6, 3.8)	2.1 (1.3, 2.9)
Sex			
Male	12.6 (9.8, 15.4)	2.8 (1.4, 4.2)	1.9 (1.1, 2.7)
Female	11.3 (9.3, 13.3)	2.4 (1.7, 3.1)	1.2 (0.8,1.6)
Occupation			
Manual	13.5 (11.0, 16.0)	3.3 (2.3, 4.3)	2.2 (1.5, 2.9)
Non-manual	10.1 (7.7, 12.5)	1.9 (0.8, 3.0)	0.8 (0.4, 1.2)

UK National Study of Hearing and the factors included in this were limited to those in Table 83.2. This leaves studies that report on single factors as the highest level of evidence available for these factors.

Genetics and race

The incidence of COM varies in different populations and, in the developed world, is highest in Eskimos, American Indians, New Zealand Maoris and Australian Aborigines.[104] It appears that the prevalence of COM, at least in populations predisposed to it, is declining. In one study of New Zealand Maori children,[105] the prevalence of COM decreased significantly from 9% in 1978 to 3% in the corresponding months of 1987 ($p < 0.02$).

It is difficult to answer the question of whether genetic factors influence COM because of confounding variables such as low socioeconomic grouping of some genetic groups with a high incidence of COM. It is known, however, that there is a high incidence of COM in American Indians, and this incidence varies considerably among different tribes of American Indians, a finding that is likely to have a genetic basis.[106] In a prospective population-based, 2-year cohort study on the incidence of both active and inactive COM in a high-risk Greenlandic population,[107] being of Inuit descent was identified as a risk for the condition, with a HR of 5.56.

In a review of COM in developing countries[108] high levels of COM were noted in some countries, but rates varied considerably. This is likely to be due to population characteristics and environmental factors rather than antibiotic usage.

Environment

As has already been stated, the prevalence of COM is greater in lower socioeconomic groups. The reason for this is multifactorial. In a cohort study, with results on 12 000 children[109] factors significant for ear discharge (although not necessarily COM) were general health scores, maternal smoking and day-care attendance. While sometimes quoted as a factor, the effect of breastfeeding was weak and did not show statistical significance. The decrease in prevalence of COM in New Zealand Maori children from 1978 to 1987 is thought to be due to improvement in both health care and housing conditions.[105] In Koch's prospective population-based 2-year cohort study[107] on the incidence of both active and inactive COM, identified risk factors included: attending childcare (hazard ratio (HR) = 3.18) and household smokers (HR = 4.56).

Eustachian tube dysfunction and upper respiratory tract infections

Eustachian tube dysfunction is more common in patients with COM than in individuals free from middle ear disease.[110] It is not known, however, if the Eustachian tube dysfunction is the initiating factor in COM or whether it is a result of COM. Koch et al.[107] also showed that upper respiratory tract infections (URTIs) increased the risk of COM, but whether URTI is an independent risk factor in COM was unclear and, whereas there are many studies which examine the relationship with AOM and URTIs, studies which examine this relationship with COM are scant.

Gastro-oesophageal reflux disease (GORD)

There has been interest in the role of GORD in ear disease but only anecdotal evidence exists that there may be a relationship between GORD and COM.[111] A systematic review concluded that there may be a higher prevalence of GORD in children with OME and recurrent AOM and that the presence of pepsin or pepsinogen in the middle ear could be related to physiologic reflux, although a cause and effect relationship was unclear.[112]

Craniofacial abnormalities

The incidence of COM in cleft palate patients followed up to 10 years of age is around 20%, with 2% of them having a cholesteatoma.[113] The tensor veli palatini muscle is hypoplastic in cleft palate children and may predispose to Eustachian tube dysfunction.[114]

Autoimmune disease

It is not known if autoimmune disease predisposes to COM. In one study, however,[115] COM was present in 29% of consecutive patients with ankylosing spondylitis.

Immune deficiency

AIDS is associated with higher levels of COM compared to the human immunodeficiency virus (HIV)-negative population. This had been suggested[116] and was the subject of previous debate, although it was known that AIDS could present as aural polyps due to *Pneumocystis carinii* infection.[117] Higher-level evidence has been presented[118] in a case control study of children in Sub-Saharan Africa (Angola) which found a rate of active COM of 26% in HIV-positive children versus less than 4% in the HIV-negative group (with similar findings of dry tympanic membrane perforation rate of 9% versus 1% and bilateral hearing loss of >25 dB of 13% versus 1% in the HIV-positive versus HIV-negative groups). Antiretroviral treatment is associated with a lower prevalence of COM in HIV-infected individuals.[119]

FACTORS INFLUENCING ACTIVITY OF CHRONIC OTITIS MEDIA

Infection

The mucopus removed from ears with active COM is rarely sterile.[120] Microbiology cultures frequently yield multiple organisms and these vary depending on climate, patient population and whether antibiotics have or have

not been used recently. Studies therefore report different isolates in differing proportions. In a prospective study of patients whose active ears were swabbed and cultured in the clinic,[121] 64% cultured only aerobes, 32% both aerobes and anaerobes, and 5% had no growth. In those with aerobes (Table 83.3) most ears had several isolates with a mean of 2.5 different aerobes. None of the patients in this study had been treated with oral or topical antibiotics for the previous 4 weeks.

There is debate about whether the presence of a cholesteatoma influences microbiological findings. Some studies have shown no difference in the microbiological cultures between squamous epithelial disease and mucosal disease[121] whereas other studies have suggested that *Pseudomonas* is less common in squamous epithelial disease.[122] It seems obvious and logical to assume that the activity of the ear in COM would be caused by pathogenic organisms. However, cultures from almost 50% of patients with inactive COM yield an identical flora to that found in active COM.[120] Furthermore, although anaerobes can be isolated from 32% of ears, their elimination by metronidazole does not cause the ear to become inactive.[123] *Pseudomonas aeruginosa* is infrequently found in the normal ear and rarely initiates acute infection. *Pseudomonas* is ubiquitous in our physical environment and has a predilection for moist areas. It is thought to infect tissues first by adherence to epithelial cells by means of pili or fimbriae.[124] In common with *Pseudomonas* infections in other sites of the body, normal tissues usually resist such attachment, unless there is cellular injury such as in chronic lung disease in cystic fibrosis. This phenomenon of 'opportunistic adherence' may represent an important step in the pathogenesis of middle ear infections as it does in respiratory infections. Thus it could be argued that the bacteria in COM are secondary invaders with the mucosal inflammation caused by other factors.

Biofilms

Bacteria preferentially exist in complex, surface-attached organizations known as biofilms which confer advantages over their planktonic counterparts and express markedly different phenotypes. Biofilm bacteria have greater antimicrobial resistance and host defences and can best be thought of as 'self-assembling multicellular communities'. These biofilms are important in chronic infections. Studies to examine the presence of biofilms in active COM have shown a 60% biofilm incidence as opposed to 10% in the control, uninfected group.[125] Biofilms are more abundant in squamous OM,[126] where 82% of cholesteatoma ears were found to have biofilms as opposed to 42% of the mucosal COM and 9% of the control, normal middle ear (cochlear implant) group.

TABLE 83.3 Aerobic bacteria isolated from patients with active COM who had had no antibiotic therapy in the previous 4 weeks; *n* = 83 (from Sweeney et al.)[120]

Bacteria	Number of isolates	% ears
Proteus spp.	79	95
Staphylococcus aureus	33	40
Pseudomonas spp.	25	30
Coagulase-negative staphylococci	24	30
'Coliform' bacilli	21	25
Other*	23	28
Total	**205**	

* Other includes *Corynebacterium* spp., *Escherichia coli*, *Streptococcus faecalis*, *Streptococcus pyogenes*.

Upper respiratory tract infections

Although many patients report activity of COM with a URTI, this has not been examined scientifically. URTIs produce transient Eustachian tube dysfunction in healthy individuals[127] and, as the respiratory mucosa of the Eustachian tube continues into the middle ear, this may become infected, resulting in activity of the mucosa either primarily or secondary to bacterial superinfection.

AETIOLOGY OF CHRONIC MUCOSAL OTITIS MEDIA

It is generally believed that mucosal COM arises from an episode of AOM where, after rupturing, the tympanic membrane fails to heal. Before immunization was practical, COM resulting from a single infection of measles was common, and it has been shown that acute measles may cause severe necrotizing otitis media.[128] A permanent perforation of the pars tensa can also result from the insertion of a ventilation tube in the tympanic membrane, which fails to heal. Long-stay ventilation tubes (T tubes) increase the risk of this occurring over simple grommets, with a perforation resulting in 2.2% of children treated with grommets compared with 16.6% treated with T tubes. The relative risk of long-term ventilation versus simple grommets was 3.5 (CI 2.6, 4.9).[129]

If COM is a sequela of AOM, the predisposing factors of AOM and COM should be the same. If there is a small but tangible risk of the tympanic membrane failing to heal after an episode of AOM, the number of attacks of AOM would increase the risk of COM developing, the risk of perforation being cumulative with each acute infection. There is evidence that the number of siblings, the type of day care, sex, duration of breastfeeding, maternal socioeconomic class and prematurity are all independent factors in the development of AOM in the first year of life (Table 83.4)[130] It would seem reasonable to assume that these factors are likely to be associated with the development of COM and there is evidence of association of some of these factors with COM (see above).

AETIOLOGY OF CHRONIC SQUAMOUS EPITHELIAL OTITIS MEDIA (CHOLESTEATOMA)

There is general acceptance of the theory that OME predisposes to chronic retraction of the pars tensa or flaccida and that this subsequently progresses to cholesteatoma.

TABLE 83.4 Variables associated with the parental report of acute otitis media during the first year of life, when the preceding variables have been taken into account, with the respective odds ratio[130]

Variable		Odds ratio	95% confidence interval
Number of siblings	≥3 vs 0	2.5	1.9, 3.4
	1–2 vs 0	2.0	1.3, 2.9
	≥3 vs 1–2	1.3	1.0, 1.7
Type of day care outside home vs at home		1.6	1.4, 1.9
Male vs female		1.3	1.2, 1.5
Duration of breastfeeding (months)	<3 vs ≥9	1.5	1.2, 1.8
	3–5 vs ≥9	1.4	1.3, 1.6
	6–8 vs ≥9	1.3	1.1, 1.5
Maternal socioeconomic status	Class 3 vs class I	1.8	1.3, 3.1
	Class 2 vs class 1	1.7	1.2, 2.3
	Class 3 vs class 2	1.1	1.0, 1.2
Prematurity yes vs no		1.4	1.1, 1.8

In a retrospective study of almost 46 000 Australian children who had a ventilation tube (VT) insertion operation,[131] 460 children developed cholesteatoma. The cumulative percentage of children who developed cholesteatoma within 15 years after one VT was 0.9%, after two VTs it was 2.1%, after three VTs it was 3.8%, and after four or more VTs it had risen to 5.2%. The rate of developing cholesteatoma increased 10% for each additional year in age before the first VT. For children who underwent two or more VTs, the rate of cholesteatoma increased 21% with each additional year between VTs. Adenoid removal was associated with a 27% reduction in the rate of developing cholesteatoma. This study concluded that 'children with persistent or refractory middle ear disease who required multiple VTIs were at increased risk of cholesteatoma'. First VTs inserted at an early age, subsequent VTs inserted without delay, and adenoid removal were associated with a reduced rate of cholesteatoma development.

VTs are not a panacea for cholesteatoma prevention but their use by aerating the middle ear may play a part in the reduction of cholesteatoma rates, perhaps by preventing retraction. Even if this is the case, why some cases of retraction progress and others do not is uncertain. Several other factors in cholesteatoma genesis have been postulated including the following.

Squamous metaplasia

There has been long-standing debate over the aetiology of chronic squamous epithelial OM. One theory suggests that cells from which a cholesteatoma arise originate from metaplasia of the middle ear mucosa. Another theory suggests that a cholesteatoma arises from the skin of the tympanic membrane. Although squamous metaplasia of respiratory epithelium occurs in the lower respiratory tract, it is unlikely to be a source of middle ear cholesteatoma. The best evidence suggests that cholesteatoma arises from skin cells of the tympanic membrane. All cells contain a cytoskeleton made from filaments comprised of protein subunits. The cytokeratins are a family of these proteins found in epithelial cells and middle ear cholesteatoma has a cytokeratin pattern typical of skin and closely resembling skin of the external auditory meatus.[132] Cholesteatoma sacs are found in close proximity to the tympanic membrane and are not encapsulated but are connected to the tympanic membrane by a neck of invaginated squamous epithelium, and the tympanic membrane appears to follow progressive changes from normal to retraction pockets and then to cholesteatoma.[133] This inference in the progression to cholesteatoma comes from histological studies of temporal bones. A large cohort study is needed to identify if there is a real progression from normal to retraction pockets and then to cholesteatoma. This would require subjecting thousands of children to otoscopic examinations for many years, and until this study is attempted the question of whether retraction pockets form cholesteatomas is unanswered.

Misplaced epithelium

If cholesteatomas are derived from the skin of the tympanic membrane, there are various ways in which this skin might become trapped in the middle ear and mastoid. Cholesteatomas may form from retraction pockets, from papillary ingrowth through the tympanic membrane, from ingrowth of squamous epithelium through a perforation or from implantation of squamous epithelium in the middle ear.

Cholesteatomas are most likely to arise from a retraction pocket in the pars flaccida or the posterosuperior part of the pars tensa and the initiating factor is probably dysfunction of the Eustachian tube resulting in negative middle ear pressure. Because of their greater blood supply compared with the rest of the tympanic membrane, the pars flaccida and the posterosuperior quadrant of the pars tensa are more affected by inflammatory cell infiltration in AOM and in OME.[134] This may leave the fibrous

layer in these areas thinner than the fibrous layer in the remainder of the tympanic membrane. Further evidence that cholesteatomas arise from retraction pockets comes from the fact that retraction pockets are frequently found after surgical removal of a cholesteatoma and grafting of the tympanic membrane. Retraction pockets and cholesteatoma can also be induced in some experimental animals by electrocautery to the Eustachian tube orifice.[135]

Ingrowth of skin through a tympanic membrane perforation has been suggested as a cause of cholesteatomas. These 'perforations', however, are more likely to be the misdiagnosed opening of a retraction pocket. It is assumed that the retraction continues to grow and the sac fills with the desquamated cells leading to the accumulation of keratin and cholesteatoma formation.

It is the case, however, that retraction pockets are common whereas cholesteatomas are uncommon. There are factors in the development of cholesteatoma other than just Eustachian tube dysfunction. Ruedi[136] suggested that papillary ingrowth of squamous epithelium through its own basement membrane in the pars flaccida could result in a cholesteatoma. Inflammation in the middle ear in addition to retraction pocket formation is likely to be an important factor and the retraction pocket formation and papillary ingrowth of squamous epithelium may coexist as a mechanism for the aetiology of cholesteatoma.[137]

In cholesteatoma, as in a normal wound, there is hyperproliferation and migration of the epithelium but, unlike the situation in a wound, this growth pattern persists.[138] It may be that the area of maximum growth is found in the neck of the cholesteatoma sac.[139]

Cholesteatomas may result from implantation of squamous epithelium into the middle ear. This could occur as a result of trauma to the tympanic membrane, either through injury or by surgery. Although likely to exist as a mechanism for their development, it could only account for a small proportion of cholesteatomas.

DIAGNOSIS AND ASSESSMENT

Iain R.C. Swan

INTRODUCTION

Examination of the ear with a microscope is the 'gold standard' for the diagnosis of COM although to reach an acceptable standard requires training, aided by operative experience exploring ears that have previously been otoscopically assessed. History taking and investigations are an aid to management rather than to diagnosis.

OTOSCOPY

Whenever there is a suggestion of COM, otoscopy is improved by using a microscope and appropriate aural speculum. This also greatly facilitates aural toilet, which is almost always required to fully visualize all areas. Such toilet can be any combination of suction, irrigation, mopping or instrumental removal (see Chapter 73, Clinical examination of the ears and hearing).

An otoscopic camera linked to a monitor gives a good overall view of anatomy and pathology that is particularly applicable if there is an open mastoid cavity. It is also helpful in viewing the anterior recess of the tympanic membrane, which is often blocked from view by the anterior canal bulge. A camera is extremely useful for teaching and to explain disease to the patient.

After any aural toilet, the clinician has to assess all areas of the external ear and the tympanic membrane to decide if there is pathology and if so what the pathology is (see **Table 83.1**). Before illustrating examples of various pathologies in different areas, some aspects that are generally applicable are discussed.

OPERATION SCARS

Prior to otoscopy, operation scars should be looked for. Endaural scars (see **Figure 73.2** in Chapter 73, Clinical examination of the ears and hearing) can be difficult to detect but suggest previous middle ear surgery which may have included canal wall-down mastoid surgery. Postauricular scars (see **Figure 73.3** in Chapter 73, Clinical examination of the ears and hearing) suggest previous surgery requiring access to the middle ear or mastoid singly or in combination.

SITE OF PATHOLOGY

Anatomically the pars tensa can be divided into four quadrants (**Figure 83.9**) but pathology, such as perforations, tends to be anterior, posterior or inferior (**Figure 83.10**). Hence, division into thirds rather than quarters is preferred. To record the proportion of the pars tensa involved by a specific condition, percentages are preferred to non-defined terms such as small, large and subtotal. By definition, all perforations of the pars tensa are 'central', indicative of 'tubotympanic disease'. The pars flaccida in the attic has to be cleared of any debris and assessed for pathology which may occur alone or along with pars tensa disease. By definition, all attic disease is 'atticoantral' and 'marginal'. The attribution of the term 'marginal' goes along with the absence of an annulus, which is not normally present in the attic/pars flaccida. If the term 'marginal' is applied to pars tensa pathology, its interpretation becomes confusing and should be avoided. The annulus is almost invariably present in pars tensa perforations unless it has been previously removed surgically.

OPEN MASTOID CAVITIES

These are usually created surgically but can occur spontaneously by the natural resolution of attic cholesteatoma, albeit the resultant cavity is usually small and confined to the atticoantral region (**Figure 83.11**). Open mastoid cavities can be difficult to detect if there is a narrow external auditory meatus or the cavity is not in continuity with the attic/antrum (**Figure 83.12**). If an ear has been operated on, and in particular if there is a postauricular scar, the

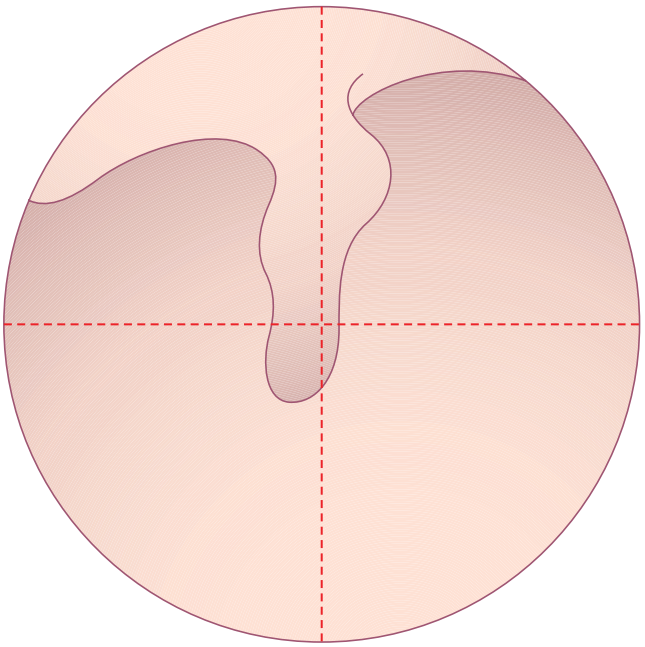

Figure 83.9 The four quadrants of the pars tensa (right ear).

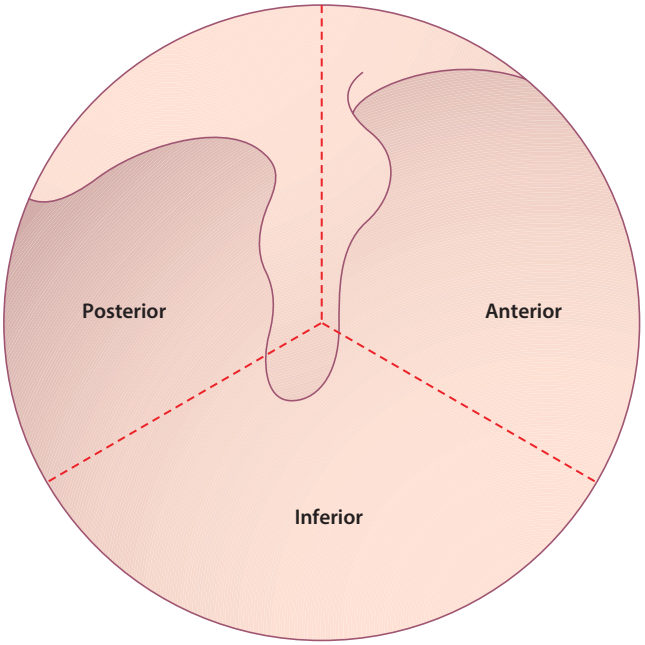

Figure 83.10 The three thirds of the pars tensa (right ear).

posterosuperior canal wall should always be closely examined. Sometimes, because of a narrow external auditory meatus or a high, residual posterior canal wall, an open cavity cannot be fully viewed.

ACTIVE OR INACTIVE?

A decision as to whether an ear is currently active, i.e. inflamed with the production of inflammatory products including pus, is primarily based on visualization of an inflamed mucosa and secretions. In squamous epithelial disease that is active with a cholesteatoma, there is almost invariably associated

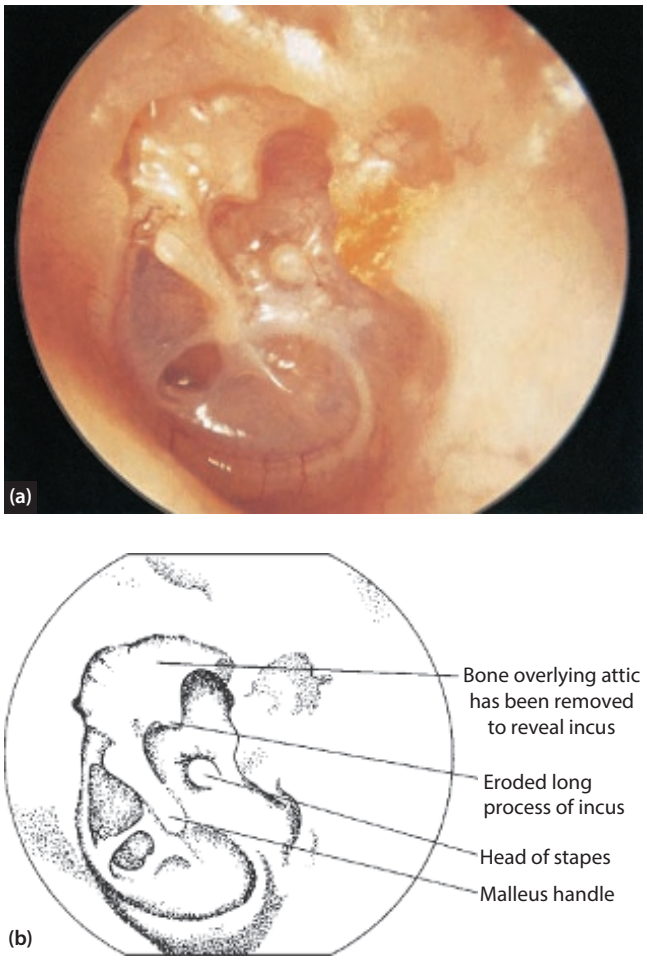

Figure 83.11 Left atticotomy. The attic has been exposed by drilling and is lined by a dry retraction pocket, part of which is out of vision. The malleus handle and body are present, as is the body of the incus. The long process of the incus has been eroded. The pars tensa is intact but retracted onto the head of the stapes.

mucosal disease that can be seen and produces the secretions, perhaps along with squamous epithelial debris. Secretions, and in particular mucopus, can dry and be mistaken for wax. Once removed, the underlying disease may still be active or have become inactive (Figures 83.13 and 83.14).

OTOSCOPIC DIAGNOSTIC CATEGORIES

In an ear with COM that has not previously been operated upon, it should be possible otoscopically to put the ear into one of four diagnostic categories (see Table 83.1).

Healed otitis media

This term is given to an ear where the pars tensa is intact but abnormal. Such a diagnosis can be, and often is, in association with other middle ear conditions such as OME. The most common abnormality of the pars tensa is chalk patches/tympanosclerotic plaques, there being no

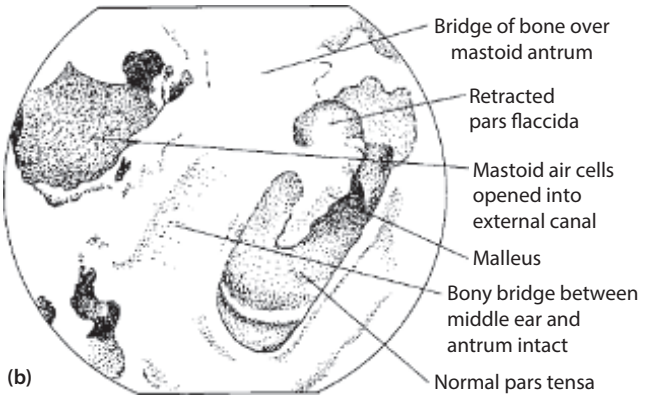

Figure 83.12 Right inactive modified (Heath) mastoidectomy. The pars tensa is normal. The pars flaccida is retracted but inactive. Posteriorly, the mastoid air cells have been surgically opened into the external canal by partial removal of the posterior canal wall. The bridge of bone over the incudal fossa and the mastoid antrum is normally removed in a modified radical mastoidectomy (and in an attico-antrostomy). It has not been removed in this case. There is no evidence of activity.

clear distinction between these two terms (Figure 73.17 in Chapter 73, Clinical examination of the ears and hearing; and Figure 83.15). The other abnormality covered by the definition of healed otitis media is thin replacement membranes, usually circular in outline and suggestive of an old perforation that has healed without the middle, fibrous tissue layer (Figure 83.16). When there is uncertainty as to whether such an area is a perforation or not (Figure 83.17), pneumatic otoscopy can be of value, or the patient can be asked to perform a Valsalva manoeuvre. Replacement membranes may be slightly retracted (Figure 83.18), when the additional diagnosis of OM with effusion should be considered. The distinction between these localized and more generalized, posterior marginal retractions is discussed below.

Inactive (mucosal) COM

This diagnosis implies a permanent perforation of the pars tensa and that the middle ear mucosa, as seen through the perforation, is inactive (Figures 83.19, 83.20 and 83.21).

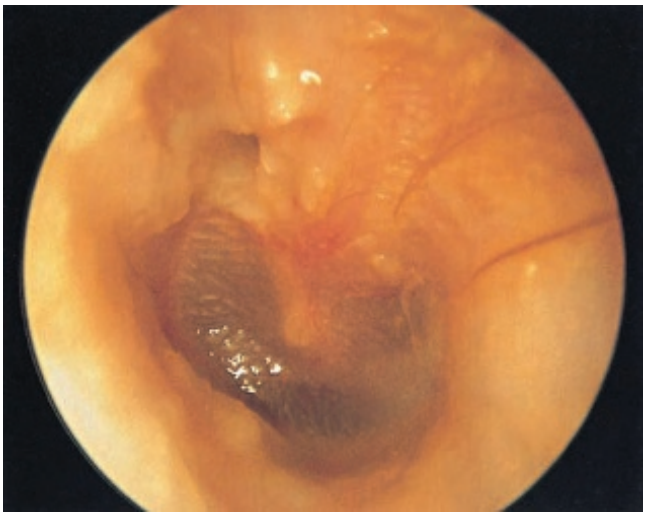

Figure 83.13 Left active COM. Pars flaccida obscured by pus. The pars tensa is normal.

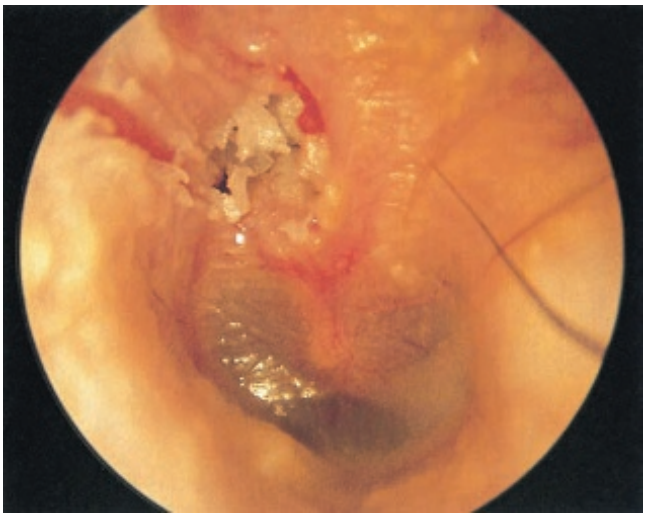

Figure 83.14 Same ear as Figure 83.13 after aural toilet. Active COM clearly visible affecting pars flaccida in the attic. The white debris is squamous epithelial debris, indicative of cholesteatoma.

Active (mucosal) COM

Activity is evident, usually with a generally inflamed middle ear mucosa, but sometimes with granulation tissue that is localized (Figure 83.22) and which can become polypoidal (Figure 83.23).

In both active and inactive COM, particularly when the defect involves the posterior third, the intactness or otherwise of the ossicular chain should be assessed and recorded (Figures 83.21, 83.24 and 83.25). Surgical classifications for these have been proposed but most prefer to record what the defects are, if any.

Inactive (squamous) retractions

These can occur in the pars tensa or the pars flaccida. Pars tensa retractions are primarily of the posterior tympanic membrane, the classification most used to document their

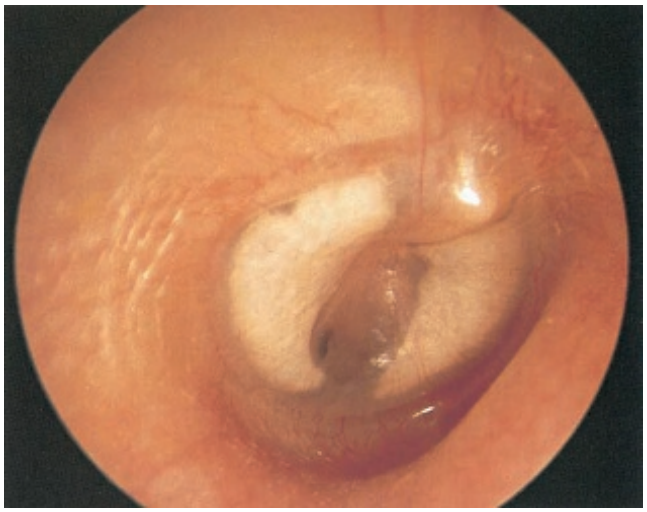

Figure 83.15 Tympanosclerotic plaques, one anterior, one posterior (right ear).

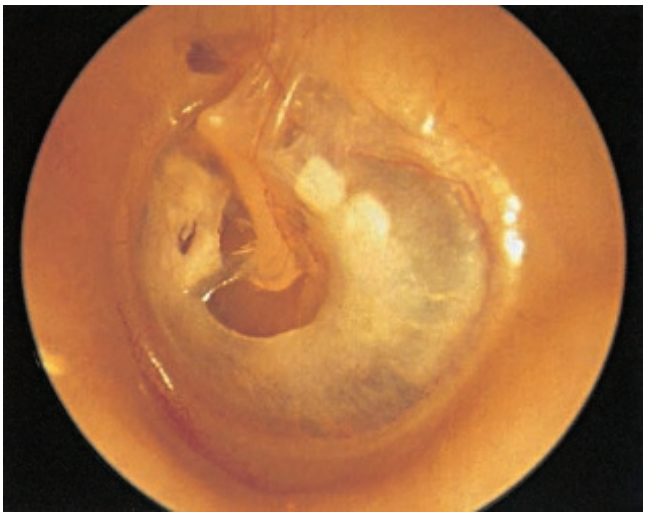

Figure 83.17 Scarred pars tensa associated with left healed otitis media.

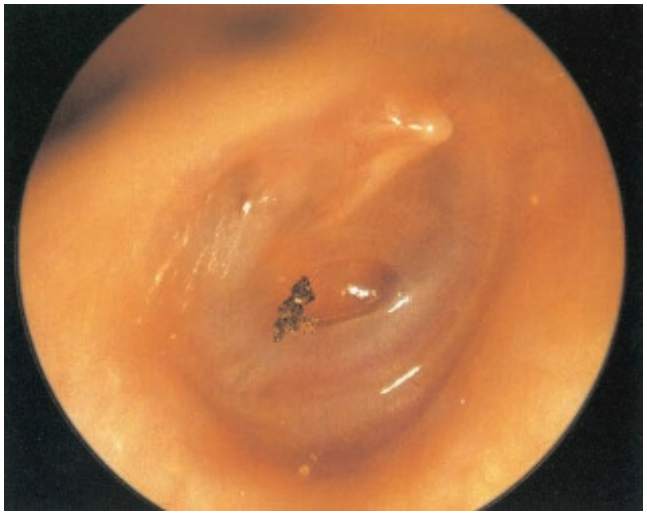

Figure 83.16 Healed otitis media (right). In this ear there is a thin replacement membrane over what is presumed to be an old inferior perforation.

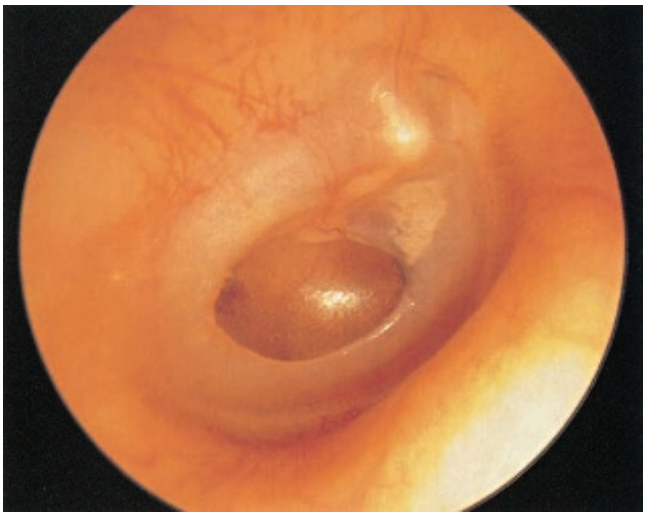

Figure 83.18 Localized retraction of pars tensa affecting central area (right ear).

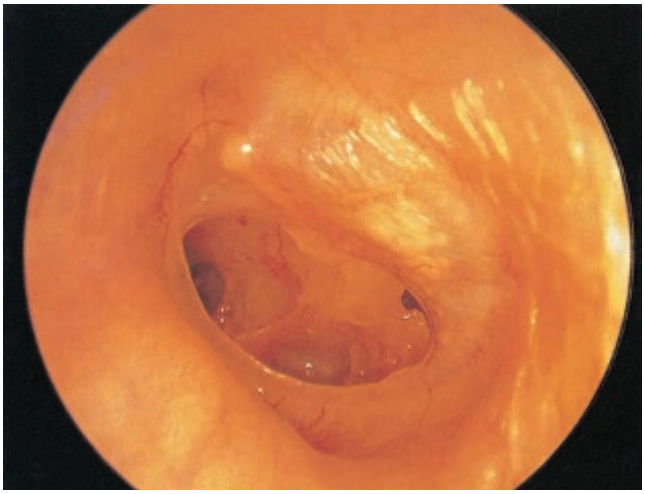

Figure 83.19 Inactive left COM. There is anterior inferior pars tensa defect through which the middle ear mucosa can be seen to be normal, i.e. not inflamed.

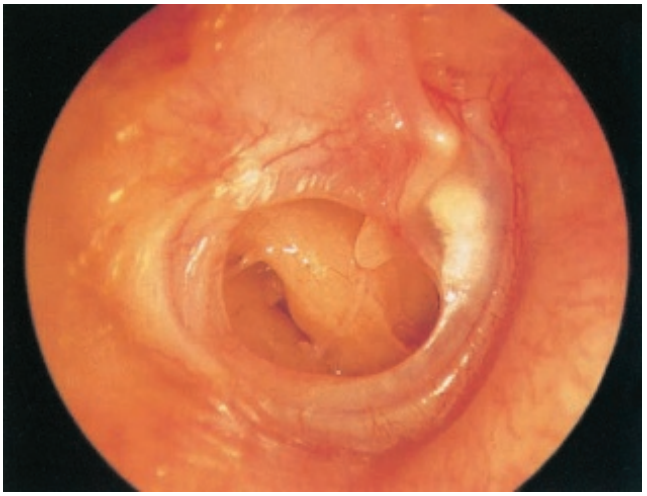

Figure 83.20 Inactive (mucosal) chronic otitis media, right ear.

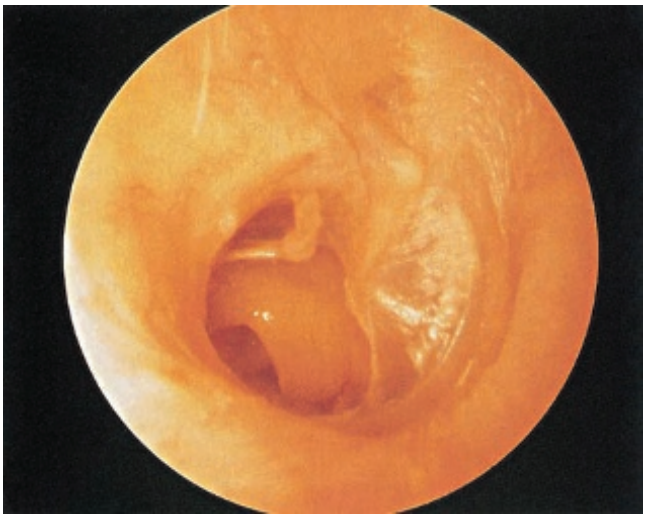

Figure 83.21 Not eroded long process of incus in inactive (mucosal) COM (right ear).

Figure 83.23 Left active mucosal COM. There is pus and debris on the canal wall. The tympanic membrane cannot be fully visualized but there appears to be an inferior defect. The main finding is a polyp protruding through the perforation and granulation tissue on the remaining tympanic membrane.

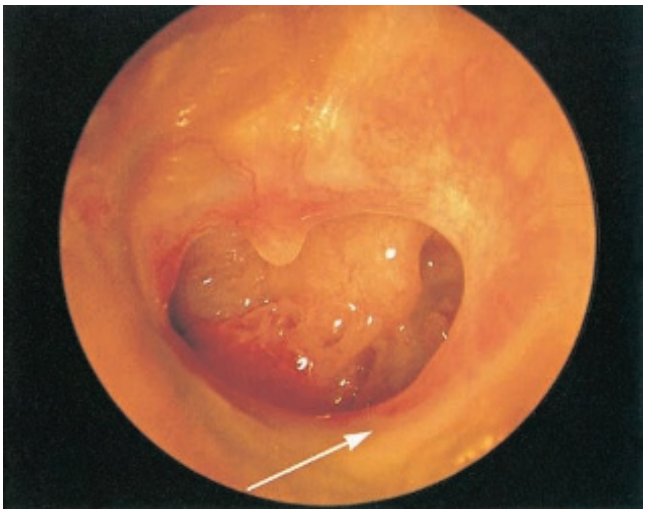

Figure 83.22 Left active mucosal COM. There is pus on the canal wall. The middle ear mucosa, seen through a 60% inferior pars tensa perforation, is minimally inflamed. The activity is mainly from granulation tissue on the edge of the perforation (arrowed).

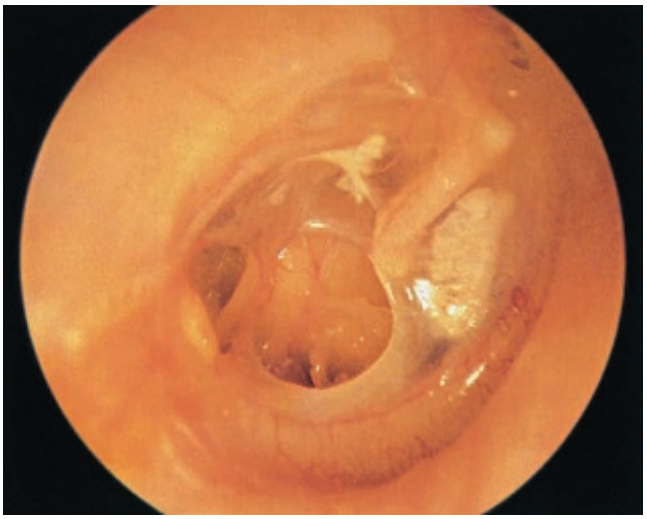

Figure 83.24 Posteroinferior perforation in inactive (mucosal) COM (right ear).

degree being that of Sadé and Berco.[140] In essence, what requires to be recorded is what structures the pars tensa is retracted onto and whether the pars tensa is adherent to them. Most important is whether the retraction is totally in view or whether there are areas out of view that might not be self-cleansing and have the potential to become active with a cholesteatoma (Figures 83.26, 83.27, 83.28, and 83.29).

Pars flaccida retractions have been diagrammatically classified into four stages by Tos et al.[141] (Figure 83.30). In stage 1, the pars flaccida is dimpled and more retracted than normal but not adherent to the malleus (Figure 83.31). In stage 2, the retraction is adherent to the neck of the malleus and the full extent of the retraction can be seen (Figure 83.32). In stage 3, part of the retraction is out of view and there may be partial erosion of the bony attic wall (Figure 83.33). In stage 4, there is definite erosion of the attic wall with the full extent of the retraction being uncertain because it is out of view (Figure 83.34). Tos's classification is relatively simple to apply, the only difficulty being making a distinction between stages 3 and 4. Hence, these are often grouped together as stage 3/4.

Cholesteatoma (active squamous disease)

Cholesteatomas are the end stage of (squamous epithelial) retractions of the pars tensa (Figure 83.35) or flaccida (Figure 83.33) that are not self-cleansing, retain epithelial debris and often elicit a secondary, inflammatory mucosal reaction. In the majority of cases the extent of the cholesteatoma cannot be determined otoscopically because the retraction pocket containing the debris is not fully in view.

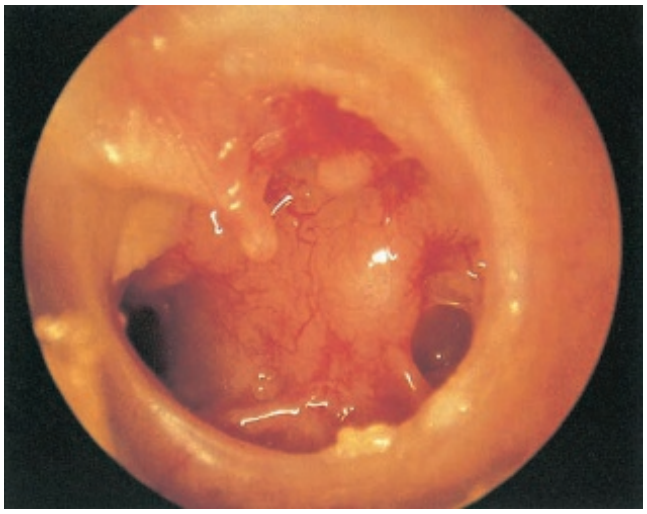

Figure 83.25 Active left mucosal COM. In this ear the stapes is seen through the perforation. The long process of the incus has been eroded.

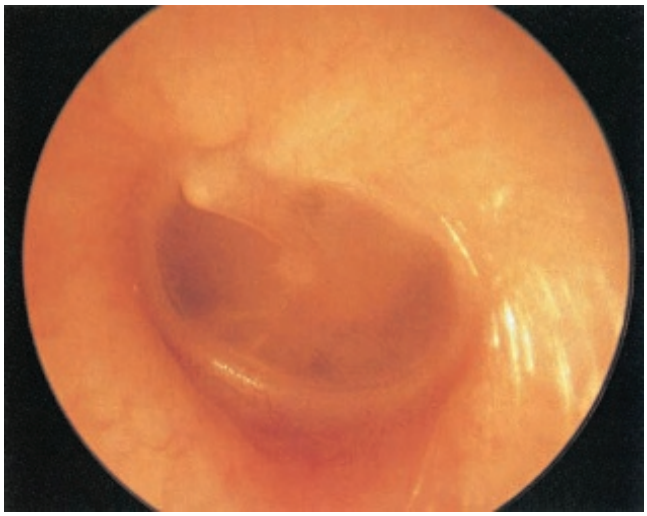

Figure 83.26 Stage 1: pars tensa retracted. There is no middle ear fluid (left ear).

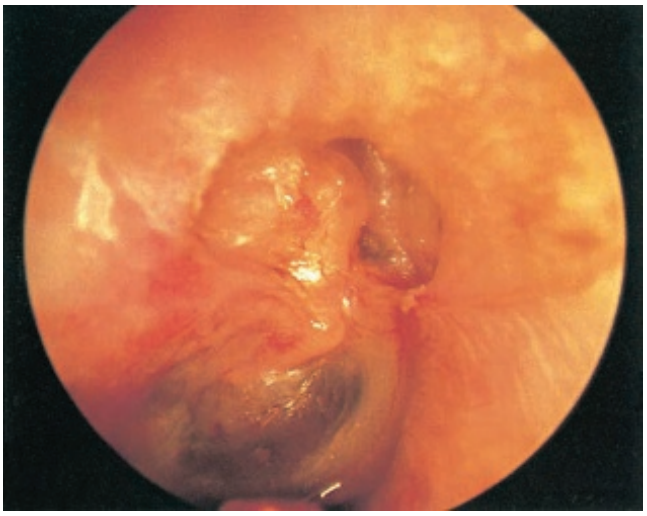

Figure 83.34 Stage 4 retraction of pars flaccida. Erosion of bony attic wall and part of retraction out of view. No activity (right ear).

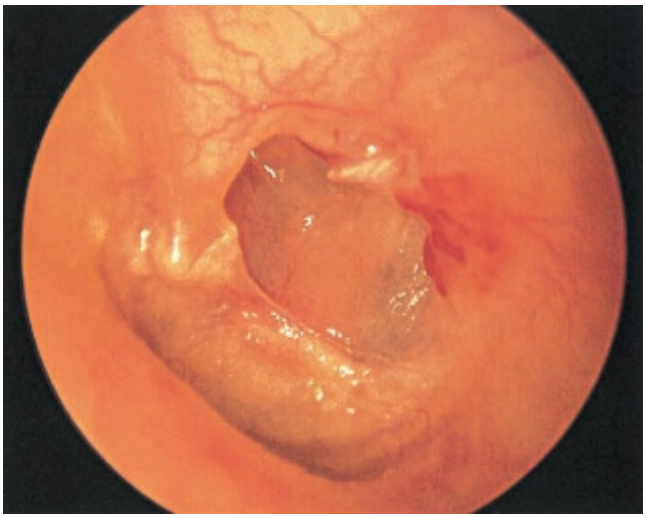

Figure 83.35 Posterior atelectactic pars tensa with erosion of posterior canal wall, as well as long process of incus and stapes superstructure. Prominent granulations on posterior canal wall suggestive of progressive cholesteatoma (left ear).

HISTORY

As COM will be diagnosed in the majority of cases by otoscopy, history taking should focus on symptoms and previous management. This allows future management and potential outcomes to be discussed more appropriately. An exception to this attitude is when there is a history of peripheral type vertigo. If present, this merits more detailed assessment (see 'Labyrinthine complications' below).

The majority of adults (~80%) presenting with COM report a hearing impairment and approximately 70% an ear discharge (Table 83.5).[142] Even in those with currently active COM, only around 75% will report a current discharge and there is no difference in this report whether a cholesteatoma is present or not. There also is no apparent difference in the smell associated with cholesteatoma compared with active mucosal disease.[143]

TABLE 83.5 Symptoms of active COM, broken down into mucosal disease and cholesteatoma (squamous disease)

Symptom	Percentage	
	Active mucosal	Cholesteatoma
Hearing loss	74	83
Otorrhoea	69	56
Otalgia	37	39
Childhood ear disease	26	43

Reprinted from Sheahan et al.,[142] with permission.

Enquiry will be made as to any previous surgery and about recent topical aural medications and how effectively they were used.

AUDIOLOGY

Pure-tone audiometry, air and bone conduction with appropriate masking will provide numerical values to the degree of hearing impairment, the magnitude of the air–bone gap and whether there is an associated sensorineural impairment for each of the two ears. Such information is important to inform decisions regarding management.

ADDITIONAL INVESTIGATIONS

Additional investigations are only relevant if they modify, to a material extent, decisions that have been previously made based on otoscopy, history and pure-tone audiometry.

Vestibular assessment

Vestibular assessment will be performed on those with episodes of peripheral-type vertigo and some patients undergoing revision surgery. A fistula test, if positive with the production of acute vertigo accompanied by nystagmus, is suggestive of a semicircular canal fistula created by a cholesteatoma or previous mastoid surgery. A negative fistula test does not exclude such conditions. Caloric testing to determine whether there is residual vestibular function after previous surgery can be helpful in determining which surgical procedures are applicable.

Imaging

High-resolution computed tomography (CT) scanning in both the coronal and axial planes of the temporal bone is recommended in the pre-operative evaluation of cholesteatoma.[144] CT may help to assess the extent of disease in a partially aerated mastoid. However, cholesteatoma appears as a homogeneous mass with similar density to oedematous mucosa and to brain tissue. In the absence of aeration, the extent of disease is rarely visible, though it may be suggested by erosion of air cells. CT shows the pneumatization of the mastoid which may influence surgical approach and will demonstrate any anatomical variants. It may demonstrate erosion of the bony labyrinth, most commonly the lateral semicircular canal, the tegmen tympani, or of the facial canal, but cannot be relied upon to do so.[145]

Diffusion-weighted magnetic resonance imaging (DW-MRI) differentiates cholesteatoma and inflammatory tissue and brain. It has been shown to be reliable at detecting small residual or recurrent cholesteatoma after surgery, and at assessing the intracranial extension of cholesteatoma.[146] As DW-MRI becomes more widely used, it is likely to replace second-look operations in some patients after intact canal wall mastoid surgery.

Endoscopy

The endoscope is sometimes useful in the outpatient clinic. It may allow assessment of the extent of a retraction pocket in a patient who is not particularly fit for surgery. It may help to visualize the middle ear in patients with very narrow ear canals.

Bacteriology

Bacteriological and fungal cultures are of potential value only when the ear is active or if there are infective complications. If systemic antibiotic therapy is being contemplated, culture of any secretions with antibiotic sensitivity pattern of any growths being assessed can be of value in deciding which antibiotic to prescribe as most do not cover the full range of bacteria that can be isolated as potential pathogens from the ear. The same could be said for topical antibiotic therapy although, if gentamicin or ciprofloxacin is chosen, their spectrum is broad enough to cover most probabilities.

NATURAL HISTORY, MANAGEMENT AND OUTCOMES

Iain R.C. Swan

INACTIVE MUCOSAL CHRONIC OTITIS MEDIA

Natural history

Inactive mucosal COM (see **Figure 83.19**) is the condition of the middle ear where the structure and often the hearing are impaired by the presence of a permanent tympanic membrane defect, but in which there is no active infection or mucoid discharge. Such an ear may remain inactive, become active or even occasionally heal.

PROGRESSION TOWARDS HEALING

The progression towards healing is presumably impaired by the disease that resulted in COM in the first place. This is usually recurrent episodes of acute infection with

perforation of the tympanic membrane, which initially heals successfully within a few days, but after a variable number of attacks the tympanic membrane fails to heal. This is regarded as a result of failure of the blood supply to the perforation edges due to endarteritis, but there may be other factors related to repair mechanisms at cellular level. If for any reason the blood supply improves, this may tip the balance in favour of healing. There are no data on the probability of this occurring but observation and experience suggest that natural healing is a relatively rare event in adults though it appears to occur more often in children. Lehmann et al.[147] reported a significant reduction in the prevalence of tympanic membrane perforations in Aboriginal children due to improved hygiene after the opening of a community swimming pool. It is probable that closure will only occur following a period of disease inactivity and this is the goal of medical therapy in mucosal disease and indeed the goal of surgical treatment is to achieve a healed state.

PROGRESSION TOWARDS ACTIVITY

Progression towards activity is more common, theoretically provoked by factors such as a URTI or the ingress of water, particularly if contaminated by bacteria or irritants. The diverse flora occurring in active ears and the fact that the bacterial flora are similar in mucosal and squamous epithelial disease suggest that bacterial contamination is not the primary event in most cases.[121] It is the increased mucus production that provides the culture medium for opportunist organisms to flourish. The fact that the same organisms may be isolated from inactive as from active ears in 50% of cases would also support this contention.[120] Traditional concepts about the role of sinonasal disease in the precipitation of activity in COM are not supported by convincing evidence.

Presentation

Inactive COM presents with a hearing impairment or may be an incidental finding in older patients with a mixed hearing impairment. Some patients present because of discomfort in the ear during swimming when water gets into the middle ear. A careful history of discharge should be sought. If the only history of discharge is many years previously, this may not influence management. However, many patients have more recent episodes of discharge and this does influence management.

Examination

Pure-tone audiometry assesses the magnitude of the conductive hearing impairment due to the disease. The degree of air–bone gap depends on:[148]

- the size of the perforation in the tympanic membrane
- erosion of the ossicular chain, most commonly the long process of the incus and sometimes also the stapes superstructure
- significant granulation tissue around the ossicular chain which can reduce its mobility
- tympanosclerosis around the ossicular chain.

If surgery is contemplated, microscopic examination is important as this may give some information about the state of the ossicular chain.

Management

Management options are surgery, a hearing aid or no treatment. Hearing aids should always be considered in the management of hearing disability (see 'Hearing aids in chronic otitis media' below).

OBJECTIVES OF SURGERY

The aim of middle ear surgery for hearing is reduction in the patient's hearing disability, not just closure of the air–bone gap. Hearing disability is largely dependent on the hearing in the better-hearing ear, therefore the hearing thresholds in the non-operated ear need to be taken into account when considering the likely benefit to the patient from reconstructive surgery. If successful closure of the air–bone gap still leaves the patient with significantly poorer hearing in the operated ear, then benefit from successful surgery is dubious. The objectives of any surgery should be carefully considered. Dry perforations that are symptom-free do not usually require closure. If the only symptom is a hearing impairment, the chances of improving hearing with surgery should be considered carefully, not just the hearing in the operated ear but the overall hearing ability of the patient. In patients with a history of intermittent activity, surgery to close the perforation is probably indicated to minimize future activity. Those patients whose main symptom is discomfort when swimming should be encouraged to wear ear plugs. These are usually extremely effective at preventing discomfort and are a simpler and safer option than surgery.

MYRINGOPLASTY

Tympanoplasty refers to any operation involving reconstruction of the tympanic membrane and/or the ossicular chain. Myringoplasty is a tympanoplasty without ossicular reconstruction. Over the years many methods have been used for closing perforations. The most widely used and accepted method is underlay graft of temporalis fascia or sometimes perichondrium. Cartilage has become increasingly popular as a graft material, particularly when the tympanic membrane is retracted (see discussion of myringoplasty in 'Inactive squamous chronic otitis media' below). The basic procedure is to excise the rim of the perforation so that there is a raw surface from which new tissue will grow. The mucosa on the undersurface of the remaining tympanic membrane near to the perforation is removed or scraped with a sickle knife or similar instrument to provide a bed for the graft. This is then placed under the tympanic membrane remnant and acts as a scaffold for new growth of the squamous epithelial layer. The mucosa over the promontory should be carefully preserved to reduce the likelihood of post-operative adhesions between the graft and the promontory.

Outcomes: tympanic membrane take rate

The success rate in achieving an intact tympanic membrane in expert hands is often quoted as around 95%. However, when results of large numbers of operations in the hands of many surgeons are reported, the success rate is much lower (**Table 83.6**). Palva and Ramsay[149] looked at the outcome of 281 myringoplasties in their department. The closure rate in Palva's hands was 97%, while in the hands of other members of the department it was only 74%. Similarly, Vartiainen[150] reported that the successful tympanic membrane closure rate for trainees was 78% compared to 95% for the senior staff. Successful outcome seems to be significantly influenced by the expertise of the surgeon. Many reports of results are based on relatively short follow-up of 6–12 months. However, longer-term follow-up suggests that some ears which are initially intact develop recurrent perforation.[151]

The closure rate is reported to be higher in small perforations (74%) than large perforations (56%).[154] Numerous authors have reported that the failure rate in anterior perforations is higher. However, this failure rate can be greatly reduced by anchoring the anterior margin of the graft beneath the annulus.[156]

There is no evidence that prophylactic antibiotics influence closure rate or other outcomes. A Cochrane review found 11 randomized trials of prophylactic antibiotics in middle ear surgery. None of these trials reported significant difference in outcomes between the prophylactic antibiotic and control groups.

Revision surgery can be considered in those ears where the graft fails. The possible reasons for failure should be considered and, if necessary, the surgical method can be modified. Halik and Smyth[151] found that only 60% of tympanic membranes were intact after revision surgery, which is a much lower success rate than usually claimed for primary surgery.

Outcomes: hearing

Successful closure of the tympanic membrane usually gives only a small improvement in hearing (Table 83.7).

It is uncommon to get total closure of the air–bone gap in myringoplasty, as closure of a tympanic membrane perforation does not make the ear a normal ear. In those patients in whom the air–bone gap is 35 dB or more, there will be either erosion or fixation of the ossicular chain.[148] Here, surgery would require myringoplasty and ossiculoplasty (see below).

TABLE 83.6 Successful closure rate in myringoplasty

Reference	No. of cases	Closure rate (%)
Kotecha et al.[152]	1070	82
Wielinga et al.[153]	555	88
Lee et al.[154]	423	64
Black and Wormald[155]	211	78

Complications

The complication rate in myringoplasty is low in all series. Kotecha et al.[152] reported one facial nerve palsy in 1070 patients and one extradural abscess.

OSSICULOPLASTY

The most common pathology in the middle ear is erosion of the long process incus. This is reasonably straightforward to correct surgically. The preferred option is to place a prosthesis between the handle of malleus and the head of stapes. Various materials are used, most commonly autograft incus or head of malleus and alloplastic prostheses. When the stapes superstructure is also missing, the malleus handle has to be connected to the stapes footplate and autograft materials are rarely suitable. Occasionally there is also erosion of the malleus handle; here the prosthesis connects the tympanic membrane directly to the stapes superstructure or footplate. The choice of material is largely dependent on the situation in the operated ear and the surgeon's personal preferences. Homograft materials are not recommended because of the theoretical risk of transferring prion disease.

Outcomes

There are many reports in the literature of the outcome of ossiculoplasty. Iurato et al.[157] reviewed 20 published reports of the results of ossiculoplasty when the malleus and stapes superstructure were present. In expert hands, a post-operative air–bone gap of 0–10 dB is achieved in only 50% of patients while 80% have an air–bone gap of 0–20 dB. Iurato found no reported difference in hearing outcome between different types of prosthesis.

When there is erosion of the stapes superstructure as well, the success rates of surgery are generally lower. Mills[158] reported a mean hearing improvement after ossiculoplasty of 14 dB when the stapes arch was intact and 6 dB when it was eroded. Shinohara et al.[159] reported 68% 'success' rates at 1 year with partial ossicular replacement prostheses where only the incus needs to be replaced. This compares with 46% for total ossicular replacement prostheses where the incus and the stapes superstructure are absent, though 'success' was not defined.

Most authors report the results of surgery after 3–12 months. Those who look at long-term results report that success rates are lower: at 5-year follow-up, Shinohara's 'success' rates had fallen to 60% (from 68% at 1 year) and 34% (from 46%).[159]

Myringoplasty and ossiculoplasty can be carried out as a one- or two-stage operation. It is generally accepted that the success rate of ossiculoplasty is higher if the procedure is staged, but this is to be expected as only those ears that have a closed aerated middle ear are chosen for the second-stage procedure. Staging does require two separate operations, and most surgeons would carry out a one-stage procedure if it seemed feasible in that particular ear. It would seem much more efficient to attempt a one-stage procedure and revise it if it fails.

TABLE 83.7 Hearing after successful myringoplasty

Reference	No. of cases	Mean hearing improvement (dB)	Residual air–bone gap (dB)
Lee et al.[154]	261	8.1	–
Palva and Ramsay[149]	281	8.0	9.3

TYMPANOSCLEROSIS AND SURGERY

Tympanosclerosis is found in the middle ear in around 25% of ears at surgery. In some cases, the mobility of the ossicular chain is reduced by tympanosclerosis in the attic or in the oval window. If the ossicular chain is intact and only the incus and head of malleus are fixed, this can be corrected by removing the incus and head of malleus and reconstructing the ossicular chain between handle of malleus or tympanic membrane and stapes. Alternatively, the outer attic wall can be removed and the malleus and incus mobilized. This is often effective in the short term, but there is a tendency for refixation of the ossicles by fibrous tissue or bone.

When the stapes is involved, surgery involves mobilization of the stapes or stapedectomy. Results of stapes surgery in tympanosclerosis are not as good as in otosclerosis with a post-operative air–bone gap of 20 dB or less reported in only 72% (111 of 154 operations)[160] and 70% of cases (45 of 64 operations).[161] The complications of surgery, such as dead ear, are reported to be more common; Albu et al.[162] reported a 4% (1 of 25) and Gormley[163] a 5% (3 of 67) incidence of post-operative sensorineural loss.

THE EUSTACHIAN TUBE AND SURGERY

An aerated middle ear is necessary for middle ear function. Sometimes reconstructive middle ear surgery that appears technically successful at the time of surgery subsequently has a poor outcome because of non-aeration of the middle ear. A functioning Eustachian tube is necessary for an aerated middle ear. Assessment of Eustachian tube function pre-operatively is a poor predictor of the successful closure of the tympanic membrane.[164] If the contralateral ear is atelectatic, suggesting poor Eustachian tube function, it is unlikely that the Eustachian tube will function in the operated ear.

New methods of improving Eustachian tube function have been tried in recent years. In laser tuboplasty, soft tissue in the wall of the Eustachian cushion is ablated. Kujawski and Poe reported improved tubal function in 65% of patients,[165] but long-term outcomes are not yet known. In balloon Eustachian tuboplasty, a balloon catheter is inserted into the tubal ostium and inflated for 2 minutes. Sudhoff et al. reported that 87% of 351 patients were satisfied with the improvement in tubal function after 12 months;[166] long-term results are awaited. In actively inflamed ears, it is possible for Eustachian tube function to improve when the middle ear mucosa reverts to a more normal state after closure of the tympanic membrane. It may sometimes be worthwhile inserting a VT in the tympanic membrane, or in the graft, as a temporary method of improving aeration, hoping that the function of the Eustachian tube will improve.

KEY POINTS

- The degree of hearing impairment depends on the size of the perforation and the state of the ossicular chain.
- Myringoplasty closes perforations in 64–95% of cases, depending on the experience of the surgeon.
- As the hearing improvement from ossiculoplasty when the malleus and stapes are present is only 14 dB, hearing aids should always be considered in management.

ACTIVE MUCOSAL CHRONIC OTITIS MEDIA

Natural history

Active mucosal COM (see **Figure 83.25**) may remain active, become inactive or progress to complications. Continuing activity may be the result of infection with a particularly virulent or persistent organism, commonly *Pseudomonas*. Impaired immunity plays a role in some groups of patients such as diabetics but the increased incidence of active COM in deprived communities in the developed world (see 'Aetiology of chronic otitis media in general' above) suggests that nutritional and environmental factors including hygiene play a part in predisposing individuals to COM.[147]

PROGRESSION WITH CONTINUING ACTIVITY

Continuing activity of COM is likely to result in increasing damage to the ossicular chain and potentially to the inner ear. The former is common but the latter seems to be relatively rare. The precise incidence of ossicular damage in COM is unknown but if there is significant ossicular involvement a substantial deterioration in hearing results. The otorrhoea, particularly with multiple infecting organisms,[167] may be a factor relevant to more rapid deterioration. The inflammatory reaction in the middle ear associated with granulation tissue is agreed to be the most likely factor for ossicular damage occurring. The non-specific changes in bone associated with the inflammatory reaction include osteoclastic and osteoblastic activity which results in the resorption and remodelling of bone. Frequently, permanent damage to the most finely constructed parts of the chain occurs, mainly to the incus long process and the stapes superstructure where there is abundant osteoclastic activity but osteoblastic influences appear weak. The same process may play a part in the development of a sclerotic mastoid in COM where osteoblastic activity predominates.

HEARING IN ACTIVE MUCOSAL COM

One of the cardinal symptoms of COM is hearing loss and usually this is conductive in type although sensorineural loss may occur (see 'Sensorineural hearing loss' below). In the early stages of disease, conductive hearing impairment occurs in most cases but this is usually mild and often only causes significant handicap if disease is bilateral. As the disease process advances only slowly, the patient appears to adapt to the loss so that thresholds of 30–40 dB HL are common with little complaint from the patient. In mucosal disease, the size of the perforation in the pars tensa is relevant to the hearing loss but other important factors such as the presence of granulation tissue, mucus, adhesions and tympanosclerosis are also of importance in determining the hearing level. If the ossicular chain loses continuity, there may be a substantial increase in hearing impairment with thresholds increasing up to 50–60 dB HL in such cases. In bilateral disease this constitutes a significant handicap and hearing rehabilitation including reconstructive surgery may be a priority for the patient.

Presentation

The two main symptoms of active mucosal COM are otorrhoea and hearing impairment. The discharge varies in quantity and character. It may be continuous or intermittent, mucoid or purulent. In patients with intermittent otorrhoea, an increase in discharge may follow a URTI or entry of contaminated water into the middle ear, most commonly when swimming. However, many patients present with hearing difficulty as their only symptom. Though they have active mucosal COM, they are unaware of otorrhoea as the quantity is insufficient to appear at the external auditory meatus. The small amounts of discharge dry up at the medial end of the external auditory canal and form crusts. These crusts are sometimes mistaken for wax by inexperienced otoscopists. The hearing impairment is conductive, though older people may present primarily with age-related sensorineural hearing impairment but have an additional unilateral conductive component. On questioning, these patients will often report that they had otorrhoea when they were younger.

Examination

The hearing should be assessed by pure-tone audiometry. As potentially ototoxic agents are commonly used in the management of active mucosal COM, it is important to record the hearing before treatment. There is usually associated hearing impairment which is mainly conductive. Bacteriology is usually not necessary unless complications are suspected or initial antibiotic therapy fails to reduce the inflammation. *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the most commonly reported pathogens, most of the other organisms being Gram-negative coliforms (see 'Factors influencing activity of chronic otitis media' above).

Management

AURAL TOILET

The initial stage in management is thorough aural toilet. This is most effectively carried out with a microscope and suction which also allows accurate assessment of the extent of ear pathology. However, some clinicians use gentle syringing with saline or antiseptic agents. In the past, aural toilet was carried out with cotton wool on probes, but this is probably not as effective. It is, however, an effective way for the patient to clean his or her own ear between clinic visits prior to the insertion of topical medication.

TOPICAL MEDICATION

Numerous studies have been carried out over many years comparing various topical agents: antibiotics, steroids, antifungals and antiseptics. Topical antibiotics with steroids are significantly better than dry mopping alone,[168] dry mopping in combination with a topical saline solution[169] or topical aluminium acetate solution.[170] Topical antibiotics are more effective than oral.[171, 172] or intramuscular antibiotics.[173]

Gentamicin or neomycin, usually with hydrocortisone, has been the most popular topical agent for many years. More recent studies have compared topical quinolone antibiotics (ciprofloxacin or ofloxacin) with these more traditional agents. Miró et al.[174] compared topical ciprofloxacin with topical polymyxin B, neomycin and hydrocortisone suspension and found no significant difference in effectiveness (91% and 87%, respectively) in a study of 322 patients. Tong et al.[175] reported a significant difference in the effectiveness of topical ofloxacin (93%) compared with neomycin, polymyxin B and hydrocortisone (71%, $p = 0.04$) in a small study with 52 patients.

SUMMARY

Topical antibiotic therapy is the most effective means of treating active otorrhoea in COM. Topical aminoglycosides have been shown to be ototoxic in animals and can be ototoxic when administered parenterally in humans. There have been several anecdotal reports of possible ototoxicity from topical preparations in humans, though it is difficult to separate the effects of treatment from the effects of the disease. There is no conclusive evidence that topical aminoglycosides are ototoxic when used in treatment of COM.[32] The consensus view in the UK is that their use is acceptable but they should only be used in actively discharging ears and for a limited time.[176] The available evidence suggests that quinolones are at least as effective at reducing otorrhoea as aminoglycosides. As they do not appear to be ototoxic in animal experiments, quinolones may be preferable to aminoglycosides in active COM. An overview of the scientific literature on the management of active mucosal COM is provided by Cochrane reviews.[177, 178]

Though medical management is effective in reducing otorrhoea in most cases, it recurs in many patients. Recurrence of activity 4–6 weeks after completion of treatment was reported in 5%[174] and 43%[179] of patients.

SURGERY

In those cases that do not become inactive on medical management, surgery is required to heal the ear. Those cases that become inactive should have closure of the perforation (see 'Myringoplasty' above) to prevent recurrence of activity, together with ossiculoplasty if appropriate.

Myringoplasty

Though it is preferable to make active ears inactive before surgery, this is not always possible, and surgery should not be postponed because of this. Activity in the ear has been suggested as a cause of failure of tympanoplasty. However, Kotecha et al.[152] and Black and Wormald[155] found no influence of the condition of the ear at the time of surgery on the subsequent graft take rate. A Cochrane review found no evidence that the success rate of surgery is influenced by prophylactic antibiotic therapy.[180]

Role of adjuvant cortical mastoidectomy

Many authors suggest that a cortical mastoidectomy should be carried out at the same time as myringoplasty in active ears. Mishiro et al.[181] compared 104 ears treated by tympanoplasty alone with a previous group of 147 ears treated by tympanoplasty with mastoidectomy. There was no significant difference in tympanic membrane closure rates between groups (94% in tympanoplasty alone and 91% in tympanoplasty with mastoidectomy). Balyan et al.[182] reported 81 ears that were actively discharging at the time of surgery treated with tympanoplasty without mastoidectomy (53 ears) and tympanoplasty with mastoidectomy (28 ears). There was no significant difference in the graft success rates between these groups (91% and 86% respectively). Hall et al.[183] reviewed five studies comparing tympanoplasty with and without mastoidectomy and found no evidence that mastoidectomy increases the success rate of surgery in these ears.

AURAL POLYPS

In some cases, aural polyps are found protruding from the middle ear. In compliant patients, these can sometimes be removed or partially removed in the clinic with suction or perhaps small aural forceps using microscopic vision. It should be remembered that polyps can be attached to the stapes superstructure or to the facial nerve, and that damage to these structures can occur. Cauterization of polyps with silver nitrate on a stick may be helpful, though this should be done with care as damage to the facial nerve can occur. Both methods should be followed by topical treatment as outlined above.

In those with persistent otorrhoea and an aural polyp not managed in the outpatient clinic, the polyp should be removed. If this requires an anaesthetic, it would seem more efficient to perform the definitive surgery at the same time whenever possible, rather than simply removing the polyp and listing the patient for further surgery at a later date. Removal of polyps usually causes bleeding in the ear that interferes with surgical access, but this can be greatly reduced by the use of a laser in the removal of the polyp.

KEY POINTS

- In many patients with active mucosal COM, the only symptom is hearing impairment.
- Initial management is aural toilet and topical antibiotics with or without topical steroids.
- Quinolones are probably preferable to aminoglycosides because of the theoretical risk of ototoxicity, though there is no evidence that they are more effective.
- Definitive management is surgery, at least to close the perforation, but preferably to improve hearing as well.
- There is no evidence that prophylactic antibiotics influence the outcome of surgery.
- There is no evidence that the outcome of surgery is poorer in active ears.
- There is no evidence that concomitant mastoidectomy improves outcomes after tympanoplasty.

HEALED OTITIS MEDIA

Natural history

Healed otitis media (see **Figure 83.16**) may be the end result of episodes of AOM or OME. It may also be the end result of natural healing of ears with either mucosal or squamous COM. It is also the aim of surgery in most cases of COM irrespective of its type or activity.

PROGRESSION OF HEALED OTITIS MEDIA

The usual outcome in healed otitis media is a stable ear which does not accumulate debris and in which the hearing impairment does not increase. Such ears frequently have tympanosclerosis in the tympanic membrane that does not progress or result in any hearing impairment. In a few cases, tympanosclerosis affects the ossicular chain, particularly in the attic, and may result in a conductive impairment that is difficult to treat surgically. The incidence of and risk factors for tympanosclerosis have been studied by several authors. The incidence of tympanosclerosis in all cases of COM is estimated at 25%.[184] The incidence of attic tympanosclerosis fixing the ossicular chain is low and the factors which trigger this in otherwise currently healed ears is unknown. Tympanosclerosis of the pars tensa is reported to resolve in some cases, but this is not common.[185] It is generally thought that tympanosclerosis occurs less commonly in squamous epithelial disease and in active mucosal disease, but supporting evidence is lacking.

PROGRESSION TOWARDS ACTIVITY

Reperforation of the tympanic membrane may occur if there is a subsequent episode of AOM or minor trauma. The most likely causes for the latter are barotrauma and ear syringing but there is no evidence that defines the frequency of this occurring. Episodes of AOM are most likely to occur in children but may occur occasionally in adults, particularly if there is a predisposition to chronic ear disease. The tympanic membrane rarely heals normally. Although the

membrane may heal to a state of intactness, the supporting fibrous layer of the drum may be weakened or fail to regenerate, resulting in a thin scar at the site of the previous perforation or indeed the whole membrane may be thin and attenuated. If chronic Eustachian tube dysfunction persists, as it often will, the drum becomes retracted and may become draped over and adhere to the structures in the medial wall of the middle ear, a condition known as adhesive otitis media. This condition may be exacerbated or precipitated by inflammatory adhesions within the middle ear.

HEARING IN HEALED OTITIS MEDIA

The hearing in healed otitis media may be normal or there may be a mild conductive hearing impairment unless there is ossicular damage or fixation. There may also be an underlying sensorineural hearing impairment from any of the causes of this or specifically as a result of cochlear damage related to previous infection. Once the healed state has occurred, further increase in either conductive or sensorineural hearing impairment is unlikely but there is no evidence that looks at this issue specifically.

Presentation

Patients with healed otitis media may present with a hearing impairment. In elderly patients, it is commonly an incidental finding when they present with age-related hearing impairment. Some patients give a history of ear problems many years previously, often in childhood, but many do not recollect ever having had otorrhoea.

Examination

Diagnosis is made on otoscopy. As the only symptom is hearing impairment, the hearing thresholds in each ear must be assessed. Pure-tone audiometry determines the magnitude of the conductive hearing impairment. Many cases have a minimal air–bone gap, but in ears where there is fixation of the ossicular chain by tympanosclerosis or by adhesions in the middle ear, or erosion of the ossicular chain, most commonly of the long process of incus, the air–bone gap can be up to 60 dB.[148]

If there is a significant air–bone gap and surgery to improve the hearing is contemplated, careful microscopic examination of the ear should be carried out as this may give information about the extent of pathology, particularly tympanosclerosis, and the likelihood of reconstructive surgery being successful (see **Figure 83.7**).

Management

Management is only indicated in the presence of significant hearing disability and hearing aids should always be considered (see 'Hearing aids in chronic otitis media' below).

SURGERY

Many patients, particularly younger ones, prefer surgery, which will usually include ossiculoplasty. It should, however, be borne in mind that the success rates of surgery are limited. Successful surgery requires a well-aerated middle ear, but careful examination of the ear will usually give appropriate information about aeration. Significant adhesions in the middle ear limit the success of surgery as these frequently recur after surgery. Tympanosclerosis may also reduce the chances of successful surgery (see 'Inactive mucosal chronic otitis media' above).

KEY POINTS

- As hearing impairment is usually the sole symptom, hearing aids are often the optimal management option.

INACTIVE SQUAMOUS CHRONIC OTITIS MEDIA

Inactive squamous COM is defined as retraction of the pars tensa or pars flaccida with the potential to be active with retained debris (cholesteatoma). There may be associated damage to the ossicular chain and other middle ear structures. It is commonly referred to as 'tympanic retraction' or a 'retraction pocket'. Typical examples of inactive squamous COM in the pars tensa and pars flaccida can be seen in the section on 'Diagnosis and assessment' above (see **Figures 83.26–83.30**).

The majority of evidence is from personal case series that use a number of different classifications of retractions. Consequently, it is difficult to make meaningful comparisons between series. Furthermore, the retractions are frequently reported in case series in association with OME. The results of treatment for such retractions can be impossible to disentangle from the effects of treatment for the OME.

Examination

The ear should be carefully examined when a retraction is present and particular attention should be drawn to the following possible changes. Where possible, a clinical photograph should be obtained to enable comparisons to be made over time, because diagrams and staging systems, such as those developed by Sadé and Tos, have been shown to be unreliable.[186–188]

RETRACTION OF THE PARS FLACCIDA

Classify the retraction according to Tos. Can I see the fundus of the retraction pocket or not? Is this thought to be self-cleansing or not? Whether a retraction pocket is self-cleansing or not is a qualitative judgement based upon size and appearance. A small, clean retraction pocket in the pars flaccida or pars tensa is likely to be self-cleansing, but such judgements can only be confirmed over time by clinical review.

RETRACTION OF THE PARS TENSA

Is this retraction pocket thought to be self-cleansing or not? What is the relationship of the tympanic membrane to the incudostapedial joint? Is there partial or complete

erosion? What effect has this had upon hearing thresholds? Has the bony ear canal at the level of the tympanic membrane been eroded by long-standing retraction of the pars tensa and become wider? This can be evaluated because structures not normally visible, such as the stapedius tendon and facial nerve, becoming visible. Is the pars tensa adherent to the promontory or not? Whether or not the tympanic membrane is adherent to the promontory may be difficult to evaluate, but Charachon[189] and Gersdorff and Garin[190] argued that autoinflation may provide evidence of such adherence.

Tympanometry may be helpful. An unusually high peaked tympanogram, type A_d, is suggestive of tympanic membrane hypermobility or ossicular discontinuity and may provide further evidence of adherence of the tympanic membrane to the promontory or not. Sadé[191] reported a long-term series of 59 patients with 'hyperinflated' tympanic membranes, in which the middle ear pressure is elevated above atmospheric pressure resulting in ballooning out of the tympanic membrane, so-called hyperectasis. A type A tympanogram with a peak above atmospheric pressure would be indicative of hyperectasis. Sadé[191] noted that hyperectasis was preceded by atelectasis and that this hyperinflated state could persist for weeks, months or even years. If the pars tensa is adherent to the promontory, the perceived wisdom is that the retraction is likely to be long standing although this has not been formally tested in studies. A type B, or flat, tympanogram will suggest the presence of a middle ear effusion, in association with a retraction, and if accompanied by an associated hearing loss, may be a factor in deciding management.

OTHER FACTORS

The role of allergy and sinonasal infection is traditionally thought to be important and usually is included in the treatment of middle ear disease. The precise role of these other factors is not clear other than a general interference with Eustachian tube function. Any relationship between sinonasal factors and tympanic retraction has not been formally examined in clinical studies, but clinical examination of the nose would have a place if symptoms, such as obstruction or discharge, are present.

Natural history

The first assumption is that pars tensa and pars flaccida retractions are clinical consequences of the same predisposing factors. If so, then pars tensa and pars flaccida retraction should coexist. There is good case series evidence that pars tensa and pars flaccida retractions coexist. In a series of 250 adults and children with atelectatic tympanic membranes, Luntz et al.[192] found evidence of pars tensa retraction in 60% and pars flaccida retraction in 86%. Both sites of retraction were found in 49% and only one site in 53%. Another large case series (n = 327) also found a similar association between pars tensa and pars flaccida retraction; if pars tensa retraction was Sadé grade 1, then pars flaccida retraction was present in 43%, and if grade 2 then in 61%, respectively.[193] The lesson here is that, if pars tensa retraction exists, a careful examination should be made to see if pars flaccida retraction is present and vice versa.

PROGRESSION OF RETRACTION POCKETS

Once a retraction of either site is present, the key clinical question is whether such a retraction is likely to progress, remain static or resolve. They may reach such a size and configuration that they cease to become self-cleansing and accumulate inactive squamous debris. This debris may become infected and the clinical picture can then be characterized by repeated episodes of discharge, often with symptom-free intervals in between: intermittently active squamous COM. There is evidence that tympanic retraction can behave in this way, although reliably identifying those ears that will progress from those that will remain stable is not possible. Consequently, regular review is necessary. Retraction may lead to histological changes in the tympanic membrane with loss of elasticity and rigidity so that the tympanic membrane no longer 'drives' the ossicular chain or areas of the tympanic membrane may be eroded leaving a perforation. Tympanic retraction may also damage middle ear structures, for example erode the long process of incus.

There is evidence from follow-up of pars tensa retractions in children with OME that it is a dynamic condition with around 70% resolving spontaneously.[194] Studies of retraction of the tympanic membrane in children and adults over a longer period usually include surgical and medical treatment groups which makes it much more difficult to infer the natural history of this condition. Certainly the balance of evidence when a retraction is in association with otitis media in children is that VTs do little to affect the condition.[195,196] Indeed, the insertion of a VT may significantly increase the chances of retractions and atrophy of the pars tensa.[197] Charachon,[198] in a study of adults and children (n = 95) of stage 1 and 2 (Charachon classification) tympanic retractions followed up over a period of 5 years, found that 16% deteriorated to stage 3 (follow-up 82%) and underwent surgery.

RETRACTION POCKETS AND CHOLESTEATOMA

That there is a relationship between tympanic retraction and significant pathology, such as cholesteatoma, is suggested by several temporal bone studies[199–202] and experimental animal work.[203,204] Longitudinal population studies indicate that there is a significant association between cholesteatoma and pars flaccida retraction in adults and pars flaccida and pars tensa retraction in children.[205,206]

Certain clinical groups have a greater chance of middle ear pathology leading to significant changes to the tympanic membrane. Children with a cleft palate have an approximately 20% chance of developing retraction in the pars tensa[207,208] and those with Turner syndrome have approximately a 50% chance of tympanic pathology.[209] There is, somewhat surprisingly, no evidence that those with cystic fibrosis are more likely to develop tympanic or middle ear changes compared with the general population.[210]

No studies were found that specifically examined the natural history of tympanic retraction and erosion of the ossicular chain, particularly in relation to any change in hearing.

Management

The general assumption is that the complications described above have a reasonable chance of occurring despite the lack of research evidence that this actually happens. A wide variety of treatments have been proposed, but none has been submitted to a randomized controlled trial. Consequently, there is only case series evidence of the efficacy of various treatments.

MANAGEMENT OF NASAL DISEASE

There is evidence that a poorly functioning Eustachian tube plays a role in the pathogenesis of tympanic retraction, so it is common practice to look for and treat any sinonasal disease such as infection or allergy. This practice seems reasonable but no case series could be identified of such management of retraction pockets. Small case series examined the usefulness of tubal insufflation in the management of tympanic retraction. One series (n = 13) politzerized atelectatic middle ears with either carbon dioxide, oxygen, air or nitrogen.[211] The tympanic retraction did disappear, only to slowly reappear at a speed corresponding to the diffusion coefficient of the gases used. No long-term benefit was seen.

AURAL TOILET

Sadé[212] maintains that small retraction pockets can be managed by regular suction cleaning and many experienced otologists would agree with this view. However, no case series has reported its efficacy.

SURGICAL TREATMENTS

Surgical treatments have been undertaken to prevent complications such as discharge, progression of tympanic retraction and restoration of hearing. They are conveniently divided into:

- management of the tympanic membrane
- ventilating the middle ear.

MANAGEMENT OF THE TYMPANIC MEMBRANE

Surgical management of the tympanic membrane is essentially an anatomical approach designed to restore the normal anatomical appearance. The thin retracted tympanic membrane, lacking its normal elastin and collagen component, is unable to withstand any negative middle ear pressures and can become more retracted over time. This has led to a wide variety of surgical approaches.

Excision, no graft

Some have argued that the retracted tympanic membrane is abnormal, should be excised and a new 'normal' eardrum will naturally grow in its place. Sharp and Robinson[213] found that after one excision there was no recurrence in 65% of cases with a mean follow-up of 14 months, but 8% (5 of 66) of ears had persisting perforations. Others have combined excision with insertion of a VT in the remaining tympanic membrane.[214–216] All were small personal case series of less than 40 ears. The incidence of recurrence of the tympanic retraction and persisting perforation were of the same order. The evidence is not of good quality so it is difficult to make a case for inserting a VT at the same time as excising the retraction pocket.

Excision, myringoplasty

A number of larger case series combine excision of the tympanic retraction with a conventional myringoplasty using a variety of graft materials: temporalis fascia,[217–221] dura[222] and reinforcement with cartilage.[205, 223–230] These studies have variable follow-up periods and frequently include both children and adults and other treatments such as insertion of a VT, reconstruction of the ossicular chain or mastoid exploration. These case series suggest that recurrent retraction may be more reliably prevented with cartilage than with temporalis fascia grafts alone. However, there is no good evidence that myringoplasty has any benefit over a watch-and-wait policy in the management of retraction pockets.[231]

Excision, myringoplasty with cortical mastoidectomy

The role of mastoid surgery, undertaken at the same time as the tympanoplasty, seems to suggest that no further benefit is gained.[232–234] However, there may occasionally be a place for removal of small quantities of osteitic bone in the posterosuperior quadrant of the pars tensa to 'marsupialize' a tympanic retraction that is beginning to become no longer self-cleaning.[235]

VENTILATION TUBES

At first sight, to many clinicians, the use of VTs for tympanic retraction would seem obvious. Assuming that the basic pathophysiology is Eustachian tube dysfunction, if air could once again gain access to the middle ear, normal pressures would be restored and the tympanic retraction stabilized or reversed. Evidence that VTs play a temporary role was demonstrated by Sadé et al.[236] They closed a long-term VT used in the management of retraction and showed that retraction returned within 1–2 hours in 89% (33 of 37 cases). Despite this, the evidence seems to suggest that long-term benefit from VT insertion in established retraction is not so straightforward.

Much of the evidence to support or refute the use of VTs has been gained from studies that have been principally concerned with the treatment of OME. Such studies suggest that the use of VTs[195, 237, 238] had no long-term effect on the tympanic membrane. Indeed, the use of VTs in OME seems to increase the prevalence of pars tensa atelectasis and attic retraction. A meta-analysis of both randomized controlled trials and case series of OME showed that long-term VTs increased the risk of perforation

by 3.5 (95% CI, 1.5–7.1) and cholesteatoma by 2.6 (95% CI, 1.5–4.4).[197] The apparent lack of success of VTs in the management of tympanic retraction may be because histological changes have taken place in the tympanic membrane rendering the situation irreversible.

In ears with very poor aeration, Yung[239] has devised a method of inserting a permanent titanium vent into the mastoid antrum at the time of tympanoplasty. This allows aeration of the middle ear and has been successful in a significant proportion of patients. The technique requires surgical expertise and regular long-term follow-up to unblock the vent. It is not yet commercially available.

HEARING LEVELS AND RETRACTION

No studies have tried to associate hearing levels and degree of retraction. Such an association is unlikely to exist with pars flaccida retractions. Significant retractions of the pars tensa are likely to interfere with sound conduction, but erosion of the ossicular chain, usually the incus, will have a greater effect. In addition, no studies were found on the use of hearing aids in tympanic retraction, but this management makes sense, is by definition safe, and is likely to be how many patients are managed.

RECOMMENDATIONS FOR MANAGEMENT FOR AN INACTIVE RETRACTION

In an adult patient

If the patient is an adult (over the age of 12), the Eustachian tube function is likely to be normal and the retraction has a substantial chance of being stable. If there is no significant hearing loss and the retraction pocket is self-cleansing, then follow-up on an occasional basis would be appropriate until it seems clear that it is not progressing. If the retraction pocket is not self-cleansing, then it may be managed with regular microscopic suction clearance.

If there is a conductive hearing impairment, this may be due to loss of effectiveness of the atelectatic tympanic membrane or an ossicular problem. The decision to manage this surgically will depend upon the wishes of the patient, the hearing in the other ear and the expertise of the surgeon. The eardrum may be reconstructed with a graft with a cartilaginous component to help prevent recurrence of retraction. An ossiculoplasty would also be performed where relevant.

In a child under 12 years

In a child under 12 years there is a greater likelihood that a retraction will be unstable and it is important that such children are kept under review. If the hearing is normal, or near normal, then intervention is probably not necessary. If there is modest retraction and a hearing loss due to the presence of a middle ear effusion, then the usual guidelines for managing OME should be followed. There is no evidence that ears with OME and a retraction should be managed any differently as spontaneous resolution is common.[194]

If the retraction is progressing, with, for example, clinical evidence that the incudostapedial joint is beginning to be eroded, or the fundus is beginning to disappear out of view, then most otologists would recommend surgery. The situation is an exercise in damage limitation because the feeling is that, left untreated, this particular retraction will progress to incudostapedial joint erosion or a cholesteatoma. There is an argument for simply excising the abnormal atelectatic tympanic segment and hoping that a more normal tympanic membrane will grow back. The child and their guardians need to be advised that there is a good chance of leaving a tympanic perforation, but that this may be preferable to ossicular erosion or a cholesteatoma. There is little evidence that inserting a VT at the same time influences the outcome. Many otologists would argue that it is possible to go further and consider a tympanoplasty with thin cartilage or pallisades to reinforce the tympanic membrane and prevent a recurrence. There is an increasing body of evidence that this can be accomplished with good hearing and with an eardrum that can remain stable for a good period of time.

There is no evidence that concomitant exploration of the mastoid improves the outcome and this should, by and large, not be considered unless the possibility of unexpected cholesteatoma needs to be ruled out.

KEY POINTS

- Self-cleaning retraction pockets are usually stable in adults but they should be followed carefully in children.
- There is no evidence that surgical management of self-cleaning retraction pockets influences the natural history.

ACTIVE SQUAMOUS CHRONIC OTITIS MEDIA (CHOLESTEATOMA)

Natural history

Active squamous epithelial disease (**Figure 83.36**) is a retraction pocket filled with keratinous debris which may remain active or become inactive. In the former case the disease may or may not anatomically extend. The factors upon which this depends are not clear, but the issue of whether the degree of sclerosis of the mastoid is relevant is controversial. In well-pneumatized temporal bones, such as in children, the disease is frequently extensive, expanding down the well-formed air cell tracts. Squamous epithelial disease is more commonly found in poorly pneumatized sclerotic bones, but whether the sclerosis is relevant to the aetiology of the disease or is caused by it has also not been fully resolved. The evidence suggests that the most important factor in the development of mastoid sclerosis is poor Eustachian tube function. In a prospective study of cleft palate children in whom one ear only was managed with a VT, the mastoid air cell system was noted to be larger on the ventilated side in 86% (19/22) of ventilated ears.[240] Poor Eustachian tube function and reduced middle ear cleft volume has been shown to be characteristic of ears with cholesteatoma.[241]

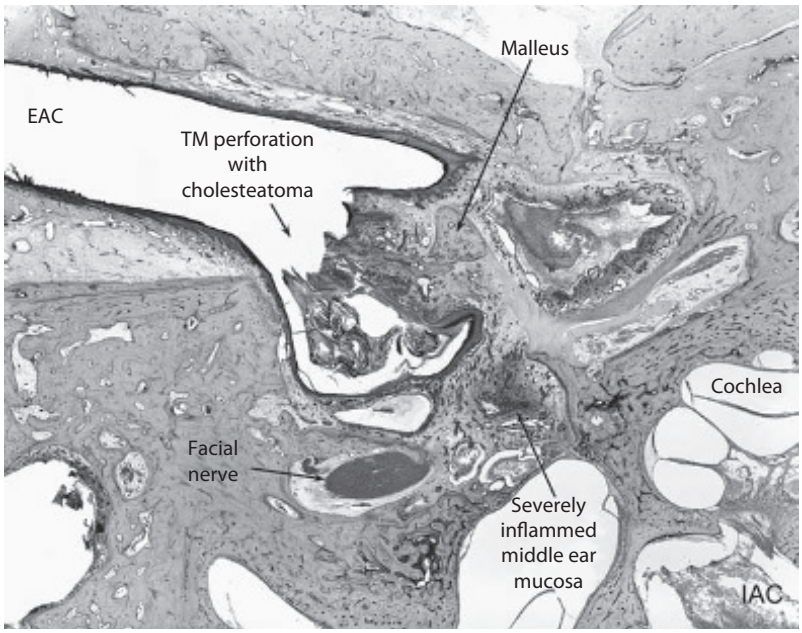

Figure 83.36 Axial temporal bone section from an 18-year-old woman with active squamous epithelial COM (cholesteatoma). There is a posterior perforation of the pars tensa extending to the annulus with ingrowth of squamous epithelium into the middle ear forming a cholesteatoma. Note the retained keratin within the cholesteatoma sac. There is granulation tissue within the middle ear that surrounds the cholesteatoma sac. EAC, external auditory canal. IAC, internal auditory canal. (*Magnification ×8.*)

PROGRESSION TOWARDS HEALING

There are no figures available which define the proportion of cases of active squamous epithelial disease which heal but cases are occasionally encountered where the patient has a well-formed 'atticotomy' or 'mastoidectomy' cavity but denies ever having surgery. In these cases presumably the disease process has selectively resulted in bone erosion of the outer attic wall and in some cases the whole posterior meatal wall. The epithelial migration pattern is restored from medial to lateral and the ear develops a 'normal' albeit widened external meatus or 'automastoidectomy' cavity.

In a proportion of cases, also undefined in the literature, there is a change from an active keratin producing retraction pocket to one that no longer produces or accumulates squamous epithelium but reverts to a clean, non-progressive retraction. This is only likely to occur if the retraction pocket is small and in the situation of established cholesteatoma, by definition active squamous epithelial COM, spontaneous reversion to inactivity must be rare but its frequency has not been documented.

PROGRESSION OF ACTIVE DISEASE

The natural history of cholesteatoma is for anatomical progression of disease over a variable timescale with inevitable involvement of the ossicular chain and possible involvement of the labyrinth by erosion of the lateral semicircular canal. The serious and potentially life-threatening sequelae of intracranial and intratemporal complications are discussed below (see 'Intracranial complications'). The timescale for this is extremely variable and it is likely that many patients live with active squamous epithelial disease with minimal disability or inconvenience. Bacteriology is non-specific with a wide range of organisms frequently cultured. Madana et al. found *Pseudomonas* in 32%, *Proteus* in 20% and *Staphylococcus aureus* in 19% in children with cholesteatoma.[242] As with mucosal disease, these organisms are likely to be opportunistic rather than primarily pathogenic (see 'Factors influencing activity of chronic otitis media' above). As the disease process advances, erosion of bone takes place as the lesion enlarges, by the mechanisms of osteoclastic and osteoblastic remodelling discussed in 'Active mucosal chronic otitis media' above. Although bone erosion in cholesteatoma takes place in the absence of acute inflammation and granulation tissue formation in some cases, the norm would be for the disease process to be associated with chronic granulation tissue formation with osteitis in the adjacent bone.

HEARING IN ACTIVE SQUAMOUS COM

It is well recognized that hearing is often preserved until a very late stage in ears containing cholesteatoma in spite of the ossicular chain being disrupted. Severe erosion of the incus with absence of the long process is common in established cholesteatoma and frequently the disease engulfs the whole incus and the malleus head. The stapes superstructure is also often involved and may be eroded. Fortuitously for the patient, hearing preservation occurs because the cholesteatoma sac bridges the gap between the functioning part of the ossicular chain and the inner ear. The unfortunate consequence is that removal of the disease surgically may reduce the hearing by increasing the air–bone gap. Involvement of the incus in cases of cholesteatoma is almost universal but precise figures are not available. Fortunately, in many cases it is possible to reconstruct the middle ear in such a way that hearing loss is minimized.

Presentation

Classically, active squamous COM presents with foul-smelling otorrhoea and hearing impairment. However, many patients complain only of hearing impairment and

are unaware of any discharge from their ear as the quantities of pus are small and these dry up and form crusts. Sometimes, the inexperienced otoscopist can miss the disease as the pars tensa appears normal, but a small crust obscures the attic (see **Figure 83.11**). The crust can be mistaken for wax, though wax only occurs in that site if the patient pushes it there with a cotton bud.

Examination

Microscopic examination is usually required to allow thorough cleaning of the discharge and to confirm the diagnosis. In very inflamed ears, a cholesteatoma may not be visible at first presentation. Sometimes there is an aural polyp obscuring the attic or posterior pars tensa; such a case should be assumed to be a cholesteatoma until proven otherwise. Removal of crusts can be uncomfortable and, particularly in children, may require an anaesthetic. When debris is removed from a retraction pocket in the attic or posterior pars tensa, the extent of the retraction pocket may not be visible with a microscope. Examination with a rigid endoscope may be helpful if knowledge of the extent is important for management decisions.

IMAGING

Many clinicians favour radiology before undertaking surgery for cholesteatoma. CT has been the standard method of imaging for many years. It provides very good resolution of anatomical landmarks. Its disadvantage is poor differentiation of cholesteatoma from other soft tissues, such as granulation tissue, cholesterol granuloma[243] or brain tissue. Bone erosion of the scutum and the incus and malleus though rarely the stapes can be demonstrated. CT can often demonstrate erosion of the inner ear with fistula formation or dehiscence of the facial nerve, but a negative CT does not rule out a fistula. Fistulae are reported to occur in 10–15% of cases of cholesteatoma but the sensitivity of CT at identifying fistulae is not reliable (**Table 83.8**). Dehiscence of the facial nerve is identified surgically in up to 19% of cases of cholesteatoma,[244] most commonly in the horizontal portion.[244] Fuse et al. reported that facial nerve dehiscence was detected on CT in only 66% of 29 cases.[245] Yu et al. found that the condition of the facial canal on CT corresponded with surgical findings in only 67 of 76 ears (88%).[246] The surgeon should not rely on CT but should assume that there is a fistula and that the facial nerve is dehiscent in all cases to minimize the complications of surgery.

Conventional MRI shows cholesteatoma as a soft-tissue mass but does not differentiate this from other soft tissues. It does not provide enough bony detail to be useful on its own. More recently, non-echoplanar DW-MRI has been shown to be very reliable at detecting cholesteatoma and differentiating it from other soft tissues.[250] It has been shown to be of value in detecting residual cholesteatoma and reducing the necessity for second-look surgery.[251]

If intact canal wall surgery is to be considered, knowledge of the anatomy, in particular the pneumatization of the mastoid, is important. If the mastoid is acellular, intact canal wall surgery is more difficult. If canal wall-down surgery is planned, some experienced surgeons do not consider radiology necessary, unless intracranial complications of disease are suspected. There is no evidence that pre-operative CT influences the surgical management of cholesteatoma in canal wall-down surgery.[252, 253]

Management

The aims of management of active squamous COM are to relieve the patient's symptoms and to minimize the risks of complications of the disease. However, complications are rare (see 'Complications of surgery' below). Surgical removal is the only effective treatment for cholesteatoma, but surgery has potential complications too. Are the risks of the treatment greater than the risks of the disease? The likelihood of complications of the disease varies with the life expectancy of the patient, while the risks of surgery vary inversely with the skill of the surgeon. When surgical treatment is considered appropriate, topical treatment for granulations and associated mucosal disease while awaiting surgery may lessen the otorrhoea and therefore be socially beneficial (see 'Active mucosal chronic otitis media' above). Some patients, particularly the elderly, may be unfit for surgery and the risks of the disease may be minimal. In these cases, careful aural toilet with removal of squamous debris from the retraction pocket and topical treatment at regular intervals may keep the symptoms at a level acceptable to the patient. Hearing aids should always be considered when there is hearing disability (see 'Hearing aids in chronic otitis media' below).

The aims of surgery for active squamous COM are:

- eradication of disease
- an epithelialized, self-cleaning ear
- hearing maintenance or improvement.

The principle aim of surgery for cholesteatoma is to completely remove disease and minimize the risk of recurrence, but, in addition, the ear should be returned to as near normal as possible. The ear should be self-cleaning and should not require regular aural toilet, and the hearing should be restored, although this is not always possible. The idea that the aim of surgery is simply to remove disease in order to create a safe ear is obsolete. Many patients present because of hearing impairment and will not be satisfied with management that provides no apparent benefit.

There are many different surgical techniques for managing active squamous COM, which can largely be categorized as open cavity (canal wall-down) and closed cavity (canal wall-up) mastoidectomy. Over the last 30 years

there has been much discussion among otologists about the comparative benefits of these techniques, and there is no more agreement now than there was 30 years ago.

CANAL WALL-DOWN MASTOIDECTOMY

The traditional method for removal of cholesteatoma was modified radical mastoidectomy using the posterior to anterior approach. The mastoid was opened behind the external auditory canal, the cholesteatoma identified and followed forwards through the aditus into the attic with removal of the posterior bony wall of the canal. This usually resulted in a large cavity, much larger than is required to control the disease. Large cavities can be problematic: many continue to discharge and, even if well epithelialized, they often do not self-clean so regular clinic attendance is required for removal of squamous debris and wax from the cavity.

Small cavity mastoidectomy, or atticoantrostomy, the anterior to posterior approach, has become more popular. The cholesteatoma is identified in the epitympanum or posterior mesotympanum and followed backwards. Sadé[254] gave a very clear description of the surgical method. Smyth and Brooker[255] showed that this technique resulted in a much smaller cavity with a mean volume of 1.4 cm^3 compared with 2.4 cm^3 after modified radical mastoidectomy, and that there was no difference in the number of ears that continued to discharge between the two techniques. In addition, when the cholesteatoma is small, surgery can be limited to atticotomy and the defect in the attic wall can be closed with tragal or conchal cartilage with its perichondrium attached.

Wormald and Nilssen[256] evaluated the mastoid cavities in 101 patients attending an outpatient clinic between 6 months and 20 years after mastoidectomy. The cavity was actively discharging in 52% and dry in 48% of patients. They found the following significant differences in the active cavities:

- high facial ridge
- sump in cavity below floor of external auditory canal
- perforation in tympanic membrane
- small external auditory meatus.

The problems of mastoid cavities can be reduced by good surgical technique and by partial obliteration of cavities, either with cartilage or prosthetic materials. The cavity must be rounded and smoothly contoured with no overhanging ridges and no facial ridge in order to allow migration of epithelium. The tympanic membrane should be repaired to close all communication between the mastoid cavity and the mesotympanum and Eustachian orifice. The meatus should be an adequate size relative to the size of the cavity, so a meatoplasty is almost always required. The conchal cartilage removed from the meatus should be used to reduce the size of the cavity.

Canal wall-down surgery has lower rates of recurrence of cholesteatoma (5–15%) and recurrences are usually easily identified in the outpatient clinic, so second-look operations are rarely necessary. Residual cholesteatoma should be a rarity in competent hands. A significant proportion of patients (20–25%) continue to have otorrhoea, either intermittent or continuous, after mastoid surgery.[257–259] Experienced otologists of repute have much higher success rates at creating dry ears. Smyth and Brooker[255] reported that only 5% of ears were moist 5 years after surgery. This is probably an indication that attention to detail in these operations results in much better outcomes for the patients.

CANAL WALL-UP MASTOIDECTOMY

Canal wall-up mastoidectomy (combined approach tympanoplasty) has the advantage of leaving an intact external auditory canal and no mastoid cavity. However, the incidence of recurrent and residual cholesteatoma is high (20–50%), therefore second-look operations after 12–18 months are necessary in most cases, and some cases require further procedures subsequently. Second look can often be avoided nowadays by the use of DW-MRI.

The advantage of canal wall-up mastoidectomy is the preservation of a (relatively) normal external auditory canal and the absence of a mastoid cavity. It has been claimed that post-operative hearing thresholds are better, but there is no evidence for this as all reports are case series and outcomes depend on selection of patients. Many authors claim that their hearing outcomes after canal wall-down mastoidectomy are comparable.

A minority of surgeons, most of whom are experienced otologists, favour this procedure. It is technically more difficult and requires significantly longer operating time. In addition, at least one further operation may be required. Patients must be made aware of this. More recently, some surgeons have recommended canal wall-up surgery with obliteration; these ears are followed up with diffusion-weighted MRI to exclude residual cholesteatoma.[251]

CANAL WALL-UP VERSUS CANAL WALL-DOWN MASTOIDECTOMY

Reconstruction of the middle ear can be achieved with either technique and there is no evidence that the long-term hearing results differ between procedures. It has been claimed at times that post-operative hearing results are better following canal wall-up mastoidectomy. These claims are usually based on an author's comparison of cases that have undergone one of these procedures. It must be remembered that the procedure is not randomized but is the one thought most appropriate for the patient. Some authors have pointed out that, though the post-operative hearing thresholds are worse after canal wall-down mastoidectomy, the pre-operative hearing thresholds are also worse.[260] Karmarkar et al.[261] found no significant difference in post-operative hearing results between 176 cases of canal wall-down mastoidectomy and 257 cases of canal wall-up procedures. Toner and Smyth[262] reported better hearing outcomes 1 year after surgery for canal wall-up compared with canal wall-down mastoidectomy. However, at long-term follow-up (mean of 9 years), there was no significant difference between groups. Many

surgeons, by doing canal wall-down surgery but partially obliterating the cavity, achieve an outcome that is similar to canal wall-up surgery.

PARS TENSA CHOLESTEATOMA

Cholesteatoma arising from the pars tensa may be confined to the middle ear, most commonly growing into the facial recess and sometimes spreading anteriorly beneath the pars tensa and malleus handle. This can be removed by opening the facial recess, which is more easily accessible than inexperienced surgeons sometimes think. When the cholesteatoma grows anteriorly, care must be taken not to leave some under the tympanic membrane remnant. Complete clearance from the oval window, especially when there is an intact stapes superstructure, can be difficult. If there is doubt over clearance of disease, the tympanic membrane can be closed and the ear reopened after 12–18 months.

OSSICULOPLASTY IN ACTIVE SQUAMOUS COM

The incus is probably the most commonly used prosthesis for ossicular reconstruction. The possibility of an allograft incus from an ear with cholesteatoma containing squamous cells has been explored. Rupa et al.[263] examined histologically 60 mallei and 53 incudes from ears with cholesteatoma and found no evidence of squamous epithelial cells, while Dornhoffer et al.[264] examined 11 incudes removed at the time of surgery in ears with cholesteatoma and found evidence of squamous epithelial cells in seven incudes (64%). There is thus the theoretical risk that the use of such an incus could cause a recurrent cholesteatoma. The possibility that these cells could regenerate without a blood supply seems remote. No case of recurrent cholesteatoma arising from an allograft incus has been reported in many extensive surgical series.

COMPLICATIONS OF SURGERY

Complications of mastoid surgery are not uncommon. In an audit of results in the UK, facial palsy occurred in 1% and dead ear in 2% of 365 canal wall-down mastoidectomies.[258] Wormald and Nilssen[265] reported the outcome of mastoid surgery in 1024 patients. The incidence of intra-operative facial nerve palsy was 2% and of total loss of hearing was 2%. The incidence of facial palsy is widely accepted to be rare in the hands of expert surgeons. However, total loss of hearing also occurs in the hands of experts, usually in ears where there is a fistula into the inner ear.

PROBLEM MASTOID CAVITIES

Mastoid cavities that continue to discharge can usually be corrected surgically. Regular aural toilet over many years with frequent antibiotics is ineffective and is poor medical practice in the modern world. Most commonly the problem arises because of poor surgical technique at the initial mastoidectomy: the meatus may be too small, a high facial ridge may have been created, there is a sump in the mastoid tip or the tympanic membrane has not been closed. If the cavity is well epithelialized but debris collects, correction of the cause of poor drainage – narrow meatus, high facial ridge – may result in significant improvement. For cavities with more extensive disease, revision surgery requires meticulous surgical technique. Jackson et al.[266] give a careful description of the principles of management of problem cavities. In their series of 541 ears, 89% were clean, healed and dry after revision surgery.

However, many surgeons nowadays prefer to obliterate, at least partially, large cavities that are not epithelialized. Revising these cavities and making them even larger rarely succeeds in creating a dry ear. Skin does not readily grow on bare bone and the naturally moist environment in the ear encourages the growth of respiratory mucosa. The cavity can be made smaller by obliteration which can be achieved by filling the cavity with bone pâté [267]or hydroxyapatite granules.[268] Both of these materials must be covered by a vascularized fascioperiosteal flap. Alternatively, the posterior canal wall can be reconstructed with a hydroxyapatite prosthesis.[269] The different methods of mastoid obliteration have not been directly compared. In numerous case series using these and other techniques, the proportion of patients who have dry ears following obliteration is reported as 80–95%.[270] Irving et al.[271] reported better symptom scores in patients who had mastoid obliteration than in patients who had revision mastoidectomy. Meticulous surgical technique is considered necessary to avoid leaving squamous epithelium in the obliterated cavity, though cases of this have not been reported.

KEY POINTS

- Cholesteatoma continues to enlarge in most patients, but the rate of progression on average is very slow.
- The preferred management in patients who are otherwise fit is surgery.
- The aims of surgery are to remove disease, to create a trouble-free ear and to improve the hearing.
- At least 1% of patients get a facial palsy and 2% a dead ear after mastoid surgery in the UK. The incidence is very much lower when the surgery is performed by experienced surgeons.

HEARING AIDS IN CHRONIC OTITIS MEDIA

Healed COM

Hearing aids are straightforward and effective forms of management. When listening in low- and medium-level environments, a person with a conductive hearing impairment will have poorer speech recognition ability than someone with a sensorineural impairment of the same degree. The person with the conductive hearing impairment will, however, derive more speech recognition benefit from hearing aids than the person with the

sensorineural hearing impairment.[272] There is no evidence to compare successful surgery with provision of hearing aids in this patient group. For many patients, hearing aids are the more acceptable form of management. Their success rate in lessening disability is much greater than that of surgery and the complication rate is much smaller. In patients with hearing disability and bilateral healed COM, a hearing aid is appropriate even if surgery is planned for the poorer-hearing ear. Unless surgery is very successful, they will still have a hearing disability afterwards.

Inactive COM

Many people believe that closure of the perforation in inactive COM is necessary prior to fitting a hearing aid, though there is no evidence to confirm this. It is accepted that some patients with inactive COM who are fitted with a hearing aid then develop active COM and otorrhoea. However, the likelihood of this happening is not known. Adults who have a history of intermittent otorrhoea are probably likely to develop further otorrhoea when using a hearing aid. However, the chances of otorrhoea in a patient with a totally inactive ear and no recent history of otorrhoea are probably small, though there is no evidence to confirm this. A sensible management plan in such a patient would be to try a hearing aid. If the ear becomes active, the tympanic membrane should be repaired. If the ear remains inactive, then the patient has avoided an unnecessary operation.

The only presenting symptom in patients with inactive squamous disease is hearing impairment. If they have a hearing disability, a hearing aid is often the most effective management.

Active COM

Hearing aids are effective in patients with hearing disability, as in inactive mucosal COM. However, closure of the external auditory canal with a hearing aid usually exacerbates the otorrhoea, so the otorrhoea should be managed first and the preferred option is usually surgical repair of the tympanic membrane. In some patients, for example patients who are medically unfit for surgery and patients with only one hearing ear, surgery is better avoided. Such patients can often be managed by regular aural toilet and occasional topical treatment.

All otologists have some problem discharging mastoid cavities that are resistant to all attempts at treatment. Occasionally, such a patient has bilateral problem cavities or has a profound hearing loss in the opposite ear. If such a patient requires hearing amplification, conventional air conduction hearing aids cause problems: they exacerbate the activity and the otorrhoea interferes with the function of the hearing aid. These patients can often be effectively managed with a bone-anchored hearing aid (BAHA) (see Chapter 93, Bone-conduction hearing aids) that does not interfere with the disease.[273] Such management often has the additional benefit of reducing the amount of discharge from the cavity.

KEY POINTS

- In many patients with COM, the main symptom is hearing disability and this should be managed at an early stage.
- Conventional hearing aids are effective management of patients with hearing disability and inactive COM.
- Bone-anchored hearing aids can be very effective management of patients with hearing disability and active COM which does not respond to treatment.

COMPLICATIONS OF ACTIVE CHRONIC OTITIS MEDIA

Classification of complications

The complications of active COM may be classified as intratemporal (cochlea, labyrinth and facial nerve), sometimes expressed as extracranial, and intracranial. Extracranial complications are postauricular abscess, facial palsy, petrous apicitis and Bezold abscess (neck abscess as a result of direct extension from suppuration in the mastoid tip). Intracranial complications are meningitis, brain abscess, extradural abscess subdural abscess, lateral venous sinus thrombosis and otitic hydrocephalus.

RELATIVE INCIDENCE OF COMPLICATIONS

In a large series of 268 patients with complications of COM, the incidence of extracranial complications was 32%, intracranial complications was 56% and combined intracranial and extracranial was 12% (Table 83.9).

RISK OF COMPLICATIONS

Traditionally, ears with squamous epithelial disease have been regarded as being more at risk of serious complications as opposed to those with mucosal disease. In fact, the evidence confirms that there is a significant risk with both types of disease. Singh and Maharaj[274] report an incidence of 41% squamous epithelial versus 59% mucosal disease in their group of extracranial complications and 59% squamous versus 41% mucosal disease in the intracranial group. In the combined group, 58% had squamous epithelial disease and 42% had mucosal disease.

Otorrhoea as an obvious symptom may or may not be present and there is no evidence that ears with COM are more or less likely to suffer complications if they are

TABLE 83.9 Relative incidence of complications in active mucosal and squamous COM

Extracranial	%	Intracranial	%
Postauricular abscess	75	Brain abscess	51
Facial palsy	6	Subdural abscess	20
Bezold abscess	2	Extradural abscess	10
Petrous apicitis	0.2	Lateral sinus thrombosis	20
Meningitis	12		

Reproduced from Singh and Maharaj,[274] with permission.

actively discharging. However, the development of pain may indicate that an acute infection has supervened and that there may be a build-up of pus under pressure in the middle ear or mastoid. Although there is no direct evidence that such ears have a higher incidence of complications, the clinician should bear this possibility in mind. As discussed above, the incidence of brain abscess arising from mucosal disease is significant and indeed otogenic abscess may occur from ears previously treated by mastoidectomy.[275] The annual risk of developing an otogenic brain abscess has been estimated at 1 in 10 000, making the lifetime risk of a 30-year-old patient with chronic ear disease of the order of 1 in 200.[276]

MORTALITY FROM COMPLICATIONS

The intracranial complications of COM are serious, with a mortality of 8% in the series of Singh and Maharaj.[274] Of the 15 deaths, 7 were in ears with squamous epithelial disease and 8 in ears with mucosal disease. There was 1 death from meningitis, the others being from brain abscess (12) and subdural abscess (2). There were no deaths from extracranial complications.

Extracranial complications

SENSORINEURAL HEARING LOSS

It has been suggested that toxins in COM can damage the cochlea. However, comparison of the two ears in patients with unilateral COM and no history of any factors predisposing to hearing loss have shown no difference in bone-conduction thresholds between the diseased ears and the contralateral normal ear (Dumich and Harner,[277] 200 patients; Noordzij et al,[278] 69 patients). Browning and Gatehouse[279] found no difference in bone-conduction thresholds between 395 ears with COM and 920 control ears after correcting for the Carhart effect. It has been suggested that the risk of sensorineural hearing loss may increase with age.[280] One recent study found a strong association between COM and sensorineural loss, but the authors comment that their data showed extreme variability, which implied that there may by a group of patients particularly vulnerable to sensorineural loss.[281] On the evidence available it seems reasonable to conclude that sensorineural hearing loss may occur as a result of COM, but that this is a rare occurrence and does not affect the great majority of patients. Sensorineural hearing loss may result from the treatment of active COM with potentially ototoxic eardrops, but most practising otolaryngologists regard this as rare, probably at least as rare as sensorineural hearing loss due to the disease.

SUDDEN SENSORINEURAL HEARING LOSS

Sudden sensorineural loss may also occur, but the incidence and precise reasons for this have not been defined nor has the precise relationship to the COM as distinct from other causes.

LABYRINTHINE COMPLICATIONS

Acute bacterial labyrinthitis or cochleolabyrinthitis is a serious complication that often results in a dead ear. Fortunately, in the context of such a common disorder as COM, it is a relatively rare event to lose all the hearing from mucosal disease and the main risk to the inner ear may be from surgery. Similarly, balance disturbance is a serious complication due to labyrinthine involvement by the infective process and may be the first sign of the development of a labyrinthine fistula, almost invariably into the lateral semicircular canal. Chronic low-grade imbalance, with or without detectable nystagmus, implies the development of a labyrinthine fistula. This entity can occasionally result in sudden acute vertigo although this is rare. Erosion of the bone overlying the lateral canal arises in both mucosal and squamous epithelial disease, particularly if there is extensive granulation tissue formation. The frequency of fistulae at surgery is usually reported as 10–15%. The mechanism is likely to be the inflammatory reaction provoking osteitis in the labyrinthine bone which is then subject to the forces of osteoclastic and osteoblastic activity with the osteoclastic element predominating. When the inflammatory process is eliminated by surgery, bone regeneration may occur over such a fistula.

FACIAL NERVE COMPLICATIONS

The incidence of facial palsy is small in the context of the commonness of the disease and it is usually associated with dehiscence of the fallopian canal. Erosion of the bony fallopian canal can occur in active mucosal COM but probably more commonly in squamous epithelial disease where it has been reported in up to 19% of cases,[244] particularly in the presence of granulations, and granulation tissue may form on the nerve sheath itself. Removal of this granulation tissue, which may be exuberant enough to form a polyp, is extremely hazardous to the nerve and should only be carried out under direct vision.

MANAGEMENT OF EXTRACRANIAL COMPLICATIONS

Labyrinthine complications

Acute labyrinthitis should usually be managed medically with bed rest, intravenous antibiotics and labyrinthine sedatives such as prochlorperazine. The patient should be observed carefully for early signs of meningitis. When the general condition has improved, usually after several days, the middle ear and mastoid should be formally explored and appropriate surgery carried out.

Patients with active squamous COM and a suspected labyrinthine fistula should have early surgical management to prevent deterioration of inner ear function. Most surgeons recommend a canal wall-down mastoidectomy. The cholesteatoma matrix should be left undisturbed over the semicircular canals until all other disease is removed and all other aspects of the procedure such as meatoplasty are completed. The matrix should then be carefully lifted and the fistula identified. It is

then peeled off the membranous labyrinth and the fistula is immediately sealed with fascia and bone dust. The fascial graft for the tympanic membrane provides a further layer of closure. Though the risks of loss of cochlear function are higher in large fistulas, Herzog et al.[247] reported no loss of cochlear function in 17 fistulas not exceeding 2 mm.

Facial nerve complications

In the presence of a facial nerve palsy, active COM should be managed urgently and almost always surgically. Appropriate intravenous antibiotics should be commenced on admission. Squamous COM should be managed by the appropriate surgical approach and the cholesteatoma matrix should be carefully dissected off the fallopian canal and facial nerve. Active mucosal COM should be managed by cortical mastoidectomy and exploration of the middle ear with careful removal of granulation tissue from the fallopian canal. Some surgeons believe that the canal should be widely decompressed and the nerve sheath opened, but others think that removal of disease is adequate and that opening of the nerve sheath increases the risk of surgical trauma to the facial nerve. Complete recovery of facial function can be expected in most cases after careful surgical management within a few days of onset. Delay in management results in poorer outcomes.[282]

Intracranial complications

ROUTES OF INFECTION OF THE CRANIAL CAVITY

There are several routes by which sepsis may spread to the cranial cavity from an infected ear and, indeed, considering the proximity of the dura and sigmoid sinus to the infective process, in many cases, it is surprising that intracranial complications are not more common. These routes are most commonly by direct erosion of osteitic bone by the inflammatory process or via infected thrombophlebitis of the emissary veins traversing the bone and also the dura. Infection may also reach the cranial cavity via fractures and surgical defects. Normal anatomical points of weakness, such as the oval and round windows and the internal auditory meatus and cochlear aqueduct, are other possible routes for infection entering the cranial cavity.

OTOGENIC INTRACRANIAL SEPSIS

The main intracranial septic complications are meningitis and intracranial abscess. The latter may be subdivided into extradural abscess, subdural abscess and intracerebral or cerebellar abscess. Thrombophlebitis of the sigmoid sinus and otitic hydrocephalus are the other main complications.

MENINGITIS

Meningitis usually presents as an acute illness with severe headache, neck stiffness and in the later stages drowsiness and coma in a systemically ill patient. Early diagnosis is essential to minimize the risk of death and serious sequelae such as sensorineural hearing loss. The suspicion of meningitis should be raised in any otherwise fit individual with a severe acute pyrexial illness with headache who has a history of a discharging ear, particularly if there is neck stiffness. The diagnosis is confirmed by lumbar puncture, and culture of cerebrospinal fluid will identify the organism.

INTRACRANIAL ABSCESS

In intracranial abscess the presentation is often much more insidious, with low-grade headache, occasionally more severe, mild pyrexia and in the later stages drowsiness, lethargy and weakness. Subdural abscess tends to present more acutely and may be accompanied by fits and focal neurological signs depending upon site, whereas abscess within brain tissue has a notoriously insidious onset with symptoms developing over several days, and neurological signs, dependent upon site, relatively infrequent. Classically, there is an early period of more acute symptoms due to a localized encephalitis with associated brain oedema. The predominant symptoms are headache and vomiting with fever and general malaise. These symptoms then settle as the abscess develops and the more insidious symptoms supervene. The most common sites for otitic intracranial abscess are temporal lobe and cerebellum, as would be expected from their proximity to the temporal bone. The frequency of and mortality from brain abscess have declined markedly in recent years, with mortality of 6–14% quoted in one series.[283] The diagnosis is made by CT scanning, which should be undertaken early if any of the above symptoms develop in a patient with COM.

LATERAL VENOUS SINUS THROMBOSIS

Lateral venous sinus thrombophlebitis is a rare but extremely serious complication of COM requiring urgent recognition and treatment. Infection spreads to the venous sinus directly from the mastoid or via any of the venous channels draining the middle ear and mastoid. Prior to the development of infected thrombus within the lumen of the sinus, there may be abscess formation in the close vicinity of the vein. Initially, mural thrombus forms in the sinus which gradually propagates and organizes. Septic embolization frequently occurs which may result in metastatic abscess formation and occlusion of the sinus may result in raised intracranial pressure. The clinical features will frequently be modified by antibiotic therapy but pyrexia, otalgia and mastoid and neck tenderness in a systemically ill patient are suggestive. Drowsiness and lethargy supervene as the illness progresses and the disease is frequently complicated by other intracranial septic complications such as meningitis or brain abscess. Papilloedema is frequently present and highly suggestive of the diagnosis. The investigation usually undertaken first is CT scanning but MRI may add further information, particularly about venous flow in the sinus.

OTITIC HYDROCEPHALUS

Otitic hydrocephalus (benign intracranial hypertension) is the rarest of the intracranial complications of ear disease and may occur after an episode of AOM, as well as complicating COM. The aetiology remains obscure but the consensus view is that it results from lateral sinus thrombosis, presumably with concomitant obstruction of other intracranial venous channels.[284] Symptoms are the same as those mentioned above, which may raise the suspicion of any intracranial complication, and the presence of papilloedema is suggestive. Early CT scanning is necessary to make the diagnosis and rule out more serious intracranial septic complications.

MANAGEMENT OF INTRACRANIAL COMPLICATIONS

General principles

The basic principles of management of intracranial sepsis resulting from COM are:

- antibiotics
- full neurological observations
- neurosurgical advice
- management of the ear.

Broad-spectrum intravenous antibiotics in effective dosage should be started. A bacteriology swab of the ear should be taken but choice of antibiotic agent should not await the results of culture and sensitivity, especially as ear swabs do not necessarily correlate with abscess swabs. Choice of antibiotic depends on the location of the patient, as the likely organisms vary in different parts of the world. In addition, the range of drugs available and the likely resistance of organisms change with time.

Full assessment of the neurological condition of the patient should be recorded and regularly monitored. The neurosurgeon will usually decide on the management of the patient, but this decision may be influenced by the neurological condition and its progress.

Meningitis

Treatment is antibiotic therapy and observation. Management of the ear should be deferred for a few days until the patient's condition improves. However, if the patient's condition does not improve after 48 hours, or if it deteriorates, then immediate exploration of the ear is indicated.

Intracranial abscess

Abscesses usually require drainage. Otogenic extradural abscesses usually lie adjacent to the temporal bone. The most appropriate surgical approach to the abscess is through the mastoid, therefore the ear disease should be managed at the same time.

Subdural and intracerebral abscesses were traditionally managed by the neurosurgeon, by aspiration through a burrhole, which may require to be repeated, or by craniotomy and excision of the abscess. More recently, these abscesses have been managed by transmastoid drainage of the abscess with mastoidectomy, either canal wall-up or wall-down depending on the pathology in the ear.[285, 286]

Lateral venous sinus thrombosis

Most clinicians advocate early surgical management of the ear. It used to be thought that the lateral sinus should also be opened. After clearing disease from the mastoid, the bone covering the lateral sinus is removed, the sinus opened and the infected clot removed. However, more recent case series have recommended mastoidectomy and antibiotics without opening the sinus.[287, 288]

Otitic hydrocephalus

Otitic hydrocephalus may result from raised intracranial pressure associated with lateral venous sinus thrombosis.

Management is reduction of the raised intracranial pressure by steroids, diuretics and hyperosmolar dehydrating agents. Treatment may need to be continued for many weeks. Occasionally a ventriculoperitoneal shunt may be required.

BEST CLINICAL PRACTICE

- ✓ Complications should be considered in any patient with COM who is generally unwell and in particular with symptoms such as pyrexia and headache.
- ✓ Early and effective management of complications is important. Expert, non-otolaryngological advice may be required.

FUTURE RESEARCH

- ➤ Advances in sequencing technologies and mass spectrometry for gene expression and proteomics.
- ➤ Use of bioinformatics to anlayze gene networks.
- ➤ Development of mouse models for CSOM and cholesteatoma.
- ➤ Development of bacteriophages, small interfering RNA (siRNA) in treatment of COM.
- ➤ Novel methodologies for middle ear drug delivery.

KEY POINTS

- Chronic otitis media (COM) implies a permanent abnormality of the pars tensa or flaccid.
- Active mucosal COM is often associated with destruction of the ossicular chain.
- Cholesteatoma is a benign keratinizing epithelial-lined cystic structure found in the middle ear and mastoid.
- Epithelial cells in cholesteatoma are derived from the tympanic membrane.
- In the rare instances of cholesteatoma occurring behind an intact tympanic membrane it has been shown that the cholesteatoma is derived from the tympanic membrane.
- The prevalence of COM is greater in lower socioeconomic groups.
- COM in cleft palate patients followed up to 10 years of age is around 20%, with 2% of them having a cholesteatoma.
- Studies to examine the presence of biofilms in active COM have shown a 60% biofilm incidence as opposed to 10% in the control, uninfected group.
- OME predisposes to chronic retraction of the pars tensa or flaccida and this subsequently progresses to cholesteatoma.
- Tympanosclerosis is found in the middle ear in around 25% of ears at surgery.

CHAPTER 84

MYRINGOPLASTY

Charlie Huins and Jeremy Lavy

SEARCH STRATEGY

Data in this chapter may be updated by a Medline and Embase search using the keywords: myringoplasty, tympanoplasty, tympanic membrane, perforation, chronic otitis media and focusing on surgery and management.

INTRODUCTION

Myringoplasty can be defined as the surgical repair of the tympanic membrane.[1] In the majority of cases the damage is likely to be a persisting perforation of the drum but there are also situations where a thin or retracted drum may need to be reinforced. This chapter will focus on the perforated eardrum but some of the techniques described are also applicable to reinforcement myringoplasty. Wullstein in 1956[2] classified tympanoplasty, with myringoplasty being classified as a Type I tympanoplasty.

HISTORY

Descriptions of artificial animal-based plugs being used to cover perforated tympanic membranes date back to the 1640s.[3] Such plugs probably served the purpose of keeping the ear dry and therefore reducing the risk of infection, but it is unlikely that there would have been any positive effect on the hearing acuity of the ear. For the first accounts of more sophisticated treatment one has to wait until the 1850s when Yearsley described an artificial eardrum consisting of moistened cotton wool.[3] This was inserted into the perforation and plugged it, often affording a noticeable improvement in hearing. Toynbee describes an artificial eardrum comprising a gutta percha disc and a silver wire. Around this time William Wilde and Roosa were advocating the use of cautery to the remnant tympanic membrane to encourage healing. Silver nitrate and trichloracetic acid were commonly used agents. Joynt (1919) combined cautery with the use of a paper patch overlying the perforation; Blake first described the paper patch on its own in 1887. In 1878 Berthold described his technique of using a full-thickness skin graft, describing this alongside 'freshening' or excision of the perforation edges to 'render these parts into a wound'; he is also credited with being the first to use the term 'myringoplasty'. Ely described a similar technique but his work was not published until a year later in 1879.

Although these techniques were being described in the medical literature, they were not consistently successful and it was not until the 1950s with Wullstein's split skin graft and Zollner's pedicled skin graft that higher rates of successful repair were being reported, albeit only up to 71% in ideal cases.[4] The other crucial development that was occurring around this time was that of the operating microscope. The availability of illumination and magnification afforded by the operating microscope transformed this area of surgery probably more than any other.

The use of skin grafts was associated with a relatively high rate of reperforation, inflammation and cholesteatoma formation.[5] Attention passed to other graft materials, with Zollner describing fascia lata (1956), Heerman temporalis fascia (1958) and Shea vein grafts (1960). Since then the list of potential graft materials has expanded to include perichondrium, cartilage, periosteum, fat, subcutaneous tissue, amniotic membrane, dermal matrix, fibroblasts, animal pericardium and sclera!

AETIOLOGY

Infection

The commonest cause of an acute perforation is following an episode of acute otitis media. Spontaneous healing of such perforations is the norm, with 70–80% healing within 30 days,[6, 7] with pre-existing tympanosclerosis, malleus injury, infection and large perforations negatively influencing spontaneous closure rates.[8] Loss of contact inhibition of the squamous epithelial cells is postulated to be the driver for repair of acute injuries to the membrane. When a perforation becomes chronic, the margin of the perforation can be seen to be stable with the squamous epithelial cells coming into contact with the epithelial cells of the mucosal layer, creating a barrier against further vascular proliferation.[9]

Trauma

A direct blow to the ear can result in rupture of the tympanic membrane. This can be an isolated injury or, in cases of more severe trauma, can be associated with fractures of the temporal bone and damage to other structures in the middle ear. Barotrauma related to air pressure changes with air travel or water pressure and diving can similarly cause rupture, as can direct trauma such as with a cotton bud.

Iatrogenic

Iatrogenic trauma from middle ear surgery or following the extrusion of a ventilating tube (VT) should be evident from the history. The risk of a chronic perforation following short-term VT is 2.2%, with long-term VTs increasing the risk to 16.6%.[10]

PRESENTATION

Perforations may be completely asymptomatic and can be found incidentally. The majority of patients, however, will present to the ENT surgeon as a result of their symptoms, the commonest being discharge and hearing loss.

Discharge

A mucoid discharge from the ear, be it simple mucus or mucopurulent, should always alert the clinician to the likelihood of a tympanic membrane defect. There are no mucous glands in normal ear canal skin whereas they are in abundance within the middle ear mucosa. Discharge, in most cases, is associated with infection. This can be from ingress of potentially infective organisms from the outside into the middle ear through a pre-existing perforation or from mucosal reaction to a systemic infection (e.g. an upper respiratory tract infection), with the rapid build-up of mucopus resulting in an acute perforation.

Common pathogens include *Pseudomonas*, *Staphylococcus aureus* and *Moraxella*.[11] A swab for microscopy, culture and sensitivity is not routinely sent, being reserved for cases of recurrent infections not responding to 'standard' topical antibacterial medications, in immunocompromised individuals or where suspicion of unusual bacteria is present.

Management of mucopurulent discharge from the ear would follow guidelines set by NICE,[12] with first line being thorough microsuction to reduce the bacterial load followed by regular application of topical antibiotic preparation to the external ear canal. It is acceptable to use short courses of a topical antibiotic with or without corticosteroid, but careful consideration must be given to potential risk of aminoglycoside-induced ototoxicity in patients with a suspected or confirmed perforation.[13] In such circumstances many ENT surgeons would use quinolone-based drops as they are not ototoxic.[14] An ENT-UK position paper stated that a short course of topical aminoglycoside-based drops in the presence of a perforation was acceptable since pus in the middle ear associated with otitis media carries a higher risk of ototoxicity than the drops themselves. This course must be short and stopped as soon as the infection has cleared.[15] An oral antibiotic may also be given in severe or unresponsive infections. An ear wick may be used for severe infections, but the duration of use of each wick should be kept to a minimum.

Hearing loss

Hearing loss can vary depending on the size and location of the perforation. More severe hearing loss should alert the clinician to the possibility of coexistent ossicular involvement/discontinuity. Very small perforations may not cause any hearing loss, but larger defects can cause moderate conductive hearing loss (CHL) due to loss of surface area available to absorb sound energy.[16]

Perforations tend to affect the lower frequencies, having less of an impact as frequency increases.[16]

The site of the perforation has not been seen to correlate with the magnitude of hearing loss, except for those affecting the posterosuperior quadrant.[16] Complete ossicular discontinuity can result in a maximal CHL of around 60 dB.

INDICATIONS FOR MYRINGOPLASTY

The three principal indications for myringoplasty are recurrent otorrhoea, hearing loss due to a chronic perforation, and the desire to swim without having to waterproof the ear.[17]

Infection

The presence of a perforation exposes the middle ear to the risk of recurrent infection from external sources. This can have a significant effect on the quality of life, together with a risk of progression of the middle ear pathology.[18]

Hearing loss

The repeated insult of infections is not only unpleasant for the patient but can affect hearing through both the presence of mucopus and the potential destruction of the ossicular chain. The distal aspect of the long process of the incus is the most vulnerable part of the chain, due to its tenuous blood supply. Erosions at this point can lead to loss of continuity with the stapes and hence a CHL.

Small perforations under 25% may not lead to any significant hearing deficit. Perforations greater than 25% have been shown to cause a greater CHL as size increases.[16] Post-operative audiometric gain has been shown to correlate well with increasing size of the repaired perforation,[19] with those >50% demonstrating a greater pre-operative loss and greater post-operative gain.[20] Exposure of the ossicular chain appears to be more of a factor for hearing loss than loss of the round window baffle effect; perforations in the posterosuperior quadrant have a larger CHL than other sites. Perforation-induced hearing losses appear greatest at lower frequencies with less influence on higher frequencies.[16]

Social

In the presence of a perforation, the general advice is to protect the ear from water to prevent pain and infection, though there does not appear to be any high quality evidence to support this. To enable swimming without the need to protect the ear from water, particularly in children, is a relative indication for myringoplasty.

CONTRAINDICATIONS TO MYRINGOPLASTY

Cholesteatoma

The presence of cholesteatoma is an absolute contraindication to myringoplasty alone. All squamous epithelium must be excised from the middle ear prior to closure of the tympanic membrane defect to prevent further progression of the cholesteatoma and its subsequent well-recognized complications.

Contralateral hearing

Relative contraindications include a contralateral dead ear. Hearing loss from myringoplasty is rare at 1.5%, potentially from infection or manipulation of the drumhead and ossicular chain during surgery.[21]

Bilateral perforations

Should bilateral perforations be present, most would advocate operating on one ear at a time. While the incidence of severe hearing loss from myringoplasty is rare,[21] unilateral surgery avoids any risks to the contralateral ear, leaving this side available for hearing and communication, certainly while the post-operative packing is present (in the other). However, other studies have suggested that bilateral myringoplasty is safe, reduces costs and increases patient satisfaction, with post-operative packing causing only a modest CHL that is readily acceptable to patients.[22]

Eustachian tube dysfunction

Severe Eustachian tube dysfunction can be extremely challenging to treat. Attempting to elevate a Sade grade IV retraction from the ossicular chain can increase the risk of hearing loss. There is also an increased chance of an iatrogenic cholesteatoma should any epithelial cells be left *in situ*.[23] Reconstructing the tympanic membrane using cartilage can provide more resilience against the negative middle ear[22] but, despite this, recurrence of the retraction can occur.[18]

As when considering all surgery, the general medical fitness of the patient must be taken into account. Multiple factors adversely affect wound healing and can potentially influence the surgical result and should therefore be optimized prior to surgery. Chronic general medical conditions, such as diabetes and cardiovascular disease, lead to poor oxygenation of tissues, with infection and stress disrupting neuroendocrine immune equilibrium. Medications, obesity, smoking and alcohol consumption and poor nutrition should be optimized prior to surgery.[24] The insult of a general anaesthetic must also be taken into account for patients with multiple medical comorbidities. Myringoplasty can frequently be performed under local anaesthetic and particular consideration for this should be made in this patient group. Day-case surgery for tympanoplasty is increasingly the norm without compromising patient care and safety.[25]

FACTORS INFLUENCING TREATMENT OPTIONS

Various tympanoplasty prognostic scoring systems have been proposed, including SPITE (surgical, prosthetic, infection, tissues and Eustachian tube) and MERI (Middle Ear Risk Index), to try to stratify possibilities of success.[26] Other factors to consider prior to surgical intervention include patient age, presence of infection, status of the other ear, reperforation rates, the influence of the mastoid and smoking.

Timing and age

There is a debate as to whether age plays a part in success rates following myringoplasty. Some would advocate avoiding such surgery in younger children, awaiting Eustachian tube (ET) maturity prior to contemplating perforation repair. Morphological changes in the ET that accompany improvement in function are most marked after the age of 7 years,[27] with many managing these patients conservatively until after this age, assuming these patients were relatively asymptomatic. Others, however, suggest that age does not play a part in surgical outcomes

and will offer surgery to children younger than 7 years old. The state of the contralateral ear is an important guide as to overall function of the ET. Problematic perforations, such as those with recurrent infections or marked hearing loss causing developmental delay, may warrant earlier operative intervention.

Adenoidectomy

Evidence regarding the contribution of adenoidectomy to myringoplasty success is conflicting,[17] with the majority of reviews suggesting that prior adenoidectomy confers no benefit in success rates of myringoplasty.[28–31]

Infection

The literature has differing opinions regarding the influence of infection present at the time of surgery on outcomes. Up to 20% of perforated ears (both wet and dry) have been shown to grow pathogens on culture[32] and infection is one of the most common causes of failure in myringoplasty.[33] Some studies demonstrate that the presence of infection at time of surgery negatively influences outcomes, with higher rates of failed perforation closure, retraction pocket formation and myringitis.[18] The majority of studies, however, have shown that the presence of infection does not negatively influence surgical outcomes and therefore most surgeons would not be deterred from proceeding in the presence of active infection.[34, 35]

Other ear

A normal contralateral ear is a positive predictor of success of tympanoplasty as this suggests favourable overall Eustachian tube function.[26]

Conversely, abnormalities in the opposite ear should be checked to exclude the possibility of bilateral hearing loss or even the presence of cholesteatoma. With the presence of abnormalities in the other ear, success of graft uptake has been found to be poorer.[26, 36]

The presence of a bilateral perforation may influence the choice of graft material. Though there is little evidence to support any one particular graft material producing more favourable results over another,[17, 25] the use of cartilage is becoming more popular, particularly in this group, subtotal perforations and revision surgery, due to its perceived superior resilience over temporalis fascia alone and therefore potential higher closure success rates.

Reperforation rates

The literature quotes success rates of 60–99% in adults and 35–94% in children.[37] Most studies have short follow-up periods yet reperforation can occur several years after the initial surgery. There are relatively few long-term studies, with some suggesting that success rates fall over time from around 85% at 1 year to 78% at 10 years.[36] Reperforation rates in children under 15 years have been quoted at 18%, over double the rate of that in adults.[18]

Most failures occur in the early post-operative period, mainly due to graft failure from infection with graft necrosis or failure of the anterior aspect of the graft – the most tenuous area due to this region's apparent hypovascularity compared to the rest of the tympanic membrane.[5, 18, 38] Following initial failures, there are no clear guidelines as to whether surgical revision is indicated and, if so, how long one should wait before reoperating, though 3 months would seem a reasonable time to allow for the postsurgical changes to resolve.

Mastoid

The influence of the mastoid air cell system on chronic otitis media (COM) is still subject to debate. Poor pneumatization of the mastoid, together with Eustachian tube dysfunction, often predispose to chronic suppurative otitis media.[7] It is thought by some that mastoidectomy can improve outcomes in non-cholesteatomatous COM surgery by creating a reservoir of aerated bone to buffer pressure changes in the middle ear and by eradicating residual mucosal disease hidden in the mastoid air cells.[33, 39] While a recent study comparing myringoplasty alone with the same in combination with mastoidectomy did not show any statistically superior advantage with the latter, that group obtained better hearing results and required fewer subsequent ear procedures.[40] Other studies have demonstrated the presence of residual mastoid disease on CT scans of the temporal bones in patients whose graft had failed,[33] with mastoidectomy being advised in cases of COM not responding to pre-op intensive medical treatment[41] or in revision cases.[39] Although mastoidectomy has been claimed to be a safe procedure that neither significantly increases operative time nor results in further complications,[17] others argue that mastoidectomy does not improve surgical outcomes and exposes the patient to increased surgical risks.[42, 43] A recent literature review did not show any benefit of performing mastoidectomy with tympanoplasty for uncomplicated perforations.[44] More complicated otological disease, such as active mucosal COM or repeat perforations, show worse outcomes and may benefit from concurrent mastoidectomy, but there is insufficient evidence to recommend this.[45]

Social

The influence of smoking on surgical outcome is not clear. Some studies suggest no statistically significant effect on graft take rate[19] whereas others have noted the local, regional and systemic negative effects of smoking on the middle ear and Eustachian tube.[26, 46] Locally, nicotine causes cutaneous vasoconstriction, and increases thrombosis risk with carbon monoxide reducing the oxygen carrying capacity of blood. Regionally, chemical irritation leads to increased mucous viscosity and reduced mucociliary clearance with Eustachian tube obstruction. The systemic negative effects of smoking are well documented in the literature, particularly on the respiratory system.

INVESTIGATIONS

Ear swab

The value of microbiological culture of all discharging ears has not been shown to be statistically beneficial over empirically treated ears.[47]

Audiometry

All patients with a perforation or perceived hearing loss should undergo audiometric testing at the time of their clinic visit. This allows for quantification of the degree of hearing loss and can assist the surgeon in predicting what may be found in the middle ear at the time of surgery. Certainly, audiometry pre- and post-operatively allows for analysis of surgical outcome, both for surgeons to audit their results (and perhaps change their practice) and to demonstrate to the patient a successful outcome. The hearing in the contralateral ear is an important factor in guiding decision making in myringoplasty.

Imaging

Most myringoplasties do not require pre-operative imaging. In those in whom the history is unusual, or examination findings suggest further pathology, a fine-cut CT of the temporal bone can reveal unexpected opacification or unusual bone erosion, together with providing some insight into the state of the ossicular chain.

In cases with sensorineural asymmetry, a difference of greater than 20 dB at two adjacent frequencies is an indication for screening for the rare possibility of a concurrent vestibular schwannoma. T1-weighted MRI with gadolinium of the internal acoustic meatus is the gold standard investigation of choice.[48]

GRAFT MATERIALS

Since the full-thickness skin graft, first used by Berthed in 1878, many graft materials have been tried.[17] From autologous, to allogenous and heterogeneous, a wide spectrum of alternatives is available and there is no one ideal material.[17, 25]

The least invasive and perhaps simplest is the paper onlay technique, using a thin cigarette paper or similar placed onto the tympanic membrane as an outpatient procedure. This has been used with reasonable success to assist closure of small perforations, occasionally requiring repeat applications for a successful outcome. It is least successful for large perforations.[26]

Of the autologous materials, temporals fascia is the most frequently utilized for all perforations given its availability, the abundance of tissue and ease of use. Success rates of 77–99% in adults and 35–94% in children are quoted,[37] depending on experience and technique,[38] though multiple other factors may be influential. Easily harvested via a postauricular or endaural approach, a separate scalp incision, hidden in the hairline, may also be used during a permeatal approach. Treating the fascial graft prior to use with formaldehyde[18] does not appear to enhance successful closure rates, while the topical application of adhesive following graft placement is claimed to do so, although the median follow-up was relatively short at 4 months.[49]

Perichondrium from either the tragus or concha provides an alternative material, with the former being easily accessed either via a small and cosmetically acceptable retrotragal incision or by extending an existing end aural incision (if used as the approach). Several surgeons prefer tragal perichondrium due to its ease of harvest, particularly for the permeatal approach, and its long-term reliability.[50]

Cartilage, either from the tragus or concha, is gaining popularity as a more reliable material. A composite graft from the tragus provides a very practical material with a good thickness and curvature for use in tympanoplasty, together with a very low metabolic rate.[50] Keeping the cartilage attached to the perichondrium helps placement and aids graft stabilization and is now considered one of the best materials for use in larger perforations (greater than 50%),[17] adhesive otitis media and revision surgery for recurrent perforations, with quoted closure rates of up to 100%.[50]

Fashioning a cartilage 'butterfly' is a technique that has been proposed for smaller perforations less than 6 mm, with the cartilage disc being circumferentially incised by 1 mm. This groove is engaged into the perforation rim, thereby stabilizing the graft. Mild myringitis was encountered in 11%, resolving within 3 months, with a quoted closure success rate of 94%.[51]

There is some debate as to whether the hearing gain obtained with cartilage is inferior to that of fascia or other more flexible material. Short-term post-operative hearing with cartilage is not as good as that with temporalis fascia or perichondrium, but results at 1 year were the same,[50] with long-term hearing outcomes of cartilage and fascia being equivalent.[52, 53] This is presumed to be due to the partial resorption of cartilage over time[50] which causes it to lose its rigidity.[54]

Other autologous materials have been used, either locally accessible such as periosteum, subcutaneous tissue, ear canal or other skin graft and fat, the latter usually being harvested from the lobule or post auricular region[55] though umbilical fat has also been used.[56] Fascia lata and vein[57] provide a more distant autograft. Autograft and xenograft have been combined using fat and a hyaluronic acid ester (Epidisc) with quoted overall closure rates being 92.7%.[55, 58]

Experimental investigations of allogeneic materials include extracellular matrix in the form of urinary bladder matrix (in 14 animals with a closure in 13 out of 14 ears at the end of the experiment at 12 weeks)[59] and stem cells.[60] Results were encouraging though numbers were very small in both studies.

Alloderm, processed from human allograft skin and rendered immunologically inert, can provide an alternative when temporalis fascia is not available, with a success rate of 87.5%, equivalent to that of temporalis fascia.[61]

Several xenogenous materials have been investigated. Equine and bovine pericardium were found to be inferior

to temporalis fascia.[38] Basic fibroblast growth factor (FGF) has been studied since exogenous bovine FGF stimulates the proliferation of fibroblasts and vascular cells, induces endothelial cell migration, releases matrix-degrading proteases and forms tubular structures resembling blood capillaries.[62, 63] FGF has been used either in combination with atelocollagen, a type 1 collagen material derived from calf dermis, with closure achieved in 92% of 87 patients,[64] or to large (greater than 50%) traumatic perforations applied either via a Gelfoam patch over the perforation, or as drops alone with very encouraging results of 97% and 100% closure respectively within 10 days, compared to 55% in the control group within 41 days.[65]

TECHNIQUES

Two main techniques have been described for placement of graft materials, namely overlay and underlay. Overlay derives its name from the graft being placed lateral to the fibrous layer of the drumhead and hence over the fibrous annulus, the epithelial layer having been elevated alone and then replaced onto the graft. The underlay technique involves placement of the graft medial to the entire tympanic membrane, with elevation of a flap of ear canal skin together with the drumhead being most commonly used for access, stabilizing the graft under the fibrous annulus. A prospective randomized controlled study of both techniques did not show any difference in temporalis fascia graft uptake rates between the two techniques.[23] The authors concluded the underlay technique to be superior due to its technical ease, shorter post-operative healing time, fewer complications and better hearing gain.

There is debate as to correct placement of an underlay graft, particularly with a medialized handle of malleus. Usually the graft should pass under the malleus though, with a subtotal or central perforation with an exposed umbo, some advise a small hole in the centre of the graft through which the umbo can pass to try to prevent the 1.4% risk of graft lateralization.[18]

Access can be achieved permeatally or utilizing a cartilage-avoiding incision – endaural or postaural – depending on the location of the perforation and size of the ear canal. Since the development of the binocular microscope in the 1950s, this has become the standard for all middle and inner ear surgery. Recently, endoscopic techniques have been gaining popularity with the advantages of minimal access surgery and avoidance of visible scars.

COMPLICATIONS

Risks of reperforation have been discussed earlier in this chapter.

Retraction of the drumhead following grafting can occur in up to 10%,[18] with some suggesting the use of cartilage to try to prevent this.[50, 52, 53, 66]

Elevation of the anteroinferior aspect of the tympanic membrane runs the risk of anterior blunting, a risk with both overlay and underlay techniques.[23] Various techniques or packing methods have been proposed to try to prevent this as it can impact on hearing outcomes.

The incidence of iatrogenic cholesteatoma, particularly with the overlay technique which runs a higher risk of leaving some squamous epithelium medial to the graft, can be as high as 4.4%.[67, 68]

Myringitis can occur, influenced by the presence of infection[18] or choice of material,[51] though most cases resolve within 3 months with short-term topical medication and observation.

BEST CLINICAL PRACTICE

- ✓ Most surgeons wait until the patient is at least the age of 7 years before considering myringoplasty.
- ✓ The presence of infection at the time of surgery does not negatively impact success rates.
- ✓ Adenoidectomy confers no benefit on success rates for myringoplasty.
- ✓ There is insufficient evidence to support concurrent mastoidectomy during tympanoplasty.
- ✓ Temporalis fascia is the most frequently used autologous material, with the use of cartilage increasing in popularity for larger perforations (greater than 50%).
- ✓ Cartilage tympanoplasty has equivalent long-term hearing outcomes to temporalis fascia or perichondrium.
- ✓ Underlay and overlay techniques have similar outcomes.

FUTURE RESEARCH

- ➤ The quality and quantity of randomized controlled trials are limited.
- ➤ Further research should involve levels 1 and 2 evidence with regard to:
  - ➢ the role of mastoidectomy with tympanoplasty in chronic otitis media
  - ➢ ideal minimal age for surgery
  - ➢ the role of tissue engineering and growth factors should be a productive area for future research.

KEY POINTS

- Around 70–80% of acute perforations heal spontaneously within 30 days.
- The risk of chronic perforations following short-term ventilation tubes is 2.2% rising to 16.6% with long-term tubes.
- Aminoglycoside antibiotics are ototoxic but quinolone-based are not; a short course of topical aminoglycoside-based drops in the presence of a perforation is acceptable but, if used, this should be stopped as soon as the infection has cleared.
- Three indications for myringoplasty are recurrent infections, hearing loss and social impact such as pain on swimming.
- Success rates for myringoplasty are 60–99% in adults and 35–94% in children.
- Post-operative retraction of the drumhead can occur in up to 10%.
- The risk of iatrogenic cholesteatoma is 4.4%.

CHAPTER 85

OSSICULOPLASTY

Daniel Moualed, Alison Hunt and Christopher P. Aldren

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: ossiculoplasty, ossicular chain, reconstruction, prosthesis, middle ear, hearing, with additional searching of secondary sources.

INTRODUCTION

This chapter covers the principles and practicalities of surgery to correct ossicular chain abnormalities with the aim of improving hearing. The surgical priorities when treating chronic middle ear disease are first to make the ear safe, then to make it dry, and finally to make it work. The last of the three is often the most difficult – and of great concern to the patient – which is why ossiculoplasty can be both challenging and rewarding.

AETIOLOGY/PATHOLOGY

Conductive hearing loss due to ossicular chain abnormalities may be either congenital or acquired, and is due to either ossicular chain discontinuity or fixation.

Congenital

Deformities of the ear occur in approximately 1 in 15 000 births with isolated middle ear abnormalities or 'minor' malformations being less common than 'major' malformations which may also involve the tympanic membrane and external ear.[1, 2] Favourable results following surgical reconstruction of major malformations are dependent on the severity of the abnormality. The status of the ossicles, presence of the round window, pneumatization of the middle ear space, and course of the facial nerve are key determinants.[3] Prognostic grading systems such as the Jahrsdoerfer score can be used to predict the likelihood of achieving good hearing outcomes.[4]

A diverse range of isolated middle ear deformities has been described, the most common being fixation of the stapes footplate which may occur in isolation (which is often bilateral) or in association with stapes superstructure or other ossicular abnormalities.[5] Epitympanic fixation of the ossicular heads and ossicular discontinuity are described less frequently.[6] The most challenging cases involve aplasia of the oval or round window; however, fortunately these are rare. Surgery for congenital ossicular chain abnormalities should only be attempted by experienced otologists after careful consideration of alternatives which include air- or bone-conduction hearing aids.

Acquired

The majority of ossicular chain defects arise as a consequence of chronic otitis media with or without cholesteatoma. Ossicular chain erosion is much more common in the presence of cholesteatoma (**Table 85.1**). The most common acquired abnormality is erosion of the long process of the incus, which may be confined to the incudostapedial joint (ISJ) or extend a variable distance superiorly. The stapes superstructure may be partially or completely eroded, whereas the malleus handle is the most frequently preserved. Shortening or absence of the malleus handle is generally associated with subtotal perforations.

Ossicular disruption secondary to trauma may occur following direct injury to the tympanic membrane,

TABLE 85.1 Ossicular chain defects in 1211 consecutive chronic middle ear cases

Defect	% Incidence with cholesteatoma *n* = 692	% Incidence without cholesteatoma *n* = 519
Ossicular chain intact	27	71
Incus alone eroded	26	18
Incus and stapes eroded, malleus intact	24	7
Incus, stapes and malleus eroded	11	2
Incus and malleus eroded, stapes intact	8	2
Stapes alone eroded	2	0.4

TABLE 85.3 Modifications to classification system by Kartush[9]

Group	Ossicular status
O	Intact ossicular chain
E	Ossicular head fixation
F	Stapes fixation

TABLE 85.5 Middle Ear Risk Index 2001[13]

Otologic factor	Maximum score

Previous surgery	2
Smoking	2

barotrauma or temporal bone fracture. These defects are further described in Chapter 91, Ear trauma. Idiopathic cases of resorption of the long process of the incus in the absence of active suppurative ear disease have been described in the literature but are rare.[7]

CLASSIFICATION OF DEFECTS

The value of a classification system is to enable a systematic description of pre-operative ossicular status to facilitate meaningful analysis of surgical outcomes. Given the multitude of surgical approaches for correcting ossicular chain abnormalities, it is essential when evaluating results that the pathologies are comparable. While each patient will present a subtly unique anatomical situation, defects can be broadly characterized by the presence or absence of different components of the ossicular chain.

The most widely used classification system is the Austin–Kartush system which applies to situations without an intact incus. First proposed by Austin in 1971,[8] four distinct

TABLE 85.2 Austin classification of ossicular chain defects with absent incus[10, 11]

Group	Ossicular status	Abbreviation	Prevalence (%)
A	Malleus handle and stapes superstructure present	M+ S+	60
B	Malleus handle present, stapes superstructure absent	M+ S–	23
C	Malleus handle absent, stapes superstructure present	M– S+	8
D	Malleus handle and stapes superstructure absent	M– S–	8

TABLE 85.4 Belluci classification of otorrhoea[12]

Otorrhoea	Risk value
Dry ear	0
Occasionally wet	1
Persistently wet	2
Persistently wet + cleft palate	3

anatomical situations are described (Table 85.2). This was modified by Kartush in 1994,[9] with the addition of three further categories to include a normal ossicular chain, and cases of fixation (Table 85.3). Situations not covered by the Austin–Kartush classification are rare and include isolated malleus handle fracture and fracture of the stapes superstructure. The classification also makes no specific allowance for partial incus erosion where incus remnant preservation is attempted.

PROGNOSTIC FACTORS

The ideal scenario in which to perform ossiculoplasty is in a stable well-ventilated middle ear, with an intact tympanic membrane, in the absence of ongoing middle ear infection or cholesteatoma. Absence of any of the above factors increases the risk of failure, as do patient factors such as smoking status.[13]

The Middle Ear Risk Index (MERI) was devised by Kartush in 1994 and generates a numeric value which corresponds to severity of disease, and the likelihood of a successful outcome following surgery.[9] This can be used to guide case selection and counselling of patients pre-operatively but is perhaps most useful for research purposes. It is an amalgamation of the Austin–Kartush classification of ossicular defects, the Belluci classification of otorrhoea (Table 85.4),[12] and takes into consideration the presence of tympanic membrane perforation, middle ear granulation, and cholesteatoma. The MERI was originally scored 0–12, and was later modified in 2001 to include smoking and increase the weighting for granulation and cholesteatoma thus giving a score of 0–16 (Table 85.5).[13] Alternative risk stratification or scoring

systems include the Ossiculoplasty Outcome Parameter Staging (OOPS) index,[14] or SPITE factors (surgical, prosthetic, infection, tissue, Eustachian).[15]

KEY POINTS

- Use of a classification system such as the Austin–Kartush allows a meaningful analysis of results and comparison of results between surgeons.
- Ossiculoplasty results are significantly affected by the status of the middle ear.

MATERIALS FOR RECONSTRUCTION

The ideal material for ossicular reconstruction should be biologically stable (resistant to resorption and non-reactive), of the correct mass and stiffness, be easy to handle, and ideally low cost. There are many options for reconstruction which can be broadly divided into autografts, homografts and alloplastic materials.

Autograft

Autografts are tissues that are harvested from the same patient on which they are to be used, and can include ossicles, cortical bone and cartilage. Their primary advantage is excellent biocompatibility with low risk of extrusion. When available, an autograft offers a low-cost solution compared to ossicular prostheses.

Incus interposition is an example of a well described and popular technique in situations with an intact malleus handle and stapes superstructure.[16, 17] Cartilage tends to be less stable due to displacement or resorption and is less commonly used.[18, 19]

Limitations to the use of autologous ossicles are that the incus is not uniformly present in diseased ears, while technical skill and time are required to sculpt the incus to the required shape. There is a risk of implanting residual disease if the ossicle has been enveloped in cholesteatoma, therefore careful assessment of its integrity is required. Some surgeons recommend autoclaving ossicles prior to reimplantation to reduce the risk residual disease[20] but this is not widely practised.

Homograft

Homograft material is derived from human donor tissue. A wide choice of pre-prepared graft material is available with options including cortical bone, cartilage, ossicles, and *en bloc* ossicular chain with tympanic membrane attached.[21, 22]

Benefits over autografts include a shortening of the operative time as pre-prepared prostheses can be inserted directly or with minimal modification. Homografts offer reconstructive options that may be absent or eroded in diseased ears, and do not carry the risk of residual cholesteatoma provided they are harvested correctly.

The major barrier to the use of homograft materials is the potential risk of disease transmission from donor to recipient, with viral infections and the transmissible spongiform encephalopathy Creutzfeldt–Jakob disease (CJD) of particular concern.

The majority of cases of iatrogenic CJD transmission have occurred following neurosurgical procedures using infected dural grafts.[23] Two cases of CJD transmission have occurred following ear surgery, one as a result of cadaveric dura mater, and another due to the use of pericardium. There are no reported cases of CJD transmission from the use of homograft tympanic membranes or ossicles while they have been used in thousands of procedures.[24, 25]

A combination of serological donor screening, and appropriate methods for ossicle preparation can reduce the risk of disease transmission to a very low level. However, ongoing concerns about potential infectivity combined with significant infrastructure required to maintain an ossicle bank, and the improvement in artificial materials mean that homografts have fallen out of favour in many countries.

Alloplastic materials

The use of alloplastic materials for ossiculoplasty was first described in 1952 by Wullstein who used a 'palavit' (vinyl–acrylic resin) columella prosthesis to connect a mobile stapes footplate with the tympanic membrane.[26]

Since that time, a wide range of materials have been used in the search for a prosthesis that retains its structural integrity yet can be easily shaped or modified. Of equal importance is that the prosthesis does not induce unwanted inflammatory reactions in middle ear tissues yet bio-integrates in such a way that it is not extruded.
Materials that have been used include:

- solid plastics: polytetrafluoroethylene, polyethylene
- solid metals: stainless steel, gold, titanium
- porous sponge-like plastics: Proplast®, Plasti-Pore®
- ceramics: aluminium oxide, hydroxyapatite.

Solid plastics and stainless steel were some of the earliest materials used but were largely abandoned due problems with absorption at bony interfaces and extrusion.[27] Plasti-Pore® became one of the most widely used artificial materials following its introduction in 1976, but it has high extrusion rates when placed in contact with the tympanic membrane therefore cartilage interposition is required.[28] Histopathological studies have also shown porous plastics can elicit a foreign body giant cell reaction with evidence of implant degradation.[19]

Hydroxyapatite is a calcium-based bio-ceramic with a mineral composition similar to bone and continues to be a popular and proven material with low extrusion rates.[29] Some prostheses are compound designs to take advantage of the different properties of the materials, for example a hydroxyapatite head that can be placed directly against the tympanic membrane with a composite shaft that can be easily trimmed to length.[30]

Titanium implants were introduced in the early 1990s,[31] and have excellent mechanical properties due to high rigidity allowing low-weight prosthesis designs.

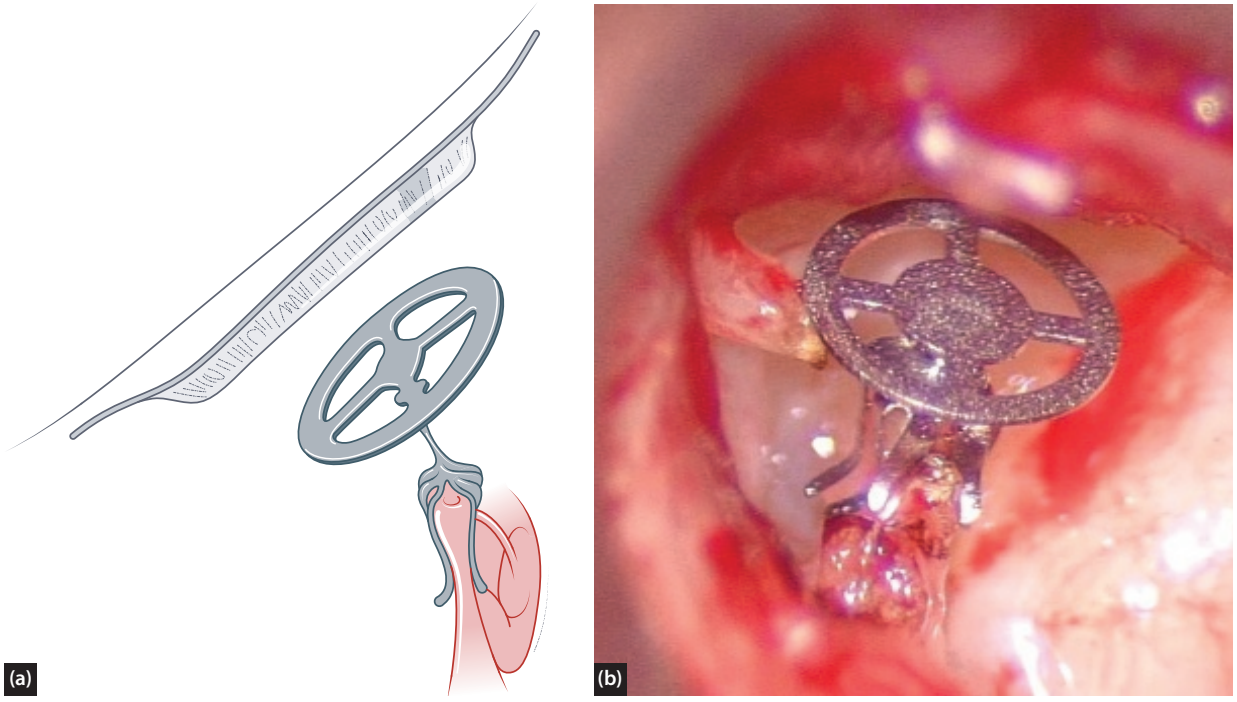

Figure 85.1 PORP on intact stapes. (a) Partial ossicular replacement prosthesis *in situ* on intact stapes superstructure. The cartilage and perichondrium graft lies between the prosthesis and the tympanic membrane. **(b)** Partial clip prosthesis sitting on stapes inferior to eroded incus long process which remains in place.

Complex designs are possible with open head configurations to improve visualization during placement, and delicate 'claw' attachments to fasten securely to the stapes head (Figure 85.1a). Titanium is biocompatible with low extrusion rates of less than 5%.[27] While most surgeons interpose cartilage between a titanium prosthesis and the tympanic membrane, Pringle has questioned whether this is necessary.[32]

KEY POINTS

- Autograft incus continues to be a widely used material for ossicular reconstruction.
- Ideal prostheses should not induce reaction in the middle ear.

BOX 85.1 Terminology

PORP = partial ossicular replacement prosthesis. Generally used to mean a prosthesis that is designed for situations with an intact stapes superstructure.
TORP = total ossicular replacement prosthesis. For use in situations where there is no stapes superstructure and the prosthesis restores a connection with the stapes footplate.

Ossicular reconstructions are referred to as **columellae** when the sound transmission is restored with an ossicle to tympanic membrane connection, and **assemblies** where there is an ossicle-to-ossicle connection.

SURGICAL OPTIONS TO CORRECT SPECIFIC DEFECTS

Due to the wide variation in surgical practice and increasingly large range of prostheses available it is not possible to give an exhaustive account of all surgical options for each reconstruction. What follows are illustrative examples of proven surgical strategies.

Box 85.1 introduces ossicular reconstruction/replacement terminology.

Eroded long process of the incus

This is the most common ossicular chain defect encountered in patients with chronic middle ear disease of all aetiologies.[33] Early attempts to restore hearing in cases of ISJ separation included stapediopexy where the tympanic membrane is brought into direct contact with the stapes head.[34] This approach has the obvious disadvantage of losing the amplification and dampening functions of the ossicular chain. Preservation of the natural anatomy is preferable and can be achieved by the following methods.

BRIDGING WITH AUTOLOGOUS TISSUE

Where there is a small distance of separation between the stapes head and incus long process remnant, interposition bridging may be attempted.[34] Materials that are most frequently used for this purpose include autologous cortical bone – harvested from the mastoid or external auditory canal – or cartilage.[35] Reconstruction of longer defects may be unstable and can lead to unpredictable results.[16] Bridging material may be partially resorbed, displaced, or form bony ankylosis with the canal wall.

PROSTHESIS

The first dedicated ISJ replacement prosthesis was reported in 1993 and consisted of a basic cuboidal hydroxylapatite design with a circular aperture for the stapes head and a groove to accommodate the long process remnant.[36] A variety of other prostheses have been developed over time, differing in both material and design. The interface with the stapes head may be a simple cup although more recent adoption of titanium and improved manufacturing techniques allow more complex designs such as self-securing clips.[37] The prosthesis may accommodate the incus long process remnant with a groove, wire coil or circumferential crimping attachments.

BONE CEMENT/BONE PATE

The use of bone cement to reconstruct the long process of the incus is a more recent development and has been shown to give good hearing results at least in the short term. Studies show 80% of patients achieve air–bone gap closure to within 20 dB at 1 year.[38, 39] Care must be taken when applying bone cement to avoid spillage onto the stapes footplate or unintended fixation to the posterior canal wall.

An alternative to cement is the use of bone pate which can be collected by drilling healthy mastoid cortex. This option works best where there is still a partial connection between the long process of the incus and the stapes head (Figure 85.2). Some surgeons mix the bone dust with blood and/or fibrin glue to aid adhesion.

Eroded incus with malleus and stapes present (Austin–Kartush type A)

In cases where the incus is partially or completely eroded and anatomical reconstruction of the ossicular chain is not

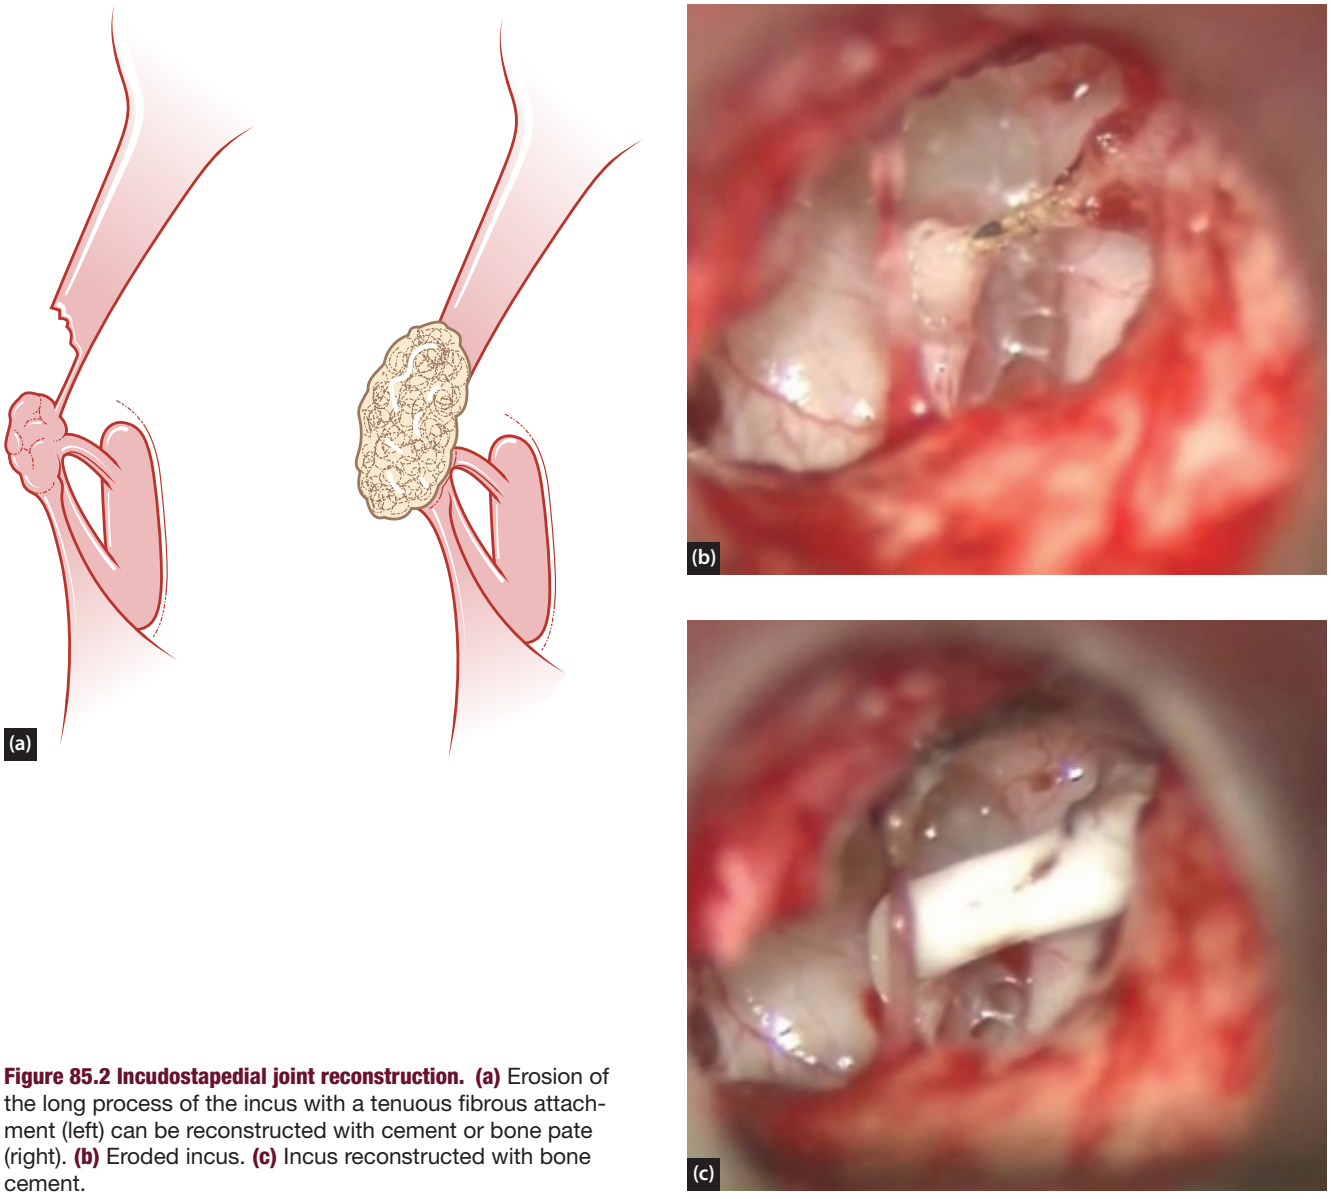

Figure 85.2 Incudostapedial joint reconstruction. (a) Erosion of the long process of the incus with a tenuous fibrous attachment (left) can be reconstructed with cement or bone pate (right). **(b)** Eroded incus. **(c)** Incus reconstructed with bone cement.

possible, there are several alternative options for restoring hearing when the malleus handle and stapes superstructure remain intact.

AUTOLOGOUS OSSICLE INTERPOSITION

Repositioning the incus as a method for restoring the function of the ossicular chain was first described in 1957 by Hall and Rytzner,[40] since which time it has been shown to be a stable option for reconstruction.[41]

When the body and short process of the incus are intact, it may be used for reconstruction provided the surgeon is confident it harbours no residual disease. Ossicle forceps and a microdrill are used to sculpt the ossicle into the desired shape with a variety of configurations possible.

The classical method involves placing the body of the incus on the stapes head with the short process directed towards the malleus handle and medial to it.[16] Modifications of the technique include creating a groove in the short process so that it rests against the malleus handle, or alternatively lateral to the malleus handle.[39] The malleus head may be used where the incus is not available (**Figure 85.3**), although usually it is brought into direct contact with the tympanic membrane, in contrast to the incus assembly which aims to rest against the malleus handle. Cartilage and sculpted cortical bone can be used although these are more prone to resorption or ankylosis.[18]

The use of homograft ossicles or cortical bone has also been described[22, 42] and continues to be used in some countries, with up to 90% of patients achieving <20 dB air–bone gap in one series of cases receiving sculpted homograft incus interposition.[43]

PARTIAL OSSICULAR REPLACEMENT PROSTHESIS

Selecting an appropriate ossicular replacement prosthesis requires careful consideration of the anatomical configuration of the middle ear and ossicles. The two main options for prosthesis placement are stapes to malleus or stapes to tympanic membrane.

Stapes to malleus

Advantages of this configuration are preservation of the catenary lever mechanism of the tympanic membrane.[44] Placing the prosthesis medial to the handle of the malleus may also reduce the rate of extrusion as compared to prostheses in direct contact with the tympanic membrane.[45]

A significant drawback is that in most situations the malleus–stapes offset means the vector of force is never perfectly in the line of the stapes, thereby resulting in inefficient energy transfer (**Figure 85.4**). When the malleus–stapes offset is of sufficient magnitude for the interposition prosthesis to have an angle greater than 45 degrees relative to the vertical axis of stapes movement, significant tilting movements occur at the footplate with resultant marked loss of sound transmission.[46]

This can be improved by malleus relocation, which involves separating the malleus handle from the tympanic membrane, division of the tensor tympani at its insertion, and stretching or avulsing the anterior suspensory ligament by pulling posteriorly on the neck of the malleus. The superior ligament is left in place to support the malleus. The malleus handle is placed more posteriorly towards a position overlying the stapes head (**Figures 85.5** and **85.6**).[47]

Stapes to tympanic membrane

This approach can be used in cases where the malleus handle orientation is unfavourable due to anterior angulation or medial displacement. The disadvantage of this method is that the catenary lever mechanism is lost, and the prosthesis may be unstable as it does not have any fixed lateral attachment other than the relatively compliant tympanic

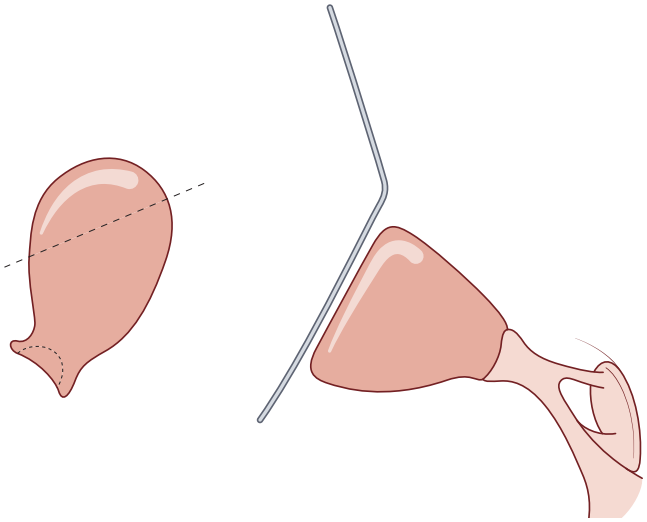

Figure 85.3 Malleus head reconstruction with intact stapes. The malleus head can be used in a stapes-to-drum configuration to reconstruct Austin–Kartush type A or C defects. The left-hand image indicates the reshaping required prior to use.

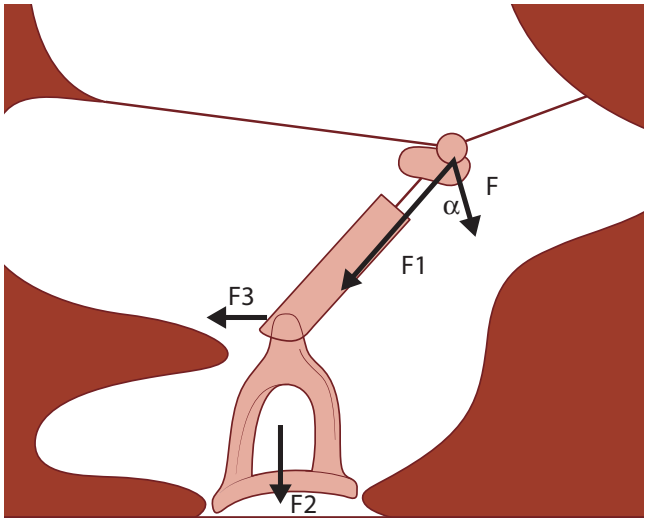

Figure 85.4 If the malleus is very anterior and medial, angle α increases. As angle α gets larger the desirable force through the footplate F2 decreases and the undesirable tilting force F3 increases (Courtesy of Robert Vincent).

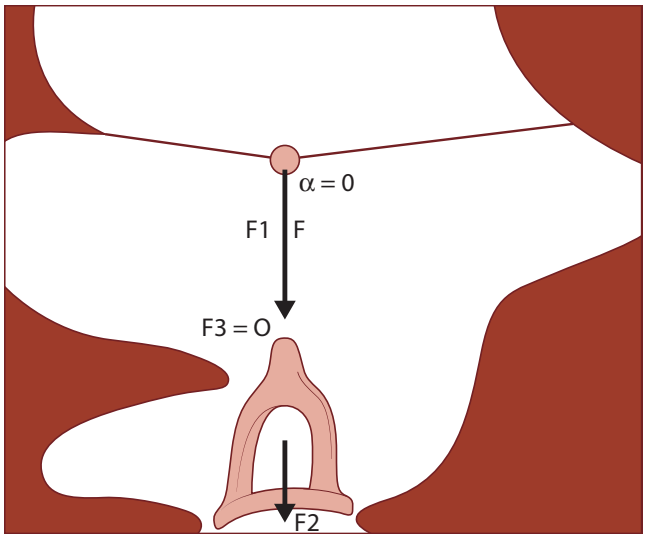

Figure 85.5 When the malleus is repositioned over the stapes, the undesirable tilting force F3 is reduced (Courtesy of Robert Vincent).

membrane. Some prostheses require interposition of a thin cartilage strip between the tympanic membrane and the head of the prosthesis to reduce the risk of extrusion although not all surgeons feel this is necessary.[27, 32]

Most prosthesis designs are in the shape of a drawing pin with a strut which attaches to the stapes head, and a perpendicular flat disc which may be centred on the strut or eccentrically placed. Some newer designs have an open head which allows the surgeon to visualize the stapes during insertion thereby facilitating this manoeuvre.

Interestingly, some surgeons advocate using TORPs in the presence of an intact stapes. The prosthesis shaft is placed between the stapes superstructure and the facial nerve directly onto the stapes footplate. This aims to improve prosthesis stability and energy transfer.[48]

Malleus present, stapes absent (Austin–Kartush type B)

When the stapes superstructure is absent, mechanical coupling between the stapes footplate and the tympanic membrane or malleus handle must be achieved. This type of reconstruction is inherently less stable due to the distance that must be bridged and the absence of a fixed attachment point on the stapes footplate. Several studies using multivariate analysis have identified presence of the stapes superstructure as being a key determinant of success following ossiculoplasty, with poorer hearing outcomes to be expected when it is absent.[49–51]

HOMOGRAFT OSSICLE

Autologous incus is rarely available as a reconstructive option in this situation as absence of the stapes superstructure will almost invariably be accompanied by a degree of long-process erosion. Homograft incus has been used extensively for this purpose with most reports describing the long process resting on the footplate and a sculpted notch at the opposite end to accommodate the malleus handle.[22, 42, 52] Results for this technique are highly variable.

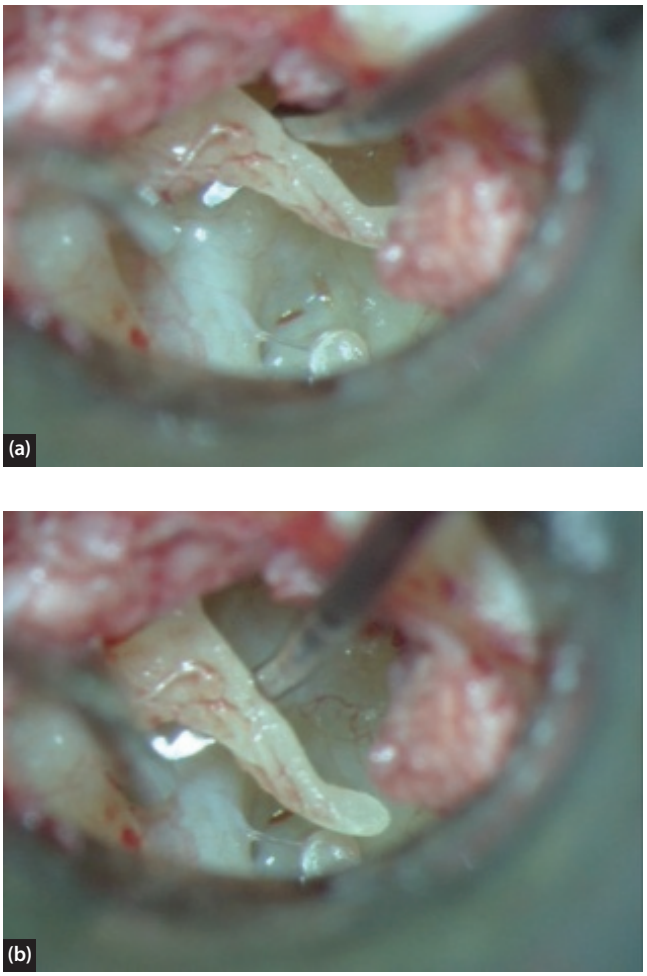

Figure 85.6 (a) A heavy hook is placed anterior to the neck of the malleus, which has been separated from the tympanic membrane and divided from the tensor tympani. It is then pulled posteriorly and the anterior malleolar ligament gives way to allow the malleus to be placed more posteriorly. (Robert Vincent.) **(b)** The repositioned malleus now lies directly over the stapes. (Robert Vincent.)

TOTAL OSSICULAR REPLACEMENT PROSTHESIS

TORPs bear structural similarity to PORPs with the range of head designs often shared, however the strut is longer to reach the stapes footplate, and the medial end of the prosthesis is often flattened to rest on the footplate rather than cupped. As with PORPs, some designs of TORP are shaped specifically to accommodate the malleus handle with a notch or groove, whereas others have a flat disc leaving both footplate-to-malleus and footplate-to-tympanic membrane options open.

One of the challenges of this type of reconstruction is the tendency for prosthesis displacement. TORPs can be placed directly on the stapes footplate, although stability may be improved with a cartilage ‘shoe’ or a

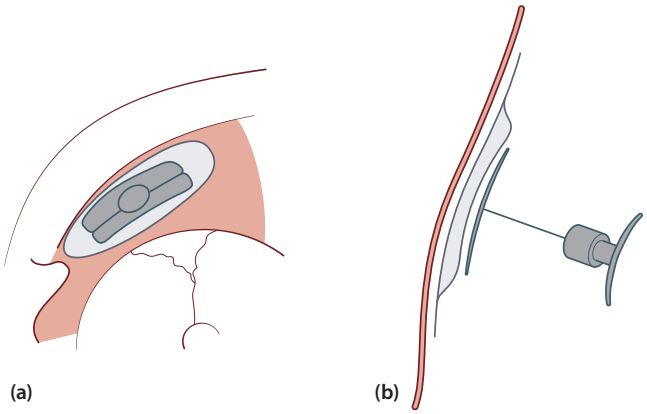

Figure 85.7 TORP with footplate shoe. (a) The footplate prosthesis in position on the oval window beneath the facial nerve. **(b)** A typical configuration with a cartilage and perichondrium graft between the prosthesis and tympanic membrane.

specially designed footplate prosthesis.[53, 54] The footplate shoe acts as an anchoring point for the medial end of the prosthesis, thereby reducing displacement while also helping to direct the vector of force through the centre of the footplate improving sound transmission (Figure 85.7).[55]

Malleus absent, stapes present (Austin–Kartush type C)

Several retrospective analyses have shown absence of the malleus handle to be a major independent prognostic factor resulting in poorer hearing outcomes following reconstruction.[56, 57] This is partly due to the loss of the amplification produced by the tympanic membrane–malleus handle complex, and loss of a solid point of fixation for any reconstructed assembly.

The simplest surgical option is to proceed with a stapes-to-tympanic membrane reconstruction as described above for type A defects. An alternative approach is to recreate the malleus handle, either with autologous material or with a prosthesis. Homograft tympanic membrane with attached malleus handles have also been used widely.[58]

NEOMALLEUS

Creation of a neomalleus strut can be achieved with incus, cortical bone or cartilage. Black showed superior hearing outcomes with a neomalleus assembly technique as compared to collumella only approach.[59] He described a neomalleus strut being placed medial to the tympanic membrane graft with the preferred source being a strip of cartilage from the root of the helix.

MALLEUS REPLACEMENT PROSTHESIS

The design and use of a malleus replacement prosthesis is a recent development described by Vincent et al. Patients receiving the malleus replacement prosthesis showed improved hearing results as compared to using a footplate to tympanic membrane TORP (12.5 dB air–bone gap and 23.3 dB respectively) and reduced prosthesis displacement.[60]

Malleus and stapes absent (Austin–Kartush type D)

This is the most challenging ossicular defect and is likely to lead to the poorest outcomes. It may be managed with a combination of the above techniques and will require reconstruction with autologous tissue, ossicle interposition or TORP. The reconstruction may be footplate-to-tympanic membrane, or alternatively a neo–malleus or malleus replacement prosthesis may be used to improve stability.

OPERATIVE CONSIDERATIONS

Length of prosthesis

Several studies have investigated the effect of the tension of the ossicular reconstruction on sound transmission at the oval window. Lower-tension reconstructions with a short prosthesis resulted in better sound transmission than higher-tension reconstructions with a long prosthesis.[46, 61] The beneficial effect of a more loosely fitting prosthesis on hearing must be balanced against the potential increased risk of displacement.

Staged reconstructions

As the majority of ossicular chain defects arise as a consequence of chronic suppurative otitis media, tympanic membrane retraction or cholesteatoma, the primary goal of the initial operation is generally to achieve a safe, dry ear. The decision whether to attempt ossicular chain reconstruction at the first operation or whether to perform a staged reconstruction at a later date depends on several factors.

The most important issues to consider are the risk of recurrent or residual disease. Eustachian tube function is a key determinant of outcome following tympanoplasty surgery,[62, 63] and the associated tympanic membrane retraction causes specific problems in ossiculoplasty due to increased risk of prosthesis displacement or extrusion. Similarly, where there is judged to be a significant risk of residual cholesteatoma, performing primary ossiculoplasty can complicate potential revision surgery if the recurrence involves the reconstructed ossicular chain.

In ears at higher risk of retraction or residual disease it may be prudent to delay reconstruction until a disease-free, aerated middle ear space has been achieved. However, it is often possible to offer primary reconstruction, particularly as improved imaging techniques with diffusion-weighted magnetic resonance imaging allow the option for radiological cholesteatoma surveillance without necessitating second-look surgery.[64, 65]

AUDIT AND RESEARCH

One of the challenges facing ossiculoplasty surgeons is being able to predict what outcome is likely to be achieved with a particular type of reconstruction or prosthesis. While published series may give an indication of the range of outcomes that can be expected, it is essential that surgeons are aware of their own results when consenting patients for surgery. Individual data collection and self-audit may be facilitated by specialized software or internet-based data entry.[66, 67]

There is a paucity of randomized controlled trials for evaluating ossiculoplasty methods or prostheses. Most results published in the literature are case series from a single surgeon or institution, with comparisons often occurring at the time of transitioning between an established method and a newer approach. Comparing results between studies may be confounded by several uncontrolled variables such as population differences, case complexity (although previously mentioned risk scoring systems may help adjust for this) and, perhaps most importantly, surgical technique.

It is important to be aware of variation in the way results are reported as there is no universally accepted measure of a 'successful outcome'.[68] The main considerations following ossiculoplasty are hearing results, and complication rates which may be prosthesis-related (extrusion, displacement, inflammatory reaction) or general (graft failure, taste disturbance, etc.). Most studies report short observation periods of 1 year; however, it has been established that audiometric results frequently deteriorate over time, and complications may present after many years.[56, 69]

KEY POINTS

- While prosthesis design and surgical technique undoubtedly affect results, the status of the middle ear is probably the most significant factor in outcome.
- Surgical results from ossiculoplasty tend to deteriorate over time.

BEST CLINICAL PRACTICE

✓ As ossiculoplasty results are variable, surgeons should endeavour to record their own results to enable accurate consent of their patients.

CHAPTER
86

EUSTACHIAN TUBE DYSFUNCTION

Holger H. Sudhoff

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: Eustachian tube, Eustachian tube dysfunction, imaging, chronic otitis media focusing on diagnosis, surgery and management.

INTRODUCTION

The Eustachian tube (ET) is part of a system including the nose, palate, rhino-pharynx and middle ear spaces.[1] This comprises the tympanic cavity, which includes the bony ET and the mastoid air cell system (**Figure 86.1**). The tympanic cavity and mastoid cells are interconnected and allow for gas exchange and pressure equalization. The ET is a complex organ consisting of a dynamic, mucosal lined canal, cartilage, surrounding soft tissue, peri-tubal muscles, superior bony support and the sphenoid sulcus. Clinical experience as well as numerous patient studies and animal models prove that the ET plays an important role in various middle ear pathologies.[2–4] Despite improvements in the understanding of ET function, significant uncertainties remain due to its complex anatomy, multiple functions as well as the impact of intrinsic and external factors.[5,6] Intermittent transitory tubal dilation is probably the major mechanism for equalizing middle ear cleft and ambient atmospheric pressure.[7] Barometric and chemical receptors within the middle ear cleft are assumed to provide autonomic nervous system feedback that impacts on the frequency of involuntary tubal opening.[8,9] Our understanding of the anatomy and physiology of the ET still continues to evolve. Recently, McDonald et al. demonstrated that the ET might have a sequential peristaltic-like mechanism.[10]

Currently, there are various medical and surgical interventions available for chronic obstructive ET dysfunction

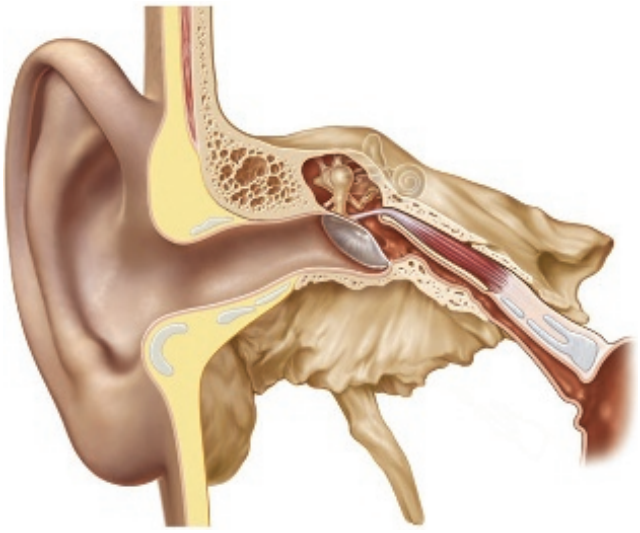

Figure 86.1 Temporal bone drawing of the cartilaginous and bony portion of the ET and middle ear spaces.

including balloon Eustachian tuboplasty (BET) and laser or microdebrider tuboplasty.[11–17] However, the small sample sizes in the reviewed literature represent a significant limitation when assessing their efficacy. The majority of available studies are underpowered and unable to detect a significant effect.[18] Long-term results with these procedures still have to be established.

DEFINITION

The term Eustachian tube dysfunction (ETD) describes impairment of ET function and leads to a variety of symptoms and physical findings. The condition does not necessarily lead to detectable middle ear pathologies. Dysfunction of the ET can be either acute or chronic. Acute ETD can occur during nasal congestion due to a common cold or allergic rhinitis, for example, and is generally transient. ETD lasting longer than 3 months consecutively is considered chronic. Chronic ETD can be due to obstruction or to a patulous (branching) Eustachian tube (PET). ETD is nevertheless a poorly defined condition.[18]

AETIOLOGY

Allergic disposition with accompanying mucosal hyperplasia and nasopharyngeal acid reflux may play an important role in ETD. ETD can lead to clinical symptoms such as aural fullness, impaired pressure equilibration, altered middle ear aeration, hearing loss and autophony (the unusually loud hearing of a person's own voice).

ETD is estimated to be present in about 1% of the general population.[19] Because the most common cause of obstructive dysfunction is mucosal inflammation within the cartilaginous ET, patients should be questioned about inflammatory processes such as allergic rhinitis, chronic rhinosinusitis, laryngopharyngeal reflux (LPR) and smoke exposure.[20, 21] ETD has been found to be associated with a higher number of nasopharyngeal reflux events and higher reflux finding score in adult patients.[22] Paediatric ETD may be caused by adenoidal hypertrophy and mucosal swelling due to acute or chronic upper respiratory tract infections. Cleft palate, granulomatous diseases, cystic fibrosis, Samter's triad and Kartagener syndrome are predisposing factors. ETD may be a contributing factor to vertigo.[23, 24] It is important to distinguish ETD from other causes of aural fullness such as temporomandibular joint (TMJ) disorders, superior semicircular canal dehiscence syndrome, Ménière's disease and increased intracranial pressure employing a tailored assessment. Almost 40% of all children up to the age of 10 years develop temporary ETD.[25, 26] Studies accessing paediatric and adult patient cohorts demonstrate that ETD is detectable in up to 70% of patients undergoing middle ear surgery.[27] Good ET function is believed to be important for the successful outcome of middle ear surgery.[28, 29] Patients with a PET usually present with positional autophony and hearing both voice and breathing sounds or aural fullness.[26] The precise distinction between the obstructive and 'patulous' ET is essential for appropriate medical or surgical treatment but is often challenging. Patients with PETs may benefit from augmentation or reconstructive procedures.[30, 31]

ASSESSMENT

A large variety of methods have been employed to assess ET function,[31–39] with more than 40 described in the literature.[31] None is able to give detailed insight into all aspects of ET physiology and pathology. Clinical tests such as otoscopy, endosocopy, Politzer test, Valsalva (exhaling into a closed airway by pinching the nose and closing the mouth) and Toynbee manoeuvre (pinching the nose and swallowing) may give initial guidance. Manometric testings (tympanometry, reflex decay tympanometry, nine-step inflation deflation test, modified inflation deflation test, forced response test and tubomanometry (TMM)) have some value.[31–39]

TMM was described by Estève in 2001[36, 37] and is a tool to measure the opening of the ET tube and the transportation of gas into the middle ear by registering pressure changes (**Figure 86.2**). A stimulus of a controlled gas bolus is applied to the nasopharynx during swallowing and recorded by a pressure sensor in the occluded external ear canal. If ET opening is registered, the time of opening in relation to pressure application can be measured (opening latency index or index R). An R value of <1 indicates early opening of the ET, which is considered optimal.[36]

TMM R values have been used together with clinical symptoms to generate an ET score, a semi-objective rating system used for quantification and inter-individual as well as prospective comparison of ET function (**Table 86.1**).[12] The ET score can range from 0 (= complete obstruction) to 10 (= normal tubal function). The clinical symptoms 'clicking sound when swallowing' and 'positive Valsalva manoeuvre' are rated with 0 points for 'never', 1 point for 'sometimes' and 2 points for 'always'. TMM results at 30, 40 and 50 mbar are incorporated in the ET score as well. An immediate opening of the ET ($R \leq 1$) is weighted with 2 points, a delayed opening ($R > 1$) with point and no opening (negative or not measurable R) with 0 points. The ET score gives a quantitative assessment of ET function and allows inter-individual as well as prospective comparison.

The pressure chamber is a useful device for assessing ET function under varying pressure conditions, regardless of whether the eardrum is intact or perforated.[31] However, pressure chambers are complex, expensive and not widely available.

For the technique of sonotubometry, sound is applied via a probe in the nose. Sound is then measured in the external auditory canal and fluctuations during swallowing are recorded.[31]

There are numerous other approaches to assess ET function such as phototubometry, scintigraphy, ultrasound, application of dye and taste-bearing substances, electromyography, flowmetry, and (opto)tensometry.[31] At present, none of these methods has produced data of clinical significance.[18, 33]

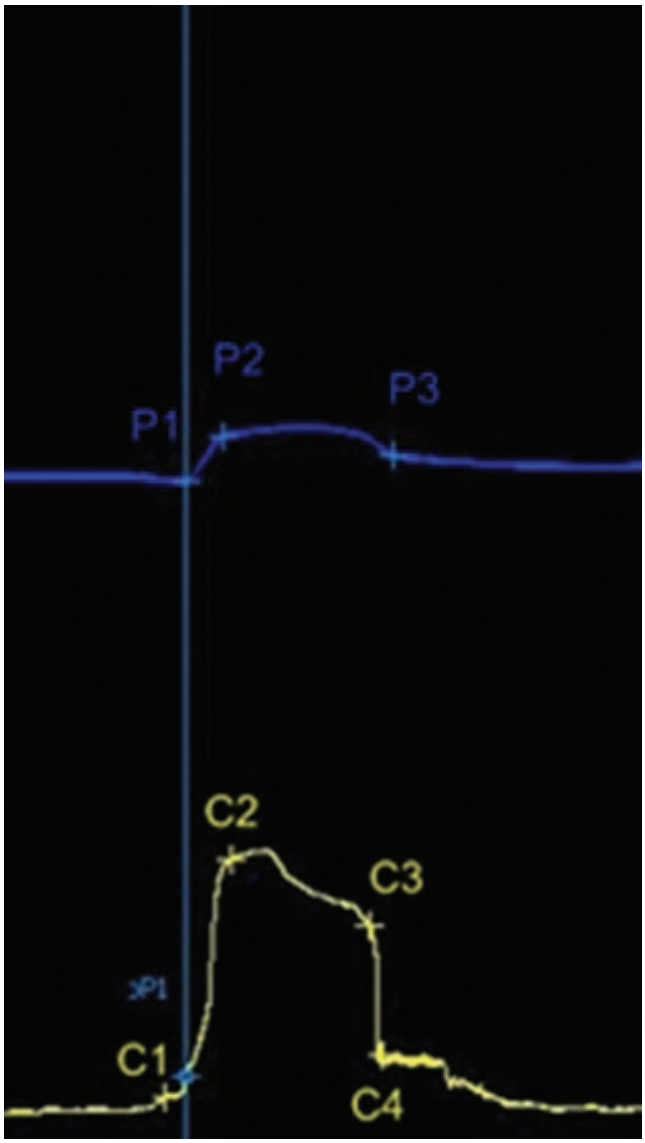

Figure 86.2 ET measurement. The yellow line represents the pressure in the nasopharynx, the blue line the pressure in the external ear canal.

Imaging with computed tomography (CT), cone beam tomography and magnetic resonance (MR) has long been used to examine anatomic and functional deficiencies as well as to rule out pathology in the nasopharynx or superior canal dehiscence syndrome (SCDS)[4, 20] (see Chapter 65, Superior semicircular canal dehiscence).

TABLE 86.1 The Eustachian tube score

Symptom/finding	2 points	1 point	0 points
Clicking sound when swallowing	Always	Sometimes	Never
Positive Valsalva manoeuvre	Always	Sometimes	Never
TMM 30 mbar	R<1	R≥1	No R
TMM 40 mbar	R<1	R≥1	No R
TMM 50 mbar	R<1	R≥1	No R

A seven-item ETD questionnaire (ETDQ-7) was recently developed to assess patient symptoms (**Table 86.2**).[38, 39]

The lack of high-quality studies means multiple gaps remain in the evidence base for assessment of ETD.[18, 40]

PATULOUS EUSTACHIAN TUBE

A patulous Eustachian tube (PET) (tuba aperta, hyperpatent ET) may lead to an enormous reduction in quality of life. Symptoms of PET include autophony, breath synchronous tinnitus, pressure sensation in the ear, and hearing loss. In combination with so-called 'sniffing', it may rarely lead to the development of cholesteatoma.[41] Due to the diffuse symptoms, the correct diagnosis of this disease and especially the distinction from obstructive ETD can be challenging. The movement of the tympanic membrane in synchrony with respirations is not always present but is diagnostic when seen. PET disorders may occur in two types: the PET type, in which the lumen remains anatomically open, even at rest. The other type, the semi-patulous Eustachian tube, is a less severe form. In the latter the tube lumen is anatomically closed at rest but, due to low tubal resistance to airflow, it may open during exercise. It may then become patent due to a decrease in peritubal extracellular fluid volume attributable to disease, exercise, weight loss (leading to reduction of Ostmann's fat pad which lies inferomedial to the ET) or concurrent medical treatment for another condition.

TABLE 86.2 The ETDQ-7 questionnaire – a tool for the evaluation of chronic obstructive Eustachian tube dysfunction[37]

Over the past 1 month, how much has each of the following been a problem for you?	No problem		Moderate problem			Severe problem	
1. Pressure in the ears?	1	2	3	4	5	6	7
2. Pain in the ears?	1	2	3	4	5	6	7
3. A feeling that your ears are clogged or 'under water'?	1	2	3	4	5	6	7
4. Ear symptoms when you have a cold or sinusitis?	1	2	3	4	5	6	7
5. Crackling or popping sounds in the ears?	1	2	3	4	5	6	7
6. Ringing in the ears?	1	2	3	4	5	6	7
7. A feeling that your hearing is muffled?	1	2	3	4	5	6	7

The incidence of PET has been reported with 0.3% of the general population.[42] Münker diagnosed this condition in 6.6% of 100 women with normal ears.[43] Pulec reported on 41 cases identified at the Mayo Clinic in 19 years in 1964.[44] Clinicians' awareness of patients with PET generally results in a higher recognition of this disorder. Only 10–20% of the patients seek medical help for their complaints.[44]

A PET can be best diagnosed through a well-structured examination including patient history, physical examination with thorough observation of movements of the tympanic membrane, and tympanometry with reflex decay. Tympanometry with reflex decay is helpful in the diagnosis but it requires an intact tympanic membrane and it should be evaluated in comparison with the contra lateral side. TMM does not require an intact tympanic membrane and is a valuable tool in diagnosing ET disorders. TMM allows a definite distinction of patulous and obstructive ET dysfunction.[36, 37] TMM regularly reveals an immediate opening with $R < 1$.

When the diagnosis of patulous ET is made, thorough counselling of the patient is important. It is important for the patient to acknowledge that the disease is annoying but harmless. All treatment options have to be outlined to the patient and conservative treatment should be regarded as the first choice. If conservative measures do not lead to an improvement of the symptoms, there are several surgical or interventional treatment options.

Oestrogen nasal drops or oral administration of saturated solution of potassium iodide has been used to induce swelling of the ET opening. Nasal medication containing diluted hydrochloric acid, chlorobutanol and benzyl alcohol has been demonstrated to be effective in some patients. This has been reported to be well tolerated with little or no adverse effects.[41, 44]

Myringotomy and grommet insertions have demonstrated ability to reduce symptoms but are not definitive therapy.[45] In a retrospective analysis of 46 patients (60 ears) with patulous ET, grommets significantly reduced the symptoms in 53% of the ears.[46] An additional option for symptomatic treatment is the augmentation of the tympanic membrane with cartilage especially in severely atrophic eardrums. The effect of augmentation can be tested by placing a small piece of paper on the tympanic membrane prior to surgery.

There are different surgical strategies such as the PET reconstruction with, for example, cartilage, the Kobayashi plug or the injection of Vox® implants into the torus tubarius.[28–30] In patients with ETD that is refractory to medical management, newer surgical techniques may provide symptomatic relief with a reasonable duration.[29, 30] Continued basic science research into the cause of dysfunction, the mechanisms of benefit from intervention and long-term clinical outcomes are necessary.

MEDICAL MANAGEMENT

Medical management of ETD should be directed at the underlying cause. There is currently low evidence of any efficient medical therapies for ETD.[18] Pharmacological interventions include application of nasal steroids, antihistamines, inhaled and systemic decongestants.[47–49]

A randomized, double-blind, placebo-controlled trial studied the effect of a decongestant agent (xylometazoline chloride 0.1%) and placebo (saline 0.9%) applied directly to the pharyngeal opening of the ET. The study concluded that a topical decongestant improves ET function but only at unphysiologically high pressures.[48] Another trial investigated the efficiency of intranasal aqueous triamcinolone acetonide in treating the tympanometric signs and symptoms of ETD.[47] Their findings did not support the use of intranasal steroid sprays to treat the manifestations of ETD.[47]

POLITZERIZATION/OTOVENT™/ EAR POPPER®

No statistical difference in equalization of the middle ear pressure was found between Valsalva manoeuvres, Toynbee manoeuvres and Ear Popper®. The Ear Popper® is an automated device that is applied to the nose and delivers a regulated flow of air into the nasal cavity in healthy adults under physiological conditions.[50, 51] The automated device's ease of administration and its ability to control airflow suggest that it has the potential to be an effective home treatment that can be administered by the parents or guardians of children suffering from otitis media with effusion.[52, 53] Autoinflation using the Otovent™ system was found to be an effective short-term treatment for children with OME when used regularly under supervision.[52] However, available data are too limited to draw any definite conclusion.

LASER TUBOPLASTY

Kujawski, Poe and Caffier reported on their results of laser Eustachian tuboplasty. It seems to be a feasible, safe and in suitable cases effective treatment of chronic obstructive ETD. Using a KTP-laser, inflamed or hyperplasic tissue and sometimes also cartilage is resected from the pharyngeal orifice of the ET. This technique is reported to be successful in almost 70% after 1 year.[13–15]

BALLOON DILATION EUSTACHIAN TUBOPLASTY

Balloon dilation Eustachian tuboplasty (BET) is a minimally invasive interventional method to treat chronic obstructive ETD. It is usually performed with the patient under general anaesthesia.[54] A balloon catheter is introduced into the ET via the nose, under transnasal endoscopic vision.[11, 12] Once the balloon is correctly positioned in the cartilaginous portion of the ET, it is filled with saline up to a pressure of 10 bars. The pressure is maintained for 2 minutes (**Figure 86.3**). BET can be performed as a unilateral or bilateral procedure in adult patients and children

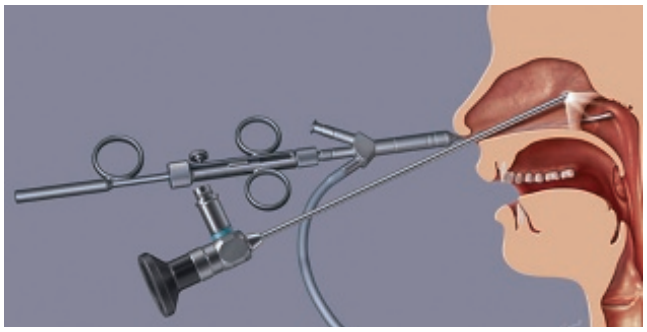

Figure 86.3 Instruments for balloon dilatation Eustachian tuboplasty (Spiggle & Theis Medizintechnik, Overath, Germany).

Figure 86.4 Novel insertion tool with three angled extensions: 30°, 45° and 70°, colour-coded according to Hopkins endoscopes.

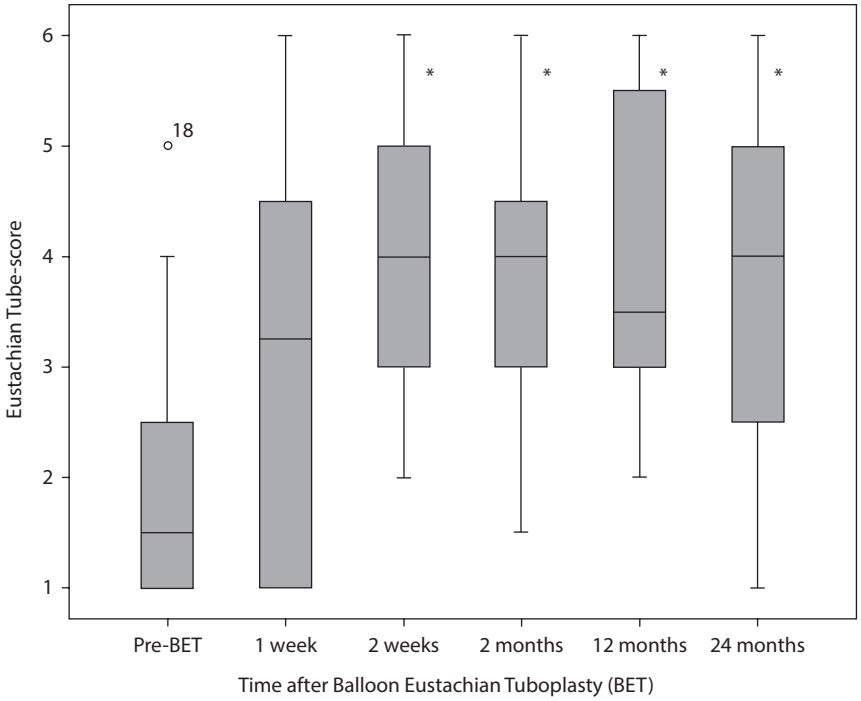

Figure 86.5 Eustachian tube score (see Table 86.1) at the 2 months follow-up. Patients with 24 months follow-up data available were included ($n = 22$). (Asterisks indicate $p \leq 0.001$ in Wilcoxon's test.)

from the age of 7 years. For younger children, additional data are required and currently under investigation.[55] BET is indicated for symptomatic patients with an ET score of ≤5 and the presence of at least one of the following clinical symptoms of obstructive ETD:[56]

- uncomfortable sensation of pressure in the ears especially with changes of atmospheric pressure (e.g. on an aeroplane)
- inability to perform Valsalva manoeuvre
- chronic otitis media with effusion
- middle ear atelectasis
- recurrent middle ear diseases (e.g. perforation, cholesteatoma)
- failed tympanoplasty (e.g. protruding middle ear prosthesis).

In a series of more than 400 patients suffering from obstructive ETD, approximately 80% reported a subjective benefit from BET, and had a significant improvement of their ET score without serious side effects.[56] Significant scarring in the nasopharynx, for example following radiotherapy for nasopharyngeal tumours or after injury of the torus tubarius during adenoidectomy, can be technically challenging. Cleft palate patients do not seem to benefit from BET since the underlying pathology in these cases is a muscular dysfunction rather than obstruction of the ET.[56] Poe et al. described a quite similar method of BET with a modified catheter in 2011 and 2014.[16, 57] They performed the dilatation with a modified sinuplasty balloon with 12 atm for 1 minute and later 2 minutes. Post-operatively all treated patients were able to perform the Valsalva manoeuvre.[16] BET does not seem to require

imaging in normal cases.[58, 59] The results of the present data seem to reveal BET as a safe and effective method.

DISCUSSION

ETD is often regarded as a 'black box' in which the function of the system remains unclear.[18] It has become increasingly clear that there are a variety of underlying reasons leading to ETD. Their identification and treatment is crucial for clinical improvement. Over many years, a variety of different treatment options for chronic obstructive ET dysfunction have been proposed. They range from nasal decongestives and steroids to golden tube conductor wires, grommet insertion and tympanoplasty. Convincing evidence of long-lasting benefit is absent. More recent publications focus on balloon catheter dilation of the ET, microdebriders and laser tuboplasty and these appear more promising.[11–17]

BET as a minimally invasive treatment for obstructive ETD was presented in 2008.[11] A balloon catheter with a newly designed endoscope to widen the cartilaginous portion of the ET was introduced. The available results for the treatment of obstruction of the ET are promising. There are uncertainties about the use of the procedure in children due to the obvious anatomical differences. Additional studies are necessary to identify patients who are most suitable candidates for this procedure and defining cut-off levels for the procedure. Patient selection is the most crucial point and requires more clinical data.[56]

The results of the present data seem to prove BET as a safe and effective method. BET may have potential to improve the long-term results of tympanomastoid surgery through the enhancement of middle ear ventilation.[60–62]

CONCLUSIONS

ETD is still a poorly defined condition. Due to the limited and poor-quality evidence, it is difficult to draw definite conclusions on the effectiveness of any therapy. Consensus on diagnostic criteria for ETD is required to define inclusion criteria of future trials. There is, however, emerging work with encouraging, but preliminary, results that suggest evidence for safety in the surgical management of ETD. As with many newly introduced techniques, the current data remain limited to non-controlled case-series, with heterogeneous data collection methods and lacking substantial long-term outcomes. Nevertheless, short-term data provide favourable results. Recent treatment options including BET and patulous ET surgery may be offered as a treatment option to selected patients.

ACKNOWLEDGEMENTS

We would like to thank the following: Dr Stefanie Schröder, Dr Ulf Reineke, Dr Lars-Uwe Scholtz, Dr Ingo Todt, Dr Thorsten Ockermann, Dr Tarek Abdel-Aziz.

BEST CLINICAL PRACTICE

- ✓ Clinical assessment will vary what investigations are available. Ideally assessment should include otomicroscopy, tympanomatry, Rinne's and Weber's tuning fork tests and pure tone audiometry and nasopharyngoscopy (to visualize the orifice of the Eustachian tube). There is no single test to diagnose Eustachian tube dysfuntion. Therefore at this stage we have to rely on the clinical observations (symptoms and signs) detailed above.
- ✓ A number of tests for Eustachian tube function have been described, including tubomanometry, sonotubometry, nine-step inflation-deflation test and pressure chamber tests. At the current time, these tests can be useful research tools.

FUTURE RESEARCH

- ➤ Our understanding of ET anatomy and physiology still remains incomplete, including the epidemiology of Eustachian tube dysfunction, development and validation of patient-reported symptom scores and subjective and objective pressure tests, the development of a core set of outcome measures and further randomized controlled trials of treatments for Eustachian tube dysfunction.
- ➤ There is a strong requirement for consensus on the definition of ETD and for the development of precise diagnostic and treatment criteria.
- ➤ All current studies suggest that balloon dilation of the Eustachian tube is beneficial to patients with Eustachian tube dysfunction. Additionally, placebo controlled trials are still needed.

KEY POINTS

- Sound conduction requires a stable air compartment within the middle ear spaces maintained by a functioning ET.
- ETD plays a significant role in various middle ear pathologies.
- There are a number of methods of assessing ET function, but none provides detailed insights into all aspects of ET physiology and pathology.
- Management of any underlying allergies or reflux is necessary for long-term success in patients with obstructive dysfunction.
- Patients with problems with pressure equilibration or chronic otitis media may be potential candidates for balloon dilation of the cartilaginous portion of the Eustachian tube (BET).

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: ear, endoscope, otoendoscopy, endoscopy, microscope, surgery and otology.

INTRODUCTION

In otology, the operating microscope revolutionized ear surgery by improving the accuracy and safety of operative procedures. Indeed, the use of the microscope with microinstruments led to otology being one of the first fields of minimally invasive surgery. The advantages of the operating microscope are obvious: it delivers a stable image in the familiar head-on view with the ability to vary magnification while freeing both of the surgeon's hands to operate. However, its straight-line view is also the microscope's main limitation as it is unable to navigate around anatomical corners to provide a wide and variable direction of view, unlike the endoscope. Modern advances in endoscope design have provided a new tool for the examination of anatomical structures in the middle ear and more challenging applications extend to neuro-otological operations such as the removal of acoustic neuromas. A spectrum of approaches currently exists between totally microscopic ear surgery and totally endoscopic ear surgery, with an increasing number of otologists using the endoscope to some extent during an otologic procedure. This chapter deliberately concentrates on the otoendoscope, often to the exclusion of the microscope, as traditional or conventional methods are covered elsewhere. The authors vary in their views from mixed usage to a totally endoscopic approach but all believe that the otoendoscope is an essential piece of equipment for the best practice of otology. Each individual must decide his or her own position with respect to the degree of usage of the otoendoscope.

HISTORY OF OTOENDOSCOPY

Although the fibre-optic endoscope was invented in 1954 by Hopkins,[1] otoendoscopy only began with the use of the fibre-optic hypodermic microscope by Long in 1965.[2] Subsequent forays by Mer[3] in 1967 involved practical issues with manoeuvring the great mass of the microscope to attempt safe passage into the middle ear space. Around the same time, Proctor, Donaldson and Wigand were all undertaking detailed studies of the middle ear spaces and their significance, especially the sinus tympani, epitympanic sinus and protympanum, which were the anatomical blind spots for the operating microscope.[4–6]

From the early 1980s onwards, otoendoscopy was increasingly used to inspect and diagnose middle ear disease, particularly residual disease after canal wall up mastoidectomy procedures.[7–11] Second-look operations in patients who had previously undergone intact canal wall mastoidectomy with tympanoplasty operations were performed with the aid of otoendoscopes to exclude residual epitympanic or mastoid cholesteatoma.[9–11] Thomassin strongly influenced the field of endoscopic middle ear surgery by emphasizing the use of endoscopes to search for and remove disease in the anterior epitympanic recess, tubal orifice and sinus tympani with special microinstruments and observed a distinct reduction

of residual cholesteatomas as a result. He also advocated the otovideoendoscopic technique, which involved coupling of the endoscope to a camera and performing the operation while looking at the video image.[12]

In addition, Eustachian tube endoscopy with small fibre-optic endoscopes had begun in 1976 and was developing alongside middle ear endoscopy, with many studies initially using a nasopharyngeal approach to investigate the relationship of Eustachian tube pathology with chronic otitis media and cholesteatoma.[13, 14]

OTOENDOSCOPY VERSUS THE MICROSCOPE

Debate continues unabated as to whether the role of the otoendoscope remains that of an adjunct to the microscope or if it truly has come into its own as an alternative. On the one hand, otomicroscopy with magnification and a sharp image is advantageous whenever it is possible to get the entire area of surgery into the field of view. On the other hand, the advantages of the otoendoscope are clear in terms of its manoeuvrability, proximity of image, wide field of vision and angle of view (Figure 87.1). Its direction of view is also variable and is influenced by the angulation of endoscope employed, usually 0, 30, 45 or 70 degrees (Figures 87.1 and 87.2). It represents a more advanced form of minimally invasive surgery than the microscope alone and is hence associated with reduced surgical morbidity.

Proponents of entirely transcanal endoscopic ear surgery argue that, although there is a spectrum of use of the endoscope as described previously, the reduced morbidity afforded by the endoscope arises from the fact that no postauricular or endaural incision is required to gain appropriate access to the middle ear space. Moreover, there is a reduced requirement to violate healthy tissue purely to access a relatively limited area of disease. When the endoscope is used as an adjunct to microscopic surgery,

although there are clear clinical gains in terms of access, these advantages of reduced morbidity are largely lost.

It is acknowledged that the operating microscope does not allow good surgical control of the hidden areas in the middle ear such as the sinus tympani, the anterior epitympanum, the protympanic recess and the facial sinus recess. Bowdler and Walsh compared the accessibility of different middle ear subsites in canal wall-up and canal wall-down temporal bone dissections, using the 0 degree 4.0 mm diameter and 70 degree 2.7 mm diameter Storz® rigid otoendoscopes and operating microscope.[15] In canal wall-up dissections, the sinus tympani, facial recess, protympanum, attic and posterior tympanotomy could be seen with the 0 degree otoscope and good views of the sinus tympani and Eustachian tube were obtained with the 70 degree otoscope. In comparison, the microscope failed to give a view of the sinus tympani either through the posterior tympanotomy or via the ear canal (**Figure 87.3**). In canal wall-down dissections, the otoendoscopes were able to offer a good view of all sites but once again, the microscope provided poor views of the sinus tympani. Karhuketo reported similar advantages with 1.7 mm diameter 0, 30 and 90 degree endoscopes over the microscope.[16] In fact, the view offered by the endoscope so differs from that of the microscope that Marchioni published

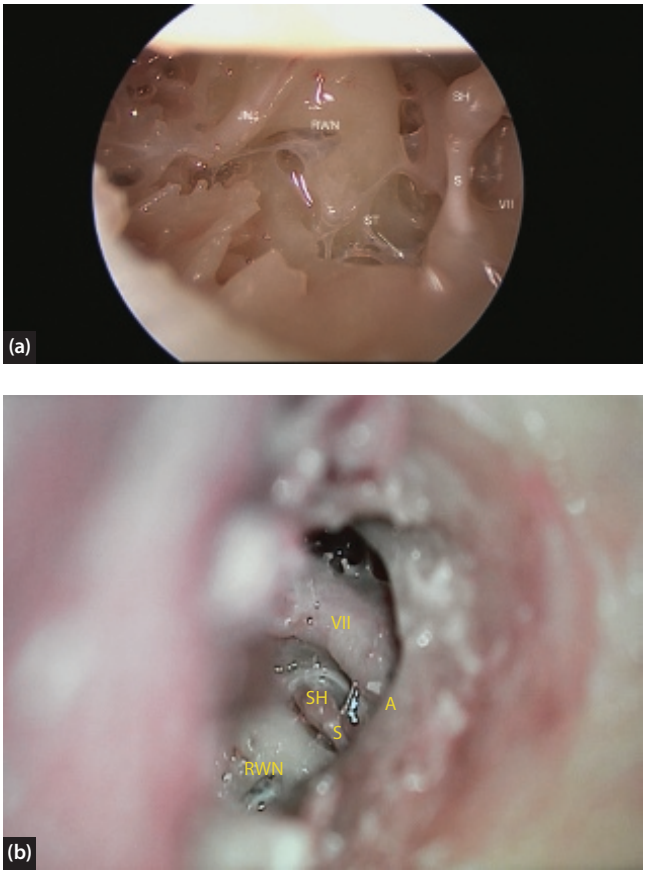

Figure 87.3 **(a)** View of the sinus tympani obtained with 0° endoscope. **(b)** View obtained with the microscope with optimal positioning through the ear canal. a detailed anatomical report of the sinus tympani using the transcanal endoscopic approach, classifying the sinus tympani into various types based on morphology and depth (**Figure 87.4**).[17] A new term 'finiculus' was also devised to describe the ridge of bone that marks the border between the retrotympanum and hypotympanum.[17]

Another example of this difference in access between the two techniques is the facial recess. If approached through transcanal endoscopy, it ceases to be a recess and becomes merely a small depression on the posterior wall of the mesotympanum that can be reached within minutes of the start of the operation. In contrast, microscopic technique requires a cortical mastoidectomy and subsequent identification of the facial nerve, providing a limited keyhole access in the space between the chorda tympani and the facial nerve.

The use of the otoendoscope is, however, accompanied by several disadvantages. For example, using the otoendoscope leaves only one hand free to operate. Another perceived disadvantage is the lack of true three-dimensional (binocular) vision during the operation, but with sufficient experience, this appears to have limited impact. The more common limitation for otoendoscopy tends to be peri-operative haemorrhage that leads to fogging and smearing of the endoscope tip, hence it has to be cleaned often. Frequent irrigation can be helpful in clearing the field of blood but may often be inadequate in clearing the sinus tympani and epitympanum.[18] New instruments are in development which address the limitations of standard instruments when used with an endoscopic approach (**Figure 87.5**). Less frequently, due to the inherent rigidity of the instrument, otoendoscopy may be limited by the extreme curvature of the external auditory canal (EAC). Anatomical structures such as the mallear body and lateral semicircular canal may also be difficult to see.[19] Thomassin found that 2.7 mm diameter endoscopes had an advantage over their 1.7 mm cousins in this respect.[12] Current transcanal endoscopic ear surgery relies on 3 mm or 4 mm endoscopes for most applications. Furthermore, smaller diameter endoscopes are extremely fragile; the shorter its working length, the less the bending torque achievable with the same force, but the 1.7 mm endoscopes are unable to tolerate any bending.[20]

Safety issues

Safety issues surrounding endoscopy have focused on the risk of thermal injury to the middle ear. An *in vivo* canine study found that the temperature rise at the lateral semicircular canal increased in relation to endoscope diameter and the Hopkins rods (3.0 mm and 1.9 mm diameter) produced the same or greater heating effect as a warm 44 °C water caloric test.[21] More worrying findings were the discovery of a 5 mm burn on the medial wall of the middle ear when using a 3 mm Hopkins rod and charring effects on the edge of the myringotomy. MacKeith et al. measured the temperature reached by the tip of the endoscope and found that, although temperatures at the tip of the endoscope were sufficient to cause thermal injury, measurements taken 5 mm from the tip were far lower

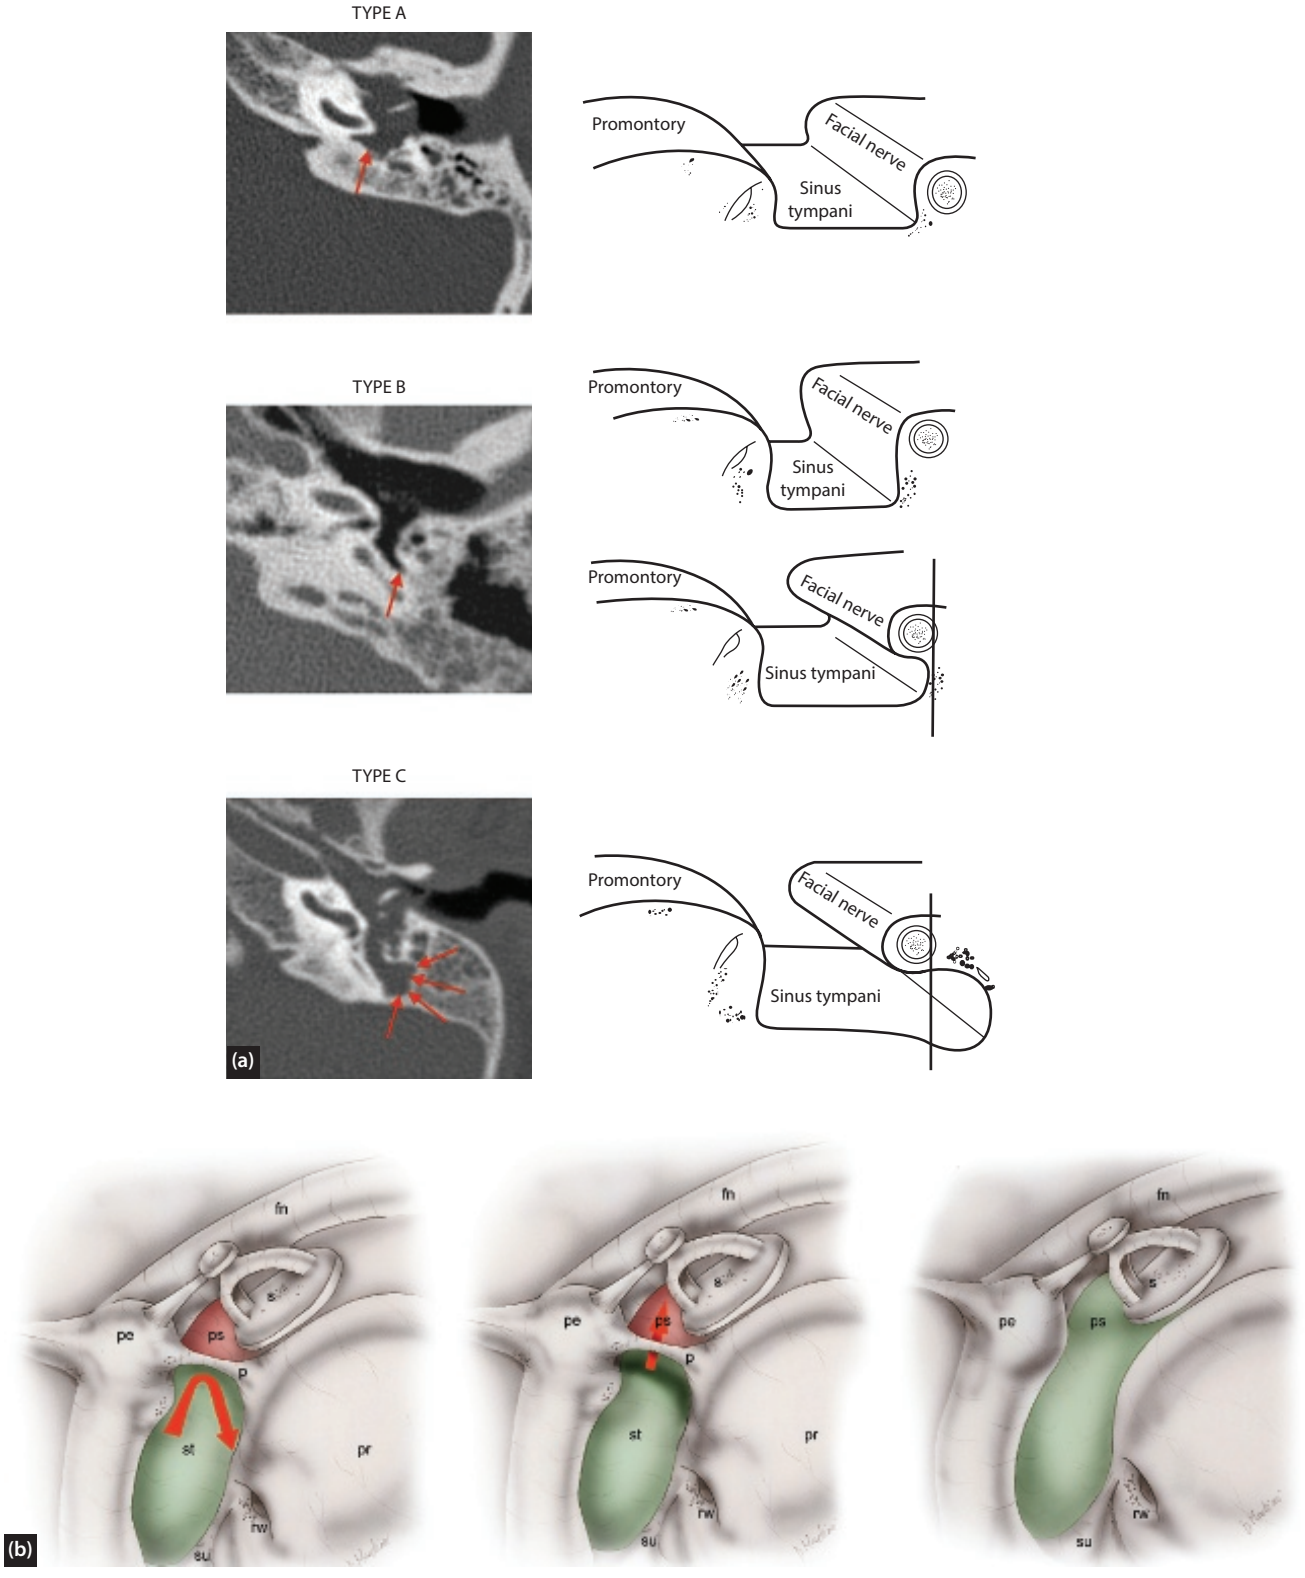

Figure 87.4 (a) Anatomical classification of the sinus tympani based on morphology and depth on axial CT scan. Type A – limited sinus tympani; Type B – deep sinus tympani with medial extension with respect to the facial nerve; Type C – deep sinus tympani with posterior extension with respect to the facial nerve. **(b)** The sinus tympani lies medial to the pyramidal eminence, stapedius muscle and facial nerve and it lies lateral to the posterior semicircular canal and vestibule. The superior limit of this space is represented by the ponticulus, while the inferior anatomical limit is represented by a prominent ridge extending from the styloid eminence to the posterior rim of cochlear window niche: the subiculum. Different morphologies of the ponticulus are shown here. fn – facial nerve; pr – promontory; rw – round window; st – sinus tympani; p – ponticulus; ps – posterior sinus; s – stapes; pe – pyramidal eminence; su – subiculum. and cooling took place rapidly when the endoscope was removed.[22] In addition, the learning curve in otoendoscopy means that it will take some time for the surgeon who is accustomed to an entirely microscopic technique to adapt accordingly. Lack of endoscopic experience or indelicate tissue handling may lead to unsafe advancement during otoendoscopic exploration and possible forceful dislocation or fracture of ossicles.[19]

GENERAL REQUIREMENTS

Pre-operative imaging with high-resolution computed tomography (CT) is recommended before any middle ear procedure where the endoscopic and microscopic approach is planned, but for many surgeons this is equally true of any procedure for middle ear cleft disease. Standard axial, sagittal and coronal views are not as helpful in the true endoscopic setting as they are in the microscopic setting. The best series of views to use are reconstructed along the plane of the external auditory meatus to allow the surgeon to anticipate what he/she will duly encounter endoscopically (Figure 87.6).

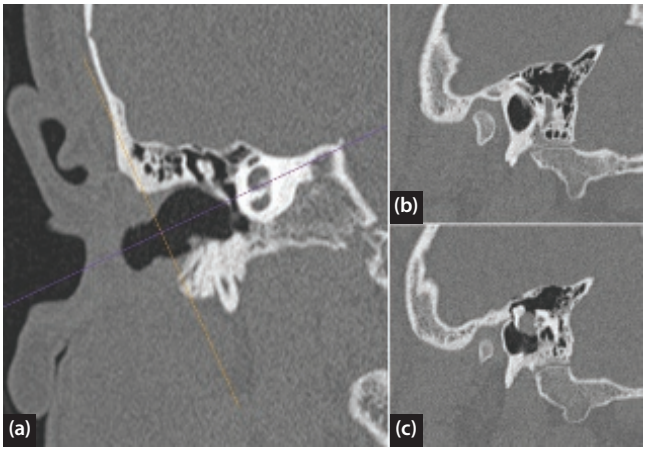

Figure 87.6 Reconstruction of CT scan images along plane of external auditory meatus, best used for pre-operative planning in endoscopic ear surgery.

Endoscope specifications

There are two schools of thought when it comes to selecting which type and size of endoscope to use for ear surgery. Many otologists will use both operating microscope and endoscopes symbiotically, performing part of their surgery with 2.7 mm diameter 0, 30 and 45 degree endoscopes and rarely, using the 70 degree endoscope as well as the 1.9 mm endoscopes, especially to pass through the posterior tympanotomy. Others may undertake the majority of their surgery using a 14–18 cm long 4 mm diameter 0 degree Hopkins rod and endoscope, the very same endoscope used for sinus surgery (Figure 87.7). The latter practice has been termed endoscopic ear surgery (EES) to denote its distinction from the former and is steadily gaining popularity among some otologists.[17, 23, 24] The advantages of using a longer and wider endoscope include a wider field of view, as well as the fact that the surgeon's hands are farther away from the ear canal and hence less likely to interfere with one another intra-operatively.

Digital camera specifications

Although using a high-quality Hopkins rod is essential in otoendoscopy, the digital camera attached to the endoscope also needs to be of high specification. One of the most important considerations is that it should be a camera whose imaging system uses three charge-coupled devices (CCDs), where each one takes a separate measurement of the primary

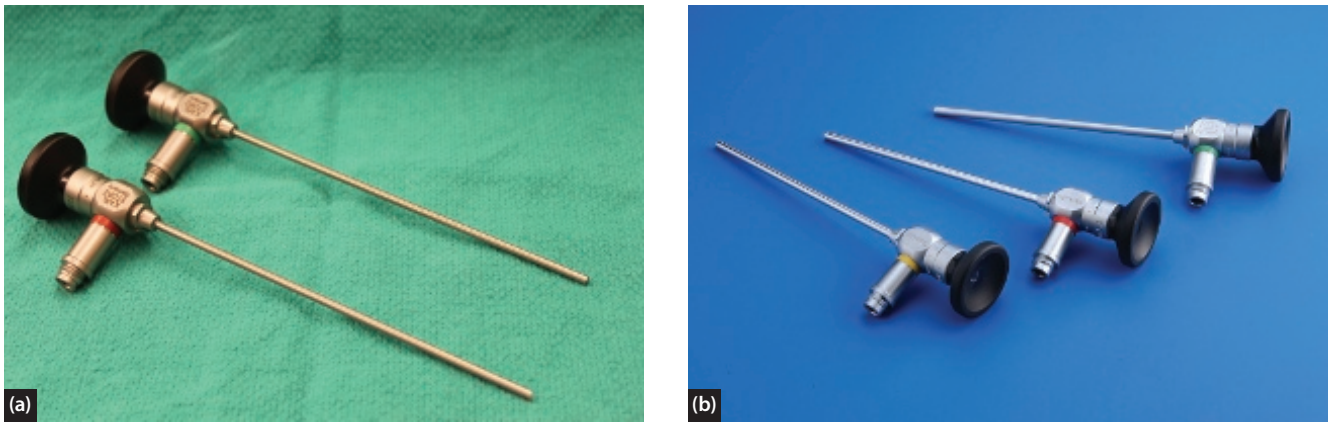

Figure 87.7 (a) Straight and angulated endoscopes (length 14 cm, 4 mm diameter) used in endoscopic ear surgery. **(b)** Straight and angulated endoscopes (length 11 cm, 2.7 mm diameter) more suitable for diagnostic purposes in ear surgery.

colours, red, green or blue light for each pixel, rather than a single CCD camera which can only detect one-third of the colour information for each pixel.[25] Three CCD cameras generally provide superior image quality through enhanced resolution and lower image noise. Single CCD cameras are prone to 'red-out' when they are used in a very small area with a lot of bleeding.[25] Even though there is not much bleeding during EES, the field tends to become reddened, causing complete saturation of the camera. The entire field assumes an orange hue that makes the identification of anatomical structures extremely challenging.

DIAGNOSTIC INDICATIONS

Extent of retraction pockets and cholesteatoma

The diagnostic potential of the endoscope lies most commonly in the evaluation of retraction pockets and cholesteatoma, particularly in blind spots such as the sinus tympani, attic, protympanum and hypotympanum.[7–10] Endoscopy can be performed in the clinic setting as part of the otological examination to assess the extent of middle ear disease and assist in planning the surgical approach. Serial photodocumentation of retraction pockets over a follow-up period may help the otologist to decide whether to adopt a conservative management approach or embark upon surgical intervention.[26]

Ossicular continuity through perforation

Evaluation of ossicular chain continuity may be undertaken endoscopically through an existing tympanic membrane perforation, as demonstrated by Nomura.[27] This procedure may be performed in the outpatient setting with the application of local anaesthesia if required.

Otoendoscopy through myringotomy

Middle ear endoscopy may also be carried out through a myringotomy for many indications such as unexplained conductive hearing loss,[20] perilymphatic fistulas[28] or occult cholesteatoma.[29] Fabinyi and Klug reported on the pathological findings in the middle ear of 60 patients using the transtympanic endoscopic approach, concluding that this method could be used to rule out ossicular anomalies and check for displaced stapes prostheses.[30] Ogawa made the diagnosis of idiopathic perilymphatic fistulas with a 45 degree 1.2 mm diameter Olympus® endoscope through a myringotomy and went on to close the fistulas with fascia and fibrin glue after elevating a tympanotomy flap.[31]

Laser-assisted tympanostomy assisted by otoendoscopy was first performed by Silverstein to examine the relationship between healing of secretory middle ear disease and the tympanic membrane.[32] He went on to use endoscopy to evaluate round window patency as the presence of adhesions might affect the instillation of intratympanic medication in cases of Ménière's disease and sudden sensorineural hearing loss, noting that 17% of patients had partial round window obstruction while 12% had total obstruction.[33] More recently, Kakehata used a similar technique in the outpatient setting to insert the endoscope through a 2 mm laser-assisted myringotomy for assessment of the ossicular chain and stapedial fixation in otosclerosis.[34] The location of the perforation was made between the oval and round windows with a single pulse of 10 watts from the Otoscan™ carbon dioxide laser. Diagnosis of stapes fixation with this technique involved direct endoscopic observation of the stapedial reflex, which was achieved by evaluating the mobility of the stapes in response to contralateral sound stimulation.[34]

THERAPEUTIC USES

Tympanoplasty/ossiculoplasty

The least complicated therapeutic application of endoscopy in ear surgery is probably that of tympanoplasty. Endoscopic type I tympanoplasty (myringoplasty) was first described in 1992 with a graft take rate of 92% and air–bone gap closure to less than 10 dB in 83% of cases.[35] Subsequent studies of endoscopic transcanal myringoplasties followed, with similar success rates as microscope-assisted cases.[36, 37] Tarabichi described his endoscopic technique in a series

of 165 patients and felt that its greatest potential was in tympanoplasty and cholesteatoma surgery.[38] Endoscopic transtympanic tympanoplasty and ossiculoplasty with columella reconstruction or interposition with tragal cartilage was later described in another study, albeit small, with acceptable post-operative hearing results.[24]

Retraction pocket surgery

The use of endoscopy in the surgery of retraction pockets imparts the ability to 'see round corners' to ensure that no epithelium has inadvertently been left in the middle ear cleft after the retraction pocket has been dissected free. It enables the surgeon to retrace the sac, starting from the mesotympanum and continuing through its twists and turns around the ossicles and ligaments. This improved access also facilitates preservation of the ossicles while ensuring the complete removal of the matrix, rather than piecemeal and through different access portals.[23] Tarabichi described an endoscopic transcanal tympanotomy with extended atticotomy and tragal cartilage reconstruction technique in 168 patients with retraction pockets/cholesteatoma and reported a recurrence rate of 7%.[39] He concluded that, while this approach allows the use of the ear canal as the direct and natural access point to cholesteatoma within the mesotympanum, attic, facial recess, sinus tympani, hypotympanum and Eustachian tube, it does not improve access to mastoid disease. Endoscopic access through a mastoid antrostomy may still be required to evaluate an extensive retraction pocket from a posterior perspective.[40]

Mastoid surgery

Numerous techniques have been proposed to facilitate removal of cholesteatoma from the sinus tympani, such as the use of intratympanic mirrors or the retrofacial approach to the sinus tympani, but these methods have not been widely accepted.[41, 42] The last 20 years have seen a myriad of reports on the use of rigid endoscopes to inspect and clear disease in the middle ear.[8, 11, 40, 43] The most detailed studies originated from Thomassin et al.,[10] where the most of the operation was performed with the microscope and the endoscope was employed only in certain situations: at the end of primary canal wall-up mastoidectomy procedures to verify the degree of eradication, when the cholesteatoma had reached the posterior region of the tympanic cavity, the epitympanic recess, or when there was extension to the level of the orifice of the Eustachian tube. Thomassin used a camera coupled to the endoscope whenever it was possible to perform true endoscopic surgery.

Otoendoscopy can also be helpful in canal wall-down mastoid procedures. Yung studied 92 such cases, consisting of small cavity mastoidectomies, canal wall reconstruction and primary obliteration following open cavity mastoidectomies, with 2.7 mm and 4.0 mm diameter (30 and 70 degree) rigid endoscopes.[43] He found that more than one-third of cases had disease extending into the sinus tympani, which was made visible and accessible with the use of side-viewing endoscopes.[43] He did not use the otovideoendoscopic technique recommended by Thomassin et al.[10] as the attachment of the video camera to the endoscope increased the weight of the endoscope and made it more difficult to be manoeuvred. Yung concluded that routine use of endoscopes to control the sinus tympani gives the otologist more confidence at the end of the operation that eradication of the disease is complete as it provides direct vision and also allows better documentation of operative findings.

Minimally invasive second-look combined approach tympanoplasty

Second-look surgery to check for residual and recurrent cholesteatoma is common practice after canal wall-up mastoidectomy operations, as the rate is reported to be higher than with canal wall-down procedures, varying from 10% to 43%.[44–46] One major reason for this is poor access, particularly to the sinus tympani and anterior epitympanum with the operating microscope, leading to increased residual disease. Thomassin et al. showed that the rate of residual disease detected at second-look surgery could be reduced from 47% to 5% with the routine use of otoendoscopy at primary surgery.[10] More recently, Ayache et al. reported the use of otovideoendoscopy to identify and excise residual disease overlooked by otomicroscopy in canal wall-up procedures.[47] Otoendoscopy revealed rates of 44% residual disease in the epitympanum and 34% in the retrotympanum with conversion to canal wall-down procedure avoided in many cases. Their study also suggested that the need for a second-look look combined approach tympanoplasty (CAT) procedure after endoscopic removal at primary surgery would be influenced by the quality of excision achieved with endoscopy.

With the aid of endoscopes, the morbidity of second-look procedures can be reduced by using a minimally invasive approach. A 1 cm stab incision is made anteriorly to the original postauricular incision in the sulcus that allows insertion of a 2.7 mm endoscope into the mastoid cavity to search for residual disease (**Figure 87.8**). Any residual pearls of disease may then be removed without resorting to wider exposure. The posterior tympanotomy may also be reopened through this approach to allow insertion of the endoscope, although a 1.7 mm endoscope is usually required. The accuracy of detecting residual cholesteatoma with this endoscopic technique was verified by performing conventional second-look mastoidectomy procedures with the microscope on the same patients; the results after both techniques were similar.[48] Moreover, the operating time with this approach is shorter than reopening the original incision.[18] McKennan reported that patients find it more comfortable and also reduces the time taken off work.[9] Factors that may require reopening of the original postauricular incision, however, include excessive bleeding, extensive recurrence, reossification over the mastoidectomy site, scar tissue in the mastoid or middle ear cleft, dehiscent facial nerve and lateral semicircular canal fistula. More experienced surgeons would not deem any but the first two factors to be absolute contradictions.

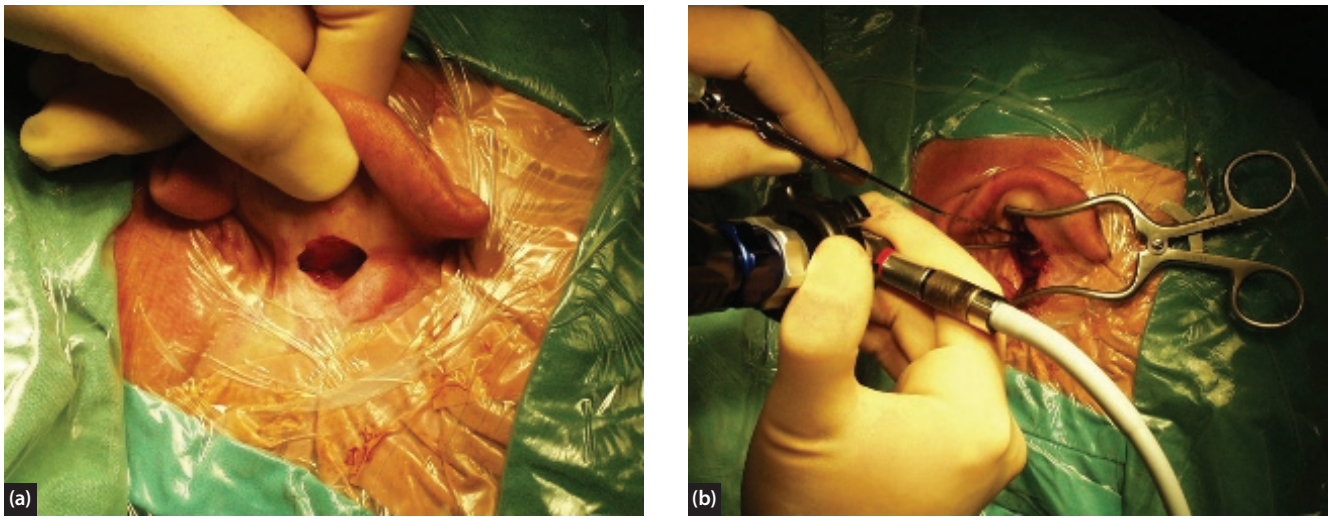

Figure 87.8 **(a)** Performing a minimally invasive stab incision at second-look combined approach tympanoplasty (CAT) surgery. **(b)** Insertion of a 0° (and subsequently a 30°) rigid endoscope into the stab incision to assess for residual disease.

Newer applications

NEUROTOLOGIC SURGERY

Endoscopy of the cerebellopontine angle is not new, but Magnan first described its use in patients with vestibular schwannoma, trigeminal neuralgia hemifacial spasm and incapacitating vertigo.[49] He inserted 1.7mm and 4.0mm 0 degree and 30 degree angled Hopkins rods through a small retrosigmoid craniotomy to access the cerebellopontine angle endoscopically to help identify the relationship between nervous and vascular structures. Endoscopic assistance also helped to prevent cerebrospinal fluid leak after vestibular schwannoma surgery by helping to find patent air cells so that these could be sealed with bone wax and fat grafts.[18]

The role of the endoscopic surgery in the inner ear and internal auditory canal (IAC) is limited and usually used as an adjunct to the microscopic approach. The endoscopic approaches of the inner ear and petrous bone may be summarized as combined transmastoid approaches (translabyrinthine suprameatal, transotic, infralabyrinthine approaches); combined retrosigmoid approach; and exclusive endoscopic transcanal approach.[50, 51] With the combined transmastoid approach, after the microscopic step in the translabyrinthine and transotic approaches, the introduction of the endoscope into the mastoid cavity gives a good view of the geniculate ganglion, medial and anterior portion of the intralabyrinthine facial nerve and removal of residual disease without manipulation of the nerve. With the combined retrosigmoid approach, the aim is to obtain good control of the intrameatal portion of the nerve endoscopically, removing the residual acoustic neuroma within the inner canal, and it is similar to the use of endoscopy in the retrosigmoid neurosurgical approach.

The third approach is the exclusive endoscopic transcanal approach which is still in its infancy.[51] This approach allows endoscopic access to the inner ear from the EAC, preserving facial nerve function and avoiding the need for mastoidectomy or external incisions. After removal of the tympanic membrane and ossicular chain, access to the medial wall of the vestibule is possible. This wall lies adjacent to the fundus of the IAC, representing a portal to access the inner ear and IAC. Endoscopic removal of the bone between the geniculate ganglion and the medial wall of the vestibule will give direct access to the intralabyrinthine path of the facial nerve all the way to the IAC. The use of high-speed drills as part of the endoscopic approach provides a number of challenges, namely the accumulation of bone dust and the need for constant irrigation. Although an otologic drill can be used, for this surgery, it is usual to make use of piezoelectric cutting instruments to remove bone without injury to soft tissues and minimize the production of bone debris. Removing the medial wall of the vestibule will allow direct access to the intrameatal portion of the facial nerve, obtaining entire control of the first segment of the facial nerve.

Although there are currently few indications for the entirely transcanal approach to the inner ear, the technique has been used successfully to remove cochlear schwannomas and small intracanalicular acoustic neuromas. The necessity to approach the lesion through the labyrinth and/or the cochlea makes the technique suitable only in situations where the preservation of hearing is not planned. While far less invasive than a traditional translabyrinthine approach, an endoscopic excision of a lesion of the inner ear or IAC has few indications as the technology currently stands. The risk of bleeding following the removal of the tumour in the IAC makes the endoscopic approach a risky proposition, as there is no way to control haemorrhage under these circumstances owing to the limited access to the IAC at its medial end.

ENDOSCOPIC STAPEDOTOMY

Endoscopic stapedotomy is another novel application of EES. Poe performed stapedioplasties (stapedotomies without prosthesis insertion) in 11 patients by making argon ion laser cuts under endoscopic assistance in the anterior crus and footplate, so as to mobilize the posterior segment

of the stapes while the anterior portion remained fixed.[52] He reported that these patients' hearing improved with air–bone gap closure to a mean of 8.3 dB. More recently Nogueira published a series of 15 patients who had undergone fully endoscopic stapedotomy using a transcanal approach.[53] He used 4.0 mm 0 degree and 30 degree endoscopes, the former to elevate a tympanomeatal flap and the latter to inspect the middle ear and for subsequent stapes work. The advantages associated with the use of endoscopy during stapes surgery include achieving excellent exposure of the oval window niche without removal of healthy bone from the EAC, avoiding any manipulation of the chorda tympani and obtaining a good view of the anterior crus of the stapes to allow its removal without blind manoeuvres.[53]

ENDOSCOPIC COCHLEAR IMPLANTATION

Currently, the use of an endoscopic approach in cochlear implantation is controversial. No case series have yet been published regarding this application of otoendoscopy, but there have been a number of individual cases presented at conferences on EES. The surgical technique involves the routing of the electrode through the epitympanum after a 'well' has been created for the receiver. A small cortical mastoidectomy is fashioned to allow access to the middle ear via the epitympanum after which the ear canal skin is raised from the bony portion of the EAC without the requirement for transection. Once the middle ear has been reached, the implant is guided into the cochleostomy under endoscopic guidance. Another technique involves the passing of the electrode down the ear canal within a bony groove into the middle ear after which the groove is filled with bone wax or other material.

Supporters of these techniques claim that the electrode can thus be placed in a minimally invasive fashion without risk to the facial nerve that is inherent in a technique that requires access through a posterior tympanotomy. The elevation of the tympanic membrane and the skin of the posterior canal wall, however, may lead to an additional route for infection of the mesotympanum and there have been a number of cases of extrusion of the electrode from its groove in the posterior EAC wall through the skin of the EAC, all requiring explantation.

FUTURE DIRECTIONS AND INNOVATIONS

3D otoendoscopy

The disadvantage of the two-dimensional view that comes with an endoscopic approach has been of little hindrance to the development of EES. This mirrors the development of endoscopic sinus surgery in this regard. The development of 3D endoscopy is an area that shows promise; the limited dimensions of the EAC make the use of twin endoscopes very challenging and the 3D view that is achieved by the Da Vinci® robot system cannot be achieved in the ear canal with current technology. To overcome this limitation, 3D CCD chips have been developed to allow a 3D image to be generated with a chip with a diameter of 3.3 mm. This may pave the way for the routine use of 3D camera systems for this purpose.

SUMMARY

Fibre-optic technology, endoscopic expertise, microinstrumentation and laser equipment have all greatly improved over the past few years. It is likely that otoendoscopic surgical techniques will prove increasingly important in otologic surgery. Most of the anatomical spaces in the middle ear that are considered challenging to access with the microscopic technique can easily be approached with endoscope-assisted surgery. The inclusion of the endoscope in microscopic procedures on middle and inner ear pathology, as well as in neuro-otological procedures, could potentially help the surgeon to achieve improved results with regard to the preservation of important structures, limitation of injury to healthy bone for access and allowing a minimally invasive approach in certain situations. At present, opinion continues to be divided as to whether the role of endoscopy in otology should be that of an all-encompassing technique or more as a useful adjunct to the microscope. Regardless, exciting developments in technology and expertise mean that otoendoscopy is likely to remain a key tool of technique in the otologist's armamentarium into the future.

KEY POINTS

- The microscope has traditionally been the workhorse of ear surgery but modern advances in endoscope design and endoscopic surgical techniques have ushered in a new era for the rigid endoscope as a key tool in otology.
- New anatomical terms to describe detailed middle ear anatomy have been devised to accommodate the different view obtained endoscopically.
- There are currently two schools of thought when it comes to selecting size and type of endoscope for ear surgery, divided between shorter 2.7 mm diameter endoscopes, and longer 3 or 4 mm diameter rigid endoscopes. The latter practice has been termed Endoscopic Ear Surgery (EES).
- A wide range of diagnostic indications exist for endoscopic ear surgery, most commonly the assessment of the extent of retraction pockets and cholesteatoma.
- Multiple therapeutic applications exist for the endoscope in middle ear surgery, ranging from endoscopic tympanoplasty and retraction pocket surgery, to minimally invasive second look canal wall up mastoid surgery.
- Newer applications include endoscopic stapedotomy, endoscopic cochlear implantation and total transcanal approaches to the inner ear.
- The role of endoscopy in otology continues to grow in importance but debate remains as to whether the endoscope in ear surgery should be exclusively used with the omission of the microscope or if the endoscope will endure instead as a useful adjunct to the microscope.

CHAPTER 88

TUBERCULOSIS OF THE TEMPORAL BONE

Ameet Kishore

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: tuberculosis, otitis media and temporal bone.

DEFINITION

Tuberculosis is a chronic granulomatous infection caused by *Mycobacterium tuberculosis*. Other mycobacteria such as *Mycobacterium bovis*, *Mycobacterium avium* and *Mycobacterium fortuitum* can also cause infection referred to as 'atypical tuberculosis' or non-tuberculous mycobacterium (NTM) (see also Chapter 37, Cervicofacial infections). While tuberculosis (TB) is predominantly pulmonary, 12–15% of reported cases of TB involve extrapulmonary sites.[1] Rarely the temporal bone may be involved with TB – tuberculous otitis media or tuberculous otomastoiditis.

PREVALENCE

The WHO estimates there are 8 million cases of TB reported annually.[2] The majority of these occur in Asia (55%) and Africa (31%). TB of the temporal bone, however, is extremely uncommon and constitutes less than 1% of all cases of chronic otitis media.[3, 4]

Tuberculous otitis media is even rarer in developed countries and its incidence in the UK is said to be only 0.04% of cases of chronic otitis media.[5, 6] The advent of BCG vaccination and the use of effective antituberculosis therapy have led to a significant reduction in incidence of TB particularly in developed countries.[2] In a previous review of the literature, of the 320 cases of tuberculous otitis media reported in the medical literature between 1986 and 1990, 83% were from Africa.[7]

In developing countries, where TB is still endemic, tuberculous otitis media remains an important differential diagnosis of chronic otorrhoea that is unresponsive to conventional treatment. In a study from Africa, of over 11 000 patients with TB identified over a 6-year period, 43 (0.37%) were diagnosed as having tuberculous otitis media.[4]

PATHOGENESIS

Tuberculous otitis media occurs frequently in ears with pre-existing chronic middle ear infection where the organisms enter the middle ear through an existing tympanic membrane perforation.[8, 9] There are two other potential routes through which the tubercle bacilli may reach the middle ear: either through the Eustachian tube or by haematogenous spread from another focus.[10, 11] Pulmonary tuberculosis may predispose to the development of tuberculous otitis media by providing a source for haematogenous spread to the temporal bone.[12] Tuberculous otitis media in children has been reported to be secondary in up to 50% of cases.[8]

Tuberculous otitis media may present in different pathological phases. In the acute phase there is congestion

followed by thickening of the tympanic membrane and the appearance of tubercles and perforations. The chronic form is slow and painless with perforations and pale pink granulation tissue. The necrotic or caseous form destroys the bone with sequestrum formation.[13]

DIAGNOSIS

The clinician needs to have a high index of suspicion of tuberculous otitis media in patients living in highly endemic areas who present with otorrhoea not responsive to conventional treatment. Up to 50% of patients with tuberculous otitis media may give a history of exposure to TB.[14–16] The initial symptoms and signs are frequently non-specific and similar to those of chronic otitis media. The patients may have symptoms and signs of pulmonary tuberculosis such as cough, night sweats and fever, and should have a thorough clinical examination and a chest X-ray.[17] The prevalence of active or inactive pulmonary tuberculosis in patients with tuberculous otitis media can range from 14% to 93%. However, a number of patients may not present with findings suggesting pulmonary tuberculosis if the disease is inactive.[8, 12]

CLINICAL PRESENTATION

The classical description of tuberculous otitis media is painless otorrhoea, multiple perforations, pale granulations, early severe hearing loss and bone necrosis.[4, 18–20] Otoscopic examination reveals a tympanic membrane perforation through which the middle ear mucosa may appear pale or denuded.[13–15] The bone of the middle ear cleft may be denuded of mucosa in up to 30% of patients.[12]

Multiple tympanic membrane perforations were once considered a hallmark of the disease, but this is seldom reported and is thought to be rare.[21, 22] Small perforations may coalesce to form a single, large perforation.[19, 20] Ng has suggested a triad of signs for tuberculous otitis media: regional lymphadenopathy in the absence of typical systemic features of TB refractory otitis unresponsive to conventional antimicrobial agents, and the presence of complications such as facial nerve palsy or sensorineural hearing loss relatively early in the course of the disease.[23] The hearing loss is usually conductive due to tympanic membrane perforation, although it is not uncommon to have a mixed hearing loss which is disproportionate to the disease due to the occurrence of labyrinthitis. Hearing loss out of proportion to otoscopic findings, the absence of otalgia and the presence of complications such as a facial nerve paresis should alert the clinician to the possibility of tuberculous otitis media.[3, 16, 24] Facial palsy is reported in 10–20% of patients and occurs early in the disease process.[11, 16, 25] It has been suggested that the presence of a facial palsy in the absence of a cholesteatoma should alert the clinician towards the possible diagnosis of tuberculous otitis media.

BACTERIOLOGY

While a positive culture for the acid-fast bacillus *Mycobacterium tuberculosis* confirms the presence of tuberculous otitis media, ear discharge provides a poor yield for positive cultures. This is believed to be due to the low bacterial count in the ear discharge.[11, 26] A positive swab for culture and sensitivity is diagnostic in less than 20% of cases of tuberculous otitis media.[8, 27] Polymerase chain reaction (PCR) has been used to detect mycobacterium tuberculosis in pus or tissue specimens to confirm the diagnosis.[28]

HISTOPATHOLOGY

Histopathological examination of a biopsy specimen is the most definitive way of confirming the diagnosis of tuberculous otitis media.[4, 28] This necessitates a biopsy of granulation tissue, middle ear polyps from the external canal or tissue removed at mastoidectomy. The microscopic finding of granulomata with caseous necrosis, epithelioid cells and Langerhans giant cells is a strong indicator of TB. The false-negative rate of histopathological diagnosis has been suggested to be 10%.[4] In one series of patients, however, the diagnostic yield from histology of middle ear biopsy and aural polypectomy was only 30% and 35% respectively.[15]

IMAGING

Plain skull X-rays are non-specific. They may demonstrate haziness or erosion within the mastoid air cells that are similar to the findings in any other form of chronic otitis media.[29] **A CT of the temporal bone is the radiological investigation of choice** and will usually demonstrate the presence of soft tissue in the middle ear cleft with a relatively well-preserved mastoid air cell system. There is typically minimal sclerosis of the mastoid, mucosal thickening of the bony external auditory canal, or soft-tissue extension within the external auditory canal without erosion of the scutum.[11, 21, 30] With advanced disease, CT may demonstrate diffuse destruction of the temporal bone in contrast to selective destruction of the scutum seen in active squamous chronic otitis media.[20] A CT is important when assessing the degree of involvement of the temporal bone and the likelihood of any complications such as facial nerve involvement, erosion of the semicircular canals or labyrinthine ossification.

DIAGNOSTIC CHALLENGES

TB of the temporal bone is seldom considered as the initial diagnosis in a patient with a discharging ear owing to its rarity. This, however, explains the frequent delay in diagnosis.[18] This is particularly true in developed nations. In developing countries in Africa and Asia, the index of suspicion should be higher. Many patients have no previous history of TB infection and have a normal chest X-ray.[3]

The absence of disease-specific clinical findings and the very high false-negative rate of bacteriological culture makes it difficult to confirm the diagnosis of tuberculous otitis media early in the disease process.[11] **The widespread use of neomycin- and gentamicin-containing ear drops can mask the clinical features of tuberculous otitis media as these drugs have a weak antituberculous effect.**[15, 26, 31]

As early treatment can prevent complications such as irreversible hearing loss and facial nerve palsy, the clinician needs to have a high index of suspicion.[11]

The differential diagnosis of tuberculous otitis media includes other chronic conditions affecting the temporal bone such as Wegener's granulomatosis, histiocytosis X, chronic otitis media, cholesteatoma, histoplasmosis, blastomycosis, syphilis and lymphoma.

COMPLICATIONS

Complications of tuberculous otitis media are commoner and tend to be more severe in children. Facial nerve paralysis has been reported in 16% of adults and 35% of children with tuberculous otitis media.[4] Profound hearing loss can occur following spread of infection into the cochlea.[5, 19, 20, 32] Granulation tissue invading the Fallopian canal and compressing the facial nerve results in a facial nerve palsy in 10–20% of patients.[11, 24, 25, 33, 34] Other complications reported are postaural fistula, temporomandibular joint involvement,[34] intracranial complications such as meningitis, tuberculomata,[35] otitic hydrocephalus[36] and multiple cranial nerve palsies.[4, 31]

MANAGEMENT

The two components of treatment are antituberculous therapy and surgery. Medical management with antituberculous therapy is the mainstay of treatment once the diagnosis has been confirmed.[4, 5, 11, 12, 18, 26, 28] Antitubercular treatment using the current standard medication of isoniazide, ethambutol, pyrazinamide and rifampicin may be required for a minimum period of 6 months. Treatment over a longer period may be required in cases of disseminated TB and meningitis.[37] Patients may only require medical treatment.[38, 39]

Surgery may be required to obtain tissue for histology, drain a subperiosteal abscess or remove a bony sequestrum.[4, 18] The incidence of sequestrum formation may be as high as 30%.[27] Surgery may be indicated in the presence of facial nerve palsy for the purposes of a facial nerve decompression if medical management fails to demonstrate clinical improvement in facial nerve function.[4, 18]

Resolution of the otorrhoea with medical management alone can begin to be seen after 2–3 weeks of treatment and the disappearance of granulation tissue can be observed in 1–5 months.[12, 17] Some authors have suggested that combined modality treatment of surgery and antituberculous therapy is likely to be more effective and result in quicker healing with better outcomes.[11, 16, 20, 24] The role of surgery for facial nerve palsy in tuberculous otitis media is contentious as similar results are reported with medical management alone.[4, 14] In the case of bilateral tuberculous otitis media resulting in bilateral profound hearing loss, cochlear implantation is an option for hearing restoration. However, the labyrinthine ossification that follows tuberculous otitis media can make surgery difficult.[40]

KEY POINTS

- Tuberculous otitis media is a rare condition and constitutes 0.3–0.9% of all patients with chronic otitis media.
- Most cases have been reported from countries where TB is endemic such as in Africa and Asia.
- There are no specific clinical features as symptoms and signs are similar to chronic active otitis media.
- The confirmation of diagnosis is difficult as bacteriology is insensitive. Histopathology is often required to confirm the diagnosis.
- Complications such as profound hearing loss and facial nerve paralysis can occur early in the disease process.
- The mainstay of management is medical using antituberculous treatment for 6 months or longer.
- Surgery in the form of mastoidectomy with or without a facial nerve decompression is reserved for patients who do not respond to medical treatment, for removal of sequestrum, drainage of a subperiosteal abscess or facial nerve decompression.
- The clinician should have a high index of suspicion in patients with persistent otorrhoea that is resistent to standard medical treatment or where complications occur disproportionately early in the disease.

SEARCH STRATEGY

Definition and pathology

Data in this section may be updated by a Medline search using the search string ("Temporal Bone/pathology"[Mesh]) AND "Otosclerosis/pathology"[Mesh].

Aetiology

Data in this section are may be updated by a search in PubMed, Embase, CINAHL and the Cochrane Library using synonyms for 'otosclerosis' and 'aetiology' in title and abstract.

Incidence

Data in this section may be updated by a Pre-Medline and Medline search using the keywords otosclerosis and incidence, and otosclerosis and prevalence.

Diagnosis

Data in this section may be updated by a Medline search using the keywords otosclerosis and diagnosis.

Natural history
Data in this section may be updated by a Medline search using the keywords otosclerosis; audiometry, pure-tone; hearing loss, otosclerosis and natural history.

Management options: fluoride
Data in this section may be updated by a Medline search using the keywords otosclerosis and sodium fluoride.

Management options: hearing aids
Data in this section may be updated by a Medline search using the keywords otosclerosis or stapes surgery, and hearing aid.

Management options: surgery
Data in this section may be updated by a Medline search using the keywords otosclerosis or stapes surgery, and 5015 references were identified. Each key topic was cross-referenced independently (e.g. antibiotic prophylaxis, steroids, etc.).

DEFINITION AND PATHOLOGY

Thanos Bibas

DEFINITIONS

Otosclerosis is a localized hereditary disorder of bone metabolism of otic capsule enchondral bone that is characterized by disordered resorption and deposition of bone.[1–2] It is thought to result from increased and pathologic bone remodelling and the basic lesion consists of areas of bone resorption by osteoclasts and new bone formation by osteoblasts, accompanied by vascular proliferation and tissue stroma.

Clinical otosclerosis refers to lesions that affect the stapes, stapediovestibular joint or round window membrane and thus cause conductive hearing loss. In cases of mixed hearing loss it is assumed that there are lesions affecting the cochlear endosteum as well. **Cochlear otosclerosis** refers to lesions involving the cochlear endosteum without affecting the stapes or the stapediovestibular joint, thus causing pure sensorineural hearing loss, with no conductive element. It is considered very rare, but prevalence is difficult to judge as some authors include cases with mixed hearing loss. **Histologic otosclerosis** refers to histopathological lesions that do not affect the stapes, stapediovestibular joint or cochlear endosteum, and thus remain asymptomatic during life.[2] Although the prevalence of histologic otosclerosis has been estimated as high as 8.3%, an unselected series of temporal bones has found a prevalence of 2.5%.[3]

HISTOPATHOLOGY

Bone remodelling in the otic capsule and animal models

The otic capsule is unique compared to the rest of the bony skeleton in that it exhibits limited remodelling. There is a gradient of decreased remodelling rate from the periphery of the otic capsule towards the membranous labyrinth. It has been hypothesized that otic capsule remodelling is related to the ratio of two cytokines, osteoprotegerin (OPG) and RANKL (receptor activator nuclear-kb ligand).[4] OPG is a potent inhibitor of osteoclast maturation and functions in competition with RANKL (an activator) for the osteoclast RANK receptor. OPG is highly expressed within the spiral ligament and perilymph and may easily diffuse into the lacunocanalicular network of bony otic capsule through intercellular gaps of the inner ear lining. Impedance of the patency of this signalling pathway may lead to increased bone remodelling and development of the abnormal otosclerotic pattern.[5] Although there are no good animal models for otosclerosis, OPG knockout mice demonstrate progressive loss of hearing, stapes fixation and abnormal focal bone remodelling with many histological similarities to human otosclerosis.[4] However, active remodelling in these mice occurs throughout the entire skeleton and diffusely within the otic capsule. It also involves the incus and malleus, which is rare in otosclerosis, and the effects are reversed by administration of bisphosphonates.[6]

Light and electron microscopy findings

The earliest indication of otosclerotic process is resorption of enchondral bone around blood vessels, with consequent enlargement of perivascular spaces followed by deposition of immature (woven) bone. Through continuous remodelling, more mature bone (lamellar bone) is deposited, mediated by osteoblasts. Active otosclerotic foci are characterized by increased vascularity and increased bone turnover, while inactive (sclerotic) foci consist of dense mineralized bone. Both types may coexist in the same focus.[2] The connective tissue stroma in otosclerotic foci consists of fibroblasts and osteocytes, while there is complete absence of acute inflammatory cells. Electron microscopy studies usually describe osteoclasts in the centres but not in the periphery of otosclerotic foci, thus possibly indicating a lesser role in bone resorption in the advancing front.[7]

Origin, sites of involvement and distribution of lesions

The most common site of involvement is the cochlear wall anterior to the oval window. This is followed by the round window niche and the cochlear apex.[8] Less frequent sites include foci posterior to the oval window, the walls of the internal auditory canal, around the cochlear duct and the semicircular canals, the entire footplate (**Figures 89.1** and **89.2**), and involvement of the middle ear ossicles.[9] Invasion of labyrinthine spaces and the vestibular aqueduct are rare, while invasion of the internal auditory canal or the facial nerve canal have not been reported.

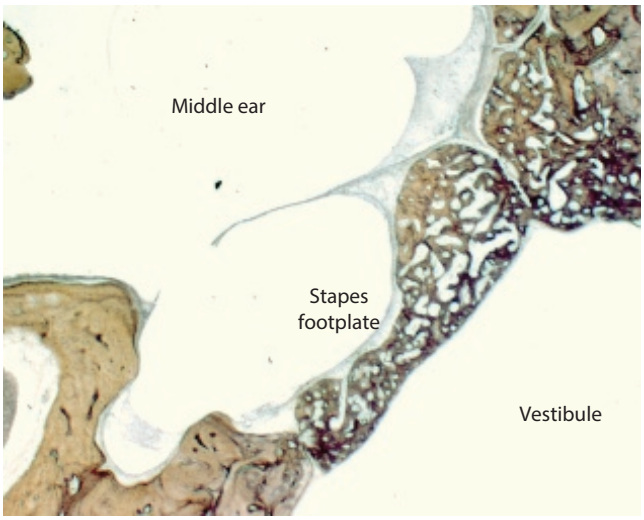

Figure 89.1 Left temporal bone of a 27-year-old female patient with a history of bilateral otosclerosis and Hodgkin disease. The entire stapes footplate is replaced by otosclerotic bone and is fixed both anteriorly and posteriorly. (UCL Ear Institute Temporal Bone collection, specimen F23.)

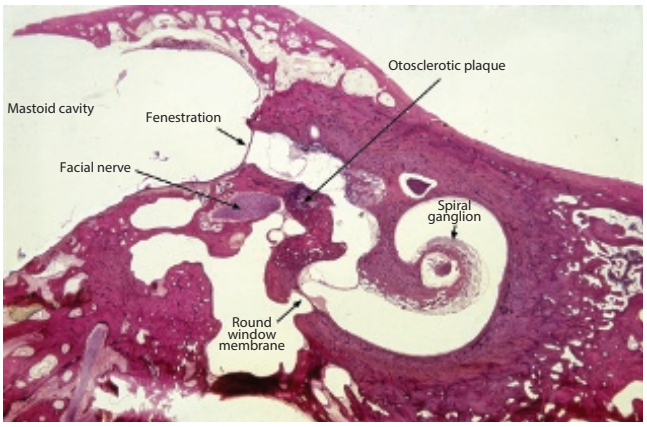

Figure 89.2 Right temporal bone of a 49-year-old female patient with bilateral otosclerosis and bilateral surgical fenestration of the lateral semicircular canals. This specimen is unique as it is sectioned in the vertical plane to demonstrate the fenestration, as well as the oval and round windows in a single section. There is a surgically created window of the LSSC measuring 1.3 mm in the vertical diameter, which is bridged by a thin layer of squamous epithelium. The ampulla appears normal. There is a large otosclerotic plaque causing thickening of the footplate of the stapes. Otosclerotic bone at the superior and inferior margins of the oval window overlaps and partially obliterates the oval window. Round window niche and membrane and spiral ganglion in the basal turn appear normal. (UCL Ear Institute Temporal Bone collection, specimen F267R.)

Michaels and Soucek studied in detail the development of the otic capsule in relation to the origin of the otosclerotic plaques.[10] In all but 2 of the 65 temporal bones studied, a single plaque of otosclerosis occupied much of the otic capsule posterior to the cochlea. Each of the posterior plaques had a well-defined edge at the periosteum lining the otic capsule, extending from the level of the posterior edge of the processus cochleariformis to a level of approximately one-third of the distance along the tensor tympani muscle from the processus. It is the progression of this that will eventually involve the stapes footplate, leading to fixation and conductive hearing loss. In addition, in 42 of these temporal bones there is also a plaque of otosclerosis in the anterior cochlear part of the otic capsule, showing a wide area of contact with the periosteal surface bordering the canal for the internal carotid artery. In both types of plaques, the pattern of change suggests that they commence at the periosteum and, as the immature advancing front of the plaque grows outwards, the tissue that is left behind matures with time, so that the most mature bone in the plaque is near the periosteum.

Very rarely, large cavities may form within otosclerotic foci, a condition termed cavitating otosclerosis.[11] These cavities may act as a 'third window' in cases where the cavitation is in contact with the endosteum of the scala tympani, and may be implicated in persistence of the air–bone gap following a successful stapedectomy. Cavitating foci may also communicate with the CSF space in the internal auditory canal, and may result in gushers during cochlear implantation. There is also an increased risk of the implant electrode being misplaced through a cavitating lesion to the pericochlear cavity.[11]

Conductive hearing loss

Conductive hearing loss is usually related to pathology (narrowing or ankylosis) of the annular ligament, especially the posterior part. A recent study showed that the size of the air–bone gap appeared to be determined by the extent and degree of this pathologic change, and that bony ankylosis was associated with an air–bone gap greater than 30 dB. However, the degree and extent of bony footplate ankylosis could not be reliably predicted by the size of the air–bone gap. Since a lack of bony ankylosis increases the risk of a floating footplate during stapes surgery, one should be aware of this complication even in cases with large air–bone gaps.

Other factors that may contribute to conductive pathology in cases of otosclerosis include complete obstruction of the round window niche (this is frequently associated with a persistent air–bone gap following stapes surgery, and if recognized pre-operatively may be a contraindication to surgery), cavitating otosclerosis (due to a 'third window' effect) and malleus fixation (see 'Surgical pathology' below).

Sensorineural hearing loss

Although the effect of otosclerosis on cochlear function has been controversial in the literature, most temporal bone studies show that, in cases with otosclerosis and sensorineural hearing loss, the hair cells, stria vascularis and spiral ganglion cells either are unaffected or their loss is insufficient to account for the recorded hearing thresholds.[2] Some studies have shown that, when sensorineural hearing loss occurs, it is often in cases with otosclerotic involvement of the endosteum, where it tends to induce hyalinization and atrophy of the spiral ligament.[12] In contrast, in a study of five temporal bones with pure cochlear otosclerosis, one case had normal hearing, while in the rest,

the reduction in the population of cochlear elements was not related to the extent and location of endosteal involvement.[13] However, a temporal bone study by Doherty and Linthicum using objective estimates of stria vascularis width and quantification and localization of spiral ligament hyalinization within the cochlea demonstrated a direct relationship between stria vascularis atrophy and sensory hearing loss that correlated well with the amount of spiral ligament hyalinization.[14] It is worth mentioning that, although temporal bone pathology studies have demonstrated that pure cochlear otosclerosis does occur, its incidence appears to be quite low and that otosclerosis as a cause of idiopathic sensorineural hearing impairment in individuals without clinical evidence for otosclerosis in the form of stapedial fixation is rare.[2]

Vestibular symptoms

Vestibular symptoms may be experienced by 10–30% of patients with otosclerosis but its pathophysiology is obscure in most cases. In a comprehensive temporal bone study by Saim and Nadol, the incidence of vestibular symptoms was correlated with the degree of sensorineural hearing impairment.[15] These cases also demonstrated degeneration of Scarpa's ganglion, which was independent of the severity of otosclerotic involvement of the vestibular end organs. Conversely, almost half of temporal bones in the same study demonstrated involvement of the superior vestibular canal or cribrose area, regardless of vestibular symptoms.

Vestibular symptoms may also be caused by comorbid pathology, such as Ménière's disease. Otosclerotic foci may rarely involve the vestibular aqueduct, but it may also occur without any prominent associated pathology. Yoon et al. looked at 128 temporal bones with otosclerosis, and direct involvement of the vestibular aqueduct was observed in four temporal bones from two patients.[16] In all four, the vestibular aqueduct was filled with active otosclerotic foci. The lumen of the endolymphatic duct and sac was narrowed as a result of fibrosis, and endolymphatic hydrops was observed, which was more severe in the pars inferior than the pars superior. Collapse of the ductus reuniens and dilated saccule was seen in three temporal bones. Issa et al. studied the position of the saccular and Reissner's membranes in relation to the stapes footplate in eight temporal bones from patients with otosclerosis and Ménière's disease. It was found that the saccular and Reissner's membranes did not contact the stapes footplate in cases where pre-operative bone-conduction levels were 35 dB or better at 500 Hz and there was no high-frequency loss. Stapedectomy was reported successful and it was therefore concluded that surgery does not increase the risk of sensorineural hearing loss when these criteria are met.[17]

SURGICAL PATHOLOGY

Stapes surgery

In a histologic human temporal bone study, Pauw et al. measured the distances between the medial surface of the stapes footplate and the utricle and the saccule in normal and otosclerotic bones.[18] No statistical difference was found between the two groups and they concluded that the safest place for a stapedotomy is in the central and inferior-central thirds of the footplate. However, a 0.4 mm stapedotomy piston can be introduced relatively safely to a depth of 0.5 mm in the vestibule over the entire surface of the stapes footplate. Although stapes experiments in animal studies have showed an association between saccular rupture and hair cell loss in the basal and middle turns, it is not clear whether these are associated with the rupture itself, or by shock waves in the perilymphatic spaces following aggressive manipulation of the footplate. However, collapse of the saccular wall by a contact injury from the piston can lead to endolymphatic hydrops postoperatively, presumably by interfering with the longitudinal flow of endolymph.[19]

Although closure of the air–bone gap to within 10 dB is observed in the majority of primary stapedectomies, a residual or recurrent conductive hearing loss may occur. In a comprehensive human temporal bone study by Nadol, it was found that the most common histopathological findings related to conductive hearing loss after stapedectomy included resorptive osteitis of the incus at the site of prosthesis attachment, obliteration of the round window by otosclerosis, and a malpositioned prosthesis at the oval window.[20] Round window obliteration resulted in the largest air–bone gap, but in most of the temporal bones there were more than one finding that could account for this.

Although malleus fixation may be a cause of residual conductive hearing loss, its isolated incidence in temporal bone studies is 1–8%.[21, 22] In an otopathological study of 1108 bones, fixation of the malleus was observed in only 1% of the cases, was usually unilateral and involved the lateral epitympanic wall rather than the anterior mallear ligament.[22] However, temporal bone studies have shown that the incidence of malleus fixation seems to have a higher incidence in patients with otosclerosis. In a temporal bone study by Nandapalan et al. it was apparent that otosclerotic bones have a significantly higher incidence of hyalinization of the anterior malleal ligament (AML), which seems to be related to the duration rather than the severity of otosclerosis.[23] In another study by Oktay et al., although no relationship between hyalinization of the AML and otosclerosis was found, otosclerosis seemed to be a predisposing factor for bony fixation of the head of the malleus to the lateral epitympanic wall.[21] It is therefore prudent to evaluate mobility of the malleus in all stapes surgery.

Cochlear implantation

Cochlear implantation in otosclerotic patients may be complicated by round window obstruction and/or facial nerve stimulation. The round window may be partially or completely obstructed by otosclerotic foci. In rare instances, there is formation of new bone in the scala tympani of the basal turn of the cochlea.[24] Intraoperatively this can potentially cause difficulties at

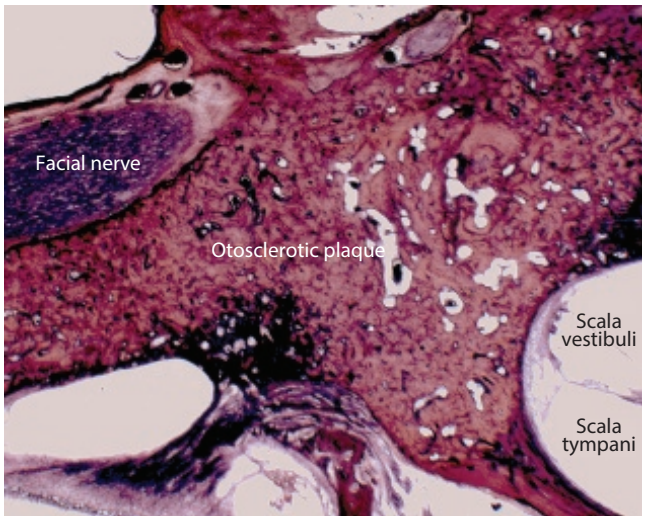

Figure 89.3 Left temporal bone of an 86-year-old male patient with otosclerosis. A large otosclerotic plaque is extending from the cochlea endosteum to the medial aspect of the facial canal in the horizontal segment. (UCL Ear Institute Temporal Bone collection, specimen F41.)

inserting the electrode arrays, necessitating a cochlear drill-out. The incidence of unintentional facial nerve stimulation is significantly higher in patients with otosclerosis than in the general population, especially when a straight electrode is used.[25] Full-thickness involvement of the otic capsule between the cochlea endosteum in the basal turn and different parts of the facial canal may explain the incidence of facial nerve stimulation in these cases, possibly due to altered spread of the current (**Figure 89.3**). It is therefore suggested that a perimodiolar electrode should be preferred, especially in cases in which the pre-operative CT scan suggests that the otic capsule is involved between the facial nerve canal and the upper basal turn of cochlea.

Facial nerve dehiscence

The histopathological incidence of facial nerve dehiscence in otosclerosis was studied by Nomiya et al. in 84 cases compared to 102 age-matched controls.[26] No significant difference was found between temporal bones with and without otosclerosis. Interestingly, the otosclerotic focus did not invade the inside of the canal and did not show any deformity of the canal or injury of the nerve, thus explaining the lack of facial nerve palsy in otosclerosis. It is also suggested by the authors that otosclerotic lesions have the potential to close dehiscences of the facial canal in the oval window area.

AETIOLOGY

Arnold J.N. Bittermann, Inge Wegner and Wilko Grolman

In this chapter we are looking for evidence to support the aetiology of otosclerosis. Aetiology has been a topic of discussion for decades now, but in modern medicine the evidence base has rightfully gained much importance.

GENETIC PREDISPOSITION

OTSC1 (chromosome 15q25-26), *OTSC2* (chromosome 7q34-36), *OTSC3* (chromosome 6p21.3-22.3), *OTSC4* (chromosome 16q21-23.2), *OTSC5* (chromosome 3q22-24) and *OTSC7* (chromosome 6q13-16.1) are monogenetic otosclerosis loci.[27] A recent study has shown mutations and altered expression of the *SERPINF1* gene in patients with familial otosclerosis. This gene encodes PEDF (pigment epithelium-derived factor) which is a known regulator of bone density and is the first disease-associated gene to be identified in otosclerosis.[28]

Monogenic otosclerosis is relatively rare and in most patients otosclerosis occurs without a clear familial background or with only a few affected family members, suggesting the involvement of both genetic and environmental factors.[29] Genes associated with this complex form of otosclerosis include *COL1A1*, *TGFB1* and *RELN*.

A systematic literature search reveals different association and family studies of a genetic cause of otosclerosis. However, the number of studies with low risk of bias is limited. Risk of bias concerns the methodological strengths and limitations of a study. The fewer the methodological limitations, the lower the risk of bias. High-quality studies show that otosclerosis in Japanese patients is not linked to the *NOG* gene[30] and that a polymorphism in the Sp1 binding site located on the *COL1A1* gene is associated with otosclerosis[31] as well as *OTSC1*.[32] Studies with a moderate risk of bias show a statistically significant association of otosclerosis with the *ACE* gene,[33] the *AGT* gene,[33] *OTSC2*,[34] the *RELN* gene,[35, 36] the *TGFB1* gene[36] and 11q13.1.[36] Family-based studies of moderate quality show a statistically significant association of otosclerosis with *OTSC2*,[37] *OTSC5*,[38] *OTSC8*[27] and *OTSC10*.[39] It is important to note that results from studies with moderate to high risk of bias may report spurious associations due to their bias and low statistical power. Interestingly, sex-specific association of *COL1A1* to otosclerosis could be found in one study.[40] The same goes for the *RELN* gene.[36] One single-nucleotide polymorphism (SNP) in the *COL1A1* region was associated with female gender (odds ratio 1.395) and one SNP in the same region with male gender (odds ratio 0.865).[40] One SNP in the *RELN* gene was identified that was associated with male gender (odds ratio 1.392). These findings suggest that both the *COL1A1* and *RELN* gene association with otosclerosis might be influenced by gender, which we should expect since the dominance of presentation is in women.

KEY POINTS

- Despite the extensive availability of studies on the genetic aetiology of otosclerosis it is not possible to assign one or more responsible genes that play a key role in the pathophysiological pathway that leads to otosclerosis.

VIRAL INFECTION

The possibility that a persistent viral infection of the otic capsule may cause otosclerosis was first proposed based on the histological similarity between otosclerosis and Paget's disease, along with mounting evidence of a viral aetiology of Paget's disease.[41, 42]

Otosclerotic foci show all the characteristics of chronic inflammation.[43] An initial active and lytic phase of bone resorption, with proliferation of blood vessels, osteoclasts and mononuclear cells, is followed by the formation of new bone. Support for this hypothesis comes from immunohistochemical evidence of measles virus proteins and antigenicity in active otosclerotic lesions.[44, 45] More recently, two studies have shown an increased expression of specific measles virus receptor CD46 isoforms in otosclerotic footplates.[46, 47] Furthermore, lower levels of anti-measles virus IgG were found in serum from otosclerosis patients with virus-positive footplates compared to healthy controls without otosclerosis and otosclerosis patients with virus-negative otosclerotic footplates.[48–50] In this context, Karosi et al. have shown that combining the assessment of anti-measles virus IgG serum level and the presence of conductive hearing loss results in high diagnostic specificity of 90% and high sensitivity of 96% during the pre-operative evaluation of patients suspected of otosclerosis.[50] Elevated levels of anti-measles virus IgG have been detected in perilymph.[48, 51] Others have found measles virus RNA in archival and fresh frozen footplate specimens with otosclerosis.[52–55] However, failure to do so has also been reported.[56–58] The complete measles virus RNA sequence has never been reported, nor has the isolation of measles virus from otosclerotic samples been successful. It may be argued that the reason is that measles virus titres in otosclerotic samples are too low to be detected. This in turn raises the question whether such a low level of virus could ever cause disease.

Decreasing numbers of stapes surgery and a shift towards older patients following the introduction of vaccination programmes in the US and Europe have been reported by various surgeons.[59–61] Epidemiological surveys of hospitalized otosclerosis patients showed a significant decrease in otosclerosis among the vaccinated population.[62] Interestingly, the decrease in the vaccinated female group was minor in comparison with the male group, which may indicate gender-specific differences in susceptibility or reactivity to measles virus. However, the measles virus hypothesis does not explain why otosclerosis is extremely rare among Africans,[63] despite the fact that the measles virus does occur frequently in African children.

KEY POINTS

- Inconsistencies between current research studies mean that the role played by the measles virus in otosclerosis remains uncertain.

AUTOIMMUNE DISEASE

It has been suggested that otosclerosis represents a form of autoimmune disease with humoral autoimmunity to type II collagen or a closely related antigen that is abundantly present in the regions of predilection. The available evidence is somewhat conflicting. Elevated circulating antibodies against type II collagen[64–66] and type IX collagen[66] in the blood of patients with otosclerosis have been reported. Others, however, have not found a difference in the circulating autoantibody levels between otosclerosic patients and healthy controls.[67–69] A subgroup of patients with disease duration of between 3 and 5 years did show increased autoantibody concentrations in one of these studies.[68] Animals immunized with type II collagen have been found to produce lytic bone lesions in the otic capsule that strongly resemble otosclerosis.[70–72] In similar animal models such otogenic lesions have not been identified.[73, 74]

Criticism of this hypothesis is based on the ubiquitous presence of type II collagen in other sites and the concurrent production of joint lesions in type II collagen-immunized animals, which is not a feature of otosclerosis. Also, patients with relapsing polychondritis have extremely high titres of circulating antibodies against type II collagen, with involvement of multiple organ-sites, but without evidence of otosclerosis.[75]

CYTOKINES

As mentioned above under 'Genetic predisposition', several genes encoding for cytokines have been associated with otosclerosis. These cytokines are transforming growth factor β1 (TGF-β1) and bone morphogenetic protein (BMP).

Bone morphogenetic protein, an inflammatory cytokine that is part of the TGF-β superfamily, may be involved in pathological bone remodelling in otosclerosis. BMPs play a pivotal role in bone formation as well as the healing cascade of bone.[76, 77] Various isoforms, such as BMP2, BMP4, BMP5 and BMP7 have been detected in fresh frozen footplates with active otosclerotic foci.[78–80] Significant expression of BMP receptors 1B and 2 has been shown, whereas BMP receptor 1A was always absent within otosclerotic foci.[78]

HORMONAL FACTORS

Since angiotensin II stimulates the secretion of TNF-α, the renin–angiotensin-aldosterone system (RAAS) may play a role in the regulation of bone remodelling. This theory was first presented by Imauchi et al. in 2008.[33] There is conflicting evidence regarding the association between genes encoding RAAS and otosclerosis.[33, 81] To date, active expression of members of the RAAS family has not been confirmed in otosclerotic stapes footplates.[82]

INCIDENCE

George G. Browning, Arnold J.N. Bittermann, Inge Wegner and Wilko Grolman

GENERAL

It is important to distinguish histological otosclerosis from clinical otosclerosis. In case of histological otosclerosis, otosclerotic foci could be present within the temporal bone without clinical symptoms such as hearing loss and vertigo.

Literature reporting the incidence of otosclerosis is limited. Prospective studies, exclusively designed to identify the incidence of histological and clinical otosclerosis, are rare. Recent studies, describing otosclerosis incidence, mostly present the epidemiology of a variety of otologic disorders including otosclerosis as a subpopulation.[83] This could result in biased results and conclusions. The publication of Declau et al. is the best available evidence reporting the incidence of histological otosclerosis.[84] The incidence of clinical otosclerosis is best described in the publication from the British National Study of Hearing.[85]

HISTOLOGICAL OTOSCLEROSIS

The 'gold standard' for the reporting of the incidence of histological otosclerosis would be a prospective study of the histology of bilateral temporal bones removed consecutively from a population. Such a study has been reported from the University of Antwerp, Belgium, where harvesting of the ossicular chain is routine, as everyone is classified as a donor candidate unless otherwise indicated.[84] The study was of 118 consecutive pairs of temporal bones from white individuals whose mean age was 63 years. The bones were processed and the gross sections visually screened to identify possible bones with otosclerosis. These bones, along with any others that had a suggestion of otosclerosis on microradiography, proceeded to conventional histology. Four of the 118 individuals were found to have histological otosclerosis, an incidence of 3.4%. Two of the patients had bilateral otosclerosis. In none of the four bones where the stapes was still present was it fixed. The limited size of this study did not allow for gender and age to be investigated. This incidence is considerably lower than that of approximately 8% reported from larger temporal bone collections.[86–88] The reason for this is almost certainly a bias to process bones likely to have ear pathology. In these collections, the proportion of males to females is about equal. Age makes no difference to the incidence of histological otosclerosis over the age of 10 years.[86] The percentage of bones with histological otosclerosis that have ankylosis of the stapediovestibular joint is only approximately 12%. Taking these two figures together, it makes the likelihood of clinical otosclerosis in the white population to be approximately 1%. Insufficient data have been reported from temporal bone collections to calculate the effect of gender and age on the incidence of clinical otosclerosis.

One collection had 576 bones from black individuals and only 5 (0.9%) had histological otosclerosis.[86] Ohtani et al evaluated a total of 1011 temporal bones from an unselected series of temporal bones from 507 Japanese persons without signs of otosclerosis. Histologic otosclerosis was found in 15 out of the 1011 ears (1.48%).[88]

CLINICAL OTOSCLEROSIS

Despite the existence of histological otosclerosis, in daily practice, only otosclerosis resulting in complaints such as hearing loss will be clinically relevant. Many prospective studies have reported the incidence of audiometrically assessed hearing impairments in a sample of the population. Unfortunately, few have included otoscopy and bone-conduction thresholds, which are essential to identify patients with clinical otosclerosis. However, the British National Study of Hearing included these measures. They defined presumptive clinical otosclerosis as an ear where the tympanic membrane was normal, the tympanogram was peaked with normal pressure range and associated with an air–bone gap of 15 dB or greater over 0.5, 1 and 2 kHz.[85] In adults, the overall prevalence of otosclerosis was 2% (confidence interval 1.5 to 2.7) with an equal distribution between men and women (Table 89.1). It was only when the air–bone gap was 30 dB or greater that women were (×3) more likely to have otosclerosis than men. The incidence increased with age, those aged 41–60 years were twice and those aged 60–80 years were four times as likely to have clinical otosclerosis.

The proportion of patients that had had surgery was less than 10% and this explains the relatively low population prevalence of otosclerosis reported from clinical series. These are considerably influenced by the proportion of patients with an impairment that seek advice, the referral pattern and the attitude of the specialist to surgery and hearing aids. Studies that report audiometric outpatient data are likely to be less biased. In one such study

TABLE 89.1 Population prevalence per 100 of the presumptive diagnosis of otosclerosis (reprinted from Browning and Gatehouse,[85] with permission)

	Otosclerosis (%)	95% CI
Overall	**2.1**	**1.5, 2.7**
Age (years)		
18–40	1.6	0.6, 2.6
41–60	2.2	1.3, 3.1
61–80	3.0	1.7, 4.3
Sex		
Women	2.0	1.3, 2.7
Men	2.2	1.2, 3.2

Non-manual	1.5	0.8, 2.2
Manual	2.7	1.9, 3.5

from Copenhagen, the prevalence over a 5-year period of clinical otosclerosis was 2% of patients seen with a hearing impairment.[89, 90] When the proportion of individuals that have bilateral as opposed to unilateral otosclerosis is examined, both clinical and temporal bone case series are likely to be biased towards reporting a higher proportion having bilateral disease. From these, approximately 75% of patients have bilateral disease. Unfortunately, the UK National Study of Hearing[85] did not report its results in this format. In 2012, Hannula et al. presented an epidemiological study on the prevalence of ear diseases in Finland. A total of 850 native Finnish subjects with an age between 54–66 years old were randomly selected. Within this group, the prevalence of otosclerosis was 1.3%.[83] Declau et al. also included an extrapolated estimation of clinical otosclerosis, based on their temporal bone findings and indicated that clinical otosclerosis has a prevalence of 0.3–0.4% among the white ethnic population.[84]

The incidence of clinical otosclerosis in non-Caucasians must be considered unknown because of their dependence on surgical series. These report that surgery for otosclerosis is uncommon in Mongoloid races and is extremely rare in Negroid races.

DIAGNOSIS

George G. Browning and Christopher P. Aldren

OTOSCOPY

Otosclerosis is the presumptive aetiology of a conductive hearing impairment in the presence of a normal, mobile tympanic membrane. The 'gold' reference standard of diagnosis is made at surgery, when it should be possible to exclude the considerably rarer causes of such an impairment, such as congenital ossicular chain abnormalities and other diagnosis (5% and 3% of cases respectively).[91] Ossicular chain discontinuity subsequent to head trauma will give a similar presentation but can be diagnosed by the temporal relation of the hearing loss to the trauma in the history. A 'flamingo flush' or Schwartz sign, a red blush of the tympanic membrane over the promontory, is said to be due to the vascularity of an active otosclerotic focus but is rarely seen.

Otosclerosis can also occur when the tympanic membrane is abnormal, such as in chronic otitis media. This is because otosclerosis will occur in the same percentage of patients with such a condition as it does in the general population (approximately 2%).[85] Thus, in patients with chronic otitis media, around 2% of them will have otosclerosis as an additive component to their conductive hearing impairment. This additive component only becomes apparent when stapes fixation is identified at surgery for pathology other than otosclerosis.

SURGICAL DIAGNOSIS

On raising a tympanomeatal flap, the middle ear will appear anatomically normal. The bone around the oval window may be whiter than normal but no clear junction between otosclerotic and non-otosclerotic bone will be apparent, as in histological sections (Figure 89.4). The mobility of the stapes and other ossicles will be assessed. Minor degrees of fixation are difficult to assess as long as the ossicular chain remains intact, which is the case until the incudo stapedial joint is divided. After surgical removal of part of the bony attic wall to visualize the stapes footplate, it will usually be seen to be thicker than normal. Occasionally, the oval window will be filled with obliterative otosclerosis. If the footplate is found not to be fixed, alternative causes of the conductive hearing loss such as fixation of the malleus should be sought.

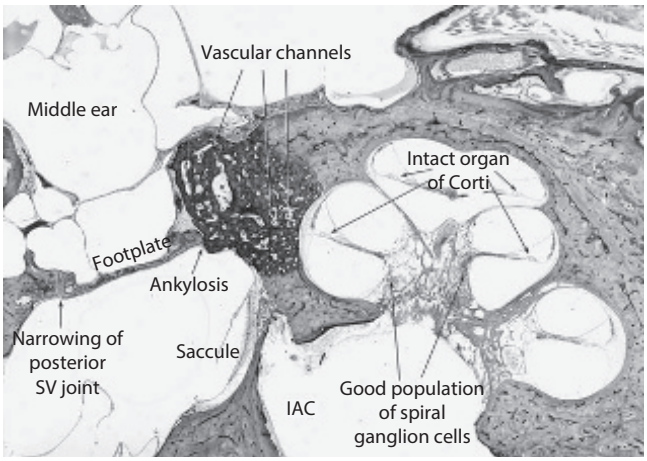

Figure 89.4 Temporal bone section in the axial plane from an 85-year-old man with clinical otosclerosis. There is a single focus of otosclerosis anterior to the oval window, which contains many vascular channels. The focus has caused ankylosis of the anterior portion of the stapes footplate and has also pushed the footplate posteriorly, resulting in narrowing of the posterior stapediovestibular (SV) joint. The otosclerotic focus has also reached the endosteum of the basal turn of the cochlea. Note that the sensory and neural elements of the cochlea are intact, including the organ of Corti, stria vascularis and spiral ganglion cells. IAC, internal auditory canal. (**Magnification ×13.**)

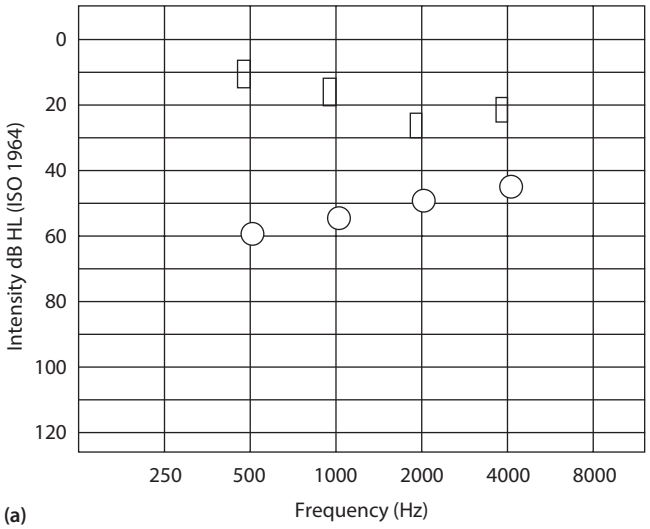
HISTOLOGICAL DIAGNOSIS

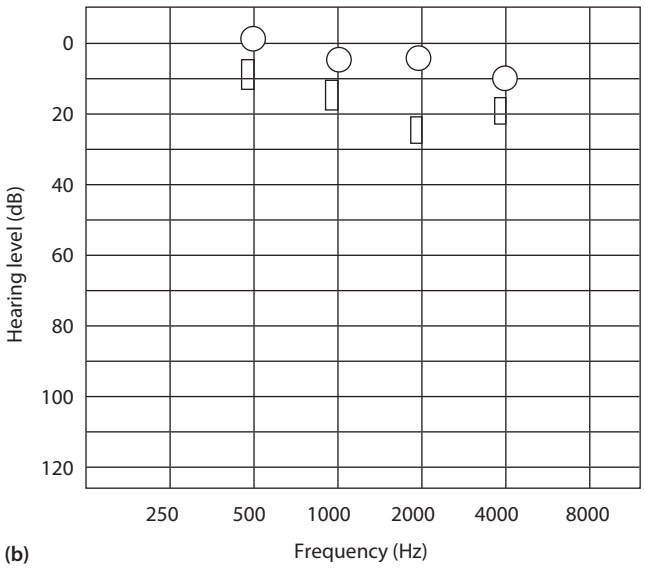
Histological confirmation of otosclerosis is more readily obtained if a total stapedectomy is performed. However, now that stapedotomy is the favoured surgical procedure, the stapes superstructure is the only material available. As fracturing of the crura to remove it occurs in non-otosclerotic bone, histology of this specimen is usually valueless.

PURE-TONE AUDIOMETRY

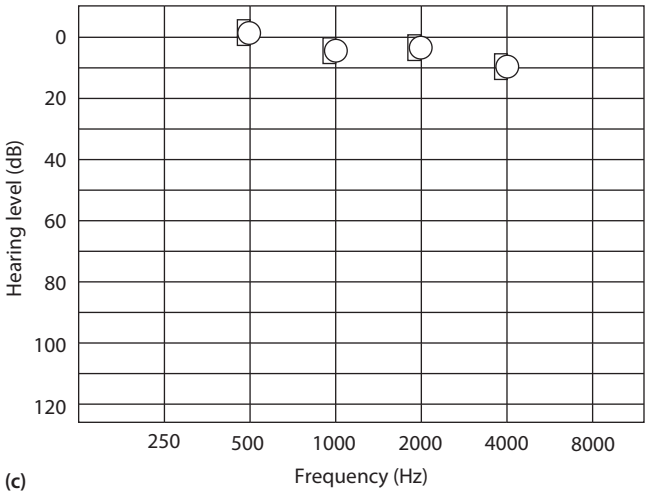
Pure-tone audiometry with appropriate masking will be required to confirm, by the presence of an air–bone gap, any clinical suggestion of a conductive hearing impairment. In those with normal bone-conduction thresholds, the air–bone gap will usually have the classical pattern of being greater at the low frequencies (Figure 89.5) with a Carhart notch.



(a)



(b)



(c)

Figure 89.5 **(a)** Pre-operative audiogram showing classical appearance of a conductive impairment in clinical otosclerosis. The air–bone gap in the right ear is greater at the lower frequencies and a Carhart notch is present at 2 kHz. **(b)** Audiogram of the same patient following successful stapes surgery using the pre-operative bone-conduction thresholds. The air–bone gap has been overclosed. **(c)** Audiogram of the same patient using the post-operative bone-conduction thresholds. The air–bone gap has been closed and the bone-conduction thresholds are better than the pre-operative ones, with elimination of the notch at 2 kHz.

Air–bone gap

The magnitude of the middle ear conductive impairment can only be measured by magnitude of the air–bone gap; the difference between the average air-conduction thresholds and the average bone-conduction thresholds. Traditionally, a three-frequency average over 0.5, 1 and 2 kHz has been recommended, primarily as the air–bone gap is greatest at these frequencies. Others use a four frequency average over 0.5, 1, 2 and 4 kHz, as the air-conduction average of these more accurately reflects the monaural hearing disability. The technical criticism of using this four-frequency average is that the bone-conduction thresholds at 4 kHz are less reproducible than at the lower frequencies. The American Academy of Otolaryngology and Head and Neck Surgery[92] recommends that a four-frequency average over 0.5, 1, 2 and 3 kHz be taken. In practical terms it probably does not matter what air-conduction four-frequency averages are taken as they are usually within 2–3 dB.[93, 94]

What the magnitude of the air–bone gap has to be to diagnose a conductive impairment is usually taken as 10 dB irrespective of what frequencies are averaged. This is because any lesser gap might be due to test/retest error of the audiometric assessment. What the magnitude of the air–bone gap has to be to justify consideration of surgery as a management option has historically been taken as 20 dB. However, many recent series include patients with smaller air–bone gaps down to 10 dB. The assertion is that, if an air–bone gap of between 10 and 20 dB can be closed to the pre-operative bone-conduction, the patient will materially benefit. Before patients with such a small air–bone gap are operated upon, it is essential for a surgeon to audit his results to ascertain how often this occurs in otosclerotic individuals with larger air–bone gaps.

Carhart notch

The Carhart notch is closely related to the Carhart effect. This effect was initially described following successful stapes surgery where overclosure of the air–bone gap occurred when the post-operative air–bone gap was calculated using the pre-operative bone-conduction

thresholds. However, on testing the post-operative bone-conduction thresholds, these had improved, particularly at 2 kHz, where the Carhart notch had been eliminated (Figure 89.5). The magnitude of this effect has been variously calculated (Table 89.2) but averages an improvement over 0.5, 1 and 2 kHz of at least 12 dB.

The reason this occurs is that, when the skull is vibrated by bone-conduction sound, the sound is detected by the cochlea via three routes. In Figure 89.6 route A is by direct vibration within the skull, route B is by vibration of the ossicular chain, which is suspended within the skull, and route C is by vibrations emanating into the external auditory canal as sound and being heard by the normal air-conduction route. In a conductive hearing impairment the latter two routes are deficient but are regained by successful reconstruction surgery. Hence the bone-conduction thresholds improve following surgery. The reason that there is a Carhart notch at 2 kHz before the surgery is that the Carhart effect is greatest around that frequency.

Coincidentally, though the notch was initially described in otosclerosis, it occurs in all ears that have a conductive impairment irrespective of the aetiology. Although in non-otosclerotic ears there is the potential for the Carhart effect to occur following surgery, this seldom happens because the surgery is usually less effective at correcting the conductive hearing impairment than it is for otosclerosis.

Many otosclerotic patients will have a mixed hearing impairment, the potential aetiologies of the sensorineural component being discussed below. In mixed impairments the Carhart notch tends to disappear (Figure 89.7). With increasing sensorineural hearing impairments it becomes increasingly difficult to mask the bone-conduction thresholds (Figure 89.8) and in severe, profound and total hearing impairments (Figure 89.9) to decide whether there is a conductive

TABLE 89.2 The magnitude of the Carhart effect (dB) from various authors (reprinted from Browning,[99] with permission)

component or not.[100] In these circumstances, various factors in the history or investigations can increase the certainty with which clinicians can come to a diagnosis of otosclerosis.

Given that the Carhart notch can be seen in any case of ossicular chain fixation it is perhaps not surprising that a recent literature review showed little to support the predictive value of the Carhart notch in the diagnosis of otosclerosis.[101]

HISTORY

The classic history is of a progressive hearing loss in early adulthood. In those with a severe or profound impairment, an earlier audiogram showing a mixed impairment or a history of a previous operation to improve the hearing as an adult will be suggestive of otosclerosis. A family history of hearing problems, unless it is clearly identified as being an otosclerotic history, covers too many potential aetiologies to be of value. A history of deterioration of the hearing during pregnancy is often cited to occur and indeed 50% of those with bilateral and 25% of those with unilateral otosclerosis will report such a change.[102] However, no data are available on how many individuals with hearing impairments due to other causes report such deterioration. The audiometric evidence for deterioration is retrospective and uncontrolled for time.[103] Certain features of a patient's history may suggest a diagnosis other than otosclerosis. These are early age of onset, no history of progression, associated discharge or trauma, associated vertigo.

TYMPANOMETRY

As might be expected, the compliance in ears with subsequently surgically confirmed otosclerosis is less than normal but the range is such that in an individual ear it does not add to the diagnosis.[104] The same comments also apply to multifrequency/multicomponent tympanometry.[105] If there is any doubt about there being otitis media with effusion as an alternative diagnosis, tympanometry is obviously then of value.

RADIOLOGY

High-resolution CT (HRCT) scanning is able to detect abnormal bone densities within the otic capsule. HRCT shows active otosclerosis as hypodense or lucent areas within the otic capsule, typically anterior to the oval window (**Figure 89.10**). The stapes footplate may be seen to be thickened. Other typical findings are narrowing of the oval and round window niches and a classic double ring sign around the cochlea. During the inactive sclerotic phase of disease, bone densities increase towards normal and CT diagnosis may be more difficult. Quesnel et al. compared HRCT with histology in cadaveric temporal bones from patients with known otosclerosis. Two blinded

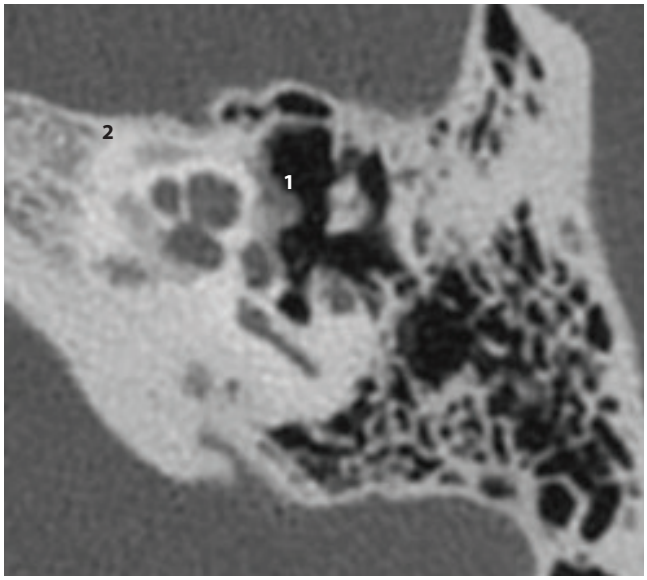

Figure 89.10 Axial CT scan of the left middle ear through the stapes footplate showing lucency anterior to the stapes footplate (1) and around the cochlear (2).

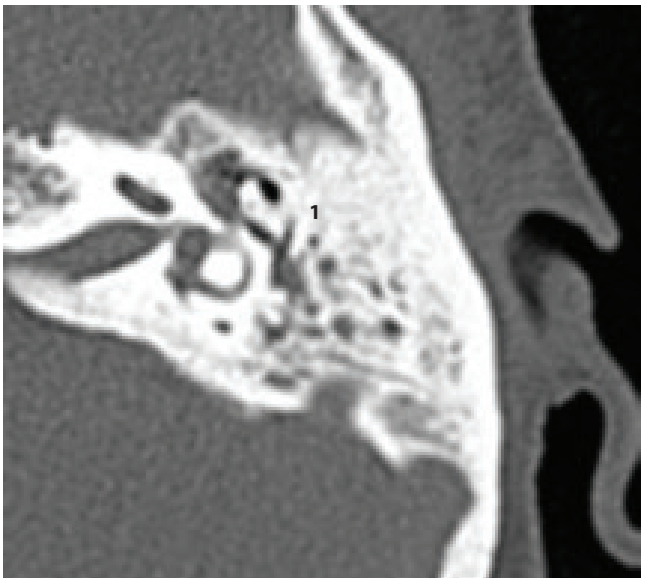

Figure 89.11 Axial CT scan of the left temporal bone showing the incus fused to the lateral wall of the attic (1).

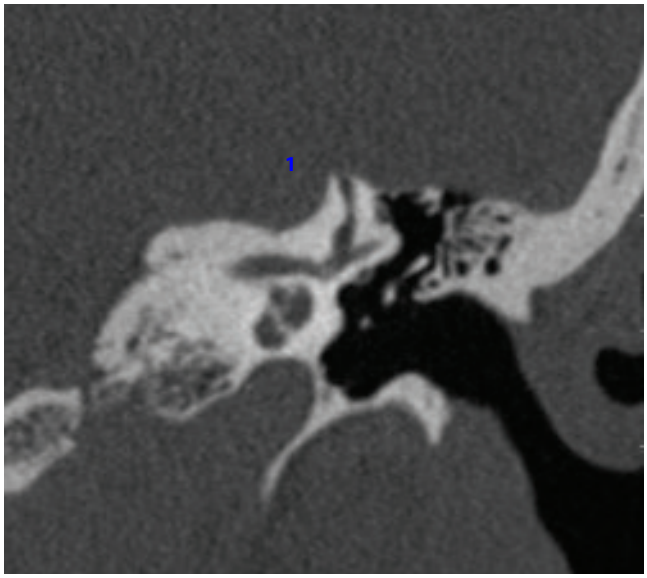

Figure 89.12 Coronal CT scan of the left temporal bone showing superior semicircular canal dehiscence (1).

neuroradiologists correctly identified 8 of 10 otosclerotic temporal bones from a group including 36 control non otosclerotic bones. There were three false positives where an area of lucency anterior to the oval window was due to soft tissue and not otosclerosis. This gives a sensitivity of 80% and specificity of 91.6% against the gold standard of histological diagnosis.[106] Various studies have compared CT and surgical findings with typical sensitivity of 70–80%. More recent studies with better CT scanning techniques using smaller pixel sizes have shown sensitivity for fenestral otosclerosis of over 90%.[107] With these improved sensitivities the case for routine CT scanning is growing, although many surgeons would not use CT scanning for classic cases of otosclerosis given the accuracy of the clinical assessment. CT does, however, have the ability to detect other pathologies such as malleus head fixation, incus fixation (**Figure 89.11**), superior semicircular dehiscence (**Figure 89.12**) and widened vestibular aqueduct as well as the extent of disease and anatomical variants. HRCT is therefore recommended if the diagnosis is in doubt, for example with early-age onset or associated vertigo. It is also of value if cochlear implantation is being contemplated. Pre-operative CT scanning is now obligatory in France prior to stapes surgery.

Cone beam CT scanning has the ability to resolve very thin slices down to 0.3 mm but with lower radiation doses than HRCT. Sensitivities appear similar to HRCT.[108, 109]

MRI scanning is useful if cochlear implantation is contemplated.

AUDIOLOGICAL ELIGIBILITY FOR SURGERY

Because clinical otosclerosis is a presumptive diagnosis in patients with a conductive hearing impairment and no evidence of other middle ear pathology, it is important that one is certain that there is indeed a conductive hearing impairment before deciding that an individual patient might benefit from surgery.

In the majority of patients, the pure-tone audiogram will be the audiological deciding factor provided this can be relied upon, particularly in the appropriate masking of bone-conduction thresholds. Traditionally, it was felt that there had to be at least an air–bone gap of 20 dB or more to benefit from surgery and the majority of stapes surgeons still use this cut-off. However, experience would suggest that an improvement in the hearing of less than 20 dB is appreciated by patients, particularly if they have a bilateral hearing impairment. Hence, experienced stapes surgeons may operate on ears with an air–bone gap of

10–20 dB, knowing that in a high proportion of them the air–bone gap will be closed.

More recently, some surgeons have been operating on patients with an air–bone gap of 10 dB or less. The concept here is that in reality there is the potential for a greater improvement in the air-conduction thresholds than 10 dB because of the Carhart effect.[110] The problem with this approach is that air–bone gaps of 10 dB or less may be artefacts of the audiometric test method. Hence, these authors suggest that there should be other evidence of a conductive hearing impairment, such as multiple audiograms, an absent acoustic reflex or appropriate tuning fork test results.

DIAGNOSIS OF COCHLEAR OTOSCLEROSIS

Two distinct situations exist when the diagnosis of cochlear otosclerosis may be made. The first is where there is a mixed impairment and the conductive component is due to clinical otosclerosis. The second is where there is a pure sensorineural impairment and aetiology is being sought.

In association with clinical otosclerosis

There is no reason why otosclerosis should protect against the majority of recognized aetiologies for a sensorineural impairment with the possible exception of noise trauma. It is therefore possible to compare individuals' bone-conduction thresholds with age-, sex- and socioeconomic-controlled population values. However, before doing this, they have to be corrected for their artificial depression due to the Carhart effect. The majority of papers do not do this. In addition, surgery can cause a sensorineural hearing impairment so the judgement can only be made on unoperated ears. When this is carried out, the data are again conflicting. Browning and Gatehouse found, on average, individuals with otosclerosis have no poorer thresholds than expected in the population.[111] However, both Topsakal et al. and Redfors and Moller also showed significantly greater sensorineural loss in non-operated otosclerotic ears than in age-matched controls.[112, 113] In post-operative studies examining progressive sensory hearing loss over time the data are again conflicting, with one 20-to-30-year-longitudinal study[114] showing the bone-conduction thresholds in patients after fenestration surgery for otosclerosis deteriorating with time at the same rate as the general population (1 dB every 2 years) but another with follow-up at 30 years showing significantly greater loss.[113, 115] Whatever the cause, there are undoubtedly a number of otosclerotic patients with a mixed hearing impairment, where the sensorineural impairment is considerably greater than expected from population data. Indeed, in cochlear implantation programmes, such patients make up approximately 1% of the population (see 'Cochlear implantation' below).

In the absence of a conductive impairment

To date, from the hundreds of temporal bones reported with histological otosclerosis, only three patients have been reported with a sensorineural impairment and no clinical otosclerosis in one or both ears. In these patients, the otosclerotic focus surrounds the cochlea without involvement of the oval window.[116, 117] On the other hand, there are many case reports of cochlear otosclerosis being diagnosed radiologically in individuals with a bilaterally normal middle ear and a pure sensorineural impairment. Evaluation of CT scans to identify differing areas of density is subjective and methods that calculate the density of various anatomical areas are superior. If this is carried out, the range of normal values overlaps that of patients with suspected pure cochlear otosclerosis.[118]

KEY POINTS

- Otosclerosis is the presumptive aetiology of a conductive hearing impairment in the presence of a normal, mobile tympanic membrane.
- Tympanometry does not generally aid the diagnosis of clinical otosclerosis.
- The case for pre-operative CT scanning is growing as scanning becomes more accurate.

NATURAL HISTORY

George G. Browning

CONDUCTIVE HEARING IMPAIRMENT

Ideally, to study the natural history of otosclerosis, one would like to follow up a cohort of young adults with serial audiometry over many years. This would enable the clinician to answer the following three questions that would be of clinical interest in the management of patients:

- How likely is unilateral otosclerosis to become bilateral with time?
- What is the average rate of progression of the magnitude of the air–bone gap in the better and poorer ears?
- Are there some individuals in whom the air–bone gap deteriorates and others in whom it does not?

Unfortunately, no study of this type has been identified. The main body of data available as an alternative way of trying to address these questions are surgical series that have been followed up for some years and report the non-operated otosclerotic ear as well as the operated ear. It is unfortunate that the operated ear, which in many instances will start as the poorer hearing ear, cannot be used to describe the natural history because the operation itself can have an effect on both the air- and bone-conduction thresholds. Reporting the natural history in the non-operated ear is likely to underestimate the magnitude of change in the air- and bone-conduction thresholds because in many instances it will be the better, and hence less affected, ear.

For an average of 9.5 years, Vartiainen et al.[119] followed up a series of patients that they had operated on one ear for

otosclerosis. In 122 of them, the other ear had clinical otosclerosis and their interest in reporting these ears was to see whether fluoridation of the water supply made any difference to the progression of the disease (see 'Fluoridation of drinking water' below). The 91 patients that had low levels of water fluoridation are those that are of particular interest because they are the larger group. Taking threshold averages over 0.5, 1 and 2 kHz, there was a yearly deterioration in the air-conduction thresholds of 2.1 dB, in the bone-conduction of 1.2 dB and the air–bone gap of 0.9 dB. Hence, one could postulate that the air–bone gap in an otosclerotic ear would deteriorate by around 10 dB every 10 years. The deterioration in the bone-conduction thresholds is just slightly greater than that which might be expected due to ageing and could be partly related to the Carhart effect.[120]

KEY POINTS

- From the limited data available in patients with unoperated otosclerosis, the air–bone gap and the bone-conduction thresholds both deteriorate by around 1 dB per year. Hence, the air-conduction thresholds will deteriorate by around 2 dB per year.

MANAGEMENT OPTIONS: FLUORIDE

George G. Browning and Christopher P. Aldren

FLUORIDATION OF DRINKING WATER

Sodium fluoride is a known inhibitor of osteoclast activity and so a stabilizer of bone turnover. It also leads to increased calcium deposition in otospongiotic foci and decreased bone remodelling.[121] This property makes it a potential treatment for otosclerosis and its use was first reported in 1964.[122] The release of cytokines from bony remodelling adjacent to the cochlear spiral ligament may be responsible for the sensorineural hearing loss sometimes seen in otosclerosis. Sodium fluoride has the potential to reduce this.

Flouridation of the drinking water to 1 mg/L in the town of Kuopio, Finland, between 1959 and 1992 allowed Vartiainen to compare patients exposed to fluoridated drinking water for an average of 21 years with those in the surrounding areas who had a natural low level 0.1 mg/L of fluoride in the drinking water with no added flouride. They found no difference in the prevalence of clinical otosclerosis over a 25-year period.[123] They also followed the change in hearing over an average of 9 years in the operated ears of patients who had had surgery for otosclerosis from the two populations. They found no significant difference in deterioration of bone-conduction or air-conduction over time in the operated ears. In the same patient population they were able to assess hearing loss in the non-operated ears. At presentation the hearing in the non-operated ear in the patients from the fluoridated water area was significantly better. Looking at those patients with >10 dB AB gap in the non-operated ear for an average of 9 years they noted a non-significant reduction in progression of the hearing loss in those in the area with fluoridated water.[120]

In another study comparing patients from areas of low and high water fluoride levels, those from the low area had a ×4 incidence of clinical otosclerosis.[124] However, their exposure was for all of their lives averaging 21 years and the level of the fluoride in the water was nearly twice as high at 1.9 mg/L as the low-fluoride areas. Targets levels for optimum flouride for dental health in the UK are 1 mg/L. It must be concluded that fluoridation of tap water to 1 mg/L has no impact on the prevalence of clinical otosclerosis but may slow the rate of deterioration of hearing in non-operated ears.

ORAL FLUORIDES

Flouridation of tap water gives a daily intake of 0.53 mg. However, oral fluoride supplements allow much higher doses to be given.

A number of case controlled series comparing patients with and without sodium fluoride supplementation are suggestive of benefit.[125, 126] In a double-blind Danish randomized controlled trial 43 untreated otosclerosis patients were given 40 mg sodium fluoride daily together with 500 mg of calcium gluconate and 400 units of vitamin D. The control group of 52 otosclerosis patients had the calcium gluconate and vitamin D but not the sodium fluoride. All patients had between 12 and 24 months of treatment. In the control group 13 of 52 saw their average air-conduction reduce by over 10 dB during the study which was significantly greater than 3/43 in the treatment group.[127] Unfortunately, no data were reported on the bone-conduction thresholds. It would appear that high-dose oral fluoride may decrease the rate of hearing loss in otosclerosis patients. There are no studies looking specifically at the optimum time period of treatment, however typically 2 years is recommended.

Data on side effects from the use of long-term high-dose sodium flouride come from the literature on osteoporosis treatment. Synovitis, gastrointestinal disturbance with pain and vomiting, painful plantar fasciitis and anaemia are commonly seen.[128]

The highest strength of sodium fluoride tablet available in the UK is 2.2 mg. This means that, to emulate the Danish study above, 20 tablets would need to be taken each day. This combined with the risk of side effects, the limited data on efficacy and the excellent results from stapedotomy mean that few UK surgeons currently use sodium fluoride. However, it may be considered in otosclerosis patients with progressive sensory hearing loss.

BIPHOSPHONATES

Biphosphonates are frequently used in the treatment of osteoporosis and Paget's disease. They are known to reduce bone remodelling and as such like sodium fluoride

may offer benefit in patients with otosclerosis. Early studies showed little benefit however a recent study using new third generation biphosponates showed a reduction in rate of progressive sensory hearing loss in patients with cochlear otosclerosis.[129] These drugs require further investigation but may reduce the deterioration of sensorineural hearing loss over time.

MANAGEMENT OPTIONS: HEARING AIDS

Peter A. Rea and Christopher P. Aldren

CONVENTIONAL HEARING AIDS

The importance of conventional hearing aids is not reflected in the number of publications on the subject: they make up less than 2% of the literature on otosclerosis.

Conventional hearing aids offer one of the four options in otosclerosis management, the others being no treatment, surgery and rarely bone-anchored hearing aids.

As a primary treatment, hearing aids are a particularly effective method of managing conductive hearing impairments. Hearing thresholds obtainable compare favourably with surgical outcomes. The choice of surgery or hearing aids in pure conductive hearing impairment depends on other factors: attitude to risk, aesthetic and comfort considerations, hearing-specific functional status and quality of life. Surgical risk is discussed under 'Management options: surgery' below. The perceived aesthetic disadvantages of hearing aids are particularly important in otosclerosis because of the relatively young population being treated. However, modern hearing aids can be very discreet and patients are often pleasantly surprised if they try them. Surprisingly little is published on hearing-specific health status and quality of life outcomes in the treatment of conductive hearing impairments. The limited literature available suggests that hearing-specific health status may be significantly improved by hearing aids. In contrast, quality of life measures are typically at population averages pre-treatment and, perhaps surprisingly, do not improve further.[130] Randomized trials comparing hearing aids to surgery are not available.

As the patient ages, the conductive impairment may become mixed with sensorineural impairment secondary to both age-related and cochlear otosclerosis. In this situation, recruitment may become a problem. Eventually, the level of hearing impairment may exceed the power of hearing aids alone. Suitable comparisons between hearing aids for mixed conductive and sensorineural impairments and surgical outcomes are not available.

FAR-ADVANCED OTOSCLEROSIS

Far-advanced otosclerosis (FAO) was first described by House and Sheehy in 1961 as a patient with otosclerosis with average air-conduction of over 85 dB and bone-conduction unmeasurable due to limits of audiometric equipment.[131] These patients are beyond the help of conventional air-conduction aids alone and can be managed in one of three ways: stapedectomy and subsequent conventional hearing aids, cochlear implantation or the new direct acoustic cochlear stimulation (DACS) device. A careful history to distinguish FAO from a pure sensorineural hearing impairment is essential. Clues include the timescale of the hearing impairment, family history, previous audiograms showing an air–bone gap, normal speech and CT evidence of cochlear otosclerosis.

A patient with FAO may, for example, have a sensorineural impairment of 65 dB HL with an air–bone gap of an additional 60 dB. This may show a complete hearing impairment on an audiogram. Stapedectomy, however, may raise the air-conduction threshold to 65 dB HL. This could be satisfactorily aided. Case series report successful hearing aid use post-stapedectomy in 46–82% of these patients.[132] While cochlear implantation gives the best overall results in these patients, it is much more expensive and so in many cases stapedotomy with conventional hearing aid offers a good first-line treatment, with cochlear implantation reserved for failures.[133] Following a review of the literature, Merkus et al. produced an algorithm to aid decision-making. Patients with pre-op speech discrimination <30%, more severe changes on CT scanning and small air–bone gaps do worse with stapedotomy and should be considered for primary cochlear implantation.[134]

During post-stapedectomy rehabilitation with hearing aids it is likely to be the sensorineural rather than conductive hearing loss that is being aided. Functional recovery, as demonstrated by word recognition scores, may continue for months or years post-surgery. It has been proposed that this reflects acclimatization or recovery from auditory deprivation.[135] Thus, both improved auditory thresholds and recovery from auditory deprivation may be noted with dual therapy.

As a 'rescue' treatment many years after surgery for otosclerosis, hearing aids are likely to be needed frequently. Truly long-term figures are notoriously difficult to obtain. From their series of large fenestra stapedectomy, Smyth and Hassard[136] estimated a requirement for a hearing aid on average 13 years after surgery and at 21 years after small fenestra surgery. Shea's figures[137] showed the need for a hearing aid at 30 years post-surgery in 30% of patients in whom initial stapedectomy had been successful. In a study following up stapedectomy patients at 30 years after surgery Redfors and Moller found that 66% of ears had moderate to profound hearing loss worthy of aiding. They also noted that the progression of sensorineural hearing loss was greater in operated compared with than the non-operated ears.[113]

It has been argued that all patients considering surgical treatment of otosclerosis should undergo a reasonable trial of hearing aid use to allow a fully informed consent to be obtained,[138] though this view is far from universally held. Informed consent requires available options to be discussed in a manner a patient will understand, so a trial of an aid may be the best method of addressing this. It is certainly a luxury to be able to offer a 'risk-free trial' of one of the options.

BONE-ANCHORED HEARING AIDS

Bone-anchored hearing aids (BAHA) have been proposed as an alternative method of managing otosclerosis in a limited number of situations. Selection criteria are similar to those typically used in BAHA programmes for other conditions. A specific benefit is that they do not produce the risk of a dead ear that may result from stapedectomy. An only hearing ear with otosclerosis combined with difficulty using a conventional aid, or a post-fenestration cavity, would be typical scenarios. Outcome data are limited. Objective testing of free-field thresholds and speech discrimination scores appears similar to conventional aids. Subjective outcomes including comfort and sound quality have been reported in a small series of patients with otosclerosis to be better with a BAHA than with a conventional aid.[139]

DIRECT ACOUSTIC COCHLEAR STIMULATION

The direct acoustic cochlear stimulation (DACS) device is of use in patients with mixed hearing loss where a successful stapedotomy alone would not allow the patient to manage without a hearing aid. The device consists of an active middle ear implant attached to a stapes prosthesis. First described by Hausler et al. in 2008,[140] the DACS allows direct acoustic stimulation of the perilymph via the stapes prosthesis. Subsequently developed by the Cochlear company, the Codacs™ has recently been reported to give good hearing in 14 patients. Indications were a minimum average bone-conduction of over 30 dB and with an additional air–bone gap of over 30 dB. Average pre-op unaided hearing and conventional hearing aided thresholds were 86 dB and 52 dB respectively. Post-operative aided Codacs™ thresholds were 37 dB.[141]

COCHLEAR IMPLANTATION

Patients with FAO or failed stapedotomy may be candidates for cochlear implantation and these patients make up approximately 10% of adult cochlear implant programmes. Their audiological results are comparable to those of non-otosclerotic patients receiving cochlear implants. Rea showed speech discrimination scores (using binaural CID sentences) improved from 12% (range 0–52%) pre-operatively to 88% (range 22–100%) post-operatively,[142] results which are mirrored in other series.

However, there may be problems in electrode placement due to otosclerotic ossification of the round window or basal turn of the cochlear which may necessitate extra drilling. Ossification of the apical region of the cochlear can lead to incomplete electrode placement. Non-auditory stimulation from the cochlear implant is also reported to be commoner in otosclerosis patients. Most commonly this is facial twitching but also can be otalgia and dizziness. This is thought to be due to demineralization of the otic capsule.[143] These pitfalls are summarized in Table 89.3.

TABLE 89.3 Pitfalls of cochlear implantation in otosclerosis

Source	Pitfalls
Resulting from previous otosclerosis surgery	Incus subluxation Severe middle ear adhesions Tympanic membrane vulnerable at site of bony curettage Ossification of scala tympani from post-stapedectomy labyrinthitis
Resulting from disease process	Obliteration of round window by spongiotic bone Incomplete electrode placement 'Looping' of electrode through soft spongiotic bone in cochlea Facial nerve stimulation by electrodes within cochlea

BEST CLINICAL PRACTICE

✓ For best clinical practice in relation to hearing aids, see Chapter 54, Hearing aids, and Chapter 93, Bone-conduction hearing aids.

FUTURE RESEARCH

➤ No randomized trials can be found comparing outcomes using hearing aids versus stapedectomy.
➤ Evidence for the role of bone-anchored hearing aids remains limited.

KEY POINTS

- Conventional hearing aids are effective in the management of hearing loss in otosclerosis.
- Their role is likely to increase with technological advance.
- A trial should at least be discussed prior to contemplating surgery.
- They may be used in addition to stapedotomy in FAO.

MANAGEMENT OPTIONS: SURGERY

Peter A. Rea and Rinze A. Tange

HISTORICAL PERSPECTIVE

Three distinct phases can be identified in the development of surgery for otosclerosis: mobilization and extraction of the stapes, in late 19th-century Europe; fenestration of the horizontal semicircular canal in the first half of the 20th century; and mobilization of the stapes revisited, along with stapedectomy and stapedotomy with prostheses in the latter half of the 20th century.[144, 145]

In 1876 Kessel described his work on the columella of pigeons, and the stapes of dogs and humans. He removed the footplate 'allowing a new membrane to form'. He, and

other early otological adventurers, also removed the malleus, incus and tympanic membrane to 'free up' the footplate. Miot and Boucheron from Paris reported cases in the 1880s in which the stapes was rocked to mobilize it after removal of part of the tympanic membrane. They noted the technique to be most successful in early ankylosis. Their efforts were limited by poor surgical equipment, poor illumination, lack of magnification, lack of antibiotics and consequent risk of deaths from meningitis, lack of adequate or standardized audiometry and lack of understanding of the functioning of the ossicles as shown by the 'ossiculectomy' technique described. While these surgeons were perhaps ahead of their time, not surprisingly due to the limited success and risks of serious complications stapes surgery fell into disrepute and in 1900 Siebenmann, Politzer and Botey stated 'mobilization of the stapes in otosclerosis is not only useless, but often harmful'. This was to remain the consensus view for the next 50 years.

Fenestration of the horizontal semicircular canal can be traced back to 1897, and was developed by Sourdille (1930) through his multistage operations. It was Julius Lempert in 1938 who described a single-stage endaural technique that became the mainstay of otosclerosis surgery for two decades. There was a 65% chance of the fenestration remaining patent and a 2% risk of serious complication. On long-term follow-up over half the patients had hearing better than prior to surgery.

Modern stapes surgery re-emerged in 1952 when Rosen had a patient whose hearing was restored following 'palpation' of the stapes. Stapes mobilization became accepted as the treatment of choice for those with only partial ankylosis, though re-ankylosis tended to develop a few years later. Fenestration was reserved for footplates that could not be mobilized. John Shea rediscovered the stapedectomy procedure and reconstructed the sound transmission system with a prosthesis. The first prosthesis inserted in 1956 was a replica of a normal human stapes. A huge backlog of untreated otosclerotic ears was operated on in the following decades, during which time the technique evolved. In the first decade of stapedectomy, the fenestration procedure fell from favour. In the next 10 years, the use of prostheses and a living oval window seal gained popularity, and in the subsequent decade the debate over small versus large fenestra surgery emerged. More recently, technological advances and research contributions have refined our approach, but the caseload is diminishing.

CONTRAINDICATIONS TO SURGERY: CONTROVERSIES IN OTOSCLEROSIS SURGERY

The smaller number of operative cases, coupled with increasing numbers of otolaryngology trainees with some exposure to this potentially demanding surgery, raises the question, 'who should be performing stapes surgery?' Opinions vary widely. The evidence suggests that there is a significant association between experience and both technical ability and surgical outcomes for stapes surgery.[146] While rules are not established, it seems sensible that only a limited number of surgeons need training in this operation, and only a limited number need to perform it. A requirement for individuals to audit their results is emphasized in the literature.

Returning to the patient, the indications for surgery have been discussed under 'Diagnosis' above. Controversies, or 'when not to operate' above, will be reviewed here. Caution should be exercised when interpreting the survey figures quoted for current practice: they do not necessarily equate to best practice.

Age

Large series of stapes surgery report cases between 6 and 92 years of age. Surgery in children represents only a very small proportion of operations. This reflects both the common use of hearing aids to manage otosclerosis in children and the rarity of cases in this age group. We reviewed the five largest paediatric series covering 200 cases, and found post-operative air-conduction was within 10 dB of pre-operative bone-conduction in 89%. One series followed their children for a mean 11.6 years post-operatively. None redeveloped a conductive impairment, and sensorineural thresholds deteriorated at a mean 0.7 dB (range 0–2.3 dB) per year.[147] Special precautions are required when contemplating surgery on children with a conductive hearing impairment, however, in particular the risk of congenital middle and inner abnormalities. In the presence of a mixed hearing impairment, CT imaging of the temporal bone is advised to rule out inner ear abnormalities that may be associated with a cerebrospinal fluid gusher, in particular X-linked progressive mixed hearing impairment. The incidence of obliterative otosclerosis, at 26–41%, is also reported to be much higher in children than adults having stapes surgery. The results of surgery at the other end of the age spectrum, aged 70–92 years, are reported to be similar to those in a younger adult population.[148] In summary, caution is required when considering surgery in children, while no upper age limit needs to be applied in adults on technical grounds alone.

Occupation and leisure activities

Occupation and leisure activities that may predispose to barotrauma are important. Historically, military pilots were grounded after surgery, but they may now fly military jets in several countries post-stapedectomy. Commercial air travel, snorkelling, scuba diving, strenuous activities and parachuting have also been cautioned. Clinical evidence of the feasibility of such activity was suggested by a study from The House Ear Clinic. Questioning 208 patients who had snorkelled, scuba dived or parachuted following stapes surgery, no immediate relationship to otological difficulties was identified.[149] No consensus exists between surgeons regarding advice to patients. In the UK, 18% of otolaryngologists give no flying restrictions, while 82% suggest avoidance for between 1 and 24 weeks.[150] In a survey of members of the American

Otological Society, 12% gave no restrictions on flying post-stapes surgery, 20% recommended a 2-day restriction and 60% suggested 2 weeks or more. Similarly, with scuba diving, 35% recommended restrictions for between 1 and 6 months, while more than 50% recommended permanent abstinence.[151] The suggested time delay is said to allow the connective tissue seal time to mature. A post-operative test has now been proposed: applying tympanometric pressure of 400 mm H_2O to the ear while recording nystagmus matches the maximal possible displacement of the prosthesis. If pathological eye movements are not evoked, and the appearances of the tympanic membrane are normal, it is suggested diving or parachuting can be safely performed.[152]

Ménière's disease and general vestibular symptoms

Ménière's disease is often stated as a contraindication because of the proximity of the distended saccule to the footplate. A small clinical and temporal bone study suggested that the saccule did not contact the footplate in patients with bone-conduction levels of 35 dB HL or better at 500 Hz and with no high frequency impairment, concluding surgery could be performed within these constraints.[17] Caution is, however, clearly required. More general vestibular symptoms do not appear to be a contraindication to surgery. This is supported by a large temporal bone study that found a strong association between loss of Scarpa's ganglion cells and vestibular symptoms in patients with otosclerosis, suggesting neuronal degeneration and not hydrops to be the cause.[15] Clinical studies have shown no difference in hearing outcomes between patients with or without pre-operative vertigo.

Unilateral otosclerosis

Whether to operate on unilateral otosclerosis is contentious. It is worth remembering that unilateral conductive hearing impairment is less likely to be caused by otosclerosis than bilateral impairment. A survey in the UK revealed 81% of consultants may operate for unilateral otosclerosis.[139] However, a patient's disability is mainly determined by the hearing threshold in the better hearing ear. So, to be of maximum benefit, surgery will have to provide symmetrical hearing in this group: in effect closing the post-operative air–bone gap to within 10 dB. The initial bone-conduction will also have to be near normal, or be able to be normalized after surgical correction of the Carhart effect. Most papers quote this degree of closure being achieved initially in 80–95% of procedures but, as will also be shown under 'Hearing outcomes' below, longer-term results may not be as good. Patients may still, however, have some benefit in certain circumstances even when symmetrical hearing is not achievable.

Second-side surgery

Second-side surgery is equally controversial. Seventy-five percent of UK consultants surveyed would perform bilateral stapes surgery.[150] The perceived risk is of delayed bilateral cochlear impairment. Total cochlear impairment may occur many years after a stapes procedure, but the risk is low, at around 1%. The potential benefits are twofold. A second-side operation gives both a greater chance of obtaining one normally functioning ear, and also of gaining binaural hearing. This has been demonstrated by de Bruijn et al. and is clearly illustrated in **Figure 89.13**.[153] The incremental benefits to the individual appear significant,

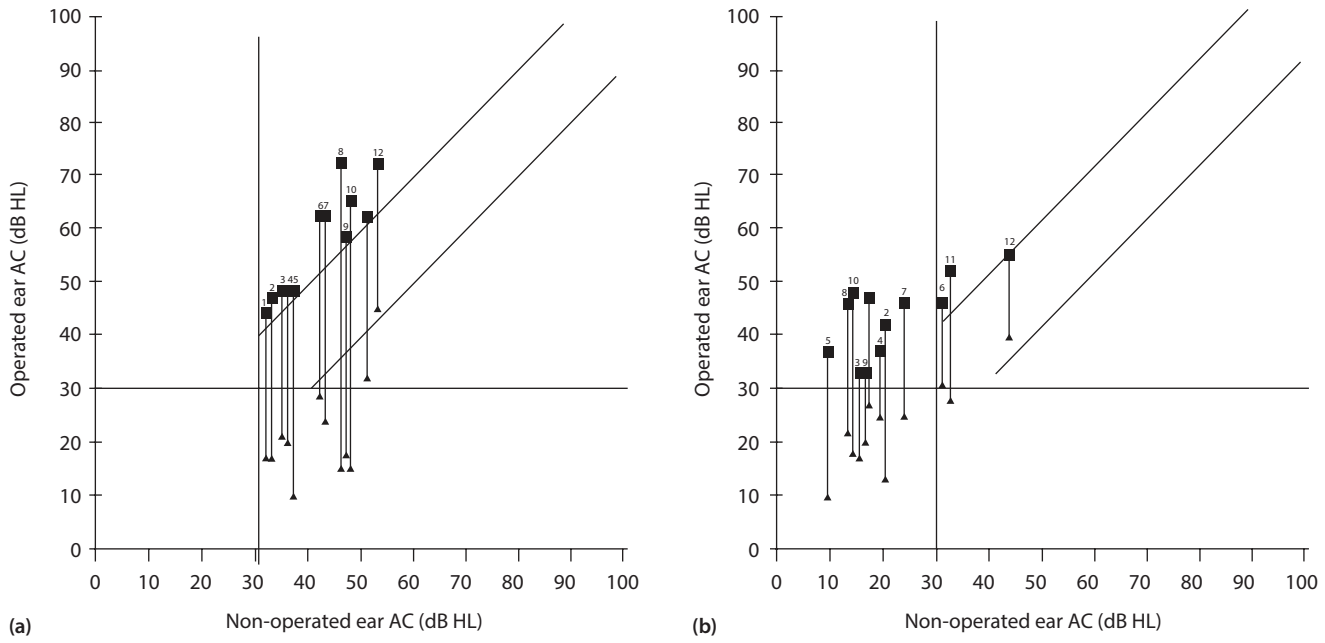

Figure 89.13 Pre- (■) and post-operative (▲) air-conduction (AC) thresholds. Each patient is indicated by an Arabic numeral. **(a)** Results from stapedotomy on the first side. **(b)** Results after stapedotomy on the second side. Reproduced from Vartiainen et al.,[119] with kind permission of S. Karger AG, Basel.

but are less with second-side surgery than with first.[154] Using the American Medical Association (AMA) criteria it was found that the 'Binaural Hearing Impairment Score' fell from 26% to 10% after surgery to one side, and from 11% to 7% after second-side surgery. The 'Impairment of the Whole Person Scores' fell from 9% to 4% and 4% to 2%, respectively.

Air–bone gap

Twenty dB is traditionally taken as the minimum air–bone gap before considering surgery. Some expert stapes surgeons will operate on patients with air–bone gaps of as little as 10 dB in the belief that overclosure will allow a relatively greater improvement in air-conducting thresholds. One series of 136 stapes procedures on patients with air–bone gaps of 10 dB or less equalled or overclosed the pre-operative bone-conducting threshold in 90% of cases, producing a mean air-conduction improvement of 17 dB. It is worth noting that a further 18 patients in this series did not have stapes surgery performed at all at the exploratory tympanotomy, suggesting that diagnosing otosclerosis may be more difficult in this group.[110]

Other factors

A number of other factors are frequently cited. General health and safety of anaesthesia may be significant. Active infection in the outer or middle ear and pregnancy are absolute contraindications to surgery. Whether surgery should be deferred until no further childbirth is planned is debatable. Lippy et al. looked at the hearing results before and after surgery for otosclerosis in women with and without children and found those with children were slightly better. No correlation between the number of children or breastfeeding with hearing loss was seen.[155] Eustachian tube dysfunction is cited as a potential contraindication though quantifying this is not clearly described. Active otosclerosis as indicated by the 'Schwartze sign' is quoted as a contraindication, though much of the evidence is anecdotal. Diabetes has been considered a relative contraindication, though this is not supported by a literature review.

SURGICAL TECHNIQUES

Medical prophylaxis

The ear is prepared with an aqueous antiseptic solution. There is no evidence to support the use of steroids or antibiotics peri-operatively. Indeed, the use of prednisolone has been reported to increase post-operative vertigo.[156]

Anaesthesia

Stapes surgery may be performed under either local or general anaesthesia. A surgeon's personal experience strongly influences the decision. In the UK, over 90% of procedures are performed under general anaesthesia but local anaesthesia is much more popular in Europe. There is no evidence to support superior hearing results or differences in post-operative vertigo with either anaesthetic technique.[157]

General anaesthesia has the advantages of flexibility if complications or difficulties are encountered, and of a motionless operative field. Hypotensive anaesthesia is useful to reduce bleeding.

Local anaesthesia is also generally well tolerated. Short-acting intravenous analgesia and sedation may be given at the beginning of surgery, while infiltration of local anaesthetic (1% lidocaine) and dilute adrenaline (1 : 30 000–1 : 100 000) is performed. Initial infiltration of the posterior wall of the external auditory meatus via the postaural sulcus is followed by slow direct infiltration of the canal skin just lateral to the bony and cartilaginous junction. A pretragal injection may also be made to reduce discomfort if a retractor is used. Some surgeons recommend sedation throughout the procedure; others prefer the patient fully awake to prevent movement on sudden arousal. Local anaesthesia allows the patient to report dysequilibrium, which may be useful in revision surgery where adhesions can extend into the vestibule. Confirmation of hearing restoration after prosthesis placement is also possible as the surgeon talks to the patient. Difficulty may result if complications are encountered during surgery, in particular those that may induce vertigo. Transient facial palsies may result from the infiltration. Patients may complain of the noise, dizziness, anxiety, backache, claustrophobia and discomfort.

Exposure

The surgery can usually be performed through a purely permeatal approach although some surgeons use an endaural incision. When using a permeatal approach a speculum holder is very useful to stabilize the speculum and give a stable platform to allow the surgeon to stabilize his or her hands. A tympanomeatal flap is elevated from 7 o'clock to 12 o'clock (in the right ear), hinging forwards just posterior to the handle of the malleus. The chorda tympani nerve is gently freed from any mucosal folds. The posterosuperior bony annulus is reduced with curettes, drill or hammer and gouge, further releasing the chorda tympani if required. A heavy hook can be useful to remove the bony covering of the chorda tympani and liberate the nerve. Enough bone should be removed from the annulus to expose the stapes, oval window, facial nerve and the base of the pyramid.

Establishing the diagnosis

Anatomical anomalies which may compromise surgery, such as a persistent stapedial artery or overhanging facial nerve, should be identified, as should alternative causes of the hearing impairment such as tympanosclerosis. The stapes superstructure should be gently palpated to check for fixation of the footplate. The diagnosis is often clearer after disarticulation of the incudostapedial joint. The footplate and round window should be examined for evidence of otosclerosis, in particular very extensive disease.

If there is complete obliteration of the footplate, a drill-out of the footplate will be required and inexperienced surgeons may choose not to proceed. Total round window obliteration is rare, occurring in less than 1% of operative cases, not easily corrected, and associated with poor outcome. The malleus should be palpated to test for fixation of the malleus head, anterior ligament and malleoincudal joint. Again, this assessment is more easily performed after disarticulation of the incudostapedial joint.

Restoring the sound transmission mechanism

The historical review described many ways in which sound transmission may be restored across the stapes footplate. While variations on all these themes are still practised, stapedotomy is now used most widely. The surgical methods will be outlined first. A more detailed outcomes review of specific technical aspects is made under 'Hearing outcomes' below.

Stapedectomy and partial stapedectomy

The steps in a stapedotomy are shown in Figure 89.14. First, the incudostapedial joint is divided using a joint knife. This should be inserted from the posterior aspect of the joint and moved anteriorly as the stapedius tendon will reduce movement of the stapes superstructure. The mobility of all ossicles is then reassessed to make sure the stapes is indeed fixed and that a fixed malleus is not missed. The stapedius tendon is now divided with a laser, scissors or microhook. The stapes superstructure may now be removed by fracturing the crura down, away from the facial nerve, but it is better to first divide the posterior crus with a laser or crurotomy scissors to reduce the risk of mobilizing the footplate. If possible, the anterior crus should also be divided prior to removing the stapes. This may be hidden from view but can be accessed by feel using a handheld laser. The laser should be angled away from the facial nerve. The distance between the footplate and the incus should now be measured. It is most common to measure from the undersurface of the incus to

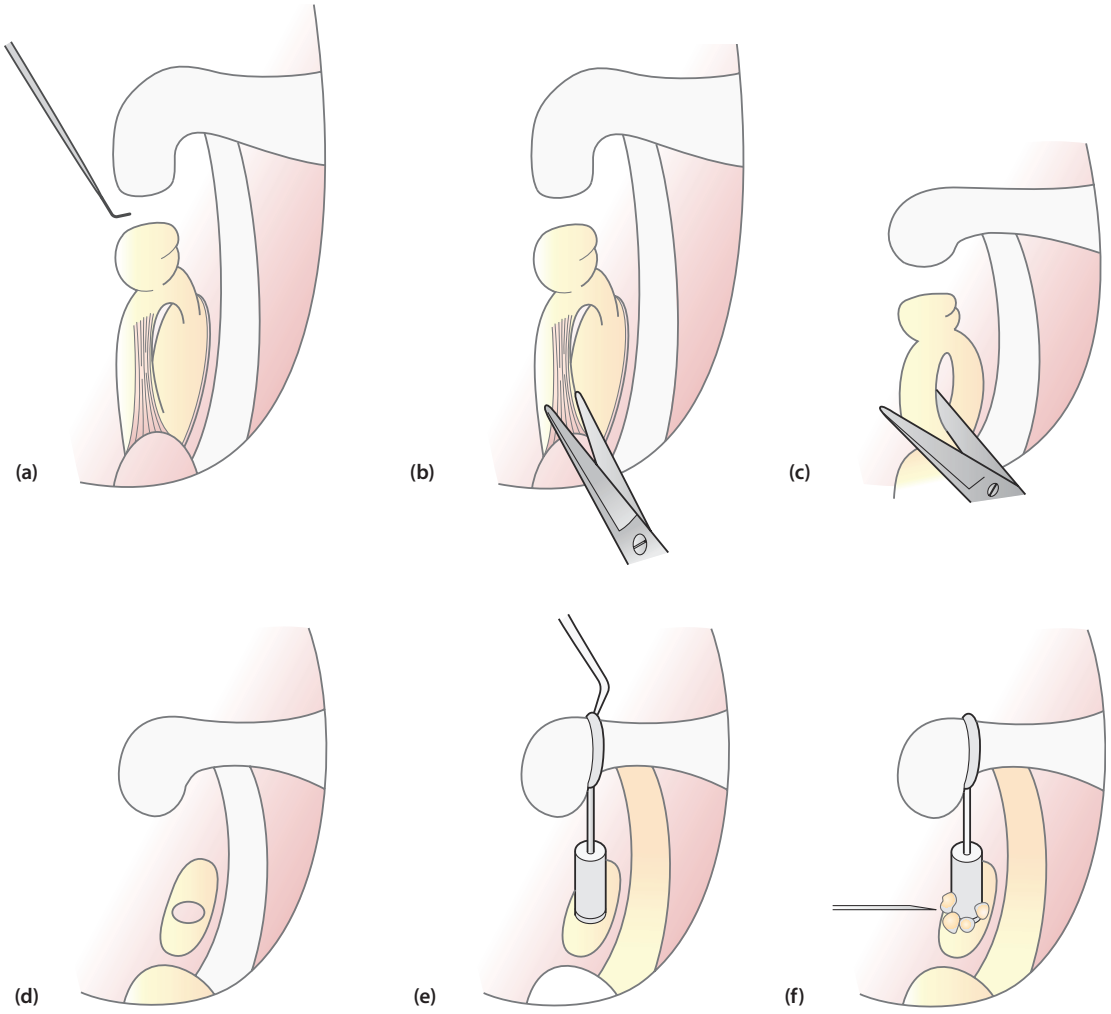

Figure 89.14 Steps in stapedotomy. **(a)** Following disarticulation of the incudostapedial joint, a fixed footplate is confirmed. **(b)** Division of the stapedius tendon. **(c)** Division of the posterior crus of the stapes using crurotomy scissors or a laser followed by down fracture of the crura. **(d)** Stapedotomy drilled in posterior third of the footplate. **(e)** Following insertion of the prosthesis, final adjustments are made and crimping carried out if required. **(f)** Packing around the footplate with fat or connective tissue.

the footplate. If the footplate is thickened, the measurement should be made again after the footplate is thinned just before the stapedotomy is performed. Manufacturers do differ in their labelling of prostheses, though the length is usually from the bottom of the loop. The functional length of the piston is from the upper surface of the lower half of the loop to the tip of the shaft. It therefore is the sum of the shaft length and the thickness of the loop material. For wire pistons the thickness of the loop material is negligible; for the Teflon loop piston this is 0.5 mm and has to be taken into consideration when cutting the shaft. The prosthesis selected should be 0.25 mm longer than the distance from the undersurface of the incus to the surface of the perilymph to allow sufficient penetration. This will usually result in a 4.25 mm, 4.5 mm or occasionally 4.75 mm prosthesis being selected.

The stapedotomy should be made at the junction of the middle and inferior thirds of the central portion of the footplate where the distance between the underside of the footplate and membranous labyrinth is greatest.[18] It may be made with a laser, electrical microdrill or handheld perforator. The perforation should be slightly wider than the prosthesis. If a 0.4 mm prosthesis is being used, it is usual to fashion a perforation of approximately 0.5–0.6 mm. The tighter the fit, the less the need for a connective tissue seal. However, if too tight, the hearing will be reduced as movement of the prosthesis will be impaired. In thick footplates the perforation should be of sufficient size to prevent the prosthesis touching the side of the hole, especially if it cannot be suspended absolutely perpendicular to the footplate. An interposition graft is placed over the footplate perforation at this point if used. If a Teflon loop is chosen, it must first be opened out on the shaft of a middle ear needle and then positioned on the incus with the help of crocodile forceps or an otological suction tube, where it will close around the long process of the incus. The shaft is simultaneously positioned in the footplate perforation. Wire loops will need crimping, or closing with laser or diathermy in the case of certain alloys. The piston is then assessed for adequate tightness at the incus and length at the footplate. Blood, fat or a connective tissue seal is usually then placed around the footplate perforation in an attempt to seal it, if a vein graft has not been placed over the stapedotomy first (this is discussed further below under 'Hearing outcomes'). The tympanomeatal flap is then replaced and the external ear canal packed.

Stapedectomy has fallen in popularity as stapedotomy has risen, though it was still the technique of choice for 19% of UK otolaryngologists in 2002.[150] The approach to the footplate is the same as for stapedotomy (**Figure 89.15**). A control hole is made in the footplate. The whole footplate or more typically the posterior third is removed with picks. The defect is covered with a connective tissue graft, most commonly vein from the forearm, and the prosthesis placed on the graft and suspended from the long process of the incus.

Footplate mobilization

In the 1950s, Rosen developed the stapes mobilization technique, but refixation occurred in months. In 1956, Fowler developed the anterior crurotomy technique with similar results. A recent variation is the laser stapedotomy minus prosthesis (STAMP) procedure. All these techniques depend on a lack of ankylosis at the posterior stapediovestibular joint. The laser procedure described by Silverstein et al. uses a handheld laser probe to vaporize the anterior crus of the stapes and perform a linear stapedotomy across the anterior third of the footplate. The stapes mobilizes if otosclerosis is confined to the anterior third of the footplate. It is claimed to be possible to achieve this in one-third of operative cases.[158, 159]

Revision surgery

Revision surgery is more technically challenging than primary stapes surgery. The clinical indications for revision operations are summarized in **Table 89.4**, while the discussion that follows will outline the possible findings at revision surgery. Three themes emerge from reviewing the literature. First, local anaesthetic is more frequently, though not exclusively, described as being advantageous. This is because the presence of adhesions between the prosthesis or footplate graft and the membranous labyrinth may induce vertiginous symptoms on manipulation of the prosthesis during revision surgery under local anaesthetic. This may prevent the surgeon further traumatizing the membranous

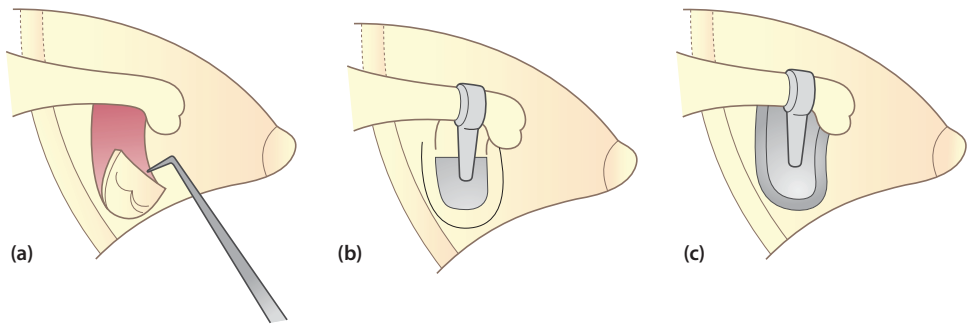

Figure 89.15 Steps in stapedectomy. **(a)** After division with picks, the posterior footplate fragment is removed. **(b)** If the anterior fragment remains fixed, the partial oval window defect is covered with vein or fascia and the prosthesis positioned. **(c)** If the anterior footplate has become unstable, it is removed and a larger graft used to cover the oval window.

TABLE 89.4 Pre-operative indications for revision stapes surgery in 522 cases (reproduced from Lippy et al.[160] with permission)

Indication	Cases (%)
Conductive hearing loss	92.5
Dizziness	2.5
Sensorineural hearing loss/perilymph fistula	1.9
Far-advanced otosclerosis	1.7
Distortion or vibration	1.1
Previous fenestration	0.2

labyrinth and so prevent a dead ear. Second, a much wider variety of surgical techniques may need to be employed to deal with the related ossicular pathology. Third, many centres recommend the use of lasers for revision surgery. Advocates state that vaporizing middle-ear adhesions with a laser allows more accurate assessment of the underlying pathology, aids removal of a non-functioning prosthesis, and allows a new fenestration to be fashioned without manipulating the footplate. These variables will be analyzed under 'Hearing outcomes' below.

PERI-OPERATIVE HAZARDS

Surgical approach

The external auditory canal may be excessively narrowed by pathology such as exostoses. While on occasions it may be necessary to correct these in a separate operation, it is frequently possible to do both operations at once.

Tympanic membrane perforation is reported to occur during approximately 2% of stapes operations. The procedure need not be abandoned as the perforations are usually small tears which can easily be repaired with an underlay myringoplasty. A spare piece of vein from a vein graft makes an ideal repair material but tragal perichondrium can also be used. Long-term results are unchanged.[161]

Anatomical

The chorda tympani nerve needs to be gently displaced from the operative field. This may require extended bony curettage. The facial nerve is dehiscent above the oval window in approximately 10% of ears. It may rarely herniate down over the oval window. In the former case, caution is needed. In the latter, surgery may need to be abandoned although a bucket handle prosthesis which sits under the lenticular process often allows a better angle with the shaft of the prosthesis coming from further inferiorly than a standard prosthesis. Care should be taken at revision surgery where a dehiscent nerve may be embedded in fibrous tissue and vulnerable as this is cleared. The facial nerve canal may also overhang the footplate limiting surgical access. Again, a bucket handle prosthesis can be useful in this situation.

Major vascular anomalies are rare. An aberrant internal carotid artery needs no further elaboration. A persistent stapedial artery may run from the facial canal between the stapedial crura. This may obstruct safe access and cause troublesome bleeding. There are reports of safely dividing smaller vessels and proceeding with surgery. Anatomical accounts of the stapedial artery giving segmental supply to the facial nerve and even brainstem are noteworthy for the brave contemplating dividing larger vessels.

Access to a narrow oval window niche can be improved in selected cases by drilling on the promontory with a microdrill, without evidence of significant sensorineural impairment in published series.

Other diagnoses

Congenital abnormality, fracture or post-inflammatory fixation or erosion of the ossicles must be identified. Their management is beyond the scope of this chapter.

The management of tympanosclerotic fixation of the stapes footplate remains controversial and to some is a contraindication to surgery. It has been historically considered to have a high rate of post-operative sensorineural hearing impairment, the highest reported being 26%, though this assumption stems from only a small proportion of the published series. We reviewed 14 case series totalling 382 stapedectomies and stapedotomies. Dead ears are reported in 2.6%. Surgery may need to be staged as tympanic membrane perforation frequently coexists. Surgical techniques are also varied because of the frequent associated fixation of the other ossicles. Consequently, a total ossicular replacement prostheses is often required. Hearing outcomes are inevitably not as good as with surgery for otosclerosis. Vincent et al.[162] clearly reported series showed closure of the post-operative air–bone gap to 10 dB in 39% and 10–20 dB in a further 31%. Only 22% achieved normal bilateral hearing on the Glasgow Benefit Plot.

Osteogenesis imperfecta has also traditionally been associated with poorer stapedectomy outcomes than for otosclerosis. This in part reflects the progressive mixed nature of the hearing impairment that has been shown to worsen late outcomes.[163] There are also higher risks of a floating footplate and unusual ossicular or tympanic ring fractures. Authors of the larger case series conclude surgery is a reasonable alternative to hearing aids, particularly when hearing aid use alone does not provide adequate amplification.[164]

Ossicular problems

Ossicular problems may arise as a complication of surgery or be identified in combination with footplate fixation. The incus may be displaced during curettage of the bony annulus or instrumentation of the oval window. If it can be maintained in its anatomical position, an incus to footplate prosthesis can still be employed, otherwise a malleostapedotomy will be required. Congenital or inflammatory fixation of the incus may be encountered. Incus–malleus fixation has been reported in 1% of stapedectomies.

Malleus head fixation is typically reported in primary otosclerosis surgery at a rate of 1%, though Causse quoted 10.6%.[165] This may reflect how carefully it is sought. It has become an area of particular interest following the work of Fisch who reports partial or total malleus fixation in 46% of his revision stapedectomies. This is seven times the rate of most other authors. He employs an epitympanotomy to examine the anterior malleolar ligament, as well as the incudomalleolar joint, both sites of potential fixation. A malleostapedotomy is recommended in most cases.[166] Biomechanical evidence emphasizes the importance of a particularly firm attachment of the wire loop to the malleus handle to prevent tilting movements of the angulated prosthesis.[152]

Stapes footplate

Peri-operative difficulties with the stapes footplate increase the risk of sensorineural hearing damage. Minimal stapes fixation or a previous mobilization procedure predispose to a floating footplate. This occurs in less than 1% of procedures. A preliminary burr hole in the footplate prior to fracture of the crura may reduce the risk of a floater. If it does occur, it may be possible to drill an inferior marginal burr hole to aid extraction of footplate fragments. Others advise placing a tissue graft and prosthesis on the footplate. If in doubt, it may be safest to place a large tissue graft over the footplate and not revisit for at least 6 months to allow refixation.

In 3–11% of cases the footplate may be solid or obliterated. Otosclerotic foci within the footplate itself may produce a thick 'rice grain' footplate. This situation is also associated with an increased risk of a floating footplate. The oval window may become extensively involved with new bone in obliterative otosclerosis. Wide saucerization of the footplate has been associated with high rates of sensorineural hearing damage. A stapedotomy technique is recommended, but the perforation should be wide enough to prevent lateral contact of the prosthesis onto surrounding bone, which would cause attenuation of sound transmission.[165] If the footplate reobliterates, revision surgery has been associated with very high rates of sensorineural hearing damage.

A cerebrospinal fluid 'gusher' is rarely encountered. Causse and Causse [165] quoted 0.03% in his series. It presents as a rapid flow of fluid on entering the vestibule. It is most commonly seen in congenital mixed hearing impairment. There are reports of it originating from either an abnormally wide cochlear aqueduct or an internal auditory canal defect. No individual has large experience of this condition. The patient should immediately be positioned head up. It is then most commonly managed by a tissue graft over the oval window with a prosthesis to anchor it. The use of a lumber drain has been advocated by a minority. There were occasions when the flow could only be stemmed by ablation of the cochlear aqueduct or packing the internal auditory canal.

The operative field should be dry enough to prevent blood entering the oval window. The aspiration of blood or perilymph from the oval window is significantly associated with high-frequency sensorineural hearing damage.

POST-OPERATIVE COMPLICATIONS

Conductive hearing impairment

Post-operative conductive hearing impairment may present immediately after surgery, suggesting the sound transmitting mechanism was never successfully restored, or months or years later. Statistical analysis of published data is difficult in part because the exact nature of the previous surgery is often in doubt, as it is difficult at revision surgery to assess the entire footplate, which is often encased in fibrous tissue. This is important as the literature does not clearly distinguish the differing risks of each complication between stapedectomy and stapedotomy techniques, despite the use of lasers in revision surgery having improved assessment of the footplate. However, we have reviewed 19 major series published between 1980 and 2003, adequately describing 2670 revision stapedectomies and stapedotomies. Three causes of failure were particularly frequently reported. Prosthesis displacement out of the footplate was identified in 953 cases (36%, range 18–82%), and incus erosion in 549 (21%, range 5–32%). Bony regrowth over the fenestration was less consistently quoted but where stated it was found in 1–24% of each series.

Displacement of the prosthesis out of the oval window fenestration has a number of possible causes. A short prosthesis may be displaced from the vestibule simply by Valsalva or sneezing. A short piston may result not only from incorrectly measuring the distance from long process to footplate, but also from the distortion of the loop around the long process of the incus that may result from the variable diameter of the long process, different loop properties and different crimping techniques.[167] Contracture of the connective tissue seal over the fenestration appears capable of pushing the prosthesis out of the vestibule. There is anecdotal evidence to suggest that the thicker the oval window sealant, the greater the lateralization of the prosthesis. This would imply that a vein graft, being very thin, would be most suitable, followed by perichondrium, fat and fascia. In theory, better still is a tight laser stapedotomy. This may require no seal and so may reduce the risk of lateralization.[168] Traction from adhesions between the prosthesis and adjacent structures appears capable of displacing a prosthesis, so minimizing surgical trauma around the oval window is recommended. Anecdotal evidence also suggests that middle ear adhesions, lateralization of the oval window neomembrane and prosthesis migration are more severe following stapedectomy than stapedotomy. Finally, an intact footplate that was never fenestrated is frequently reported. No conclusions can be drawn from the literature as to whether any specific prostheses are particularly prone to these complications.

Necrosis of the long process of the incus causes loosening of the attachment of the prosthesis and a conductive

hearing impairment. The hearing impairment may fluctuate. Although often attributed to a reduction in blood supply secondary to cutting the stapedial tendon, and pressure on the long process from the prosthetic loop, some authors have claimed two other observations make this unlikely. The marrow of the incus may be able to provide adequate blood supply, and the frequent findings of a circumferential bony defect filled with granulation tissue are said to be more typical of a foreign body reaction.[165] It is common for both long process erosion and displacement from the vestibule to coexist. Necrosis should be distinguished from loose attachment of the prosthesis to the long process of the incus through faulty crimping, a complication that may be easily corrected.

Bony regrowth is more common in cases that initially demonstrated obliterative otosclerosis. It is reported both within a year of primary surgery and many years later.

Fibrous adhesions fixing either the ossicles or prosthesis are reported in 8–24% of revision operations. Such fixation develops independently of the incus or malleus fixation discussed previously, though both should be sought at revision surgery.

Footplate refixation may be encountered following mobilization procedures, though these are performed rarely now.

Sensorineural hearing damage

This may occur peri-operatively or present many years after surgery. Quoted results are subject to publication bias and an absence of randomized trials. Caution is also required as the largest series reflect the results of established experts. The majority of recent publications on stapedotomy quote no dead ears or cases of severe sensorineural damage in their series. One of the largest series of stapedotomies identified 13/1911 (0.7%) cases of sensorineural damage, combining early and late failures.[169] Rates for stapedectomy are generally higher and range from 0 to 11%, though are not necessarily directly comparable. However, one of the largest series reported no immediate cases of permanent sensorineural impairments in over 4000 procedures.[170] Revision surgery is usually associated with higher rates of sensorineural hearing damage. Reviewing 20 papers analyzing 2585 revision procedures, we identified 113 cases of severe sensorineural hearing impairment, a rate of 4.4%. Sensorineural impairment was identified in 0–20% of each series, while a dead ear rate of 0–14% was quoted. Length of follow-up was variable. This is significant as approximately half the episodes of acute sensorineural hearing impairment in both primary and revision cases were delayed, often by very many years.

Early mild sensorineural hearing loss is common. Sperling et al. noted 62% of patients had some sensorineural threshold shift in at a least one frequency when measured at day 5 post-operatively. This reduced to 32% at 6 months.[171]

Causes of peri-operative sensorineural damage are most often attributed to surgical trauma, in particular, extensive drilling associated with obliterative otosclerosis (particularly revisions), floating footplates and perilymph aspiration. Congenital footplate fixation and cerebrospinal fluid (CSF) gushers make up a second group. Delayed sensorineural damage is often unexplained. Causes include barotrauma from air travel and blast injury, reparative granuloma, perilymph fistula and suppurative labyrinthitis. An association with influenza has been quoted.

These late conductive and sensorineural failures, which could total several per cent of procedures, may influence the decision to proceed to surgery. In addition to the slow progressive cochlear impairment, they are discussed under 'Natural history' above.

Facial nerve injury

Immediate temporary facial nerve palsy may occur immediately post-operatively as a result of local anaesthetic infiltration. Delayed temporary facial palsy is well described between days 4 and 10 post-operatively. Rates of 0.1–0.5% are quoted. The cause is unknown but in some cases it may result from facial nerve swelling, resulting from the nerve being heated by a drill or laser. Full recovery is always reported over days or weeks. The role of steroids is not clear.

Permanent injury is very rare in stapes surgery (0.07% in the largest series). It is reported in association with aberrant nerves crossing the footplate, with laser or burr injury in the presence of a dehiscent canal and while clearing fibrous tissue from the footplate during revision surgery.

Vertigo

Transient dysequilibrium or vertigo post-operatively is not uncommon and can be managed with vestibular sedatives. Vertiginous symptoms combined with sensorineural hearing impairment and tinnitus occurring in the first week post-operatively most commonly result from a 'serous labyrinthitis' from which a rapid recovery can be expected. No treatments have been shown to improve outcomes.

Should dysequilibrium persist or arise later, a cause should be sought. Benign positional paroxysmal vertigo was reported in 4/63 post-stapedectomy patients in one study, all successfully treated with the Epley manoeuvre.[172] Vertigo is reported in 20–35% of patients with reparative granuloma and one-third of patients with a perilymphatic fistula. Both conditions are discussed below. An overlong prosthesis may cause vertigo and may be diagnosed by a positive fistula test on pneumatic otoscopy. Other causes described include a depressed footplate, bony fragments compressing the saccule, suppurative labyrinthitis, endolymphatic hydrops and vestibular schwannoma. Careful neuro-otological examination is required. Diagnosis of the labyrinthine cause is reported to be possible in many cases using HRCT scanning.

Perilymphatic fistula

A primary perilymphatic fistula is, by definition, present at the end of stapedectomy, a secondary fistula develops

months or years later. The largest series quote oval window fistula rates of 0.25–2.5% following stapedectomy. Rates appear significantly lower following stapedotomy. Fistulae are reportedly identified at 1.5–12% of revision operations. In many ways, symptoms are similar to those of endolymphatic hydrops: a persistent or fluctuating hearing impairment in 71–87% of cases, which may be sensorineural, mixed or conductive in nature; vertigo in approximately one-third of patients and dysequilibrium in a further third; tinnitus in 28–45%; and sometimes a sense of fullness in the ear. Some patients with a fistula have presented with meningitis. A positive fistula test may be present in two-thirds of cases. The greatest risk factor for a fistula is repeatedly reported as having been the use of gelatin sponge to seal a stapedectomy, a technique now largely abandoned. Treatment should be prompt. At re-exploration, if the prosthesis is displaced, the defect should be grafted and anchored with a new prosthesis. If the prosthesis still enters the vestibule, there may be adhesions with the membranous labyrinth and it may be safest to pack the footplate with fat without disturbing the vestibule.

Reparative granuloma

This is a well-recognized cause of early post-stapedectomy hearing impairment. The term granuloma is a misnomer. It refers to granulation tissue formation around a stapes prosthesis and the oval window which may extend into the vestibule. Early stapedectomy series quoted rates of 1.3–5%. A more recent postal survey of American otologists suggested an incidence of 0.1% post-stapedectomy and 0.07% post-stapedotomy,[173] though this is likely to be an underestimate. They are associated with the type of graft material used, most commonly Gelfoam or fat, and rarely with perichondrium, fascia or vein. Reparative granuloma usually presents 1–2 weeks post-stapedectomy, though a recent paper had one severely destructive case occurring 2 years after surgery.[174] It should be suspected when the commoner symptoms of 'serous labyrinthitis' fail to settle. They present with deterioration in hearing after an initial post-operative improvement in 70–100% of cases. The hearing impairment is progressive or sudden and sensorineural or mixed. It is associated with vertigo in 20–35% of cases and sometimes tinnitus.[161] There may also be otalgia.[174] Examination shows a dull red tympanic membrane, particularly in the posterior–superior quadrant. Management is controversial. Most papers advise early surgical intervention within 2 weeks of stapedectomy. It is uncertain whether the granulation tissue and prosthesis or granulation tissue alone should be removed. Outcomes are split evenly between hearing improvement, stabilization and profound impairment.

Many surgeons would now advocate a more conservative policy of steroids and antibiotics initially and some would consider delayed surgery if no improvement occurred. CT and MRI can be useful in assessing the extent of the granuloma which can rarely be very large and destructive.[174] Evidence-based conclusions cannot be drawn.

Discomfort to loud noise

This symptom has been reported in 35–41% of patients following stapes surgery and, although it frequently settles, it can persist on long-term follow-up.[175] It may, of course, reflect solely the improved hearing in the operated ear as normal hearing subjects will experience noise intolerance at certain volumes and loudness discomfort levels seem little changed. The role of stapedius tendon reconstruction is discussed under 'Hearing outcomes' below.

Alteration in taste

Damage to the chorda tympani nerve is reported in up to 30% of procedures, while in revision series the nerve has been quoted as being found intact in as few as 20% of cases. Sectioning or stretching the nerve may result in a metallic taste, impairment of taste, dry mouth and soreness of the tongue, typically for 3–4 months following surgery, though on occasion much longer. Cutting the nerve appears to lead to greater and longer-lasting symptoms than preserving it.[176] Bilateral damage will produce severe symptoms. For similar levels of damage, altered taste is noted more commonly after otosclerosis surgery comparted with cholesteatoma surgery as it is thought the chorda may often have pre-existing damage in cases with cholesteatoma.[177]

Cholesteatoma

Cholesteatoma has been reported in the oval window secondary to skin elements implanted during harvesting of a fat graft.

Meningitis

Meningitis and death have been reported, particularly in the older literature, following stapedectomy with fistula formation. Some authors have advocated exploratory tympanotomy in any patient with meningitis who has a stapes prosthesis to exclude a fistula.

HEARING OUTCOMES

Background

Reviewing outcomes data for middle ear surgery is not straightforward and is discussed under 'Conductive hearing impairment' above. The techniques used for stapes surgery have evolved gradually over four decades, with multiple variables to contend with including fenestration size and technique, graft material, prosthesis diameter and design, stapedius tendon repair, pathological severity and surgical expertise. Published series often combine several techniques. Reporting methods have also evolved making direct comparisons difficult. Randomized trials are notable for their scarcity. Furthermore, several series have quoted converting approximately 20% of stapedotomies into stapedectomies because of technical difficulties. This may introduce further bias as the results of stapedectomy

are made to appear worse as they reflect more difficult cases. Meta-analyses either are not possible or have not been attempted.

When comparing technical factors such as the type of prosthesis or biomaterial, closure of the air–bone gap is often a satisfactory measure. Cochlear damage may be broadly assessed by comparing pre- and post-operative bone-conduction or speech discrimination. The hearing gain experienced by the patient in one ear is best assessed by the air-conduction thresholds. However, from a patient's perspective, two other outcomes matter. First, the reduction in their auditory disability. This depends very much on the hearing in the better ear, information that historically was rarely presented. Second, 'average' outcomes become meaningless. It is the relative likelihood and implication of good, bad or very bad results that are important, which explains the role of presenting data in audiometric 'bins' of 10 dB, or graphically, to highlight extreme outliers.

Comparison of different techniques

STAPEDECTOMY VERSUS STAPEDOTOMY

As the debate between small or large fenestra techniques evolved, there were many series published from excellent centres quoting closure of the air–bone gap to less than 10 dB in over 90% of cases using either stapedectomy or stapedotomy techniques, though typically pre-operative bone thresholds have been used.[178–180] When comparing their stapedectomy series to their subsequent stapedotomy series, it is apparent that more than the size of the fenestra had changed. Often the piston and grafting technique altered making direct comparison difficult. However, a trend began to emerge that suggested stapedotomy was less traumatic to the membranous labyrinth, resulted in fewer complications and offered potentially better hearing gain in frequencies of 4 kHz and above. The benefits that have been claimed are shown in **Table 89.5**.

In 1978, Smyth and Hassard[181] offered a more direct comparison that supported the developing consensus. Reviewing results of 750 stapedectomies and stapedotomies, the immediate hearing outcomes were similar in the two groups except for sensorineural impairments of greater than 20 dB, which occurred in 1.5% of stapedectomies but no stapedotomies. Most impairments could be related to surgical trauma while trying to remove the footplate. The rate of fistulae was also higher in the stapedectomy group (2.0% versus 0.6%).

TABLE 89.5 Suggested benefits of small versus large fenestra techniques

Technique	Suggested benefits
Stapedectomy	Better low-frequency hearing gain May be only method technically possible
Stapedotomy	Better high-frequency hearing gain Lower incidence of: • perilymphatic fistula • sensorineural hearing impairment • lateralization of graft • post-operative vertigo • revision surgery More stable hearing gain Less 'labyrinthine trauma'

In reviewing the literature, we identified only one randomized controlled trial comparing stapedectomy (59 cases) and stapedotomy (32 cases).[182] This supported the consensus that higher-frequency hearing outcomes tend to be better with stapedotomy. In keeping with many studies, the need for revision was greater in the stapedectomy than stapedotomy group (7% versus 3%).

Direct comparison between the case series that make up the rest of the literature is difficult. The majority of publications show a similar degree of early closure of the air–bone gap in lower frequencies with both large and small fenestra techniques. Short-term closure to within 10 dB (most papers using pre-operative bone-conduction) occurred in 54% to over 95% of cases, with the majority of the published series quoting 80–95%. However, there is a clear majority that report better high frequency (4–8 kHz) outcomes for stapedotomy over stapedectomy. This has been shown to be associated with better speech discrimination in a small number of publications. The clinical significance of this has been questioned. A minority of papers report better low-frequency gain for stapedectomy, but this is not always maintained on longer-term follow-up.

Long-term hearing outcomes are addressed in several papers. The largest cohort has been followed by Shea.[137] He reviewed more than 4100 primary stapedectomies in his series of 14 449. Although the details of follow-up are unclear, the size of the series makes the findings influential. Both total and partial stapedectomies were performed with a variety of grafts. Averaging hearing at 0.5, 1 and 2 kHz, and identifying those with an air–bone gap of 10 dB or less and no loss in speech discrimination of greater than 10%, he quoted success in 95% at 1 year post-operatively, 90% at 6–10 years, and 63% at greater than 30 years. Most importantly, he believed that sufficient sensorineural impairment would be present in 30% of patients by 20 years post-operatively and that a hearing aid would be required.

A long-term follow-up in Finland comparing stapedectomy and stapedotomy obtained an impressive 63% follow-up at an average 20 years post-operatively.[175] Mean hearing results were not statistically different between the groups on short- or long-term follow-up. Air- and bone-conduction thresholds fell at a similar rate of 0.9 dB per year in both groups, which matches other publications that have previously quoted 0.6–1.2 dB per year. These numbers imply there is little worsening of the conducting mechanism on longer-term follow-up in the 'average' patient, but does not address individual failures. At an average 20 years after surgery, 37% of the group were occasional or regular hearing aid users, results very similar to those of Shea.[137]

STAPEDOTOMY TECHNIQUES

Stapedotomy techniques have been compared in a number of studies. No differences in outcomes were identified in

a prospective study between the use of a microdrill and handheld microperforator.[183] KTP, CO_2, erbium:YAG and argon lasers have all been frequently used in stapes surgery since initial results were published in 1980. There are potential risks to the membranous labyrinth with their use including photothermal, photochemical and photoacoustic damage. There are reports of temporary threshold changes using the CO_2, KTP and erbium:YAG lasers. The authors of a study using the erbium:YAG discontinued its use on the basis of their findings. The use of lasers versus the microdrill was reviewed in 550 cases at The House Ear Clinic in Los Angeles and similar results were reported,[184] the same finding to a review of the use of picks, drills and lasers in Marquet's series of 1681 procedures.[169] Despite this report, there is evidence to suggest that laser stapedotomy may have a lower complication rate than traditional methods. Rauch and Bartley[185] published a comparison between argon laser fenestration and traditional techniques and demonstrated a fivefold greater rate of footplate fracture using conventional fenestration methods. CO_2 and argon lasers have been compared and no outcome differences found. A recent systematic review was inconclusive on which was the optimum laser to use for stapes surgery.[186]

CONNECTIVE TISSUE SEALS

The use of connective tissue seals to cover the fenestration is another area of controversy. They will increase the surface area to transmit energy (this needs to be remembered when considering piston diameter outcomes which are discussed under 'Prosthesis types' below), may prevent perilymph leakage and restore the stiffness of the annular ligament in theory. It has already been mentioned that vein appears to be the most suitable material for stapedectomy. For stapedotomy it is not easy to compare series because of multiple variables, in particular the size of the stapedotomy is often not reported. Certainly, Causse[187] has reported excellent results using vein. Many otologists prefer not to interpose a graft but fashion a tight-fitting stapedotomy and seal the fenestration with blood or fat placed around the prosthesis.

ENDOSCOPIC STAPEDOTOMY

With the current interest in endoscopic ear surgery it is not surprising there are an increasing number of studies looking at endoscopic stapes surgery. These studies have demonstrated that endoscopic stapes surgery is safe and has similar audiologic outcomes to microscopic stapes procedures. Advantages compared to peraural stapes surgery would appear to be few but possibly a reduced amount of resection of the bony annulus is required.[188, 189]

PROSTHESIS TYPES

Prostheses vary in their design, material (Teflon, steel, gold, platinum, titanium and alloys), weight, diameter and anchorage to the long process of the incus. There are many good publications comparing piston diameter. Theoretical constructs would favour larger piston diameters, particularly in frequencies below 1.5 kHz. (If this argument sounds familiar, remember that a larger fenestration will effectively increase the sound-transmitting area of the end of the piston, and the largest fenestration is a stapedectomy.) This has to be balanced against the perceived risk of increased labyrinthine trauma and the technical limitations of larger fenestrations.[165] A minority of studies show no difference in hearing outcomes between different piston sizes, a majority appear to show benefit for larger pistons, particularly for frequencies up to 2 kHz. Teig and Lindeman[190] attempted to avoid the many confounding variables and demonstrated a 0.6 mm piston produced mean hearing results 4–10 dB better than a 0.4 mm piston, while a 0.8 mm piston was better than the 0.6 mm piston by 5–7 dB. While temporal bone studies have also suggested superiority of larger pistons,[191] a recent systematic review showed no evidence to support the superiority of large pistons over smaller diameter pistons.[192]

There are some published data to suggest that heavier pistons (steel – 12.5 mg, or gold – 10 mg) may produce better results in the lower frequencies, while lighter pistons (Teflon – 3 mg) may be better in higher frequencies,[165] a trend well illustrated by de Bruijn et al.[193] At present, there is insufficient evidence to confirm these differences are of clinical significance.

The material used is important only in that it must attach firmly to the incus and not incite a foreign body reaction. There are a number of individual case series of different products but most studies fail to show significant differences in hearing results between the prostheses as the majority are small and lack statistical power.

There has been a growth in use of self-crimping pistons made of thermally triggered alloys, of which a number of varieties are available. The piston is placed as normal but then heated with diathermy or a laser which causes it to self-crimp. Early results suggest these prostheses may be easier to use as satisfactory crimping is often felt to be one of the most difficult parts of the operation.[194] It is also felt that these pistons perhaps give more consistent results. Although long-term hearing results are not yet available, mid-term results appear stable.[195]

PRESERVATION OF THE STAPEDIUS TENDON

This is proposed as a method of preserving the blood supply to the long process of the incus, of reducing discomfort at high sound pressure levels and of improving speech intelligibility. Evidence regarding the benefits to blood supply is limited and it is likely much may be obtained from the marrow in any case. Causse et al. series[196] of 3457 tendon reconstructions was published in 1997 and claimed to show improved speech intelligibility in noise and reduced intolerance of loud noise, but the analytical methods used make it difficult to draw conclusions. A large questionnaire study by another group failed to show any difference in outcomes. Of note is that the surgeons at the Causse clinic no longer reconstruct the stapedius tendon due lack of perceived benefit to the patients.

Revision surgery

Revision surgery is associated with a greater risk of sensorineural hearing impairment, as described above, and with poorer hearing outcomes than primary stapes surgery. It is particularly difficult comparing case series because of the variables involved. However, we have reviewed 24 series and found closure of the air–bone gap (using old reporting guidelines) to within 10 dB was achieved in 54% (mean value unweighted for series size, range 17–81%).

While there are many claims that revision surgery is safer under local anaesthetic, it is difficult to establish this from the literature.

The use of a laser is often advocated for revision surgery to allow adhesions to be cleared from the oval window, to free an ankylosed prosthesis from the incus, to sculpture the incus or to control bleeding. Most papers comparing revision surgery with and without a laser do not report any differences in hearing outcome. However, in Lippy et al. series of 483 revisions,[160] it was noted that in the period the laser was not available, closure to within 10 dB was achieved in 70% of cases and when it could be used, if required, this increased to 80%.

Malleostapedotomy is usually reserved for cases of severe incus erosion.

The more revisions an ear has undergone, the less likely a good result can be expected. Lippy et al.,[160] for example, quote closure to 10 dB in 76% of first revisions, 66% of second, 57% of third and 38% of fourth revisions.

TINNITUS OUTCOME

Tinnitus is common in those undergoing stapes surgery, being reported in 56–79% of cases pre-operatively. Surgery is a successful method of alleviating this symptom. The results of seven series involving 696 patients with tinnitus were looked at. Post-operatively, 44% (mean unweighted for series size, range 27–64%) of patients had no tinnitus, 34% (16–56%) had less tinnitus than pre-operatively, 16% (8–27%) had equal symptoms and 5% (1–11%) had more tinnitus.[197] Looking at those who had no tinnitus pre-operatively, symptoms are reported to occur in 0–16% post-operatively, with most papers quoting no new cases.

Several authors have reported that the prognosis for low-pitched tinnitus is particularly good after surgery, while the prognosis for high-pitched tinnitus is poor. This has not been corroborated by all studies.

COCHLEAR IMPLANTATION

Cochlear implantation is a potential management option for those patients with FAO in whom other modes of sound amplification have failed. Otosclerosis accounts for approximately 10% of implants in adult programmes. Most patients being considered will have had surgery for otosclerosis previously, either stapes procedures or fenestration. If not, stapedectomy in combination with conventional aiding should be seriously considered prior to proceeding to implantation.

This population has its own unique surgical challenges, due to both previous surgery and the disease process. These have been summarized in **Table 89.3**.

In a large series presented by one of the authors,[142] speech discrimination scores (using binaural CID sentences) improved from 12% (range 0–52%) pre-operatively to 88% (range 22–100%) post-operatively, results which have been mirrored in other series.

BEST CLINICAL PRACTICE

- ✓ A trial of a hearing aid should be discussed before proceeding to stapes surgery.
- ✓ Stapes surgery should be performed only by those who undertake it regularly.
- ✓ Appropriate outcome data should be audited by individual surgeons.

FUTURE RESEARCH

The surgical correction of hearing impairment caused by otosclerosis has a long and interesting history. It is currently one of the most successful operations we have to improve hearing. Large gaps remain in our knowledge, however.

- ➤ More accurate and standardized outcomes data will allow comparisons between techniques and refinement of the indications for surgery.
- ➤ Further exploration of patient-orientated outcomes, both for hearing aids and surgery, will help the debate over treatment of unilateral disease and bilateral surgery.
- ➤ Randomized trials rather than case series are desirable and possible for stapes surgery and hearing aid use, but they may require multicentre studies. These are required to assess variations in technical aspects of surgery, such as prosthesis design, dimensions and graft material. These will eventually allow meta-analysis of results and clearer guidelines, something still not currently possible on evidence-based criteria.

KEY POINTS

- Stapes surgery is an effective treatment for both the hearing loss and tinnitus of otosclerosis.
- Debate continues over indications for stapes surgery, in particular its role in unilateral disease and in second-side surgery.
- Revision surgery carries higher operative risks than primary surgery.
- Stapedotomy seems to be associated with fewer complications than stapedectomy.

CHAPTER 90

OTOLOGICAL EFFECTS OF PAGET'S DISEASE

Ian D. Bottrill

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search and a search of the Cochrane and Bandolier libraries using the keywords: osteitis deformans, Paget's disease of bone, temporal bone, deafness, hearing loss, tinnitus, vertigo, imbalance, dizziness and focusing on pathogenesis, aetiology, diagnosis and management.

DEFINITION

Sir James Paget gave the first account of the disease which bears his name in 1877.[1] The disease was initially termed 'osteitis deformans'. Paget's disease of bone (PDB) is a progressive, focal disorder of bone remodelling and is the second most frequent metabolic bone disorder. There is an increase in osteoclastic activity producing bone reabsorption, with reactive stimulation of osteoblasts producing increased bone deposition, resulting in bone that is architecturally unsound. This leads to bone pain, deformity and fragility. Affected individuals typically have enlargement of the skull with involvement of the pelvis, tibia or femur. It is interesting to note that skeletons from archeological sites in Western Europe are the only ones to show evidence of Paget's disease.[2] This chapter will focus on the impact of Paget's disease on the temporal bone. [Level 1 evidence]

EPIDEMIOLOGY

PDB is the second most common bone disease in the world. It has a 3:2 male predominance. The disease is more common in Britain, North America, Australia and New Zealand. It is rare in Scandinavia, Asia and in non-white races.[3] The UK prevalence in the over 55 year age group is 0.3%; incidence rates for clinically diagnosed PDB rise steeply with age.[4] The same study found that, over the 10-year study period, the incidence of PDB disease declined significantly with time.

AETIOLOGY

The exact cause of PDB is unknown. The current opinion and evidence support an interplay between genetic and environmental factors, possibly viral infection of the bone cells, as the cause. The first gene found to be affected in PDB is the *SQSTM1* gene; currently more than 25 mutations have been identified in this gene. This gene encodes p62, a protein that is involved in regulating osteoclast function. Those patients who carry the abnormal gene are more likely to develop more advanced disease than PDB patients who do not express this abnormal gene. Other candidate genes have also been isolated in recent years.[5]

Polyclonal antibodies reveal paramyxovirus antigens in pagetic osteoclasts compatible with measles and respiratory syncytial virus infections. Studies with monoclonal antibodies implicate measles, simian virus and human parainfluenza virus. Electron microscopic studies have shown that the nuclei in pagetic osteoclasts have a fingerprint pattern, which supports a viral infection as a possible aetiological agent.[6] However, not all studies have found paramyxovirus particles or RNA in pagetic bone. In addition, there have been no convincing viral particles isolated from the cells of pagetic osteosarcoma, and it has not been possible to pass the disease to uninfected cells in culture.

PATHOPHYSIOLOGY

Bone changes

The basic abnormality is increased bone turnover in the involved bones. PDB can exist in monostotic and polyostotic form, with 10–30% of patients having monostotic disease. Any bone can be involved, with the most frequently affected bone, in decreasing order, being the pelvis, femur, skull, tibia, vertebrae, clavicle and humerus.

The changes in bone occurring in PDB can be divided into three phases: osteolytic, mixed and osteoclastic.[7] In the temporal bone a fourth phase has been described: a lamellar remodelled phase, in which the osteoblastic pagetic bone may undergo a process of remodelling into quite normal-appearing lamellar bone with distinct Haversian canal systems. This process is particularly seen in relation to the internal auditory canal, producing bossing of pagetic bone. In the temporal bone the endochondral bone is more resistant to resorption.[8, 9]

Different histological phases may coexist within a single temporal bone specimen.[7] Within the temporal bone, histological studies have shown that PDB involves the periosteal bone first. With increasingly aggressive disease, the process may extend into the enchondral layer and may finally invade the endosteal layer. [Level 1 evidence]

Symptoms and signs

In the early stages, the disease may be asymptomatic. Symptoms gradually progress, frequently starting with pain, stiffness and fatigability. The bone pain of PDB is typically constant, deep and boring. The cause of the pain is likely to be related to the increased periosteal blood flow exerting intraosseous pressure and stimulating bone pain fibres.

HEARING LOSS IN PAGET'S DISEASE

Sir James Paget, in his original publication, recognized hearing loss as a complication. The prevalence of hearing loss in PDB is quoted has varying between 13% and 40%. Van Staa et al.,[4] in their large epidemiological study, found that patients with PDB had a greater risk of hearing loss compared to age and sex matched controls (relative risk 1.6; 95% confidence intervals 1.3–1.9). This study was based on questionnaire data and did not include audiometric testing. A study by Young et al.[10] compared audiometric data in a group of patients with PDB selected at random from a tertiary hospital database and compared this with age- and sex-matched controls. They found the PDB group had significantly elevated auditory thresholds when compared to the control group: 41/75 PDB had a pure-tone average threshold of >40 dB compared to 8/76 controls. The hearing loss is typically of a high-frequency sensorineural nature.

It has also been noted that PDB may be associated with a low-frequency air–bone gap. Baraka[11] attempted to determine the rate of progression of hearing loss in patients with PDB. He reported that, on average, patients with PDB experience a greater reduction in hearing over time compared with age-matched controls. The pagetic ears deteriorated by approximately 2 dB per annum compared to 0.5 dB per annum in controls. His conclusions are limited by the very small sample size (4 patients with a minimum of 4 years of regular testing out of an initial study population of over 100 patients with proven PDB). Tinnitus is also slightly more common in Paget's than in controls, with a relative rate of 1.5 (95% confidence intervals 1.1–2.2).

The majority of pathological studies published relate to isolated case reports. Khetarpal and Schuknecht[7] have reviewed reported cases and tabulated the proposed mechanisms of sensorineural and conductive hearing losses, demonstrating the wide variation in suggested aetiology for the two types of deafness. Of the 26 temporal bones in 16 individuals, the only consistent feature they demonstrated was age-related histological changes. Pagetic lesions were present in the periosteal layer in all 26 temporal bones. In 22, they demonstrated extension to the enchondral layer and the endosteal layer was involved in 14. They found no evidence of ossicular fixation to account for the air–bone gap that was documented in seven individuals. The essence of their study was that 'both the conductive and sensorineural components of the hearing loss in Paget's disease are caused by changes in bone density, mass and form that dampen the finely tuned motion mechanics of the middle and inner ears'.[12] However, Dimitriadis et al.,[13] in their temporal bone study of eight subjects showed stapes fixation in two bones and a fractured stapes footplate in one specimen. The conductive component does not improve surgically even if otosclerosis coexists.

Historically, the hearing loss has been attributed to narrowing of the internal auditory canal[14] with compression of the vestibulocochlear nerve. Latterly this association has been brought into question. Monsell et al.[15] also looked for evidence of nerve compression as a cause of the sensorineural deafness. In a study of 64 ears with radiographically confirmed PDB of the skull, they demonstrated no relationship between the mid canal diameter and minimum diameter of the internal auditory canal and the hearing thresholds. In addition, auditory brainstem responses were normal in 56 out of the 64 ears, indicating that a retrocochlear lesion is unlikely to be the source of the hearing loss. However, this study did not look at tests for cochlea hearing loss (e.g. recruitment) to support their hypothesis. In a separate study Monsell et al.[16] also demonstrated a strong and statistically significant relationship between the bone mineral density of cochlea capsule versus both the high-frequency pure-tone air-conduction thresholds and the air–bone gap in subjects with Paget's disease of the skull. This latter study supports the conclusions from Khetarpal and Schuknecht's earlier histological study. In Dimitriadis et al. study they found occlusion of the inferior cochlear vein in 78% of cases leading to secondary changes in the stria vascularis and postulated fluid homeostasis abnormalities.

VESTIBULAR DISTURBANCE IN PAGET'S DISEASE

The literature regarding vestibular disturbance in PDB is not as extensively reported as studies on hearing loss.

The incidence is generally reported to be in the region of 20–30% of individuals with PDB suffering from vestibular dysfunction, but this is not compared to age-matched controls.[9] However, van Staa et al.[4] compared the frequency of reported dizziness/giddiness in 2456 patients with PDB compared to 7395 age- and sex-matched controls. They found rates of 5.0% and 3.7% respectively, producing a crude relative rate of 1.3 (95% confidence interval 1.2–1.5).

In Khetarpal and Schuknecht's study, vertigo was recorded in 4 of the 16 subjects investigated. The symptoms have the characteristic of motion-provoked imbalance. Histological analysis of these patients with imbalance did not reveal any changes such as loss of hair cells in the maculae or cristae. Even with histological evidence of pathology of the vestibular system, not all patients with changes had a history of imbalance. They found that losses of vestibular nerve fibres, greater than normal for age, occurred in nine ears of six subjects, three of whom had a history of vertigo.

DIAGNOSIS

PDB is often found incidentally on X-ray or laboratory tests performed for other reasons. It can be diagnosed through radiology, radionuclide bone scanning, and biochemical tests of bone resorption or formation. Plain X-ray findings in the early stages of the disease may be confined to osteolytic lesions in the involved bones. As the disease progresses, further radiographic changes occur, including increased bone density, abnormal architecture, cortical thickening, bowing and overgrowth. Microfractures may be seen in long bones. Laboratory testing should include renal function and liver function tests, calcium, albumin, alkaline phosphatase and 25-hydroxyvitamin D.

Computed tomography may show the involvement of the temporal bone (**Figures 90.1** and **90.2**) and in extreme cases may show complete obliteration of the otic capsule. When PDB affects the temporal bone, it typically spreads from the petrous apex laterally, producing a washed-out appearance of the involved bone caused by extensive demineralization. The process frequently affects the internal auditory canal first, progressing to involvement of the otic capsule. In advanced disease, the deposition of irregularly mineralized bone occurs, resulting in thickening of the petrosa and narrowing of the internal auditory canal. Nuclear medicine scans using technetium-labelled phosphonates show increased nuclide localization to the pagetic sites and can be a useful screen for disease extent.

Abnormal laboratory investigations include an elevated serum alkaline phosphatase (or bone-specific alkaline phosphatase). This enzyme is a marker of new bone formation and not resorption. The degree of osteoclastic activity can be assessed by measuring urinary hydroxyproline/creatinine (a measure of collagen breakdown) as well as measurements of urinary and serum deoxypyridinoline, N-telopeptide and C-telopeptide. Serum calcium and phosphorus levels usually are normal, but serum calcium may increase during bedrest.[16] [Level 1 evidence]

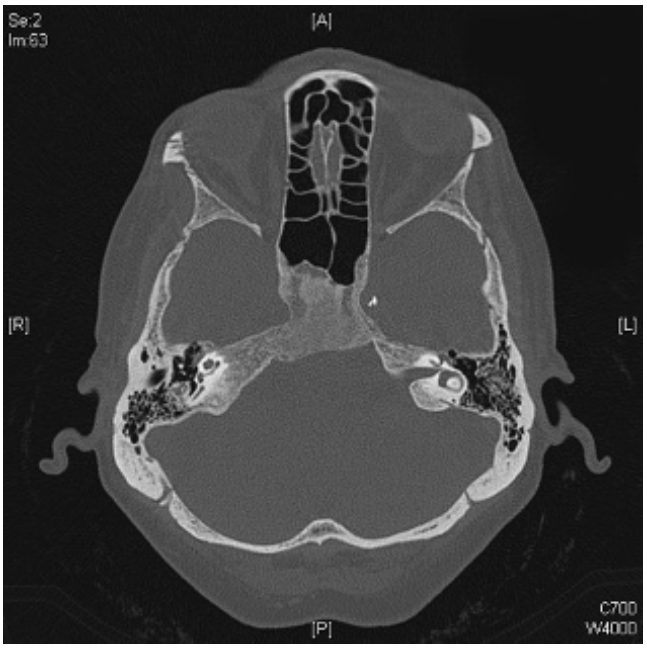

Figure 90.1 CT Paget's axial.

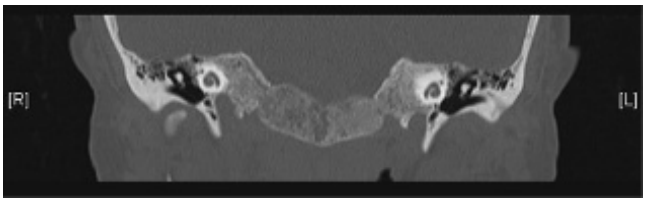

Figure 90.2 CT Paget's coronal.

MANAGEMENT OPTIONS

From the clinical descriptions and research findings it would appear that early PDB is not associated with significant otological complications. With advanced disease, otological complications do occur but with only modestly increased rates compared to the normal population. It is unlikely that the otolaryngologist is likely to pick up a new, early case. The patient will usually be under the care of the rheumatologists and combined management will be required. The dilemma is what to do with the known case who may present in the otolaryngology clinics.

Four main methods of treatment exist for PDB: physiotherapy, antiresorptive therapy, analgesics and surgery. Drug therapy is the mainstay of treatment for the non-otological aspects of the disease but may have beneficial effects on the otological aspects of the disease as well.

The current criteria for treating Paget's disease vary, ranging from those who treat only advanced disease to those who intervene early, to try to prevent the development of any complications, with no conclusive evidence to support either strategy. Crisp[17] lists his indications for the treatment of PDB (**Box 90.1**). He quotes skull disease as an indication for treatment but does not expressly mention audiovestibular symptoms.

Drug therapy is based on antiresorptive therapy. The mainstays of drug treatment are the biphosphonates.

BOX 90.1 Indications for treatment (reproduced from Crisp,[17] by permission of Oxford University Press)

1. Pain arising from the site of known PDB
2. Early, potentially deforming disease
3. Osteolytic lesions, especially in weight-bearing bones
4. Skull disease
5. Complications:
   a. progressive neurological syndrome
   b. fissure fractures (avoid etidronate)
   c. immobilization hypercalcaemia
   d. high-output cardiac failure
6. Disease in patients aged under 55 years
7. Serum alkaline phosphatase and/or urine hydroxyproline concentration more than twice the normal upper limit
8. Patients likely to undergo joint replacement at involved sides within 6 months, primarily to reduce blood loss due to hypervascularity present in active pagetic bone

These drugs act to reduce bone turnover and normalize the raised biochemical markers. Early biphosphonate use required daily treatment for 6 months, but as newer drugs have been introduced current recommendation is for a single 5 mg intravenous dose of zolendronic acid. Reid et al.[18] double-blind randomized trial showed a single infusion of zoledronate produced greater level of biochemical disease control when compared to daily treatment of risedronate for 2 months. In an open follow-up, of up to 6.5 years, the relapse rate with risedronate was 20% compared to 0.7% with zolendronic acid. [Grade A evidence]

Reid et al.[19] did, however, report a single case of potential otic toxicity related to pamidronate infusions. Their patient received five infusions of the drug and immediately after the second to fifth infusions the patient reported problems with tinnitus, vertigo and hearing loss. With the exception of the tinnitus, his symptoms resolved completely. No other report of potential otic toxicity exists in the literature with regard to biphosphonate treatment.

The results of middle-ear reconstruction in PDB are generally poor due to the lack of a consistent pathology to explain the conductive hearing loss. Modern hearing aids offer a useful modality in the management of both the conductive and sensorineural loss. There are other surgical modalities mentioned in the literature, including the use of a bone-anchored hearing aid in one subject.[20] Because of the vascularity of the bone, the procedure was performed in two stages, to allow the fixture to osseointegrate. There are also case reports of the use of cochlear implantation with reasonable results.[21]

OUTCOMES

There is no direct evidence that aggressive treatment of PDB is associated with the prevention of progression or a reduction in risk of future complications.[17] However, indirect evidence, as shown below, suggests that this may be the case. The evidence for this includes:

- the failure to treat PDB has been associated with further destruction of bone and progression of bony deformities
- successful treatment of PDB has been associated with restoration of normal patterns of bone deposition.

Lando et al.[22] reported the use of calcitonin and etidronate in two patients with polyostotic PDB with rapidly progressing sensorineural hearing loss demonstrating stabilization of hearing in one patient and improvement in the other. Other studies (references 13–18 in their paper) confirm these findings with calcitonin alone.

Complications of clinical conditions

The most devastating complication of PDB is the development of osteosarcoma. This occurs in less than 0.1% of patients with PDB but at a significantly higher rate than in non-affected individuals. It tends to occur more frequently in the polyostotic variant of the disease. In van Staa et al. study[4] the incidence rate was found to be 0.1 per 100 person-years.

Skull expansion may lead to disfigurement, typically frontal bossing. Extensive involvement of the skull base, producing softening of the bone, may lead to platybasia – the descent of the cranium on the cervical spine – which may lead to vertebrobasilar compromise. Skull involvement may also lead to headaches and other cranial nerve involvement.

Pain, osteoarthritis, deformity and fractures are commonly associated with PDB. Other rarer complications include high-output cardiac failure, when more than one-third of the skeleton is affected, hypercalcaemia and hyperuricaemia.

Although remission after treatment is related to the degree of biochemical control, and very strong histological evidence that effective suppression promotes more normal bone remodelling, evidence is lacking that intensive treatment inhibits the development of long-term complications.[17]

KEY POINTS

- Paget's disease commonly affects the skull.
- It is a condition of abnormal osteoclast activity.
- Otological sequelae occur more commonly than in age- and sex-matched controls.
- The weight of evidence supports direct involvement of the otic capsule as the cause of the otological symptoms.
- Treatment with biphosphonates can suppress osteoclastic activity although the long-term benefits on the otological complications remain unproven.

CHAPTER 91

EAR TRAUMA

Stephen C. Toynton

SEARCH STRATEGY

All searches were performed using Medline Plus, Embase using Ovid, PubMed, Google Scholar, and the Cochrane database. Original or definitive references have been given priority over more recent ones that do not add significantly to the knowledge base.

Auricular haematoma and associated injuries

Ear surgery, ear external, external ear, pinna, auricle, auricular, helix and concha were all searched against, individually: trauma, haematoma, pseudocyst, cyst, chondritis and chondromalacia. Specific terms also searched were: auricular haematoma, otohaematoma, haematoma auris, wrestler's ear, asylum ear, cauliflower ear, hyperchondroplasia auris traumatica, auricular pseudocyst, benign idiopathic cystic chondromalacia, endochondral pseudocyst.

External ear canal trauma

Ear surgery, ear external, external ear canal, external auditary canal and external auditary meatus were all searched against, individually: trauma, injuries, wounds, lacerations and fractures. Specific terms also searched were: meatal step fracture and canal cholesteatoma.

Traumatic tympanic membrane perforations

Tympanic membrane and ear drum were searched against, individually: trauma, perforation, acute injury. Specific terms/phrases also searched were: traumatic perforations of the tympanic membrane, blast injury, primary blast injury, caustic ear injury, caustic trauma, batteries, CSF otorrhoea and cerebral spinal fluid.

Ossicular trauma

Ossicles, ossicular chain, malleus, incus and stapes were searched against, individually: trauma, fracture, dislocation, conductive hearing loss, hearing loss, head injury and temporal bone fracture.

Temporal bone trauma

Temporal bone, fracture, injury, head injury, trauma, craniocerebral trauma, epidemiology, CSF leak, vertigo, imbalance, otorrhoea, perilymph, fistula, deafness, hearing loss and evaluation using the keywords ossicle, ossicle and dislocation, middle and (ear and adhesions), middle and (ear and trauma), traumatic and tympanic and (membrane and perforation).

Whiplash injuries

The same terms as were used for temporal bone trauma were searched, but adding: whiplash injuries, whiplash-related disorder, therapy, vertigo, hearing loss, physical therapy techniques, neck and rehabilitation.

Otitic barotrauma and otitic decompression illness

There are a number of different clinical conditions that are included under the umbrella term of ‘otitic barotrauma’. Each has been searched separately with the primary search terms: diving, scuba, SCUBA, diving medicine, hyperbaric medicine, decompression illness, flight, aviation and aviation medicine in all the subgroups.

External ear barotrauma (external ear squeeze, reversed ear, reverse ear squeeze)

Ear external, external ear canal, ear canal, external auditary canal and external auditary meatus were searched against the primary search terms. Specific terms: external ear barotrauma, external ear squeeze, reversed ear, reverse ear, reverse ear squeeze. Neither original research papers nor specific reviews were found.

Middle ear barotrauma (barotitis media, middle ear squeeze)

Middle ear barotrauma, barotitis media, middle ear squeeze, middle ear trauma, haemotympanum and perforation were searched against the primary search terms. This delivered several hundred results, almost all of which are review articles, adding little to the overall knowledge. Additional specific terms: prevention of middle ear barotrauma, otalgia, decongestants, pseudoephedrine, xylometazoline, oxymetazoline. This identified four randomized controlled trials.

Caloric vertigo

Caloric vertigo was searched against the primary search terms. Searches failed to reveal any reports or research specifically targeting this.

Inner ear barotrauma (compression inner ear barotrauma)

Inner ear and inner ear barotrauma were searched against the primary search terms. Specific terms: perilymphatic fistula, round and oval window fistula(e/s), fluorosceine and cochlin-tonoprotein. Numerous citations were found, including review articles, but no randomized controlled trials.

High-pressure nervous (neurological) syndrome (isobaric gas counterdiffusion)

High-pressure nervous syndrome, high-pressure neurological syndrome, isobaric gas counterdiffusion were searched against the primary search terms. Despite numerous references, very few were relevant to otology.

Alternobaric vertigo

Alternobaric vertigo, asymmetric pressure, pressure difference and differential middle ear pressure were searched against the primary search terms.

Barotraumatic facial palsy (facial baropareisis, alternobaric facial palsy)

Barotraumatic facial palsy, facial baropareisis, alternobaric facial palsy, were searched against the primary search terms. Additional searched terms included facial palsy, facial paresis, neuropraxia, nerve injury. Sporadic case reports were identified and several animal studies.

Decompression illness

For detailed accounts of the physiology and practice of decompression illnesses extensive general texts are available relating to both diving and aviation medicine. Highly recommended are: 'The physiology and medicine of diving' in *Bove and Davis' Diving medicine*[1] and *Fundamentals of aerospace medicine*.[2] Diving texts usually refer to the effect of altitude in aviation when relevant. Searches including the above terms failed to locate any randomized controlled trials. Level 1 evidence was available in both pathology and physiology studies.

Cerebral air gas embolism

Searched against primary terms also with additional search terms including: intracranial embolism, air embolism, CAGE and accidents.

AURICULAR HAEMATOMA AND ASSOCIATED INJURIES

The following are covered in this section:

- auricular haematoma (otohaematoma, haematoma auris, wrestler's ear)
- cauliflower ear (hyperchondroplasia auris traumatica)
- auricular pseudocyst (benign idiopathic cystic chondromalacia, endochondral pseudocysts).

AURICULAR HAEMATOMA

Definition

An auricular haematoma is a collection of blood occurring in the subperichondrial layer or an intracartilagenous space of the pinna.

Aetiology and natural history

The most frequent modern associations are wrestling, boxing and rugby union.[3–5] There is a very important link with non-accidental injury in children.[6, 7] Spontaneous haematomas are extremely unusual although possibly occur in patients with hypertension or with severe coagulopathies.[8, 9] Folding the helix into the concha may lead to auricular haematoma formation.[10] In the veterinary literature auricular haematoma was thought to have an autoimmune aetiology. This theory has now been discarded in favour of trauma.[11]

Auricular haematomas usually occur on the anterior (lateral) surface of the pinna. Here the skin is firmly attached to the perichondrium. The shearing of the perichondrium and an attached thin underlying cartilage layer creates a potential space, the plane of cleavage being within the cartilage itself, that is filled with blood following the rupture of small vessels[4, 12–14] (**Figure 91.1**). Any haematoma within the posterior soft tissues is readily absorbed with minimal effect on the cartilage.

Early evacuation results in good resolution with minimal cosmetic deficit. If the auricular haematoma is not removed, there is an invasion of chondroblasts into the organizing haematoma, forming granulation tissue which results in new cartilage formation.[15] As the perichondrium is the source of new cartilage growth, this occurs on the anterior surface, from the side of the separated perichondrium. Breeches in the perichondrium result in the cartilage buckling over the haematoma and causing the typical irregularities associated with a 'cauliflower ear' (see 'Caulifower ear' below).[15] Trauma to the thinned skin overlying the helix may result in infection, pain, cosmetic deformity and meatal stenosis. In the most chronic cases ossification or 'petrification' may occur between the cartilage layers resulting in a bone hard area.[16, 17]

Reports of auricular haematoma occurring in Morquio-Brailsford disease (osteochondrodystrophia deformans, mucopolysaccheridosis type IV) and Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy (SHML)) do not describe a convincing association.[18, 19]

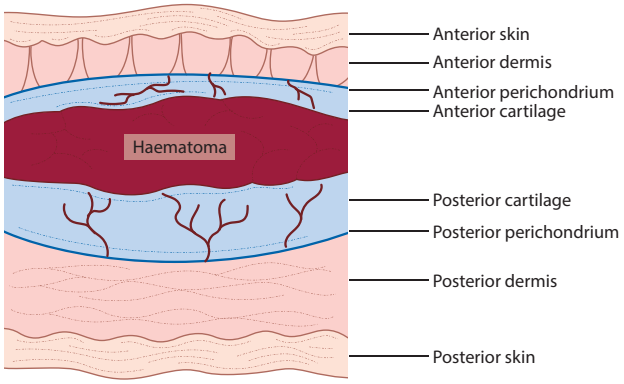

Figure 91.1 Splitting of cartilage layer by haematoma. (Modified with permission from Bull and Lancer.[12])

Figure 91.2 Recurrent auricular haematoma, previously incised and aspirated.

CAULIFLOWER EAR

Cauliflower ear is hyperplastic proliferation of the external ear cartilage following repeated episodes of trauma (typically auricular haematoma) or perichondritis from infection or other causes of inflammation. Improvement of this deformity is difficult. Specialist texts on plastic surgery to the pinna should be consulted.

AURICULAR PSEUDOCYST (BENIGN IDIOPATHIC CYSTIC CHONDROMALACIA)

Definition

An auricular pseudocyst is an intracartilaginous cystic collection, devoid of any epithelial lining, containing viscous, straw-coloured, sterile fluid, similar to an auricular haematoma in its anatomical location and its treatment. It is more often seen by dermatologists due to its association with local irritation and dermatoses.

Aetiology and natural history

Intrachondral pseudocysts are swellings of straw-coloured, slightly gelatinous fluid, high in glycosaminoglycans, occurring in cartilage spaces with no epithelial lining.[20] There is a low risk of progression to a cauliflower ear, unless acute trauma or infection intervene. They are usually located in the triangular fossa.

The pathoaetiology is thought to be a chondromalacia probably caused by repeated minor trauma, although often there is no such history. They usually occur in adult men between 30 and 40 years of age.[21] There appears to be an increased incidence in motorcycle helmet wearers but not due to a single episode of trauma.[22]

CLINICAL FEATURES OF AURICULAR HAEMATOMA AND PSEUDOCYST

Auricular haematomas present as a painful acute swelling, usually of the anterior surface of the conchal bowl, antihelix or helix. After several days the tenderness decreases leaving a non-tender, slightly fluctuant, bluish-coloured lump. Rarely, infection may intervene, particularly if associated with local cuts or abrasions. A specific history of trauma is almost always present. If this is not forthcoming, then assault and non-accidental injury must be strongly suspected. The condition is so unusual in children and so strongly associated with local trauma that, almost regardless of the alleged history, a Child Protection Team should be asked to investigate.

Auricular pseudocysts are painless and symptom-free, usually with no history of preceding trauma. Local areas of skin irritation are a frequent association.

MANAGEMENT OF AURICULAR HAEMATOMA

There are no formal comparative studies.[23] All recommendations are based on level 4 evidence.

Treatment regimens are based on the requirement to:

- evacuate the haematoma
- remove granulation tissue
- compress or obliterate the dead space to prevent reaccumulation.

Evacuation of haematoma and granulation tissue removal

ASPIRATION

Aspiration is performed under sterile conditions from the anterior surface in the area of maximum fluctuation. It may be attempted for up to 48 hours post trauma. There is, however, an apparent high recurrence rate. If aspiration has been delayed, appears incomplete or there is a recurrence, or if granulation tissue has formed, formal incision and curettage will be required.[4] A closed liposuction method has been described,[24] but the anterior and posterior approaches are both frequently used.

Anterior approach

The incisions are made along the inferior border of the helix along the scapha, in the antihelical fold, or along the conchal fold, as necessary.[3, 25] The skin and elevated periosteum and any associated anterior cartilage layer are incised along the same line. The flap is elevated, the underlying haematoma evacuated and the granulation tissue curetted off the underlying cartilage, including any damaged or necrotic cartilage. Care must be taken not to perforate the posterior skin. The flap is then returned and the incisions carefully closed (**Figure 91.3**).[4, 26] Measures to prevent reaccumulation are required.

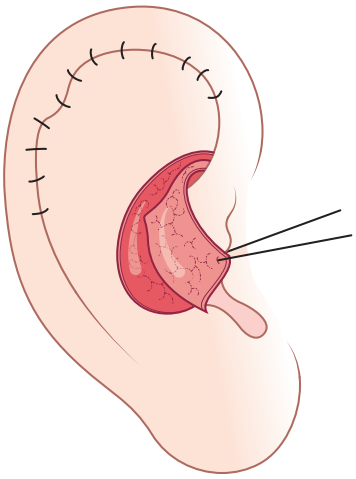

Figure 91.3 Anterior approach. (Modified with permission from Giffin.)[3]

Posterior approach

This approach is preferred in patients who wish to continue to play sport straight away and in those who already have a degree of cauliflower ear following repeated trauma. It may provide better cosmesis. An incision is made opposite the haematoma, on the posterior aspect, down to the surface of the cartilage. A 5 mm window of cartilage is removed, releasing the haematoma, taking care not to perforate the anterior skin.[27] Any granulation tissue on the anterior cartilage surface is easily curetted via this window, which may be enlarged if necessary. The incision does not require closure. Measures to prevent reaccumulation are mandatory (**Figure 91.4**).

Non-surgical methods and compression or obliteration of the dead space

Alternative methods include the injection of sclerosants, such as OK-432, steroids, streptomycin with hyaluronidase, triamcinolone or even fibrin glue, although two or three treatments per ear are often required.[28–33]

Recollection must be prevented but simple bandages and bolsters do not work well. Sutureless compression techniques include the use of moulded silicone, thermoplastic splints, swimmer's nose clip.[34–37] Suction drainage via a posterior incision or an indwelling 18-gauge catheter with a pressure dressing is an alternative.[12, 37–39] Despite their effectiveness, these drains may be accidentally removed and interfere with continuing sport. Compression suture methods with absorbable, or non-absorbable, through-and-through mattress sutures are most commonly used over bolsters and are probably the most effective (**Figure 91.5**).[40] The bolster material enables the application of even pressure to both sides. Bolsterless techniques using sutures alone, or with silicone moulds, plastic tubing or buttons on both sides are alternatives.[40–45] The author prefers using dental rolls as their sponginess enables better definition of the contours and helps to prevent overtightening of sutures. The patient may return to contact sports although a head guard to provide extra protection is advised.

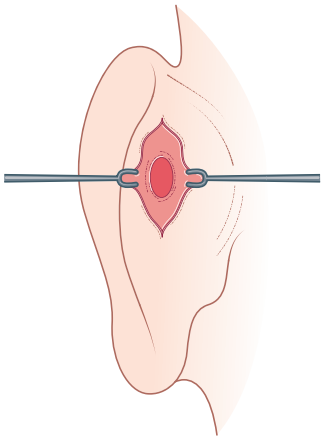

Figure 91.4 Posterior approach with cartilage window.[27]

Figure 91.5 Through-and-through sutures over bolsters (dental rolls or soft tubing).

TREATMENT OF AURICULAR PSEUDOCYST

The treatment principles are the same as above but, as there is no granulation tissue, curettage is unnecessary. Recurrence approaches 100% for simple aspiration without compression.[46, 47] A popular technique is deroofing by removal of a disc of anterior skin and the underlying perichondrium. The exposed cartilage is allowed to granulate with a bolster compressing the surrounding areas.[48] A simple method of achieving this is with a skin biopsy punch.[49] The anterior and posterior drainage techniques described above are equally applicable to auricular pseudocysts. The success of bolsterless techniques is widely described,[42, 43] and superior to sutureless compression.[50]

PREVENTION OF AURICULAR HAEMATOMA AND PSEUDOCYST

The use of headgear in wrestlers approximately halves the rate of haematomas from 52% to 26%; 10.6% of those regularly using headgear, and 26.6% of those who do not, develop them.[51]

The use of tape around the head covering both ears and/or the application of lubricants are frequent preventative measures used by rugby union players, although these measures are relatively ineffective. Wearing headgear gives a relative risk of about 0.59, demonstrating reasonably effective protection.[52]

KEY POINTS

Auricular haematoma and associated injuries

- Early haematoma evacuation is recommended.
- Curettage of granulation tissue is important if drainage is delayed.
- Whichever surgical approach is used, compression sutures are recommended.

EXTERNAL EAR CANAL TRAUMA

MILD TRAUMA

Minor bruising, lacerations or small subcutaneous haematomas are often caused by the use of cotton buds or sharp implements in an attempt to remove wax or to alleviate irritation. External ear barotrauma may cause similar injuries. Such injuries are usually inconsequential. No specific treatment is usually required; however, if there are any signs of infection, then an appropriate topical antibiotic drop should be prescribed. In those who cannot keep their ears dry for the following 14 days, prophylactic acetic acid ear drops may be used.[53, 54]

MODERATE AND SEVERE TRAUMA

Moderate or severe trauma may present with bleeding from the external meatus. A history of trauma should always be sought, especially if the patient is found unconscious. Soft-tissue lacerations may result in canal stenosis (see Chapter 77, Acquired atresia of the external ear).

Association with mandibular fractures

Ear canal bleeding with pain is a frequent presentation of temporal bone fractures and also of those of the tympanic plate associated with mandibular trauma and condyle fractures. The association of trismus with bleeding and pain is highly suggestive of such injuries.[55, 56] Mandibular trauma, particularly posterior dislocation of the condyle, may result in damage to the cartilaginous parts of the external auditory canal with laceration and bleeding and, more rarely, fracture of the tympanic plate. This may occur without an associated condylar fracture. Although the initial impression may be of an external ear canal fracture, one of the mandible must be excluded.[57] Three-dimensional CT imaging is useful in fully assessing tympanic plate fractures.[58] Extreme bleeding may indicate an associated jugular bulb tear with blood coming from either a tympanic membrane perforation or a fracture line through the temporal bone. Death may result.[59]

There are no appreciable differences in presentation, or of the features of the fractures, between adults and children.[60] The management of mandibular fractures is beyond the scope of this publication.[61]

FRACTURES OF THE EXTERNAL AUDITORY MEATUS

Temporal bone fractures, with resulting tegmen defects, may be seen as a longitudinal step defect extending medially and including the annulus. They are usually associated with a haemotympanum. A tympanic membrane perforation with ossicular disruption may coexist. Severe displaced fractures may result in herniation of brain and meninges (meningoencephalocele) into the external canal.[62, 63]

Management

As most cerebrospinal fluid (CSF) leaks close spontaneously, initial conservative management is indicated. Rarely, when they do not, surgical intervention is required, usually via a middle fossa approach. If there is a superior meatal roof defect associated with the presence of granulation or polypoid soft tissue, MRI is recommended to exclude prolapsed intracranial contents. A mastoid approach may be considered for access to the ossicles or facial nerve, in which situation the opportunity should be taken to smooth off any meatal step deformities and to reinforce or fill any wide fracture lines to prevent the potential formation of canal cholesteatoma.

Canal cholesteatoma

Trapped non-migratory keratin may result from the growth of an inclusion dermoid caused by superficial trauma or irregularities within the walls of the external canal interfering with skin migration. Trapped keratin acquires the features of tympanic cholesteatoma with local bone destruction and may erode adjacent structures.

Unlike non-traumatic cases, which are often self-limiting (see Chapter 76, Keratosis obturans, primary auditory canal cholesteatoma and benign necrotizing otitis externa), surgical intervention is usually necessary. The cholesteatoma should be removed and the canal bone smoothed, enlarging the defect as necessary to create a flat profile. An associated soft-tissue meatoplasty may also be required to aid self-cleansing. Bone pâté and thinned cartilage sheets may be used to fill bone defects, particularly if the fracture, or drilling, has resulted in a posterior canal wall defect into mastoid air cells. Such repairs should be covered with temporalis fascia or perichondrium.

KEY POINTS

External ear canal trauma

- Minor abrasions usually require no treatment.
- Blood from the external meatus requires that both temporal bone and mandibular fractures are excluded.
- If a fracture is suspected, any meatal soft tissue should be left alone pending imaging to exclude herniation of brain/meninges.

FOREIGN BODY TRAUMA

Foreign body trauma is covered elsewhere in this volume (see Chapter 34, Foreign bodies in the ear, nose and throat).

TRAUMATIC TYMPANIC MEMBRANE PERFORATIONS

Tympanic membrane perforations may occur as the result of a pressure wave in the external ear canal, or by direct penetration. About 50% are attributable to slap injuries or direct blows. Self-inflicted penetrating injuries account for about 25%, with 25% being due to causes that include diving and aviation barotrauma, foreign bodies such as button batteries, other caustic substances, insects, welding debris and blast injury. Associated tinnitus and vertigo have been reported in 30.8% and 8.1%, respectively, but only in 2.0% and 0% during follow-up.[64]

TYMPANIC MEMBRANE PERFORATION AS A MARKER OF PRIMARY BLAST INJURY

Primary blast injury (PBI) is defined as: 'A combination of tympanic membrane perforation, pneumothorax, pulmonary contusion, non-penetrating facial sinus injury and bowel perforation'. The presence of tympanic membrane perforation has been considered a significant predictor of PBI. A study of US soldiers demonstrated, unexpectedly, that only 16% of all blast exposure patients had perforations, 50% of these being bilateral. Only 7% of blast injuries had PBI and only half of these had tympanic membrane perforations. Therefore, the presence of a perforation would appear to be a poor predictor of PBI.[65]

TYMPANIC MEMBRANE PERFORATION AS A MARKER OF CONCUSSIVE HEAD INJURY

The presence of a perforated tympanic membrane, from head trauma, is a strong predictor for concussive head injury. The relative risk appears to be about 2.76.[66]

CAUSTIC PERFORATION

The most common cause of caustic membrane perforation is button batteries in children. There were an estimated 3748 battery-related emergency department visits among children in the USA between 1990 and 2000.[67] This may be a presentation of non-accidental injury.[68] Electrical shorting between the battery terminals from mucosal contact, and possibly cerumen, causes battery leakage. The battery may become corroded at the crimp area, resulting in a permanent short, considerably speeding up the leakage and consequent trauma. Severe burns may result. Ear drops act as an electrolyte, rapidly enhancing the process, and therefore must not be used.[70] Local inflammation and erosion may extend into surrounding structures and cause deafness, facial palsy, meatal stenosis and even death.[68, 71] As these complications may occur quickly, removal of the button battery, thorough irrigation of the meatus with sterile water and any necessary debridement, should be performed urgently.

Damage from button batteries can occur quickly and they should be removed as a matter of urgency. The reader is referred to the section entitled 'Batteries and magnets' in Chapter 34, Foreign bodies in the ear, nose and throat.

CLINICAL ASPECTS

A careful history of the trauma modality is required, with attention given to concomitant injuries such as those associated with penetrating injury, temporal bone fractures, blast injury and lightening strike. Examination should include the pinna and canal, with microscopy as necessary. Microsuction may be required to observe the tympanic membrane in detail.

Injuries range from mild injection of the vessels over the malleus handle, to actual perforation. These changes may be classified in the same way as those resulting from barotrauma (see **Table 91.8** below). CSF otorrhoea requires exclusion.

Any foreign body should be removed. If a general anaesthetic is necessary, the opportunity should be taken to apply cigarette paper or absorbable gelatin sponge to any perforation. Infections should be treated with aural toilet and topical quinolone antibiotic drops. In the outpatient situation, if the patient is tolerant, clearance of blood, wax and keratin debris by microsuction is appropriate. Application of a paper patch or absorbable sponge is straightforward with the aim of speeding up spontaneous healing. In the intolerant patient, when no foreign body is present, no active treatment is appropriate.

A 3-month interval should pass before considering a formal repair as early surgery may have worse outcomes than conservative treatment or paper patches.[72] A reasonable exception to this policy might be when a quick, strong repair is desirable, such as in elite water sport athletes or commercial divers.

PROGNOSIS

Spontaneous resolution rates are high, typically 80–94%. Poorer outcomes are observed with increasing age and perforation size[73, 74] and are significantly lower in blast injury.[75] The worst follow welding injuries.[64]

Large studies have shown that the mean time for spontaneous healing is about 1 month, and a majority will have healed within 3 months. A slower speed of healing occurs if there is a middle ear infection. The site of the perforation is, however, insignificant. Penetrating injuries, and a

history of ear syringing post trauma, are the only risk factors important in predicting non-healing.[76, 77]

Office treatments, such as paper or gelfoam patches, are unlikely to increase the likelihood of healing but increase the speed of healing by up to 17 days (28.2±3.6 days in the spontaneous healing group 11.1±2.1 days, $p = 0.0017$ for sponge patching).[78] The biocompatibility, and lack of tissue toxicity, of cigarette papers has been validated.[79] There appears to be no extra advantage in formally repairing in the acute stage (12.5±1.9 days),[80] with no advantage in painstakingly aligning the perforation edges.[81, 82] Small underpowered studies of new interventions, such as the application of epidermal growth factor or hyaluronic acid, may enhance the rapidity of healing but not the chance of healing.[83, 84] Nanofibrillar patches, similar in structure to spiders' webs, have also given promising results.[85]

KEY POINTS

Traumatic tympanic membrane perforations

- Caustic substances, particularly batteries, should be removed straight away.
- No liquid, including drops, should be administered if a battery is present.
- Primary blast injury is a clinical condition whose definition includes tympanic membrane perforation, but this is a poor predictor for the condition.
- Tympanic membrane perforation is a good predictor for concussive head injury.
- Application of a cigarette paper patch or gelfoam increases speed of healing but not the likelihood.
- Surgical repair is only indicated after 3 months as over 80% of perforations heal spontaneously.

OSSICULAR TRAUMA

Most ossicular injuries are dislocations that are identifiable radiologically.[86] Any of the joints may be affected but dislocation of the incus is the most frequent (**Figure 91.6**; **Table 91.1**).[87–90] This may simply be disruption of the incudostapedial joint with minimal incus displacement, although with more severe trauma there may be complete separation.[91] Dislocation out into the ear canal may be associated with a tegmen fracture.[92]

Fractures of the ossicles are much less frequent,[86] being mostly of the incus long process.[93] Studies of cadavers following severe head injuries have noted a variety of damage that includes disconnection of the malleoincudal or incudostapedial joints and fractures of the malleus or stapes.[94] The malleus handle may be fractured, particularly in cases of middle ear barotrauma.[95, 96] Complete malleus dislocation has also been described.[88] Isolated fracture dislocation of the stapes footplate is very rare[97] and almost always the result of penetrating injuries, with associated pneumolabyrinth and perilymphatic fistula.[98] Trauma to the stapes may result in fracture of the arch,[88, 91, 93] or dislocation of the whole stapes.[99] In some cases, a combination of these lesions may be found and there may also be fractures of the bony external auditory meatus or fixation of the incus and/or malleus.[93, 100] Ossicular disruption following trauma may occur without perforation of the tympanic membrane.[101]

TRAUMA MODALITIES

Skull trauma from blows to the temporal, parietal or occipital region (with or without fracture of the temporal bone)

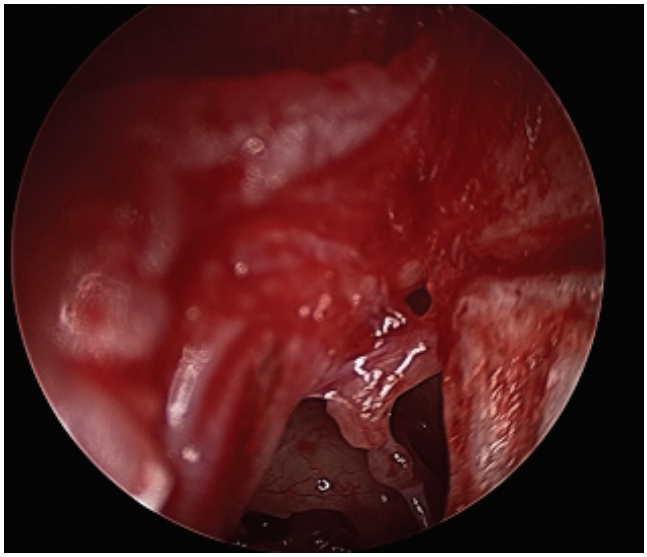

Figure 91.6 Dislocated incus; showing adjacent canal fracture.

is the main cause; other modes of injury are rare.[102] About 60% occur without a concomitant temporal bone fracture.[101] Hearing loss occurs in about 22.5% of temporal bone fractures.[103] Around 16–30% of these have a conductive component, of which some will be due to transient causes such as a haemotympanum.[103, 104] Direct penetrating trauma is less common[105, 106] and may be iatrogenic as a result of intratympanic injections, particularly if there has been previous middle ear surgery or stapedectomy.[107] Other causes include middle ear barotrauma, surgical trauma and lightening strike.[108] Several large studies identify similar aetiologies. Drill-induced trauma to the incus during tympanomastoid surgery usually causes incudostapedial joint dislocation and a corresponding conductive hearing loss. Permanent sensorineural hearing loss is also highly likely in this situation but prophylactic disarticulation of the incus does not protect against it in a standardized guinea pig model.[109] Simple manipulation of the ossicles during surgery should, however, not result in a sensorineural deficit.[110] Digital pressure applied to the external auditary meatus may result in a sudden pressure change resulting in an isolated malleus fracture.[96] A comprehensive forensic post-mortem study looking at head injury victims using multislice CT methods suggests that the type of energy imparted is more important than simply the amount.[111] Damage to the ossicular chain may also occur secondary to osteoradionecrosis.[112] Congenital incus dislocation has also been described.[113]

DIAGNOSIS

A conductive component to the hearing loss following trauma of any sort should alert the surgeon to the possibility of ossicular injury. It may be difficult to diagnose ossicular disruptions that occur without perforation of the tympanic membrane, or once it has healed. Once acute sequelae, such as a haemotympanum, have resolved, further evaluation is necessary. Patients may present at variable times after the traumatic event, sometimes many years later.

INVESTIGATIONS

An initial audiometric assessment should be performed as soon as is practical after the injury. The initial conductive loss is often due to a haemotympanum or tympanic membrane perforation. A concomitant sensorineural loss may partially resolve (cochlear concussion). Rarely, however, audiometry may be normal,[114] or become so following healing despite a lack of reduction of the dislocation or fracture.[115] Any haemotympanum should be allowed to clear and time given for natural healing processes to take place before repeating the audiometric assessment, as excellent spontaneous hearing resolution may take place.[115] A varying degree of conductive impairment may therefore be present, often accompanied by a high-frequency impairment due to cochlear trauma. A tympanogram may show unusually high compliance, with a high peaked type A_D tympanogram, although this may occur in normal ears.

High-resolution CT is the imaging of choice for investigating ossicular trauma. Both axial and coronal images are needed for the evaluation of fractures and dislocations of all three ossicles. Reformated images are useful.[86] Three-dimensional CT imaging gives better information about the spacial orientation of the ossicles,[101] but virtual endoscopy enables even more of the ossicular chain to be seen, particularly the stapes crura.[116] This technique has given excellent predictive results of 100% in a small series of 17 patients.[117]

MANAGEMENT

Conservative management

Since surprisingly good hearing recovery may take place with fibrous healing when the incudostapedial joint is disrupted, even if the incus is entirely displaced,[115] a 3-month period is recommended prior to surgical exploration. Those patients who do not wish to undergo surgery should be offered aiding. Results from ossiculoplasty are inversely related to the degree of ossicular disruption. Coexisting sensorineural losses with major ossicular disruption may make surgical intervention unjustifiable, particularly if there is normal hearing in the contralateral ear. Detailed CT scanning is therefore recommended to aid this decision. Before undertaking surgery for a unilateral conductive deficit, consideration should be given to the likelihood of an adequate surgical result providing true benefit.[118] An exception may be when the air conduction thresholds in a mixed loss are sufficiently high that aiding would give poor results. In such cases, provided speech discrimination is adequately preserved, ossiculoplasty with the intention to aid post-operatively is a justifiable approach ('surgery for aiding').

Surgery

After elevating the tympanic membrane, identification of the nature and exact location of the ossicular injury is essential. After major trauma there is usually little doubt, although minor dislocations and fractures may be difficult to locate with confidence. A methodical process should be used whereby the malleus, incus and stapes head are palpated in turn while carefully watching the stapes footplate under high power. The impression of a lag, or failed transmission of movement, is indicative of the site of injury. Adhesions may be present around the specific site of injury. Watching the stapes superstructure rather than the footplate may result in missing subtle crural fractures. Delay in operating makes little difference to the long-term results.[119]

Since 1957 many surgical techniques have been described.[88] The displaced incus may be replaced by any standard ossiculoplasty method (see Chapter 85, Ossiculoplasty). Fixing it in its anatomical position via a posterior attic approach, combined with a tympanotomy, may be very successful.[120] Good results have been

described for the repair of simple incudostapedial subluxation with cartilage tip interposition, cement[121] or cyanoacrylate glue.[122, 123] Disappointing results using incus tip techniques may occur due to an unrecognized subluxation of the malleoincudal joint. Such cases may be identified at revision surgery where consideration should be given to an incus replacement technique. Cartilage repair of an isolated malleus fracture is straightforward and should give good results.[124] In cases of isolated stapes crural fractures, a strut or piston may be placed between the incus and footpate.[88, 93] A laser stapedotomy technique, however, gives more stability and is also useful for cases of stapes luxation.

RESULTS

There are no published randomized controlled trials (RCTs) addressing any aspect of ossicular chain trauma surgery. Numerous publications give the results of small series of specific interventions, or larger ones giving their overall results. The larger series available are presented in Table 91.2. These all include cases with a range of middle ear pathology and treatments, resulting in small numbers and therefore making conclusions difficult. Physiological repositioning of the incus has been described in several small series as giving the most impressive results,[91, 93, 120] the transmastoid posterior attic approach achieving the best.[120] Conventional ossiculoplasty techniques should give better results when performed for trauma than chronic suppurative otitis media in that there is usually no associated middle ear pathology and Eustachian function is normal. Soft-tissue adhesions within the middle ear and attic may compromise the outcome of treatment.[120] Cases with a greater degree of damage to the middle ear structures represent a greater reconstructive challenge than those with isolated incus dislocation.

TABLE 91.2 Hearing results (case series only)

Author(s)	Year	Ears	Technique(s)	Air–bone gap<10dB post-operatively (%)

			Ossiculoplasty	25
			Overall	54

KEY POINTS

Ossicular trauma

- A variety of fracture/dislocation combinations is possible.
- The tympanic membrane may be intact.
- A conductive hearing impairment that persists following head trauma is most likely to be due to incus dislocation (62%).
- High-definition 3D CT scanning, or CT virtual endoscopy, is helpful in establishing the diagnosis.
- The cause may only be definitively determined by exploratory tympanotomy.
- The results of reconstructive surgery are generally better than those obtained in chronic suppurative otitis media, as the middle ear space is healthy.

TEMPORAL BONE TRAUMA

EPIDEMIOLOGY/AETIOLOGY

The overall incidence of temporal bone injuries is not determinable, and that reported for fractures varies widely. One estimate is that 8.5/100 people have either lost consciousness or suffered temporary confusion as a result of a head injury.[125] Blunt trauma to the temporal bone is much more frequent than penetrating injury. Skull base fractures occur in 3–30% of head injury attendances to Emergency Departments, 9–40% of these having temporal bone fractures.[126–128] About 7.9% are bilateral.[129] Men in their late twenties and early thirties predominate (male : female 2.8–4 : 1).[127, 129–131] Temporal bone trauma without fracture has similar aetiologies. Road traffic accidents probably account for about 50%, other frequent causes being falls (16–40%), assaults (10-37%) and, in the US, gunshot wounds (3–30%).[132–134] The profile may be different where medicolegal proceedings are taking place, when as many as 45% of cases may be due to work related injury.[131]

About 15% occur in children (males : females 2 : 1), the peak incidence being at approximately 5 years of age. Falls from a height predominate as the cause (40%) in children, with road traffic accidents accounting for only 34%.[60]

INNER EAR TRAUMA WITHOUT TEMPORAL BONE FRACTURE

Inner ear concussion (labyrinthine concussion, cochlear concussion, inner ear concussive syndrome) and mild traumatic brain injury

'Concussion' describes a temporary unconsciousness or confusion, with other symptoms, caused by a blow to the head. The term is often used synonymously with mild traumatic brain injury. This has been defined as: 'A traumatically induced physiological disruption of brain function

characterized by brief loss of consciousness (30 minutes or less), any alteration in mental state at the time of accident, anterograde or retrograde amnesia, negative neuroimaging [CT], Glasgow Coma Scale [GCS] score of 13–15 and post traumatic amnesia of not more than 24 hours'.[135, 136] The terms 'mild' and 'minor' are often used interchangeably although minor head injury is sometimes used to indicate extremely mild injuries in patients with an initial GCS of 15.

Head injuries account for about 1.4 million Emergency Department attendances per annum in the UK, approximately 90% of all traumatic brain injury being classified as mild. About 80% are discharged directly from the Emergency Department.[137] Although CT scans may be normal, MRI scanning has demonstrated a high incidence of parenchymal injury even when the GCS was as high as 14.[136, 138]

HEARING LOSS

About 52% of patients suffering from mild traumatic brain injury experience a subjective short-term transient hearing loss for several hours to 2 days immediately after the trauma.[139] Despite this, several studies have found no evidence of permanent hearing loss, as measured by pure-tone audiometry.[149, 150] More detailed audiometric evaluation has, however, suggested abnormal amplitude differences of transiently evoked otoacoustic emissions and absent stapedial reflexes in 12/31 patients.[139] Despite the implication that almost all concussive symptoms and signs recover, any associated hearing losses may very rarely be permanent even in those whose other symptoms have resolved.[131, 141] Histological analysis has demonstrated microfractures involving the otic capsule when imaging has been negative, suggesting an explanation for this.[141] No accounts of hearing loss, without dizziness, could be found.

A study of 100 consecutive head injury patients found 44% of those with mild traumatic brain injury to have auditory symptoms; this figure increased to 75% in the moderate/severe brain injury group. In both groups, about 75% of patients were found to have measurable vestibular abnormalities. Those few patients having a conductive loss all had a sensorineural component. Auditory abnormalities were shown to increase with the severity of the head injury whereas vestibular abnormalities were no more frequent in those with more severe injuries.[131]

TINNITUS AND HYPERACUSIS

Fifty-three percent of all patients suffering from traumatic brain injury develop tinnitus, particularly following trauma directly to the ear. Hyperacusis occurs to some degree in 87%. These symptoms may be due to direct cochlear injury, trauma to the auditory nerve and to brain parenchyma. Tinnitus and hyperacusis may be present in as many as 21% of those injuries where there is no measured hearing loss.[131, 142]

DIZZINESS AND VERTIGO

Dizziness may be described within four categories: vertigo, pre-syncopal light-headedness, multisensory dizziness, and psychophysiologic dizziness. Of these, only the symptom of vertigo may be clearly linked to the vestibular system.[143] This affects about 24% of patients with mild traumatic brain injury.[134] Possible specific sites of injury include the vestibular nuclei, the labyrinth or the upper cervical spine.[144, 145] Symptoms almost always resolve within 10 days.[146]

MANAGEMENT

A careful history, with particular reference to witnesses, is important in determining the modality and severity of any head injury. The initial assessment and investigations are in the domain of the emergency physician and, as necessary, the neurology and neurosurgical teams. The evaluation should, however, include a full neuro-otological examination. A policy of no active treatment for an isolated sensorineural hearing loss is appropriate. In patients with vertigo, undefined dizziness and tinnitus, CT of the temporal bones is indicated. Bed rest, head elevation and avoidance of straining are advised. A diagnosis of perilymphatic fistula should be considered (see below). Other causes of sensorineural loss, which may be coincident, may require exclusion with MRI.

No studies have specifically addressed the use of steroids although, given the likely aetiological factors of shear, microfractures and the assumed consequent inflammation, their use in cases of mild traumatic brain injury and cochlear concussion might seem persuasive. Large RCTs have not, however, found any benefit for the overall outcome with steroid treatment in any level of traumatic brain injury.[147]

Audiovestibular symptoms with or without hearing loss are a major component of traumatic brain injuries. A full range of supportive and rehabilitative measures should be provided, including hearing aids, vestibular rehabilitation, tinnitus and hearing therapy as well as general psychosocial rehablitation.[148] The evidence for psychogenic causes for audiovestibular symptoms is weak.[131]

PROGNOSIS

During the first week following their injury most patients report a range of symptoms that include headaches, dizziness, fatigue, memory deficits, anxiety and depression.[149] Up to 40% of patients have persistent residual symptoms one year later.[150, 151] Those with three or more symptoms beyond 3 months are defined as having postconcussive syndrome.[152] There is some evidence to suggest that there is the rare occurrence of a progressive hearing loss. This may be immunologically mediated via the HSP 70 antigen.[153]

Perilymphatic fistula

Rupture of the round or oval windows may occur with or without a temporal bone fracture. The management is as for other causes of perilymphatic fistulae (see 'Inner ear barotrauma' below).

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) is the most common cause of vertigo post trauma, affecting 61% of the

patients who consult for persistent symptoms.[131] In a large retrospective study, 67% required multiple repositioning manoeuvres in the post-traumatic group compared to only 14% in the idiopathic.[154] It has been hypothesized that this worse prognosis may be due to an increased incidence of bilateral involvement and the occurrence of additional labyrinthine injuries, such as microscopic haemorrhages or tissue shearing[154, 155] (see also Chapter 64, Benign paroxysmal positional vertigo).

Delayed endolymphatic hydrops (post-traumatic Ménière's syndrome, secondary Ménière's disease)

Symptom combinations indistinguishable from Ménière's disease, either in the same or the contralateral ear, may develop some years after the initial onset of a sensorineural hearing loss following trauma of almost any sort, including acoustic trauma, head injury with and without fracture, infectious sequelae of measles, mumps and syphilis, and acoustic trauma.[156–158] Symptoms may also develop following surgical trauma, particularly stapes (and historically fenestration) surgery.[159] The prevalence is uncertain but it would appear to be uncommon. One study of patients with endolymphatic hydrops found a history of trauma in 5/31 patients (16%) including in contralateral ears.[157] The management of this condition should be as for idiopathic Ménières disease (see Chapter 63, Ménière's disease).

KEY POINTS

Mild traumatic brain injury

- Around 90% of traumatic brain injury is classified as mild.
- About 52% with mild traumatic brain injury have subjective hearing loss.
- Persistent measurable hearing loss is very rare.
- Tinnitus and hyperacusis may occur without hearing loss.
- Around 24% have dizziness or vertigo that has usually resolved within 10 days.
- Benign paroxysmal positional vertigo (BPPV) is the most common vestibular condition but it may be more resistant to repositioning manoeuvres than the idiopathic type.
- Perilymphatic fistula is a rare consequence.
- Clinical features of endolymphatic hydrops may occur in both the affected or contralateral ear many years later.

EAR TRAUMA WITH TEMPORAL BONE FRACTURE

Classification

The most commonly used system classifies temporal bone fractures according to their orientation relative to the axis of the petrous ridge: longitudinal or transverse.[160, 161] Most series describe 80–90% of fractures as longitudinal and 10–20% as transverse.[133] Although a convenient system, it has not been proven to correlate well with clinical signs or outcomes. Fractures have been found to be randomly placed or comminuted, and they are often not adequately described by the traditional classification.[162] True longitudinal fractures are uncommon so alternative classifications attempt to include oblique and complex fracture orientations.[91, 163]

An alternative system considering fractures as otic capsule violating or sparing is becoming more widely adopted.[60, 126, 132] This system emphasizes the structures involved rather than simply describe the fracture orientation.[127] Otic capsule fractures are associated with an increased incidence of serious sequelae.[126] Facial nerve paralysis, CSF leak and profound hearing loss were twice, four times and seven times, respectively, more likely in otic capsule violated cases. Some caution is, however, required as others have found no statistical difference using this differentiation.[127, 129] An attractive approach is simply to differentiate between petrous and non-petrous fractures. In one study CSF leak was only 1.1 times more common in transverse than in longitudinal fractures but was 9.8 times more common in petrous than in non-petrous fractures. Facial nerve injury is also more strongly correlated with fractures through the petrous temporal bone than with other fracture types. Sensorineural hearing loss did not correlate with the transverse fracture classification but was significantly more prevalent in petrous fractures.[164]

No convincing new classification system has evolved that repeatedly achieves reliable reproducibility to justify standard adoption. Therefore, a more descriptive strategy is suggested where the clinician combines the classifications by describing the fracture both in terms of its predominant orientation and whether it involves the petrous bone, otic capsule and brain parenchyma.

Temporal bone fractures in children

In children there is a relative increase in transverse fractures with 59% being longitudinal and 41% transverse.[60] This may be due to the different stress and resistance lines in the paediatric skull as a result of non-fused sutures and different bone density.

Clinical features of temporal bone fractures

HEARING LOSS

Any pattern of loss – immediate, delayed, transient, permanent or progressive – may be seen in cases of temporal bone fracture.[133] A conductive hearing loss of greater than 20 dBHL is likely to occur in two-thirds of patients tested within 72 hours of injury, with 17% persisting 6 weeks afterwards.[165] The management of conductive injuries is discussed above (see 'Ossicular trauma'). Although a persistent hearing loss is rare in cases of mild head injury, a sensorineural loss is often found in patients who have sustained a temporal bone fracture. The affected frequencies are usually at 4 kHz and higher.[131, 140] The degree of hearing loss is proportional to the degree of head injury.[130]

Complete loss of hearing in the affected ear is reported in about 17% of patients with a fracture.[165] Tinnitus and hyperacusis are frequent symptoms, and their management should be supportive.[131]

SYMPATHETIC HEARING LOSS

A delayed and progressive loss, without vestibular symptoms, may occur many months or years following the injury. It is thought to occur in 1–11% of ears following temporal bone fracture and to be immunologically mediated.[166] Similar occurrences have been identified after revision stapes surgery,[167] and vestibular schwannoma surgery.[168] Exposure of antigens from traumatized cochleovestibular membranes is thought to lead to immune sensitization and hence an attack on the contralateral ear. The same mechanism has been hypothesized as the cause of delayed progressive hearing losses occurring in the injured ear.[169] Animal studies have supported this mechanism.[170, 171]

VERTIGO

Similar rates of post-traumatic dizziness occur following severe temporal bone trauma and after minor head injuries. It occurs in at least three-quarters of cases.[131] Where the petrous bone/otic capsule are spared then a mechanism of vestibular concussion is thought to occur and resolution should be relatively fast, taking a matter of days.[146] This is unlike the destructive process with fractures through the otic capsule where resolution as a result of central adaptation may take up to 12 months.[133]

Clinical examination

A complete neuro-otological examination should be performed including a conscious state assessment (Glasgow Coma Scale), and examination of the cranium looking for evidence of penetrating injury, lacerations and mastoid bruising (Battle's sign) indicative of a skull base fracture. The absence of external injuries, particularly soon after the injury, does not preclude an underlying fracture. Cranial nerve examination is mandatory, with particular reference to facial nerve function. Examination of the neck, and the rest of the body, should be performed in conjunction with emergency physicians as appropriate. Tuning fork tests may be useful until formal audiometry is practical. Clinical tests of balance, gait and cerebellar function should be performed as soon as the patient's general state permits.

Otoscopic examination may reveal cerumen, blood, oedema, a canal step fracture, CSF, haemotympanum and tympanic membrane perforation. A good view may be difficult to obtain. Syringing and irrigation methods of cleaning are contraindicated due to the risk of ascending infection via open fractures and tympanic membrane perforations. Microsuction is rarely useful in the early stages of management; imaging usually gives sufficient information for the necessary decision-making. It is, however, indicated if infection is observed in the meatus. CT images should be available enabling any risk to be evaluated. Any soft tissue encountered should be left alone. Packing the meatus should be performed only in cases of uncontrolled haemorrhage. If this is required, a pack without a radio-opaque marker should be used to prevent interference with subsequent imaging.

Investigations

IMAGING

High-definition CT scanning is the investigation of choice. Better CT technology will increase the diagnostic rates of both temporal bone trauma with fracture[172] and mild traumatic brain injury, where a negative CT scan forms part of the diagnostic criteria.[135] It is the recommended initial investigation for the evaluation of all head injuries in patients with a Glasgow Coma Scale score of 14 or less.[173] If available, a high-definition temporal bone scan should be obtained straight away as part of the brain scan evaluation, particularly if temporal bone trauma is suspected; if not, then scan as soon as is practicable. Where hearing loss or vertigo is evident, but with no fracture demonstrated on CT, T1-weighted MRI may demonstrate a hyperintense signal in the labyrinth indicative of haemorrhage,[174] and may also identify temporal lobe contusion.[175] In the recovery phase labyrinthine enhancement may also be seen on MRI suggestive of an inflammatory process.[172] Targeted imaging may be necessary to examine specific injured structures, such as gadolinium-enhanced MRI of the facial nerve, or angiography for vascular injury. Despite CT findings, patient management is primarily guided by symptoms and clinical signs.[176]

HEARING ASSESSMENT

Clinical speech and whisper tests and tuning fork tests give useful initial hearing information long before the patient is sufficiently well to undergo formal audiometry. Early baseline audiometry is useful so that subsequent progress or deterioration may be monitored. In cases of bilateral temporal bone fracture, urgent hearing assessment is indicated and an audiometer should be taken to the bedside if necessary. Formal audiometry 6 weeks following temporal bone injury usually allows sufficient time for a haemotympanum to resolve, enabling assessment of residual conductive and sensorineural deficits.

Tympanometry will assist in determining the role of middle ear fluid in any conductive impairment. Rarely, evoked response audiometry may be useful in unconscious patients or children.

VESTIBULAR ASSESSMENT

Following head injury of any type, dizziness is a predominant, but often non-specific, symptom.[143] The presence of nystagmus may provide evidence of vestibular involvement although the observed movements may be complex if there is cerebellar trauma (see Chapters 49, Physiology of equilibrium and Chapter 62, Evaluation of balance). The typical finding of a horizontal nystagmus may be observed

with the fast phase directed away from the side with the failed labyrinth. Gait testing, augmented by other clinical tests such as Romberg and Unterberger tests, is useful, particularly in documenting resolution.

Caloric testing and other electro- or videonystagmographic tests seldom influence management, but they may be important during recovery to document the extent of any deficit and to objectively document progress or deterioration, particularly in the context of ongoing medicolegal proceedings.[177]

Treatment

ACUTE GENERAL

The general management of head trauma is outside the clinical domain of the otolaryngologist. A team approach is, however, indicated.

ACUTE SPECIFIC

Steroids

Despite widespread use for otological indications, such as sudden acute idiopathic sensorineural hearing loss, there are no convincing data suggesting benefit from the use of systemic steroids.[178] The use of intratympanic steroids has attracted much recent interest and may achieve better results (see Chapter 60, Idiopathic sudden sensorineural hearing loss). These techniques are unlikely to be applicable in the acute phase following temporal bone fracture for both practical reasons and the presence of a haemotympanum. Large randomized controlled studies have demonstrated no benefits with the use of steroids in overall outcome when used in the acute setting, even finding a very significant increase in mortality in more serious cases of traumatic brain injury.[147, 173] In view of this there is no justification for their routine use.

Antibiotics

Meningitis complicates about 2% of skull base fractures.[179] The routine use of prophylactic antibiotics confers no benefit with respect to: frequency of meningitis (even in patients with a CSF leak), all-cause mortality, meningitis-related mortality, or the need for surgical correction in patients with CSF leakage.[180]

MEDIUM AND LONG TERM

The management of any conductive loss is discussed above. Persistent mild to moderate hearing losses may be fitted with conventional air-conduction aids. Unilateral profound losses may benefit from a CROS or bone-anchored hearing aid with the aim of counteracting the head-shadow effect, convincingly improving hearing in noise performance.[181] Improvements in directional discrimination have, however, proved disappointing,[182, 183] although even in the elderly 65% satisfaction was evident.[184] Cochlear implantation in such cases may soon be shown to provide the best results, although availability and funding issues may prevent it.[185] If disabling tinnitus persists, implantation may be the treatment of choice.[186] MRI, as well as promontory stimulation testing, are necessary to check the integrity of the VIIIth nerve components if no hearing is elicited. CT scans should also be examined to check the integrity of the cochlea for implantation.

Regular monitoring of patients with progressive losses is important as an obliterative labyrinthine process may compromise successful implantation in the future. If there is a significant delay between the time of the injury and that of implant surgery, repeat imaging is essential preoperatively to rule out labyrinthitis ossificans or other structural abnormalities that may prevent successful electrode insertion.[187]

In patients with bilateral otic capsule fractures, and profound bilateral deafness, bilateral implantation is indicated as soon as the patient is sufficiently well to undergo confirmatory hearing tests and to tolerate general anaesthesia.[188, 189] If returning function in one or both ears is suspected, the worse ear should be implanted and the other carefully monitored. This ear may then be implanted if subsequent deterioration is observed. Implantation provides good rehabilitation results although persistent facial nerve stimulation secondary to electrical leakage through fracture lines occasionally causes difficulties.[190]

The management of tinnitus and vestibular symptoms should be managed as for temporal bone trauma without fracture (see above).

KEY POINTS

Temporal bone fracture

- Descriptions of fractures as longitudinal or transverse have a poor correlation with actual fracture orientation or clinical features.
- Fractures in children are more likely to be transverse.
- All patterns of hearing loss are possible.
- The absence of external injuries does not preclude an underlying skull base fracture.
- Ear syringing is contraindicated as it risks ascending infection.
- High-definition CT is the investigation of choice.
- MRI is indicated if neurological or vascular injury is suspected.
- Use of steroids may increase mortality.
- There is no evidence of any benefit conferred by the routine use of antibiotics.
- In cases of complete hearing loss, cochlear implantation should be performed as soon as possible before intracochlear fibrosis or calcification preclude effective electrode placement.

Complications of temporal bone fracture

FACIAL PALSY

Facial nerve palsy complicates about 7% of temporal bone fractures, dependimg on the type of trauma and fracture pattern.[191] Penetrating trauma has a higher incidence of about 52%.[192] Facial nerve injuries occur in 10–25% of longitudinal fractures, in 38–50% of transverse,[133] and are more common with otic capsule violating fractures.[191] Sixty-six percent of fractures are located at the geniculate

ganglion, 20% at the second genu, 8% in the tympanic segment and 6% in the mastoid portion. Six percent of geniculate ganglion lesions exhibited a second site of trauma in the mastoid portion.[193]

Clinical issues

It is important to ascertain whether the onset of the facial palsy was immediate or delayed and if partial or complete. These details are often unclear due to other potentially life-threatening issues (e.g. a palsy may not be noticed in ventilated patients). The implication of an immediate palsy is that the nerve has been directly traumatized, impinged or perhaps transacted. Delayed onset, even if only by a few minutes, and any residual function, imply neural continuity. Those cases where time of onset cannot be ascertained are best considered as immediate onset.[191]

Investigation

An excellent prognosis for recovery exists in cases of partial or delayed facial nerve palsy. Elecrophysiological testing is only necessary in cases of immediate complete palsy or in those cases of complete paralysis, with an uncertain history, that were thought to have been of delayed onset but have failed to improve. The timing of electrophysiological investigations remains controversial (see Chapter 112, The facial nerve and its non-neoplastic disorders). Most protocols are derived from studies performed on patients with idiopathic, Bell's palsy. Electroneuronography performed at about 10 days post injury is advocated but in patients with severe trauma this is usually not practical.[193] If it shows no response, electromyography is indicated. There is an established standard whereby good recovery of facial function is expected if the decline in the compound action potential on electroneuronography does not reach 90%. Although this seems to have evolved into a treatment threshold, 67% of patients who reach this level of degeneration also have excellent outcomes. A comparative study between idiopathic and traumatic facial palsies only demonstrated the importance of the 90% threshold in the idiopathic group.[194]

High-definition CT should have been performed in all patients as part of the head injury assessment. In cases of complete facial palsy contrast MRI may identify the main location of injury. This may be particularly useful if there is a comminuted or double fracture, or if no fracture is seen to be in the vicinity of the nerve on CT.[195]

Treatment

There is no evidence that any intervention for incomplete palsies gives superior results to no treatment. All of these patients are expected to make a complete, or almost complete, recovery (House–Brackmann I or II).[126, 191]

Steroids Systemic steroid treatment is usual for both delayed and immediate cases of facial palsy despite there being no controlled studies specifically examining their use in this setting. As they improve the degree of recovery and reduce synkinesis in Bell's palsy, without evidence of harm,[196] until there is evidence to the contrary, their use may be justified although the degree of coexisting traumatic brain injury takes priority. This often precludes the use of steroids as their use increases mortality.[147] There is no comparative study examining the optimum dose nor duration of treatment. An appropriate dosing regimen is 1 mg per kg per day of prednisolone, or equivalent, for 1–3 weeks, with a taper for longer courses.[133]

Surgical decompression The role and timing of surgery remains controversial. There are no RCTs to assist decision-making and no direct comparisons of treatment versus no treatment. Studies have not convincingly made the case for surgery. Complete nerve transection that cannot spontaneously recover accounts for about 14% of cases[193] and complete, immediate palsies, treated conservatively, may expect a 50% chance of complete or near-complete recovery without surgery.[191] A standard has evolved whereby immediate palsies showing the requisite 90% degeneration on electroneuronography within 2 weeks of injury are considered for surgery. Further research is clearly required. Despite these uncertainties, early identification and repair of a transacted nerve, and decompression of a clearly impinged nerve, are appropriate. This will only be achieved if immediate, complete palsies are comprehensively investigated, differentiating them from other cases that are more likely to recover spontaneously.

KEY POINTS

Post-traumatic facial nerve palsy

- Facial palsy complicates 7% of temporal bone fractures.
- Only complete, immediate onset, palsies require electrophysiological testing.
- A finding of 90% degeneration on electroneuronography at 14 days is a commonly used standard for consideration for surgical intervention although 67% with this result have good resolution without intervention.
- With no treatment 50% of complete immediate-onset palsies achieve good recovery.
- About 100% with incomplete palsies achieve House–Brackmann I or II grade recovery.
- Steroids may be effective but must only be used only if there is no significant associated brain injury.

OTHER NERVE PALSIES

Additional cranial nerve injuries occur in 7.8% of cases of temporal bone fractures. These consisted of VIth nerve injury when the petrous apex was fractured, also lower cranial nerve palsies as a result of jugular foramen haematoma.[193]

CEREBROSPINAL FLUID LEAK

Clinical features

Estimates of the frequency of CSF leaks following temporal bone fracture vary widely between 11% and 33%.[191, 197] Most (81%) resolve spontaneously within 5 days and 95% within 14 days,[191] although it is likely that many go unnoticed.

The risk of meningitis in temporal bone fracture is about 2%,[179] which probably increases to 7% with a CSF leak.[191] Concurrent ear infection increases this risk to as much as 20%.[191] Low-pressure headache and increasing risk of meningitis occur if leaks persist. Larger defects are probably less likely to heal spontaneously.

Management

Although not validated, bed rest with head elevation and avoidance of straining and lifting is advocated. If the leak has not stopped within 10 days, insertion of a lumbar drain is a sensible intervention. Prophylactic antibiotics are unhelpful in the absence of an ear infection.[180]

The requirement for surgical closure is unusual. Location of a persistent leak is not necessarily straightforward, particularly with comminuted fractures. The presence of a defect on a CT scan is not necessarily the site of the leak. Peri-operative fluorescein cysternography is sometimes useful for identifying the site.[198] For larger defects there is a risk of herniation of meninges and brain into underlying spaces. An MRI scan is also recommended to establish this pre-operatively. It is probable that some cases of meningoencephalic herniation go unrecognized but, due to the risk of infection, repair is recommended.[199]

The surgical approach and method used varies according to authors' preferences; however, large defects and revision cases are best closed by a middle fossa, extradural approach, sometimes with a combined mastoid approach. Smaller defects in more accessible areas of the tegmen and posterior fossa may be successfully closed via a transmastoid approach, with or without disarticulation of the ossicular chain. Numerous different materials, including autologous cartilage, temporalis fascia, fascia lata, and porcine- and bovine-derived artificial dura have been used. No superior results have been described with any particular material. If no hearing remains in the ipsilateral ear, consideration should be given to repair with a blind sac closure.[199] Rarely this may require the addition of a subtotal petrosectomy in those cases that violate the otic capsule.[200]

KEY POINTS

Post-traumatic CSF leaks

- CSF leaks complicate 11–33% of temporal bone fractures.
- Around 95% resolve spontaneously within 14 days.
- Large tegmen defects and persistent CSF leaks should be surgically closed to prevent meningitis.

RECURRENT LATE MENINGITIS AND MENINGOCOELE/ENCEPHALOCOELE

Despite spontaneous healing, recurrent CSF leaks and meningitis may occur, even many years after the primary injury. The diagnosis is often made when CSF is found in the middle ear when ventilation tubes are being inserted for an assumed middle ear effusion, or when a defect is noted on a CT scan performed prior to a lumbar puncture for meningitis.[133] MRI is indicated if there is a large defect, or if any suspicion of herniation of intracranial contents is seen on CT. Defects should be repaired and reinforced.

VASCULAR INJURY

Fractures of the bony canals of the internal carotid artery and sigmoid venous sinuses are relatively common but publications are sparse and mainly confined to the neurosurgery and neuroradiology literature. Those patients with worse injuries and a lower GCS are more likely to have a fracture involving the carotid canal.[201] Only 4% of skull base fractures result in vascular injury despite about a quarter of fractures entering the carotid canal. Sixty-two percent occur at the junction between its lacerum and cavernous portions (the spheno-occipital suture), and about 18% of these sustain a vascular injury. Fractures through the petrous segment are less common but carry a higher, 25%, risk of vascular injury.[201] Internal carotid artery dissection with carotid–cavernous fistula is a rare consequence.[193] Intimal damage resulting in aseptic sigmoid sinus thrombosis is rare (1 in 82 temporal bone fractures).[163]

A high index of suspicion is required in those patients with more severe skull base fractures, particularly if there is evidence of otic capsule fracture or cranial nerve palsies. The jugular and carotid canals should be routinely, and carefully, examined on the CT scan with a low threshold for requesting angiography. Examples are shown in **Figure 91.7**.

WHIPLASH INJURY

DEFINITION

This is indirect injury to the neck caused by an acceleration–deceleration incident resulting in a flexion–extension injury of the cervical spine. There is no direct trauma. Whiplash injury (or whiplash-associated disorder (WAD)) is the resulting functional impairment.[202] The term whiplash implies an amplification of relatively small forces into larger ones.

CLASSIFICATION

In 1995 the Quebec Task Force (QTF) produced a landmark consensus publication that provided a useful classification of these injuries into five grades, dependent on clinical symptoms and signs (**Table 91.3**).[202] Symptoms and signs should occur within 72 hours to be considered attributable to the whiplash trauma.[203, 204]

EPIDEMIOLOGY

The incidence varies greatly between 70 and 300 per 100 000 population.[202, 204] There are estimated to be more than one million new patients per year in the US. In the UK 250 000 patients per annum cost an estimated £3 billion[205, 206] with legal submissions occurring at a rate of about 150 per day. They increased by 268% in the year following the introduction of the compulsory use of seat belts.[205]

TABLE 91.3 Whiplash-associated disorder grading system after the Quebec Task Force conference

Grade	Symptoms and signs
0	Nil symptoms
I	Complaint of pain on motion, but no pain on physical examination
II	Complaint of pain on motion, with pain on physical examination
III	As grade II, but with neurological symptoms
IV	Fracture or dislocation

Adapted with permission from Spitzer et al.[202]

AETIOLOGY

Simulated accidents have shown that a 5 mph (8 km/h) rear-end car collision results in a positive acceleration of 8.3 G and 4.7 G of the head and chest, respectively. Below 3 mph (4.8 km/h) the difference between the displacement of the head and that of the chest is small or absent, causing no real whiplash movement of the head on the neck.[207, 208]

Despite what are clearly surprisingly large forces, the causes of many of the resulting symptoms remain unclear but incude soft-tissue neck trauma, skeletal spine damage and vascular or direct trauma to the spinal cord/brain stem or vestibular nuclei. Transient ischaemia or haemorrhage in the labyrinth as a result of transient compression of the vertebral artery, direct labyrinthine concussion, the noise of the collision causing acoustic trauma and psychological triggering of a pre-existing hearing disorder are also hypothesized.[177, 202]

CLINICAL FEATURES

General

Symptoms usually begin within 72 hours of the incident, the most common being neck pain and stiffness, with or without definite clinical signs such as tenderness or a decreased range of motion (grades I and II). Symptoms are shown in Table 91.4[204] and are similar to those reported in patients following head injury (see above).

Otological

In a study of 197 731 cases of whiplash 15–20% developed late whiplash syndrome with persistent complaints including headache, vertigo, instability, nausea, tinnitus and hearing loss.[209]

HEARING LOSS

Subjective hearing loss occurs in approximately 13%.[210, 211] Measurable hearing loss by pure-tone audiometry, in patients with grade I and II whiplash injury is at most rare and has not been confirmed by various studies.[212, 213] Some patients complain of hearing difficulties,

TABLE 91.4 Mild whiplash (grade I and II): most frequent symptoms experienced in the first week following injury

Symptom	Approximate prevalence (%)
Neck pain	94
Neck stiffness	96
Interscapular pain	35
Headache	44
Numbness/paraesthesia	22
Vertigo	15

usually of poor speech discrimination, despite having a normal audiogram. A controlled 'speech in noise' study has shown demonstrable abnormalities in 30% of whiplash patients as compared to 5% of matched controls.[213] No study could be found associating the degree of whiplash injury to pure-tone audiometry findings or to audiological symptom scores. However, given the deceleration nature of the injury, it is reasonable to suppose that severe cases of whiplash (grade III and IV) may induce intralabyrinthine trauma similar to that found in head injury (see above). Therefore, any patient sustaining a whiplash injury who complains of hearing loss, tinnitus or vertigo should undergo a full neuro-otological assessment.

TINNITUS

Despite appearing in the list of acute symptoms, tinnitus does not appear to occur as a persisting symptom attributable to minor (grade I and II) whiplash.[212,213] More severe whiplash injury has many of the features of minor head injury, although no specific associations between audiological symptoms and whiplash-related disorders have been confidently identified.[204]

VESTIBULAR SYMPTOMS

The most common vestibular problem after whiplash injury is BPPV and it is usually a feature of more severe injury (grade III). Its management is as for the idiopathic condition (see Chapter 64, Benign paroxysmal positional vertigo).[214] As in BPPV following head injury, the condition may be more refractory to repositioning techniques requiring more treatments.[215]

Only 3.65% of those with low-grade (I and II) whiplash injury undergoing medicolegal assessment for otological and vestibular symptoms complained of non-specific dizziness symptoms in the acute phase following their original injury. Caution should therefore be exercised before attributing such symptoms to whiplash injury.[212]

TABLE 91.5 Guidelines for imaging in whiplash injury

Grade	Imaging
I	No X-ray examination **Exceptions:** Over age 65 years, concurrent skeletal disease (e.g. rheumatoid arthritis). History of neck surgery. Unsafe to examine
II	Plain X-ray or CT **Exceptions:** CT mandatory if any spinal nerve root or cord symptoms
III	CT Additional investigation with MRI often indicated

Adapted from Jansen et al.[204] and National Institute for Health and Care Excellence[218]

The nature and causes of the imbalance that often occurs in the late whiplash syndrome remains unclear. A study using electronystagmography only found abnormalities if there was a concomitant minor head injury. Posturography was, however, similarly positive in both groups, making a labyrinthine cause unlikely.[216] Comparative studies have found some evidence of vestibulopathy by VNG testing: 19% in whiplash (11% peripheral, 5% central, 3% indeterminable) compared to 60% in minor head injury.[217]

INVESTIGATIONS

Imaging

Indications depend on the clinical grade of whiplash injury (Table 91.5).[218]

Other tests

Audiometry should be performed as soon as possible in any patient complaining of hearing loss. Other tests are seldom necessary in the acute phase. Every attempt should be made not to overinvestigate as this may be linked to a poor outcome.[218] Neurophysiological tests should be reserved for use in those patients who do not make a full recovery.

TREATMENT

A Cochrane review was unable to support or refute the effectiveness of conservative treatments in grade I and II whiplash injury.[219] There is only limited evidence for mobilization strategies over immobilization collars.[218,220] In the acute phase of whiplash injury simple analgesics are recommended.[218] High-dose intravenous steroids given in the first 8 hours after injury decrease neck pain at 1 week but there was no difference in outcome at 6 months.[221,222] There is no strong evidence to support the use of any patient advice strategies.[223]

Hearing losses and tinnitus should be treated on their own merits. Dizziness, vertigo and imbalance have been shown to be effectively improved by vestibular exercises, even if differentiation between these vestibular symptoms

in various studies is unclear.[204, 224] The performance of vestibular rehabilitation exercises in patients with neck pain and limitation of neck movements is safe. Their symptoms and signs are correlated with their self-perceived dizziness handicap score.[225] Stress disorders, anxiety, sleeplessness and depression should be addressed to ensure optimum overall outcomes.[204]

PROGNOSIS

Mild (grade I and II) whiplash injury spontaneously recovers in 97–100% within 1 year.[202, 226, 227] Overall (grades I– IV) most patients recover within 8 weeks[202] but 14–50% develop WADs.[228, 229] It is possible that up to 50% of all patients have minor residual symptoms that may persist for as much as 2 years.[230] Degenerative changes seen on initial MRI scans all progress over 10 years but in over 50% of patients symptoms improve. There is no correlation between the progression of the degenerative findings and patient symptoms.[206]

Audiovestibular symptoms are uncommon initially (3.6–13%) and are expected to completely disappear within 5 months. Dizziness is, however, such a frequent complaint of more severe cases that the prognosis of this should be considered to be that of the overall condition.[212]

Systematic reviews strongly suggest that high initial pain intensity is the strongest indicator of a poor prognosis.[204, 218, 231] Other indicators are: the severity of the initial trauma, double collisions (rear-end followed by front-end collision), serious car damage, previous mental ill-health and a high grade of WAD.[206] Worse outcomes have been refuted in older patients, women, high acute psychological response, angular deformity of the neck, rear-end collision and compensation.[204, 231] The interactions between physical injury and an individual's pre-existing medical and mental condition significantly affect their illness behaviour. The worse the perception of the initial injury, the worse their neck pain at 1 month.[232] Despite most fully recovering within 2 months, not recovering by this time holds a worse prognosis. Likewise, if not resolved by 6 months, long-term difficulties are likely.

Controversy exists regarding the effects of seeking compensation, or malingering, on patient outcome. Studies from Lithuania and Greece, where there is no cultural expectation of compensation or of chronic disability, have excellent outcomes within 12 months. The very few patients with residual symptoms had them prior to their injury.[218, 226, 227] There is very little evidence to suggest that seeking compensation in itself is linked to the severity of patients' symptoms.[233] The resolution of legal cases, or the receipt of compensation, does not appear to improve outcomes.[234, 235] Ongoing research is investigating why countries such as Britain have such high numbers of claims.[236]

More high-quality research is required into the neuro-otological symptoms and outcomes following whiplash injury.

KEY POINTS

Whiplash injury

- Whiplash injury is extremely unlikely at speeds under 3 mph (4.8 km/h).
- There are persistent symptoms in approximately 20% of cases.
- Subjective hearing loss is seen in 13%.
- Objective hearing loss is rare and very rare, or absent, in grade I–II whiplash injury.
- Tinnitus is not a feature of grade I–II whiplash injury.
- Dizziness/vertigo is a rare complaint in grade I–II whiplash injury but common in more severe cases.
- Benign paroxysmal positional vertigo is the most common vestibular complaint.
- Around 97–100% of all symptoms in grade I–II whiplash injury recover within 1 year.
- Encouraging activity rather than rest and immobilization is recommended in patients with grade I–II whiplash injury.
- If vertigo or dysequilibrium is a symptom, vestibular rehabilitation should be provided. [Grade A]

OTITIC BAROTRAUMA AND OTITIC DECOMPRESSION ILLNESS

INTRODUCTION TO OTITIC BAROTRAUMA

'Barotrauma' is defined as an injury produced by mechanical forces caused by a change of pressure in a gas-filled space.[237] Otitic barotrauma, therefore, encompasses those pathological conditions of the ear induced by pressure changes. Severe cases occur from sudden large pressure changes, such as slap injuries typically sustained during an assault, when water skiing, high board diving and blast injury. Mild occurrences are common in airline passengers, scuba divers and in single-breath free diving.[237, 238]

The physics and pathophysiology behind most of the clinical entities are established. An exception is the exact role of 'bubbles' in the pathoaetiology of decompression illnesses. There is some temporal bone evidence for the various conditions described, but some of the pathophysiological explanations relating to the described inner ear conditions are incomplete. Most of the respiratory physiology, particularly relating to compression and decompression, and the fate of gases in the body, was established in the early 20th century by John Haldane.[239]

Pressure/volume relationships

The clinical conditions resulting from barotrauma are most easily described by considering the physiological events that occur during subaqua diving with scuba apparatus. Similar events occur during flight but, because of the lower pressures involved, the resulting barotraumatic injuries are usually less pronounced. Boyle's law describes the inverse relationship between the pressure of a gas and the volume it occupies (**Table 91.6**). Its importance is demonstrated by the relative bubble volume decrease observed

TABLE 91.6 Gas laws

Law	Detail	
Boyle's law	The volume (V) a gas occupies is inversely proportional to its pressure (P) at a constant temperature (T).	($V = k/P$, where k is a constant)
Dalton's law	The total pressure of a gas mixture always equals the sum of the partial pressures each gas would exert if it alone occupied the available volume.	($P_T = pP_1 + pP_2 + pP_3$ ..... pPn)
Charles's law	At a constant pressure the volume of a gas dissolved in a liquid is proportional to the temperature.	($PV = RT$, where R is a universal gas constant)
Henry's law	The amount of gas that will dissolve in a fluid, at a given temperature, is proportional to the partial pressure of that gas.	

TABLE 91.7 The effect of depth (seawater) on gas volume

Depth (m)	Atmospheres pressure	Pressure (kPa)	Volume (%)	Bubble (%) diameter
0	1	101	100	100
10	2	202	50	79.3
20	3	303	33	69.3
30	4	404	25	63.3
40	5	505	20	58.5

with increased pressure (Table 91.7). The pressure increase with depth is a linear relationship of approximately 1 kPa for every 10 cm, while descent in air from 5500 m to sea level represents a pressure increase of only 0.5 atmospheres (50.5 kPa) (Figure 91.8). When diving, the largest percentage change in gas volume occurs during the first 10 m of descent (Table 91.7) (the first 1000 m of altitude for aviators), the ambient pressure doubling to 2 atmospheres and the corresponding gas volume being halved. This explains not only why a diver's impression of middle ear pressure change is maximal during the first 10 m, but also why the risk of developing otitic barotrauma is greatest in shallow dives or in low-flying, non-pressurized aircraft.

AMBIENT PRESSURE

The concept of ambient pressure is central to the understanding of the mechanisms involved. The external pressure is uniformly distributed over an object. In a system that has no air spaces within it, this pressure is transmitted equally throughout the structure. This is of particular relevance to the vasculature. If a large vein (e.g. the internal

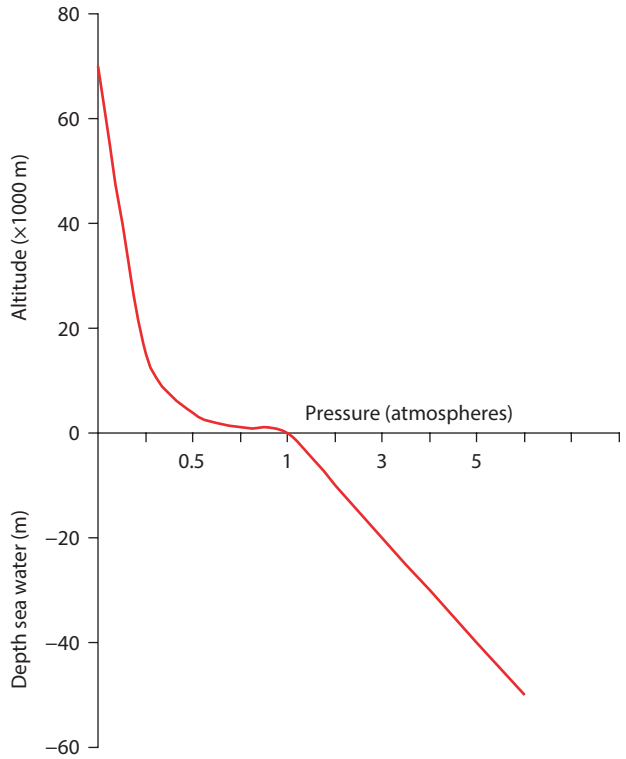

Figure 91.8 Altitude and depth versus pressure.

jugular) has pressure applied from the outside, provided that the whole body is submerged, it will transmit that pressure onwards. Head-out immersion causes a significant squeezing of blood volume from the lower limbs into the chest and into the head causing an increasing cardiac output and raised intracranial pressure with headaches.[238, 240] In the diver, or aviator, the pressure is equally applied to all body structures, there is no differential pressure across any membranes or systems so function is essentially unchanged. The exception, however, is when there is an air-filled cavity within the body. As the middle ear is a bony cavity, no distension or expansion is able to take place. The vasculature within the wall of the middle ear is, however, in continuity with that of the rest of the body, and therefore the intraluminal vascular pressures reflect the ambient pressure. If there is a relatively negative middle ear pressure due to a failure to equalize via the Eustachian tube, then there will be an increasing difference between the intraluminal vascular pressure and the middle ear pressure. If a sufficient gradient exists, then oedema and even rupture of those vessels within the mucosal lining will occur.

PHYSIOLOGICAL CONSEQUENCES OF COMPRESSION (DESCENT)

Figure 91.9 illustrates a diving model whereby the external auditory meatus is separated from the middle ear by the tympanic membrane, with the Eustachian tube connecting the middle ear cavity with the nasopharynx. During breathing, the nasopharynx is filled with inspired air from a compressed air cylinder via a regulator. This air pressure is equilibrated, by the regulator in the mouthpiece, to be equal to the ambient external pressure, provided the diver continues to breathe normally. As the diver descends, the ambient pressure increases. The middle ear pressure becomes increasingly negative compared to the ambient pressure unless equalization via the Eustachian tube takes place. This occurs by the voluntary action of the tensor and levator palati muscles opening the usually closed tube.[241] If the Eustachian tube cannot be opened effectively, the equalization of the pressure within the middle ear space with that of the external ambient pressure cannot occur. The relatively negative pressure within the middle ear will increase with further descent, resulting in a pressure differential across the tympanic membrane, which is therefore pushed inwards by the external ambient water pressure. This stretching is perceived as a sensation of external pressure and discomfort, which stimulates further attempts at equalization. If this does not prove possible, then the diver should return towards the surface to decrease the pressure gradient, thereby improving the ability to equalize. If this is not done and descent continues, then middle and inner ear barotrauma may occur.

The perception of the requirement to equalize occurs at a maximum of 86 cm (2.6 ft) reflecting a pressure change of only 8.7 kPa (60 mmHg). At this pressure, if no equalizing manoeuvre is performed, then mucosal congestion and oedema will occur. This is because the ambient pressure is reflected in the vasculature of the middle ear. This increases the transmural pressures, thus increasing transudation. Continued descent results in 'Eustachian locking', which occurs at a pressure difference of about 13 kPa (90 mmHg), an equivalent depth of approximately 1.3 m (3.9 ft).[242, 243] At this pressure, the power of the levator palati muscles is insufficient to voluntarily overcome the external closing pressures. Should this situation occur, middle ear barotrauma will follow. If the pressure gradient across the tympanic membrane is large, and occurs before the middle ear fills with an effusion or blood, then the tympanic membrane may rupture. If this occurs in one ear only, then a sudden influx of cold water into the middle ear may result in unequal thermal stimulation inducing a rigorous caloric vertigo.

The pathoaetiology of inner ear barotrauma is illustrated in Figure 91.9. The perilymphatic space is separated from the middle ear by the oval and the round window membranes. Alterations in intracranial and corresponding CSF pressures may be transmitted to the inner ear fluid compartments via the cochlear and vestibular aqueducts. If the diver or aviator fails to equalize his middle ears, then the pressure within the external ear canal will cause the tympanic membrane to be pushed inwards with a resultant inward force on the stapes footplate via the ossicles. This causes a corresponding bulging of the round window membrane into the middle ear space. The pressure gradient is also increased by the ambient pressure of the spinal fluid transmitted through the aqueducts to the inner ear fluids, this pressure being relatively positive compared to the middle ear pressure. Sufficient pressure by these mechanisms alone may be generated to cause round window membrane rupture; however, a forced Valsalva manoeuvre would certainly increase the intracranial, and therefore CSF, pressures by up to three times

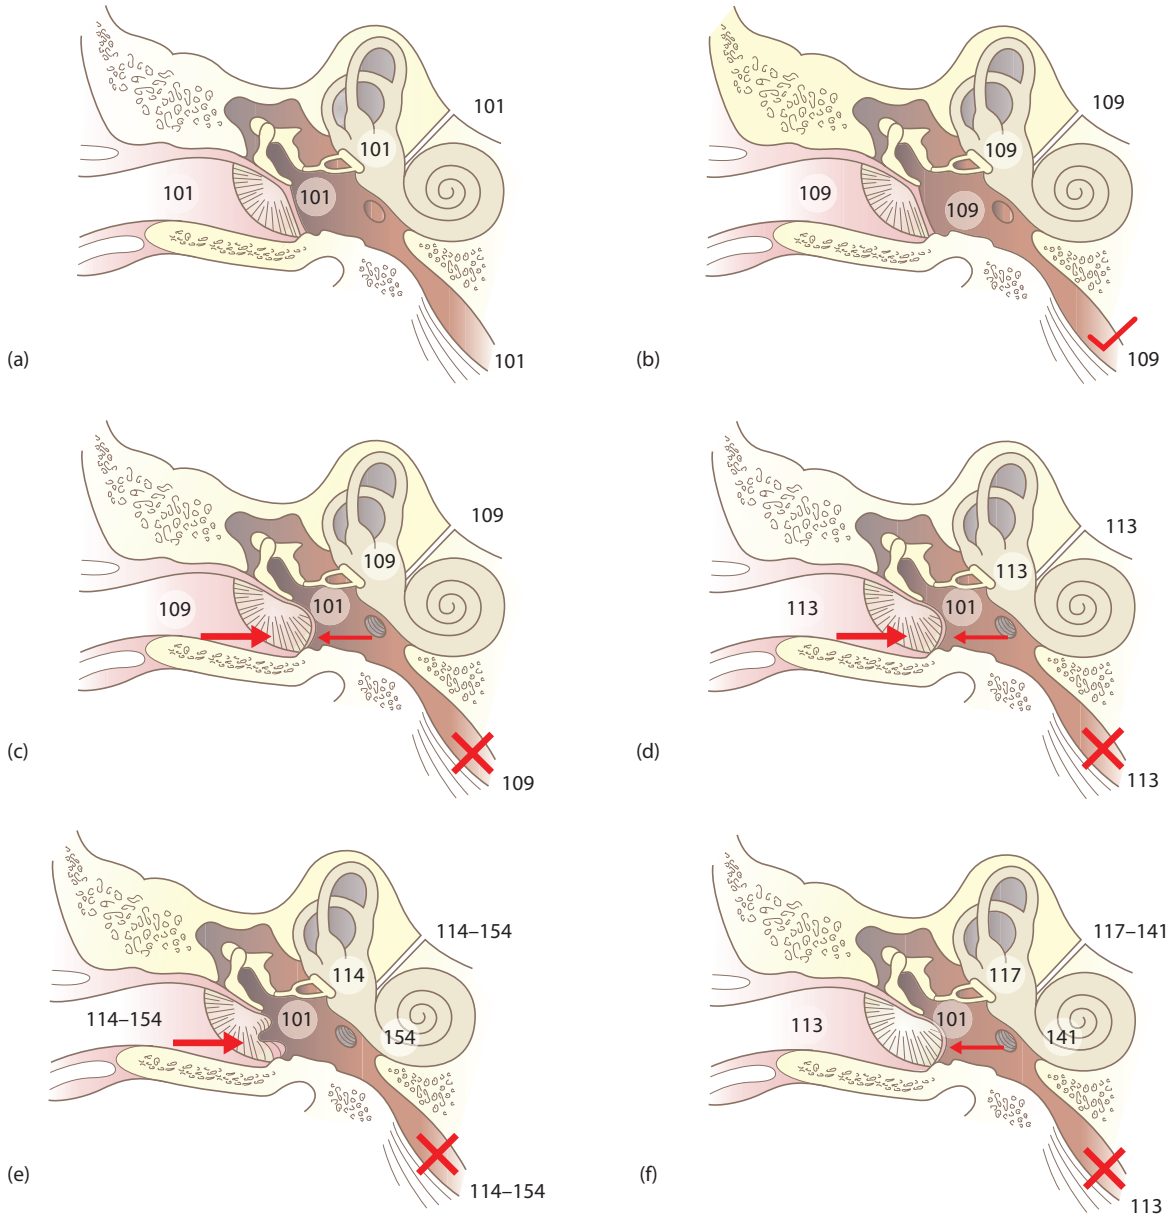

Figure 91.9 Otitic barotrauma on descent: theoretical pressure changes (kPa) and potential pathology. **(a)** Equal pressures on surface (sea level). Actual inner ear perilymph pressure is really slightly higher than ambient pressure. **(b)** Normal equalization with descent. **(c)** Depth 0.86m and pressure difference of 8 kPa, bulging tympanic membrane and round window into the middle ear. **(d–f)** Blocked and locked Eustachian tube. **(d)** 1.29 m with 12 kPa pressure difference. **(e)** Tympanic membrane ruptures at variable pressures. **(f)** Forced Valsalva increases CSF and perilymph pressure resulting in round window rupture. Adapted with permission from Farmer JC, Thomas WG. Ear and sinus problems in diving. In: Strauss R (ed.). *Diving medicine.* New York: Grune and Stratton; 1976.

that of normal. Studies in cats have demonstrated that the round window will rupture at pressure gradients of between 16 and 40 kPa (120–300 mmHg).[244] A perilymphatic fistula may therefore be expected to occur at the oval or round windows due to these implosive, or explosive, forces.[245] It is possible that these events are more likely to occur in patients with a congenital weakness of the annular ligament, or in those who have had stapes surgery, chronic middle ear disease, or perhaps have congenitally large cochlear or vestibular aqueducts.

PHYSIOLOGICAL CONSEQUENCES OF DECOMPRESSION (ASCENT)

If normal equalization of the middle ear pressures has occurred during descent, then the middle ear pressure is equal to that of the surrounding ambient pressure. During subsequent normal ascent, as the middle ear pressure exceeds that of the ambient pressure, passive ventilation of air through the Eustachian tube into the pharynx occurs.[246] When flying, this is normally every 13.25 m (43.5 ft) of ascent, regardless of the speed

of decompression.[247] If both Eustachian tubes are functioning correctly, the only conditions experienced on ascent are decompression illnesses.

During a diver's descent (or, for the aviator, during the previous flight), mild middle ear barotrauma may occur due to suboptimal Eustachian tube function, resulting in mucosal oedema and possibly haemorrhage. As a result, the usual passive ventilation, which should occur during subsequent ascent, can no longer take place. To continue ascending in these circumstances would result in a relatively positive middle ear pressure (**Figure 91.9**) compared to the ambient pressure, causing an outward bulging of the tympanic membrane. By similar mechanisms to those described during descent, the reverse effect on the oval and round windows may be seen. The tympanic membrane is pushed outwards and a traction force is applied to the oval window via the ossicles. This is accompanied by an inward force on the round window membrane. The pressure gradient is increased further as the perilymphatic pressure, reflecting the ambient pressure, has decreased with ascent. It is possible, therefore, for perilymphatic fistulae to occur during this phase of a dive. A sudden outflow of air down the Eustachian tube is sometimes described, immediately followed by the symptoms and signs of a perilymphatic fistula.

Clinical features

The manifestations of otitic barotrauma may be conveniently divided into the following three categories, which are discussed below:[248]

- compression injuries
- injuries at high pressure
- decompression injuries.

COMPRESSION (DESCENT) INJURIES

External ear barotrauma (external ear squeeze, reversed ear, reverse ear squeeze)

This occurs when a pocket of air is trapped within the external auditory meatus by cerumen, earplugs, foreign bodies or exostoses, although it is usually due to the wearing of a tight-fitting diving hood. The insertion of occlusive earplugs during aircraft descent is an uncommon cause.

If Eustachian tube function is normal, then, with increasing compression, the pressure of the trapped meatal air becomes negative compared to that of the middle ear and the external ambient pressure. As a result, the pressure gradient across the tympanic membrane results in it being displaced outwards. If with sufficient force, perforation may occur.

The main symptom is of pain, increasing with depth. The ear canal skin and tympanic membrane become injected and petechial haemorrhages, and bleeding, may be observed. The immediate remedial action is to decompress by ascending. If relevant, the diving hood should be adjusted or modified and the meatus cleaned, preferably by microsuction. The ear should be kept dry and diving avoided until the skin appears normal and the causative factor is addressed. Occlusive earplugs should be avoided when diving to more than 1.5 m and when flying.

KEY POINTS

External ear barotrauma

- External ear barotrauma involves a trapped air pocket in the external meatus.
- Pain increases in proportion to compression.
- There are tympanic membrane features as for middle ear barotraumas.
- **Prevention:** avoid occlusive earplugs and headgear.
- **Treatment:**
  - clear external meatus of blood/wax debris
  - use antibiotic drops for secondary infection
  - surgically repair any perforation if spontaneous healing fails
  - consider exostectomy.
- **Advice:** complete resolution should be observed and the causative factor corrected prior to further flying/diving.

Middle ear barotrauma (barotitis media, middle ear squeeze)

Middle ear barotrauma is the most frequent pressure-induced ear condition and may occur wherever there is Eustachian tube dysfunction resulting in a transtympanic pressure gradient.[249] Commercial flights, scuba and free diving, rollercoaster rides[250] and hyperbaric therapy are common causes. Transient evidence of middle ear barotrauma has been demonstrated in 5% of adults and 25% of young children after flying.[251]

CLINICAL FEATURES

Predicting who might be at risk during flight is difficult. Tympanometry is unhelpful as it is usually normal. Many people who have no problems with their ears when flying cannot voluntarily equalize their middle ear pressures. The sensation of equalization when performing the Valsalva manoeuvre has a poor (0%) predictive value for potential barotrauma. The Toynbee test has a positive predictive value of 25%. A nine-step inflation/deflation tympanometric Eustachian tube test has a much better chance of accurate prediction (25% positive predictive value, 75% negative predictive value).[252] Reliable (100%) predictive results have been obtained by combining the nine-step test with the Toynbee test.[253] Studies have correlated poor mastoid pneumatization with an increased chance of developing middle ear barotraumas. When estimating mastoid area by the simplified rectangular method, no patients with a mastoid area greater than 34.7 cm^3 sustain barotrauma, whereas those less than 13.6 cm^2 suffer from it.[254, 255]

For diving, the inability to 'equalize' by performing the Valsalva manoeuvre is a useful guide. Those unable to equalize both ears have a 91% chance of developing middle ear barotrauma compared with only 37% of controls.[256] Sonotuberometry and tubotympanometry have been suggested in an uncontrolled study, as methods that may accurately predict those who will develop middle ear barotrauma.[257] The speed of descent appears to be an important factor. The faster the compression, the less opportunity exists for equalization, especially if the person is distracted, working or asleep, particularly during the aircraft's descent.[258]

Initial symptoms are the sensation of a blocked ear and a strong desire to equalize. Progressive otalgia results with increased compression and there is an inability to equalize. An initial minimal conductive loss is due to the decreased compliance that results from the transtympanic pressure differential. The development of a middle ear effusion will follow quickly if the middle ear vacuum effect is maintained. This has been confirmed experimentally by introducing carbon dioxide into unilateral ears in monkeys, which results in the development of rapid negative middle ear pressures ('underpressure'). Subsequent MRI scans showed that the contrast leaked into the middle ears readily in those with induced negative pressure, but not into the control ears.[259] Mucosal oedema predictably occurs, even in those with normal Eustachian function, after repeated or long duration dives.[260] The increasing pressure differential may result in a perforation of the tympanic membrane and this is characterized by sudden severe pain. If diving, a sudden ingress of water into the middle ear may result in caloric vertigo (see 'Caloric vertigo' below). Severe middle ear barotrauma may also result in ossicular damage. Larger conductive losses may be observed with damage to the stapes footplate,[261] incus dislocation[262] and even a fractured malleus handle.[95, 263]

Examination of the tympanic membrane will reveal changes varying from a normal appearance (with mild symptoms), to free haemorrhage with a tympanic membrane perforation. These changes have been classified (**Table 91.8**)[264] and are a modification of Teed's four-grade classification.[265] Pure-tone audiometry and tympanometry are minimum investigations, a conductive hearing loss with decreased compliance and a negative middle ear pressure being expected. These tests should be used to monitor resolution in more severe cases. A treatment regimen has been suggested on the basis of a three-level clinical classification of severity.[242]

- Type 1: When there are symptoms of middle ear barotrauma, but no (or minimal) signs, no specific treatment is required.
- Type 2: When significant signs are present, but no perforation, conservative treatment is indicated with either oral or topical nasal decongestants.
- Type 3: Where there is middle ear barotrauma with perforation, an initial observation period is recommended with cleaning of the affected ear if necessary.

A myringoplasty is indicated in those cases that fail to heal spontaneously. Patients should be advised to await complete resolution of their symptoms before they return to diving or flying. Although Farmer's recommendations are of Grade C, and not specifically evidence-based, they are the result of a wide clinical experience, and are logical and consistent with established practice. As perforations secondary to middle ear barotrauma are usually found in otherwise healthy ears, the surgical results should be better than in cases following otitis media.

TABLE 91.8 Tympanic membrane appearance in middle ear barotrauma

Grade	Symptoms and signs
0	Symptoms, no signs
1	Redness and retraction
2	Intratympanic membrane haemorrhage
3	Gross tympanic membrane haemorrhage
4	Haemotympanum
5	Perforation

PREVENTION OF MIDDLE EAR BAROTRAUMA

Medical

High-quality RCTs have shown a strong effect for oral pseudoephedrine in the prevention of barotrauma when flying but not for topical xylometazoline.[266, 267] Similar results have been found in scuba divers.[268] No significant difference was found in the occurrence of otalgia between two groups of children under 6 years taking oral pseudoephedrine or placebo.[269] The use of oral psudoephedrine is recommended before flying, in those with mild Eustachian symptoms. This advice should not, however, be extended to scuba divers with acute Eustachian dysfunction due to the larger risk of middle ear barotrauma and the greater potential consequences of it.

Slowing down the rate of change of pressure is beneficial. The use of occlusive earplugs when diving or flying is contraindicated due to the risk of external ear barotraumas; pressure-equalizing earplugs are currently sold at many airports, but their benefit remains unproven. Small studies have suggested no benefit,[270] or possibly even an increase in the incidence of barotrauma.[271] A recent small double-blind, controlled pressure chamber study does, however, suggest that a 7-minute delay in the time taken to equalize the external ear canal pressure may be achieved, and that despite no measurable improvement in Eustachian tube function, symptoms are significantly improved. Slower rates of compression when delivering hyperbaric treatments may decrease the frequency.[272]

The use of nasal balloon inflation (auto-Politzerization) using Otovent™ (Abigo, Sweden) may be helpful in improving the ability to equalize by those who have difficulties performing equalization manoeuvres.[251]

Surgical

Performing myringotomies (often as a simple local anaesthetic procedure), and the insertion of ventilation tubes, may be appropriate for preventing otalgia and middle ear barotrauma in those wishing to fly. This procedure is clearly contraindicated for diving.

Eustachian tube balloon dilatation (balloon Eustachian tuboplasty) is gaining popularity and may become the treatment of choice, particularly for those who suffer from equalization difficulties flying.[273]

EUSTACHIAN TUBE DYSFUNCTION AND NASAL SEPTAL DEVIATION

The role of the nasal airway and nasopharynx in Eustachian tube function is complex and has been the subject of much research. There is, however, little knowledge regarding the effect of nasal surgery on the ability to equalize middle ear pressure. Only one controlled study has been attempted where posterior septal surgery considerably increased the ability to equalize to 10 m as compared to controls.[273] The author's experience is in marine biology students or commercial divers, who stand to lose their careers or licences because of inability to equalize their middle ear pressures. Despite some success, caution is advised, especially in those with minimal septal anomalies. More validation is required regarding the efficacy of this procedure.

DIVING AND FLYING AFTER MIDDLE EAR SURGERY

There are no specific data that precisely identify a 'safe' post-operative period after which it is safe to fly. Following reconstructive surgery most surgeons advise a restriction of any activity which might result in a sudden change in the middle ear pressure, for several weeks. Tympanic membrane grafts and ear canal healing should be complete before water sports are resumed, and flying should not be permitted until any aural packs are removed and healing verified. Slap injuries following stapes and total ossicular replacement surgery may be prevented by the use of earplugs. Evidence of adequate Eustachian function should be obtained prior to resuming diving or flying. Scuba diving after stapes surgery remains controversial and there are no good studies addressing this. Some patients insist on continuing with the sport and report no difficulties.[274] Animal experiments have shown no significant increase in inner ear barotrauma after stapedectomy when compared to control ears.[275] Safe diving should be possible in those post-tympanoplasty patients whose Eustachian function appears adequate.[249] If, however, it is poor, given the mechanisms of fistula formation, it is likely that particularly those who have undergone stapes surgery are at an increased risk of a perilymphatic fistula and even prosthesis displacement. As there are potentially fatal consequences of a perilymphatic fistula when diving, pursuing this after stapes surgery is considered by many to constitute an unnecessary risk. If patients are insistent, strict advice regarding Eustachian function and a post-operative wait of 6 months is recommended.

KEY POINTS

Middle ear barotrauma

- Middle ear barotrauma is very common during flight and scuba diving.
- The perceived ability to 'equalize' is a useful predictor for diving, but not for flying.
- Speed of compression is an important risk factor.
- Conductive hearing loss is usual.
- Oral pseudoephedrine and Otovent™ balloon may be effective preventative measures.
- Surgical repair of the tympanic membrane and even ossicles may be necessary.
- Nasal septal (vomeroethmoidal) surgery may improve the ability to 'equalize' middle ear pressures.
- Consider Eustachian tube balloon dilatation.
- **Prevention:**
  - oral decongestants [Grade A]
  - Otovent™ balloon
  - consider Eustachian tube balloon dilatation
  - no flying or diving with upper respiratory infections
  - identify those at risk
  - asymmetric equalizers
  - inability to voluntarily equalize at sea level (divers)
  - nasal obstruction.
  - treat nasal conditions
  - consider septal surgery
  - myringotomies/ventilation tubes for flying.
- **Diagnosis:**
  - obtain specific history: pain on descent
  - otoscopic appearance (Table 91.8)
  - audiometry: conductive loss.
- **Treatment:**
  - conservative/symptomatic initially
  - elective repair of the tympanic membrane and/or ossicles
- **Advice to patients:**
  - complete resolution is expected in mild cases
  - scuba adiving is contraindicated if problems persist
  - oral decongestants are helpful before flying/diving. [Grade A]

CALORIC VERTIGO

Asymmetrical contact of cold water with both tympanic membranes, or cold water ingress into one middle ear via a perforation, may result in a caloric effect. Causes include wax, exostoses, otitis externa, tight diving hoods, leaking earplugs or a foreign body in the external meatus. It is usually short-lived and mild. Cold water ingress through a tympanic membrane perforation may give severe symptoms. The colder the water, the more pronounced is the effect. On surfacing, the caloric stimulus is removed and the vertigo is self-correcting.

A history of Eustachian tube dysfunction may be present and examination may reveal a perforation or impacted ear wax. No residual audiological nor neurological signs or symptoms should be present after surfacing.[264]

KEY POINTS

Caloric vertigo

- Caloric vertigo involves the asymmetric exposure of each ear to cold stimulus.
- It is short-lived and self-correcting.
- It is very common in mild forms.
- There are no residual audiological or neurological symptoms or signs.

Inner ear barotrauma (compression inner ear barotrauma)

The pathophysiological mechanisms have been described above (see 'Physiological consequences of compression'). Histopathological studies have demonstrated three different pathological entities in the inner ear resulting from compression barotrauma:

- inner ear haemorrhage
- labyrinthine membrane tears
- perilymphatic fistula.

Various clinical matches have been proposed to explain the corresponding distinct patterns of presentation seen in temporal bone specimens.[276]

INNER EAR HAEMORRHAGE

This gives transient, or minimal, vestibular symptoms and mild to moderate sensorineural hearing loss. A good recovery is expected.

LABYRINTHINE TEARS

Tears of the labyrinthine membrane may produce similar symptoms, but any loss is permanent, often at 1–2 kHz. Patients may present with symptoms closely resembling those of an acute Ménière's disease attack, with vertigo and tinnitus, complete with the characteristic low-frequency hearing loss. Temporal bone studies have demonstrated Reissner's membrane rupture.[277] Similar occurrences have also been shown in airline passengers, either with or without labyrinthine window rupture.[278] Temporal bones from divers who died under such circumstances showed bleeding into the middle ear and mastoid. Inner ear damage consisted of haemorrhage around Reissner's and the round window membranes, as well as rupture of the utricle and saccule.[279] Implosive forces to the inner ear due to middle ear overpressure (occurring on ascent with a locked Eustachian tube) may cause more severe inner ear trauma than the more commonly occurring barotrauma on compression (descent).[280]

PERILYMPHATIC FISTULA

The diagnosis and management of perilymphatic fistula generates considerable debate. The condition was first recognized in aviators, although it has became of great interest in diving medicine.[281, 282] Detailed descriptions of labyrinthine window ruptures and inner ear trauma associated with inadequate middle ear pressure equalization were published in the early 1970s.[283, 284] Perilymphatic fistula is a well-recognized consequence of head injury, surgery, congenital anomalies, cholesteatoma and neoplasia. Spontaneous fistulae possibly occur, without any recognized aetiological factors, although controversy surrounds both their existence and management.[285–287] As many as 0.5% of divers have suffered from a perilymphatic fistula.[288]

Clinical features

The exact timing of the onset of symptoms relative to the injury is the single most helpful piece of clinical information. The dive profile is important for scuba divers and this will also assist in deciding if the dive was one from which a decompression illness could reasonably result (see below). The time of onset of these symptoms is usually definite in aviators but may only be recognized on surfacing in divers. A typical history is of difficulty equalizing the middle ear pressure during descent, particularly during an upper respiratory infection, resulting in a rigorous Valsalva manoeuvre being attempted. There is a sudden onset of vertigo, an accompanying hearing loss (sensorineural or mixed) and often tinnitus.[289] Muffled hearing and occasional, but persistent, dysequilibrium may be the only symptoms. Any acute symptoms often resolve rapidly after several days, although mild dysequilibrium (which may change to transient vertigo on straining), mild persistent nausea and motion intolerance, often with a subtle sense of 'not coping', are the most common symptoms of a chronic perilymphatic fistula. Fluctuating hearing is typical.

A perilymphatic fistula should be suspected in an otherwise healthy ear (or in one with evidence of middle ear barotrauma) if there is a sensorineural hearing loss of rapid onset, constant or intermittent dysequilibrium, positional nystagmus, Tullio phenomenon, a positive fistula sign and tinnitus. The main differential diagnosis is of inner ear decompression illness (**Table 91.9**). It is an important distinction as recompression in error may cause further middle and inner ear barotrauma. Conversely, not recompressing a patient with a decompression illness may result in permanent cochleovestibular damage, further progression of the decompression illness and even death.

Clinical signs

Examination of the tympanic membrane may reveal signs of middle ear barotrauma (see **Table 91.8**) but, unless it is an acute presentation, the appearance is often normal. A full neurological examination, including of the cranial nerves, should be performed. Nystagmus may be present, usually towards the contralateral side, but this may disappear over a few days as symptoms of vertigo often give way to the more typical dysequilibrium. The Romberg test is normal in more mild cases and, if it is possible to perform the Unterberger step test, this often yields a positive result. The 'side-step' test, a modification of the Singleton 'side-step turning test'[290] has been described, and has promising results.[291] With the eyes closed, the patient takes two consecutive broad steps sideways, and then stops with both feet together. A subsequent sway or overshoot in the same direction as the steps were taken is regarded as a positive result, the affected ear being on the side towards the direction of movement. Dix–Hallpike tests for positional vertigo are often positive but often do not give the typical results for BPPV. The nystagmus may be difficult to identify, is not usually rotatory and is often not towards the downward ear. The latency may be short or absent with little sign of any fatigability.[292]

TABLE 91.9 Differential diagnosis of inner ear barotrauma and labyrinthine decompression illness

	Middle ear barotrauma	Inner ear barotrauma	Inner ear decompression illness
Phase of dive/flight symptoms first noticed	Usually descent, possible on ascent (reverse squeeze)	Usually descent; may occur on ascent, or just after surfacing (<10 min)	Only during or after ascent; usually after surfacing; more likely near surface
Difficulty equalizing middle ear pressure	Yes	Yes	Not usual
Associated middle ear barotrauma	N/A	Usual	Not usual
Associated non-otological symptoms	None	None	Usually other symptoms of decompression illness
Vertigo	None	Usual	Usual – dysequilibrium may predominate
Sensorineural hearing loss	None	Frequent	Frequent – may be difficult to ascertain
Effect of recompression on symptoms	Worsened	Worsened	Improvement
Hearing loss	Conductive loss	Mixed loss – common (85%)	SN loss (38–66%)*

*Nachum et al.[345]

Investigations

The larger the fistula, the more likely are the clinical signs, and any special investigations, to be positive. Baseline pure-tone audiometry should be performed as soon as possible. Fistula tests are unreliable. An improvement in pure-tone thresholds when lying for 30 minutes compared to sitting (Frazer test), and external auditory meatus pressure change fistula tests using a Siegel's speculum, are only positive in 25–40% of surgically proven fistulae.[293, 294] Improved results (being positive in 90% of proven cases) have been obtained when using accurate pressure stimulation with tympanometry in conjunction with electronystagmographic recordings. The results, however, include fistulae from other causes, such as temporal bone trauma, post-surgical and congenital.[294] Unfortunately, it is the more subtle presentations, with smaller or intermittant fistulae, that cause the diagnostic uncertainty. In an attempt to address this, extensive studies utilizing transtympanic electrocochleography with tone-burst stimuli to confirm the presence or absence of surgical, post-traumatic and spontaneous fistulae have been performed.[295] Despite reasonable validation during stapes surgery, this method of investigation has not gained popularity. High-definition MRI and CT scans may prove useful. Their use may assist making the diagnosis, but the predictive value is unknown and probably low overall. The results of radiological investigations therefore should be considered only in the context of other clinical findings. Features which may be seen include intralabyrinthine air,[296, 297] fluid in an otherwise non-diseased mastoid or middle ear, and fluid in the round window niche on T2-weighted MRI.[298] Confirmatory tests at the time of surgery are considered below.

Treatment

Treatment options are based on hearing and balance restoration and preservation. Opinions vary between a conservative, expectant strategy and surgery. The results of hearing conservation and salvage are poor. This is probably because of frequent diagnostic delays that contribute to the permanence of any sensorineural hearing loss. For this reason, immediate surgery in all suspected cases has been advocated by some.[299] This approach clearly does not allow any time for spontaneous closure to take place. Many prefer an initial conservative approach, including bed rest for a minimum of 5 days. Exploration is then reserved for (i) those with progressive hearing deterioration observed on daily, or more frequent, audiometry, (ii) failure of the vestibular symptoms to improve after 5 days, (iii) failure of complete resolution after 1 month.[292] In reality there is a range of severity of the presenting symptoms and signs so, in the absence of definitive trial results, a pragmatic approach is suggested. This should be dictated by the observations that surgery seldom improves a hearing loss, although it may stabilize it, and that dysequilibrium is well treated, but the timimg of surgery for this indication is relatively unimportant. The initial management should therefore be dictated by the severity of the hearing loss. The following treatment strategies assume that a typical presentation of hearing loss with imbalance has occurred.

Moderate to severe hearing loss The overall picture is inevitably influenced by the time taken for the patient to present to the otologist. Emergency exploration is of relevance in more severe acute cases with both a significant sensorineural hearing loss and vertigo (30–40 dB HL or worse). Given the overall poor prognosis for hearing, there is no advantage in delaying and immediate exploration is therefore recommended.

Minimal hearing loss (high-frequency only, or mean 20 dB HL loss) Many patients with inner ear barotrauma do not have an obvious history and findings consistent with a perilymphatic fistula. For those with more mild sensorineural hearing losses and vestibular symptoms, an initial conservative approach is reasonable. Bed rest is

advised, with elevation of the bed head to 30–40 degrees. Raising the intracranial pressure by coughing, straining, vomiting or performing the Valsalva manoeuvre should be avoided. This is also recommended as the initial management of all cases where there is any suspicion of a perilymphatic fistula, while deciding on further action. Steroids are often prescribed, despite the lack of evidence for their use, particularly when a presumed diagnosis of an intralabyrinthine haemorrhage or tear is supposed. An initial conservative approach has become more favourable as surgical exploration appears to treat vestibular symptoms more effectively than it does improve the sensorineural hearing loss.[300] This may be because some of those reported may not have had fistulae, but intralabyrinthine pathology only. Patients should have daily audiometry performed and this should be repeated immediately if there is any subjective deterioration. If confirmed objectively, surgical exploration should be performed without delay.

Mild to moderate hearing loss (20–40 dB HL) If presentation is less than 24 hours following the event, and vestibular symptoms and signs predominate, then immediate exploration is appropriate. After 24 hours, the need for exploration should be judged predominantly on serial daily, or more frequent, audiometric findings. An ear with evidence of deteriorating hearing should always be explored, without waiting until the next day to validate the deterioration. If the hearing has spontaneously improved, it is reasonable to wait for 5 days before exploration for persistent vestibular symptoms; if there is no hearing loss, a conservative strategy may be followed for up to 4 weeks. Once stable good hearing has been verified, this may be at home provided that rest and the above-mentioned precautions are observed. Some surgeons do not perform surgery before 2 weeks have passed as spontaneous resolution is often encountered. The earlier the presentation with hearing loss, the worse the hearing loss, and the worse the vestibular component, the stronger is the indication for urgent surgery.

Despite a trend towards a conservative approach, several other issues should be considered. An exploratory tympanotomy should present very few surgical risks if performed by a specialist otologist in an otherwise medically fit patient.[301] There is little evidence to support either the conservative or aggressive surgical strategy but deterioration is necessarily a retrospective finding. The overall morbidity, inconvenience and cost of 2 weeks or more of bed rest are often ignored. Overall, a low threshold for exploration is recommended.

Future studies

The identification of idiopathic perilymphatic fistula remains controversial.[287] However, it is unlikely that any further significant progress will occur until a reliable marker of perilymph (possibly cochlin-tonoprotein) is identified and studies on those patients with sudden hearing loss and vestibular symptoms, without a suggestive fistula history, are performed.

Acute sensorineural hearing loss without vestibular symptoms

A sudden hearing loss may occur in the absence of any vestibular symptoms. An isolated intracochlear decompression illness is the main differential diagnosis, so the appropriate history, including middle ear symptoms associated with inner ear barotraumas, must be sought. An intracochlear haemorrhage is the probable aetiology and this may be apparent on MRI. Despite a lack of convincing evidence, oral or intratympanic steroids should be considered for patients with moderate and severe losses (see Chapter 60, Idiopathic sudden sensorineural hearing loss). An immediate tympanotomy would be difficult to justify unless serial audiometry suggests fluctuating hearing without overall spontaneous improvement. In those cases where there is a dead ear, alternative pathologies require exclusion (see Chapter 60, Idiopathic sudden sensorineural hearing loss).

Care should be taken that all patients are followed up, as cases of perilymphatic fistula presenting with chronic dysequilibrium are encountered many months or even years after the event.

Surgery for perilymphatic fistula

Numerous series and case reports have been published covering a broad spectrum of aetiologies, usually post-trauma or congenital fistulae in children.[300, 301] A standard tympanotomy is performed but care must be taken to avoid mucosal damage. Identification of the site of the fistula is notoriously difficult. It may be useful to place the patient in a head-down position and increase the ventilatory pressure. Unfortunately, this also encourages bleeding, which may further increase the degree of uncertainty.

Intra-operative identification using intrathecal fluoroscein is not reliable for locating perilymphatic fistulae as the timing of the injection relative to the surgery, the slow and unpredictable diffusion rate of the marker into the perilymph and the differing patencies of the cochlear aqueduct make it unreliable.[302] Intravenous fluoroscein is not useful as it appears as a transudate in the middle ear and is not taken up readily into the perilymph.[303] Mixing it with the local anaesthetic infiltration may be useful as perilymph, not being stained, will appear to displace any fluorescein containing fluid.[304]

Careful inspection of the round and oval windows, around the middle ear and the Eustachian tube orifice for a source of the leak is performed. An endoscopic technique may have the advantage of keeping the dissection to a minimum hence decreasing the amount of blood and exudate in the middle ear at the time of surgery.[305] Despite these advantages, when used alone, the method may not be adequate to exclude a perilymphatic fistula,[306] and the adequacy and interpretation of the view is more important than the method used. The round window membrane itself is usually hidden within the bony niche and it is easy to mistake mucosal folds for the true round window membrane. If this occurs, or if endoscopic methods are unfamiliar or unavailable, then curetting away the bony overhang should enable a better view. If a drill is used, it may be useful to mix fluorescein into the irrigation fluid.

Care is required not to traumatize the membrane. Any fistula found should be covered with a tissue plug and supported by absorbable middle ear packing material. If no definite fistula is observed, it is sensible to place a tissue graft in the round window and over the footplate. Fat has the advantage of filling in depressions whereas vein is useful due to the 'sticky' nature of its adventitial surface. The author usually uses both.

It is probably unwise to perform ossicular surgery at the same procedure. Given the possibility of a cochlear concussion type of injury, the inner ear may be susceptible to even minor degrees of further trauma. Repair of the tympanic membrane should, however, be performed at the time. If a delayed exploration for persisting dysequilibrium with a stable sensorineural loss is performed, appropriate ossicular surgery might be considered, provided the necessary audiological criteria are satisfied.

Confirmatory intra-operative tests

The collection of fluid for analysis as a confirmatory test for the presence of perilymph may provide retrospective evidence for a perilymphatic fistula. Beta 2-transferrin is 100% specific but its low sensitivity of 29% makes this test not worthwhile.[307, 308] Cochlin-tonoprotein is a 16 kDa protein that has been identified in human perilymph.[309] It is not present in other body fluids[310] and has been found in 92% of perilymph samples, as compared to 0% of CSF, from the same patients.[311] There is a claimed specificity of about 98%.[311] There may therefore be a confirmatory diagnostic test available in the future.

Results

The data available are difficult to interpret as some patients without surgically identified fistulae improve as a result of, or despite, their surgery. Spontaneous improvement is often seen in more mild cases, even if no surgery is performed. Despite these restrictions, surgical intervention appears to relieve vestibular symptoms (87%) and to improve the hearing in about 40% of sudden hearing loss cases.[299] Other reports suggest that hearing stabilization, rather than necessarily improvement, is achieved in most cases.[301]

KEY POINTS

Inner ear barotrauma

- There are three types of inner ear barotrauma: inner ear haemorrhage, labyrinthine tears and perilymphatic fistulae.
- The history of pressure/time profile of the incident is important.
- The most suggestive symptom is dysequilibrium with manoeuvres which increase intracranial pressure.
- Other symptoms include sensorineural hearing loss (may fluctuate), chronic dysequilibrium, mild nausea, unaccustomed motion sickness, vertigo, tinnitus, positional vertigo and Tullio phenomenon.
- Clinical fistula signs are only useful if positive.
- Otoscopy is sometimes normal.
- The decision for surgical exploration is based on the severity of the presenting hearing loss and failure of the vestibular symptoms to resolve.
- Surgical results are good for vestibular symptoms and relatively poor for hearing improvement.
- **Prevention:**
  - as for middle ear barotrauma (above)
  - avoid over-rigorous attempts to equalize middle ear pressure
  - identify those at risk:
    - as for middle ear barotrauma (above)
    - previous perilymphatic fistula.
- **Diagnosis:**
  - must distinguish from decompression illness (**Table 91.9**)
  - obtain the exact nature and timing of symptoms
  - establish the time/pressure profile
  - conduct a full neurological examination, including postural balance tests
  - pay attention to the direction and nature of nystagmus, with/without the removal of optic fixation
  - maintain monitoring with daily audiometry
  - conduct a tympanometric held pressure fistula test with electronystagmography
  - consider tone-burst electrocochleography.
- **Treatment:**
  - always consider the need for early surgery – continue to review
  - use steroids for moderate and severe hearing losses
  - carry out immediate surgical exploration if there is short presentation and moderate/severe hearing loss
  - surgical exploration for:
    - progressive hearing loss
    - persistent disequilibrium
    - close obvious fistulae, if unclear then cover both windows with fat/vein adventitia.
- **Advice to patient:**
  - complete resolution is expected in mild cases
  - scuba diving is contraindicated if problems are persistent
  - take decongestants before flying/diving
  - beware of lifting/straining/flying for 6 weeks post-operatively.

INJURIES AT HIGH PRESSURE

High-pressure nervous (neurological) syndrome (isobaric gas counterdiffusion)

High-pressure nervous syndrome may occur when divers are exposed to extremely high pressures. The characteristic symptoms are of tiredness, general dizziness and tremors (both postural and intentional, of the hands and even of the whole body) that may progress, with increasing pressure, to ataxia and myoclonus. Unlike nitrogen narcosis, psychomotor impairment exceeds intellectual impairment. The depth at which the condition occurs depends on the compression rate. Symptoms may occur at high pressure, but characteristically soon after changing the inspired gas mixture to one that includes a second inert gas. The sudden onset of vertigo and nausea with nystagmus has been reported as part of this syndrome.[312] Permanent vestibular damage has been described, but there is no hearing loss.[313, 314]

KEY POINTS

High-pressure nervous syndrome

- High-pressure nervous syndrome occurs with extreme pressure exposure.
- It usually occurs on changing inspired gas mixtures.
- It is characterized by tiredness, general dizziness and tremor.
- It may progress to include vertigo, ataxia and myoclonus.
- Psychomotor impairment exceeds intellectual impairment.
- Permanent vestibular damage may result, with no hearing loss.

DECOMPRESSION (ASCENT) INJURIES

Alternobaric vertigo

This is a condition of asymmetrical middle ear overpressure stimulation occurring in divers,[315, 316] air passengers and crew.[317] It usually occurs in those who describe unilateral equalization problems. On ascent, failure of equalization due to minor middle ear congestion and oedema, or unilateral Eustachian tube dysfunction, may lead to a relatively higher pressure in one middle ear. Of 2053 Swedish divers, 22% described symptoms consistent with alternobaric vertigo at some time during their diving careers.[318] The condition occurs on ascent or within 2 minutes of surfacing. Episodes are not usually severe, with a maximum duration of about 10 minutes. Divers may also describe a tumbling sensation, or a tilting of their surroundings, rather than simple rotation. Experimental evidence supports these clinical observations, with true vestibular nystagmus demonstrated when middle ear overpressure was present in only one ear during controlled decompression in a pressure chamber.[319, 320] Animal studies have also demonstrated an increase in vestibular neuronal impulses as a response to middle ear overpressure.[321] It is, however, not exclusively a condition of ascent. Twenty-seven percent of cases occurred during descent.[315]

KEY POINTS

Alternobaric vertigo

- Alternobaric vertigo is caused by asymmetric middle ear overpressure.
- It is common in divers and aircrew.
- It often has a preceding history of unilateral difficulties 'equalizing'.
- It usually occurs with decompression (27% with compression) or within 2 minutes of surfacing. It is rare for signs to persist for more than 10 minutes.
- There are no permanent sequelae.

Barotraumatic facial palsy (facial baropareisis, alternobaric facial palsy)

A transient facial nerve palsy may occur as a result of high middle ear pressure during ascent. It has been described in both aviators and divers.[322, 323] A correct diagnosis is important to avoid potentially hazardous, and unnecessary, recompression treatment. It is probably due to a pressure-induced neuropraxia in an individual with a congenital dehiscence of the facial nerve in its intramastoid portion (0.5–57% of all temporal bones).[324] Animal studies have demonstrated that blood flow in the vasa nervora of the facial nerve decreases if increased middle ear pressure is transmitted through a dehiscence of the facial canal.[325] A neuropraxia has also been induced by applying increasing pressures to an exposed part of the facial nerve in cats.[326] In a non-dehiscent facial canal, pressure may be transmitted through the fenestra of the chorda tympani.[327] The blood flow, and the palsy, rapidly return to normal when the middle ear pressure is relieved. The condition may be associated with alternobaric vertigo. It is important to rule out other causes of facial palsy (see Chapter 112, The facial nerve and its non-neoplastic disorders). Clinical evaluation should include complete general neurological and neuro-otological examinations, the main differential diagnosis being a decompression illness. A facial palsy due to this would be very unlikely to occur in isolation without any other neurological symptoms or signs. Patients are likely to have associated symptoms and signs of otitic barotrauma (see Table 91.8). The onset is typically rapid and the condition resolves after a few minutes. This would be very unlikely to be the case if a decompression illness were the cause.

If there is a bulging tympanic membrane, then a myringotomy should be performed, although a persisting palsy should be investigated and treated as for a decompression illness. Recompression treatment may worsen symptoms when Eustachian tube dysfunction is still present, but it is clearly not indicated when a diagnosis of isolated barotraumatic facial palsy has been made. If a decompression illness is also suspected, or if uncertainty as to the true diagnosis persists, a myringotomy should be performed and a grommet inserted prior to proceeding with recompression treatment. A full recovery is expected.

KEY POINTS

Barotraumatic facial palsy

- Barotraumatic facial palsy is caused by middle ear overpressure during ascent.
- It involves neuropraxia secondary to compression of the vasa nervora.
- No other neurological symptoms or signs are present.
- It is often associated with mild middle ear barotraumas.
- Rapid spontaneous resolution is expected.
- Myringotomy should be performed if there is persistence, when a bulging tympanic membrane is identified.

NON-BAROTRAUMA-ASSOCIATED INNER EAR PROBLEMS IN DIVERS

Frequent high pressure exposure itself has been refuted as a cause of sensorineural deafness.[328, 329] Animal studies have suggested inner ear damage,[330, 331] but with adequate controls no histological inner ear damage was then

found even after the application of extra high ambient pressures.[332] The predominant cause of increased hearing thresholds in commercial divers is noise induced with no evidence for hearing loss or vestibular impairment associated with diving itself.[333, 334] There is a similar lack of convincing evidence in sports divers.[335]

DECOMPRESSION ILLNESS AND HYPERBARIC MEDICINE

Pathophysiology

VENTILATORY EFFECTS

The exchange of oxygen and carbon dioxide between the alveoli and blood occurs down concentration gradients. Assuming normal ventilation, as oxygen is utilized by respiration, there is a continuous transfer of oxygen into the blood from the alveoli, with carbon dioxide transfer in the opposite direction. Pulmonary transfer of inert gases depends on the solubility of that gas in blood. At low ventilation rates, highly soluble gases exchange slowly as they remain more easily equilibrated with their blood concentrations across the alveolar membranes. Gases, such as nitrogen and helium, have low solubility in blood (i.e. tend to remain in gas phase rather than solution), resulting in their rapid exchange almost whatever the ventilation rate. Thus equilibration of their alveolar–arterial gas tensions readily occurs.

Henry's law states that the amount of gas dissolved in a tissue is proportional to the pressure on that tissue. During descent (compression), the increased ambient pressure results in a greater amount of nitrogen dissolved in both the arterial and venous blood. During ascent (decompression), as the ambient pressure falls, a gas phase will form within the tissue unless the gas is metabolized or removed at a sufficiently fast rate. Nitrogen and other inert gases, which cannot be metabolized, are only transferred via a concentration gradient from the tissues back into the blood stream. Nitrogen has a low partition coefficient (water/oil, 0.19) as it is more soluble in lipids than in water. Consequently, its transfer from the tissues to the vasculature is slow. Once in the blood it is transported to the lungs where the gas tensions in the pulmonary capillaries are equilibrated with the partial pressures of gases in the alveoli before exhalation. If subsequent decompression is too rapid, nitrogen bubbles will form.

BUBBLES

A bubble in the body is only absorbed when its nitrogen partial pressure exceeds the nitrogen tension in the surrounding blood/tissue.[239] If a short dive takes place, there will be little time for nitrogen to dissolve and diffuse into tissues, and therefore a rapid ascent is possible. When decompressing after a longer dive, carbon dioxide will come out of solution very quickly due to its high solubility. Provided adequate ventilation continues, it traverses the alveolar membranes and is expired so quickly that bubbles do not have time to form. Due to nitrogen's low partition coefficient, interstitial nitrogen microbubbles will form and subsequently enlarge, unless the rate of transfer through the endothelium into the vasculature exceeds the rate of their formation. Likewise, primary intravascular bubbles will form if the rate of nitrogen forming a gaseous phase is faster than the lungs' ability to remove the excess dissolved nitrogen. Doppler ultrasound has shown that bubbles are present in the venous systems of many divers during decompression, without consequence.[336] These bubbles pass through the venous system until they are trapped and filtered by the pulmonary vascular bed, where diffusion into the alveoli occurs. Pathological effects may be seen if there is: saturation of the pulmonary filter (resulting in arteriovenous shunts), a patent foramen ovale of the heart or rupture of alveoli (or a pre-existing lung bulla) causing pulmonary barotrauma.

Exercise significantly affects tissue uptake of nitrogen during compression[337] and speeds expulsion on decompression.[338] Obesity (nitrogen being more soluble in lipids than in water) and increased age may increase the tendency to develop decompression illness, although this is disputed.[339]

KEY POINTS

Hyperbaric pathophysiology

- Increased ambient pressure (compression) increases the amount of dissolved gases in blood and tissues.
- Decompression results in a gas phase, unless metabolism or removal are at a sufficient rate.
- Nitrogen transfer from tissues to blood is slow (low partition coefficient).
- Short dives give insufficient time for nitrogen to dissolve and diffuse into tissues.
- Exercise during compression increases the amounts of dissolved nitrogen.
- Vascular bubbles forming on decompression cause vascular occlusion and direct endothelial damage.

Hyperbaric oxygen treatment (therapy)

Bubbles in the blood are a common occurrence in decompression situations. They are inconsequential, unless their number or size is sufficient to cause symptoms. The two central concepts of hyperbaric medicine are the ability to (i) dissolve gas nuclei by rapid compression and (ii) increase the amount of gas in solution.

The Undersea and Hyperbaric Medical Society indications for hyperbaric oxygen treatment are shown in **Box 91.1**. A systematic review has found that convincing results have only been achieved in treating decompression illness and gas embolism.[340] This is supported by established physiology, results from animal experiments and extensive clinical experience spanning over 100 years. Using the Grading of Evidence, Assessment, Development and Evaluation (GRADE) system for reviewing evidence, the evidence level has been elevated from C to A for these indications.[341] There is a convincing physiological case for its use in carbon monoxide poisoning. In conditions such as clostridial myonecrosis, synergistic gangrenes, crush syndromes and osteomyelitis, results are difficult to assess as its role is predominantly adjuvant and, therefore, controlled studies are very difficult to perform. Anecdotal and series reports describe good results in many cases.

BOX 91.1 Approved indications for hyperbaric oxygen therapy

Air or gas embolism
Carbon monoxide poisoning
Clostridial myositis and myonecrosis (gas gangrene)
Crush injury, compartment syndrome and other acute traumatic ischaemias
Decompression illnesses
Arterial insufficiencies: central retinal artery occlusion
Enhancement of healing in selected wound problems
Severe anaemia
Intracranial abscess
Necrotizing soft-tissue infections
Osteomyelitis (refractory)
Delayed radiation injury (soft tissue and bony necrosis)
Skin grafts and flaps (compromised)
Thermal burns
Idiopathic sudden sensorineural hearing loss
(Source: Undersea Medical Society 2014, www.uhms.org. Reproduced with permission.)

Hyperbaric oxygen treatment is indicated in all cases of suspected decompression illness because failure to treat is associated with permanent functional damage, and death.

Pathological effects of bubbles on the inner ear

Obstruction of small vessels may cause damage to susceptible organs, including the inner ear. Animal experiments following forced decompression showed evidence of irritation of the semicircular canal endostea with osteoblastic and fibroblastic differentiation, finally leading to fibro-osseus labyrinthitis,[342] and also to cause both bubbles and haemorrhages in the labyrinthine fluid spaces.[343] In humans vascular obstruction, haemorrhage and exudates in the inner ear fluid spaces and bubbles within endostial bone immediately around the semicircular canals. Microfractures into the pericanal spaces and new bone growth have been described.[344]

KEY POINTS

Hyperbaric treatment

- Hyperbaric treatment increases the amount of gas in solution.
- It dissolves gas nuclei by rapid compression.
- It is highly effective for cases of decompression illness and gas embolism.
- It has an adjuvant role in gangrenes, crush syndromes and osteomyelitis.
- Failure to give hyperbaric oxygen treatment rapidly in decompression illness is associated with permanent functional damage.

INNER EAR DECOMPRESSION ILLNESS

Decompression illnesses have been classified into two types:

- Type I: Musculoskeletal pain predominates, although cutaneous features (itching, urticarial rash, burning sensation) and systemic symptoms of malaise, anorexia and fatigue are also included.
- Type II: Cardiorespiratory and/or central nervous system involvement.

As many as 70% of all divers with this condition have followed their decompression tables correctly, many reports occurring after shallow sport dives.[345] The diagnosis may be very difficult to distinguish from inner ear barotrauma, especially as both often coexist with middle ear barotrauma. A careful history of the dive profile, the timing of the onset of symptoms, and their exact nature, is essential. The verification of the dive history is usually straightforward as many divers now carry electronic dive computers that provide at least a depth/time printout. The onset of decompression illness symptoms is usually only a few minutes (but may be as long as up to 36 hours) after surfacing. A history of symptoms starting when returning from a diving holiday by air is not uncommon as flying after diving may exacerbate, or even cause, decompression illness.[346] There is an increase in the tendency for more nitrogen to come out of solution due to the lower partial pressures of the inspired air and the decreased ambient pressure at altitude.

Organs with high metabolic rates and unit blood flow, such as the stria vascularis, are more susceptible.[347, 348] Isolated vestibular or hearing symptoms are rare. A history of other symptoms attributable to a decompression illness should be sought. Localized pain (91.8%), numbness or paraesthesia (21.2 %), muscular weakness (20.6%) and skin rash (14.9%) are the most frequently described. Non-specific dizziness or vertigo was the fifth most common (8.5%) with auditory disturbance occurring in only 0.3%.[349]

The time of onset is an important factor when attempting to differentiate decompression illness from other conditions. In cases of central nervous system (type II) decompression illness, 50% of patients report the onset of their symptoms within 10 minutes of surfacing and 90% within 3 hours.[350] Type I decompression illness has a longer delay, but 90% become symptomatic within 6 hours of surfacing. Most patients presenting to the otolaryngologist following a dive or a sudden decompression aviation incident, who do not only have middle ear barotrauma, will complain of dizziness or vertigo. Very few of these, however, will have either inner ear barotrauma or inner ear decompression illness (**Table 91.10**). True vertigo is unusual,[351] as is a sensorineural hearing loss (**Table 91.11**). The low numbers of inner ear barotrauma and perilymphatic fistula patients emphasizes the relative rarity of these conditions, and also the difficulties establishing a diagnosis when frequent complex symptoms and signs coexist, with the presentation often being delayed.

Clinical signs

Otoscopy, fistula tests and a full neurological examination, Romberg, Unterberger, head-thrust and Dix–Hallpike positional tests should all be performed if possible. Nystagmus may be present and the use of Frenzel glasses

TABLE 91.10 Coexisting symptoms in 97 consecutive divers presenting to a tertiary centre with 'dizziness'

Symptom	Number of patients
Paraesthesia	26
Joint pain	25
Pain in limbs	18
Weakness in limbs	11
Hearing loss	9
Back pain	5
Abdominal pain	4
Skin rash	4
Unconsciousness	4

to remove optic fixation typically enhances the nystagmus occurring with peripheral vestibular lesions. The clinical assessment should concentrate on differentiating not only between inner ear barotrauma and inner ear decompression illness, but also between a localized peripheral vestibular and a brainstem decompression illnesses. The distinction between central and peripheral causes of vertigo is discussed elsewhere (see Chapter 62, Evaluation of balance). Clinical features, which may aid in the differential diagnosis, are shown in Table 91.9.

Investigations

Investigations for general dizziness and hearing loss should be performed as appropriate, and as soon as the clinical situation allows (see Chapters 49, Physiology of equilibrium and Chapter 62, Evaluation of balance). Otological evaluation is often only practical after substantial hyperbaric and supportive treatment. An audiogram may be possible, but caloric and electronystagmographic testing is not well tolerated in the acute stage. Intracranial gas bubbles may form within any of the tissue or fluid spaces, including within the endolymph and perilymph. Probably more commonly however are embolic phenomena caused by large quantities of bubbles that have not been filtered by the pulmonary bed. Patients with evidence of an inner ear or other intracranial decompression illness should therefore undergo echocardiography to exclude a patent foramen ovale, which may occur in 48-80% of cases.[351–353]

Treatment

Recompression treatment should be instigated straight away. If there has been any suggestion of middle ear barotrauma, difficulty with middle ear pressure equalization, doubt as to the exact diagnosis, or a possibility of an overlooked perilymphatic fistula, then performing myringotomies (and preferably the insertion of grommets) beforehand is essential. The clinical features in a small series of 29 cases of inner ear decompression illness were as follows: pure vestibular involvement in 10 (34%), localized cochlear insult in 4 (14%), combined cochleovestibular event in 15 (52%). Two-thirds had a hearing loss at presentation. Consistent with most publications, they described a great difference in decompression illness resolution if treated with hyperbaric oxygen treatment within 6 hours (53% complete resolution of symptoms) as compared to those treated after this time (only 1 of 9 patients' symptoms resolved). Overall, only 6 of the 19 patients (32%) with cochlear damage made a full recovery.[345]

KEY POINTS

Inner ear decompression illness

- Many scuba divers have followed decompression tables correctly.
- Inner ear decompression illness may occur after shallow 'sports' dives, in common with other decompression illness.
- The differential diagnosis between inner ear decompression illness and inner ear barotrauma may be difficult (Table 91.9).
- Inner ear decompression illness may be precipitated by flying soon after diving.
- Isolated vestibular/cochlear decompression illness is rare; concurrent decompression illness symptoms/signs should be expected.
- All cases must be screened for a patent foramen ovale;
- Recompression within 6 hours is mandatory for all cases.
- **Prevention:**
  - avoid sudden decompression
  - ensure sufficient decompression times when diving
  - identify those at risk

  - those working/exercising under compression conditions
  - previous decompression illness
  - repeated dives
  - flying after diving.
- **Diagnosis:**
  - must distinguish from inner ear barotrauma (Table 91.9)
  - obtain exact nature and timing of symptoms
  - establish time/pressure profile
  - comprehensive neurological examination, including postural balance tests
  - echocardiography to exclude patent foramen ovale.
- **Treatment:**
  - urgent fluid resuscitation
  - early recompression hyperbaric oxygen therapy, within 6 hours
  - recompress if in doubt
  - myringotomy/grommets if impaired consciousness or equalization difficulties.

MIDDLE AND INNER EAR BAROTRAUMA SECONDARY TO HYPERBARIC OXYGEN TREATMENT

Middle ear barotrauma is the most common complication of hyperbaric oxygen therapy occurring in about 8% of patients undergoing repeated treatment dives.[354, 355] The incidence of vestibular symptoms with hearing loss is about 1.5% of dives or in 3% of those treated.[355] This is far more likely to occur in those in whom the indications included osteoradionecrosis of the head and neck region.[356] An inability to voluntarily autoinflate the middle ears prior to treatment increases the risk of developing middle ear barotrauma.[357] Unconscious patients or those with artificial airways while anaesthetized have a 94% chance of barotrauma, therefore routine insertion of ventilation tubes in such patients is indicated.[358] Other risks include the elderly, females, a history of cardiovascular disease and head and neck cancer, particularly following radiotherapy.[359]

KEY POINTS

Middle and inner ear barotrauma secondary to hyperbaric oxygen treatment

- Barotrauma is a common sequela of hyperbaric therapy.
- Risk is increased with:
  - increasing frequency of treatments
  - unconscious patients
  - osteoradionecrosis of temporal bone
  - inability to voluntarily equalize middle ear pressures
  - cardiovascular disease.
- There should be a low threshold for prophylactic myringotomies/ventilation tubes.

CEREBRAL AIR GAS EMBOLISM

Cerebral air gas embolism (CAGE) is the most serious and dramatic event for both scuba divers and aviators. It may occur during any depth of dive, even in swimming pools. It is usually seen in inexperienced divers who breath-hold when surfacing in an emergency. Ascent of only 1 m, without exhalation, is sufficient to produce microalveolar tears. Massive air gas embolism therefore occurs in the brain and the rest of the body. Involvement of the coronary arteries and brain are the predominant causes of the high rate of sudden death. Symptoms and signs are typically of very sudden onset and occur on ascent or very soon after surfacing. These include chest pain, severe dyspnoea, subcutaneous crepitus, dysphagia, dysphonia, general or focal seizures, confusion, hemiplegia, focal weakness, visual field defects and blindness. Blood-stained frothy sputum is a common feature.

Vertigo is commonly described and may be the presenting symptom in about 25% of cases. This usually occurs without either sensorineural hearing loss or tinnitus. Usually other neurological signs develop rapidly. The main differential diagnosis being of inner ear decompression illness, but the history, speed of onset, severity, associated signs and symptoms (such as surgical emphysema in the neck and on X-ray) usually prevent diagnostic difficulties. Emergency treatment is to place the patient in the Trendelenberg (head-down) position breathing oxygen. Following this, recompression takes priority over all other treatment and assessment options.[360]

FUTURE RESEARCH

➤ This chapter has provided an in-depth review of the otological conditions associated with barotrauma and hyperbaric conditions. While the underlying physics and physiology are well researched and understood, the clinical conditions, their diagnosis, treatment and prognosis are not.

ACKNOWLEDGEMENTS

The sections on ossicular trauma, temporal bone trauma and whiplash injuries have been modified and updated from the previous edition of this book. Some of the original text and referencing provided by Robert Mills and Desmond A. Nunez has been maintained. Their expertise and contributions are fully and gratefully acknowledged. The author would also like to thank Dr P. Bryson MRCP, Former Director, Diving Diseases Research Centre and Hyperbaric Medical Centre, Plymouth, UK, for his help and technical advice.

CHAPTER 92

OTALGIA

Philip D. Yates

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: earache, otalgia, referred otalgia, geniculate neuralgia, carotidynia, glossopharyngeal neuralgia, temporomandibular joint and earache and/or otalgia, and by the Cochrane Database of Systematic Reviews.

INTRODUCTION

Otalgia can arise from pathology within the ear (primary otalgia) or as a result of disease processes elsewhere (secondary or referred otalgia). While in children otalgia is much more frequently otogenic, in adults referred otalgia is the more common cause.[1]

Anatomy

The sensory supply of the ear is highly complex and not fully determined. It is this complexity that can lead to diagnostic difficulty in a patient presenting with otalgia, particularly when it is the only symptom. There are four cranial nerves and two cervical nerves that contribute to the sensory supply of the ear. The greater auricular nerve and, to a lesser extent, lesser occipital nerve supply sensation to the whole of the cranial surface of the pinna and to the lateral surface below the meatus (C2 and C3) (**Figures 92.1** and **91.2**). The auriculotemporal nerve, a branch of the mandibular division of the trigeminal nerve, supplies the lateral surface of the tympanic membrane, the external acoustic meatus and the lateral skin of the pinna above the level of the external meatus. The auricular branch of the vagus (Arnold's nerve) supplies the posteroinferior quadrant of the tympanic membrane, posteroinferior meatal skin and an area of the concha. The extent of facial nerve innervation of the ear roughly corresponds with that of the vagus, but its contribution is sparse.

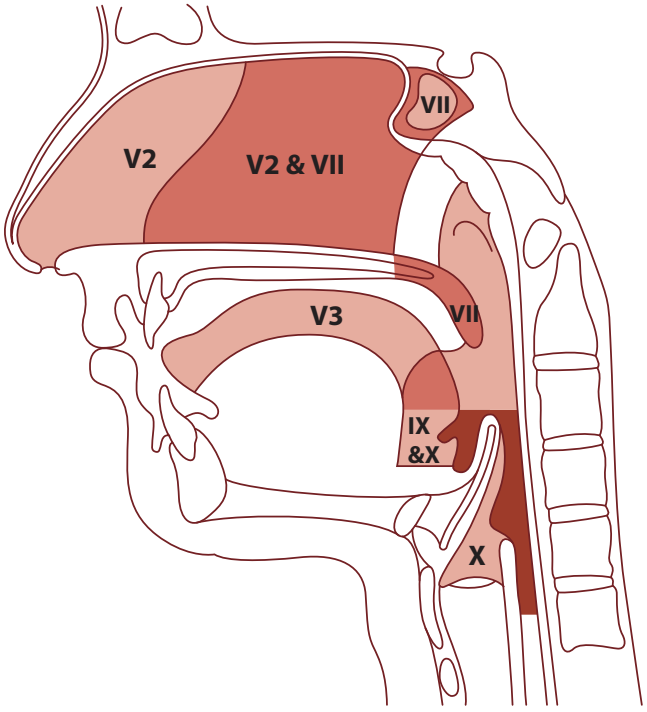

Figure 92.1 Otalgia arising from head and neck sources. Essentially any pathology residing within the sensory net of cranial nerves V, VII, IX and X and upper cervical nerves C2 and C3 can potentially cause pain referred to the ear. Adapted from Scarbrough et al. *Am J Clin Oncol* 2003; **26**(5): e157–62.[8]

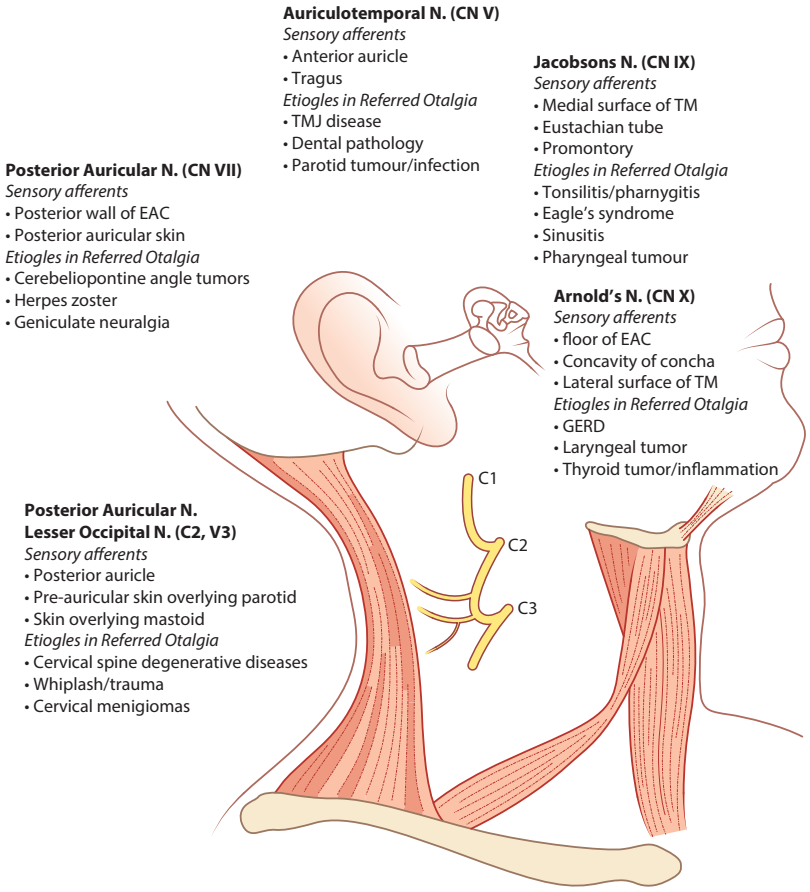

Figure 92.2 Complex sensory innervation of the ear and periauricular structures and various aetiological causes in referred otalgia. Adapted from Jaber et al. *Otolaryngol Head Neck Surg* 2008; **138**(4): 480.[22]

The middle ear is supplied by the tympanic branch of the glossopharyngeal nerve (Jacobson's nerve).[2, 3]

Referred pain is a commonly encountered clinical phenomenon, although its mechanism is not fully understood. **The trigeminal nerve is probably the most common pathway of origin of referred pain to the ear.** The mandibular division of the trigeminal nerve carries sensation from the anterior two-thirds of the tongue, floor of the mouth, palate, lower teeth, major salivary glands, temporomandibular joint (TMJ) and mandible. Referred pain arising from structures in these areas tends to be perceived in the ear canal. Although the facial nerve is mainly motor, it has sensory divisions including the nervus intermedius of Wrisberg and the greater superficial petrosal nerve, which conveys sensation from the posterior nasal cavity and sphenoid sinus. The glossopharyngeal nerve receives sensory input from the posterior third of the tongue, palatine tonsils, nasopharynx, hypopharynx and parapharyngeal and retropharyngeal spaces. Pain referred from these structures tends to be perceived as a deep intense otalgia. The vagus nerve supplies the valleculae, supraglottis, thyroid gland and more distant sites within the thorax including the tracheobronchial tree and oesophagus. The upper cervical nerves (C2 and C3) innervate the muscles and facet joints of the cervical spine.[4, 5]

The fact that sensory innervation of the ear is so diverse means that the potential origin of referred otalgia is widely distributed through the head and neck, and even beyond.

PRIMARY OTALGIA

External and middle ear diseases can lead to otalgia, and most otolaryngologists and primary care physicians are trained to recognize an abnormality in these areas. Conditions of the ear resulting in localized pain are discussed elsewhere in this book and further discussion will not be duplicated in this chapter. Table 92.1 summarizes the causes of primary otalgia.

REFERRED OTALGIA

In a patient presenting with otalgia with no identifiable primary cause, an origin for the referred pain must be sought. In some cases, for example a patient with acute follicular tonsillitis associated with earache, the diagnosis is obvious and therefore requires no further discussion here. However, in many cases referred otalgia can represent a diagnostic challenge and it is the aim of this chapter to highlight the possible causes.

TABLE 92.1 Causes of primary otalgia

Site	Possible cause(s)
Pinna	Chondrodermatitis nodularis helicis Chronic relapsing perichondritis Trauma/haematoma Cellulitis Herpes zoster oticus Malignancy
External canal	Otitis externa: • acute • chronic • benign necrotizing • 'malignant' Furuncle Bullous myringitis Keratosis obturans/canal cholesteatoma Trauma Herpes zoster oticus Malignancy
Middle ear	Otitis media +/- complications Malignancy
Inner ear	Noise discomfort

MALIGNANCY

Although malignancy is not the commonest cause of referred otalgia, its importance as a potential cause warrants this differential being high on the assessing clinician's list. Malignant tumours of the upper aerodigestive tract can present with various symptoms depending on their site of origin. It is important to remember that referred otalgia may be part of a symptom complex, or perhaps more importantly, can be the sole presenting symptom. A full examination of the oral cavity and flexible nasendoscopy to examine the pharynx and larynx are therefore an essential part of the assessment of a patient with otalgia in the absence of local pathology within the ear. The presence of otalgia, dysphagia, nodal metastasis and weight loss have all been shown to be independent predictors of duration of survival of patients with head and neck cancer.[6]

The majority of oropharyngeal carcinomas arise within the lateral wall, commonly involving the tonsil or the tongue base. Unlike carcinomas of the oral cavity, oropharyngeal tumours may not be visible until they are at an advanced stage and therefore imaging may be required to identify a primary in this area. Lymph node metastases are common at presentation. Like other aerodigestive tract malignancies, the most significant aetiological factor is smoking and to a lesser extent alcohol, but with a significant synergistic effect. However, HPV infection has had a dramatic effect on oropharyngeal malignancy rates and has been responsible for a significant increase in incidence over the last decade or more. This increase has been seen in younger patients (40–60 years) and non-smokers.[7]

Otalgia and odynophagia are often presenting symptoms of hypopharyngeal malignancy. On occasions, a supraglottic malignancy may lead to otalgia before involving the glottis and presenting with hoarseness, which is the cardinal symptom of laryngeal malignancy. The nasopharynx is not usually a subsite referring pain to the ear, but otalgia has been reported as being the presenting symptom in up to 14% of patients with nasopharyngeal carcinoma.[8]

Neoplasms arising in the infratemporal fossa can cause referred otalgia via the trigeminal nerve, Arnold's nerve or Jacobson's nerve. In a retrospective review of 18 cases presenting over a period of 8 years, all cases had otalgia with normal otological findings and a minority had subtle cranial nerve signs such as reduced corneal reflex. Adenoid cystic carcinoma was the most common pathological diagnosis, followed by adenocarcinoma, squamous cell carcinoma and osteogenic sarcoma.[9] If more common causes of otalgia cannot be identified by physical examination and appropriate investigation, an MRI scan with gadolinium enhancement should be considered to diagnose this rare finding.

While still rare, temporal bone metastases are seen more frequently due to the increasing incidence of cancer and to increase in life expectancy.[10] Haematogenous spread is the commonest route of spread and the commonest sites for the primary tumour are breast, lung, kidney, stomach and prostate. Although temporal bone metastases are often asymptomatic, they may present with otalgia, hearing loss (conductive, sensorineural or mixed), facial nerve paralysis and balance disturbance. The triad of symptoms of otalgia, periauricular swelling and facial nerve weakness should raise the suspicion of temporal bone malignancy. CT scanning will usually be diagnostic. Treatment is almost always palliative.[11]

DENTAL

Dental disorders are the most common cause of referred otalgia and were traditionally thought to account for up to 5.75% of all cases seen in an ENT clinic, but recent work by Fenton et al. suggests they may be considerably less frequent.[12–14] Dental otalgia may arise from the teeth, periodontal tissues or the TMJ.

Teeth/periodontal tissues

Dental pain arising from the teeth and periodontal tissues poses a diagnostic problem to a trained dentist, so it is understandable that referred otalgia from dental pathology may present more of a challenge when presenting to an ENT clinician. The commonest cause of inflammation of the dental pulp (pulpitis) is dental caries. The pain of pulpitis is often poorly localized as the sensory innervation is mainly via non-myelinated type C pain fibres. Chronic pulpitis may fluctuate over a period of weeks or months and, with poor localization of pain and lack of physical signs, is difficult to recognize. Pain associated with acute apical periodontitis and acute apical abscess tends to be severe, throbbing and localized to the affected tooth but, if the inflammation is mild and chronic, localization

may be poor. Partially erupted or impacted wisdom teeth can lead to inflammation of the surrounding soft tissue (pericoronitis). Chronic pericoronitis can present as poorly localized facial/jaw pain with referred otalgia.[15]

Temporomandibular joint dysfunction syndrome

The cardinal features of TMJ dysfunction are diffuse pain felt in or around the joint, crepitus and trismus. Pain is the most common and prevalent symptom. The true prevalence of TMJ dysfunction is not certain but it is estimated that between 20% and 40% of the population suffer from symptoms at some time.[15] Pain from the TMJ, or from related tissues, is common but there is often no definable organic disease. Sufferers of referred otalgia from TMJ dysfunction are more likely to be female, with statistically significant elevated levels of physical comorbidity and psychological stress.[16] Otalgia has been reported to be a symptom of TMJ dysfunction in 64% of patients.[17] Bruxism is a major aetiological factor and has been reported to be present in more than 50% of cases.[18] Patients who have a tendency to bruxism at night often awake with pain that settles during the day. Those who clench or grind their teeth through the day, perhaps secondary to stress, are prone to symptoms in the evening.[15]

The most reliable diagnostic clinical finding in TMJ dysfunction is tenderness of the masticatory muscles. In a large study of patients with TMJ dysfunction, muscle tenderness was seen in the majority of patients, with tenderness of the lateral pterygoid reported in 85%. Tenderness of the joint itself was reported in 67% of patients and 38% had crepitus on auscultation.[18] Intraoral palpation of the lateral and medial pterygoids frequently reveals tenderness, and this finding is more commonly seen in patients with referred otalgia.[19] Patients who have bruxism will often have flattening of the occlusal surfaces of the molar teeth, worn incisors and linear scarring of the buccal mucosa and lateral border of the tongue. Patients should also be assessed for malocclusion as this may cause stress on the TMJ, predisposing to TMJ dysfunction. Radiology rarely contributes to the diagnosis but MRI can demonstrate joint effusion or internal derangement of the joint.[5]

The mainstay of treatment for TMJ dysfunction is rest, a soft diet and simple analgesia, particularly nonsteroidal anti-inflammatory drugs. Application of local heat can be of benefit. Benzodiazepines or low-dose tricyclic antidepressants can help symptoms for more refractory symptoms, but there is risk of dependence. A small proportion of patients may require further investigation and treatment by maxillofacial surgeons, using occlusal splints in the first instance. TMJ surgery is generally considered only as a last resort.

Costen's syndrome[20] includes a variety of ear symptoms thought to originate from the TMJ. The original description was a constellation of symptoms including otalgia, tinnitus, impaired hearing, dizziness and aural congestion. Active treatment of TMJ dysfunction has been shown to relieve otological symptoms.[21] However, Bush et al.[22] found no association of TMJ dysfunction with tinnitus or dizziness, concluding that these symptoms may be more related to psychological distress.

CERVICAL

With the increasing age of the general population, cervical spine degenerative disease (CSDD) must be considered as an increasingly common cause of referred otalgia. Pain referred from the cervical spine is usually persistent retroauricular or infra-auricular and is frequently related to neck movement. In a retrospective study, Jaber et al.[23] found that 42% of referred otalgia was secondary to cervical disorders and the majority of these (37/51) were secondary to CSDD. The condition was also found to be much more common in females (4:1, female:male). This makes referred pain from the upper cervical plexus (greater and lesser auricular nerve) second only to pain referred from the region of the trigeminal nerve.

If cervical otalgia is suspected, clinical examination combined with imaging of the cervical spine is indicated. Imaging studies of the cervical spine have a high false-positive and false-negative rate. MRI of the cervical spine has been shown to be abnormal in nearly 20% of asymptomatic patients,[24] and therefore results should only be interpreted alongside the clinical findings.

First-line treatment of CSDD should be conservative with treatments such as analgesia and physiotherapy.[23]

NEURALGIA

Otalgia can present as one of the features of various cranial neuralgias. Trigeminal neuralgia and post-herpetic neuralgia are the commonest forms of craniofacial neuralgia, both of which have a similar incidence.[25] Trigeminal neuralgia has an incidence ranging from 4–5/100 000 per year up to 20/100 000 per year after the age of 60, and is more common in females than males.[25] It is defined as a sudden, usually unilateral, brief stabbing recurrent pain in the distribution of one or more of the branches of the fifth cranial nerve. Because of this classic mode of presentation and the fact that otalgia is only infrequently reported as a symptom of trigeminal neuralgia, it is not discussed further here. Herpes zoster oticus is often associated with severe acute otalgia, which can persist in the form of a post-herpetic neuralgia. Although the origin of the pain at presentation may initially not be obvious, the diagnosis becomes clear once the typical herpetic vesicles erupt.

Primary neuralgias should be considered as a diagnosis of exclusion and in most cases an MRI scan of the affected cranial nerve is indicated.

Glossopharyngeal neuralgia

The International Headache Society defines glossopharyngeal neuralgia as a severe transient stabbing pain experienced in the ear, base of tongue, tonsillar fossa, or beneath the angle of the jaw.[26] It is much less common than trigeminal neuralgia, the incidence being between 0.2 and 0.7 per 100 000 per year.[27, 28] Glossopharyngeal

neuralgia has been described as two clinical types based on the distribution of the pain: a tympanic type which mainly affects the ear, and an oropharyngeal type which affects the throat.[29] The onset of pain is commonly provoked by swallowing and on occasion by coughing, yawning or talking. A trigger zone may be present within the preauricular or postauricular area, the neck or external auditory canal. Symptoms are paroxysmal and last for seconds to minutes and remission periods occur. Because it is rare, glossopharyngeal neuralgia is often misdiagnosed.[30]

Glossopharyngeal neuralgia usually occurs without any evident lesion affecting the glossopharyngeal nerve. However, most authors implicate vascular compression of the nerve at the root entry zone as the main cause of 'idiopathic' glossopharyngeal neuralgia.[31] From MRI findings and observations during posterior fossa surgery, the posterior inferior cerebellar artery is the most frequent vessel responsible for compressing the glossopharyngeal nerve.[32] Secondary causes of glossopharyngeal neuralgia include stylohyoid syndrome, cerebellopontine angle tumours, parapharyngeal space lesions, pharyngeal malignancy, posterior fossa arteriovenous malformations and multiple sclerosis.[29, 33]

Patients with neuralgia do not respond to conventional analgesic drugs. Since the mechanism of pain begins in demyelinated fibres which become hyper excitable and generate high-frequency discharge, the ideal drugs are those which are able to limit the discharge frequency. Currently, the first-line medical treatment of neuralgia is with carbamazepine.[31] Although about two-thirds of patients who take carbamazepine for neuropathic pain can expect to achieve good pain relief in the short term, two-thirds can expect to experience at least one adverse event.[34] Surgery for glossopharyngeal neuralgia most commonly involves microvascular decompression.[35] This procedure has demonstrated complete pain relief in 64–75% of patients and substantial improvement in a further 16–25%.[36, 37] Nerve section can also be performed, either through a posterior fossa approach, through the neck or with a transtonsillar approach.

Stylohyoid (Eagle's) syndrome

The stylohyoid syndrome results in neuralgia secondary to an elongated styloid process or mineralization of the stylohyoid ligament. The condition was first reported by Eagle[38] in 1937 and subsequently came to bear his name. The normal styloid process is approximately 2.5 cm long and is generally accepted to be elongated if its length exceeds 4 cm. An elongated styloid process is said to be present in 4% of the population, but it has been reported that only 4% of these people present with symptoms.[39] Although Eagle originally described the syndrome as arising following tonsillectomy, later studies have concluded that tonsillectomy is not always an aetiological factor.[40, 41] Symptoms are postulated to occur as a result of compression of the hypoglossal nerve, impingement of the carotid vessels or inflammatory changes at the insertion of the stylohyoid ligament.[41] In fact, the existence of this syndrome is controversial and the Headache Classification of the International Headache Society dismissed it as 'not sufficiently demonstrated'.[26] The symptoms are classically a dull pharyngeal pain, often located within the tonsillar fossa, with radiation to the ipsilateral ear, odynophagia and a foreign body sensation. Although there may not be any specific findings on examination, the styloid process may be palpable in the tonsillar fossa and this can aggravate symptoms. Local injection of local anaesthetic can temporarily relieve symptoms. Radiological diagnosis of an elongated styloid process can be made either by orthopantomography or CT scan. Conservative management with steroids and local anaesthetic along with carbamazepine have been suggested but surgical reduction of the styloid process is considered the preferred treatment.[41, 42] Excision can be performed either transorally through the tonsillar fossa or via an external transcervical approach.

Geniculate neuralgia

Geniculate neuralgia, also known as intermediate nerve neuralgia or tic douloureux of the nervus intermedius, is a rare disorder characterized by brief paroxysms of neuralgic pain felt deeply in the ear. The intermediate nerve (of Wrisberg) is a root of the facial nerve containing sensory and parasympathetic fibres. It is considered to be responsible for the sense of taste in the anterior two-thirds of the tongue, floor of the mouth, palate and sensory information from the skin of the external auditory canal as well as the mucous membranes of the nasopharynx and nose. Its cell bodies are located within the geniculate ganglion. The cutaneous field of the nervus intermedius has been described as the zone of Ramsay Hunt (or zoster zone) and consists of the tympanic membrane, auditory meatus, tragus, concha and the groove between the pinna and scalp.[43] Although the aetiology is often not clear, symptoms have been ascribed to vascular loops[44, 45] and previous herpes zoster infection.

The literature on this condition stresses surgical management, concentrated on the nervus intermedius and geniculate ganglion, and vascular decompression.[44–47] Histological examination of the geniculate ganglion has concluded that geniculate ganglionectomy alone is inadequate, and that nervus intermedius section is also required.[47] Pulec[46, 48] has reported a 30-year experience excision of the nervus intermedius and geniculate ganglion via a middle fossa approach in 64 patients. All patients bar one (who had Lyme disease) had excellent results with respect to relief of ear pain. Other case series describe a combination of microvascular decompression of various cranial nerves combined with section of the nervus intermedius.[44, 47]

MISCELLANEOUS

inflammatory conditions affecting the pharynx and parapharyngeal spaces, larynx, major salivary glands cervical lymph nodes and the thyroid can all cause referred otalgia. Cardiac pain can also present as otalgia via vagal pathways.

Vestibular schwannoma (VS)

Although the commonest presenting symptoms of a vestibular schwannoma are progressive unilateral hearing, tinnitus and disequilibrium, otalgia can be a presenting feature. Studies reporting the incidence of otalgia in this condition suggest it is present 4–5% of the time,[49, 50] although in one study a further 25% complained of mastoid ache on direct questioning.[50] It is hypothesized that otalgia/mastoid ache is due to either compression of the nervus intermedius or dural stretching. The cranial dura mater is innervated by the upper three spinal nerves (C1–C3) and by the three divisions of the trigeminal nerve. As a result of this, pain arising in the dura can be referred to the ear. Indeed, a case of a non-traumatic subdural heamatoma presenting with otalgia as the sole feature has been reported.[51]

Cholesterol granuloma

As discussed above, malignancy within the petrous temporal bone can present with otalgia. Equally, benign processes in this area can cause otalgia. Cholesterol granulomas are expansile lesions of the temporal bone and can present with various symptoms including otalgia, pressure, hearing loss, vertigo and tinnitus.[52]

Nasal/sinus disease

The vidian nerve and greater superficial petrosal nerve supply the posterior ethmoids, sphenoids and nasal mucosa. Inflammation of the posterior ethmoids or sphenoid sinus can therefore cause referred otalgia although this is not a common pathway.[4]

Laryngopharyngeal reflux

As with many medically unexplained symptoms of the aerodigestive tract, laryngopharyngeal reflux (LPR) has been implicated as a cause of otalgia in both children and adults.[53, 54] It is hypothesized that the upper airway mucosa is more sensitive to tissue damage from acid exposure than oesophageal epithelium, therefore otalgia can occur in the absence of other symptoms more typical of gastro-oesophageal reflux.[55]

BEST CLINICAL PRACTICE

- ✓ Otalgia in the absence of discharge, hearing loss or otoscopic abnormality while the patient is symptomatic should raise suspicion of secondary otalgia.
- ✓ Expert dental examination may reveal the primary source of the pain to be the teeth/periodontal tissues or TMJ.
- ✓ Careful examination of the upper aerodigestive tract should be part of the routine clinical examination of a patient with unexplained otalgia.
- ✓ Further investigation/imaging should be guided by clinical suspicion.
- ✓ If a neuralgia is suspected, the opinion of a neurologist should be sought to guide medical management.

KEY POINTS

- Isolated unilateral otalgia may be an indicator of an otherwise asymptomatic malignancy in the aerodigestive tract.
- Dental and cervical disorders are relatively common causes of referred otalgia.
- Numerous neuralgias have been implicated as causes of referred otalgia, but all are rare.

CHAPTER 93

BONE-CONDUCTION HEARING DEVICES

James Ramsden and Chris H. Raine

SEARCH STRATEGY

Data in this chapter may be updated by a search on Medline, Embase, Cochrane, TRIP and NICE Evidence Search for systematic reviews, meta-analyses, randomized controlled trials, prospective non-randomized clinical studies and health economics studies looking at the following devices: Sophono, Bonebridge, Baha systems and Ponto.

INTRODUCTION

Hearing impairment varies in severity and can affect patients of all ages. Hearing loss in infancy and during childhood can significantly impact on communication, language development and education. For adults it can lead to reduced quality of life, depression, social isolation and impact on employment.

Hearing loss may be unilateral or bilateral. In most situations, acoustic hearing devices (ACHDs) will provide benefit (see Chapter 54, Hearing aids). Patients who for various reasons are unable to use ACHDs now have access to a wide variety of audiological implants; each has different indications, benefits and drawbacks. Broadly speaking, bone-conduction hearing aids (BCHAs) can be helpful for purely conductive hearing loss, for mixed or mild to moderate sensorineural hearing loss (SNHL), and for single-sided deafness (SSD).

Related devices include middle ear implants (MEIs) (see Chapter 95, Middle ear implants), cochlear implants (CIs) (see Chapter 94, Cochlear implants) and auditory brainstem implants (see Chapter 96, Auditory brainstem implants). This chapter focuses on bone-conduction hearing devices (BCHDs) that aid conductive, mixed or mild to moderate SNHL and SSD.

HISTORY

The principles of hearing by conducting sound through bone have been known about for centuries. Following the development of the carbon microphone, transcutaneous 'oscillators' emerged in the early 1920s. It was in 1977 that Anders Tjellström first implanted patients with percutaneous bone-anchored hearing aids, ushering in the modern era of bone-conduction hearing.[1] This followed Per-Ingvar Brånemark's well-known work with titanium implant osseointegration.[2] Tjellström's implants allowed direct sound transmission to bone, avoiding the attenuation of the soft tissue over the mastoid. Nobel Pharma commenced initial production, with the Entific company subsequently created to take things forward. For additional background information, Mudry and Tjellström's paper is recommended.[3]

PHYSIOLOGY

Bone-conduction hearing devices (BCHDs) deliver sound energy to both inner ears.[4] The overall principle is to establish pressure differences between the scala tympani and the scala vestibuli such that there is movement of the

basilar membrane and hence neural stimulation. There are multiple complex sound pathways[5] (Figure 93.1):

- **Outer ear:** In addition to normal air conduction, bone-conduction (BC) sound vibrations enter the external auditory canal (EAC) via soft tissue and bone vibrations which are transmitted to the tympanic membrane (TM). The sound energy to the TM can change notably if the EAC is occluded.[6, 7]
- **Middle ear:** With a normal ossicular chain connected between the TM and stapes footplate, the ossicles have been shown to vibrate in phase with low frequencies but become decoupled at higher frequencies.[8]
- **Inner ear:** Sound and vibration transmission relies on fluid pressure changes and inertia/fluid inertia. Sound is therefore acting both by direct inertial forces through bone but also from the outer and middle ear.

Transcranial transmission is recognized to be quite efficient and hence the contralateral ear requires masking when BC audiometry is performed. Transcranial transmissions are close to 0 dB for frequencies up to 700 Hz and decrease with higher frequencies.[9]

This has clinical implications because BC sensitivity is fairly similar between percutaneous and transcutaneous modes of transmission for frequencies below 1 kHz.[10] There would be an expected 5–15 dB improvement in efficiency with percutaneous systems when a BC transducer is directly attached to the skull at higher frequencies. Transmission increases through the skin in line with the area of skin transducer interface.[11]

In cases of bilateral stimulation a low transcranial transmission is better for binaural cues; for single-sided deafness a high transcranial transmission is better. Looking into the benefit of bilateral implants, an improvement in terms of hearing thresholds, sound localization and speech perception has been reported.[12] Binaural fitting is preferred for bilateral conductive loss when the BC thresholds do not vary by more than 20 dB in the higher frequencies of 3 kHz and 4 kHz. In cases of unilateral hearing loss the contralateral ear should have a BC average of ≤20 dB HL to reduce the head shadow effect.[13]

CLASSIFICATION

BCHDs should be considered in context with other implantable devices such as middle ear, cochlear and brainstem implants. All these have a role in helping with hearing rehabilitation when acoustic aids are unable to give benefit.

BCHDs are broadly categorized as either **percutaneous**, i.e. where the device is in direct contact with the skull, or **transcutaneous,** where the skin and soft tissue are interposed. Percutaneous systems are well established, with a titanium abutment passing through the skin to allow a hearing aid to pass the sound directly into the bone. The transmission across the skin is 'passive' as there is no active component apart from the external hearing aid.

Transcutaneous systems are those with intact skin. These can pass the sound passively across the skin, or can be active with an internal vibrating actuator or amplification device (Table 93.1).

CLINICAL INDICATIONS

BCHDs are generally used for the rehabilitation of hearing loss only when conventional acoustic aids cannot be fitted, or have been trialled and have failed to improve the hearing.

Common current indications include the following:

- **Conductive and mixed losses**
  - congenital causes such as atresia or microtia (see Chapter 12)
  - acquired causes such as chronic otitis media or ossicular pathology (see Chapter 83)
  - chronic discharging ear (such as chronic suppurative otitis media (CSOM) or recurrent otitis externa) (see Chapter 78 and Chapter 83)
  - inability to wear a hearing aid following radical mastoid surgery
  - unilateral mixed hearing loss.
- **Single-sided deafness – sensorineural or conductive**
  - trauma resulting in hearing loss.

TABLE 93.1 Surgical classification of BCHDs

Type of device	Skin relationship
Percutaneous	Passive
Transcutaneous	Passive (skin drive)
	Active (direct drive)

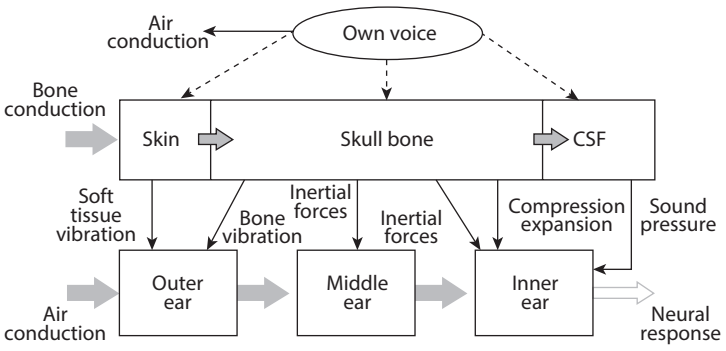

Figure 93.1 A model of the pathways involving sound conduction (reproduced courtesy of Stefan Stenfelt Karger publications).[9]

- unsuitable ear canal for a conventional hearing aid, e.g.
  - in a radical mastoid cavity
  - an extremely narrow ear canal
  - 'blind sac' ear canal closure
  - lateral temporal bone resection
  - extensive cranial base surgery.

ASSSESSMENT

The assessment of patients must be within a multidisciplinary team (MDT) framework, to ensure that the most appropriate system is used, as alternative devices such as MEIs and CIs complement the whole process.[14]

The devices are in continuous development. New systems will emerge in the future so it is recommended to follow the manufacturer's fitting criteria, but not to implant at the upper end of such fitting criteria, as a small additional drop in hearing will mean that the device is no longer suitable.

In 2016 NHS England published commissioning guidelines.[15] Funding would be considered for the following:

1a Patients with unilateral or bilateral conductive or mixed hearing loss within the manufacturer's fitting criteria
AND
Stable BC thresholds (≤15 dB deterioration in >2 frequencies in a 2-year period)
OR
1b Unilateral sensorineural hearing impairment (including SSD) where the better ear has BC hearing thresholds within the manufacturer's fitting criteria including SSD
AND
2 The patient has trialled an ACHA or wireless CROS/BiCROS hearing aid for a minimum of 4 weeks, or is anatomically or physiologically unable to undertake a trial of an ACHA
AND
3 Has trialled a BCHD on a softband or headband for a minimum of 14 days and shown benefit in speech tests.[10]

Systems are available to trial processors in a passive transcutaneous format. These are supplied as headbands and elasticated softbands and the recently introduced Sound Arc (manufactured by Cochlear) and the adhesive skin attachment ADHEAR (manufactured by MED-EL) prior to any surgical intervention (**Figure 93.2**).

Figure 93.2 Sound Arc.

For the child with congenital meatal atresia/microtia, consider carefully the management of the pinna, be it with prosthetics or reconstruction so that surgical approaches used for BCHDs do not compromise future reconstruction. Surgical correction of meatal atresia is now rarely performed in the UK (see also Chapter 16, Microtia and external ear abnormalities).

BCHDs will not be commissioned for:

- patients with a bone disease that is unable to support an implant
- patients who have a sensitivity or allergy to the materials used
- patients with physical, emotional or psychological disorders that, despite suitable treatment and support, would interfere with surgery or the ability to allow suitable rehabilitation such that significant benefit would be unlikely.

SURGICAL OPTIONS

Percutaneous (bone-anchored) devices

Two devices are currently available in the UK – the Baha® (Cochlear™ Bone Anchored Solutions) and the Ponto bone-anchored hearing system (Oticon Medical). The Cochlear Baha system was initially commercially available from 1984 (manufactured by Entific), and the Oticon from 2009.

Both are semi implantable, with a titanium osseointegrated fixation into the skull and a skin-penetrating abutment to facilitate attachment for the sound processor aid. This abutment allows for direct and effective transmission of sound vibrations to the skull and hence to the inner ear (**Figure 93.3**).

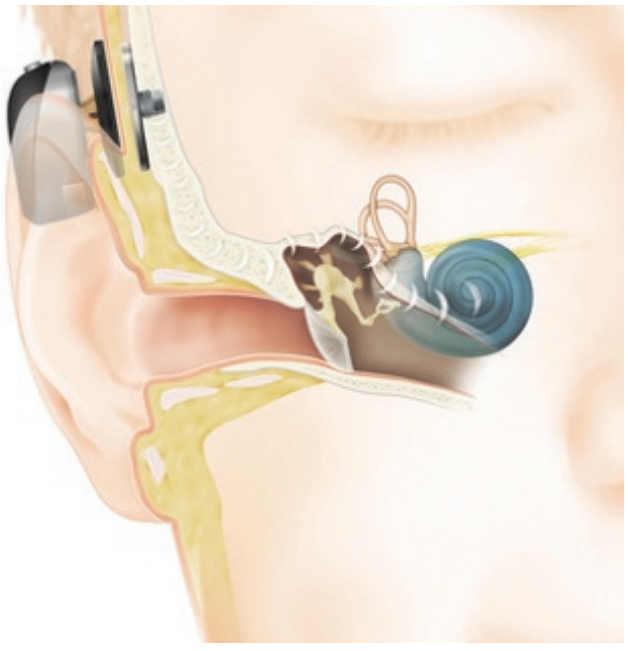

Figure 93.3 The Cochlear BAHA system (courtesy of Cochlear Limited).

Figure 93.4 Cochlear connect based on the BA400 abutment and BI300 implant (courtesy of Cochlear Limited).

In 2010 Cochlear introduced changes to the osseointegrated titanium fixture which included a wider base (4.5 mm versus 3.75 mm) for increased stability, smaller treads at the implant neck to improve load distribution and a tioblast™ coating for faster osseointegration to the BI300 system. In 2012 it further modified the abutment with a hydroxyapatite coating (BA400) (Figure 93.4).

Oticon Medical's system similarly comprises an implant and options of various lengths of percutaneous abutments to cater for various skin thicknesses which enable tissue preservation surgery. The dermatome to take split skin is no longer used.

Audiological criteria

The results of presurgical assessment with a transcutaneous processor give a good indication of outcome as skin attenuation can account for 10–15 dB. The power of processors has increased, with BC levels of about 65 dB over 1, 2 and 3 kHz using the most powerful processor currently available.

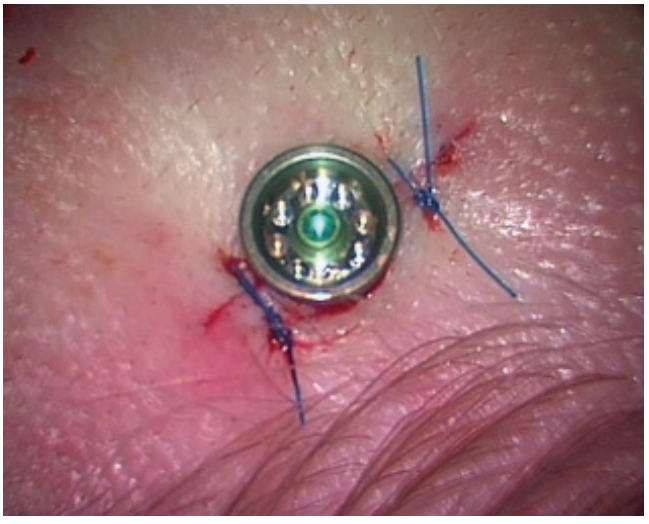

Figure 93.5 Oticon abutment inserted using minimal extended incision.

Surgical considerations

The Food and Drug Administration have set a minimum age for paediatric use at 5 years. However, the minimum age for implantation is debated and there is no fixed worldwide guideline. In 2005 an international consensus was issued regarding BCHAs, which recommended that surgery not be undertaken prior to age 2–3 years. This was to allow the skull to reach a minimum thickness and conditions to be suitable to fit the fixture and allow osseointegration.[16]

Though successful implantation has been reported in patients as young as 14 months, the complication rate is inversely proportional to the age at implantation.[17] It is important to stimulate hearing as early as possible, and therefore in children too young for implantation the use of a BCHA via a softband, which holds the hearing aid to the skin of the scalp via a metal or elastic headband, is advocated from about the age of 3 months.

In the past, bone-anchored hearing aid (BAHA) surgery on children was staged, but the newer tissue-preserving single-stage implants mean this is not always necessary. A simple linear incision eliminates the need for a skin flap (Figure 93.5).

However, in children a longer time to osseointegrate is recommended to compensate for the thinner bone, although this is subject to further evaluation at present.[18]

The implantation is usually performed under local anaesthetic and is well tolerated, although anxious patients and children may require sedation or general anaesthetic.

MRI compatibility

With the external processor removed, the remaining titanium implant and abutment are non-magnetic and pose no issue with MRI compatibility. A small area of artefact will, however, be caused adjacent to the implant.

Outcomes

The main post-operative difficulties from transcutaneous BAHAs relate to the protrusion of the abutment through the skin. There are cosmetic issues, although these vary in importance in different cultures. A practical and quite

TABLE 93.2 Classification of cutaneous complications of transcutaneous abutments in BAHAs (after Holgers et al.)[19]

Severity	Complication(s)
Grade 0	No skin reaction
Grade 1	Redness with slight swelling
Grade 2	Redness, moistness and moderate swelling
Grade 3	Redness, moistness and moderate swelling with tissue granulation
Grade 4	Profound signs of infection, resulting in removal of the implant

frequent (up to 10% of patients) difficulty with percutaneous BAHAs is that the skin requires daily hygienic care and there can be skin overgrowth around the abutment, skin infection and low-grade inflammation. This requires medical attention and can occasionally lead to loss of the fixture/abutment.

The most useful classification of cutaneous complications of transcutaneous abutments in BAHAs was suggested by Holgers et al. (**Table 93.2**).[19] This scale, which ranges from 0 to 4, with 0 being reaction-free skin around the implant and 4 being overt infection requiring implant removal, is usually used to report skin complications.

These complications seem to affect children more than adults. There is a higher rate of fixture loss (up to 14% over 15 years) in the paediatric population.[20] A much higher rate of fixture loss occurs with the shorter 3 mm fixture, so a 4 mm fixture should always be used where practical.

Challenges in a paediatric setting include accommodating for growth and increases in soft-tissue thickness, especially during puberty. The abutment is available in various lengths and may be changed to adapt to the child's growing needs.

Passive transcutaneous devices

Two passive systems are available for use with adults and children: the Sophono™ (Medtronic, Boulder, CO) and the Cochlear™ Baha® Attract (Cochlear™ Bone Anchored Solutions). Both depend on the fixation of an internal magnet to the skull, which is passive. An external hearing aid with oscillator can then be attached to an external magnetic pad, made soft with padding, to allow the firm attachment of the device to the skin. This then transmits the sound in a similar way to a softband, although there is additional transmission of sound through the firm connection of the internal magnet to the bone. One of the benefits of such systems is a reduction in the risk of inflammation, injury and the psychological problems that are associated with percutaneous devices.[21]

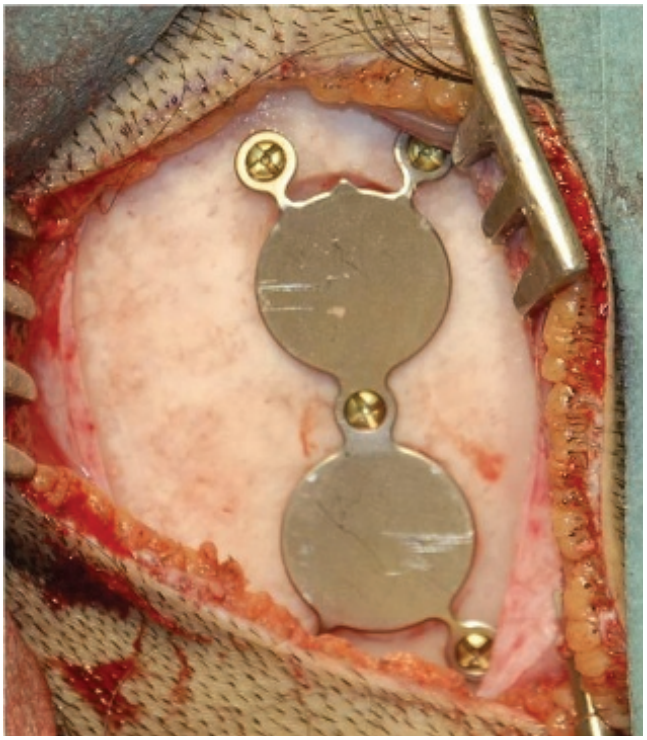

Figure 93.6 The Sophono plate *in situ*.

SOPHONO™

Professor Siegert initially published his results of the 'Otomag' system, a partially implantable bone-conduction device, in 2011.[22] The Sophono Alpha 2 MPO™ system comprises a surgically implanted internal plate containing twin hermetically sealed magnets (**Figure 93.6**) and the external digital sound processor is coupled to a base plate housing twin magnets corresponding to the internal ones. The processor transmits vibrations through the skin into the bone and then to the cochlea. The device is intended for people with conductive hearing loss, SSD and mixed hearing loss.

Audiological criteria

As processors have developed, so has candidacy. BC hearing thresholds should be ≤45 dB or in the case of SSD, ≤20 dB in the contralateral ('good') hearing ear. However, care should be taken to stay well within these limits as there is high-frequency attenuation in all passive transcutaneous devices which limits amplification significantly.

Surgical considerations

Magnets are implanted into shallow 2 mm bone beds in a one-stage procedure. They are secured with five titanium screws (**Figure 93.6**). The skin above the magnets should be reduced to a thickness of 4–5 mm, which reduces the attenuation to less than 10 dB compared to direct bone stimulation. Programming typically commences 4–6 weeks after surgery.

MRI compatibility

The Sophono™ is MRI conditional up to 3 Tesla.[23] It is reported that the magnets create a 5 cm shadow/artefact.

BAHA® ATTRACT SYSTEM

A new transcutaneous system, the Baha® Attract, uses a magnet to secure the BAHA. While a major advantage in a paediatric setting is eliminating the soft-tissue complications of a BAHA, disadvantages include artefact on subsequent MRI scans and possible dampening of the high-frequency signal through the skin.

Audiological criteria

These are essentially the same as the Sophono, and caution should be exercised if there is significant SNHL at the high frequencies.

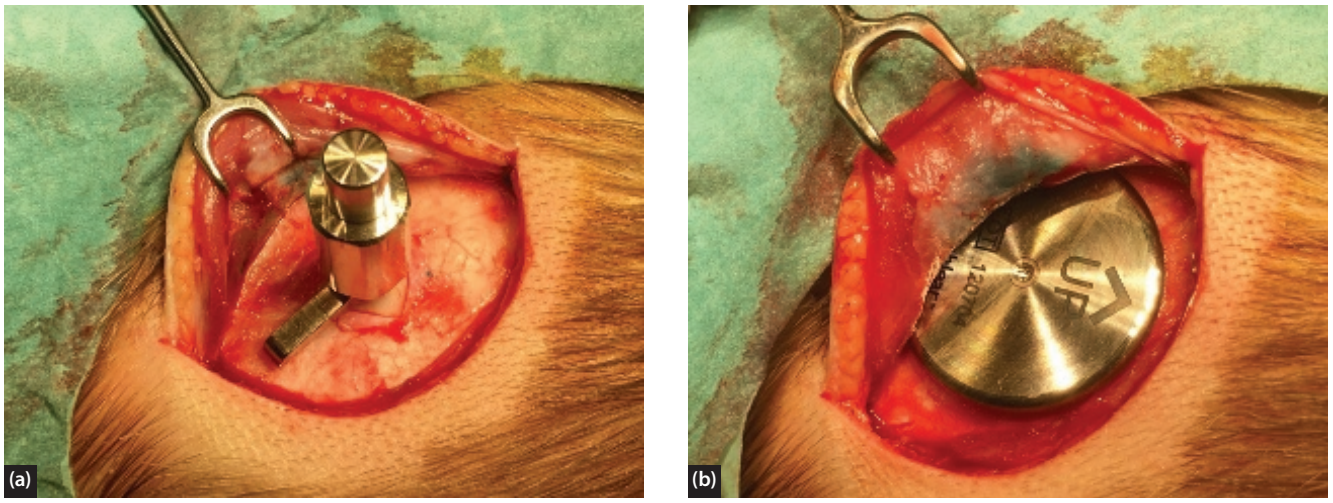

Figure 93.7 The BAHA® Attract. (a) A rotating sizer is used to make sure the bony bed is flat with no secondary points of contact with the magnet. **(b)** The BAHA Attract magnet *in situ*.

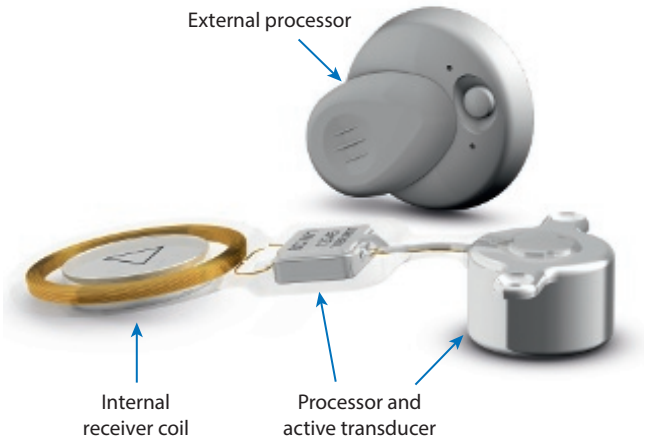

Figure 93.8 The Bonebridge components.

Surgical considerations

The system is based on the established osseointegrated BI300 implant secured to the skull behind the pinna and a BIM400 implant magnet that are implanted beneath the skin. Surgery is usually performed under local anaesthetic as a one-stage procedure. Surgically the magnet has to be correctly aligned and must not be in contact with the bone. A special bone bed indicator is used to ensure compliance (**Figure 93.7**). Prior to closure the optimal skin thickness is 3–6 mm. If the skin is too thick, the processor may be less efficient or fall off.

MRI compatibility

Non-clinical testing has demonstrated that the BIM400 implant magnet, in combination with the BI300 implant, is MRI conditional in a static field of 1.5 Tesla. An image artefact is approximately 11.5 cm.[24]

Active transcutaneous devices

There is currently one commercially available active transcutaneous system. This is the Bonebridge, an active semi-implantable internal device produced by MED-EL (Vibrant MED-EL Hearing Technology GmbH). Other devices are in clinical trials.

Introduced in September 2012 following on from the principles of the successful development of the Vibrant Soundbridge middle ear implant (see Chapter 95, Middle ear implants), the Bonebridge consists of an external audio processor and an internal BC implant (**Figure 93.8**). The internal component has a receiver coil, a magnet, a demodulator and a bone-conduction floating mass transducer (BC-FMT) secured to the bone by two titanium screws. The power to drive the FMT is transmitted transcutaneously via an inductive link to the internal coil, processed by the demodulator and then relayed to the BC-FMT, which then transduces the signals into mechanical energy. Osseointegration of the titanium screws is not thought to be crucial.

Audiological criteria

The Bonebridge is designed for patients with conductive and mixed hearing losses as well as SSD. The BC level should be better than 45 dB between 500 Hz and 4 kHz and 20 dB or better in the contralateral ear for SSD. There should be stable thresholds and no evidence of auditory neuropathy, retrocochlear or central hearing impairment.[25, 26]

Surgical considerations

The principle of surgery is the placement of the BC-FMT either within the mastoid or in the retrosigmoid position. The BC-FMT should not be placed in an unhealthy mastoid. Surgery is typically performed under general anaesthesia but local anaesthesia is a practical option.[27] Because of the size of the device, surgery is reserved until there has been sufficient skull growth to accommodate it.

It is recommended that radiological planning using 3D reconstruction be performed prior to surgical intervention (**Figure 93.9**).

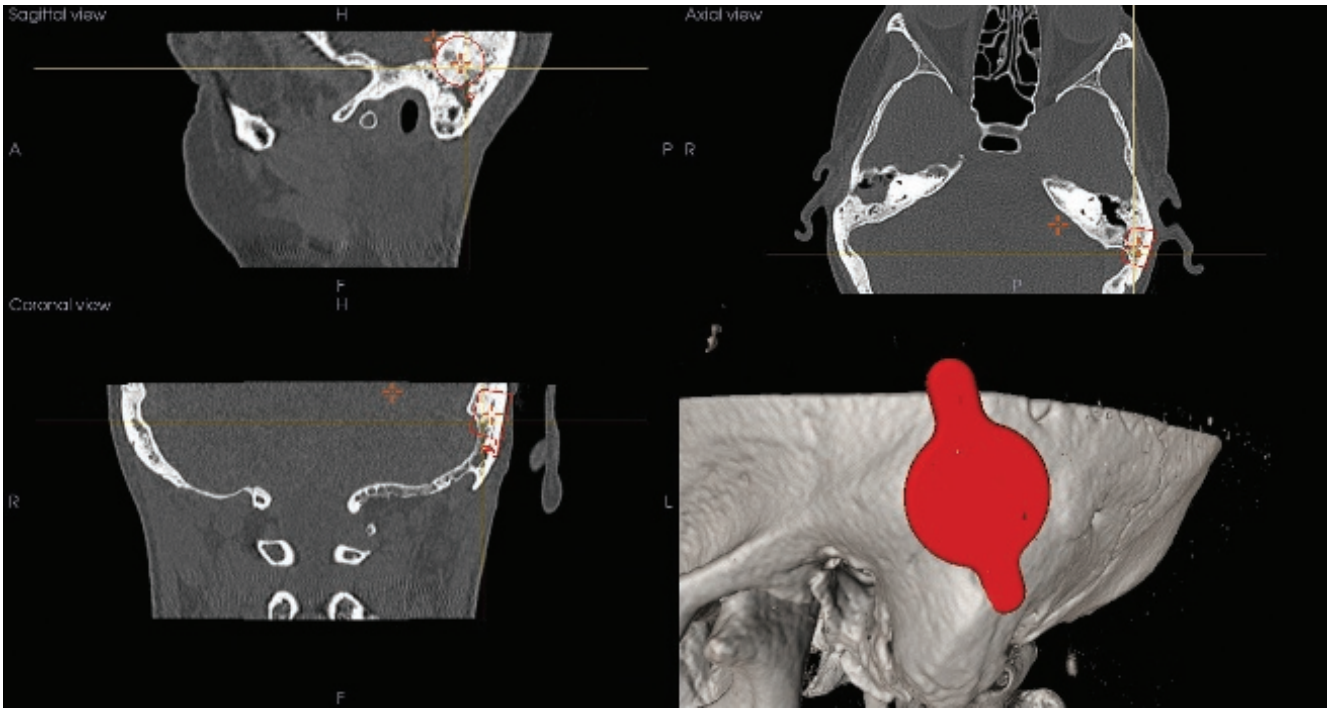

Figure 93.9 3D planning using radiological images.

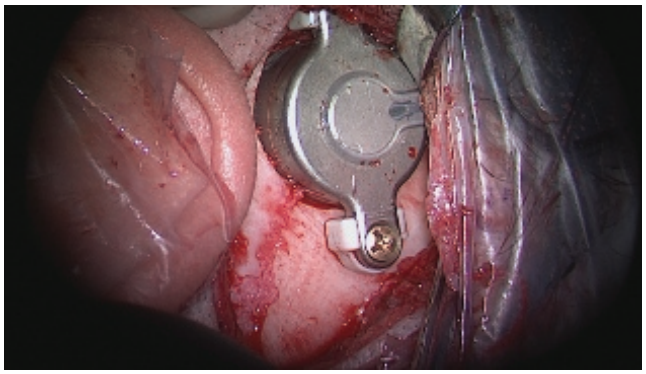

Figure 93.10 The Bonebridge *in situ* with 'lifts'.

Compression of the sigmoid sinus and/or dura may be necessary but 'lifts' of up to 4 mm can be used and are often required. The device is held in place by titanium screws (Figure 93.10). The system was found to be safe and effective.[28]

MRI compatibility

The device has a non-removable magnet. Following testing, the manufacturers report the device is conditional to 1.5 Tesla. As with the presence of a magnet, image artefacts will occur.

CONCLUSION

New devices continue to be introduced and current technology continues to evolve. With time, new indications continue to arise in the treatment of paediatric deafness. Despite the rapidity of introduction of new technology, it is important that the introduction and application of this into patient care be conducted in a rigorous evidence manner. In achieving this, it is essential that good collaboration continues between the clinicians and industry and, most importantly, that regular and thorough feedback from patients and caregivers about the influence on these on their quality of life is sought.

BEST CLINICAL PRACTICE

- ✓ A multidisciplinary team should oversee all children considered for BCHDs.
- ✓ Implanting children with percutaneous devices at too young an age risks an increase in complications. Children should be aged at least 2 years to permit sufficient growth in the skull. The FDA has set a minimum age of 5 years.
- ✓ Careful planning is especially important for children with microtia so that later reconstruction or cosmesis is not compromised.
- ✓ A simple linear incision with no elaborate skin flaps is usually sufficient for BAHA surgery.
- ✓ Some devices and device components cause difficulty with MRI scanning. Devices may also cause issues with airport security systems. Make sure clinicians, patients and parents are aware by consulting individual manufacturer's guidelines.

KEY POINTS

- A range of devices to transmit sound energy to the inner ear via the bones of the skull (BCHDs) is now available.
- BCHDs are used for the rehabilitation of hearing loss when conventional acoustic aids cannot be fitted or have been trialled and have failed to improve the hearing.
- Indications for use are increasing.
- Very good results are now reported in children with single-sided deafness.

CHAPTER 94

COCHLEAR IMPLANTS

Andrew Marshall and Stephen Broomfield

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: cochlear implants, cochlear implantation AND hearing implants, surgery, candidacy, criteria, standards, adults, paediatric, children, elderly, quality of life, outcomes, complications and future.

INTRODUCTION

Cochlear implants have transformed the management of severe to profound hearing loss, particularly in both the very young and the elderly. Cochlear implant surgery and the subsequent rehabilitation are normally straightforward for implant centres within the UK and across the developed world. The technology has had greatest impact in transforming the education of children born with a profound hearing loss who are implanted early. The majority of these children attend mainstream education, using spoken language to communicate.

At the other end of the age spectrum, it is recognized that there is significant unmet need in the treatment of severe to profound hearing loss in the adult population, particularly the elderly.[1] The impact of this unmet need can have a significant effect on the individual's health and impose a financial burden on society as a result.[2]

BASIC PRINCIPLES

Cochlear implantation (CI) is considered in patients with severe to profound hearing loss who are failing to gain sufficient benefit from appropriate and well-fitting hearing aids. Audiological and other criteria for implantation are different for adults and children and are discussed further below. The external part of the cochlear implant detects the sound signal and converts it to an electrical signal which is transmitted to the internal processor. The way in which the signal is passed into the electrode array depends on the speech processing strategy utilized by that device. Each implant manufacturer has developed strategies that they believe have advantages over the others.

All cochlear implants make use of the tonotopic arrangement of the auditory system, whereby high-pitched sounds are transmitted through spiral ganglion cells corresponding to the basal turn of the cochlea, and low-pitched sounds by those at the apex of the cochlea. In normal young adults, there are approximately 35 000 auditory nerve fibres; it is estimated that at least 10 000 are required for speech recognition using a cochlear implant.[3] The success of an implant depends upon the transmission of the signal to the auditory cortex via the auditory pathways from the ear, followed by appropriate central processing to ensure understanding of the signal. Consideration of these central functions therefore forms part of the assessment of the cochlear implant candidate.

Performance with a cochlear implant is optimized postoperatively through a process of programming known as 'mapping', combined with intensive rehabilitation. The cochlear implant team is therefore multidisciplinary and includes teachers of the deaf, speech and language therapists, psychologists, audiologists, audiological scientists, radiologists and surgeons. Widely accepted standards exist for the assessment and management of patients being considered for CI.[4–6]

CANDIDACY

In the earliest years of cochlear implants, the technology was considered to be experimental and was offered only to the most profoundly deaf adults. In modern practice, the reliability and outcomes of CI have improved and criteria for candidacy have evolved to include both adults and children with some residual hearing as well as congenitally deaf infants. Criteria differ according to the healthcare systems and funding arrangements of individual countries. In England and Wales, the National Institute for Health and Care Excellence (NICE) have stipulated the following criteria for CI, based on clinical and cost-effectiveness assessments:[7]

- A cochlear implant should be considered for any person with a severe to profound hearing loss who does not gain adequate benefit from acoustic hearing aids.
- Severe to profound deafness is defined as the ability to hear only sounds louder than 90 dB HL at 2 kHz and 4 kHz without hearing aids.
- Hearing aids should be used for at least 3 months unless inappropriate or contraindicated.
- Adequate benefit with hearing aids is defined as:
  - For adults, a score of 50% or greater on Bamford–Kowal–Bench sentence testing at a sound level of 70 dB SPL.
  - For children, speech, language and listening skills appropriate to age, developmental stage and cognitive ability.
- Assessment should be by a multidisciplinary team and the tests used should be adapted to take into account the candidate's disabilities as well as their language and communication ability.
- Simultaneous bilateral CI is recommended for children and for adults who are blind or who have other disabilities that increase their reliance on auditory stimuli as a primary sensory mechanism for spatial awareness.

The audiological assessment of potential cochlear implant recipients usually also includes an auditory brainstem response (ABR) test. This aids in: validating the accuracy of the behavioural responses; detecting a central problem or absent cochlear nerve; and (in older patients) ruling out non-organic hearing loss.

Special cases

In many cases, a candidate clearly meets the above criteria and, following a full assessment (described in 'Assessment' below), decision-making is straightforward. Often, however, there are additional factors that must be taken into account. These factors are likely to lead to a further evolution of cochlear implant candidacy criteria in future.

Adults

RESIDUAL HEARING

Traditionally, any residual hearing in an ear receiving a cochlear implant would be lost. With current surgical techniques (described in 'Surgical technique' below), it is possible to preserve hearing in some cases. This allows for combining a hearing aid with a cochlear implant in the same ear, known as electric–acoustic stimulation (EAS). Typically, this applies to the patient with a 'ski-slope' hearing loss, i.e. some hearing in low frequencies, dropping abruptly to a severe to profound loss in the higher frequencies such that the criteria for CI are still met. Specially designed electrode arrays are available for this situation, for example the 'Hybrid' electrode (Cochlear Ltd) that is shorter than other electrodes, entering only the basal turn of the cochlea and therefore covering just the higher frequencies. Many surgeons prefer, however, to use a medium or standard-length atraumatic electrode with which residual hearing can often still be preserved; but should hearing be lost, the full range of frequencies is covered by the electrode, ensuring optimal performance.

THE ELDERLY

With the rising average age of the population of developed countries, cochlear implant candidates increasingly present in their seventies and eighties. There is good evidence that this group perform well with cochlear implants, with similar speech perception and improvement in quality of life when compared to younger recipients.[8, 9] Recently, a link between hearing impairment and cognitive decline in older adults has been shown,[10] and CI may have a role to play in improving social interaction and preventing cognitive decline in profoundly deaf elderly patients.[11]

FAR-ADVANCED OTOSCLEROSIS

The term 'far-advanced otosclerosis (FAO)', first used by House and Sheehy in 1961, is applied to the patient with otosclerosis and a profound hearing loss. Such patients may undergo stapedectomy in an attempt to restore their ability to wear hearing aids. However, results from CI are also good, with some series finding patients with FAO to be among the best performers, possibly due to the fact that the otosclerosis process generally spares the sensory elements of the cochlea.[12] Studies suggest that the outcomes of CI in FAO are equivalent to those in other aetiologies of deafness, with an improved quality of life.[13, 14] Patients with FAO are more prone to non-auditory stimulation (e.g. facial nerve stimulation), though in most cases this can be easily resolved by switching off the electrodes that are responsible, albeit with some potential reduction in performance.[13, 15, 16]

NEUROFIBROMATOSIS TYPE 2

Hearing loss in patients with neurofibromatosis type 2 (NF2) may be secondary to bilateral vestibular schwannomas or their treatment. Using modern surgical techniques, it is sometimes possible to excise tumours with preservation of the cochlear nerve. This allows for consideration of CI rather than auditory brainstem implantation, with more reliable outcomes. Intra-operative testing using electrically evoked auditory brainstem responses or cochlear nerve action potentials may be used to determine whether

a cochlear implant is appropriate. In England, the four specialist NF2 centres have agreed a protocol for the management of hearing loss in this challenging group.[17]

SINGLE-SIDED DEAFNESS

Following CI in a group of patients with single-sided deafness (SSD) who underwent surgery as a primary treatment for troublesome tinnitus, it was discovered that not only did the tinnitus improve but, in addition, the patients experienced significant audiological benefit.[18] It became apparent that previous concerns regarding the brain's ability to integrate electrical and acoustic signals from the two ears were unfounded. For patients with SSD, CI provides particular improvement in speech recognition in noise.[19] Criteria in the UK do not yet allow for CI for SSD, as cost-effectiveness is yet to be established.

PATIENTS OUTSIDE CURRENT CRITERIA

Whatever audiological criteria are applied, all cochlear implant centres frequently encounter patients who are struggling to hear using standard hearing aids but whose speech recognition scores are outside those criteria. Despite this, such patients often benefit significantly from CI.[20] Similar findings have been reported in children.[21] This highlights the need continually to review selection criteria and to reassess the measures used for assessment.

Children

ADDITIONAL DISABILITIES

In the early days of CI, children with significant additional disabilities (including cognitive impairment, developmental delay, visual impairment and communication disorders) were considered unsuitable candidates. As candidacy criteria have expanded, such children have been increasingly assessed for CI. In addition, with infants receiving CI before the age of 12 months, a number of children are diagnosed with additional disabilities (e.g. autistic spectrum disorder) only after their cochlear implant. Traditional assessment tools and post-operative speech perception measures may be unsuitable for children with additional disabilities, many of whom will never develop oral communication; decision-making and post-operative rehabilitation therefore often rely upon the experience of the cochlear implant multidisciplinary team.[22] Careful counselling of parents is crucial to decision-making and to ensure realistic expectations of outcome.

AUDITORY NEUROPATHY SPECTRUM DISORDER

Auditory neuropathy spectrum disorder (ANSD) is characterized by absent auditory brainstem responses with normal otoacoustic emissions. The prevalence of ANSD may be as high as 10% in children with permanent hearing loss.[23] There is a range of functional hearing impairment in ANSD, and in cases with severe to profound hearing loss CI can be an effective means of rehabilitation.[24] However, as the hearing in ANSD may improve over time, a period of observation is recommended before proceeding to surgery. This explains why the majority of children with congenital sensorineural hearing loss (SNHL) are observed until at least the age of 6 months, when behavioural hearing assessments are possible and the decision to proceed to surgery can be made with increased confidence. Longer periods of observation may be appropriate in some cases, though timely intervention is crucial to ensure optimal cochlear implant outcomes.[25]

ANATOMICAL ABNORMALITIES

Congenital profound SNHL is associated with inner ear anatomical abnormalities in approximately 20% of cases.[26] The cochlear nerve itself may be absent or hypoplastic; such cases require careful clinical and electrophysiological assessment to determine whether cochlear or auditory brainstem implantation is appropriate.[27] In some cases such abnormalities are isolated findings, but they may be associated with other anatomical variations (e.g. facial nerve position) or particular syndromes (e.g. CHARGE syndrome). Pre-operative assessment and surgical planning must be undertaken with additional care to ensure appropriate management of these complicated cases.[28]

ASSESSMENT

Medical

When considering cochlear implantation, patients who are found to meet the audiological criteria must undergo additional medical, otological, imaging and psychological assessments. Modern surgical and anaesthetic techniques mean that CI surgery is straightforward in uncomplicated cases. The pre-operative assessment of the patient considering CI focuses on ensuring fitness for general anaesthesia. This particularly applies to the very young and very elderly. CI is possible under local anaesthesia in adult patients who may not be fit for surgery otherwise.[29]

Otological

CI is contraindicated in patients with active middle ear infection or cholesteatoma, as infection around an implant may be associated with an increased risk of meningitis.[30] In addition, chronic infection is extremely difficult to eradicate and may necessitate device removal or lead to the device extruding. In such cases, any infection or disease in the middle ear or mastoid must be fully eradicated prior to implantation, with surgical treatment being required in many cases. Perforations of the tympanic membrane should be closed to provide a barrier against infection. In patients who have had canal wall-down mastoid surgery previously, or who require it to treat their disease in preparation for implantation, the usual recommendation would be to obliterate the middle ear and mastoid cavity and close the ear canal with a blind sac procedure. This must be done with meticulous surgical technique to

reduce the risk of development of cholesteatoma, which may remain asymptomatic for many years.[31] In cases that require surgical treatment for middle ear or mastoid disease, CI can be performed simultaneously or as a staged second operation, usually 3–6 months later.[32,33] The management of otitis media with effusion (glue ear) in children requiring CI, or who develop it following implantation, remains controversial. However, significant complications related to ventilation tube insertion either prior to, or following, CI are rare.[34]

Imaging

Cross-sectional imaging is a key part of pre-operative planning prior to CI. Identification of cochlear or cochlear nerve aplasia, which would make implantation impossible, is particularly important in prelingually deafened infants. Magnetic resonance imaging (MRI) is therefore the preferred initial imaging modality in this group.[35] Other abnormalities, including inner ear anomalies, cochlear lumen obliteration (e.g. following meningitis or in cochlear otosclerosis), middle ear pathology and anatomical variations (e.g. low-lying dura or anterior position of the sigmoid sinus) should also be identified pre-operatively. Computerized tomography (CT) scanning may improve the identification of such anomalies, and is routine practice in some centres. It is the authors' practice to use CT scanning selectively in infants, to avoid exposure of the developing brain and orbits to ionizing radiation. In adult patients, previously undiagnosed coexisting pathologies (e.g. acoustic neuroma) may be identified using MRI scanning, which is again the modality of choice.[36]

Psychological

The clinical psychologist is an important member of the cochlear implant team. Every patient and parent considering CI must be carefully counselled, to ensure that they are prepared for the surgery and post-operative rehabilitation, to ensure realistic expectation of outcome, and to discuss potential concerns regarding the process. While in some cases this work can be done by the other members of the multidisciplinary team, the psychologist is best placed to explore the complex social, family, cultural and peer-related issues that are not uncommon in this population.[37] Some groups, including adolescents, patients with a long duration of deafness and patients with a history of psychiatric problems, may have a particular need for psychological input prior to CI.

DEVICES

There are four manufacturers providing cochlear implants for use in the UK (Advanced Bionics, Cochlear, MED-EL and Oticon Medical (previously Neurelec)). A full discussion of the differences between the available devices is outside the scope of this chapter. Outcomes are generally similar with all devices (see 'Outcomes' below), and all have similar reliability according to internationally agreed reporting guidelines.[38] All of the devices share a similar basic design:

- the external part: the microphone, sound processor and transmitter coil
- the internal receiver–stimulator package
- the intracochlear electrode.

These components are summarized below.

The external part: the microphone, sound processor and transmitter coil

This part of the cochlear implant detects the acoustic signal and converts it to an electrical signal with both temporal and spatial components. The encoded signal is transmitted to the internal device using radiofrequency via the external coil. New developments in the external components include: the position of the microphone (including devices that are a single magnetic unit, with no behind-the-ear processor); improved functionality drawing on advances in hearing aid technology (for example the Advanced Bionics Naida system that allows direct communication between the cochlear implant and a hearing aid in the contra-lateral ear to provide bimodal hearing); wireless connectivity to external devices; improved waterproof capability.

The internal receiver–stimulator package

This contains the internal magnet, telemetry coil and hermetically sealed electronics system. There is also a ground electrode for current return, either incorporated within the package or as a separate electrode placed under the temporalis muscle. Once received, the decoded signal is sent to the electrodes within the cochlea according to the processing strategy being used. New developments in the receiver–stimulator package include new processing strategies and smaller size. In addition, the latest generation of cochlear implant devices are all compatible with MRI scanning to 1.5 Tesla without magnet removal. Special precautions may be required to reduce potential complications.[39] Stronger MRI fields may necessitate magnet removal, though new designs such as MED-EL's rotating magnet that self-aligns when in the MRI field allows MRI scans up to 3 Tesla with the magnet *in situ*.

The intracochlear electrode

The electrode that is placed into the cochlea is in fact a group of individual wires, each ending at a contact point along the silicone casing. The number of individual wires varies depending on the manufacturer and type of electrode. Electrodes have become generally smaller in an attempt to reduce the trauma of insertion and allow for hearing preservation as well as the potential use of future technologies that might require preservation of cochlear function. Modern electrodes can be inserted via the round window or through small cochleostomies with a diameter of 0.5–0.8 mm.

The optimal resting position of the electrode within the scala tympani is debated; various manufacturers advocate lateral wall, mid-scala or modiolar-hugging designs. There is also much debate as to the optimal length of electrode; longer electrodes may allow for stimulation of the full length of the spiral ganglion cells but are also more likely to cause trauma to the apical basilar membrane. New imaging techniques to calculate the cochlear duct length may allow for an electrode of optimal length to be selected for individual patients.[40] Some electrode designs are available for specific situations: examples include the short electrode for EAS (see above), the compressed array or split/double electrode for cochlear ossification, and the electrode with a stopper incorporated into the silicone casing for plugging the cochleosotomy in case of a perilymph gusher.

OUTCOMES

Advances in technology in recent years, in particular the improvement in speech-processing strategies, have led to improved speech perception with CI. In infants, speech perception is of paramount importance for the development of spoken language. Other outcomes in children and adults, such as effect on educational achievement, social interaction, employment and quality of life, are also important. Key evidence regarding outcomes can be summarized as follows.

Outcomes in children

- Earlier age at CI is associated with better language development. This is now well accepted and has been shown in many studies. Many children implanted before 18 months of age show a similar rate of language development as normal hearing peers. Those implanted after 3 years of age may struggle to catch up, and it is recognized that a proportion of children will remain language-delayed when compared to normal hearing peers.[41,42] It is important to note, however, that children with cochlear implants consistently show a higher level of language attainment than profoundly deaf children using hearing aids.
- The importance of early age at implantation is due to the fact that there is a 'sensitive period' of around 2–3 years during which development of the central auditory system shows greatest neural plasticity.[43] The introduction of universal newborn hearing screening has allowed for the early identification of children with profound hearing loss.
- The preferred age of implantation of profoundly deaf infants in the UK is currently considered to be around 12 months. There is emerging evidence that even earlier implantation (between 6 and 12 months) may be optimal, and this has been shown to be safe in experienced centres.[44]
- Cognitive impairment is an important factor in outcome following CI. Children with additional disabilities that include cognitive impairment may never acquire spoken language. Nonetheless, CI may still be an important method of improving quality of life in this group.[22]
- Other factors associated with improved language outcomes in children include the fitting of up-to-date processors, greater residual hearing prior to implantation, better interaction between parent and child, and higher socioeconomic status.[45]

Outcomes in adults

- Duration of severe or profound deafness (and not age at implantation) is the most important factor in predicting speech perception outcomes in adult patients. As with neural plasticity in infants, this is due to a deterioration in the spiral ganglion cell population and the central auditory pathways with a long period of auditory deprivation (e.g. 20–30 years).[46]
- Duration of deafness is often a key consideration in deciding which ear to implant. A common scenario is the patient presenting with one ear that has been unaided for more than 20 years and a small amount of residual hearing on the other side; such a patient is advised to undergo implantation in the better ear, putting the residual hearing at risk to ensure optimal outcome with the cochlear implant (compare this to the more usual situation where the preference is to implant the worse-hearing ear to optimze hearing aid use on the contra-lateral side).

Special considerations

When considering outcomes, some situations warrant special attention.

BINAURAL HEARING

Patients with binaural hearing, bilateral cochlear implants or bimodal hearing (a cochlear implant in one ear and a hearing aid in the other) have improved outcomes when compared to those using a unilateral implant. Advantages include sound localization, spatial acuity and improved speech understanding in challenging listening environments, such as in the presence of background noise (see Wanna et al.[47] for a review of this topic). Some of these advantages improve over time, often years, following implantation. Quality of life is improved in bilateral cochlear implant recipients compared to unilateral recipients, though in sequentially implanted cases the relative increase is higher following the first implant.[48] Due to the advantages offered, there is increasing interest in CI in SSD (see 'Candidacy' above).

For similar reasons, cochlear implant manufacturers are increasingly working closely with hearing aid companies to improve the compatibility of the two devices and thereby provide optimal binaural hearing when only one cochlear implant is inserted.

MUSIC PERCEPTION

Despite recent advances in cochlear implant technology, music perception in implant recipients remains generally poor.[49] Recently developed music test batteries have shown limited ability among postlingually deafened

adults in melody, pitch and timbre identification, albeit with some notable exceptional cases. Rhythmic identification remains normal in implant users when compared to the normal population. Some prelingually deafened infants are able to enjoy music, and there is much current interest in the use of musical training in postimplantation rehabilitation.

SURGICAL TECHNIQUE

The majority of cochlear implant surgeries undertaken in the UK are via the transmastoid approach, accessing the cochlea via the facial recess. Other surgical techniques have been described including the suprameatal[50–52] or the transcanal approaches (with or without use of an endoscope).[53–55] The transmastoid approach will be discussed here.

Most surgeons use a postaural incision, sufficient in length to allow the implant to be introduced. The surgeon should avoid placing the incision line directly over the receiver–stimulator package to minimize post-operative wound complications.

The soft tissue is dissected down to the periosteum, which is incised to create an anteriorly or posteriorly based flap. A cortical mastoidectomy is then performed. A subperiosteal pocket is created to house the receiver–stimulator. Some surgeons may drill a well in the bone to secure the implant and/or tie the implant down to secure it in position. However, with the evolution of thinner implants without a 'footprint', more surgeons are choosing simply to create a subperiosteal pocket. Often, a gutter is drilled for the electrode as it passes into the mastoid cavity.

A posterior tympanotomy is created to give access to the round window niche, taking care to preserve the chorda tympani. Depending on the surgeon's preference and the access achieved, the entry into the cochlea may be via a cochleostomy, via the round window membrane (once the niche has been drilled away), or by opening the round window in an anterior and inferior direction. Optimal placement of the electrode is within the scala tympani.

Once inserted, a soft-tissue seal is placed around the electrode as it enters the cochlea, to prevent the leak of perilymph. The residual electrode wire is coiled within the mastoid cavity, and the wound is closed in layers.

Hearing preservation

Increasingly surgeons are adopting less traumatic approaches to entering, and introducing the electrode, into the cochlea. This has come about due to the development of less traumatic electrodes, a recognition that atraumatic insertion leads to the electrode remaining within the scala tympani with better outcomes,[56] an understanding that paediatric recipients are likely to undergo multiple implant surgeries in the same ear over the course of their lifetime, and the need to preserve residual low-frequency hearing in individuals who are going to use combined electro-acoustic stimulation (EAS).

Hearing preservation surgery is undertaken in individuals with good or aidable low-frequency hearing as described earlier. The surgeon may opt for a shortened or full-length electrode. Electrode insertion can be via a separate cochleostomy, or via the round window membrane.[57–59] Most surgeons advocate a slow electrode insertion, to minimize intra-cochlear pressure change, when attempting to preserve hearing. Various steroid regimes are employed, including a systemic dose on induction of anaesthesia (e.g. dexamethasone), steroid solutions placed into the middle ear or soaked onto spongistan placed directly onto the round window membrane (e.g. triamcinolone), and varying regimes of post-operative steroid administration. All of these options are an attempt to protect cochlear function thus preserving residual hearing to facilitate EAS.

Challenging cases

Although the majority of cochlear implant surgeries are straightforward, there are some scenarios that can prove more challenging. These include cochlear ossification, perilymph gushers and abnormally formed cochleas.

Cochlear ossification is most frequently encountered if the patient has had meningitis. The degree of ossification can range from a small amount of immature bone in the proximal end of the basal turn to complete ossification and obliteration of the cochlea. It may be possible to predict the degree of ossification with pre-operative imaging and in this circumstance performing both MRI and CT scanning can be helpful. However, sometimes the surgeon may come upon ossification without prior notification from imaging, in particular if there has been a delay between imaging and surgery or if there is early scarring or bone formation in the proximal basal turn.

In early ossification, it is usually possible to drill through the immature bone and identify the cochlear duct in the more distal basal turn. If this is not the case and the cochlear duct cannot be identified, the surgeon may opt to insert the electrode into the drilled-out channel (partial insertion), or to consider a dual-array electrode, drilling a further channel anterior to the oval window to access the middle turn of the cochlea. In the significantly ossified cochlea the results can be difficult to predict.[60] In completely ossified cochleas, it may be necessary to consider an auditory brainstem implant (ABI) in place of CI.

A cerebrospinal fluid (CSF) gusher may occur in an abnormal inner ear, most commonly in patients with abnormal cochleas such as in X-linked deafness. Lesser degrees of perilymph leakage are most commonly seen in large vestibular aqueduct syndrome (LVAS) (**Figures 94.1** and **94.2**). In a true gusher, when the cochlea is entered, there is a rapid and significant filling of the mastoid cavity with CSF. The head of the patient should be raised and, when the flow of CSF slows, the electrode should be inserted in the usual manner. Following insertion, care should be taken to pack muscle or soft tissue tightly around the insertion of the electrode into the cochlea to stop any further leak. If a leak persists, despite all of the above, then a lumbar drain should be considered in the immediate post-operative period to reduce the pressure of the CSF and allow the leak to settle.

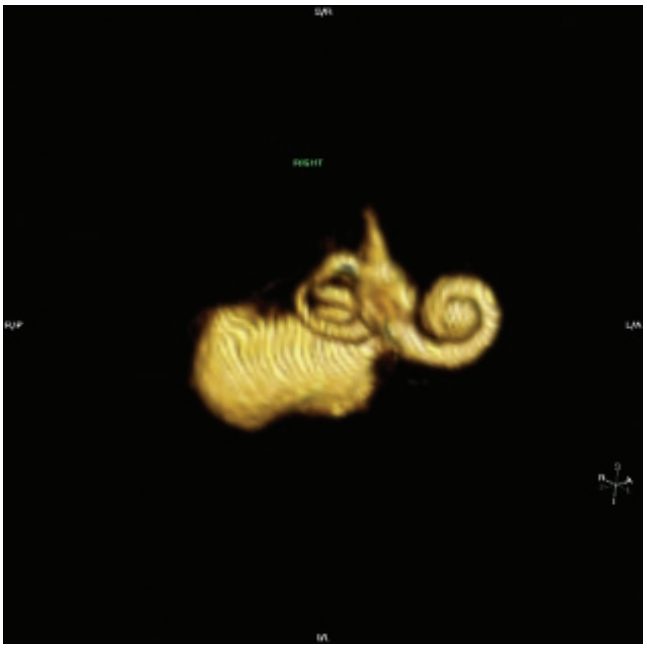

Figure 94.1 3-D reconstruction of the inner ear showing large vestibular aqueduct.

Figure 94.2 Axial T2-weighted MRI scan showing bilaterally enlarged vestibular aqueducts.

Due to the high quality of pre-operative imaging, it is possible to understand the anatomy of each cochlea to be implanted and the challenges they present. The surgeon may choose to use a shortened electrode in a malformed cochlea, or may request a custom electrode from one of the manufacturers in special cases such as a common cavity.

COMPLICATIONS

Complications in cochlear implant surgery can be classified by severity and timing:

- A major complication is one occurring during or after surgery that requires a major surgical intervention or results in a permanent disability (e.g. facial weakness).
- A minor complication is one that can be managed by medical measures or a minor surgical procedure (e.g. wound aspiration).

There are many published series quoting overall major and minor complication rates. Bhatia et al. looked at rates in 300 consecutive paediatric implants. They found major complications to occur in 2.3% of cases and minor complications in 16% of cases.[61] A recent prospective audit of 1397 paediatric bilateral cochlear implants in the UK reported a major surgical complication rate of 0.9%, with a minor complication rate of 6.5%, excluding device failure.[62]

Vertigo

Vertigo after CI is not uncommon.Most series report subjective and/or objective symptoms of dizziness or vertigo, usually transient, in approximately 30% of adult implant recipients.[63–65] In their series of 146 implanted adults, Enticott et al. noted that one-third of patients had vestibular disturbance and patients over the age of 70 were more prone to permanent injury.[65]

In a retrospective case review by Steenerson et al. almost three-quarters of adults with implants experienced vestibular symptoms, relieved by vestibular therapy. Of the 47 patients they studied, 74% experienced post-operative vertigo or imbalance; 19 of these 35 patients had experienced some imbalance sensations pre-operatively.[66] Forty-eight per cent demonstrated benign paroxysmal positional vertigo (BPPV) with positive Dix–Hallpike responses, arising from the implanted ear.

Limb et al. noted that BPPV occurs more frequently after CI than in the general population, and that routine BPPV treatment is effective in this group.[67]

With the advent of routine bilateral implantation, there is the potential risk of causing bilateral vestibular hypofunction. In patients with a pre-operative balance problem, vestibular assessment may be a useful adjunct enabling the team to select which ear to implant if unilateral implantation is proposed (i.e. opting for implanting the ear with poorer vestibular function).

The reported incidence of dizziness is less in the paediatric population.[68]

Device failure

With successive generations of implants, each manufacturer has pushed the agenda of device reliability. This is significant, as a large proportion of implant recipients are infants who will require an implant for the duration of their lifetime. Increasingly, a significant proportion of an implant programme's workload is replacing failed devices in their existing patients.

Device failure after CI surgery is one of the more common problems, although it should not be considered as a surgical complication, the cause rarely being surgical mismanagement. Trauma is linked to failure despite the device being built to withstand significant impact. Similarly, the device may fail suddenly or insidiously over time, sometimes referred to as 'soft' failures.

An implant is classed as failed if 50% of the electrodes are non-functioning. In a series of more than 900 implants from 1985 to 2003, Lassig et al. noted a device failure rate of 3.7%.[69] Battmer et al. looked at the European experience of 12 856 implants and found a similar device failure rate of 3.8%.[70]

Experience has shown that reimplantation is safe and effective (e.g. Woolford et al.).[71] Other studies, however, have shown variable post-reimplantation performance (e.g. Henson et al.)[72] and have also noted that patients need careful counselling regarding the possibility of differences in sound quality and speech recognition performance with the replacement device.

The facial nerve

Immediate post-operative facial palsy is due to damage to the nerve from direct trauma or by thermal injury. Facial nerve monitoring is commonly used and may help reduce problems. Gibbin et al. reviewed 1524 patients.[73] Four had an immediate partial facial nerve palsy, two of whom made a complete recovery. One immediate complete palsy occurred and partially recovered, leaving a permanent disability rate of 0.2%.

In the UK paediatric bilateral audit there were two (0.2%) temporary, partial facial nerve palsies in the post-operative period and no permanent facial palsies.[62]

Facial nerve stimulation has been reported to occur in between 7%[74] and 25%.[12] It occurs more frequently in patients with otosclerosis, particularly with the use of non-modiolar hugging electrodes in severe disease.[13] Facial nerve stimulation can be controlled by device reprogramming in nearly all cases.

Rare complications

MAGNET DISPLACEMENT

Many of the cochlear implant designs feature removable magnets. This facilitates temporary magnet removal, when an MRI is required of an implant recipient's brain, to minimize artefact on the scan. If an implant recipient experiences a degree of trauma over the implant, it is possible for the magnet to become displaced from its silicone pocket. The external component may then not connect to the internal device, as the coils are not aligned, or the displaced magnet may be palpable through the skin in an abnormal position. An X-ray confirms the diagnosis (**Figure 94.3**). A revision procedure is required to remove the displaced magnet and replace it within the implant or if the electrode is not fully functional following removal (this can be determined using intra-operative telemetry testing).

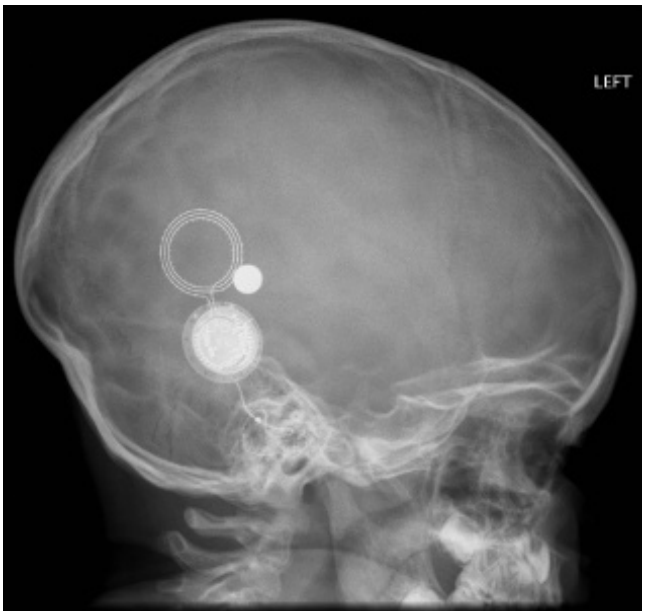

Figure 94.3 Plain lateral skull X-ray showing magnet displaced outside of the receiver-stimulator package.

TIP FOLD-OVER

Depending on the electrode design and insertion technique used, it is possible for the electrode tip to fold over upon itself. This may only involve a few electrodes, or a more significant portion of the array (**Figure 94.4**). This may not be recognized at the time of surgery, and is usually detected on post-operative imaging. The surgeon may choose to leave the implant if there is a minor degree of fold-over, or they may choose to revise the procedure. At revision, it may be possible to salvage the existing electrode by removing and reinserting (on-table imaging for confirmation of correct positioning is recommended), but the team should be prepared to use a second device if this is not possible or if the electrode is not fully functional following removal (this can be determined using intra-operative telemetry testing).

LOOKING TO THE FUTURE

Despite recent advances in CI, there is clearly still a great deal of work to be done to maximize the potential benefit to patients receiving this life-changing intervention. Some areas for potential developments include the following.

Unmet need

Despite the fact that many healthcare systems in the developed world already offer CI to appropriate patients, there are a large number of eligible patients, particularly adults, who are missing out on the potential benefits of this technology. For example, a recent study in the UK found that while 74% of eligible children between the ages of 0 and 3 years received an implant (increasing to 94% by age 17 years), only 5% of eligible adults underwent surgery.[1] This perhaps reflects a lack of awareness of the criteria for and benefits of CI in the wider medical and audiological

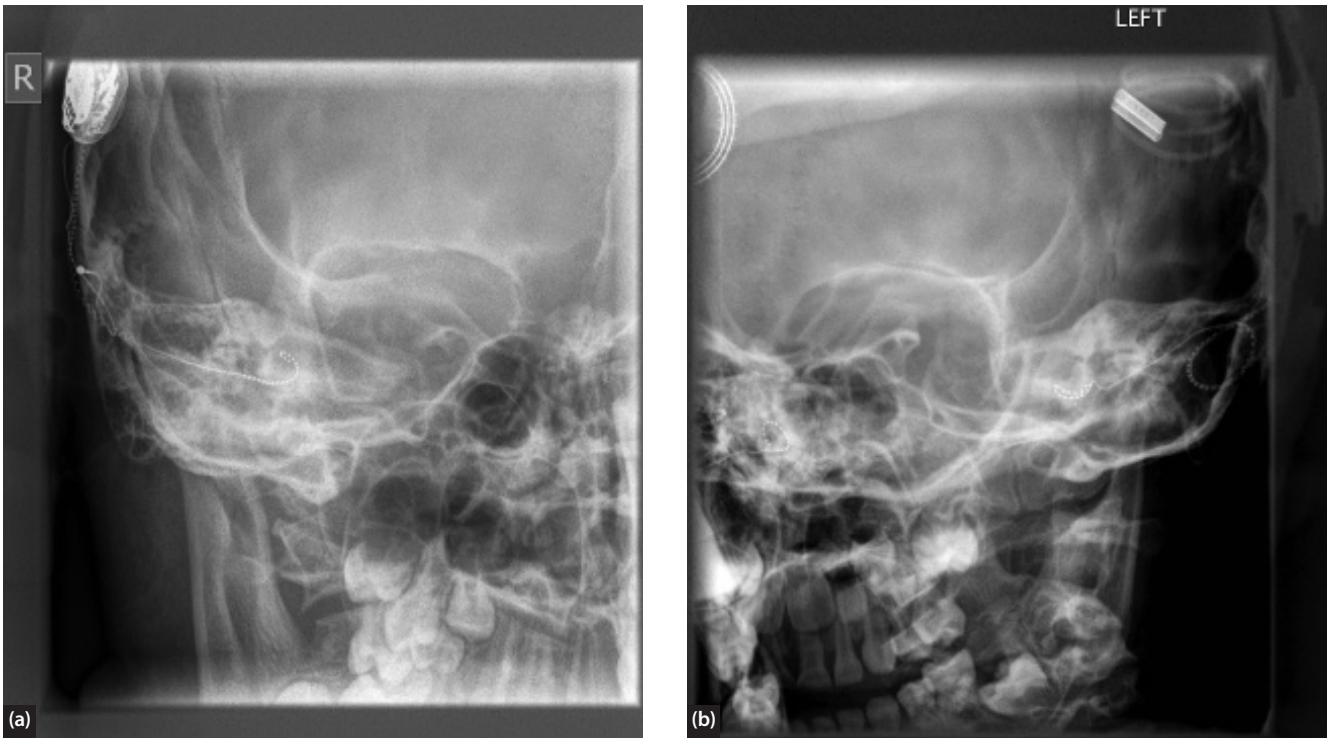

Figure 94.4 Plain skull X-rays showing **(a)** tip rollover of the distal electrode (note also incomplete electrode) and **(b)** more significant fold-over of the electrode.

communities as well as the general public. The unmet need in developed countries also highlights the huge burden of undertreated (or untreated) profound deafness in the developing world. While CI has been performed in many developing nations in isolated cases on a humanitarian basis,[75] wider implementation of CI is likely to require a change in the political and financial structures surrounding health care in such countries. Interestingly, uptake of CI in large numbers in emerging economies such as India and China has led to new avenues for research (e.g. the performance of cochlear implants in patients using tonal languages) and cochlear implant manufacturing, with global implications.

New technology applied to current devices

With the increasing uptake of CI, the cumulative number of adults being looked after by an individual centre rises rapidly, placing a significant burden on the professionals within that team. To reduce this demand, and to better serve patients who may be geographically remote from their cochlear implant centre, new methods of programming individual implants remotely have been explored. The majority use web-based connections between the implant audiologist and the patient. In future, software may allow the computer-literate patient to alter his or her own map without any external input.

Developing technologies

While the current design of the cochlear implant is continually being improved and updated, and new processing strategies developed, there are other potential developments that could change the nature of cochlear implants altogether.

- **The totally implantable cochlear implant (TICI).** Early prototypes of completely implanted cochlear implants have shown that such a device can be safe and effective.[76] Challenges remain in designing a microphone that can detect external signals without picking up unwanted noises related to movement, breathing, etc.
- **Drug-eluting electrodes.** These could be used to introduce anti-inflammatory or neurotrophic agents directly into the inner ear to prevent postimplantation neural degeneration, to prevent progression of deafness, or to improve the interface between the electrode and the neural elements.[77]
- **New insertion techniques.** As CI evolves, the need for atraumatic insertion is becoming increasingly important. This is reflected in the design of new implant electrodes. There has also been much interest in the use of robots to ensure a smooth and atraumatic electrode insertion (Zhang et al.)[78] and for minimally invasive and atraumatic drilling of the temporal bone and cochlea (Assadi et al.).[79] Such an instrument could potentially allow CI in remote settings using telesurgery.
- **New methods of neural stimulation.** At present, cochlear implants transmit an electrical signal through multiple electrodes and are therefore prone to current spread, meaning that the neural stimulation is not as specific as required for optimal performance. This has led to research into different ways to stimulate the auditory pathway (e.g. using optical stimulation).[80] To date, these techniques have not been applied in clinical

practice, but they may be important for future devices, particularly when used in combination with biological nanotechnology.

Inner ear treatment

Perhaps the ultimate measure in the management of profound sensory hearing loss will be treatment of the underlying aetiology and restoration of natural hearing. Such treatments would potentially have huge implications for patients with presbyacusis, the leading cause of deafness worldwide. Current research is examining the role of stem-cell and gene therapy in treating deafness (e.g. Kanzaki);[81] cochlear implants in the future may be as much about delivering such therapies to the inner ear to restore natural hearing as providing artificial stimulation.

KEY POINTS

- Cochlear implants have transformed the management of severe to profound hearing loss.
- Criteria to identify potential cochlear implant candidates differ between countries. In England and Wales, the NICE guidelines state that a patient must have severe to profound hearing loss (audiogram worse than 90dBHL at 2 and 4KHz) as well as failure to benefit from hearing aids (in adults, worse than 50% score on BKB sentence test at 70dB SPL; in children, failure to gain speech and language skills appropriate to age and development).
- Newborn hearing screening programmes allow early identification of children with severe to profound deafness. Implantation at or before 12 months of age gives optimal outcomes.
- Criteria are constantly evolving and cochlear implants may be appropriate for some patients with residual hearing, single-sided deafness, complex needs or anatomical abnormalities.
- Surgery is usually via a cortical mastoidectomy and posterior tympanotomy. Modern techniques allow for preservation of hearing in some patients. Serious complications are rare.
- One of the greatest challenges in cochlear implantation is to overcome the unmet need in both developed and developing countries.
- In addition to the continually improving electrode design, processing strategies and surgical techniques, future advances in cochlear implantation may include a totally implantable device, improved neural stimulation, routine use of drug-eluting electrodes and inner ear treatment with gene or stem-cell therapies.

CHAPTER 95

MIDDLE EAR IMPLANTS

Maarten J.F. de Wolf and Richard M. Irving

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the phrases 'middle ear implants', 'implantable hearing devices', 'middle ear implantable hearing devices' and 'vibratory ossicular prostheses', searched as keywords and also by combining the sets 'hearing aids' (all references) with 'middle ear' (all references).

INTRODUCTION

The primary impetus for active middle ear implant (AMEI) development is the desire to overcome many of conventional hearing aid shortcomings such as distortion, feedback, occlusion effect, discomfort and ear canal irritation. Next to that, AMEIs offer the potential for improved sound clarity, because most AMEIs bypass the external auditory canal (EAC) and do not use a speaker for signal amplification. A common characteristic of all implantable hearing aids is that the transducer is coupled to the ossicular chain or directly to the inner ear fluid. These implantable devices were initially designed for the treatment of sensorineural hearing loss (SNHL) in patients with healthy middle ears. Indications have expanded to patients with mixed hearing loss and middle ear malformations.[1] With the application of prostheses and coupling elements, the systems now cover all types of middle ear reconstructions for patients with moderate to severe mixed hearing loss.[2,3] This chapter addresses the application as well as the results of AMEIs for these indications.

HISTORY AND DEVICE DEVELOPMENT

Wilska[4] is credited with being the first to use electromagnetic induction to stimulate the middle ear, in the 1930s. Iron particles were placed on the tympanic membrane of a human subject and stimulated by an electromagnetic coil placed in the ear canal. Since then, and particularly over the past 30 years, much work has been done looking at different sites and methods of attachment of microphone, amplifier and transducer.

The majority of devices have utilized a postauricular microphone with resultant loss of the pinna effect. Overcoming this by placing the microphone in the EAC has been tried, but to date this has not been successful, largely due to problems with feedback.

Devices have predominantly used either a coil and magnet (electromagnetic) or a piezoelectric mode of transmission. The piezoelectric transducer works on the principle that, when a voltage is applied to a particular ceramic (piezoceramic or piezoelectric crystal), it causes a proportional deformation and hence displacement of that ceramic. This voltage-dependent displacement can then be coupled to the ossicles to drive them (used in the TICA and Envoy systems, see 'Devices no longer available' and 'Current devices' below). In the case of the electromagnetic transducer, the electrical signal is used to produce an electromagnetic field by means of a transduction coil. This then drives a magnet that can be attached to the ossicles in a variety of ways to transfer the vibrations.

The coupling mechanism of the device is the method by which the transducer is connected to one of the middle ear ossicles or cochlear windows. Most of the different devices are connected to one of the middle ear ossicles with or without need for disruption of the ossicular chain. The possibility of hydroacoustic transmission, via a

water-filled tube, either to the ossicles or directly to the round window membrane has been investigated.[5]

A major problem with these devices has been to produce a device that is small enough to fit within the confines of the middle ear and yet powerful enough to produce the required gain. Over recent years technological advances have resulted in a number of devices that have fulfilled these basic requirements. The translation from theory to a viable surgical and financial product has, however, proved extremely difficult and many projects have ultimately ended in failure.

CURRENT DEVICES

Vibrant Soundbridge (MED-EL, Innsbruck, Austria)

The Vibrant Soundbridge (VSB) developed by Symphonix and currently by MED-EL is an active semi-implantable hearing device. It consists of an internal, surgically implanted part – the vibrating ossicular prosthesis (VORP) – and an external audio processor. The VORP consists of a receiving coil, conductor link and transducer. The transducer employs a small electromagnetic coil and enclosed magnet to produce vibrations in this floating mass transducer (FMT), which can be coupled to the ossicles or round window. The VSB obtained the European certification mark for implantation in 1998 (Symphonix Devices Inc., 2000) and has also received Food and Drug Administration (FDA) approval.[6] In addition, the VSB received the European Union CE Marking for treatment of conductive and mixed hearing loss in adults (2008) and children (2009).[7]

Direct acoustic cochlear implant (DACI) (Cochlear Ltd, Sydney, Australia)

Initially called the direct acoustic cochlear stimulator (DACS, Phonak Acoustic Implants, Phonak AG, Stäfa, Switzerland) and later the Codacs™ Investigational Device, this device consists of an implantable electromagnetic transducer, which transfers acoustic energy directly to the inner ear via a conventional stapes prosthesis. An audio processor is worn externally behind the implanted ear. The stapes has to be removed in total. In order to restore the natural sound transmission of the ossicular chain, a second stapes prosthesis is placed in parallel to the first one into the oval window and attached to the patient's own incus.[3] This implant is indicated for profound mixed hearing loss. The device is CE approved but to date there has been no FDA approval.

Otologics semi-implantable middle ear transducer (MET) and fully implantable Carina (Otologics, Boulder, Colorado, USA, later Cochlear (Sydney, Australia)

This device is currently fully implantable, although the initial trials were done with a semi-implantable version, which has CE approval.[8] The technology was purchased by Cochlear (Sydney, Australia) in September 2012. The semi-implantable MET uses an external unit called the button external audio processor, containing a microphone, battery, signal processor and transmitter. The transducer drives an electromagnetic probe coupled to the body of the incus. The tip of the probe is made of aluminium oxide, which forms a fibrous connection with the incus body. The ossicular chain is left intact.

The fully implantable Carina uses the same electromagnetic transduction system, but consists of a subcutaneous microphone, battery and an electronic receiver connected to a transducer. The latter is used in patients with mixed hearing loss with a variety of implantation sites and aetiologies, including the round window and footplate.[9, 10] The device is CE marked for this purpose in Europe and South America.

Fully implantable Envoy Esteem Device

This device comprises a piezoelectric sensor placed on the incus body, acting as an internal microphone, and a driver cemented to the stapes head. Implantation of the device requires disarticulation of the ossicular chain with removal of the lenticular process of the sensor interface linked to the body of the incus, and the driver is cemented to the stapes head.[11] This device is indicated for patients with SNHL. CE marking was accomplished in 2006, and the FDA granted approval in 2010.[12]

EMERGING TECHNOLOGIES

Maxum Hearing Implant (Ototronix, LLC, Texas, USA)

The SOUNDTEC Direct Drive Hearing System (DDHS), initially designed by SOUNDTEC Direct, is another semi-implantable device containing an electromagnetic transducer. The implanted part consists of a magnet attached to the incudostapedial joint via a titanium alloy wire ring. Placement requires a transmeatal approach. The electromagnetic coil forms part of the external portion of the device and is placed deep in the ear canal.[13] The SOUNDTEC DDHS has had FDA approval,[6] but the results have been mixed.[14] The device was removed from the market in 2004 because of device-related adverse events. In 2009 Ototronix purchased the SOUNDTEC technology, and the device was rereleased as the Maxum Hearing Implant after incorporating several notable upgrades, including a self-crimping Nitinol wire that obviates incudostapedial joint separation. To date there are no clinical studies concerning this new upgraded system.

Semi-implantable middle ear electromagnetic hearing device

For this semi-implantable middle ear electromagnetic hearing device (SIMEHD), the magnet is cemented to the incus body and a titanium frame fixed to the temporal

bone supports an implanted electromagnetic coil. The gap between magnet and coil can be adjusted on the frame. Both magnet and coil are encased in titanium.[15] The SIMEHD has been implanted in cats and a human study has been proposed.[15]

Piezoelectric round window implant with infrared optical signal

This AMEI comprises a micro transducer, placed on the round window. It can receive power and signal transmission through an infrared optical transmitter located in an external unit. This also contains a microphone, sound processor and battery and is placed in the ear canal.[16] Notably, this AMEI can be implanted endaurally without mastoidectomy. The system has not yet been tested *in vivo*.

EarLens tympanic contact transducer

This device consists of a magnet placed in a silicone lens that sticks to the tympanic membrane by oil-induced surface tension. A small induction coil is placed in the ear canal.[17]

DEVICES NO LONGER AVAILABLE

Semicircular canal piezoelectric vibrator

This device stimulates inner ear fluids directly by means of a lateral canal fenestration, bypassing the middle ear. Welling and Barnes[18] used a piezoelectric biomorph material that could activate the auditory system via vibromechanical stimulation and thus showed the feasibility of this approach.

University of Bordeaux implantable piezoelectric transducer

The device consists of a piezoelectric biomorphic material with a short rod and platinum ball placed against the round window. However, since its initial publication in 1995,[19] no reports have been published regarding application of this technology to living individuals.

Rion partially implantable hearing aid

The Rion partially implantable hearing aid (PIHA) uses a piezoelectric transducer connected to the head of the stapes or footplate by a hydroxyapatite coupling. The transducer is held in place by a fixing plate screwed to the temporal bone.[20] This device has been implanted in patients in Japan under Japanese approval but is no longer in production.

Totally implantable cochlear amplifier

Developed by Implex, the totally implantable cochlear amplifier (TICA) was the first fully implantable middle ear device. Comprising an ear canal subcutaneous microphone and piezoelectric transducer, the device was revolutionary but problems with feedback necessitated disarticulation of the chain. The device is no longer in production.[21, 22] The technology was purchased by Cochlear to be implemented in cochlear implants.

PATIENT SELECTION

Candidates

Ideal candidates for middle ear implants are patients with high-frequency sensorineural or mixed hearing loss, in which amplification with conventional hearing aids – with or without stapedotomy – or bone-conduction implant (BCI) has failed. In most cases failure is caused by acoustic feedback, occlusion effect, insufficient high-frequency amplification or wearing discomfort. Although the VSB and the MET/Carina is cleared for use in patients under the age of 18,[7, 23] the majority of these devices have been placed in adults. Candidates should not have any skin conditions that may prevent attachment of any external component of the device and should be medically fit for surgery and the anaesthesia required. In addition, candidates should have been appropriately counselled by a surgeon and be judged to have realistic expectations. Further selection is made based upon audiological and otological conditions.

Audiological

Current devices are most suitable for mild to severe SNHL. In case of conductive or mixed hearing loss, the main objective of AMEI placement is to overcome the residual sensorineural component. Preferably, hearing loss should ideally be stable, while accepting very slowly progressive losses. The Codacs system is specifically designed for patients with a profound mixed hearing loss such as in advanced otosclerosis.[3] Aided thresholds for the candidates' present hearing aid should be taken into consideration. Tympanometry and acoustic reflexes may be required to assess middle ear function and speech audiometry to assess retrocochlear loss. The worse-hearing ear is usually selected for implantation.

Otological

In general, there should be an absence of retrocochlear or central involvement in the hearing loss. Middle ear inflammation must be controlled prior to implantation. In case the external processor is worn in the EAC, the ear canal must be assessed before surgery in order for it to be suitable. Beleites et al[1] suggested a classification of the different types of applications of AMEIs for specific pathological middle ear situations.

A Type A vibroplasty involves the coupling of an AMEI on an intact ossicular chain in patients with a mild to moderate SNHL (the classic indication). Different attachment points to the ossicular chain (e.g. umbo, incus or stapes) are used. The stapes head and footplate are the most favourable attachment points.[24] AMEIs that can be considered for this situation are the VSB, MHI and Carina.

Type B vibroplasty consists of aided hearing by means of an AMEI – mostly the VSB – coupled to a remnant of the ossicular chain, which is in most cases the stapes or its footplate. Although still experimental, solutions with the Carina and Esteem using additional couplers or passive prostheses are being researched.[25–29]

Type C vibroplasty involves the coupling of the actuator on one of the middle ear window membranes. The VSB is the only implantable actuator to suit this application on the round window. In recent years round window coupling has become an increasingly common alternative for the 'classic' coupling of the VSB on the long process of the incus.[1]

Type D vibroplasty is described as the direct coupling of an AMEI to the inner ear fluid. For this approach, the oval window is mostly used. The DACI system was designed for this application, but the VSB combined with a conventional stapes piston can also be used.

SURGICAL CONSIDERATIONS

For the AMEIs on the market today (VSB, MET/Carina, DACI and Envoy) the surgical approach is similar to that of a cochlear implant. It compromises retroauricular transmastoidal access to the middle ear via the facial recess (VSB) atticus (Carina) or a slightly different approach is needed to gain access to the round window niche (Codacs). Sometimes a combined approach is needed to gain sufficient access to the middle ear in case of a joined placement with a passive implant. An implant bed is drilled in the cortical temporal bone to accommodate the internal receiver and conductor link. For most implants (Carina, Esteem and Codacs) the transducer is fixed to the cortical bone in the mastoid cavity by means of cement or screws. Although the mastoid has more space available than the tympanic cavity, allowing stronger transducers, this procedure requires meticulous placement and is slightly more difficult than placement of other AMEI systems with separated coil and magnets (MHI and EarLens), which only require an transmeatal tympanotomy. The performance of the latter, however, depends heavily on the distance between the coil and magnets.

For VSB placement the posterior tympanotomy should be large enough to pass a 3 mm diamond burr in order to ensure sufficient space to site the FMT. For a classical placement its attachment clip is folded and crimped around the long process of the incus, although with the introduction of a short process clip this approach without a posterior tympanotomy is proving more popular and technically more straightforward. Also, placement of the FMT on the stapes head, footplate or round window can be performed.

The main advantages of these procedures are that they utilize an approach already familiar to otologists and do not require disruption of the ossicular chain, in case of an intact ossicular chain. However, bone work is required close to the facial nerve and there is also concern about crimping the clip to the long or short process of the incus. If the clip is crimped too tightly, there is a potential for necrosis of the long process of the incus; if it is too loose, the implant may fail. Placement of the FMT, other than the classical way, can be challenging. A consensus statement was published in 2014 to address this issue.[30]

For placement of the Codacs system a special 'retromeatal approach' is used to assess the facial recess at the level of the oval window. The device is electronically and mechanically tested during surgery.

For an MET/Carina device, the bone work is away from the facial nerve but perhaps less familiar to the otologist. An atticotomy is performed to expose the incus body and malleus head. A laser is used to make a hole in the body of the incus. The transducer is then inserted into the mounting system secured to the skull and the probe tip is aligned with the laser-made hole in the incus. Fine-positioning of the probe tip is made by screw adjustment.[8] For the Carina, a separate microphone connected to the implanted sound processor is placed in a postauricular subcutaneous pocket. For the Esteem system a large facial recess opening is needed so that resection of chorda tympani is often inevitable. Intraoperative testing by means of laser Doppler vibrometry is needed to assess the mobility of the incus and stapes. Hypomobility will require aborting the surgical procedure at this point. Meticulous cleaning of the stapes head and incus is needed for adequate placement of the sensor and driver.

RESULTS

Surgical results

In general, complications regarding AMEI implantation are poorly reported and may be subject to reporting bias.[31–33] Worldwide, the VSB has been implanted in the largest group of patients. Initial audiological and surgical results for this device came from a European multicentre trial including 47 patients.[34, 35] They showed no major complications in terms of permanent facial weakness or profound sensorineural loss. One delayed onset of temporary, partial facial weakness occurring 10 days post surgery was reported.[35] Clinical experience with this device has been described in a number of studies.[26, 34–41] Complications mainly consisted of damage to the chorda tympani[34, 42] and dislocation of the FMT, particularly in type C vibroplasty.[38, 41, 43] A consensus statement published in 2014 proposed a specific surgical technique to address the variable results due to the dislocation issue.[30] Also extrusion of the (sometimes) accompanied passive prosthesis has been reported.[26] Another frequently reported symptom following VSB implant surgery is aural fullness.

Initial studies on the Codacs system showed that most common post-surgical complaints were tinnitus, deterioration of bone conduction and vertigo. No major device-related adverse effects were noted.[3, 33, 44–46]

The most common event reported for the Carina device was device malfunction or failure, mostly related to charging. This occurred in 17.6% of patients in a pooled population of 68 patients. Device malfunction led to four explantations and three revision surgeries. Partial device extrusion occurred in four patients and resulted in two explantations.[10, 47–53]

After placement of the Esteem device, 8% of the patients in a pooled group of 87 patients reported facial weaknesses,

while 30% of the patients reported taste disturbance, mostly caused by a chorda tympani lesion, which was temporarily experienced in approximately 50% of the cases. Also, 13% of the patients underwent explantation or revision surgery because of insufficient benefit or device malfunction.[11,12,54–56]

Pooled data from a systematic review by Klein et al.[57] showed that, overall and in experienced hands, AMEIs are considered a safe alternative to amplification options such as conventional hearing aids (CHAs) or osseointegrated BCIs for patients with mixed hearing loss. Taking into account the challenging pathology of COM, advanced otosclerosis and congenital malformations,[33] Tysome et al.[31] concluded that AMEIs were safe to implant for SNHL, based on his systematic review.

With regard to long-term results, most studies show no initial decline of bone-conduction threshold after implantation. However, one study reported a mean threshold elevation of 8 dB in post-operative hearing thresholds in a series of 20 patients 2 years post implantation.[42] This might suggest overstimulation-induced cochlear trauma.

Patient-reported outcome measures

The Abbreviated Profile of Hearing Aid Benefit (APHAB) self-assessment questionnaire[58] was mostly used to evaluate patient satisfaction for all AMEIs. In general, patients experience a significant improvement of benefit for all current AMEIs in terms of ease of communication, reverberation and listening in background noise compared to the unaided situation. Regarding comparison with previous conventional hearing amplification, far less information is available. APHAB results suggest that patients experienced more benefit from the VSB over conventional amplification.[35,59,60] Kraus et al.[12] reported clinically significant greater benefit with the Esteem compared with CHAs in all subcategories. Jenkins et al.[10] found the Carina to be superior in all subcategories. However, the data are not statistically significant. The most convincing significant increase of benefit was seen for the Codacs system compared to the use of a conventional hearing aid and the unaided situation.[3,44,46] Overall, the reported benefits included improved quality of sound, elimination of occlusive effect, and an improved ability to lead an active lifestyle when compared with CHA use. With regard to subjective hearing improvements, patients generally prefer the sound quality of an AMEI to that of a CHA. Direct ossicular stimulation maximizes the ability to hear high-fidelity, naturally produced sound. Additionally, the proximity of the implant transducer to the cochlea reduces distortion.[32]

Audiology results

AMEIs in sensorineural hearing loss (type A vibroplasty)

Since open-fit hearing aids and AMEIs both service patients with high-frequency hearing loss, it seems logical to compare the benefit of these devices. However, since these patients are by definition dissatisfied with conventional aids, such a comparison is difficult, due to a patient bias.[61] AMEIs currently used in type A vibroplasty are the VSB on the long proces of the incus, Esteem and Carina. Functional gain between pre-operative non-aided and aided versus post-operative implanted conditions has been tested, both in quiet and noisy environments. Studies showed statistically significant post-operative AMEI-assisted hearing improvement in varying levels (ranging from 16 dB to 48 dB) compared to pre-operative unaided condition.[9–12,35,48,56,60–70] Compared to the best aided pre-operative condition, a positive – but not significant – functional gain was demonstrated in most studies. Some studies report a (clinically) statistically significant improvement with the VSB device[35] and Carina device[9,10,48,66] compared to optimally fitted conventional hearing aids, respectively. In general the functional gain was quite similar among the devices.[9–12,35,48,56,60–65,67–70]

In a quiet environment, these comparisons showed a statistically significant improvement in most studies.[11,12,48,71] However, word recognition scores declined in one study.[72] Finally, when comparing AMEI performance (VSB) to the best aided condition in a noisy environment, clinically statistically significant improvements were demonstrated too.[73] This suggests that AMEIs have a functional gain at least as good as, if not better than, conventional hearing aids. However, reports are contradicting and sparse.

AMEIs in mixed hearing loss (type B, C and D vibroplasty)

For the heterogeneous group of pathologies causing mixed hearing loss (otosclerosis, tympanosclerosis, cholesteatoma), different strategies for hearing rehabilitation have been proposed. AMEIs most commonly used for mixed hearing loss are VSB, MET/Carina and Codacs. In general, the status of the middle ear affects the performance of the AMEI. Reduced load impedance due to a partially missing ossicular chain is usually an advantage that improves performance.

Mostly, a VSB coupled on the round window (type C vibroplasty) is used to service mixed hearing loss. The results of the VSB with its actuator coupled to one of the cochlear windows shows statistical significant difference in terms of speech perception in quiet and in noise compared to conventional hearing aids.[38,39,74,75]

However, audiological results in round window placement (type C vibroplasty) of the VSB vary due to effectiveness of the coupling.[1,74,76,77] Recent publications report that adequate coupling might account for as much as 20 dB of the hearing benefit.[78,79] A type C vibroplasty with the MET/Carina has shown to provide an improvement of functional gain over the unaided situation, but there was no comparison with conventional hearing aids.[50,51,80] An interesting situation is the presence of a fixed stapes footplate.[23] Some authors perform a round window vibroplasty, others a clipping of the VSB on the fixed stapes. The results remain variable and some even with limited benefit.[78] Although it has been suggested that, with a VSB or Carina device placed on the round window, SNHL due to oval window fixation can be serviced, there was no comparison with conventional aiding.[51,81] Research has shown that the round window application of the VSB can be used in chronically diseased middle

ears, after subtotal petrousectomy with obliteration of the middle ear cavity, and in atretic ears.[82, 83]

As an alternative to round window placement, the VSB can be coupled to the stapes head by means of a partial ossicular replacement prosthesis (PORP) or on the footplate by means of a total ossicular replacement prosthesis (TORP) (type B vibroplasty). Although there is a risk of extrusion, the audiological results are promising and are comparable with placement on the ossicular chain or round window.[27–29, 84] Another solution to stapes fixation could be a type D vibroplasty, although opening the inner ear is not always possible. The DACI system or a VSB or Carina system in combination with a conventional stapes can be used. Significant improvement in terms of functional gain, speech perception in noise and word recognition scores was seen in favour of the Codacs compared to conventional hearing aids in several studies.[3, 44–46] Both the Carina and VSB–stapedotomy combination showed favourable results, but these were not compared to conventional hearing aids.[53, 85–87]

Recently, Zwartenkot et al.[88] compared the maximum output of both the Codacs and the VSB, mostly used in a vibroplasty type B, to bone-conduction devices and found that only with the Codacs is a patient capable of using his full dynamic hearing range. Nonetheless, only patients with advanced otosclerosis were included and long-term data are not yet available.

BEST CLINICAL PRACTICE

- ✓ Implantation of these devices using the classical indications of moderate to severe SNHL is now well established, although it should only be carried out in centres with considerable experience in implantation otology and after a proper trial with optimal fitted conventional aiding such as hearing aids or bone-conduction devices.
- ✓ The evaluation of middle ear implants for patients with mixed or conductive losses including otosclerosis should be undertaken only within the context of a clinical trial.

FUTURE RESEARCH

- ➤ The fundamental for the development of implantable hearing aids is based on the desire to provide an alternative hearing solution than conventional hearing aids for patients with moderate to severe hearing loss. Benefits for the patients would in theory include hearing improvement, as well as an increased potential for an active lifestyle.
- ➤ AMEIs have gained substantial improvements over the years in terms of sound quality and patient comfort. However, most theoretical advantages of an AMEI are still unaccomplished, as most studies do not reveal a statistically significant improvement compared to optimally fitted conventional hearing aids. Overall, the benefits of AMEI do not yet convincingly outweigh the drawbacks of this technique in all patients, especially since some patients experience unstable progressive hearing loss, which could exceed the output capabilities of their implanted device.
- ➤ The use of visible external components in semi-implantable devices still restricts patients from certain activities, while in the canal components may still result in an occlusion effect and canal irritation. Likewise, placement of one of the fully implantable devices requires ossicular resection, which could leave a patient with a more pronounced conductive hearing loss. There are also concerns of long-term device reliability and the need for revision surgery or battery replacement in totally implantable systems.
- ➤ Although use of AMEIs is expanding to patients with mixed hearing losses, the population benefiting is limited. On the one hand, the indications exclude patients with mild to moderate hearing loss. On the other hand, indications for cochlear implantation are steadily extended. Therefore, AMEI companies may suffer signicant financial obstacles. To be successful, their devices will need to be priced in such a way as to be competitive to other devices, especially the non-implantable alternatives and the more traditional bone-conduction devices.
- ➤ The level of evidence and the quality of the included studies were judged to be moderate to low. More comprehensive data comparing device performance with conventional hearing aids or alternatives for speech in noise is needed. More long-term follow-up data are also needed.

KEY POINTS

- Middle ear implants are classically indicated for patients with mild to severe SNHL as an alternative to a conventional amplification aid.
- The indications have expanded to moderate and severe mixed hearing loss by means of the round window membrane stimulation of direct inner ear fluid coupling.
- A middle ear implant service requires close collaboration between an experienced audiologist and otologist. To date these services have developed on the back of pre-existing cochlear implantation programmes. This trend is likely to continue.
- The current devices have established in being safe in terms of extrusion and maintaining residual hearing.
- Overall device performance is comparable to, and some are slightly better than, conventional hearing aids.
- Patients describe a higher satisfaction with AMEIs in terms of sound quality.
- More comprehensive data comparing device performance with conventional hearing aids or alternatives for speech in noise are needed.

CHAPTER 96

AUDITORY BRAINSTEM IMPLANTATION

Shakeel R. Saeed and Harry R.F. Powell

SEARCH STRATEGY

Data in this chapter may be updated by a search using the keywords: 'auditory brainstem implantation in NF2' and 'auditory brainstem implantation in neurofibromatosis type 2'. The chapter is written without detailed explanation about neurofibromatosis type 2 or cochlear implantation, which are covered in separate chapters.

INTRODUCTION

The auditory brainstem implant (ABI) is indicated in severe to profound hearing loss when congenital or acquired abnormalities of the cochlea or auditory nerve (or sometimes both) preclude cochlear implantation (CI). The congenital group (invariably infants and children) includes those with dyplastic or aplastic cochleas and/or auditory nerves while the acquired group predominantly comprises neurofibromatosis type 2 (usually adults) and occasionally acquired cochlear diseases such as otosclerosis or post-meningitic cochlear ossification.

HISTORY

A single-channel ABI was first used to successfully stimulate the cochlear nucleus in 1979.[1] Prior attempts to elicit auditory sensations by stimulating the inferior colliculus had failed.[2] The House Institute developed their implant for patients with neurofibromatosis type 2 (NF2) who had no remaining hearing having undergone surgery for bilateral vestibular schwannoma (VS).[1, 3] Two ball electrodes were implanted near the surface of the cochlear nucleus.

The first multichannel device was implanted in 1991 and subsequently modified.[4, 5] Cochlear® Limited (Sydney, Australia) produced the device which had 21 electrode contacts and was based on their Nucleus™ cochlear implant (CI). In the UK, the use of the ABI was first introduced by Richard Ramsden in Manchester as part of a European multicentre clinical trial, paving the way for the utility of ABI in NF2 in the UK.[6] In 1997 the first MED-EL (Innsbruck, Austria) ABI was carried out. The device was based on their Combi 40+ CI. It has a paddle array of 12 electrode contacts on a 5.5 mm × 3.0 mmm soft silicone matrix and works with an external audio processor in the same manner as a CI. At the time of writing both the Cochlear® and MED-EL ABI are commercially available devices.

The aim of ABI is to rehabilitate patients with no hearing as a result of absence or damage to the auditory nerves and thereby no cochlea to brainstem connections.

ABI IN ACQUIRED HEARING LOSS – NF2 AND NON-NF2 DISORDERS

ABIs were initially designed for patients with NF2.[1, 3] Bilateral VSs are the pathological hallmark of NF2, occurring in 90–95% of patients.[7] NF2 patients may also have multiple central and peripheral nerve system tumours including meningiomas and gliomas. Less commonly, juvenile cataracts and skin lesions are a feature.

Hearing loss occurs as a result of tumour growth causing auditory nerve compression or cochlear damage from ischaemia, infarction or tumour involvement. The rate or extent of hearing loss does not correlate with tumour size or tumour growth.[8] Patients report hearing loss to be the most disabling symptom of the disease.[9] Auditory rehabilitation is therefore one of the key considerations in NF2 management and decision-making. Gold-standard care is delivered by MDTs.

AUDIOLOGICAL ASSESSMENT

The English consensus protocol for auditory rehabilitation in NF2[10] recommends annual audiological assessment as part of the regular review process for NF2. This involves pure-tone audiometry (PTA) and speech discrimination testing with the Arthur Boothroyd (AB) word test as well as hearing aid review to maintain optimum performance. If speech discrimination scores (SDS) fall below 50%, Bamford–Kowal–Bench (BKB) sentence testing is recommended. This should trigger assessment for auditory implantation if scores are below 50% in best-aided conditions at the optimum sound intensity (identified by the SDS), in accordance with the National Institute for Health and Care Excellence (NICE) guidelines.[11]

Auditory implant assessment involves free-field speech discrimination testing with and without lip-reading with hearing aids and potentially environmental noise discrimination tests as well. Sudden deterioration or noticeable progressive hearing loss requires interim review and reassessment.

The decision to operate/offer an auditory implant is complex and is underpinned by MDT decisions about patient tumour management.[7, 12] This involves consideration of patient factors, tumour factors (including size and growth rate), the contralateral ear/tumour and facial nerve function CI may be possible and assessment of auditory nerve function is therefore important to try to predict whether a functional auditory pathway still exists from the cochlea. Promontory electrical stimulation in an apparent dead ear involves electrical stimulation through a transtympanic needle placed on the promontory to attempt to elicit an auditory percept in a conscious patient. Auditory perception suggests a functioning cochlear nerve (CN) but does not predict outcome with a CI.[13] Transtympanic electrical auditory brainstem response (TTEABR) testing is useful in assessing the CN: it has been shown to correlate well with CI-evoked EABR and aids decision-making in patients with CN aplasia/hypoplasia.[14, 15] It may also aid decision-making pre-operatively in NF2 patients.

INTRA-OPERATIVE MONITORING

Intra-operative monitoring of the auditory nerve to aid hearing preservation has been used with varying degrees of success. Proponents use a combination of direct cochlear nerve action potential (CNAP) monitoring and fast auditory brainstem responses (ABR).[16] The ABR is elicited by a 104 dB sound pressure level click stimulus from an ear mould placed inside the ear canal pre-operatively. A combination of analogue and digital filters with specific software enables an interpretable trace and the surgeon is alerted if there is a change in latency of wave V of >0.5 milliseconds. To monitor the CNAP, a multistrand silver wire attached to a cotton pledget is placed proximal to the tumour adjacent to the CN. This acts as the positive electrode, and together with surface negative and ground electrodes enables monitoring of the CNAP. Any change in morphology of the wave is reported to the surgeon. CNAP is difficult to use in the middle fossa approach, as the brainstem proximal to the tumour is relatively inaccessible.

In a study of intra-operative monitoring in 75 patients with serviceable hearing undergoing VS surgery, it did not improve the rate of serviceable hearing preservation.[16] Absent or diminished fast-ABR or CNAP at the end of the procedure correlated with poor post-operative hearing in almost all cases. Sensitivity was poor; over 50% of those with a response after tumour resection did not have serviceable hearing preserved. Problems with these monitoring techniques include persistent presentation of a suprathreshold stimulus; difficulties with placement and maintenance of position of the positive electrode for CNAP; response to surgical manipulations; and interference or artefact from electrocautery.

The presence of post-tumour resection ABR, CNAP, EABR or CI-evoked EABR provides some prognostic information and is an indicator of residual auditory nerve transmission of electrical stimulation. In this situation CI may be worthwhile. In contrast, if these are negative and/or the auditory nerve has definitely been sacrificed, then ABI is the auditory rehabilitation choice.

MULTIDISCIPLINARY DECISION-MAKING

The English consensus of the options and numerous permutations for decision-making with regards to auditory rehabilitation in NF2 are shown in **Table 96.1**.[10] Surgery is usually only offered once hearing has deteriorated below 50% on BKB sentence testing. ABI may be indicated when planning VS excision where CN preservation is not likely to be possible or previous contralateral excision has taken place and there is no remaining hearing or a poorly performing/failed CI/ABI.

CN preservation surgery may be attempted for growing tumours up to 3 cm intracranial tumour diameter (ICTD), but the likelihood of success diminishes progressively over 1 cm ICTD. Hearing preservation is rarely possible for tumours >1.5 cm ICTD. For patients with no serviceable hearing and when intra-operative/post-resection evoked potentials are present, CI is the aim but there is still the possibility of a non-functioning CI.

TABLE 96.1 Indications for cochlear implantation and auditory brainstem implantation in neurofibromatosis type 2

	Cochlear implantation	Auditory brainstem implantation
VS excision planned	CN preservation thought possible	VS in contralateral ear and • CN preservation not thought possible **OR** • CN preserved but intra-operative ECAP and EBAR poor
		Contralateral VS excised and • no contralateral hearing **OR** • contralateral CI/ABI providing poor hearing rehabilitation
Bilateral profound hearing loss and no VS excision planned	Bilateral small to medium-sized stable tumours Stable unilateral tumour where previous contralateral VS excised and CN lost Hearing preserved at previous VS surgery	

CN, cochlear nerve; EABR, electrically evoked brainstem response; VS, vestibular schwannoma.

Counselling of patients requires comprehensive explanation and may take multiple sessions. As well as an introduction to the implants and an explanation of the risks of surgery and alternatives as part of formal consent, there are a number of key areas that must be emphasized:

- Pictorial explanation of the site/positioning of the implants is advised.
- The possibility of the implant being a 'sleeper' device while serviceable hearing is present in the contralateral ear is important to address in specific cases.
- The range of possible outcomes and the difficulties with predicting prognosis/benefit should be explained.
- Managing patient expectations is crucial.[10]
- It is important to stress the immense workload and commitment required by the patient and team for rehabilitation.

Introducing the patient to one who has previously been through surgery and the process of auditory habilitation with a CI/ABI is beneficial.

SURGICAL CONSIDERATIONS

There are a number of surgical approaches. The middle fossa, retrosigmoid and retrosigmoid–retrolabyrinthine approaches are options when aiming for hearing preservation in small tumours, the middle fossa approach being favoured when there is more tumour in the fundus of the internal auditory canal. However, hearing preservation is not often attempted in NF2 patients in England since common practice is to wait until the hearing has deteriorated. Translabyrinthine and retrosigmoid approaches are the two commonest approaches for larger tumours. A modified translabyrinthine approach has been described to enhance access for large tumours.[17] The extent of tumour resection has been classified as total (complete excision), near-total (<1% of tumour volume remaining), subtotal (1–5% of tumour remaining) and partial (>5% of tumour remaining).[7]

The aim of surgery in NF2 is total tumour removal with preservation of the facial nerve and CN. Surgical approach should be chosen based on experience and selecting the one most likely to enable optimal access to achieve the above. For unknown reasons, VSs in NF2 are 'more aggressive' than sporadic VS, which makes preservation of the cochlear and facial nerves more surgically challenging.[7] The tumour biology in NF2 is thought to be different and it is postulated that NF2 schwannomas may encapsulate the fibres of the CN rather than the stretching and spreading that is associated with sporadic VS.[18] Preservation of function is vital[19] hence more commonly nowadays, when there is severe adherence to critical structures (particularly in sporadic VS surgery), a small cuff of tumour may be left to avoid major complications.[12] However, this has implications of future growth, ongoing long-term surveillance and possible further treatment requirements that are not taken lightly, especially in NF2.

Total tumour excision is achievable in 78–92% of patients.[7, 12, 20] The cohorts undergoing surgery vary between centres; some units only offer surgery for patients when tumour growth is observed, others advocate early surgical intervention, as they believe this affords better functional outcomes. As expected, the centres with lower total tumour excision rates generally have better functional outcomes. The English consensus is for hearing deterioration or tumour growth to trigger reassessment, MDT discussion and consideration of the options with the patient and family.[10]

Auditory implantation usually takes place after tumour resection at the same operation. If a retrosigmoid approach has been used, a cortical mastoidectomy and posterior tympanotomy to enable EABR testing and potential subsequent CI are necessary. There are important considerations for all VS surgery that have specific implications for outcomes of auditory rehabilitation.[21]

Meticulous surgical technique is essential to minimize brainstem trauma from direct physical damage or collateral effects of electrocautery. A secondary effect of electrocautery is neural damage from repeated stimulation and excitotoxicity. There is therefore an argument for early division of the vestibulocochlear nerve at the brainstem. This decision may be made early with a large tumour, or cases where it is deemed unlikely to be able to preserve the CN. ABI would then be performed. To prevent migration of the receiver–stimulator, a well or anterior lip is usually drilled on the skull to recess the CI or ABI that is placed in a tight periosteal pocket. A channel for the array can also be drilled from the well to the edge of the craniotomy/mastoidectomy.

Particular challenges for ABI in NF2 include distortion of the brainstem anatomy making placement more difficult than in non-tumour cases. Subsequent remodelling/moulding of the brainstem to fill the tumour void may lead to movement or displacement of the array.

Intra-operative implant evoked ABR testing is a critical step in ABI surgery to optimize paddle position. Usually the four corners of the array are activated in succession, followed by other electrodes as necessary. Based on the presence or absence of ABR, the merits of adjustment of the paddle are discussed with the surgeons. Subsequent repositioning with further testing occurs until placement is optimal. Simultaneous facial and glossopharyngeal nerve monitoring take place to pick up any non-auditory stimulation and anaesthetic vigilance and close attention to the electrocardiogram is also warranted. The silicone mesh on the ABI paddle can be trimmed prior to placement. The advantage of the mesh is that it aids adherence to the brainstem, although, conversely, this may be a disadvantage when repositioning. Maintenance of the optimum position is crucial but challenging. If the implant is placed deep in the lateral recess, the brainstem itself may hug the implant and help keep the paddle stable, but this depends on the amount of distortion left by the tumour and the optimum position dictated by the EABR. Fibrin and dural sealants can be used to help prevent displacement as retraction is relaxed and closure takes place. Anchoring the array in the cavity or at the craniotomy edge should also be considered.

POST-OPERATIVE CARE

Post-operative care and recovery is similar to that for non-implantation VS surgery. Antibiotic prophylaxis for intracranial surgery is in keeping with antimicrobial guidelines, which vary from one unit to another. Meningitis risk should be explained as part of the consent, and pre-operative vaccinations 2 weeks or more before surgery are advised as per CI.

Device activation for CI patients follows the same procedures as for non-NF2 CI recipients. However, ABI activation is done with the patient nil by mouth in a setting (usually either an anaesthetic room or recovery) where there is cardiac monitoring and an anaesthetist present. This is due to the possibility of non-auditory stimulation and, in particular, the risk of vagal stimulation causing bradycardia, tachyarrhythmia or the need for a secure airway. Programming of the ABI involves stimulating each electrode in turn and then in groups across the array. Threshold and comfort levels are varied. Auditory perception with feedback on loudness and pitch enables programming, with the aim of access to a good range of frequencies while avoiding non-auditory stimulation. Numerous appointments over the first year enable adjustment of current levels according to progress and changes in perception. Speech and language therapists and habilitation specialists play a crucial role in helping the patient to learn to recognize sounds. Motivation, commitment and perseverance are important for the patients to be able to maximize their potential benefit from their implant. Assistive listening devices may also help to optimize performance in day-to-day situations.

TUMOUR SURVEILLANCE

Ongoing interval magnetic resonance imaging (MRI) is an important consideration in these patients who invariably require tumour surveillance, either of residual ipsilateral VS or contralateral VS. Previously with the Cochlear® device, temporary removal of the magnet reduced pain and discomfort during scanning and diminished the extent of the artefact/signal void from the implant body. There were, however, resultant problems with infection[22] and degradation of the magnet can occur with multiple removal and reinsertions over time.[10] The most recent MED-EL ABI implant is MRI conditional, enabling patients to be scanned in a 1.5 Tesla machine without the need for magnet removal so there is no pain/discomfort. This is due to an advance in magnet polarity technology where the magnet is self-aligning and rotates freely within its housing. Despite this innovation, artefact remains a problem, posing an issue for monitoring especially with ipsilateral residual VS, and hence magnet removal/replacement may still be necessary.

OUTCOMES

Outcomes of ABI are far more variable than outcomes of CI. CI placement in the scala tympani naturally guides the array around the cochlear turns close to the spiral ganglion neurons with presumed tonotopic organization. Comparatively uncertain positioning in the lateral recess of the fourth ventricle adjacent to the cochlear nucleus is then reliant on patient perception and feedback of auditory tones with pitch ranking for subsequent programming of the ABI. Patient factors, either NF2/tumour-related or from concurrent medical problems, may cause disabilities that interfere with programming and auditory habilitation. Intra-operative factors from mechanical or ischaemic damage to the cochlear nucleus or brainstem are also likely to influence outcomes.[21] Furthermore, habilitation and performance take longer with ABI and may not

plateau for several years[5] compared to several months for most CI users.

Initial hearing benefits with ABI ranged from sound awareness, identification of some environmental sounds and improved performance over lip-reading alone when communicating face-to-face.[6, 23–25] Better results were achieved with non-NF2 patients[26] and subsequently 'open-set' speech recognition (understanding without visual cues) has been reported in NF2.[27–31]

Collaborators from multiple centres have tried to identify reasons for better outcomes.[21] They looked at good performers, those with speech recognition scores >30%, totalling 26/84 patients in a series from June 1997 to September 2011 and found that short duration of deafness (<1 year) was associated with a mean increase in word recognition score of 20%. This suggests a possible degenerative process in the brainstem or higher auditory centres with time. Good results have, however, been reported with deafness durations of 15 years or more.[32] Two surgeons who operate with the patient in the semi-sitting position have achieved the best ABI outcomes. The effect of gravity on the cerebellum enables lower intracranial venous pressure, which in turn means less bleeding when compared to the supine position. This may, however, be a surgeon effect or in part due to less electrocautery use. The semi-sitting position does carry an increased risk of air embolism and tension pneumocephalus[33] and this approach is therefore only recommended for teams familiar with it. The maximum comfortable level (MCL) can be an indicator of distance/proximity to the cochlear nucleus[34] and a relationship between lower thresholds and better outcomes with higher stimulation rates was observed, the inference being (as one would expect) that proximity of the paddle to stimulable tissue is important. Increasing number of distinct pitch electrodes also had a positive correlation with performance such that number alone has less of an influence than the spectrum of pitch perceptions achieved with those in use. Good results where ABI provides more than an aid to lip-reading are definitely achievable in NF2, even in large tumours, but outcomes remain variable and difficult to predict.

ABI IN CONGENITAL HEARING LOSS

The experience described above of ABI in NF2 provided an impetus for exploration of the utility of this technology in non-NF2 patients in whom a CI could not be utilized. A small but important group is those infants and children with bilateral congenital profound hearing loss who are identified through newborn hearing screening programmes and referred for CI and found to have inner ear or CN abnormalities that preclude CI. These include children with absent cochleas or absent CNs or a combination thereof. While the precise incidence or prevalence of such abnormalities is unknown, it is a reasonable estimate that for every 100 children referred for CI one or two will have the abnormalities described and therefore not be suitable for a CI (Saeed, personal observation). For the parents or care-givers of such children this proves to be a substantial additional burden as they are often still coming to terms with the realization that their child has bilateral profound hearing loss and are then advised that the highly successful CI intervention is not appropriate. This challenging situation draws heavily on the skills acquired by experienced CI/skullbase teams in terms of assessment, surgery, habilitation and, critically, the management of the expectations of the family in terms of commitment to the habilitation process and outcomes of ABI in such children.

Nevertheless, based on the outcomes of ABI in a substantial number of non-NF2 adults, Colletti and his team extended the indications for ABI to include such children.[35, 36] This pioneering work served as catalyst for other centres across the world to utilize ABI in selected congenitally deaf children. In the UK the first three children were implanted by Richard Ramsden and his team in Manchester in 2005 and this was followed by teams in the USA, Turkey, Korea and, subsequently, London and Cambridge in the UK.[37–39] The emergent literature emphasized the importance of careful case selection as well as the surgical and habilitative challenges in such children but also the variable outcomes, ranging from no auditory benefit, environmental auditory perception through to development of vocabulary and the slow trajectory in achieving these outcomes when compared with children undergoing CI.

In an attempt to standardize the assessment and indications for ABI in children internationally, Sennaroğlu convened a meeting of key stakeholders in Istanbul which resulted in the first consensus statement, published in 2011.[15] This was followed up by a second such meeting and a second consensus statement in 2016.[40] Such a collaborative exercise involving 20 centres from 11 countries explored the clinical and radiological indications and timing of surgery, habilitation and evaluation of outcomes and emphasized the importance of appropriate teams managing such complex children. Key points include:

- The importance of a comprehensive MDT drawing on extensive CI and lateral skullbase experience and the management of the expectations of the family was emphasized.
- It was agreed that, in order to balance the potential auditory benefit based on neural plasticity against the metabolic stress of intracranial surgery and anaesthesia, the optimal age for ABI in congenitally deaf children is 18–24 months.
- The children with cochlear and or CN aplasia should be considered for ABI while those children with hypoplastic CN should be offered a CI in the first instance with a view to fast-tracking for ABI if the CI does not confer any benefit.
- It was also recognized that the majority of ABI recipients do derive auditory perception but not necessarily speech acquisition, in contrast to children with a CI.
- Finally, it was clear from the accrued global experience that those children with additional physical or cognitive disabilities fared less well than the non-sydromic otherwise healthy children.

In one of the largest series examined to date, Sennaroğlu and his team have reported the longer-term outcomes (<1 year) in 35 children undergoing ABI.[41] The majority of the recipients achieved grade 5 on the Categories of Auditory Performance (CAP) scale, implying understanding common phrases without lip-reading. The outcomes, however, as expected, were not as good as a comparable age group that had undergone CI, and those children with additional disabilities fared less well than those who had no additional physical or cognitive problems. Nevertheless, as has been observed by all who work in this field, in appropriately selected infants and children and appropriately counselled families, the ABI is a viable option for the family to consider as part of the habilitative process for their congenitally profoundly deaf child.

In summary, the assessment, surgery and management of a child undergoing ABI for congenital profound deafness, as well as the counselling of the child's family, is a complex process that is continuing to evolve as experience among centres undertaking this work continues to accrue. CI programmes that identify a child who is not suitable for a CI should refer the child to an ABI centre so that the family can have the benefit of appropriate multidisciplinary evaluation.

FUTURE RESEARCH

- ABI design to optimize the placement of the electrode array paddle with reference to the tonotopicity of the cochlear nuclei.
- Electrophysiological evaluation of the cochlear nerve post-NF2 surgery or the hypoplastic cochlear nerve.
- Auditory habilitation and rehabilitation of ABI recipients to improve outcomes.

KEY POINTS

- A vast number of factors affect decision-making and outcomes for this complex patient group. The multidisciplinary teams for neurofibromatosis and auditory implantation must work cohesively. In particular, the roles of the audiological scientists for pre-operative investigation, peri-operative monitoring/testing and post-operative programming are crucial to guide patient-centred decisions. Surgical and peri-operative management by experienced teams with fastidious attention to every detail are paramount.
- Outcomes continue to be varied; but, with centralization of services, technological advances, increasing experience and ongoing International collaboration, improvement will be seen in patient pathways, shared decision-making, quality of care and patient benefit.

CHAPTER 97

IMAGING OF THE TEMPORAL BONE

Steve Colley

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search from using the following keywords: temporal bone, imaging, CT and MRI.

INTRODUCTION

The temporal bone is a complex anatomical area that is made up of five osseous components: the squamous, mastoid, petrous, tympanic and styloid portions of the temporal bone. Anatomically, the temporal bone may be separated into five distinct regions that demonstrate some specific types of pathology, and can dictate the optimum imaging method depending on the area of concern and the pathology suspected. These anatomical sub divisions of the temporal bone are: the external ear; the middle ear and mastoid; the inner ear; the internal auditory canal (IAC); and the facial nerve canal.

The imaging modalities used in common practice include computed tomography (CT), magnetic resonance imaging (MRI), nuclear medicine and, more recently, cone beam computed tomography (CBCT). The main imaging methods utilized in temporal bone imaging are CT and MRI, and a brief overview of scanning techniques, benefits and disadvantages is summarized as follows.

SCANNING TECHNIQUES

Computed tomography (CT)

Multidetector CT scanning allows extremely quick acquisition of imaging of the temporal bones. The data acquired is a volume, which can then be reconstructed in a variety of imaging planes depending upon the anatomical area being scrutinized. Typical temporal bone CT images are acquired at a thickness of 0.5–0.6 mm, and they provide excellent bony detail of the external auditory canal (EAC), middle ear and mastoid, ossicular chain, inner ear, and the facial nerve canal. CT also allows accurate identification of masses or opacification within the anatomical areas of the temporal bone, but suffers from its ability to differentiate between different types of opacity (e.g. fluid versus cholesteatoma).

CT utilizes ionizing radiation. The dose employed in CT of the temporal bones is more of an issue in imaging of children, adolescents and young adults – especially where repeat imaging is employed. CBCT offers a reduced radiation dose in comparison to MDCT, and is certainly an effective alternative in these settings.

Magnetic resonance imaging (MRI)

MRI utilizes strong magnetic fields (30 000 to 60 000 times greater than the earth's magnetic field) in order to produce images based upon the mobility of nuclei, especially protons within water molecules.

Advantages include excellent soft tissue contrast, and the ability to visualize and resolve the cranial nerves as they traverse CSF and the IAC. MRI can also differentiate between differing types of soft tissue opacification in the middle ear and mastoid, helping discriminate cholesteatoma from inflammatory or post-surgical changes.

Disadvantages of MRI include longer scanning times (up to 45–60 minutes), artefact from movement, surgical implants and metal, and safety issues secondary to the strong magnetic fields employed.

ANATOMICAL VARIANTS

Before considering the different types of pathology encountered in the temporal bone, there are a number of anatomical variants that are highly relevant for radiologists to assess and cover in reports, in order to avoid prolonged procedures and operative complications in a surgical field where access is often rather limited.

Tegmen tympani

A low-lying tegmen may hinder access to the middle ear via a mastoid approach, and pre-operative recognition is important in order to avoid breach during surgery.

Sigmoid sinus

The sigmoid sinus passes along the posterior margin of the mastoid, and varies greatly in the degree of anterior indentation in to the mastoid cavity. An anteriorly located sinus may have a very thin slip of cortical bone between it and the mastoid cavity, and sinus injury could result in significant bleeding complication during surgery.

Jugular fossa

Wide variation exists in the size and height of the jugular fossa and jugular bulb, both between patients and on either side in the same patient. A high riding jugular bulb may project into the hypotympanum, it may have a thin bone covering that may be damaged at surgery or be completely dehiscent of bone covering, or a small diverticulum may protrude from the jugular bulb towards or into the hypotympanum (Figure 97.1).

Carotid canal

Whilst there may be very minor variations in the internal carotid artery (ICA) canal course, these are generally insignificant. A true aberrant ICA is rare, but it is vitally important to identify on pre-operative imaging studies. Failure of the normal cervical carotid artery development leads to anastomosis between inferior tympanic artery and an enlarged caroticotympanic artery. An aberrant ICA is formed, which traverses the middle ear cavity.

Typically, an aberrant ICA passes through the infero medial middle ear cavity, adjacent to the cochlear promontory (Figure 97.2). In addition to a significant intra operative surgical complication risk, it may present as a pulsatile retro tympanic mass, or cause CHL via mass effect on the incudostapedial joint.

Facial nerve canal

The normal VIIth nerve canal arises from the anterior lateral IAC, passing to the geniculate ganglion (anterior genu). The geniculate segment then passes posteriorly along the middle wall of the middle ear, lying below the lateral semi-circular canal, above the oval window niche and stapes superstructure. At the posterior genu, the canal turns another 90 degrees, forming the descending or mastoid segment, which exits the temporal bone at the stylomastoid foramen. Variation in VIIth canal anatomy is important to highlight pre-operatively, to avoid inadvertent injury and to plan potentially difficult middle/inner ear access. More common variations include a nerve that protrudes inferiorly into the oval window niche, a dehiscent tympanic segment with no discernable bone covering, or a truly aberrant VIIth nerve course.

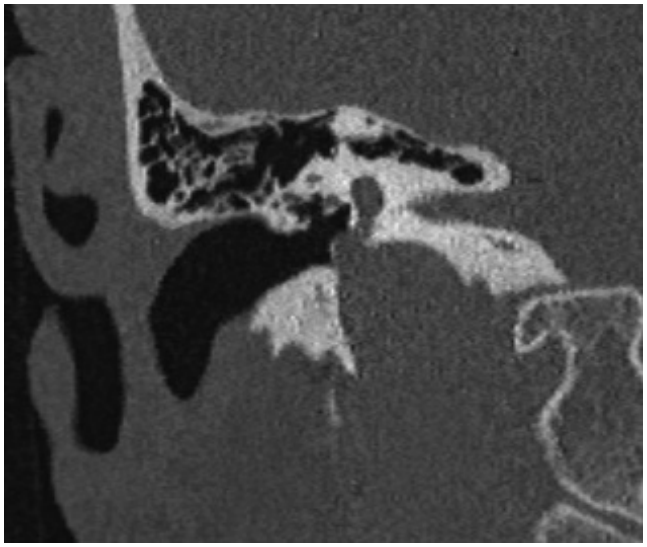

Figure 97.1 Coronal CT showing high riding right jugular bulb, protruding into hypotympanum.

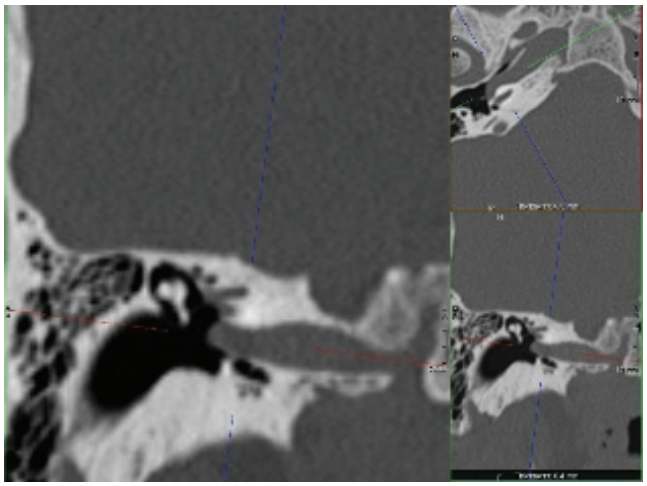

Figure 97.2 Coronal and axial CT with aberrant right ICA course, passing into middle ear cleft, just lateral to cochlear promontory.

IMAGING OF TEMPORAL BONE PATHOLOGY

Acute otitis media and mastoiditis

A mild degree of mastoiditis will generally been seen with acute otitis media. The more prevalent use of antibiotics in treatment of acute otitis media has reduced the number of significant cases of mastoiditis. The importance for radiologists is to identify the potentially serious coalescent mastoiditis, and any complications arising from mastoid infection.

Uncomplicated, or mild mastoiditis is seen as fluid within the mastoid air cells but, importantly, with preservation of the internal bony septations and peripheral bone margins. Destruction of the internal bony septations indicates the presence of acute coalescent mastoiditis, which requires prompt treatment to prevent complications such as soft tissue or intracranial extension and abscess formation.

When a more aggressive mastoiditis is present, the bony margins of the mastoid and surrounding soft tissue planes should be assessed. Infection can spread through the sutures to form a subperiosteal abscess, and extending into the upper neck, forming a Bezold abscess. Infection may spread posteriorly into the sigmoid sinus, or superiorly into the middle cranial fossa.

Chronic otitis media

Chronic otitis media (COM) is usually due to Eustachian tube dysfunction, and has a clinically different presentation to acute infection, being generally painless with chronic discharge with or without CHL often present. Negative middle ear pressure may cause tympanic membrane retractions, and subsequent acquired cholesteatoma formation. Imaging usually shows a middle ear and mastoid effusion, with increased sclerosis of the adjacent bony structures. Further complications from chronic otitis media include ossicular erosions (without cholesteatoma) due to chronic surrounding hyperaemia, and ossicular chain fixation. Fixation of the ossicles secondary to COM may be fibrous or calcific, the latter being termed tympanosclerosis. Calcifications with COM may affect the tympanic membrane, or surround and fix the ossicles in the epitympanum (Figure 97.4).

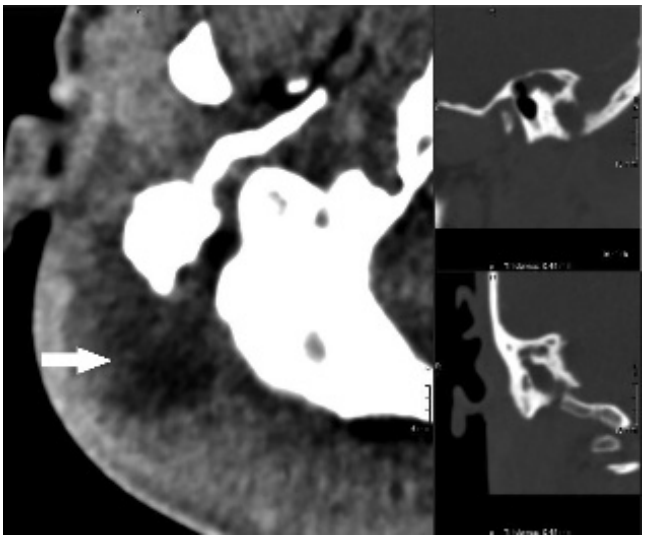

Figure 97.3 Axial, coronal and sagittal CT images showing right masoiditis, with loss of internal bony septation, and Bezold abscess below the mastoid tip (arrow).

Figure 97.4 Coronal CT showing diffuse ossification (tympanosclerosis) in the medial left epitympanum (arrow) with adjacent chronic effusion. Note the normal right epitympanum.

Necrotising (malignant) otitis externa

Necrotising otitis externa (NOE) usually presents in elderly patients with ear discharge and severe otalgia, generally with an underlying history of diabetes or chronic immune suppression. *Pseudomonas aeruginosa* are the most common causative organisms.

Imaging has a role to play in diagnosing presence and extent of disease, identifying complications, and in the long-term management and follow-up of this complicated and often difficult to manage condition. CT is normally the first imaging technique, and MRI can provide complimentary information when there is evidence of bone involvement and osteomyelitis.

Early disease is seen as subtle soft tissue thickening in the EAC. Disease can progress and invade the submucosa and spread beyond the bony or cartlagenous confines of the EAC. Early changes suggesting an aggressive or progressive form of NOE are the identification of subtle cortical bone erosions (osteomyelitis). Comparison with the normal contralateral side is often of benefit here (Figure 97.5).

Infection can then spread along a few different, but predictable, pathways: the petrotympanic fissure allows infection to spread from the middle ear to the temporomandibular joint (TMJ) and the soft tissues below the skull base. Disease extension medially to the carotid canal is often seen and, again, comparison with the contralateral side can help pick up early osteomyelitis and bone erosions in this region. Inferiorly, disease can spread through the soft tissue spaces below the skull base, and assessment of these regions is important on imaging (Figure 97.6).

Invasion of the central skull base (central skull base osteomyelitis) may occur from direct extension along the

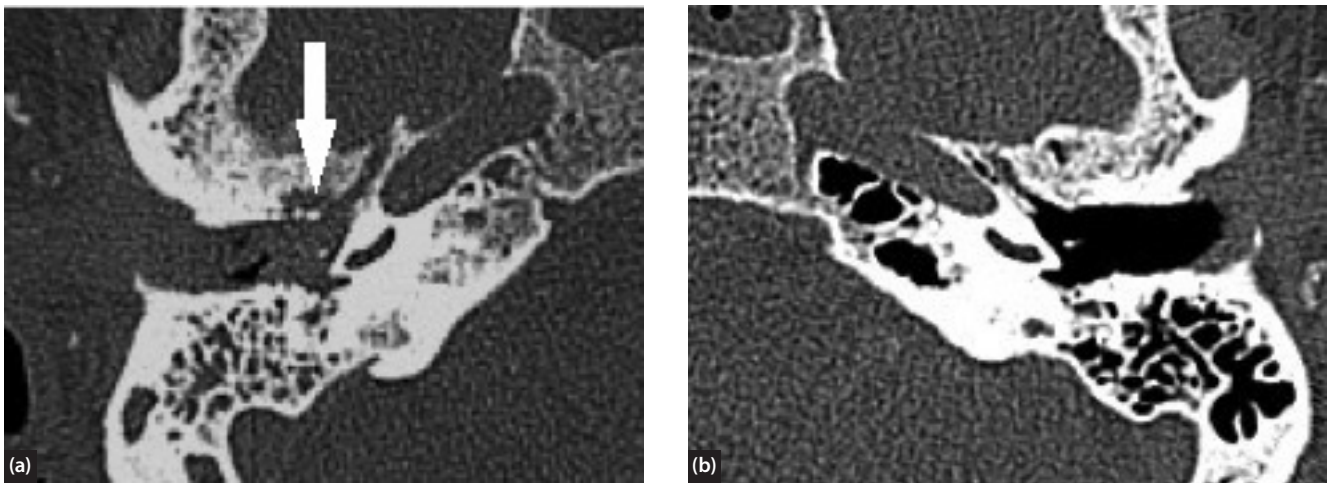

Figure 97.5 a and b Axial CT with thickened soft tissue in EAC, middle ear effusion and early subtle erosion of anterior epitympanum (arrow). Normal left middle ear for comparison.

Figure 97.6 Axial CT in patient with NOE, with diffuse infiltration of soft tissue beneath the skull base, and loss of normal fat planes. Normal fat planes depicted by left sided arrow.

petrous apex and across the petroclival fissure, or from subtemporal disease directly invading the lower clivus. MRI is better at detecting early central skull base disease, with bone marrow changes being apparent on standard T1 weighted images before frank cortical destruction occurs. Intracranial extension of disease, either direct from the mastoid and middle ear, or via neural foramina, is best identified on MRI (Figure 97.7).

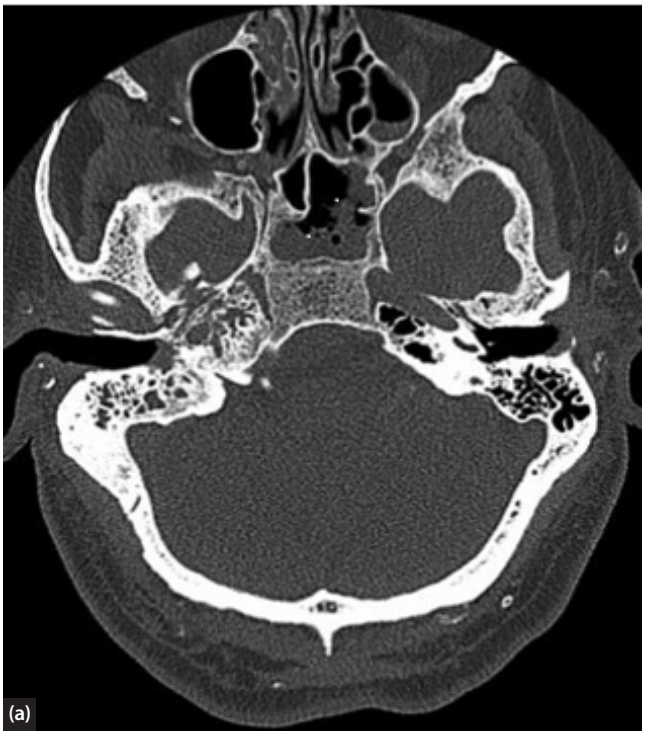
Imaging may be used to follow up patients and dictate appropriate antibiotic treatment duration. There remains confusion as to the best imaging strategy in follow-up of NOE. It is clear that both CT and MRI abnormality can persist after adequate disease treatment, and notably abnormality can remain in the bone marrow on MRI with imaging improvement lagging behind clinical improvement. Various nuclear medicine studies have been utilized in follow-up of NOE, with ^{99m}Tc or Gallium 67 bone scans potentially helping in follow-up; however, Gallium scans are thought better for follow-up, as imaging tends to return more rapidly to normal after infection has settled.[1]

Cholesteatoma

Cholesteatomas are a collection of keratinizing squamous cells in the middle ear cleft, which are associated with resorption or erosion of adjacent bony structures. Lesions may be congenital (occurring anywhere in the temporal bone) or acquired (middle ear location), the latter being far more common (around 98% of cholesteatomas)[2] as a complication of chronic otitis media.

Initially, CT is the imaging method of choice in depicting middle ear opacification and bone erosions of the scutum and adjacent ossicular. A normal CT has extremely high NPV for absence of cholesteatoma. The limitation of CT is that it cannot differentiate mucosal or inflammatory middle ear disease from the soft tissue mass of a cholesteatoma, cholesterol granuloma, granulation tissue or malignancy.[2] CT is also the best modality for detecting bone erosions that are seen with high frequency in both pars flaccida and pars tensa cholesteatomas.

Acquired cholesteatomas arise from invaginations of the tympanic membrane, or grow into the middle ear via perforations. The former type, derived from an apparently intact membrane, are more common, and typically arise from the pars flaccida region. Keratin accumulates in the lateral epitympanic (Prussak) space, and causes scutum erosion, medial displacement of the ossicular chain, and ossicular erosion (Figure 97.8). Cholesteatoma growing into the middle ear via a perforation usually arises from the pars tensa. These 'secondary acquired' cholesteatomas are often located medial to the ossicular chain, and cause



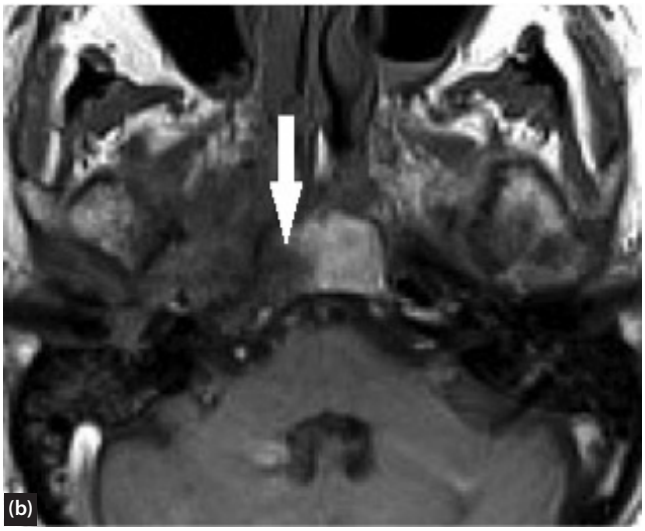


Figure 97.7 Axial CT (a) and T1 weighted MRI without fat suppression (b) in patient with right NOE. Normal bone cortex is preserved on CT, but T1 MRI shows early marrow infiltration and loss of normal fatty marrow signal (arrow) in keeping with early central skull base osteomyelitis.

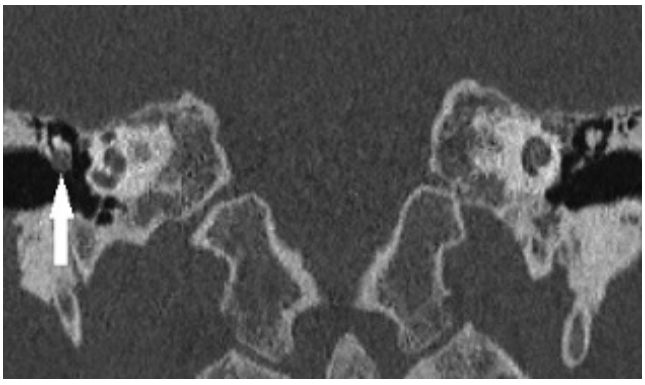

Figure 97.8 Coronal CT with 4 mm right lateral epitympanic pars flaccida cholesteatoma (arrow), with early ossicular erosion.

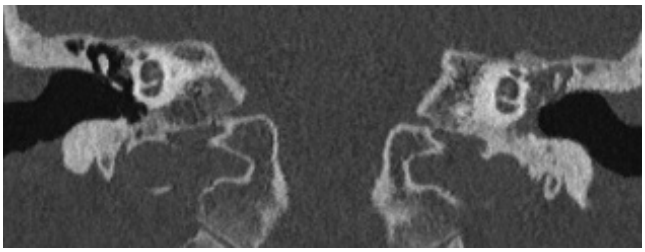

Figure 97.9 Coronal CT with left middle ear soft tissue opacification, with subtle lateral displacement and erosion of the ossicular chain compatible with pars tensa cholesteatoma.

early erosion of the long process of incus (LPI) and tend to more erosion of the inner ear structures (Figure 97.9).

Modern MRI techniques utilizing functional imaging sequences can assist in delineating extent of disease, but more importantly can now detect recurrence, replacing routine second-look surgery in many centres. Functional MRI utilizes diffusion weighted imaging (DWI), which characterizes tissues based upon the mobility of water molecules within them. Inflammatory disease will have good water mobility, whereas cholesteatoma, with tightly packed keratin and limited extracellular space, show reduced water diffusion. Early MRI techniques (echo-planar DWI – EPI) showed significant artefact at bone, soft tissue and air interfaces with both false positive and false negative results. Newer non-echo-planar (non-EPI) DWI does not suffer from such artefact, and allows imaging of sufficient resolution to detect cholesteatoma down to 2 or 3 mm diameter, without post-contrast sequences.[3] Positive scans typically show high signal on the b1000 sequence, with matched low signal on the Apparent Diffusion Coefficient Map (Figure 97.10).

A number of potential complications should be sought on imaging. Labyrinthine fistula due to lateral semicircular canal erosion (Figure 97.11) can result in vertigo, imbalance and sensorineural hearing loss. Less commonly, cochlear promontory erosion may occur. Importantly, the tegmen should be assessed for potential erosion or breach, as a meningocoele should be excluded in such cases pre-operatively.

Otosclerosis

Imaging is not always employed in the diagnosis of typical otosclerosis with CHL, but may be utilized in patients with sensorineural or mixed hearing loss, or an atypical history. CT is the imaging method of choice, as it depicts the early bone changes associated with otosclerosis in both fenestral and retrofenestral disease.

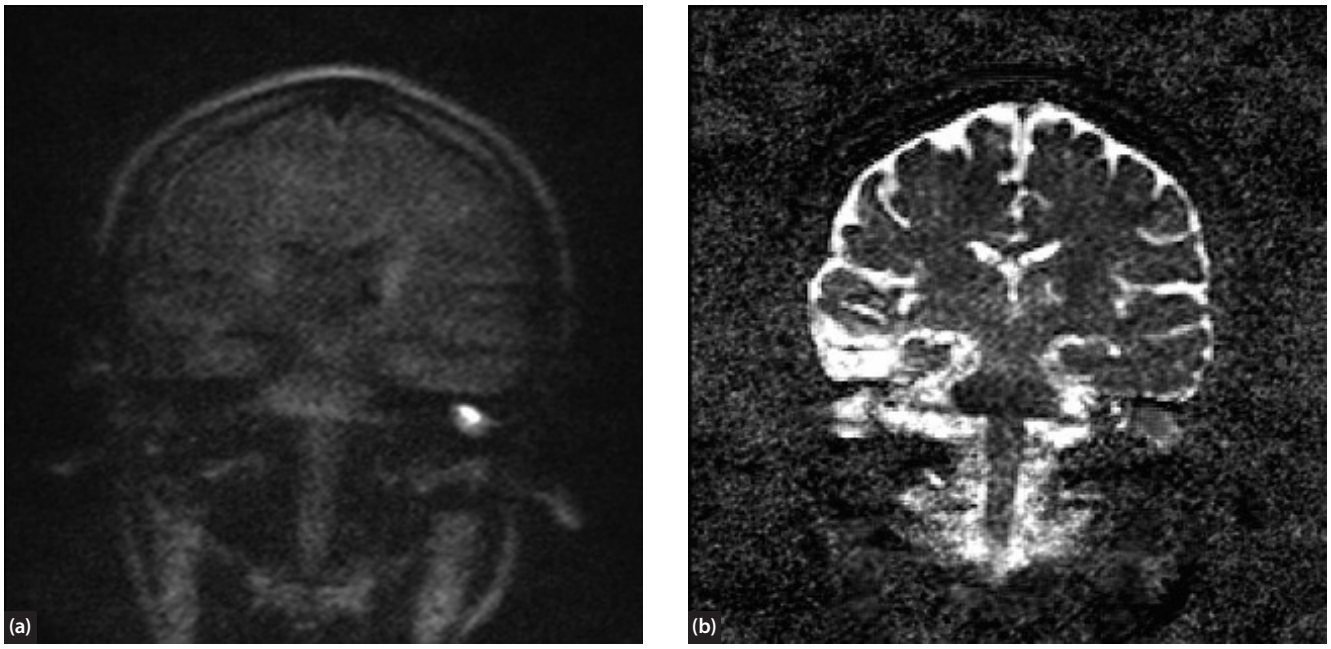

Figure 97.10 Coronal DWI MRI shows left sided high signal on the b1000 sequence (a) with matched low signal on the ADC map (b), compatible with left sided cholesteatoma.

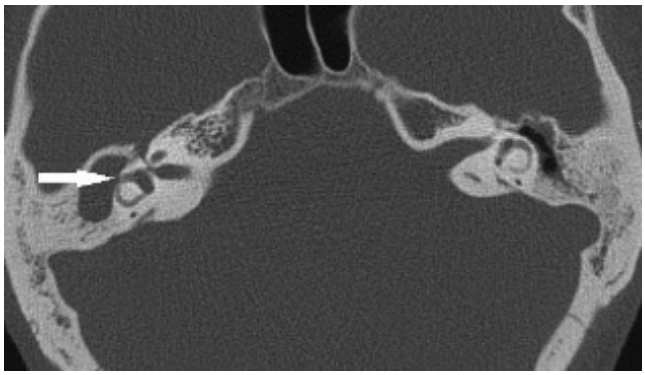

Figure 97.11 Axial CT shows right sided epitympanic cholesteatoma, with erosion of lateral semi-circular canal (arrow). Note normal bone covering of left lateral semicircular canal.

Thin section CT shows low-density (demineralized) plaques in early disease, which typically affects the fissula antefenestrum at the anterior border of the oval window. The otoscerotic plaque can extend to involve the stapes foot-plate, occlude the oval window and extend to the cochlear promontory and round window region. Disease is often bilateral (up to 85% of cases).[4]

Retrofenestral disease is the less common of the two types of otosclerosis – and often considered a continuation of fenestral disease. Low density is seen extending around the otic capsule, termed the fourth ring of Valvassori (Figure 97.12). Again, disease is usually bilateral.

CT for assessment of otosclerosis should also be used to evaluate alternative causes of conductive hearing loss (CHL). Anatomical temporal bone variants described at the beginning of the chapter should also be sought prior to considering surgical treatment – normally with stapedectomy and ossicular prosthesis in the setting of fenestral disease.

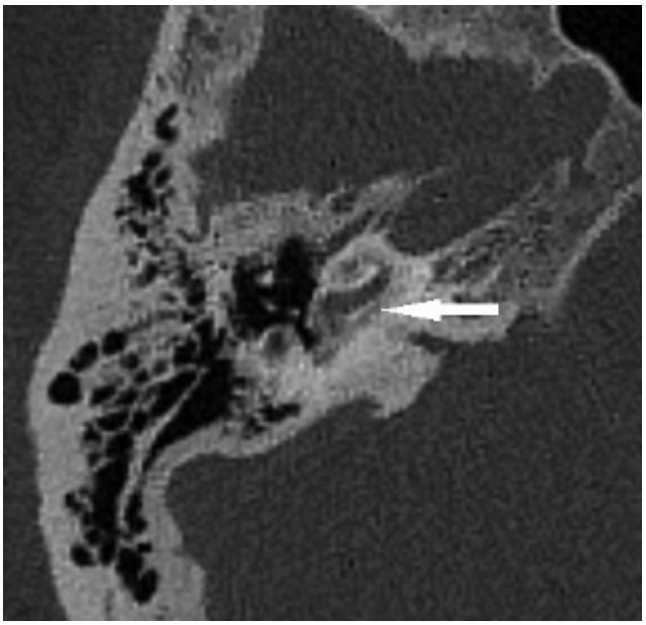

Figure 97.12 Axial CT at the level of the basal turn of cochlear shows low density surrounding the cochlea (arrow), indicating retrofenestral otosclerosis.

Superior semicircular canal dehiscence

Superior semicircular canal dehiscence (SSCD) has been increasingly recognized as a cause of a variety of vestibular and auditory symptoms. SSCD is thought to be due to a bony defect affecting the arcuate eminence of the superior canal, resulting in a mobile third window into the labyrinth. Absent bone over the SSC, however, is described in up to 13% of asymptomatic individuals.[5]

Thin section CT scans can demonstrate bone thinning and bone defects. Images should be reconstructed in

planes parallel (plane of Pöschl) and perpendicular (plane of Stenver) with respect to the superior canal to allow accurate demonstration of defects, the angle they subtend, and to help plan surgery if symptomatic.

Temporal bone trauma

Temporal bone fractures normally result from high-impact blunt trauma, such as road traffic accidents, falls from height or direct assault. High resolution CT is the imaging method of choice, and is normally undertaken as part of an initial trauma CT study. A dedicated temporal bone CT should be considered when there is suspicion of a temporal bone fracture but no obvious injury on initial trauma study. Traditional classification has described fractures as longitudinal or transverse, with respect to the long axis of the temporal bone (i.e. longitudinal fractures passing transversely through the temporal bone on an axial image, and transverse fractures running antero-posterior on axial images).[6]

Longitudinal fractures are by far the most common, accounting for up to 90% of temporal bone fractures. These fractures are more commonly associated with CHL, which may be due to tympanic membrane (TM) involvement, haemotympanum or ossicular chain disruption (fracture or dislocation, or both) and normally spare inner ear structures (**Figure 97.13**). Transverse fractures more commonly pass through the otic capsule and internal acoustic meatus (IAM), and are hence more commonly associated with sensorineural hearing loss, facial nerve paralysis and cerebrospinal fluid (CSF) leak.

Facial nerve paralysis is seen more commonly with transverse fractures (up to 50%) than longitudinal fractures (10–20%). Onset is usually more rapid with transverse fracture patterns due to nerve transaction in the labyrinthine segment, whereas longitudinal fractures may have delayed onset due to nerve contusion or compression from adjacent haematoma.

Further complications that should be considered are CSF leak, meningitis, meningocoele from tegmen involvement, and vascular injury to the carotid canal or jugular fossa. Delayed complications can include labyrinthine ossificans and post-traumatic cholesteatoma.[7]

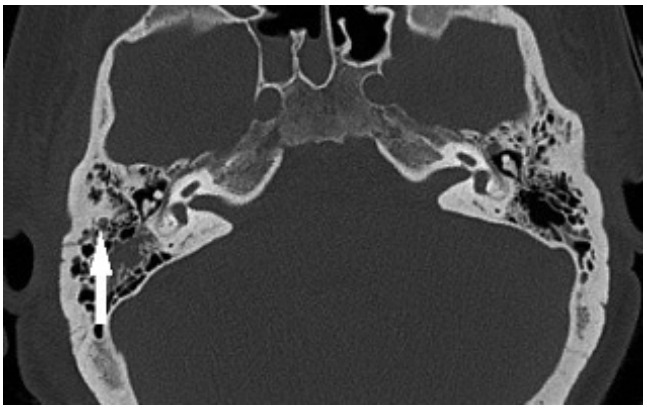

Figure 97.13 Axial CT showing right longitudinal temporal bone fracture (arrow), with incudostapedial joint disruption and widening. Note normal left incudostapedial joint.

TEMPORAL BONE TUMOURS

There are a number of benign and malignant tumours that may affect the temporal bone. Benign lesions include vestibular schwannoma, cholesterol granuloma, paragangliomas, facial nerve haemangioma, and osteomas. Malignant lesions include squamous cell carcinoma (SqCC) and other rarer EAC tumours, direct invasion (e.g. nasopharyngeal cancer or parotid malignancy) or perineural spread, or distant metastases.

Vestibular schwannoma

Vestibular schwannomas are the most common CPA and IAC tumour, accounting for 70–80% of lesions, with meningioma and metastases less common. MRI is preferred for detecting tumours and delineating extent. Thin section T2 weighted images (constructive interference in steady state, (CISS), Fast Imaging Employing Steady-state Acquisition (FIESTA)) (**Figures 97.14** and **97.15**) provide excellent CSF high signal and clear delineation of the cranial nerves traversing the IAC. Post-contrast thin section T1 weighted images can help pick up small or subtle lesions, and assist in follow-up.

Small lesions appear homogenous on T2 sequences, and show homogenous enhancement. Larger lesions may show heterogeneity on T2 and post contrast sequences due to areas of cystic change. Such cystic lesions often demonstrate more rapid growth patterns, but respond better to radiosurgical techniques than solid lesions.[8]

Lesions may be purely intra-cannalicular, extend through the IAC meatus to the cisternal compartment (producing a typical 'ice cream cone' appearance) or, less commonly, may be purely cisternal. Larger lesions may cause mass effect upon the brainstem and 4th ventricle. Occasionally, lesions may undergo acute internal

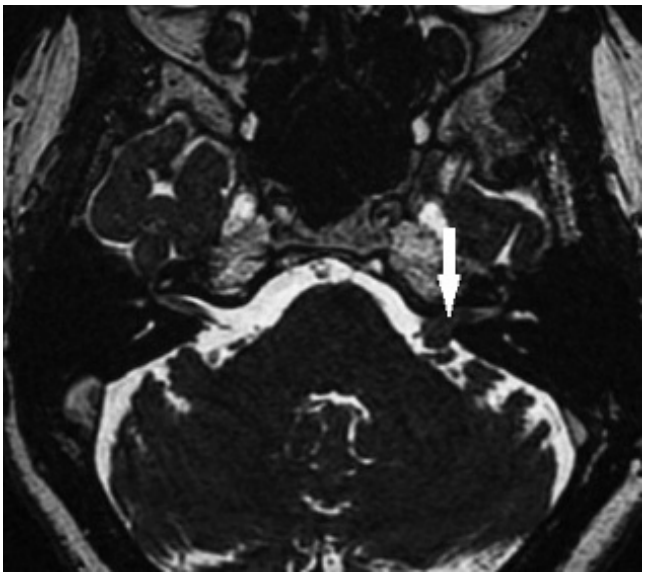

Figure 97.14 Axial CISS MRI showing left sided vestibular schwannoma (arrow), with intra cannalicular and cisternal component, but no brainstem compression.

haemorrhage with rapid expansion and development of cerebellar signs and vomiting.

Post-treatment scanning should assess volume reduction and, importantly, post-contrast T1 sequences may show nodular enhancement associated with tumour recurrence or regrowth.[9]

Cholesterol granuloma

Regardless of the aetiology of cholesterol granuloma, it is the repeated haemorrhage and accumulation of blood products that creates typical imaging appearances of high T1 and T2 signal intensity on MRI scan. There is no appreciable enhancement post-contrast, but T1 weighted scans pre-contrast should be performed in order to identify the characteristic high signal intensity. Diffusion weighted MRI does not show restriction. CT often shows a degree of smooth bone erosion.[2]

Paragangliomas

Temporal bone paragangliomas include glomus tympanicum, glomus jugulare and jugulotympanicum lesions, the latter being a combination of the former two.

Glomus tympanicum paragangliomas are the most common middle ear tumour.[10] On CT, tumours are seen as a nodular area of soft tissue located on the cochlear promontory. Lesions are often small but may extend to the TM and attic if larger, but do not normally cause erosion of the ossicular chain.

Glomus jugulare tumours are the most common lesions to arise in the jugular foramen, with schwannomas and meningiomas being less common. The glomus tumours arise from the jugular bulb, the Xth nerve ganglion, or from the Arnold or Jacobsen nerves.

CT of glomus jugulare shows a typical pattern of permeative bone destruction that involves the carotico-jugular spine early in the disease process. Large lesions may extend to the middle ear (jugulotympanicum tumours) or below the skull base. MRI scanning shows prominent post-contrast enhancement of lesions. Larger tumours may show a classical 'salt and pepper' appearance, which is a combination of flow voids from intratumoural vessels, and areas of microhaemorrhage.

Facial nerve haemangioma

These vascular lesions typically affect the geniculate ganglion, Fallopian canal and anterior aspect of the tympanic facial nerve canal. Low density change may surround an expanded geniculate ganglion on CT, progressing to permeative bone loss, and distinctive intralesional spicules of bone. Thin section MR imaging may show prominent enhancement of the tumour.

Figure 97.15 Axial CT shows a well demarcated soft tissue nodule behind the right TM, overlying the cochlear promontory – typical of a glomus tympanicum tumour.

Malignant tumours

Malignant lesions in the EAC are most commonly SqCC, with other histopathological types being numerous but much less common. CT and MRI imaging are complementary in assessment of such tumours. The aim of imaging is to assess the degree of aggressive tumour invasion into the various temporal bone anatomical sites, and involvement of critical neural and vascular structures, which would affect surgical planning (e.g. facial nerve or dural invasion). Where biopsy has proven a malignant lesion, appropriate staging should be obtained, which should include a CT of the neck and chest for SqCC, and sometimes systemic whole-body CT, or PET CT where metastasis is a diagnostic possibility.

KEY POINTS

- CT and MRI are the main imaging modalities used for temporal bone imaging.
- There are a number of important anatomical variants that should be sought by radiologists interpreting temporal bone imaging studies.
- Identification of anatomical variants can assist surgical planning and reduce potential complications.
- A variety of inflammatory, non-tumoral and tumour pathologies may affect the temporal bone.

ANATOMY OF THE SKULL BASE AND INFRATEMPORAL FOSSA

Charlie Huins

SEARCH STRATEGY

Data may be updated by a search using the following keywords: anatomy, temporal bone, skull base, anterior and lateral.

OVERALL TOPOGRAPHY OF THE SKULL BASE

In this chapter, the surgical anatomy of the skull base with reference to otolaryngology will be covered. In depth detail of the ear and nose are covered in separate chapters; details regarding the surgery of all aspects of the skull base are dealt with in the relevant chapters.

Anatomically, the skull base can be considered from both superiorly – within the cranial cavity – and inferiorly, and both aspects will be described here. The boundaries of the skull base are:

- *anteriorly* - by the upper incisor teeth
- *posteriorly* - by the superior nuchal line of the occipital bone
- *laterally* - by the remaining upper teeth, the zygomatic arch & its posterior root, and the mastoid process.

The three main areas of the skull base will therefore be described:

1. anterior
2. posterior
3. lateral.

ANTERIOR SKULL BASE

The anterior skull base forms the floor of the anterior cranial fossa, and a 'roof' over the orbits and ethmoid air cell system (sinuses). It is formed by the frontal bone, the cribriform plate of the ethmoid, the lesser wings and the body of the sphenoid.

The orbital part of the frontal bone forms the roof of the orbital cavity from its superomedial articulation with the nasal bones (the conjoint of these three being the Nasion), to its fusion with the zygomatic bone superolaterally, the anterior aspect being the supraorbital rim; medially, to form the medial orbital wall, it articulates from front to back with the nasal bone, the frontal process of the maxilla, the lacrimal bone, and the paper-thin orbital plate of the ethmoid bone (lamina papyracea) to its posterior articulation with the lesser wing and anterior part of the body of the sphenoid.

The ethmoid bone consists of:

- the central perpendicular plate
- the cribriform plate
- the paired labyrinths.

The midline perpendicular plate forms the central superior aspect of the nasal septum, articulating anteroinferiorly with the quadrilateral cartilage and posteroinferiorly with the vomer. It extends superiorly as the crista galli; either side of the crista lie the cribriform plates, through which pass 20 or so olfactory nerve filaments on each side. The labyrinths, containing numerous air cells, lie medial to the orbit and form part of the lateral wall of the nose, being anterior to the body of the sphenoid. They occupy much of the upper part of the maxillary hiatus, a large defect in the medial aspect of the maxilla, itself closed by several

bones, and the medial aspect of these is surgically important in endoscopic sinus surgery. The superior and middle conchae ('turbinates') are part of the ethmoidal labyrinth, as is the bulla ethmoidalis anteriorly. The lamina papyracea, the paper-thin orbital plate of the ethmoid, separates the ethmoid sinuses from the orbital cavity, knowledge of which is important for endoscopic access to the medial aspect of the orbit, such as for (medial) periorbital abscess drainage, orbital decompression or access to infraorbital/intrazonal tumours.

Two important structures are in this region, providing the blood supply to part of the nasal cavity. The first, found 24 mm posterior to the anterior lacrimal crest on the frontal process of the maxilla, along the frontoethmoid suture on the medial wall of the orbit, is the anterior ethmoidal foramina, transmitting the anterior ethmoidal artery; 12 mm behind this is the posterior ethmoidal foramina and its corresponding artery; 6 mm behind that lies the optic nerve in its canal. The second, found at the top of the perpendicular plate of the palatine bone, posterior to the maxillary hiatus (and so the middle concha), is the sphenopalatine foramen. This transmits the corresponding neurovascular bundle, important in control of the main blood supply to the nasal cavity and also in treating juvenile nasopharyngeal angiofibroma. Of note is the fact that the sphenopalatine artery rarely presents as one arterial trunk, as it divides in two or more (up to 10 branches) just after exiting the sphenopalatine foramen.

The posterosuperior nasal cavity is formed by the sloping anterior aspect of the body of the sphenoid; on the anterior aspect of this, the sphenoethmoidal recess, lying above and behind the superior concha, contains the sphenoidal sinus ostium.

Posterior to the inferior concha, the Eustachian tube orifice marks the medial end of its cartilaginous portion, behind which is found the fossa of Rosenmüller. This lies just anterior to the anteromedial aspect of the foramen lacerum and hence the petrous apex (see below). A nasopharyngeal carcinoma involving this fossa of Rosenmüller may invade upwards through the foramen lacerum, sometimes producing a lateral rectus palsy by compressing the VIth cranial nerve as it crosses the apex of the petrous bone and enters the cavernous sinus.

The salpingopharyngeus muscle arises from the posterior aspect of the tubal orifice, running vertically downwards inside the pharynx to insert into the posterior border of the thyroid cartilage. Its contraction, stimulated via the pharyngeal branch of the vagus, opens the tube.

The pharyngobasilar fascia, a rigid membrane connecting the superior constrictors to the skull base, with two 'paratubal' muscles arising either side of it. Levator palati arises medially (within the pharynx) and tensor palati originates laterally (outside the pharynx). Collectively, they aid opening of the tube due to their attachment to its cartilaginous portion.

Endoscopic endonasal approaches to the central skull base gain access to the:

- frontal sinuses
- cribriform plate
- olfactory bulbs
- frontal lobe
- ethmoid roof
- sphenoid sinus
- pituitary gland
- suprasellar region
- cavernous sinuses
- mid-clival regions.

The latter are accessed trans-sphenoidally; the pair of sphenoid sinuses vary greatly in size, each side separated by a septum usually not in the midline. When small, the sinus lies in front of the pituitary fossa but, when large, may extend beneath the fossa posteriorly to the basiocciput. Tiny at birth, their main development is during puberty. Superior to the sinus lie the pituitary fossa and middle cranial fossa, laterally is found the cavernous sinus and internal carotid artery (ICA), and posteriorly the posterior cranial fossa and pons.

Traversing the superolateral wall of the sphenoid is the optic nerve in its canal on each side; laterally lie the internal carotid arteries and inferiorly the pterygoid canal with its nerve. Further detail of this region is covered in Volume 1, Chapter 87, Anatomy of the nose and paranasal sinuses.

POSTERIOR SKULL BASE

The posterior skull base forms the base of the posterior cranial fossa and is formed by the occipital bone. It houses the cerebellar hemispheres together with the pons and medulla oblongata, the latter of which extends through the foramen magnum, the largest foramen in the skull base and encased by the basilar part of the occipital bone (basiocciput). Either side of the anterior aspect of the foramen magnum are the convex occipital condyles which articulate, via hyaline cartilage, to the convex surface of the atlas, allowing a nodding motion and slight abduction only; rotation is achieved via the atlantoaxial joints. Behind each condyle is the shallow condylar fossa perforated by the condylar canal carrying an emissary vein from the sigmoid sinus to the suboccipital plexus. Above the occipital condyle is the hypoglossal canal carrying the XIIth cranial nerve, which emerges medial to the jugular foramen.

The foramen magnum is oval shaped with the fibrous dura mater attaching to its margins; below this, the latter projects down the spinal canal as the spinal dura mater (theca); above it sweeps up into the posterior cranial fossa. Passing through the foramen, within the dural sheath in the subarachnoid space, lie the lower medulla with the cervical roots of the spinal accessory nerves, the spinal arteries and veins and the vertebral arteries.

A number of ligaments arising from the axis attach to the anterior margin of the foramen magnum: the membrana tectorial, the vertical limb of the cruciform ligament, together with the apical and pair of alar ligaments of the odontoid peg. The anterior and posterior atlantooccipital membranes attach to their corresponding edges of the foramen magnum.

The basiocciput extends forward from the foramen magnum to fuse with the basisphenoid. Along its midline, one third of the way from the foramen magnum to the posterior edge of the nasal septum, lies the pharyngeal tubercle, marking the midline attachment of the pharyngobasilar fascia and the highest fibres of the superior constrictor. Anterior to the tubercle, the bone forms the roof of the nasopharynx. Posterior to it attach the uppermost prevertebral muscles, longus capitis in front of rectus capitis anterior. Separating the nasopharynx from the prevertebral region is the pharyngobasilar fascia, with the prevertebral fascia just behind it.

Posterior to the foramen magnum and hence the basiocciput, the squamous part of occipital bone continues up to fuse along the lambdoid suture with the parietal bones superiorly and mastoid regions of the temporal bones laterally. Externally, a midline crest, the external occipital crest, extends from the foramen magnum up to a projection of bone around 6cm below the lambda, the external occipital protuberance. This crest separates the two sides of the occipital area. Either side of the external occipital protuberance, a concentric ridge of bone extends around to the mastoid process - the superior nuchal line - providing the surface landmark for the attachment of the tentorium cerebelli the transverse sinus (**Figure 98.1**). Sternocleidomastoid attaches to the lateral half of this line, trapezius to the medial half.

The muscles of the back of the neck are attached below this line. Each half of the occipital area is further subdivided by another concentric line – the inferior nuchal line – thus dividing this area into four. The two areas adjacent to the foramen magnum receive the rectus muscles, acting to extend and rotate the head, generally innervated by C1. The two areas between the nuchal lines receive semispinalis medially and superior oblique muscles laterally, giving lateral flexion to the head and also innervated by C1.

Surgical approaches via the occipital bone and posterior skull base include the retrosigmoid and lesser used suboccipital approach to cerebellopontine angle tumours, together with access to:

- occipital bone
- sigmoid sinus
- posterior cranial fossa
- foramen magnum
- upper cervical spine.

LATERAL SKULL BASE

The lateral skull base covers the remaining base of the skull between the anterior and posterior regions described above. Most surgical approaches to this both this area and midline structures anterior to the foramen magnum are made from a lateral, antero- or anterolateral direction.

It is bordered anteriorly by the anterior border of the *sphenoid* body together with its greater wings, and the zygomatic arch; the posterior border is the occipital bone. Laterally it is made up of the squamous and petrous parts of the *temporal bone*. Various regions relate to the undersurface of the sphenoid and temporal bones, which will be expanded upon below.

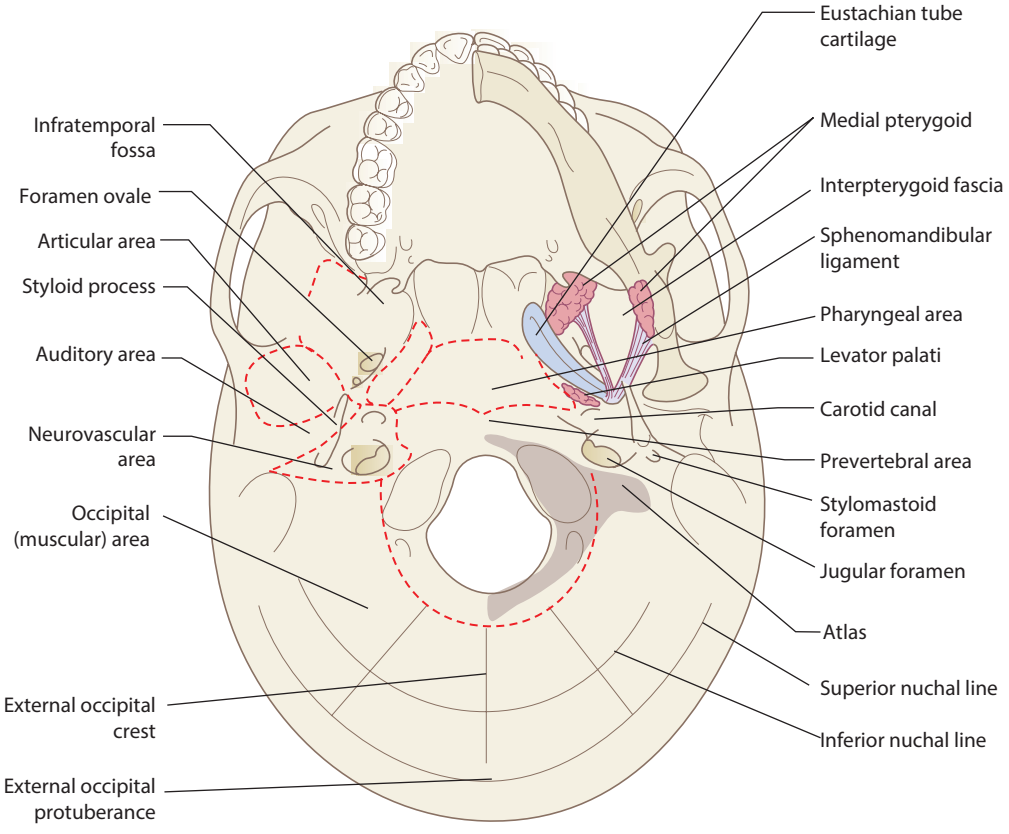

Figure 98.1 The skull base viewed from below. On the right half of the skull are indicated the regions of the central base.In the left half the mandible has been added in the occlusion, with the interpterygoid fascia and Eustachian tube in position. Redrawn from van Huijzen (1984), with permission of S. Karger.

Sphenoid bone

The anterior aspect of the lateral skull base is made up from the body, posterior border of the lesser wings, and the greater wings of the sphenoid superiorly, with the medial and lateral pterygoid plates inferiorly.

The central part of the sphenoid is the *body*, between the clinoid processes, its sloping inferior surface forming the roof of the postnasal space and containing the sphenoid sinus. Its superior surface is hollowed as the pituitary fossa, or sella turcica ('Turkish saddle'), itself roofed by a sheet of fibrous dura mater, the diaphragma sellae. This sheet is continuous laterally as the roof the cavernous sinus, this lying on and grooving each side of the sphenoid body.

Extending superolaterally from the body are the *lesser and greater wings* of the sphenoid, the former anterosuperior and the latter originating posteroinferior from the body, thereby encasing the obliquely slanting *superior orbital fissure*; the contents of this are the ophthalmic nerve and veins, together with the oculomotor, trochlear and abducent nerves.

Extending laterally, the greater wing articulates anteriorly with the frontal bone, laterally with the zygomatic bone and posteriorly with the petrous part of the temporal bone; it therefore forms part of the floor of the middle cranial fossa.

Medially, just in front of the petrous part of the temporal bone, the greater wing is perforated posteriorly by the small *foramen spinosum* (containing the middle meningeal vessels) and, anteromedial to this, by the much larger *foramen ovale* (transmitting the mandibular and lesser petrosal nerves). Occasionally, two smaller foramina also exist in proximity to the foramen ovale – the foramen of Vesalius medially and the innominate foramen posteriorly; anterior to the foramen ovale, the *foramen rotundum* extends forwards, transmitting the maxillary nerve to the pterygopalatine fossa.

Perforating through the base of the lesser wing is the *optic canal*, through which passes the optic nerve and ophthalmic artery.

Of note, the sharp posterior edge of the lesser wing of the sphenoid forms the posterior aspect of the anterior cranial fossa.

Dropping down, from the base of the greater wing of the sphenoid are the pterygoid plates. The *medial pterygoid plate* forms the posterior part of the lateral nasal cavity, articulating anteriorly with the vertical plate of the palatine bone. Inferiorly, it ends as the pterygoid hamulus, around which the tendon of tensor palati hooks. The cartilaginous Eustachian tube grooves the upper aspect of its posterior border, above which the border splits to pass posterolaterally to enclose the scaphoid fossa and give attachment to the tensor palati.

The *lateral pterygoid plate* extends backwards into the infratemporal fossa, giving attachments laterally to the lower head of the lateral pterygoid and medially to the deep head of the medial pterygoid; both involved in protruding the mandible and opening the mouth.

Temporal bone

The temporal bone consists of four parts, which each ossify independently and later fuse:

1. squamous
2. petromastoid
3. tympanic
4. styloid.

The *squamous* part is the largest, forming the convex lateral aspect of the temporal fossa. It articulates anteriorly with the greater wing of the sphenoid and posterosuperiorly with the parietal bone; where these three meet (together with the frontal bone) is an important landmark - the pterion, the weakest part of the skull under which passes the middle meningeal artery (MMA). A fracture here runs the risk of laceration of the MMA and thereby an extradural haematoma.

The *zygomatic* process of the temporal bone originates anteriorly, below which is the mandibular fossa housing the synovial temporomandibular joint. Behind this, the squamous part (together with part of the petrous bone) forms the anterior aspect of the external ear canal, the remainder formed by the curved c-shaped tympanic part of the temporal bone. Medially, the squamous part adjoins the petrous part which, together with the mastoid part (commonly collectively called the petromastoid), forms part of the medial bony external ear canal and thereon encases the middle and inner ear.

Anteriorly, the squamous part's inferior surface forms the posterolateral aspect of the infratemporal fossa, whilst on its lateral surface, the curved temporal line (suprameatal crest) delineates the lower aspect of the attachment of the temporalis fascia, limiting the origin of the temporalis muscle and, together with a small triangle of bone at the posterosuperior aspect of the external auditory meatus, the suprameatal (Macewen's) triangle, are important superficial landmarks for cortical mastoidectomy.

The petrous part is full adult size at birth. However, the *mastoid* process is absent, leaving the stylomastoid foramen near the lateral surface of the skull, covered only by thin fibres of sternocleidomastoid (SCM); the extracranial facial nerve is therefore very superficial and vulnerable in neonates. As the SCM grows, it draws down and thereby develops the mastoid tip, palpable in the second year of life, thereby protecting the emerging facial nerve on its medial surface. This mastoid process is filled to a varying degree by air cells, the *sigmoid sinus* deeply grooving its inner surface, itself receiving the superior petrosal sinus at its upper end, the latter draining part of the cavernous sinus. The deep surface of the mastoid is grooved by the digastric ridge for the origin of the posterior belly of the digastric muscle; just medial to this, the *facial nerve* exits the skull base through the stylomastoid foramen, the styloid process lying just anteromedial to this. Medial to the digastric notch, the occipital groove indents the mastoid bone along the temporo-occipital suture, in which lies the occipital artery.

Angled forwards and medially at 45 degrees, the anterior aspect, the apex, of the pyramidal shaped *petrous* part joins the clivus medially and greater wing of sphenoid anterolaterally; its tip forms the posterolateral boundary of the ragged-shaped foramen lacerum, the latter closed in life by dense fibrous tissue.

The superior surface of the petrous temporal bone contributes to part of the floor of the middle cranial fossa, a sharp ridge along its posterosuperior aspect, angled at 45 degrees, separating this from its near vertical posterior surface which borders the anterior aspect of the posterior cranial fossa. Several important landmarks can be found on this superior surface. Most laterally, just medial to its articulation with the squamous part of the temporal bone, the petrous part forms the roof of the epitympanum, the tegmen tympani. Running along the posterior aspect of the petrous ridge is found the groove for the superior petrosal sinus. Between the two, posteromedial to the tegmen tympani, a curved prominence - the arcuate eminence - is made by the underlying superior semicircular canal. Just anteromedial to this is found the hiatus and groove for the greater petrosal nerve, passing obliquely to the foramen lacerum; the groove for the lesser petrosal nerve lies just anterolateral to this en route to the foramen ovale. Towards the anteromedial aspect of the superior surface, the trigeminal impression houses the trigeminal ganglion.

The posterior aspect of the petrous bone is perforated by the internal auditory meatus (IAM), through which pass the VII and VIII cranial nerves, together with the superior and inferior vestibular nerves and the labyrinthine artery, an internal auditory branch of the basilar artery. Just behind the IAM, a small slit leads to the aquæductus vestibuli containing the endolymphatic duct.

Inferiorly, medial to the base of the styloid process, the petrous bone is hollowed to form the jugular fossa, itself the lateral aspect of the jugular foramen. Divided into three compartments by two transverse septa of fibrous dura, this transmits the jugular vein in the posterior compartment; the middle compartment is shared by the vagus nerve (X) and cranial root of the accessory (XI); the glossopharyngeal (IX) and inferior petrosal sinus occupy the anterior compartment.

Above this, the jugular bulb is the point at which the sigmoid sinus feeds into the upper end of the internal jugular vein. It usually lies inferior to the posterior part of the floor of the middle ear, divided from it by a thin bony covering that may be dehiscent, leaving only mucosa to separate it from the middle ear cavity. However, its position is extremely variable and it may intrude right up into the middle ear ('high jugular bulb').

The ICA enters the skull base through the carotid canal just anterior to the jugular foramen, separated from it by a wedge of bone; erosion of this 'keel' of bone is an early finding in patients with a glomus jugulare tumour. It traverses the petrous apex at an oblique direction, passing anteriorly, superiorly and medially. It gives off some small intrapetrous branches, including the caroticotympanic artery, which may enlarge as feeding vessels for a glomus tumour.

It emerges just lateral to the petrous apex to enter the cavernous sinus (see below). The carotid sheath in the neck will be discussed below in 'Inferior skull base'.

Superolateral to the emerging carotid artery at the apex, the bony Eustachian tube connects to its cartilaginous portion, itself lodged between the greater wing of sphenoid and the petrous apex (see **Figure 98.1**). It is in reverse proportions to the external auditory canal: the lateral third (around 1 cm long) is bony within the petrous bone, originating from the anterior mesotympanum (middle ear); the medial two-thirds is cartilagenous. This transition from bone to cartilage – the isthmus – marks the Eustachian tube's narrowest point. Angled forwards, inferiorly and medially at around 30 degrees and 45 degrees respectively, the cartilaginous portion grooves the posterior border of the medial pterygoid plate before opening into the nasopharynx, as described above.

Posteromedial to the traversing carotid artery, within the dense 'otic capsule' of the petrous temporal bone, are the inner ear structures, practically full adult size at birth.

Housed within an osseous labyrinth, the membranous labyrinth contains endolymph, running throughout the inner ear structures; surrounding this membrane labyrinth is perilymph, which does not communicate with the endolymph. The most anterior structure of the osseous labyrinth is the cochlea, behind which lies the vestibule followed by the semicircular canals, in that order; the parts of the membranous labyrinth, in the same order from front to back, are the cochlear duct, saccule and utricle (within the vestible, concerned with vertical and horizontal movement detection respectively) and semicircular ducts (concerned with kinetic balance). The conical-shaped cochlea lies at an oblique angle; its base at the fundus of the internal acoustic meatus and its apex directed across the long axis of the petrous bone, pointing anterolaterally towards the middle ear. It curls two and three-quarter turns around the central modiolus containing the spiral ganglion.

Detailed anatomy of the middle and inner ear can be found in the Chapters 46, Anatomy and embryology of the external and middle ear and 47, Anatomy of the cochlear and vestibular system: Relating ultrastructure to function. However, brief mention of the innervation will be made here. The tympanic branch of the IXth nerve (Jacobson's nerve) leaves the glossopharyngeal nerve at the petrous ganglion and passes through a canaliculus in the keel of petrous bone between the jugular and carotid foramina to supply the middle ear (tympanic plexus).

The auricular branch of the Xth nerve (Arnold's nerve) passes behind the internal jugular vein and enters the mastoid canaliculus on the lateral wall of the jugular foramen, from which it emerges by way of the tympanomastoid fissure to supply the skin of part of the external auditory meatus.

The *tympanic* part of the temporal bone lies lateral to the petrous bone, its lateral border ending at the cartilagenous part of the external auditory canal. The posterosuperior surface is concave, forming the anterior, floor and part of the posterior wall of the bony ear canal. Where each extent of the c-shaped bone attaches, a suture line forms along the ear canal – anteriorly the tympanosquamous

and posteriorly the tympanomastoid sutures; the skin is particularly adherent along these. The inferior aspect of the tympanomastoid suture line is an important operative landmark for identifying the facial nerve as it exits the stylomastoid foramen.

Medially, the tympanic part houses the tympanic sulcus, in which lies the fibrous annulus for attachment of the tympanic membrane.

Anteroinferiorly, the tympanic part makes up part of the posterior boundary of the mandibular fossa.

Arising from the inferior aspect of the fusion of the tympanic and petrous bones, the *styloid* part of the temporal bone projects downwards and forwards, giving attachment to several ligaments and muscles bearing its name.

Three muscles attach to the styloid process, each having a different nerve supply but all involved in swallowing:

- stylopharyngeus
- stylohyoid
- styloglossus.

The stylopharyngeus arises from the medial aspect of the base of the styloid process and slopes down across the lateral aspect of the ICA before passing between the superior and middle pharyngeal constrictors alongside the pharynx, inserting into the posterior border of the thyroid cartilage. It is both innervated and traversed by the glossopharyngeal (IX) nerve, the sensory part crossing over the muscle to reach the tongue; its action is elevation of the pharynx and larynx.

The stylohyoid arises from the posterolateral aspect of the base of the styloid process, passing anterolaterally to the posterior belly of digastric with which it shares its innervation from the facial nerve (VII). It inserts onto the greater cornu of the hyoid, its attachment here perforated by the intermediate tendon of digastric, to give retraction to the hyoid.

The styloglossus is the shortest of the three, arising from the anterolateral aspect of the styloid process, passing downward and forwards between the internal and external carotid arteries to insert into the side of the tongue, innervated by the hypoglossal (XII) nerve, retracting the tongue.

The external carotid artery is intimately related to these muscles above. Running deep to the stylohyoid (and hence the posterior belly of digastric, it lies superficial to the stylopharyngeus and the styloglossus en route to the parotid gland. Conversely, the retromandibular vein runs superficially to all elements of the styloid apparatus.

Facial nerve

The VIIth cranial nerve emerges from the brainstem, between the pons and olive. The nervus intermedius emerges between the pons and inferior cerebellar peduncle. Joining the main facial nerve in its cisternal segment, it traverses the cerebellopontine angle to enter the porus of the IAM, together with the VIIIth cranial nerve, as mentioned above. Lying anterosuperiorly in the IAM, it is above the cochlear nerve, the superior and inferior vestibular nerves being posteriorly located. At the lateral extent of the IAM, the facial nerve passes through its narrowest portion via the labyrinthine segment, between the cochlea and vestibule. It exits this segment to form the geniculate ganglion before turning backwards at its first genu. Here, it gives off the greater superficial petrosal nerve which runs in its groove along the floor of the middle cranial fossa between two layers of dura mater; intra-operative traction on this nerve can result in a facial palsy secondary to haemorrhage or oedema.

From the first genu, VII runs in its horizontal tympanic segment in the medial wall of the middle ear, passing above the promontory. It curves over the oval window niche before reaching the second genu, just inferior to the lateral semicircular canal, at which point it curves downwards into its vertical mastoid segment behind the external auditory canal. The nerve to Stapedius branches off here, reaching the muscle via a tiny canaliculus. Just before it exits the skull base, VII gives off the fibres of the nervus intermedius as the chords tympani, thereafter passing through the stylomastoid foramen as a purely motor nerve.

The extracranial facial nerve gives off the posterior auricular nerve (supplying the occipital belly of occipitofrontalis) and a muscular branch (supplying the posterior belly of the digastric and stylohyoid), before swinging forward to enter the parotid gland and dividing into its upper and lower branches. Further divisions in the parotid result in the five branches supplying motor innervation to the muscles of facial expression.

NOTABLE REGIONS OF THE SKULL BASE

Cavernous sinus

The *cavernous sinus* extends from the apex of the orbit back to the apex of the petrous temporal bone, its medial and inferior walls being deep grooves into the body and base of the greater wing of the sphenoid respectively. The medial, upper and lateral walls are made up of a fold of the inner layer of dura, medially continuous with the diaphragma sellae; posterolaterally, the wall is medial to the anterior parts of the trigeminal (*Meckel's*) cave, itself containing the trigeminal ganglion.

Containing cranial nerves III, IV and V (ophthalmic and maxillary branches) embedded within its lateral wall and, inferolaterally, VI, the sinus' main content is the ICA as it emerges from the petrous apex through the superior aspect of the irregular foramen lacerum and projects upwards, forwards and medially to the anterior clinoid process, a small posterior extension of the lesser wing. Here, just posterior to the optic canals, the ICA perforates the dura mater to enter the middle cranial fossa, immediately dividing into its terminal branches.

Each sinus also receives blood from the orbit and cerebral hemispheres, and each drains via the superior and

inferior petrosal sinuses to the sigmoid sinus and internal jugular vein respectively.

INFRATEMPORAL FOSSA

As the greater wing articulates with the squamous temporal bone, just in front of the articular eminence, it forms the medial roof of the *infratemporal fossa*, a space beneath the skull between the pharynx and the ramus of the mandible. Anteriorly, this infratemporal surface ends in the inferior orbital fissure behind the maxilla, transmitting the maxillary nerve. Laterally, the superior extent of the fossa is the space deep to the zygomatic arch, its lateral extent limited by the ramus of the mandible. The medial pterygoid muscle, together with the interpterygoid fascia, mark the medial border. The posterior boundary is the styloid process, with the carotid sheath behind. It has no anatomical floor, being continuous down into the neck.

The contents include the deep lobe of the parotid, the lateral and medial pterygoid muscles, the insertion of the temporalis muscle into the coronoid process, the maxillary artery and its branches, the mandibular nerve and otic ganglion, chorda tympani, the pterygoid venous plexus and maxillary veins.

Lateral pterygoid muscle

This muscle arises from two heads: the upper from the infratemporal surface of the greater wing of the sphenoid, the lower from the lateral surface of the lateral pterygoid plate. Passing backwards, these two heads converge forming a tendon that inserts into the front of the neck of the mandible. Supplied by the mandibular division of the Vth nerve, it acts to open the mouth by pulling the condyle forwards, down the articular eminence.

Medial pterygoid muscle

Also arising from two heads, the larger of these arises from the deep (medial) surface of the lateral pterygoid plate; a small slip joins from the tuberosity of the maxilla and the pyramidal process of the maxilla, initially passing over the inferior free edge of the lateral pterygoid. Angled laterally, posteriorly and inferiorly, it inserts into the angle of the mandible (Figure 98.2), acting to close the mouth and move the mandible towards the opposite side in chewing. It is innervated by the mandibular nerve.

Maxillary artery

A terminal branch of the external carotid artery, the maxillary artery enters the infratemporal fossa as the other terminal branch, the superficial temporal artery, passes laterally up behind the temporomandibular joint (see Figure 98.3.) Passing deep to the neck of the mandible, between this and the sphenomandibular ligament, it runs a variable course around the lateral pterygoid muscle medially towards the pterygomaxillary fissure and hence into the pterygopalatine fossa.

Traditionally, the artery is described in three parts in relation to the lateral pterygoid muscle. Proximal, on and distal to this; five branches come from each part.

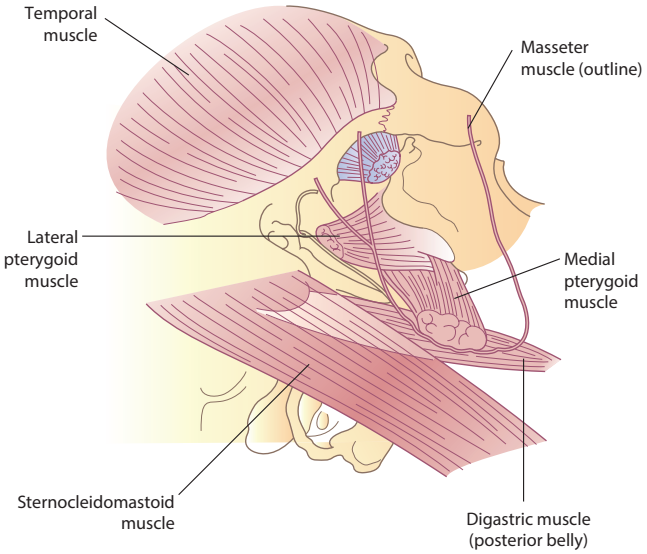

Figure 98.2 The superficial muscles of the central skull base. Redrawn from Goldenberg (1984), with permission.

The first part of the maxillary artery gives off the:

- inferior alveolar artery
- middle meningeal artery
- accessory meningeal artery
- deep auricular artery
- anterior tympanic artery.

The inferior alveolar artery passes down to join the inferior alveolar nerve and enter the mandibular foramen. The MMA passes straight up through the foramen spinosum, while the accessory meningeal artery passes through the foramen ovale. The deep auricular artery passes up to supply the external auditory canal and the anterior tympanic artery enters the petrotympanic fissure on its way to the middle ear.

The second part of the maxillary artery gives off five branches to the soft tissues:

- lateral and medial pterygoid muscles
- temporalis muscle
- lingual and long buccal nerves.

The third part of the artery divides in the pterygopalatine fossa, these five branches accompanying nerves including branches of the pterygopalatine ganglion, supplying the orbit, nose and palate. Of note, the *sphenopalatine artery* enters the nasal cavity through the sphenopalatine foramen to form the cavity's principal arterial supply. Endoscopic cautery or ligation of this artery is performed for persistent epistaxis; however, as mentioned previously, it rarely presents as one arterial trunk, as it divides in two or more (up to 10 branches) just after exiting the sphenopalatine foramen.

The pterygoid plexus and maxillary veins

The pterygoid plexus of veins lies within and on the lateral surface of the lateral pterygoid muscle, and receives tributaries corresponding to the branches of the maxillary artery.

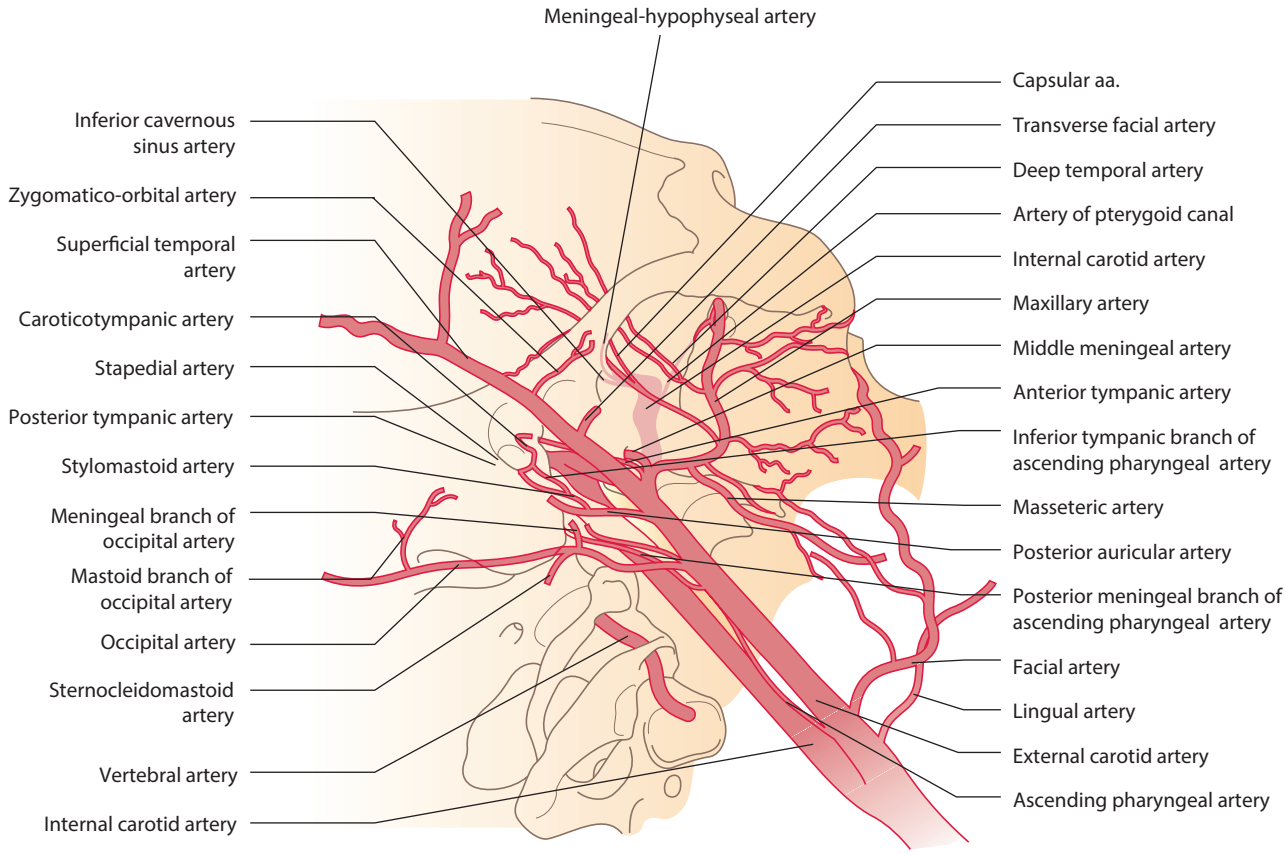

Figure 98.3 The arteries of the central skull base. Redrawn from Goldenberg (1984), with permission.

The plexus drains into two short, large maxillary veins which pass horizontally backwards deep to the neck of the mandible to join the superficial temporal vein and form the retromandibular vein (Figure 98.4).

The pterygoid plexus has three important communicating veins.

1. The inferior ophthalmic vein passes through the inferior orbital fissure to join the facial vein.
2. A connecting vein passes vertically down from the cavernous sinus via the foramen ovale or, when present, the foramen of Vesalius.
3. The deep facial vein runs forward beneath the zygoma to join the anterior facial vein.

These connections can allow infection from the face to spread by way of the pterygoid plexus to produce a cavernous sinus thrombosis.

The mandibular nerve

The mandibular nerve passes through the foramen ovale and, after a short course just deep to the upper head of the lateral pterygoid muscle, the main trunk divides into anterior and posterior divisions (Figure 98.5). Before it does so, the main trunk gives off the sensory nervus spinosus (which re-enters the middle fossa through the foramen spinosum) and the motor nerve to the medial pterygoid, which also supplies the tensor palati and tensor tympani.

The anterior division is motor except for the long buccal nerve. The latter passes between the heads of the lateral pterygoid to swing forwards and downwards on the deep surface of the temporalis muscle, and then pierces the buccinator to supply the mucous membrane of the cheek. The motor branches supply the temporalis, masseter (by a branch which emerges through the mandibular notch) and the lateral pterygoid.

The posterior division is sensory, except for the mylohyoid nerve. The auriculotemporal nerve springs from two roots, which pass either side of the MMA, and pass backwards between the sphenomandibular ligament and neck of the mandible. The inferior alveolar nerve swings downwards on the surface of the medial pterygoid muscle, passes between the sphenomandibular ligament and neck of the mandible, and gives off the mylohyoid nerve before entering the mandibular foramen. The lingual nerve is joined by the chorda tympani 2 cm below the base of the skull and passes downwards and forwards on the medial pterygoid, grooving the mandible before entering the mouth.

The otic ganglion lies close to the mandibular nerve just below the foramen ovale, between the nerve and the tensor palati muscle. It relays secretomotor fibres for the parotid gland, which it receives by way of the lesser superficial petrosal nerve and transmits to the auriculotemporal nerve. The lesser superficial petrosal nerve leaves the middle fossa through the foramen ovale, or sometimes through its own foramen, the foramen innominatum.

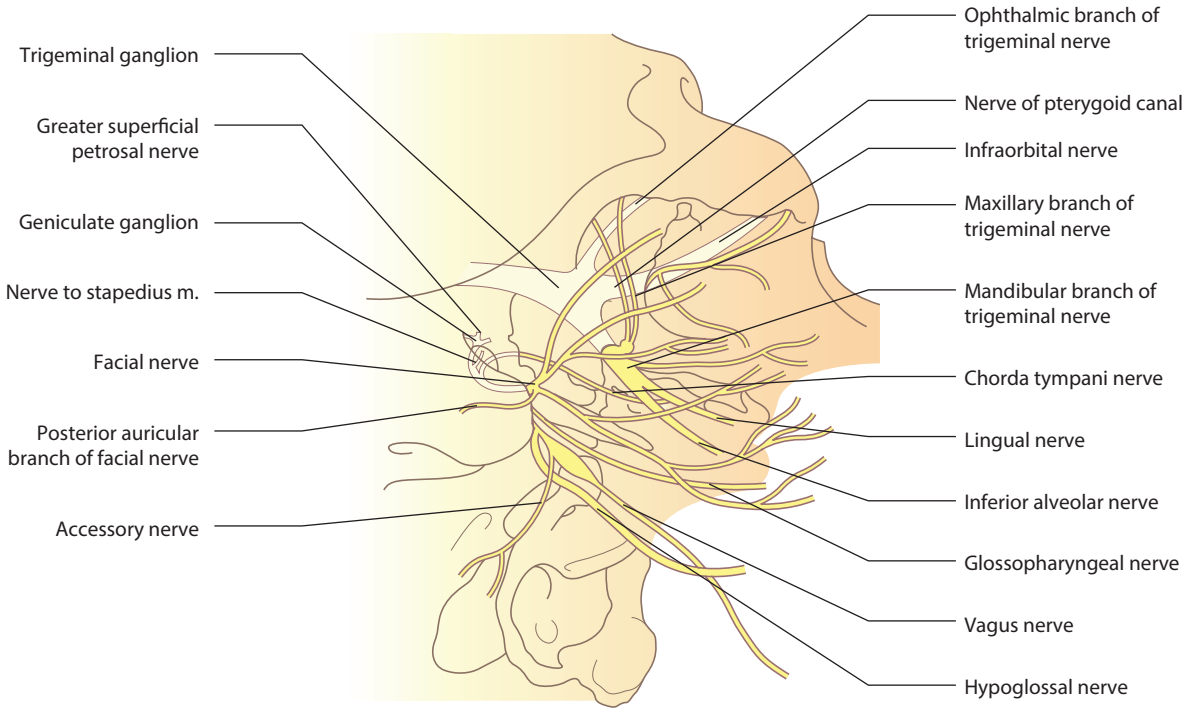

Figure 98.5 The nerves of the central skull base. Redrawn from Goldenberg (1984), with permission.

PTERYGOPALATINE FOSSA

A cone-shaped depression deep to the infratemporal fossa, posterior to the maxilla near the orbital apex, the small pterygopalatine fossa contains the terminal third of the maxillary artery, the maxillary nerve (V_2), the pterygopalatine ganglion just in front of the pterygoid canal (itself containing the Vivian nerve, a union of the greater and deep petrosal nerves, which then runs anteriorly to the sphenopalatine ganglion) and fat. Its roof is the body of the sphenoid and medially it abuts the

perpendicular plate of the palatine bone in the lateral nasal wall. It has several communications to other parts of the skull base, principally laterally via the pterygomaxillary fissure to the infratemporal fossa, medially via the sphenopalatine foramen to the nasal cavity and anteriorly via the inferior orbital fissure to the orbit; posteriorly, the pterygoid (Vidian) canal has been described, with the foramens rotundum and lacerum communicating to the middle cranial fossa.

MECKEL'S CAVE

As the trigeminal nerve leaves the pons in the posterior fossa, it runs forwards along the superior aspect of the petrous part of the temporal bone, grooving its surface. Passing under the superior petrosal sinus, an evagination of the tentorium cerebelli (inner layer of dura and the arachnoid) surrounds it to form the trigeminal cave of Meckel, lying in the trigeminal impression on the superior aspect of the petrous apex. Here lies the trigeminal ganglion, its posterior half therefore bathed in cerebrospinal fluid. The anterior half of the ganglion, together with the three divisions of the trigeminal nerve, lie in front of Meckel's cave, the dural and arachnoid layers having fused at the halfway point of the trigeminal ganglion. An extradural approach to the anterior half of the cave is therefore possible via the middle fossa.

The sphenomandibular ligament

The sphenomandibular ligament is a fibrous band joining the spine of the sphenoid to the lingula of the mandible. It is derived from the first branchial arch (Meckel's) cartilage. Anteriorly, it blends into the interpterygoid fascia, which separates the lateral and medial pterygoid muscles, stretching forward as a sheet to be attached to the posterior edge of the lateral pterygoid plate.

PAROTID SPACE

The space enclosed within the capsule of the parotid gland lies partly superficial to the mandible, and extends through the retromandibular space behind the infratemporal fossa to abut against the parapharyngeal space (Figures 98.6 and 98.7).

PARAPHARYNGEAL SPACE

The parapharyngeal space is described as having two compartments:

1. pre-styloid
2. retro- or post-styloid.

These compartments are separated anatomically by the styloid process of the temporal bone and its associated apparatus (see 'Temporal bone' above).

Pre-styloid compartment

This compartment contains the two palati muscles and two arteries, the ascending palatine and ascending pharyngeal (see Figures 98.8, 98.7 and 98.9 respectively).

The tensor palati muscle arises from the skull base between the pterygoid fossa and the spine of the sphenoid and is attached to the lateral side of the Eustachian tube. It tapers down to a tendon, which takes a right-angled

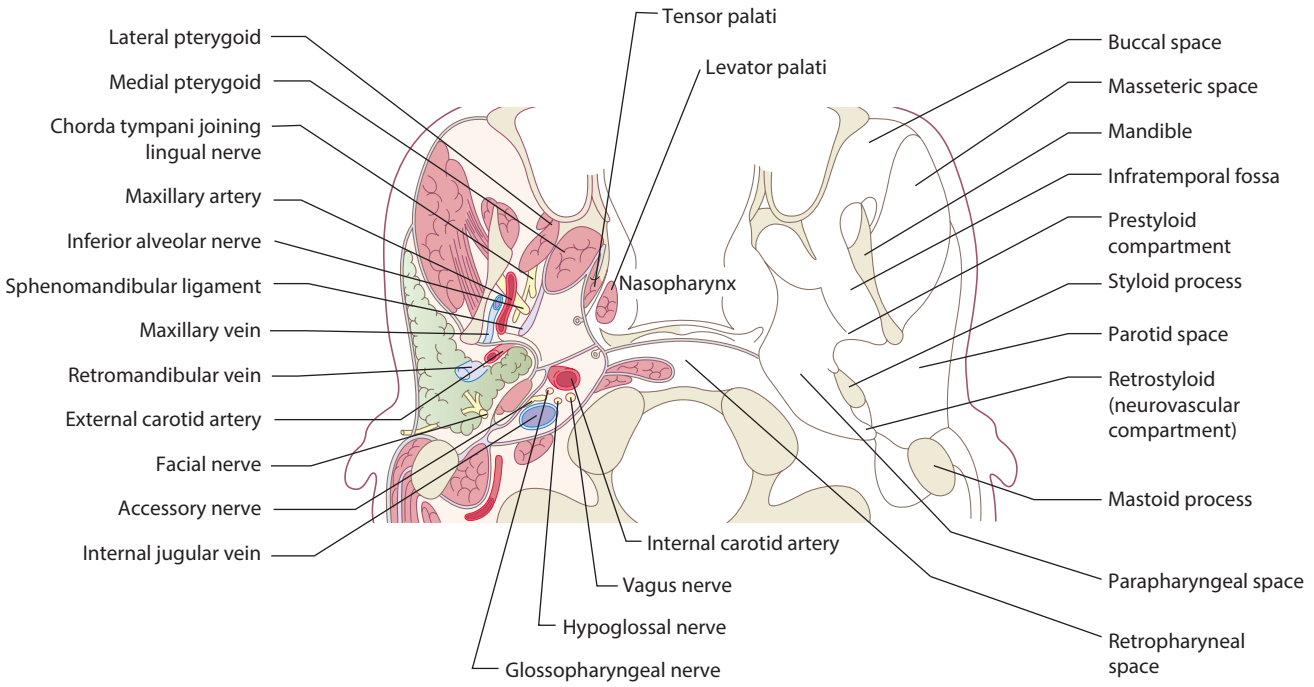

Figure 98.6 The central part of a horizontal section of the head passing through the foramen magnum, between the Eustachian tube and the palate. In the left half all relevant structures have been drawn; on the right, the different compartments are indicated as they appear at this level. Redrawn from van Huijzen (1984), with permission of S. Karger

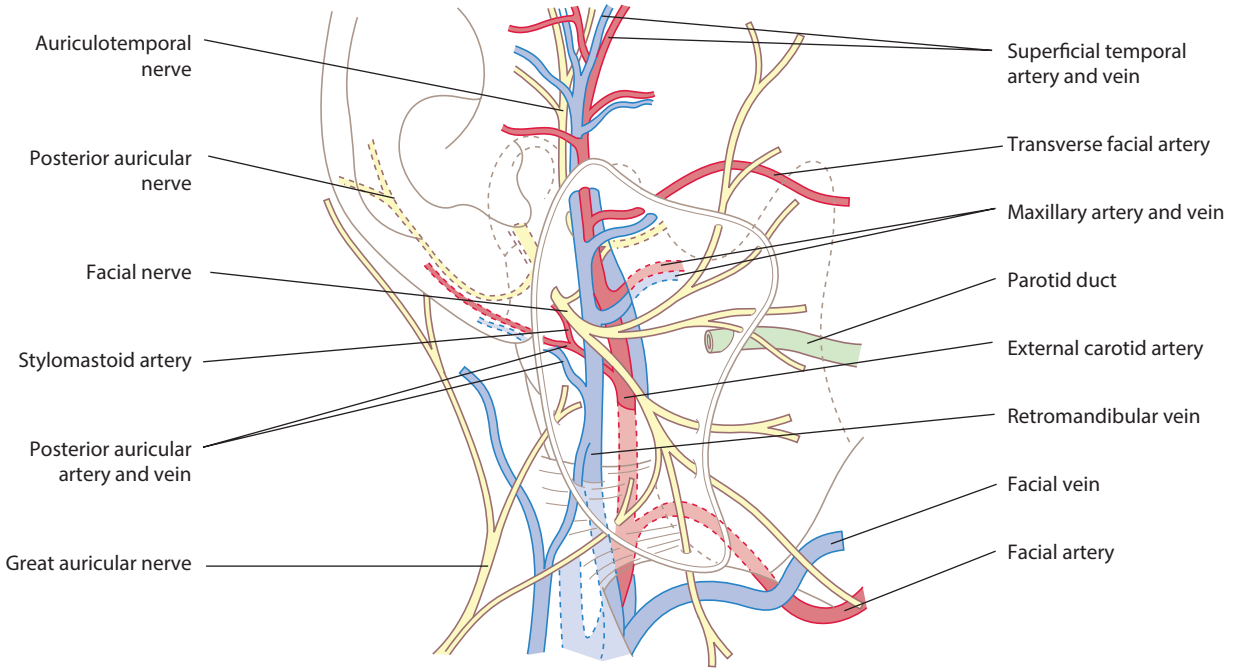

Figure 98.7 The structures of the parotid space, viewed from the lateral aspect. The parotid gland has been removed from its capsule, leaving the vessels and nerves intact. Redrawn from van Huijzen (1984), with permission of S. Karger.

turn around the hamulus to enter the pharynx, where it broadens into a flat aponeurosis; this triangular sheet blends with its counterparts on the opposite side and is attached to the posterior edge of the hard palate (the crest of the palatine bone). It is supplied by the nerve to the medial pterygoid, a branch of the trigeminal nerve. The action of this muscle is to tense the palate so that other muscles can raise and lower it.

The levator palatini muscle arises from the petrous apex anterolateral to the carotid foramen and from the

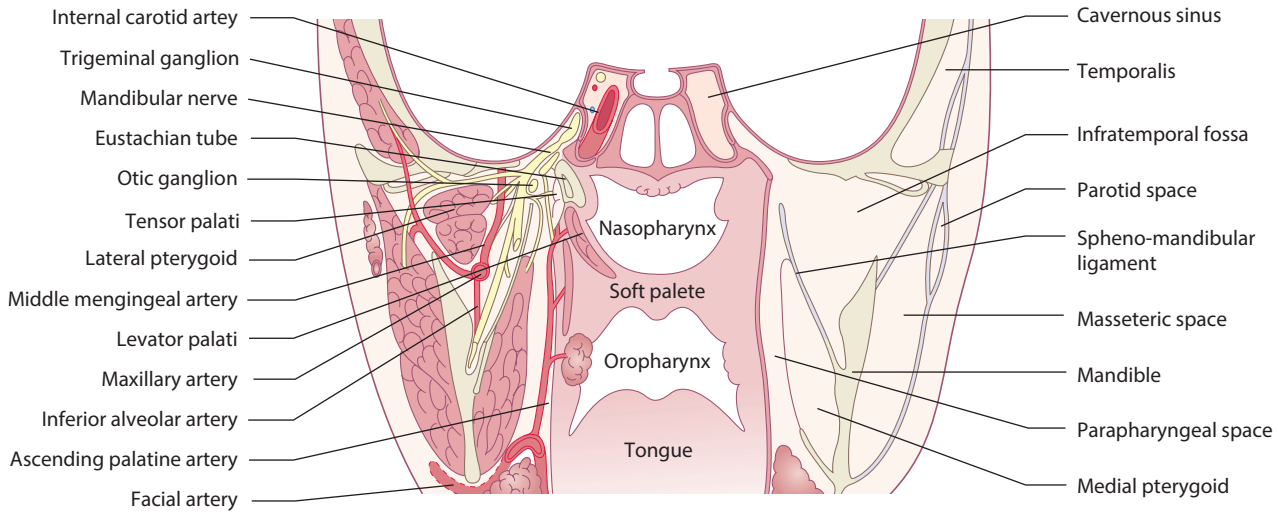

Figure 98.9 Coronal section of the head passing through the foramen ovale. On the left, all relevant structures are illustrated; on the right, the main compartments are shown. Redrawn from van Huijzen (1984), with permission of S. Karger.

medial end of the tubal cartilage and is inserted into the upper surface of the palatal aponeurosis. Supplied by the Xth nerve by way of the pharyngeal plexus, it acts to raise the soft palate and close off the nasopharynx.

The ascending palatine artery, a branch of the external carotid artery, ascends a little more posteriorly along the superior constrictor to supply the pharynx, the middle ear and the meninges. Often it is a major feeding vessel to a glomus tumour (see Figure 98.3).

Retrostyloid compartment

This corresponds to the neurovascular space and contains the carotid sheath.

INFERIOR SKULL BASE

Carotid sheath

The carotid sheath itself is not a membranous fascia, but a dense network of areolar tissue that surrounds the ICA and vagus nerve. It is virtually absent over the internal jugular vein, however, which is thus able to expand greatly during periods of increased blood flow. The carotid sheath is attached to the skull base around the carotid foramen and continues downwards as far as the aortic arch.

In the neck, the carotid sheath, together with the pretracheal fascia, is firmly attached anteriorly to the deep surface of the sternomastoid. Posteriorly, it is not attached to the prevertebral fascia, but is free to slide over it. This means that pus tracking laterally from a parapharyngeal abscess passes behind the sheath and behind the sternomastoid, to point in the posterior triangle.

The ICA passes vertically upwards from the carotid bifurcation in the neck to enter the carotid foramen (see Figure 98.3). It has no branches, but carries with it the carotid plexus of sympathetic nerves from the superior cervical ganglion.

The internal jugular vein descends from the jugular bulb to lie behind the ICA on the lateral mass of the atlas (see Figure 98.4). Just below the base of the skull, it receives the inferior petrosal sinus. As it descends, it passes across on to the lateral side of the ICA, receiving tributaries from the pharyngeal plexus of veins and is crossed on its lateral side by the accessory nerve. The deep cervical lymph nodes also lie on the lateral side of the vein.

The glossopharyngeal nerve (IX) lies lateral to the inferior petrosal sinus as it emerges from the anterior part of the jugular foramen (see Figure 98.5 and Figure 98.10). The nerve passes down on the lateral surface of the ICA and then gently curves forward around the lateral side of the stylopharyngeus, medial to the external carotid artery towards the tongue.

The vagus nerve (X) emerges from its superior ganglion in the middle compartment of the jugular foramen and runs straight down in the back of the carotid sheath between the carotid artery and jugular vein (see Figures 98.5 and 98.10). Just below the skull base, it is dilated into its inferior ganglion, where it receives a connection from the accessory nerve carrying fibres from the nucleus ambiguus.

The accessory nerve (XI) is just lateral to the vagus in the middle compartment of the jugular foramen and runs straight down in the back of the carotid sheath between the carotid artery and jugular vein (See **Figures 98.5** and **98.10**). It immediately begins to curve away posteriorly across the lateral surface of the internal jugular vein, medial to the styloid process and posterior belly of the digastric, giving a branch to the sternomastoid before piercing the muscle to gain the posterior triangle.

The hypoglossal nerve (XII) emerges from the anterior condylar foramen, medial to the carotid sheath and spirals in a lateral direction behind the vagus between the internal jugular vein and ICA (that is, through the carotid sheath) (see **Figures 98.5** and **98.10**). It then swings forwards lateral to the carotid arteries, deep to the styloid muscles and digastric, on its way to the tongue.

The cervical sympathetic trunk lies behind the carotid sheath in front of the prevertebral fascia, just medial to the vagus nerve. It ends superiorly at the superior cervical ganglion. The deep petrosal nerve arises from this ganglion and passes superiorly to join the greater superficial petrosal nerve to form the Vidian nerve.

MUSCLES SUPERFICIAL TO THE LATERAL SKULL BASE

Four muscles that lie lateral to the base of the skull are important in achieving surgical exposure of the area, namely:

1. masseter
2. temporalis
3. sternomastoid
4. digastric.

These are briefly described below (see also **Figure 98.2**).

The masseter muscle arises from the zygomatic arch and is inserted into a wide area on the lateral aspect of the mandible from the angle forwards along the lower border, and upwards over the lower part of the ascending ramus. It is supplied by the Vth nerve by way of the masseteric branch from the anterior division of the mandibular nerve and its action is to close the jaws.

The temporalis muscle arises from the temporal fossa on the side of the skull and from this large origin it converges in the shape of a fan to be inserted into the coronoid process of the mandible. It acts to close the jaws and its posterior fibres also retract the mandible.

The sternomastoid muscle arises by two heads from the manubrium and the clavicle. It is inserted into a curved line extending from the tip of the mastoid process to the superior nuchal line of the occiput. It is supplied by the XI nerve and its main action is to protract the head (moving it forwards while keeping it vertical with a horizontal gaze).

The digastric muscle arises from the digastric notch on the medial surface of the mastoid process. Two muscular bellies (anterior and posterior) separated by an intermediate tendon are described. The posterior belly narrows anteriorly into the intermediate tendon, which passes through a fibrous sling on the hyoid near the lesser cornu, and then expands into the anterior belly, which runs beneath the mylohyoid to its insertion into the digastric fossa on the lower edge of the mandible. The posterior belly is supplied by the VIIth nerve (nerve to digastric) and the anterior belly by the Vth nerve (mylohyoid nerve). Its action is to depress and retract the chin.

Surgical approaches to the following structures may be made via lateral skull base approach:

- middle ear, mastoid and associated structures
- sigmoid sinus and jugular bulb and uppermost part of the internal jugular vein
- middle cranial fossa
- parotid gland
- facial nerve
- inner ear, cochlear and vestibular nerves
- petrous apex
- infratemporal fossa
- carotid artery
- IX, X, XI and XII
- Eustachian tube
- clivus
- basiocciput
- basisphenoid
- nasopharynx.

KEY POINTS

- Intimate knowledge of the course of the facial nerve through the temporal bone and its relation to the lateral semicircular canal is essential for safe mastoid surgery.
- The relationship of the sigmoid sinus, jugular bulb, carotid artery and inner ear structures must be understood for extended mastoid exploration, such as towards the petrous apex.
- Identification of the bulbar nerves and their relationship to the carotid sheath and jugular foramen prevent morbidity in paraganglioma surgery.
- Detailed understanding of the course of the carotid arteries and optic nerves in the lateral walls of the sphenoid sinus are essential in extended endoscopic sinus surgery.

CHAPTER 99

EVALUATION OF THE SKULL BASE PATIENT

Jeyanthi Kulasegarah and Richard M. Irving

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: otalgia, CSF otorrhoea, hearing loss, pulsatile tinnitus, vestibular schwannoma, cerebellopontine angle and skull base, with the use of wildcards.

INTRODUCTION

This chapter aims to provide a simple framework for the assessment of patients with skull base lesions. It is difficult for it to be all embracing and therefore the more common conditions have been covered discussing typical symptoms, signs and investigations in such patients. In writing the chapter, the major difficulty has been that most of the literature deals with skull base lesions in terms of aetiology (e.g. studies of vestibular schwannomas (VS)) rather than the incidence of specific symptomatology (e.g. deafness). It has been necessary to focus on the few studies that have looked at clinical manifestations and collate these with findings from other studies. Due to the relatively low incidence of skull base lesions, most studies are of low impact (i.e. level 3 or 4 evidence).

The skull base has an intricate, three-dimensional conformation that is closely associated with and penetrated by numerous vital neurovascular structures. In order to understand the complexity and clinical manifestations of specific lesions it is extremely important to have a thorough understanding of the anatomy of the skull base. The skull base can be broadly sub-classified into three distinct areas: anterior skull base, central skull base and posterior skull base.[1] The anterior skull base is formed by the posterior wall of the frontal sinus (anterior border); lesser wing of the sphenoid bone and anterior clinoid processes (posterior border); cribriform plate of the ethmoid bone (midline) and nasal cavity, ethmoid sinus and orbits (inferior border); and orbital plates of the frontal bone (lateral border). The central skull base is mainly formed by the sphenoid bone and the temporal bone anterior to the petrous ridge.[2] The central skull base is further divided into midline sagittal, off-midline parasagittal, and lateral compartments.[2] The midline sagittal compartment includes the body of the sphenoid and the portion of the clivus anterior to the basisphenoid. The sella turcica is a depression in the superior surface of the body of sphenoid bone for the pituitary gland. The parasagittal compartment contains important components, which include carvernous sinus, superior orbital fissure, foramen rotundum, vidian canal and foramen lacerum. The carvernous sinus forms the superior and medial boundary of the parasagittal compartment while the parapharyngeal and masticator spaces are along the inferior aspect.[2] The sphenoid triangle, squamous part of temporal bone, and temporomandibular joint forms the lateral compartment of the central skull base. The posterior skull base is formed anteriorly by the posterior surface of the clivus, laterally is formed by the posterior surface of the petrous temporal bone superiorly and the condylar part of the occipital bone inferiorly. The mastoid temporal bone and the squamous occipital bone form the posterior portion of the posterior skull base.

The skull base is composed of a vast number of different tissues and cell types, and consequently can be affected by many different disease processes that include inflammation, trauma, benign and malignant neoplasia, and congenital abnormalities. The more common skull base lesions are shown in **Table 99.1**.

The symptoms produced by any skull base lesion are determined by its anatomical location. Anterior skull base disease may produce hyposmia, diplopia, blindness and

TABLE 99.1 The more common lesions found in different areas of the skull base

Anterior skull base	Central skull base	Posterior skull base
Mucocoeles	Pituitary adenoma	Vestibular schwannoma
Inverted papilloma	Craniopharyngioma	Meningioma
Juvenile angiofibroma	Cavernous sinus meningioma	Cholesteatoma
Olfactory neuroblastoma	Chordoma	Paraganglioma
Nasopharyngeal carcinoma	Chondrosarcoma	Squamous cell carcinoma
Lymphoma	Plasmacytoma	Schwannoma
Encepholocele	Encepholocele	Fibrous dysplasia
Meningioma	Meningioma	Metastasis
Schwannoma	Schwannoma	Endolymphatic sac tumours
Fibrous dysplasia	Fibrous dysplasia	
Metastasis	Metastases

frontal headaches. Central skull base lesions may cause facial numbness, in addition to headaches and diplopia. If the greater wing of the sphenoid is also involved, central and vertex headaches, loss of the corneal reflex and trismus can develop. In general terms, posterior skull base lesions usually produce deafness and tinnitus at an early stage, associated in some cases with vertigo and disequilibrium. Facial palsy is a characteristic, though typically late, feature of posterior skull base lesions. It can also cause neck stiffness, difficulty swallowing and hoarseness.

Different disease processes may produce different symptoms at the same location; for example, irritation or invasion of the dura by a neoplastic process is more likely to produce pain than benign lesions such as cysts. So, the nature of a lesion is important in determining the symptoms and signs that it may produce, as well as the site and extent of the lesion concerned.

EPIDEMIOLOGY

Posterior skull base lesion, in particular, cerebellopontine angle (CPA) tumours, predominate in any typical skull base practice and the literature reflects this with little epidemiological information available on other conditions. Within the CPA, VSs are the most common lesions and therefore the management of these tumours forms a major part of any skull base surgeon's work. In a series of 1354 CPA lesions, VS accounted for 91.3%, meningiomas 3.1%, epidermoids (cholesteatomas) 2.4%, facial nerve tumours 1.2% and other cranial nerve tumours 0.2%.[4] Less common lesions included intrinsic brain tumours, metastatic tumours, dermoids and lipomas. In another study of 305 CPA tumours, VS comprised 80%.[5] Smaller studies have shown much greater incidences of rare CPA tumours. Kartush et al.[6] reported two patients with rhabdomyosarcoma and one patient with a chondrosarcoma out of a total of 82 cases. Bozorg Grayeli et al.[7] reported 18 patients with paragangliomas and 18 other patients with malignant lesions that included 8 epidermoid carcinomas and 3 chondrosarcomas in a series of only 81 patients. Undoubtedly, the disease spectra reported in the smaller series were skewed by the effects of local factors and personal practices of individual clinicians.

The incidence of VS based on the Danish data has shown a steady increase of VS from 7.8 VS per 1 million population per year in 1976[8] to a peak of 123 VS per 1 million population per year in 2004. From 2004, the incidence seems to have plateaued to 19 per 1 million population per year in 2008 and may reflect the approximate true incidence of VS.[9]

SYMPTOMS OF SKULL BASE DISEASE

Hearing loss

The hearing loss can be conductive, sensorineural or mixed, depending on the precise site of the abnormality. For example, otitis media with effusion may develop as a result of Eustachian tube obstruction or compression by a tumour. Deafness caused by VS is usually of a high frequency sensorineural type and develops in 80–90% of patients,[10] but low frequency sensorineural loss (500 Hz) is characteristic of larger tumours.[10] In the modern era, due to the wide availability of magnetic resonance imaging (MRI) and the heightened awareness of these lesions, VS are generally detected at an early stage when unilateral sensorineural deafness is the only clinical manifestation. The typical history is that of a gradual hearing loss over the course of years, perhaps even decades, as these tumours grow very slowly. A survey of 580 VS patients found 84% of respondents had hearing loss worse in one ear. Of these, 64.8% had progressive hearing loss, 14.7% had sudden hearing loss, and 13% had both progressive and sudden hearing loss.[11]

Sudden sensorineural deafness has been reported as the presenting feature in 6.5–10.2% of patients.[12] The presumed aetiology maybe labyrinthine artery vascular occlusion, a rapid expansion of the tumour due to haemorrhage, oedema or cyst formation, or alterations in inner ear biochemistry.[13] Typically, 30% of VS that present with sudden hearing loss have caused total loss of function in that ear by the time they are diagnosed compared with only 16% of VS with progressive deafness.[14, 15] Patients who present with sudden hearing loss may have symptoms of an upper respiratory tract infection and sometimes also with vertigo. Labyrinthine function tests in these patients often show reduced or absent caloric responses. When other neurological symptoms and signs are present, the true diagnosis is often considerably delayed as clinicians are misled by the plethora of abnormalities. Similarly, the screening of patients with idiopathic sudden sensorineural deafness by MRI, has found a large number of VS. In one series of 295 patients with sudden onset sensorineural hearing loss, VS was found in 4% of patients.[16] In another

series, there were 10 cases (1.85%) of VS diagnosed in 542 cases of sudden onset sensorineural hearing loss.[17]

Almost 90% of skull base paragangliomas present with a conductive hearing loss.[18] A glomus tympanicum may present early with conductive deafness; whereas an advanced glomus jugulare may present with a mixed deafness when the middle and inner ears are both involved. Fifty to 80% of CPA meningiomas produce auditory symptoms, a much lower incidence than in VS.[19] When confronted with a CPA lesion in a patient with normal hearing, pathology other than a VS should be suspected.

Otorrhoea

Infected otorrhoea is such a common symptom that its presence does not immediately suggest serious underlying pathology unless persistently tinged with blood. For this reason, a temporal bone tumour may be overlooked in these cases and delay in diagnosis is common. Extensive temporal bone cholesteatomas and paragangliomas can present with otorrhoea and is reported in 61% of external auditory canal cancers.[20]

Cerebrospinal fluid (CSF) otorrhoea can be caused by bony erosion or insufficiency as a result of trauma, prior surgery, chronic ear infection, or destructive processes such as cholesteatoma or tumour, leading to temporal bone encephaloceles and/or CSF fistula. However, over the last two decades, there has been a significant increase in the number of spontaneous cases, where no discernible cause can be found. Several studies have demonstrated a strong link between obesity, empty sella syndrome and elevated intracranial pressure among these patients. In one series of 89 cases, nearly 40% of the cases occurred without antecedent trauma, chronic ear disease or surgery, and were considered spontaneous.[21] The mean delay between symptom onset and diagnosis was nearly 3 years, and over 10% of patients had symptoms over a decade,[21] as the majority of these patients present with persistent otorrhoea and hearing loss, mimicking chronic otitis media.

Tinnitus

Tinnitus may be either subjective (only audible to the patient) or objective (the clinician can hear the sound). Subjective tinnitus commonly occurs secondary to hearing loss. Less than 10% of tinnitus is due to pulsatile tinnitus,[22] also known as pulse synchronous tinnitus, which is produced by (i) a hypervascular tumour, for example a paraganglioma; (ii) compression of a major vessel by a tumour, for example a jugular foramen schwannoma; or (iii) an arteriovenous malformation or fistula. It is often possible to identify the cause of pulsatile tinnitus with careful examination and imaging, but in up to 30% of cases no cause is found.[23] **Table 99.2** lists the causes of pulsatile tinnitus. Unilateral subjective tinnitus may be the only presenting symptom of VS and warrants further investigation similar to unilateral or asymmetric sensorineural deafness. The incidence of tinnitus with VS can vary from 11% to 63%.[24, 25] Glomus tumours usually present with pulsatile tinnitus (50%) and deafness (30%), but they can occasionally cause otalgia (7%), a feeling of fullness within the ear (4%) and persistent otorrhoea (3%).[26]

TABLE 99.2 Causes of pulsatile tinnitus reported in the literature

Type of lesion	Aetiology
Arterial lesion	Extracranial arteriovenous malformation
	Dural arteriovenous fistulae
	Carotid cavernous fistulae
	Aneurysm of internal carotid artery or vertebral artery
	Fibromuscular dysplasia of internal carotid artery
	Dissection of internal carotid artery
	Atherosclerosis
	Vascular anomalies of ear (persistent stapedial artery, carotid-cochlear dehiscence)
	Vascular compression of VIIIth nerve
	Migraine
Venous lesions	Jugular bulb anomalies (high riding jugular bulb, enlarged jugular bulb, jugular bulb diverticulum)
	Abnormal condylar/mastoid emissary veins
	Diverticulum of sigmoid or transverse sinus
	Stenosis, stricture of segmentation of transverse sinus
Skull base, temporal lesions	Paragangliomas
	Temporal bone tumours (metastasis, basal meningiomas, haemangiomas, Heffner tumours)
	Labyrinthine fistula
	Meningocele/meningoencephalocele
	Otosclerosis
	Superior canal dehiscence
	Cholesterol granuloma
	Paget's disease
	Histiocytosis X
Miscellaneous	Anaemia
	High cardiac output
	Hyperthyroidism
	Benign intracranial hypertension

Data from Hofmann et al., 2013 and Callander, 1920.[22, 27]

Vertigo and dysequilibrium

True vertigo and dysequilibrium affect between 11% and 50% of patients with VS.[24, 25] The character of the vertigo or dysequilibrium produced by VS is extremely variable and tends to differ from those caused by more common vertigo-inducing syndromes in that nausea is absent in up to 63% and described as mild in 18%.[10] However, vertigo or dysequilibrium is the presenting symptom in 32% of intratemporal lesions.[7] A worryingly large number of patients with VS, as many as 10%, may be labelled as having Menière's disease because of the presence of sensorineural deafness, unilateral tinnitus, episodic vertigo

and pressure sensations within the ear.[14] In order to avoid diagnostic delay, all patients with such symptoms require further investigation in the form of MRI.

There have been a number of reports in the literature of patients with skull base and intracranial tumours who have presented with symptoms and signs of benign positional paroxysmal vertigo (BPPV) (e.g. meningiomas, VS, gliomas, lipomas and CPA cholesteatomas).[28] Non-benign positional vertigo should be suspected in patients with: (i) the presence of other signs or symptoms of neurological disorders (e.g. headaches, double vision); (ii) appearance of nystagmus without dizziness in positional testing; (iii) atypical nystagmus, especially downward-beating vertical nystagmus; (iv) poor response to therapeutic manoeuvres; and (v) recurrence of symptoms on at least three occasions.[29] It is therefore recommended that these patients should be investigated by MRI scan.

Tullio phenomenon is sound-induced episodic vertigo and dysequilibrium and has been associated with a number of conditions, including superior semicircular canal dehiscence (SSCD),[30] perilymph fistula[31] and middle ear osteoma.[32] In a series of 65 patients with SSCD, 60 patients had vestibular manifestations and Tullio phenomenon was noted in 90% of patients.[30] Oscillopsia is an unpleasant blurring and jumping of the external world during active and/or passive head movements. If oscillopsia is only present during head movement, the likely underlying cause is bilateral defect in the vestibulo-ocular-reflex (VOR). The more common causes are post-meningitic vestibular failure, gentamicin toxicity or bilateral idiopathic vestibular failure. If oscillopsia comes in brief attacks and is unrelated to head movements, it is usually due to irritative VIIIth nerve and brainstem lesions.[33]

Headache, otalgia and facial pain

The presence of localized cranial or facial pain and neurological symptoms should alert the clinician to the possibility of a skull base lesion. These symptoms may also suggest more advanced disease. Lesions with an intracranial, inflammatory component are more likely to cause intense headache (e.g. giant cholesterol cysts and tumours that obstruct sinuses). In one series of skull base lesions, the incidence of headache was 18%.[10]

Otalgia can be classified into otogenic otalgia, which originates from external, middle and inner ear, and referred otalgia, which arises from pathology outside the ear. Referred otalgia is associated with: (i) auriculotemporal nerve (cranial nerve V3); (ii) posterior auricular nerve (cranial nerve VII); (iii) Jacobson's nerve (cranial nerve IX); (iv) Arnold's nerve (cranial nerve X); (v) greater auricular nerve (C2); and (vi) lesser occipital nerve (C3). Severe otalgia is a cardinal symptom of intratemporal malignancy, particularly carcinoma of the external auditory canal or middle ear.[7]

Trigeminal schwannomas may present with facial pain that can be either episodic, like trigeminal neuralgia, or persistent. However, in a series of 120 trigeminal nerve lesions, the presenting symptom, in decreasing order of incidence, was facial hypoaesthesia or paraesthesia, weak mastication, tics and deafness.[34] More than 75% of these lesions also had other neurological symptoms, particularly other cranial nerve deficits, most notably diplopia caused by a lateral rectus muscle weakness. As many as 11% of VS may have an atypical presentation with other cranial nerve symptoms, pain over the mastoid or headache. On the whole, these tend to be larger tumours.[24] In a series of 55 large VS, over 50% of patients had trigeminal hypoaesthesia, while trigeminal neuralgia occurred in about 5% of patients.[35] Other tumours that may mimic trigeminal nerve tumour and present with facial pain include cavernous sinus meningioma, metastasis to skull base, haemangiopericytoma and chordomas spreading to the cavernous sinus.[36]

Ophthalmic symptoms

Diplopia on lateral gaze due to VIth nerve involvement is a characteristic feature of petrous apex pathology. At the tip of the petrous apex, the VIth nerve is within Dorello's canal, which makes it susceptible to various pathologic processes. Blurred vision can result from involvement of the optic tracts, raised intracranial pressure or lesions of the anterior skull base.

Facial palsy

Facial palsy is a very important presenting feature of intratemporal lesions and is established in 30% of patients before diagnosis.[7] The possible underlying pathologies include VS, meningioma, cholesteatoma, facial nerve tumours (schwannoma, haemangioma, neurofibroma), carcinomas (squamous cell carcinoma, adenoid cystic carcinoma) and paragangliomas. Facial nerve schwannoma is the most common neoplasm to cause facial nerve palsy, but it is responsible for less than 5% of all facial nerve palsies,[37] with geniculate ganglion involvement being the most common. Facial nerve haemangiomas, on the other hand, which were previously considered rare tumours, are now as frequent as facial schwannomas.[38] Clinically, haemangiomas present with facial nerve palsy and hemifacial spasm at an earlier stage than schwannomas.[39] Within the CPA, abnormal facial nerve function is found in 10–50% of patients with meningiomas, compared with less than 5% in patients with VS.[19] Among patients with jugular paragangliomas, facial nerve weakness or paralysis is present in 11–17% of patients.[40, 41] Glomus faciale are an exceedingly rare cause of facial nerve paralysis but should be considered in the differential diagnosis. Malignant involvement of the intratemporal portion of the facial nerve from head and neck malignancies may occur. The prognosis of patients with squamous cell carcinoma of the temporal bone who present with facial nerve paralysis is poor and comparable to that of T4 disease, leading to the modification of the University of Pittsburgh staging system in 2000.[42] Unexplained cases of facial palsy or those that fail to show any sign of recovery always require radiological investigation.

Lower cranial nerve symptoms

Jugular foramen tumours that extend medially and anteriorly can present with loss of bulbar function, hoarseness, dysphagia, dysarthria or shoulder weakness. They often cause these deficits long before the development of auditory or vestibular symptoms. Any isolated or combination of lower cranial nerve palsies should be investigated by imaging the skull base. The sequence of images must be extended to include the full length of the relevant nerve(s). Neuralgias of the lower cranial nerve include the uncommon glossopharyngeal neuralgia and the even more rare laryngeal nerve neuralgia. Glossopharyngeal neuralgia is characterized by attacks of excruciating unilateral pain of short duration of the ear, throat or neck. Pain can be triggered by swallowing, chewing, coughing, yawning or head movements and in about 10% of patients it is also associated with syncope due to reflex bradycardia.[43] There are seven reported cases of schwannoma of tympanic branch of glossopharyngeal nerve (Jacobson's nerve).[44]

RELEVANT MEDICAL HISTORY

The acquisition of a past medical history is essential for all patients. For those in whom a glomus tumour is suspected, symptoms or conditions that may be caused by catecholamine excess must be sought, for example, palpitations, labile hypertension, and so on. It is also important to ascertain the general fitness of the patient, with particular emphasis on their medical fitness to tolerate future management.

FAMILY HISTORY

Familial predisposition to some skull base tumours can happen in the hereditary cancer syndromes. Neurofibromatosis type 1 (plexiform neurofibroma), neurofibromatosis type 2 (VS and meningioma), paragangliomas and von Hippel–Lindau syndrome can all have implications for the patient's family. The genetic basis for these diseases is well established now and while some may arise as a result of spontaneous mutations, a large proportion do not.

EXAMINATION

Otoscopy

Otoscopy of both ears may provide valuable information regarding the underlying aetiology. Examination of the ear canal may demonstrate the presence of a mass or ulcer, indicative of a squamous cell carcinoma (SCC), the most common primary malignancy of the external auditory meatus. SCCs make up 82% of all ear canal cancers; others include basal cell carcinoma, adenoid cystic carcinoma, melanoma, adenocarcinoma, lymphoma and metastases.[10] Glomus jugulare tumours often infiltrate the floor of the external auditory canal and can be detected clinically as an area of hypervascularity and, sometimes, obvious, frank tumour.

A red pulsatile mass behind the tympanic membrane may be a glomus tympanicum tumour, but could also be a meningioma or adenoma. If arising from the hypotympanum with the classical appearance of the 'setting sun', a glomus jugulare tumour is the most likely diagnosis. Overall, paragangliomas are by far the most common tumours affecting the middle ear cleft and they can sometimes be made to blanch by pneumatic otoscopy. It is important to perform this examination with a microscope in order to enable the clinician to determine whether or not the tumour extends below the lower margin of the annulus. If it does not, the lesion is probably restricted to the middle ear or mastoid; if it does, significant skull base infiltration is possible and more detailed imaging is required.

Head and neck examination

In suspected malignant disease of the temporal bone, it is important to rule out a mass over the mastoid, squamous temporal bone, the parotid or the neck, as these may signify either direct spread or metastases.[17] Examination of the neck is also important in patients with glomus tumours to identify synchronous paragangliomas or detect direct extension of a large tumour into the neck (e.g. glomus jugulare or vagale). Auscultation should be carried out over the upper neck and mastoid and an audible bruit should be taken as being indicative of underlying pathology.

Neurological examination

A thorough neurological examination is essential as it may demonstrate subtle signs that are indicative of the underlying pathology and its probable extent. The minimum assessment must detail the function of the cranial nerves and the state of the optic discs, and test cerebellar function. A more complete examination, including the peripheral nervous system, may be indicated in some cases with extensive intracranial or coexistent spinal disease (e.g. NF1 and NF2). Similarly, the skin must be scrutinized for signs of freckling or pigmented patches in those suspected of having NF2.

The most useful screening tests for optic nerve disorders are visual acuity, visual fields, pupillary reflexes and fundoscopy. Fundoscopy may indicate the presence of incipient or established hydrocephalus. A careful examination of eye movements will reveal any involvement of the nerves supplying the extraocular muscles.

It is essential to appreciate that asymmetry of corneal sensation may be the only sign of trigeminal involvement. Reduced corneal reflexes, facial hypoaesthesia and weakness in the muscles of mastication are more obvious signs of trigeminal dysfunction. Trigeminal deficits can result from primary trigeminal lesions, petrous apex lesions, extensive infralabyrinthine lesions and CPA tumours. Facial hypoaesthesia is present in up to 4% of patients with skull base lesions[6] and loss of the corneal reflex is an important sign in patients with VS, indicating that the tumour may be more than 2 cm in diameter.

Facial weakness is present in up to 30% of all skull base lesions and clinicians should grade the degree of

weakness according to a recognized scale such as the House–Brackmann (HB) system.[18] The majority of skull base tumours do not present with a complete paresis but an asymmetry, particularly at rest. In fact, only 15% of patients present with a HB grade IV weakness or worse.[6] In VS, only about 7% of patients have abnormal facial nerve function at the time of presentation.[5] A diagnosis of VS in the presence of facial weakness should be made with caution.

Asymmetric palatal elevation or an abnormal gag reflex suggests IXth and Xth cranial nerve palsies. Laryngeal examination must be carried out to assess vocal cord function and laryngeal competence. The tongue should be examined for deviation on protrusion, wasting and fasciculation, all of which are signs of a XIIth nerve lesion. Palsies of the IXth, Xth, XIth and XIIth nerves are usually caused by infralabyrinthine disease, though occasional translabyrinthine lesions can involve the jugular foramen, its contents and the surrounding areas. Parapharyngeal tumours, particularly paragangliomas, may involve the sympathetic plexus around the internal carotid artery and cause a Horner syndrome (ptosis, meiosis, anhydrosis and enopthalmus). In a series of 36 patients with glomus tumours, 30 had deafness and tinnitus, 13 had facial weakness, 13 had dysphagia and hoarseness (IXth and Xth), 12 had shoulder weakness (XIth) and 14 had tongue weakness and fasciculation (XIIth).[45] Lower cranial nerve weakness with associated skull base lesions may occur in particular distributions giving rise to various syndromes, such as Horner syndrome, Collet-Sicard syndrome, Vernet syndrome or Villaret's syndrome (**Table 99.3**).[43]

TABLE 99.3 Syndromes of lower cranial nerves associated with skull base lesions

Syndrome	Definition	Aetiology
Collect-Sicard syndrome	Palsy of the IX, X, XI and XII cranial nerves	Glomus jugulare
		Skull base metastasis (breast, prostate, renal, lung)
		Hypoglossal schwannoma
		Neck fibrosarcoma
		Jugular foramen neuroma
		Skull base osteomyelitis
		Haemangiopericytoma of skull base
		Thrombosis of sigmoid-jugular complex
		Carotid artery dissection
		Head/C1 injury
Vernet syndrome	Palsy of the IX, X and XI cranial nerves	Osteolytic metastatis of petrous pyramid
		Skull base fracture
Villaret's syndrome	Palsy of the IX, X, XI, XII and ipsilateral Horner's syndrome	Paragangliomas
		Carotid artery dissection
		Skull base metastasis

Data from Finsterer and Grisold 2015.[43]

Vestibular examination

Spontaneous and induce nystagmus are common findings in neurotologic disorders. Examination of the eyes demonstrates spontaneous nystagmus in up to 46% of patients with VS.[10] The examination for induced nystagmus includes positional testing (Dix–Hallpike), head shaking and looking for either sound- or pressure-induced nystagmus (Fistula sign). Elimination of optic fixation by using Frenzel's glasses may improve the sensitivity of these tests. Balance and coordination can be tested in the clinic using a variety of tests. Romberg and Unterberger testing can indicate an uncompensated peripheral vestibular lesion. A positive Romberg's test can indicate abnormalities with the dorsal columns, whereas Unterberger's will induce turning towards a paretic and away from an irritative lesion of the labyrinth. Tandem gait may be instructive and any patient who can tandem walk backwards has excellent balance. Cerebellar testing includes coordination tasks, such as finger-nose-finger, heel-shin and rapid alternating motion and the patient is observed for dysmetria or dysrhythmia. The presence of limb dysmetria or dysdiadochokinesia is a useful indicator of cerebellar disease.

INVESTIGATIONS

Audiology

All patients with lateral skull base tumours should have an assessment of their hearing. Air- and bone-conduction pure-tone audiometry is the minimum requirement. The addition of speech audiometry to this protocol is preferable and mandatory whenever hearing preservation surgery is contemplated. It is worth noting that about half (49%) of all skull base patients have severe to profound deafness at the time of presentation and a third (33%) mild to moderate hearing loss.[7] Auditory brainstem responses (ABR) are no longer documented routinely. In the past it was used in a diagnostic role to determine which patients required more detailed investigation. MRI has now superseded that role.

Vestibular function tests

Caloric testing is by far the most common vestibular function test described in relation to skull base lesions and in particular with reference to VS. In general terms, they are non-specific and, like evoked response audiometry, cannot be utilized usefully in the diagnosis or screening for VS. Caloric asymmetry (>25%) may be present in up to 66% of patients with CPA tumours and this can further increase with tumour size.[10] Similarly, electronystagmography (ENG) and videonystagmography (VNG) can demonstrate abnormal function in up to 50% of all skull base lesions,[7] but these tests are seldom employed routinely.

Tests of facial function

Electroneurography (ENoG) has been used both pre- and post-operatively as a predictive test in patients with

skull base lesions. Kartush et al.[6] subjected a series of patients with tumours to ENoG and found that a significant reduction in response did not correlate with post-operative facial nerve function. However, in patients with VS, a correlation was found between pre-operative ENoG amplitude and tumour size. In other situations, a 20% or greater reduction in the amplitude of the pre-operative ENoG correlated well with facial nerve involvement by cholesteatoma or non-VS tumours.[6] Electromyography, maximal stimulation testing and electrogustometry have also been described and used to assess the degree of facial function prior to surgery, but have been shown to be of little clinical relevance.

Radiology

The advent of high resolution imaging modalities has totally revolutionized the investigation and management of patients with skull base lesions. There are four principal reasons for imaging: (i) screening; (ii) investigation of suspicious symptoms or signs; (iii) surgical planning and navigation; and (iv) for monitoring size, extent or recurrence of lesions.

The investigation and targeted screening tool of choice for VS is MRI. At first, gadolinium-enhanced MRI was employed, but this has now been superseded by fast spin echo T2-weighted images. Daniels et al.[46] reported the diagnostic outcome of screening 1070 patients with unilateral sensorineural deafness with MRI. From this group of patients they found 56 VS, 27 other CPA lesions, 29 inner ear lesions and 15 lesions affecting the brain parenchyma. Data from Iceland has shown that, about 10% of VS diagnosed were an incidental finding on imaging.[47] Diffusion-weighted imaging (DWI) can increase the conspicuity of skull base lesion and can be used to differentiate between malignant from benign lesions. DWI has also proven to be useful for identifying recurrent tumours, and differentiating these from post-treatment changes.[48] Non-echo-planar imaging DWI can be used to detect recurrent cholesteatoma and confers a positive predict value of 93 to 100%.[49, 50]

The purposes of imaging are not simply to confirm the presence of an abnormality but also to discern characteristics that might indicate the nature of the problem. Equally important are the assessment of size, relationship to other structures and detection of imminent complications, for example, hydrocephalus. In some conditions, NF2 being the best example, additional scans of the entire neuraxis are required to detect other tumours.

In several instances, both computed tomography (CT) and MRI are complementary and essential. There are a number of good examples to illustrate this point. In the assessment of facial nerve tumours, CT portrays the extent of bone destruction and gives an indication of the speed of the destructive process, while MRI can suggest whether the lesion is a schwannoma or an angioma. Similarly, the assessment of SCC of the temporal bone would be incomplete without both CT and MRI as the combination is highly predictive of the actual operative findings.[46]

MRI and CT are adequate for the evaluation of most patients with skull base lesions, but some may also require carotid and vertebral artery angiography as well. Presently, selective angiography can be undertaken by intra-arterial catheterization and injection with contrast into every feeding artery but, if far less detail is required, magnetic resonance angiography (MRA) gives considerable information in a non-invasive way. The assessment of patients with glomus tumours almost always needs a combination of CT, MRI and angiography. CT demonstrates the extent of temporal bone destruction. Gadolinium-enhanced MRI is exquisitely sensitive and will detect even very small glomus tympanicum tumours, while in larger parapharyngeal tumours flow voids give the characteristic 'salt and pepper ground' appearance that is so suggestive of paragangliomas. Subsequent carotid angiography then confirms the diagnosis, defines the blood supply and determines the integrity of the circle of Willis and potential for cross-flow should the carotid have to be sacrificed. It may also demonstrate the target vessels for pre-operative embolization to minimize intra-operative blood loss.

Cone-beam CT (CBCT) is being increasingly used in anterior and lateral skull base imaging. It is an advancement in CT imaging that provides relatively high isotropic spatial resolution of bony structures with a reduced radiation dose reported to be 60% of conventional CT scans.[51] CBCT provides much better images of the ossicular chain within the middle ear, and inner ear imaging is sufficient to diagnose most malformations and dysplasia, traumatic lesions, labyrinthine wall erosion or dehiscence.[52, 53] A low sensitivity to metallic artefacts makes it the imaging of choice in the follow up of cochlear implants. However, its lacks soft tissue contrast and therefore in cases of tumoral, septic or hematic soft tissue infiltration, HRCT and MRI are mandatory.

Positron emission tomography (PET) and single photon emission computerized tomography (SPECT) can be extremely helpful in certain circumstances where biopsy is difficult or potentially dangerous. PET is useful in identifying metabolically active tissues and can differentiate between post-therapeutic changes, for example, granulations and scars from recurrent and residual disease. By contrast, SPECT is 50% more effective at detecting skull base destruction than CT and also shows specific uptake in glomus tumours followed by rapid 'wash-out' of the radiotracer that suggests a benign vascular tumour.[22] This form of dynamic imaging is not possible with MRI. However, both PET and SPECT have limited resolution and can fail to detect small lesions.[23]

In some circumstances isotope scans can be helpful. The detection of multiple paragangliomas or metastatic disease has been facilitated by radionucleotide scintigraphy with metaiodobenzylguanidine (MIBG) or indium-11-octreotide.

General investigations

For the most part, other investigations are limited to those required to assess suitability or fitness for surgery. However, 24-hour urine collection for excreted catecholamines (vanillylmandelic acid (VMA)) is a wise precaution

in patients with paraganglioma, as it can detect a secreting tumour that could cause problems during surgery. The initial screening for paraganglioma should also include measurements of plasma-free metanephrines and urinary fractionated metanephrines.[54]

BEST CLINICAL PRACTICE

- ✓ The cornerstone of diagnosis remains imaging, which can provide an accurate 'tissue' diagnosis in many instances.
- ✓ Subsequent management, undertaken by a multidisciplinary team in a tertiary referral unit, depends on characteristics of the lesion (aetiology, site and extent) together with patient factors (age, general fitness, severity of symptoms).
- ✓ Management consists of simple surveillance, surgery and/or other therapeutic modalities, such as radiotherapy.

FUTURE RESEARCH

- ➤ Due to the rarity of skull base lesions, most of the literature is level 3–4 evidence. There is a place for larger, multicentre trials, in order to provide level 1 and 2 evidence for the investigation and management of these challenging conditions.

KEY POINTS

- Skull base lesions are infrequently encountered by general otorhinolaryngologists and require a high index of suspicion in order to avoid diagnostic delay.
- They may present with symptoms that could be mistaken for a more common otological pathology.

CHAPTER 100

VASCULAR ASSESSMENT AND MANAGEMENT

Joe J. Leyon, Kurdow Nader and Swarupsinh Chavda

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords: skull base surgery, embolization and interventional neuroradiology. The evidence is generally at level 3 or 4, with some animal studies at level 1 evidence. However, there is always the possibility that the results and conclusions drawn from these animal studies may not be reproducible in humans.

INTRODUCTION

The skull base is anatomically complex, particularly with respect to its blood supply. Many skull base tumours are either intrinsically hypervascular or secondarily involve the arteries and veins of the brain that enter and exit the cranium through the skull base. Angiography and interventional techniques have a pivotal role in the investigation and treatment of these conditions. Pre-operative embolization aims to devascularize hypervascular tumours selectively in order to improve intra-operative conditions while preserving blood supply to surrounding normal tissues. Permanent occlusion of the internal carotid artery (ICA) when possible enables the safe removal of those tumours that have an intimate relationship with the ICA.

It must be appreciated that angiography and intervention carry risks. The potential benefits that they offer must outweigh the risks of their possible complications. These risks differ from operator to operator and can be minimized by the combination of experience and detailed knowledge of relevant anatomy, pathology and procedural techniques. These techniques are certainly not for the occasional operator.

CATHETER ANGIOGRAPHY

Indications and technical considerations

Diagnostic angiography is an essential part of the pre-operative evaluation of skull base tumours, particularly if neurointerventional endovascular treatment is being considered. As well as evaluating the suitability of a tumour for embolization, it also provides the surgeon with information regarding the anatomy of the Circle of Willis and the likely tolerance to potential carotid sacrifice.

Primary assessment is made by computed tomography (CT) and magnetic resonance imaging (MRI) in order to determine the following features:

- exact tumour location
- relationship to surrounding bone, nerves, major blood vessels, brain and dura
- pattern of tumour extension
- degree of vascularity
- presence of intratumoural vessels (MRI)
- vascular territories involved by the tumour.

Diagnostic angiography and subsequent intervention can be performed in one session under general anaesthesia. Owing to the complex nature of these lesions, it is not uncommon to perform diagnostic angiography under local anaesthetic as a separate procedure prior to intervention. A size '4' French sheath and catheter is used and is introduced by the trans-femoral route. Subtraction images, fluoroscopy and a map of the vascular structures – the 'road map' – are acquired. The road map superimposes fluoroscopic images onto a previously acquired image of the vessels. This enables the guidewire and catheter to be imaged in relation to the vessels and facilitates safe navigation.

The angiographic protocol is tailored according to the vascular territory in which the tumour is located. At the very least, both ICAs and external carotid arteries (ECAs) are examined. Vertebral artery injection and selective ascending pharyngeal artery injection may be considered, the latter in view of its extensive supply to the skull base, temporal bone and dura. For any skull base tumour that is related topographically to a segment of the ICA, determination of the intracranial collateral circulation at the level of the Circle of Willis is absolutely mandatory. A comment is always made on the anatomy of the anterior and posterior communicating arteries, which may be best visualized by cross compression. This is achieved by compressing the carotid artery on the contralateral side to the vessel catheterized to visualize the anterior communicating artery, and compressing the ipsilateral carotid artery during a vertebral artery injection to visualize the posterior communicating artery. Temporary impediment to flow encourages flow of contrast across these communicating arteries.

A more detailed angiographic assessment is required for tumours in which embolization is being considered. This includes identification and characterization of all feeding pedicles, a search for collateral supply to the tumour, dangerous arterioarterial anatomoses or any arterial supply to cranial nerves, skin or pinna. In addition, it is also important to assess the vascular composition and angioarchitecture of the tumour as well as its venous drainage or any dural venous sinus involvement. Features of tumour angioarchitecture include compartmentalization, flow characteristics and arteriovenous shunts (**Figure 100.1**).[1]

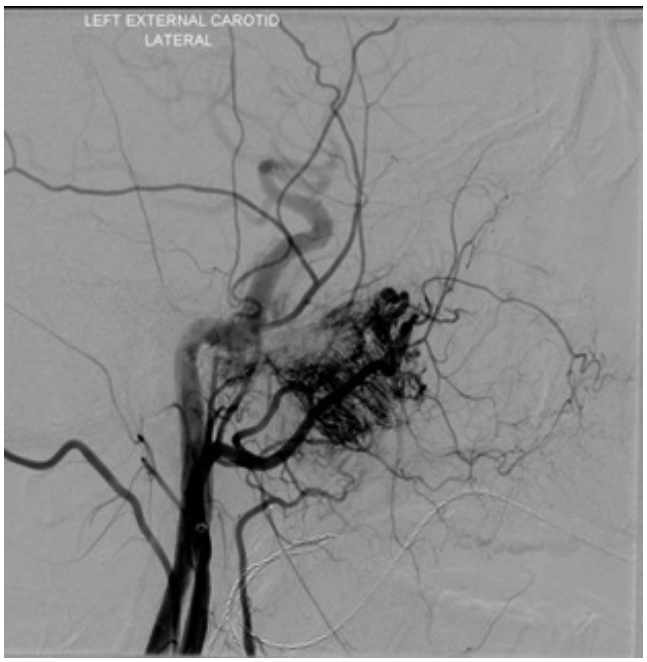

Figure 100.1 External carotid angiogram of an extensive glomus jugulare tumour; superselective angiogram of one compartment of the tumour demonstrating compartmentalization of arterial supply, typical of glomus tumours.

Risks

Carotid angiography carries a risk of permanent neurological deficit of less than 1%.[2] Other complications include arterial dissection, haematoma of the groin and reactions to contrast media that can range from a relatively minor itch to anaphylactic shock. The risk of contrast-induced nephropathy has been shown to be low even in patients undergoing emergency endovascular treatment for stroke.[3] Patients should be warned that it is normal to experience transitory unpleasant sensations or pain during the procedure, particularly following more selective catheterization and contrast injection of ECA branches.

INTERNAL CAROTID ARTERY TEST AND PERMANENT OCCLUSION

Tumours of the skull base may be intimately related to the ICA or may receive significant arterial supply from extradural ICA branches. These features can limit the surgeon's ability to obtain a complete resection. It is in precisely these cases that assessment of the cerebral circulation to tolerate permanent sacrifice of a major vessel is warranted. Given that this is a high-risk procedure, it should only be undertaken if occlusion is intended or likely.

The balloon test occlusion (BTO) is performed under local anaesthetic as this enables assessment of both motor and sensory function, speech and visual fields. Following femoral arterial puncture, a guiding catheter is placed in the ICA. The patient is fully heparinized. A soft micro-balloon is inserted through the guiding catheter into the ICA to the point of anticipated permanent occlusion and then inflated. The occlusion test lasts approximately 30 minutes, during which both clinical and angiographic evaluation is performed, the latter via a second catheter into the contralateral ICA via the contralateral femoral artery. Clinical tolerance of BTO would imply a reduced risk with parent vessel sacrifice, but does not eliminate the risk of stroke, which can happen due to haemodynamic and thromboembolic causes. When crossflow through the Circle of Willis is evaluated, any delay in transit of contrast medium on the side of the occlusion is also assessed. This is best achieved by comparing the appearance of the cerebral veins in the cerebral hemispheres. Adequacy of collateral blood flow can also be assessed by a number of methods such as transcranial Doppler ultrasound, single photon emission CT, xenon CT, pharmacologically induced hypotension, CT or MR perfusion techniques, measurement of arterial sump pressure, EEG and transcranial Doppler ultrasonography.[4, 5] A recently published study in 150 subjects utilizing BTO to assess adequacy of collateral circulation reported a stroke risk of 16% and TIA risk of 8% with parent vessel sacrifice; however, another smaller study in 31 patients reported no neurologic sequelae with parent vessel occlusion in patients who passed both BTO and single photon emission computed tomography (SPECT).[6, 7]

Permanent balloon occlusion of the ICA can be achieved by replacing the non-detachable balloon with a detachable balloon, which is positioned in precisely the same location as the temporary balloon. There are also other devices which can be used to occlude major vessels such as coils, Amplatzer vascular plug (AVP) and the microvascular plug. The AVP can be delivered through the guiding catheter to occlude vessels such as the common carotid artery, the ICA or the vertebral artery while the microvascular plug can be delivered through a microcatheter to occlude intradural vessels.[8, 9]

An external–internal carotid bypass should be considered for those patients who fail the test procedure yet need carotid occlusion. In this way the risk of stroke is reduced after permanent balloon occlusion.[10] In the event that there is doubt about the need to sacrifice the carotid, a balloon occlusion test should be performed prior to surgery and intra-operative permanent ICA occlusion can precede tumour resection if carotid involvement is found during the operation.[11]

EMBOLIZATION OF SKULL BASE TUMOURS

Indications

The main indication for pre-operative embolization of skull base tumours is to reduce intra-operative blood loss and improve visualization of the operative field during surgery. This may translate into shorter operative times and lead to a safer, easier and more successful surgical procedure. Embolization is rarely curative but improves the rate of radical tumour removal and reduces the surgical complication rate and the incidence of recurrence. Other indications for embolization include palliation of symptoms by inducing a reduction in size of the tumour and control of haemorrhage that has been caused by tumour erosion of a vessel wall.

The aim of tumour embolization is complete obliteration of the vascular bed within the tumour. Simply occluding the feeding arteries with emboli may result in the recruitment of a new collateral blood supply and make removal of the tumour even more difficult. Tumours with a rich vascular bed are most suitable, a feature that is usually indicated by the degree of contrast enhancement seen on CT or MRI. This is not always the case as increased contrast enhancement can be produced by accumulation in extravascular intercellular spaces. It does not necessarily indicate high vascularity but certainly cannot be ignored.

Skull base tumours that may benefit from pre-operative embolization include meningiomas, glomus tumours, chordomas, sarcomas, oestrogenic tumours, metastases, olfactory neuroblastomas and juvenile angiofibromas.

Catheters and embolic materials

Microcatheters enable superselective catheterization and embolization of individual feeding arteries and are generally less than 0.02 inches in diameter. Two basic types of microcatheter are used: flow-directed catheters and over-the-wire catheters. Flow-directed catheters take advantage of antegrade blood flow and are therefore more suitable for tumours that have high flow arteriovenous shunts, whereas over-the-wire catheters require the use of a guidewire and are employed in tumours with slower blood flows. While smaller microcatheters can access smaller vessels, their luminal diameter limits the size of the embolic agent that can be injected.[12] Embolic agents can be classified into mechanical agents, particulates and liquids.

Mechanical agents include coils and Gelfoam and are used in vessel occlusion proximal to the tumour. Gelfoam powder is derived from pork-skin gelatin. It is a pliable material that can be cut to appropriately sized particles and is used for more proximal vessel occlusion, often following embolization of distal vessels with particulate material.

Particulate agents achieve penetration into the tumour and can further be classified into non-spherical agents such as polyvinyl alcohol (PVA) particles and spherical particles such as Embosphere® and Embozene®. Spherical particles are the most widely used particulate embolic agents for embolization of skull base tumours and are available in a range of sizes from 40 µm to 1300 µm. Spherical particles offer more predictable embolic penetration compared to PVA.[13] Smaller particles have the ability to penetrate into vessels with a diameter of 40–60 µm. However, the use of particles with sizes in the 40–140 µm range, although more effective in inducing tumour necrosis, is also more likely to cause ischaemia of normal tissue.[14] Evidence also shows that they have a longer occlusive effect.[15–17] Particles smaller than 80 µm may risk cranial nerve palsy, likely due to occlusion of vasa nervorum, while angiographically non-visualized arterial anastomoses would be in the 50–80 µm size range. It is therefore recommended to use particles more than 150 µm.[18]

Liquid embolic agents include dehydrated alcohol, acrylate glues such as N-butyl-cyanoacrylate (NBCA), Onyx® Liquid Embolic System (ev3 Neurovascular, Irvine, CA) and Precipitating Hydrophobic Injectable Liquid (Microvention, Inc, CA). The main application of dehydrated alcohol is the percutaneous treatment of haemangiomatous malformations of the head and neck while other agents are used in embolization of cerebral arteriovenous malformations and dural fistulae. NBCA is also sometimes useful for embolization of tumours exhibiting rapid arteriovenous shunting, in which particles may pass directly though the tumour to the lungs. Liquid embolic agents can also be injected into the tumour upon direct puncture and have been suggested to decrease intra-operative blood loss.[19]

Technical considerations and complications

Embolization is preferably performed under general anaesthesia. This guarantees optimal working conditions by reducing unwanted patient movement, caused by pain,

and enabling haemodynamic monitoring. Local anaesthetic may be adequate for short, relatively painless procedures but requires a cooperative patient.

The vascular anatomy of the skull base is complex. It is important that the likely sources of arterial supply are considered thoroughly, together with any common anatomical variants and potential pathways of communication between the intra- and extracranial arteries, before embolization is attempted. As a general statement, any foramen, especially those carrying a cranial nerve, can be expected to contain a potential site of communication between these circulations. In addition, at each segmental level, residual metameric communications can be expected, particularly between the vertebral arteries and the ascending cervical, deep cervical, ascending pharyngeal and occipital arteries. Unless actively sought, these small vessels are easily overlooked, even on high-quality angiography. Even a small volume of embolic material in these vessels can lead to cranial nerve palsies or stroke. The operator should also be aware that in the course of embolization, as blood flow towards the target decreases, the direction of flow in collateral pathways may reverse and result in flow through extra- to intracranial anastomoses that were not evident on the initial angiogram. Repeated angiograms may have to be performed in the course of the procedure to exclude this possibility.

Other serious complications include blindness and skin necrosis. Blindness can usually be attributed to inadvertent injection of embolic material into the ophthalmic artery through anastomoses with the middle meningeal artery, other arterioarterial anastomoses or unrecognized variant origins. Skin necrosis is caused by embolic occlusion of cutaneous branches of the ECA. The pinna is particularly susceptible, and embolization in the anterior and posterior auricular arteries should be conducted with extreme care.

Three commonly treated tumour types – paragangliomas, juvenile nasopharyngeal angiofibromas and meningiomas – are now discussed in more detail.

PARAGANGLIOMAS

Angiography has several potential roles in the management of paragangliomas. They are:

- identification of the blood supply and flow dynamics to the tumour
- delineation of the venous drainage and demonstration of intraluminal tumour in the internal jugular vein
- assessment of the Circle of Willis for possible carotid occlusion
- detection of synchronous tumours.

Carotid occlusion should be considered when:

- imaging shows extensive destruction of the horizontal portion of the carotid canal (Fisch class C3)
- tumour is present within the foramen lacerum and cavernous sinus (Fisch class C4)
- there is the presence of large caroticotympanic and/or cavernous branches from the ICA.

A number of studies have shown that pre-operative embolization of paragangliomas provides significant benefit. Comparison of surgical data for embolized and non-embolized tumours indicates that pre-operative embolization of paragangliomas of 3 cm or more with PVA is safe, facilitates surgery and results in significantly reduced operative bleeding, shorter operative times and decreased surgical risk.[20–22] Liquid embolic agents such as Onyx or PHIL™ can also be used for transarterial embolization; they can also be injected with direct tumoural pucture.[23, 24] In a study comparing transarterial particulate embolization with direct puncture and percutaneous embolization of carotid body tumours with Onyx, a significant reduction in intra-operative blood loss was observed. Blood transfusion requirement, operative time, and complications were also less in the direct puncture group. Despite the evidence, it is not a universally accepted view and, ultimately, the decision whether to embolize depends on the location and extent of tumour as well as local practice and experience of the surgeon and interventional neuroradiologist.[25–29]

Knowledge of the angioarchitecture of these tumour types is required before embolization. The typical angiographic appearance is that of a tumour with enlarged feeding arteries, an early and intense, slightly inhomogeneous tumour blush, and early appearing draining veins. Histological studies have shown that there is a centripetally orientated system of intratumoural arterioles with a diameter of approximately 90 µm at the tumour periphery and of 300–600 µm in the centre. There are intratumoural arteriolo-arteriolar anastomoses as well as arteriolar-venous shunts.[30] This arrangement of vessels may prohibit the use of smaller particles due to the potential risk of distal migration of emboli into the systemic circulation. NBCA, a polymerizing glue, is indicated in certain cases. The majority of paragangliomas exhibit a multi-compartmental blood supply, with an arterial supply and venous drainage confined to a single area. Separate injections of embolic agent have to be made into each feeding artery to achieve complete transarterial embolization (**Figure 100.2**). Encapsulation of the tumour restricts recruitment of feeders from adjacent territories.[31]

All paragangliomas are supplied by branches of the ascending pharyngeal artery. Its inferior tympanic branch supplies glomus tympanicum tumours, the neuromeningeal branch supplies glomus jugulare tumours and the musculospinal branch supplies glomus vagale and carotid body tumours. The latter acquire an additional blood supply from the carotid body artery that arises directly from the carotid bifurcation. These tumours splay the ICA and ECA. Glomus vagale tumours, on the other hand, displace both ICA and ECA anteriorly and receive additional blood supply from muscular branches of the occipital artery. Contributions from meningeal arteries such as the mastoid artery, a meningeal branch of the occipital artery, indicate intracranial

Figure 100.2 Complete particle embolization of extensive glomus jugulare tumour. **(a)** Pre-embolization; **(b)** post-embolization.

extradural extension. Supply from the anterior inferior or posterior inferior cerebellar arteries indicates intradural spread, and in these cases the risk of posterior fossa stroke precludes embolization.

JUVENILE NASOPHARYNGEAL ANGIOFIBROMAS

Angiofibromas are non-encapsulated fibrovascular tumours that arise in the region of the sphenopalatine foramen. Although benign, they show an aggressive growth pattern and spread through foraminae or fissures. Their vascular components consist of endothelial-lined vascular spaces that are without muscular layers. As a result, these tumours tend to bleed profusely and patients may present with epistaxis.

Pre-operative embolization is an important tool for reducing intra-operative blood loss and is considered by many to be essential. Several retrospective studies, albeit small, have illustrated the effectiveness of pre-operative embolization of these tumours. Prior to the use of endovascular techniques, average intra-operative blood loss was reported to be approximately 2000 mL; this has now been reduced to less than 1000 mL by the routine use of embolization.[32, 33]

Angiographic assessment of juvenile angiofibromas prior to embolization aims to define the blood supply, vascular composition and venous drainage of the tumour as well as any dangerous anastomoses. The distal internal maxillary artery, together with its sphenopalatine and pterygovaginal branches, supplies the tumour at the site of origin in the anterior nasopharynx and posterior nasal cavity. Larger tumours that extend into the sphenoid sinus, infratemporal fossa or parapharyngeal space receive additional supply from further ECA branches, namely the accessory meningeal, ascending pharyngeal and ascending palatine arteries. Further supply from branches of the internal carotid and vertebral arteries are features of advanced tumours and, in some, there may be bilateral blood supply. Other angiographic features of these tumours include an early vascular blush that is intense but inhomogeneous and persists until the late venous phase. Once the feeding vessels have been identified, embolization of the tumour compartments can be performed. Permanent balloon occlusion of the ICA may be indicated in those rare tumours that extend into the cavernous sinus (**Figure 100.3**).[34, 35]

Direct percutaneous punctures may again be done in juvenile angiofibromas for embolization with Onyx prior to surgery. A study comparing transarterial embolization to direct percutaneous embolization with Onyx found significantly lower intra-operative blood loss and red blood cell transfusion requirements.[36]

MENINGIOMAS

Meningiomas are often hypervascular although this feature is somewhat dependent on histological subtype, the angioblastic and transitional types tending to be more vascular than fibroblastic or syncytial types (**Figure 100.4**). Psammomatous subtypes are sometimes almost avascular. Tumoural calcification is more common in histological subtypes associated with less vascularity.

There is usually a dual blood supply to meningiomas. A radial pattern of vessels derived from meningeal arteries penetrate the tumour from its base while an additional supply may be derived from its cerebral surface through pial cortical arteries arising from the ICA. The relative contribution of meningeal and pial arterial supply is variable, ranging from an exclusive meningeal supply to a dominant pial supply. Embolization is most effective when an exclusive meningeal supply is present.

The location of the meningioma determines its blood supply and may also be a good predictor of suitability for devascularization. Some of these tumours present to otolaryngologists or require their input for removal, for example frontobasal meningiomas that arise in the

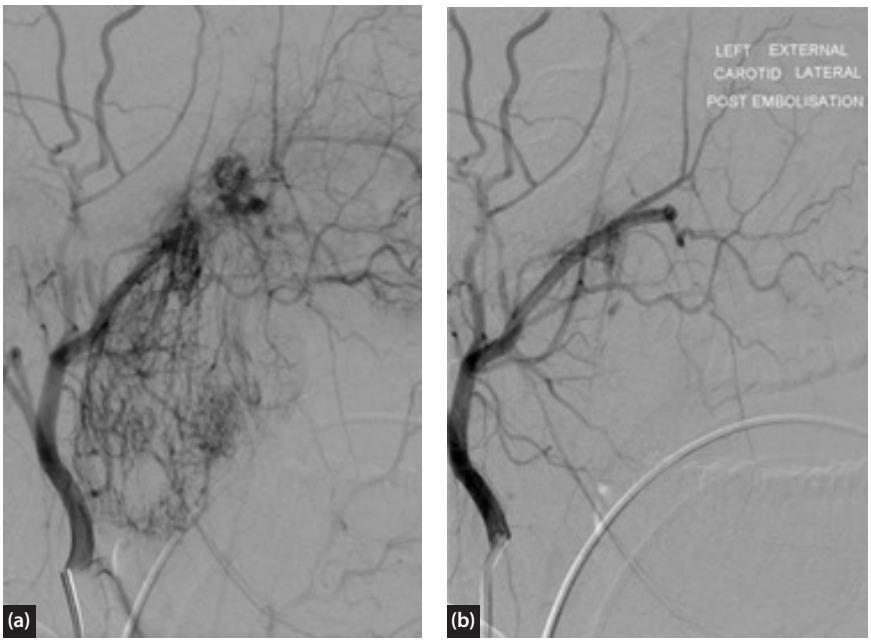

Figure 100.3 (a) Selective angiogram of angiofibroma; (b)post-embolization.

orbital roof, olfactory groove and planum sphenoidale. Orbital roof meningiomas are supplied by the anterior frontal meningeal artery, which arises from the recurrent meningeal branch of the second portion of the ophthalmic artery and from anterior branches of the middle meningeal artery. Meningiomas of the olfactory groove and of the planum sphenoidale receive their dural supply from the anterior and posterior ethmoidal arterial branches of the ophthalmic artery. The small size of these dural branches, the unfavourable vessel geometry and the dangers associated with the ophthalmic artery territory are all factors that limit the role of, although do not preclude, embolization of frontobasal meningiomas.

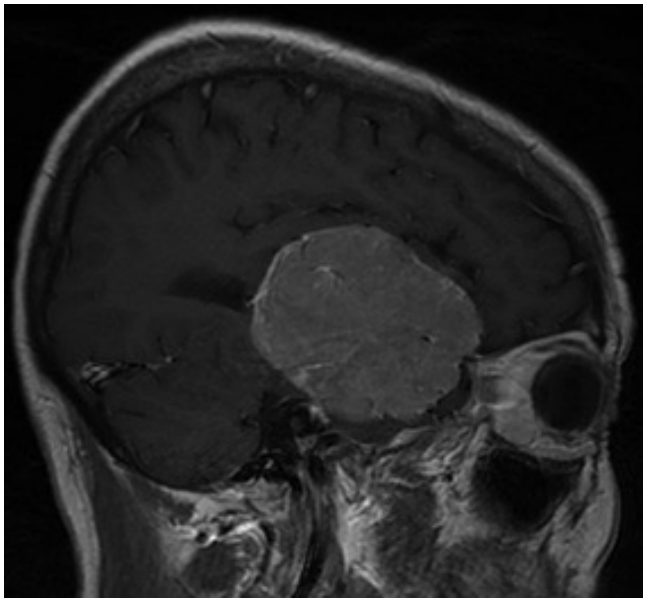

Figure 100.4 Post contrast T1 Sagittal image showing the large vascular skull base meningioma.

The efficacy of embolization can be assessed with gadolinium-enhanced MRI, which may show loss of flow signal void, decrease in contrast enhancement and new areas of non-enhancement indicating tumour necrosis.[37–39] The optimum timing of surgery following embolization is a matter of some debate. Some surgeons prefer to perform surgery within hours of embolization to avoid the effects of acute peritumoural oedema developing, while others prefer to let tumoural necrosis take place, a process that usually takes about four days.[40, 41] It is thought that corticosteroids given immediately before embolization limit tumour swelling.

Many studies have now reported the efficacy of embolization in meningiomas showing effective embolization, reduction in blood loss to tumour volume and improved surgical and functional outcomes (**Figure 100.5**).[42–49]

Complications

In addition to the technical complications already described, there have been reports of tumoural haemorrhage and hemiparesis secondary to tumour oedema.[45, 50] Risk factors include large tumour size and the presence of cysts. Vessel damage and subsequent arteriovenous shunting due to catheter and guidewire manipulation at a sharp bend of a feeding artery has also been reported.[51, 52] A review of 36 studies involving 459 patients reported two mortalities, once again highlighting that these procedures should only be done by experienced interventionalists.[53] It is worth nothing that reported complication rates in meningioma embolization have fallen from as high as 21% to 6% in the more recent literature.[54]

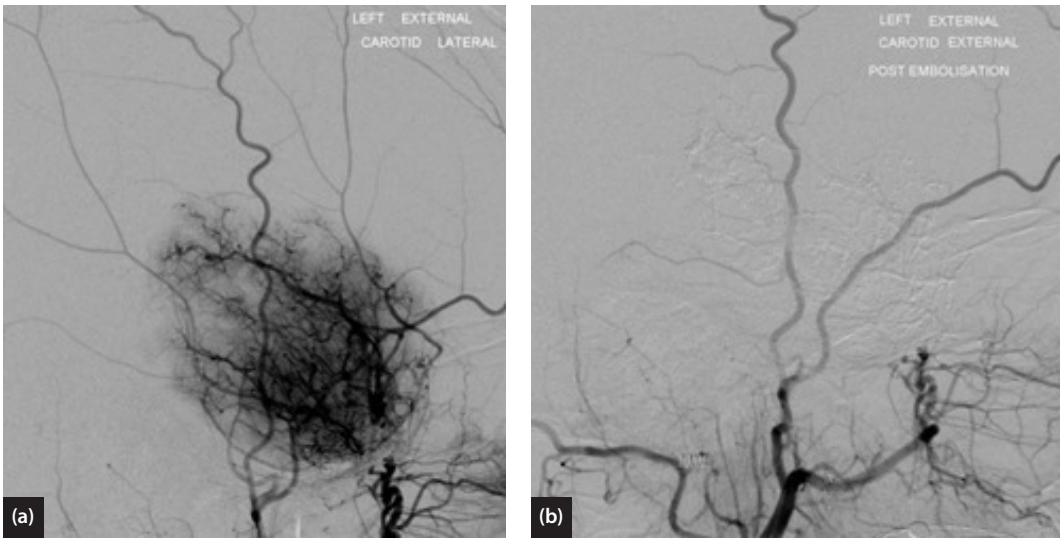

Figure 100.5 Complete particle embolization of extensive skull base meningioma. **(a)** Pre-embolization; **(b)** post-embolization.

BEST CLINICAL PRACTICE

- ✓ Angiography should be undertaken whenever a skull base tumour surrounds or is closely adherent to the ICA.
- ✓ Angiography is mandatory for vascular skull base tumours.
- ✓ Trial balloon occlusion or crossflow studies should be undertaken before any surgery in which the carotid artery might be lost.

KEY POINTS

- Both carotid angiography and embolization carry risks and the patient should be made aware of them.
- The angiographic protocol is tailored to the particular needs of the patient and their tumour type.
- Interventional techniques can make some tumours operable and decrease morbidity.

CHAPTER 101

NATURAL HISTORY OF VESTIBULAR SCHWANNOMAS

Mirko Tos†, Sven-Eric Stangerup and Per Caye-Thomasen

SEARCH STRATEGY

Data in this chapter may be updated by a prospective and continuous data collection of data from all patients in Denmark, diagnosed with a unilateral sporadic vestibular schwannoma since January 1976, and supported by a Medline search using the keywords: acoustic neurinoma and vestibular schwannoma (VS): anatomy, pathology, histopathology, epidemiology, incidence, growth and natural history.

INTRODUCTION

Unilateral vestibular schwannoma (VS) (**Figure 101.1**) is a benign tumour arising from abnormally proliferative schwann cells, which envelope the lateral portion of the vestibular nerve in the internal acoustic meatus. At a consensus conference[1] it was determined that the term 'acoustic neuroma', often used in the past to describe this entity, should be replaced by the more accurate term 'vestibular schwannoma'.

The aetiology of VS is not known. Recent advances in molecular biology indicate that a defect of chromosome 22q may be responsible for the development of both the unilateral sporadic VS and the bilateral VS in neurofibromatosis type 2.

Because the tumour develops in the nerve sheath, it compresses rather than invades the nerve on which it arose, thereby leaving a plane between the nerve fibres and the tumour. This feature facilitates dissection of the meatal portions of most tumours at surgery. As the VS grows, it gradually fills all the internal acoustic meatus (**Figure 101.2a, b**) and eventually protrudes out of the porus (**Figure 101.2c**).

Bone resorption is an active, slowly progressive process, caused presumably by increased vascularization, fibrosis and adhesions in the tumour area, where the pressure from the tumour, due to its growth, plays an important role. The degree of bone resorption of the internal acoustic meatus varies in VS. Some large and giant tumours have minor or modest bone resorption, some small- and medium-sized tumours have extensive resorption extending inferiorly as far as the cochlear aqueduct and superiorly to the middle fossa dura. Extra-meatal expansion of the tumour into the relatively large and empty pontine cistern initially develops silently (**Figure 101.3**). Growth and extension in this direction causes some displacement and stretching of the VIIth and VIIIth cranial nerves on the anterior aspect of the tumour and of the anterior inferior cerebellar artery (AICA) on the inferior aspect. Angioneogenesis is visible at surgery, with new small vessels running from the porus to the extrameatal portion of the tumour. After further growth, the tumour expands sufficiently to touch and compress the cerebellum and trigeminal nerve. During this process, the VIIth and VIIIth nerves are thinned or ribboned, become compressed and even more stretched. At the same time, the internal acoustic meatus continues to become more and more widened. Further growth and expansion causes compression and displacement of the brainstem and the fourth ventricle, which leads gradually to hydrocephalus.

CLASSIFICATION OF SIZE

Reporting the size of VS has always been a great problem. The main problem has been the inclusion and addition of the intrameatal element to the overall size of the tumour.

† deceased.

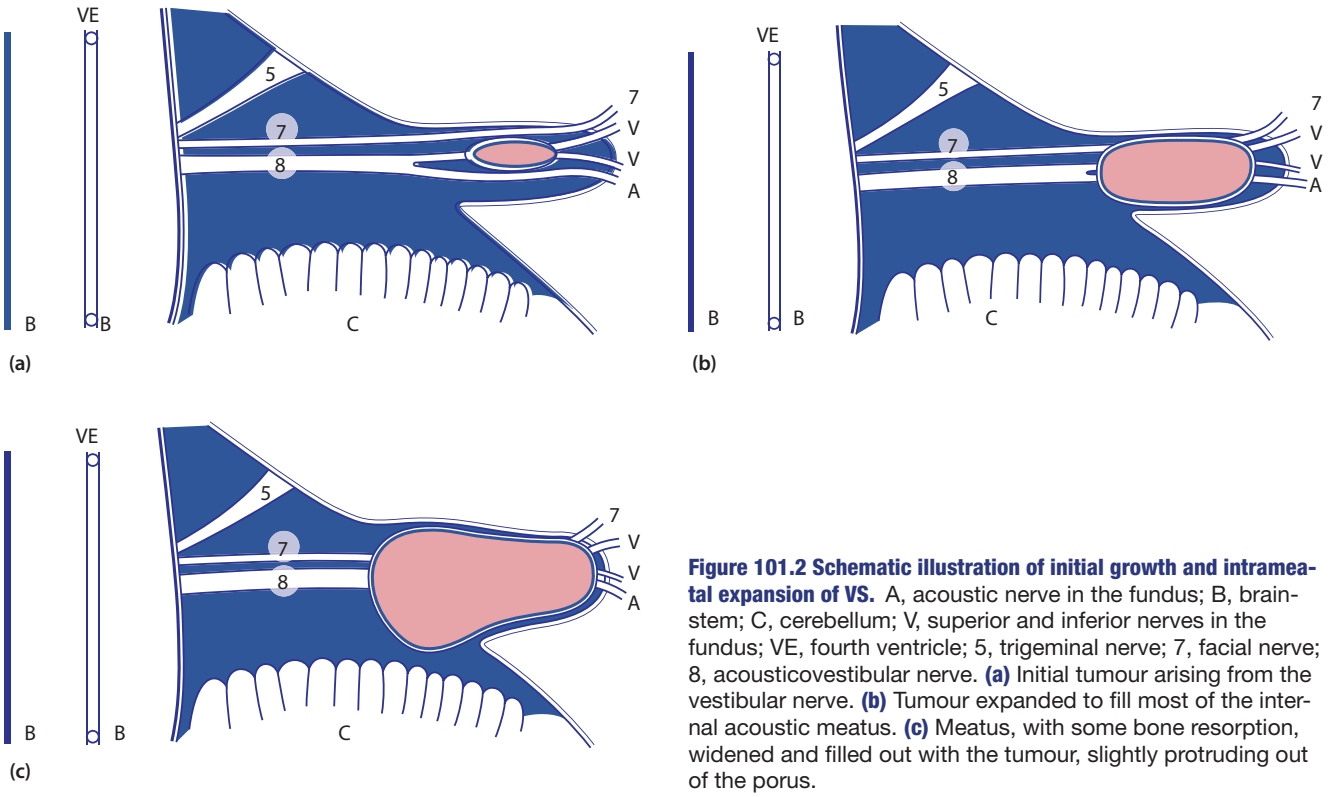

Figure 101.2 Schematic illustration of initial growth and intrameatal expansion of VS. A, acoustic nerve in the fundus; B, brainstem; C, cerebellum; V, superior and inferior nerves in the fundus; VE, fourth ventricle; 5, trigeminal nerve; 7, facial nerve; 8, acousticovestibular nerve. **(a)** Initial tumour arising from the vestibular nerve. **(b)** Tumour expanded to fill most of the internal acoustic meatus. **(c)** Meatus, with some bone resorption, widened and filled out with the tumour, slightly protruding out of the porus.

At the Consensus Meeting on Reporting Systems on Vestibular Schwannoma in 2003,[2] the classification scheme shown in Table 101.1 was proposed and recommended for adoption. It is based on the size of the largest extrameatal diameter and it was further recommended that a note should be made if the fundus is empty or filled by tumour and whether the VS is cystic. If the tumour is entirely within the meatus without any extension out of the porus, the term 'intrameatal' should be used. The extrameatal size of such a tumour is zero.

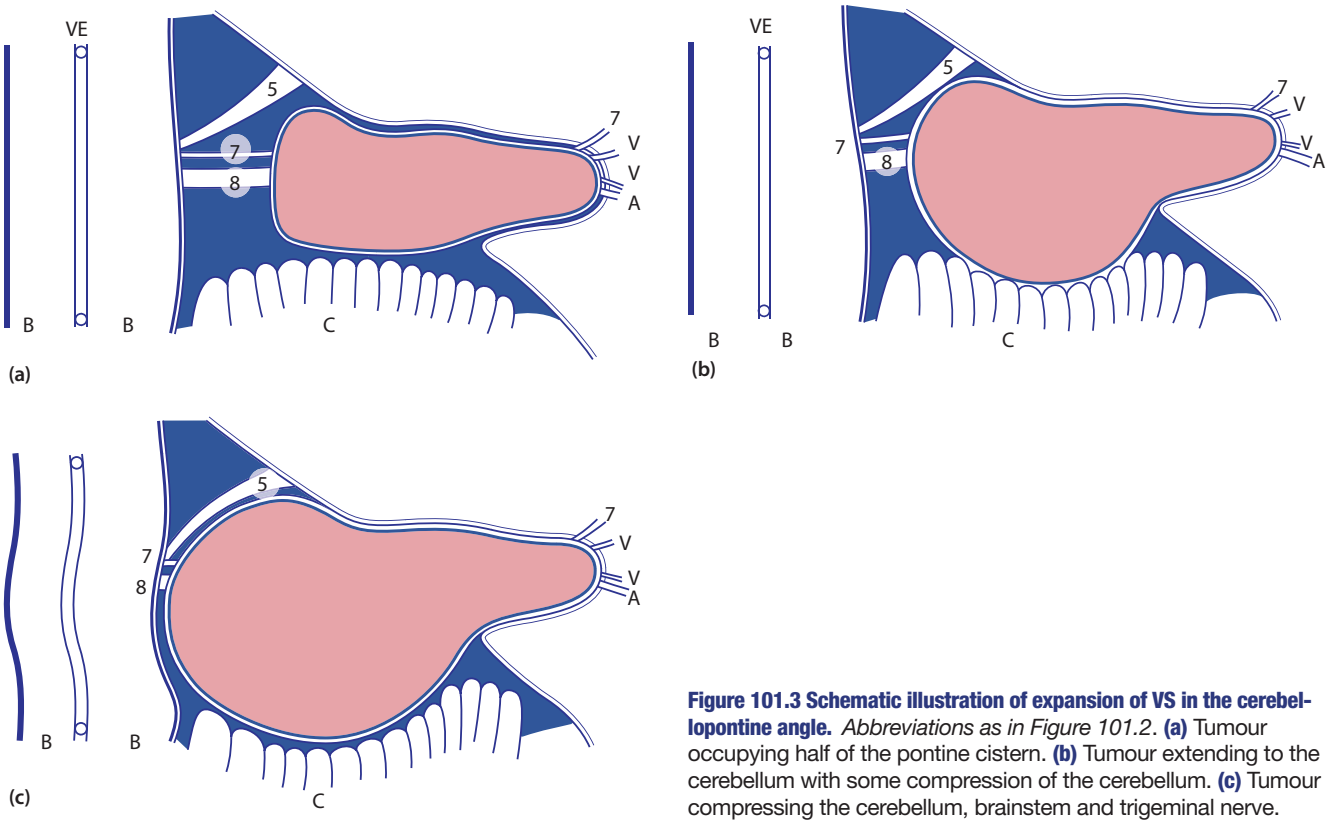

Figure 101.3 Schematic illustration of expansion of VS in the cerebellopontine angle. *Abbreviations as in Figure 101.2*. **(a)** Tumour occupying half of the pontine cistern. **(b)** Tumour extending to the cerebellum with some compression of the cerebellum. **(c)** Tumour compressing the cerebellum, brainstem and trigeminal nerve.

TABLE 101.1 Classification of VS according to size

Classification	Grade	Size (mm)
Grade 0	Intrameatal	0
Grade 1	Small	1–10
Grade 2	Medium	11–20
Grade 3	Moderately large	21–30
Grade 4	Large	31–40
Grade 5	Giant	>40

SYMPTOMS

In more than 90% of patients, the first symptom is unilateral progressive hearing loss with or without tinnitus. In 5–10% of cases, hearing loss is sudden and may be profound. Classically, there is a slowly progressing retrocochlear hearing loss, which is more pronounced in the higher end of the auditory range and is often accompanied by poor speech discrimination. However, it is salutary to note that the hearing was good with normal speech discrimination in 17% of our patients. The caloric test was normal in 8% of our patients, significantly more often (14%) in medium-sized than large tumours. Except for the hearing, symptoms caused by a VS, depend largely on its size. Seventeen per cent had nonacoustic first symptoms[3] such as vertigo, trigeminal or cerebellar symptoms.

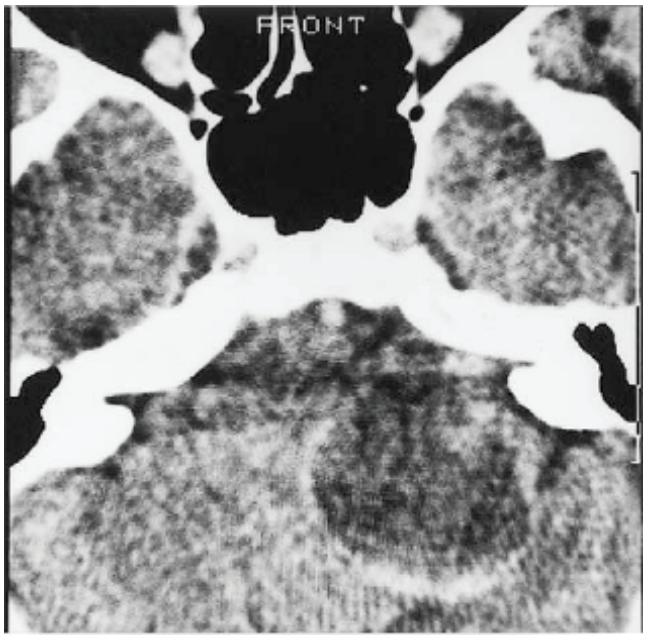

Figure 101.4 A large cystic tumour with a large hypodense area on CT scan.

CYSTIC VESTIBULAR SCHWANNOMA

Cyst formation within VS (Figure 101.4) is seen regularly and is easily detected by MR. This has been thought to represent degenerative change or coalescence

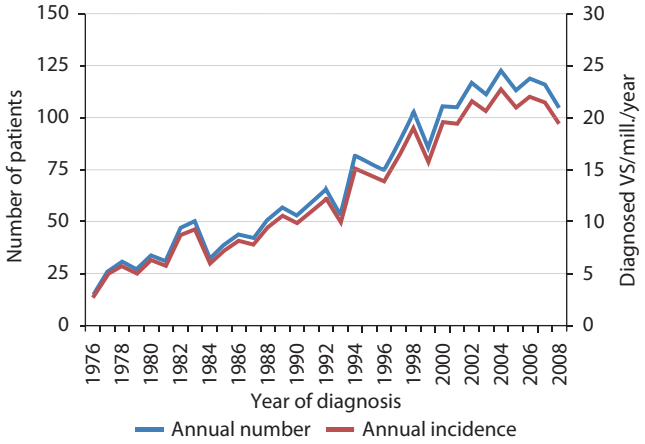

Figure 101.5 Annual number of diagnosed VS and corresponding annual incidence/million/year.

of microcysts in Antoni A tissue. More recently, it has been shown that cystic tumours contain an increased amount of Antoni B tissue that is surrounded by a membrane-like structure composed of Antoni A type cells.[4] Therefore, three criteria are required to be present before a tumour can be termed 'cystic'. First, there must be a hypodense/hypointense area on CT/MR. Second, perioperative identification of the cystic elements must be achieved and, third, there must be histological verification of S-100 positive membrane. Using these criteria, in our series of 773 resected VS, in the period 1976–96, 5.7% were cystic, making an incidence of 0.4 cystic VS per million population per year.

Several studies have shown that the surgical outcome of cystic VS is less favourable than that of solid tumours of comparable size. Furthermore, the cystic elements expand, causing displacement of the brainstem and compression of the fourth ventricle and hydrocephalus. The large size of these tumours at diagnosis, and their cysts, which can increase in size dramatically, have been considered by some to represent a contraindication for treatment by either radiotherapy or a 'wait and scan' policy.

DIAGNOSIS

Until the mid 1980s, diagnosis of VS was based on X-ray, X-ray tomography and computerized tomography. The first magnetic resonance imaging (MRI) scanner became available in most countries from 1980 and over the following years more MRI scanners were introduced. Today, VSs are diagnosed by MRI, except in a few patients with metallic implants, extreme obesity or claustrophobia. At diagnosis, 20% of the patients had a purely intrameatal tumour and in 80% the tumour extended into the cerebello-pontine angle. Nowadays, all patients with unilateral audiovestibular symptoms that cannot be readily explained should proceed to MR imaging with gadolinium enhancement.

Incidence

Several centres have reported an increasing number of diagnosed VS during the last several years.[5,6] In the period from January 1957 to July 1976 the incidence of VS in Denmark was estimated to be 5.4 VS per million per year. This estimate was based on publications from Danish neurosurgical departments.[7,8] Since 1976, the number of diagnosed VS has been constantly increasing from 3 VS per million per year in 1976[9] until an apparent peak in 2004, with 123 diagnosed tumours (23 VS per million per year, **Figure 101.5**).

The increase in the number of diagnosed VS has plausibly been caused by several factors, the most important being continuously improving access to diagnostic equipment (i.e. MRI). Another cause may be heightened symptom awareness amongst the general population and especially among the elderly, as a longer and healthier lifetime may be expected in the developed countries. Better and more widespread audiological testing equipment, as well as easier access to diagnostic imaging, may in addition have heightened the awareness of a possible VS amongst general practitioners and otolaryngologists.

Tumour size at diagnosis

From a mean extrameatal size of about 30 mm in the mid-1970s, the tumour size at diagnosis has decreased continuously over the decades to a mean size of 10 mm in the most recent period from 2003–08. In the 1970s, no purely intrameatal tumours were diagnosed, whereas the large and giant tumours constituted about 40% of all the tumours. Now, the intrameatal tumours constitute 33%, whereas the large and giant tumours constitute about 6% of the diagnosed tumours (**Figure 101.6**).

Age at diagnosis

The age of the patient at the time of diagnosis of the VS has been slowly increasing from 49 years in 1976 to 58 years in 2008 (**Figure 101.7**).

Analyzing the diagnostic age distribution throughout the 33-year period, the number of patients aged 40 years or younger has remained almost unchanged. Thus, the increasing number of diagnosed VS is primarily constituted by patients belonging to the age group older than 50 years.

In the beginning of the period covered, 81% of the patients were 60 years or younger and only 4% older than 70 years. At the end of the period, 59% of the patients were younger than 60 years and 12% older than 70 years.

In the age group of 40 years or younger, the mean tumour size at diagnosis was 23 mm. The size decreased with increasing age, and was 13 mm in the group of patients 70 years or older, even though the mean tumour size decreased throughout the period.

GROWTH PATTERN AND HEARING

The natural history of VS growth is enigmatic. The tumour may grow continuously or only to a certain size,

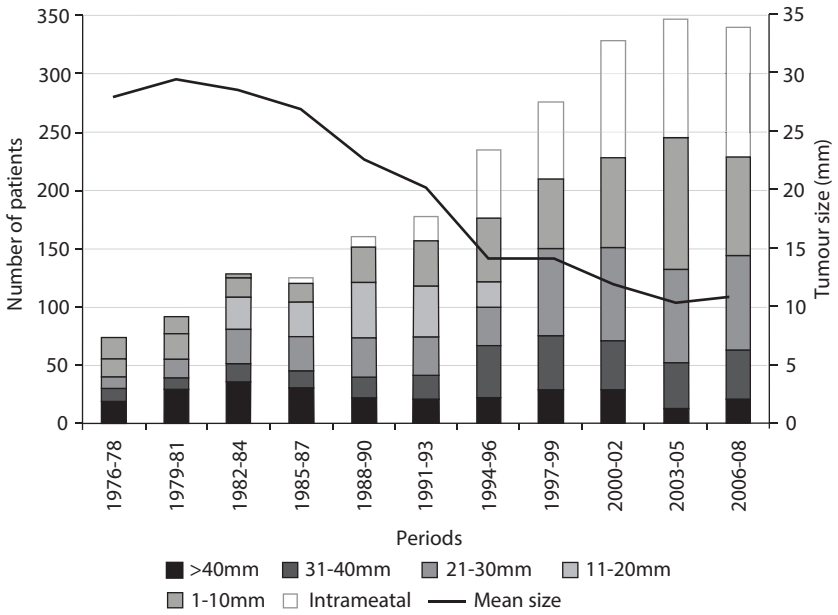

Figure 101.6 Mean size (mm) of diagnosed VS through the period 1976 to 2009.

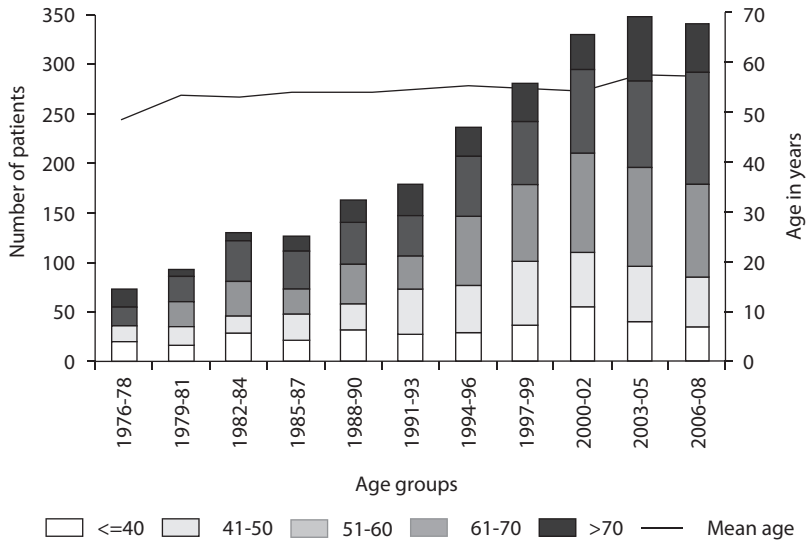

Figure 101.7 Mean age at diagnosis of VS through the period from 1976 to 2009.

followed by stagnation or even shrinkage. Progressive growth in the cerebello-pontine angle will eventually lead to compression of the brain stem and/or the cerebellum, occlusion of the fourth ventricle and subsequently incarceration.

The percentage of growing tumours has been reported to vary from 30% to 90%,[10–27] depending at least in part on the length of the observation period. Most growth observation studies have, however, surveyed a relatively small number of patients and have further been subject to considerable referral bias and patient selection bias, by only including very old patients, patients unwilling to undergo surgery or patients not eligible for surgery due to significant concurrent disease.

Tumour growth

Determined tumour growth rate may depend on the diagnostic tool (CT versus MRI),[13] the method of measurement (number or plane of dimensions assessed)[28] and criteria for the determination for growth (number of millimeters).

The present criterion for growth of a purely intrameatal tumour was growth to extrameatal extension.

For intra- and extrameatal tumours, growth was defined as an increase of at least 3 mm in the largest extrameatal diameter, in order to rule out inter-individual measuring variability and error due, for example, to unaligned scanning images. Largest diameter measurement is adequate when merely questioning absolute growth,[18] which is the

parameter relevant for a clinical assessment and decision-taking, as it is the absolute size that determines the risk of brain stem or adjacent cranial nerve compression. The adequacy of largest diameter measurement has, however, been questioned by one group of investigators, advocating Bayesian tissue classification and partial tumour volume segmentation on MR images for control of tumour growth.[26] Volumetric determination of relative growth rate is definitely mandatory when addressing basic science issues, as a tumour may grow in only one or two dimensions and as, for example, 2 mm growth in a 6 mm tumour is dramatically different from 2 mm growth in a 26 mm tumour, considering, for example, the rate of cellular proliferation.

Growth of intrameatal tumours

Of the intrameatal tumours, 83% remained purely intrameatal during the observation. In 17%, the intrameatal tumour increased in size to extrameatal extension. Of the tumours that grew, 64% grew during the first year, 23% during the second year, 5% during the third year and 8% during the fourth year of observation. No tumour growth occurred after the fifth year of observation (**Figure 101.8**). There were no significant differences in growth between male and female patients or between different age groups.

Growth of extrameatal tumours

Of the extrameatal tumours, 1% decreased in size, 70% remained unchanged and 29% increased in size during observation. Growth was determined during the first year of observation in 62%, during the second year in 26 %, during the third year in 10 % and during the fourth year of observation in 2%. No tumour growth occurred after the fifth year of observation (**Figure 101.8**).

There was no significant difference in the proportion of patients with growth between male and female patients, age groups or diagnostic tumour size. Importantly, the growth occurrence or rate is not related to gender or age, which is in agreement with a recent publication addressing potentially predictive parameters for tumour growth.[29]

Spontaneous change of hearing level

The hearing quality may be evaluated by the pure tone hearing and by speech discrimination.

In order to classify the pure tone hearing, the pure tone average (PTA) is most frequently used. The PTA is calculated as the mean sum of the hearing level (dB) at the frequencies 500 Hz, 1000 Hz and 3000 Hz, or 500 Hz, 1000 Hz, 2000 Hz and 4000 Hz.

The speech discrimination (SD) test is performed in a quiet environment, using word list scoring by phonemes correctly repeated at the most comfortable hearing level.

Over the period 1976–2008, the PTA at diagnosis has improved from 60 dB in 1976 to 50 dB in 2008 (**Figure 101.9**). In the same period the SD at diagnosis has improved from 30% in 1976 to 60% in 2008 (**Figure 101.10**).

Different hearing classifications systems may be used to evaluate the overall hearing acuity.

The AAO-HNS classification

The American Academy of Otolaryngology – Head and Neck Surgery (AAO-HNS) classification of the hearing level is as follows: class A: PTA < 30 dB and SD >= 70%; class B: PTA < 50 dB and SD >= 50%; class C: PTA > 50 dB and SD >= 50%; and class D: SD < 50% (**Figure 101.11a**).[30] Most authors consider AAO class A as good and preservable hearing.

At diagnosis, 19% of the patients had AAO class A hearing on the tumour ear. The hearing deterioration during observation is seen in **Figure 101.12**. After one year, 26% had lost class A hearing, whereas this was the case for 45% after 5 years and 54% after 10 years.

The word recognition scoring (WRS) classification

The word recognition scoring (WRS) classification[31] has: class 0: designates patients with 100% speech discrimination; class I: SD = 99% to 70%; class II: SD = 69% to 50%;

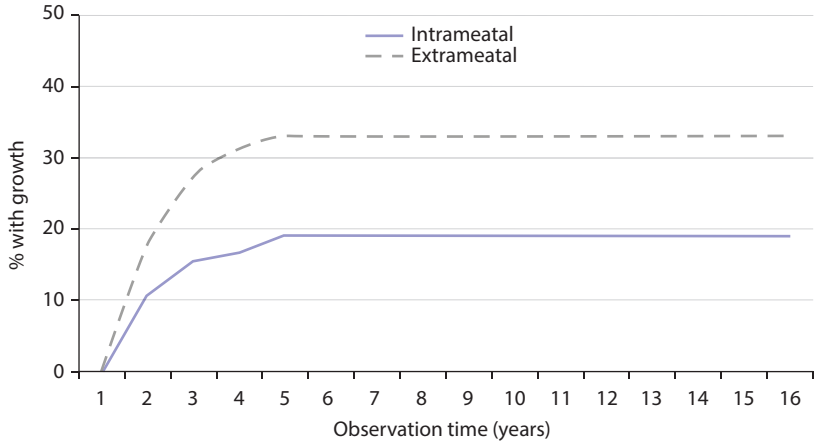

Figure 101.8 Nelson-Aalen curve of growth of intrameatal and extrameatal VS.

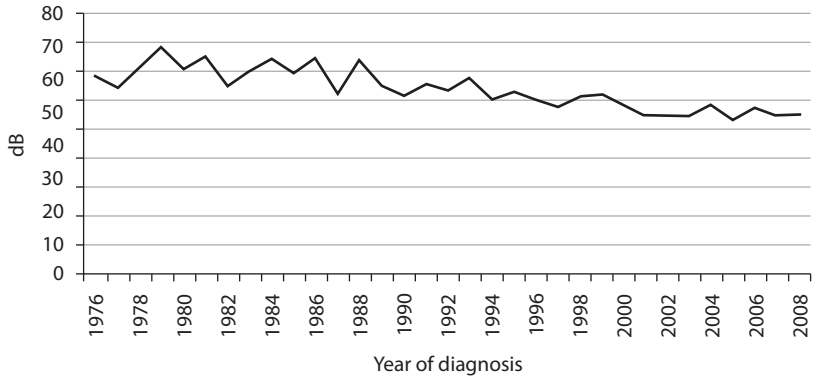

Figure 101.9 Mean PTA (dB) at diagnosis through the period from 1976 to 2008.

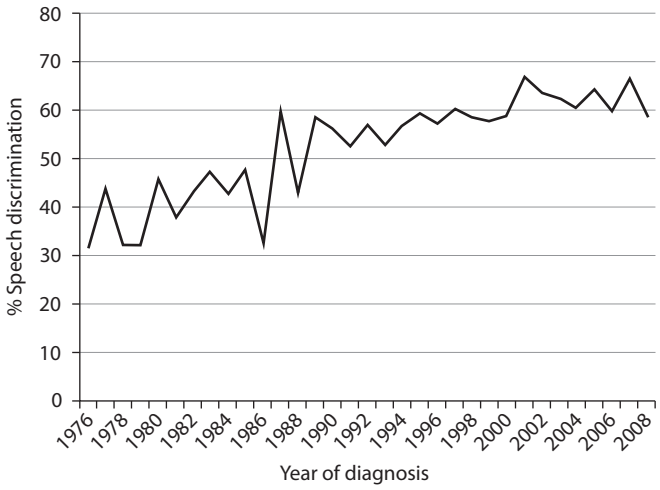

Figure 101.10 Mean speech discrimination at diagnosis through the period from 1976 to 2008.

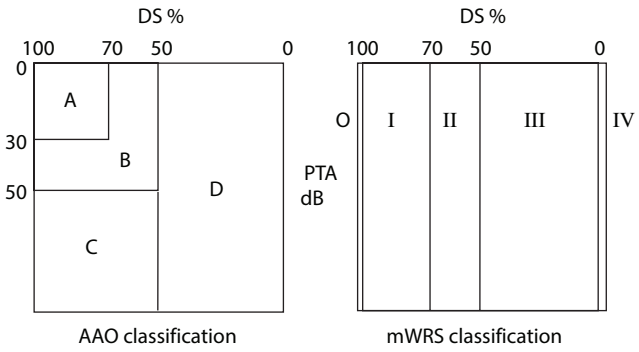

Figure 101.11 AAO and WRS classification of hearing quality.

class III: SD=49% to 1%; and class IV: SD=0% (Figure 101.11b). The hearing is considered good if the SD score is 70% or better (WRS class 0 or I).

At diagnosis, 17% had good hearing (WRS class 0) on the tumour ear, and 36% had WRS class I.[32] In the group with 100% SD at diagnosis (WRS class 0), 3% had lost good hearing after the first year. After 5 years, 12% had lost good hearing and after 10 years 31% had lost good hearing. In patients with even a minor loss of speech

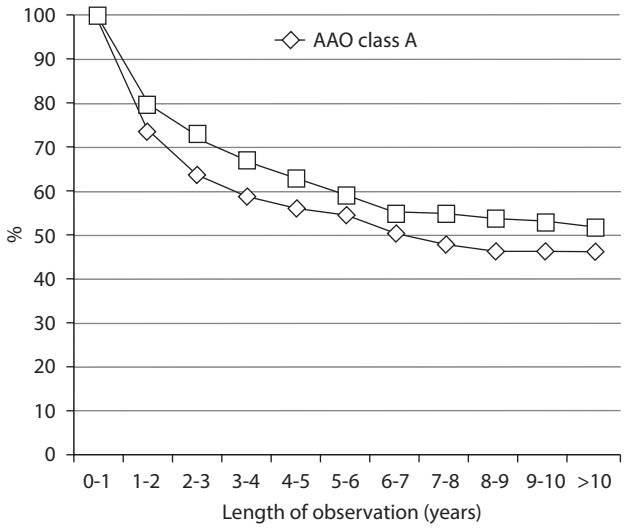

Figure 101.12 Preservation of good hearing (AAO class A or WRS class 0/1) during observation, for patients with good hearing (AAO class A or WRS class 0/1) at diagnosis (*n*=932).

discrimination at diagnosis (WRS class I), 18% had lost good hearing after 1 year, 60% after 5 years and only 38% of the patients with a speech discrimination loss between 1% and 10% maintained good hearing (Figure 101.13).

SPONTANEOUS COURSE OF HEARING AND ACTIVE TREATMENT

Hearing preservation after surgery is usually reported as the results after 1 year, and is reported to vary between 24% and 83%.[33–35] In a study from House Ear Clinic from 2003,[36] the long-term hearing preservation after surgery was evaluated over a five-year period in 38 patients. Of these 38 patients, 61% had AAO-HNS class A-B hearing after surgery. Over the subsequent five-year period, 30% lost class A-B hearing. The great variability in the success rate of hearing preservation after surgery may be explained by difficulties in comparing data, due to variable definitions of good or serviceable hearing and different reporting of the size of the operated tumour. Some surgeons include the intrameatal

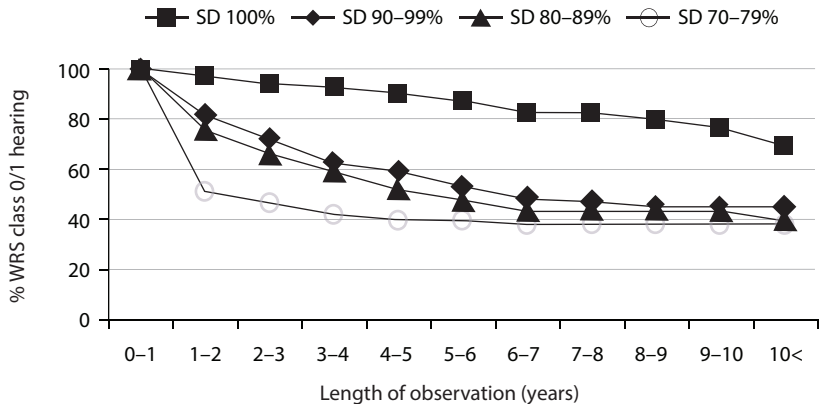

Figure 101.13 Preservation of good hearing (WRS class 1) during observation related to the different SD groups at diagnosis (*n* = 932).

part of the tumour in size measurement, while others measure the extrameatal part only. Most authors agree that the chance of hearing preservation is significantly reduced for tumours with an extrameatal diameter of more than 15 mm, while others have good results of hearing preservation in large tumours.[37] Hearing preservation surgery may be performed by the middle fossa approach, the retrolabyrinthine approach or by the retrosigmoidal approach. Comparing the approaches, it seems that the results are better by the middle fossa approach in small and intrameatal tumours.

The hearing preservation results after radiotherapy is reported to vary between 33% and 79%.[38–40]

During 'wait & scan', 73% of patients with AAO-HNS class A hearing at diagnosis preserve good hearing after one year of observation. According to the WRS classification, 87% of patients with WRS class 1 hearing at diagnosis maintain good hearing. The spontaneous outcome is emphasized further by patients with 100% SD at diagnosis (WRS class 0), in which 99% of tumour ears preserve good hearing after 1 year, whereas 91% of patients preserve good hearing after 5 years of observation, and 68% after 10 years.[32]

The main clinical implication of the hearing results is that the results indicate that it may be possible to identify patients who have a good chance of maintaining good long-term hearing spontaneously, by focusing on the speech discrimination at the time of diagnosis. Thus, a small non-growing tumour with 100% discrimination should be allocated to 'wait and scan', since it is highly likely that the tumour will not grow, and the patient will preserve good long-term hearing spontaneously and thus have an outcome superior to radiotherapy or hearing preservation surgery.

A TREATMENT STRATEGY BASED ON THE NATURAL HISTORY OF TUMOUR GROWTH AND HEARING

As more, primarily small and medium-sized VSs are diagnosed and need to be treated, the medical community is in need of a treatment strategy based on hard data on the spontaneous course of hearing and the growth pattern of these tumours.

Based on the data presented above, our centre has adapted and proposed the following strategy for all sporadic, unilateral VSs smaller than 15–20 mm extrameatal: yearly MRI for 5 years, followed by MRI every other year for 4 years, followed by MRI after 5 years, after which the observation is terminated, if no growth occurs. A rigid data interpretation indicates no reason to follow patients for more than 5 years, as tumour growth only occurred within the first 5 years after diagnosis. We have, however, chosen the above treatment policy as only a limited number of tumours have been followed for more than a decade, and to be on the safe side. If significant growth occurs, active treatment (surgery or radiotherapy) is recommended. Naturally, special considerations may indicate an aberration from this management policy (e.g. observation of old patients with large tumours or surgery for small tumour in patients insisting on a primary operation). However, unless realistic hearing preservation is intended[41] or special reasons (e.g. patient psychology) prevail, there are no available data indicating or substantiating a reason for active treatment of a non-cystic, non-growing VS smaller than 15 mm. Although reasonably surmounted, both surgery and radiotherapy are associated with risks, and the quality of life of our patients appears to be significantly better when their disease is observed.

Primary treatment of tumours larger than 15–20 mm is recommended, as further growth extends the tumour diameter into the range associated with a considerable increase in treatment comorbidity (e.g. damage to the facial nerve function). Cystic tumours are not eligible for radiotherapy and primary surgery is recommended, as these tumours may display sudden and dramatic growth, which implicates a poorer surgical outcome. NF-2 associated VSs are treated individually, as these tumours often display a distinct growth pattern and often are subjects of special consideration.

BEST CLINICAL PRACTICE

- ✓ The size of a VS should be recorded according to the International Consensus Guidelines.
- ✓ Patients allocated to a 'wait and scan' management policy should be observed with annual MRI for at least 5 years.
- ✓ Patients with small non-growing tumours and 100% speech discrimination should be managed conservatively.

KEY POINTS

- The term 'acoustic neuroma' should be replaced by the more accurate term 'vestibular schwannoma'.
- When reporting the size of vestibular schwannomas, the largest extrameatal diameter should be recorded and a note made of whether the VS is cystic.
- Symptoms caused by VS depend largely on its size, but good hearing may be found even in large tumours.
- Trigeminal symptoms and signs together with ataxia indicate a large tumour with significant brainstem compression.
- The precise incidence of VS in the population is not known, but the number of diagnosed tumours is increasing, probably due to easier access to diagnostic tools. The incidence is not less than 25 tumours per million per year.
- Only one fifth of the intrameatal and one third of the extrameatal tumours grow, and in almost all cases within the first 5 years after diagnosis.
- In patients with 100% speech discrimination at diagnosis, most maintain good hearing, in contrast to patients with even a minor impaired discrimination, where about 60% lose good hearing after 5 years observation.

INTRODUCTION

This chapter introduces the indications for surgical management of vestibular schwannoma (VS), explaining the current management philosophy. The common approaches to the cerebellopontine angle (CPA) are described with explanation of the advantages and disadvantages of each. A review of the current literature with particular focus on developments of adjunctive surgical techniques has been undertaken.

With the advent of high quality imaging and the increased level of awareness amongst clinicians seeing patients with otological complaints, the diagnosis of VS is frequently made earlier.[1] As a result, the tumours are detected at a smaller size and the incidence appears to have increased from the previously quoted 1:100 000 per year to 1:80 000 per year.[1–3] In addition, the epidemiological work of many has shown that a high proportion of patients with VS have static tumours.[4] Although surgery has a role for those with large tumours (>30 mm maximal intracranial diameter), beyond which the role of stereotactic radiotherapy is considered minimal, for smaller tumours, a conservative approach is commonly advised.[5, 6] There is no way of predicting which tumours will grow at the time of initial diagnosis and the majority of patients are offered active monitoring.[7] This active monitoring involves serial scanning to detect any evidence of growth, after which an intervention is offered. Despite this commonly held belief, some growth in small and intracanalicular tumours is tolerated without the need for urgent intervention.[8] Many series have shown 60–70% remain stable with no growth for many years.[9]

Historically the intervention offered was surgery. However, the skull base multidisciplinary team is increasingly offering patients the choice of surgery or radiotherapy, delivered as a single fraction (Gamma Knife) or multiple fractions. This is beyond the scope of this chapter as it is covered elsewhere.

Nevertheless, surgery remains the mainstay of treatment and this chapter deals with the commonly favoured approaches to the CPA. Certain generalizations apply to surgery, whichever approach is employed. Each of the three approaches described has its own advantages and disadvantages and these will be highlighted. The surgical outcomes will be discussed and the complications of surgery mentioned.

HISTORY

It is interesting to look at the history of the two main surgical approaches now in common use, the suboccipital (retrosigmoid) approach and the translabyrinthine approach, and to look at the vitriolic arguments that characterized the debate between the neurosurgeons and the emerging genre of neurotologists in the middle of the 20th century. Going back to the end of the 19th century, it remains unclear whether it was Ballance[10] in London or Annandale in Edinburgh who performed the first successful VS removal. Although Ballance's case was earlier,

Cushing was of the opinion that his case was a meningioma, and said of Annandale's case: 'a brilliant result, the first recorded'.[11] Be that as it may, these operations were carried out though the suboccipital approach by multi-tasking general surgeons before the emergence of neurosurgery as a separate specialty after the First World War. Undeterred by peri-operative mortality of apocalyptic magnitude (Krause in 1903 reported an 84% death rate),[12] surgery of the CPA developed in the hands of the new breed of neurosurgeon, of whom the leaders were the two great Americans Harvey Cushing and Walter E Dandy. Cushing[13] proposed intracapsular debulking of the tumour whereas Dandy[14] was a strong advocate of total removal. Despite their advances it is significant that as recently as the 1950s there still prevailed an attitude amongst many neurosurgeons that surgery should be deferred until the tumour was in fact a threat to life. An article by Pennybacker and Cairns in 1950[15] is worth reading in that it encapsulated much of the thinking of the time.

It was this situation that William House found so unacceptable in the 1960s. He could not see the logic of letting a small or medium-sized tumour become a large or giant tumour before performing an operation that was almost inevitably bound to be associated with a poor outcome or even death. He therefore proposed surgery as soon as the diagnosis could be made and suggested the translabyrinthine approach to the CPA.[16] This approach was first suggested by Panse as long ago as 1904[17] but was dismissed as inappropriate and remained in obscurity for half a century. House endured many hostile confrontations with the neurosurgical community, whose objections were as much due to the fact that otologists were becoming involved with this type of surgery as with the approach itself. Battles raged at international meetings as to which approach was better. It now seems quite clear that the 'best' approach is the approach that gives the best results in the hands of the individual surgeon. Beyond that the argument is sterile. Many developments occurred in the second half of the 20th century that led to improvements in surgical outcomes regardless of approach. There is no doubt that the advent of microsurgical technique was a major breakthrough. So too was the understanding of the importance of the blood supply of the brainstem from the work of Atkinson.[18] Neuroanaesthesia made important strides and enabled surgeons to take many painstaking hours over the surgery (an offer they were happy to accept!). Also, of course, early diagnosis enabled House's vision of early diagnosis and treatment to come a long way to fruition.

SURGICAL APPROACHES TO THE CEREBELLOPONTINE ANGLE

Translabyrinthine approach

This is now the favoured approach for the removal of VS for the majority of neurotologists. Its advantages are the avoidance of cerebellar retraction or resection, and the early identification of the facial nerve at the lateral end of the internal auditory meatus (IAM). Its disadvantages are that it involves destruction of the inner ear and so is not an option for hearing preservation surgery. It has a higher incidence of cerebrospinal fluid (CSF) fistula than other approaches and it is said by its detractors to provide only limited access to the posterior fossa. This criticism is in fact unfounded, and a well performed translabyrinthine approach will allow removal of a VS of any size.[19] It can be extended posteriorly to allow further access to the posterior fossa, jugular foramen, hypoglossal canal and foramen magnum. It can be extended anteriorly to allow access to the petrous apex and clivus (transcochlear approach). It can be extended superiorly to allow access to the middle fossa, and inferiorly to allow access to the jugular foramen and upper neck. Morrison combined the translabyrinthine approach with the middle fossa approach as the translabyrinthine transtentorial approach for large or giant tumours.[20] The technique gives excellent exposure of the tumour and of the brainstem but there is an unacceptable incidence of post-operative epilepsy and occasional temporary dysphasia if the dominant temporal lobe is retracted. The basic translabyrinthine operation is the essential starting point for many lateral skull base operations and must be a routine exercise for all aspiring neurotologists and skull base surgeons.

The key stages in the operation are:

1. Skin and periosteal flaps
2. Extended cortical mastoidectomy
3. Bony labyrinthectomy
4. Skeletonization of the jugular bulb and vertical portion of the facial nerve
5. Skeletonization of the IAM
6. Identification of the facial nerve at the lateral end of the internal meatus
7. Opening of the posterior fossa through the dura of the posterior surface of the petrous bone
8. Removal of tumour using standard neurosurgical techniques
9. Closure with obliteration of the middle ear and petrosectomy defect, usually with abdominal fat.

DETAILS OF THE TRANSLABYRINTHINE APPROACH

Position

The patient is placed on the operating table in the supine position with the head turned 30 degrees away from the surgeon and supported either in a soft head ring or fixed in the Mayfield clamp. Two-channel neuromonitoring for the facial nerve is usually sufficient, but with very large tumours it may be necessary to monitor the lower cranial nerves as well. The anaesthetist should be reminded that neuromuscular blocking agents must not be used after intubation.

Skin incision

A curved incision above and behind the pinna is planned, to allow adequate access for bone removal behind the

lateral sinus and anterior access to the labyrinthine part of the facial nerve. For tumours up to about 2.5 cm intracranial diameter the incision can be about 3 cm behind the postauricular sulcus but for larger tumours the incision should be sited further back to allow exposure of the dura behind the lateral sinus. The anterior limb should extend to a line tangential to the anterior wall of the external auditory canal.

Musculoperiostial flap

It is desirable to create a separate flap that can be used during closure to secure the abdominal fat plug. The flap can be pedicled superiorly or anteriorly. The superiorly based flap has the advantage that, if necessary, it can easily be extended upwards to allow access to the middle cranial fossa.

Cortical mastoidectomy

The secret of the operation is the extent of the bone removal (Figure 103.1). Using cutting and coarse diamond paste burrs, bone is removed up to the middle fossa dura, exposing it widely, both over the floor of the middle fossa and some 3–4 cm up the squamous portion of the temporal bone. If needed, this allows easy retraction of the dura with the instruments during tumour removal. In a similar manner, bone is removed from the sigmoid sinus and from the bone overlying the posterior fossa dura for 2–3 cm behind the sinus. Some surgeons like to leave an island of thin bone over the sinus that can be retracted with the sinus and provides some protection for the sinus. The sinus can thus be compressed backwards to increase access. During preparation of the sigmoid sinus, troublesome bleeding may be encountered from a large emissary vein. If possible it is better to anticipate trouble and identify and control the vein before making it bleed. Its bony canal can be skeletonized and obliterated with bone wax or, alternatively, the vein can be coagulated with bipolar diathermy. Coagulation should not be too close to the main sinus otherwise the manoeuvre may simply convert a small bleed from the emissary vein into a large bleed from the sinus. Care must be taken to avoid damage to the superior petrosal sinus, which runs along the posterior petrous ridge and therefore in the angle created by the bone removal between the middle and posterior fossa dura. The bipolar diathermy, if applied lightly over the dura or the surface of the sigmoid sinus, will make it retract and increase access. Bleeding from the superior petrosal sinus and, indeed, even from the lateral sinus, is easily controlled with pressure and the application of haemostatic mesh (Surgicel). Should more dramatic bleeding occur, it is still possible to apply a tie-over mesh, possibly with the addition of muscle, to avoid tying off the sinus, which is a last resort. Air embolus is only a theoretical risk in our experience.

Attention can now be turned to further bone removal medially. Ensuring the mastoid tip is removed with exposure of the digastric ridge, which aids in identification of the descending facial nerve.

Bony labyrinthectomy

A standard total bony labyrinthectomy is performed (Figure 103.2). Care must be taken in drilling out the ampulla of the posterior canal, which lies medial to the second genu of the facial nerve. The ampulla of the superior semi-circular canal should be retained as it is a landmark for the superior vestibular nerve (SVN). In drilling out the superior canal the surgeon will encounter the subarcuate artery, which runs under the canal and leads to the posterior fossa dura just behind the porus of the internal meatus. The endolymphatic duct can be traced from the vestibule along the line of the common crus where it turns through 90 degrees towards the posterior fossa dura and widens out to become the sac. The bone over the posterior fossa dura between the labyrinth and the anterior margin of the sigmoid sinus should be removed and access is further enhanced, especially in small temporal bone, if bone is

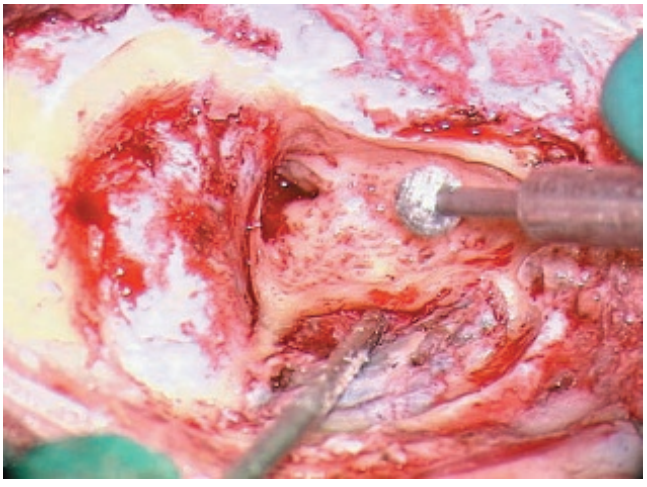

Figure 103.1 Translabyrinthine approach, right ear. Extended cortical mastoidectomy has been performed. Note the wide bone removal over the middle fossa dura and the sigmoid sinus, allowing the dura and the sinus to be retracted and the access improved.

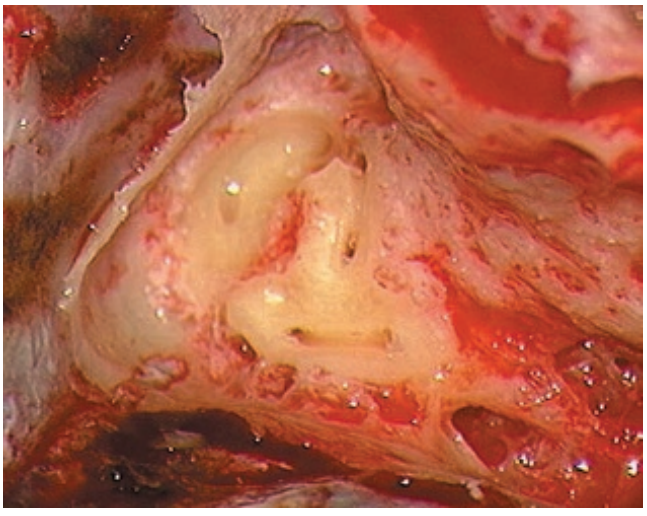

Figure 103.2 Translabyrinthine approach, right ear. Bony labyrinthectomy.

progressively removed from the dura of the middle fossa. It is by removing these bony boundaries of the petrous bone so that the limits of the resection are the soft and compressible dural surfaces that the surgeon gets maximum access to the posterior fossa. This is one of the secrets of success in the translabyrinthine operation. Although opening of the labyrinth almost inevitably leads to total hearing loss there have been attempts to perform a conservative labyrinthectomy with sealing of the vestibule and thus isolation of the cochlea from the labyrinth with preservation of the hearing. This technique was first described by McElveen et al.[21] with a further updates by Magliulo et al.[22, 23] These authors conserved class 1 or class 2 hearing in 7 out of 12 patients treated in this manner.

Others have shown that preservation of the cochlear nerve in the CPA and IAM allows subsequent cochlear implantation.[24, 25] Currently in attempting cochlear nerve preservation, a three-channel intracochlear electrode is inserted during the latter stages of the approach and tumour dissection to allow monitoring of the cochlear nerve function.[26]

Skeletonization of the jugular bulb and the vertical portion of the facial nerve

The jugular bulb is the lower limit of bone removal and in nearly all cases bone should be removed down to its level. The height of the bulb does vary enormously. In some very large, well pneumatized temporal bones with a low bulb and a small tumour it may not be absolutely necessary to expose the bulb. On the other hand it is not at all uncommon for the dome of the bulb to rise up to, and beyond, the level of the floor of the internal meatus, even as high as the middle fossa dura, and in these cases the surgeon must be prepared to mobilize and depress it. This is done by gently freeing the bulb from its bony bed and packing it downwards using haemostatic mesh (Surgicel) and bone wax. Bleeding, sometimes quite brisk, may occur but it is usually easy to control. Bone wax provides excellent protection for the mobilized bulb from the rotating shaft of the drill during the subsequent creation of the inframeatal gutter. The retrofacial air cells are exenterated and bone may be removed over the vertical portion of the facial nerve until the sheath is visible through the bone. The exact extent of bone removal over the nerve depends on the access in the individual temporal bone and the size of the tumour.

Skeletonization of the internal meatus

A U-shaped gutter is drilled below, behind and above the internal meatus (**Figure 103.3**). The extent of bone removal should be approximately 270 degrees round the meatus, and is much faster if the temporal bone is well pneumatized. An extended translabyrinthine approach has been described with removal of bone around the internal meatus to a full 360 degrees by retracting the contents of the meatus inferiorly and carefully continuing drilling towards the petrous apex.[27] This modification is helpful in dealing with lesions of the petrous apex, but is not necessary for the great majority of VSs. It is important to check the degree of meatal expansion on the pre-operative scan. Superiorly bone is removed between the meatus and the dura of the middle cranial fossa, from which the bone should be removed to allow superior elevation of the temporal lobe and easier access. One should constantly keep in mind the position of the facial nerve in the anterosuperior quadrant of the meatus, and remember that in an expanded meatus it may in fact be very close to middle fossa. To guard against inadvertent facial nerve trauma, the inferior meatal gutter is drilled first, allowing the meatal contents to displace inferiorly when the drilling turns to the superior side, where the nerve is immediately under the dura. One should be on the lookout in a pneumatized temporal bone for tumour that has eroded out of the meatus and into the air cell system. In such a situation the facial nerve may be engulfed by tumour and appear to be running through the tumour. Inferiorly one frequently encounters the cochlear aqueduct in a position superomedial to the jugular bulb. It is heartening if a brisk flow of CSF results as this allows the intracranial contents to slacken off and ease the subsequent opening of the posterior fossa. The cochlear aqueduct is a useful guide to the position of the lower cranial nerves, which are just anteroinferior to the duct. Subsequent bone removal round the meatus should be above the level of the aqueduct. When drilling round the porus, especially behind it, one must be aware of the possibility of an arterial loop lurking just under the dura, especially with a large tumour or if CSF has not been run off. There should now be an eggshell of bone over the dura of the internal meatus and the posterior fossa dura adjacent to the porus. At the lateral end of the meatus the transverse crest and the canal for the SVN should be sought. The latter runs from the lateral end of the meatus towards the retained ampulla of the superior semi-circular canal, and is a constant and reliable landmark. As the surgeon looks through the microscope it runs from 12 o'clock to 6 o'clock in the surgical field. Bone should now be picked off the dura of the internal meatus and the posterior cranial fossa if any remains.

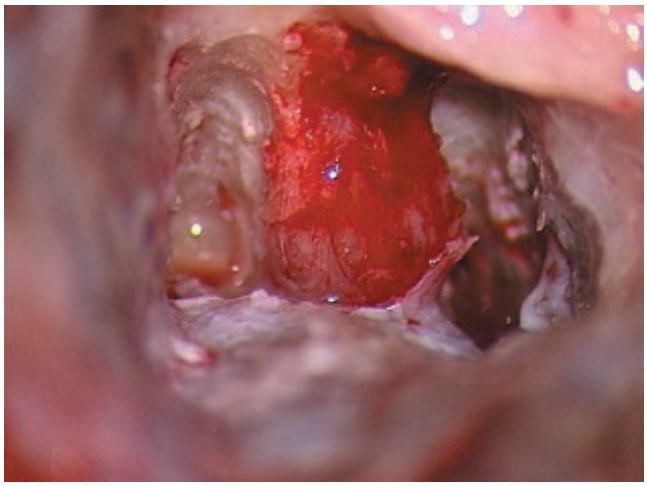

Figure 103.3 Translabyrinthine approach, right ear. The internal meatus has been skeletonized and the intrameatal portion of the tumour exposed.

Opening the posterior cranial fossa and internal auditory canal

The dura is opened to make full use of the exposure. The upper limit is close to the superior petrosal sinus, the lower limb close to the jugular bulb. The medial limb is at the level of the porus. The dura is usually thin superiorly but can be very tough inferiorly where it is bilaminar. If CSF has already escaped though the cochlear aqueduct, this step of the operation is easy, because the cerebellum and any important blood vessels have dropped away from the dura. If the intracranial pressure is high, however, this can be a surprisingly difficult exercise, as the cerebellum tries to force its way out, often accompanied by arterial loops. Careful use of neurosurgical patties provides protection until CSF can be released. This is usually done by carefully opening the subarachnoid space at the lower pole of the tumour with a dissector. Alternatively, if a lumbar drain has been inserted the anaesthetist can be asked to run off some CSF. The dura of the internal meatus should be cut from lateral to medial at the level of the transverse crest, with the superior and inferior dural flaps reflected off the tumour, which is usually arising from the inferior vestibular nerve, and the other internal auditory canal (IAC) nerves.

Identification of the facial nerve

The facial nerve is displaced from its normal position by the tumour, but in the majority of cases it is displaced in a fairly predictable way. It runs along the anterosuperior quadrant of the meatus as far as the porus where it is displaced to a variable extent anteriorly and/or superiorly before turning down over the front of the tumour to the brainstem, which it joins just above the pontomedullary junction. Thus in the translabyrinthine approach the tumour is usually between the surgeon and the facial nerve. However, this is not always the case. There are occasions when the facial nerve is rotated backwards in the meatus and comes to lie on the posterior surface of the tumour. This may occur if the tumour arises on the cochlear nerve. It may on occasion be displaced down to the floor of the meatus and run in a more inferior position to the brainstem. If the tumour turns out to be a meningioma, the relationship of the nerve to the tumour may be variable, and it commonly runs over the posterior surface of the tumour. It is therefore essential to establish the relationship of the nerve to the tumour before any tumour is removed. At the lateral end of the meatus the SVN has already been identified. The exposed intrameatal portion of the tumour should be closely examined, both visually and using the facial nerve monitor, to be sure that the nerve has not been displaced on to the posterior surface. Assuming this is negative the nerve should then be sought in front of the SVN both visually and with the monitor. The routine identification of Bill's bar, the vertical crest separating the SVN from the facial nerve, has been abandoned by many surgeons now that reliable monitoring is in use in every case, but it may be useful to do so in cases of doubt. Access to the anterosuperior part of the meatus may be helped by careful debulking of the tumour in the lower half of the meatus.

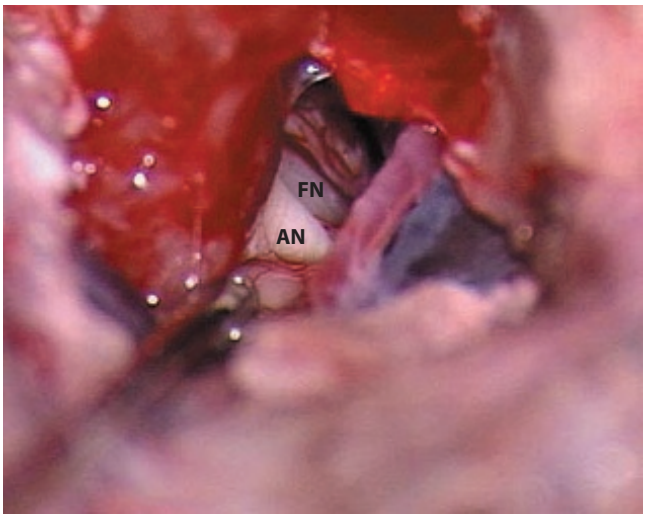

Figure 103.4 Translabyrinthine approach, right ear. The posterior fossa has been opened. The medial pole of the tumour is seen and below it the audiovestibular nerve (AN) and (deeper) the facial nerve (FN) on the brainstem.

It is also useful to try to identify the facial nerve on the brainstem at the earliest opportunity (Figure 103.4). With a small tumour it may be immediately obvious in front of the audiovestibular nerve and usually separated from it by a loop of the anterior inferior cerebellar artery (AICA). With a larger tumour it may not be possible to see it until some intracapsular debulking of the tumour mass has taken place. Once both proximal and distal ends of the nerve have been identified the surgeon starts to form a mental image of the likely course of the nerve in relation to the tumour. This three-dimensional conceptualization of the relationship between tumour and nerve is only acquired with considerable experience and makes tumour removal much more predictable and rapid.

Tumour removal

With tumours confined to the internal meatus or with little intracranial extension, dissection can start at the fundus and proceed medially, keeping to the arachnoid plane, and little difficulty should be encountered, although even small tumours may be surprisingly adherent to the facial nerve just at and medial to the porus, and sharp dissection may be needed (Figures 103.5 and 103.6). With larger tumours, debulking of the inside of the tumour is carried out so that the tumour is converted from a solid ball to a hollow ball. This technique is based on the fact that as the tumour expands all important structures such as the facial nerve and AICA are pushed before the tumour and are to be found in the arachnoid sheath on the outside of the tumour capsule. Dissection that is confined to the inside of the tumour should be safe. A number of techniques and instruments can be used for debulking. If the inside tumour is very soft it is possible to reduce the volume quite rapidly with suction alone. More solid tumours may require the use of the cavitational ultrasonic surgical aspirator (CUSA). The CUSA is certainly effective but one must be sure to use it with great care because it is

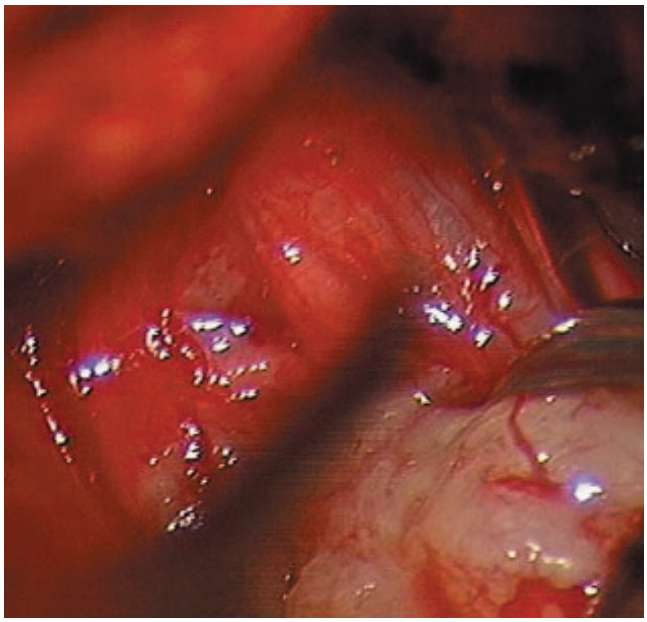

Figure 103.5 Translabyrinthine approach, right ear. The tumour is dissected off the facial nerve (FN) in a lateral to medial direction.

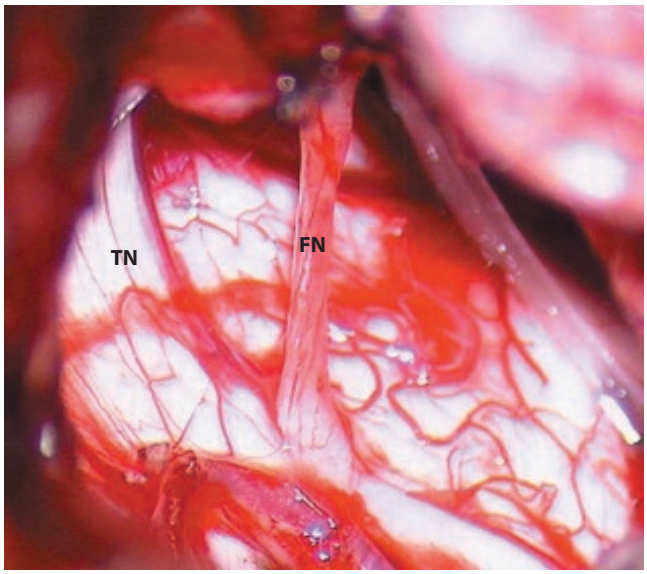

Figure 103.6 Translabyrinthine approach, right ear. Tumour has been removed completely. The facial nerve (FN) can be seen crossing the CPA to the meatus. The trigeminal nerve (TN) is seen more cranially and a loop of AICA inferiorly.

not difficult to penetrate the capsule on the far side of the tumour and risk causing damage to the facial nerve, AICA or the brainstem. It also tends to produce quite a bit of bleeding from the tumour, necessitating frequent coagulation using bipolar forceps. As the tumour bulk reduces it becomes progressively easier to manipulate the tumour capsule, and careful retrograde dissection of the capsule off the brainstem end of the facial nerve may allow the surgeon an increasingly confident image of the path that the nerve is taking. When dissecting at the lower pole one must be careful to protect the lower cranial nerves and AICA, although it must be said that it is not usually difficult to dissect them off the tumour and damage to these structures is rare. With a combination of lateral to medial and medial to lateral dissection the tumour is removed from the facial nerve. The extent to which one can follow the traditional advice to stay in the arachnoid plane varies from tumour to tumour and it is very important that the surgeon knows just where he is in relation to that plane at any moment in the operation. When dissecting the tumour off the facial nerve in the internal meatus he is within the arachnoid plane. When dissecting in a retrograde manner from the stem he is outside the arachnoid plane. Failure to appreciate this subtle difference in location carries the risk of dividing the nerve. In the internal meatus and close to the brainstem the plane between the facial nerve and the tumour is usually quite easy, but at a point at or just medial to the porus it may be almost impossible to identify and sharp dissection may be necessary to get the tumour off the nerve. This is the point where the facial nerve is most likely to be lost. In addition to difficulties with the plane, it is here that the nerve becomes very thin and may be impossible to differentiate visually from the surrounding arachnoid, although the monitor does certainly help. The facial nerve is placed at further risk if the tumour extends far forwards towards the petrous apex carrying the facial nerve with it. The surgeon may in fact decide to leave a small nubbin of tumour on the nerve at this point to reduce the risk to the facial nerve. There is good evidence that these small fragments become devitalized and either disappear on follow-up scanning or at least seem to remain biologically inert.[28,29] Dissection of the capsule off the trigeminal nerve and the brainstem is usually not difficult but some tumours bury their way into the stem and very gentle technique is required to separate one from the other. There may be occasions when the surgeon chooses to leave a fragment of tumour behind, especially if the anaesthetist reports repeated or sustained changes in the pulse or blood pressure during manipulation on the stem. The VIth nerve can usually be seen running up the length of the stem. Large tumours may make contact with this nerve and it must be handled carefully. Even quite gentle dissection can cause a temporary dysfunction of the nerve with transient post-operative diplopia. All blood vessels apart from obvious tumour vessels should be treated with the greatest respect. It is not possible to tell which branches of AICA are essential and it is wise to assume that they all are.

Special attention should be drawn to the unique surgical problems with the so-called medial tumour that arises in the CPA without involving the internal meatus and is usually large at presentation.[30,31] Because they have little attachment to the internal meatus these tumours tend during surgery to be suspended on the VIIth/VIIIth nerve pedicle or even on the facial nerve alone. The surgeon has to be particularly careful to avoid traction on this pedicle if avulsion of the facial nerve is to be avoided.

After tumour removal, haemostasis must be secured. Care must be taken with the use of the bipolar diathermy in the vicinity of the facial nerve. Rather than risk thermal damage to the nerve, one should allow bleeders close to

the nerve to stop spontaneously or use a small fragment of Surgicel to assist haemostasis.

Closure

This is one of the most important steps in the translabyrinthine operation. CSF fistula remains one of the most common post-operative problems, even in large series from experienced centres. To minimize the risk, careful obliteration of the middle ear and the temporal bone defect is essential. Harvest of free autologous fat (and fascia) from the abdominal wall or thigh is performed and prepared for use. The incus is removed and a posterior tympanotomy created. The middle ear, Eustachian tube and vestibule are obliterated with muscle or fascia and bone wax. The supra and inframeatal gutters are obliterated with fat and obvious air cell tracts sealed with bone wax. The temporal bone defect is obliterated with abdominal fat either in strips or in one large piece. Some surgeons first seal off the posterior fossa and drilled anterior surface of the petrous bone with fascia lata from the thigh or fascia from the superficial layer of the external oblique from the anterior abdominal wall. The repair is secured with fibrin glue, although excessive reliance on biological glues is to be regarded with caution. It is possible that they may interfere with the body's natural healing response and, when they are absorbed, actually predispose to CSF fistula.[32] Although predominantly remaining in the surgical bed, post-operative imaging has shown embolic distribution of fat throughout the CSF with no clinical significance.[33] The periosteal flap is then sutured back over the fat and the skin closed in two layers. A firm pressure dressing is applied and kept in place for a week. It should not, however, be so tight that it causes pressure changes in the skin of the forehead. The use of a peri-operative lumbar drain is not routine but is employed in some centres.

Middle fossa approach

The middle fossa approach is one of the possible routes of access for hearing preservation surgery. The internal meatus is approached extradurally from above through a small craniectomy. It has the advantage of allowing good visualization of the lateral extent of the internal meatus. The approach is somewhat cramped, however, and access to the posterior fossa limited, certainly through the standard middle fossa approach. The maximum size of tumour that can comfortably be removed is about 1–1.5 cm in intracranial diameter, which is in fact about the limit beyond which the possibility of hearing preservation recedes. Furthermore there is a small but real risk of epilepsy following extradural retraction of the temporal lobe. Aggarwal et al.[34] described two cases of single ictal events that had the effect of prohibiting the patients from driving for a period of one year. In the extended middle fossa approach (EMFA), more bone is removed in front of and behind the meatus and access to the posterior fossa increased. This approach is more suited to removal of petrous apex lesions such as congenital cholesteatomas or meningiomas, and Wigand et al., who did much to develop this technique, are able to remove VSs with an intracranial diameter of as much 3 cm by this approach.[35, 36]

The key stages in the middle fossa approach are:

1. Skin and soft tissue incisions
2. Middle fossa craniectomy
3. Extradural approach to upper surface of temporal bone and to posterior fossa
4. Skeletonization of internal meatus
5. Identification of facial and vestibular nerves
6. Removal of tumour
7. Closure

DETAILS OF THE MIDDLE FOSSA APPROACH

Position

The patient is supine with the head on a head ring or in a neurosurgical clamp. The essential point is that the intermeatal line should be perpendicular to the floor. This ensures that the internal meatus is in the same plane as the external meatus and assists the surgeon's orientation in identifying the internal meatus. Facial nerve monitoring is routine with auditory monitoring added in cases of attempted hearing preservation.

Incision

A 6–7 cm vertical or gently backward curving incision starts at the level of the zygomatic arch just in front of the pinna. The temporalis muscle is exposed and an inverted T-shaped incision is made though the muscle down to the skull.

Craniectomy

A 5 cm × 5 cm square bone flap is cut with about two-thirds in front of the intermeatal line and one third behind it. The dura over the temporal lobe is exposed. The lower edge of the craniectomy should be at the level of the floor of the middle fossa – it may be necessary to remove further bone down to the floor of the fossa with bone nibblers. Air cells are frequently opened and should be sealed off with bone wax or muscle.

Exposure of upper surface of petrous bone

The dura is elevated off the surface of the petrous pyramid. This is facilitated considerably by the administration of intravenous mannitol at this stage and the dura can be elevated as far medially as the petrous ridge and the superior petrosal sinus. A middle fossa retractor is introduced. As the dura is elevated troublesome bleeding is often encountered from the venous plexus that surrounds the middle meningeal artery in the region of the foramen spinosum. This is controlled with Surgicel packing. As the dura is elevated the greater superficial petrosal nerve is identified running up from the region of the middle meningeal artery to the geniculate ganglion. It is frequently adherent to the dura and may have to be separated from it by sharp dissection. One should also be aware that the geniculate ganglion may be dehiscent in up to 5% of individuals and

at risk of damage as the dura is elevated.[37, 38] The arcuate eminence is the other important landmark to be identified. It corresponds approximately to the superior semi-circular canal.

Location of the internal auditory meatus

There are two favoured approaches to the internal meatus. In the method originally proposed by House, the geniculate ganglion is identified and the facial nerve is followed medially along its labyrinthine segment until the meatus is reached. This method involves drilling between the cochlea anteriorly and the superior semi-circular canal posteriorly. If either of these structures is breached the hearing will be lost. The other approach was suggested by Fisch and others. The angle between the line of the greater superficial petrosal nerve and the plane of the superior semi-circular canal is bisected and that gives the line of the internal meatus. If necessary the superior canal may be blue-lined to establish the exact anatomy of the area, and good quality CT images of the temporal bone will provide the surgeon with important information on the degree of pneumatization that will be encountered as the internal meatus is approached. The internal meatus is skeletonized anteriorly, superiorly and posteriorly. At the lateral end Bill's bar is identified and the ampulla of the superior canal blue-lined. Medially the porus is skeletonized and the dura of the posterior fossa increasingly exposed. Initial drilling of the medial end of the internal meatus is advised, where there is usually more bone overlying the canal, whereas laterally the nerves become more superficial to the middle fossa.[39]

Identification of the facial, cochlear and vestibular nerves

The dura of the meatus is opened longitudinally with scissors as far as the porus and access to the posterior fossa can be gained by opening the dura in front of and behind the porus. The facial nerve is identified in the anterosuperior quadrant of the meatus and is protected under the cut dural edge. The SVN may be seen to be running into the tumour, or alternatively may be seen to be running over the surface of the tumour depending from which branch of the vestibular nerve the tumour arises. The cochlear nerve is concealed under the facial nerve and cannot be seen at this stage. If the tumour does reach right to the fundus, identification of the neural structures lateral to the tumour is easier. Careful positioning of the retractor under the superior petrosal sinus usually provides adequate access into the posterior fossa where the medial pole of the tumour and the facial and vestibulocochlear nerves are identified. It is rarely necessary to divide the sinus. As mentioned previously it takes the surgeon considerable experience to picture these three-dimensional relationships in his or her mind.

Tumour removal

The principles of tumour removal are no different from those outlined in the description of the translabyrinthine approach. The surgeon must recognize that the facial and cochlear nerves lie in the arachnoid plane. Debulking of the inside of the tumour can proceed safely, both inside the meatus and in the posterior fossa. One major difference from the translabyrinthine approach is that the facial nerve lies between the surgeon and the tumour and is thus more vulnerable to damage from instrumentation. When the stage of dissection of the capsule of the facial and cochlea nerves is reached, it is important to remember that the forces applied to the tumour should be in a medial to lateral direction in order to minimize stretching effects on the fibres of the cochlear nerve as they pass through the basilar membrane at the *habenula perforata*.

Closure

The internal meatus is closed with a free muscle plug. A couple of dural hitch stitches are inserted to minimize the risk of an extradural collection, the free bone flap is replaced and secured with non-absorbable ties and the muscle and skin closed in layers.

Retrosigmoid approach

This approach has evolved from the classic suboccipital operation that was favoured by neurosurgeons for the removal of all posterior fossa tumours but particularly for large ones. A very large portion of the occipital bone was removed, from the transverse sinus above to the foramen magnum below and from the sigmoid sinus laterally to the midline. Such a large craniectomy is now rarely necessary and a much smaller retrosigmoid craniectomy of around 5 cm × 5 cm allows good access to the posterior fossa, although the exact amount of bone removal will depend upon the preference of the surgeon and the size of tumour to be removed. The advantage of the retrosigmoid/suboccipital approach is that it allows the possibility of hearing preservation in small tumours. The disadvantage is that, especially for large tumours, considerable cerebellar retraction may be necessary, and even on occasion resection of part of the cerebellar hemisphere. Kim et al.[40] report, however, that the significantly greater cerebellar retraction that is necessary for retrosigmoid surgery does not result in greater long-term balance and disability as compared with those patients who have undergone the translabyrinthine approach.

Post-operative headache is more common with this approach than with the translabyrinthine operation.[41, 42] The mechanism is unclear, although several have been proposed including dural irritation around the IAM, adherence of scalp flap to the dura, extent of dissection of the neck muscles and occipital nerve injury.[43–45] If the facial nerve is lost near the fundus of the internal meatus, it is virtually impossible to perform a primary nerve grafting procedure.

DETAILS OF THE RETROSIGMOID APPROACH

Positioning

The operating position depends on preference. Neurosurgeons will favour the lateral position or park-bench position with or without the use of a clamp.

The sitting position has largely been abandoned in the UK because of the risk of air embolus if the venous sinuses are opened. It does have the considerable merit of enhanced visibility for the surgeon as gravity keeps the field clear of CSF and blood. Neurotologists may find that the supine position with the head turned to the opposite side provides access just as easily. Facial nerve monitoring electrodes will be in place, as will electrodes for intra-operative recording of auditory evoked potentials in cases where hearing preservation is the aim.

Incision

A vertical or slightly curving incision is made about 3 cm behind the mastoid process, from above the level of the transverse sinus to the level of the tip of the mastoid. The soft tissues may be incised down to the bone, but the authors prefer to maintain a superiorly based musculoperiostial flap to assist in the closure.

Craniotomy and exposure of the tumour

A 5 cm × 5 cm craniotomy is made using the drill, taking the mastoid emissary vein as the starting point, and the bone dust is retained for closure. The anterior and superior limits of bone removal are the sigmoid and the transverse sinuses respectively. It is essential to get as close to the sigmoid sinus as possible so that the surgeon's line of sight is along the posterior surface of the petrous pyramid. As the drilling progresses, any mastoid air cells encountered must be closed using bone wax or muscle, to minimize the risk of post-operative CSF leakage. The extent of bone removal required is to some extent determined by the size of the tumour; some advocate completing the craniotomy to the level of the foramen magnum, allowing wider exposure and enabling access to drain CSF. The dura is opened through a U-shaped flap based anteriorly on the posterior edge of the sigmoid sinus and the cerebellar hemisphere is exposed. In order to get good exposure of the tumour, CSF must be run off from the CPA, usually initially by accessing the cisterna magna. This is not always easy as the cerebellum is in the way, but with gentle retraction and reduction of the intracranial pressure by the anaesthetist, this is achievable and an instrument can be passed into the subarachnoid space. Now the cerebellum falls away under its own weight and if the surgery is for a small tumour, as in a hearing preservation operation, little retraction is needed (**Figures 103.7** and **103.8**).

Tumour removal

The previously outlined principles apply. Intracapsular debulking is safe and allows one progressively to handle the capsule of the tumour. It is desirable to identify the facial and audiovestibular nerves on the brainstem as soon as possible, and to note the position of AICA. The intracranial part of the tumour can be dissected off the facial and audiovestibular nerves back to the porus of the internal meatus, but for complete tumour removal the IAM must be drilled out. One of the principles of tumour removal for hearing preservation is that dissection should be in a medial to lateral direction in order to avoid traction on the fibres of the cochlear nerve as they pass from the cochlea through the habenula perforata into the internal meatus.

Drilling of IAM

A dural flap should be elevated over the IAM. This may be based either laterally or medially. The medially based flap has the advantage that it may be turned in over the facial and auditory nerves for protection during the drilling. The internal meatus should be skeletonized above, behind and below, though at least 180 degrees and as far laterally to the fundus as possible. The obstacles to this are the jugular bulb if it is high, and the posterior semi-circular canal.

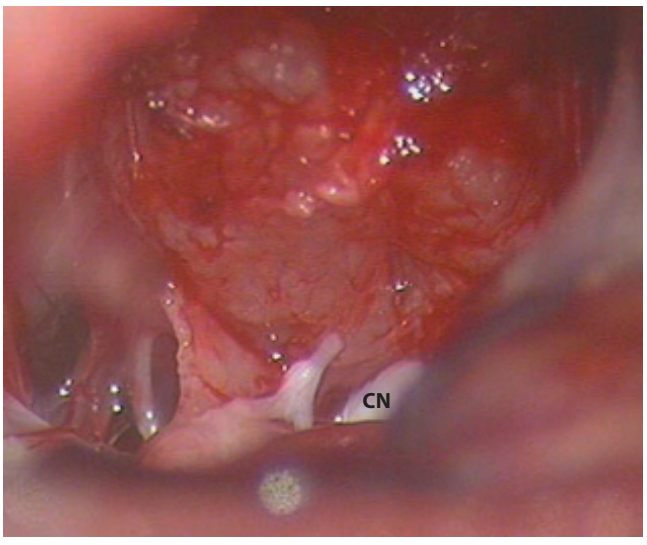

Figure 103.7 Retrosigmoid approach, left ear. Small tumour with cochlear nerve (CN) seen at medial pole.

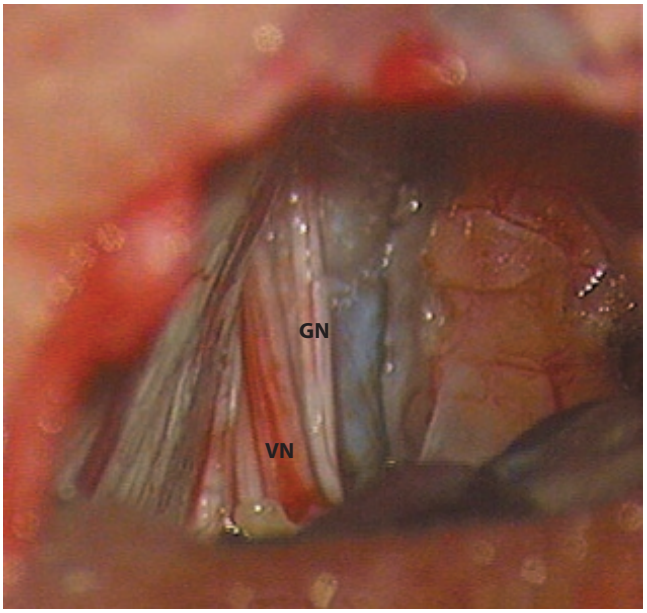

Figure 103.8 Retrosigmoid, left ear. Lower cranial nerves seen below lower pole of tumour. GN, glossopharyngeal nerve; VN, vagus nerve.

A high bulb is more difficult to depress through the retrosigmoid approach than in the translabyrinthine operation. Opening the posterior semi-circular canal is not important unless hearing preservation is intended. The surgeon must look out for the blue line of the canal and avoid it. The combination of a high bulb and an unfavourably placed posterior canal can make the surgical view to the fundus almost impossible. When the bony removal is complete the dura of the internal meatus is opened and tumour removal continues in a medial to lateral direction. If there is a decrease in the magnitude of the auditory brainstem response (ABR), dissection should be halted and local vasodilating agents such as papaverine applied to the vessels in the IAM. As stated above, despite one's best efforts, it may be impossible to see right to the fundus and the last fragment of tumour may have to be removed 'blind'. This manoeuvre clearly carries a risk of damage to the facial and cochlear nerves, and of course there is the risk that tumour may be left behind at the fundus. Some surgeons find it useful to inspect the fundus with a 30 degree fibre-optic rigid endoscope to ensure completeness of removal.[46] Complete endoscopic tumour dissection through a 'key-hole' retrosigmoid craniotomy has also been described.[47]

Closure

After haemostasis is achieved, any remaining air cells are obliterated with bone wax. The dural flap is repaired as far as possible. The repair may be strengthened with fascia or with artificial dura. Steps should be taken to ensure, as far as is possible, that the subcutaneous soft tissues do heal directly on to the dural repair. The authors mix up a pâte of bone dust and tissue glue, which sits on the dural repair and fills the bony defect. A separate periostial flap is then used to cover the pâte repair and the skin and subcutaneous tissues are closed in layers. Hydroxyapatite cement has been used successfully to repair the drilled bony defect in the porus acousticus as a method of preventing CSF rhinorrhoea.[48]

EXTENDED OR COMBINED APPROACHES

There are occasions when extended approaches are applicable, whether via a translabyrinthine approach with transtentorial extension or by utilizing a retrolabyrinthine approach combined with a retrosigmoid and middle fossa bone removal. Occasionally it may be advisable to stage the surgery for very large tumours, with a primary debulking operation and subsequent 'completion'.[49] However, it is quite possible that the 'second stage' may be delivered as single fraction radiotherapy, should the remnant grow.

NOTE ON THE AUDITORY BRAINSTEM IMPLANT

The auditory brainstem implant is increasingly used to rehabilitate patients with neurofibromatosis type 2 (NF2) who are totally deaf and have no functioning cochlear nerves as a result of their bilateral VS or the surgery to remove them. The auditory brainstem implant electrode array comprises 21 small disc electrodes mounted on a Silastic paddle, which is placed onto the surface of the cochlear nucleus. This is found in the floor of the lateral recess of the fourth ventricle, which is entered through the foramen of Luschka. The procedure is usually performed as a combined operation following tumour removal, via either a translabyrinthine or a retrosigmoid approach. The foramen is located by following the glossopharyngeal nerve upwards and the stump of the VIIIth nerve if present downwards. The choroid plexus is seen emerging from the foramen. The taeniae of the fourth ventricle may have to be divided and there is often an arterial loop that has to be moved to one side. The cochlear nucleus is identified by its very white colour and by a fairly constant thin vein that runs over its surface. Intra-operative neural responses using electronically evoked auditory brainstem responses (eABR) are performed to ensure optimal placement of the whole paddle.

OUTCOMES AND COMPLICATIONS

The two key determinants of outcome and complications in VS surgery are the size of the tumour being removed and the experience and surgical skills of the team removing it. Not surprisingly the bulk of the literature on this subject emanates from experienced centres reporting their results: this in effect represents the benchmark for outcomes and complications. Evidence of surgical outcomes from teams undertaking occasional VS surgery are limited. However, the evidence as it exists shows adverse outcomes and higher complication rates when parameters such as death, facial nerve function and CSF leak rates are examined.[50, 51] The evidence for centralisation in NF2 care is certainly strong.[52]

Following enthusiasm from many quarters and the agreement of the British Skull Base Society and the Society of British Neurosurgeons, mandatory data collection for a national audit in VS management is now ongoing in the UK (https://orioncloud.org).[53]

The single most important factor in all studies quoting facial nerve and hearing preservation and extent of resection is the tumour size.[54] Many feel that there is a difference in outcomes between solid and cystic tumours, with cystic ones faring less well with surgery.[55–57] This is by no means universal.[58] It is commonly believed that they are also less successfully treated with radiotherapy.

Facial nerve outcomes are of the utmost importance to the patients, and multiple attempts to improve prognostic information for pre-operative counselling as well as post-operative prediction have been made. Reviewing the pre-operative imaging, the size of the tumour, the anterior extent and the shape have all been correlated with poorer facial function.[59] Intra-operative neurophysiological stimulation has been used with some success to try and predict the degree of facial dysfunction post-operatively.[54, 60–66]

Complications after VS surgery are quite frequent but the vast majority of patients undergoing tumour removal do not suffer any significant long-term sequelae. As complications and outcome are inextricably linked, the two are considered together.

Death, stroke, haemorrhage, brain injury

As indicated earlier in this chapter, the early results of VS surgery were not encouraging, with peri-operative mortality of over 80%.[12] The efforts of Cushing,[13] Dandy[14] and Pennybacker and Cairns[15] brought the death rate down to more acceptable levels, but it was not until the era of microsurgery in the 1960s that it really came down the levels we see today, at around 1% or less in specialist centres.

The actual causes of death have not changed much over the years: vascular events and their effects on the brain and general medical complications associated with major surgery such as myocardial infarction, pulmonary embolus and pneumonia. A meta-analysis including over 30 000 operations for VS focusing on non-audiofacial outcomes showed an overall mortality rate of 0.2%. Approximately 20% of patients experienced one surgically attributable complication.[67] The likelihood of serious vascular events is for the most part related to tumour size and is considered in more detail below.

ARTERIAL BLEEDING

Vigorous arterial bleeding is not a common occurrence during VS surgery. The surgeon must of course take great care to identify and protect the major arterial systems in the posterior fossa, notable the anterior and posterior inferior cerebellar arteries (AICA and PICA) and the superior cerebellar artery (SCA). Gentle handling of tissue, adherence to correct tissue planes and the avoidance of traction are essential. If serious bleeding does occur it must, of course, be controlled with the minimum of damage to the arterial tree, and precise identification of the bleeding point. A small side hole in even a large vessel can often be controlled with skilful and accurate use of the bipolar diathermy. Alternatively, minor degrees of arterial bleeding may be controlled by application of a piece of muscle to the affected site. Serious injury to the main trunk of AICA requiring clamping is of grave significance and carries a high risk of death. It is fortunately excessively rare. Less uncommon is damage to more distal branches of AICA. The extent of brainstem damage in the event of loss of these vessels is variable and depends on the degree of anastomosis from PICA and SCA. It may give rise to fatal infarction of the lateral tegmental pons or the damage may be confined to the cerebellar peduncle, as pointed out by Hegarty et al. (**Figure 103.9**).[68] This may result in serious gait, balance and co-ordination problems. The distal branch in question may loop into and out of the IAM. The vessel must therefore be identified, separated from the tumour and preserved in order to avoid these potential problems. Feeding vessels from branches of AICA to the tumour may be cauterized close to the tumour but, as a rule, every attempt is made to preserve all arterial vessels encountered by remaining in the arachnoid sheath between the tumour and the neurovascular structures of the posterior fossa.

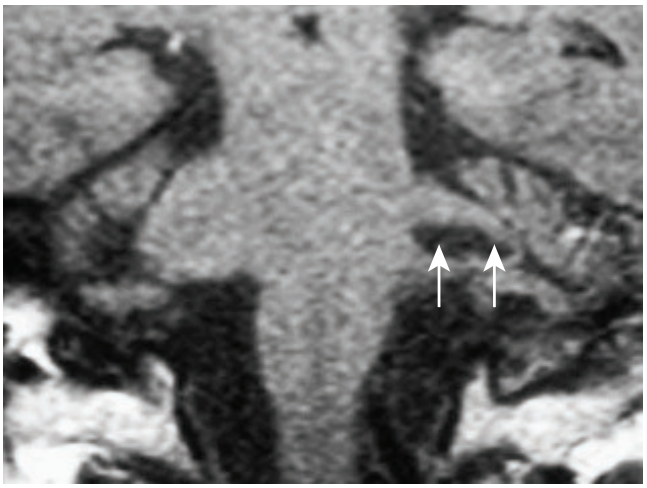

Figure 103.9 Peduncular infarct (arrowed).

VENOUS BLEEDING

Troublesome venous bleeding may occur during the petrosectomy in the translabyrinthine approach and during tumour removal itself. Bleeding from the mastoid emissary veins is readily controlled by a combination of bipolar cautery and the use of bone wax. During the skeletonization of the lateral, sigmoid and superior petrosal sinuses and the jugular bulb, inadvertent injury to the dura of these structures gives rise to dramatic venous haemorrhage. Despite this, careful use of haemostatic mesh (Surgicel) over the tear with compression using bone wax and a neurosurgical cottonoid usually solves the problem and allows the procedure to continue, as the dural sinus veins are a low-pressure system. Care must be taken to prevent air embolism but it should be emphasized that this is an exceptionally rare occurrence, especially since the sitting position for surgery has been abandoned in the UK. Excessive compression of the jugular bulb should be avoided as it may give rise to lower cranial neuropathies. In the experience of the authors it has never been necessary to ligate the lateral venous sinus or the internal jugular vein in the neck to control bleeding from the venous sinuses encountered during the petrosectomy.

During tumour removal itself, the petrosal vein (Dandy's vein) is invariably encountered. This fragile vein drains the brainstem and cerebellar hemisphere and is a tributary of the superior petrosal sinus. It is easily torn during tumour dissection and it is mostly safe to clip or cauterize and divide the vein rather than have to deal with the troublesome back bleeding from the superior petrosal sinus.[69]

Finally, numerous often quite substantial veins are encountered between the arachnoid sheet and the brainstem. These are best dissected away from the tumour and then coagulated if necessary, but the surgeon must be aware of the risk of venous infarction of the brainstem from the indiscriminate sacrifice of these vessels. Overall, while venous bleeding can be troublesome and occasionally dramatic, it is rare for it to lead to hypovolaemia and it is very uncommon to have to transfuse a patient during a VS resection. Finally, the incidence of air embolism during

VS surgery has declined significantly since the almost universal adoption of the supine or lateral position of the patient as opposed to the sitting position.

POST-OPERATIVE HAEMATOMA

The risk of a post-operative haematoma is greatest in the first 72 hours after the operation but continues for about a week. Failure to regain consciousness after surgery is the classic sign of a posterior fossa haematoma and necessitates immediate re-exploration of the operative site. Signs of a delayed haematoma in a patient who has already woken up from the anaesthetic include progressive hypertension, bradycardia, reduction in consciousness level and alterations in pupil size and reactivity. These signs should be recognized by assiduous post-operative neurological observation and recording of the Glasgow Coma Scale. If time permits, a CT scan will confirm the diagnosis but in the rapidly deteriorating patient immediate return to theatre and evacuation of the haematoma is required to save the patient's life. When the translabyrinthine approach has been employed, the wound can be reopened in the ward or the recovery room and the abdominal fat removed. This may bring about a rapid improvement in the patient's neurological status, and he may then be returned to theatre for more leisurely haemostasis.

Ventricular haemorrhage, whether intra-operatively or after surgery, is a rare but very serious complication. External ventricular drainage may help but the condition carries a high risk of death.[70]

In contrast, a small haematoma without neurological sequelae may be managed conservatively, and be left to reabsorb naturally. The incidence of serious post-operative haematoma is approximately 1% and contributes to the overall mortality risk of this type of surgery.[67]

BRAIN INJURY

Cerebellum

The cerebellum is at risk of injury during opening of the dura of the posterior fossa and during tumour removal itself. The mass effect of a large tumour will push parts of the cerebellum against the overlying dura, compressing the cerebellar surface vessels. Minor degrees of venous injury are tolerated without problems but more substantial injury is likely with prolonged cerebellar retraction during retrosigmoid surgery. A degree of encephalomalacia of the superficial lateral part of the cerebellar hemisphere is frequently noted on post-operative MR imaging, though this does not usually give rise to any clinical manifestations.[40] The surface of the cerebellum may become oedematous during removal of large tumours but the historic procedure of resecting the lateral one third of the cerebellum for access and creation of space for post-operative swelling is rarely required now with modern surgical and anaesthetic techniques. Less commonly, parenchymal injury or oedema extends into the deeper parts of the cerebellum. This may signify venous insufficiency of the cerebellum or a cerebellopontine haematoma. This type of injury may well leave the patient with prolonged or permanent ataxia.

Brainstem

Direct injury of the brainstem is avoided by maintaining the subarachnoid plane between the tumour and the brain. In small and medium-sized tumours the plane between the brain and the tumour is usually easily identified and adhesions between the two tend not to be particularly dense and are readily divided. As discussed above, vascular injury is avoided by careful dissection and preservation of arterial anatomy. With larger tumours, however, there is often a degree of malacia of the brainstem due to prolonged compression by the tumour. In these instances the brain is very soft and breach of the pial layer can occur easily. In addition, ischaemia of the brainstem due to traction during tumour removal may give rise to bradycardia or even asystole. Both respond to cessation of dissection of that particular part of the tumour and appropriate intra-operative resuscitative measures. Rarely, the procedure needs to be abandoned due to persistent changes in the vital signs. Direct injury of the brainstem parenchyma is uncommon and the more likely cause of serious or fatal injury is secondary ischaemia consequent to the tumour dissection or injury to vessels such as the AICA as described above.

Temporal lobe and seizures

Seizures after translabyrinthine or retrosigmoid surgery are extremely rare. This, however, is not the case for transtemporal (middle fossa) tumour removal. The middle fossa approach (invariably in an attempt to preserve hearing with a small tumour) involves extradural retraction of the temporal lobe. This carries a risk of seizures, as noted by the authors in two cases.[34] While the fits did not lead to a residual neurological deficit, in both instances the patients were legally obliged to refrain from driving until they were fit-free for a year. Long-standing electroencephalographic changes have been reported[71] in patients undergoing middle fossa VS surgery. In addition, injury to or occlusion of the vein or veins of Labbé, which drain the inferior and lateral temporal lobe, carries the risk of venous temporal lobe oedema and infarction leading to seizures, dysphasia or even loss of life. These veins drain into the distal transverse sinus so are potentially at risk from excessive packing of the proximal lateral venous sinus in order to control bleeding during translabyrinthine or retrosigmoid surgery.

Cranial neuropathies

FACIAL NERVE

Of all the potential sequelae of VS surgery, without doubt the one concern raised by patients above all others is that of post-operative facial function. Most patients expect to survive their operation, be free of disability and be tumour free. It is their facial function that is usually at the forefront of their minds. On this basis, a full and frank discussion with reference to one's own facial nerve outcomes is required in order to secure informed consent for the surgery. Facial nerve preservation refers to

anatomical preservation of the facial nerve, while facial function refers to the physiological function of the nerve at a defined time post-operatively. Both are determined largely by tumour size and experience of the surgical team and, to a lesser but important degree, by the nature of the tumour (solid or cystic)[55–58] and the surgical philosophy of the team. The latter is important. Those surgeons who attempt to remove every last bit of tumour may well find their facial nerve outcomes are less favourable than those who have a low threshold for leaving tumour remnants in order to maintain the anatomical and functional integrity of the nerve.[72–75] It is vital, therefore, when examining facial nerve outcomes, to put the results in context: what is the rate of residual or recurrent tumour in the series that is being studied? In the experience of the authors, if a small nubbin of tumour is particularly adherent to an attenuated facial nerve (often just medial to the porus of the internal meatus) then it reasonable to leave this remnant in order to preserve the facial nerve. Usually, imaging a year later shows the nubbin to have disappeared. If it has not disappeared, serial imaging almost invariably shows the size of the residuum to have remained static.[29]

Facial function is assessed using a grading system, of which the House-Brackmann (HB) system is the most common in general use and relatively easy to use. Nevertheless it is far from perfect and suffers the same criticism that is applicable to any system that tries to fit a dynamic spectrum of movement into a finite number of categories (in the case of the HB system, six categories).

Stratifying the patients by tumour size is helpful in presenting facial nerve results. For intracanalicular tumours and tumours with a maximum intracranial diameter on imaging of less than 1.5 cm, most large series publish facial nerve anatomical preservation rates approaching 100%.[76–78] This is in keeping with the authors' series in which loss of the facial nerve is rare when removing such small tumours. Facial function outcomes for this group is between 80% and 95% HB grade I or II. At this juncture a comment about what constitutes a good facial outcome is required. From the patient's perspective, anything less than normal facial function post-operatively represents a less than ideal outcome. However, the patient will invariably take into account the size of the tumour that he or she presents with (as will the surgeon when counselling the patient) and with larger tumours, HB grade II or even III may be considered satisfactory. When reporting results, therefore, by convention most surgeons consider HB grade I or II as a satisfactory outcome. HB grade III is not a satisfactory outcome for small or medium-sized tumours, though some surgeons fail to appreciate this point when presenting their results.

For medium-sized tumours (maximum intracranial diameter 1.6–2.5 cm), anatomical facial nerve preservation rates fall to around 90% with HB grade I or II outcomes between 80% and 90%.[78, 79] An interesting observation occurs for tumours greater than 2.5 cm intracranial diameter: the facial nerve outcomes decline in an almost inverse linear proportion to the size of the tumour.[80–82] However, this threshold may change with increasing experience of the surgeon. A meta-analysis of more than 10 000 patient outcomes showed a cut-off of 20 mm.[54] Overall, for large and giant (more than 4 cm) tumours, anatomical preservation of the nerve occurs in between 65% and 80% with normal or good facial function (HB I or II) in 50–70%.[83–85]

In assessing facial function, consideration must be given to synkinesis, either the involuntary closure of the eye when the patient smiles or eats or, less commonly, unwanted movement of the corner of the mouth in time with blinking. The phenomenon may detract from an otherwise good facial nerve outcome and cause the patient considerable distress. The judicious use of botulinum toxin may be necessary to minimize this phenomenon. The development of a multidisciplinary facial palsy service in centres offering skull base surgery has allowed improvements in the rehabilitation of patients with facial palsy.[86]

NERVUS INTERMEDIUS

The importance of the function of the nervus intermedius (NI) is perhaps overlooked when reporting the results of VS surgery. Understandably, the nerve is not in the forefront of the surgeon's mind when trying to remove a large tumour and preserve the facial nerve itself. Nevertheless, the morbidity of loss of NI function should not be underestimated. Difficulties with a dry eye (even with normal facial and trigeminal function), altered taste and dryness of the nose and mouth can be very troublesome for the patient.[87] Aberrant re-innervation leading to gustatory tearing can also be troublesome. Attempts should be made to preserve the nerve, though with larger tumours it is often impossible to identify it as a separate entity.

TRIGEMINAL NERVE

Tumours of less than about 2 cm intracranial diameter do not usually come into contact with the trigeminal nerve, which lies antero-superiorly and medial to the tumour. Smaller tumours may stretch the trigeminal nerve as the brainstem is displaced to the opposite side of the posterior fossa. Inadvertent injury to the trigeminal nerve during the removal of small and most medium-sized tumours is rare. For larger tumours, however, there is invariably indentation, stretching and compression of the trigeminal nerve to some degree. This may or may not be associated with trigeminal symptoms pre-operatively. Even large tumours do dissect off the nerve fairly easily in most instances, however, particularly if the surgeon remains within the arachnoid plane between the tumour and the nerve and therefore the incidence of trigeminal symptoms post-operatively lies between 3% and 15%.[88] Such damage can have grave consequences for the eye if there is a concomitant facial weakness, as the loss of corneal sensation with a dry eye (nervus intermedius) and incomplete eye closure puts the unprotected cornea at risk of ulceration leading to loss of vision.

ABDUCENS AND TROCHLEAR NERVES

Palsies of these two oculomotor nerves are uncommon.[84] The abducens nerve may be inadvertently injured during packing of the superior petrosal sinus for control of

haemorrhage from the sinus or from anterior tumour dissection. The resultant paresis invariably recovers over a period of several weeks to a few months. Damage to the trochlear nerve is extremely uncommon although in theory it may be at some risk of injury during anterosuperior tumour dissection towards the free edge of the tentorium cerebelli.

LOWER CRANIAL NERVES

Injury to the lower cranial nerves may cause significant morbidity and a protracted hospital stay, due to the effects on swallowing and the competency of the upper airway. The glossopharyngeal, vagus and accessory nerves are at risk during two stages of surgery: the petrosectomy during translabyrinthine surgery; and during the removal of the inferior pole of the tumour. The relationship of the internal meatus, the cochlear aqueduct, the jugular bulb and the lower nerves has been described above. By keeping above the cochlear acqueduct during skeletonization of the IAM, and by avoiding over-compression of the jugular bulb, damage to these nerves should be avoided.

In small and medium-sized tumours, the intracranial tumour resection puts the lower cranial nerves at almost no risk as long as the nerves are identified early in the procedure. With larger tumours the multiple nerve rootlets of the glossopharyngeal and vagus nerves are stretched and splayed over the inferior pole. Dissection of the tumour off these nerves is usually straightforward and their function is therefore almost invariably preserved. Post-operative lower cranial nerve palsies are uncommon (less than 1%) except in revision cases when fibrosis and distortion of the anatomy can make the dissection more difficult. In such instances, and in larger tumours, electrophysiological monitoring of the vagus using electrodes on the endotracheal tube (NIM TriVantage® EMG Tube) as well as the XIth and XIIth nerves should be considered. Finally, during surgery, manipulation of the IXth and Xth nerves can cause profound but temporary bradychardia and even asystole, and the anaesthetist needs to be warned when dissection of the lower pole of the tumour is taking place.

CSF leakage

Leakage of CSF after VS surgery is the commonest significant post-operative complication. CSF leak rates reported in the literature vary depending on the approach, the size of tumour, the extent of petrous bone pneumatization and primary versus revision surgery.[89–91] The literature is conflicting when comparing the incidence of CSF leakage after translabyrinthine, retrosigmoid and transtemporal approaches – several studies cite no difference and others cite a higher incidence after translabyrinthine surgery, while others cite a higher incidence after the retrosigmoid approach.[42, 67, 90–92] The leak may be classified as minor (requiring no additional surgical procedure to deal with it) or major, necessitating a return to theatre. A subcutaneous scalp collection of CSF with or without leakage through the wound is considered a minor leak, as it is usually remedied with reapplication of a firm pressure dressing and an additional full-thickness scalp suture at the site of leakage, which is often at the bottom end of the wound. Such collections and leaks tend to occur within the first week of surgery and can be dealt with at the bedside, without a need to return the patient to theatre. In addition, continuous lumbar CSF drainage for 3–5 days usually solves this problem. The latter may be used electively after all VS surgery or in response to scalp collections or leaks that persist despite the conservative measures described above. Lumbar drains, however, are not without their own problems. They inherently incur a degree of immobility in the patient at a time when one would wish to encourage mobilization to enhance vestibular rehabilitation and reduce the risk of venous thrombo-embolism. In addition, the drain represents a portal for sub-arachnoid infection and may lead to pneumocephalus if there is entry of air from the nasopharynx through the temporal bone into the posterior fossa as the CSF is siphoned off.[93] Pneumocephalus may lead to a significant neurological deterioration, particularly if the air collects in the ventricles or is under tension. The use of lumbar drains after VS surgery is therefore not universal and evokes debate amongst surgeons who undertake this type of surgery.

It has also been postulated that the inflammation associated with meningeal irritation may result in a spontaneous resolution of CSF rhinorrhoea post-operatively. This has not been our experience and we would advocate early intervention with reoperation and blind sac closure, combined with lumbar CSF drainage if necessary.[94]

Revision surgery and surgery following failed radiotherapy is considered more risky and results in poorer outcomes.[95]

CSF otorrhoea

An intact tympanic membrane at the time of surgery should guard against any leakage of CSF via the external meatus. Any injury to the tympanic membrane or external ear canal skin during VS surgery is rare. CSF otorrhoea has, however, been described in relation to the use of bioglue to seal the Eustachian tube opening and the middle ear.[32] The glue had led to an acute myringitis with perforation of the tympanic membrane and additionally failed to prevent CSF entering the middle ear.

CSF rhinorrhoea

Leakage of CSF through the temporal bone air cells via the Eustachian tube into the nasopharynx remains a troublesome complication that invariably prolongs the patient's hospital stay and often necessitates a return to theatre. Ultimately the leak has to be stopped lest the patient develops intracranial infection. In the retrosigmoid approach the air cell system is most commonly opened posterior to the lateral venous sinus and around the IAM. In both instances most surgeons utilize bone wax to obliterate these cells in an attempt to seal communications between the CPA and the temporal bone. During translabyrinthine surgery the temporal bone surgery is much more extensive

and air cell tracks anterior to the IAM and around the jugular bulb are potential conduits for CSF to enter the middle ear or Eustachian tube directly. In addition, subluxation of the stapes may have the same effect. On this basis several methods to reduce the risk of CSF rhinorrhoea have been described by various surgeons, illustrating that no single method is universally successful. These include using pieces of muscle, fat, fascia, bone wax and tissue glue to seal the areas described. In addition, some surgeons advocate routine lumbar drainage for a few days post-operatively.

Interestingly, there is evidence that despite packing the Eustachian tube at the time of surgery, the middle ear regains ventilation via the tube and, in addition, packing of the tube or waxing opened mastoid air cells didn't result in a reduction of CSF rhinorrhoea.[89, 96] However, like others, it is our practice to ensure the Eustachian tube is tightly packed and the middle ear cleft filled with fat.

Finally, there is the occasional patient who, despite all measures at primary and subsequent surgery, continues to suffer CSF rhinorrhoea. In these instances (less than 1%) the only remaining option is to undertake permanent CSF diversion such as a lumbo-peritoneal or ventriculoperitoneal shunt. It is postulated that in these patients there is a subclinical post-operative hydrocephalus that drives the persistent leak.

Intracranial infection

MENINGITIS, ENCEPHALITIS, CEREBRITIS

Meningitis after VS surgery is one of the more common serious complications occurring in 1% to 5% in the reported larger series.[79, 97] It is invariably associated with CSF leakage (usually rhinorrhoea) and may occur within the first week of surgery or as a delayed event weeks or even months later. In the latter situation the CSF leakage may have passed unnoticed by the patient and the surgeon. Most VS surgeons give prophylactic peri-operative antibiotics empirically as there is no formal evidence that this measure reduces the incidence of post-operative infections. The diagnosis requires clinical vigilance as headache and neck stiffness are not uncommon after VS surgery.[41] In addition, many patients develop low-grade pyrexia within the first week after surgery, which in part may be due to an aseptic meningeal irritation due to blood, air and bone dust in the subarachnoid space. If any doubts exist, a lumbar puncture will confirm the presence of a leucocytosis, though the causative organisms are often not isolated or cultured. The treatment regimen will vary from institution to institution but parenteral Vancomycin and Ceftriaxone are the current first-choice empirical treatment. CSF culture will guide ongoing management and, if sterile after 3–7 days, a diagnosis of aseptic meningitis can be made and the antibiotics stopped. This treatment schedule almost invariably resolves the problem, although rarely the infection may progress to a fulminant encephalitis or cerebritis, both of which carry a high mortality.

OUTCOMES

Tumour extirpation: Residual/recurrence

In the majority of cases undergoing VS surgery, the aim is to remove the tumour completely while maintaining perfect facial nerve function. It was previously thought unacceptable to subject the patient to the inherent risks of this type of surgery and then not remove the tumour in its entirety. However, it is fair to say that this philosophy has changed. While total removal has the obvious benefit of reassuring the patient that their tumour has gone and there is very little chance of recurrence, the evidence is very clear that the facial nerve outcomes are worse when comparing near-total to subtotal, and again in total versus near-total.[75]

There are instances where a planned subtotal removal procedure is reasonable: in patients with large tumours giving rise to hydrocephalus in the elderly; or in those who have concomitant medical problems that necessitate as short a procedure as possible. The residual tumour in these instances can then be monitored with serial imaging and the residuum dealt with by way of further surgery or stereotactic radiotherapy if it grows to a size that once again requires intervention.

The impression of the operating surgeon as to the extent of resection when a 'subtotal resection' has been performed is open to interpretation. It is considered important to document the size of the residual tumour with early post-operative contrast-enhanced MRI.[81] In addition, the post-operative imaging in patients who have undergone incomplete removal often shows no enhancing tissue at all.[28]

Following presumed gross total excision there is a documented rate of recurrence. Despite expecting it to be zero, it has been shown to be in the order of 1–3%. However, it goes without saying that a higher rate of recurrence is expected in situations where a visible quantity of tumour remains, either in subtotal removal or near-total removal, where in both there is lack of clarity as to what exactly is meant. Subtotal removal suggests a solid mass of tumour is left, whereas in near-total removal a linear remnant adherent to the facial nerve is all that remains. One series reporting rates of regrowth showed 3% of patients subjected to gross total excision had regrown, compared to 21% and 22% regrowth rates for near-total and subtotal resections respectively.[72] Choosing to stop tumour dissection short of obtaining a complete resection is usually a consequence of maintaining good facial nerve function. However, in addition to the facial nerve, attempting to preserve integrity of the cochlear nerve and functional hearing may impair a complete resection. This is more often the case in the middle fossa approach because the bone drilling required to visualize this area directly puts the inner ear structures (and therefore the hearing) at risk and tumour removal at the fundus is almost a blind procedure.[98] Intra-operative endoscopy may help in this situation.[46, 99] Finally, there is some debate about the frequency and length of imaging follow-up needed after surgery

before declaring the patient tumour-free. Practice varies from a single scan 1 year post-operatively (as advocated by the authors) to imaging 2, 5 or even 10 years after the surgery.

Hospital stay

The median hospital stay for patients undergoing VS surgery under the care of the authors is 7 days. The literature varies citing a hospital stay of between 5 and 10 days if the immediate convalescence is uncomplicated.[19] The commonest cause of delay in discharge from hospital is CSF leakage, particularly CSF rhinorrhoea. Management of this complication invariably prolongs the hospital stay, particularly if further surgery is required to rectify the leak. One study calculated an additional 13.3 days in hospital in patients who developed post-operative CSF leak.[32] The two causes of a more prolonged hospital stay (several weeks or more) are bulbar symptoms due to brainstem injury or lower cranial neuropathies and the development of meningitis.

Vertigo/balance/return to work or previous physical activity

Many patients with a VS describe a period of vertigo, dysequilibrium or imbalance when questioned directly about pre-operative symptoms. The gradual reduction in vestibular function on the affected side due to the tumour is compensated for by the opposite vestibular end organ, vision, proprioception and the central nervous system such that day-to-day balance is rarely a problem for most individuals before surgery.

Post-operative balance problems depend on the degree of pre-operative impairment, with those with a complete canal paresis on caloric testing seemingly unfazed by the loss of vestibular function. However, those with a functioning labyrinthine system pre-operatively have acute vestibular failure with a paralytic nystagmus and are functionally much worse for a few days until compensation can occur.[100] Other than for initial symptomatic relief, vestibular sedatives should therefore be avoided to allow for this process to occur. In addition, the implementation of vestibular-ocular reflex exercises further accelerates the rate of compensation.[101]

In an attempt to mitigate the impact of acute vestibular failure in patients undergoing translabyrinthine surgery for VS, a chemical labyrinthectomy with intratympanic gentamicin and focused vestibular exercises (prehab) have been shown to reduce vestibular dysfunction immediately after surgery, but also longer term.[102, 103]

In those individuals who have already slowly lost much of their vestibular function due to the tumour, the post-operative vertigo may be minimal. Over the ensuing weeks and months the majority of patients find that their balance recovery is such that they can resume their pre-operative occupation or return to a comparative level of physical activity.[104] However, as expected, an individual with a complete unilateral vestibular deficit cannot be expected to have perfect balance and this may be more noticeable in the dark or with sudden movements. The patient's perception of their balance dysfunction is important, with over 10% perceiving disequilibrium as disabling.[100] Patients with occupations that rely on fine balance therefore need to be counselled in this respect.

Tinnitus

Unilateral tinnitus is one of the cardinal symptoms of a VS. Occasionally it represents the sole presenting symptom.[105] Tinnitus probably remains the most troublesome symptom following surgery for VS. Most clinicians advise that patients presenting with tinnitus are very likely to have persistence of their tinnitus post-operatively and studies support this viewpoint.[106–108] An interesting observation described is that of gaze-evoked or enhanced tinnitus after VS surgery. This is probably a rewiring phenomenon in the brainstem.[107, 109]

Hearing preservation

In discussing the possibility of hearing preservation, a number of issues need to be considered. The commonest presenting symptom of VS is unilateral hearing impairment. As in any hearing impairment, the degree of resultant disability needs to be taken into account with respect to the better, often normal contralateral ear. This is well recognized in reconstructive middle ear surgery such as ossiculoplasty and stapedotomy, where the patient's perception of benefit will only be realised if the middle ear surgery brings the hearing within a defined level of the opposite ear (Belfast rule of thumb, Glasgow benefit plot).[110, 111] On this basis the audiometric criteria for considering hearing preservation surgery advocated by the authors is a pure tone average of 30 dB or better and a speech discrimination score of 70% or better in the affected ear, if the opposite ear is normal (Gardner Robertson class A).[112] This in itself significantly reduces the number of potential hearing preservation candidates. In addition, the tumour should be less than 1 cm diameter intracranially and be well away from the fundus of the internal meatus in order to have a realistic chance of preserving not just a functioning cochlear nerve but also the fine vasculature in the internal meatus that supplies the cochlea. In reality, few patients meet these requirements and in our experience of those that do, the hearing is preserved at the pre-operative level in one in three. In our experience, perhaps the best way to preserve good hearing in a patient with a small tumour is to leave the tumour alone and only intervene of there is evidence of growth on serial imaging.[6, 113] This philosophy of the place of hearing preservation surgery is not uniform by any means.[114] The literature is replete with difficulties when it comes to evaluating this aspect of VS surgery. First, much of the earlier literature fails to define what is meant by good hearing, useful hearing or serviceable hearing in the affected ear. This makes evaluation of hearing outcomes very difficult.[115] Second, many surgeons advocate attempts to preserve hearing at 50 db pure tone and 50%

discrimination scores in the presence of normal contralateral hearing. Some surgeons will even attempt to preserve any measurable hearing, although the utility of this is questionable. While such attempts are acceptable if no additional harm is done, the risk of a higher facial palsy rate (particularly in the transtemporal approach)[116] or a higher incidence of residual tumour in the retrosigmoid approach raises the issue as to whether such hearing preservation attempts are justified.

In attempting to preserve functional hearing, the proponents of both middle fossa and retrosigmoid approaches report good results, even in larger tumours.[117] Vast amounts of evidence exist arguing for one approach over another, although it seems that no one approach confers all the benefits and none of the complications.[118, 119]

Hearing preservation rates vary depending on the size of the tumour, the resultant tumour—nerve interface and the level of hearing pre-operatively.[120, 121] Continuous monitoring of the cochlear nerve during tumour dissection has been shown to improve the preservation of hearing.[122–124] In addition to the actual size of the tumour, the amount of tumour filling of the IAC also has an effect. In cases where there is some CSF lateral to the tumour the rate of preservation is also higher.[125]

Finally, more recent quality of life assessments of patients undergoing VS surgery suggest that the loss of the impaired hearing is not as significant a handicap as one might imagine[126] and, indeed, it is the experience of the authors that the loss of impaired distorted hearing actually allows the patient to gain better overall hearing using the normal contralateral ear alone. This observation is in part responsible for the more recent development in auditory rehabilitation described below.

HEARING REHABILITATION

Complete unilateral hearing loss is an inevitable consequence of translabyrinthine VS surgery and occurs in a large proportion of those undergoing other approaches, including those in which hearing preservation is attempted. Therefore the hearing handicap of single-sided deafness (poor sound localization, reduced intelligibility of speech in noise and overall ease of listening) should be minimized as much as is possible. Advances in hearing aid technology in the form of behind-the-ear aids utilizing wireless contralateral routing of signal have enabled excellent rehabilitation of VS patients at presentation, as well as following intervention.[127] Bone-anchored hearing aid (BAHA) technology has also developed and allows an alternative method of hearing rehabilitation.[128, 129]

As well as accessing the hearing in the contralateral ear, simultaneous or sequential cochlear implantation and translabyrinthine surgery has been performed with good results, both in patients with sporadic tumours and those with NF2.[25]

Quality of life

The patient's perception of their facial appearance, their hearing handicap, their ability to perform routine daily tasks of living and their overall quality of life is of greater importance to them than the surgeons' perspective of success in managing their condition. The emphasis on patient reported outcome measures (PROMs) is reflected across the whole medical literature and VS management is no exception. The development of the first disease-specific quality of life instrument, the Penn Acoustic Neuroma Quality of Life (PANQOL) scale has given the ability for all professionals managing patients with VS to report their outcomes in a similar manner.[130] The UK Skull Base community has adopted this measure as part of the compulsory prospective VS audit that is ongoing[131] (https://orioncloud.org).

At different stages of each individual patient's journey, a change in their perception of quality of life may be anticipated. Diagnosis is a time associated with significant uncertainty and stress and a subsequent reduction in quality of life.[132] Conservative management, where appropriate, provides the highest chance of maintaining a good quality of life. However, there remains an ongoing health and psychological burden in the requirement for regular imaging. Dizziness has the most significant impact on quality of life, with tinnitus also rated as having an impact. Hearing, interestingly, doesn't seem to influence quality of life.[133]

At the stage of intervention, and in particular surgery, the patient is most likely to experience a reduction in quality of life.[134] The potential impact on mobility, balance and facial function is condensed into a short period. This is reflected in the scores in the assessment tool up to 5 years. Longer-term follow-up has shown no significant difference between any of the three groups.[134]

Ongoing collection of quality of life and other surgical outcome data will provide guidance to those professionals involved in the management of VS; with this it is hoped that the standards can be further raised.

KEY POINTS

- The management of a patient with a vestibular schwannoma has evolved over the last 20 years such that many small tumours are managed conservatively.
- Surgery remains the treatment of choice for large tumours and continues to be a viable option for growing small- and medium-sized tumours.
- The outcomes of surgery are largely dictated by the size of the tumour and the experience of the team managing the patient.
- All patients with a diagnosis of vestibular schwannoma must be given the benefit of a multidisciplinary evaluation which includes neuro-otology, neurosurgery, radiation oncology and radiology.

SEARCH STRATEGY

Data may be updated using a PubMed or MedLine search using the following keywords: stereotactic radiosurgery, stereotactic radiotherapy, meningioma, pituitary adenoma and vestibular schwannoma.

OVERVIEW OF STEREOTACTIC RADIOSURGERY DELIVERY TECHNIQUES

Principles of stereotactic radiosurgery

The term 'stereotactic radiosurgery' is applied to techniques involving a well-defined co-ordinate base that enables the precise localization of a tumour and targeting of radiotherapy treatment. Localization may be achieved through the use of a fixed or removable headframe, or using the patient's own anatomy to determine a Cartesian based co-ordinate system. Using this with magnetic resonance imaging (MRI), it can be used to target pathological lesions including skull base tumours. Stereotactic radiosurgery uses ionizing radiation to ablate a volume of tissue, or to alter its biological activity, thus preventing further growth. The dose of radiation can be either delivered in a single treatment (stereotactic radiosurgery (SRS)) or in several fractions (stereotactic radiotherapy (SRT)). The decision of whether to deliver the dose in a single or multiple fractions will be based on the type of delivery equipment, and the requirement to allow nearby healthy tissue to recover in the intervals between each radiotherapy dose fraction. SRS is generally restricted to targets less than 3 cm in diameter and steep dose gradients are essential due to the risk of damaging adjacent normal tissue.

The delivery equipment for SRS can be broadly divided into two categories: modified conventional linear accelerators; and dedicated stereotactic devices. Both categories utilize enhanced imaging to determine tumour location and targeting, and a high-resolution collimation system to achieve sharp dose gradients.

MODIFIED CONVENTIONAL LINEAR ACCELERATORS

Modified conventional linear accelerators have the advantage that they offer flexibility for the workflow of a radiotherapy department, since they can be used to treat a wide range of indications. The equipment is readily available; however, a modification is often required to the machine to enable it for stereotactic use, such as a secondary high-resolution small field multi-leaf collimator (MLC). In order to correctly position the patient, additional stereoscopic X-ray images are often acquired, which, in conjunction with a modified treatment couch and patient fixation system, can achieve sub-mm delivery precision.

DEDICATED STEREOTACTIC MACHINES

Dedicated machines, such as the CyberKnife linear accelerator (Accuray) and the Gamma Knife unit (Elekta), utilize high-precision patient localization and high-resolution radiation beam collimation to deliver dose with sub-mm precision without need for modification.

The high collimation means the units are restricted to treating small volumes. The ability to deliver beams from multiple (several hundred) angles provides the steep dose gradient required to protect against normal tissue damage when using SRS.

The Gamma Knife unit uses a fixed array of 192–201 radioactive cobalt sources to deliver the dose to a patient wearing a rigid stereotactic frame to achieve precise targeting. The Gamma Knife was developed for intracranial SRS several decades ago and the current version has been subject to significant refinement. A CyberKnife unit uses stereoscopic imaging of the patient for precise localization without the need of a headframe (**Figure 103.1**). Since the linear accelerator on the CyberKnife unit is mounted on a robotic treatment arm it is not restricted to any angular position, unlike gantry mounted modified conventional accelerators. The size of the beams can be varied by changing the collimators, and complex dose distributions can be achieved by moving the patient and by blocking sources (Gamma Knife) or by changing the beam angles (CyberKnife). These variables allow treatment plans to be formulated that precisely match even irregular tumour volumes.

The Gamma Knife system uses a surgically attached headframe to enable localization to the machine. The Gamma Knife is dedicated to intracranial or skull base pathology and it is not possible to target disease extending into the neck. A CyberKnife unit uses digitally reconstructed radiographs of the skull from a planning CT scan to produce sub-mm localization. The system is also able to use the spine or fiducial markers to enable extracranial treatment delivery. Intracranial targeting accuracy of a CyberKnife machine is <0.5 mm, and <1 mm extracranially. Intrafractional patient movement during delivery is detected via the stereoscopic X-ray system and corrected by changes to the robotic delivery path, rather than repositioning the patient. Since the system does not require a headframe for positioning, there is no loss in delivery precision if the dose is delivered in one (radiosurgery) or over several (radiotherapy) fractions.

Figure 103.1 CyberKnife unit.

Patient treatment

Prior to any treatment being carried out, several preparation stages are required as well as offering the patient appropriate counselling and support.

Pre-treatment imaging is required for target definition; usually this is MRI but other modalities may be appropriate depending on the pathology of the target. Imaging (often computed tomography (CT)) is also required for localization and this needs to be performed using the treatment immobilization device. For stereotactic frame-based systems (e.g. Gamma Knife) this imaging is performed after application of the frame on the day of treatment. For stereoscopic imaging-based systems (e.g. CyberKnife) this can be done in advance. These images need to be transferred to the planning software. A multistage and multidisciplinary process then ensues, with the images from the various modalities being fused and the target and critical structures defined. A plan is subsequently produced that aims to highly conform the prescribed dose to the target and minimize the dose to the adjacent structures and organs at risk. This plan is subject to a rigorous schedule of checks before treatment can be delivered. The planning process often involves several specialist disciplines dependent upon local set-up and can include radiation oncology, neurosurgery, neuro-radiology and medical physics.

Treatment time depends on the system used and complexity of the target and plan. Typical delivery times are in the order of 1 hour. The patient is positioned on the couch using the system-appropriate immobilization device and localized by use of either a stereotactic headframe or imaging. Once this step is complete, treatment delivery can begin. If the patient moves, this step will need repeating. As with all photon treatments, the patient does not feel anything but can see and hear the machine moving. Treatment is generally delivered as an outpatient and general anaesthesia is not required, but it can be considered for young children.

Further information

For an extensive introduction to skull base and intracranial radiosurgery using all platforms, readers are referred to *Principles and practice of stereotactic radiosurgery*, edited by Chin.[1]

MENINGIOMAS

Role of radiosurgery in meningioma management

The majority of skull base meningiomas are benign and classified as WHO Grade 1.[2] Many are well demarcated; however, they can be difficult to excise completely due to risks of damaging adjacent neurovascular structures such as those within the cavernous sinus. They therefore represent an ideal target for consideration of SRS. Treatment may be considered following partial

resection, either to prevent regrowth or to improve symptoms. As a primary treatment, SRS can be used providing there is a high degree of confidence in the radiological diagnosis and early intervention is warranted. One of the main limitations of SRS for skull base meningiomas are dose constraints to the optic pathway, which is sensitive to the high doses per fraction delivered with this technique. Radiation induced optic neuropathy (RION) is rare if the dose is limited to < 8 Gray in a single fraction.[3] Where it is not possible to achieve safe optic pathway constraints (typically for lesions within 2 mm of the optic nerves/chiasm), fractionated radiotherapy treatment offers similar local control rates without significant risk of RION.

The timing of intervention with SRS or fractionated radiotherapy for skull base meningioma remains controversial. Contrary to surgery, the philosophy with radiotherapy is to treat while the tumour volume is low and prior to clinical deterioration. However, growth kinetics for benign meningiomas can be complex and difficult to predict. Some remain relatively indolent for many years and many small (sub-2 cm) skull base meningiomas do not cause any symptoms within 5 years, supporting an initial period of observation.[4] Given that observation carries a risk of increasing tumour volume, associated with a greater risk of toxicity with SRS, serial MRI scans and clinical examination are essential for active monitoring.

Clinical outcomes

Both SRS and fractionated radiotherapy offer effective treatment for skull base meningiomas with 10-year local control rates typically exceeding 85% (**Table 103.1**).[5–11] However, evidence is confined to retrospective studies and many fail to clearly distinguish outcomes between primary treatment at presentation, treatment immediately following surgery and treatment at progression with or without earlier surgery. In a retrospective multicentre analysis of 3768 patients with benign meningiomas, 5- and 10-year progression free survival (PFS) were 95.2% and 88.6% respectively with a permanent morbidity incidence of 6.6%.[6] Prescribed doses for benign meningiomas are typically in the range of 12–15 Gy with single fraction SRS.[12] Due to increased risk of morbidity SRS is typically used for tumours with volumes less than 8 cubic centimetres (generally < 3 cm). Multisession SRT (up to 5 fractions) using a platform such as CyberKnife is now being successfully used for larger volume tumours although more mature data are awaited.[13] Cranial nerve deficits have been reported following SRS for anterior skull base meningiomas. In one series of 763 patients with sellar/para-sellar meningiomas with mature follow-up, new or worsening deficits were seen in 9.6% of patients, with the trigeminal nerve being most adversely affected.[8]

TABLE 103.1 Selected published long-term local control rates using radiosurgery and fractionated radiotherapy for meningioma

Reference	Patients (n)	Technique	Median dose	Local control
Debus 2001[7]	189	FSRT	56.8 Gy	96% (10 years)
Milker-Zabel 2005[9]	317	FSRT	57.6 Gy	89% (10 years)
Kondziolka 2008[5]	972	GK	13 Gy	87% (10 years)
dos Santos 2011[10]	88	Linac SRS	14 Gy	83% (10 years)
Tanzler 2011[11]	146	CFRT IMRT FSRT	52.7 Gy	96% (10 years)
Sheehan 2014[8]	763	GK	13 Gy	82% (10 years)
Santacroce 2012[6]	4565	GK	14 Gy	87% (10 years)

FSRT, fractionated stereotactic radiotherapy; GK, Gamma Knife; CFRT, conformal radiotherapy; IMRT, intensity modulated radiotherapy; SRS, stereotactic radiosurgery; Gy, Gray.

Optic nerve sheath meningiomas

Optic nerve sheath meningiomas (ONSM) have an intimate circumferential relationship with the optic nerve and can interfere with its vasculature. The natural history of most ONSMs is variable but symptoms of optic pathway compression can occur including painless loss of visual acuity, visual field deficiencies, relative afferent pupillary deficits or proptosis.[14] Observation with serial neuro-ophthalmological assessment to determine rate of symptomatic progression is often considered initially. Presentation with significant optic pathway symptoms and progressive decline in function are considered indications for intervention. Surgical intervention including biopsy is associated with high risk of damage to vision, therefore primary radiation is often considered the treatment of choice. Due to the sensitivity of the optic pathways to high doses per fraction, fractionated radiotherapy is safer than SRS. With the use of highly conformal fractionated radiotherapy, vision commonly stabilizes, and improves in approximately one-third of patients.[15, 16]

Atypical and anaplastic meningiomas

A small proportion of meningiomas are WHO grade 2 or 3 due to atypical or anaplastic pathological features. These tumours have a high propensity for recurrence and can invade surrounding tissue. There remains a paucity of high quality data to guide management. In principle, SRS is generally not suited to tumours with an infiltrating margin. One combined analysis of series using SRS estimated a median 5-year PFS or 59% for Grade 2 and 13% for Grade 3 meningiomas.[17] The definitive role of SRS is unclear although in the authors' experience it has been helpful in selected cases including palliation.

KEY POINTS

- Five-year control rates in excess of 90% with acceptable neurological morbidity may be achieved with SRS for grade 1 meningiomas.
- The timing of intervention with SRS remains debated, given that many grade 1 tumours grow slowly.
- Fractionated radiotherapy is preferable to SRS for tumours in close proximity to the optic pathways or of larger volume unsuitable for resection.

PITUITARY ADENOMAS

Pituitary adenomas are classified by size and ability to hypersecrete hormones (functional versus non-functional adenoma (NFA)). Functional adenomas are typically microadenomas (i.e. <1 cm in size) presenting with clinical seqeulae of hormone hypersecretion while NFAs may be diagnosed incidentally or present with symptoms from local pressure such as visual disturbance.

Therapeutic goals include the reversal of symptoms from pressure or hormone hypersecretion, maintain normal hormone function and ideally prevent regrowth in the future through definitive treatment providing the risks are acceptable. Options available include surgical resection, medical therapy, fractionated radiotherapy, SRS and observation. A multidisciplinary approach is essential.

Non-functional adenomas

Symptomatic non-functional adenomas (NFAs) often require surgery to reverse clinical problems such as visual disturbance caused by optic pathway compression. However, complete resection may not be feasible, particularly if the tumour extends into the cavernous sinus. Furthermore, high late recurrence rates are seen, even in patients thought to have had a complete resection.[18] Despite potential high rates of recurrence, observation following initial surgery is still appropriate in the absence of adverse features, given that most tumours grow slowly and progression can be detected through serial imaging. SRS or fractionated radiotherapy are commonly reserved for recurrence or progression.

Although there is a lack of randomized data, a matched cohort comparison clearly confirmed that early adjuvant radiotherapy improves PFS over surgery alone.[19] A UK series with a median follow-up of 9.1 years reported actuarial PFS of 97% and 96%, at 10 and 20 years respectively, following radiotherapy.[20] However, concerns exist over the use of routine adjuvant radiotherapy, due to the risks of long-term consequences including hypopituitarism, potential increased of stroke and radiation induced cancers.

SRS offers an attractive alternative for low volume inoperable tumours (of an adequate distance from the optic apparatus) and is increasingly used in preference over fractionated radiotherapy (**Figure 103.2**). A retrospective combined analysis of 512 patients treated with SRS reported actuarial PFS of 95%, 91% and 85% at 5, 8, and 10 years respectively.[21] All patients were treated with Gamma Knife and the median follow-up was 36 months with 37.3% of patients completing 5 or more years of follow-up. Tumour volume was the strongest predictor of progression. New or worsened hypopituitarism was seen in 21% of patients. Similar local control rates have been shown with other SRS platforms.[22] The authors are not aware of any data confirming an increased incidence of stroke following SRS; however, dose to the adjacent carotid is often high and carotid stenosis has been documented as a rare event.[23] Steep dose gradients make it possible to reduce the dose to the hypothalamic-pituitary axis with some investigators suggesting safe limits to preserve function; however, mature data are lacking and tumour coverage should take priority.[24] Case reports of second malignancy following SRS do exist; however, one population-based study failed to show any increased risk.[25]

Functional pituitary adenomas

Excluding prolactinomas, where medical therapy is the primary treatment of choice, complete microsurgical resection is often considered the optimum treatment. However, cure through surgical resection may not always be possible due to local invasion and risks of injury to neurovascular structures. SRS is considered a useful adjunct for functional tumours, and may remove the need for ongoing medical therapy.

A review of retrospective data was recently published by Sheehan et al.[21] Although radiological control rates were high, endocrine remission rates varied considerably between series and did not reflect the high rates of local control. The review suggested that SRS was most effective for Cushing's disease where biochemical remission rates were typically in the region of 50% (range 0–100%). This was followed by acromegaly with an overall average endocrine remission rate of 43.6% (range 0–82%). The overall remission rate for prolactinomas was only 30% (range 23.3–41%).

Compared to surgery, there is a latent period of at least a year post-SRS prior to biochemical remission, during which medical therapy needs to continue. Higher doses are required to treat functional tumours; however, morbidity is generally low providing adequate clearance is achieved from the optic pathways.

KEY POINTS

- SRS can be used for low volume (typically <5 cc) recurrent or progressive non-functioning adenomas that are unsuitable for surgical resection.
- SRS is a useful adjunctive treatment in functional pituitary tumours; however, biochemical response rates are variable despite high rates of local control.
- Long-term follow-up is required to monitor for pituitary insufficiency following any radiation to the hypothalamic pituitary axis.

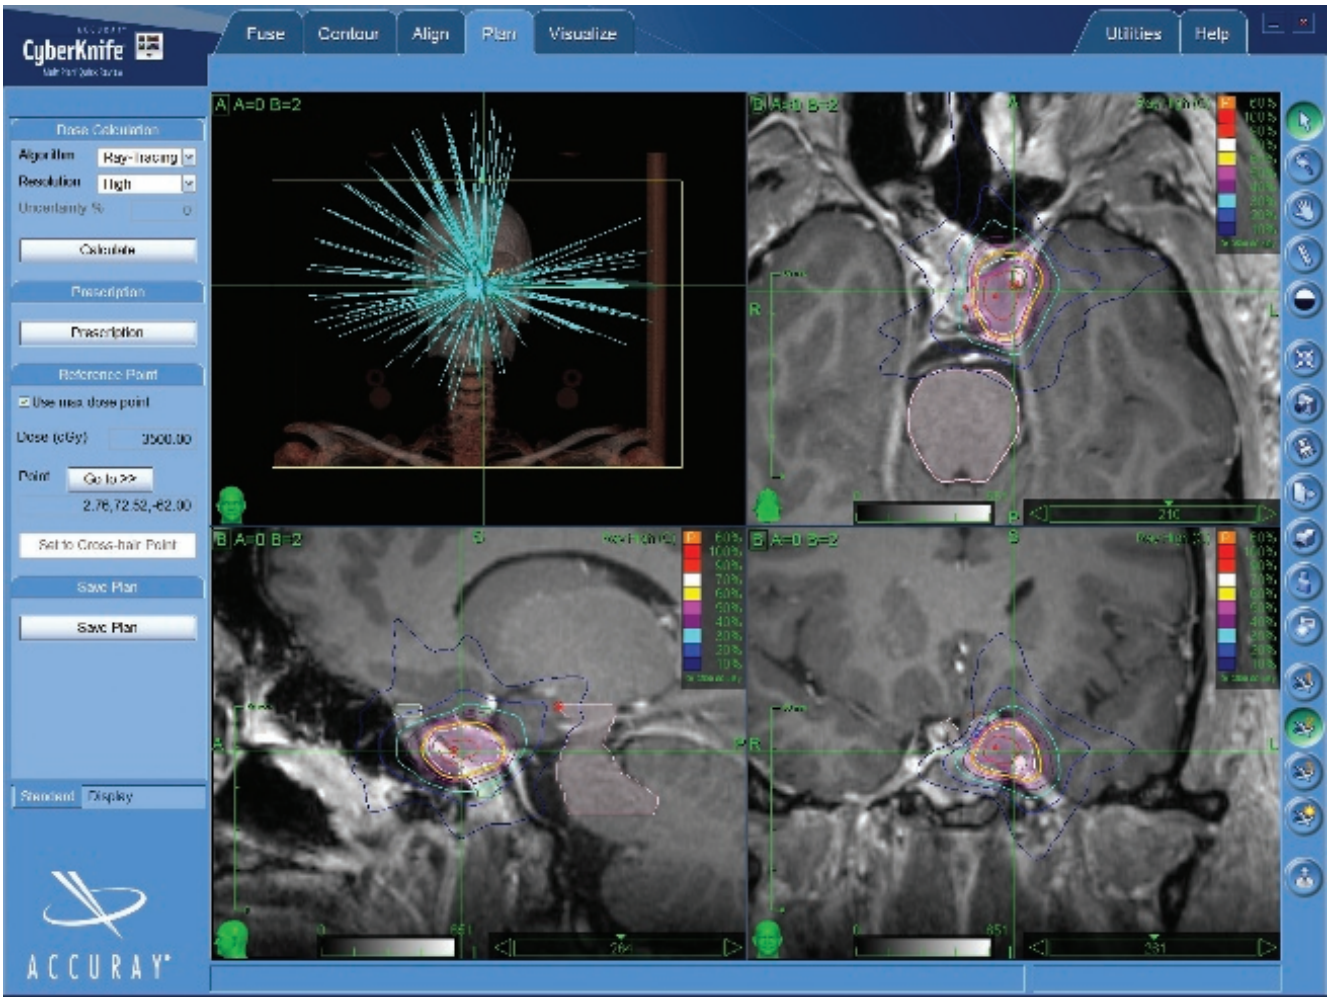

Figure 103.2 Example of pituitary tumour SRS plan (MultiPlan, CyberKnife, Accuray), showing high conformality and steep dose fall off to chiasm and carotids.

VESTIBULAR SCHWANNOMA

Although vestibular schwannomas (VS) are slow-growing, benign tumours, progressive enlargement can cause morbidity. Management strategies for VS include observation with serial MRI (usually indicated for small, newly diagnosed tumours), surgical resection and radiotherapy (both SRS and fractionated). Radiotherapy is used to stop growth (and hence avoid surgery) but is also used in some centres to preserve auditory function. However, the benefits of early intervention with regards to hearing preservation with radiation versus observation remain unproven and this issue continues to be debated.

Numerous published reports of high local control rates (predominantly using Gamma Knife) with minimal toxicities have established SRS as an accepted alternative to surgical resection (**Table 103.2**). [26–28] Similar outcomes have also been reported for other SRS platforms.[29] However, observation with annual imaging and hearing evaluation is believed to have a role in the management of small minimally symptomatic tumours, as SRS or resection can potentially compromise function.[30] Growth can be unpredictable, however, and if significant may limit future therapeutic options. As a result, deciding between early definitive treatment and observation can be challenging.

Currently, most centres prescribe 12–13 Gy to the margin of the tumour (**Figure 103.3**). Over time, the recommended dose has reduced from 16 Gy, which has lowered the incidence of cranial nerve complications, without adversely affecting local control rates.[31]

SRS is generally recommended for tumours < 3 cm in extra canalicular diameter with no significant brainstem compression, as tumour swelling post-radiosurgery can lead to 4th ventricular distortion with resultant obstructive hydrocephalus.

Following SRS, transient enlargement of the tumour followed by stability or even regression (i.e. 'pseudoprogression') is known to occur. In one series, 23% of VS treated with SRS underwent pseudoprogression, most commonly regressing at 24 months post-treatment.[32] As a result, only tumours that begin or continue to enlarge after 24 months post-SRS should be considered as treatment failures, and further intervention (most commonly resection) should not be rushed. The length of clinical and

Reference	Median follow-up (years)	Patients (n)	Platform	Median marginal dose (Gray)	Local control	Definition of local control	Cranial nerve V preservation (%)	Cranial nerve VII preservation (%)
23	2.9	232	Gamma Knife	15 Gy	97%	No additional surgical intervention	98.5%	99%
24	5.6	216	Gamma Knife	13 Gy	98.3% (10 years)	No additional surgical intervention	94.9%	100%
25	8.1	75	Linac	14 Gy	92%	No change in tumour volume	100%	92%
26	5	103	Gamma Knife	13 Gy	91.1%	No additional surgical intervention	99%	95%

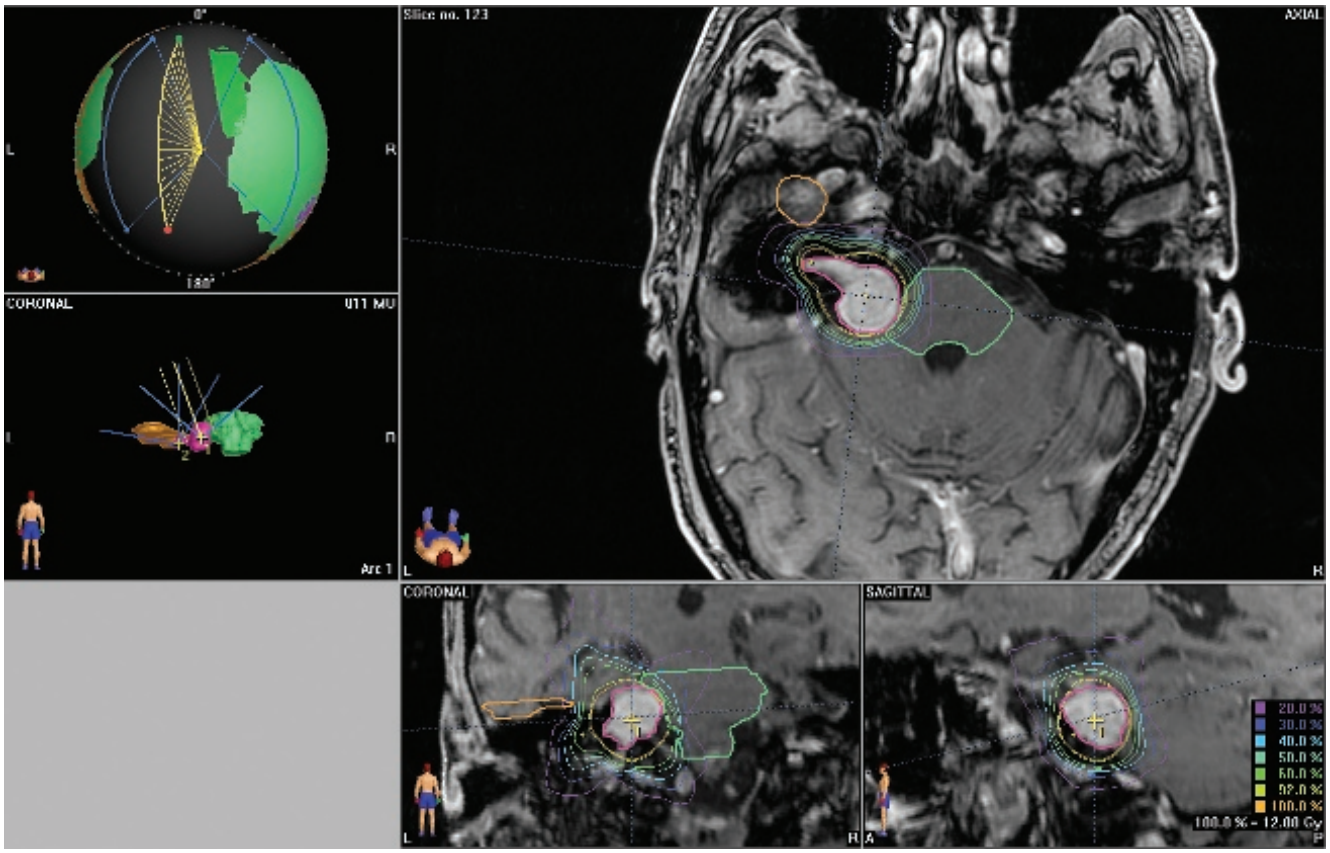

Figure 103.3 Typical dose distribution achieved using BrainLab generated SRS plan (linear accelerator platform).

radiological follow-up required post-SRS is controversial. In the authors' centre, patients are routinely imaged for 10 years post-radiosurgery.

Preservation of cranial nerve function

Following SRS with a marginal dose of 12–13 Gy, published trigeminal nerve preservation rates vary from 78.7% to 100%.[33, 34] The aetiology of trigeminal neuropathy post-SRS is complex and multifactorial. Factors associated with trigeminal dysfunction in published series include: tumour volume; maximum dose received by the trigeminal nerve and brainstem; and length of nerve irradiated.[33] The likelihood of trigeminal toxicity is no doubt higher for patients with tumour in contact with the nerve as a result of post-radiosurgery swelling.

The risk of a persisting facial nerve palsy post-SRS is low with contemporary radiosurgical doses and planning techniques (Table 103.2). Pre-existing facial nerve palsy and hemi-facial spasm is associated with an increased risk of worsening CNVII dysfunction after radiosurgery.[26]

The majority of patients with VS have unilateral sensorineural deafness at presentation. However, for patients with 'serviceable' hearing (Gardner-Robertson Grades I–II), some centres advocate early radiosurgery to preserve auditory function. To date there are no prospective, randomized data to inform practice, and large variations in hearing outcomes are reported between published series. Regis et al. reported prospective non-randomized hearing data for patients with intracanalicular VS managed with observation versus immediate Gamma Knife SRS with a marginal dose of 12 Gy. This series reported improved hearing preservation rates in patients who underwent early radiosurgery (77%, 70% and 64% at 3, 4 and 5 years, respectively) as compared to 75%, 52% and 41% in the observation group.[35] The authors of this chapter therefore support early intervention with SRS in patients with serviceable hearing.

There may be radiobiological advantages of fractionated radiotherapy over SRS in terms of reducing risk of cranial neuropathy and improving hearing preservation. Similar local control rates have also been reported.[36] No prospective comparison has been carried out with SRS to date, however.

Radiosurgery for NF2 vestibular schwannomas

Patients with neurofibromatosis type 2 (NF2) usually have bilateral VS and are therefore at risk of developing bilateral deafness, trigeminal and facial neuropathies at a young age. Results of surgery and radiotherapy for NF2-associated VS are worse than for sporadic unilateral tumours. Tumour control rates are lower and iatrogenic hearing loss is more common.[37, 38]

Plotkin et al. identified that vascular endothelial growth factor (VEGF) is expressed by VS and medical therapy with bevacizumab (an anti-VEGF monoclonal antibody) may improve hearing in some (but not all), as well as reducing tumour volume in the majority of patients with NF2-associated VS.[39] As a result, bevacizumab is increasingly being used as first line management in this patient group when intervention is required.

CHONDROSARCOMA AND CHORDOMA

Small, relatively well-demarcated residual tumours can represent an attractive target for SRS. There are some data reporting use of SRS for small chordomas or chondrosarcomas that are relapsing or remain visible targets after surgery.[40–42] However, series using fractionated radiotherapy with doses in excess of 70 Gy report the highest rates of local control.[43, 44] The local control rates for chondrosarcoma are more favourable than for chordoma. Fractionation permits treatment of a wider region including the presurgical bed. Delivering such high doses of radiotherapy in such close proximity to critical neural structures (in particular brainstem) demands maximum surgery and highly conformal techniques such as proton therapy, fractionated SRT or imaged guided intensity modulated photon radiotherapy. The role of SRS remains uncertain for those patients suitable for resection and high dose fractionated radiation.

GLOMUS TUMOURS

Glomus tumours (also known as paragangliomas or chemodectomas) are rare, benign tumours that can develop in a number of locations including in and around the ear (glomus tympanicum and glomus jugulare). If causing local mass effect on the brainstem, surgical resection is preferred. However, these tumours are often intimately involved with surrounding neurovascular structures and complete excision is usually impossible without significant morbidity. SRS and fractionated radiotherapy are both therapeutic options, given with the aim of tumour control rather than eradication. A meta-analysis, combining results from 276 patients, showed pooled local control following radiotherapy (both fractionated and SRS) as initial, combined and salvage treatment was good, ranging from 79% to 100%.[45] SRS is preferred for relatively small, well demarcated tumours that are in difficult surgical locations. Timing of intervention remains debated given that many tumours will remain relatively indolent for many years.

KEY POINTS

- SRS is an established therapeutic option for VS < 3 cm with no significant brainstem compression with local control rates in excess of 90% with marginal doses of 12–13 Gy.
- It is postulated that early radiosurgery preserves serviceable hearing, although prospective randomized data are lacking.
- Post-SRS cranial nerve preservation is high and treatment-associated complications are low.

CHAPTER 104

NEUROFIBROMATOSIS 2

D. Gareth R. Evans

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed search using the keywords neurofibromatosis 2/NF2.

HISTORICAL OVERVIEW

The neurofibromatoses consist of at least three distinct autosomal dominantly inherited disorders: neurofibromatosis 1 (NF1), neurofibromatosis 2 (NF2) and schwannomatosis. Historically, these conditions were aggregated as generalized neurofibromatosis (von Recklinghausen disease). NF2 was first described by Wishart in 1822.[1] The heritable nature of NF2 was reported in 1920 by Feiling and Ward,[2] who described a three-generation family with vestibular schwannomas (VS). The autosomal dominant transmission (i.e. a 50% risk of transmission from an affected parent) was confirmed in a large family reported by Gardner and Frazier in 1930.[3] NF1 was delineated by von Recklinghausen in the late 19th century; Harvey Cushing aggregated NF1 and NF2 in 1916,[4] and his scientific stature was such that, despite reports that the conditions were different, many decades were to pass before the distinction between the two diseases was widely recognized. The neurofibromatosis literature prior to 1985 is scattered with cases of NF2 being described as part of von Recklinghausen disease, with cases of bilateral vestibular schwannomas being included in large series of NF1.[5] The conditions were recognized as separate entities only when the *NF1* and *NF2* genes were localized to chromosomes 17 and 22 in 1987 and NF2 was cloned in 1993, respectively. The two diseases were clinically delineated at a US National Institutes of Health (NIH) consensus meeting in 1987.[6] Subsequent studies have indicated that NF2 is a genetically homogeneous condition, with no evidence of exclusion of classical NF2 (bilateral VS) from the *NF2* locus on 22q. Indeed, genetic analysis in Manchester detects aberrations in the NF2 gene in 95% of familial cases. The initial studies on small numbers of families were confirmed in all studies of people with bilateral VS that have been undertaken since the identification of the *NF2* gene in 1993. However, it is possible that there is another closely linked gene that affects NF2 phenotype.

MOLECULAR GENETICS

The initial keys to identifying the *NF2* gene were studies of tumour material.

Chromosome studies of meningiomas highlighted chromosome 22 as the likely location of the *NF2* gene, since many tumours had loss of all or part of chromosome 22. Subsequent cytogenetic studies of schwannomas also confirmed that loss of chromosome 22 or its long arm was by far the most frequent event, which was later confirmed by DNA studies.[7] Seizinger et al. demonstrated loss of constitutional heterozygosity of chromosome 22, with DNA markers being lost in tumours from a person with NF2.[7] Linkage studies then confirmed that all affected members of a large family carried the same copy of chromosome 22.

The *NF2* gene was identified by the simultaneous discovery of constitutional and tumour deletions in a cell membrane-related gene, termed merlin or schwannomin.[8, 9]

Standard mutation techniques, such as single-strand conformational polymorphism analysis or denaturing gradient gel electrophoresis, detect 35–66% of pathogenic mutations. The majority of these mutations are protein-truncating mutations (frameshift or nonsense mutations) and lead to a smaller and probably non-functional protein product. C>T transitions causing nonsense mutations are the most common mutations in the *NF2* gene. Genotype-phenotype correlation studies have found that missense mutations (which result in a complete protein product) and large deletions (which result in no protein product) each cause predominantly mild phenotypes.[10–13] Patients with splice-site mutations have variable clinical manifestations. The more severe phenotype in patients with protein-truncating mutations may be due to a dominant negative effect, with mutant protein dimerizing with the normal product, leaving less wild type protein for tumour suppression. This is supported by a positional effect of mutations (particularly for meningiomas with more severe disease associated with mutations in exons 1–4 and mild disease in the last two exons with mutations).[13]

Some people with mild NF2 are somatic mosaics, in whom a smaller proportion of cells contain the mutated *NF2* gene. One of the clues to the existence of mosaicism in NF2 was that *NF2* mutations were harder to find in blood in sporadic cases than in people who had inherited the disease from an affected parent. In mosaicism, the initiating mutation happens after conception, leading to two separate cell lineages. The proportion of cells affected depends how early in development the mutation takes place. Evidence suggests that as much as 25–35% of NF2 cases without a family history of the disease are mosaic, carrying the mutation in too small a proportion of their cells to be detected from a blood sample.[14, 15] This accounts for the milder disease course in many individuals with unfound mutations, and since only a subset of germ cells will carry the mutation, there is less than a 50% risk of transmitting the disease to their offspring.[15, 16] However, if an offspring has inherited the mutation, they will be more severely affected than their parent, since the offspring will carry the mutation in all of their cells.[17] Mosaicism may be particularly likely in NF2 if the tumours are anatomically localized, for example, limited to one side.[16] The mosaic mutation can be detected by analyzing tumour material from an affected individual. If an identical mutation is found in two tumours from that individual, their offspring can be tested for the presence of the mutation. Other causes (apart from mosaicism) of the low detection rate for constitutional *NF2* mutations using standard techniques are large deletions and rearrangements at the *NF2* locus. The chances of mosaicism depending on age at onset and laterality and the risks to children can be found in recent publications.[15, 16]

NF2 PROTEIN

The NF2 protein (merlin or schwannomin) is a cell cytoskeleton-associating protein of 595 amino acids coded by the 17 exons of the *NF2* gene. The name 'merlin' derived from the sequence homology and shared overall domain structure with ERM (moesin, ezrin and radixin) superfamily of membrane-cytoskeleton linker molecules. Alternative splicing of exon 16 gives rise to two isoforms, which differ by the last C-terminal 11 amino acids. The NF2 protein is expressed in many tissues including neurons, Schwann cells and meningeal cells. Mutant NF2 protein impairs cell adhesion, motility and spreading properties, which are known to be essential for tumour formation. Loss of NF2 protein is the main and possibly the only rate-limiting step in the formation of all schwannomas and most meningiomas. Merlin is localized to the cell membrane/cytoskeletal interface and appears to have a number of different roles involving interactions including the Ras/Raf/MEK/ERK, FAK/Src, PI3K/AKT, Rac/PAK/JNK, mTORC1 and Wnt/β-catenin pathways.[18] NF2 links receptors at the plasma membrane to their cytoplasmic kinases to facilitate contact inhibition. However, NF2 can also interact with a large number of cytoplasmic and nuclear proteins that affect cell cycle progression. NF2 may also, through these pathways, reverse the functional inhibition of conventional tumour suppressor pathways.[19]

EPIDEMIOLOGY

An estimate of the birth incidence of NF2 (1 in 50 000) was made at the 1987 NIH Consensus Conference on the Neurofibromatoses, but this was not epidemiologically based. In the UK, population-based studies have estimated the birth incidence of NF2 as 1 in 33 000 people.[20, 21] A smaller study in southern Finland estimated the birth incidence as 1 in 87 000.[22] Both studies were based on hospital records and cancer registries, and the higher incidence in the UK study is likely more reliable as it is based on a larger area with longer follow-up. Initial estimates of prevalence suggested that as few as 1 per million were affected in the US.[6] The diagnostic prevalence in the UK population-based study is now 1 in 56 000.[21] This has probably increased due to early diagnosis and improved survival. The annual incidence rate for NF2 was estimated as 1 per 2 355 000, [20] equivalent to about 1 case per year for each health region in the UK or over 100 cases per year in the US. The birth incidence is significantly higher than the diagnostic prevalence because many people do not develop features of the condition until the third decade of life or later, and many other people die before this time. The diagnostic prevalence is likely to rise, as the median 15-year survival from diagnosis more than 20 years ago[23] will lengthen due to improvements in early diagnosis and tumour treatment.

Individuals who inherit a pathogenic mutation in the *NF2* gene will almost always develop symptoms by 60 years of age; [23] very occasionally, such people will have apparent non-penetrance (have no features of the disease even late in life). The transmission rate is 50% in the second generation and beyond, but the risk of transmission in apparently sporadic cases of NF2 is less than 50% due to mosaicism.[16, 17] Anecdotal evidence suggested that, in

many NF2 families, the disease course 'breeds true'. More recent research has established that the intra-familial correlation of clinical manifestations of NF2 (age at onset of symptoms, age at diagnosis and number of intracranial meningiomas) is greater than the inter-familial correlation. Stochastic events such as loss of the second *NF2* allele clearly play a role in the natural history of the disease, since the disease course is not identical even in monozygotic twins with NF2.

Initial indications of a maternal gene effect (earlier age at onset in individuals who inherited the *NF2* mutation from their mother) have not been borne out by further study,[20] nor is there evidence for anticipation (an increase in disease severity with successive generations). An apparent worsening of the disease course in affected females is due mainly to meningiomas, not on schwannoma growth and development, and there is no gender difference in risk of mortality.[23, 24]

CLINICAL MANIFESTATIONS, DIAGNOSTIC CRITERIA AND DIFFERENTIAL DIAGNOSIS

Bilateral VS are pathognomic for NF2. Schwannomas of the other cranial, spinal and peripheral nerves are very common. Meningiomas are present in about half of patients, primarily intracranially (including optic nerve sheath meningiomas) but also in the spine, and lifetime risk probably approaches 75%.[13] Less frequently, there are low-grade central nervous system (CNS) malignancies (ependymomas and very rarely gliomas) (**Table 104.1**).[23, 25–29] Individuals may present with cranial meningiomas or a spinal tumour long before the appearance of a VS.

Most individuals with NF2 present with hearing loss (often initially unilateral) that may be accompanied or preceded by tinnitus. Other vestibular presenting symptoms of VS are dizziness or imbalance. About 20–30% of cases present with an intracranial meningioma, spinal tumour or cutaneous tumour. When NF2 presents in early childhood, the first sign is often a non-VIIIth nerve tumour. Adult presentation is therefore quite different from paediatric presentation, in which VS causes only 15–30% of initial symptoms. There have been a number of recent reports of mononeuropathy in NF2, which is most common in people who present at young ages. Mononeuropathy affecting the facial nerve causes facial palsy similar to Bell's palsy, which does not fully recover. Some children present with wasting of muscle groups in a lower limb, similar to polio, which again does not fully recover. In adults, a more generalized polyneuropathy develops in about 3–5% of patients, often associated with an 'onion bulb' appearance on nerve biopsy.[7] This can progress, leading to severe muscle wasting and even death.

Ophthalmic abnormalities are very common in NF2. Between 60–80% of people have cataracts,[7, 10] which are usually presenile posterior subcapsular lenticular opacities that rarely require removal. Cortical wedge opacities are also common and may be present from near birth. Optic nerve sheath meningiomas and retinal hamartomas can cause visual impairment in the first years of life; misdiagnosis of each of these abnormalities as retinoblastoma has led to the eye being removed in the first few years of life.

Skin abnormalities are useful in diagnosis, but cutaneous features of NF2 are much more subtle than those seen in patients with NF1. About 70% of NF2 patients have skin tumours but only 10% have more than 10 skin tumours and there appear to be at least three different types. The most frequent type is a plaque-like lesion, which is intracutaneous, slightly raised and more pigmented than surrounding skin, often with excess hair (**Figure 104.1**). More deep-seated subcutaneous nodular

TABLE 104.1 Clinical characteristics of NF2 patients in four studies

Characteristic	Study			
	Kanter et al.[26]	Evans et al.[23]	Parry et al.[27]	Mautner et al.[28]

Optic sheath meningioma (%)*	N/A	4.1	4.8	8.0

* In Mautner et al.[29] the frequency of optic nerve sheath tumours is for all histological types (i.e. schwannomas and meningiomas).

Figure 104.1 Plaque-like lesions on the arm of a patient with NF2. These are raised, often slightly pigmented lesions that are also frequently hairy.

Figure 104.2 Subcutaneous schwannoma on a major nerve in the upper arm in a patient with NF2.

tumours can often be felt, sometimes on major peripheral nerves. These tumours are detected as a fusiform swelling of the nerve with thickened nerve palpable on either side (Figure 104.2). There are also occasional intracutaneous tumours similar to those in NF1. The great majority of these tumours are schwannomas, but occasional definite neurofibromas may be found.

The Manchester (modified NIH) diagnostic criteria for NF2 are shown in Box 104.1. The original NIH criteria have been expanded to include patients with no family history who have multiple schwannomas and or meningiomas but who have not yet developed bilateral VIIIth nerve tumours. Constitutional mutations in the *NF2* gene are found as frequently in patients who fulfil these modified criteria as in sporadic cases with bilateral VS (Box 104.1). This justifies future inclusion of these individuals as having 'definite' NF2, rather than having only one criterion (bilateral VS) for 'definite' NF2 in isolated cases. In addition, the inclusion of criteria for 'probable' NF2 (unilateral VS < 30 years plus other NF2 criteria, or two or more meningiomas plus other NF2 criteria) is a helpful addition. Since 50% of cases are new mutations, the modified criteria increase sensitivity but are unlikely to reduce

BOX 104.1 Diagnostic criteria for NF2 (these include the NIH criteria with additional criteria)

Bilateral vestibular schwannomas or family history of NF2 plus:

- unilateral VS *or*
- any two of: meningioma, glioma, neurofibroma, schwannoma, posterior subcapsular lenticular opacities.

Additional criteria:

- unilateral VS plus any two of: meningioma, glioma, neurofibroma, schwannoma, and posterior subcapsular opacities *or*
- multiple meningioma (two or more) plus unilateral VS *or* any two of: glioma, neurofibroma, schwannoma, and cataract.

Note: 'Any two of' refers to individual tumours or cataract, not to tumour types.

specificity because chance associations of typical NF2 disease features in people without NF2 are extremely rare. A new scoring-based system for diagnosis, the so-called 'Baser' criteria, has also been developed.[30]

The main possible differential diagnostic dilemmas are in people with multiple non-cranial schwannomas who do not have a family history of NF2. All require a cranial MRI scan. Some of these people develop NF2 and others are somatic mosaics. There are nonetheless a small group of people with tumours largely confined to the spine and subcutaneous nerves, with sparing of the VIIIth nerve, who do not have a constitutional *NF2* mutation detection using conventional techniques.[31, 32] These individuals may pass the condition on to their children, and in families where this happens there is still tight linkage to the *NF2* locus, although *NF2* mutations are found in only a minority of patients with this variant form of the disease.[32] Around 50% of familial cases and 10% of sporadic schwannomatosis cases have now been shown to be due to *SMARCB1* mutations.[32] Confusion with NF1 is unlikely since only 1–2% of NF2 patients have more than 6 café-au-lait macules and Lisch nodules are rare in NF2. Nonetheless, review of tumour histology is a wise precaution in equivocal cases. NF1 is extremely unlikely in a person with a schwannoma who does not meet the NIH criteria for NF1; conversely, NF2 is very unlikely in a person with multiple neurofibromas.

NEURORADIOLOGY

Several groups of individuals are at risk of having NF2 and should be investigated using MRI. These are people with a family history of NF2; people under 30 years old who present with a unilateral VS or meningioma; people with multiple spinal tumours (schwannomas or meningiomas); and people with cutaneous schwannomas.[16] The 'gold standard' in terms of diagnostic precision

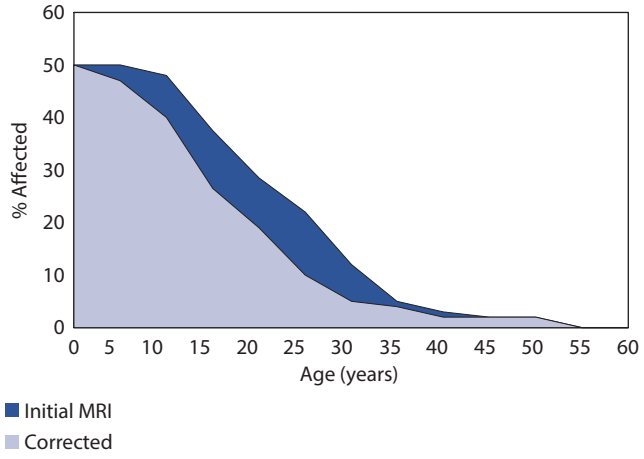

Figure 104.3 Decrease in risk from 50% by age of an individual with a normal cranial scan and an affected parent with NF2.

is magnetic resonance imaging (MRI) with gadolinium enhancement. Initial assessment should include full spinal imaging in addition to a cranial scan. MRI will now detect tumours as small as 1–2 mm in diameter on cranial and spinal nerve roots. Many of these small spinal tumours will never lead to symptoms. Using MRI of the full spine, there are tumours in 80–90% of NF2 patients[28] but only 30% of these patients have symptomatic spinal tumours.[23, 26, 27] Intramedullary tumours, often associated with a syrinx, are mainly found in the upper cervical spine and brainstem. On biopsy, these tumours are usually low-grade ependymomas and the great majority do not progress. Another common finding is schwannomas on other cranial nerves. The Vth nerve is most frequently affected. It is rare for non-VS cranial nerve schwannomas to grow to a size where surgical excision is required. Meningiomas are detected on MRI as enhanced areas on the meninges around the spinal cord, brain or optic nerves. They can form confluent areas on scan or 'meningioma en plaque'. The growth rates of VS are often slow but are extremely variable; on average, growth rates are higher in younger patients.[13] Meningiomas usually have faster growth rates than VS.

CT scans have been largely replaced by MRI due mainly to their poor sensitivity at detecting small VS (**Figure 104.3**). Some NF2 patients have intracranial calcification, but this sign is not useful enough in diagnosis to supplement MRI with CT. Without firm clinical justification, repeated CT scans should be avoided in NF2 due to the tumour-prone nature of the disease and the possibility of radiation-induced tumours.

PATHOLOGY

The main tumour sites, their frequency and pathology are presented in **Table 104.1**. As previously noted, schwannomas can develop at all locations in the body where there are nerves with Schwann cells. The reason for the predilection for the superior vestibular branch of the VIIIth cranial nerve is unknown. Schwannomas are encapsulated tumours of pure Schwann cells, growing around the nerve that may contain blood vessels and have areas of sheets in intertwining fascicles (Antoni A) and looser arrangements (Antoni B). The tumours stain for S-100 protein and vimentin. In NF2, schwannomas tend to be more multifocal and have a more lobular architecture than sporadic tumours.[33] Spontaneous malignant transformation of these tumours to malignant peripheral nerve sheath tumours is recognized, but is more than 10 times as likely to happen after radiation treatment.[34] The background rate of 0.5% for CNS malignancy in NF2 is also very much less than for NF1. A small proportion of nerve-related tumours in NF2 are pathologically delineated as neurofibroma. In these tumours, there is an admixture of cell types (Schwann cells, fibroblasts and mast cells) and the tumour usually has identifiable axons within it. Neurofibromas are mainly found in the skin (where they are still outnumbered by schwannomas by a factor of 5–10) but are also found on the spinal nerve roots. Neurofibromas in NF2 do not develop intracranially. There is currently no evidence of histological or molecular differences between neurofibromas in NF1 and those in NF2. Halliday et al.[35] showed that, in a series of spinal schwannomas and neurofibromas, all spinal tumours in patients with NF1 were neurofibromas, while, with one exception, all spinal tumours in patients with NF2 were schwannomas (one patient had a mixed tumour). In contradistinction to NF2, schwannomas and meningiomas are not found in excess in NF1.[36]

The second most characteristic tumour of NF2 is meningiomas, which usually develop supratentorially in the falx and around the frontal, temporal and parietal regions. Surgical excision of meningiomas around the spinal cord can be difficult. Although there are different histological types of meningioma (meningothelial, fibroblastic and transitional), there is no evidence for a clinical subdivision into NF2-related and non-NF2 related meningiomas. Collision tumours consisting of a schwannoma and meningioma are sometimes seen, particularly in the cerebello-pontine angle. Antinheimo et al.,[22] in a study of all meningiomas and schwannomas in an 11-year period in the Helsinki area, found that 3% of schwannoma patients and 1% of meningioma patients had NF2. A further 2% of schwannoma patients and 4% of meningioma patients had multiple tumours without fulfilling clinical diagnostic criteria for NF2. The great majority of NF2 patients do not present with an isolated tumour, and there is only a small risk of NF2 after a truly isolated VS (no other features of NF2 on clinical examination or scan).[37] However, it is important to recognize that as many as 10% of those presenting in childhood with an apparently isolated meningioma develop NF2.

Low-grade ependymomas and occasionally gliomas also develop; they are very indolent and rarely metastasize. The primary location for these tumours is in the cervical spine and brainstem.

Recently a new era in drug therapy was heralded by evidence that the VEGF antibody bevacizumab had efficacy in shrinking growing schwannomas in NF2.[38]

CLINICAL MANAGEMENT

NF2 presents complex management issues and patients should be managed by a multidisciplinary team consisting of a neurosurgeon, otolaryngologist, audiologist, ophthalmologist, neuroradiologist and geneticist. Surgical results are certainly far better when managed by an experienced team.[39, 40] Indeed there is now firm evidence of a statistically significant reduced risk of mortality for NF2 patients managed at speciality centres in the UK.[25] Radiation treatment can have a role for patients who have particularly aggressive tumours, who are poor surgical risks or who refuse surgery. Teams that are experienced in the positioning of brainstem implants can offer partial auditory rehabilitation to those who are deaf, although results are still behind those achievable for cochlear implants. Because detection of tumours at an early stage is effective in improving the clinical management of NF2, presymptomatic genetic testing is an integral part of the management of NF2 families.

Once a mutation has been identified in an affected individual, a 100% specific test is available for that family. Linkage analysis is still possible in rare families where no mutation is identified. In sporadic cases, testing of a tumour specimen usually identifies the underlying mutation and creates a test for offspring, especially in those with mosaic disease.[15, 16] Age at onset curves aid genetic counselling; for example, it can be seen that the risk of having inherited NF2 for an asymptomatic at-risk individual of 25 years of age, prior to screening, decreases to 25% (see **Figure 104.3**).[16, 41] At-risk individuals who have been shown not to have inherited the mutated *NF2* gene do not need further follow-up.

OUTCOMES

Even with improvements in microsurgery and use of radiation therapy, the great majority of individuals with NF2 become completely deaf. The tumours in NF2 are more difficult to treat than those of sporadic unilateral VS because NF2 VS are often multifocal, appearing like a 'bunch of grapes' around the vestibular nerve in particular. Histologically, NF2 VS are more lobular and less vascular than their sporadic counterpart,[33] which leads to a greater risk of facial nerve damage in NF2. Loss of facial nerve function and the resultant disfigurement is one of the most feared aspects of the condition for many people with NF2, although in good surgical hands this complication is now much less common.[39, 40] Patients may also be severely disabled by a combination of poor balance, visual problems and weakness due to spinal tumours. Indeed, many people with severe NF2 become wheelchair-bound in early adulthood, and many with severe, multi-tumour disease die in the second and third decades of life.

SCREENING PROTOCOL

Children of affected patients are at 50% risk of NF2 and screening for the disease can start at birth. Cataracts can affect vision in early life and other tumour implications are present in the first 10 years of life, particularly intracranial meningiomas. Screening for VS should start at 10 years of age because it is rare for VS to become symptomatic before then, even in severely affected families. Annual audiological tests, including auditory brainstem response, are still a useful adjunct to MRI.[41] Surgery is unlikely to be more successful for tumours <6 mm in diameter than for tumours 6–10 mm in diameter, but VS growth is higher in younger patients. Even in multiple affected patients of similar ages in NF2 families, however, there can be dramatic differences in VS growth rates. For these reasons, MRI screening every 2 years for those under 20 years old and every 3 years for those aged over 20 years should be sufficient for asymptomatic at-risk individuals without tumours. The initial MRI scan can be at about 10–12 years old, or earlier in severely affected families. Once tumours are present, MRI screening should be annual. Spinal tumours are found very frequently on MRI, as discussed previously. While only 30% of patients with spinal tumours have symptomatic tumours that may require operation, a full annual neurological examination is a wise precaution. In most families, it is now possible to develop a genetic test so that only those individuals who have inherited an *NF2* mutation need to be followed.

FUTURE PROSPECTS

Localization and cloning of the *NF2* gene has allowed precise diagnosis when a specific mutation is found in a family. Clinical factors that are closely related to mutation type, such as age at onset or age at diagnosis, predict the risk of mortality and VS growth rate more strongly than the type of constitutional *NF2* mutation. This may be particularly useful in patients with new mutations, in whom insight into the likely speed of tumour progression and risk of other tumours may not be apparent, but it should be noted that such aggregate correlations may be less useful in predictions for individual patients. DNA predictive testing for 70% of families is available with flanking markers or mutation testing, but there is currently little demand for prenatal NF2 diagnosis in the UK. A less controversial option may be pre-implantation diagnosis, which is being evaluated for other genetic diseases such as familial adenomatous polyposis and cystic fibrosis.

Replacement of the tumour suppressor product in the tumours through viral vectors or direct recombination of the *NF2* gene, although requiring great advances in our knowledge, could be very rewarding. Use of newer drugs, such as anti-angiogenesis and drugs targeted at the NF2 pathway, may also offer promise.[42]

KEY POINTS

- NF2 is an autosomal dominant condition caused by mutations in the NF2 gene on chromosome 22q.
- De novo cases have a high chance of having mosaic disease where the genetic mutation is present in only some of the cells and transmission risk is lower to children.
- Although treatment is primarily surgical, newer drug therapies particularly with bevacizumab are showing promise.

CHAPTER 105

NON-VESTIBULAR SCHWANNOMA TUMOURS OF THE CEREBELLOPONTINE ANGLE

Simon K.W. Lloyd and Scott A. Rutherford

SEARCH STRATEGY

A Medline search the MESH headings Cerebellopontine Angle OR CPA was carried out. A further search was performed for the following MESH headings: neoplasm, tumour, meningioma, epidermoid cyst, CPA cholesteatoma, arachnoid cyst, glomus jugulare, lipoma, dermoid cyst, facial schwannoma, trigeminal schwannoma, vagal schwannoma, cranial nerve neoplasms, glossopharyngeal schwannoma, jugular schwannoma, chondrosarcoma, chordoma, endolymphatic sac, cochlear schwannoma and haemangioma. A search combining the first and second searches was then performed. Finally, the headings vestibular schwannoma and acoustic neuroma were excluded. Additional searches for other rarer pathologies were also performed.

INTRODUCTION

Lesions of the cerebellopontine angle (CPA) are uncommon, making up 6–10% of intracranial tumours; 80–90% are vestibular schwannomas (VS), with the remaining 10–20% a heterogenous mixture of predominantly benign pathologies, although malignant also occur.[1–9] Pathology may arise from any of the anatomical structures that are found within or adjacent to the CPA. **Table 105.1** summarizes the types of pathology that may occur. Meningiomas and epidermoid cysts are the commonest non-vestibular schwannoma tumours of the CPA, making up approximately 10% and 6% respectively in this location.

SYMPTOMS AND SIGNS OF NON-VS CPA TUMOURS

Lesions of the CPA cause damage to the neurological structures traversing the CPA and it is not usually possible to differentiate between different pathologies based on symptoms and signs. Most present with audiovestibular compromise in the form of sensorineural hearing loss, tinnitus or vertigo.[7, 10, 11] Other cranial nerves may also be affected resulting in altered facial sensation, facial weakness, twitching or spasm and lower cranial nerve weakness depending on the position and nature of the lesion.

Larger tumours also cause brainstem compression that may result in ataxia, headache, hydrocephalus and, in the extreme, may compromise brainstem reflexes, particularly respiratory drive. Onset of symptoms and signs is usually insidious.

It is important to note that the majority of patients with these clinical features have no tumour but have other non-neoplastic pathology such as ischaemic disease, migraine or other neurological conditions.

IMAGING OF NON-VS CPA TUMOURS

Where symptoms and signs are often unhelpful in differentiating between CPA pathologies, modern radiological techniques have, in contrast, revolutionized the diagnosis of CPA pathology. This paradigm shift in the ability to diagnose and differentiate between CPA pathologies has resulted in fundamental philosophical changes in the management of CPA pathology with conservative management and stereotactic radiosurgery becoming increasingly popular in the management of such lesions.

Magnetic resonance imaging (MRI) is the gold standard imaging modality. It provides excellent definition of soft

TABLE 105.1 Differential diagnosis of non-vestibular schwannoma lesions of the cerebellopontine angle

	Benign	Malignant
Lesions arising from the CPA	• Meningioma • Epidermoid cyst • Arachnoid cyst • Trigeminal schwannoma • Facial schwannoma • Lower cranial nerve schwannoma • Lipoma • Dermoid cyst • Tuberculoma • Sarcoid granuloma • Neurenteric/enterogenous cyst • Trigeminal ganglioneuroma • Solitary fibrous tumour • Melanocytoma • Lipomatous glioneurocytoma • Benign glandular peripheral nerve sheath tumour • Neurocytoma	• Metastases (breast, gall bladder, nasopharynx, parotid) • Malignant melanoma • Lymphoma • Neuroectodermal tumour • Malignant peripheral nerve sheath tumour • Haemangiopericytoma
Temporal bone lesions involving the CPA	• Cholesterol granuloma • Glomus jugulare • Haemangioma	• Squamous cell carcinoma • Chondrosarcoma • Chordoma • Endolymphatic sac tumours (Papillary adenoma/adenocarcinoma) • Plasmacytoma
Intra-axial lesions involving the CPA	• Low grade glioma (Ependymoma/Astrocytoma) • Choroid plexus papilloma • Glioependymal cyst • Lipomatous hamartoma • Cysticerosis • Haemangioblastoma • Plasma cell granuloma	• High grade glioma (Glioblastoma/Malignant astrocytoma) • Medulloblastoma • Meningosarcoma • Choroid plexus carcinoma

TABLE 105.2 Table showing the imaging characteristics of the common pathologies affecting the CPA

Lesion	CT	CT + contrast	MRI T1- weighted	MRI T2-weighted	MRI + Gadolinium	Special features
Vestibular schwannoma	→	+	↓	↓/↑	+	'Ice cream cone'; heterogeneous enhancement if cysts
Meningioma	↑	+	→/(↑)	→/↓/(↑)	+	'Dural tail' on post-contrast imaging; may be calcified
Epidermoid	↓	–	↓	↑	–	Bright on DWI b1000 trace; internal structure may be visible on T1-W and T2-W MRI; close to CSF on T1-W and T2-W MRI; not CSF signal on FLAIR MRI
Lipoma	↓/fat	–	↑/fat	↑/fat	–	Complete saturation on T1 fat saturation MRI; chemical shift artefact on T2-W MRI
Arachnoid cyst	↓/CSF	–	↓/CSF	↑/CSF	–	
Glomus tumour	→/↑	+	↓	↑	+	'Salt and pepper'; T1-W MRI, bright haemorrhagic foci; T2-W MRI, dark flow voids
Choroid plexus tumour	→/↑	+	→/↓	→/↑	+	May be calcified; MRI may not distinguish papilloma from carcinoma; children > adults

↓, hypodense (CT)/hypointense (MRI) to brain; →, isodense (CT)/isointense (MRI) to brain; ↑, hyperdense (CT)/hyperintense (MRI) to brain; +, enhancement; –, no enhancement; CSF, cerebrospinal fluid; DWI, diffusion-weighted imaging; FLAIR, fluid-attenuation inversion recovery.

tissue structures. Axial and coronal T1-weighted imaging with gadolinium enhancement and T2-weighted imaging are widely used. Fat suppression in conjunction with gadolinium-enhanced imaging is also extremely helpful. Diffusion-weighted imaging (DWI) MRI has been introduced in the last decade and is also helpful, particularly in identifying epidermoid tumours.

High-resolution axial and coronal computed tomography (CT) is often a useful adjunct to MRI and provides excellent definition of bony structures.

Table 105.2 summarizes the radiological characteristics of the common CPA pathologies.

Other forms of imaging may also be helpful. This includes MR angiography and traditional angiographic imaging.

These are particularly helpful in delineating vascular lesions such as glomus tumours.

BENIGN LESIONS ARISING FROM THE CPA

Meningiomas

DEFINITION AND PATHOLOGY

Meningiomas arise from clusters of epithelial cells that are present at the tips of arachnoid villi that are concentrated in the walls of venous sinuses, in their tributary veins and at the cranial nerve exit foramina.[11, 12] They may be well circumscribed or, more rarely, *en plaque* when their growth pattern results in a flat lesion. Bony infiltration via Haversian canals can occur and may result in hyperostosis that is demonstrable radiographically. They displace or surround cranial nerves and blood vessels rather than invading them. Nevertheless, they can become strongly adherent to these structures.[10, 12]

Histologically, meningiomas may be graded from 1 to 3 according to the WHO grading system.[10–16] Grade 1 tumours make up 81% and are described as classical. Grade 2 tumours make up 15% and are described as atypical. Grade 3 tumours make up the remaining 4% and demonstrate malignant features including the ability to metastasize either haematogenously or via CSF.[17] Grade 1 and 2 tumours are regarded as benign. Meningiomas often contain 'psammoma bodies', spherical calcifications responsible for a sandy appearance of the tumour surface.

Most tumours are regarded as being idiopathic with the exception of those associated with neurofibromatosis type 1 and type 2. Twenty per cent of adolescents with meningiomas have some form of neurofibromatosis.[13] Some authors have suggested an endocrine aetiology based on high concentrations of progesterone receptors, moderate numbers of androgen receptors and a low level of oestrogren receptors within meningiomas. A recent meta-analysis of the influence of hormone replacement therapy on development of meningiomas in women suggests that there is an association.[18] There may also be an association with androgen use in males.[19] Irradiation to the head is also associated with an increased risk of meningiomas.

EPIDEMIOLOGY

Meningiomas account for approximately 10–20% of all intracranial neoplasms. The incidence increases with age, the average age at the time of diagnosis of posterior fossa meningiomas being approximately 43 years.[13] Between 5% and 10% of all meningiomas arise in the CPA and are more common in middle-aged females. Second to vestibular schwannomas, meningiomas are the most common neoplasm found in the CPA, constituting roughly 10% of lesions in this location.[10–12]

CLINICAL PRESENTATION

Meningiomas differ from vestibular schwannomas in their clinical presentation. Audiovestibular symptoms are common but are often less marked and of shorter duration in patients with meningiomas compared with vestibular schwannomas.[2, 4, 7, 10, 12, 14, 20–23] Hearing loss is present in 41–80% of patients. This is usually sensorineural in nature but may be conductive if the middle ear is involved.[24] Tinnitus is present in about 15–60% of patients and dysequilibrium is a presenting symptom in 20–60% of patients. Other cranial nerve symptoms and signs tend to be more common with meningiomas than with vestibular schwannomas, occurring in up to 30% of patients. Fifth and seventh nerve symptoms are present in up to 20–60% and 10–50% of patients respectively.[4, 7, 10, 12, 14, 22, 23] Cerebellar signs are reported in about 30–90% of patients.[7, 12, 14, 21–23]

DIAGNOSIS

CT scans usually reveal a durally based homogenous tumour that is either iso- or slightly hyperintense. They avidly take up contrast.[10, 11] Peri-tumoural oedema may also be demonstrated, as may bony erosion, hyperostosis and intra-tumoral calcification. CT is superior to MRI in evaluating bone involvement and calcification of the tumour and is also helpful in demonstrating extension into the middle ear.[11, 13]

The gold standard imaging modality for demonstrating meningiomas is, however, MRI. T1-weighted imaging shows a homogenous iso- or hypointense tumour relative to brain parenchyma that is durally based. They take up gadolinium although they often enhance less avidly than vestibular schwannomas (**Figure 105.1**). With gadolinium, a dural tail is seen in around 60% of tumours. It has not been established whether the changes are neoplastic or represent reactive changes in the meninges adjacent to the tumour.[11, 13, 14] They are very variable in intensity on

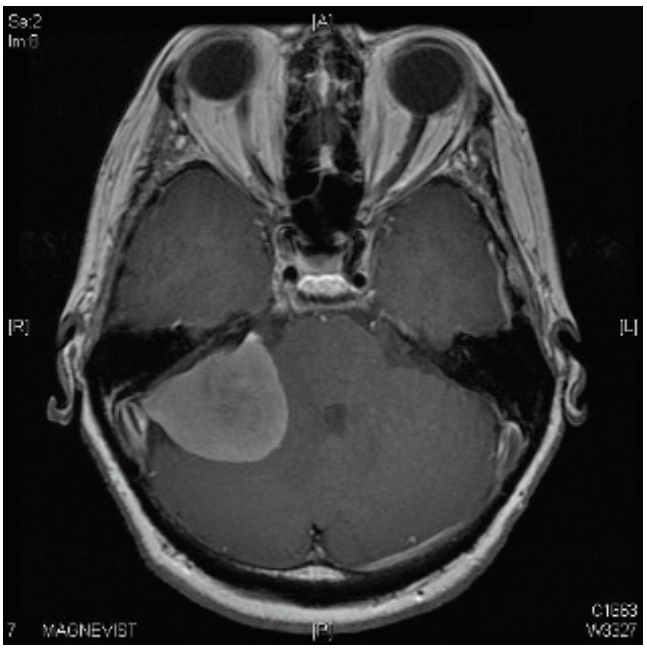

Figure 105.1 T1-weighted axial MRI scan with gadolinium enhancement showing a large right CPA meningioma.

T2-weighted imaging.[10, 11, 13, 14] Again, MRI may identify significant peri-tumoral brain oedema.

The natural history of untreated meningiomas is generally benign. A systematic review by Sughrue et al. have demonstrated that, over a 4 year period, 50% demonstrate growth. Half of these increase in size by less than 10% per annum.[25]

TREATMENT

For selected cases, particularly for those patients with severe co-morbidities, advanced age or small tumours, observation with serial MRI has become increasingly popular. This reflects the generally benign natural history of meningiomas. This type of management is, however, less effective for meningiomas compared to vestibular schwannomas that demonstrate growth in only 20–30% of cases.

For large or symptomatic tumours, the treatment of choice for meningiomas is surgical excision and the ideal is complete resection of tumour together with involved dura and affected underlying bone. Although complete macroscopic clearance has been described in up to 91% of CPA meningiomas,[26] complete resection is not always possible, particularly if there is extensive bony involvement or strong adherence to neurovascular structures or brain.[27] The extent of resection may be graded using the Simpson criteria.[28] This and the histological grade of the tumour determines recurrence rates. For example, for Simpson grade I tumours, the recurrence rates for WHO grades 1 and 2 respectively are 12% and 41%.[16] **Table 105.3** summarizes the Simpson criteria together with the 10-year recurrence risk for each grade.

Surgical approach is determined by hearing status and the size and location of the tumour, including involvement with neurovascular structures as well as local preferences. The retrosigmoid approach is the standard neurosurgical approach to the posterior fossa and offers the possibility of hearing preservation in appropriate cases.[20, 26, 29, 30] The translabyrinthine approach offers direct access to the CPA and may offer lower mortality and improved facial nerve outcome compared to the retrosigmoid approach, but sacrifices residual hearing.[3, 30–32] A combined translabyrinthine-retrosigmoid approach can be used for tumours greater than 3–4 cm. The transcochlear approach offers anterior exposure to facilitate resection of tumours extending into the region of the clivus, Meckel's cave and the petrous portion of the internal carotid artery, and may be used in combination with a trans-tentorial approach if required.[30, 32] The middle fossa approach may also be used for tumours within the internal auditory canal that have a small CPA component.

Several authors have investigated the potential role of radiotherapy as a primary treatment modality and for recurrent or residual tumours.[33, 34] A number of types of radiotherapy have been used. Historically, external beam radiotherapy was used but this achieved relatively poor control rates of around 85%.[35, 36] Latterly, fractionated stereotactic radiotherapy and stereotactic radiosurgery have been used. For WHO grade 1 tumours, these techniques produce growth control rates of 86–99% although control becomes less likely with increasing tumour volume.[34, 37, 38] Similarly, brachytherapy with iodine-125 seems to be of value in both recurrent and primary skull base meningiomas.[39]

Medical therapies including hormone therapies, temozolomide, hydroxyurea, alpha-interferon, mifepristone and COX-2 inhibitors are currently being investigated but results to date have generally been disappointing.[13, 40, 41] Targeted chemotherapy aimed at blocking specific growth factors or intracellular signalling pathways are currently under investigation.[42]

TABLE 105.3 Table summarizing the Simpson criteria for completeness of tumour removal

Simpson grade	Completeness of resection	10-year recurrence[28]
I	Complete removal including underlying bone and associated dura	5–9%
II	Complete removal and coagulation of dural attachment	15–19%
III	Complete removal without resection of dura or coagulation	12–29%
IV	Subtotal resection	19–40%

Epidermoid cysts

DEFINITION AND PATHOLOGY

Epidermoids or primary cholesteatomas are keratinous cysts that originate from inclusion epithelial cells trapped during neural tube closure between the third and fifth weeks of gestation. In the CPA, they are thought to originate from transplantation of epithelial cell rests by the laterally migrating optic and otic capsules or developing neurovasculature.[2, 11, 43] They are distinguished from dermoids by the absence of skin adnexal components. They increase in size slowly by the accumulation of keratin and cholesterol produced by the desquamation of the squamous epithelial lining of the cyst and their growth rate is similar to that of normal skin and not the exponential growth seen with most neoplasms.[2, 11, 43] They insinuate around neurovascular structures, irritating rather than displacing them, and they fill the cisterns from which they arise following the line of least resistance.[10, 43, 44] Thirty to 40% of epidermoids occur in the CPA but they can be found elsewhere in the brain.[2, 11, 43] Macroscopically, these tumours have a soft texture and a pearly white colour. Microscopically, they are avascular tumours lined by stratified squamous epithelium that surrounds a mass of keratinous debris and, frequently, cholesterol crystals.[10, 43]

EPIDEMIOLOGY AND AETIOLOGY

Epidermoids account for 0.2–1.8% of all intracranial neoplasms and constitute 5–9% of tumours in the CPA.[2, 11, 43, 45] They may be slightly more common in

males than in females. They are not associated with any other congenital abnormalities.[43]

CLINICAL PRESENTATION

Because of their slow growth, CPA epidermoids may be asymptomatic for years.[2, 7, 43] As with meningiomas, hearing loss is less common than with vestibular schwannomas, occurring in 50–80% of cases.[4, 7, 43, 46–48] Fifth and seventh nerve symptoms occur in 30–50% of cases. Cerebellar signs or signs of increased intracranial pressure may also occur.[4, 7, 43, 46–48] Lower cranial nerve symptoms and signs are more rare.[4, 7, 43, 46–48] Spontaneous meningitis without surgery has been reported and an intracranial epidermoid should be suspected in a patient with repeated episodes of aseptic meningitis.[49] Malignant transformation of epidermoids into squamous cell carcinoma has been reported and present with more severe and rapidly progressive symptoms.[50, 51]

DIAGNOSIS

As with other types of CPA pathology, MRI is the imaging modality of choice.[11] On T1-weighted imaging, the lesions are heterogenous and of low signal showing no enhancement with gadolinium, although granulations around the cyst may enhance. T2-weighted imaging is particularly helpful and shows a high signal homogenous lesion that is lobulated, conforming to the shape of the cistern in which it has developed (**Figure 105.2**).[11] Large epidermoids compress adjacent brain. In addition, FLAIR or DWI is usually diagnostic with the lesion having high signal. This is very helpful in differentiating epidermoid cysts from arachnoid cysts.[52]

CT may also be used and shows a lesion with similar signal to CSF. There are not usually any changes within the adjacent bone. CT is often, therefore, not particularly helpful. Atypical MRI and CT appearances have been reported.[53, 54]

TREATMENT

Microsurgery is the treatment of choice with the retrosigmoid approach being the standard approach, although the translabyrinthine and middle fossa approaches may be used if required.[4, 7, 46–48] The goal of surgery is decompression of the cyst and, if possible, removal of the capsule. The interior of the tumour can be easily removed using suction or curettage. The capsule can, however, be very difficult to remove because of the way that epidermoids engulf neurovascular structures, and total removal is associated with a significantly higher morbidity and mortality.[4, 7, 43, 46–48] A comparison of recent major series shows a rate of total removal of between 0% and 97%. Most authors advocate subtotal removal of the tumour rather than compromising neurovascular function. Surgery may be repeated but is often only required every decade or more.[4, 7, 43, 46–48] Post-operative aseptic meningitis may occur in up to 40% of cases and is almost unique to this condition. This complication may be avoided by the use of prophylactic steroid use and minimal intra-operative spillage of tumour. If it occurs, the patient should be treated with antibiotics and steroids.

Even in modern series, recurrence rates of up to 35% have been reported.[4, 7, 43, 46–48] Serial imaging of any recurrence should be performed and a conservative approach taken, given that tumours may not become symptomatic during the patient's normal life span.

Arachnoid cysts

DEFINITION AND PATHOLOGY

Arachnoid cysts are congenital malformations of the arachnoid and are histologically characterized by a cyst wall that resembles arachnoid[55] and a cystic space filled with CSF or xanthochromic fluid.

EPIDEMIOLOGY

Arachnoid cysts make up approximately 1% of all intracranial lesions and the CPA represents the second most

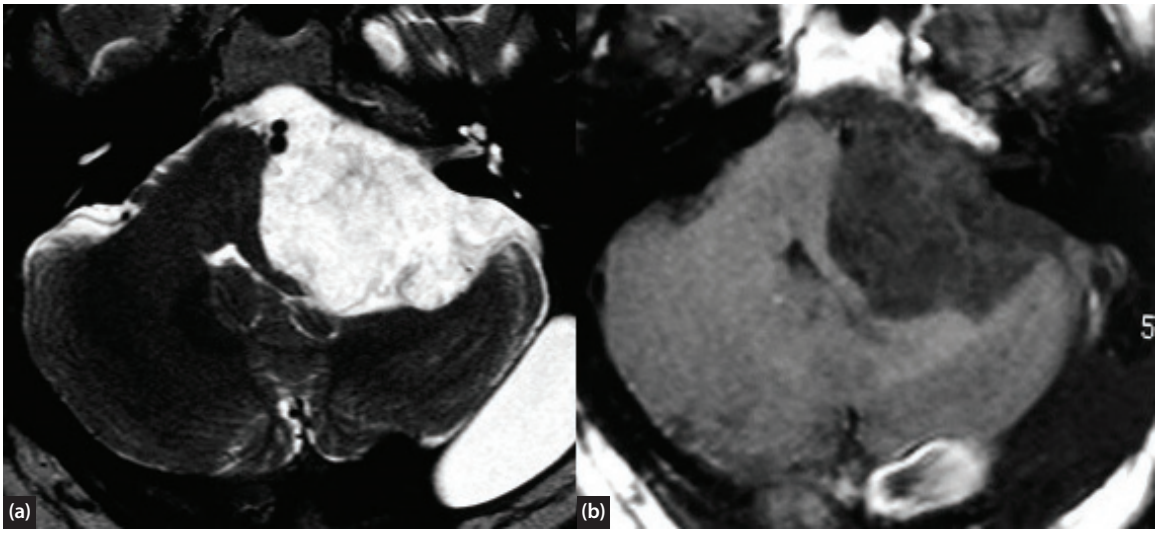

Figure 105.2 Axial MRI scans showing a large left CPA epidermoid. **(a)** T1-weighted scan without gadolinium enhancement. **(b)** T2-weighted scan.

common location after the Sylvian fissure. The aetiology remains unknown, but abnormal CSF flow, trauma or inflammation have been proposed.[56]

CLINICAL PRESENTATION

Eighty-five per cent of cysts are asymptomatic. Symptomatic cysts present with symptoms similar to other CPA lesions, with gradual onset of cranial nerve dysfunction especially of the VIIIth cranial nerve.[56–60] Sudden sensorineural hearing loss has been reported[61] and there have been a number of reports of hemifacial spasm.[62, 63] They may also present with symptoms of brainstem and cerebellar compression, and syringomyelia has been described.[64]

DIAGNOSIS

MRI is the primary diagnostic imaging modality. The cysts are heterogeneous in their appearance but they have the same signal as CSF, being hypointense on T1-weighted images and hyperintense on T2-weighted images (**Figure 105.3**). No enhancement is seen.[10, 56, 60] The cyst wall is smooth and round and the cysts compress or displace adjacent structures. Erosion of adjacent bone may also be seen.[44] They may be confused with epidermoid cysts and diffusion weighted imaging is helpful in differentiating these two pathologies. Only 2% of them demonstrate growth.

TREATMENT

Asymptomatic cysts require no treatment and should be followed by serial MRI scans. For symptomatic cysts, microsurgical decompression and fenestration via the retrosigmoid approach is the most commonly recommended procedure,[10, 11] although some authors have described an endoscopic approach.[65, 66] Sporadic reports of cyst recurrence after inadequate fenestration exist and some authors advocate complete cyst resection.[60] Others suggest cystoperitoneal shunts but these appear to be less effective than fenestration.[56, 60]

Lipomas

DEFINITION AND PATHOLOGY

CPA lipomas are likely to be congenital malformations and not actual neoplasms.[67–70] They may result from the failed dissolution and aberrant differentiation of the meninx primitiva, the mesenchymal derivative of neural crest,[67, 70, 71] which contains mature adipose cells accompanied by a varying degree of fibrovascular tissue. Blood vessels and nerves pass directly through them and are not displaced.

EPIDEMIOLOGY

These are rare tumours with an incidence of 0.08% in autopsy cases.[71, 72] They make up approximately 0.05–0.1% of CPA tumours,[11, 44, 67, 71, 73–78] although this may be an underestimate given that they may be mistaken for vestibular schwannomas.[71, 79] It is thought that only 9% of intracranial lipomas are found in the CPA, with interhemispheric lipomas being the most common.[70] A male preponderance has been reported by several authors.[73, 79, 80] Mean age at diagnosis is around 50 years.[80] Bilateral tumours have also been described.[71]

CLINICAL PRESENTATION

They present clinically with similar symptoms to other more frequent CPA tumours like vestibular schwannomas,[11, 67, 71, 73–75, 77, 79–81] although the onset of symptoms may be more insidious. Hearing loss is the most common presenting symptom followed by tinnitus and dizziness.[71–73, 76, 79, 80] Reports regarding their effect on the facial nerve vary in the literature, with some series showing no effect on facial nerve function and others suggesting that up to 9% of cases have facial nerve weakness.[73]

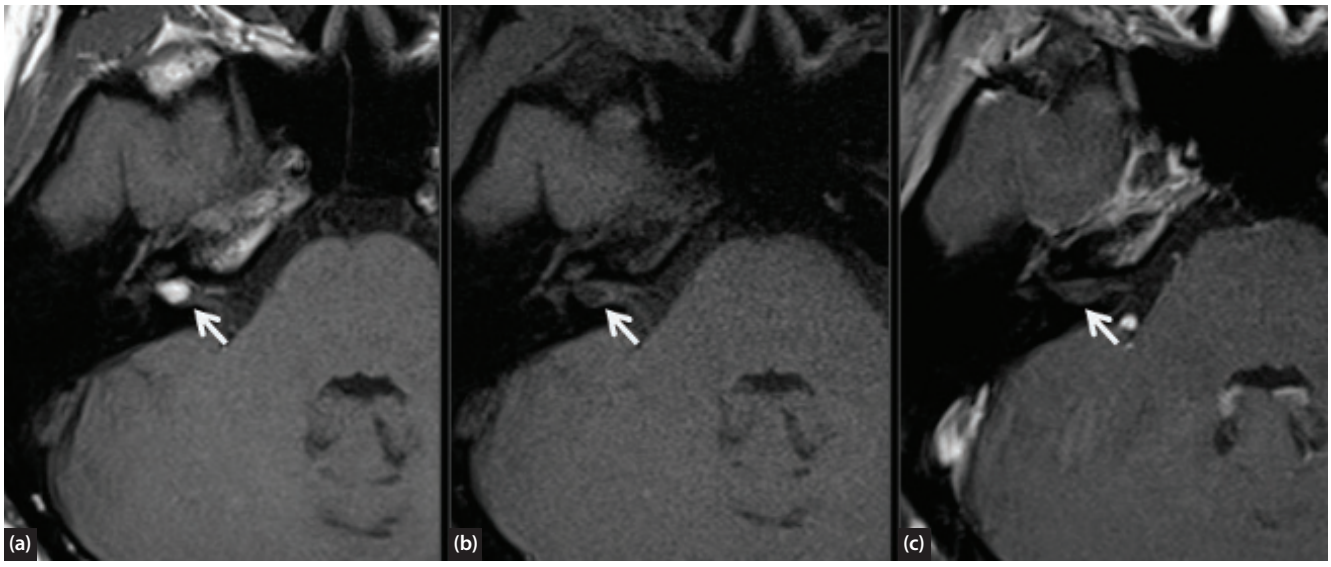

Figure 105.3 An intracanalicular right sided lipoma. (a) Very high signal intensity on axial non-contrast enhanced, T1-weighted imaging. **(b)** Hypointense on axial T1-weighted following fat suppression. **(c)** No enhancement following administration of gadolinium.

Other reported symptoms include hemifacial spasm[82, 83] and trigeminal neuralgia.[68, 84, 85] Weakness of other cranial nerves (with the exception of the vestibulocochlear nerve) has not been reported.

DIAGNOSIS

On MR imaging, lipomas have the same imaging characteristics as subcutaneous fat with high intensity on non-enhanced T1-weighted MRI studies, with progressive iso- to hypointensity with increasing T2 weighting. They produce no signal with fat suppression sequences.[75, 77, 80, 86, 87] The latter is extremely useful in differentiating lipomas from other CPA pathology (**Figure 105.4**). Furthermore, lipomas have also been said to display the MRI phenomenon of chemical shift and this may assist further in confirming the diagnosis. This phenomenon consists of a ring of low signal intensity at the posterior edge of the mass because of mis-registration of the fatty tissue at the interface with soft tissue and cerebrospinal fluid.[71]

Most of the literature suggests that CPA lipomas rarely grow,[11, 71–73, 78–80] with only one documented case of a CPA lipoma demonstrating growth in the current literature.[71] It has, however, been hypothesized that CPA lipomas might fluctuate in size, depending on the patient's weight.[71] This is not a consistent finding in the literature, however.[80]

TREATMENT

Because they are very unlikely to grow, conservative management has become the mainstay of management with some authors suggesting that long-term follow-up is not required.[80] Surgical removal has, however, been performed in cases with symptoms related to compression phenomena, mostly of the cranial nerves[67, 71–73, 79] or in cases of misdiagnosis.[78] In many of these cases, total removal of the lipoma has been very difficult and surgery has been associated with significant post-operative morbidity.[67, 71–73, 79] This is because CPA lipomas tend to be adherent to cranial nerves and the brainstem, making dissection challenging.[71, 73, 78] Most authorities therefore recommend subtotal removal if surgery is indicated. Both the translabyrinthine and retrosigmoid approaches have been described.[11, 67, 71]

Non-vestibulocochlear cranial nerve schwannomas

Schwannomas are the commonest neoplasm of cranial nerves and may develop on the V, VII or lower nerves. Symptoms reflect the nerve involved. Overall, they constitute 2–3% of all CPA tumours. Microscopically, non-vestibular schwannomas cannot be distinguished from vestibular schwannomas.

Facial schwannomas

DEFINITION AND PATHOLOGY

Facial nerve schwannomas (FNS) are rare benign tumours of the Schwann cell sheath of the facial nerve. Tumour may develop at any point along the course of the nerve from the CPA to the muscular branches in the face. Single or multiple segments of the nerve can be involved although the latter is more common.[88] The CPA is involved in 22 to 46% of cases depending on the series reviewed.[88, 89]

EPIDEMIOLOGY

FNS tend to present in the fourth or fifth decades of life[88] and have a male preponderance.[90]

CLINICAL PRESENTATION

In a meta-analysis of 427 patients, the commonest presenting symptoms were facial weakness and hearing loss occurring in 63% and 51% of cases respectively.[91] Facial weakness tends to be more common with tumours involving the extracranial segments of the nerve, especially the geniculate and labyrinthine segments. It can be of variable severity and may be transient or progressive or recurrent.[92, 93] The proportion of patients showing deterioration of facial function following diagnosis ranges from 21% to 38% depending on the series.[88, 94] Audiovestibular symptoms are more common with tumours involving the CPA and internal auditory canal (IAC),[95] although conductive hearing loss may occur if the middle ear is involved.

DIAGNOSIS

The gold standard diagnostic tool for the identification of a FNS is T1-weighted MRI with gadolinium enhancement. This allows identification of multiple segments of the facial nerve, a feature that is highly suggestive of FNS. Nevertheless, it may be extremely difficult to differentiate FNS from other pathologies, particularly if the radiological changes are confined to the CPA or the IAC as the

appearance can be identical to that of a vestibular schwannoma. It may also be difficult to differentiate FNS from other rarer pathologies such as haemangiomas. All CPA tumours should therefore have at least one scan with gadolinium to ensure that there is no adjacent VII nerve enhancement to suggest an FNS rather than a VS.

Tumour growth (>2 mm) has been reported to occur in 14% to 31% of patients.[88, 94]

TREATMENT

In the absence of significant tumour growth, significant brainstem compression or deterioration of facial function to grade 4 or worse, most clinicians recommend conservative management. Over half of tumours are therefore managed conservatively, at least initially.[88, 94, 96]

In those patients not managed conservatively, most undergo surgical excision although stereotactic radiotherapy may also be considered.

For those having surgery, the approach depends on the segment of nerve involved but most often requires a translabyrinthine or transotic approach if the CPA is involved. If there is serviceable hearing a combined transmastoid/middle fossa/retrosigmoid approach may be considered. Facial nerve grafting with great auricular or sural nerves is carried out following tumour removal. The possibility that a CPA tumour could be an FNS rather than a VS should always be considered. Fascicle preservation surgery has also been described with successful preservation of facial function.[97] Bony decompression of the tumour may also be considered under certain circumstances and may avoid deterioration in facial function.

The indications for radiotherapy are, as yet, unclear. A single case report of treatment with stereotactic fractionated radiotherapy has shown that tumour growth can be controlled and facial function not worsened by this modality of treatment.[98]

Trigeminal schwannomas

Tumours tend to involve either the ganglion or the nerve root, or both. Fifth nerve symptoms tend to dominate over VIIIth nerve dysfunction and the patients present with facial pain or numbness.[10] Other symptoms of an expanding CPA tumour may also be present. CT scans demonstrate enlargement of Meckel's cave or foramen lacerum and the tumours tend to be hypo- or isodense and show contrast enhancement. On MRI, the tumours appear iso- or hypointense on T1-weighted images and isointense on T2-weighted images and show bright enhancement as with other schwannomas. Tumour removal is possible through combined posterior, middle fossa or infratemporal fossa approaches.[10, 99] Endoscopic transnasal removal of tumours involving the middle fossa and infratemporal and pterygopalatine fossae has also been described.[100] The use of stereotactic radiosurgery has also been reported.[101]

Lower cranial nerve schwannomas

Lower cranial nerve schwannomas account for less than 1% of all CPA lesions.[45] They develop within the jugular foramen and may extend intracranially or extracranially, often developing a dumbbell shape. Symptoms reflect the nerve involved but may also result in audiovestibular dysfunction or clinical features of brainstem compression if large. Their imaging characteristics are those of any cranial nerve schwannoma. Treatment is by conservative management unless there is significant brainstem compression, in which case surgical resection may be undertaken. The decision to proceed is easier if there has already been loss of lower cranial function. Approaches include retrosigmoid, transcochlear and infratemporal fossa approaches depending on the position of the tumour.[102, 103] Growing tumours with good lower cranial nerve function may be treated with stereotactic radiosurgery.

Miscellaneous tumours

Dermoids are midline cysts and rarely invade the CPA laterally. They contain skin adnexal components, contrary to epidermoids.[45]

Choroid plexus papillomas are rare tumours, representing less than 1% of intracranial neoplasms. They are derived from the epithelial cells of the choroid plexus and demonstrate the structure of the normal choroid plexus when benign. Most often affecting children, they typically arise in the lateral ventricles. In adults, the primary site is the fourth ventricle. Malignant forms are very rare. They may produce signs of a CPA tumour, and signs of raised intracranial pressure are almost always present. Evaluation of CPA choroid plexus papillomas is by CT, MRI and angiography. Their prognosis is excellent when total surgical extirpation is possible. When surgery is not possible, radiotherapy has been evaluated, but results are variable.[104, 105]

Enterogenous cysts[106] are midline cysts that have very rarely been reported within the CPA. They may mimic arachnoid cysts, lipoma, epidermoids or cystic vestibular schwannomas on MRI.[45] They are usually symptomatic and treatment is usually by complete excision.

Neurenteric cysts are cysts derived from notochordal gastrointestinal or respiratory cell rests. They are very rare in the CPA and are usually treated with surgical resection.[107]

Inflammatory disease such as autoimmune or idiopathic pachymeningitis can occur in the CPA and may produce symptoms of CPA pathology due to compression of CPA structures by hypertrophied dura. Similarly, granulomatous diseases, such as tuberculosis and sarcoidosis, may affect the CPA.

The vertebral and basilar arteries and some of their branches pass through the CPA and aneurysms of the vessels, although not true neoplasms, may cause a mass effect on adjacent neural structures.[10, 44, 45]

MALIGNANT LESIONS ARISING FROM THE CPA

Metastatic lesions from either intracranial or extracranial sources account for around 1% of CPA tumours. Sources of extracranial origin are breast, prostate, lung,

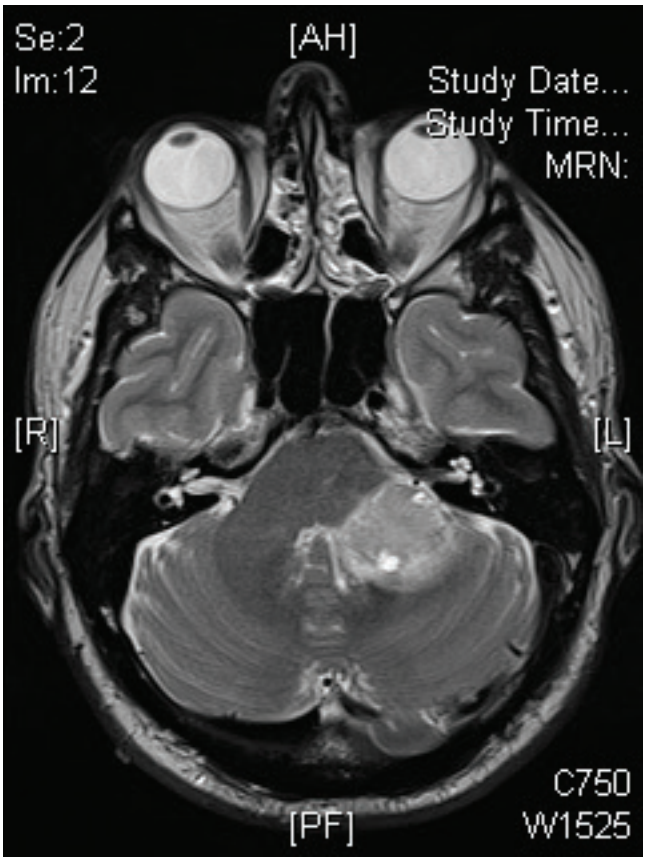

Figure 105.5 Axial T1- weighted MRI scan with gadolinium enhancement showing a left CPA metastasis.

melanoma, thyroid and gynaecological tumours.[45] They usually have similar signal characteristics to schwannomas on MRI (**Figure 105.5**). Diagnosis may be aided by lumbar puncture and CSF cytology. Solitary metastases may be treated with surgical resection or with stereotactic radiosurgery.

Melanomas of the CPA are very rare and may occur as either primary or metastatic tumours, the latter being the most common. Again, they often have similar signal to schwannomas on imaging. Prognosis is poor.[108]

CPA lymphomas are rare and occur as an extra-axial lymphoma, as extension from an intra-axial lymphoma, or as a leptomeningeal lymphoma presenting as a CPA lesion. Aggressive removal is not necessary, but radiotherapy to the lesion should be performed.[109]

BENIGN TEMPORAL BONE LESIONS INVOLVING THE CPA

Lesions originating from the structures of the skull base, especially the temporal bone, may reach the CPA by direct extension.

Cholesterol granulomas

Cholesterol granulomas arise from the apex of the petrous bone and may enlarge to reach the posterior fossa and produce nerve dysfunction (**Figure 105.4**).[44] Symptomatic cases may be decompressed via a transmastoid or endoscopic transnasal approach depending on its position.[110]

Glomus tumours (paragangliomas)

Large jugular foramen paragangliomas (Fisch type D) may present in the CPA by extension from the jugular foramen. Very rarely, primary CPA paragangliomas have been reported.[111] They are usually benign but locally aggressive, and destroy the petrous bone to enlarge to the CPA. Symptoms include pulsatile tinnitus, headache or VIIIth nerve symptoms. Examination may reveal a red pulsatile mass behind the tympanic membrane with a conductive hearing loss. Arteriography should be performed to demonstrate the extent of the tumour and the nature of blood supply. CT appearances are of a well-defined tumour with adjacent bone erosion and marked enhancement after contrast injection. They produce a characteristic 'salt and pepper' image on both T1- and T2-weighted MRI images because of intratumoral haemorrhages (**Figure 105.6**). Glomus tumours enhance intensively after gadolinium administration. Indications for treatment include brainstem compression and significant tumour growth with around 40% demonstrating growth following diagnosis.[112] Radiotherapy effectively controls growing tumours in 90–100% of cases and surgery has become less common as a result.[113–115] It is usually reserved for patients with significant brainstem compression, radiosurgery failure and those patients who already have lower cranial nerve compromise as post-operative cranial nerve deficits are common with unacceptably high morbidity.

MALIGNANT TEMPORAL BONE LESIONS INVOLVING THE CPA

Squamous cell carcinoma of the temporal bone accounts for 0.3% of head and neck malignancies. They are aggressive malignancies that invade adjacent structures.[116, 117] Lymph node metastases occur in 20%. Invasion of the carotid canal, cervical node involvement and poorly differentiated histology are poor prognostic factors. For cases that are operable, radical *en bloc* resection with preservation of the carotid artery, selective neck dissection and post-operative radiotherapy is recommended.[116, 117] It has a disease specific survival ranging from 19% to 48%.

Chondromas and chondrosarcomas are extremely rare and develop from embryonic cartilaginous remnants enclosed in the bones of the skull base.[44, 118] Both lesions are usually treated surgically.

Chordomas are very rare midline tumours arising from notchordal remnants around the vertebral axis. Intracranially they occur at the clivus although primary intradural chordomas have been reported. Whilst they are malignant they are generally fairly indolent in

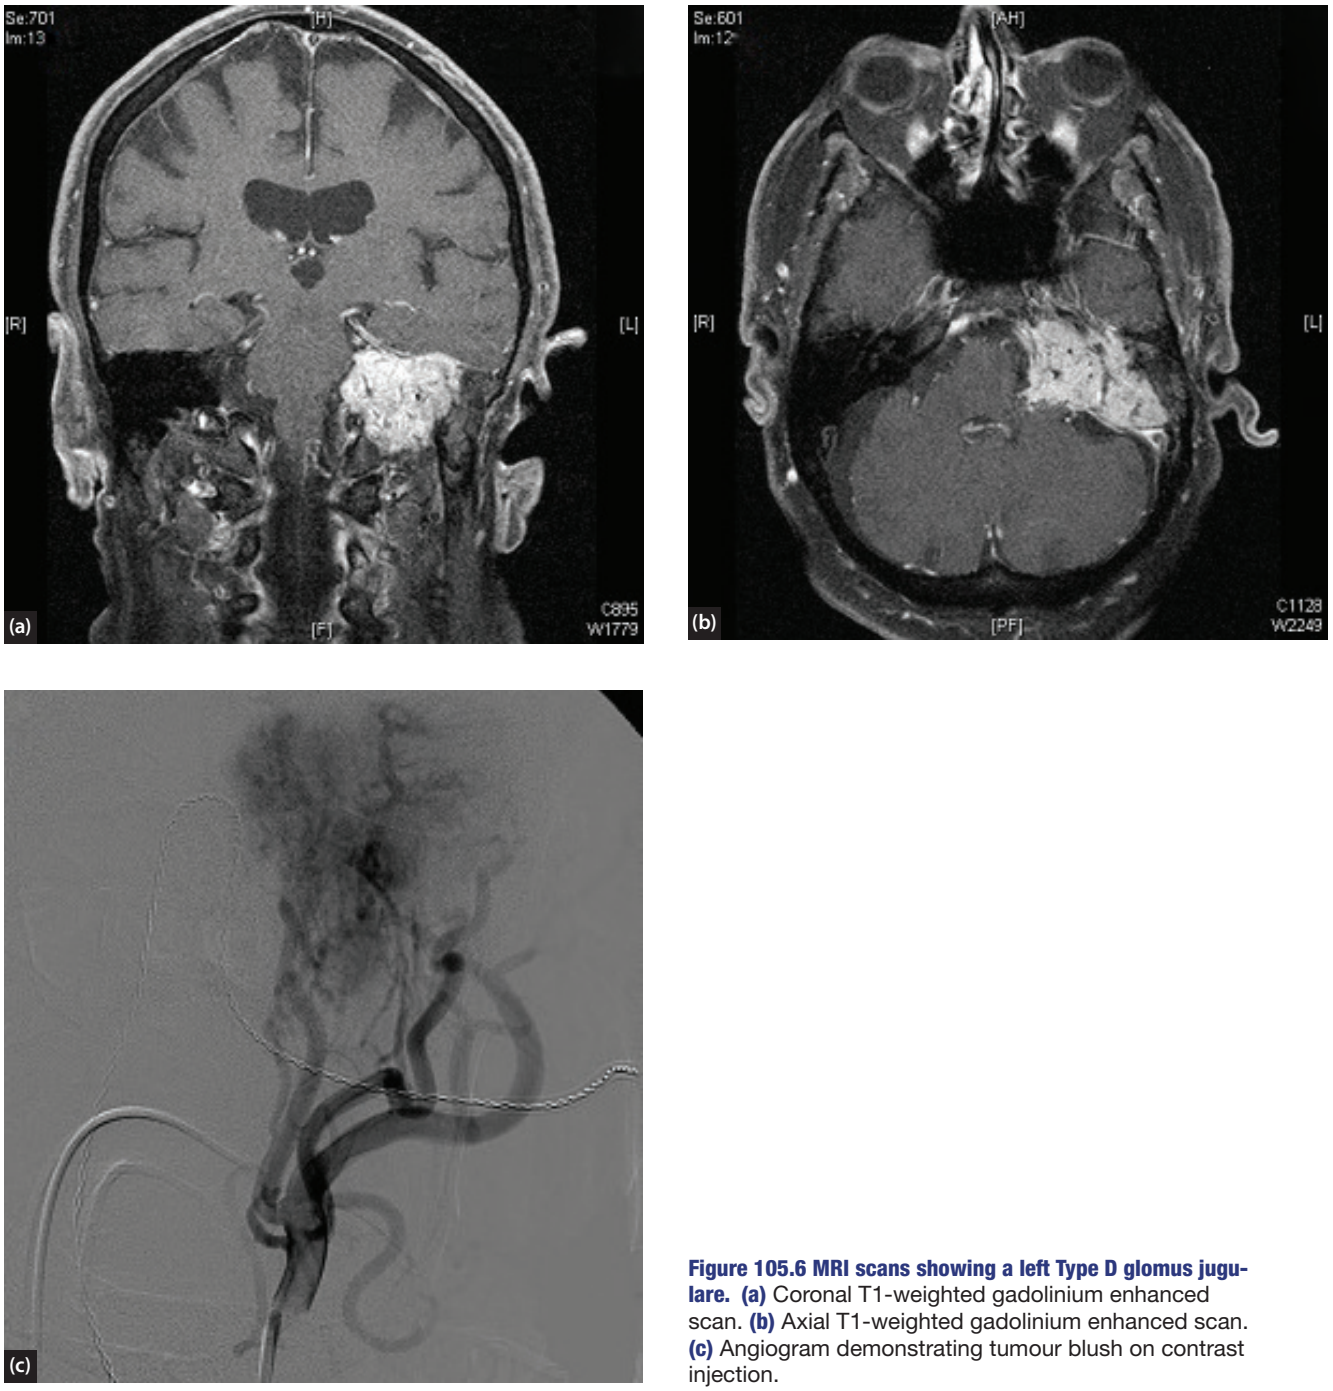

Figure 105.6 MRI scans showing a left Type D glomus jugulare. **(a)** Coronal T1-weighted gadolinium enhanced scan. **(b)** Axial T1-weighted gadolinium enhanced scan. **(c)** Angiogram demonstrating tumour blush on contrast injection.

their behaviour. Treatment is difficult but extended endoscopic endonasal approaches in combination with open approaches have increased the chances of complete resection. This is not always possible, however, particularly if the tumour extends into the inferior clivus.[119, 120] Resection should be followed by radiotherapy with proton beam therapy becoming increasingly the modality of choice. Recurrence rates are high.

Endolymphatic sac tumours are rare low-grade adenocarcinomas of the endolymphatic sac.[121, 122] Twenty per cent are sporadic but most are associated with Von Hippel Lindau Disease (4% of patients with this condition have endolymphatic sac tumours).[123] They are slow growing but locally destructive and rarely metastasize. Their presentation is similar to that of other CPA lesions. CT shows bony destruction centred on the endolymphatic sac. They have heterogenous increased signal on both T1 and T2-weighted imaging with patchy enhancement with gadolinium (**Figure 105.7**). Treatment is by wide local resection via retrolabyrinthine, translabyrinthine or retrosigmoid approaches. Cure can be achieved in 90% of moderate sized tumours but large tumours are difficult to cure. There may be late recurrence. Adjuvent radiotherapy may also reduce recurrence.

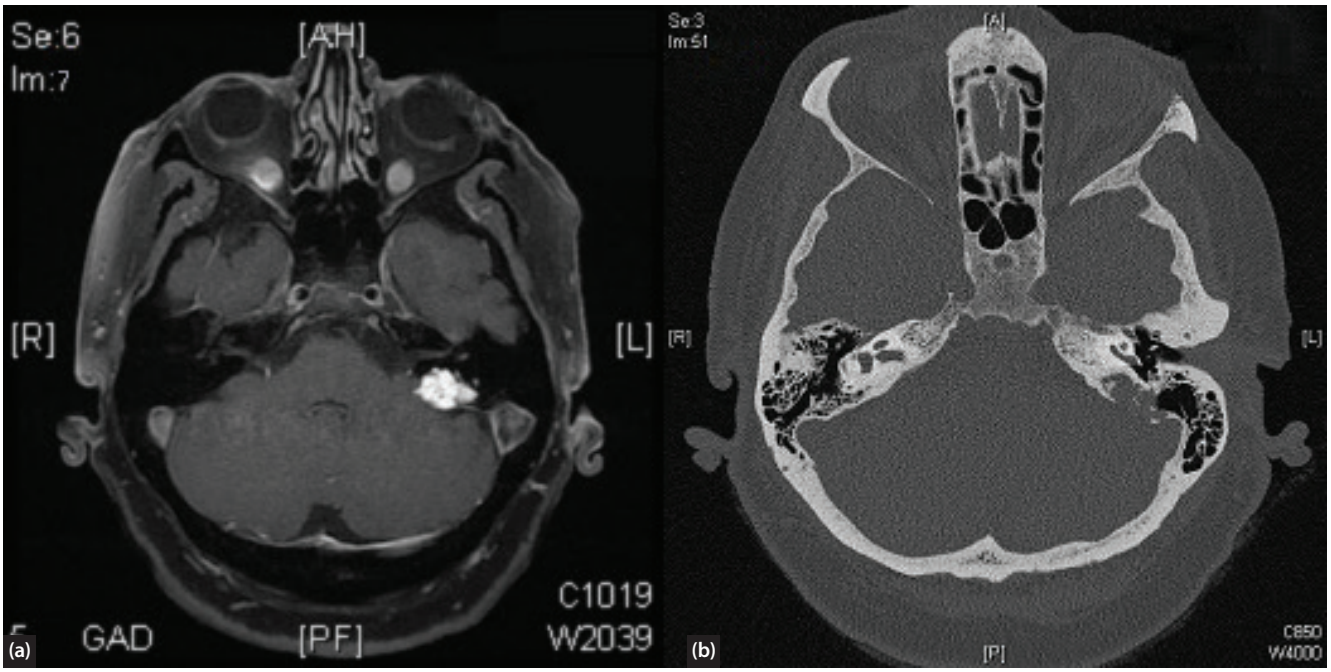

Figure 105.7 MRI scans showing a left endolymphatic sac adenocarcinoma. **(a)** Axial T1- weighted MRI scan with gadolinium enhancement. **(b)** CT scan.

BENIGN AND MALIGNANT INTRA-AXIAL LESIONS INVOLVING THE CPA

Rarely, intra-axial or intra-ventricular tumours invade the CPA. Diagnosis is difficult but subtle image signs, such as narrowing of the cisterns and oedema at the site of tumour origin, as well as the history of the patient, are sometimes helpful.

Primary central nervous system neoplasms

As few as 0.3–2% of the lesions in the CPA originate from primary brain tissue. Presenting symptoms may be typical of a CPA lesion, but an intra-axial lesion may be suspected because of the rate of progression of symptoms and the degree of non-acoustic cranial nerve symptoms.[45] The most common types of primary central nervous system tumours are medulloblastomas, astrocytomas, ependymomas and other gliomas of the brainstem.[124] It may not be possible to distinguish these lesions from vestibular schwannomas by CT although MRI may demonstrate their intra-axial status more reliably. Stereotactic biopsy has an accuracy rate of about 75% in these patients. Treatment regimens include surgery, radiotherapy or a combination of both and in some cases chemotherapy.

BEST CLINICAL PRACTICE

- ✓ All skull base pathology is best managed in a multidisciplinary setting with a core team including otolaryngology, neurosurgery and neuroradiology.
- ✓ Consider diagnoses other than vestibular schwannoma when scans are not typical and hearing loss is not the predominant symptom. All patients should have MR imaging with contrast and, if necessary, fat suppression sequences.
- ✓ Carotid angiography is helpful for certain pathologies, for example glomus jugulare tumours. Pre-operative embolization can reduce morbidity.
- ✓ The aim of surgery should be complete removal pathology but not at the expense of function. Stereotactic radiotherapy or radiosurgery are effective alternatives to surgery for some forms of growing tumour and may be used in combination with surgery in some situations.

FUTURE RESEARCH

Current understanding of the natural growth pattern of non-acoustic CPA tumours and the consequences of watchful waiting is insufficient. Future areas of research should include:

- ➤ assessment of the efficacy of subtotal surgical excision with adjuvent radiotherapy compared with radical excision
- ➤ treatment strategies for residual and recurrent tumours
- ➤ possible alternatives to surgical treatment (e.g. chemotherapy or brachytherapy)
- ➤ possible markers of tumour growth.

KEY POINTS

- One in five CPA tumours is not a vestibular schwannoma.
- Compared with vestibular schwannomas, VIIIth cranial nerve symptoms and signs are less frequent, and other cranial nerve and cerebellar symptoms and signs are more frequent in non-acoustic CPA tumours.
- The number of pathologies in the differential diagnosis of a CPA lesion is large but MRI and CT imaging often demonstrate features leading to correct diagnosis.
- Treatment most often involves surgery but some lesions may be treated conservatively or with radiotherapy.

CHAPTER 106

MIDDLE FOSSA SURGERY

Raghu N.S. Kumar, Sunil N. Dutt and Richard M. Irving

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: middle fossa surgery and middle fossa approach, combining with cerebrospinal fluid leak, facial nerve surgery, vestibular schwannoma, acoustic neuroma, superior semi-circular canal dehiscence (SSCD) syndrome, petrous apex lesions and vestibular neurectomy.

INTRODUCTION

The middle fossa (MF) approach can be used as an extradural access route to approach the MF floor, the internal auditory canal (IAC), the posterior fossa and the petrous apex. The access through this approach is via a small temporal craniotomy and visualization can be difficult owing to the limited extradural space available and desire not to apply too much pressure on the underlying temporal lobe. The access to the posterior fossa is somewhat limited and it is only when considering the many intra-temporal indications for this approach that the advantages of the MF can be fully appreciated. This chapter will focus widely, considering all the applications of this approach, and will attempt to demonstrate why it is an important skill for all neurotologic surgeons.

HISTORICAL PERSPECTIVE

The earliest description of the MF approach was by William Rose of King's College Hospital, London in 1890.[1] Rose used the approach as an access route to the trigeminal ganglion in cases of trigeminal neuralgia. In 1904, Parry[2] was the first to describe its use to access the IAC. In the early twentieth century, many authors described the use of the MF for surgery of the facial nerve, superior semi-circular canal and petrous apex. Surgical outcomes in the first half of the twentieth century were rather poor and, as a result, the approach was rarely used and fell into disrepute.

The technique was then reintroduced by William House[3] who proposed this as a technique for decompression of the cochlear nerve in cases of otosclerosis. Subsequently, it was popularized again to access and remove small and medium-sized acoustic tumours, as with it residual hearing could be preserved. Significant technical contributions have been made by Fisch,[4] who refined the approach for a variety of conditions, including the treatment of facial nerve lesions. The approach gained further support with the contributions by E and JL Garcia-Ibanez[5] on surgical landmarks in the region in relation to a large case series of vestibular neurectomies. Neurosurgeons and neurotologists considering undertaking this approach are encouraged to consider three-dimensional (3D) computerized tomographic (CT) reconstruction of the temporal bone and middle and posterior fossae prior to surgery, in order to understand the microsurgical anatomy and relations of neurovascular structures, especially where bony landmarks may be absent.[6]

SURGICAL TECHNIQUE

Surgical anatomy

The learning curve to deal with intratemporal pathology via the MF approach involves operating while at the head end of the patient and getting the 3D orientation from above downwards. The most important landmarks in this approach are the middle meningeal artery,

tegmen plate, greater superficial petrosal nerve (GSPN), facial hiatus, arcuate eminence, superior petrosal sinus and the meatal plane. Of these by far the most useful for the surgeon is the GSPN, which serves as a guide not only to the depth of dissection but also to the position of the facial nerve (**Figure 106.1**). Bento et al., in 2002, recommended opening up the tegmen tympani early in the dissection to expose two additional landmarks of importance – the cochleariform process and the tympanic portion of the facial nerve – which could effectively guide the surgeon onto the labyrinthine segment of the facial nerve more directly.[7]

The arcuate eminence has a variable relationship to the superior semi-circular canal as demonstrated by Tsunoda et al.[8] A cadaveric study on 26 temporal bones showed arc-like eminences in 92% of the specimens, but they did not necessarily correspond to the site of the superior semicircular canal. Some of these eminences corresponded to sulci of the temporal lobe, of which most were traces of the occipitotemporal sulcus. It is advisable to use landmarks in addition to the arcuate eminence in order to reach the IAC safely.[8]

There are a number of variations on the MF approach. The transtemporal MF approach as described by Fisch[4] has the advantage of minimizing dural retraction but requires consummate skill. Gjuric et al.[9] described an enlarged MF approach involving the removal of additional bone either side of the IAC and providing greater access to the posterior fossa.

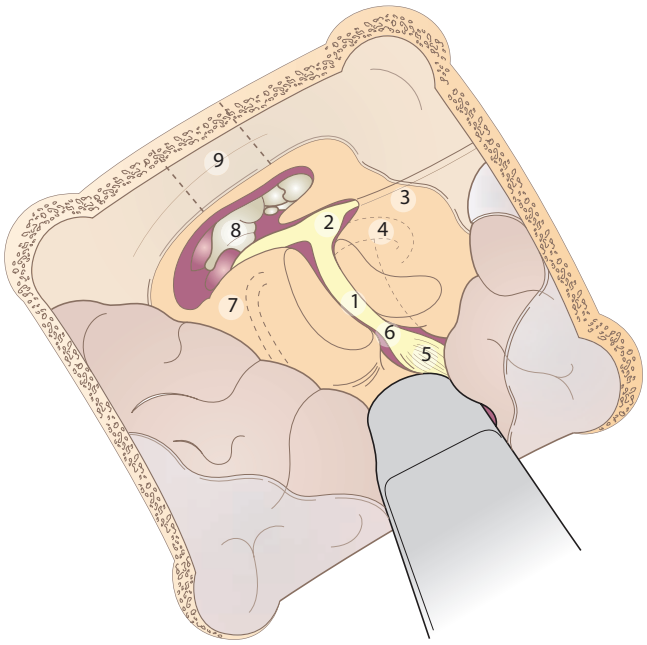

Figure 106.1 Left middle fossa anatomy with facial nerve exposed and internal auditory canal opened. 1, Labyrinthine VII; 2, geniculate ganglion; 3, greater superficial petrosal nerve; 4, cochlea; 5, internal auditory canal; 6, meatal foramen; 7, superior semi-circular canal; 8, removal of tegmen showing heads of ossicles; 9, external auditory canal position.

Patient position

The surgeon sits at the head of the operating table and addresses the floor of the middle cranial fossa from above. This is an unfamiliar orientation for most otologists and will also necessitate a change in the position of the other members of the operating team. The patient lies supine with the head rotated with the pathologic ear uppermost and with the intermeatal line perpendicular to the floor. A head holder is usually not required and a head ring stabilizes the head. Facial nerve monitoring is used routinely and it is advisable to insert a urinary catheter for the patient's comfort. Some, but not all, surgeons give mannitol to reduce intracranial pressure and obtain a larger operative field without undue compression of the temporal lobe.

Incision

This is either an inferiorly based U-shaped flap or a vertical line. It begins 0.5 cm anterior to the base of the helix, at the level of the zygomatic arch, and extends approximately 7 cm superiorly. Branches of the superficial temporal artery that are encountered at this stage should be ligated to avoid post-operative bleeding. The temporalis fascia plane is developed by finger dissection. An incision is placed in the temporalis muscle along its insertion line and it is elevated inferiorly and anteriorly taking care to preserve its neurovascular supply. Elevation of the temporalis exposes the squamous part of the temporal bone. The root of the zygoma indicates the level of the MF floor and it is crucial that the initial exposure adequately identifies this both anteriorly and inferiorly.

Craniotomy

This is sited two-thirds anterior and one-third posterior to the external auditory canal (EAC). An opening of 5 cm × 5 cm is adequate in most circumstances. It is bevelled posteriorly to minimize entry into the mastoid air cell system. The craniotomy can be cut either with an otologic burr or a craniotome to fashion a small bone flap. Utmost care should be taken not to injure the underlying dura during drilling. The opening then needs to be lowered to the level of the MF floor anteriorly and above the root of the zygoma. Any air cells entered should be sealed with bone wax.

Exposure of the middle fossa floor

Under low power of the operating microscope, dural elevation is commenced posteriorly. The superior petrosal sinus and the sulcus at the transverse–sigmoid junction are identified. A self-retaining retractor such as the Fisch, Yasergill's or House-Urban retractor is applied when the dura is sufficiently elevated. Care must be taken not to injure the geniculate ganglion as it can be dehiscent in up to 15% of temporal bones.[10] The arcuate eminence and the GSPN are then identified. It may be necessary to separate the dura using sharp dissection from the GSPN as

it can be densely adherent to it. The middle meningeal artery is anterolateral to the GSPN and dissection here is always bloody and, unless access to the apex is required, may not be necessary. If the vessel is divided, the foramen spinosum will need to be sealed with bone wax. The bone anteromedial to the arcuate eminence and posterolateral to the GSPN is termed the 'meatal plane' and lies above the IAC (Figure 106.2). It is often marked by a shallow depression. The angle between the GSPN and the arcuate eminence is bisected to identify the axis of the IAC, which was popularized by Garcia-Ibanez in 1980.[5]

Finding the internal auditory canal at its medial end (Porus Acousticus)

In medial approaches to the IAC, the dura is elevated over the meatal plane and the retractor is then inserted into the petrous ridge with its tip lodged into the bony groove of the superior petrosal sinus (as illustrated in Figure 106.2). If the ridge is not clearly identified, the placement of the retractor can be too far lateral and there is a risk of entering the inner ear when undertaking the initial bony removal. No identification of the superior semi-circular canal (SSC) is required and the GSPN is exposed only as far as its hiatus. The EAC and IAC are roughly in line, which helps with orientation.

Gentle and careful bone removal is undertaken with a diamond burr over the meatal plane, slowly reducing it over a broad area from the arcuate posteriorly to the limit of the dural elevation anteriorly. The temporal bone is usually pneumatized or filled with bone marrow anterior to the IAC. As the meatal plane is lowered, the IAC becomes visible. Its medial end is then defined and troughs are drilled both anteriorly and posteriorly to give more extensive exposure and sufficient space for safe tumour removal. At this stage, a thin layer of overlying bone is left to protect the dura of the IAC. The IAC is then followed laterally. Great care has to be exercised at this stage to ensure that no inadvertent entry into the cochlea or the SSC happens.[5]

Finding the internal auditory canal at its lateral end (Fundus Acousticus)

The margin of error at the lateral end of the IAC is of the order of 1 mm, representing the distance between the fallopian canal and the cochlea. Very precise identification is an absolute necessity if hearing is to be preserved. The lateral end of the IAC can be identified either by first finding the GSPN as described by House[3] or by using the SSC as advocated by Fisch.[4] In the former technique, the GSPN is delineated and followed proximally through its hiatus to the geniculate ganglion. Then, by tracing the labyrinthine segment of the facial nerve, the IAC is identified (Figure 106.3). A diamond burr with continuous irrigation suction is used to minimize the incidence of traumatic facial paresis post-operatively.[11–12]

The Fisch technique[4] was developed to limit the degree of dural retraction and the risk of damage to the labyrinthine segment of the facial nerve. In his technique the bone of the tegmen is removed and the SSC 'blue lined'. Having identified this, the IAC is then located within an angle of between 45 degrees and 60 degrees subtended from the ampulla of the SSC.

Completion of internal auditory canal exposure

Bone removal in the meatal plane needs to be more extensive in vestibular schwannoma surgery than for vestibular neurectomy. More radical removal of bone is carried out for access to larger vestibular schwannomas and is

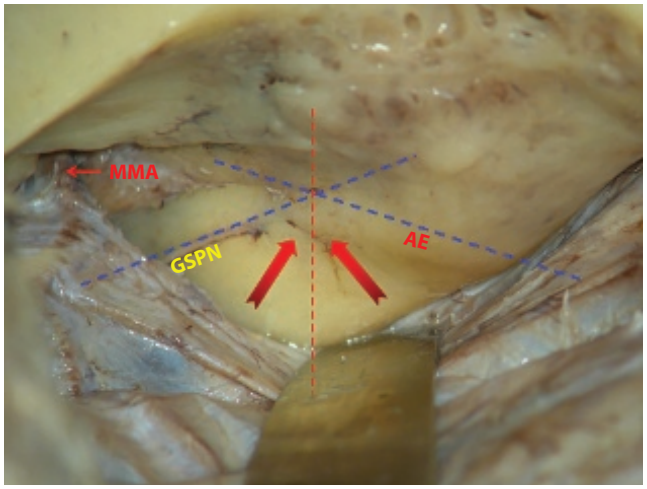

Figure 106.2 Right middle fossa floor: defining the 'meatal plane'. The IAC is identified in a tangent that bisects the angle formed by the superior semi-circular canal, SCC (identified as the arcuate eminence, AE) and the greater superficial petrosal nerve (GSPN). MMA, middle meningeal artery.

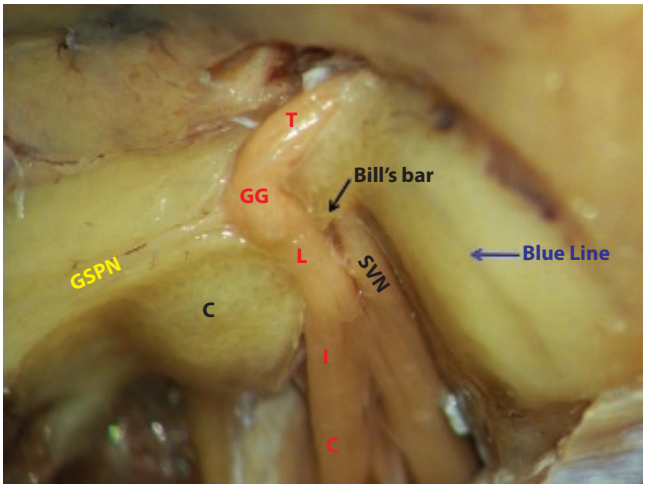

Figure 106.3 Anatomical dissection of the fundus area (right middle cranial fossa). GG, geniculate ganglion; GSPN – greater superficial petrosal nerve; T, tympanic segment facial nerve; C, cochlea; L, labyrinthine segment facial nerve; SVN, superior vestibular nerve. Also demonstrated is the blue line over superior semi-circular canal.

sometimes referred to as the enlarged MF approach.[9] Access can be improved further by division of the superior petrosal sinus.

Approximately three-quarters of the circumference of the IAC at the porous acousticus is exposed. This degree of exposure is not possible at the lateral end of the IAC because of the proximity of the ampulla of the SSC and the cochlea. Bill's bar, the vertical crest of bone separating the facial nerve from the superior vestibular nerve, is identified at the lateral end.

The fine eggshell of bone covering the dura is now carefully removed and the dura incised along the posterior aspect of the IAC, thereby avoiding inadvertent damage to the facial nerve. A dural flap is fashioned and the contents of the IAC identified.[11]

Closure

Any exposed air cell tracts must be waxed and a muscle plug is placed in the IAC. If the tegmen has been removed, it should be repaired with a bone graft or a bone pate slab to prevent dural herniation. The dura can be hitched to the skull by dural sutures to minimize the size of any extradural collection. The temporal bone flap is then fixed back into position.

CLINICAL APPLICATIONS

The indications for the MF approach can be divided into three distinct groups (**Table 106.1**):

- exposure of the MF floor
- access to the IAC and cerebellopontine angle (CPA)
- access into and through the petrous apex to anterosuperior CPA.

Initial elevation of the dura provides good access to the region of the tegmen that is ideal for repair of defects in this region. More medial dural elevation uncovers the cochlea, superior canal and facial nerve, allowing access to these structures. More medial dissection still exposes the meatal plane overlying the IAC. Bone removal in this region will reveal the IAC and can be extended to allow limited exposure of the CPA. In addition, dural elevation more medially and anteriorly exposes the petrous apex from above.[9] Pathology within the apex can be dealt with and if the apex is removed this can provide access to the anterio-superior CPA. This MF-petrosectomy extension can be combined with a posterior fossa craniotomy to access large petroclival lesions preserving inner ear function.

Internal auditory canal/cerebellopontine angle surgery

VESTIBULAR SCHWANNOMA SURGERY

The majority of small tumours are currently managed by either a conservative approach or by radiosurgery. Traditional surgical approaches remain an option in selected cases. The MF approach has been used for the removal of small vestibular schwannomas (VS) and for decompression of the IAC in bilateral tumours. The primary objectives of VS surgery are the control or complete removal of the tumour with preservation of facial nerve function and, where possible, preservation of hearing.[13] Both the MF and retrosigmoid (RS) approaches have been used for attempted hearing preservation in VS surgery. The perceived advantage of the MF approach is better visualization of the lateral end of the IAC when compared with the RS approach. In both the MF and RS approaches, there is a blind spot at the fundus, this being smaller in MF surgery.[14, 15] It is proposed as the hearing preservation approach of choice in tumours extending far into the lateral third of the IAC.[13] The main disadvantage is relatively poor access to the CPA and many surgeons would be hesitant in utilizing this approach for tumours with an angle component greater than 15 mm. In MF surgery, the facial nerve is generally found superiorly between the tumour and the operator. This has the advantage of ease of facial nerve identification but the disadvantage in that greater manipulation of the nerve may be required to remove the tumour. Additionally, control of bleeding in the CPA can be more difficult with the MF approach.[15]

Proponents of the MF approach report excellent results for hearing preservation and claim superiority over the RS in this regard. The reasons why hearing preservation should be better by this route are difficult to understand, but may possibly relate to the direction of tumour dissection. In the MF approach, small tumours can be removed in a medial-to-lateral direction, avoiding avulsion of the fine cochlear nerve endings entering the modiolus of the cochlea. The data on hearing preservation in RS when compared with the MF approach is, however, contradictory. There have been few comparative series[14] and only one prospective randomized study,[15] which reported no advantage of the MF over the RS in terms of hearing preservation. In addition, facial nerve function appears to be worse in the early post-operative period in the MF group.[14]

TABLE 106.1 Clinical applications of the middle fossa approach

IAC/CPA surgery	Middle fossa floor	Petrous apicectomy
Vestibular schwannoma	Repair of CSF leaks	Petrous apex lesions
Resection of IAC/CPA tumours	Superior canal dehiscence	Petroclival tumours
Vestibular neurectomy	Facial nerve surgery	Basilar aneurysms

VESTIBULAR NEURECTOMY

Section of the vestibular nerve can be carried out through a MF, RS or retrolabyrinthine approach. The main advantage of the MF approach is that it offers access at a more distal location where the VIII nerve is naturally divided into its vestibular and cochlear branches. The main indication for this is in patients with incapacitating Ménière's disease, unresponsive to more conservative treatment and with serviceable hearing.[5]

Middle fossa floor

FACIAL NERVE SURGERY

Indications for the MF approach have expanded to address facial nerve pathology in its intracranial, intracanalicular, labyrinthine, geniculate and tympanic segments (**Figure 106.4**). The facial nerve can be accessed through the MF floor for a spectrum of indications, namely: temporal bone fractures involving the intracranial and petrous facial nerve; benign intrinsic tumours involving the supra-tympanic facial nerve segments; nerve decompression in idiopathic recurrent facial palsy; and nerve reanimation by cable grafting it in its internal auditory meatus (IAM) and labyrinthine segments. Such an approach allows direct exposure of the proximal parts of the nerve with preservation of inner ear function, which is otherwise not possible via the trans-mastoid route alone. It is perhaps when considering pathology of the facial nerve that the MF approach clearly exhibits advantages over all others.

The MF approach to the traumatized facial nerve has proven to be a successful route. Bento et al.[16] in 2004 reviewed 220 cases where they advocated a combined MF and transmastoid approach to decompress the facial nerve for injury sustained in an unclear location but presenting with good cochlear reserve. Recently, da Franca Pereira et al. have described in detail the steps of decompression of the tympanic and labyrinthine segments of the facial nerve by middle cranial fossa approach with anatomical measurements in 20 cadavers to conclude that this is a safe, timesaving and reliable technique.[17] Aslan et al. reported a series of 13 patients who underwent facial nerve decompression via MF approach for grade VI traumatic palsy and were able to achieve grade 2 recovery in 7 (58%) patients by decompressing the geniculate ganglion within 1 month of trauma.[18] Cannon et al. have reported a series of 18 patients with traumatic complete paralysis and poor facial prognosis on electrophysiology, all of whom achieved a long-term outcome of HB III or better after MF approach was performed for primary decompression in 11 (64%) patients and repair of the facial nerve by grafting in 7 (36%) patients.[19]

The concept of decompression surgery for facial nerve paralysis of non-traumatic and non-tumorous origin remains controversial. Fisch[20] demonstrated encouraging results with surgical decompression of the nerve in its labyrinthine segment in cases of Bell's palsy and herpes zoster oticus. Marsh and Coker [21] present evidence suggesting that the meatal segment of the facial nerve is the probable site of entrapment. Unimpeded access to this region of the facial nerve can only be achieved via a MF craniotomy. Only one randomized study has attempted to address this issue and it concluded that the outcome in Bell's palsy was improved by MF decompression surgery.[22]

Cannon et al. reviewed long-term outcomes in a series of 14 patients who underwent surgical decompression for Bell's palsy within 14 days of symptom onset from 2000 to 2012.[23] Surgical criteria included greater than 90% degeneration on electroneurography (ENoG) testing and no voluntary electromyography (EMG) potentials. MF

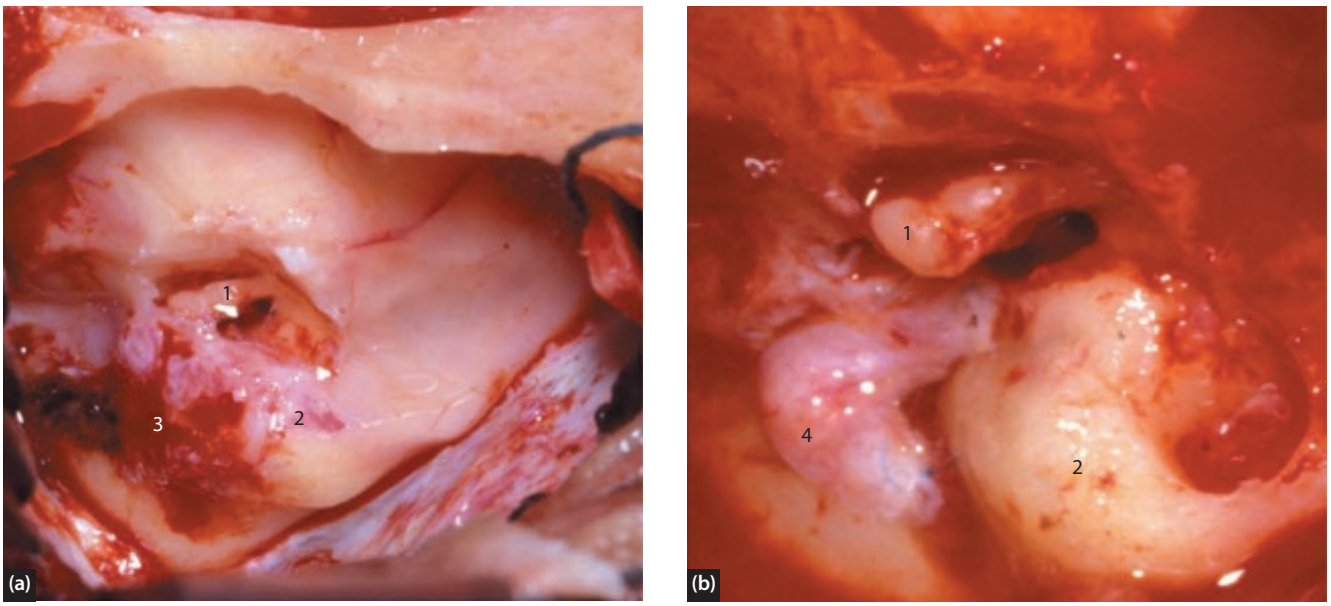

Figure 106.4 View of right middle fossa floor showing facial nerve graft (b) following removal of facial nerve haemangioma (a). 1, Heads of ossicles; 2, superior semi-circular canal; 3, facial haemangioma; 4, facial nerve graft (labyrinthine, geniculate and proximal tympanic segments).

bony decompression of the facial nerve, including the meatal foramen, labyrinthine segment, and geniculate ganglion was performed. Ten patients (72%) had regained normal facial nerve function while four cases improved to HB grade III function, with minimal morbidity in the case series. All these patients had no hearing loss of significance, which suggests MF is a viable route with hearing preservation.[23]

Decompression surgery is particularly appealing in cases of Melkersson–Rosenthal syndrome (MRS) and recurrent facial paralysis of unknown origin. MRS is a triad of recurrent alternating facial paralysis, recurrent facial and labial oedema (cheilitis granulomatosa) and fissured tongue (lingua plicata).[24] The logical conclusion is that the oedematous process affects the entire nerve within a tight bony canal, causing entrapment neuropathy. Total decompression of the entire length of the nerve using a combined transmastoid and MF approach is recommended in cases of MRS where there is a significant increase in frequency, duration and severity of facial paralysis to prevent disabling sequelae, such as synkinesis and residual facial paralysis.[24]

The benefits of MF decompression of the facial nerve in cases of recurrent facial paralysis has been demonstrated by Nyberg and Fisch.[25] They operated on a total of 14 patients, including 11 with acute paralysis with ENoG evidence of more than 90% amplitude reduction within the 10 days following the attack. Their series also included three patients who underwent decompression prophylactically to prevent further recurrences. Graham and Kartush[26] demonstrated excellent results with complete resolution in six patients with recurrent facial paralysis, who underwent total facial nerve decompression. Similarly, facial nerve decompression via MF seems to achieve better outcomes of facial nerve function than conservative treatment according to a recent report by Zhu et al., who were able to prevent further episodes by surgical decompression, providing an HB grades I–II recovery in all their cases.[27] Doshi and Irving[28] provide further evidence to support the effectiveness of MF decompression in recurrent facial nerve paralysis, with no recurrences in four cases with hearing preservation.

There is as yet insufficient evidence to propose facial nerve decompression in Bell's palsy beyond a prospective randomized trial; however, the results of decompression in cases of recurrent paralysis as mentioned above are encouraging.[25–28]

The MF approach provides a route of access to tumours involving the proximal facial nerve. Mowry et al. recommend the MF approach for debulking and decompressing facial nerve schwannomas involving the IAM. They achieved decompression with more than 70% debulking of the tumour via this approach while preserving motor fibres good enough to provide HB grade I function postoperatively at serial follow-up to 1 year.[29] Kusumi et al. also support this fact in their case report where they used a combined extradural and intradural MF approach to remove an intra-petrous GSPN schwannoma involving Glasscock's triangle, while preserving the tumour capsule in the MF floor to safely protect the geniculate ganglion and the main trunk.[30] Decompression alone without tumour debulking is an option for small tumours difficult to separate from the main nerve trunk, and with recurrent facial paralysis, with good medium-term outcomes reported in two cases.[31]

REPAIR OF TEGMEN DEFECTS, CEREBROSPINAL FLUID LEAKS AND MENINGOENCEPHALOCOELES

The conventional approach to repair of tegmen plate defects causing cerebrospinal fluid (CSF) leaks and brain hernias has been the transmastoid approach. The vast majority of spontaneous CSF leaks take place through the tegmen plate, rather than through a posterior fossa defect. Traumatic leaks are more unpredictable and many have both posterior fossa and MF components. Good outcomes are achieved with defects sealed via the MF approach to the tegmen plate when this is the site of the problem.[32–35] The major advantage of the MF approach over the transmastoid is that the repair can be carried out without disturbing the middle ear and ossicles. Also, large or multiple defects can be detected more easily and dealt with by the MF approach.[33]

The procedure can be carried out through a 'mini' temporal craniotomy with a window of less than 4 cm.[22, 23] While drilling, bone dust is collected using a bone-pate collector that is essentially a filter-trap attached to the suction apparatus. After elevation of the dura, all the defects in the tegmen are exposed and sealed with an oblong slab of bone pate mixed with blood and fibrin glue (Tisseel; Immuno, Vienna, Austria). This pliable graft material is insinuated into every defect and crevice in the tegmen using neuropatties. A large free graft of temporalis fascia placed between the dura and the bone-pate slab provides additional reinforcement. Recurrence of CSF leakage has been reported after soft tissue repairs and hence the rationale for using bone pate, which over time is believed to form an adequate layer of viable bone (**Figure 106.5**). More recently, Braca et al. have used autologous dural grafts with synthetic polymer glue to seal successfully tegmen defects with CSF leaks and encephalocoeles in eight patients via the MF approach.[36]

SUPERIOR SEMI-CIRCULAR CANAL DEHISCENCE SYNDROME

Sound- or pressure-induced vertigo caused by a bony dehiscence of the SCC into the middle cranial fossa is a rare cause of otologic symptoms including autophony and vertigo.[37] Disabling vertigo in two of these patients from the initial series prompted plugging of the dehiscent canal via a middle cranial fossa approach with good results.[37] Alternative approaches to address the dehiscence have been subsequently described, including the transmastoid and MF/transmastoid routes. Debate continues as to which is the most appropriate and effective although in some cases, especially where there is an associated encephalocoele the MF approach may be preferred.

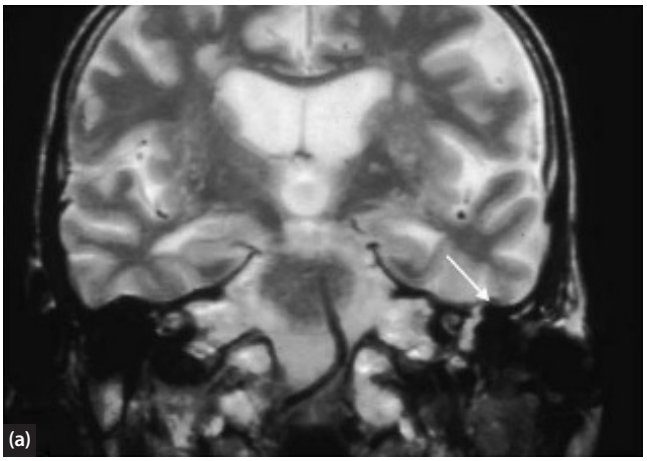

Figure 106.5 (a) Pre-operative coronal T2-weighted image demonstrating a tegmen CSF leak. Arrow shows site of leakage. **(b)** Post-operative coronal CT scan demonstrating bone pate repair. Arrow shows site of repair.

A series with 43 cases of superior canal dehiscence syndrome (SCDS) who underwent surgical plugging by the MCF approach has been reported by Ward et al.[38] Plugging of the canal was performed using fascia strips, bone dust and bone chips, which are gently but securely placed inside the dehiscent canal to obliterate the canal lumen for 2–3 mm beyond either end of the dehiscence. Careful avoidance of unnecessary force on or suction near the membranous labyrinth was observed throughout the procedure. The repair was then covered with hydroxyapatite cement, followed by a layer of fascia and fibrin glue. The authors concluded that low frequency air–bone gap decreases following surgical plugging and appears to be due to both increased bone-conduction (BC) thresholds and decreased air-conduction (AC) thresholds. Surgical plugging via a middle cranial fossa approach in SCDS is associated with mild high frequency sensorineural hearing loss that persists in 25% but no change in speech discrimination.[38–39]

Petrous apicectomy

The MF craniotomy provides the shortest and most direct route to the petrous apex. By elevation of the dura medial and anterior to the IAC, the anterior apex can be exposed as far as Meckel's cave and the ipsilateral cavernous sinus. Primary lesions within the apex, the most common being cholesterol granulomas, chordomas, cholesteatomas and chondrosarcomas, can be approached in this way (**Figure 106.6**). Lesions in Meckel's cave, including schwannomas and meningiomas, when small, can be accessed solely by a MF approach, whereas larger lesions may require an orbitozygomatic craniotomy.[40–42] The bone of the anterior petrous apex conforms to a rhomboid shape bounded by the IAC and cochlea laterally and posteriorly, the intrapetrous carotid anteriorly, and medially by the Gasserian

Figure 106.6 Petrous apex chondrosarcoma with large middle fossa and small posterior fossa components. This large lesion could be removed by a middle fossa transpetrous apex approach.

ganglion. If this rhomboid of bone is removed, the dura of the anterior–superior CPA is exposed and opening this provides limited access to the CPA. Additional exposure can be obtained by transection of the superior petrosal sinus and the mandibular branch of the trigeminal nerve. Access is provided to the ventral surface of the pons and upper clivus. This approach has been used for basilar tip aneurysms and petroclival and Meckel's cave tumours with limited CPA extension.[40–42]

COMBINED APPROACHES

The MF approach can be combined with any of the existing skull base approaches of the anterior, lateral and posterior skull base. While the MF approach is an extradural, subtemporal route consisting of an anterior petrosectomy, an extended approach (combined petrosal) anterior to this is used by neurosurgeons for intradural lesions of the superior CPA and prepontine clivus and cavernous sinus lesions. The 'rule of two fans' technique wherein vascular, nervous, fibrous and osseous structures are localized within two bordering fans, one centred around the geniculate ganglion in the MF floor and one centred around the Gasserian ganglion (perpendicular to the geniculate fan structures) is popular in dealing with lesions such as sphenopetroclival tumours, neoplasms with transtentorial extensions and vertebrobasilar aneurysms.[43]

Combining the MF approach with the transmastoid approach for clearance of extensive lesions is popular and has its advantages. A large defect with CSF otorrhoea after a mastoidectomy is best managed by a combined approach.[44] O'Connell et al. have described a combined transmastoid-middle cranial fossa approach for repair of lateral skull base CSF fistula and encephaloceles using a suture 'pull-through' technique. This method facilitates reliable placement of a composite graft in the centre of lateral skull base defects through a small craniotomy that minimizes temporal lobe retraction.[45]

A middle ear cholesteatoma with intracranial extension would necessitate a MF craniotomy.[46] A giant facial nerve schwannoma extending from the middle cranial fossa to the mastoid region is best cleared by a combined MF and transmastoid approach.[47] In the extended MF and transpetrous approaches, a thorough understanding of the horizontal segment of the petrous internal carotid artery (pICA) (**Figure 106.7**), its normal anatomy with variations and relations to surrounding neural and osseous structures is essential.[48]

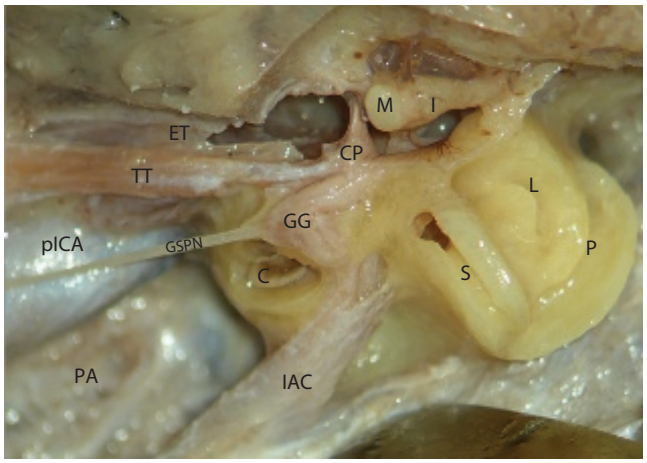

Figure 106.7 Extended dissection of the right middle cranial fossa and petrous region to demonstrate the intrapetrous internal carotid artery (ICA) and its relations. INFORMED CONSENT IN MIDDLE FOSSA SURGERY

The risks and complications that are discussed with a patient undergoing MF surgery will vary depending upon the precise pathology that is anticipated.

Inadvertent entry into the inner ear, damage to its blood supply or to the VIIIth nerve, can result in hearing loss, tinnitus or balance disturbance. Weakness of the face may develop and be accompanied by damage to the sensory component of the facial nerve. An extradural haematoma may accumulate and can be limited by suspending the dura to the edges of the craniotomy. CSF leakage is less common than in posterior fossa surgery but, nevertheless, can be equally tedious and dangerous as there is a definite risk of infection or meningitis. There has been much debate regarding the possibility of temporal lobe damage following MF surgery. The risk is in the order of 1 in 50 patients having a single early post-operative seizure following a MF exposure of the IAC.[10] Aggarwal et al.[49] described two cases of single ictal events which had the effect of prohibiting the patients from driving for a period of one year. A long-term predisposition to seizures has not been described. Retraction trauma leading to cortical injury, aphasia or hemiparesis has not been described either, but there is some suggestion that temporal lobe function is affected at least temporarily following surgery and may lead to some transient memory loss. There are additional risks in MF transpetrous surgery that include damage to the intrapetrous carotid artery, trigeminal neuropathy and ophthalmoplegia.

KEY POINTS

Middle fossa approaches:

- provide access superior and medial to the otic capsule preserving inner ear function
- provide excellent access to the proximal intratemporal facial nerve
- allow for the repair of tegmen defects with preservation of middle ear function
- small- and medium-sized VS can be removed with preservation of hearing.

ACKNOWLEDGEMENTS

The authors wish to thank Professor Mario Sanna and Dr Sampath Chandra Prasad for **Figures 106.2, 106.3** and **106.7**.

CHAPTER 107

JUGULAR FORAMEN LESIONS AND THEIR MANAGEMENT

Rupert Obholzer

SEARCH STRATEGY

In this chapter we review the anatomy, pathology, and management options for jugular foramen lesions. Data in this chapter are based on a Medline search using the keywords: jugular foramen and neoplasm (or cancer or tumour), surgery, conservative treatment (or therapy), radiotherapy, radiosurgery and diagnosis.

INTRODUCTION

A number of pathological lesions and conditions can develop in the jugular foramen, all of which are quite rare. There is only a scant amount of data on the incidence and prevalence of jugular foramen lesions, but several hundred cases have been described in the literature. Most are solitary case reports or record small series of patients and emphasize surgical techniques and outcomes. No controlled studies have been undertaken on this subject, so the scientific level of evidence in the body of literature is fairly low. This applies to many aspects of jugular foramen lesions, such as their diagnosis, biological behaviour and therapeutic options. At present, there are no exact or universally accepted management protocols. Surgical intervention in the region of the jugular foramen is often difficult and sometimes hazardous, due to the close proximity of nerves, arteries, veins and intracranial structures.

Surgery should therefore not be the default treatment, but one strategy to be considered in parallel with assessing the merit of conservative management or radiotherapy.

A team approach is often the key to success. Therefore, it is generally agreed that diagnostic examinations, decision-making and treatment should be carried out in a multidisciplinary setting in tertiary referral centres.

ANATOMY

The jugular foramina are the second largest openings in the skull base, after the foramen magnum. Their anatomy varies considerably.[1, 2] The left and right jugular foramina are asymmetrical. Usually the left is smaller than the right, which is presumed to have some relation with the dominance of right cerebral venous drainage. They are extremely important anatomical structures, because they harbour vital vascular and neural pathways.

The lateral part of the jugular foramen is a sigmoid-shaped tunnel, while the medial part looks like a canal in the cephalocaudal direction. The joint between the petrous bone and the occipital bone is part of the petrosphenooccipital suture of Gruber (named after the Russian anatomist Wenaslaus Leopoldovich Gruber) and constitutes the ventromedial aspect of the jugular foramen. The end of the occipital mastoid suture between the mastoid and the occipital bone forms the dorsolateral aspect of the jugular foramen. The incisura jugularis (the curved indentation in the occipital bone) constitutes the dorsomedial wall of the jugular foramen. Its counterpart in the petrous bone forms the ventrolateral wall of the jugular foramen. At the caudal aspect of the jugular foramen, both incisurae jugulares have a so-called intrajugular process. These processes protrude into the lumen of the jugular foramen (**Figure 107.1**) and divide it into

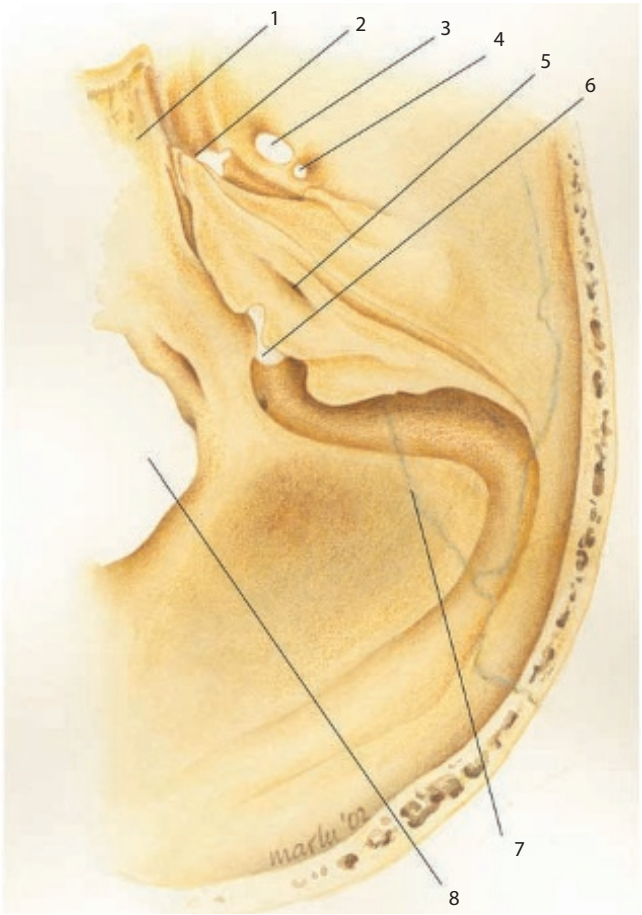

Figure 107.1 Superior view of the skull base (right side) as shown from above. 1, clivus; 2, foramen lacerum; 3, foramen ovale; 4, foramen spinosum; 5, internal auditory canal; 6, jugular foramen; 7, suture of Gruber; 8, foramen magnum.

lateral and medial parts. The lateral part (pars venosa) is filled by the sigmoid–jugular complex, while the medial part (pars nervosa) contains the inferior petrosal sinus, the cranial nerves IX, X and XI, the superior ganglion of the glossopharyngeal nerve and the jugular ganglion of the vagus nerve.[3]

The transverse sinus is an important structure in the venous drainage system of the brain, which opens into the sigmoid sinus. Venous flow proceeds via the jugular foramen through the skull base towards the IJV in the neck. Several venous pathways drain into the sigmoid–jugular complex: the superior and inferior petrosal sinuses, the occipital sinus and the mastoid and condylar emissary veins. The most important is the inferior petrosal sinus that contains the effluence of the cavernous sinus and the basilar plexus. The dome of the jugular bulb is in close contact with the floor of the hypotympanum, the vestibule, the posterior semicircular canal, the vestibular aqueduct and the internal auditory canal. The lateral side of the jugular bulb is close to the mastoid (vertical) segment of the facial nerve. The jugular foramen lies in close proximity to the internal carotid artery: only a small osseous spine separates the vertical part of the carotid canal from the jugular foramen (**Figures 107.2** and **107.3**).

SYMPTOMATOLOGY

Disease in the jugular foramen causes a variety of symptoms and signs. These are discussed in Chapter 111, Clinical neuroanatomy. In clinical practice, perhaps the

most common is the jugular foramen syndrome, also known as Vernet's syndrome (named after the French neurologist Maurice Vernet). This syndrome comprises paralysis of the cranial nerves IX, X and XI. Obstruction or thrombosis of the sigmoid–jugular complex by tumour or infection may develop and is frequently asymptomatic because the venous drainage system of the brain has sufficient alternative routes or pathways. In rare cases, a thrombosed sigmoid–jugular complex may give rise to retrograde thrombosis of the inferior petrosal sinus and eventually even to thrombosis of the cavernous sinus. This condition then leads to the cavernous sinus syndrome, that is, paralysis of cranial nerves III, IV and VI, oedema of the conjunctiva and upper eye lid, venous congestion in the fundus of the globe and proptosis. Blockage of the cerebral venous drainage through the jugular foramen can also cause increased intracranial pressure and give rise to epileptic seizures and visual obscurations.[4] This is a life-threatening situation that needs urgent attention if multiple neurological deficits are to be avoided.

The symptoms caused by lesions that develop in the jugular foramen are not just confined to their effect on local anatomical structures. Sometimes symptoms are related to more extensive or distant pathology. For example, thrombosis in the jugular foramen is frequently the result of ear pathology, such as chronic otitis media, with or without cholesteatoma. Other factors that might induce thrombosis in the venous structures in the jugular foramen include trauma, various coagulopathies and vessel wall pathology from tumour invasion or systemic vasculitis. Jugular foramen pathology may cause facial nerve palsy and audiovestibular symptoms as a result of the close proximity of the jugular foramen and the vertical part of the facial nerve, cochlea, labyrinth, internal auditory canal and the cerebellopontine angle. Tumours are not the only cause of pulsatile tinnitus; arteriovenous malformations, high jugular bulb or jugular bulb diverticulum are also associated with this symptom. In these latter conditions, the patient should notice a decrease or disappearance of their tinnitus when the IJV in the neck is compressed.

DIAGNOSIS OF JUGULAR FORAMEN LESIONS

Patients in whom a jugular foramen lesion is suspected should undergo a standard triad of diagnostic procedures: first, a clinical examination; second, additional investigations such as audiometry; and third, imaging. The presence of jugular foramen pathology can be substantiated with a high level of probability by the first two steps, but imaging techniques are absolutely necessary to prove the existence and extent of a pathological process.

History and physical examination

The clinical history of patients with jugular foramen pathology is variable. Features to be sought have been discussed in Chapter 99, Evaluation of the skull base patient. Symptoms may result from damage to the contents of the jugular foramen (i.e. cranial nerves IX, X and XI) or to the venous structures of the sigmoid–jugular complex. There may also be symptoms that result from dysfunction of the cochleovestibular system or the facial nerve. For example, paragangliomas of the jugular foramen may present with facial palsy, the insidious development of lower cranial nerve palsies having gone largely unnoticed. In cases with extensive intracranial involvement, ataxia resulting from the compression of cerebellar structures, visual disturbances and vomiting caused by obstructive hydrocephalus may be more prominent features. Infectious disorders of the jugular foramen, such as those caused by chronic otitis media with or without cholesteatoma, may be accompanied by purulent otorrhoea. In some rapidly progressive cases, malaise, fever, headaches and stiffness of the neck may be present and in this situation there should be concern that patients might develop meningitis.

Physical examination should include a complete inspection of the ears, nose and throat and neck. Cranial nerve function must be documented accurately. If the patient has visual symptoms, an ophthalmological opinion is essential.

Additional examinations

Pure-tone and speech audiometry should be performed along with appropriate vestibular tests. Patients with paragangliomas should have their blood pressure checked and either 24-hour urinary collection for catecholamine metabolite assessment or an assay of plasma free metanephrines. This is indicated for two reasons, the identified head and neck paragangliomas may rarely have the capacity to secrete catecholamines, such as noradrenaline and dopamine, and secondly, the patient is at increased risk of having an intra-abdominal paraganglioma or pheochromocytoma, with a greater propensity to secretion.

Imaging

High resolution computed tomography (CT) and magnetic resonance imaging (MRI) are the methods of choice and should be acquired in all patients.[5] T1- and T2-weighted MRI sequences before and after the administration of gadolinium can detect most common lesions in the jugular foramen, such as schwannomas and meningiomas, and portray the precise extent of the tumour both within the infratemporal fossa and intracranially. Paragangliomas, however, require a different policy: besides visualization of the size and extent of the tumour, adequate mapping of vascular structures is a prerequisite to accurate diagnosis. This can be achieved by either magnetic resonance or CT angiography (MRA / CTA) or conventional carotid angiography. MRA with gadolinium enables precise mapping of the vasculature and its relationship with the tumour and surrounding anatomical structures. Moreover, this method accurately displays the size and extent of the tumour. CT images should be made in at least two planes. CT gives more precise information about bone destruction and gives all the information a surgeon would need in relation to temporal bone anatomy if surgery were envisaged.

It is important to visualize the fallopian canal, the middle ear with its ossicles, the absence or presence of a bony lamina between the jugular bulb and the hypotympanum, the position and shape of the internal auditory canal and the carotid canal.

Various scintigraphic techniques may be useful to diagnose some types of pathological condition in and around the jugular foramen. In patients with chronic infections, diagnostic information can be obtained with scintigraphy using radioisotopes, such as technetium-99 methylene diphosphanate and gallium-67 citrate. The former isotope identifies osteoblastic activity, whereas the latter documents the activity of the infectious process. Endocrine activity in paragangliomas can be demonstrated with iodine-123 metaiodobenzylguanidine. Octreotide scintigraphy may contribute to the detection of paragangliomas at multiple locations.

Patients presenting with a jugular foramen paraganglioma should also be screened for other paragangliomas, which are particularly common as manifestations of succinate dehydrogenase gene mutations, typically SDHB or SDHD.[6]

This can be done using positron emission tomography (PET) with 18F-DOPA or 18FDG glucose, although MRI imaging of head, neck, mediastinum, abdomen and pelvis will achieve the same result without radiation exposure, and is therefore the preferred modality for ongoing screening of such patients.

PATHOLOGY

Broadly speaking, pathological conditions involving the jugular foramen can be divided into three categories: neoplasia; infectious conditions; and miscellaneous. The pathological conditions that have been found in the jugular foramen are listed below, the majority being neoplastic disorders. Most of the lesions originate in the jugular foramen or in adjacent structures. The list does not include incidental lesions that originate from more distant head and neck regions and occasionally spread into the jugular foramen, for example, parotid tumours and nasopharyngeal carcinoma, or metastases from distant lesions:

- paragangliomas (also known as glomus tumours)
- schwannoma
- meningioma
- osteoclastoma
- myxoma
- neurofibroma
- haemangiopericytoma
- chondromyxoid fibroma
- angioma
- ceruminoma
- giant cell tumour
- plasmocytoma
- endolymphatic sac tumour
- cholesteatoma
- cholesterol granuloma
- cholesterol cyst
- neurenteric cyst
- amyloidoma
- rhabdomyosarcoma
- adenoid cystic carcinoma
- chondrosarcoma
- sarcoma
- malignant schwannoma.

Neoplasia

Paragangliomas are the most common lesions in the jugular foramen. Schwannomas and meningiomas are the second and/or third most frequent lesions. Schwannomas usually have developed from the cranial nerves IX, X or XI. Meningiomas generally originate intracranially and eventually invade the jugular foramen, although intraosseous meningiomas may occur.[7] Reports of lesions other than paragangliomas, schwannomas and meningiomas are scant and therefore our knowledge of less common jugular foramen lesions is somewhat fragmentary.

PARAGANGLIOMAS

The term paraganglioma is derived from the site of origin of the tumour. In the temporal bone, paraganglia are present in the adventitia of the jugular bulb and along the IXth and Xth cranial nerves, and in the middle ear in association with Jacobsen's plexus. Chromaffin and non-chromaffin paragangliomas have been distinguished according to their intrinsic ability to take up and stain with chromium salts. In the past, a chromaffin paraganglioma was considered capable of producing adrenalin, whereas its non-chromaffin counterpart was not. This distinction between chromaffin and non-chromaffin paragangliomas has since become outdated, as both tumours are now known to synthesize all types of catecholamines. The term chemodectoma should be reserved for tumours that originate from the chemoreceptor system. The paraganglia in the temporal bone do not belong to this histological entity, in contrast with those in the carotid sinus. Therefore, the term chemodectoma is less appropriate for lesions in the jugular foramen and in other parts of the temporal bone.

The term glomus tumour is also inaccurate, because the word glomus means a small, circumscribed histological structure in which arterioles connect directly with veins, a situation found in small cutaneous lesions also known as glomus tumours. However, the term glomus or glomus tumour is commonly used in the historical literature to refer to paragangliomas.

Temporal bone paragangliomas can be divided into one of three categories: jugular paragangliomas; jugulotympanicum paragangliomas; and tympanic paragangliomas. Only the tympanic paraganglioma is confined to the tympanic cavity. These tumours originate in the middle ear, as opposed to jugular paragangliomas, which develop from the adventitia of the jugular bulb. The term jugulotympanic is appropriate for those tumours in which it is impossible to define the site of origin, and for tympanic tumours that have extended to involve the jugular foramen and widely invade the temporal bone.

There is a female predominance.[8] The appearance of the lesion is lobular, pulsatile and red-purple in colour. Its microscopic appearance is dominated by the presence of groups of characteristic neurosecretory cells.

Up to 40% of patients with head and neck paragangliomas have a mutation of the succinate dehydrogenase gene that makes them prone to developing multiple paragangliomas. A proportion of these patients will have multiple tumours at presentation, which may include intra-abdominal tumours with a higher propensity to secrete catecholamines. Paragangliomas are considered to belong to the amine precursor uptake and decarboxylation (APUD) tumours. Consequently, associations have also been described between paragangliomas and a variety of other APUD tumours, such as various forms of multiple endocrine adenomatosis. Moreover, concomitant occurrence has been described with Von Hippel–Lindau disease, renal cell carcinoma, neurofibromatosis and vestibular schwannoma.

Several classifications have been proposed for paragangliomas in the temporal bone, based on symptoms and/or the size and extent of the tumour. Nowadays, staging is performed by means of MR and CT imaging. The most frequently used classification was the one developed by Fisch (**Table 107.1**)[9] in which tumours are classified from A to C based on extension within the temporal bone with tumours that affect the jugular foramen belonging to class C. Class C is subdivided according to the relationship between the tumour and the carotid artery, and Class D is used in addition to the A–C moniker to describe the extent of intracranial involvement where this is present.

The biological behaviour of paragangliomas is usually indolent: it can take many years or even decades for slight growth to become apparent. However, even without any substantial increase in the volume of the lesion, symptoms of progressive cranial nerve deficits may develop, presumably as the result of local erosion and compression by the tumour. In **Figures 107.4** and **107.5**, two illustrative cases are shown.

TABLE 107.1 Classification of paragangliomas in the temporal bone according to Fisch

Classification	
Class A	Limited to the middle ear (mesotympanum)
Class B	In the middle ear (meso- and hypotympanum) and the mastoid
Class C	Tumour originates in the dome of the jugular bulb, destroying the overlying bone; the tumour may spread inferiorly, posteriorly, superiorly, laterally and/or medially; class C is subdivided into four categories, according to the size and extension of the tumour
Class D	Intracranial extension; class D is subdivided into two categories according to the presence or absence of intradural extension; these two categories are subdivided again according to the depth of invasion of the posterior fossa and the degree of medial displacement of the posterior fossa dura, respectively

Reproduced with permission from Fisch.[9]

SCHWANNOMAS

Synonyms for schwannoma include nerve sheath tumour, neuroma, neurilemoma and neurinoma. Nowadays, schwannoma is the generally agreed term because the lesion develops from the Schwann cells in the perineurium. The pars nervosa of the jugular foramen is the site of origin, and the cranial nerves IX, X or XI are primarily affected.

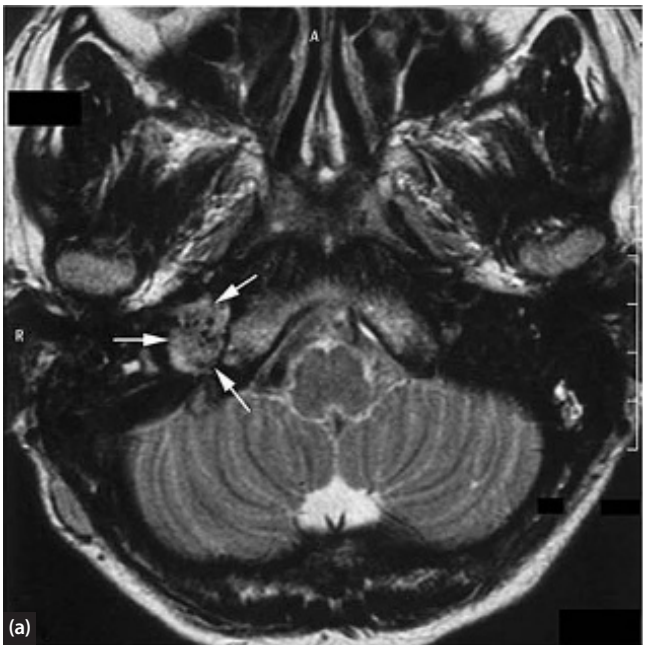

Figure 107.4 A 42-year-old woman presented with a mixed sensorineural-conductive hearing loss of about 50 dB on the right side in combination with a reddish-blue discolouration of the tympanic membrane. (a) T2-weighted axial MRI showing the lesion in the axial plane (arrows). **(b)** T1-weighted coronal slices, showing the involvement of the jugular bulb and the sigmoid–jugular complex (arrows). *(Continued)*

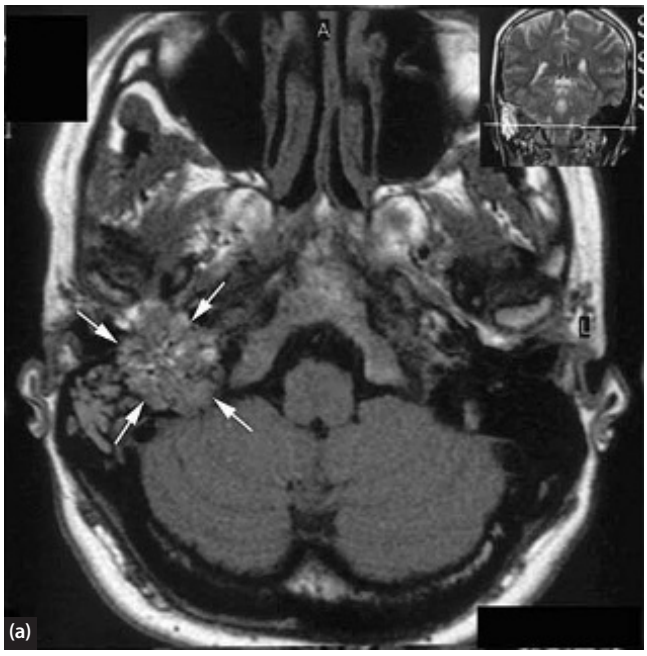
Figure 107.4 (Continued) A 42-year-old woman presented with a mixed sensorineural-conductive hearing loss of about 50 dB on the right side in combination with a reddish-blue discolouration of the tympanic membrane. (c) Subtraction image (that is, T1 with gadolinium minus T1). Diagnosis: Jugular paraganglioma, presumably a class C lesion according to the classification of Fisch.[9]



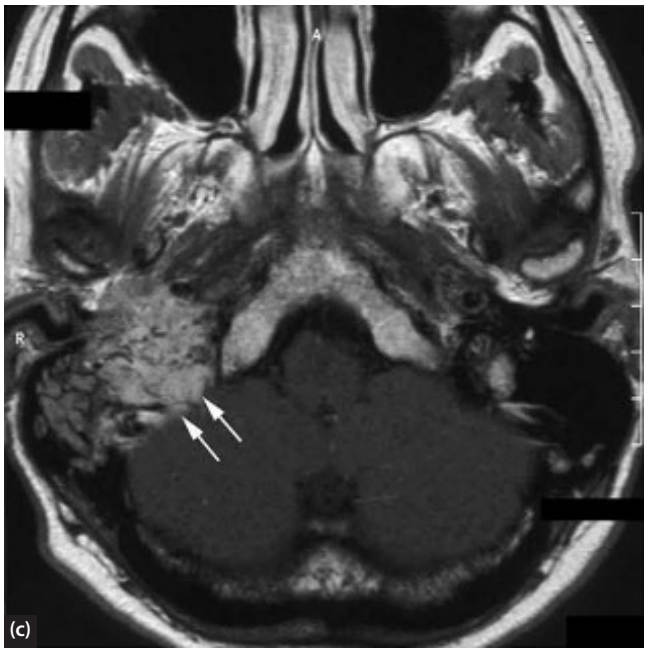


Figure 107.5 A 25-year-old woman presented with right-sided mixed sensorineural-conductive hearing loss of about 60 dB and pulsatile tinnitus. The right tympanic membrane had a reddish-blue discolouration. (a) Axial T1-weighted MRI showing a mass lesion around the right jugular foramen (arrows) with the characteristic appearance of a paraganglioma. **(b)** Coronal MRA; absence of flow in the right sigmoid–jugular complex and internal jugular vein. **(c)** Axial T1-weighted MRI with gadolinium demonstrating involvement of the posterior fossa dura (arrows). *(Continued)*

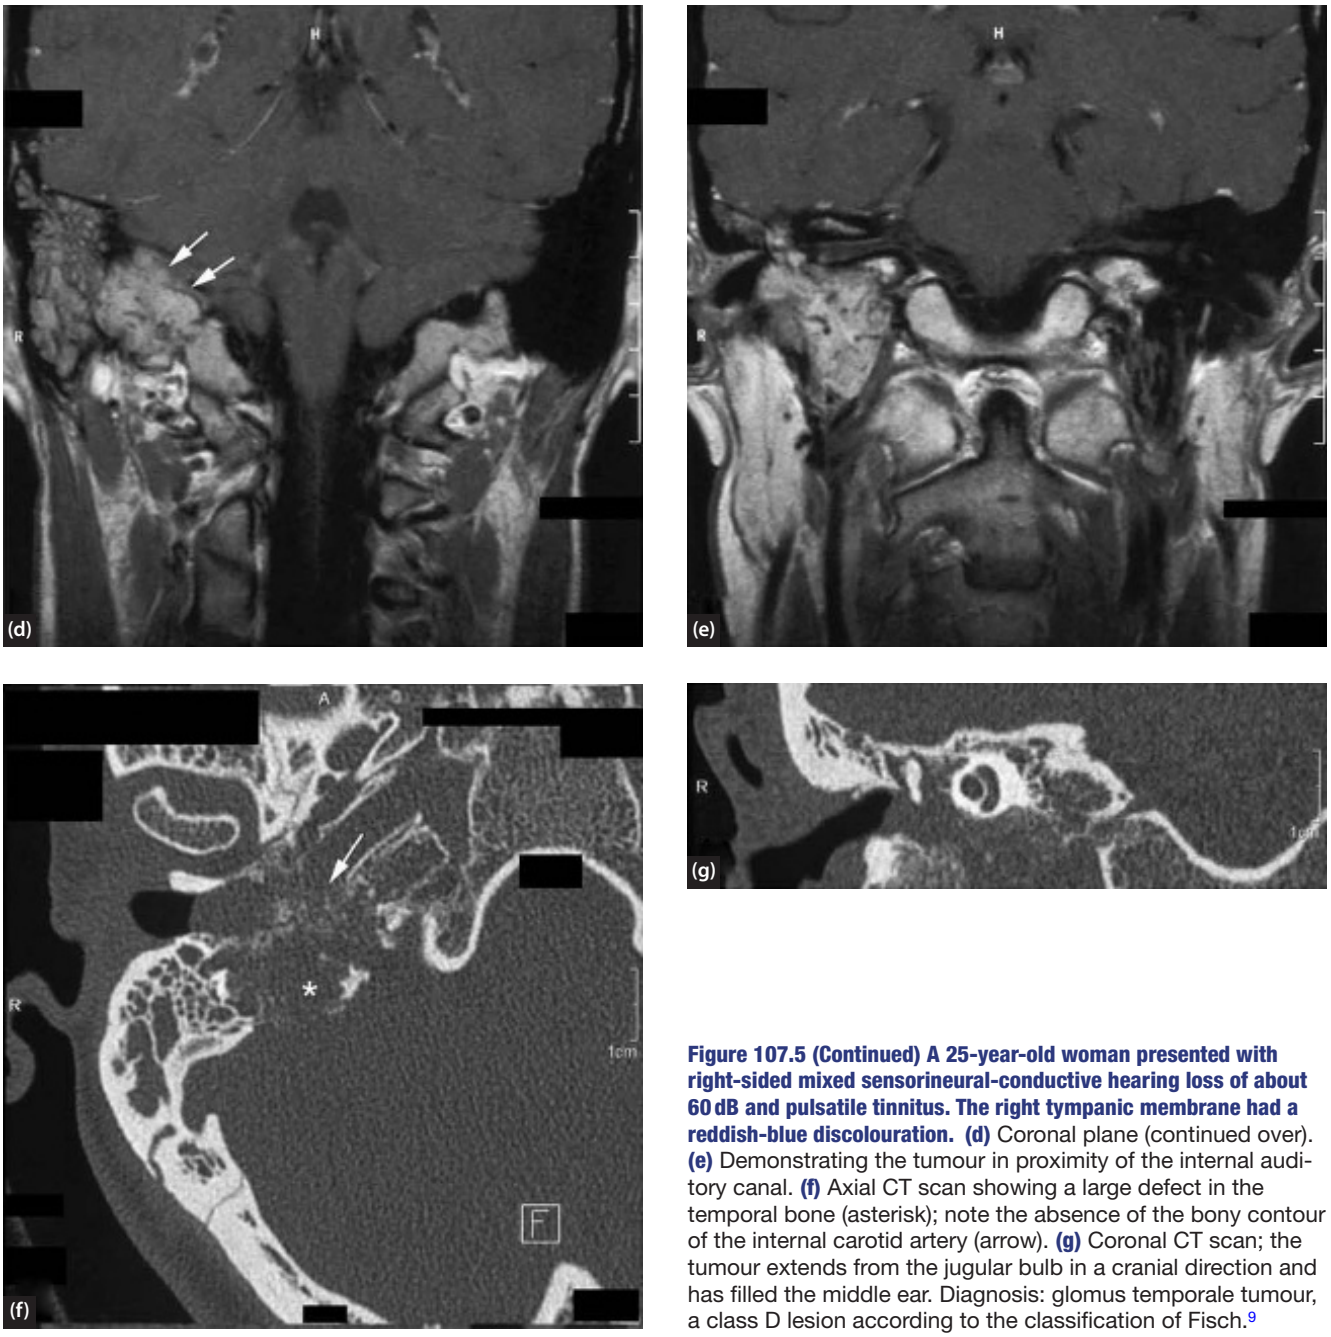

Figure 107.5 (Continued) A 25-year-old woman presented with right-sided mixed sensorineural-conductive hearing loss of about 60 dB and pulsatile tinnitus. The right tympanic membrane had a reddish-blue discolouration. (d) Coronal plane (continued over). **(e)** Demonstrating the tumour in proximity of the internal auditory canal. **(f)** Axial CT scan showing a large defect in the temporal bone (asterisk); note the absence of the bony contour of the internal carotid artery (arrow). **(g)** Coronal CT scan; the tumour extends from the jugular bulb in a cranial direction and has filled the middle ear. Diagnosis: glomus temporale tumour, a class D lesion according to the classification of Fisch.[9]

As a result, a schwannoma is usually localized in the medial part of the jugular foramen. Kaye et al.[10] and Pellet et al.[11] classified jugular foramen schwannomas according to their size and extension (Table 107.2). A further classification has been proposed by Franklin et al. (Table 107.3).[12]

Their histopathological appearance is identical to that of sporadic vestibular schwannomas. Antoni type A and type B tissues can be distinguished. Type A tissue is characterized by densely packed cells, whereas type B tissue is fairly hypocellular with a myxoid stroma. Both types can develop in different proportions. Fatty degeneration, haemorrhage, necrosis and cyst formation may also be seen. The biological behaviour of schwannomas in the jugular foramen does not differ from that in the internal auditory meatus or the cerebellopontine angle, often slow growing or apparently static. Rapid increase in size may be seen and is usually the result of intratumoral haemorrhage and cyst formation.

MENINGIOMAS

Intracranial meningiomas represent about 15–20% of all brain tumours. Basal meningiomas can penetrate the skull base through any of the natural foramina (e.g. the foramen magnum, the optic canal and the jugular foramen). Locally aggressive meningiomas sometimes invade

TABLE 107.2 Classification of jugular foramen schwannomas, according to Kaye et al.[10] and Pellet et al.[11]

Classification	
Type A	Primarily growing intracranially into the cerebellopontine angle
Type B	Growing into the jugular foramen
Type C	Primarily growing extracranially into the neck
Type D	Dumb-bell-shaped tumour, growing from the jugular foramen intracranially and extracranially

TABLE 107.3 Classification of jugular foramen schwannomas, according to Franklin et al.[12]

Classification	
Type A	Confined to the neck
Type B	In the neck and extending into the jugular foramen
Type C	In the jugular foramen and extending along the internal carotid artery
Type D	In the jugular foramen and extending intracranially

Reproduced with permission from Franklin et al.[11]

TABLE 107.4 Meningiomas: World Health Organization classification

Classification	
Grade I (typical)	• Meningothelial (syncytial) • Fibrous (fibroblastic) • Transitional (mixed) • Psammomatous • Angiomatous • Microcystic • Secretory • Clear cell • Chordoid • Lymphoplasmocyte-rich • Metaplastic
Grade II (atypical)	Papillary
Grade III (anaplastic)	Malignant

Reproduced with permission from Kleihues et al.[13]

bone and form new openings (e.g. from the anterior fossa through the cribriform plate into the nasal cavity and from the middle fossa into the temporal bone). About one in five intracranial meningiomas have such extracranial extensions. The histopathology and vascularity of these tumours varies widely. Some classifications have been proposed mainly based on morphological characteristics. The World Health Organization classification is the most generally accepted (Table 107.4).[13] About 10 percent of meningiomas undergo malignant transformation and very occasionally metastasize to the lung, liver or kidney. Females are more frequently affected than males. The peak age of incidence is in the fifth decade.

The medial aspect of the jugular foramen is invaded by meningiomas whose site of attachment lies either anteriorly or at the level of the lower clivus. The lateral aspect is invaded by lesions that originate more posteriorly at the dorsal aspect of the petrous bone. The lower cranial nerves are more susceptible to damage when the medial part of the jugular foramen is involved. Sometimes the tumour also erodes bone and grows through the jugular foramen into the infralabyrinthine bone and tympanic cavity. The tumour can also extend through the jugular foramen into the upper neck, occasionally within the lumen of the internal jugular vein (IJV). Biological activity varies, but slow progression is the most usual pattern.

METASTATIC LESIONS

The common malignancies that arise in the lung, breast, prostate, kidney, stomach and thyroid gland can metastasize to the skull base, including the jugular foramen. Less common malignancies that develop in adjacent structures such as the posterior fossa, temporal bone, infratemporal fossa and nasopharynx, can also spread into the jugular foramen. Some histological types, such as adenoid cystic carcinoma, are more common than others. This tumour may originate in the deep lobe of the parotid gland and spread into the skull base. Metastases from haematological neoplasms and extramedullary plasmocytomas are also seen in the temporal bone and in the jugular foramen, usually as a result of haematogenous spread. Lymphatic spread of malignancies into the jugular foramen is very uncommon. Like many other jugular foramen lesions, metastases make their presence known by causing cranial nerve dysfunction (VII to XII). Erosion of bone usually accompanies metastatic disease and this is clearly seen on CT images as radiolucent areas in bony structures.

Infectious conditions

The most frequent infectious conditions that affect the jugular foramen are:

- acute otitis media
- chronic otitis media
- chronic otitis media with cholesteatoma
- varicella zoster virus
- osteomyelitis
- epidural empyema
- necrotizing skull base osteomyelitis.

The majority are related to otitis media, predominantly the chronic type, with or without cholesteatoma. Intracranial disorders that result in jugular foramen pathology, such as meningitis and epidural empyema, are also frequently related to some type of otitis media.

Miscellaneous disorders

A high jugular bulb is defined as reaching beyond the level of the inferior border of the tympanic annulus. It is a well-known entity that protrudes anteriorly and laterally, and is visible behind the tympanic membrane or in the external auditory canal. It may even reach the ossicular chain and give rise to conductive hearing loss. In patients with a high jugular bulb, myringotomy and tympanoplasty may lead to severe haemorrhage if the condition is not recognized pre-operatively.

Jugular bulb diverticulum is another vascular disorder. The diverticulum develops from the jugular bulb and extends towards the posterior semicircular canal, the internal auditory meatus or the posterior fossa. Vestibular symptoms, sensorineural hearing loss or even facial nerve palsy may be associated with this. The condition can also cause symptoms similar to those in Ménière's disease. In Figures 107.6 and 107.7, two illustrative cases are shown.

MANAGEMENT

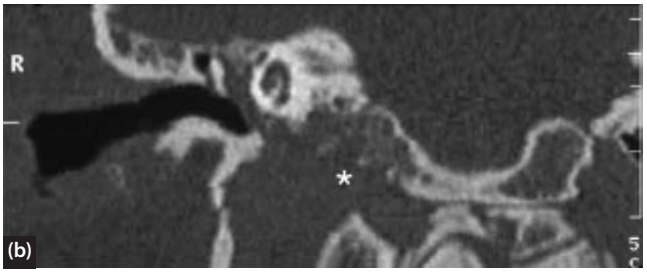
The goals of management must be clearly defined in this complex area, and the following discussion pertains primarily to the three commonest pathologies in this area, paragangliomas, schwannomas and meningiomas, all of which typically have a relatively indolent natural history.

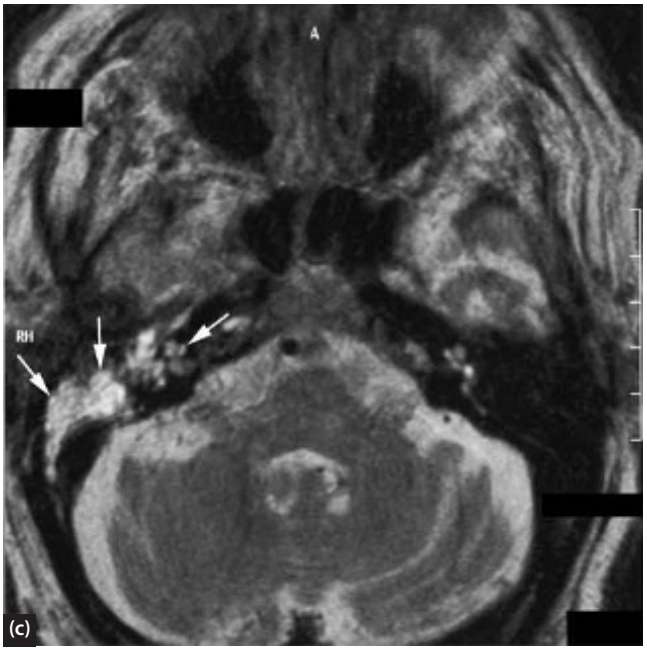
It is generally the case that the gradual onset of venous outflow obstruction is relatively well tolerated, as collateral veins develop, although exceptions occur.

The primary goals of treatment are therefore:

1. to address presenting symptoms
2. the preservation of remaining neurological function (that which has been lost will generally not return)
3. to avoid intracranial disease extension and the associated risk of brainstem compression.

For the majority of processes affecting the jugular foramen, the likelihood of these occurring in the next few years if





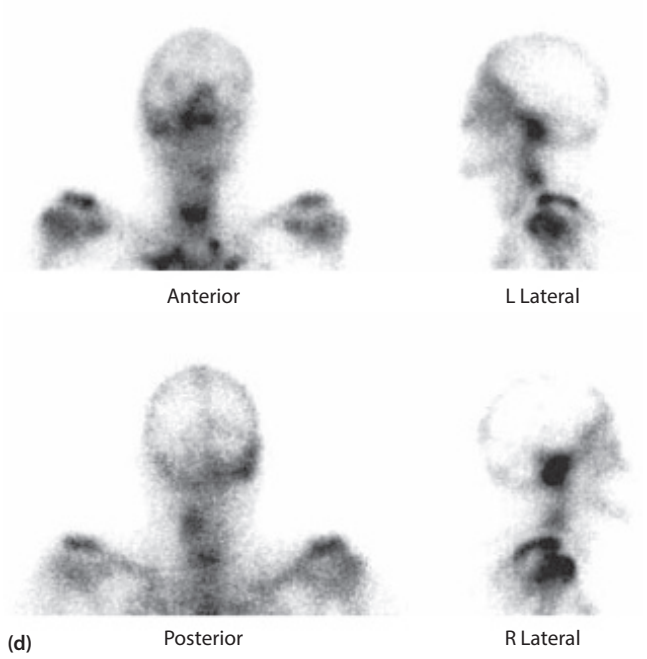


Figure 107.6 A 78-year-old man with a history of diabetes mellitus, polyneuropathy and chronic otitis media presented with right-sided facial palsy (House-Brackmann grade III) and signs of involvement of cranial nerves IX, X and XI. (a) Axial CT scan showing an irregular defect in the right petrous apex (asterisk) extending towards the jugular bulb. **(b)** The coronal plane (asterisk). **(c)** T2-weighted MRI; the right mastoid and some petrous apex cells are filled with fluid (arrows). **(d)** Scintigram (technetium-99m diphosphanate) with signal enhancement in the area of the right temporal bone. Diagnosis: jugular foramen syndrome as a result of petrositis/osteomyelitis of the skull base.

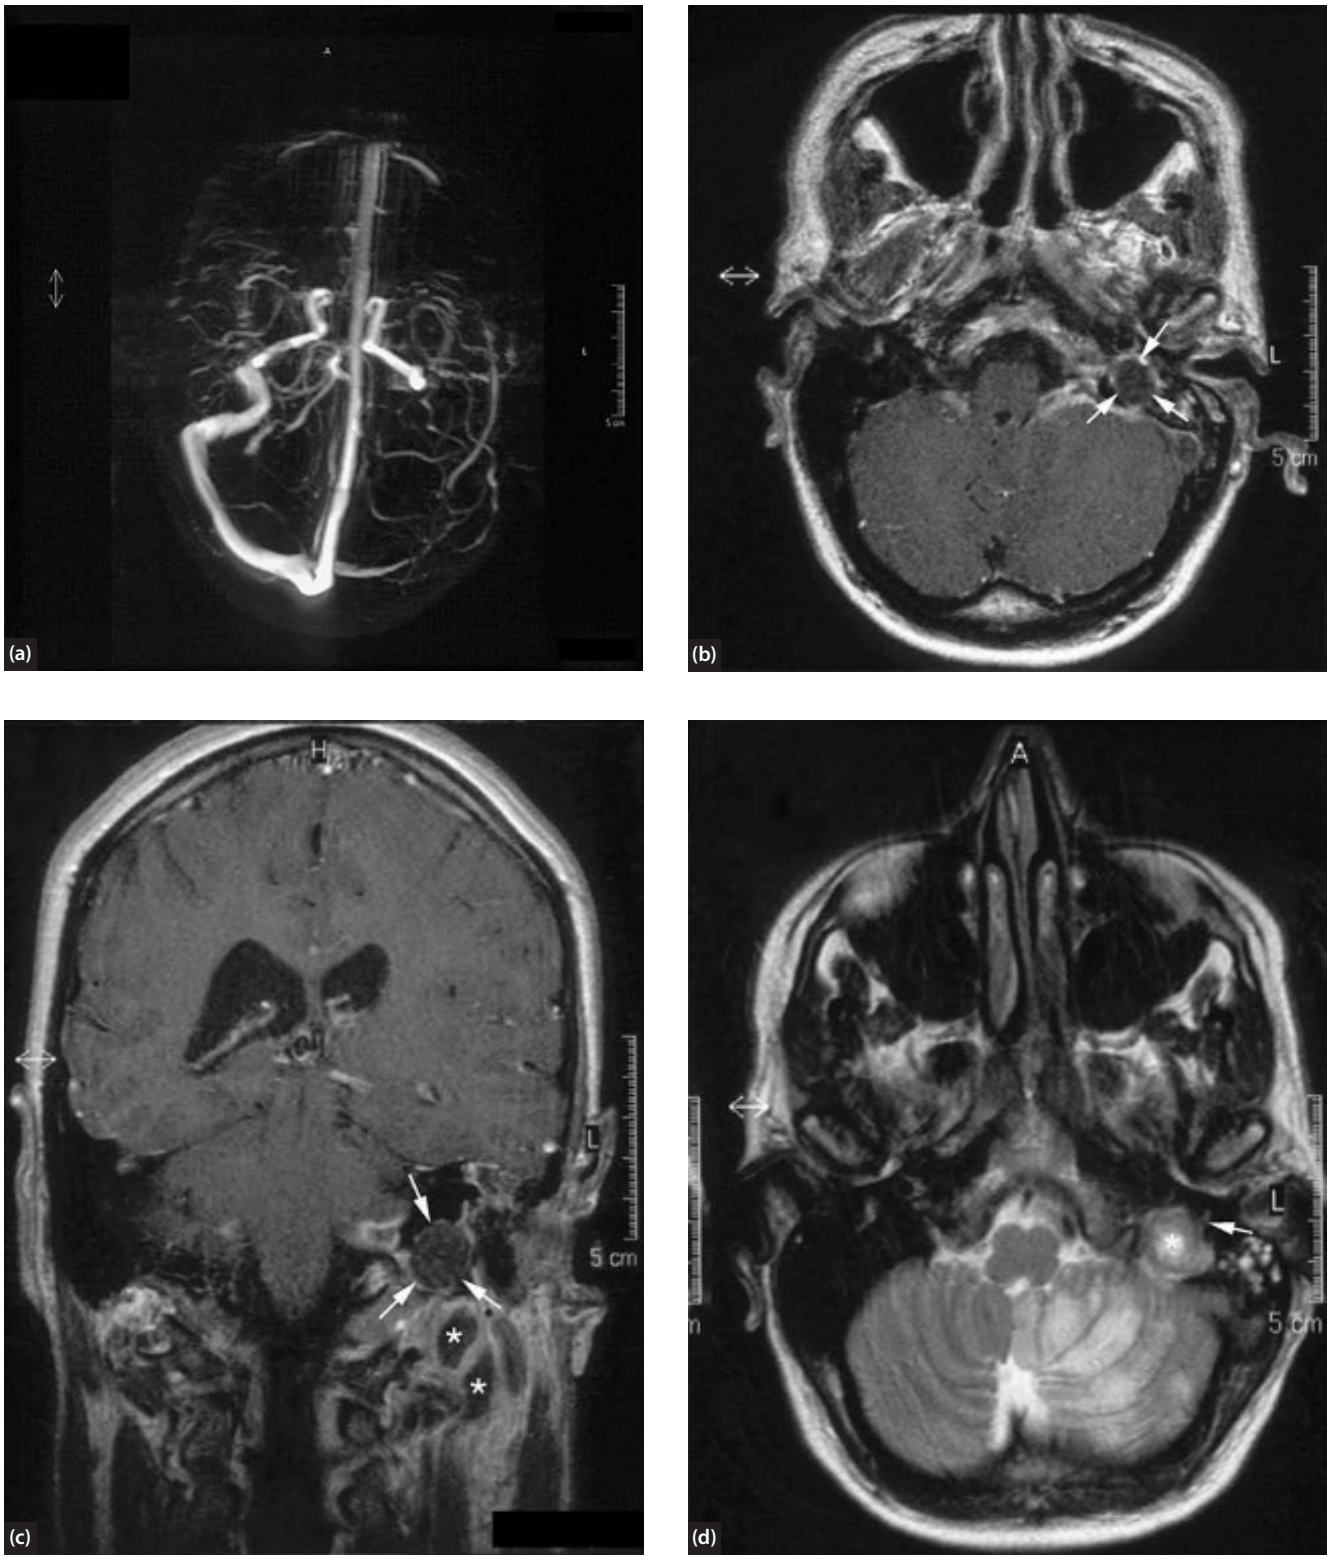

Figure 107.7 A 42-year-old man presented with fever, headache and 40 dB conductive hearing loss on the left side. Moreover, there were clinical signs of involvement of the cranial nerves VII (House-Brackmann II), IX, X, XI and XII. **(a)** MRA showing absence of flow in the left transverse sinus and sigmoid–jugular complex. **(b)** T1-weighted coronal MRI after administration of gadolinium. Mass lesion in the left jugular foramen (arrows). Multiple cystic lesions in the upper neck (asterisks). **(c)** T1-weighted axial MRI after administration of gadolinium. Note mass lesion in the jugular foramen (arrows). **(d)** T2-weighted axial MRI. The lesion in the left jugular foramen is depicted as a hyperintense area (asterisk); a small band suggests the presence of a connection with the middle ear (arrow); this was confirmed during surgery. Diagnosis (made intra-operatively): cholesteatoma in the left jugular foramen with thrombosis of the sigmoid–jugular complex and multilocular abscesses in the upper neck.

the disease is left untreated is low, and it is important that well intentioned intervention does not hasten the onset of disability.

Historically, the presence of a space-occupying lesion once formed sufficient grounds to proceed directly to surgery. It was believed that something that should not be there had to be removed, in view of the threat to adjacent vital structures.

Although the body of literature on jugular foramen lesions still focuses on surgical treatment, much can also be said for non-surgical or conservative management.

Which approach is appropriate depends not only on the nature and extent of the lesion but also on the patient. Advanced age or poor physical condition are contraindications for surgery. As conservative management becomes more widely practised there is also an increasing body of evidence that while paragangliomas, schwannomas and meningiomas may progress rapidly, the majority do not, and spontaneous regression of schwannomas is well recognized. In many cases, progression of the disorder may be extremely slow, sometimes so slow as to be undetectable.

An initially expectant policy may therefore be justified. In general, the choice of surgery, non-surgical or conservative management should not be made until a wide range of aspects concerning the patient and the disorder have been fully considered.

Wait-and-see policy

The size of a jugular foramen lesion can now be accurately measured, monitored and documented with the available imaging modalities of CT and MRI.

In many cases, the lesions do not pose a threat during the whole of the patient's life. However, there are also a number of lesions that show considerable progression and cause progressive neurological deficits and risks to life.

The main problem is therefore to identify those lesions that will progress in the future. Although theoretically histological features of the tumour could provide some insight into its biological behaviour, in most cases taking a biopsy from a jugular foramen lesion is not feasible, and for the commoner pathologies even histology is often unable to distinguish between aggressive and indolent forms of the disease. One potential surrogate marker for future behaviour of paragangliomas is metabolic activity as evidenced by standardized uptake value (SUV) max on FDG PET (fludeoxyglucoze), with higher SUV correlating with an increased tendency to growth.

It is logical to assume that larger tumours are more likely to pose an early threat to the patient than smaller lesions, and one might therefore be more inclined to treat these surgically. However, post-operative morbidity and mortality is also potentially more significant in patients with larger tumours, hence patients with minimal symptoms may be tempted to explore non-surgical options. Conversely, patients with small tumours may tolerate surgery relatively well; however, the risk associated with leaving the lesion is also minimal.

It must be emphasized that these considerations only apply to the three most common jugular foramen lesions. Conditions other than a paraganglioma, schwannoma or meningioma require a different approach, depending on the nature of the lesion. In many of these lesions, it is questionable whether surgery or any other form of treatment will be beneficial to the patient.

Medical therapy

There are very few indications for medical treatment for jugular foramen lesions. Antibiotics are important for all infectious conditions of the jugular foramen, such as those associated with chronic otitis media. Acute sepsis and its complications cannot usually be cured by even the most potent antimicrobial medication, so surgery will invariably be part of the therapeutic strategy. Necrotizing osteomyelitis in contrast is not amenable to surgery, other than to provide tissue for culture, and must be addressed with long term antimicrobial therapy.

Radiotherapy

Conventional fractionated radiotherapy has been demonstrated to be as efficacious as surgery in providing long-term tumour control in jugular and vagal paragangliomas, with a lower risk of iatrogenic cranial nerve damage.[14–16]

The aim is to destroy the microvascular tissue and bring about sclerosis and fibrosis, hence the tumour will not disappear, but may regress over time.

With modern radiotherapy techniques it is relatively straightforward in the vast majority of tumours to limit the dose delivered to the brain to within its tolerance. The cochlea is likely to be affected, however, and treating the middle ear component of a jugular paraganglioma with radiation will invariably compromise the tympanic membrane and risk radiation induced exposure of the bony ear canal floor.

Radiotherapy may be an option for patients whose paraganglioma is impossible to remove surgically (i.e. to patients with extensive class C and D tumours), although in some cases the degree of brainstem compression may present a contraindication, and debulking surgery may be a prerequisite.

In the elderly and those whose life expectancy is limited by other conditions it may be more appropriate not to treat the jugular foramen lesion at all, although a rapidly progressive tumour may be treated with radiotherapy.

The role of radiotherapy in meningiomas is neither sharply delineated nor universally accepted. The indolent nature of these lesions impairs assessment of the contribution that radiotherapy might make to slowing down or stopping progression. Moreover, meningiomas represent a fairly heterogeneous histological group of lesions, which may all react differently to irradiation. A clinical trial randomizing WHO grade 1 meningiomas subtotally resected to either radical radiotherapy or conservative management was instituted by the EORTC clinical trials group but it was abandoned due to low enrolment (EORTC 22021–26021). A similar trial looking at WHO grade 2 and 3 meningiomas is ongoing

but is yet to report results (as of March, 2018, EORTC 22042–26042), although in this cohort of patients radiation is generally considered of more benefit.

In addition, the anatomical localization and extension of meningiomas in and around the jugular foramen differ from one patient to another to a greater extent than for other pathologies, complicating the comparison of different treatments.

All these factors complicate the realistic evaluation of the value of radiotherapy as a treatment for meningiomas.

The jugular foramen lies in close proximity to delicate and vulnerable structures. Therefore, single-dose stereotactic radiosurgery is likely to be chosen in preference to conventional radiotherapy for common benign lesions in the jugular foramen, such as meningiomas and schwannomas.

Stereotactic radiosurgery

Stereotactic radiosurgery is rapidly gaining popularity as a treatment modality for tumours of less than 3 cm maximum diameter. It forms an alternative to microsurgical removal of a variety of benign lesions in the skull base, including those arising in the jugular foramen. The principles of this method of treatment are described in Chapter 103.

Most experience with stereotactic radiosurgery in skull base tumours has been gained on vestibular schwannomas, and for suitable tumours (i.e. predominately solid tumours of less then 3 cm maximum diameter results are excellent). Smaller series of non-vestibular and jugular foramen schwannomas demonstrate similar high rates of tumour control, with a lower incidence of cranial neuropathy than that associated with surgery.[17, 18]

Stereotactic radiosurgery for jugular paragangliomas has been demonstrated to be as efficacious as external beam radiotherapy, with a similar low rate of iatrogenic cranial neuropathy, and has the merit of being a single fraction treatment.[14]

The role of both radiotherapy and radiosurgery in the management of meningiomas throughout the skull base remains ill defined, and this also applies to this subsite. In view of the ambiguous nature of the evidence, clinical trails are now underway that should better define this issue, in particular for WHO grade 2 meningiomas.[19]

Generally, stereotactic radiosurgery can be considered for patients with small volume progressive disease and minimal symptoms, residual disease after surgery, inoperable tumours and in patients of advanced age or with poor physical condition.

SURGICAL MANAGEMENT

Surgical treatment for lesions in and around the jugular foramen is one of the most challenging procedures in head and neck surgery. Various surgical approaches have been described; lateral transtemporal techniques are the most widely used. A major key to success is the surgeon's knowledge of anatomy, particularly in view of the close proximity of a considerable number of important anatomical structures in this delicate area.[20]

The facial nerve nearly always causes a major obstruction to the direct surgical access of the jugular foramen. It goes without saying that it is absolutely imperative to avoid severing or damaging this important nerve. Various surgical approaches have been described, all with the intention of preserving the anatomical integrity of the facial nerve in combination with adequate surgical exposure.[21] During surgery in the region of the jugular foramen, cranial nerves VII–XII are particularly vulnerable. It should be emphasized that any damage to the VII cranial nerve results in far more serious morbidity than impairment of one or more of the other cranial nerves. Therefore, continuous intra-operative facial nerve monitoring should be performed routinely. Monitoring of X and XII nerves is also advisable in cases where pre-operative function is normal.

The internal carotid artery is another major issue for concern. The vertical part of the carotid canal lies close to venous and nervous structures in the jugular foramen. Some lesions invade the petrous carotid artery, which makes preservation of this vessel problematic. In rare occasions pre-operative stenting or balloon occlusion of the carotid may be appropriate.

Pre-operative embolization

Paragangliomas are the most common lesions found in the jugular foramen. If surgical removal is planned embolization should be considered. Selective arteriography is performed and the tumour embolized via branches of the external carotid artery. There is general agreement that pre-operative embolization significantly reduces blood loss during surgery and this facilitates complete removal of the tumour; however, embolization itself carries a small risk of stroke. The timing of embolization is subject to debate, consensus appears to be that it should take place within 48 hours of surgery, although some surgeons advocate waiting 4–6 weeks after embolization prior to surgery.

Similarly, intra-operative haemorrhage is also the main cause of problems during the surgical removal of meningiomas, particularly those that are extremely vascular. Excessive bleeding can lead to incomplete tumour resection, damage to adjacent structures and post-operative morbidity. It is therefore sensible to assess their vascularity by angiography and undertake superselective embolization in selected cases. Thus, two of the most common lesions in the jugular foramen – paragangliomas and meningiomas – should be investigated with conventional angiography and embolization undertaken where indicated.

Permanent balloon occlusion of the proximal and distal petrous carotid artery should be undertaken where it is likely that the artery is not salvageable. In this situation, the tumour can be embolized via the nutrient vessels that branch off the internal carotid artery by means of inserting a catheter proximal to the balloon. This should be done at least a month prior to definitive surgery, to minimize the risk of a watershed cerebral infarct in the event of intra-operative hypotension.

If carotid occlusion is not tolerated the artery can be reinforced with a covered stent, which minimizes the risk of iatrogenic bleeding at the time of tumour resection.

Surgical approach

The requirement of the surgical approach is that it provides adequate exposure of the tumour, and of the key structures at risk in tumour resection. In the management of jugular foramen lesions, these key structures are the facial nerve and the internal carotid artery.

A wide range of approaches has been described, and choice of approach will be dictated by the patient's anatomy and pathology, the goal of surgery (debulking versus complete resection) and surgical preference.

The basic concepts of all the lateral transtemporal surgical approaches described in the literature are fairly similar. A wide retroauricular incision is made to gain access to the lateral aspect of the temporal bone (**Figure 107.8**). This incision is extended downwards into the neck to expose the structures in the infratemporal region. Then, a wide cortical atticomastoidectomy is performed with skeletonization of the sigmoid sinus. A cranially based tympanomeatal flap can be developed if exposure of the tympanic cavity, in particular the hypotympanic region, is required. After detachment of the tendon from the sternocleidomastoid muscle, the mastoid tip is removed. The mastoid segment of the fallopian canal is skeletonized, from the second genu towards the stylomastoid foramen. The bone anterior to this part of the facial nerve is removed and, at the same time, the dome of the jugular bulb is exposed. A diamond burr is used to remove as much bone as possible that covers the sigmoid sinus and the jugular bulb, so that the fallopian bridge is the only structure that overlies the jugular bulb. As a result, the facial nerve may impair adequate exposure of lesions involving the jugular foramen, but the degree of access required also depends on the pathology. In many cases, the vertical segment of the facial nerve has to be transposed, particularly if the lesions are extensive and bulky. There are two ways to deal with this problem. The first method preserves the ear canal, tympanic membrane and middle ear structures, whereas the second method involves performing a subtotal petrosectomy to gain wide access to the facial nerve. Another possibility is not to transpose the facial nerve. Von Doersten and Jackler[22] reviewed the different ways of handling the facial nerve in jugular foramen surgery.

CONSERVATIVE FACIAL NERVE MANAGEMENT

According to some authors, lesions can be removed without any interference to the facial nerve (**Figure 107.9**).[23–25] There is no doubt that this is possible in certain cases. It typically requires the axis of surgical approach to move postero-inferiorly, to the so-called far-lateral approach. However, the anatomical relationship between the mastoid segment of the facial nerve and the jugular bulb varies considerably. When the space between the two is small, it may be difficult to achieve adequate exposure. In patients with a relatively small tumour and sufficient working space between the vertical segment of the nerve and the jugular bulb, it is usually possible to leave the facial nerve undisturbed. The nerve should preferably remain covered

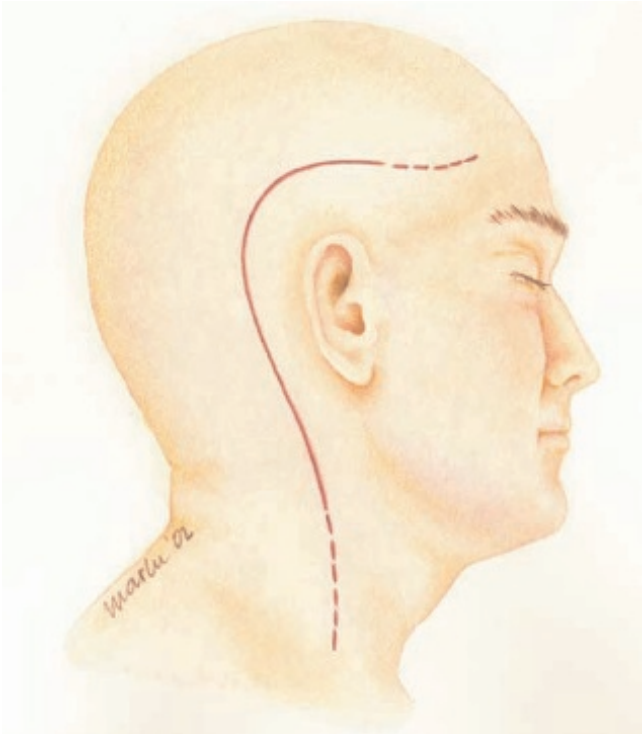

Figure 107.8 The skin incision for the several types of transtemporal approaches to the jugular foramen region.

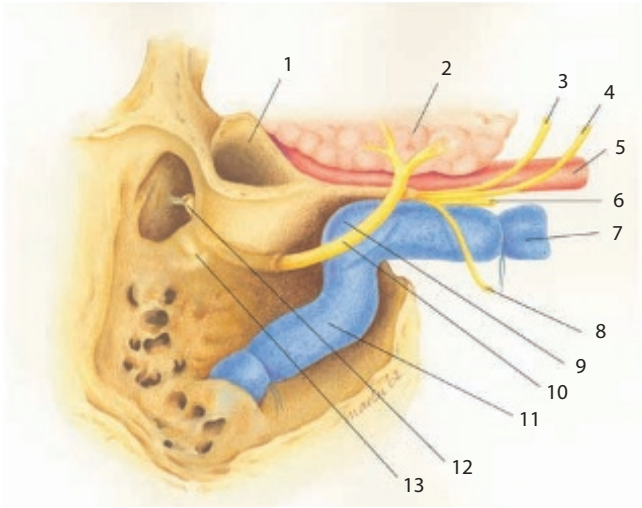

Figure 107.9 Conservative facial nerve management. The right jugular foramen region is exposed without transposition of the facial nerve. After the atticomastoidectomy, the sigmoid–jugular foramen region is exposed. The facial nerve is skeletonized and left *in situ*. The sigmoid–jugular complex is controlled by sutures around the sigmoid sinus and the internal jugular vein. 1, External auditory canal; 2, parotid gland; 3, glossopharyngeal nerve; 4, hypoglossal nerve; 5, internal carotid artery; 6, vagus nerve; 7, internal jugular vein; 8, spinal accessory nerve; 9, jugular bulb; 10, facial nerve; 11, sigmoid sinus; 12, incus; 13, semicircular canals.

by a bony shell (fallopian bridge). In these cases, a large amount of bone anterior to the facial nerve has to be removed to enable wider access to the jugular foramen. Some type of facial nerve transposition may need to be considered if visibility is poor and there is always the risk of incomplete tumour removal.

LIMITED FACIAL NERVE TRANSPOSITION, CANAL WALL UP

This technique involves complete removal of the bony covering of the mastoid segment of the facial nerve, from the second genu down to the stylomastoid foramen. Outside the stylomastoid foramen, the nerve is followed and mobilized over its intraparotid course: first the main trunk and then the temporozygomatic and cervicofacial branches. The subdivisions of these branches are also mobilized and the overlying parotid tissue is removed. Care should be taken to preserve the stylomastoid artery at this stage, to minimize the risk of post-operative facial weakness. After this part of the procedure there is some mobility of the nerve, such that it can be pulled anterolaterally, away from the jugular bulb (**Figure 107.10**). Whether this provides enough exposure is a subject of controversy. It has been stated that this is sufficient for all jugular foramen lesions, but this opinion is not shared universally.[26] According to Fisch,[9] far greater access is needed to achieve adequate exposure and enable total resection of the tumour.

FACIAL NERVE TRANSPOSITION, CANAL WALL DOWN

In order to be able to mobilize the facial nerve more extensively, atticomastoidectomy should be extended to subtotal petrosectomy. This involves removal of the skin of the external auditory meatus along with the tympanic membrane, the malleus and incus, drilling away the posterior canal wall and extensive exenteration of pneumatic cells. As a result, the facial nerve can be uncovered, not only in its mastoid segment, but also in its tympanic part. Then, after mobilization of the intraparotid facial nerve as described above, the nerve can be rerouted anteriorly. The hinge point (pivot) may be located at the second genu, but wider exposure is achieved when the nerve is displaced anteriorly with the hinge point at the first genu (**Figures 107.11** and **107.12**).[22]

MANAGEMENT OF THE SIGMOID–JUGULAR COMPLEX

Damage to the sigmoid sinus or the jugular bulb is a serious risk during jugular foramen surgery. If the vessel wall is punctured, the initial bleeding is fairly simple to control, but retrograde haemorrhage from the IJV may follow. Therefore, the venous blood flow must be blocked at two levels: cranially and caudally to the lesion (i.e. upstream and downstream) (**Figures 107.9–107.12**). It is logical to start with blocking the main flow on the cranial side, the sigmoid sinus. Two methods have been described, ligating the vessel or packing it with Surgicel, both preferably below the level of a preserved mastoid emissary vein. The upper neck can be explored by extending the retroauricular incision downwards. Accordingly, the IJV can be found easily in a later stage of the procedure, after the sternocleidomastoid muscle has been detached from the mastoid process and the mastoid tip has been removed. After identifying the surrounding structures, such as the

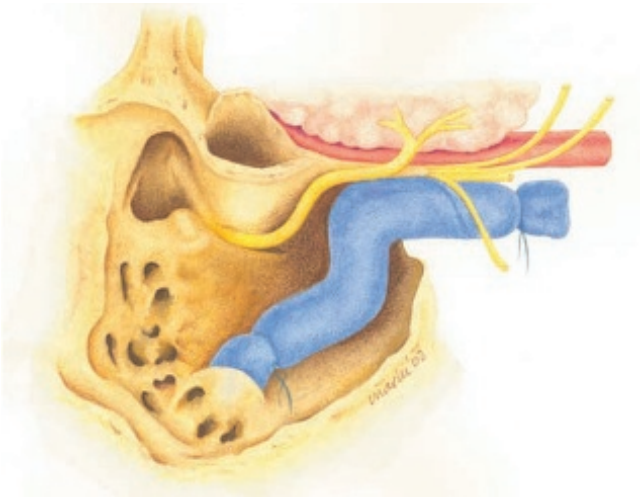

Figure 107.10 Facial nerve transposition, canal wall up. The right jugular foramen region is exposed with a limited transposition of the facial nerve. After an atticomastoidectomy, the mastoidal segment part of the facial nerve is uncovered. The intraparotid part of the nerve is exposed and mobilized. The nerve can then be pulled anteriorly in order to provide access to the jugular bulb. (See also **Figure 107.5**.)

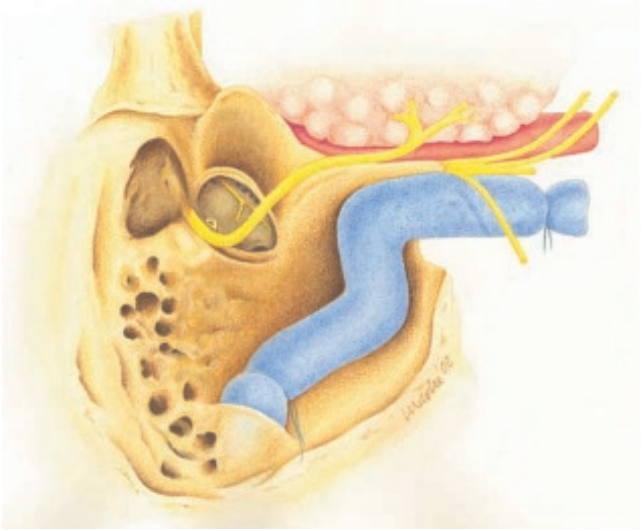

Figure 107.11 Facial nerve transposition canal wall down. The right jugular foramen region is exposed using a more extensive transposition of the facial nerve. After a canal wall down atticomastoidectomy, the tympanic membrane, the malleus and the incus are removed. The facial nerve is uncovered in its mastoidal and tympanic segments. The intraparotid part of the nerve is exposed and mobilized. The nerve can then be rerouted anteriorly with the hinge point at the second genu. (See also **Figure 107.5**.)

internal carotid artery and the cranial nerves IX, X, XI and XII, the IJV should be ligated as high up as possible to avoid bleeding from veins that drain into it in the upper neck. The inferior and superior petrosal sinuses and the mastoid and condylar emissary veins drain into the sigmoid–jugular complex. Usually in a later stage of the procedure, the sigmoid sinus and the jugular bulb have to be opened to remove the tumour. Then bleeding can be expected from these sinuses and emissary veins, which should be dealt with by the use of haemostatic agents.

MANAGEMENT OF THE INTERNAL CAROTID ARTERY

Preservation of the internal carotid artery is of crucial importance during surgery for jugular foramen lesions. The tumour may be attached to the internal carotid artery or be in close contact with it. Visualization of the plane between the tumour and the petrous carotid artery is extremely important. Therefore, the operative field should be as bloodless as possible. All sources of venous haemorrhage must be meticulously controlled, either by ligation or by packing with haemostatic agents. Management of the internal carotid artery is particularly important in patients with paragangliomas. This artery is less likely to be threatened by schwannomas or meningiomas. Paragangliomas may invade the carotid canal, first in its vertical part and eventually along the horizontal part on to the foramen lacerum. They will typically receive part of their blood supply from the petrous carotid artery, via its caroticotympanic or dural branches. In very large tumours, permanent balloon occlusion of the internal carotid artery must be considered, but only if there is sufficient collateral circulation. The latter can be tested pre-operatively during the angiography procedure by temporary occlusion with clinical and radiological surveillance. According to Andrews et al.,[27] permanent balloon occlusion is a safe procedure and does not cause any serious ischaemic deficits, as long as the tolerance test shows sufficient patency of the circle of Willis.

Extensive lesions and malignant tumours may require wide resection with sacrifice of the internal carotid artery. It should also be emphasized that not all patients have sufficient collateral circulation to allow permanent balloon occlusion. In these cases the artery may be stented, with a covered stent to provide reinforcement, or an extracranial–intracranial bypass procedure may be considered.

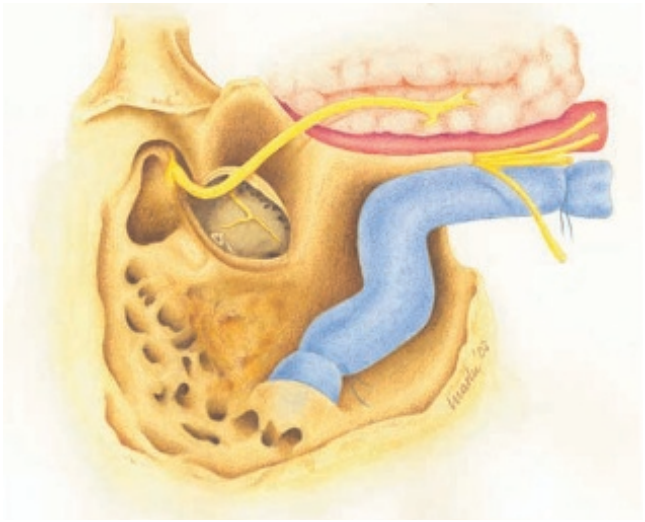

Figure 107.12 Facial nerve transposition, canal wall down. Maximum exposure of the right jugular foramen is achieved by rerouting the facial nerve anteriorly with the hinge point at the first genu. (See also **Figure 107.5**.)

Surgical approaches other than the lateral approach

Although lateral transtemporal surgical approaches are widely accepted, various other surgical techniques have been described (**Table 107.5**).[11, 28–32] These methods invariably involve combinations of well-known neurosurgical techniques. It should be noted that there is not the slightest scientific evidence to suggest that one technique is better than another. Comparative randomized controlled studies have not yet been introduced in this field. Actually, this would hardly be possible for three reasons:

1. the variability and incomparability of pathology in the jugular foramen
2. differences in surgical skills (the human factor)
3. non-uniformity in the way the outcomes are presented. It cannot be expected that this situation will change in the near future.

TABLE 107.5 Surgical approaches other than lateral transtemporal techniques

Approach	Reference
Combined suboccipital and infralabyrinthine–transcervicomastoid approach	Kim et al.[28]
Retrosigmoid suboccipital and combinations with transtemporal approaches	Lee et al.[29]

Petrooccipital trans-sigmoid approach and combinations with transtemporal approaches	Mazzoni et al.[31]
Widened transcochlear approach	Pellet et al.[11]
Juxtacondylar approach	George et al.[32]
Endoscopic assisted retrosigmoid	Samii et al.[33]

Tumour resection

The close proximity of the internal carotid artery to the jugular foramen seriously complicates the surgical management of a variety of lesions in this area. The aim of all surgical strategies is complete tumour resection with maximum anatomical and functional preservation of nervous and vascular structures. Whether this goal can be achieved depends mainly on the skills of the surgeon and the nature and extent of the pathology. As stated under 'Neoplasia' above, the three most common tumours that affect the jugular foramen are paragangliomas, schwannomas and meningiomas. Paragangliomas usually arise in the lateral part of the jugular foramen (**Figure 107.13**), whereas schwannomas tend to be primarily located in the medial part (**Figure 107.14**). Meningiomas originate in the meninges of the posterior fossa and may eventually fill one or both parts of the jugular foramen, and are likely to encase rather than displace nerves, making functional preservation particularly challenging (**Figure 107.15**). Dumb-bell-shaped tumours are fairly common, because they can extend intracranially as well as into the infratemporal fossa. Factors that play a role in the final outcome of the surgical procedure are control of haemorrhage, appropriate surgical orientation and, last but not least, meticulous microsurgical tissue handling by a skilled surgeon.

Control of venous haemorrhage has been dealt with in Chapter 100, Vascular assessment and management in skull base surgery. Damage to the internal carotid artery is likely to be followed by uncontrollable arterial haemorrhage. This is a serious complication that deserves special attention. Avoiding this situation is a major concern in patients whose tumours infiltrate the carotid canal, such as class C paragangliomas.

After tumour resection, the cavity is filled with abdominal fat. Lumbar drainage may be considered if the resection of a bulky tumour has left a voluminous cavity with wide access to the posterior fossa. Blind sac closure of the external ear canal is performed if the middle ear has not been preserved.

Post-operative management and rehabilitation

In the period immediately following surgery, the patient should be admitted to a well-equipped high dependency care unit for at least 24 hours. Cardiovascular stability must be monitored and safeguarded. Afterwards, the recovery period can be continued in a standard hospital ward. Post-operative care also focuses on the early detection of cranial nerve palsies, because these are the most common complications after jugular foramen surgery. Facial nerve palsy, hearing loss, vertigo, dysphagia and hoarseness are the most obvious symptoms. Functional deficits of cranial nerves XI and XII are usually less embarrassing to the patient. It cannot be expected that function will recover in a nerve that was already compromised pre-operatively.

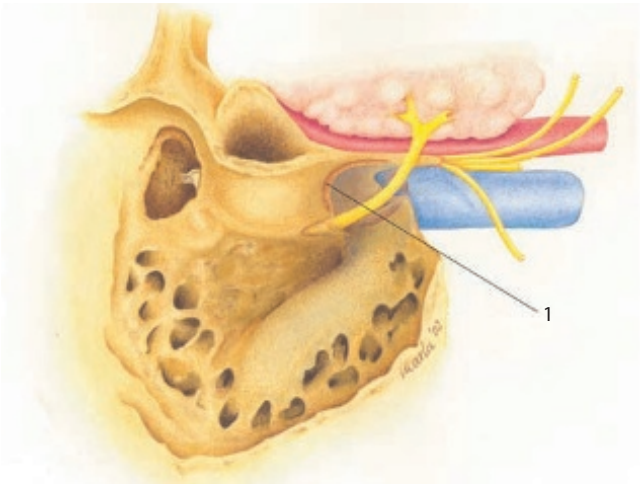

Figure 107.14 1, Right-sided schwannoma in the jugular foramen: localization primarily in the medial part. (See also **Figure 107.5**.)

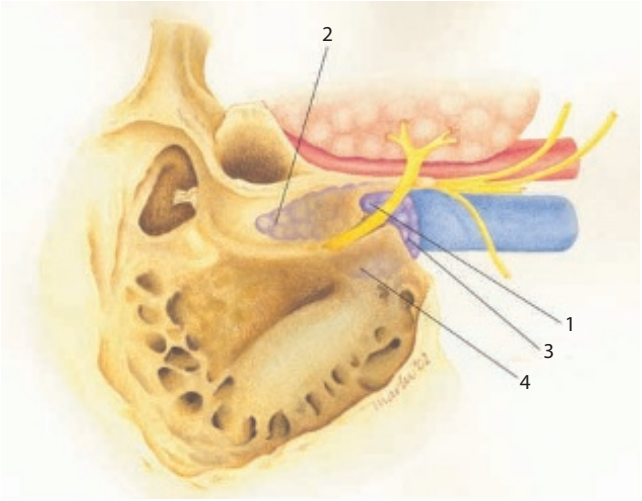

Figure 107.13 1, Right-sided paraganglioma arising from the jugular bulb; 2, extension usually takes place into the hypotympanum; 3, the jugular vein; 4, the sigmoid sinus. (See also **Figure 107.5**.)

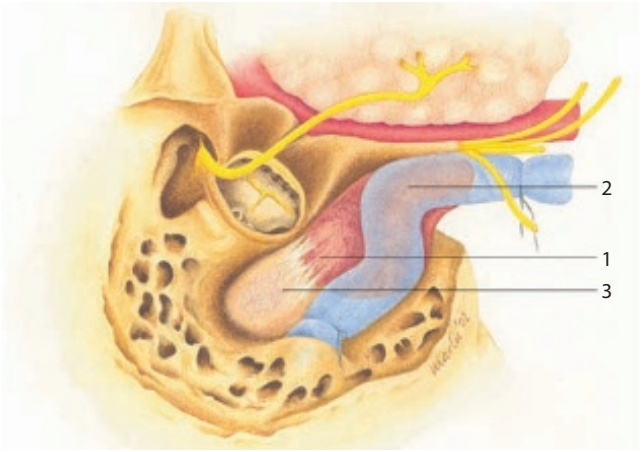

Figure 107.15 1, Right-sided meningioma arising intracranially; 2, extending into the jugular foramen; 3, the facial nerve rerouted and the dura of the posterior fossa exposed. (See also **Figure 107.5**.)

Eye protection is the first step in the care for patients with facial nerve palsy. Lower cranial nerve deficits result in speech and swallowing problems. A specialized multidisciplinary team is required to plan an adequate rehabilitation programme. Depending on the neurological status, a variety of patient-customized measures can be taken.

BEST CLINICAL PRACTICE

- ✓ An in-depth risk versus benefit analysis has to be carried out when deciding on the best management for jugular foramen lesions, in which the risk of progression of the lesion is weighed against the risks of treatment, including surgery.
- ✓ Planning of the treatment should be customized to the patient and to the nature and extension of the lesion. The choice is between radiotherapy stereotactic radiosurgery, microsurgery and a wait-and-see policy, or a combination of these.
- ✓ Only a minority of patients are best served by immediate surgical resection.
- ✓ Among the variety of surgical techniques, the lateral transtemporal approach has received the most attention and widest acceptance. This approach is mostly applied by otologist/head and neck surgeons, because it requires experience with microsurgery on the temporal bone.

FUTURE RESEARCH

- ➤ There are two major issues in the deficiencies of our current knowledge: the biological behaviour of the majority of the jugular foramen lesions and the value of different therapeutic strategies. The best treatment for many jugular foramen lesions is still the subject of controversy. In particular, there are uncertainties about the question whether proceeding to some type of (invasive) therapy is justified or not.
- ➤ There is a need for more knowledge on the biological behaviour of the most common pathologies in the jugular foramen, that is, paragangliomas, schwannomas and meningiomas, to facilitate stratification into those that require aggressive treatment and those that do not.
- ➤ The age threshold at which the long-term risks of radiation to a benign tumour outweigh the immediate risks of surgery remains unclear.
- ➤ The role of radiotherapy and stereotactic radiosurgery in the treatment of meningioma still has to be defined.

KEY POINTS

- The jugular foramen can be involved in a large number of pathological processes. Paragangliomas, schwannomas and meningiomas are by far the most common lesions found in the jugular foramen. All three are characterized by indolent biological behaviour in the majority of cases. However, in the long term, insidious progression may result in serious morbidity and even life-threatening situations.
- The anatomy of the jugular foramen is complex and due to its close proximity to nerves, arteries, veins, meninges, brain tissue and the cochleovestibular system, any treatment modality carries intrinsic risks, particularly surgical treatment.
- Even with regard to the most common lesions, there is no uniformity of opinion and no unequivocal guideline on the best therapeutic approach.
- None of the existing therapies are able to restore functions that have been lost due to the pathological process.
- All the surgical series in the literature describe a considerable risk of functional loss. In selected cases, however, post-operative morbidity is limited to mild inconveniences (e.g. some lower cranial nerve deficits or unilateral hearing loss).
- The skills and experience of the surgeon have a considerable influence on the operative result, while the surgical approach may also play an important role.

ACKNOWLEDGEMENTS

I would like to acknowledge the work of Professor Kees Graamans, who wrote this chapter for the previous edition of Scott-Brown, which was used as the basis for this chapter. I would also like to thank my colleague Professor Michael Gleeson for the time and effort he dedicated to sharing his knowledge of this complex field.

CHAPTER 108

PETROUS APEX LESIONS

Michael Gleeson

SEARCH STRATEGY

Data in this chapter are mainly supported by personal experience and the relatively few papers on the subject that have appeared in journals and congress proceedings since 1985.

INTRODUCTION

The petrous apex remains a huge challenge as it is situated at the frontier between otology and neurosurgery. In other words, it is not within the comfort zone of most practising otologists or neurosurgeons. To make matters worse, disease within it or involving it is relatively uncommon, and so few have regular exposure to its access. Added to this is the fact that it contains two very important structures, the cochlea and the horizontal segment of the intra-temporal carotid artery. It also abuts the cavernous sinus anteriorly and the surgeon has to be familiar with the courses of the IVth, Vth, VIth and greater superficial petrosal nerves.

For some considerable time, the petrous apex remained an elusive and relatively silent part of the temporal bone. It was the occasional site of a spreading mastoid infection, signalled by excruciating pain and a VIth nerve palsy – Gradenigo's syndrome. Much less commonly, it was recognized as a potential site of congenital cholesteatoma. Modern imaging techniques have made today's otologist more aware of a wide range of abnormalities and disease processes that are found at this site. Computed tomography (CT) and magnetic resonance imaging (MRI) have given a better understanding of the natural history of many of these conditions and identified those that can be safely watched and those that need to be treated. In recent years surgical techniques to access this part of the skull base have been developed and the expertise to undertake this surgery is being acquired by those designated to work in skull base centres. In this chapter, the issues that surround the management of petrous apex lesions are summarized.

ANATOMY

Situated lateral and adjacent to the clivus, the petrous apex is that part of the temporal bone anterior to the internal auditory meatus that is wedged between the posterior border of the greater wing of the sphenoid and the basilar part of the occipital bones (**Figure 108.1**). The superior surface is part of the floor of the middle cranial fossa, while its posterior face marks the anterior part of the cerebellopontine angle. The two faces are separated by the tentorium, which is attached to the petrous ridge. Its borders and boundaries are marked by major blood

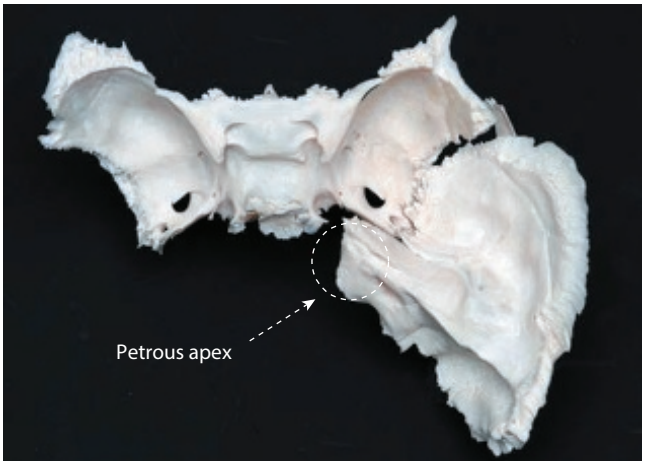

Figure 108.1 The petrous temporal and sphenoid bones. The apex is outlined to clarify its precise position.

vessels and structures, the superior and inferior petrosal sinuses above and below, and the horizontal segment of the internal carotid artery (ICA) and Eustachian tube laterally. Indeed, the apex forms the posterolateral boundary of the foramen lacerum. As an integral part of the petromastoid component of the temporal bone, the apex is preformed in cartilage. The trigeminal ganglion lies in a depression on its posteromedial aspect and the VIth nerve crosses its superior surface beneath the petro-sphenoid ligament. Like other parts of the temporal bone, the degree of pneumatization is variable. The peritubal area is frequently pneumatized, while the rest of the apex is not.

LESIONS AND THEIR PRESENTATION

Infection

As stated previously, in former times the most common disease process affecting the petrous apex was infection. The accumulation of pus or development of an osteitis may give rise to all or part of a triad of symptoms and signs that constitute Gradenigo's syndrome. The full triad of middle ear infection, deep-seated homo-lateral orbital or retro-orbital pain and a homo-lateral lateral rectus palsy may not be present, but will develop in the fullness of time if the infection is not controlled or drained.

Anatomical variants

Defects in the superior surface are occasionally seen and allow the meninges to prolapse into the apex to form a meningocele.

Cysts

Epidermoid cysts (congenital cholesteatoma) may develop in the petrous apex from sequestrated cell rests associated with Seessel's pocket. Mucosal cysts (giant petrous apex cysts) are also found in the apical part of the temporal bone and are thought to develop as a consequence of haemorrhage into the marrow spaces or isolation of a cell tract system with subsequent mucocoele formation. Mucosal cysts are generally found in well-pneumatized temporal bones. Inspection of the CT appearances of the contralateral bone can give some idea of what the state of pneumatization in the affected bone might have been before the development of the cyst. Both epidermoid and mucosal cysts develop over a long period of time, during which constant pressure on the horizontal segment of the ICA causes lateral displacement.

Unilateral hearing loss is the predominant presenting symptom associated with both of these cysts. Patients with cholesterol cysts often have a fluctuating, conductive loss presumably caused by interference with normal Eustachian tube function, while those patients with epidermoids are more likely to have a profound sensorineural deficit acquired in a slow and insidious fashion. Progressive facial weakness or palsy has always been considered the hallmark of epidermoid cysts. In contrast, facial weakness at presentation is uncommon in patients with cholesterol cysts. Regardless of the type of cyst, some patients who present with normal facial nerve function have experienced recurrent episodes of facial weakness or intermittent ipsilateral spasm in the past. Perhaps the most striking distinguishing feature is pain. A large number of patients with mucosal cysts describe a form of trigeminal neuralgia, generalized headache or otalgia and this is most uncommon in patients with epidermoid cysts.[1]

Tumours

Chordomas are derived from notochord remnants and are found in relation to the axial skeleton, most often in the sacrum and skull base. The estimated incidence is 0.5 per million. Both sexes are affected equally and most patients present in the fourth decade of life. Chordomas are slow-growing tumours and so patients often give a long protracted history that starts in a relatively benign fashion with headache or facial pain for which no cause has been found or suspected. Any symptoms are the result of pressure on cranial nerves or dural stretching. Those that develop in the clivus and petrous apex ultimately present with visual disturbance, diplopia, trigeminal deficits or neuralgia, hearing loss, voice disturbance or swallowing problems. These tumours are locally malignant and have a tendency to recur. A few, those with a relatively high proliferative index as assessed by Ki67 staining, are more likely to recur locally than others, often within one or two years of the original resection. Some have the potential to metastasize to regional lymph nodes. Patients with this form of aggressive tumour usually undergo multiple operations and eventually succumb to the disease.

Chondrosarcoma may also develop in the petrous apex, presumably from cartilaginous remnants associated with early development. The tumours are classified according to their mitotic activity and degree of differentiation. Most are low grade and as such have a very slow growth potential and long life expectancy. Like chordoma, with which they were often previously confused, chondrosarcoma produce their symptoms and signs by slow destruction of the temporal bone and its contents, dural stretching and pressure on cranial nerves. Eventually, they break through the cortex of the temporal bone and extend into the cerebellopontine angle, cavernous sinus, middle cranial fossa or into the neck. Those that extend into the cavernous sinus present with trigeminal deficits and diplopia, which is usually caused by an abducens nerve palsy. Chondrosarcomas that extend into the cerebellopontine angle cause trigeminal deficits and varying degrees of hearing loss, while those that break through the base of the skull into the neck are often relatively asymptomatic, possibly found when investigating an isolated hypoglossal palsy.

Meningiomas are the most common intracranial tumour and tend to develop around the venous sinuses. Within the temporal bone, they may develop from meningeal remnants trapped within the bone during development, but may also infiltrate the bone from an

extraosseous site. In the latter situation, they are usually part of an en-plaque tumour that covers a large part of the skull base. The adjacent bone is typically sclerotic as a result of induced osteoblastic activity. Despite their extent, trans-temporal and temporal meningiomas do little harm to the structures that they surround and encase. Growth is usually extremely slow and it may well be decades before any cranial nerve deficit becomes apparent. Some are visible as a mass in the middle ear cavity not dissimilar to, and frequently mistaken for, a glomus tumour.

Other tumours are found in the petrous apex. They are so uncommon that experience of them is largely anecdotal. Among these are plasmacytoma and histiocytosis. It should be remembered also that most of these tumours present in or after the fourth decade of life. For patients of this age, the most common bony tumour is a metastasis. A search for the primary should be undertaken if the scanning features are not characteristic of a defined entity. In the author's experience, renal cell and bronchial carcinomas have both presented in this way before the primary site became symptomatic.

INVESTIGATIONS

The main dilemma that faces the surgeon is the precise characterization of the apical lesion. Only once that is known can an appropriate management plan be devised. Fortunately, many of these tumours have specific characteristics that enable a confident diagnosis to be made from CT and MR images without resorting to open biopsy.[2] Nevertheless, there are occasions when open biopsy is the only option and the surgeon is left with the task of obtaining a diagnostic biopsy without compromising further therapy or inflicting unacceptable morbidity.

For most lesions, a combination of MR and CT imaging will determine the likely diagnosis. CT is pivotal as aggressive bone destruction is suggestive of a malignant process, whereas well-defined expansion is indicative of a benign process. T1-weighted images will distinguish between epidermoid and mucosal cysts. Epidermoid cysts give low signal on T1-weighted images, while mucosal cysts give high signal. Both types of cyst give high signal on T2-weighted images and produce a circumscribed area of bone destruction that can be detected by CT (**Figures 108.2** and **108.3**). High signal in the petrous apex without bone destruction is usually caused by either an effusion or marrow fat. The consistency or uniformity of the signal on T2-weighted images of mucosal cysts can be variable. This probably reflects the contents of the cyst, which may contain large quantities of semi-organized material.

The image characteristics of these cysts still confuse radiologists who are not familiar with the differential diagnosis and protocols necessary to establish their precise nature. Erroneous diagnoses have become more common since the advent of fast spin echo images that are used to screen patients with suspected cerebellopontine

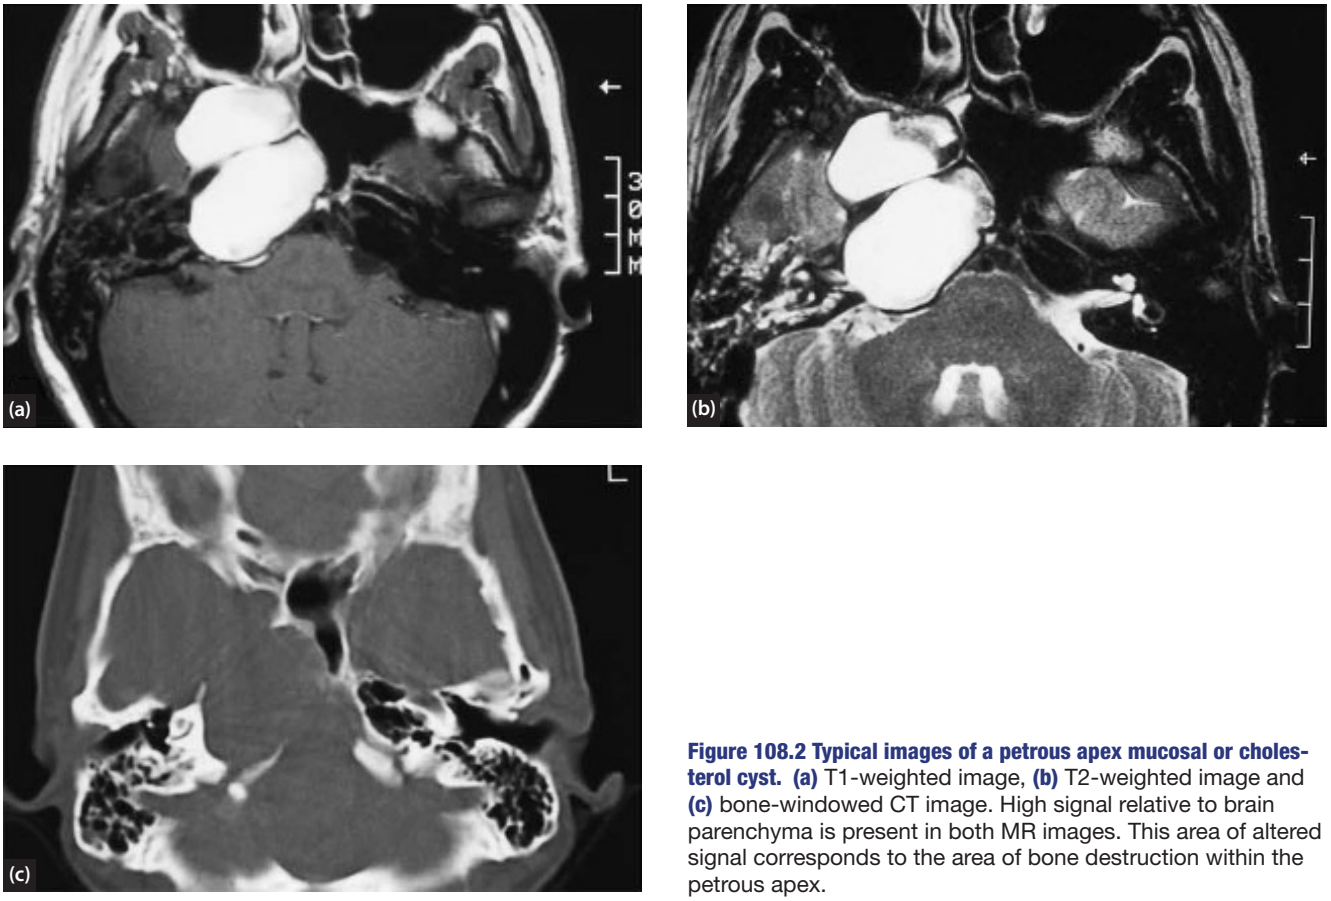

Figure 108.2 Typical images of a petrous apex mucosal or cholesterol cyst. (a) T1-weighted image, **(b)** T2-weighted image and **(c)** bone-windowed CT image. High signal relative to brain parenchyma is present in both MR images. This area of altered signal corresponds to the area of bone destruction within the petrous apex.

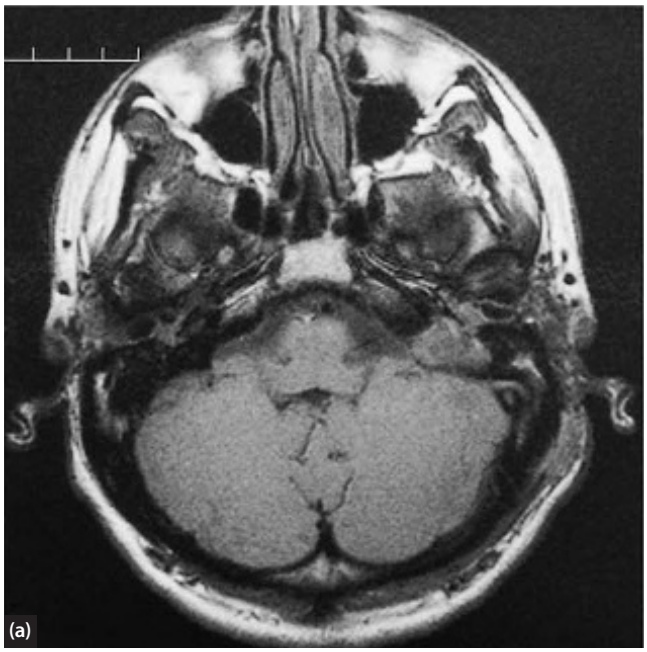

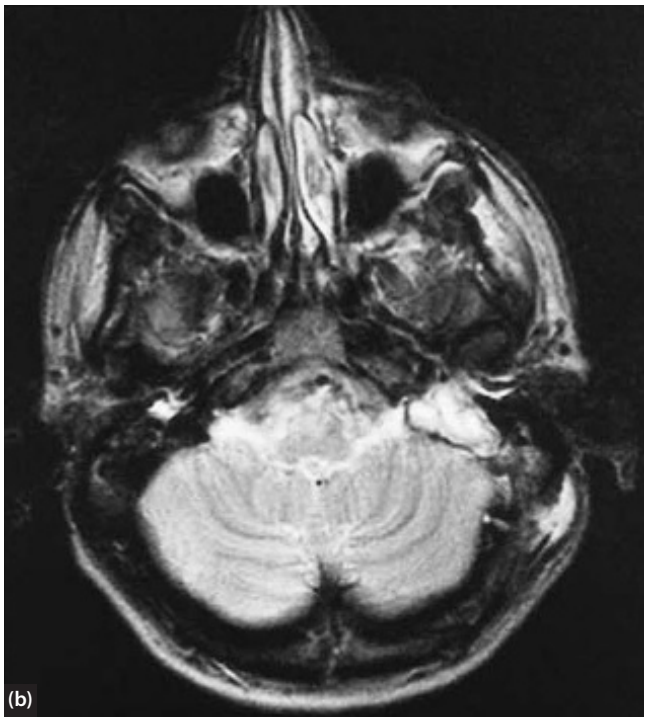

Figure 108.3 Characteristic features of left-sided, apical epidermoid cyst. (a) T1-weighted image with low signal from the petrous apex lesion; **(b)** T2-weighted image with high signal from the petrous apex lesion; **(c)** Bone-windowed CT scan showing well demarcated destruction of the left petrous apex indicative of a slow growing benign lesion.

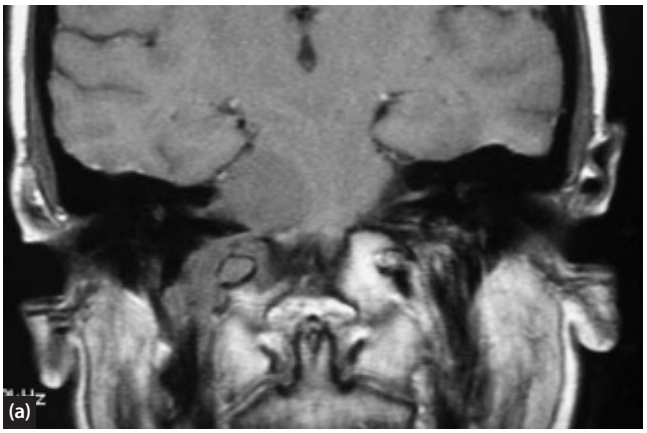
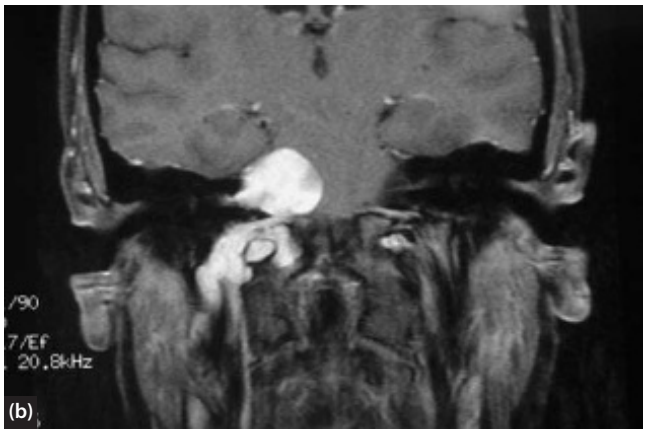
angle tumours. These sequences do not suppress fat and cannot be used in isolation to make any comment about areas of high signal situated within the petrous apex. The diagnosis can only be made with confidence on the basis of T1, T2, inversion recovery sequences and diffusion weighted images.[3, 4]

Bone destruction with foci of calcification within it is typical of chondrosarcoma. Low or iso-intense with brain on T1-weighted images, high signal is obtained on both T2-weighted images and T1-weighted images enhanced with gadolinium (Figure 108.4).

It should be remembered that chordoma almost always arise in the midline, though a few have been described in the petroclival region. Spread from the midline into the petrous apex is common. Chordoma are generally non-homogenous on T1- and T2-weighted images and characteristically have a honeycomb structure on gadolinium-enhanced images.





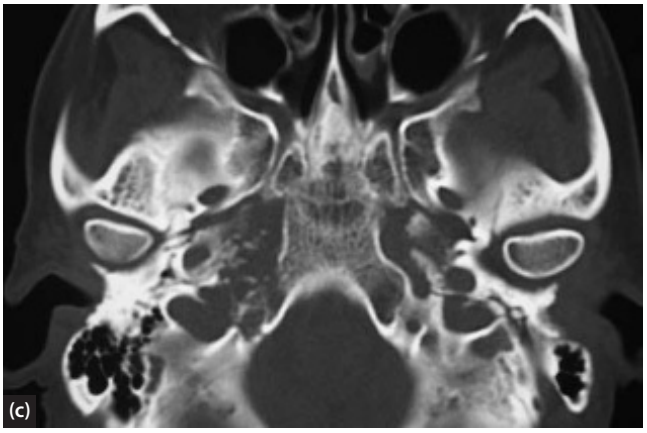


Figure 108.4 Chondrosarcoma of the right petrous apex that has spread into the cerebellopontine angle. **(a)** T1-weighted image, **(b)** gadolinium-enhanced T1-weighted image and **(c)** bone-windowed CT image of a chondrosarcoma that had spread into the cerebellopontine angle. The T1-weighted image shows low signal from the tumour, which becomes high with gadolinium enhancement. The CT scan shows foci of speckled calcification within the tumour that is characteristic of chondrosarcoma.

MANAGEMENT

General guidance

The management of infection is dealt with elsewhere in the text (see Chapter 14, Acute otitis media in children). As stated earlier, many cysts and tumours develop over years or decades. A number are probably better observed rather than treated. Growth and its effects can be safely monitored by sequential scans and clinical examination. It is prudent to consider a number of factors before deciding what the optimal and most appropriate management should be for each and every patient. Factors such as the patient's health, their age and life expectancy, the severity of their symptoms and the nature of the cyst or tumour are of prime importance. Ipsi- and contralateral cochlear function must be considered in those where hearing on the side of the lesion might be lost. The temporal bone architecture, in particular the height of the jugular bulb and relationship of the cyst or tumour to the ICA, is also critical.

Epidermoid cysts and tumours can be resected or observed. A third option, drainage, is possible for cholesterol cysts. There is no doubt that for some patients no treatment whatsoever is indicated regardless of the nature of their petrous apex lesion. In general, these are the elderly who are relatively asymptomatic. Neural deficits are rarely reversed by surgery and, if sensorineural hearing loss and tinnitus are the only complaint, a strong case can be made for a policy of 'watchful waiting'. Patients with pain and incipient facial palsy must be considered differently. For them surgical intervention is probably the only solution and each case must be evaluated on its own merits. Figure 108.7 is a flow diagram to guide management of petrous apex cysts.

Approaches

DRAINAGE

The majority of cholesterol cysts can be decompressed by drainage into the mastoid or sphenoid sinuses.[5–7] In this way, serviceable hearing can be retained. The choice largely depends on the height of the jugular bulb when contemplating drainage into the mastoid or hypotympanum. In the first instance, access to the cyst is made through a channel drilled in the space above the bulb, inferior to the posterior semi-circular canal and medial to the facial nerve (Figure 108.8). At best, this measures 4–5 mm in diameter and in patients with high jugular bulbs may not be possible. Similarly, the infra-cochlear route exploits a tract of air cells that runs between the jugular bulb, basal turn of the cochlea and ICA. Again, in patients with large or high bulbs, this potential space may not exist.

The relationship of the ICA to the cyst and posterior wall of the sphenoid sinus are the determinant factors when considering an endoscopic trans-nasal approach. If the ICA is stretched over the anterior surface of the cyst or the posterior wall is too thick, safe or adequate access to the cyst is probably not possible and it would be wiser to explore an alternative option. Serviceable hearing can be maintained by these drainage procedures and this is their main attraction. Unfortunately, some cysts are loculated, others reaccumulate and become symptomatic, while a few become infected. Total resection is then the only alternative for these unfortunate patients.

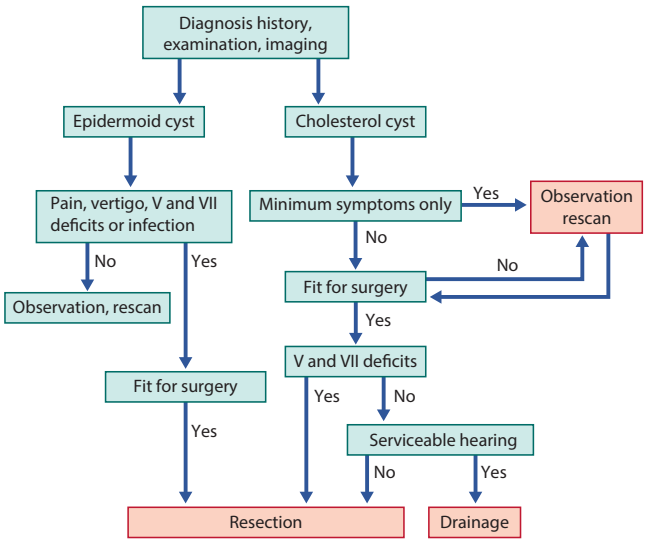

Figure 108.7 Management strategy of petrous apex epidermoid and mucosal cysts.

RESECTION

Drainage procedures are not an option for patients with epidermoids, tumours and cysts that have recurred, become infected or are incipiently inflicting a neural deficit that might be avoidable.

A number of approaches can be used to resect these lesions. Small epidermoids, cholesterol cysts and tumours can be accessed by a subtotal petrosectomy with removal of the cochlea or via the middle fossa. It is impossible to remove the lining of large cysts, epidermoids or tumours completely through these relatively narrow field techniques. For these, a wider exposure as provided by the Fisch type B infra-temporal fossa approach is necessary.[8] In this approach, following a blind sac closure of the external auditory canal, a subtotal petrosectomy is extended anteriorly by inferior displacement of the zygomatic arch, resection of the glenoid fossa of the temporomandibular joint and skeletonization of the vertical and horizontal segments of the intratemporal ICA. In this way, the ICA can be displaced and open access to the apex achieved (Figure 108.9).

The management of patients with chordoma and chondrosarcoma nearly always requires neurosurgical input.[9–12] Staged operations are the rule. For chondrosarcoma, it is probably best to remove disease in the cerebellopontine angle first. Tumour in the petrous bone can be removed at a second stage, after a suitable interval. Chondrosarcoma spreading into the cavernous sinus and sphenoid is probably best managed through a combination of a medial maxillectomy and orbitozygomatic approach. Proton beam therapy has proved successful in a large percentage of patients after radical debulking.[13] Low-grade chondrosarcomas progress very slowly indeed. After initial resection or subtotal resection, it is usually quite adequate to

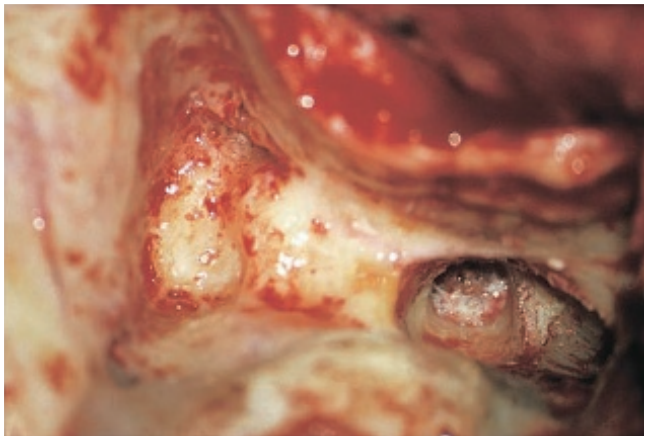

Figure 108.8 Infra-labyrinthine exposure for drainage of a petrous apex cyst. A channel has been developed beneath the fallopian canal, inferior to the posterior semi-circular canal and above the jugular bulb.

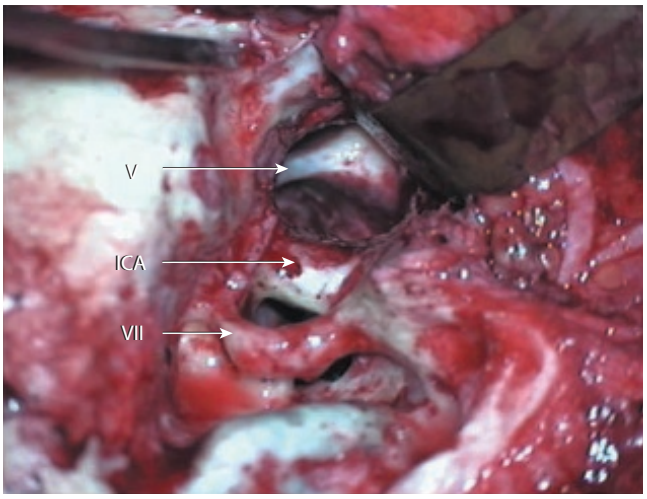

Figure 108.9 Exposure of the petrous apex by the Fisch type B approach. The facial nerve has been skeletonized in the mastoid segment and traced out into the parotid gland. The cochlea has been removed and the ICA exposed. The petrous apex is medial to the ICA and the mandibular nerve can be seen crossing the cavity.

observe clinically with interval scans. Further debulking procedures may become necessary.

Eccentric chordomas are extremely rare and chordoma in the petrous apex is far more commonly the result of spread from the clivus. It is then usually part of an extensive, multifocal tumour. Total eradication is rarely possible and even achieving a reasonable subtotal resection can be difficult. Proton beam therapy (PBT) does have a part to play in the management of this disease and has gained some popularity.[3] Figure 108.10 is a flow diagram that outlines current concepts of chordoma management.

Open cavity surgery is not an option for any of these patients. Leaving a patient with an open cavity after apex surgery is fraught with danger. Infected keratin tends to accumulate in the depths of these cavities and is difficult to remove by suction, as there is often a bottleneck between the deep and superficial portions of the cavities. Furthermore, large areas of exposed dura are usually present on the medial aspect of these cavities and so the risk of recurrent episodes of meningitis is ever present.

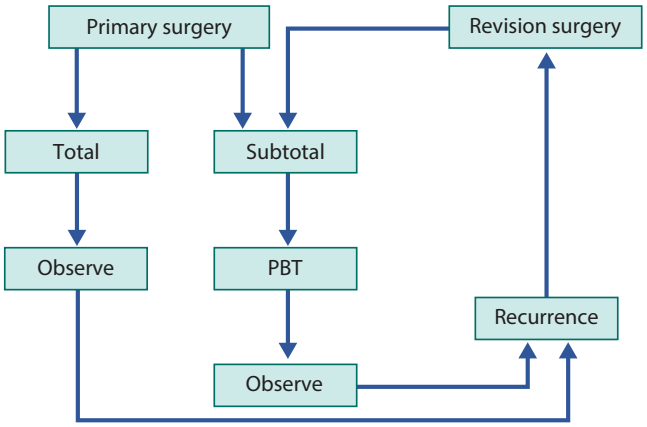

Figure 108.10 Management strategy for chordoma involving the central skull base. Redrawn with permission from Crockard et al.[9]

Complications

Drainage procedures may fail and few ever achieve permanent aeration of the cyst cavity. That the contents reaccumulate is disappointing but in itself is not an indication for further surgery. This is only indicated when the cyst becomes symptomatic.

Open access, trans-temporal access to the apex is always accompanied by a sensorineural hearing loss. This is inevitable and for most this is of no consequence as cochlear function has already been lost. Removal of the glenoid fossa has little impact on the patient and their ability to masticate. It can be reconstructed with a slip of temporalis muscle, which maintains the vertical height of the joint. Most patients experience a temporary occlusal derangement that resolves with the passage of time. Patients are usually able to eat what they like, but choose to eat hard foods on the other side. A temporary weakness of the forehead is acquired by some.

BEST CLINICAL PRACTICE

- ✓ The best exposure to the apex is afforded by the type B infratemporal fossa approach.
- ✓ Open cavity surgery should be avoided and is potentially dangerous. It leaves an inaccessible space medially that accumulates debris that inevitably becomes infected.

FUTURE RESEARCH

- ➤ Long-term outcome studies are required to determine the effect of surgical intervention on patients with low-grade chondrosarcoma, chordoma and cysts.

KEY POINTS

- Many petrous apex lesions have taken years, if not decades to develop. A large number can be managed conservatively by 'watchful waiting'.
- The diagnosis for most lesions can be made on the basis of appropriate CT and magnetic resonance imaging.
- In a middle-aged adult, always consider the possibility of a metastasis.

CHAPTER 109

APPROACHES TO THE NASOPHARYNX AND EUSTACHIAN TUBE

Gunesh P. Rajan

SEARCH STRATEGY

Data in this chapter may be updated a Medline search using the keywords: anterior and lateral skull base approaches, extended endoscopic approaches, TORS, Eustachian tube, nasopharynx, outcome, focusing on technique, surgery and results.

INTRODUCTION

In this chapter we describe and discuss the indications for, and surgical access to, the Eustachian tube and the nasopharynx. The approaches we use nowadays are the distillation of the efforts made over the years by countless surgeons who have attempted to remove disease from this particularly challenging part of the skull base. Just the briefest consideration of the passage of the Eustachian tube from its origin in the hypotympanum across the lateral skull base, through the infra-temporal fossa to the nasopharynx gives some insight to the complexity of surgery in this region. Any surgical approach must give safe and wide exposure to achieve removal of disease minimizing the associated morbidity. The last decade has seen tremendous changes with the way we access the skull base; the extended transnasal endoscopic approaches have largely replaced the open procedures to the nasopharynx, midline and paramedian skull base, especially for all benign pathology and selected malignant disease. Recently, the emergence of transoral robotic surgery has again added new possibilities to what we can potentially do in the management of the midline skull base lesions. To do justice to these recent developments we have included the transnasal endoscopic approaches into this chapter. The detailed description of these approaches is provided by Snyderman and his colleagues in Volume 1, Chapter 116, Extended anterior skull base approaches.

What follows is a brief description of the established approaches to the nasopharynx and the Eustachian tube that have withstood the test of time. The strengths and weaknesses of each approach are identified. Each of these approaches can be used in isolation or in combination if necessary.[1–14]

As with various fields in surgery, the new technologies being introduced constantly challenge us surgeons to learn and incorporate new techniques into our surgical armamentarium. This in turn means that training of future skull base surgeons will also have to change with the aim of establishing the competence in open, endoscopic and perhaps robotic techniques. It must be remembered that every patient's needs are different and that treatment has to be planned to suit the individual patient and his/her disease. It should not be forgotten that for patients with a malignant pathology, the surgical resection is the only hope of cure or respite as other therapies are ineffective alone. As with all skull base surgery, a multidisciplinary team approach is essential, utilizing the skills of all the specialities involved.

CLASSIFICATION OF APPROACHES

The aim of the skull base techniques has been to gain maximal surgical exposure while minimizing brain retraction, aesthetic and functional handicaps as far as possible.

There is often more than one way to approach a lesion, each method offering something different. Several approaches to the Eustachian tube and nasopharynx have been described. Most are entirely extradural and extracranial, while a minority access the midline skull base by intracranial and intradural pathways. Numerous surgical variations of each approach have been described but most would agree that each variation can be listed under one of the three categories: the anterior approaches; the anterolateral approaches; or the lateral approaches.

PRE-OPERATIVE ASSESSMENT AND PREPARATION

It almost goes without saying that the evaluation of the stage of disease is absolutely vital. There is no point in subjecting a patient to a major intervention and its morbidities unless there is a reasonable prospect of eradicating their disease or reducing its bulk sufficiently to alter the course of disease. Most tumours in this part of the skull base are intimately involved with the internal carotid artery (ICA) and some displace or infiltrate the cavernous sinus. It is therefore imperative that the relationship of these structures to the tumour is known as precisely as possible and the consequences of damage to the ICA are fully assessed. Most patients will require computed tomography (CT), magnetic resonance angiography (MRA) and balloon occlusion tests. The introduction of neuronavigation has proven to be very useful in this context, enhancing surgical accuracy.

The larger disassemblies of the facial skeleton and the prevertebral skull base are better undertaken after a preliminary tracheostomy. The endoscopic techniques have simplified the sleeve resections of the nasopharynx and adjacent Eustachian tube segments. Dural resection or damage is not infrequent and the possibility of cerebrospinal fluid (CSF) leaks into the nasopharynx is ever present. The addition of a lumbar drainage helps manage the persisting CSF leak post-operatively along with adequate antibiotic coverage. While some patients may be able to take food orally relatively soon after surgery, those in whom extensive osteotomies have been undertaken will not. Another consideration is that the majority of patients with malignant disease will undergo post-operative radiotherapy. For this group of patients, oral feeding may be significantly delayed, therefore considering a pre-operative PEG-insertion.

ANTERIOR APPROACHES

Transnasal extended endoscopic approaches[1, 2]

INDICATIONS

- Tumours of the nasopharynx and anterior infratemporal fossa
- Juvenile neuroangioma
- Access to tumour extension into the clivus and craniocervical junction.

CONTRAINDICATIONS

- Malignant tumours with significant dural invasion and intracranial extension (these tumours can frequently be resected using a combined open–endoscopic approach to minimize morbidity)
- Malignant lesions that require a degree of lateral access, those that extend into the lateral parapharyngeal space, cavernous sinus, posterior infratemporal fossa and posterior peritubal space.

PRINCIPLES OF THE PROCEDURE

Most extended transnasal endoscopic approaches (EEAs) are done with two surgeons using the four-hands technique and the patient in a supine position. Depending on the location of the lesion, various modifications of the transnasal endoscopic routes provide a targeted access to the different midline and paramedian skull base lesions. The transnasal, transmaxillary route with removal of the posterior maxillary wall gives the most lateral trajectory to access the anterolateral infratemporal fossa, the addition of the transpterygoid access opens up the anterior infratemporal and the peritubal compartment, which can be extended posteriorly to access the foramen lacerum and petrous apex (**Figure 109.1**). The classic transnasal pathway after reduction of the vomer and posterior septum provides the workspace to address the nasopharynx and clival lesions.[2] The reconstruction after endoscopic

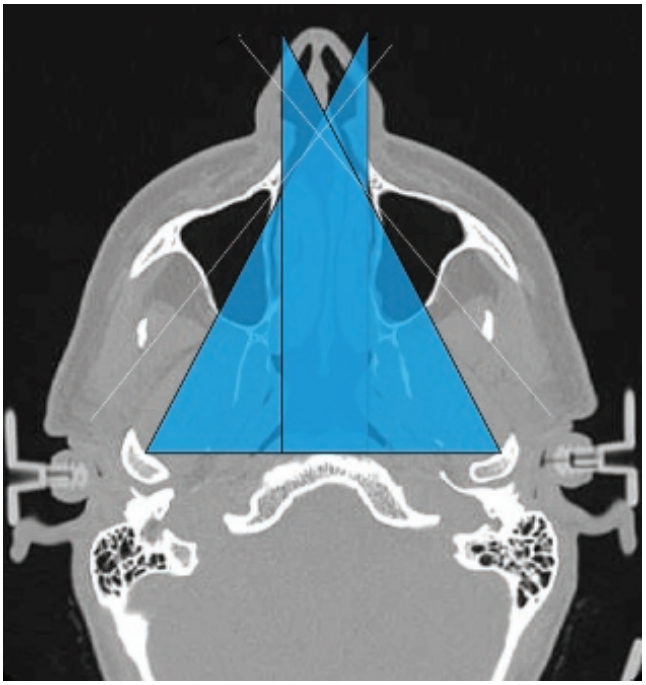

Figure 109.1 Trajectory for the endoscopic access to the anterior Eustachian Tube, peritubal space and medial infratemporal fossa (blue zone). The white lines indicate the lateral extent of the endoscopic access to the infratemporal fossa.

resections in the hostile environment of the nasopharynx and oropharynx in terms of the microbial fauna, saliva exposure and the frequent clearing movements poses a key challenge and is dealt with Volume 1, Chapter 116, Extended anterior skull base approaches. The introduction of the nasoseptal or Hadad flap has certainly simplified the reconstruction of local defects; reliable closure techniques for dural defects are constantly evolving to address this specific weakness of this treatment modality.[2]

ADVANTAGES AND DISADVANTAGES

The EEAs have revolutionized the surgical treatment of midline lesions of the skull base. With the improvement of the scope optics and HD technology, the visualization of the operation field is unparalleled. This together with the increasing portfolio of endoscopic instruments has resulted in the EEA largely replacing the open transoral and transpalatal procedures described below. The EEAs offer direct access and visualization of the pathology and allow for two surgeons to work simultaneously using the four-hands technique. Benign tumours with lateral extension into the parapharyngeal and infratemporal spaces can be accessed by these routes as in most cases the tumour extensions can be medialized into the working field.

KEY POINTS

- Advantages:
  - simple technique
  - direct approach
  - excellent visualization of the operating field.
- Two surgeon – four-hands technique.
- Limitations and drawbacks:
  - limited access to the lateral infratemporal and parapharyngeal space
  - difficult assessment of the margin status in malignant disease
  - limited data of reconstruction outcomes
  - dural reconstruction challenging
  - risk of meningitis due to wound contamination.

Transoral robotic surgery[3]

INDICATIONS

- Benign tumours of the nasopharynx and parapharyngeal space
- Indications are evolving.

CONTRAINDICATIONS

- Malignant tumours with lateral extension, significant dural invasion and intracranial extension (these tumours can frequently be resected using a combined open–endoscopic approach to minimize morbidity)
- Malignant lesions that require a degree of lateral access, those that extend into the lateral parapharyngeal space, cavernous sinus, posterior infratemporal fossa and posterior peritubal space.

PRINCIPLES OF THE PROCEDURE

Transoral robotic surgery (TORS) is the most recent surgical modality that has the potential to further improve surgery in this anatomic region. The range of the 'wrist'-mediated instrument mobility combined with the 3D-visualization of the operating field opens up a new paradigm in our specialty as exemplified by its utility in the management of HPV-positive oropharyngeal tumours. The upcoming introduction of the single-port version of the DaVinci system offers hope in the management of midline lesions. Current limitations of the technology are related to lack of haptic feedback and the lack of instrumentation to remove and remodel bone effectively.

There are several case series reporting excellent outcomes for resections of parapharyngeal tumours with no reported cases of 'first-bite syndrome' so far, which occurs frequently after transcervical removal of these tumours. More recently, salvage surgery for small recurrences of nasopharyngeal carcinoma in the posterior nasopharyneal wall has been performed using TORS with promising outcomes.[3] Detailed descriptions of TORS will be found in Volume 3, Chapter 22, Transoral laser microsurgery.

ADVANTAGES AND DISADVANTAGES

At this stage it is too early to talk about the pros and cons of TORS to address pathologies in the nasopharynx or peritubal space. More clinical data are required to provide any objective interpretation of its utility.

KEY POINTS

- Advantages:
  - direct approach
  - unparalleled instrument dexterity and mobility
  - HD 3D-visualization of the operating field.
- Limitations and drawbacks:
  - high set-up costs
  - utility and indications yet to be defined
  - current case series report on confined lesions of the posterior nasopharyngeal wall and benign tumours of the parapharyngeal space
  - clinical outcomes data evolving.

Transoral and transpalatine approaches[4, 15, 16]

INDICATIONS

- Malignant tumours of the posterior nasopharyngeal wall that are no larger than 2 cm
- Access to tumour extension into the clivus and craniocervical junction.[13, 15, 16]

CONTRAINDICATIONS

- Malignant nasopharyngeal tumours > 2 cm
- Tumours with significant dural invasion and intracranial extension

- Lesions that require a degree of lateral access, those that extend into the parapharyngeal space, cavernous sinus, infratemporal fossa and peritubal space.

PROCEDURE

The patient is placed in the supine position with their head extended as much as possible. Mayfield clamp fixation may be required if neuronavigation is employed or if it is anticipated the cranio-cervical junction might become unstable. There is no doubt that access is easier with the patient's head in a horseshoe rest that permits intraoperative manipulation of the head but this is rarely possible. A preliminary tracheostomy is established so that an unobstructed view of the oropharynx is obtained and to secure the airway post-operatively, as most patients will develop significant lingual and oropharyngeal oedema. Lumbar CSF drainage is inserted if the dura is to be opened. As this approach provides relatively narrow access through a long working distance, appropriate retracting instrumentation is crucial if sufficient exposure is to be obtained. Most surgeons opt for the Crockard wide field retractors and dissecting instruments that have been specially designed for this purpose.

After insertion of the mouth gag and retraction of the oral cavity, the soft and hard palate are infiltrated with 1:200000 adrenaline. The soft palate is split to one side of the midline. The hard palate mucosa is incised along the ipsilateral junction of the hard and soft palate within 5 mm of the maxillary dentition. This mucosal incision is extended along the palatal aspect of the alveolar ridge up to the level of the first molar and then taken in an arc across the palate to the opposite side (**Figure 109.2a**). A mucoperiosteal flap is elevated exposing the bony hard palate. The greater palatine neurovascular bundle is coagulated and divided. Exposure of the nasopharynx is increased by dissection of the muscular insertions of the soft palate from the hard palate. Great care must be taken to maintain the integrity of the remaining greater palatine vascular pedicle while doing this (**Figure 109.2b**). A self-retaining retractor is then inserted to keep the two halves of the soft palate out of the field.

Dissection through the posterior nasopharyngeal wall gives access to the lower clivus. If the lesion extends towards the sphenoid floor or the upper clivus the operative field must be enlarged. In some cases this can be achieved by removal of some palatal vomerine bone. In others, it will be necessary to perform a Le Fort I osteotomy and then split the palate in the midline, displacing each maxilla laterally. This latter approach, known as an 'open door maxillotomy', can offer unrivalled exposure of the entire clivus and cranio cervical junction.

A suitable mucosal flap is raised, hinged either laterally or inferiorly. The length of this flap varies according to the extent of the lesion being removed. The larger the flap, the better the chance of being able to approximate it at the end of the procedure (**Figure 109.2c**). If the lesion is submucosal, it is usually unnecessary to split the prevertebral fascia. But, if it is necessary to access the clivus, the prevertebral fascia and muscles have to be opened and this is best undertaken in the midline. The most helpful anatomical landmark is the anterior arch of the atlas, which is easily palpable. The narrow field afforded by this approach is insufficient for an *en bloc* resection of most tumours, so resection is usually performed in a piecemeal fashion.

Apart from very small dural tears or defects that can be plugged with muscle, primary watertight closure is virtually impossible; however, the advent of new dural sealing materials might alter this condition. The dead space created by tumour resection can be filled with autograft soft tissue secured in place by fibrin glue. It is best covered by pedicled local mucosal or mucoperichondrial flaps raised from the nasal septum and rotated into place. As much as possible prevertebral fascia, musculature and pharyngeal mucosa are reapproximated. The soft palate is readapted, preferably through a three-layered closure. In this way, the chance of an oro-nasal fistula developing is minimized (**Figure 109.2d**). If the maxilla has been split, bone plates are applied for fixation. Removal of the tracheostomy is determined by the clinical progress of the patient in terms of swallowing and resolution of oedema.

ADVANTAGES AND DISADVANTAGES

With the emergence of the EEAs the role of the transoral approaches has slipped into the background. There is much to commend the transoral approaches as they are relatively simple and straightforward to perform. They offer direct access to the lesion and, as a consequence, the surgeon is unlikely to inadvertently stray off target. Inadequacies of exposure can be resolved by local extensions in a stepwise fashion. On the other hand, a covering tracheostomy is required in most cases, the working distance is relatively long and this brings with it difficulties for the surgeon in terms of instrumentation, manipulation and visibility. Tumours with extension laterally into the parapharyngeal and infratemporal spaces cannot be accessed by these routes. Similarly, it is essential that the patient has good mouth opening otherwise a mandibulotomy might become necessary. The repair of the palate can be difficult and, despite every effort, fistulae develop in up to 40% of patients.

KEY POINTS

- Advantages:
  - simple technique
  - direct approach.
- Extendable through the LeFort I-palatal split approach.[13, 17]
- Limitations and drawbacks:
  - tracheostomy requirement
  - narrow working field and long working distance
  - possible palatal dehiscence and oronasal fistula as late complication in 30–40%
  - patients with trismus or impaired jaw opening require transmandibular approach
  - no access laterally to the parapharyngeal and infratemporal spaces
  - risk of meningitis due to wound contamination.

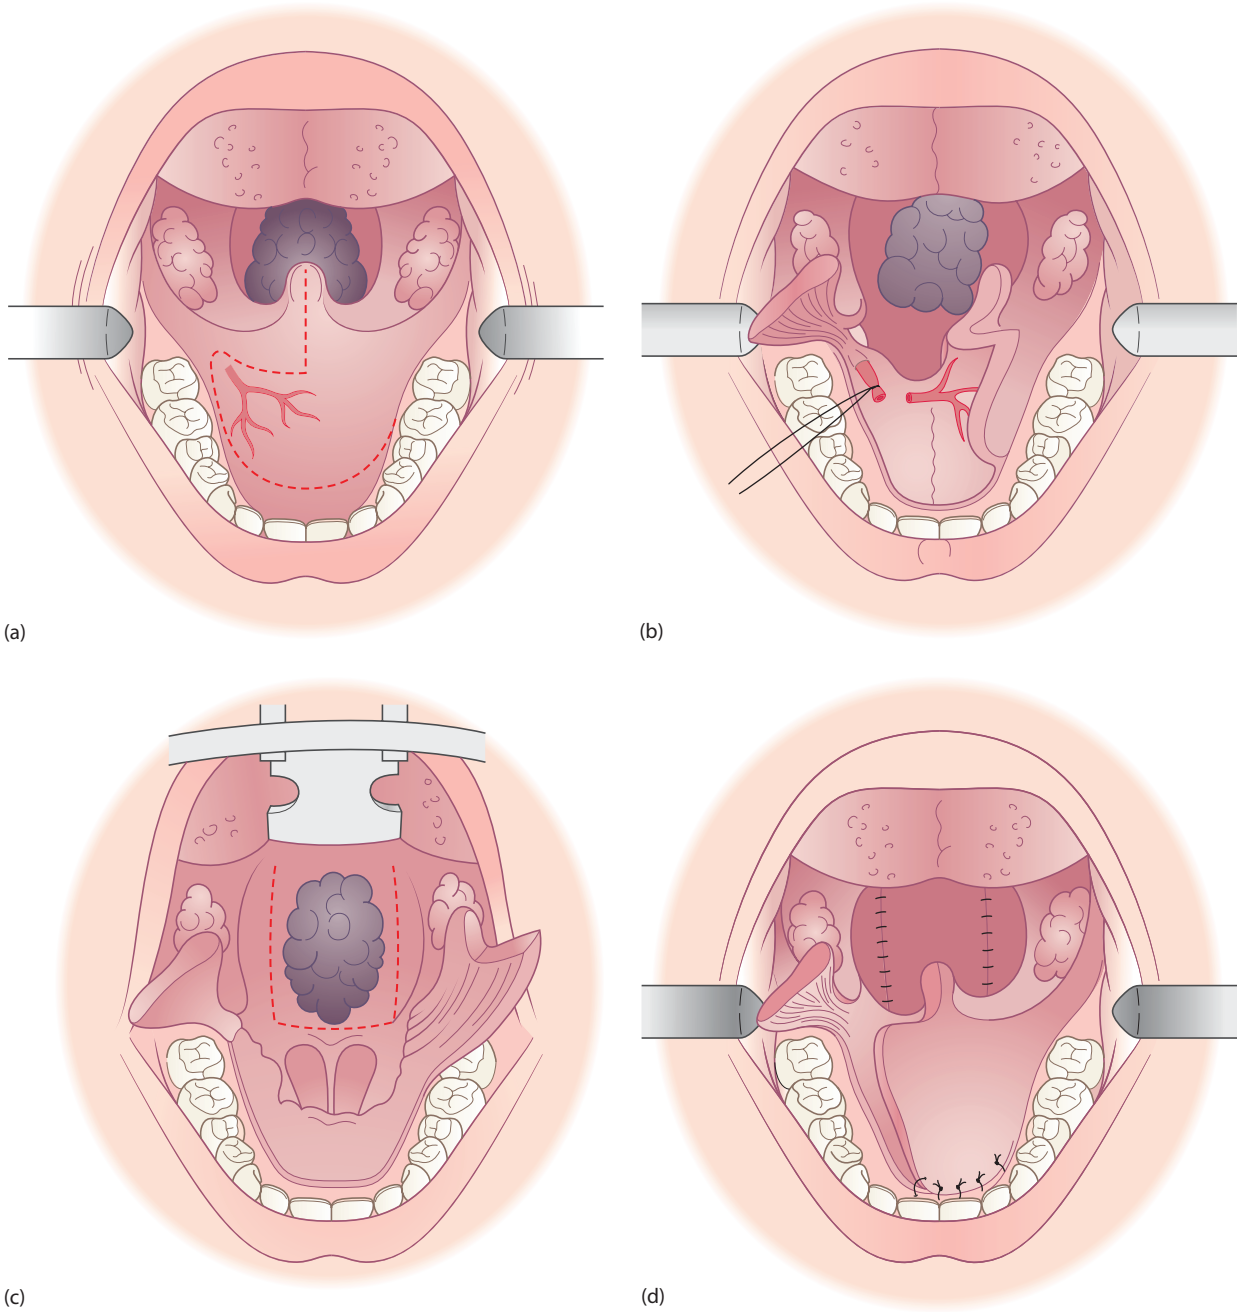

Figure 109.2 Transoral-transpalatinal approach. Redrawn from original illustrations by Margrit Pirker.

Transmandibular-transcervical approach[17, 18]

INDICATIONS

- Nasopharyngeal tumours extending into the anterior infra-temporal fossa.[15, 18]

CONTRAINDICATIONS

- Dural invasion (>2 cm²) and intracranial involvement
- Invasion of the parasellar and posterior infra-temporal region.

PROCEDURE

The patient is placed in the supine position and a tracheostomy established. An extended submandibular incision is made about 4 cm below the mandible from the mastoid tip posteriorly to rise anteriorly and split the lip (Figure 109.3a). The platysma is divided and the dissection directed beneath the submandibular gland. The tendons of the digastric and stylohyoid muscles can be released from their hyoid attachment and reflected superiorly along with the submandibular gland. This aids exposure of the mandible (Figure 109.3b). The great vessels in the carotid sheath are then identified together

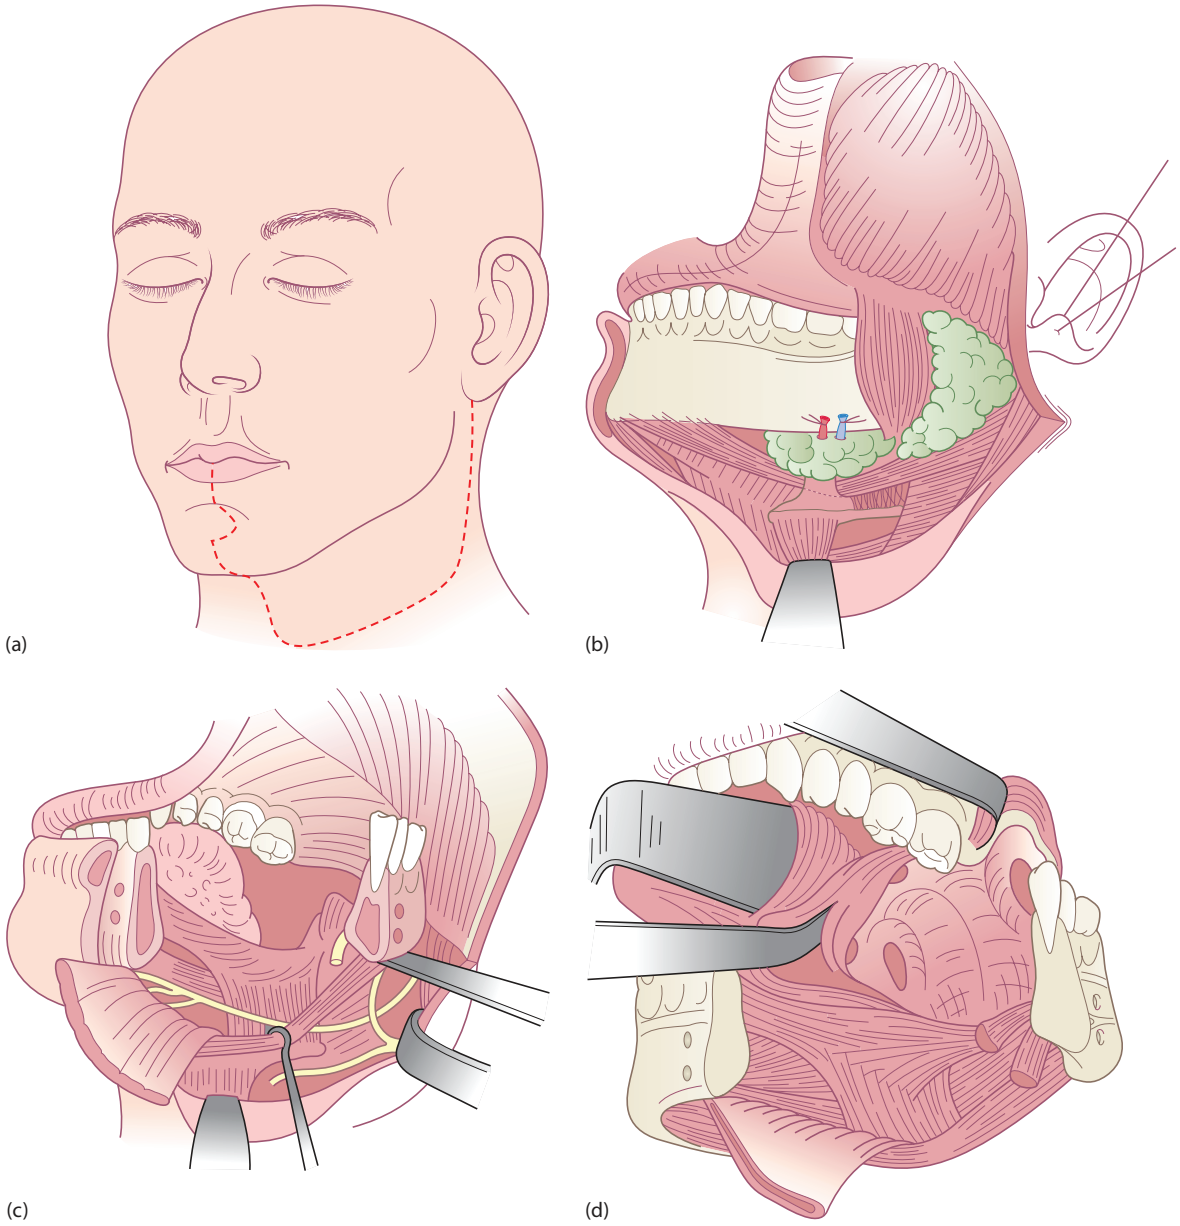

Figure 109.3 Transmandibular-transcervical approach. Redrawn from original illustrations by Margrit Pirker.

with the adjacent cranial nerves. The internal and external carotid arteries are dissected free and followed as close as possible to the skull base. A median mandibular osteotomy is performed after prefitting of mini-plates. Obviously the precise site of the mandibulotomy will be determined by the state of patient's dentition. In patients with poor dental health it is preferable to select an edentulous area (Figure 109.3c).

Dissection then proceeds across the floor of the mouth toward the parapharyngeal space. The tongue is retracted to the opposite side, the mucosa incised, mylohyoid muscle divided together with the anterior belly of the digastric muscle The lingual and hypoglossal nerves are identified and preserved (Figure 109.3c). During this stage of the approach the mandible can be steadily retracted laterally allowing entry into the parapharyngeal space which can then become continuous between the mouth and neck. Additional lateral retraction of the mandible is achieved by ligation of the external carotid artery distal to the lingual artery. By this manoeuvre access to the nasopharyngeal part of the parapharyngeal space and the anterolateral infratemporal fossa is gained (Figure 109.3d). If access to a midline lesion is required the incision is extended upward towards the hard palate and pterygoid plates ending about 1 cm medial to the gingival margin. A hemi-palatal flap is created, thereby producing an 'oropharyngeal sleeve'. Further blunt dissection lateral to and behind the superior and middle constrictor muscles produces a surgical working space (Figure 109.3d). Additional posterolateral division of the styloid musculature and glossopharyngeal nerve together with superior dissection along the retropharyngeal–prevertebral plane

allows release and retraction of the oropharynx to the contralateral side and widening of the retropharyngeal space. The precise position of the ICA should then be established and the tensor and levator muscle of the soft palate sectioned. With this, the pharyngeal and cartilaginous part of the Eustachian tube becomes accessible. Further exposure of the posterior nasopharyngeal wall can be obtained by dividing the tube and releasing the nasopharynx from the skull base at level of the pharyngeal tubercle. In this way, the whole of the pharyngeal sleeve can be displaced to the opposite side and the central skull base is exposed. Further enlargement of the operative field is achieved by removing the posterior portion of the hard palate thus widening access to nasopharynx, choanae and upper sphenoid body.

The intracranial extent of the lesion determines the amount of skull base that needs to be removed. However, if the lesion reaches the posterior aspect of the infratemporal fossa, combination with a lateral approaches may be required to allow *en bloc* resection.

Surgical closure begins with a watertight reconstruction of any dural defects. Smaller defects (< 4 cm²) can be sealed with fascial or pericranial flaps, while larger defects require musculo-fascial or microvascular free flaps. The remaining pharyngeal sleeve is reattached to the pre-spinal muscles at the skull base; exact realignment of the pharynx is achieved by suturing the Eustachian tube around an intratubal splint. The palatal muscles are reapproximated and the mucoperiosteal palatal flap is repositioned and the mucosa sutured. A palatal splint is recommended by some to encourage adherence of the flap to the hard palate. The floor of the mouth is reconstructed with resorbable sutures and the mandible fixed with the pre-fitted miniplates. A large suction drain is placed along the carotid sheath exiting though a separate stab incision in the lower neck. Finally, the lower lip is closed in three layers, taking care to achieve precise approximation of the vermilion border.

The patient should be fed by nasogastric tube for the first week, following which oral alimentation can begin. Removal of the tracheostomy tube is performed after 24 hours of uneventful plugging of the tracheostomy tube. Subsequent build-up of oral feeds is monitored by the speech pathologists.

KEY POINTS

- Advantages:
  - good access to the epipharynx, the parapharyngeal and anterior infratemporal space
  - direct approach
  - good vascular control.
- Limitations and drawbacks:
  - potential infection hazard through oral contamination
  - possible mandibular non-union
  - prolonged need for tracheostomy
  - restoration of normal or adequate swallowing often significantly delayed (mean 7 weeks)
  - temporary PEG frequently required.

ANTEROLATERAL APPROACHES

Maxillary swing technique[19]

INDICATIONS

- Nasopharyngeal tumours with limited extension into the anterior infra-temporal region.

CONTRAINDICATIONS

- Lesions involving the petrous ICA
- Lesions extending into to the petrous apex, parasellar and/or posterior infratemporal region (combination with lateral approach required).

PROCEDURE

The patient is intubated and placed in a supine position and draped. A Weber–Ferguson–Longmire incision is made, extending laterally onto the zygoma (**Figure 109.4a**). The vertical incision limb goes through the upper lip and is continued between the central incisors and onto the hard palate. After reaching the border of the hard and soft palate the incision is curved laterally to run behind the maxillary tuberosity. The facial incision is made through the subcutaneous, muscular and periosteal layers. Gentle, minimal elevation of these tissues exposes the planned osteotomy line (**Figure 109.4b**). The osteotomy is started by separating the zygoma from the maxilla, moving medially along the infraorbital rim until the frontal process is divided from the anterior maxillary wall. Then the medial maxillary wall is separated from the midline nasal complex in an antero-posterior fashion. The posterior wall is released without direct vision using an osteotome inserted through the antrum. The palatal bone is incised and a midline osteotomy fashioned. Finally, the pterygoid plates are separated from maxillary tuberosity by using a curved osteotome (**Figure 109.4c**). The entire maxilla can be swung laterally attached to the cheek flap and the masseter muscle (**Figure 109.4d**). The epipharynx is widely exposed including the cartilaginous Eustachian tubes of both sides, thus allowing *en bloc* resection of confined pathologies in this region.

After the resection has been completed, an ipsilateral turbinectomy provides useful tissue for a free graft that can placed on exposed bone in the epipharynx. Nasal packing keeps the graft in place. Closure is achieved by returning the maxilla to its anatomical position and fixation to the zygoma and contralateral maxilla with miniplates. Exact alveolar ridge alignment can be facilitated by using a pre-operatively fashioned dental splint. The facial and intra-oral incisions are closed in layers. If cartilaginous portions of the Eustachian tube were resected, a grommet should be placed on the affected side in order to prevent a chronic middle ear effusion.

Oral feeding is usually started after 72 hours. Any non-resorbable nasal packs should be removed on the 7th post-operative day and the dental plate after about a month or when all the mucosal wounds have healed.

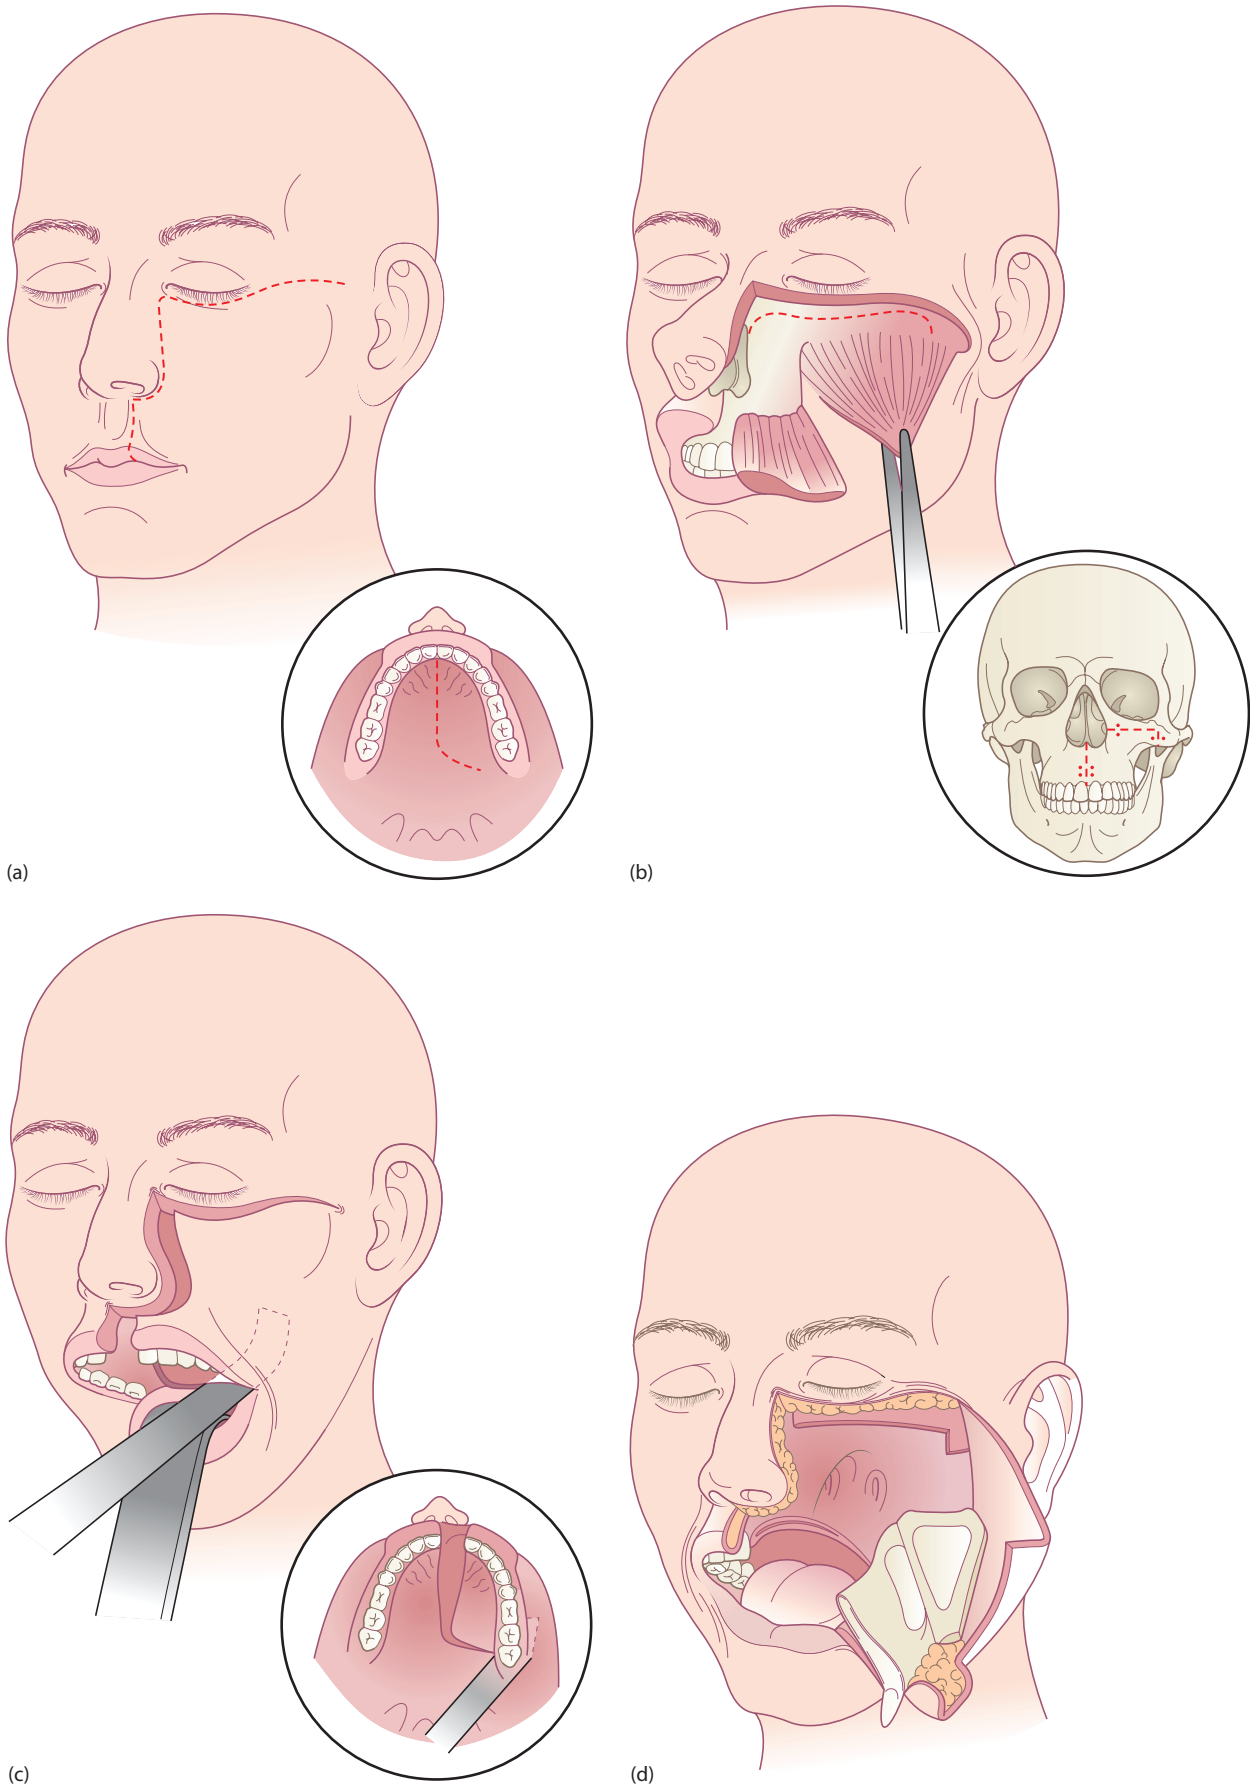

Figure 109.4 Maxillary swing approach. Redrawn from original illustrations by Margrit Pirker.

KEY POINTS

- Advantages:
  - simple technique
  - wide exposure
  - good cosmetic and functional results.
- Limitations and drawbacks:
  - limited parapharyngeal and infratemporal exposure
  - lack of vascular control
  - post-operative trismus
  - necrosis of the maxilla in some cases.

LATERAL APPROACHES

Infra-temporal approach type C[20–22]

INDICATIONS

- Infratemporal fossa tumours that extend into the temporal bone with involvement of the epipharynx
- juvenile angiofibroma Class III b–IV (Fisch)
- nasopharyngeal carcinoma.

If the lesion does not extend to the vertical portion of the petrous ICA, a variation of this approach, the preauricular Type D approach, can be used, thus avoiding blind sac closure and subtotal petrosectomy.

CONTRAINDICATIONS

- Advanced disease with extension into the sella, contralateral middle fossa or anterior skull base.

PROCEDURE

A postauricular C-shaped incision is made that extends superiorly into the temporal region and inferiorly into the neck (Figure 109.5a). The temporalis muscle, mastoid and zygoma are exposed. A periosteal flap is elevated and the external auditory canal is transsected and closed as a blind sac. The pinna and skin flap are reflected anteriorly. As a precaution, the neck is dissected so that control of the carotid and jugular vessels can be achieved. The main trunk of the facial nerve is identified together with its frontal branch so that the zygomatic arch can be exposed and divided anterior to the temporomandibular joint and again just behind the orbital rim without damaging the frontal branch. The zygomatic arch is reflected inferiorly attached to masseter muscle (Figure 109.5b). The temporalis muscle and fascia is elevated from the temporal fossa and reflected inferiorly to expose the superolateral quadrant of the infra-temporal fossa.

A subtotal petrosectomy is undertaken, skeletonizing the sigmoid sinus, ICA and middle fossa dura with preservation of the labyrinth and removal of all vestiges of skin. The temporomandibular joint capsule is exposed followed by excision of the articular disc and subsequent inferior displacement of the mandibular condyle. Additional space can be established by release of the sphenomandibular and stylomandibular ligament. The glenoid fossa is resected to give extensive exposure to infratemporal fossa and this can be enlarged further by division of the mandibular nerve and middle meningeal artery (Figure 109.5c). Access to the anterior third of the Eustachian tube and nasopharynx can be achieved by removal of the pterygoid process with its lateral and medial plates and dissection along the tube. The nasopharyngeal cavity is entered through incision of the pharyngobasilar membrane and nasopharyngeal mucosa.

After completion of the resection, closure of the nasopharynx is accomplished by rotating some of the temporalis muscle into the defect. Alternatively a bulky free flap such as the latissimus dorsi-flap can be used. The temporomandibular joint is reconstructed by interposing temporalis muscle between the condyle of the mandible and the middle fossa dura. The skin and subcutaneous tissue are closed in layers, after drain placement in the infratemporal fossa.

Normal oral feeding can be started on the first post-operative day.

KEY POINTS

- Advantages:
  - wide access to infratemporal, parasellar and temporal region
  - direct approach
  - short working distance.
- Limitations and drawbacks:
  - temporary post-operative trismus and malocclusion
  - hypaesthesia of the lower half of the face and ipsilateral tongue (V3)
  - permanent post-operative conductive hearing loss
  - temporary frontal facial paresis in 30%.

COMBINED APPROACHES

Subtemporal-preauricular infratemporal fossa approach[23]

INDICATIONS

- Large tumours (T4) of the infratemporal space extending into the nasopharynx, the cavernous sinus and the middle cranial fossa.

CONTRAINDICATIONS

- Bilateral involvement of the ICA
- Bilateral involvement of the optic chiasm[24]
- Lesions that extend into the posterior cranial fossa for which a combination with a retrosigmoid or transotic approach is required.

PROCEDURE

A preliminary tracheostomy is performed if resection of the naso-and/or oropharynx is anticipated. The ipsilateral scalp, face, neck, lower abdomen and thigh are prepared and draped. An extended Blair incision is made (Figure 109.6a) and a cervico-facial flap raised. The facial nerve trunk is identified and its major branches

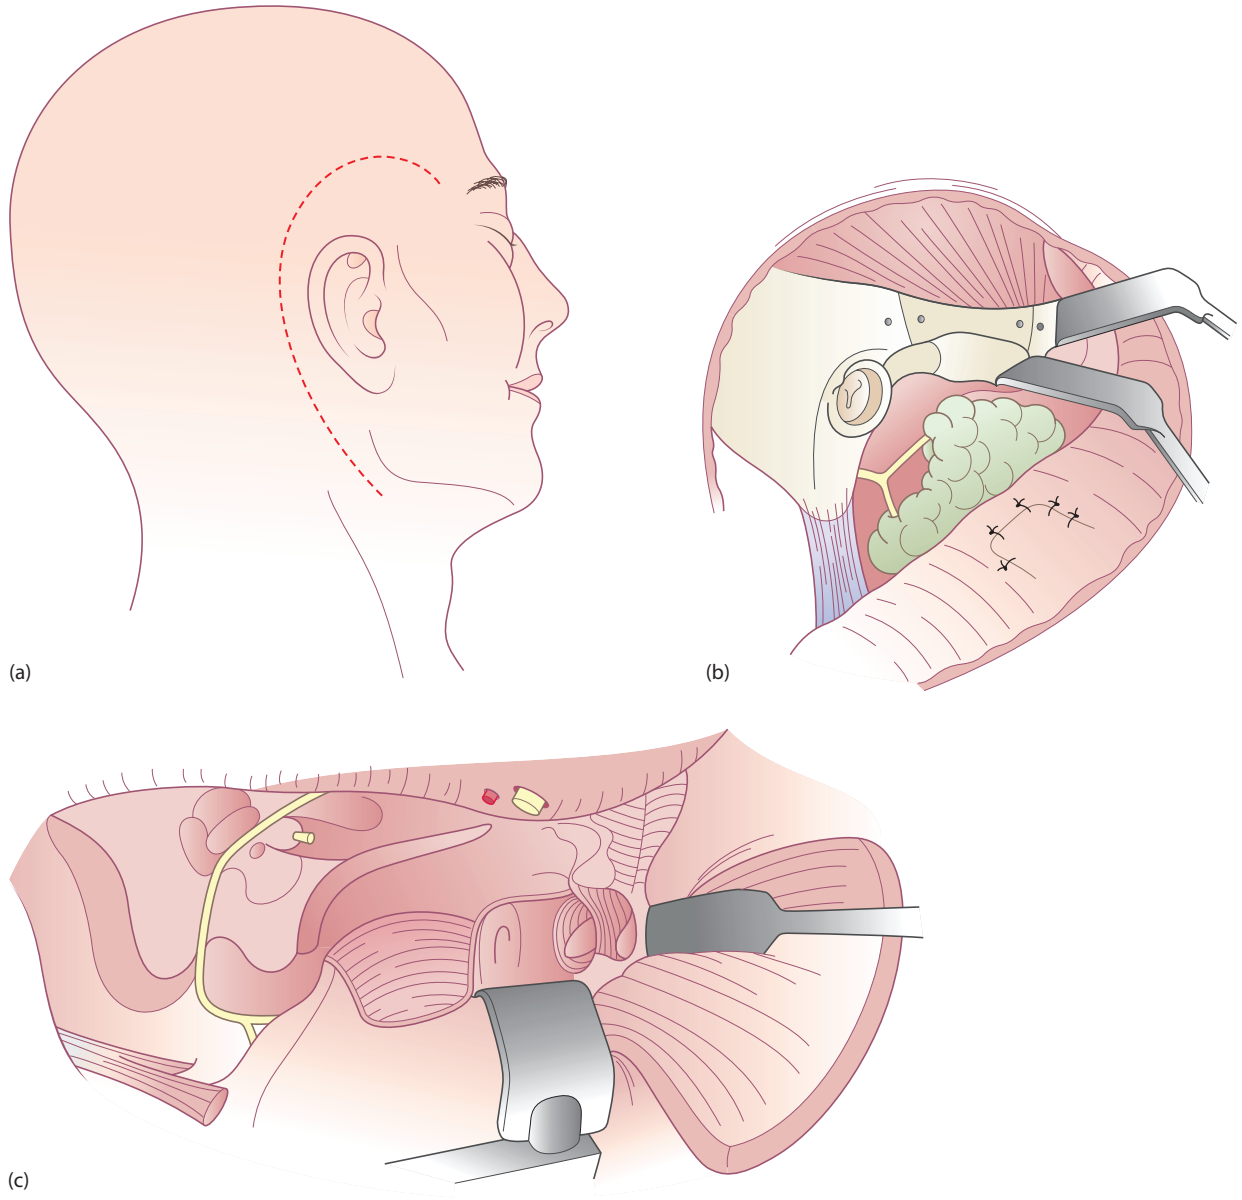

Figure 109.5 Infratemporal approach Type C. Redrawn from original illustrations by Margrit Pirker.

are dissected peripherally. The parotid gland is elevated from the masseteric fascia, the superficial temporal vessels are ligated and the temporalis muscle is elevated from the temporal squama. Osteotomies of the zygomatic arch (Figure 109.6b) permit inferior reflection of the temporalis muscle. A fronto-temporal craniotomy is then fashioned that includes the root of the zygomatic arch, glenoid fossa and the floor of the middle fossa lateral to the foramen spinosum and ovale, extending anteriorly to the pterion (Figure 109.6c).

Using a microscope, further medial dissection elevates the dura to expose the arcuate eminence, greater superficial petrosal nerve, middle meningeal artery and the mandibular nerve (V3). The middle meningeal artery is ligated and divided while the V3 can be retracted if it is not invaded by the lesion. Through this exposure, lesions around the middle third of the Eustachian tube can be addressed. Removal of more bone medial to the glenoid fossa and antero-medially along the greater wing of the sphenoid gives further access to the anterior Eustachian tube and pterygopalatine fossa. Selective removal of the pterygoid process allows access not only to the anterior third and pharyngeal ostium of the Eustachian tube but also to the posterolateral aspect of the nasopharynx. Further dissection along the pharyngobasilar membrane exposes the entire nasopharyngeal soft tissue sleeve allowing circumferential resection. If the lesion extends to the cavernous and petrous ICA, the Eustachian tube is removed completely, which gives access to the horizontal and vertical petrous segments of the ICA. Unroofing the horizontal segment of the ICA exposes the floor of the cavernous sinus. Further exposure of the inferior and medial border of the cavernous ICA is be attained by removal of the pterygoid root and the lateral walls of the sphenoid

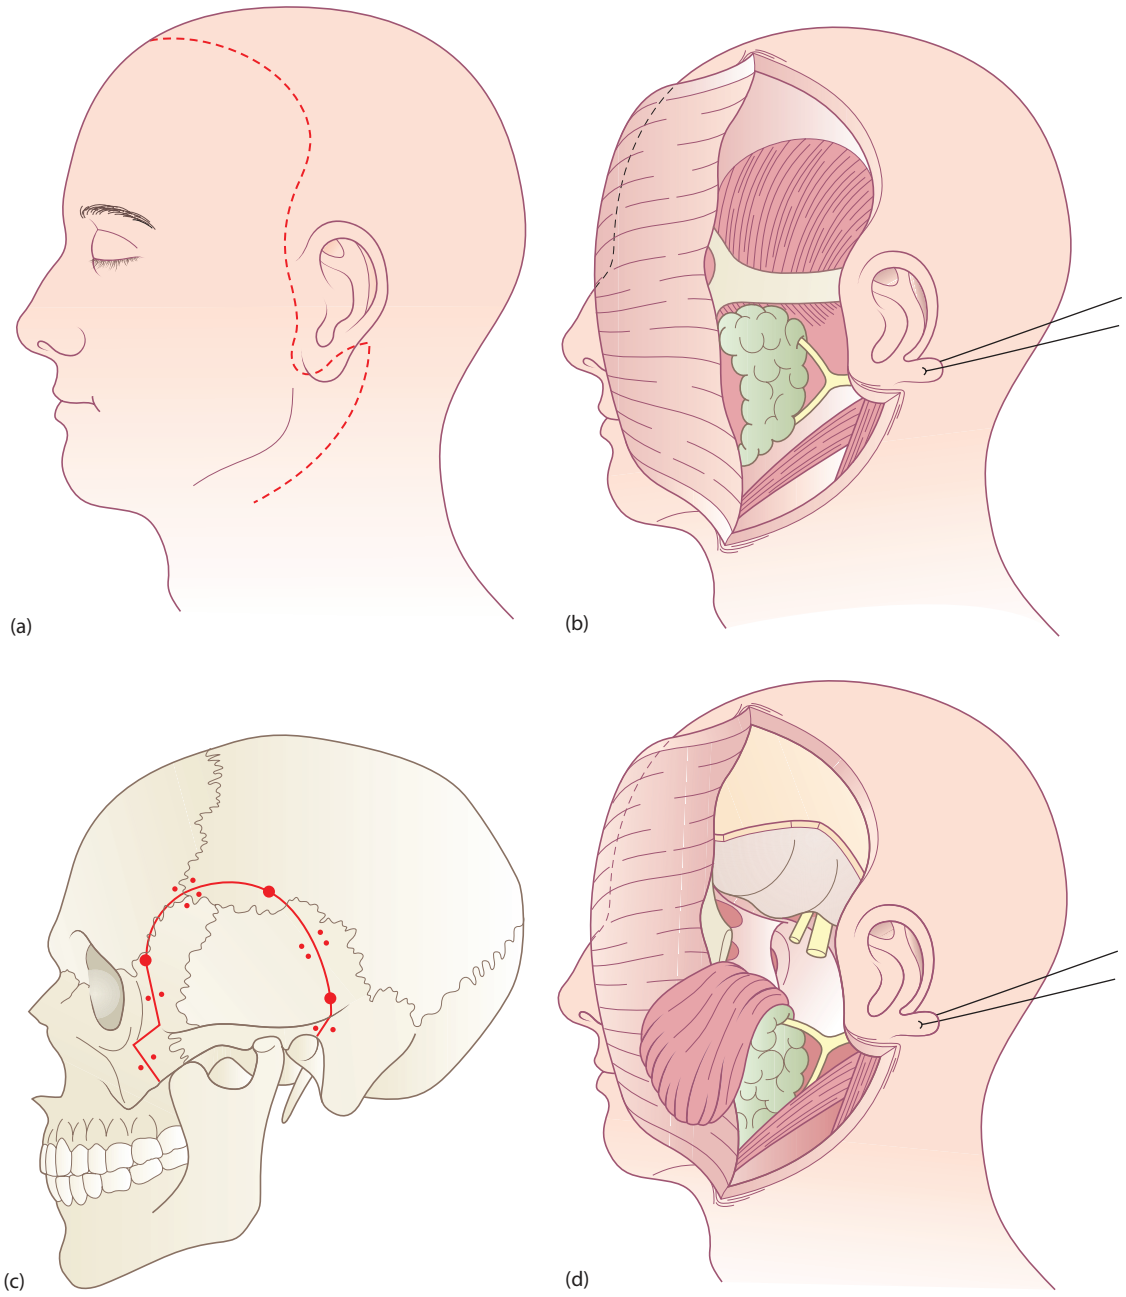

Figure 109.6 Subtemporal preauricular approach. Redrawn from original illustrations by Margrit Pirker.

body; this, however, requires transaction of the maxillary nerve (Figure 109.6d).

After removal of the tumour, dural defects can be repaired with pericranial regional flaps or with autologous fascial grafts such as temporalis fascia or fascia lata. The craniectomy bone flap is replaced and fixed with miniplates. If the defect cavity communicates directly with the nasopharynx, paranasal sinuses or skin, the exposed dura and the major vessel must be sealed off and protected by vascularized musculofascial flaps such as the radial forearm, anterior thigh or latissimus dorsi flap. Simple, passive wound drains are placed and skin closure completed.

Oral feeding can start on the first post-operative day.

KEY POINTS

- Advantages:
  - interdisciplinary approach
  - wide exposure of the infratemporal region, the petrous and cavernous segments of the internal carotid and the cavernous sinus.
  - good access for reconstruction.
- Limitations and drawbacks:
  - craniotomy required
  - CSF drainage required
  - high incidence of post-operative CSF leakage (15–20%)
  - insufficient exposure of the posterior petrous bone and otic capsule.

Facial translocation[24, 25]

INDICATIONS

- Extensive tumours (T4) of the anterior and middle skull base extending into the orbit, paranasal sinus and posterior cranial fossa with intracranial involvement.

CONTRAINDICATIONS

- Bilateral involvement of the ICA
- Bilateral involvement of the optic chiasm.[24]

PROCEDURE

The patient lies supine with the head turned 30–40 degrees to the contralateral side and positioned in an open head rest or Mayfield clamp. The ipsilateral scalp, face, neck, lower abdomen and thigh are prepared and draped. A modified Weber–Ferguson incision is made in order to create a wide cheek flap pedicled on the facial and inferior labial vessels (**Figure 109.7a**). The cheek flap includes the lateral third of the upper lip, the entire cheek soft tissue including the maxillary periosteum, lower lid, facial nerve and the parotid gland. The incision starts from the philtrum of the lip and is continued along the nasal silhouette. It then passes horizontally transsecting the medial canthus, follows the fornix of the inferior eyelid dividing the conjunctiva and the lateral canthus. It then joins the preauricular incision. By necessity, the frontal branches of the facial nerve are transsected and tagged for later reconstructive neurorrhaphy. The soft tissues of the cheek

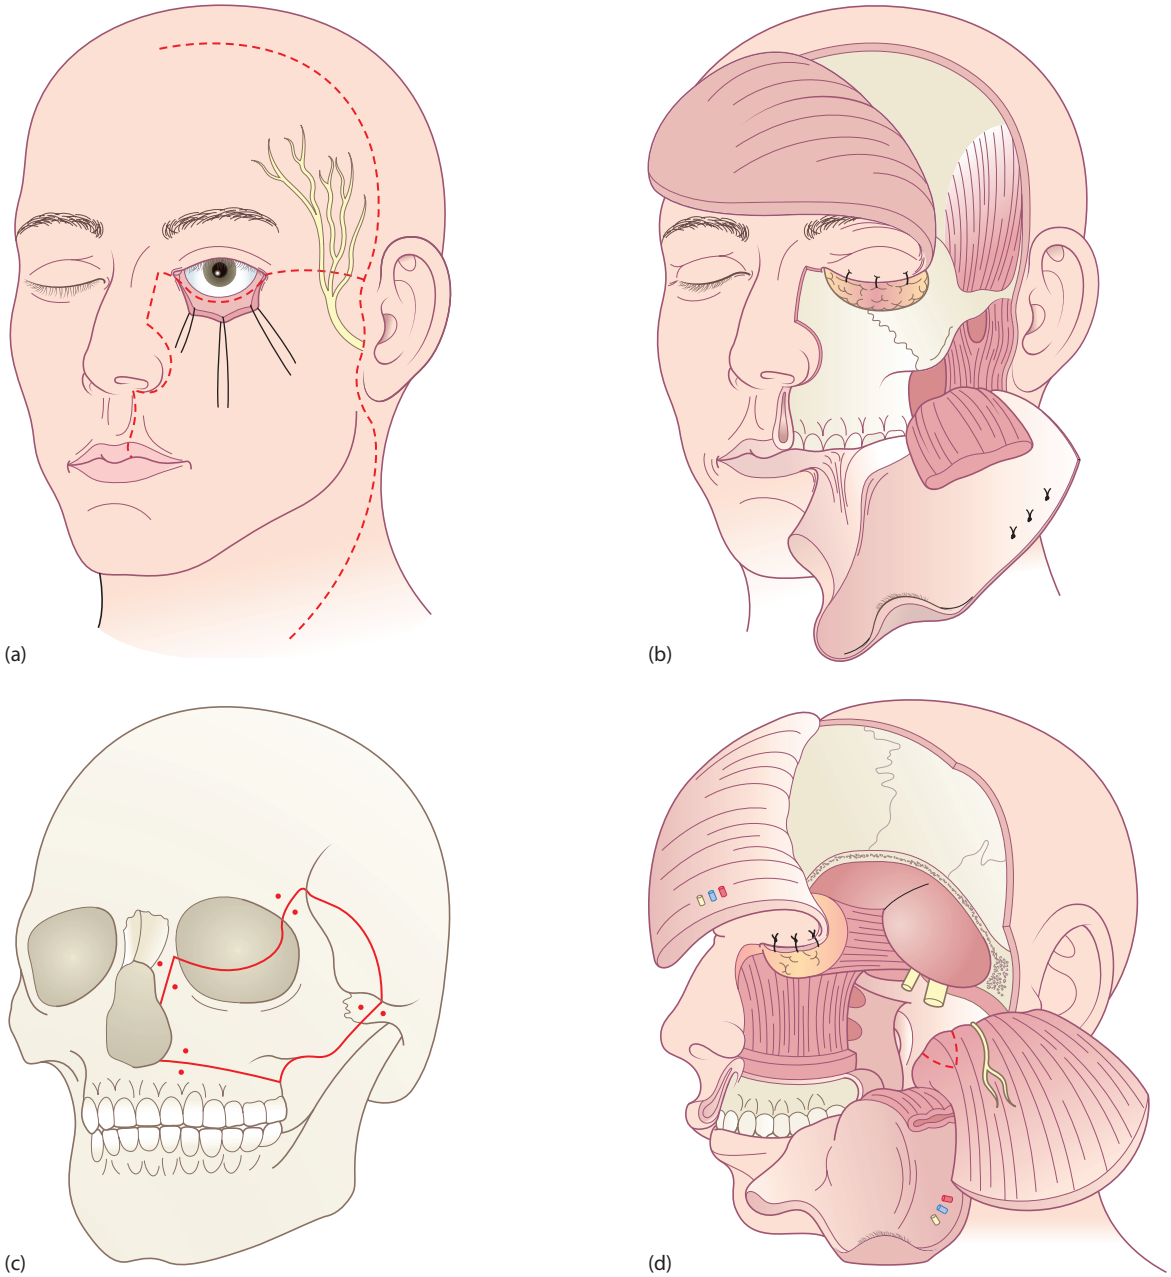

Figure 109.7 Facial translocation approach. Redrawn from original illustrations by Margrit Pirker.

are elevated from the facial skeleton and in doing so the infraorbital nerve is transsected and the masseter muscle is divided just below the zygomatic arch. A bicoronal incision is then made that meets the lateral extension of the previous transfacial incision. This allows elevation of the soft tissues from the temporal muscle and frontal bone thus creating a fronto-temporal scalp flap (**Figure 109.7b**). The latter is reflected towards the midline, while the cheek flap along with transsected masseter muscle are reflected inferiorly to the level of the hard palate. This manoeuvre requires division of the upper lip and extension of the lip incision along the gingivolabial sulcus as far as the last molar tooth (**Figure 109.7b**).

An orbito-maxillo-zygomatic free bone flap is created. Osteotomies pass through the frontozygomatic and temporozygomatic sutures laterally, inferiorly through the maxilla at the level of the nasal floor parallel to the hard palate to reach the pterygopalatine fossa; medially through the orbit in line with the inferior part of the lacrimal fossa and the tip of the inferior orbital fissure; laterally it is continued along the lateral orbital wall to join the transected frontozygomatic suture (**Figure 109.7c**). The posterior wall of the maxilla is freed from the pterygoid plates with a chisel. A subperiosteal osteotomy of the coronoid process and mandibular neck allows the temporal muscle and fascia to be mobilized from the temporal fossa and reflected inferiorly along with the mandible. This gives access to the nasopharynx, the pterygoid process, anterior surface of the sphenoid as well as the infratemporal fossa (**Figure 109.7d**). Further removal of the pterygoid processes and muscles exposes the lateral wall of the nasopharynx and foramen rotundum with the maxillary nerve. If even more access is required, it can be achieved by removal of bone from any of the exposed surfaces and by doing this the entire infratemporal, petroclival and cavernoclival borders can be visualized (**Figure 109.7d**).

Reconstruction follows the previously described steps, starting with watertight sealing of the dura with bulky microvascular free flaps (e.g. rectus abdominis, latissimus dorsi), which also eliminate the dead space and provide a well vascularized barrier between the dura and the nasopharyngeal mucosa. The free bone flaps are replaced and fixed with mini-plates. The cheek flap is realigned and the medial and lateral canthal ligaments reattached with stents being placed in the lacrimal duct. Finally, the frontal branches of the facial nerve are reanastamosed and the skin soft tissue closed in layers. Nasal packings are introduced to prevent obliteration of the nasal airway by encroachment of the reconstructive tissue in the operative defect.

Nasogastric feeding is necessary for a few days but oral alimentation can begin during the first week. Any non-resorbable nasal packs are removed on the eighth day and the lacrimal stents are left in place for 3 weeks.

KEY POINTS

- Careful patient selection and regular unit exposure are crucial for successful outcomes.
- A multidisciplinary management is mandatory.
- The detailed assessment and knowledge about the biology of pathology is the key for approach selection.
- An individually tailored approach decreases morbidity. This can frequently be achieved by a combining an endoscopic with a limited open approach.
- The endoscopic extended approaches have largely replaced the open approaches to benign lesions of the epipharynx and Eustachian tube.
- Swallow and hearing rehabilitation are key factors for quality of life.

FUTURE RESEARCH

Over the last few decades the development of multidisciplinary skull base approaches has rendered previously 'inoperable' lesions operable with minimal peri-and post-operative morbidity. The diseases managed by these approaches are not common and there are few centres with a large experience or with long-term results that would bear any form of analysis.

Improvements in the future may be achieved by:

- the expanding use of endoscopic approaches and procedures and the evolving endoscopic technology, thus further reducing post-operative morbidity and hospitalization length and improving functional outcomes
- TORS for the skull base
- new bone surgery and modelling tools
- new navigational techniques
- new dural repair techniques and products
- establishment of validated, defined indications for the established approaches
- multi-centre case-controlled or cohort studies for the most common skull base pathologies using skull base registries
- employment and evaluation of alternative or adjuvant therapies such as targeted immunotherapy, chemotherapy or Gamma Knife in an attempt to increase local tumour control.

KEY POINTS

- Advantages:
  - direct wide exposure of the anterior and middle cranial base
  - good access for reconstructions
  - radical resection of extensive tumours possible.
- Limitations and drawbacks:
  - complex multi-step surgical technique
  - craniotomy required
  - CSF drainage required
  - reconstruction and tubing of nasolacrimal system required
  - temporary or permanent palsy of the frontal branches of the facial nerve[24]
  - increased risk of post-operative osteonecrosis.

ACKNOWLEDGEMENTS

We would like to thank Margrit Pirker for bringing our intra-operative views onto paper and thus creating the essential illustrations for this chapter.

CHAPTER 110

TUMOURS OF THE TEMPORAL BONE

Marcus Atlas, Noweed Ahmad and Peter O'Sullivan

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: external auditory canal, middle ear, temporal bone and skull base neoplasm. More specific searches were made on glandular tumours, adenoma, carcinoid tumour, endolymphatic sac tumours, inverted papilloma, haemangioma, haemangiopericytoma, osteoma, chordoma, chondrosarcoma, rhabdomyosarcoma and Langerhans cell histiocytosis, focusing on their presentation, diagnosis and management.

INTRODUCTION

The most common tumours that develop in the temporal bone, glomus tumours and squamous cell carcinomas of the external auditory canal, are discussed in greater detail elsewhere in the text (see Chapter 115, Squamous cell carcinoma of the temporal bone and Chapter 107, Jugular foramen lesions and their management). This chapter is devoted to those tumours that are less common and about which relatively little is known. Some surgeons may never encounter any of these during their career.

There are two key aims of this chapter: first, to provide sufficient information for surgeons so that these uncommon conditions can be suspected at an early stage; second, to provide an overview of what is considered best practice for managing these rare entities.

All three embryonic primordial layers contribute to the normal structure of the temporal bone and, therefore, the spectrum of neoplasms that can develop within it is vast. The difference in growth rate of these tumours, in addition to their sites of origin, account for the varied presentations of these rare tumours. To complicate matters further, initially some may mimic other more common conditions such as cholesteatoma, Wegener's granulomatosis or fibrous dysplasia. Furthermore, the complex anatomical relationships of the temporal bone can make the management of tumours in this region particularly challenging.

RISK FACTORS FOR THE DEVELOPMENT OF TEMPORAL BONE TUMOURS

Genetic

To date, more than 200 mutations of the *NF2* gene have been identified (located on the long arm of chromosome 22–22q12.2). Three separate genes have been identified that are pathogenically linked to hereditary paraganglioma (on chromosome 11q23). An association has also been demonstrated between Von Hippel–Lindau (VHL) disease and endolymphatic sac tumours, the gene for VHL having been identified on chromosome 3p25. The molecular genetics of temporal bone tumours will almost certainly play a key role in the understanding and management of some temporal bone tumours in the future.[1–2]

Radiation

Ionizing radiation has been implicated in the aetiology of temporal bone tumours. Cahan et al.[3] established criteria

that needed to be fulfilled in order to make the diagnosis of radiation-induced sarcoma in bone. Some 50 years later, Lustig et al.[4] defined similar criteria for radiation-induced temporal bone tumours as follows:

- The second neoplasm must develop in the irradiated field.
- A latent period of at least several years must elapse between radiation exposure and the development of a second primary.
- The previous condition must show histological, radiographic and microscopic evidence of neoplasia.
- The second tumour must be of a different histological type from that previously irradiated.

Radiation-induced tumours of the temporal bone are rare, but there are reports in the literature of tumours, such as squamous cell carcinoma, fibrosarcoma and osteosarcoma, which fulfil the above criteria. These tumours are aggressive and tend to metastasize early. Treatment is difficult and management of reported cases has included surgical resection, chemotherapy and adjuvant radiotherapy. Reported outcomes are generally poor with 22–32% of patients surviving 2 years and a 5-year survival of 11–32%.[4]

Chronic suppurative otitis media and papillomatosis

Despite the fact that very few patients with chronic suppurative otitis media (CSOM) develop carcinoma of the temporal bone, a relationship is postulated between the development of squamous carcinoma of the temporal bone and CSOM. Many patients, 68% in one series,[5] have been treated for this condition prior to development of their tumour. The pathogenesis of this association is not understood, but the natural assumption is that cellular trauma must be a contributory factor. Jin et al.[6] isolated human papillomavirus (HPV) 16/18 at both the tissue and molecular levels in patients with carcinoma of the middle ear and associated chronic otitis media. This finding may provide a model to explain the relationship between the two. Although HPV 11 is regarded to be a low-risk variant in the uterine cervix, its behaviour in the head and neck region includes pathogenesis of squamous carcinoma in the temporal bone.[7] The transformation to squamous carcinoma of both benign and inverted papillomas of the temporal bone, recently described, suggests the question whether there should be further genetic analysis of biopsied papillomas to assess their susceptibility to malignant transformation.[8–9]

CLINICAL EVALUATION

Presentation of temporal bone tumours

The presentation of tumours of the temporal bone may be very subtle. Early diagnosis relies heavily on the level of awareness and index of suspicion of the clinician.

The presentation of a tumour can mimic that of less sinister otological conditions, such as otitis externa or CSOM. At the outset, patients present with otalgia, otorrhoea, hearing loss and vertigo. It is not surprising that early diagnosis is difficult and biopsy, the only way to make the diagnosis, is often delayed (or even misleading if taken superficially) until a relatively late stage when other more alarming clinical features such as facial palsy or bleeding have developed. Sadly, only at that stage is the true severity of the patient's pain appreciated by the clinician. Pain caused by these tumours is generally far more severe than that experienced with non-neoplastic conditions. Tumours of the temporal bone described in this chapter tend to spread locally through the Haversian system of the bone and anatomical fissures. These canals contain blood vessels and nerves in the temporal bone and provide additional pathways for tumour spread. Leonetti et al.[10] highlighted a number of ways that this group of neoplasms tended to spread. For example, tumours of the external auditory canal often extend anteriorly into the parotid gland and temporomandibular joint (**Figure 110.1**). Tumours of the middle ear spread anteriorly to involve the Eustachian tube and the postnasal space while extension superiorly rapidly involves the middle cranial fossa (**Figure 110.2**). The otic capsule and the labyrinth become involved by medial growth. Inferior spread involves the jugular foramen and lower cranial nerves. The internal carotid artery not infrequently becomes encased when

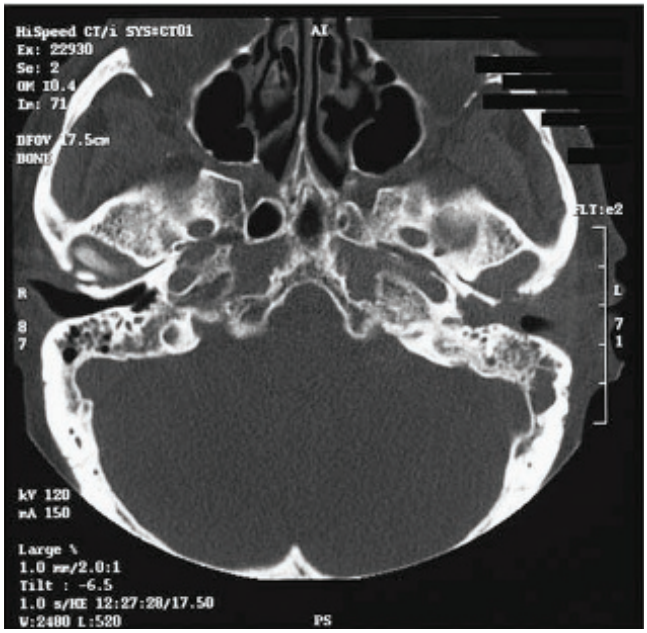

Figure 110.1 Adenoid cystic carcinoma of the left external auditory canal. High resolution axial CT of the skull base revealing soft tissue opacificaton of the left bony external canal with perforation of the anterior wall extending into the temporomandibular joint. There is slight irregularity of the posterior wall of the bony external canal with opacification of the adjacent mastoid air cells. Tumour surrounds the ossicular chain and erodes the tegmen with dural thickening on the undersurface of the left temporal lobe. Courtesy of Professor Andy White, Perth Radiological Clinic, Perth, Western Australia.

tumour extends into the petrous apex. Thus, the clinical features of temporal bone tumours may include:

- trismus
- hemifacial spasm or progressive facial weakness
- lower cranial nerve palsies (IX, X, XI and XII)
- headache and localized pain
- cervical metastases.

Investigation of temporal bone tumours

Multimodality imaging is essential to provide sufficient information to assess the stage of disease from which a sensible management plan can be derived. Thin section computed tomography (CT) will demonstrate bone erosion and gadolinium-enhanced magnetic resonance imaging (MRI) the full extent of soft tissue infiltration. Image merge techniques can contribute much to the assessment of tumour stage. The surgeon must make every effort to evaluate potential dural involvement and extent of spread to the infratemporal fossa.

The tumour should be biopsied for definitive diagnosis based on histological confirmation of tumour type, but this may not be possible until after extirpation of the lesion itself.

Staging of temporal bone tumours

Neither the American Joint Committee on Cancer (AJCC) nor the International Union against Cancer (IUCC) has a system specifically for classifying temporal bone tumours. An AJCC T4 tumour grading applies to both extensive tumours with deep temporal bone involvement and small tumours that superficially invade auricular cartilage – despite what is likely a vast difference in prognosis! A number of alternative staging systems have therefore been proposed that depend on the site and type of tumour.

Stell and McCormick[11] proposed a system for staging carcinoma of the external and middle ear that was subsequently updated by Clarke and Narula[12] (see also Chapter 115, Squamous cell carcinoma of the temporal bone). Arriaga et al.[13] have also proposed a system for staging tumours of the external auditory canal. Fisch, Glassock-Jackson and De La Cruz have all provided systems for the staging of glomus tumours. None of these classification systems have been proven in terms of prognosis, but can be used to aid multidisciplinary discussion and for selection of a suitable surgical approach if appropriate.

Classification of tumours of the temporal bone

Tumour types are summarized in Table 110.1.

TABLE 110.1 Classification of tumours of the temporal bone

Cutaneous neoplasms	Glandular neoplasms	Vascular/ haematological	Paraganglioma	Bone	Neural	Developmental and congenital
Squamous cell papilloma and carcinoma	Ceruminous adenoma and adenocarcinoma	Haemangioma	Glomus tympanicum	Osteoma	V, VII, VIII, IX, X, schwannoma	Chordoma
Basal cell papilloma and carcinoma	Pleomorphic adenoma	Haemangiopericytoma	Glomus jugulare	Secondary tumours	Meningioma	Dermoid
Malignant melanoma	Adenoid cystic carcinoma	Leukaemia	Glomus vagale	Rhabdomyo-sarcoma		Teratoma
	Middle ear adenoma	Lymphoma		Chondrosarcoma		Choriostoma
	Endolymphatic sac tumours	Plasmacytoma		Ewing sarcoma		
		Langerhans cell histiocytosis		Osteogenic sarcoma		

MANAGEMENT OF TEMPORAL BONE TUMOURS

Glandular tumours of the external auditory canal

The glandular components of the external auditory canal consist of sebaceous glands and modified apocrine glands, called 'ceruminous glands'. Previously, glandular tumours of the external auditory canal had been classified under the umbrella term of ceruminoma, but this term is non-specific and should not be used without qualification. There has been some confusion in the literature with no agreed system of nomenclature for these tumours[14] but classification of glandular tumours of the external ear by Wetli et al.[15] is relatively less complicated:

- ceruminous adenoma
- pleomorphic adenoma
- adenoid cystic carcinoma
- ceruminous adenocarcinoma.

CERUMINOUS ADENOMA

Ceruminous adenomas are well-differentiated tumours derived from the ceruminous glands. These tumours exhibit solid, cystic and papillary patterns. Ceruminous adenomas consist of an inner layer of cells that are cuboidal or columnar and are of apocrine origin with an outer layer that is myoepithelial in origin. These tumours should be widely excised because local recurrence is common. Radiotherapy has no role to play in the treatment of this type of tumour.

PLEOMORPHIC ADENOMA

Pleomorphic adenoma should also be excised. Care must be taken to avoid seeding of the local tissues by spillage of tumour during resection. Recurrence may develop many years after resection in much the same way as is seen in the major salivary glands.

ADENOID CYSTIC CARCINOMA

Adenoid cystic carcinoma of the temporal bone may display cribriform, tubular or solid growth patterns surrounded by cystic spaces. Adenoid cystic carcinoma has the propensity for significant local tissue destruction (**Figure 110.1**), perineural and perivascular invasion. It also tends to metastasize to the lymph nodes of the neck. There are no established treatment regimens. This condition is thought best managed by aggressive surgical resection followed by radiotherapy. The long-term prognosis is poor with distant (lungs, lymph nodes, skeletal) metastatic disease developing years later. Bone invasion, perineural spread and tumour extension outside the external auditory canal are considered indicators of poor prognosis.

CERUMINOUS ADENOCARCINOMA

Ceruminous adenocarcinoma is often difficult to distinguish from ceruminous adenoma as it may show very few malignant features apart from evidence of invasion into local tissue. These tumours grow slowly and tend to spread by local invasion. Metastases have been reported. Ceruminous adenocarcinomas are extremely rare and advice on treatment is largely anecdotal. Surgical resection with post-operative radiotherapy is considered to be the appropriate therapy.

In summary, benign glandular tumours of the external ear should be treated by wide surgical excision. The optimum treatment for malignant tumours has not been established and is unlikely to be forthcoming in the near future. Current opinion would suggest aggressive surgical resection followed by adjuvant radiotherapy.[16]

Glandular tumours of the middle ear

Debate continues about the nomenclature, pathology and behaviour of glandular tumours of the middle ear. The distinction between terms such as adenoma, adenomatous tumours, adenocarcinoma and carcinoid tumour of the middle ear has not always been clear, partly because of overlapping pathological features, but also because of uncertainty about the behaviour and natural history of these tumours.

MIDDLE EAR ADENOMA

In 1976, Hyams and Michaels[17] presented 20 primary middle ear tumours with an adenomatous pattern that were strictly confined to the middle ear cleft and thought to be derived from the middle ear mucosa. The tumours described in this series expanded locally. There was no evidence of bony erosion or of distant metastases. All of the patients were treated by local excision. A tympanotomy or mastoid approach was used and no patients were radiated subsequently. Follow-up data were available for 18 patients and all but one was free of tumour 4–24 years after surgery. Similar tumours have been described by other authors,[18] and Torske and Thompson[19] reviewed 48 cases of middle ear adenoma that had been referred to the Armed Forces Institute of Pathology over a period of 25 years. These tumours displayed features consistent with the diagnosis of middle ear adenoma. They lacked features of aggressive malignancy such as mitotic activity, perineural or vascular invasion. The authors suggested that the presence of neuroendocrine markers made these neoplasms indistinguishable from carcinoid tumours. It was argued that the relatively small size of these tumours, together with the relatively poor blood supply of the middle ear, explained the lack of paraneoplastic syndromes. In contrast to other carcinoid tumours, metastatic disease was not seen with middle ear adenoma. It was suggested that 'neuroendocrine adenoma of the middle ear' might be a more appropriate description.

A more recent review by Saliba and Evrard[20] examined the literature on all reported cases, and recommended a new system of classification of middle ear glandular neoplams that may have prognostic significance. Based on the

presence or absence of immunohistochemical markers and metastasis, these lesions are classified into three types:

- **Type I:** neuroendocrine adenoma of the middle ear (NEAME) in 76% of cases (positive immunohistochemistry, negative metastasis)
- **Type II:** middle ear adenoma (MEA) in 20% of cases (negative immunohistochemistry, negative metastasis)
- **Type III:** carcinoid tumour of the middle ear (CTME), only 4% of tumours (positive immunohistochemistry, positive metastasis and/or carcinoid syndrome).

Wide surgical resection is generally recommended and cure can be anticipated. Hearing can often be preserved. It has been suggested that if the tumour is intimately related to the ossicles, removal of the ossicles reduces the possibility of tumour recurrence.[20] Radiotherapy does not have a role to play in the treatment of these tumours.

TUMOURS OF THE ENDOLYMPHATIC SAC

In 1988, Gaffey et al.[18] proposed the term aggressive papillary middle ear tumour (APMET) for adenomatous middle ear tumours that have a primarily papillary architecture. As distinct from the middle ear adenoma described above, these tumours were extremely aggressive locally invading bone and possibly extending intracranially. In Gaffey's series, brain invasion was seen in one patient and no patient had evidence of distant metastases. All of these patients were treated with surgery and, in some, adjuvant radiotherapy. In 1989, Heffner proposed that the middle ear tumour previously described as the papillary middle ear tumour was in fact derived from the endolymphatic sac.[21] Li et al.[22] confirmed their findings in 1993 using similar histochemical and histopathological techniques. Terms such as Heffner tumour, low grade adenocarcinoma of endolymphatic sac origin, and aggressive papillary middle ear tumour are now obsolete and it should be described as endolymphatic sac tumour (ELST) according to the more recently published World Health Organization tumour classification.[23]

Progressive unilateral, sensorineural hearing loss is the most prominent feature of this tumour in addition to tinnitus and vertigo. This neoplasm grows very slowly; the average duration of time between onset of symptoms and diagnosis is 9 years.[21] In the past, some patients have presented with an acute unilateral sensorineural hearing loss and been misdiagnosed as Menière's disease, which is understandable considering the site of the lesion (**Figure 110.3**). The differential diagnosis includes paraganglioma, papillary choroid plexus tumours, ceruminous gland tumours, benign adenomatous tumours and metastatic disease. On microscopy, these tumours demonstrate a papillary ultrastructure, composed of cuboidal or low columnar cells (**Figure 110.4**). Nuclear size and shape may vary, but prominent pleomorphism and mitotic activity is not a feature. They are vascular in nature and invade bone in an aggressive fashion. Metastatic spread has not been reported. Growth and spread to the cerebellopontine angle and posterior fossa is most commonly seen. Extension into the middle and external ear has been reported, as well as into the middle cranial fossa, clivus, cavernous sinus and sphenoid sinus.[24] Mukherji et al.[25] showed a correlation between middle ear spread and the size of tumour. In a radiological review of 20 patients with a diagnosis of ELSTs that included CT imaging, MRI and angiography, eight of nine tumours less than 3 cm in size did not involve the middle ear, and eight of

Figure 110.3 Endolymphatic sac tumour. Courtesy of Professor Andy White, Perth Radiological Clinic, Perth, Western Australia.

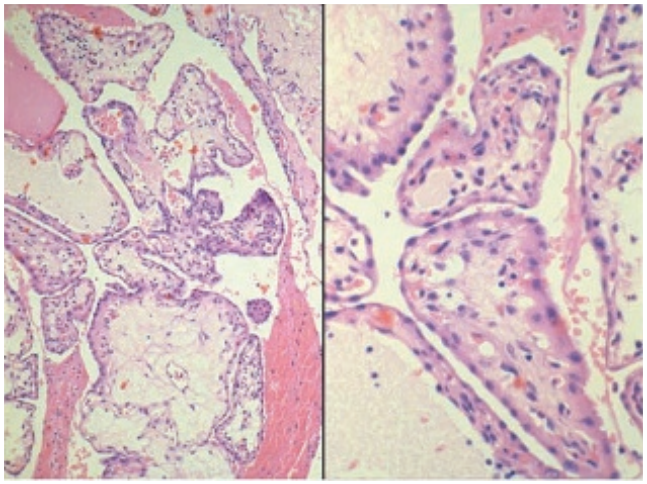

Figure 110.4 Endolymphatic sac tumour. Aggressive papillary middle ear tumour of temporal bone and endolymphatic sac. This tumour occurred in a 35-year-old female. There are papillary formations consisting of oedematous fibrovascular cores lined by a single layer of plump, cuboidal epithelial cells. Courtesy of Drs P Robbins and D Spagnolo, The Western Australian Centre for Pathology and Medical Research, Perth, Western Australia.

nine tumours of at least 3 cm demonstrated soft tissue involvement of the middle ear.[25] It was also demonstrated that the vascularity of the tumour was related to tumour size. Tumours less than 3 cm are supplied solely by the external carotid artery and, as the tumour enlarges, it obtains a blood supply from the internal carotid artery. Ultimately, the tumour may also obtain a blood supply from the posterior circulation (i.e. the anterior and inferior cerebellar arteries).

An association had been established between tumours of the endolymphatic sac and Von Hippel–Lindau (VHL) disease.[24] This autosomal dominant condition predisposes the patient to a number of conditions, including haemangioblastoma of the cerebellum, angiomatous lesions of the retina and renal cell carcinoma. The gene for this condition has been identified in the short arm of chromosome 3 (3p25) and a mutated suppressor gene has also been identified in both abnormal and neoplastic tissues of patients suffering from this condition. Gaffey et al.[18] pointed out that 15% of patients with ELSTs are known to have VHL disease. A review of the literature published in 2012 indicated an earlier age at presentation with ELST in VHL disease (31.3 years versus 52.5 years) with a female preponderance (female-to-male ratio of 2:1 for VHL disease patients versus 1:1 for non-VHL disease patients) and propensity for bilateral ELSTs in VHL disease.[26]

Recent studies have demonstrated an excellent prognosis (in terms of survival and hearing preservation) with early surgical resection without the need for radiotherapy.[27–29] Removal of the tumour is therefore advised (with pre-operative embolization if needed), the extent of the resection being determined by a number of factors that include its size, vascularity, existing neural deficits and those that might be acquired as a result of surgery. Most patients are young adults and incomplete tumour removal can lead to significant long-term morbidity. Partial tumour removal can be justified for some when complete removal might inflict unacceptable morbidity. In this respect, it is worth remembering that this is an extremely slow-growing tumour and the elderly might outlive their disease. Adjunctive radiotherapy has been used in the treatment of these tumours but its role in the treatment of ELSTs is far from established. Radiation therapy may be considered when surgical treatment is not an option or as a palliative measure following partial tumour removal.

Miscellaneous tumours of the middle ear

INVERTED PAPILLOMA

These are extremely rare tumours of the middle ear and are similar to inverted papilloma of the sinonasal system. HPV has been implicated in their pathogenesis. Like its nasal counterpart, surgery is the mainstay of treatment. It is essential that the specimen be examined for evidence of carcinoma as malignant transformation has recently been demonstrated.[9] In those patients with evidence of carcinoma, radical resection with post-operative radiotherapy has been advocated.[30]

HAEMANGIOMA

These benign vascular tumours are derived from arterioles, venules and capillaries. They develop at a number of sites in the temporal bone with the geniculate ganglion being the most common. In the middle ear they have been found coincidentally, but usually present with symptoms of conductive hearing loss. The differential diagnosis includes that of paraganglioma, high jugular bulb and adenomatous tumour. Some haemangioma may regress spontaneously, while others continue to grow and are locally destructive. Surgical excision is the treatment of choice in these cases, but as some tumours may regress spontaneously an expectant approach may be appropriate particularly if surgery might compromise middle ear function.[31]

HAEMANGIOPERICYTOMA

These are rare vascular tumours that consist of proliferating pericytes surrounding capillaries. About 15–25% of haemangiopericytomas develop in the head and neck region. Cases have been reported in the middle ear and temporal bone, although they are extremely rare. Fifty per cent are malignant, although the behaviour of even the benign form is unpredictable. Treatment is by wide surgical excision. Pre-operative embolization may be helpful. These tumours appear to be radioresistant, but it has been suggested that radiotherapy has a role to play if excision is incomplete.[32]

OSTEOMA

These are benign tumours consisting of mature lamellar bone. While well documented in the external auditory canal, they are otherwise very rare in the temporal bone. The most common site of origin appears to be the mastoid with about 20% developing in the middle ear. In half of these, the osteoma causes a conductive hearing loss and the condition is often discovered coincidentally. While easy to remove from the mastoid, an expectant approach is probably more advisable, particularly in the asymptomatic patient with middle ear disease where removal of the osteoma might compromise structures such as the ossicular chain or the VIIth nerve.[33–35]

CHORDOMA

Chordomas are rare tumours that originate from the primitive notochord. A loss of heterozygosity (LOH) study centred on the short arm of chromosome 1 (1p36 region) revealed an high incidence of 1p36 losses among sporadic chordomas.[36] They are subclassified according to site of development: spheno-occipital (35%), vertebral (15%) and sacrococcygeal (7%). Three types of chordoma are recognized: conventional, chondroid and dedifferentiated, the chondroid form being the most common. Chordomas may present more laterally in the skull base, such as at the petrous apex, the carotid canal or the jugular foramen where they are thought to arise from dendritic processes at the cephalic end of the notochord. These tumours may present at any age, but the mean age at diagnosis is

TABLE 110.2 A comparison of symptoms at presentation of chordoma and chondrosarcoma

Symptom	Chordoma (%)	Chondrosarcoma (%)
Headache	67	49
Diplopia	54	70
Intermittent diplopia	25	28
Decreased visual acuity	8	13
Facial numbness	2	23
Decreased hearing/tinnitus	2	9
Facial weakness	2	11
Dysphagia/dysarthria	2	9

Reproduced with permission from Volpe et al.[37]

between 35 and 45 years. The male to female ratio is 2:1. The most common symptoms at presentation are summarized in Table 110.2.[37]

Conventional chordoma has been misdiagnosed as chondrosarcoma in the past. Chondrosarcoma is the main differential diagnosis and despite its name has a less aggressive clinical course. It is essential to achieve accurate histological diagnosis before outlining a management plan for these unfortunate patients. CT-guided fine-needle aspiration may be useful in this respect.

Surgical removal of chordoma is the mainstay of treatment. Complete resection may be difficult but does provide the best long-term survival and lowest risk of recurrence. Successful resection depends on the degree of spread of the tumour and the degree of involvement of vital structures, such as the carotid artery and the brain. A number of skull base approaches have been described, but most fall into the category of anteromidline and lateral techniques. Successful removal also depends on accurate pre-operative assessment of the tumour and the ability of the surgeon but in many cases subtotal resection with post-operative radiotherapy is the only viable management option.

Radiotherapy as an adjunctive treatment has a significant role to play in the management of these tumours. Although a number of delivery techniques have been used, proton beam therapy is now considered the gold standard radiotherapy modality, and a prospective randomized phase III trial is underway comparing it with a newer modality – carbon ion radiation therapy.[38] However, it must be noted that if surgery (such as salvage) is needed after radiotherapy the tumour can be both fibrotic and adherent, making preservation of vital structures particularly difficult.

Crockard et al.,[39] in a review of 42 patients treated over a 12-year period, reported 5- and 10-year survival rates of 77% and 69% respectively, treated by maximum surgical cytoreduction and photon radiation therapy. A smaller, more recent study reported a higher 5-year survival of 82.5%.[40] Stacchiotti et al.[41] have demonstrated a response to chemotherapy in advanced or recurrent chordomas no longer amenable to surgery or radioresistant tumours. Molecular marker analysis of histological specimens could inform prognosis in the future as a study has demonstrated the lack of 1p36 LOH, or the presence of tumour necrosis factor receptor superfamily gene *TNFRSF8* expression, may be associated with a better prognosis.[42]

CHONDROSARCOMA

The precise origin of chondrosarcoma is not known, but one theory is that these tumours may arise from chondrocytes that persist as embryonal cell rests at or about the foramen lacerum. A number of histological types are recognized, such as hyaline, myxoid, clear cell, mesenchymal and dedifferentiated. Immunohistochemistry can help differentiate chondrosarcomas from chordomas.

Hyaline and myxoid types are more common and are sometimes referred to as 'conventional' chondrosarcoma. Evans et al.,[43] in a review of 81 patients with chondrosarcoma from varying sites, graded these tumours I–III, based on their mitotic rate, cellularity and nuclear size. A 5-year survival of 90%, 81% and 43% in grades I, II and III, respectively, has been reported. There was also a correlation between grade and metastatic rates, with a 0% metastatic rate with grade I tumours, 10% with grade II tumours and 71% with grade III tumours.

The common symptoms at presentation of chondrosarcoma of the skull-base tumours are presented in Table 110.2. These tumours grow slowly and have significant potential for local expansion. Before diagnosis, patients may have been treated for many years with non-specific symptoms, such as headaches or non-specific neurological symptoms. The mean age at presentation is in the fourth decade and the male to female ratio is approximately equal, although some studies have shown a male predominance.[44] Chondrosarcomas typically develop around the foramen lacerum, parasellar region, petrous apex and cerebellopontine angle, rather than the midline predilection of the chordoma.

Treatment protocols for chondrosarcoma continue to evolve and are multidisciplinary in nature. Surgical resection is the mainstay of treatment. Complete removal is not always possible but adjunctive radiation therapy, particularly proton beam, is used in the treatment of these tumours and has an increasing role to play in their management. Rosenberg et al., in a review of 200 patients with a diagnosis of conventional chondrosarcoma treated at the same institution, reported a 5-year local control rate of 99% and a 10-year local control rate of 98%. Both 5- and 10-year disease-specific survivals of 99% were reported when surgery was combined with high-dose fractionated proton beam radiation.[45] A recent systematic review with meta-analysis of 560 patients with cranial chondrosarcoma has demonstrated that surgical resection with post-operative adjuvant radiotherapy has the lowest 5-year recurrence rate (9% vs. 19% for radiation alone, $p < 0.011$) and is significantly better than surgery alone (9% vs. 44%, $p < 0.0001$).[46] It should be noted that chondrosarcoma has a much better overall prognosis than that of chordoma, despite similar aggressive treatment protocols.

SECONDARY TUMOURS OF THE TEMPORAL BONE

Secondary tumours of the temporal bone are classified into three types: local spread of a tumour from an adjacent site such as pharynx, parotid or sinus; distant spread of a cancer; and manifestation of a haematological malignancy (e.g. leukaemia). The spread of a tumour from an adjacent head and neck site is dealt with elsewhere (see Volume 3, Chapter 18, Metastatic neck disease). Haematological malignancies have a significant propensity to spread to the temporal bone and are not addressed further in this chapter. Gloria Cruz et al.,[47] in a review of 212 patients with primary non-disseminated malignant neoplasms, found an approximately 22% prevalence of metastases to the temporal bone. The average age of presentation corresponded to the age at which most primary tumours have their onset (i.e. the fifth to sixth decade). There was a slight male to female preponderance.

Table 110.3 summarizes the site of origin of secondary tumours of the temporal bone. The mode of presentation varies from patient to patient and up to 36% of patients have no symptoms attributable to the head, neck or ear. The most common symptom at presentation is hearing loss, followed by vertigo and facial paralysis.[47] Secondary tumours can develop throughout the temporal bone, but the petrous apex is the most common site followed by the internal auditory meatus.[47–48]

The prognosis for patients with secondary temporal bone tumours is poor. Management may involve a number of different modalities and is dependent upon the origin and nature of the original primary. Treatment, therefore, has to be individualized. Diagnosis is difficult, because so many patients are asymptomatic. In their series, Gloria Cruz et al.[47] found that all patients with temporal bone metastases had metastases at other sites. It is important to realize that metastatic disease should be excluded in any patient with a history of a previous malignancy who develops otological symptoms, particularly sensorineural hearing loss.

TEMPORAL BONE TUMOURS IN CHILDHOOD

Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is an extremely aggressive tumour of striated muscle origin that has the potential to spread locally and to metastasize. It is the most common soft tumour of childhood. In the head and neck region, RMS of the ear is the third most common site of origin after the nasopharynx and the orbit. Most of these tumours present under the age of 12 years. Four histological types are recognized: embryonal, alveolar, pleomorphic and botyroid.

Table 110.4 summarizes the most common symptoms and signs at presentation. In addition to the normal histological and radiological work up for tumours of the temporal bone, investigations should include a CT scan of the chest, bone scan and a lumbar puncture. Further investigation may then be carried out as indicated.

Definitive treatment of these tumours continues to evolve and consists of a multidisciplinary, multimodality approach that includes chemotherapy, radiotherapy with less of a role for surgery. One study, the Intergroup Rhabdomyosarcoma Study (IRS), was introduced in 1972 to establish the optimum treatment for RMS in general. A summary of the IRS classification system for staging these tumours, as introduced by Maurer et al.,[50] is shown in Table 110.5.

RMS of the temporal bone tends to be diagnosed late due to symptoms that mimic more common conditions. As a result, most patients are staged in group III and included under the umbrella term of 'parameningeal' tumours. The IRS study continued to recruit patients and investigate treatment regimes for RMS, altering the chemotherapeutic regimes and radiation fields as was deemed necessary. IRS results have been reported in every decade since the 1970s. Results of treatment for all groups have improved over the study period with the group III, 5-year survival rates overall improving from 52% in IRS-I to 59% for IRS-II to 65% for IRS-III and 73% for IRS IV.[51–53]

TABLE 110.3 Site of origin: secondary tumours of the temporal bone

Site of origin	Incidence (%)
Breast	25
Lung	11
Kidney	9
Stomach	6
Bronchus	6
Prostate	6

Reproduced with permission from Streitman and Sismanis.[48]

TABLE 110.4 Rhabdomyosarcoma: the most common symptoms and signs at presentation

Symptom	Frequency (%)
Mass in the ear region	56
Aural polyp	54
Ear discharge	40
Bleeding from the ear	30
Ear pain	22
Hearing loss	14
Facial paralysis	14

Reproduced with permission from Prat and Gray.[49]

TABLE 110.5 The IRS classification system

Group	
I	Localized disease completely resected
II	Grossly resected disease, with microscopic residual disease with or without lymph nodes
III	Gross residual disease
IV	Metastatic disease present at onset

Reproduced with permission from Maurer et al.[50]

While still a potentially aggressive and fatal condition, the outcome for childhood RMS of the temporal bone is slowly improving, with the key to survival being early diagnosis through biopsy of unhealthy tissue.

Langerhans cell histiocytosis

Langerhans cell histiocytosis (LCH), formerly called histiocytosis X, is a condition that is characterized by the proliferation of histiocytes that share the characteristic of Langerhans cells (normally located in the dermis). These cells are recognized by the presence of inclusion bodies in the cytoplasm, called Birbeck granules. Proliferation and infiltration of these cells may develop in any organ in the body, including bone, skin, lung, liver, spleen and nervous system. LCH is now the collective name for the following conditions that were previously thought to be three distinct entities, but are now recognized as one condition:

1. **Eosinophilic granuloma:** Generally refers to osseus disease alone and may be unifocal or multifocal
2. **Hand-Schuller-Christian disease:** A systemic disease identified by multifocal osseus lesions, with limited involvement of extraskeletal sites, such as lymph nodes and viscera
3. **Letterer-Siwe disease:** The most serious and rapidly progressive disease, characterized by disseminated disease with multiorgan involvement.

In the series of cases reviewed by Irving et al.,[54] 73% of patients presented with head and neck involvement, 24% of patients had involvement of the skin of the external auditory meatus and 19% had involvement of the temporal bone. The mean age of presentation was 3.2 years and the male-to-female ratio was 1.7:1. These relative percentages of head and neck and temporal bone involvement vary slightly from series to series.[55, 56]

Symptoms and signs of ear and temporal bone involvement are often indistinguishable from that of CSOM and may include a conductive or sensorineural hearing loss. Thirty per cent of patients with temporal bone involvement have bilateral involvement. The characteristic radiological appearance of the temporal bone is that of a 'punched out' or lytic appearance. While extensive destruction of the temporal bone can take place, there are only limited reports of otic capsule involvement with disease often confined to the external and middle ear.

The ultimate prognosis of patients with LCH depends on whether the disease is unifocal, multifocal or disseminated. Age at presentation of less than 2 years with organ dysfunction is an indicator of a much poorer prognosis. Unifocal disease, on the other hand, has a very good prognosis responding to local treatment, which may include local resection or radiotherapy. Most series have a 95–100% cure rate. Multifocal disease also has a good response to treatment,[57] but disseminated disease can be rapidly fatal.[54–56] Involvement of the temporal bone often implies multifocal disease, which is best treated in a multidisciplinary, multimodality fashion with a combination of chemotherapy, radiotherapy and steroid therapy (in order of preference according to current trends). Surgical treatment of temporal bone LCH is now being utilized much more selectively (for isolated disease), recognizing that there is a high risk of complications, particularly to structures such as the facial nerve.

FUTURE RESEARCH

Perhaps because of the rarity of tumours of the temporal bone, there are still large gaps in our knowledge. With some tumours, such as those of the middle ear, there is still uncertainty with regard to their nomenclature, pathology and behaviour.

- There is no generally accepted system for the classification of temporal bone tumours.
- While there are staging systems available for some individual tumour types, there is no overall agreed system for staging tumours of the temporal bone.
- The lack of accurate classifications in addition to the paucity of multicentre trials make treatment guidelines difficult.
- Randomized, multicentre therapeutic trials should be devised to address these problems and it is heartening to see that these are now taking place in the management of chordomas and chondrosarcomas.
- It is hoped further advances in molecular biology and immunohistochemistry will advance new therapeutic options.

KEY POINTS

- Temporal bone tumours are exceedingly rare and can be extremely variable in their presentation and prognosis.
- There is often considerable delay in the diagnosis of temporal bone tumours. Biopsy of any unhealthy tissue in the ear is advisable. Early diagnosis and treatment improves outcomes.
- Appropriate radiological investigation is the cornerstone of management.
- The development of unilateral hearing loss in a patient who has had a previous malignancy may indicate a secondary tumour in the temporal bone.
- Management strategies for many of these tumours rely on level 4 evidence.
- Intracranial spread is not uncommon and a multidisciplinary approach is advisable.

CHAPTER 111

CLINICAL NEUROANATOMY

John J.P. Patten

SEARCH STRATEGY

Data in the chapter may be supplemented by recourse to the standard textbooks of neuroanatomy e.g. *Gray's Clinical Neuroanatomy: The Anatomic Basis for Clinical Neuroscience*.[1]

INTRODUCTION

A neurological examination is critical in the assessment of patients with skull base disease. In this chapter, applied aspects of skull base neuroanatomy are reviewed and the differential diagnosis of neural deficits considered. In some instances, gross anatomy is of great importance and in others complex central connections require detailed elaboration to illustrate and explain the accompanying clinical disorders. The following account is always biased in the direction of practical applications, and information of limited or uncertain clinical importance has been excluded.

THE CRANIAL NERVES

The cranial nerves fall into three major groupings sharing common anatomical relationships and pathology. Differing patterns of involvement within these groups allows a very accurate differential diagnosis to be advanced, based on both the sequencing and ultimate extent of damage to the nerves in these groups. The advent of computed tomography (CT) and three-dimensional magnetic resonance imaging (MRI) has added remarkably to our ability to confirm or refute clinically suspected diagnosis in what used to be an investigational no-man's land. Scan interpretation still requires a very good knowledge of gross anatomical relationships of the intracranial and extracranial courses of the cranial nerves and these anatomical features form the bulk of this chapter.

The groupings are:

1. Cranial nerves I, II, III, IV, the ophthalmic division of V and VI and the final distribution of the cervical sympathetic
2. Cranial nerves V, VII and VIII
3. Cranial nerves IX, X, XI and XII and the cervical components of the sympathetic chain.

The influence of altered cerebellar, pyramidal, extrapyramidal and corticobulbar function on the nerves and peripheral evidence of disordered brainstem function will be detailed at the end of the chapter, or where appropriate in general discussion.

GROUP 1

In the first group, the close relationship of the olfactory and optic nerves and the varying relationship of the three nerves supplying the extraocular muscles is considered. It is also necessary to include the relationships of the first division of the Vth nerve, which traverses the orbit, to these structures, although the detailed anatomy of this nerve is dealt with in Group 2.

The olfactory nerve (I)

ANATOMY

The olfactory epithelium lies in the olfactory cleft that occupies the upper 10 mm of the nasal septum, the roof of the nasal cavity and down the lateral wall towards the origin of the superior concha (Figure 111.1). In humans, its total surface area is some 5 cm^2 and is a yellowish colour. In other species, increasing pigmentation is associated with increased sensitivity to odours. The mucosa is bathed in a lipid-rich secretion from the epithelial Bowman's glands, indicating that lipid solubility may be a critical factor in odour detection. The olfactory receptor cells, some 5 million in all, lie on the basal epithelium and extend vertically to the surface from which the terminal enlargement protrudes and gives rise to 8–20 olfactory cilia. Although these have the standard '9 + 2' fibril arrangement found in mobile cilia in other areas of the body, they are thought to be nonmotile and form a dense mat of fibrils lying on the surface of the epithelium. Pinocytic vacuoles have been demonstrated in the terminal enlargement of the receptor cells, but their functional significance remains uncertain.[1]

The receptor cells are derived from ectoderm and are unique in being replaced from stem cells every 30–50 days. They also enter the central nervous system (CNS) as very thin (0.1–0.4 µm), non-myelinated axons without synapse. These axons become grouped and ensheathed by Schwann cells forming some 20 fasciculi which are invested by pia and arachnoid mater, and pass through the orifices of the cribriform plate to enter the olfactory bulbs lying each side of the crista galli in the floor of the anterior cranial fossa. These axons synapse with dendrites of the large mitral cells of the olfactory glomeruli and each glomerulus receives axons from a wide area of the epithelium. There seems to be no functional grouping of axons. This arrangement allows a relatively small number of receptor cells to distinguish a large number of different odours. The axons of the mitral cells form the bulk of the olfactory tract but centrifugal axons of uncertain origin also pass to the olfactory bulb and undoubtedly modify activity in the olfactory glomeruli, perhaps having both inhibitory and facilitatory actions. The olfactory tracts pass posteriorly and slightly laterally crossing the floor of the anterior cranial fossa, the optic nerves and immediately above the optic chiasm. Just in front of the anterior perforated substance, each divides into medial, intermediate and lateral olfactory striae.

The termination of the medial striae is uncertain. Many fibres decussate to the opposite medial striae and these may become the centrifugal fibres of the opposite olfactory tract noted above, having facilitatory and inhibitory effects on the opposite olfactory bulb. The intermediate striae terminate in the olfactory tubercle but their further functional anatomy is unknown. The lateral olfactory striae synapse with neurons in the lateral anterior perforated substance, the lateral olfactory gyrus, the prepyriform cortex and the medial group of amygdaloid nuclei – the group of tissues that in humans represent the primary olfactory cortex. These are the only sensory pathways in humans that do not relay in the thalamus. The subsequent distribution via the limbic system then contributes to both pleasurable and unpleasant consequences of odour detection at conscious level and the appropriate

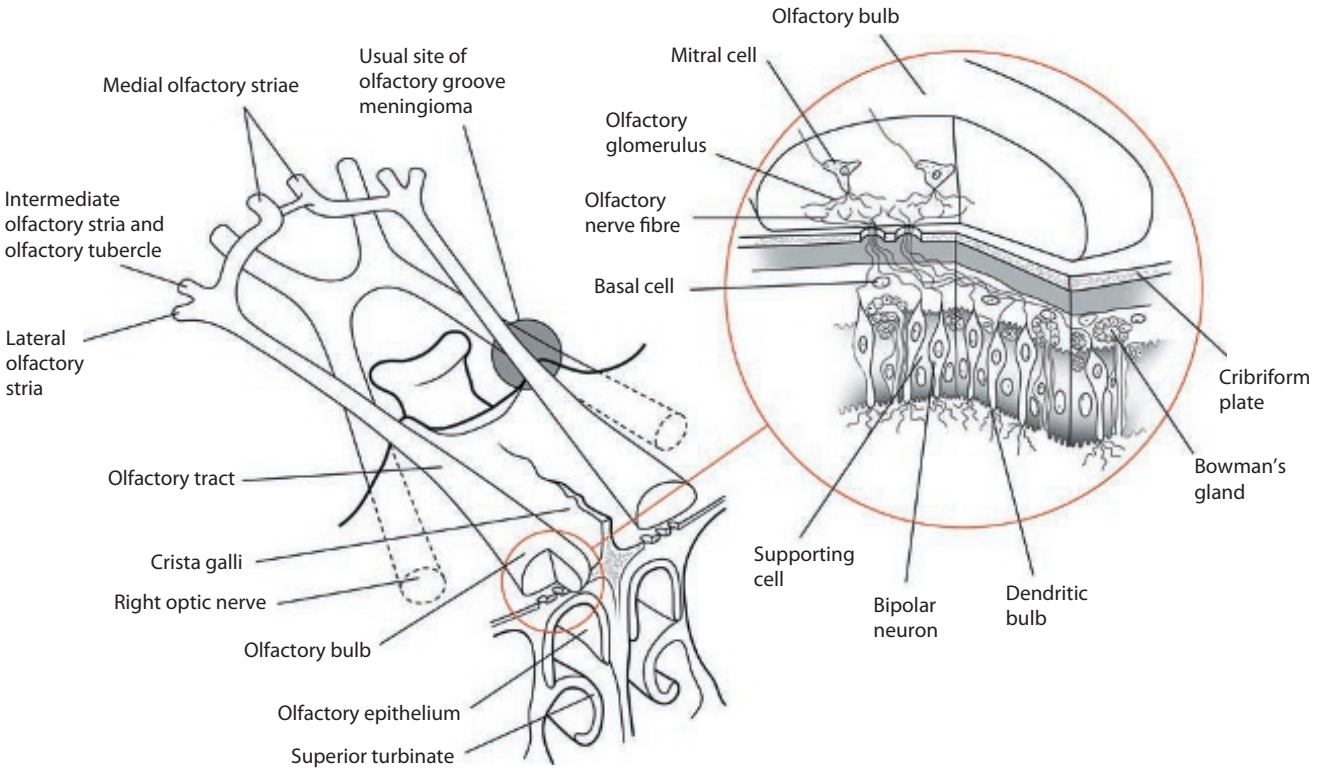

Figure 111.1 The olfactory pathways.

unconscious autonomic responses via the hypothalamus. This is related to activity in the secondary olfactory cortex located in the entorhinal complex, which includes the uncus and a tertiary olfactory cortex in the posterior orbitofrontal cortex. Descending pathways from these areas enter the pontine reticular formation in the brainstem and mediate reflex activity, such as salivation.[2]

There are also ascending projections from the midbrain raphé, the locus caeruleus and the midbrain tegmentum. These may well heighten olfaction in response to hunger and other emotional states, which emphasizes the role of olfaction in behavioural conditions, including sexual and maternal bonding, and in animals recognition of parent and offspring.[3]

PHYSIOLOGY

The receptor proteins lie in the olfactory cilia and it is likely that many different types of protein are involved. An odour must be volatile to enter the nasal cavity, actively sucked into the area of the olfactory epithelium by sniffing, which creates turbulent flow in the nasal passages, and lipid soluble to facilitate access to the fluid-bathed cilia.

Once stimulated, the resulting activity in the neuron is difficult to study. Attempts at single fibre analysis are technically almost impossible and such studies as are available demonstrate no similarities in evoked potentials from similar groups of substances or stimuli.

There is considerable evidence that some odours inhibit as well as excite and to this one must add an anatomical arrangement that allows not only local inhibition and excitation, but also crossed and possibly centrally mediated modulation by both lateral and negative feedback mechanisms. This permits humans to identify some 3000 different odours. The central pathways allow further discrimination and perhaps clarification of odour recognition. In contrast is the remarkable process of adaptation that allows continuous exposure to an unpleasant smell to diminish perception, so that the smell no longer registers. This phenomenon is interesting to consider in those patients who complain bitterly of a persistent unpleasant smell present 24 hours a day – a syndrome that commonly has a psychogenic basis, in striking contrast to patients with severe halitosis who are seemingly unaware of their problem. Further details on the physiology of the sense of smell are found in Volume 1, Chapters 89, Physiology of the nose and paranasal sinuses and 110, Abnormalities of smell.

APPLIED ANATOMY AND PHYSIOLOGY

Of obvious otolaryngological concern are simple mechanical factors interfering with access of the odour to the receptors, with simple airway obstruction, complicated by oedema or drying up of the mucosa as the most common causes of anosmia. Mechanical destruction or blockage of the nasal passages by pathology ranging from allergic rhinitis to complex vascular diseases, such as Wegener's granulomatosis, can occur. Simple polyps, nasal fractures and foreign bodies all have adverse effects on olfaction. Many drugs and generalized medical conditions that can damage or interfere with the function of a highly metabolically active tissue with a 30–50-day turnover rate, can also affect smell. These conditions include generalized metabolic disorders, such as renal failure and hepatic failure, and endocrine disorders, including diabetes, pregnancy and influenza.

Drugs affecting membrane moistness (antihistamines), cell turnover (antibiotics, antimetabolites) and cell function (anti-inflammatory agents, antithyroid drugs) may all affect both smell and taste adversely.[4]

Traumatic lesions of the olfactory fasciculi are usually caused by the shearing effect of brain movement when the head decelerates during a head injury. This complicates some 30% of serious head injuries particularly where immediate anteroposterior forces are applied to the head and a blow squarely on to the occiput is particularly likely to result in this complication. In such cases, little or no recovery can be anticipated. Severe injury of this type may actually tear the arachnoid cuffs and lead to cerebrospinal fluid (CSF) rhinorrhoea with a significant risk of subsequent meningitis.

There is circumstantial evidence that viral infections may gain access to the meninges via the same route in the absence of prior injury, *Herpes simplex encephalitis* being the most notable example. In this condition, the initial localization of the infection in the anterior temporal lobes adds support to this theory of aetiology, the virus presumably gaining access along the olfactory tract, possibly by axonal transport.[5] This is not the whole answer as in 25% of cases the virus isolated from the CSF is a different strain to that found in the oropharyngeal mucosa. Inside the skull, tumours of the olfactory groove, notably meningiomas, can cause unilateral anosmia, often unrecognized by the patient. Due to the local anatomy, progressive visual loss in the ipsilateral eye ensues – also often unrecognized by the patient. It is therefore very important to test the sense of smell in any patient with sudden loss of vision in one eye.

At central level, disorders of smell appreciation are not recognized, although behavioural, endocrinological and biochemical factors undoubtedly modify olfaction, as discussed above. Patients who complain of a continual bad smell are usually suffering from a depressive or psychotic illness. The most readily identifiable centrally based disorder of olfaction is found in uncinate epilepsy, in which an epileptic event originating in the medial temporal lobe is ushered in by the hallucination of an unpleasant smell (and occasionally taste). These olfactory hallucinations are characterized by being both unpleasant and of extremely short duration, usually only a matter of seconds, often insufficient to enable the patient to identify the odour as other than unpleasant – burning rubber or rotting rubbish being the most common descriptions volunteered.

Considerable degeneration of the olfactory glomeruli occurs with age, and olfaction is the first sensory modality to be significantly impaired by increasing age. This probably accounts for the decreasing appetite and loss of interest in food noted by the elderly with their definite tendency to over-season food.[6]

The optic nerve (II)

The orbit is entirely surrounded by structures of otolaryngological significance, only the lateral border being relatively spared from possible infection or invasive pathology other than that arising in the lacrimal gland. The frontal, ethmoid and maxillary sinuses and the lateral wall of the nose bound the orbit superiorly, medially and inferiorly, and are all prone to infection or malignant pathology.

The optic nerve enters the orbit through a tight bony canal, the optic foramen. The nerve is a direct extension of the brain and is invested with glial-derived tissue to the back of the globe, consisting of three membranes. The inner pial sheath invests the nerve and sends septae into the nerve itself, dividing the nerve into a bundle of fascicles. The intermediate arachnoid sheath is very delicate with a potential subarachnoid space inside and a subdural space outside. Both are covered by a thick extension of the dura, which merges with the sclera at the back of the globe. These membranes and enclosed spaces form a direct communication to the intracranial cavity and permit the direct transmission of raised intracranial pressure to the optic disc causing papilloedema, although the exact mechanism of the disc swelling remains uncertain, with venous compression almost certainly playing a major role.

The myelinated fibres of the optic nerve are derived from the rods and cones of the retina. As these cell processes form the most superficial layer of the retina, they are normally non-myelinated until they enter the optic disc. Occasionally, patches of persistent myelination of these fibres produce a characteristic white, fan-shaped lesion in the retina with an associated field defect, which remains unnoticed by the patient, in the same way that one is unaware of the normal blind spot. The most important papillomacular fibres conveying macular vision lie in the medial part of the nerve, only assuming their central position in the nerve as it reaches the optic foramen. In spite of this anatomy, extrinsic compression of the nerve in the orbit and the optic canal preferentially affects these papillomacular fibres, producing a central scotoma rather than a defect spreading in from the periphery, as might be anticipated on purely anatomical considerations (**Figure 111.2**).

There are 1.2 million nerve fibres in each optic nerve, just over half of which decussate in the optic chiasm. The fibres that cross are those derived from the nasal retina, conveying the temporal half field, entering the contralateral optic tract. The temporal half fibres (conveying the nasal field) pass straight into the ipsilateral optic tract.

Lesions within the orbit tend to produce mechanical displacement of the globe with consequent proptosis and diplopia. The optic nerve itself seems remarkably resistant to damage by pressure and displacement in the orbit, although an infective process may be more damaging by vascular mechanisms particularly venous thrombosis.[7, 8]

Lesions in the optic canal readily cause visual disturbance and a central scotoma is often the first evidence of a lesion at this site. This may be followed by extraocular nerve palsies and very much later, proptosis. Meningiomas or neurofibromas are the most frequent tumours arising in the posterior orbit. Neoplastic infiltration from the paranasal sinuses and nasopharynx can occur and metastatic spread from remote sites, such as the prostate in adult males or suprarenal gland in children, are well recognized. In general, the tempo of development of the signs and the presence or absence of pain will indicate the likely diagnosis.[9] The slow painless onset of symptoms usually indicates a benign lesion, while rapidly evolving symptoms, accompanied by pain, indicate a metabolic, neoplastic or infective process in the area.

Involvement of the optic nerve immediately behind the optic foramen can produce bilateral visual problems.

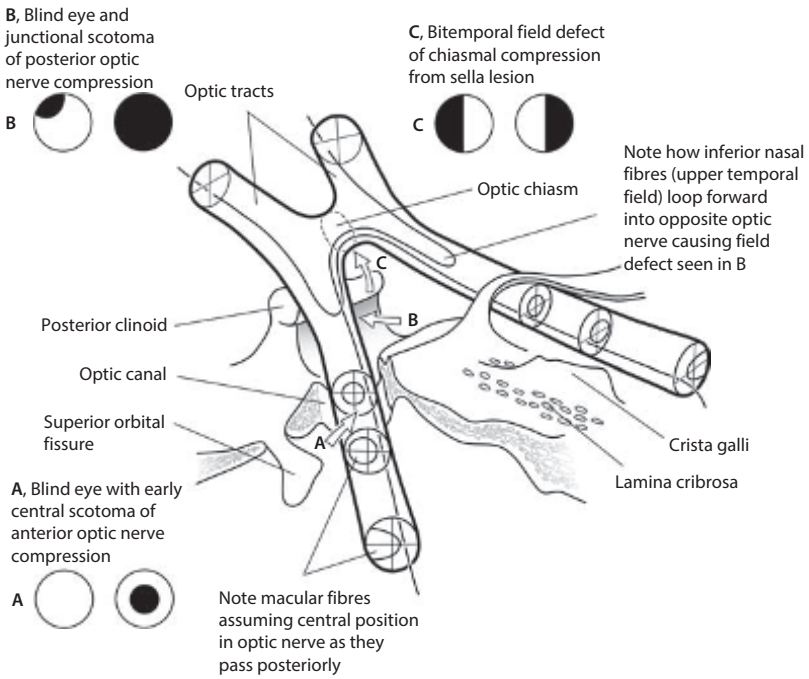

Figure 111.2 The visual pathways.

The inferior nasal fibres of the opposite optic nerve not only cross in the chiasm but also sweep forwards into the optic nerve before turning sharply to head posteriorly into the chiasm and optic tract. They can therefore be damaged by a lesion just anterior to the chiasm. A meningioma of the tuberculum sellae is the most likely lesion to be found at this site. This can produce a blind eye, an upper temporal field defect in the contralateral eye (called a junctional scotoma) and, if large, may cause loss of smell on the same side as the blind eye and eventually papilloedema in the opposite eye, the swelling in the blind eye being prevented by the compressing lesion. This constitutes the well known, but extremely rare, Foster–Kennedy syndrome.

The optic chiasm itself lies more posteriorly than is generally appreciated. It lies above and behind the pituitary gland, not on the sulcus chiasmaticus in front of the pituitary fossa of the skull. Pathological processes in the pituitary region include not only pituitary tumours but neoplasia arising in the ethmoid or sphenoid sinus, mucocoele of the sphenoid sinus and aneurysms arising from the circle of Willis or the great vessels themselves. The importance of excluding vascular anomalies or aneurysms before embarking on the transnasal approach to the pituitary fossa cannot be overemphasized. Lesions extending upwards from the pituitary, damage the underside of the chiasm anteriorly. This produces a bitemporal hemianopia, which starts in and spreads down from the upper temporal field (the lower fibres derived from lower retinal cells – therefore upper field). This field defect is rarely noticed by the patient at this early stage or indeed occasionally even when complete. When testing the temporal visual fields, particular attention should be paid to the upper temporal field to avoid missing a junctional scotoma (see 'Group 1' above and **Figure 111.2**) or the earliest signs of a developing bitemporal hemianopia. In contrast, lesions damaging the chiasm from above and behind tend to affect the lower fields first. These pathologies include craniopharyngiomas, hypothalamic tumours and a dilated third ventricle. Field defects in this area are much more readily identified by the patient as they intrude into all activities, especially reading and walking downstairs.

Because there are many situations in which visual acuity and the visual fields are of help in otolaryngological diagnosis, it is worth describing simple field examination at the bedside. Carefully examined fields, using a red and white hatpin, should be as accurate as screen testing and should only take a few minutes. The examiner should sit in front of the patient (in the traditional otolaryngological position) about 1 m from the patient. The patient should cover one eye. A white 5 mm hatpin, preferably mounted on the handle of a tendon hammer, should be brought into the patient's field of vision on four arcs, upper and lower temporal and upper and lower nasal, respectively. If all are seen at the periphery, no field cut is likely. The pin should then be brought across from the temporal field on the horizontal meridian, the patient keeping the examiner's pupil in view. The blind spot should be detected readily and can usually be compared with that of the examiner, both parties losing the object in the same area. Taking the pin across into the nasal field will detect any small scotoma as the pin will disappear again. The size and shape of the detected scotoma can then be explored and even a small scotoma can be easily confirmed by this technique. At a more sophisticated level, the very earliest evidence of a field defect can be found with the red pin. A 5 mm red pin is used. The visual field is smaller than with a white pin and for reasons that are not clear, the field defect accompanying pregeniculate optic pathway lesions affects red vision first. It is possible to detect a considerable loss of the red field before any intrusion into the white field is apparent. In the early stages, the red object may appear to change to brown or black, but care has to be taken not to confuse the normal loss of brightness of a red object as it passes into the temporal half field, as indicating an early field defect. Ultimately, of course, the red pin will not be detected at all in the affected area.

DIFFERENTIAL DIAGNOSIS OF THE PAINFUL RED EYE

Otolaryngologists are often consulted in cases where blurred vision and diplopia occur in the setting of an inflamed, proptosed eye and may even be the first opinion sought. It is therefore appropriate to consider this diagnostic situation in more detail.[10] Diagnosis falls into four main groups of disorders: inflammatory, vascular, infective and neoplastic.

Inflammatory causes

Acute thyroid exophthalmos

The eye is often injected with chemosis. Lid lag is especially noticeable on downward gaze. There may be diplopia simply due to globe displacement, but actual paralysis of the superior and lateral rectus muscles is a specific feature. In spite of its metabolic basis, the condition is usually unilateral. Vision may be threatened and acute high-dose steroids may be of value in treatment. A CT or MRI scan will usually show marked swelling of the extraocular muscles.

Pseudotumour of the orbit This is an immunologically based inflammatory disorder affecting all tissues in the orbit. It can complicate sarcoid, systemic lupus erythematosus, tuberculosis, Wegener's granulomatosis, polyarteritis nodosa or Tolosa–Hunt syndrome. Proptosis, pain and diplopia associated with a very high sedimentation rate might at first sight all seem to indicate infection. As steroids are indicated, urgent exclusion of infective disease in the paranasal sinuses is vital. CT or MRI scans show normal extraocular muscles in the midst of oedematous orbital contents and will exclude coexistent sinus infection. The condition occurs in two main age groups – between 10 and 30 years and the over 60s.

Vascular causes

Acute caroticocavernous fistula This condition usually follows known trauma with a skull base fracture. Occasionally, an aneurysmal dilatation of the carotid may

rupture into the cavernous sinus producing acute pulsating exophthalmus with marked arterial pulsation visible in the fundal veins. Carotid ligation or embolization is the procedure of choice.

Cavernous haemangioma This condition causes a gradually increasing degree of exophthalmus with proptosis aggravated by bending or straining. There is usually no diplopia or field defect and little pain. The acute proptosis on bending is both dramatic and diagnostic.

Infective causes

Local infections can readily spread into the orbit. Small boils on the nose, eyelids or face in the preantibiotic era had lethal potential and even now are extremely dangerous in diabetics and patients with impaired immunity. Paranasal sinus infection, especially of the ethmoids, can easily extend directly into the orbit. Frontal sinusitis may cause oedema of the eyelid and ptosis. In the diabetic patient, fungal infections, particularly mucormycosis, are a specific problem. The first vesicles of the viral infection *Herpes zoster ophthalmicus* usually erupt in the eyebrow after several days of severe pain and an acute red eye with eyelid oedema is often mistaken for bacterial infection until the vesicles appear.

Neoplastic causes

Any primary or secondary neoplasm may involve the orbit, by direct extension or from remote sites. Chemosis and injection may be minimal. In the elderly, pseudotumour of the orbit can be a presenting symptom of lymphoma and, as always, the importance of a general physical examination must be emphasized, in spite of such a local presentation.

The benign primary orbital tumours most often seen include lipomas, angiomas and haemangiomas. Less frequently, fibromas, myxomas and leiomyomas may be encountered.

Primary malignant orbital tumours are usually rhabdomyosarcomas that are locally invasive and usually occur in childhood. Rarely, fibrosarcoma, myxosarcoma, liposarcoma, chondrosarcoma, osteogenic sarcoma and haemangioendotheliomas may occur. Lacrimal gland tumours of variable malignancy occur and tend to be locally invasive through the roof of the orbit into the intracranial cavity.

Metastatic tumours in the orbit are secondary to carcinoma of the breast in 50% of cases. Tumours originating in the lung and kidney account for the rest. Malignant melanoma has been reported but is hard to distinguish from a primary melanoma of the ciliary body or retina. In children with neuroblastoma, orbital metastases occur in 20–50% of cases.[11]

PUPILLARY ABNORMALITIES

As the main determinant of pupil size is the incident light, it is appropriate to discuss the major pupillary abnormalities at this stage.

In a blind eye, assuming that the cause of the blindness has not simultaneously damaged the iris mechanism, the pupil will dilate or constrict in proportion to the light falling on the unaffected eye. The direct light reaction will be absent, but the consensual light reflex from the opposite eye will be intact. No consensual reflex in the normal eye will be seen when the affected eye is illuminated. This is a useful check for suspected non-organic visual loss in one eye.

In acute retrobulbar neuritis, which presents as sudden impaired central vision in one eye, the pupil reaction may be sluggish and the pupil may dilate after initial constriction in spite of a constant light source being maintained (pupillary escape phenomenon). In a patient with eye pain, aggravated by movement with blurred vision, this Marcus–Gunn pupil reaction is strongly indicative of demyelinating disease. The postulated mechanism is a decrease in the number of fibres conveying light sensation.

In IIIrd nerve lesions, damage to the efferent pupilloconstrictor fibres produces a fixed dilated pupil even though the patient perceives light normally. Incomplete lesions may merely cause a slightly dilated pupil with a sluggish reaction – an important stage in the evolution of a IIIrd nerve palsy in a patient who is deteriorating following a head injury. A useful clue in a conscious patient developing a IIIrd nerve lesion is the almost invariable accompanying ptosis. This may be followed by diplopia due to paralysis of the superior rectus muscle (see 'The oculomotor nerve (III)' below). Argyll Robertson pupils due to meningovascular syphilis have become a great rarity. This is a small pupil, usually irregular, that does not react to light but reacts normally to accommodation.[12]

A sympathetic nerve lesion (Horner syndrome) will be detected by only the most alert clinician. Due to loss of the less important pupillodilator fibres, the pupil is slightly smaller with a normal light reaction because the light reflex pathway mechanisms are unaffected. A slight and variable degree of ptosis will occur, which rarely droops lower than the edge of the pupil. As the cervical sympathetic pathway courses in and out of otolaryngological territory, a full understanding of the syndrome is essential to the otolaryngologist (see also 'Group 3' below, and **Figure 111.16** under 'The cervical sympathetic' below).[13]

A Holmes–Adie (myotonic) pupil may present as a painful eye as the affected pupil fails to constrict in bright light. The affected pupil may be larger or smaller than the other, depending on the incident light, which produces either a slower constriction or slower dilatation than in the unaffected eye. The light reaction is a very slow, with definite constriction followed by a slow dilatation. This slow myotonic reaction is often best demonstrated by maintained forced convergence for about one minute, which is a much stronger stimulus to pupil constriction. Alternatively, if the patient sits in a dark room, the pupil will become very large, but if they have just come into the clinic from a sunlit room, at first the affected pupil may be smaller than the normal pupil.[14] Vision will be blurred when the pupil is large as close focusing is impossible.

The nerve supply to the extraocular muscles

The three nerves supplying the extraocular muscles and controlling eye movements have complex central control mechanisms and peripheral courses that render them vulnerable both individually and as a group, to a wide range of surgical and medical disorders. They are of special interest to otolaryngologists because of their involvement in local neoplastic disease and in infective processes originating in the paranasal sinuses, nose and nasopharynx.

The oculomotor nerve (III)

The IIIrd nerve exits from the brainstem in the interpeduncular fossa and runs forwards, laterally and slightly downwards in the subarachnoid space towards the roof of the cavernous sinus (**Figures 111.3**, **111.4** and **111.5(a)**). In its distal subarachnoid course, it runs parallel to the posterior communicating artery, hence its unique vulnerability to damage by aneurysms, which commonly arise at either end of this short vessel. It enters the roof and then the lateral wall of the cavernous sinus in between the two layers of dura, dividing into two branches before it enters the superior orbital fissure. In the wall of the sinus it picks up sympathetic fibres from the sympathetic plexus on the carotid artery and additional parasympathetic fibres from the ophthalmic division of the Vth nerve.

The superior ramus supplies the levator palpebrae superioris and the superior rectus muscle. The inferior ramus supplies the medial and inferior recti, the inferior oblique and carries the sympathetic and parasympathetic elements to the ciliary ganglion via the branch to the inferior oblique.

The anatomy of the pupillary fibres within the nerve is of great significance. The fibres at first lie dorsolaterally, then medially and finally inferiorly, but always in the periphery of the nerve. Their blood supply is derived from the pial plexus on the surface of the nerve, while the core of the nerve is supplied by a vasa nervorum. If this latter vessel is occluded by vascular disease (diabetes, arteriosclerosis, arteritis), the pupillary fibres lying peripherally are usually spared. Conversely, if the nerve is damaged by an external compressive surgical lesion (aneurysm, tumour, abscess), the peripheral pupillary fibres are those most easily affected. In a patient who has a IIIrd nerve lesion, the involvement or otherwise of the pupil is a major diagnostic pointer. Furthermore, pain tends to be a feature of surgical lesions, so the painful onset of a IIIrd nerve lesion with pupil involvement is almost certain to indicate a compressive lesion. The absence of pain and a spared pupil is almost certain to indicate a medical cause.[15] The major exception to these generalizations is that a lesion due to diabetes can be both painful and involve the pupil, mimicking a surgical lesion. A serum glucose estimation can be a very inexpensive way of resolving this dilemma.

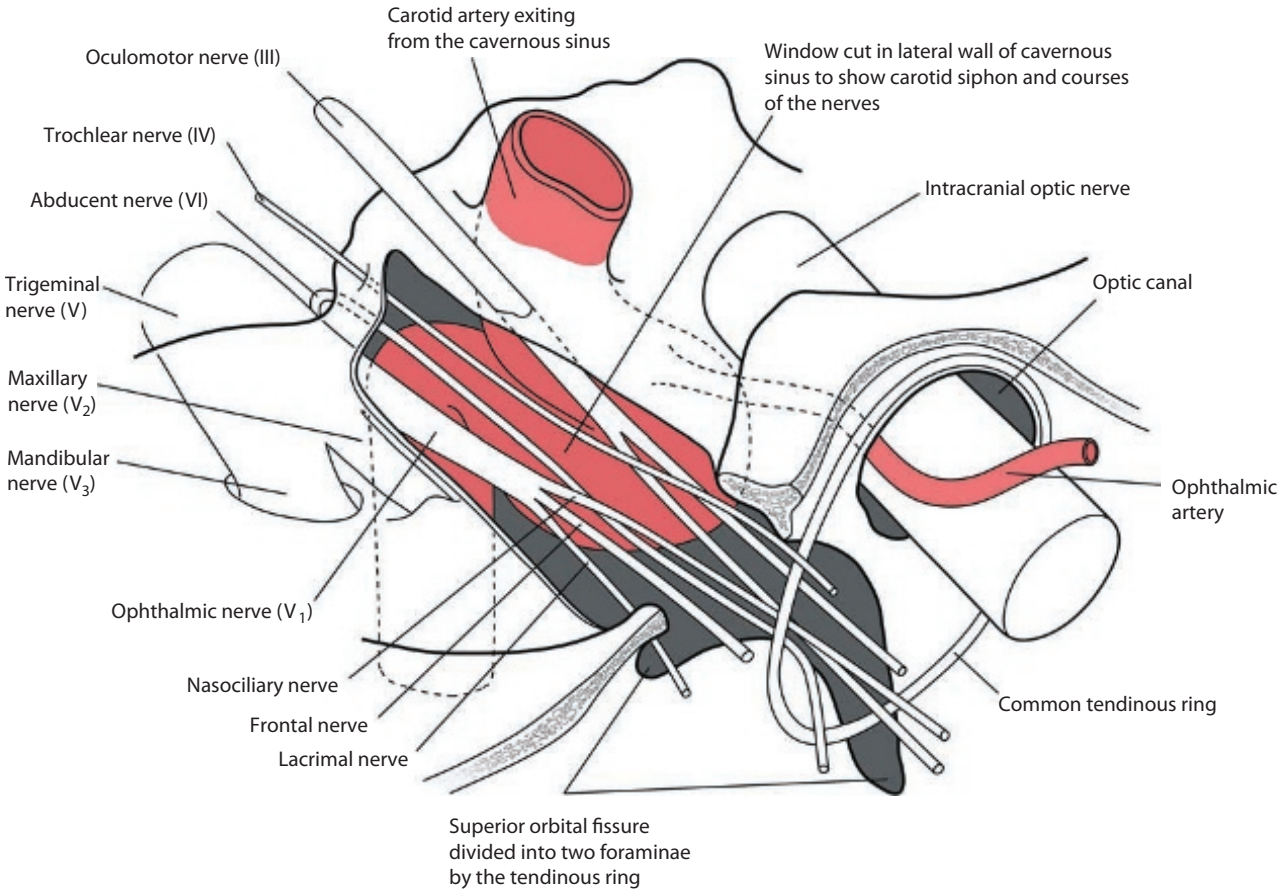

Figure 111.3 The cavernous sinus and orbital foramina.

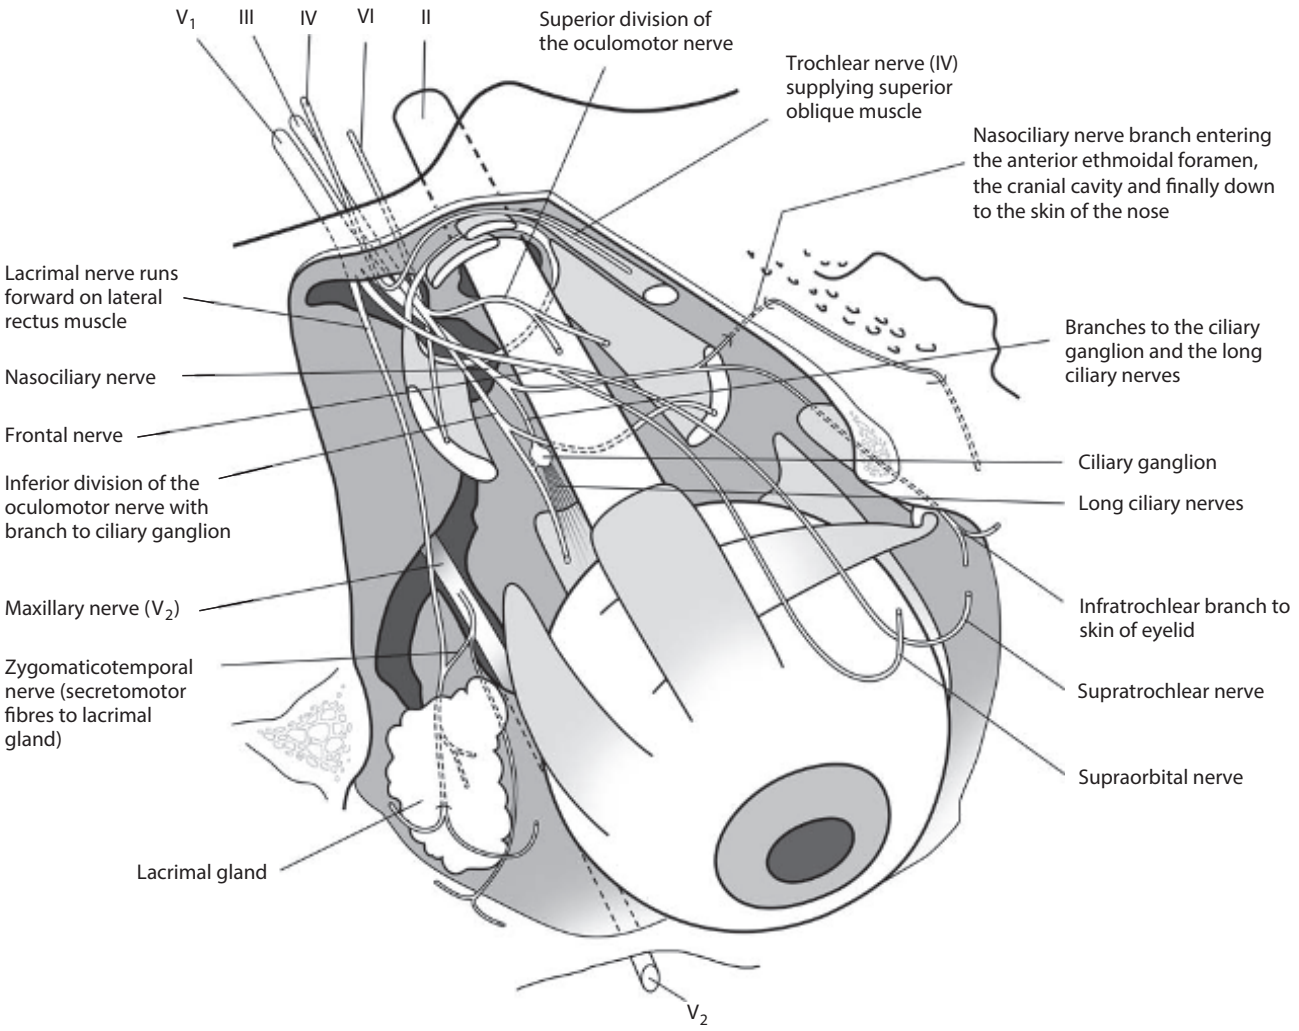

Figure 111.4 The orbital contents (right orbit from above and lateral).

CENTRAL ANATOMY

The detailed anatomical features of the oculomotor nucleus are beyond the scope of the present text. Briefly, the nucleus is shaped like an inverted V, straddling the midline (see **Figure 111.5(a)**). The lateral nuclear columns supply the eyelid and the four extraocular muscles, the superior, medial and inferior rectus and the inferior oblique. The midline nuclei have mainly parasympathetic function especially the upper midline Edinger–Westphal nucleus, which is the main central control mechanism for pupil size. The fascicles of the IIIrd nerve fan out, course towards the anterior midbrain traversing the red nucleus and the substantia nigra, converging to form the main nerve trunk, which emerges just lateral to the midline in the interpeduncular fossa.

The trochlear nerve (IV)

The IVth cranial nerve is unique in several ways. It arises in the dorsal aspect of the brainstem at the level of the inferior colliculus. It then decussates within the superior medullary velum so that the right nucleus supplies the left superior oblique muscle and vice versa (see **Figures 111.4** and **111.5(b)**). It also has the longest intracranial course and is very slender, properties that possibly protect it from damage by extrinsic pressure around the brainstem and in the subarachnoid space. It enters the wall of the cavernous sinus beneath the IIIrd nerve, but crosses it to reach a higher position as it enters the superior orbital fissure to supply the superior oblique muscle. The nerve is rarely damaged in isolation in cavernous sinus lesions, the IIIrd and VIth nerves being much more vulnerable. A vascular lesion of the nerve due to diabetes is the most common cause. Of particular importance to the otolaryngologist is the small fibrocartilaginous loop attached to the trochlear fossa in the upper medial orbit through which the muscle tendon loops. Accidental or surgical trauma in this region may easily damage the tendon interfering with the action of the superior oblique muscle, mimicking a IVth nerve palsy.[16]

The abducent nerve (VI)

The VIth nerve exits from the brainstem anteriorly at the pontomedullary junction (see **Figures 111.3**, **111.4** and **111.5(c)**).

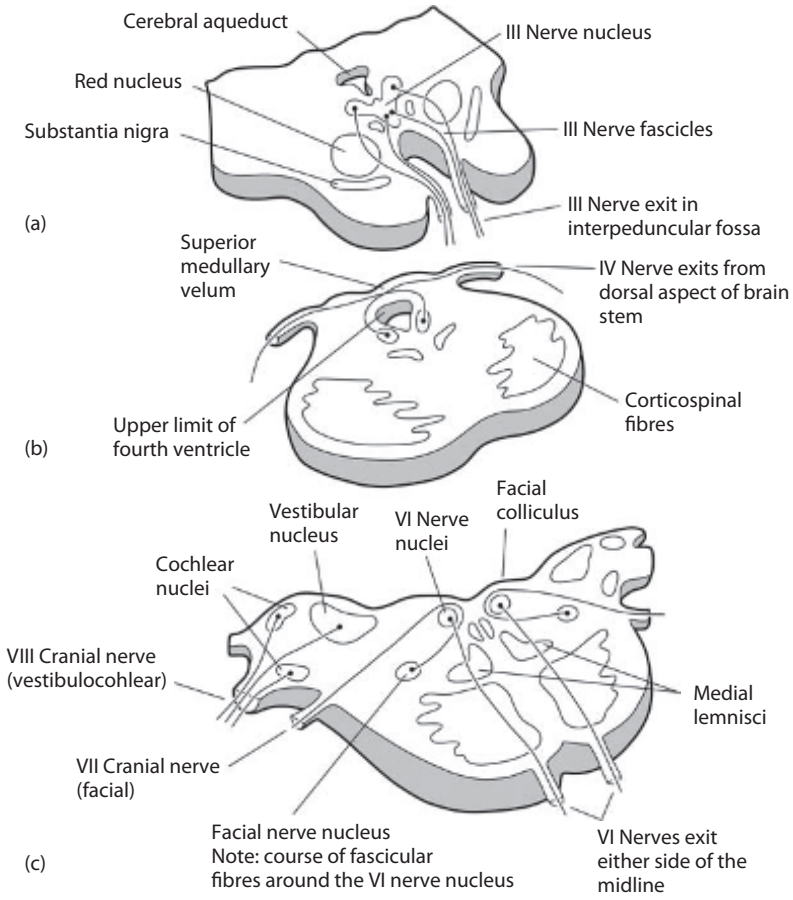

Figure 111.5 Brainstem connections of the extraocular nerves.

It is the most medial of the three nerves which exit from this groove, and ascends on the front of the pons before it angles forwards across the tip of the petrous bone to enter the bottom of the cavernous sinus in which it lies free, in close relationship to the intracavernous portion of the carotid artery. This long subarachnoid and meningeal course adjacent to the meninges renders this nerve particularly liable to damage in acute and chronic meningitis or any other meningeal process. This notably includes the remote or direct spread of malignant disease. The angulated entry into the cavernous sinus renders it vulnerable to stretch when the brainstem is pushed downwards by raised supratentorial pressure, causing the classical false localizing VIth nerve palsy, which may ultimately become bilateral if unrecognized. The nerve may become involved in inflammation of the petrous bone, secondary to otitis media. This may be combined with severe pain in the Vth nerve territory and loss of hearing, which is Gradenigo's syndrome. Inflammatory disease in the cavernous sinus and aneurysmal dilatation of the carotid siphon within the cavernous sinus are particularly likely to involve the VIth nerve, the IIIrd and IVth being involved later by the same process. Nerve trunk infarction secondary to diabetes, arteritis and arteriosclerosis occurs exactly as for the IIIrd and IVth nerves discussed above. Intracranially, both cholesteatomas and vestibular schwannoma could involve the nerve, but such involvement is surprisingly rare. As it enters the orbit it passes laterally to reach its single supplied muscle, the lateral rectus (see **Figure 111.3**). At this point it is particularly liable to damage by carcinoma infiltrating the orbit through the inferior orbital fissure from the nasopharynx.[17]

CENTRAL ANATOMY

The nucleus of the VIth nerve lies in the floor of the IVth ventricle just lateral to the midline (see **Figure 111.5(c)**). The fibres of the facial nerve sweep round it. Although derived from the same nuclear column as the IIIrd and IVth nerve nuclei, it migrates downwards during the massive developmental enlargement of the pons, but remains intimately linked to the other nuclei by the medial longitudinal bundle (see 'Central mechanisms of nerves III, IV and VI' below). The fascicles of the VIth nerve have to traverse the whole depth of the pons to reach their point of emergence at the pontomedullary junction. In its fascicular course, it lies in close relationship to the ascending medial lemniscus and the descending corticospinal pathways.

CENTRAL MECHANISMS OF NERVES III, IV AND VI

The central control mechanisms for eye movement comprise a complex group of pathways that adjust eye position to movement and posture, mainly under the influence of vestibular and extrapyramidal pathways (**Figure 111.6**).

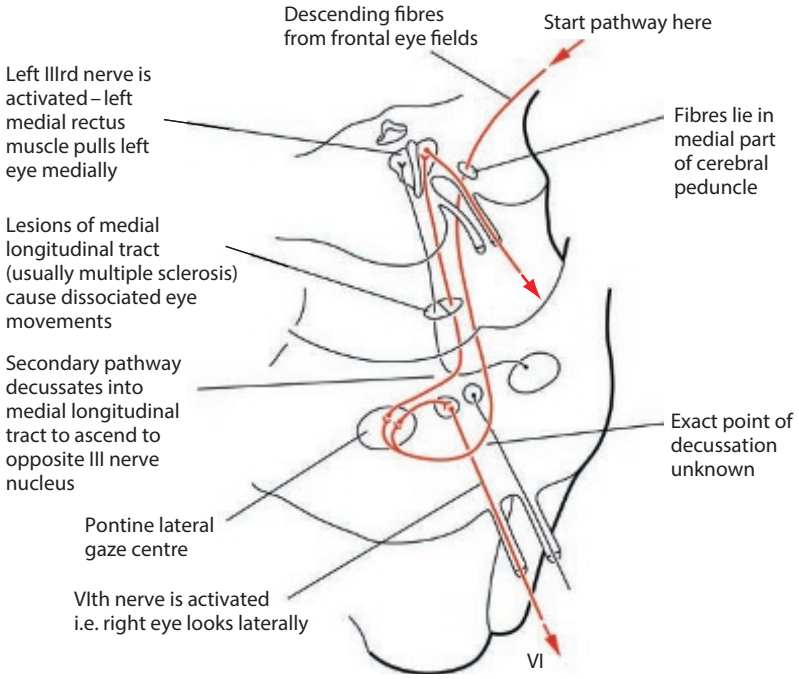

Figure 111.6 The internuclear pathways. Pathway shown moves both eyes to the right side.

There are two forms of voluntarily controlled eye movement:

1. Visual pursuit, where a specific target is fixed and followed, using parietal gaze centres closely integrated with the adjacent visual cortex
2. The ability to select a new target and relocate vision to suit, via frontal gaze centres utilizing direct voluntary pyramidal motor pathway mechanisms.

Damage in either of these areas will cause a conjugate gaze palsy, but because the range of movement of both eyes is identically affected, there is no diplopia. At brainstem level, the need to integrate eye movements controlled by three different cranial nerve nuclei widely spaced in the brainstem requires complex and extremely rapidly conducting internuclear pathways. The most critical of these is the medial longitudinal fasciculus. Damage in this pathway causes internuclear ophthalmoplegias, with disconjugate gaze palsies. These will always cause diplopia as the eyes then move independently.

The cortical influences have final relays in the brainstem in the pons bilaterally, the lateral gaze centres. There are also four gaze centres in the midbrain, two on each side, one to look up and one to look down. Eye movements occur in saccades, a series of little jerk movements without over- or undershoot, until the new position is reached. This is achieved by rapid bursts at 1000 cycles per second by cells in the gaze centres. These bursts are initiated by voluntary information from the frontal eye fields through the anterior limb of the internal capsule. Automatic movements as required in reading are controlled by visual information carried through the optic tract without projection to the visual cortex. Feedback from stretch receptors in the ocular muscles is also of great importance in this type of movement. Tracking movements are integrated in the superior colliculi, once the object to be followed has been located, using stereooptic control.

Vergence mechanisms require the voluntary frontal eye fields to work in conjunction with the parietal cortex simultaneously inhibiting those brainstem mechanisms that normally prevent convergence and divergence. Only animals with binocular stereoscopic vision have the need to converge to focus close objects.

PARIETAL LOBE LESIONS

Poor object following or pursuit gaze problems are often difficult to demonstrate clinically as lesions in these areas also tend to cause a hemianopic field defect, so that the following movement ceases as the object moves into the blind half-field. If, however, the examiner is careful to keep the object in the patient's retained field of vision, a full range of pursuit movement should be achieved if there is no gaze palsy. A tendency to ignore objects on one side in the absence of a hemianopia (an attention field defect) may be related to the inability of the eye to scan peripherally due to lack of visual input.

FRONTAL LOBE LESIONS

An active irritative lesion, such as a tumour or abscess in the frontal pole, will drive the eyes away from the lesion. A right frontal tumour may cause focal epileptic fits preceded by movement of the head and eyes to the left hand side before the patient loses consciousness. An inactive destructive lesion, such as surgical extirpation or a cerebrovascular accident, will permit the eyes to gaze preferentially towards the side of the lesion, due to the unopposed push from the intact side. This phenomenon is most readily seen in a drowsy, anaesthetized or unconscious patient.

MIDBRAIN LESIONS

Midbrain visual mechanisms are mainly concerned with up and down gaze. The classical lesion causing Parinaud's syndrome is a pineal tumour damaging the superior colliculus and the region of the posterior commissure. A lesion here blocks the light reflex relays, producing fixed dilated pupils, impairs upward gaze and causes loss of convergence.

Conversely, lesions of the inferior colliculus will impair downward gaze only. In some instances, the ineffective movements of the extraocular muscles attempting to produce up or down gaze may pull the eyeball in and out of the socket, resulting in the very rare phenomenon known as retractory nystagmus.

Lesions affecting the thalamic nuclei, either structural or pharmacological, may cause fixed deviations of up or down gaze. In patients with postencephalitic Parkinson's disease, episodes known as an oculogyric crisis were a classic feature. This can still be seen in some patients provoked by phenothiazine hypersensitivity, usually young females. Thalamic lesions may cause complex eye movement disorders with divergence with one eye up and one eye down (skew deviation) and see-saw nystagmus on attempted lateral eye movement. A midline haemorrhage between the IIIrd nerve nuclei or acute multiple sclerosis in the same area can produce a divergent squint with both eyes at the extremes of lateral gaze with retained up and down gaze limited only by the mechanical factors operating at this extreme position.

DISORDERS AFFECTING THE MIDBRAIN

Anteriorly, aneurysms of the upper basilar artery or a tortuous basilar artery (basilar ectasia) may damage and distort the emergent IIIrd nerves. Posteriorly, pineal tumours or distortion and dilatation of the posterior end of the IIIrd ventricle due to aqueduct stenosis may cause Parinaud's syndrome. Infiltration of the superior medullary velum by direct spread of a medulloblastoma may cause bilateral IVth nerve lesions and impaired down gaze. Intrinsic lesions due to vascular occlusion, haemorrhage, demyelinating disease and tumour, may all cause an anterior internuclear ophthalmoplegia (i.e. a divergent squint with loss of convergence but preserved up and down gaze).

There are three named vascular syndromes of the midbrain due to combinations of IIIrd nerve lesions and local pathway damage:

1. **Nothnagel's syndrome**: a IIIrd nerve lesion with ipsilateral ataxia due to infarction of the superior cerebellar peduncle
2. **Benedikt's syndrome**: a IIIrd nerve lesion with contralateral cerebellar movement disorder due to a lesion of the red nucleus
3. **Weber's syndrome**: a IIIrd nerve lesion with contralateral hemiparesis due to a lesion of the basis pedunculi.

These syndromes have become extremely rare with the demise of meningovascular syphilis, but are still occasionally encountered in patients with small vessel disease (diabetes, cranial arteritis, lupus erythematosus, polyarteritis nodosa, polycythaemia rubra vera, etc.). Unfortunately, the resurgence of sexually transmitted disease means that these classical syndromes should not yet be consigned to history.

PONTINE LESIONS

The pontine lateral gaze centres are often damaged by vascular lesions and demyelinating disease. This results in loss of gaze to the same side as the lesion, as the descending pathways have already decussated. In a drowsy or unconscious patient, this will result in the eyes deviating towards the unaffected side.

DISORDERS AFFECTING THE PONS

Anteriorly, the VIth nerves are often involved in bacterial, fungal or malignant meningitis due to their long meningeal course. Pontine tumours may involve the nerve nuclei or fascicular fibres and the posterior internuclear pathways. These tumours usually occur in children or adults with neurofibromatosis. Tumours blocking or infiltrating the IVth ventricle cause headache and vomiting due to CSF pathway block and VIth nerve palsies, due to stretching of the nerves by raised intracranial pressure. If the VIth nerve palsy is due to direct tumour infiltration, the VIIth nerve should also be involved, as the VIIth nerve fibres encircle the nucleus. These tumours include ependymoma, medulloblastoma, cerebellar astrocytoma or haemangioblastoma. Multiple sclerosis, haemorrhage and infarction, metabolic disorders (vitamin B deficiency), drug intoxication, fluid balance disturbance, viral infection and *Listeria monocytogenes* infection of the brainstem may all cause conjugate gaze palsies if the damage is in the lateral pons or an internuclear ophthalmoplegia with nystagmus, if the lesion is in the central pons. Vascular occlusive lesions cause strictly unilateral internuclear ophthalmoplegia as the lesion extends only to the midline. There are numerous named vascular syndromes of the pons due to a variety of combinations of damage to the nuclei of nerves VI and VII and their fascicles and the sensory, motor and cerebellar pathways. There is no special advantage in learning these by heart, but the named syndromes include those of Millard–Gubler, Foville, Grenet, Raymond-Céstan, Marie-Foix and Gasperini.[18] As a cautionary note, any hint of variability in diplopia should always raise the possibility of ocular myasthenia gravis. If combined with variable dysarthria or intermittent swallowing difficulty, a brainstem lesion may be incorrectly suspected. This is a very difficult diagnostic trap into which even experienced neurologists may fall.

INTERNUCLEAR LESIONS

Internuclear lesions are typically caused by multiple sclerosis (bilateral) or vascular disease (strictly unilateral unless haemorrhagic) (see **Figure 111.6**). In these instances, the lateral gaze centre is intact and abducts the ipsilateral eye normally. It is the relay to the opposite IIIrd nerve nucleus

that is blocked and the eye that should adduct in unison fails to move beyond the midline. If the lesion is bilateral, neither eye adducts, while the abducting eye moves normally and the mobile eye shows marked nystagmus at full abduction. This syndrome is almost diagnostic of multiple sclerosis. The integrity of the upper brainstem in such cases can be readily demonstrated by intact vertical gaze and convergence.

NYSTAGMUS

Nystagmus is covered in detail in Chapter 49, Physiology of equilibrium; and Chapter 62, Evaluation of balance. From a simplistic neurological point of view, it is a less valuable physical sign than is often thought.

The distinction into the different types (jerk, pendular, rotatory, etc.) is often less easy to make than is suggested in most descriptions. Ultimately, one is seeing the effect of a breakdown in the vestibular mechanisms as they affect the smoothness and stability of eye movements. Weak support from vestibular mechanisms will lead to poor maintenance of gaze (slow phase) and a quick restorative movement (the jerk phase), which is the feature used to define the direction of nystagmus. This is maximal when looking away from the side of a vestibular lesion, be it in the end organ, VIIIth nerve or vestibular nuclear connections.

The controlling influence over vertical eye movements also becomes apparent in the phenomenon of vertical nystagmus, which occurs with structural or metabolic lesions of the brainstem. It is important to note that vertical nystagmus means vertical displacement of the eyes, not side-to-side nystagmus when attempting upward or downward gaze. As defined, vertical nystagmus always indicates brainstem dysfunction.

Another feature of brainstem disease is jelly nystagmus, which is probably due to failure of inhibitory 'pause' neurons, which normally stop the 'burst' neurons from producing visible little saccades. In this condition, the eyes wobble with no clear-cut fast or slow component. Congenital nystagmus produces a similar type of nystagmus – the diagnostic feature being that the patient is quite unaware of it in spite of very dramatic wide amplitude nystagmus.

Cerebellar lesions, especially those affecting the flocculonodular lobes, result in nystagmus due to the loss of the stabilizing effect of input from head posture receptors. In general, the fast and therefore most readily observed phase of cerebellar nystagmus is towards the side of a cerebellar lesion.

GROUP 2

The second major grouping of cranial nerves comprises those lying in the cerebellopontine angle. The medial extent of the angle is defined by the VIth nerve, the upper extent by the Vth nerve and the lower extent by the IXth nerve. The VIIth and VIIIth nerves pass in close proximity across the subarachnoid space to enter the internal auditory canal at the start of their long intraosseous courses.

The trigeminal nerve (V)

The trigeminal nerve is the largest cranial nerve and arises from the middle of the lateral side of the pons and passes forwards and laterally across the subarachnoid space. Its large ganglion lies over the tip of the petrous bone where the nerve divides into its three divisions.

The opthalmic nerve (V_1)

The first division of the Vth nerve lies below the VIth nerve in the lateral wall of the cavernous sinus (see **Figures 111.3** and **111.4**) and is prone to damage by the same pathologies that cause extraocular nerve palsies (see above). Due to its extensive sensory distribution, severe pain in the eye, forehead, nose and scalp, extending back as far as the vertex, may result from such damage. The nerve divides into three branches as it enters the superior orbital fissure:

1. The lacrimal nerve runs along the lateral rectus muscle to supply the lacrimal gland. It also supplies the skin over the lateral eyelid and brow. It picks up secretomotor fibres from the zygomaticotemporal nerve, which it conveys to the lacrimal gland. In the skin, it receives proprioceptive filaments from the facial nerve.
2. The frontal nerve divides into two, the supratrochlear and supraorbital nerves, which supply the skin of the forehead and scalp to the vertex. They are prone to damage by minor injuries over the brow and a causalgic syndrome may follow local trauma.
3. The nasociliary nerve has important autonomic and cutaneous functions:
   a. The main trunk traverses the orbit and enters the anterior ethmoidal foramen into the intracranial cavity, runs forwards across the cribriform plate and exits the skull through a slit in the crista galli to enter the nose. It supplies the mucosa of the nasal cavity and emerges at the lower end of the nasal bone to supply the skin over the tip of the nose, alar and vestibule.
   b. In the orbit, the nasociliary nerve gives off branches to the ciliary ganglion and two or three long ciliary nerves which carry the pupillodilator sympathetic fibres and convey sensation from the cornea. This is of cardinal importance for the protection of the very delicate cornea.
   c. The infratrochlear branch is given off just behind the anterior ethmoidal foramen and lies on the medial wall of the orbit and supplies the skin of the upper medial eyelid and upper side of the nose.

THE CORNEAL REFLEX

It is essential that otolaryngologists know how to elicit this reflex correctly. The afferent limb of the reflex is via the nasociliary nerve, as above, and the efferent limb is via the facial nerve. A pointed wisp of cotton wool should be used. The examiner should ask the patient to look upwards, then, resting the hand on the patient's cheek, the wisp should be applied to the lower cornea but taking

care not to bring it into vision or a blink reflex will result. The patient will flinch, the eyeball will roll up and the eye will attempt to close. Even if the VIIth nerve is paralyzed, the eyeball will roll up and the discomfort will be felt. The opposite eyelid will also close as this is a consensual reflex. Absence of the corneal reflex is often the first clinical evidence of Vth nerve damage and should be tested obsessionally in any patient presenting with symptoms of vertigo, deafness or facial pain.

The maxillary nerve (V_2)

The middle branch of the Vth nerve ganglion lies in the extreme lower lateral wall of the cavernous sinus and exits via the foramen rotundum, passes through the pterygopalatine fossa and enters the floor of the orbit via the inferior orbital fissure (**Figure 111.7**). At first, it lies in a groove in the orbital floor and then enters the short canal and exits on to the face via the infraorbital foramen. It supplies the skin of the cheek, midlateral nose and lateral part of the alar, lower eyelid and the mucous membrane of the cheek and upper lip. In its course, it gives off the following branches:

1. Meningeal branches to the floor of the middle cranial fossa
2. Two branches to the sphenopalatine ganglion, conveying the secretomotor fibres destined for the lacrimal gland
3. The zygomatic nerve, which lies on the floor of the orbit, dividing into the zygomaticotemporal nerve (secretomotor to the lacrimal gland and carrying cutaneous sensation from the temporal area) and the zygomaticofacial nerve which, after penetrating the zygomatic bone, carries cutaneous sensation from the prominence of the cheek
4. The three alveolar nerves convey sensation from the teeth, gums and adjacent palate via the superior

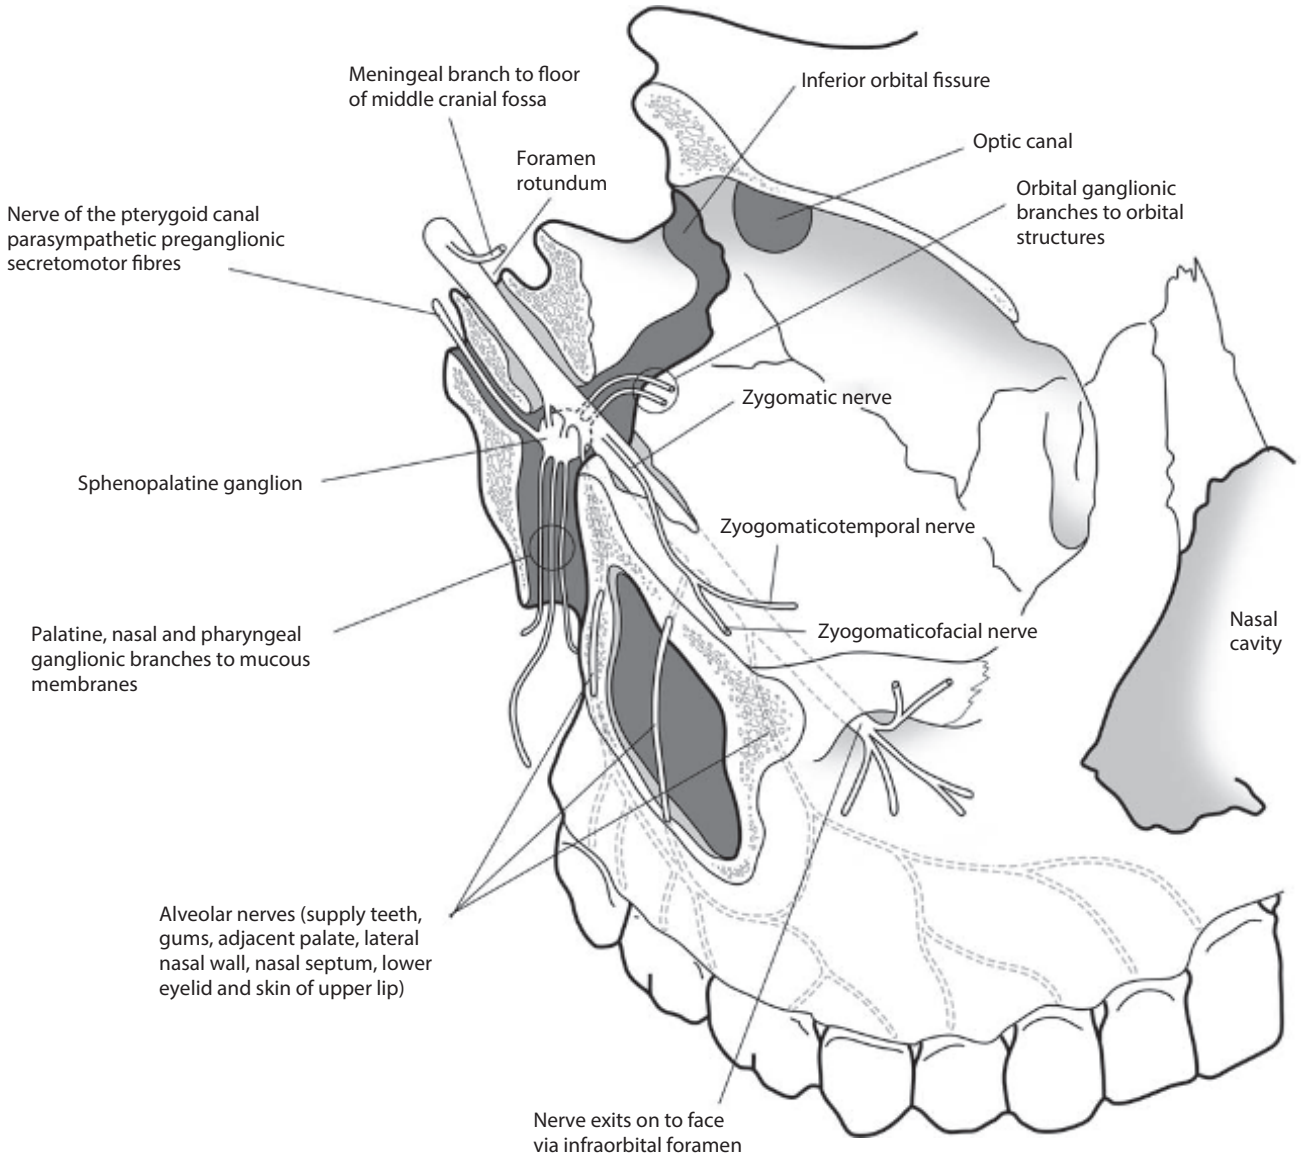

Figure 111.7 The maxillary nerve (V_2).

dental plexus. The anterior superior branch is the largest and supplies not only the incisor and canine teeth, but also the lateral nasal wall, nasal septum, the lower eyelid and the skin of the upper lip.

THE PTERYGOPALATINE (SPHENOPALATINE) GANGLION

This very large ganglion is suspended from the maxillary division, deep in the pterygopalatine fossa. It receives its main contribution from the nerve of the pterygoid canal. This carries preganglionic, parasympathetic fibres derived from the pontine lacrimatory nucleus via the nervus intermedius (VIIth nerve) and sympathetic elements derived from fibres on the middle meningeal artery. Both groups of fibres are then relayed via their subsequent complex course to the lacrimal gland in the lacrimal branch of the nasociliary nerve. The main outflow of the ganglion is via the orbital, palatine, nasal and pharyngeal nerves to the mucous membranes of the orbit, nasal passages, pharynx, palate and upper gums.

The mandibular nerve (V_3)

This is the largest branch of the Vth nerve and includes the motor branch. It exits from the skull base through the foramen ovale, the main sensory trunk being joined by the much smaller motor root, in Meckel's cave, just outside the skull (Figure 111.8). A meningeal branch re-enters the skull with the middle meningeal artery through the foramen spinosum and conveys sensation from the lateral, middle and anterior cranial fossae. A small branch, the nerve to the medial pterygoid, supplies medial pterygoid, tensor tympani and tensor veli palatini. The main nerve then divides into anterior and posterior trunks.

The anterior trunk conveys the bulk of the motor root to supply the masseter, temporalis and lateral pterygoid muscles. The main branch of the anterior trunk is the buccal nerve, which merges with the buccal branches of the facial nerve to convey sensation from the skin over buccinator, the mucous membranes of the cheek and the posterior part of the buccal surface of the gum.

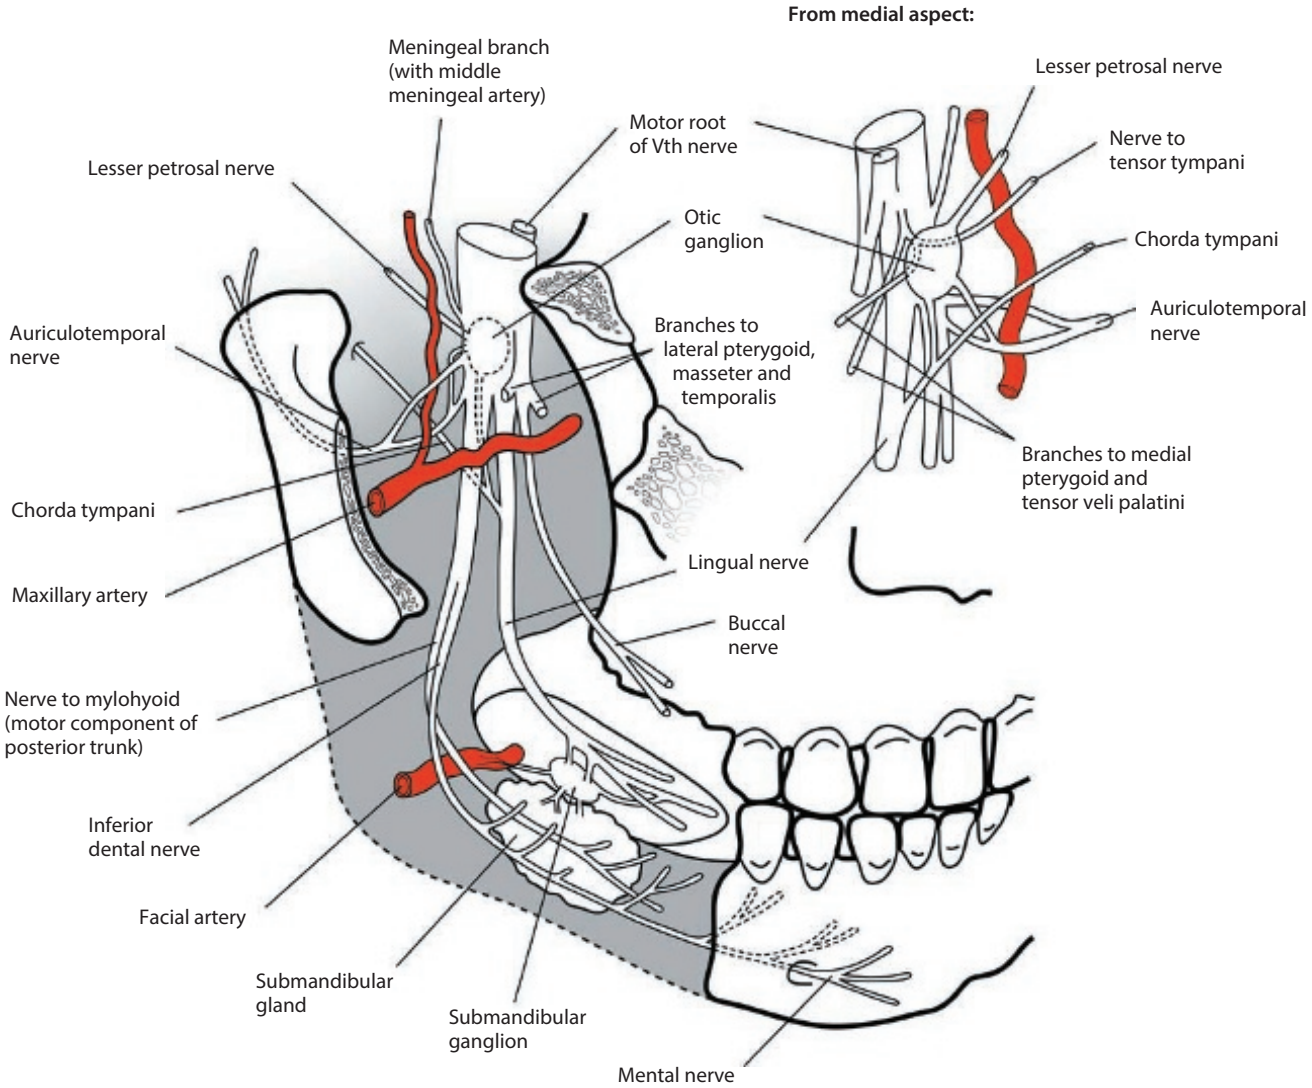

Figure 111.8 The mandibular nerve (V_3).

The posterior trunk is mainly sensory and divides into three main nerves:

1. **The auriculotemporal nerve**, which passes behind the temporomandibular joint to join the facial nerve with which it is distributed to supply the skin over the tragus, helix, auditory meatus and tympanic membrane and, via superficial temporal branches, to the skin over temporalis. It also conveys the secretomotor fibres to the parotid gland and fibres derived from the tympanic branch of the glossopharyngeal nerve via the otic ganglion (see 'The facial nerve (VII)' below).
2. **The lingual nerve**, which carries sensation from the presulcal tongue, the floor of the mouth and lower gums. It also carries the taste fibres of the chorda tympani from the mucous membranes of the anterior two-thirds of the tongue and conveys secretomotor fibres from the submandibular ganglion to the sublingual and anterior lingual glands. It communicates with the hypoglossal nerve.
3. **The inferior alveolar (dental) nerve** enters the mandibular canal running forwards in the mandible to re-emerge on the chin at the mental foramen dividing into the incisive and mental branches, supplying sensory fibres to the skin and mucous membrane of the lower lip, jaw, incisor and canine teeth. The motor component of the posterior trunk leaves the inferior alveolar nerve, just before it enters the mandibular canal, as the mylohyoid nerve supplying mylohyoid and the anterior belly of digastric.

CENTRAL MECHANISMS OF THE VTH NERVE

The central anatomy of the Vth nerve is very complicated. The small motor nucleus lies in a midposition in the upper lateral pons opposite the nerve root. It receives bilateral supranuclear innervation from corticobulbar fibres, which leave the main pyramidal pathways at the level of the nucleus (**Figure 111.9**). Direct connections with proprioceptive fibres in the adjacent main sensory nucleus allow a simple stretch reflex for mastication to operate. The jaw jerk tests the integrity of this pathway and, if greatly enhanced, indicates a bilateral upper motor neuron lesion above midpontine level, the highest stretch reflex that can be elicited.[19]

The sensory nucleus is very extensive. The cell bodies of the sensory fibres lie in the gasserian ganglion overlying the petrous apex. At least 50% of the fibres do not enter the main sensory nucleus but are concerned solely with stretch reflex activity. The other fibres form ascending and descending branches. The ascending fibres enter the mesencephalic nucleus of the Vth nerve. Their subsequent course and exact function is not understood. The descending fibres convey pain and temperature sensation and synapse in the nucleus of the descending tract of the Vth nerve, which lies adjacent to the descending tract itself and extends as low as C2 cord level. The sensory fibres derived from the facial, glossopharyngeal and vagus nerves all join the same tract and relay in the same nucleus. The secondary ascending pathway fibres swing across the brainstem, ventral to the central canal to become the secondary ascending tract of the Vth nerve, which is adjacent to the medial lemniscus,

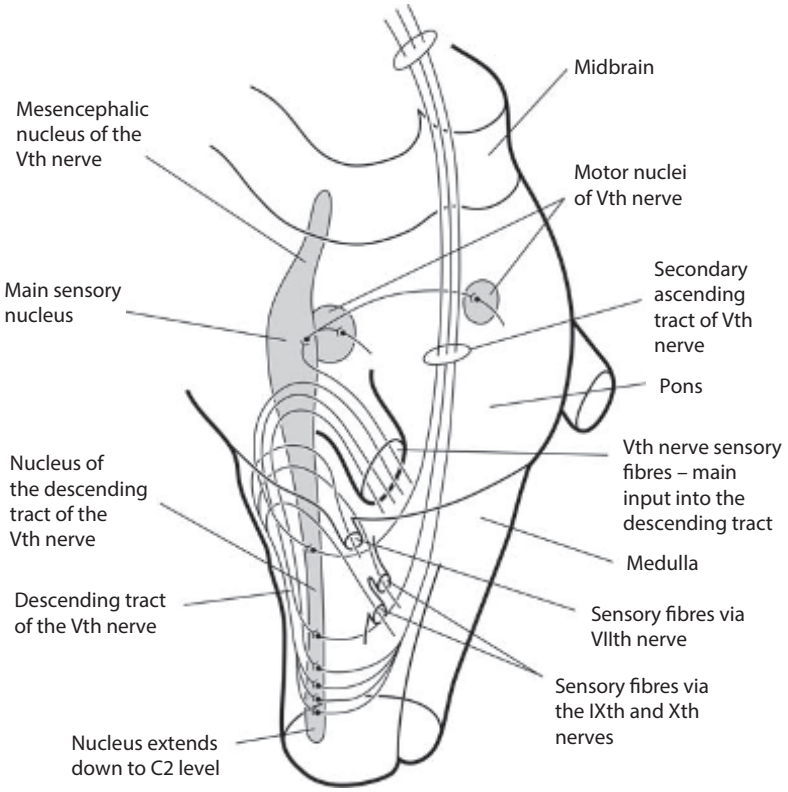

Figure 111.9 Central sensory pathways.

adding sensation derived from the face to that of the arm and leg in the latter pathway. In the decussation, these fibres are very vulnerable to damage by midline lesions, such as syringomyelia and syringobulbia, producing a classical sensory deficit, typically extending forwards from the back of the head. This is the so-called 'onion peel' or 'balaclava' sensory deficit, which may leave sensation intact only over the nose and central face in the final stages of its development.

CLINICAL ASPECTS OF THE VTH CRANIAL NERVE

Damage to the Vth cranial nerve is very important to the otolaryngologist. Branches of the nerve and its associated ganglia lie in areas often involved by otolaryngological disease, especially oropharyngeal and nasopharyngeal neoplasms. Involvement of the motor root of the Vth nerve is quite rare as it seems to be remarkably resistant to pressure or distortion. If damaged, the wasting of the masseter is usually visible and easy to demonstrate by palpation as the patient clenches the teeth. The pterygoids are tested by attempted jaw opening against resistance, the jaw deviating towards the paralyzed side.

Painless or painful loss of sensation over any part of the face, but particularly over V_2, is a very ominous finding and malignant disease in the antrum or nasopharynx is the most likely pathology. Repeated examination under general anaesthesia if necessary and biopsy of the nasopharynx are vital in such cases, to attempt to establish the cause, even if CT or MRI scanning do not clearly indicate an abnormality.

Involvement of V_1 is usually painful and nearly always accompanied by extraocular nerve palsies. It is most often damaged by lesions in and around the cavernous sinus, but may also be involved by malignant disease entering the orbit via the inferior orbital fissure.

Nasopharyngeal tumours most commonly arise in the fossa of Rosenmüller or near the orifice of the Eustachian tube. They are usually squamous carcinomas. Tumours originating in the maxillary antrum or ethmoids are usually either squamous cell carcinomas or adenocarcinomas. Some 40% of such tumours present as neurological problems. In 70% of cases, the Vth nerve is involved; in 50% of cases, the IIIrd, IVth and VIth nerves are involved. Visual pathways are affected in 8.5% of cases, and the lower cranial nerves in 10% of cases. The favourite routes of entry into the skull are through the inferior orbital fissure or via the foramen lacerum alongside the carotid artery.[20]

The maxillary division runs past the mouth of the Eustachian tube and the fossa of Rosenmüller, through the orbital floor just above the antrum and on to the face. Nasopharyngeal and antral carcinomas are particularly likely to damage this division and can cause loss of sensation as frequently as pain. The surface branches of both V_1 and V_2 are easily damaged by blunt trauma around the orbit and cheek, or divided by lacerations.

The mandibular division is involved in oropharyngeal, tonsillar and mandibular tumours and, as noted earlier, painless numbness over the chin may be the presenting symptom, rather than pain. This remains a paradox when we consider that the most common benign condition, trigeminal neuralgia, causes exquisite facial pain and yet the most serious conditions are often quite painless.

Trigeminal sensory neuropathy is a very rare condition in which painless numbness develops over the Vth nerve territory, usually starting in the second division and eventually becoming bilateral. Only the passage of time and continued failure to demonstrate an underlying lesion, allow this diagnosis to be made with certainty.[21]

The sensory root of the Vth nerve is particularly sensitive to distortion and pressure and loss of the corneal reflex is an important early sign of a lesion in the cerebellopontine angle. Rarely, extensive loss of sensation over the face may be the presenting symptom of a vestibular schwannoma, but again it is worth stressing the rarity of pain as the presenting symptom.

TRIGEMINAL NEURALGIA

This is probably the most painful condition known, the cause of which seems to be due to ageing changes in the nerve or seemingly trivial irritation by adjacent aberrant arteries. From a practical, anatomical point of view, the very strict localization of the pain in Vth nerve territory is a vital diagnostic feature. There is no such thing as atypical trigeminal neuralgia and it is not acceptable to allow the pain to radiate behind the ear, onto the neck or across the midline, and the anatomically precise distribution is the linchpin of diagnosis. The pain is usually described in two characteristic distributions. The first runs from the lower canine tooth along the lower jaw to just in front of the ear and sometimes round into the upper jaw (i.e. it involves both V_3 and V_2). The second less frequent type runs from the upper incisor or canine, up the side or inside the nose and encircles the eye, involving both V_2 and V_1. It is probably this spread over two divisions that makes simple surgical section of the peripheral branches unsuccessful in managing the condition long term, although triggering is occasionally reduced. Although it is claimed that transient sensory deficit may follow a spasm of pain, any evidence of sensory loss, impaired corneal reflex or Vth motor weakness should invalidate the diagnosis. Although trigeminal neuralgia may complicate multiple sclerosis, it is very rare as a presenting symptom of this disease.

HERPES ZOSTER OPHTHALMICUS

Most patients with this condition develop very severe pain in the distribution of V_1. The pain lasts between four and five days and during this time the diagnosis of ruptured aneurysm, cranial arteritis or acute frontal sinusitis may all have to be seriously considered. The vesicles usually appear in the inner eyebrow on day five or six and involve the entire distribution of the nerve branch. Severe chemosis of the eye and extraocular nerve palsies may further complicate the initial picture. Often, only the appearance of the vesicles will finally indicate the correct diagnosis.

ANEURYSMAL DILATATION OF THE CAROTID ARTERY

This is the other major condition in the elderly that can cause very severe pain in a V_1 distribution, with chemosis, extraocular nerve palsies and even blindness. This is usually of very sudden onset and typically develops in elderly females with long-standing hypertension.

The facial nerve (VII)

The VIIth nerve is primarily motor to the muscles of facial expression. It also carries the important taste fibres from the anterior two-thirds of the tongue via the chorda tympani and taste from the palate via the nerve of the pterygoid canal (Figure 111.10). A small but clinically important cutaneous supply to the skin of the external ear is mediated in fibres carried from the nerve via the vagus. These sensory fibres are contained in a separate trunk, the nervus intermedius, which runs with the VIIIth nerve rather than the VIIth nerve in the subarachnoid space. The cell bodies of the sensory root lie in the geniculate ganglion. The nervus intermedius also carries preganglionic, parasympathetic secretomotor fibres to the lacrimal, submandibular and sublingual salivary glands. These fibres originate in the lacrimatory nucleus and superior salivatory nucleus.

Several important branches arise from the intrapetrous part of the nerve:

- The greater petrosal nerve arises from the geniculate ganglion, carrying taste fibres from the palate and conveying preganglionic, parasympathetic fibres to the pterygopalatine ganglion, and thence via the zygomaticotemporal and lacrimal nerves to the lacrimal gland. It is joined by the deep petrosal nerve (derived from the sympathetic plexus on the carotid artery) to form the nerve of the pterygoid canal.
- A branch from the ganglion joins the lesser petrosal nerve and is then carried to the otic ganglion. This conveys secretomotor fibres via the auriculotemporal nerve to the parotid gland. It also carries sympathetic fibres derived from the carotid artery to supply the blood vessels of the parotid gland.
- A small twig, the nerve to stapedius, arises 6 mm above the stylomastoid foramen.
- The chorda tympani arises at the same level and runs forward across the middle ear and enters a canal in the petrotympanic fissure, grooves the spine of the

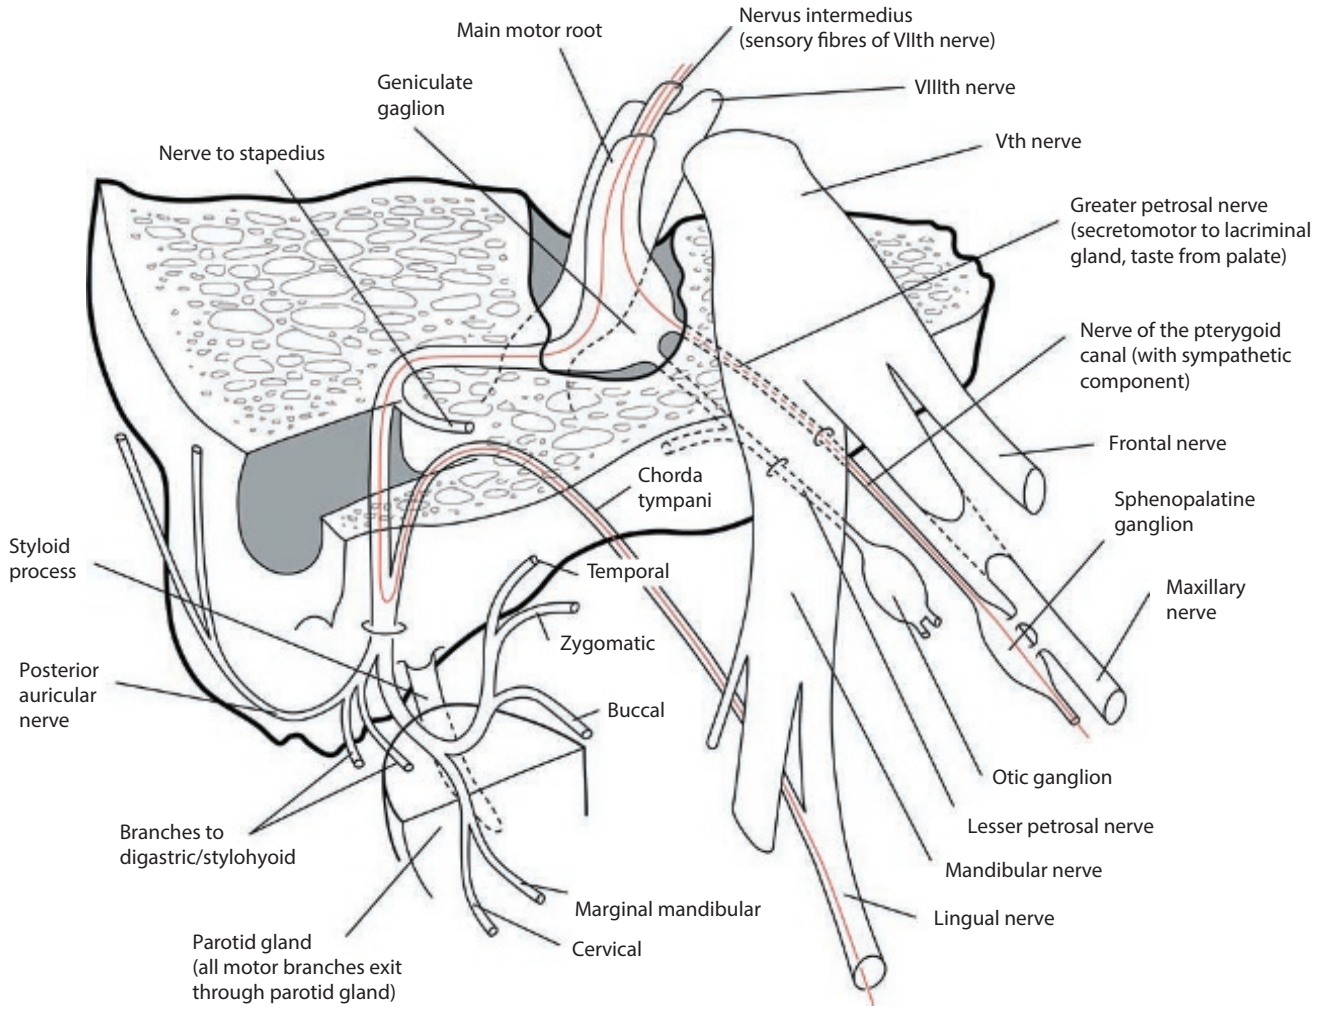

Figure 111.10 The facial nerve.

sphenoid and joins the lingual branch of the Vth nerve with which it is distributed to the presulcal part of the tongue.
- At the stylomastoid, foramen twigs join both the vagus and glossopharyngeal nerve.
- The posterior auricular nerve supplies the muscles of the ear and occipital belly of occipitofrontalis.
- The branches to the muscles of facial expression are, from above down, the temporal, zygomatic, buccal, marginal and cervical. They pass through the substance of the parotid gland before emerging in the skin and are vulnerable to disease in the parotid gland and to local surgical procedures.
- Cutaneous fibres are distributed with the auricular branch of the vagus supplying the skin on both sides of the auricle and part of the external auditory canal and tympanic membrane.

THE SUBMANDIBULAR GANGLION

The submandibular ganglion hangs from the lingual nerve. Its preganglionic fibres are derived from the superior salivatory nucleus and reach it via the facial nerve, chorda tympani and lingual nerve. These fibres are secretomotor to the submandibular and sublingual glands. The sympathetic components are derived from the sympathetic plexus on the facial artery and pass uninterrupted through the ganglion to the blood vessels of the same glands.

THE CENTRAL CONNECTIONS OF THE FACIAL NERVE

The nucleus lies in a deep position in the central pons (see **Figure 111.5**). The dorsal part of the nucleus receives bilateral supranuclear innervation, whereas the lower part of the nucleus receives mainly contralateral supranuclear innervation. This has important consequences for the clinical varieties of VIIth nerve lesions. The nucleus is closely related to the Vth nerve and this proximity is vital for the important corneal reflex and its own reflex activity via the nucleus of the tractus solitarius. The fascicular course of the nerve is unusual in that the fibres course towards the floor of the IVth ventricle, wrap around the nucleus of the VIth nerve, producing a visible enlargement in the floor of the IVth ventricle (the facial colliculus) and then retrace their course across the entire depth of the pons to exit at the pontomedullary junction. This complex arrangement is thought to be due to the embryological migration of the nucleus from its original position in the floor of the IVth ventricle to achieve its close relationship to the nucleus of the Vth nerve and the nucleus of the tractus solitarius.

TASTE MECHANISMS

Taste is mediated via taste buds; some 50 cells arranged in a pear-like cluster. These are found on the tongue, undersurface of the palate, palatoglossal folds, posterior wall of the pharynx, posterior surface of the epiglottis and the upper third of the oesophagus. They are most numerous on the lateral tongue and decrease in number with age by about 1% per annum. Each taste bud opens on the surface of the mucous membrane as a pore. The buds are found in the vallate, fungiform and foliate papillae. The life span of these cells, which are renewed from epithelial cells surrounding the bud, is about 10 days. They are therefore very vulnerable to factors inhibiting rapid cell turnover.

Two main receptor cells have been identified although they are possibly different types of the same cell. Some receptor cells have receptor sites for afferent neurons and small presynaptic vesicles. Others contain larger vesicles and have more definite ciliary processes at their tip just inside the pore. There is evidence of considerable cross-innervation of taste buds, which may indicate inhibitory and facilitatory control similar to that seen in the smell receptors. It is thought that patterns of taste over a wide area of receptors is critical in perceiving different tastes, rather than that there are specific receptors for specific tastes. There is some evidence that sweet is more readily detected on the tip and medial dorsum of the tongue, salt and sour over the lateral tongue and bitter over the posterolateral tongue, where the circumvallate papillae are most numerous.

The neural connections of the taste receptor cells are the unipolar processes of cells in the geniculate ganglion of the VIIth nerve, the inferior ganglion of the IXth nerve and the inferior ganglion of the Xth nerve. The central processes of these cells form the tractus solitarius and they synapse in the adjacent nucleus of the tract. These fibres then ascend in the medial lemniscus to the opposite nucleus ventralis posterior medialis of the thalamus. The final pathway is via the internal capsule to the sensory cortex and insula. Some information from the pons relays direct to the hypothalamus for autonomic reflex purposes.

The anatomy of the peripheral taste pathways is complex, but for practical purposes, the supply to the anterior two-thirds of the tongue is carried by the chorda tympani, but finally distributed via the lingual branch of the mandibular division of the Vth nerve (**Figure 111.11**). The facial nerve also conveys sensation from the taste buds on the palate, through the middle and posterior palatine nerves, via the greater petrosal nerve and the nerve of the pterygoid canal. Taste sensation from the vallate papillae, pharyngeal tongue and palatoglossal folds is conveyed by fibres carried in the IXth nerve. Taste sensation from the lowest part of the tongue, epiglottis and hypopharynx is carried by the vagus in fibres derived from its superior laryngeal branch. Free nerve endings of the Vth nerve are also widespread, conveying somatic sensation from these same areas. They also undoubtedly contribute to the perception of extremely strong taste stimuli, such as curry powder, carbonated drinks and acid substances. Modifications of this pattern of gustatory and simple physical stimuli, such as temperature, can alter taste sensation, heightening the unpleasant features of such highly flavoured compounds. It is clear that taste mechanisms are rather more complex than simple permutations of sweet, bitter, salt and sour. Parallel smell appreciation adds savour to taste. Patients with anosmia describe all food as ‘tasting like cardboard’

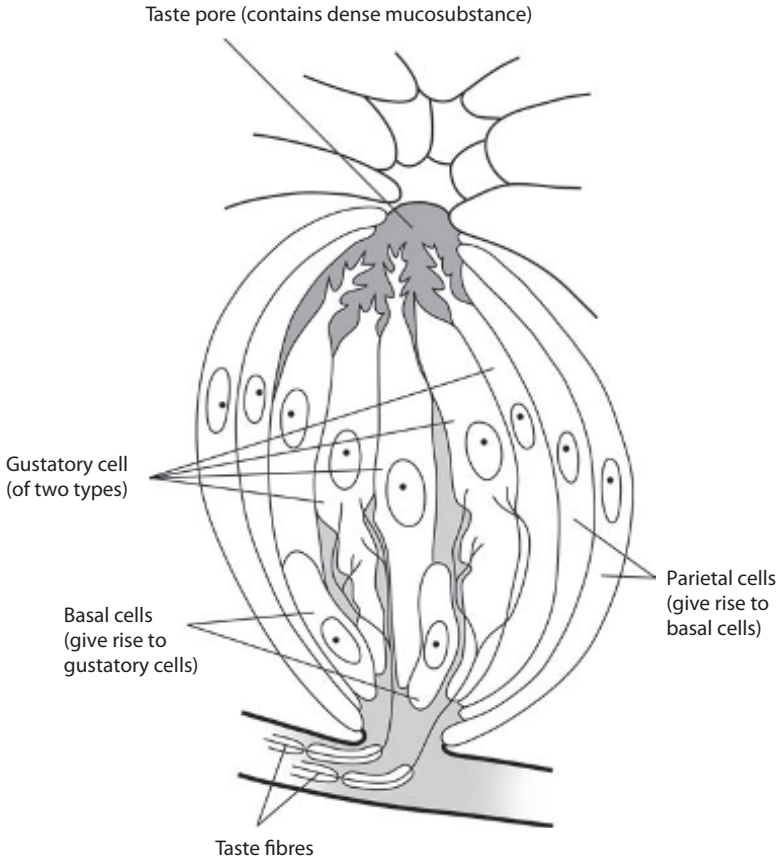

Figure 111.11 The taste bud.

and only highly spiced or flavoured foods make any impact and often not necessarily a pleasant one. Adaptation again plays a role. The modification of fruit juice flavours by the previous use of mint toothpaste, is a universally appreciated phenomenon. Because of the vital role of smell in taste appreciation and the frequent simultaneous impairment of smell, it is difficult to isolate specific disorders of taste. For example, in Bell's palsy, patients identify tastes as having a 'metallic' flavour, in spite of the lesion being strictly unilateral and there being no impairment of the sense of smell. Chemicals and systemic diseases that modify taste and smell are listed under 'The olfactory nerve (I)' above.

The chemistry of taste sensation is described in Volume 1, Chapter 110, Abnormalities of smell.

CLINICAL DISORDERS OF THE VIITH NERVE

The VIIth nerve is frequently damaged by diseases of otolaryngological origin inside the skull, in the petrous bone and in the parotid gland.[22]

For reasons noted above, a cortical lesion affecting VIIth nerve function, such as a vascular lesion or tumour in the motor strip, will cause weakness maximal in the lower face which is almost exclusively contralaterally innervated. The upper face, in particular forehead movement and eye closure, is relatively spared, due to bilateral supranuclear innervation. Thus, upper motor neuron facial weakness is, in many instances, more apparent on spontaneous smiling and speaking than during deliberate attempts to move the face to command.

Lesions affecting the whole facial nucleus or the peripheral part of the nerve should cause total unilateral facial weakness. In some instances, weakness may be more marked in the lower face, which can happen in the early or recovery phase of a simple Bell's palsy and an upper motor neuron lesion may be incorrectly suspected. Much less commonly, a very dense upper motor neuron lesion may mimic a lower motor neuron lesion by affecting all facial movements. These difficulties are stressed as the distinction is of immense diagnostic importance and mistakes are easily made. It is also worth stressing that ptosis of the eyelid is not a feature of either a lower or upper motor neurone facial palsy – a droopy eyelid should never be accepted as part of a facial weakness.

Lesions in the brainstem affecting the VIIth nerve usually also involve the VIth nerve because of the intimate anatomical relationship in the floor of the IVth ventricle. Careful examination may reveal long tract signs, such as brisk reflexes or extensor plantar responses, if the brainstem is distorted or infiltrated by the causative lesion.

The VIIth nerve lies in very close relationship with the VIIIth nerve as they both cross the subarachnoid space to enter the internal auditory foramen. This is in the region of the cerebellopontine angle and a vestibular schwannoma is the lesion most frequently found at this site. Vestibular schwannomas, although inevitably grossly distorting the

VIIth nerve, very rarely present as a VIIth nerve palsy. If there is clinical evidence of a cerebellopontine angle lesion and if the VIIth nerve is involved, alternative pathology is more likely.[23] Permanent damage to the VIIth nerve following surgical removal of a vestibular schwannoma is unfortunately very common and often unavoidable.

In the facial canal, the nerve is liable to ischaemic damage and this is the probable mechanism of Bell's palsy, where the nerve is thought to be damaged by compression, secondary to the inflammatory response to an antecedent viral infection. In nearly all cases very severe pain in the ear is experienced in the 24 hours before the onset of the Bell's palsy, particularly if herpes zoster is responsible (Ramsay Hunt syndrome). The accompanying pain and local swelling may suggest bacterial infection until the vesicles appear three to four days later. The facial paralysis is usually complete on the second day and includes occipitofrontalis and platysma.

In a straightforward Bell's palsy, hearing distortion, due to paralysis of stapedius, and impaired taste, due to simultaneous involvement of the chorda tympani, do not always occur and in mild cases the lower half of the face may be more severely affected than the upper half, mimicking an upper motor neuron lesion, as discussed above.[24] Seventy-five per cent of patients make a good recovery over three to six weeks with or without treatment. Twenty per cent make an acceptable but slow recovery complicated by the development of facial synkinesis. This is due to nerve sprouting with subsequent loss of fine control, which can turn a smile into a snarl and eye closure into a distorted grimace. Five per cent of cases make little or no recovery and may ultimately require plastic surgical repair. In some cases, aberrant regeneration may lead to lacrimation instead of salivation on eating, so-called crocodile tears.[25] It is most important that patients with Bell's palsy are not told that they have had a small stroke. Exclusion of underlying hypertension, diabetes, sarcoidosis and inflammatory arterial disease is important and more recently the recognition of Lyme disease in southern rural England suggests blood tests for *Borrelia burgdorfii* be added to the diagnostic work up in appropriate areas, typically where there is a large deer population.

Middle ear infection carries a considerable risk of damaging the nerve by similar mechanisms. Fractures through the petrous bone are often complicated by facial nerve palsy. Those of immediate onset are usually due to nerve laceration. Those of delayed onset, usually two to three days after trauma, are due to oedema and carry an excellent prognosis. Trauma to the nerve as it emerges from the stylomastoid foramen is a well-recognized complication of forceps delivery.

Benign hemifacial spasm occurs in both sexes at any age, but is most common in elderly hypertensive females. Since the advent of scanning, a surprising number of underlying lesions are found in this condition, such as cholesteatoma, vestibular schwannomas, meningiomas or aneurysms of the basilar artery. CT or MRI scanning should now be regarded as necessary investigations in all cases. The symptoms consist of a constant flickering and twitching of the facial muscles. This usually starts around the eye, producing involuntary winking, and later extends to involve the mouth. It is usually worse in company, but continues 24 hours a day. It may respond to carbamazepine (Tegretol) but if the patient's age and condition permits, posterior fossa exploration to identify vascular irritation by a small vessel may be considered.[26] Excellent control can be obtained using botulinum toxin injections in many cases. At present, the need for repeat injection every two to three months and the expense limits the use of this valuable treatment, but once a gross underlying lesion is excluded, botulinum is the treatment of choice.

CLINICAL TESTING OF THE VIITH NERVE

A standard sequence of movements should be tested. Wrinkling the forehead, followed by forced eye closure will usually detect weakness in the upper half of the face. The ability to flare the nostrils and wrinkle the nose should then be tested, followed by asking the patient to forcibly show the teeth and attempting to blow out the cheeks. Eversion of the lower lip is difficult to achieve, but tests the perioral muscles and produces striking contraction of platysma. It should only take about 30 seconds to perform these tests. Hearing should not be impaired to simple clinical testing, although the patient may report distorted hearing. In the same way, formal testing of taste with standard test flavours may be performed, but often the patient's own perception and description of altered taste will be adequate for diagnostic purposes.

Whenever the VIIth nerve is damaged, it is important to exclude coexistent Vth nerve damage, in particular to confirm the presence of the corneal reflex. Not only will the absence of the corneal reflex exclude a simple Bell's palsy, but the considerable danger to an unprotected and anaesthetic cornea will be identified. Eye movements should be carefully tested to exclude a VIth nerve lesion, which could indicate a brainstem lesion, and simple clinical tests of hearing should be performed, particularly if the corneal reflex is depressed, as simultaneous involvement of the Vth, VIIth and VIIIth nerves would strongly indicate a lesion in the cerebellopontine angle. It should be remembered that herpes zoster may affect several cranial nerves simultaneously and can cause severe pain, which, when accompanied by multiple cranial nerve palsies, can present a very difficult diagnostic situation until the vesicles appear.

The vestibulocochlear nerve (VIII)

The anatomy and physiology of the specialized end organs of the VIIIth nerve are described in Chapter 47, The anatomy of the cochlear and vestibular system: Relating to ultrastructure to function. Discussion here is therefore confined to the role of hearing impairment and balance disorders in the diagnosis of neurological disease.

Due to the anatomical proximity of the VIIth and VIIIth nerves, simultaneous involvement under many circumstances would seem likely. In reality, such damage

is quite unusual, with the exception of acute traumatic lesions of the petrous bone where both nerves are simultaneously lacerated. This peculiarity is of considerable clinical importance.

THE CEREBELLOPONTINE ANGLE SYNDROME

The classical tumour arising in the cerebellopontine angle is a vestibular schwannoma (**Figure 111.12**). Although originating on the vestibular division of the nerve, the rate of growth is usually so insidious that a purely vestibular presentation is extremely unusual. Gradual and often unrecognized impairment of hearing is the rule. Similarly, the VIIth nerve may become grossly distorted but either benign facial hemispasm or weakness as a presenting symptom is similarly unusual. In contrast, minimal pressure on the Vth nerve root as the tumour extends upwards or perhaps stretching of the Vth nerve root as the pons is displaced medially, commonly produces impairment of the corneal reflex. In spite of such distortion, pain or numbness of the face is also very unusual. Obviously, a cerebellopontine angle tumour may present as facial hemispasm, facial weakness, facial numbness or a trigeminal neuralgia-like syndrome, but in all such instances an alternative cause, such as a cholesteatoma or meningioma in the cerebellopontine angle, becomes a more likely diagnosis. If the clinical picture has evolved extremely rapidly, both metastatic carcinoma or lymphoma could be responsible. Less often, and usually in the 5–15-year age group, pontine glioma or cerebellar medulloblastoma can extend into the cerebellopontine angle, to produce this typical combination of nerve lesions.

BALANCE DISORDERS AND VERTIGO

Unsteadiness is a common symptom prompting leading to referral for an otolaryngological or neurological opinion. The most important historical feature to establish is what the patient means by their description using the terms: 'off balance', 'giddy', or 'dizzy'. So often close questioning reveals that they actually mean 'light-headed', 'floaty' or 'woozy', all non-specific symptoms usually due to anxiety. They do not include the obligatory illusion of movement of either themselves or their surroundings, which is necessary to establish that they have true vertigo and therefore justify extensive and expensive otoneurological investigations to define the cause.

Disorders of balance, such as Ménière's disease, vestibular neuronitis and benign positional vertigo, are discussed in Chapters 62–67. The frequency with which vertigo is a symptom in migraine attacks also deserves mention. A feature of all these situations is that the attacks are episodic or provoked by change of position and in the case of migraine often accompanied by or associated with headache. Disorders of balance due to structural organic disease in the CNS tend to produce continuing difficulty with balance and non-stop vertigo. The most frequent causes are multiple sclerosis and cerebrovascular accidents affecting vestibular and cerebellar connections in the brainstem. Pure cerebellar lesions are less likely to produce vertigo, unless they also distort the brainstem. They also tend to produce impaired coordination or a tendency to veer to one side while walking, rather than the drunken reeling in all directions seen in association with vertigo in patients with brainstem lesions.

GROUP 3

The final group of cranial nerves are not only anatomically bunched at their major exit, the jugular foramen, but share common nuclear origins. They also have peripheral cross-connections for final distribution that make for poor physiological distinction of function, as well as complex anatomy. Only the hypoglossal nerve with its discrete nuclear origin

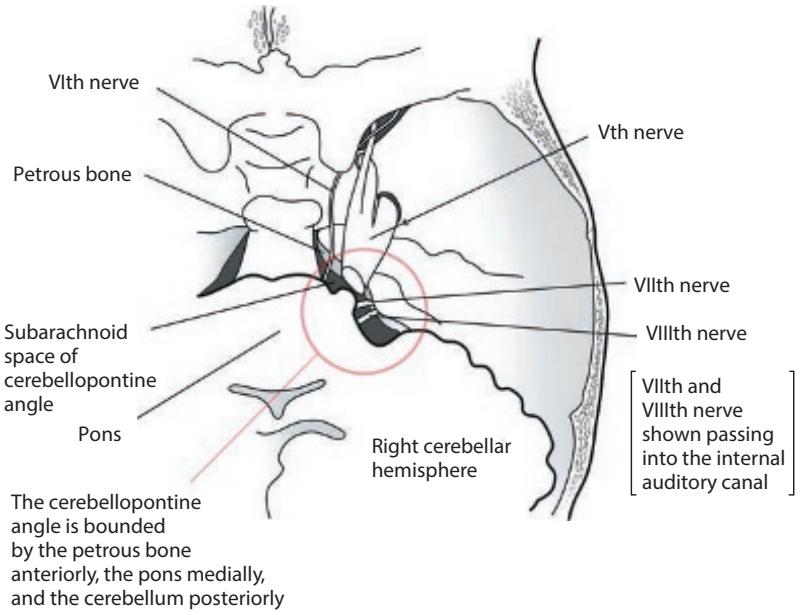

Figure 111.12 The cerebellopontine angle.

and separate hypoglossal canal can be discussed in isolation. Even then, its peripheral course brings it into close anatomical relationship with the other three nerves.

The glossopharyngeal nerve (IX)

The glossopharyngeal nerve has sensory, motor and autonomic components. The sensory ganglion cells lie in the superior and inferior ganglia of the nerve (**Figures 111.13**, **111.14** and **111.15**).

The central processes pass to the nucleus of the tractus solitarius, conveying taste sensation, and to the nucleus of the spinal tract of the Vth nerve, conveying somatic sensation. The motor nucleus lies in the upper part of the nucleus ambiguous, which receives bilateral supranuclear innervation from corticobulbar fibres. This nucleus supplies the stylopharyngeus. The autonomic parasympathetic fibres arise in the inferior salivatory nucleus. These fibres are carried in the lesser petrosal nerve via the tympanic branch to the otic ganglion. The postganglionic fibres are distributed to the parotid gland via the auriculotemporal nerve.

The glossopharyngeal nerve emerges from the brainstem in line with the vagus and accessory nerves and exits from the skull via the jugular foramen. It descends between the jugular vein and carotid artery, picking up sympathetic fibres from the carotid plexus as it loops forwards and medially to reach the soft tissues of the oropharynx, posterior tongue and palate. In its course, it gives off the lesser petrosal nerve conveying the secretomotor fibres for the parotid gland to the otic ganglion. An important nerve, the carotid branch, conveys chemoceptor and stretch reflex information, respectively, from the carotid body and carotid sinus centrally for respiratory and circulatory reflex function. The final branches of the glossopharyngeal nerve are the pharyngeal, tonsillar and lingual branches, conveying general sensation and taste sensation from the posterior third of the tongue and oropharynx.

THE OTIC GANGLION

The otic ganglion lies just below the foramen ovale, attached to the mandibular nerve but functionally carries secretomotor fibres from the glossopharyngeal nerve. These parasympathetic fibres relay in it and supply the parotid gland via the auriculotemporal nerves originating from V_3. Sympathetic fibres derived from the middle meningeal artery pass through the ganglion and are also distributed to the blood vessels of the parotid gland in the auriculotemporal nerve.

GLOSSOPHARYNGEAL NEURALGIA

This is a rare condition that presents at about one-tenth the frequency of trigeminal neuralgia. It consists of excruciatingly severe pain in the palate, throat and external auditory canal, locations demonstrating the somatic sensory distribution of the glossopharyngeal nerve. The pain has the typical burning, electric shock quality of neuralgia and is triggered mainly by swallowing. The incidence of underlying lesions inside the skull is very much higher than in trigeminal neuralgia. Both phenytoin and carbamazepine may control the pain, but MRI scanning would seem a wise precaution in all instances. Intracranial root exploration is necessary if medical treatment fails. Peripheral glossopharyngeal section has little to commend it and can seriously interfere with normal swallowing mechanisms.[27]

The vagus nerve (X)

The vagus nerve (the wanderer) is the most widely distributed cranial nerve, hence only aspects essential to otolaryngologists will be detailed. The central connections are similar to the IXth nerve (see **Figures 111.13**, **111.14** and **111.15**):

- The dorsal nucleus of the vagus contains motor and sensory components. The motor fibres are general visceral efferent to the smooth muscle of the bronchi,

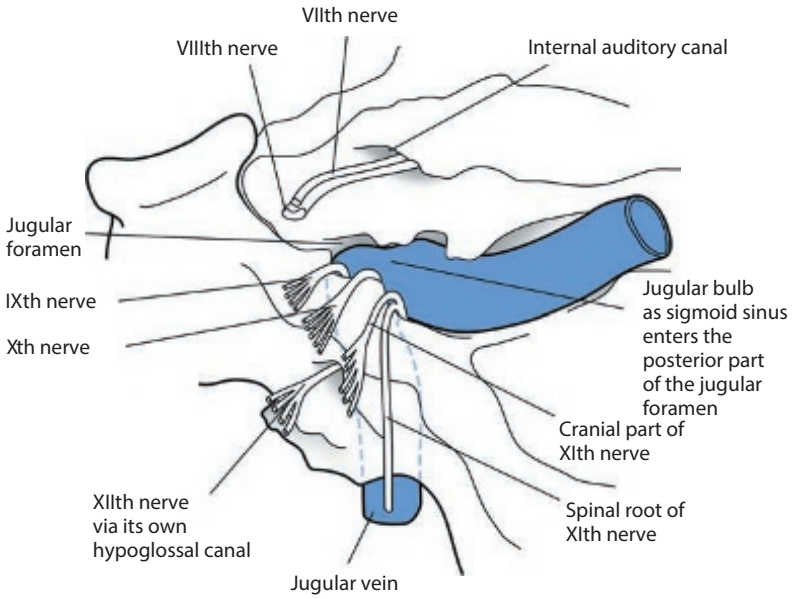

Figure 111.13 Schematic diagram of internal jugular foramen.

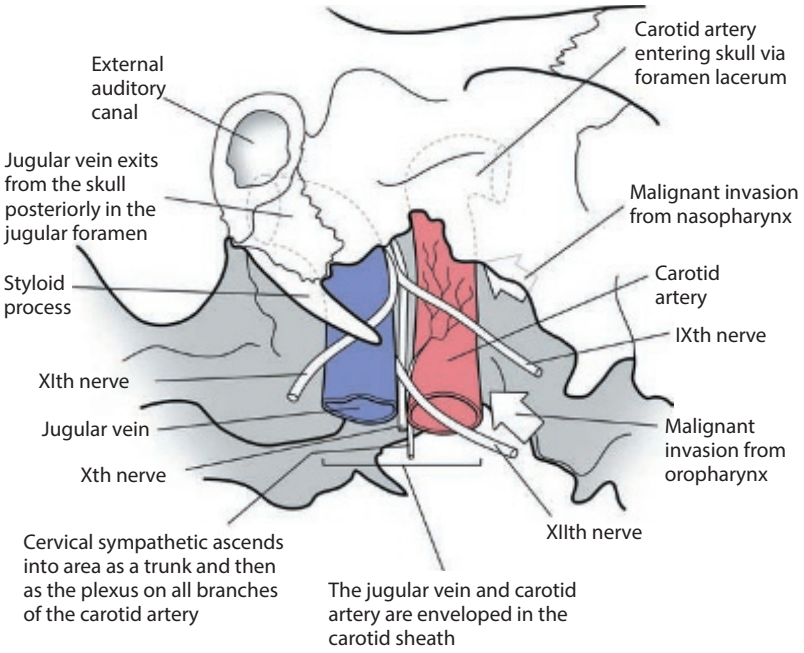

Figure 111.14 Schematic diagram of external jugular foramen. (See also Figure 111.16.)

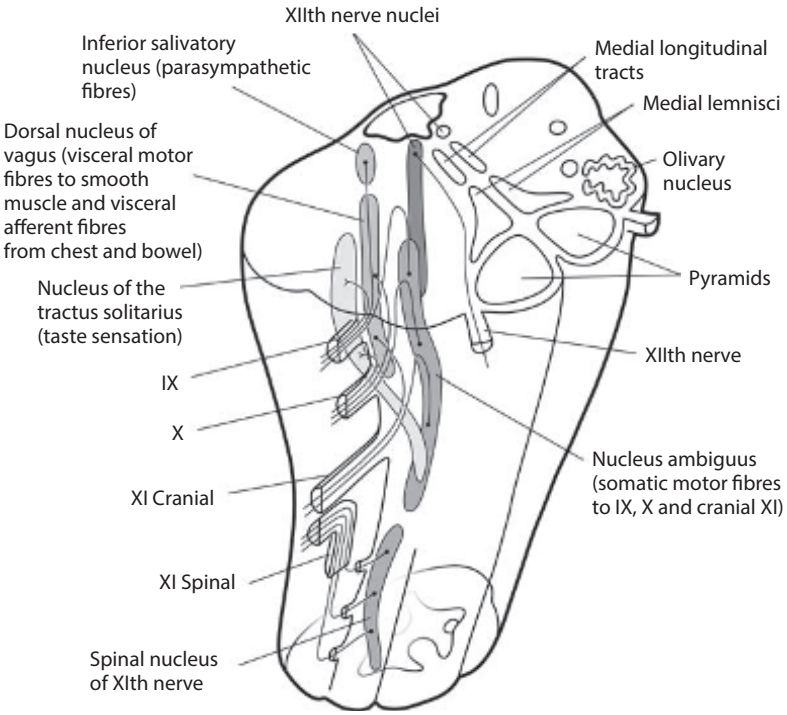

Figure 111.15 Central connections of nerves IX, X, XI and XII, viewed anterolaterally from the right side. (See also Figure 111.9 for central sensory connections via the nucleus of the descending tract of the Vth nerve.)

heart, oesophagus, stomach and intestine. The sensory fibres are general visceral afferent, originating in the oesophagus and upper bowel with cell bodies in the superior and inferior vagal ganglia.

- The nucleus ambiguus gives origin to those fibres controlling the striated muscle of the pharynx and intrinsic muscles of the larynx. It has a bilateral supranuclear innervation.
- The nucleus of the tractus solitarius is shared with the glossopharyngeal nerve and receives fibres from the taste buds of the epiglottis and vallecula.
- General somatic afferent fibres from the pharynx and larynx are found in the nerve and are believed to terminate in the spinal nucleus of the Vth nerve.

Because of these extensive nuclear connections, multiple rootlets emerge from the brainstem and form a flat cord, which enters the jugular foramen.

The superior and inferior ganglia lie in the foramen and just below an identical arrangement to the glossopharyngeal nerve. Both ganglia make connections with the accessory and hypoglossal nerves and the sympathetic

plexus on the carotid artery. Below the inferior ganglion, the cranial root of the accessory nerve merges with the vagus nerve, which then distributes its fibres to the pharynx and larynx.

The vagal branches of practical importance are as follows:

- A meningeal branch supplying the dura of the posterior fossa is given off in the jugular foramen.
- The auricular branch arises from the superior ganglion and is joined by a branch from the glossopharyngeal nerve and conveys sensation from the skin of the external ear with the branch of the facial nerve. These fibres eventually all enter the nucleus of the descending tract of the Vth nerve.
- The pharyngeal branch arises just above the inferior ganglion and distributes the spinal accessory nerve components to the pharyngeal plexus, supplying the pharynx and palate.
- The superior laryngeal nerve comes off the inferior ganglion and divides into two branches: the internal laryngeal nerve, which carries sensation from the mucous membrane of the larynx and conveys proprioceptive information from the neuromuscular spindles and stretch receptors of the larynx; and the external laryngeal nerve, which supplies cricothyroid and contributes to the pharyngeal plexus, which is of considerable importance in speech mechanisms.
- The recurrent laryngeal nerve has differing courses on each side. On the right, it loops under the subclavian artery and on the left under the aortic arch. On both sides it then ascends on the side of the trachea. It supplies all the muscles of the larynx except cricothyroid and carries sensory fibres from the mucous membranes and stretch receptors of the larynx.

The spinal accessory nerve (XI)

The cranial part of this nerve is a detached portion of the vagus and the spinal part is motor to the sternocleidomastoid and trapezius (see **Figures 111.13**, **111.14** and **111.15**).

The cranial portion arises from the lower part of the nucleus ambiguus and a small component from the dorsal efferent nucleus of the vagus. The nerve rootlets emerge in line with the vagus and are joined by the ascending spinal component and run laterally to enter the jugular foramen. The cranial portion merges with the vagus at the level of the inferior vagal ganglion and is then distributed with the pharyngeal and recurrent laryngeal branches of the vagus. These fibres probably supply the muscles of the soft palate.

The spinal root arises from ventral horn cells in the cord between C1 and C5. These fibres emerge from the cord laterally between the anterior and posterior spinal nerve roots to form a separate nerve trunk, ascending into the skull through the foramen magnum. This then exits from the skull via the jugular foramen in the same dural sheath as the vagus. It runs posteriorly as soon as it emerges to supply the sternocleidomastoid and the upper part of the trapezius and receives a major contribution from branches of the anterior roots of C3 and C4, to form the neural plexus, which supplies the cervical musculature. Evidence from surgical procedures suggests that these additional root components make important contributions, as upper cervical root section is required to denervate completely the sternocleidomastoid and trapezius. The peripheral portion of the nerve is easily damaged in lymph node biopsy and other operations in the posterior triangle of the neck.[28]

The accessory nerve is unusual in that clinical evidence indicates that the supranuclear innervation of the motor cells supplying sternocleidomastoid is ipsilateral. In hemiparetic vascular lesions, the weakness in sternocleidomastoid is on the same side as the lesion. In epileptic fits originating in the frontal pole, the head turns away from the side of the lesion (i.e. the ipsilateral sternocleidomastoid is contracting). Failure to recognize this unanticipated distribution may to the novice seem to indicate that a patient with a left hemiparesis also has a right accessory nerve lesion, and therefore a lower brainstem lesion, rather than a typical capsular cerebrovascular accident. This is an easy mistake to make unless this anatomical peculiarity is appreciated and the normality of the upper trapezius on the side of the weak sternocleidomastoid is confirmed.

The hypoglossal nerve (XII)

The hypoglossal nerve arises from a nuclear column lying in the floor of the IVth ventricle and derived from the same cell group as the nuclei of nerves III, IV and VI (see **Figures 111.13**, **111.14** and **111.15**). Like nerves III and VI, the fascicular fibres of XII have to traverse the full sagittal diameter of the brainstem to reach their exit from the ventral surface of the medulla between the pyramid and olive. The numerous rootlets combine and become two main roots with their own dural sleeves and exit the skull via the hypoglossal canal just below the jugular foramen. The nerve therefore emerges deep to the other neural structures and has to course downwards and anteriorly to emerge between the jugular vein and carotid artery, cross the inferior vagal ganglion and then pass upwards and anteriorly on hyoglossus, distributing branches to all the muscles of the tongue. It receives sympathetic fibres from the superior cervical ganglion, some fibres from the vagus and the motor roots of C1 and C2 via the ansa cervicalis. In addition, numerous filaments connect to and are distributed with the lingual nerve.

Motor fibres derived from the hypoglossal nucleus itself supply styloglossus, hyoglossus, geniohyoid and genioglossus. The fibres derived from the C1 components are distributed to sternohyoid, sternothyroid, omohyoid, thyrohyoid and geniohyoid. Although a XIIth nerve lesion paralyzes one side of the tongue as its most demonstrable feature, the larynx also pulls across to the opposite side on swallowing, because the hyoid fails to elevate on the paralyzed side.

The supranuclear innervation of the hypoglossal nucleus is usually bilateral but can be mainly contralateral, so that in some cerebrovascular accidents transient weakness of one side of the tongue may be found. The nerve is

particularly vulnerable to surgical trauma in operations on the submandibular gland and ducts and during carotid endarterectomy.[29] Paralysis following central venous catheterization has also been reported.[30]

THE CERVICAL SYMPATHETIC

Horner's syndrome due to damage to the cervical sympathetic is one of the most frequently missed physical signs in medicine. In the present context, its detection is of vital importance.

The cervical sympathetic originates in the ipsilateral hypothalamus, descends through the entire dorsolateral brainstem to the central grey matter of the cervical spinal cord at TI level (**Figure 111.16**). The sympathetic fibres leave the cord via the ventral root, join the sympathetic chain and ascend through the various ganglia to end as a plexus on the carotid artery, on which they re-enter the intracranial cavity. This ultimately distributes sympathetic fibres to all the cranial nerves innervating the pupil, glands and blood vessels of the head and neck.

The external evidence of Horner's syndrome is said to be fourfold:

1. Enophthalmos is rarely visible and of dubious authenticity.
2. Loss of sweating over the face and forehead is rarely noted, unless specifically tested by warming the patient.
3. Ptosis of the eyelid may be very subtle and somewhat variable, as the nerve endings become sensitized to circulating adrenalin due to denervation hypersensitivity. The lid rarely drops lower than the edge of the pupil.
4. Pupilloconstriction, or more accurately the failure of pupillodilatation, leads to an entirely normally reactive pupil to light and accommodation, but through a smaller range. At rest, the affected pupil is small.

Horner's syndrome may be congenital and this is associated with failure of pigmentation of the iris on the affected side, which remains blue.

The causes of Horner's syndrome are:

- lesions in the dorsolateral brainstem, especially vascular lesions in the medulla, multiple sclerosis at any level or pontine glioma
- lesions in the central cervical cord: syringomyelia, ependymoma, glioma or traumatic damage
- lesions of the TI root: apical carcinoma of the lung, cervical rib, aortic aneurysm or avulsion of the lower brachial plexus
- lesions of the sympathetic chain in the neck: thyroid carcinoma, thyroid surgery, neoplastic lesions, local trauma, accidental surgical damage or surgical extirpation for various vascular syndromes of the arm
- lesions of the carotid plexus: carotid artery surgery, carotid artery thrombosis, migrainous spasm, local neoplastic destruction of the skull base or involvement by aneurysm or malignancy in the region of the carotid siphon or jugular foramen.

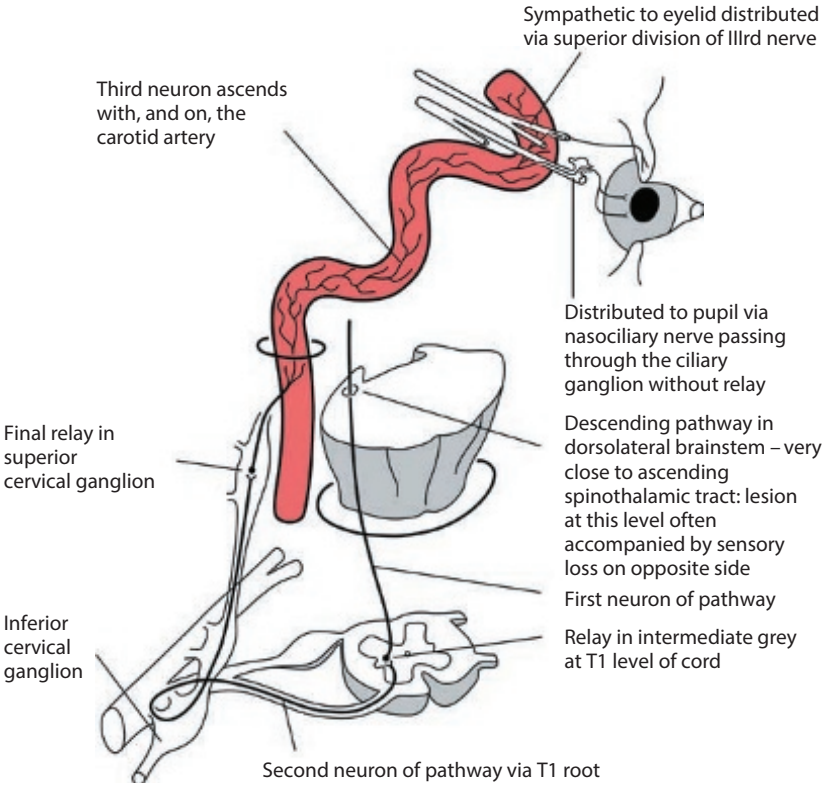

Figure 111.16 Schematic course of the cervical sympathetic nerve.

Clinical evaluation of the last four cranial nerves

Multiple involvement of these nerves is extremely common, so that the symptoms and signs of individual nerve lesions can be difficult to isolate, both from the history and on examination. Disorders of swallowing, speaking, coughing and pain syndromes are the usual presenting symptoms.

A glossopharyngeal nerve lesion will cause impaired taste sensation over the posterior third of the tongue, but this is usually asymptomatic and impossible to test. The loss of somatic sensation over the palate and oropharynx will cause impaired swallowing reflexes as the initial stimulus to deglutition is the arrival of the bolus against the palate. This will lead to occasional choking on food and fluids. Pain in the throat and ear may develop with sensory fibre irritation and then true glossopharyngeal neuralgia may follow. This characteristically will be triggered by swallowing.

Sensation over the palate should be tested by touching the palate with an orange stick and if sensation appears blunted, this can be further explored using a long sharp point. A further check can also be made by touching the posterior pharyngeal wall, while the patient says 'Ah' to elevate the palate.

A vagal nerve lesion at brainstem or jugular foramen level will affect the palate and vocal cords. Unilateral weakness of the palate causes nasal speech and a tendency for food to come back up the nose. Vocal cord paralysis will cause a hoarse, soft voice and prevent explosive coughing. The failure of airway protection when swallowing is initiated, leads to spluttering of food and fluids, with secondary regurgitation through the nasal passages. Pain in the ear may result from irritation of the sensory fibres in the nerve.

In a peripheral recurrent laryngeal nerve lesion, the palate will not be affected, but the voice symptoms will be similar, as will a tendency to choke on fluids. It has also been shown that the external laryngeal nerve with its supplied muscle, cricothyroid, has a greater role in speech than previously realized. Damage causes more severe and lasting speech problems than will result from a recurrent laryngeal nerve lesion.[31]

The integrity of the vagus can be assessed by the patient's voice, ability to cough, direct inspection of the palate and laryngoscopy.

An accessory nerve lesion is really a spinal root lesion, as the cranial part of the nerve is distributed with the vagus. Weakness and wasting of sternocleidomastoid and the upper part of trapezius is readily detected, provided it is carefully sought. Like Horner's syndrome, this is a physical finding that is very easily missed.

A hypoglossal nerve lesion produces paralysis of the intrinsic musculature of the tongue on the supplied side. This causes surprisingly little disability and is often accidentally discovered by the patient or their dentist. Once recognized, some slight difficulty with chewing may then be appreciated by the patient. In an established lesion, on examination at rest, the affected side of the tongue will be shrivelled and fasciculating. On attempted tongue protrusion, the tongue will deviate towards the affected side.

CLINICAL INVOLVEMENT OF IX, X, XI, XII AND CERVICAL SYMPATHETIC NERVES

As the last four cranial nerves lie in close proximity inside the skull and even closer outside the skull (see **Figures 111.13** and **111.14**), multiple involvement is the rule and a variety of named syndromes have been reported. Of immediate practical importance are four major anatomical features:[32]

1. The proximity of the nucleus of nerves IX, X and XI to the spinothalamic tract and descending cervical sympathetic in the brainstem produces a combination of multiple nerve involvement, sparing nerve XII and affecting spinothalamic sensation on the opposite side of the body and associated with an ipsilateral Homer's syndrome. This is seen in Wallenberg's syndrome (dorsolateral medullary infarction).
2. The XIIth nerve lies in a different brainstem vascular territory and the nerve emerges lateral to the pyramid. A vascular lesion of this area will produce a XIIth nerve lesion with contralateral hemiplegia and contralateral impairment of posture, sense and touch. As the nerve exits through a separate foramen, it is often spared by a lesion involving the jugular foramen structures inside the skull.
3. Outside the skull, all four nerves lie so close together that the XIIth nerve is more likely to be involved and is often the first structure affected by lesions infiltrating the area from the oropharynx. Any mass in this region may be palpable.
4. As the cervical sympathetic ascends into the region from below, its involvement (provided there is no evidence of a brainstem lesion, such as a spinothalamic sensory loss on the opposite side) is certain evidence of a lesion external to the jugular foramen.

The named syndromes

Eponymous syndromes have been applied to every conceivable permutation of nerve and tract involvement affecting the last four cranial nerves. Those traditionally accepted are as follows:

- **Vernet's syndrome** (of the internal jugular foramen) is characterized by involvement by nerves IX, X and XI only (an identical syndrome has been attributed to Schmidt).
- **Avellis's syndrome** (of the brainstem) involves only nerve X and the spinothalamic tract (loss of pain and temperature on the opposite side).
- **Tapia's syndrome** involves nerves X and XII. It is difficult to see how this syndrome could occur at either brainstem or peripheral level for anatomical reasons. Presumably this is a chance association.

- **Jackson's syndrome** is characterized by involvement of nerves X, XI and XII. Again it is difficult to see how this combination could develop on any logical basis. Presumably it is also a consequence of a chance combination of peripheral lesions.
- **Collet–Sicard syndrome** (of the posterior lacerocondylar space) is basically the external jugular foramen syndrome involving nerves IX, X, XI and XII, but sparing the cervical sympathetic.
- **Villaret's syndrome** (of the posterior retropharyngeal space). This is involvement of nerves IX, X, XI and XII and the cervical sympathetic and is diagnostic of a complete external jugular foramen syndrome.
- **Wallenberg's syndrome** (infarction of the dorsolateral medulla). This consists of lesions of nerves IX and X, the cervical sympathetic, contralateral spinothalamic loss in the limbs, ipsilateral spinothalamic loss in the limbs, ipsilateral spinothalamic loss over the face and severe vertigo, vomiting and hiccoughs. This is the most classical brainstem vascular syndrome encountered.

Causes (excluding cerebrovascular accidents affecting the brainstem)

- Intracranial lesions:
  - neurinomas of the XIIth nerve, less frequently nerves IX, X and XI, and rarely a vestibular schwannoma may extend down into the internal jugular foramen
  - meningioma of the lateral recess
  - cholesteatoma (particularly likely to affect nerves VII and IX)
  - meningitis (especially malignant or chronic fungal meningitis)
  - fracture of the skull base.
- Extracranial lesions:
  - thrombosis of the jugular bulb
  - metastatic tumour in carotid sheath lymph nodes
  - retropharyngeal abscess or neoplasm
  - carotid body tumour (of the glomus jugulare) may start externally and erode in through the petrous bone or start in the petrous bone and erode out through the skull base.

Clinical symptomatology

The presenting symptoms in these cases may include:

- persistent occipital headache often resembling migraine
- persistent otalgia, which may be worse on swallowing
- hoarse voice, pain in the throat or persistent sore throat
- difficulty in swallowing, choking on fluids or nasal regurgitation.

CT and MRI scanning have revolutionized the investigation of these syndromes. Previously, plain skull films, tomography and carotid angiography were used and often failed to establish a diagnosis. CT scanning will reveal very early evidence of skull base erosion or infiltration by tumour; conversely, MRI scanning can detect even a small neuroma within the jugular foramen – impossible by any other technique.

BULBAR PALSY

The differential diagnosis of lower cranial nerve lesions includes those conditions destroying motor nuclei in the brainstem. Poliomyelitis, previously a common cause, has fortunately become a historical condition, as has diphtheritic bulbar palsy. The most common cause is now bulbar motor neurone disease.

The presenting symptoms consist of a tendency to cough and splutter initially on fluids, but then extending later to include all consistencies of food. Nasal regurgitation and aspiration are common. Speech becomes progressively unintelligible and the patient typically arrives in the clinic clutching a handkerchief to the mouth and a written list of complaints. In the early stages, poor palatal movements, poor tongue movements and weakness of jaw closure and opening may be detected, but the symmetry of involvement may make it difficult to identify mild disability. Fasciculation may be seen in the tongue and facial muscles, or palpated in the masseter. Long tract signs are important and a brisk jaw jerk, increased reflexes and extensor plantar responses would provide strong supporting evidence for the diagnosis.

Myasthenia gravis of the bulbar type is the most important differential diagnosis. Although variability ought to be the hallmark of this disorder, occasionally non-fatiguable and apparently progressive difficulty can produce a confusing picture. This is further compounded by the typical occurrence of bulbar myasthenia gravis in the elderly, the same age group that is liable to develop bulbar motor neurone disease.

PSEUDOBULBAR PALSY

In earlier discussion, the fact that motor cranial nerve nuclei usually have equal, bilateral, upper motor neurone innervation has been emphasized. Only the part of the facial nerve nucleus controlling the lower face shows a major difference in having mainly contralateral supranuclear innervation. Occasionally, both the palate and tongue may be visibly affected by an upper motor neurone lesion, suggesting a variable pattern of supranuclear innervation with mainly contralateral innervation of X and XII in some cases. The accessory nerve is unique in having mainly ipsilateral supranuclear innervation.

The evidence for and the significance of these variations is found in the occurrence of pseudobulbar palsy. This is usually of acute onset consequent upon vascular disease, but is occasionally seen evolving slowly in motor neurone disease and the degenerative condition Steele–Richardson syndrome. These latter conditions produce symmetrical, bilateral, supranuclear degeneration. In vascular disease, a unilateral lesion will usually cause little or no dysfunction of the lower cranial nerves.[33] Occasionally, a patient with a classical, capsular cerebrovascular accident (CVA), in addition to the usual upper motor neurone facial weakness, will demonstrate transient ipsilateral weakness of sternocleidomastoid and upper trapezius and weakness of the palate in the early hours following the onset. Later, a stroke in the opposite internal capsule will acutely deprive

the lower cranial nerves of the residual 50% of their supranuclear innervation. This will result in the instant inability to speak and swallow and is often accompanied by severe emotional lability. In stroke-related disease, these problems will always be of acute onset. In degenerative disease, such as Steele–Richardson syndrome or motor neurone disease of upper motor neurone type, the onset is insidious. In all instances, the end result is pseudobulbar palsy.

EXTRAPYRAMIDAL DISEASE

Fine control of articulation, swallowing and the facial movements associated with speech are achieved by extrapyramidal mechanisms.

PARKINSON'S DISEASE

The loss of spontaneous facial expression and infrequent blinking constitute two of the cardinal features of this disease. In the later stages, hypophonic, tachyphemic speech is characteristic, the short, sharp whispered phrases becoming virtually unintelligible. Chewing food is extremely slowed and the patient may seem to lack the will to initiate swallowing. When one adds the slowness of cutting up and transporting food to the mouth, the cachectic state of a patient with terminal Parkinson's disease is easy to understand. The apparent sialorrhoea of Parkinson's disease actually represents a decreased swallowing rate with a normal production of saliva; it is not due to excessive secretion.

CHOREIFORM SYNDROMES

Choreiform movements of the tongue, palate and mouth conspire to produce spluttering, slurred, explosive speech. This may be seen acutely in Sydenham's chorea as a transient phenomenon or as a severe and progressively disabling problem in Huntington's chorea.

DYSKINETIC SYNDROMES

The so-called buccal–lingual–masticatory syndrome is usually a complication of prolonged neuroleptic therapy, but is also seen in mental subnormality and dementia. In these conditions, the movements do not seem to interfere with speech or swallowing, as the movements subside while speaking and eating. They are mainly a feature at rest.

The oromandibular syndrome (Meige's syndrome) in which slow dystonic opening of the jaw and mouth, in association with tongue protrusion and blepharospasm, is usually seen without neuroleptic provocation. In this condition, attempts to talk and eat aggravate the movements.

Another possibly related dystonic syndrome is spasmodic dysphonia, a disorder characterized by choking of the voice while speaking due to laryngeal spasm, especially on initial vowel sounds. The patient can usually whisper, hum and sing normally. During the choking phase, spasms in the face and neck muscles and blepharospasm may be observed.[34] Treatment with botulinum toxin is a successful form of treatment.

CEREBELLAR DISORDERS

Dysarthria is a feature of generalized cerebellar disease. It typically consists of a slurred, spluttering or scanning type of dysarthria, as breathing mechanisms are desynchronized from speech. It is associated with incoordination of tongue, palatal and facial movements. Inherited cerebellar degenerative disorders and multiple sclerosis are the most common causes, although in the latter condition the disability is often compounded by coexistent spastic dysarthria, producing the typical scanning dysarthria of this disease. Cerebellar neoplasms rarely seem to produce definite speech disturbance.

CONCLUSION

Much clinical material has been included in this chapter to illustrate the functional features of the anatomy and physiology of the cranial nerves in the clinical situation. The coverage is by no means comprehensive. It is hoped that the clinical physiology of cranial nerve function included here will enable the reader to perform a competent clinical examination of cranial nerves in those situations where the symptoms have prompted otolaryngological referral, but have a basis in neurological dysfunction.

KEY POINTS

- Abnormalities of cranial nerve function may be important manifestations of skull base and otological disease.
- A clinical neurological examination is critical in the assessment of patients with skull base pathology.
- In some instances, gross anatomy is of great importance; in others complex central connections require detailed elaboration to illustrate and explain the clinical findings.
- The advent of computed tomography (CT) and magnetic resonance imaging (MRI) has enhanced our ability to unravel suspected diagnoses in what used to be an investigational 'no-man's land'. Scan interpretation requires a very good knowledge of gross anatomy, particularly of the cranial nerves.

CHAPTER 112

THE FACIAL NERVE AND ITS NON-NEOPLASTIC DISORDERS

Christopher Skilbeck, Susan Standring and Michael Gleeson

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: facial nerve, anatomy, physiology, imaging, Bell's palsy, Ramsay Hunt, trauma, surgery, facial nerve grading system, electrophysiological tests and focusing on diagnosis and management.

INTRODUCTION

Facial palsy is a devastating handicap for our patients and probably the foremost complication that otologic and parotid surgeons fear and try to avoid. Leaving aside the potential medico-legal issues that might flow from a palsy that could have been avoided or the risk of acquiring it reduced, it has a huge negative impact on the quality of life of our patients. In recent years, otologic surgery has expanded into the cerebellopontine angle (CPA) as otologists have worked closer with their neurosurgical colleagues. It is now important that we become more competent and familiar with the management of the facial nerve in the angle as well as the temporal bone and neck. In this chapter, the surgical anatomy of the facial nerve is discussed and demonstrated in fine detail together with the non-neoplastic processes that might affect its function. The management and expected standard of care for patients with facial palsy is detailed including the levels of evidence that underpin current protocols.

SURGICAL ANATOMY OF THE FACIAL NERVE

The facial nerve can be exposed through a number of surgical windows, each of which requires a detailed three-dimensional understanding of the relevant anatomy to avoid causing iatrogenic injury intra-operatively.[1] The nerve contains motor, sensory and parasympathetic axons (Figure 112.1). Cadaveric studies have found that the total number of myelinated axons ranges between 7000 and 9000 in the motor root of the facial nerve and between 3000 and 5000 in the nervus intermedius.[2, 3] Both nerves also contain unmyelinated axons. (For an extensive account of some of the important variations of facial nerve anatomy that have been described in the literature, consult Shoja and Tubbs).[4]

INTRAPARENCHYMAL ELEMENTS, ORGANIZATION AND COURSE

Special visceral/branchial efferent (SVE) motor axons supply muscles derived from the second branchial arch, namely the mimetic facial muscles, buccinator, stapedius, platysma, the posterior belly of digastric and stylohyoid. The axons arise from neurons in the facial nuclear complex in the lateral part of the central tegmentum of the pons just rostral to the pons-medulla transition[5] and run posteromedially through the pons, arching over the abducens nucleus to raise the facial colliculus on the floor of the fourth ventricle (which may be seen in axial MRI sections), before turning anterolaterally to leave the brainstem. Neurons in the face area of the motor cortex (supranuclear neurons) project bilaterally to facial motor neurons that control muscles in the upper face (frontalis, orbicularis oculi) but contralaterally to facial motor neurons that innervate the muscles of the middle and lower face. However, sparing of the forehead in facial paralysis is not necessarily pathognomonic of a central lesion (see 'Physical examination' below). Axons supplying

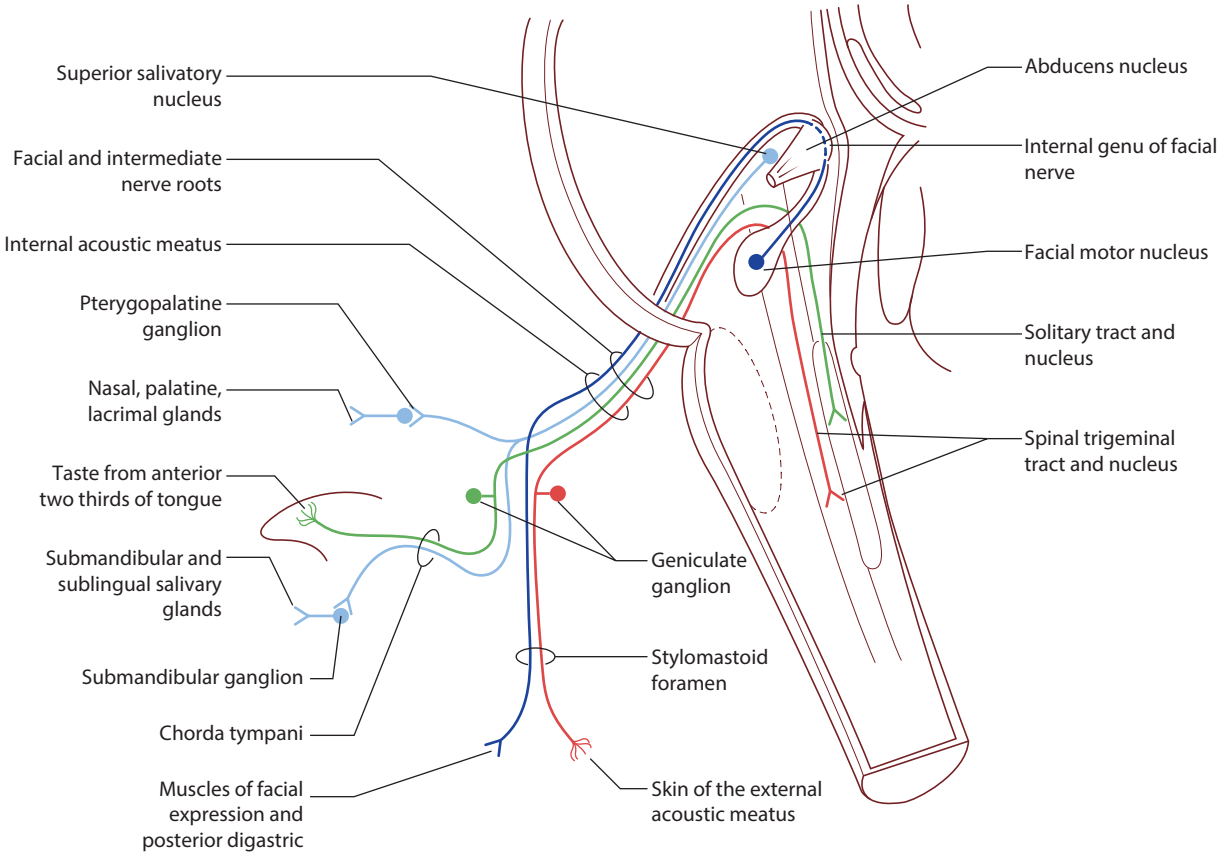

Figure 112.1 GVA axons (nasopharynx, palate, submandibular and sublingual salivary glands) not shown. Cell bodies of origin in the geniculate ganglion, project to more caudal regions of the solitary nucleus. orbicularis oculi constitute the efferent limb of the corneal reflex. Detailed information about the spatial organization of human stapedial motor neurons is unavailable, but findings in guinea pigs, cats and rats suggest that nerve to stapedius may arise from motor neurons that lie outside the main facial motor nucleus.[6] The stapedial reflex is used to test for topographical assessment of a facial nerve lesion and to assess cochlear function as it is elicited by a sound impulse of threshold + 80 dB.

As they pass through the anterolateral part of the pons the SVE motor axons are joined by general visceral efferent (GVE) preganglionic parasympathetic axons from neurons in the superior salivatory nucleus that will ultimately synapse on postganglionic neurons in either the pterygopalatine ganglion (PPG) or submandibular ganglion.

The facial nerve contains two, possibly three, types of sensory axon. Special visceral afferent (SVA) axons carry taste from the anterior two thirds of the tongue via the chorda tympani. General sensory afferent (GSA) axons carry cutaneous sensation, including pain, from the posterior aspect of the external auditory meatus (EAM),[8, 9] with the caveat that the innervation of this region is complex and largely contributed by Arnold's nerve:[10, 11] these axons are thought to be responsible for coughing during cerumen removal, idiopathic otalgia, Hitselberger's sign[12] and to be the site of vesicular eruptions in Ramsay Hunt syndrome. Several authors have suggested that the nervus intermedius also contains general visceral afferent (GVA) axons mediating pain from the tongue and oropharynx.[13] The evidence appears to be based almost exclusively on Ramsay Hunt's description[14] of the occasional distribution of vesicles on the palate in the region of the anterior pillar of the fauces and on the anterior two-thirds of the tongue in the distribution of the chorda tympani in cases of *herpes zoster oticus*. In 1915, Ramsey Hunt inferred that these clinical findings indicated the *'variable and vestigial intra-oral sensory representation'* of the facial nerve. The craniofacial muscles innervated by the facial nerve typically lack muscle spindles: proprioceptive information from these muscles may be mediated by modified cutaneous mechanoreceptors or capsular corpuscle-like structures within the muscles.[15]

The facial nerve has intra- or extracranial connections with the cutaneous branches of all three divisions of the trigeminal nerve (including branches of the auriculotemporal, buccal, mental, lingual, infraorbital, zygomatic and ophthalmic nerves); with branches of the vestibulocochlear, glossopharyngeal and vagus nerves; and with branches of the cervical plexus (including the great auricular, greater and lesser occipital and transverse cervical nerves). Various functions have been proposed for these connections.[16–18] The cutaneous connections are significant in facilitating the perineural spread of tumours that arise either within the parotid or on the face and explains why some patients

with perineural spread from cutaneous or parotid malignancies may present with vocal cord palsy.[19, 20]

The GVE, SVA, GSA (and GVA) axons form the nervus intermedius (intermediate nerve, nerve of Wrisberg) which was initially described by Heinricus Augustus Wrisberg.[21] The name reflects the fact that the nerve usually lies between the motor root of the facial nerve and the vestibulocochlear nerve as it exits the brainstem (**Figure 112.2**). The axons of the motor root of the facial nerve and the nervus intermedius intermingle within the substance of the pons but emerge separately onto the surface of the brainstem, deep in the pontomedullary sulcus. In a retrosigmoid approach, visualization of the root emerging point is impaired by the lower cranial nerves. The root entry/exit zones (REZ) of the facial nerve and nervus intermedius and the more distal transition zones (Obersteiner–Redlich zones) of these nerves, where central myelin (produced by oligodendrocytes) abuts peripheral myelin (produced by Schwann cells), are both targets in microvascular decompression for hemifacial spasm.[22–24] Surgical landmarks to the REZ on the brainstem are the pontomedullary sulcus; the junction of the glossopharyngeal and vagus nerves with the medulla; the foramen of Luschka and choroid plexus; the cerebellar flocculus (the last three structures are related to the lateral recesses of the fourth ventricle).

The subsequent course of the facial nerve is conventionally divided into intracranial (cisternal), intratemporal and extratemporal portions.

Cisternal portion

The cisternal portion is approximately 24 mm long. The motor root of the facial nerve and the nervus intermedius course anterolaterally through the CPA cistern (pontocerebellar cistern) to the porus of the internal auditory meatus (IAM), accompanied by, and usually anterior to, the cisternal segment of the vestibulocochlear nerve. The nervus intermedius may adhere to the vestibulocochlear nerve for a variable distance.[25] The nerves are ensheathed only by a delicate layer of arachnoid mater: the absence of a more robust connective tissue covering renders them not only extremely vulnerable in CPA tumour surgery but also difficult to identify during dissection of a schwannoma.

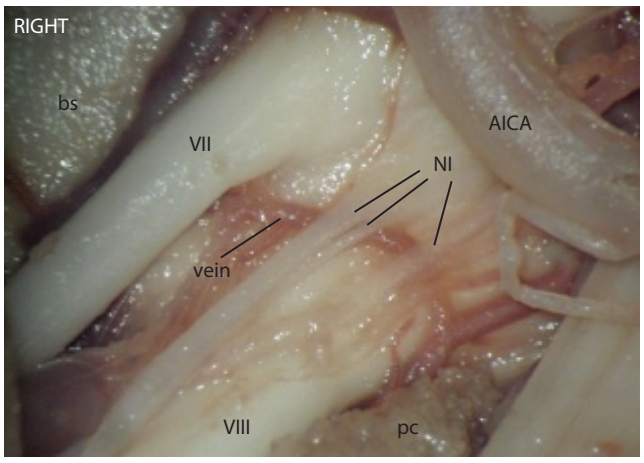

Figure 112.2 Right sided specimen showing the facial nerve (VII), the vestibulocochlear nerve (VIII), the nervus intermedius (NI), and a vein between cranial nerves VII and VIII. In this case, the NI (three bundles) arises separately from the brain stem (bs). The choroid plexus (pc) is located antero-inferiorly to the VII at the entry of the foramen of Luschka. From Alfieri et al. with permission.[22]

Intratemporal portion

The intratemporal portion is 28–30 mm long and subdivided into meatal, labyrinthine, tympanic (horizontal) and mastoid (vertical) segments. The meatal segment runs in the IAM; the labyrinthine segment runs laterally to the geniculum (first turn or genu) and the geniculate ganglion; the tympanic segment runs backwards from the geniculate ganglion to the second genu; the vertical segment runs from the second genu to the stylomastoid foramen; the extratemporal segment runs forwards into the parotid gland where it usually divides into temporofacial and cervicofacial branches. The first three segments do not display any obvious fascicular organization, which may explain why a very selective partial lesion in this part of the nerve is likely to produce a slight overall paresis of the face and also why regeneration following injury usually results in some degree of synkinesis (reinnervation of inappropriate facial muscle groups by regenerating facial axons). These proximal segments are invested by arachnoid mater but lack epineurial and perineurial sheaths, rendering suture technically challenging if not contra-indicated in favour of glue. Arachnoid cysts have been reported within the IAM and facial nerve canal, where they may compress adjacent nerves.[26] Discernible fascicles defined by perifascicular, interfascicular and intrafascicular connective tissue only appear distal to the geniculate ganglion. The number of fascicles increases proximodistally as axons are progressively segregated into specific named nerves. Although the spatial relationship of the fascicles is highly variable,[3] a very selective partial lesion affecting the lower part of the mastoid segment will produce total paralysis of the denervated muscles.

MEATAL SEGMENT

The meatal segment is 5–12 mm long. The motor root of the facial nerve and the nervus intermedius run through the IAM from its porus (medial) to its fundus (lateral wall), accompanied by the cochlear nerve and the superior and inferior vestibular nerves and the labyrinthine artery (**Figure 112.3**). The bundles that make up the nervus intermedius join the facial nerve within the IAM, typically 3 mm from the porus.[22] Different degrees of rotation between the facial and vestibulocochlear nerves have been reported within the IAM.[27] The components of the vestibulocochlear nerve rotate 90 degrees as they travel from the brainstem to the inner ear. The facial nerve remains anterior in its course to the porus acusticus and within the IAM and so lies anterior to the superior vestibular nerve in the lateral end of the meatus.[1] On cross-section, the fundus is divided into four quadrants. It is divided horizontally by a thin bony septum, the crista falciformis (transverse septum) and vertically into anterior and posterior compartments above the crista

by an important bony landmark, Bill's bar (named after **William Fouts House**). The motor root of the facial nerve and the nervus intermedius lie anterior to Bill's bar in the anterior superior quadrant; the superior vestibular nerve lies posterior to Bill's bar in the posterior superior quadrant; the cochlear nerve and inferior vestibular nerve lie below the crista, the cochlear nerve lying anterior to the inferior vestibular nerve (Figure 112.3). The close anatomical relationship between the motor root of the facial nerve, nervus intermedius and vestibulocochlear nerve along their cisternal and meatal portions explains the disturbances in lacrimation, taste, salivary flow, hearing, balance or facial motor control that may result from lesions in either the CPA or IAM.

LABYRINTHINE SEGMENT

The labyrinthine segment is the shortest (3–5 mm) and narrowest part of the facial nerve (average diameter of 0.68 mm). It is the only segment of the facial nerve that lacks anastomosing arterial cascades and so is vulnerable to embolic phenomena, low-flow states and vascular

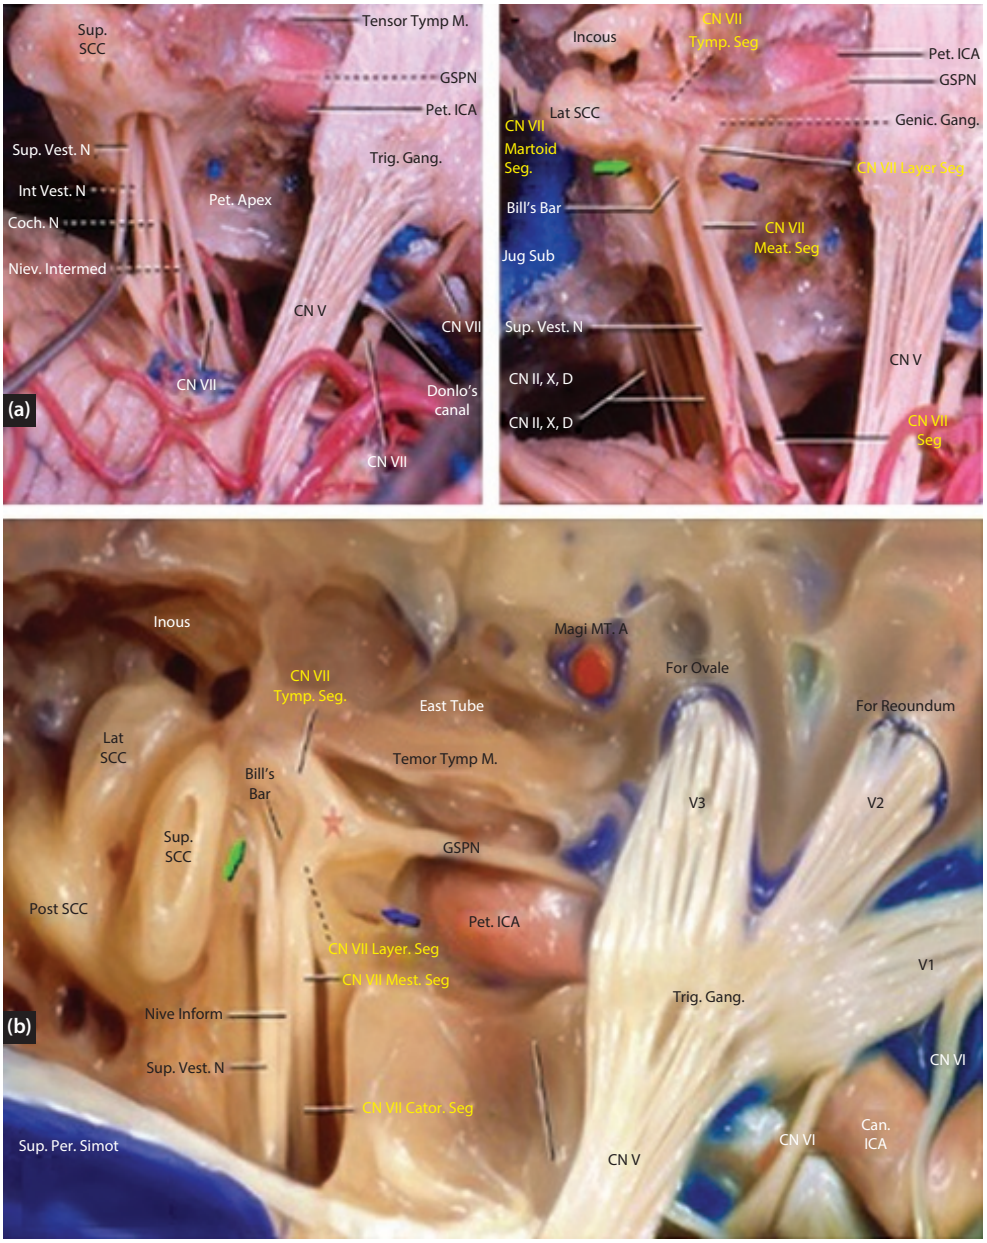

Figure 112.3 When operating using the middle fossa approach, the facial nerve runs laterally, anterior to the superior vestibular nerve and parallel to it within the IAM. This relationship is maintained in a translabyrinthine approach where the facial nerve is found to lie anterior to the superior vestibular nerve and covered by it from the surgeon's perspective, parallel to the cochlear nerve. A significantly different relationship may be encountered in vestibular schwannoma surgery as a result of displacement by tumour. However, it would normally allow the recognition of such a relationship at the level of the fundus when Bill's bar and the crista falciformis become readily identifiable. From Tanriover et al. with permission.[28]

compression: it is most likely to be affected by ischaemia in the event of oedema following trauma or inflammation.

At the distal end of the labyrinthine segment, the geniculate ganglion forms part of a sharp 'hairpin' turn, the geniculum or first genu of the facial nerve, that marks the start of the tympanic segment. At the geniculum, the nerve is cradled by the superior semicircular canal posteriorly and the cochlea anteriorly and inferiorly (**Figure 112.4**). The nerve may be accompanied by the subarachnoid space as far as the geniculate ganglion.[18]

The geniculate ganglion is a sensory ganglion: it does not contain synapses. The central processes of the GSA neurons in the geniculate ganglion carry pain from the EAM and terminate somatotopically in the spinal tract nucleus of V. The central processes of the SVA neurons in the geniculate ganglion that carry taste from the anterior two thirds of the tongue via the chorda tympani terminate somatotopically on second order neurons in the gustatory nucleus (rostral end of the solitary tract) (see **Figure 112.1**). The chorda tympani is thought to modulate trigeminal and glossopharyngeal sensitivity.[29, 30]

Preganglionic parasympathetic axons destined to synapse on postganglionic neurons in either the PPG or submandibular ganglia pass through the geniculate ganglion without synapsing. Those destined for the PPG form the greater petrosal nerve (formerly termed greater superficial petrosal nerve), the first branch of the facial nerve.

The greater petrosal nerve is an important landmark in directing operative approaches through the middle cranial fossa (MCF) to the IAM, petrous apex, trigeminal nerve and petrous portion of the ICA (**Figure 112. 4**).[28, 31] It runs anteriorly and medially from the geniculate ganglion, receives a branch from the tympanic plexus and traverses a hiatus on the anterior surface of the petrous part of the temporal bone to enter the middle cranial fossa, where it runs forwards in a groove on the bone above the lesser petrosal nerve and then passes beneath the trigeminal ganglion to reach the foramen lacerum. Here it is joined by the deep petrosal nerve (which carries postganglionic sympathetic axons from the internal carotid sympathetic plexus), to become the nerve of the pterygoid canal (Vidian nerve) destined for the PPG. Axons travelling in the nervus intermedius pass to the lesser petrosal nerve in the region of the geniculate ganglion. Contrary to their depiction in most anatomical texts, the greater and lesser petrosal nerves are not parallel but usually diverge in the area medial to the geniculate ganglion.[32]

The geniculate ganglion lies in a fossa covered by a very thin layer of bone that separates it from the floor of the MCF. Dehiscences here are not uncommon: when present they render the nerve vulnerable during middle fossa surgery and bring it into direct contact with the meninges. The geniculate ganglion may be injured by bone spicules or directly contused by a shock wave: an enlarged fossa on temporal bone CT strengthens a diagnosis of geniculate ganglion fossa (GGF) fracture in patients with traumatic facial paralysis.[33]

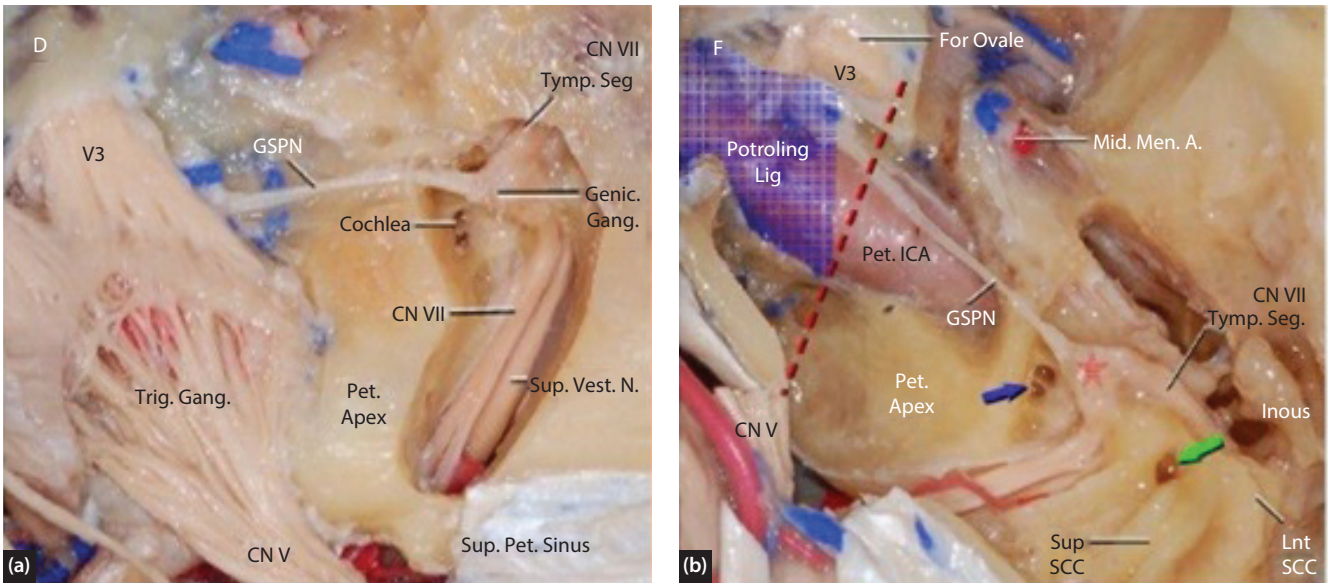

Figure 112.4 **(a)** The superior vestibular and the facial nerves have been exposed within the IAM along with the geniculate ganglion and the cochlea. The cochlea lies below the floor of the middle fossa in the angle between the labyrinthine segment of the facial nerve and the GSPN. The posterior border of the cochlea is the fundus of the IAM, and, posterolaterally, it is related to the geniculate ganglion. The cochlea should not be violated during the exposure of the lateral part of the IAM to preserve the hearing during a middle fossa approach. The bone over the tympanic segment of the facial nerve distal to the geniculate ganglion has been removed. **(b)** The trigeminal nerve has been sectioned to expose the full course of the GSPN and the petrous ICA. The interrupted red line corresponds to the posterolateral limit of the V_3 and the GSPN passes 1.7 cm from this point to the geniculate ganglion (marked with a red star). The cochlea (marked with a blue arrow) and the vestibule (marked with a green arrow) are the main structures to be preserved during the middle fossa approach. The petrous segment of the ICA passes under the petrolingual ligament to enter the cavernous sinus. The petrolingual ligament has been removed; however, the approximate position has been shown in the blue area. From Tanriover et al. with permission.[28]

During a translabyrinthine approach the labyrinthine segment is at risk while drilling along the superior semicircular canal. The ampullated ends of the superior and the lateral semicircular canals (the 'cat's eyes') should be identified; the facial nerve lies just anterior to this area. The labyrinthine segment is the part of the facial nerve that is most likely to be injured in temporal bone fractures, when it is likely to be compressed by bony fragments.

TYMPANIC SEGMENT

The tympanic segment is 8–11 mm long. It runs the length of the superior edge of the medial wall of the tympanic cavity, perpendicular to the long axis of the petrous part of the temporal bone, taking a posterior path that inclines downwards and laterally from the geniculate ganglion to the second genu at the level of the pyramidal eminence.[34] Proximally it passes just above and medial to the posterior edge of the cochleariform process and the tendon of tensor tympani. The cochleariform process is a consistent landmark, when other landmarks are obscured or have been destroyed by pathology. More distally the nerve lies above the oval window niche, just anterior and inferior to the prominence of the lateral (horizontal) semicircular canal before bending at the second genu to enter the bony mass of the styloid complex. The second genu hugs the inferior aspect of the lateral semicircular canal; this relationship is extremely constant. The pyramidal eminence is a useful landmark for the second genu. The retrotympanum contains several small sinuses around the facial canal: the sinus tympani lies medial and anterior to the canal and the facial and lateral tympanic sinuses lie lateral and posterior to the canal.[35–37] The distal aspect of the tympanic segment can be located surgically via a facial recess approach. The chorda tympani nerve and the fossa incudis can be used to identify the nerve when performing a facial recess approach. The second genu of the facial nerve runs inferolateral to the lateral semicircular canal (a relatively constant relationship). The posterior semicircular canal lies just posterior to the second genu: it also marks the superior end of the retrofacial air cells, which are helpful in delineating the medial aspect of the facial canal (**Figure 112.5**).

Developmental dehiscences are not uncommon at this level, making the nerve vulnerable during middle ear surgery, especially around the oval niche.[38–43] A dehiscent or prolapsed facial nerve should always be anticipated in the tympanic segment, especially in patients with congenital ear deformities. The tympanic segment is vulnerable to traction along its axis in longitudinal fractures of the temporal bone.

MASTOID SEGMENT

The mastoid (vertical) segment is the longest of the petrous segments (10–14 mm). It runs vertically downwards in the posterior wall of the tympanic cavity and the anterior wall of the mastoid, from the second genu just distal to the pyramidal process to the stylomastoid foramen on the base of the skull. The digastric ridge (seen on well-pneumatized bones as the medial aspect of the mastoid tip) points to the lateral and inferior aspect of the mastoid segment: a line drawn between the anterior end of the digastric ridge and the tip of the short process of the incus marks the path of the mastoid segment. The nerve may be identified by removing the mastoid tip, skeletonizing the digastric ridge and outlining the inferior part of the vertical segment of the nerve. This is particularly helpful when the extracranial trunk of a functioning nerve is encased in benign tumour recurrences at the stylomastoid foramen.

The nerve travels from the second genu posteromedially to the stylomastoid foramen anterolaterally, which means that expanding a posterior tympanotomy inferiorly in the same plane as it was fashioned could risk injury to the facial nerve. The plane of the facial nerve is almost always lateral to the level of the tympanic anulus, but it may cross it, or lie medial to it in its lower half.[44] The nerve may be damaged when elevating the tympanic anulus or when lowering the mastoid ridge overlying the nerve, as in a modified or radical mastoidectomy.

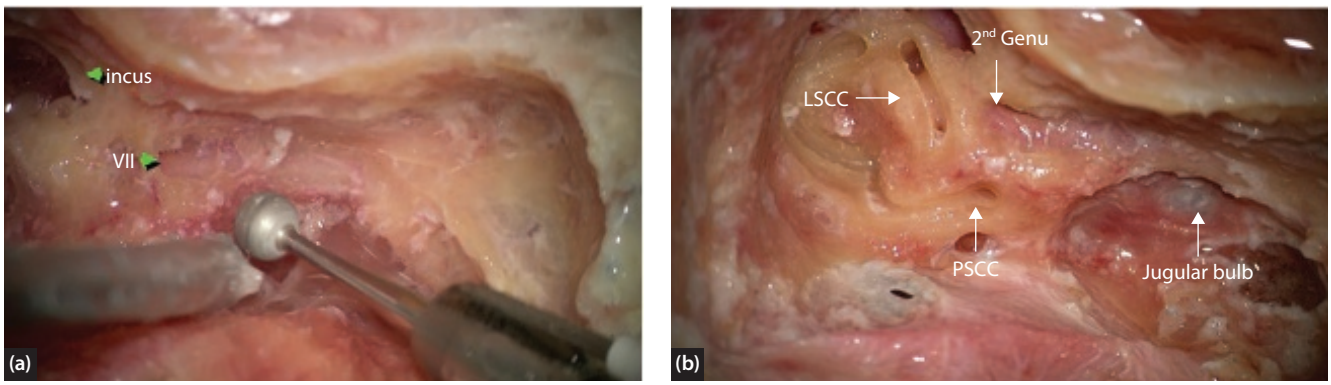

Figure 112.5 **(a)** Right-sided cadaver dissection of the temporal bone. The facial nerve has been exposed in the mastoid segment along an imaginary line from the anterior part of the digastric ridge to the tip of the short process of the incus in the mastoid antrum. **(b)** The semi-circular canals have been skeletonized and opened to demonstrate the relationship of the posterior canal to the second genu (arrowed). If the remaining bone is removed inferior to the lateral semicircular canal, there would be good access to the posterior part of the tympanic segment of the facial nerve.

Most commonly, iatrogenic injury is caused by failure to identify the mastoid antrum properly or being impeded by an overhanging tegmen. It should be remembered that the positions of both the tympanic anulus and the mastoid segment of the facial nerve change during childhood.[45]

The mastoid segment of the facial nerve has three branches, namely the nerve to stapedius muscle, the chorda tympani and the sensory auricular branch. The nerve to stapedius is a small twig given off behind the pyramidal eminence that passes forwards through a small canal to reach the muscle. The chorda tympani is usually given off approximately 5 mm proximal to the stylomastoid foramen and runs anterosuperiorly in a canal to enter the tympanic cavity via the posterior canaliculus. It then curves anteriorly across the pars flaccida of the tympanic membrane between its mucous and fibrous layers, adjacent to the posterior and anterior mucosal folds of the malleus, medial to the upper part of the handle or neck of the malleus and above the insertion of tensor tympani, lateral to the long process of the incus, to reach the anterior wall of the tympanic cavity, where it enters the anterior canaliculus (canal of Huguier) within the medial part of the petrotympanic fissure.[46] Upon exiting the skull at the petrotympanic fissure, the chorda tympani enters the infratemporal fossa where it joins the lingual nerve. A small branch communicates with the otic ganglion. The chorda tympani carries axons mediating taste from the anterior two thirds of the tongue and preganglionic parasympathetic axons that will synapse on postganglionic neurons in the submandibular ganglion. The nerve is a commonly used landmark when performing posterior tympanotomy and serves as the lateral margin of the facial recess. It is sometimes used as the medial limit of lowering the facial ridge when performing a canal wall down technique. Occasionally the chorda tympani may arise extratemporally.[47]

The facial nerve is usually surrounded by thick fibrous tissue at the styolomastoid foramen: to avoid irrevocable damage during anterior transposition of the nerve it is advisable to lift the segment *en bloc* together with fibres of the posterior belly of digastric and slivers of bone around the foramen. On leaving the stylomastoid foramen, the facial nerve initially lies below the tympanic plate, lateral to the bases of the styloid process and the carotid sheath and posterior to the parotid gland. It immediately gives off the posterior auricular nerve which passes upwards behind the ear between the parotid gland and the anterior border of sternocleidomastoid and then in the notch between the EAM and the mastoid process to supply the occipital belly of occipitofrontalis, auricularis superior and the intrinsic auricular muscles. A second muscular branch divides to supply the posterior belly of digastric and the stylohyoid muscle.

EXTRACRANIAL SEGMENT

The main trunk of the extracranial facial nerve enters the parotid gland high up on its posteromedial surface and passes forwards and downwards behind the mandibular ramus. It divides within the gland, usually just behind and superficial to the retromandibular vein and external carotid artery (ECA) into an upper temporofacial trunk and a lower cervicofacial trunk. The relationship between the nerve and vein may vary.[48, 49] In cadaveric studies of adult heads, the length of the facial nerve trunk from stylomastoid foramen to the initial intraparotid bifurcation has been found to range between 8 mm and 22 mm.[50]

The temporofacial trunk contains more axons but fewer fascicles than the cervicofacial trunk.[3] The trunks branch further to form a parotid plexus (pes anserinus) from which five main terminal branches, temporal, zygomatic, buccal, marginal mandibular and cervical, ultimately emerge. These branches diverge within the substance of the parotid and leave the gland via its anteromedial surface, medial to its anterior margin. Numerous microdissection studies have demonstrated considerable individual variations in branching patterns and anastomoses between branches, both within the parotid and on the face.[51–55] While there is no evidence to suggest that a particular classification pattern is associated with increased risk of surgical complications, it is reasonable to assume that nerves that are truly plexiform sustain surgical injury better than those that are not, since accidental division or deliberate sacrifice of a small branch in a plexiform nerve is rarely accompanied by a significant or noticeable facial weakness. While the subsequent distribution of the branches of the facial nerve on the face is variable they retain a relatively constant relationship to soft tissue planes.[4, 56]

Facial nerve injury is the most significant complication of parotidectomy.[57] In addition to intra-operative functional nerve monitoring, a number of landmarks are commonly used to identify the facial nerve trunk during surgical procedures. They include the tragal pointer, the posterior belly of digastric muscle, the junction of the bony and cartilaginous portions of the ear canal, the transverse process of the axis and the tympanomastoid suture. The main trunk of the facial nerve usually lies 1 cm medial and inferior to the tragal pointer (the medial aspect of the tragus which points inward, forming the anterior and inferior wall of the EAM). The trunk can also be identified 6–8 mm below the inferior 'drop off' of the tympanomastoid fissure or by retrograde dissection along the posterior belly of the digastric muscle towards its insertion into the mastoid process: the main trunk bisects the angle between the upper border of the muscle and the EAM. In spite of numerous cadaveric studies there is no general consensus as to which of these landmarks is the most consistent.[58, 59] Landmarks for retrograde parotidectomy, undertaken when the landmarks used in anterograde parotidectomy are not easily accessible intra-operatively, will vary according to which peripheral branch of the facial nerve is being followed retrogradely. The retromandibular vein is a commonly used landmark for the marginal mandibular branch of the facial nerve.[60] The marginal mandibular nerve may also be identified by following the facial vein proximally within the parotid tissue, where the nerve crosses lateral

to the vein. The buccal branch runs parallel and 1 cm below the zygomatic arch and often along the inferior aspect of the parotid duct.

The anatomical course of the facial nerve is subject to variations and anomalies. Because the facial nerve is the nerve of the second branchial arch, any malformations in the derivatives of Reichert's cartilage should raise suspicion of possible anomalies. Otolaryngologists should be cautious when exploring patients with external ear malformations, congenital conductive hearing loss and craniofacial anomalies.

BLOOD SUPPLY OF THE FACIAL NERVE

The arterial supply of the segments of the facial nerve is derived from branches of the vertebrobasilar and ECA systems (**Figure 112.6**).[61, 62] The labyrinthine artery (internal auditory artery) supplies the cisternal, meatal and labyrinthine segments. It usually arises directly from the AICA as it loops between the cisternal segments of the motor root of the facial nerve, the nervus intermedius and the vestibulocochlear nerves, projecting towards and often into the IAM, but it may arise from the basilar, vertebral or superior cerebellar arteries.[63] The greater petrosal nerve is supplied by the petrosal branch of the middle meningeal artery which usually passes through the bone enclosing the geniculate ganglion and tympanic segment of the nerve, less commonly it passes through the hiatus of the greater petrosal nerve: the vessel and nerve are at risk during procedures where the dura is elevated from the floor of the MCF.[64] The tympanic and mastoid segments are supplied by the facial arch, an anastomotic network formed by the superficial petrosal branch of the middle meningeal artery and the stylomastoid branch of either the occipital or posterior auricular arteries, which enters the facial canal via the stylomastoid foramen. The lowest branch from the stylomastoid artery to the facial nerve is given off at the level of the origin of the chorda tympani: collaterals of the stylomastoid artery supply the chorda tympani. Branches from the facial arch anastomose with vessels supplying the bone marrow of the facial canal and with anterior and superior tympanic branches of the maxillary artery, the posterior tympanic branch of the posterior auricular artery, and the inferior tympanic branch of the ascending pharyngeal artery.[65] The posterior auricular and occipital arteries and their branches, including the stylomastoid artery, supply the facial nerve from the stylomastoid foramen to the parotid gland. The temporofacial and cervicofacial branches that exit the parotid gland are supplied by collaterals of the superficial temporal, transverse facial, facial and maxillary arteries.

The labyrinthine portion is supplied exclusively by meatal arteries and therefore more likely to suffer from ischaemic damage than the other segments. That said, any part of the intratemporal portion of the nerve that becomes oedematous is susceptible to compression and subsequent ischaemic damage. Vascular lesions causing pulsatile compression of sensory axons likely produce neuralgia, whereas compression of motor axons will produce hemifacial spasm.

PATHOPHYSIOLOGY OF NERVE INJURY

Peripheral nerves (cranial and spinal) may be injured in a variety of ways, broadly classified as local (trauma, whether blunt or penetrating; compression: chronic traction or acute stretch; local chemical or freeze injury) or systemic (immune-mediated inflammation; diabetes

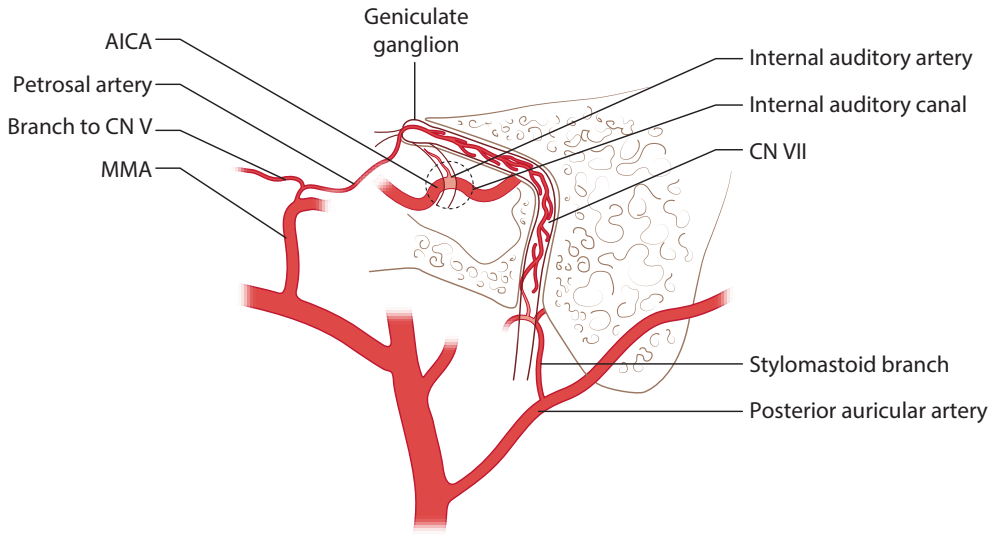

Figure 112.6 The tympanic and mastoid segments of the facial nerve are supplied by the facial arch formed by the petrosal branch of the middle meningeal artery (MMA) and the stylomastoid branch of the posterior auricular artery. AICA, anterior inferior cerebellar artery; CN, cranial nerve. Redrawn from Chen et al.[66]

mellitus; vasculitis; drug-induced). Ischaemia induced by mild pressure may produce transient paraesthesia but no obvious structural changes, recovery is usually rapid and surgical intervention is not required. Prolonged ischaemia or immune-mediated attack may cause specific loss of myelin (primary or segmental demyelination) without loss of axonal integrity, resulting in an increased refractory period of transmission and conduction slowing, followed by conduction block. If the causative agent, such as a spicule of bone or a haematoma, is removed, remyelination typically takes place within 2–4 months, usually with little residual loss of function; surgical intervention is not required. In marked contrast, any injury that physically separates axons from their neuronal cell bodies triggers a programme of molecular and cellular events at the site of the lesion and in distant parts of the injured neurons and their target organs that has a significant impact on outcome. Therapeutic intervention cannot (yet) manipulate responses that happen many centimetres from the injury and that may influence functional outcome months or even years later. Centrally, nerve injury induces reprogramming of synaptic connectivity in the cortex and spinal cord as well as responses in affected sensory ganglia that may mediate the development and maintenance of chronic neuropathic pain. Variable numbers of neurons will die when injury isolates them from their supply of retrogradely transported neurotrophins, particularly if the insult is close to the neuronal cell body. Peripherally, atrophy of chronically denervated sensory end organs and muscles may preclude their reinnervation. (The term 'Wallerian degeneration' refers specifically to the process of degeneration that takes place along a nerve distal to an injury and is named after Augustus Waller: in a seminal report read to the Royal Society of London on February 21, 1850. Waller summarized the degeneration that would come to bear his name, describing the gradual disintegration of the glossopharyngeal or hypoglossal nerves of frogs after axotomy).

The microenvironment of an acutely denervated distal stump facilitates axonal regrowth because it provides a vascularized segment of longitudinally orientated, laminin-rich basal lamina tubes filled with axon-responsive Schwann cells (**Figure 112.7**).[67] However, axonal regrowth is frustrated over time by progressive endoneurial fibrosis and Schwann cell senescence.[68–70] The cardiologists' aphorism 'time is muscle' applies equally to the consequences of delaying nerve repair too long. Early nerve repair results in improved functional outcomes.[71, 72] Surgical intervention, whether direct coaptation of stumps by gluing or suturing; or bridging a long inter-stump gap by either grafting a segment of nerve (end-to-end or end-to-side) or some form of tissue-engineered device; or by nerve transfer, may be required to enable regrowing axons to encounter and interact with Schwann cells. The mitigation of endoneurial fibrosis, muscle and sensory end organ atrophy and Schwann cell senescence remain key clinical challenges.[73]

Based on his wide experience of traumatic nerve injuries, Sir Herbert Seddon distinguished between three types of localized injuries to peripheral nerves and

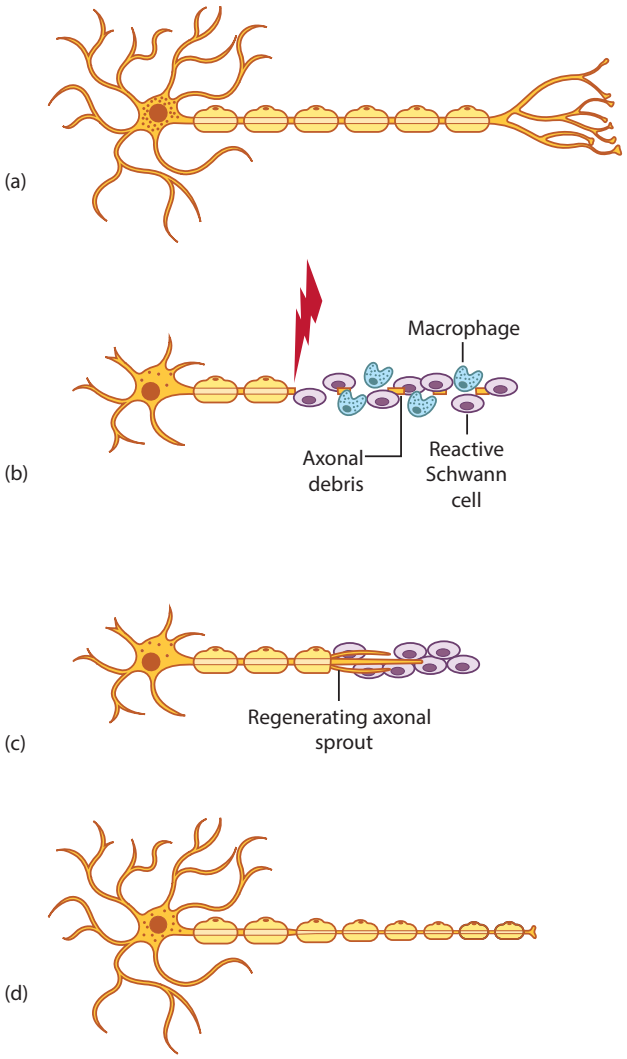

Figure 112.7 **(a)** Normal neuron and nerve fibre. **(b)** Wallerian degeneration. Axotomy results in fragmentation of the distal axon and myelin sheaths. Schwann cells proliferate and macrophages invade the distal nerve segment and phagocytose degrading materials. **(c)** Schwann cells in the distal segment line up in bands of Büngner. Axonal sprouts advance embedded in the Schwann cells and attracted by gradients of neurotrophic factors. **(d)** Axonal reconnection with end organs and maturation and remyelination of the nerve fibre. Re-drawn from Allodi I, Udina E, Navarro X.[67]

introduced the terms neurapraxia, axonotmesis and neurotmesis to describe them.[74] Neurapraxia occurs when compression or stretch produces an anoxic, physiological block of both axoplasmic transport and ion channel functions along affected axons: loss of function is usually temporary and release of the compressive agent usually results in rapid and complete recovery of function and relief of pain. Compression or traction resulting in prolonged ischaemia produces demyelination. Birch[72] points out that … '*the term neurapraxia is best reserved for those situations where electrodiagnosis has conclusively shown that demyelinating conduction block is solely responsible for the neural lesion.*' Axonotmesis occurs when a blunt injury to a nerve results in Wallerian

degeneration distal to the injury, but the connective tissue layers (epi-, peri- and endo-neurium) remain intact. Conduction ceases throughout the distal extent of the nerve within a few days of injury. With the caveat that the distance from injury site to end organ(s) may ultimately defeat successful reinnervation, there is no *a priori* reason why regrowing axon sprouts should not extend to their appropriate targets within the Schwann cell tubes that housed their parent axons: if their progress is unimpeded, recovery progresses proximo-distally (as judged by an advancing Tinel's sign) at a rate of ~1 mm/day. It must be appreciated that even when an axon reaches its target organ, subsequent reinnervation of that target is neither guaranteed nor is it synonymous with full functional recovery. Neurotmesis occurs when a nerve is either completely divided or so badly disorganized by injury that recovery without some form of surgical intervention is impossible. All the connective tissue layers of the nerve as well as the axons are disrupted at the site of injury: a wide inter-stump gap may be produced either by the injury or during subsequent intra-operative wound debridement.

Spontaneous axonal regeneration following this type of injury will be imperfect and disorderly, and may not occur at all. Distance is a significant factor in recovery, particularly after proximal injuries in limb nerves, because regrowing axons may fail to reach their target organs before the latter disappear. Changes in fibre type and loss of striated muscle mass begin within days after denervation; up to 80% of muscle volume may be lost by 4 months and irreversible muscle fibrosis and fatty infiltration occurs after 2 years.[75–77] Some reconstructive surgeons regard functional reinnervation as unlikely beyond 12–18 months. Even after repair, muscles usually exhibit weakness, impaired coordination and reduced stamina; regeneration of the largest diameter axons and coactivation of α and γ efferents may fail. Cutaneous sensory receptors undergo a slow degenerative change after denervation and may disappear after 3 years. Their reinnervation tends to reverse these changes, particularly if the injury occurs close to the end organs and the nerves involved are sensory, however, the longer the period of denervation, the less complete will be the regeneration. Attempts to increase the rate of axonal regrowth in various experimental animal models remain disappointing.

Sir Sydney Sunderland amplified Seddon's category of axonotmesis to describe progressively more invasive levels of injury to the endoneurial contents, perineurium and epineurium, respectively, correlating these new levels with more accurate prognoses of outcomes in axonotmesis injuries.[78] Recovery is typically complete after Sunderland's grade 1 (equivalent to neurapraxia) and 2 (axonal degeneration with intact endoneurium) injuries; grade 3 injuries recover partially; grades 4 and 5 (equivalent to neurotmesis) usually require surgical intervention (**Table 112.1**). Depending upon the level of tissue disruption, misdirection of regrowing axons into modality-inappropriate Schwann tubes in the distal stump is inevitable (For a review of the molecular mechanisms that have been implicated in axonal pathfinding after injury refer to the biology of chronically denervated Schwann cells).[67, 68] Regrowing axons and their associated Schwann cells may form a mechanosensitive neuroma at the end of a proximal nerve stump or a neuroma – in-continuity with the distal stump, phenomena that also compromise recovery. In 1988, MacKinnon

TABLE 112.1 Nerve injury classification and electrophysiological correlates (modified from Birch, 2011)[72]

Seddon	Sunderland	Pathology	Electrophysiological correlate
Neurapraxia	Grade 1	A transient light compression causing endoneurial oedema but no significant morphological changes. A more substantial and prolonged mechanical compression or stretch is most likely to cause a focal demyelination that may be paranodal or affect whole internodes. Anoxia plays a role in the pathogenesis	Conduction block ± conduction slowing. Nerve distal to 'lesion' shows normal conduction
Axonotmesis	Grade 2	Axons degenerate distal to the site of the lesion, irrespective of calibre or modality Endoneurium, perineurium and epineurium remain intact. Schwann cell basal lamina tubes either remain continuous across the lesion or are minimally separated within a morphologically intact perineurium and epineurium	Fibrillation Mild diminution to complete absence of SNAP and CMAP responses, in proportion to degree of axonal loss ± varying degrees of conduction block and slowing associated with demyelination
Axonotmesis	Grade 3	Endoneurium disrupted, axons degenerate distal to the site of the lesion	Fibrillations, absent SNAP and CMAP responses
Axonotmesis	Grade 4	Perineurium disrupted, axons degenerate distal to the site of the lesion	Fibrillations, absent SNAP and CMAP responses
Neurotmesis	Grade 5	Epineurium disrupted, axons degenerate distal to the site of the lesion	Fibrillations, absent SNAP and CMAP responses

'Mixed' is an additional category that combines Grades 2–4 to produce a classification that better represents common clinical scenarios (Mackinnon and Dellon, 1988).[79] SNAP, sensory nerve action potential; CMAP, compound muscle action potential.

and Dellon[79] added a Grade VI injury to Sunderland's classification to better reflect the common clinical scenario of a mixture of crush and transection injury occurring within a damaged nerve. Their classification resonates with an earlier comment by Bowden and Gutmann[75] that … '*In some cases of lesions in continuity there is a mixture of neurotmesis and axonotmesis and if there is much intraneural disturbance, the quality of spontaneous recovery may be poor.*'

The distinction between cases of conduction block (non-degenerative lesions) and those causing axon degeneration is important in prognosis. However, this can be difficult to diagnose early after an injury because Wallerian degeneration usually takes place over several days following injury which means that distal nerve excitability is usually maintained for several days. This timescale has implications on the timing of electrical testing of an injured nerve (see 'Electroneuronography (ENog)' below). In 2016, Hems summed it up well: '*The most important issue is the difference between lesions where the nerve is in-continuity (neurapraxia and axonotmesis) and those where recovery will not occur without surgical repair (neurotmesis).*[80]

Other than a sharp transection, most other injuries or disorders involving the facial nerve will not cause an all-or-nothing lesion, i.e. there is usually a mixture of all three types of injury.

May and colleagues correlated Sunderland's classification with evoked electromyography, histological change, onset of clinical recovery and final recovery according to House and Brackmann's grading.[81] May suggested that the first three degrees of injury can develop with viral inflammatory immune disorders such as Bell's palsy and herpes zoster cephalicus. It is important to remember that the time course for improvement and the extent of recovery is significantly different for incomplete facial nerve paresis compared with total paralysis: 'palsy' includes both entities, whereas 'paralysis' denotes total loss of nerve function.[82] Multiple factors affect the progress of facial nerve regeneration, including the type and severity of the injury and local wound conditions, and more general criteria such as age, nutritional status and comorbidities (e.g. diabetes mellitus).

CLINICAL EVALUATION OF PATIENTS WITH FACIAL PALSY

The history and physical examination are absolutely crucial in the evaluation of a patient with a facial nerve disorder. Every effort must be made to determine the cause. This is particularly the case for patients who present with a facial palsy when their history does not quite fit with an idiopathic palsy (Bell's palsy). In a study of 974 patients referred with a presumptive diagnosis of Bell's palsy, 96 had been misdiagnosed and of these, 47 patients had tumours.[83] Schaitkin and May[84] studied 273 patients who were seen consecutively for evaluation of acute facial nerve palsy. They found that in all cases patients or their families were satisfied if three questions could be answered: (1) what was the cause? (2) when could recovery be expected? (prognosis); (3) what could be done to promote recovery? In most patients who present with an acute facial palsy, these three questions can be answered after a thorough evaluation during the initial office visit.

History

Most patients with a facial palsy consult their general practitioner in the first instance and a large number of them will be assumed to have an idiopathic palsy. Although suggestive, the history of the onset of palsy, whether complete or incomplete, sudden or progressive, is not diagnostic. All these patterns have been noted with idiopathic palsy as well as with infections or neoplasms. Progressive facial nerve palsy over a period of more than 3 weeks, or an incomplete facial nerve palsy that does not start to recover after 3–6 weeks, should make the clinician suspect an underlying neoplasm as the cause and should dictate the need for further investigations.

Ipsilateral recurrent facial nerve palsy is occasionally seen in patients with idiopathic palsy, Melkersson–Rosenthal syndrome and tumours. In fact, the incidence of recurrent facial nerve paralysis in patients with idiopathic palsy is approximately 13% of which 38% are ipsilateral and 62% are on the contralateral side.[85] Pitts et al.[86] reported a mean interval of 9.8 years between recurrences of idiopathic palsy (range : 1 month to 43 years). They also noted that patients with a recurrence were 2.5 times more likely to have a positive family history. Recurrence is common in herpes simplex type I infection but rare with herpes zoster. May and Hardin[87] reported that in 6 of 20 patients with ipsilateral recurrence, a tumour involving the facial nerve was the cause. They recommended that a tumour be suspected in every patient who presented with an ipsilateral recurrent facial palsy. In contrast to recurrent ipsilateral facial paralysis, contralateral recurrence is almost always benign. Alternating recurrent facial nerve palsy is rare and is a feature of Melkersson–Rosenthal syndrome, a condition also characterized by facial oedema, fissured tongue and a positive family history (**Figure 112.8**). Bilateral concurrent facial nerve paralysis is most probably associated with a systemic condition, the most common being Guillain–Barré syndrome, but is also seen in patients with cerebral lymphoma, leukaemic infiltration, sarcoidosis, Lyme disease, rabies, infectious mononucleosis and Moebius syndrome.

Physical examination

A thorough head, neck, otologic and cranial nerve examination is the absolute minimum required when evaluating facial nerve dysfunction. Facial weakness can be extremely subtle, apparent only to a trained examiner and, almost

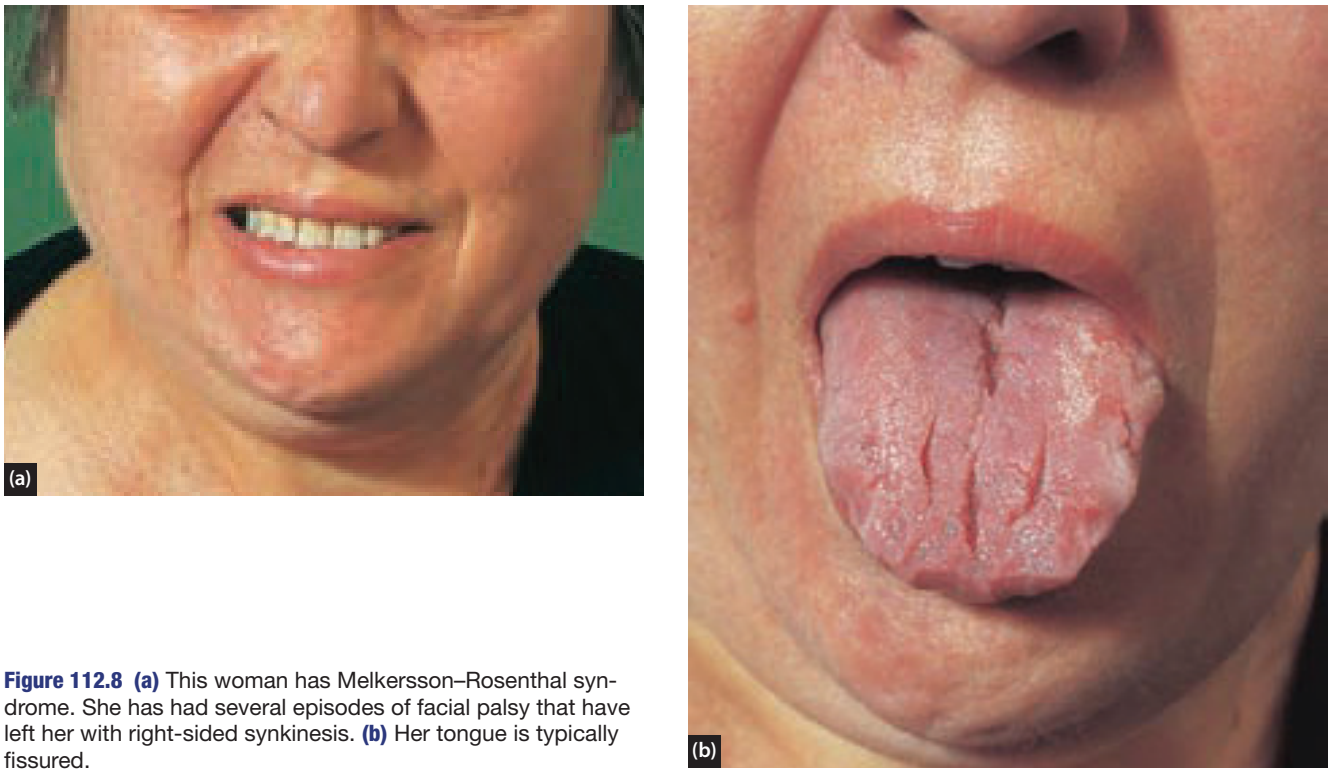

Figure 112.8 **(a)** This woman has Melkersson–Rosenthal syndrome. She has had several episodes of facial palsy that have left her with right-sided synkinesis. **(b)** Her tongue is typically fissured.

certainly, to the patient and their close friends or carers. Examination must be expanded as indicated by the individual patient's history. The degree of facial weakness must be recorded from the outset and an attempt made to localize the precise site of the cause along the course of the facial nerve i.e. intracranial, intratemporal or extratemporal. An open mind to the potential cause is essential since facial nerve palsy may be the first presentation of a systemic illness.

If symptoms or signs of other cranial nerve deficits are present, a central or systemic cause should be suspected. Sparing of forehead movement is considered to be characteristic of a central lesion but is not always the case. Normal movement can be seen in facial nucleus lesions and even peripheral lesions of the temporal branch of the facial nerve. An isolated lower facial palsy is therefore not necessarily indicative of a central lesion. A partial palsy of one or two branches strongly suggests disease localized distal to the stylomastoid foramen and a parotid malignancy should be suspected. If the parotid gland is enlarged and the patient has impaired vision or iritis, sarcoidosis is a possibility.

Facial palsy grading systems

Several systems of clinical measurement of facial nerve function have been described. In 1983, House proposed a six-point scale for reporting the recovery and outcomes of surgery for vestibular Schwannomas. This system was modified and called the House–Brackmann Staging System and has become the most widely used scheme and endorsed by the American Academy of Otolaryngology – Head and Neck Surgery.[81] It has become engrained in clinical practice and will remain so despite its shortcomings as a scientifically accurate assessment tool. In the House–Brackmann system, grade I is normal function, grade VI is complete absence of facial motor function and grades II–V are intermediate (Table 112.2).

As stated above, the House–Brackmann staging system does have limitations with respect to precision and inter-observer error. It emphasizes the characteristics of facial nerve palsy from two assessment domains. The first is gross observation and the second is movement of the forehead, eye and mouth. The fusion of static and dynamic criteria may have contributed to some disagreement between examiners. When only a global score is used, the risk of disagreement among different examiners can range from 13% to 44%.[88, 89] Yen et al.[90] reported the efficacy of the House–Brackmann grading in patients with differential facial nerve function and concluded that a single global grading number was inadequate to describe facial function and primarily reflected the function of the eye. They recommended that regional assessment using the House–Brackmann grading system should be carried out in patients with facial nerve palsy and the result should be reported for the forehead, eye, nose and mouth separately to get a more precise evaluation.

The wide acceptance of the House–Brackmann system has not prevented others from proposing new systems. Burres and Fisch[91] described a method requiring multiple measurements of movement in different parts of the face. Croxson et al.[89] showed the expected correlation between the Burres–Fisch and House–Brackmann systems in 42 patients and found considerable overlap of

TABLE 112.2 House–Brackmann staging system

Degree of injury	Grade	Definition
Normal (1°)	I	Normal symmetrical function in all areas
Mild dysfunction (barely noticeable) (1–2°)	II	Slight weakness noticeable only on close inspection
		Complete eye closure with minimum effort
		Slight asymmetry of smile with maximal effort
		Synkinesis barely noticeable, contracture or spasm absent
Moderate dysfunction (obvious difference) (2–3°)	III	Obvious weakness, but not disfiguring
		May not be able to lift eyebrow
		Complete eye closure and strong but asymmetric mouth movement with maximal effort
		Obvious, but not disfiguring synkinesis, mass movement or spasm
Moderately severe dysfunction) (3°)	IV	Obvious disfiguring weakness
		Inability to lift eyebrow
		Incomplete eye closure and asymmetry of the mouth with maximal effort
		Severe synkinesis, mass movement, spasm
Severe dysfunction (3–4°)	V	Motion barely perceptible
		Incomplete eye closure, slight movement of the corner of the mouth
		Synkinesis, contracture and spasm usually absent
Total paralysis	VI	No movement, loss of tone, no synkinesis, contracture or spasm

This system was proposed by House and Brackmann and adopted by the Facial Nerve Disorders Committee of the American Academy of Otolaryngology, Head and Neck Surgery.

Burres–Fisch scores for House–Brackmann grades III and IV. Murty et al.[88] proposed and tested the Nottingham system of subjective estimation of movement at each of several points on the face. This method correlated better with the House–Brackmann system than did the Burres–Fisch, and it was simpler to perform.

Facial nerve dysfunction includes secondary effects that complicate facial nerve injury. They usually result from aberrant neural regeneration and include synkinesis, hemifacial spasm, contracture, crocodile tears, epiphora, dysgeusia, pain and hyperacusis. These effects do not accompany the primary weakness in an orderly fashion or predictable way and have a significant influence on the patient's perception of disability, handicap and quality of life. Both the Nottingham and Sunnybrook scales have attempted to include these secondary effects in their overall score.[92] To date, none of the current measurement systems have been validated against patient self-assessment in a robust fashion. The ideal system should be user-friendly, reliable and reproducible, reflect patho-physiological events and correlate well with self-assessment.

The advent of computerized technologies prompted more accurate and objective measurements of facial function and secondary effects such as synkinesis, spasm and velocity of facial movement. These techniques have utilized superficial reflective facial fiducials, pixel subtraction techniques, the movement of standardized facial landmarks against registered static points in the midline of the face and even Moiré topography to obtain objective scores or grades. A detailed summary and critique of these techniques has been made by Brenner and Neely.[93] Their conclusion was that computer-based systems offer refinement beyond that available by all other assessment scales. However, they require specialized equipment and considerable investment of time on the part of the clinician, which is almost certainly not possible outside the research setting.

In reality, it is the effect of facial palsy, incomplete recovery and the secondary effects caused by aberrations of regeneration on the patient's quality of life that matter. Functional impairments that include difficulties in eating, drinking, speaking and conveying intimate human information and emotion are simply not captured in any of the surgeon-ranked clinical scales used in practice. Psychological consequences such as decreased self-esteem, anxiety when meeting strangers, depression and social isolation are not even considered. Patient-reported outcomes should be quoted alongside those of surgeon-ranked scales. In a thorough, systematic review undertaken by Ho et al.[94] that analyzed 598 articles indexed by the recognized databases, the Facial Clinimetric Evaluation,[95] the Facial Disability Index[96] and a questionnaire developed to study aberrant facial nerve regeneration[97] were the only instruments that satisfied all inclusion and exclusion criteria. Even these had limitations in domains that addressed self-perception of facial appearance and procedure-related symptoms or satisfaction. Ho et al. concluded that future

research was necessary to develop and validate a new patient-reported outcome instrument.

Topodiagnostic tests

Topodiagnostic evaluation of facial palsy refers to the functional testing of an individual facial nerve branch in an attempt to locate the anatomical level of dysfunction or injury. These tests are of some value but have a slightly limited correlation with the precise site of nerve damage and do not have any prognostic value. These studies are summarized in Table 112.3.

Electrophysiological tests

Electrophysiological tests have been developed to evaluate the degree of dysfunction and assumed viability of the facial nerve in the anticipation that results would provide prognostic information for recovery. This information has been used to influence management, particularly the potential impact of any surgical intervention. These tests are not normally used in the assessment of incomplete paresis, which has a higher probability of full, functional recovery. They are only used in patients with complete established paralysis, when they can aid management decisions concerning facial reanimation. Repair of the facial nerve is contraindicated when the motor end plate muscle units are no longer functional, a process that continues inexorably along with muscle atrophy in the months after total denervation. Reinnervation procedures when no muscle end plate activity can be detected by electromyography are contraindicated because they will not be successful.

The traditional tests using transcutaneous stimulation of the facial nerve to establish the minimum current required to provoke muscle movement, the nerve excitability test (NET), and the current required to achieve maximal muscle response without causing any discomfort to the patient, maximal stimulation test (MST), are rarely used nowadays (Table 112.4). Both these tests compared the response on the normal to the palsied side and could be undertaken at the bedside or in the clinic using a Hilger Stimulator: they had their limitations in terms of accuracy, reproducibility, inter-observer variation and prognostic value (Table 112.4).[98]

The two techniques most commonly used now by otorhinolaryngologists in clinical practice are electroneuronography (ENoG) and electromyography (EMG). A third technique, transcranial magnetic stimulation, also has a role in clinical practice, particularly in neurology, but has yet to be employed widely by otorhinolaryngologists.

ELECTRONEURONOGRAPHY (ENoG)

In ENoG, a supramaximal stimulus is delivered to the facial nerve trunk as it exits the stylomastoid foramen and the evoked biphasic compound muscle action potential (CMAP) is recorded using surface electrodes. The response of the paralyzed side is compared with that of the normal side, which serves as a control, and is expressed as a percentage of the normal. It has been shown that reduction in CMAP correlates well with histological axonal loss.[99] This means that if the CMAP amplitude on the affected side is 10% of the normal side, then it is assumed that

Figure 112.9 Schirmer's test. The patient had sustained a longitudinal fracture of the left temporal bone that had transected the greater petrosal nerve. She had a dry eye as is demonstrated in this test.

TABLE 112.3 Topodiagnostic tests

Test	Nerve branch assessed	Technique considerations	Assessment/ Outcome
Schirmer's test (Figure 112.9)	Greater (superficial) petrosal nerve	Strips of paper are placed in the inferior conjunctival fornix for 5 minutes and the length of paper moistened is compared between eyes	>75% unilateral decrease in lacrimation, or a bilateral decrease in lacrimation (less than 10 mm wetted for both sides at 5 minutes)
Stapedial reflex	Nerve to stapedius muscle	See Chapter 51, Psychoacoustic audiometry	Present or absent
Electrogustometry	Chorda tympani	The tongue is stimulated electrically to produce a metallic taste and the two sides are compared	Threshold of the test is compared between sides
Salivary flow testing	Chorda tympani	Wharton's ducts are cannulated and salivary flow is measured over time following a gustatory stimulus (6% citric acid on anterior part of tongue)	A reduction of 25% is considered abnormal

TABLE 112.4 Comparison of NET and MST

Test	Technique	Outcome measure	Prognostic value
NET	Compares transcutaneous current threshold required to elicit minimal muscle contraction between two sides	>3.5 mA difference is considered significant	Indicates poor recovery
MST	Compares muscle contraction at maximal nerve stimulation (~5 mA) between two sides	Equal response, reduced response or absent response	Loss of response within 10 days is associated with incomplete recovery.

90% axonal loss has been sustained. ENoG is said not to be useful until the fourth day of facial nerve paralysis. Neural conduction disappears quite rapidly after an injury that transects an axon because a degenerating axon is incapable of conducting an action potential, and most axons have at least started to degenerate within 3–4 days of such an injury.

ENoG is considered the most valuable prognostic indicator among current electrophysiological tests and its main indication is acute onset complete facial nerve paralysis. Both the percentage of amplitude reduction and rate of degeneration have been used as prognostic indicators of facial nerve recovery. In idiopathic palsy, degeneration of >90% within 14 days of complete paralysis indicates a probable poor recovery in >50% of cases.[100] ENoG does not appear to be useful in Ramsay Hunt syndrome because of multiple sites of nerve involvement. Fisch has recommended surgical intervention within three weeks in patients where traumatic injury has resulted in >90% amplitude reduction by ENG within 6 days of the injury.[101, 102] Great care has to be taken interpreting these data. Although there is good correlation between the natural history of idiopathic palsy and ENoG findings, there are no definitive data on the natural history of facial nerve injury due to other causes. The assumption that ENoG data is valid regardless of whether the paralysis was of immediate or delayed onset cannot be justified from the literature.[103]

ELECTROMYOGRAPHY (EMG)

EMG records active motor unit potentials of the orbicularis oculi and orbicularis oris muscles during rest and voluntary contraction. EMG can be used to determine:

- if a nerve in question is in continuity (volitional activity recorded)
- if there is evidence of Wallerian degeneration (fibrillation potentials)
- if there are early signs of reinnervation (polyphasic innervation potentials).

Fibrillation potentials typically arise 2–3 weeks following injury, and polyphasic reinnervation potentials may precede clinical signs of recovery by 6–12 weeks.

In cases of acute onset and complete paralysis with unfavourable ENoG recordings (>90% degeneration), the finding of active motor unit potentials indicates that some fibres are intact and suggests a favourable prognosis. As long as some active motor units can be recorded one week following a complete paralysis, severe degeneration is unlikely to take place. EMG has a role in decision making regarding surgical intervention in long-standing paralysis as follows:

- Polyphasic motor unit potentials indicate regenerative processes and surgical intervention is therefore not indicated. In this case, close follow-up studies of nerve regeneration are advocated.
- Fibrillation potentials indicate lower motor neuron denervation, but viable motor end plates. Surgical exploration is therefore indicated with a view to achieving nerve continuity, either by end-to-end anastomosis, interposition grafting, re-routing or re-innervation techniques.
- 'Silence' on EMG (no electrical output) indicates long-term denervation and suggests that muscle has been replaced by fibrous tissue. In this case, static or dynamic (microvascular innervated free muscle transfer or muscle transposition) facial reanimation is indicated.

LIMITATIONS OF ELECTROPHYSIOLOGICAL TESTING

Although electrophysiological testing may provide useful prognostic information and serve as a guide to the management of facial palsy, there are some important shortcomings.

- The electrical impulse can only stimulate normal or neurapraxic fibres and cannot distinguish whether the remaining fibres are in a state of axonotmesis or neurotmesis. Thus, it cannot distinguish between injuries which have different prognoses.
- It provides no useful information in cases of incomplete facial paralysis.
- It fails to provide information on the immediate post-paralysis period (first 72 hours).

An overview of ENoG and EMG is given in Table 112.5 and should be read in conjunction with the Nerve Injury Classification in Table 112.1.

TRANSCRANIAL MAGNETIC STIMULATION

While electrodiagnostic tests provide information about the facial nerve distal to the stylomastoid foramen, transcranial magnetic stimulation is able to stimulate the facial

TABLE 112.5 ENoG and EMG

Study	Measurement	When to measure	Use in acute onset paralysis	Use in long-standing paralysis
ENoG	Evoked CMAP compared to normal site	Between 3 days and 3 weeks	>90% of degenerated fibres suggests poor prognosis	Not useful because of desynchronization
EMG	Active motor unit potentials after voluntary forceful contraction	Complementary to ENoG, after 2 weeks	Presence of active motor potentials in response to voluntary contractions indicates good prognosis	Fibrillation potentials suggest Wallerian degeneration
		In long-standing paralysis		Polyphasic potentials suggest reinnervation

nerve within the cranium. Magnetic impulses induce an electric current within the brain and stimulate neuromuscular tissue in exactly the same way as conventional electrostimulation. The design and type of coil determines the penetration and site of stimulation. A double coil is normally employed for facial nerve studies and has the ability to focus on the infranuclear portion of the nerve, probably at the root entry zone or temporal bone itself. It is this capability that has opened up the potential to clinical and research studies of palsies caused by temporal bone pathologies and link these with information derived from MRI data.[104, 105]

INTRA-OPERATIVE NERVE MONITORING

Intra-operative monitoring is now widely used though yet to be considered a standard of care for every operation at which there is a risk of damaging the facial nerve. A number of devices are marketed that employ continuous EMG monitoring from peripheral facial muscle groups for spontaneous and electrically evoked stimulation of the facial nerve trunk or its branches. Their role in preventing facial nerve injury remains controversial, but there is little doubt that intra-operative nerve monitoring makes the trainees' learning curve safer for the patient. There are no prospective, randomized studies that have proven its efficacy in reducing the incidence of facial nerve paralysis. However, intra-operative monitoring has established itself in CPA tumour surgery, revision mastoidectomy, parotidectomy and in surgery of congenital ear abnormalities. Other considerations should be medico-legal issues that may arise in cases of facial nerve injury when the monitor was not used even though it was available, and the use of monitoring during supervised resident training.

In CPA tumour surgery it is particularly helpful for identification of the nerve at the brainstem, its displacement and distortion around the tumour, where it can be almost invisible, and within the IAM: in other words, throughout the whole of the procedure. Jackler et al.[106] have reported a reduced incidence of complete permanent paralysis following removal of CPA tumours with the use of intra-operative monitoring, while Axon et al.[107] have found a good correlation between intra-operative CMAP amplitude following tumour resection and immediate post-operative facial nerve function. Kirkpatrick et al.[108, 109] reported that intra-operative facial nerve monitoring in CPA tumour surgery appeared to predict eventual facial function accurately in small tumours, but did not predict facial nerve recovery reliably following surgery for larger tumours. Wilson et al.[110] looked at the cost-effectiveness of intra-operative facial nerve monitoring in middle ear or mastoid surgery. They found that a strategy to monitor both primary and revision surgeries had the greatest effectiveness and lowest cost. Noss et al.[111] reported that the absence of monitoring would have led to facial nerve deficits in 1–2% of their cases. Pensak et al.[112] felt that the overall outcome of mastoid surgery was definitely affected in a positive way by the presence of the monitor in 0.4% of cases during residents' training. As far as parotid surgery is concerned, several studies have demonstrated that there is no significant difference in the incidence of permanent paralysis of monitored versus unmonitored groups, but its use may have an effect on the intensity of post-operative palsy and on the recovery time in revision surgery.[113, 114] Only one study demonstrated that intra-operative monitoring led to a significantly decreased incidence of post-operative temporary paralysis (62% versus 44%), although no difference in permanent paralysis was seen.[115] These results support the observation that continuous intra-operative EMG monitoring may not affect post-operative facial nerve outcomes and EMG abnormalities do not predict facial nerve injury in parotid surgery. Pitfalls and caveats are shown in **Table 112.6**.

Blood investigations

While most patients present in a truly idiopathic fashion, some patients do not and the cause of their palsy is far from clear. In retrospect, the following blood tests might have helped to identify or exclude other less common causes: Angiotensin Converting Enzyme titres, Anti-neutrophil Cytoplasmic Antibody profile, HIV serology, Lyme serology and Syphilis serology. Obtaining the results of tests sooner rather than later is wise.

Facial nerve imaging

RADIOLOGICAL IMAGING OF THE NORMAL FACIAL NERVE

Computed tomography (CT) of the temporal bone allows identification of the Fallopian canal from the fundus of the IAM to the stylomastoid foramen (**Figure 112.10a,b&c**). The technique of high-resolution acquisition with overlapping thin sections of 0.6 mm, reconstructed into 0.3–0.4 mm sections, allows equivalent voxels of 0.3 mm^3.

TABLE 112.6 Pitfalls and caveats of intra-operative monitoring

Pitfalls and caveats
Always ask the anaesthetist to avoid neuromuscular blockade
The closer the bipolar electrodes are placed, the fewer the muscle fibres that will be represented in the EMG response
Use transparent drapes for backup
Test the integrity of the system with the anaesthetic nerve stimulator before starting the operation and check the system periodically during surgery
Even after nerve transection, the distal segment can still be stimulated for a few days, creating evoked EMG responses that may be falsely interpreted as evidence of continuity
The mastoid segment is least sensitive to nerve stimulation, so a higher setting is needed (0.5 mA in mastoid surgery as opposed to 0.05–0.1 mA in CPA tumour surgery)

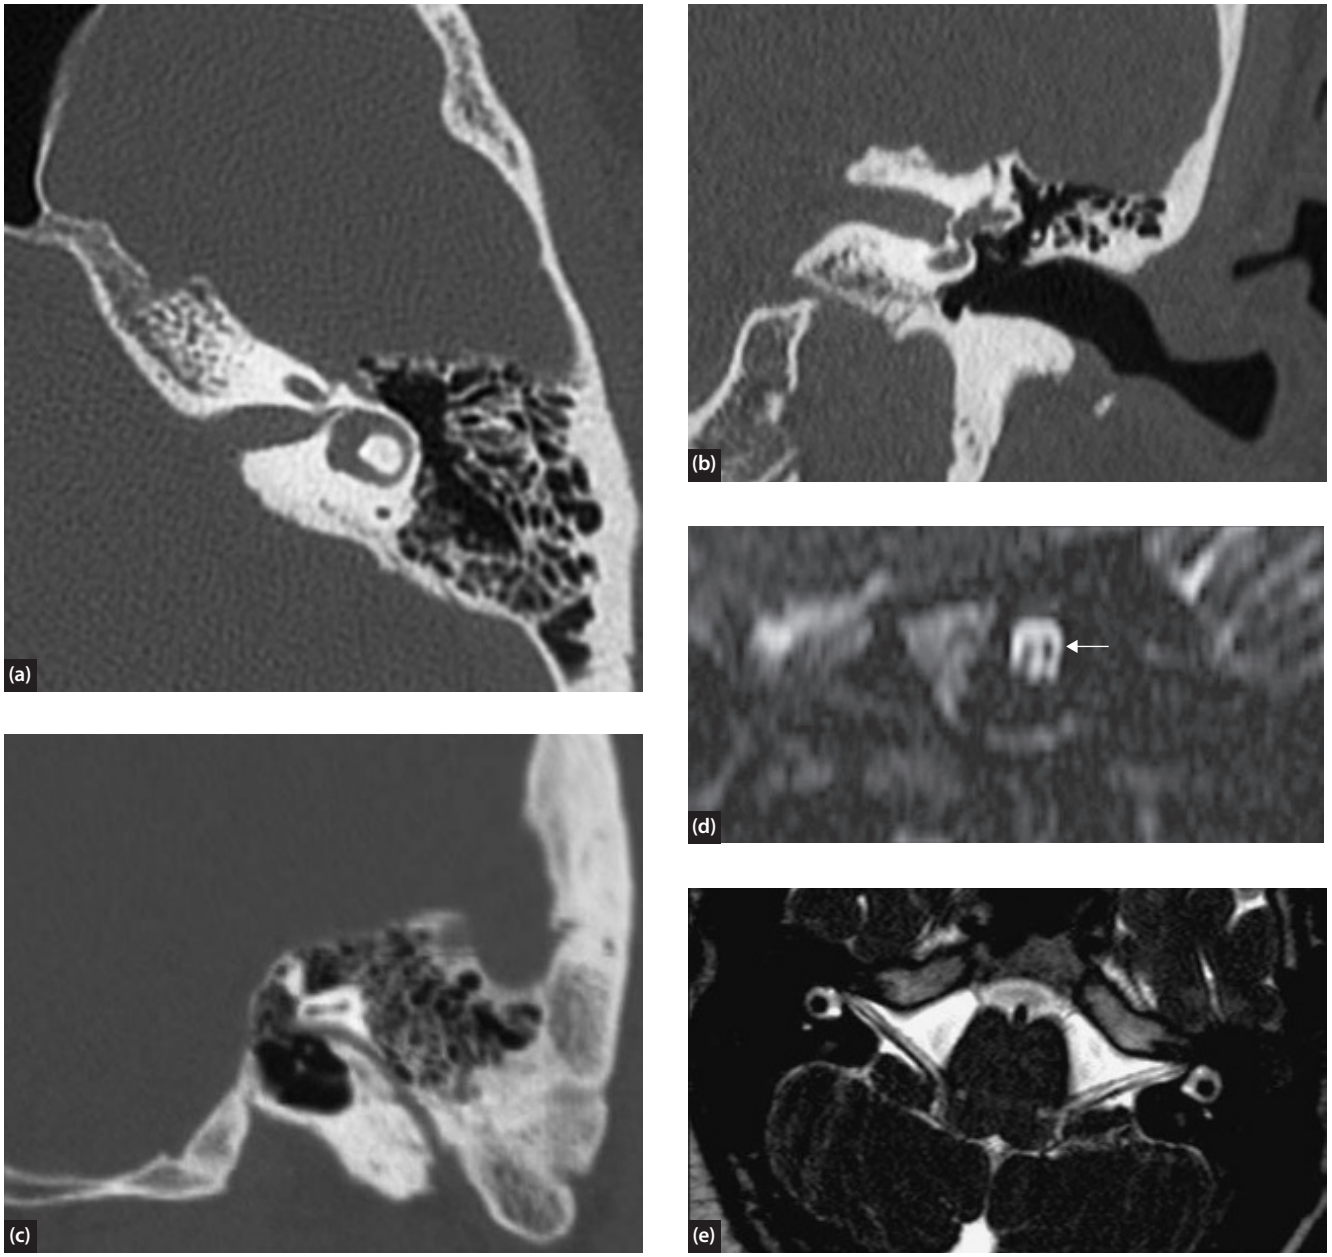

Figure 112.10 **(a)** Axial CT scan of the labyrinthine segment of the facial nerve and first genu; **(b)** coronal CT of tympanic segment of facial nerve which lies just inferior to the lateral semicircular canal; **(c)** oblique sagittal CT view of the mastoid segment of the facial nerve and second genu; **(d)** T2 DRIVE oblique sagittal MRI of facial nerve in the IAM (arrowed); **(e)** T2 DRIVE axial MRI of facial nerve in the IAM running alongside the superior vestibular nerve.

In contrast, the thin collimation performed as part of a trauma sequence CT head/brain may not provide an adequate level of detail to assess the facial nerve canal. The tympanic portion is probably easiest to identify on axial scans at the level of the body of incus and its short process. From there it can be followed proximally and distally towards the labyrinthine and descending segments respectively. The labyrinthine segment is characteristically banana-shaped on axial sections. On coronal images it may be visualized as the medial of the two circular 'eyes' directly above the cochlea. The sulcus for the geniculate ganglion is also well demonstrated in coronal sections. The mastoid segment is best visualized in coronal or sagittal views. In coronal views it is easier to follow the nerve from the stylomastoid foramen to its more proximal part. It is more difficult to identify in axial views, especially in well-pneumatized temporal bones. One way is to try and locate the pyramid or the stapedius muscle; the facial nerve lies immediately behind.[116, 117] Bance and Erb[118] have described the 'B-line': a tangent line extrapolated from the posterior border of the basal turn of the cochlea, which falls within 1 mm of the facial nerve on average. The intra-parotid facial nerve cannot be identified on CT scans. The facial nerve plane is extrapolated as a line connecting the stylomastoid foramen to a point immediately lateral to the retromandibular vein.

The intra-parotid facial nerve is not identified on CT scans. The facial nerve plane is extrapolated as a line connecting the stylomastoid foramen to a point immediately lateral to the retromandibular vein.

Cone-beam CT scanning is becoming increasingly utilized for pre-operative planning for middle ear surgery including cochlear implantation and provides good anatomical detail, particularly in respect of the facial nerve location, while exposing the patient to less ionizing radiation.

The rich perineural arteriovenous plexus which surrounds the normal facial nerve facilitates visualization on contrast enhanced T1-weighted MRI. It is usually observed in more than one segment, more commonly in the geniculate ganglion and the tympanic segments and it may enhance asymmetrically between right and left. Enhancement previously considered pathological has more recently been noted in the fundus of the IAM in normal subjects. Most radiologists believe that the intra-parotid facial nerve cannot be routinely identified on MRI. The linear, low-intensity signal seen on axial T1 scans most probably represents intra-parotid ductal ramification (**Figure 112.10**).

Imaging strategies in facial nerve palsy

The imaging strategy is largely determined by the suspected nature of the lesion. In general, a high-resolution CT (HRCT) enables superior visualization of the intratemporal segment of the facial nerve and is particularly useful in cases of temporal bone trauma, Fallopian canal involvement in chronic suppurative otitis media (CSOM) or temporal bone malignancies. MRI using paramagnetic contrast agents such as gadolinium-DTPA is known to provide better visualization of soft tissues and is particularly useful in neoplastic or inflammatory lesions. It should be remembered that both imaging techniques are complementary and may be used in combination.

IDIOPATHIC PALSY

Imaging of patients with idiopathic facial palsy who present in a typical fashion is not cost-effective. The degree of enhancement on MRI carries no significant prognostic value and the chance of acute facial nerve palsy in a tumour is remote. Imaging is only recommended if the presentation is atypical, an alternative diagnosis is suspected, surgical decompression is planned or recovery is incomplete at 6 months. MRI may be normal in the first 10 days following the onset of palsy. Post-gadolinium enhancement is characteristically asymmetric, diffuse, intense and linear (not nodular). It involves the entire intratemporal segment of the facial nerve, but is more distinct in the fundus of the IAM and labyrinthine segments and may well persist for several months after full recovery (**Figure 112.11**). However, in a case of presumed idiopathic facial nerve palsy the authors consider contrast-enhanced MRI scanning 3 months following the initial weakness if the clinical condition has not improved. In cases where the weakness is progressing, the patient should be scanned earlier.

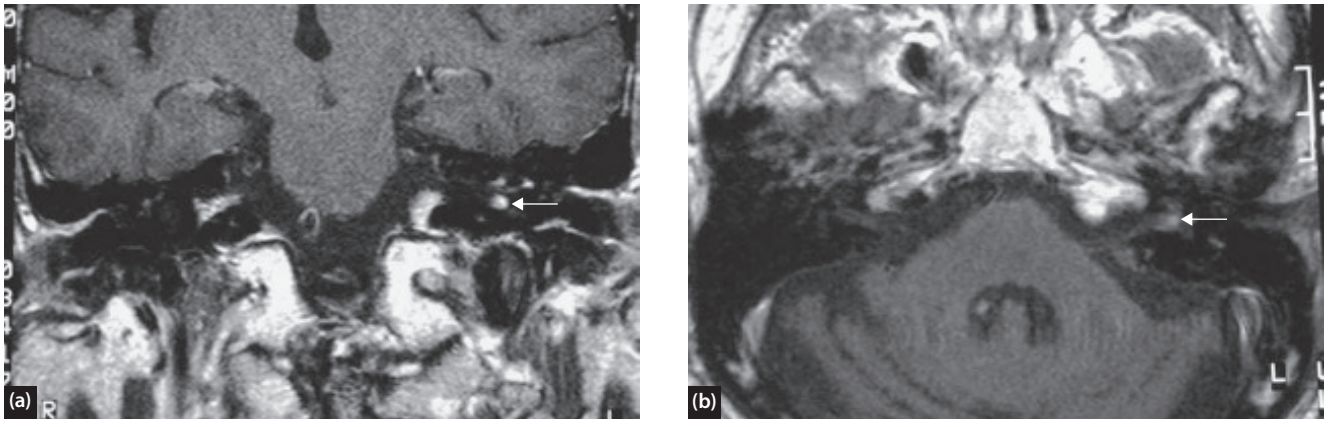

Figure 112.11 **(a)** Coronal and **(b)** axial MRI of a patient with a left-sided idiopathic palsy. Increased signal is clearly visible in the geniculate region (arrowed).

Different departments will employ various imaging protocols to ensure an idiopathic case is not masking a more sinister diagnosis. Pre- and post-contrast T1 sequences through the temporal bone, in combination with T2 sequences of the whole brain and parotid-specific fat suppression imaging can be considered a comprehensive approach.

ACUTE AND CHRONIC OTITIS MEDIA

Imaging in facial nerve paralysis in the presence of acute or chronic otitis media is generally directed towards identifying coexisting intratemporal or intracranial complications rather than the site of nerve damage. A CT scan of the temporal bone can delineate the site of erosion of the Fallopian canal, but MRI cannot differentiate between the increased signal of the facial nerve from that of surrounding inflamed granulation tissue.

TEMPORAL BONE FRACTURE

HRCT is the investigation of choice for temporal bone fractures. Facial nerve injury is usually situated just distal to the geniculate ganglion and the first genu in longitudinal fractures and just proximal to the geniculate ganglion in transverse fractures. MRI has little if any value in these instances. There is no correlation between pathological facial nerve enhancement and ENoG findings and it may be observed up to 2 years post-trauma (**Figure 112.13**).[119]

TUMOURS

MRI is the investigation of choice in these cases. Facial nerve haemangiomas enhance intensely on post-contrast T1-weighted MRI, most commonly in the area of the geniculate ganglion, and also have a typical honeycomb matrix appearance on CT. Facial nerve schwannomas show a strong enhancement with gadolinium on T1-weighted images and, when they grow to the point of filling the internal auditory canal, they cannot be distinguished from vestibular schwannomas (**Figures 112.14, 112.15** and **112.16**). Malignant parotid tumours may track up the facial nerve and a soft-tissue intensity enhancing mass is usually observed extending from the gland through an enlarged stylomastoid foramen to involve the mastoid

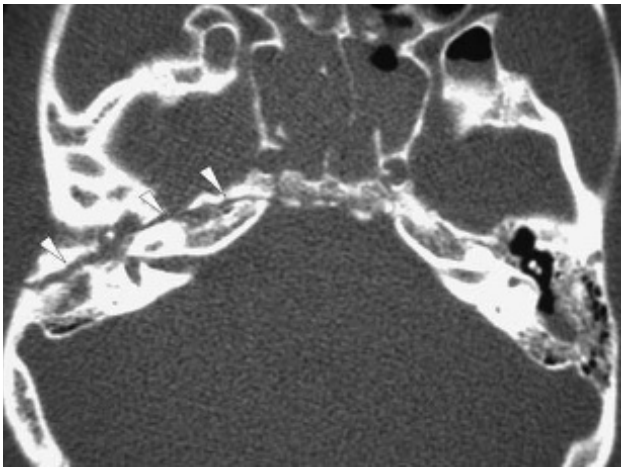

Figure 112.12 Typical CT appearance of a longitudinal fracture of the temporal bone. The fracture line (arrowed) passes anterior to the genu of the facial nerve.

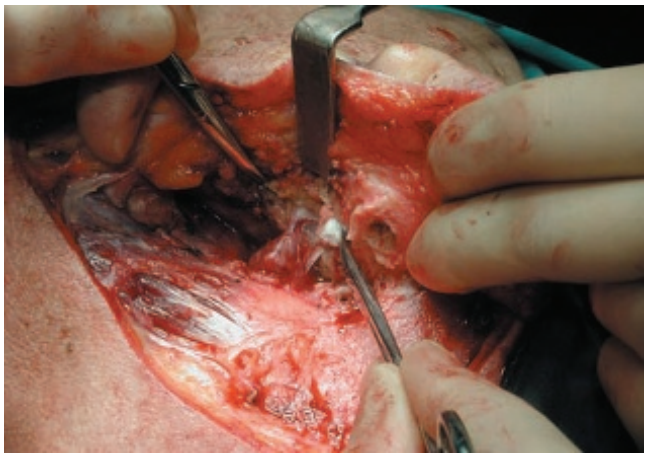

Figure 112.16 Facial nerve schwannoma, imaged in 112.14 and 112.15 seen at surgery pouting from the anterior border of the sternocleidomastoid muscle, entering the parotid gland, just beneath the transected external ear canal.

segment of the facial nerve. There is usually replacement of the hyperintense fat tissue by a hypointense signal in T1-weighted images.

DIFFUSION TENSOR IMAGING TRACTOGRAPHY

Skull base surgeons are well aware of the challenges of functional preservation of the facial nerve at the time of tumour dissection in vestibular schwannoma surgery. Intra-operative EMG is routinely employed to help locate and allow preservation of the often-thinned nerve traversing the tumour capsule. Diffusion tensor imaging (DTI) utilizes multidimensional vector algorithms to derive neural tract directional information. The aligned fibres of neural tissue can be specifically imaged. DTI has been shown to provide the surgeon with additional pre-operative information as to the location of the facial nerve with respect to the tumour within the CPA, potentially increasing the likelihood of a good facial nerve outcome.[120, 121]

MANAGEMENT OF THE PATIENT WITH A FACIAL NERVE DISORDER

As stated earlier, the management of an acute insult causing a facial nerve palsy depends to some extent on the cause, but there are also general points that apply to all (**Table 112.7**). In this section the management issues surrounding palsies resulting from the most common causes are discussed.

EYE CARE

Appropriate eye care, including advice regarding corneal protection with lubrication and patching should be instituted immediately in cases where eye closure is impaired. In those patients with severe facial weakness the blink movement is impaired and the eyelid cannot cleanse and lubricate the corneal surface. In addition, if the nerve injury involves the trunk proximal to the 1st genu, and therefore the origin of the greater petrosal nerve, the secretomotor supply to the lacrimal gland is also impaired thus compounding the problem with corneal lubrication.

Simple guidance regarding the use of large-lens sunglasses can help protect the eye from dust and debris on a windy day. Eye drops should be applied to the corneal surface frequently during the daytime, whilst at night ointment is preferred. Following the application of the ointment the eye should be taped closed. Over time, the unopposed action of levator palpebrae superioris (supplied by the oculomotor nerve) results in shortening of the upper eyelid. Patients should be advised to close their eye manually using a finger as well as attempting to stretch the upper lid to try and prevent this shortening. Upper eyelid weighting with external adhesive skin-tone coloured weights (Blinkeze™) is recommended. More formal surgical weighting or levator-lengthening procedures are used in long-standing cases of impaired eye closure. In some cases, these may be performed acutely as they can be reversed, although this is not the usual practice of the authors.[122, 123]

Idiopathic (Bell's) palsy

The term idiopathic palsy should be reserved for cases of facial paralysis that have signs and symptoms consistent with the disease and in which a diligent search for another cause is negative. The search for a cause should not simply relegate idiopathic palsy to a diagnosis of exclusion, but emphasize the diagnosis based on specific clinical features. In 1959, Taverner[124] outlined the minimum diagnostic criteria for idiopathic palsy, then known as Bell's palsy, that included: paralysis or paresis of all muscle groups on one side of the face; sudden onset; absence of signs of central nervous system disease; absence of signs of ear or CPA disease. These criteria still hold today. Classically, patients present with a prodromal illness which may include periauricular pain and general malaise. Within 72 hours they rapidly develop complete lower motor neuron facial weakness.

The annual estimated incidence of idiopathic palsy is fairly similar throughout the world, ranging between 20 and 32.7 per 100,000 in different studies.[125, 126] The condition affects approximately 1 in 65 people during their lifetime. The incidence reaches a peak between the ages of 15 and 45 years. It has a predominance in women younger than 20 years and a slight predominance in men older than 40 years, although the male to female ratio is more or less equal across the population. Recurrence rates of 4.5–15% and a familial incidence of 4.1% have been addressed in various studies. There may be genetic factors that influence the development of idiopathic palsy but quite what they might be is unclear. Idiopathic palsy is more common in pregnancy with the majority of cases being in the 3rd trimester. It is suggested that the increased incidence in the latter stages of pregnancy relates to changes in fluid balance with increased extracellular fluid leading to oedema of the nerve and subsequent compression within the Fallopian canal.[127]

TABLE 112.7 Causes of facial palsy

Causes	
Birth	Moulding
	Forceps delivery
	Dystrophia myotonica
	Moebius syndrome (facial diplegia associated with other cranial nerve defects)
Trauma	Basal skull fracture
	Facial injuries
	Penetrating injury to middle ear
	Altitude paralysis (barotrauma)
	Scuba diving (barotrauma)
	Lightning
Neurological	Opercular syndrome (cortical lesion in facial motor area)
	Millard–Gubler syndrome (abducens palsy with contralateral hemiplegia due to lesion in base of pons involving corticospinal tract)
Infection	Otitis externa
	Acute otitis media
	Mastoiditis Chronic otitis media
	Chicken pox
	Herpes zoster cephalicus (Ramsay Hunt syndrome)
	Encephalitis
	Poliomyelitis (type I)
	Mumps
	Infectious mononucleosis (glandular fever)
	Leprosy
	Coxsackie virus
	Malaria
	Syphilis
	Scleroma
	Tuberculosis
	Botulism
	Acute haemorrhagic conjunctivitis (enterovirus 70)
	Gnathostomiasis
	Mucormycosis
	Lyme disease
Metabolic	Diabetes mellitus
	Hyperthyroidism
	Pregnancy
	Hypertension
	Acute porphyria
Neoplastic	Facial schwannoma
	VIIth nerve tumour
	Jugular paraganglioma
	Tympanic paraganglioma
	Meningioma
	Haemangioblastoma
	Sarcoma
	Carcinoma (invading or metastatic)
	Anomalous sigmoid sinus
	Haemangioma of tympanum
	Hydradenoma (external auditory meatus)
	Leukaemia
	Cerebral lymphoma
	Teratoma
	Hand–Schüller–Christian disease
	Fibrous dysplasia
	Von Recklinghausen's disease
Toxic	Thalidomide (Miehlke syndrome, cranial nerves VI, VII with congenital deafness)
	Tetanus
	Diphtheria
	Carbon monoxide
Iatrogenic	Mandibular block anaesthesia
	Anti-tetanus serum
	Vaccine treatment for rabies
	Post-immunization
	Parotid surgery
	Mastoid surgery
	Post-tonsillectomy and adenoidectomy
	Iontophoresis (local anaesthesia)
	Embolization
	Dental
Idiopathic	Bell's, familial
	Melkersson–Rosenthal syndrome (recurrent alternating facial palsy, furrowed tongue, faciolabial oedema)
	Hereditary hypertrophic neuropathy (Charcot–Marie–Tooth disease, Déjérine–Sottas disease)
	Autoimmune syndrome
	Temporal arteritis
	Thrombotic thrombocytopenic purpura
	Polyarteritis nodosa
	Landry–Guillain–Barré syndrome (ascending paralysis)
	Multiple sclerosis
	Myasthenia gravis
	Sarcoidosis (Heerfordt syndrome – uveoparotid fever)
	Osteopetrosis

The prognosis for pregnant women with idiopathic palsy is notably better than among non-pregnant women with palsy. Once the child has been delivered, the clinical picture tends to improve. However, there has been reluctance among non-specialists to prescribe corticosteroids for pregnant women with facial palsy. Obstetricians and those involved with the management of pregnant women with facial palsy should be assured of the safety and efficacy of prednisolone in this special group of patients.

The aetiology of idiopathic palsy remains unclear, although microcirculatory failure of the vasa nervorum, ischaemic neuropathy, infectious, genetic and immunologic causes have all been proposed in the past. Of those possible causes, clinical and epidemiologic data lend credence to an infectious origin, which triggers an immunologic response resulting in damage to the facial nerve. Pathogens that have been implicated in the disease process include herpes simplex virus type 1 (HSV-1), herpes simplex virus type 2 (HSV-2), human herpesvirus, varicella zoster virus (VZV), influenza B, adenovirus, Coxsackie virus and Epstein–Barr virus (EBV). Recently, it has been demonstrated that an inactivated intranasal influenza vaccine increased the risk of idiopathic palsy.[128]

Murakami et al. in 1996 explored the link between herpes simplex virus (HSV) and Bell's palsy.[129] Surgical decompression for facial nerve palsy was performed in 14 patients with Bell's palsy, 9 patients with Ramsay Hunt syndrome and 12 other controls. Viral genomes of HSV-1, VZV and EBV were analyzed in clinical samples of facial nerve endoneurial fluid and posterior auricular muscle using polymerase chain reaction (PCR) followed by hybridization with Southern blot analysis. HSV-1 genomes were detected in 11 of 14 patients (79%) with idiopathic palsy but not in patients with Ramsay Hunt syndrome or in the controls. The authors concluded that HSV-1 is the major aetiologic agent in Bell's palsy. However, these results have not been replicated. Linder et al. identified HSV-1 genomic DNA in 86% of autopsied human geniculate ganglion samples taken from control patients without any previous history of facial palsy.[82] In 43% of the specimens, viral genomic DNA for VZV was found, HSV-2 genomic DNA was not detected. In all 14 geniculate ganglion preparations, either one or even both viral pathogens were found using the highly sensitive nested PCR. HSV-1, HSV-2 or VZV could not be detected in facial muscle biopsy samples taken from acute Bell's palsy patients. Linder et al. also comment, correctly, that current PCR methods are unable to differentiate between a latent and a lytic virus state. [82] To demonstrate that reactivation of HSV virus, or its switch from a latent to a lytic state, causes idiopathic palsy, a reverse transcription PCR aimed at detecting lytic state-specific mRNAs might provide the answer. Until proven otherwise, idiopathic palsy should still be called idiopathic.

Although, the majority of patients with Bell's palsy recover facial movement completely, a significant proportion have long-term issues with facial asymmetry, tightness and synkinesis. Poor prognosis has been related to complete paralysis at onset or incomplete paralysis with late onset of recovery, old age, a dry eye, abolished taste, absent stapedius reflex and postauricular pain.[128] Normal function is usually regained within 3 months in about two-thirds of all patients. No further recovery is expected after a period of 6 months has elapsed.

The pharmacological management of idiopathic palsy primarily involves oral corticosteroid medication. Evidence from the Scottish Bell's Palsy Study[130] showed clear benefit from treatment with prednisolone within 72 hours of onset of the paralysis. There was no evidence of additional benefit from oral antiviral medication in the form of acyclovir. However, other authors have found antivirals provide additional benefit and the most recent evidence from the Cochrane Database concludes that there is evidence that the addition of antiviral medication improved the rates of incomplete recovery and reduces the long-term after-effects of idiopathic palsy.[131] Based on the above evidence, most surgeons would advocate a combination of steroids and antiviral drugs. The usual recommended regime is prednisone 1 mg/kg/day for 10 days and oral acyclovir (400 mg five times daily) for 10 days.

Facial nerve disorders of viral origin

VARICELLA ZOSTER VIRUS (VZV) INFECTION (RAMSAY HUNT SYNDROME)

The strict definition of Ramsay Hunt syndrome is a peripheral facial nerve palsy accompanied by an erythematous vesicular rash on the ear (zoster oticus) or in the mouth (**Figure 112.17**). The mechanism of disease is reactivation of the latent VZV virus in the geniculate ganglion.

Figure 112.17 This patient has a complete left-sided facial palsy and a vesicular eruption in the conchal bowl of her ear which is typical of Ramsay Hunt syndrome.

Other cranial nerves are less commonly involved. The onset of palsy is usually preceded by pain which may persist and be excruciating. In a small proportion of patients, the facial palsy is accompanied by labyrinthine symptoms including tinnitus, vertigo and a sensorineural hearing loss. Diagnosis is clinical but may be confirmed by rising titres of antibodies to VZV. Examination of CSF and gadolinium-enhanced MRI have no diagnostic or prognostic value. PCR to detect VZV in ear exudates is more sensitive than VZV PCR performed on tears or blood mononuclear cells and may be positive before the development of vesicles.[132]

It has been shown that a small proportion of patients diagnosed as idiopathic palsy may in fact have a VZV infection. In 15% of cases vesicles may appear after the onset of palsy, and the diagnosis may be missed. Another reason for missing the diagnosis is the Ramsay Hunt syndrome *zoster sine herpete*. This is characterized by peripheral facial paralysis without ear or mouth rash, and the presence of either a four-fold rise in antibody to VZV or the detection of VZV DNA in skin, blood mononuclear cells or middle ear fluid.[132] Although further research is needed, perigeniculate region VZV PCR may help to distinguish between patients with Bell's palsy and patients with early Ramsay Hunt syndrome.

The prognosis for Ramsay Hunt is worse than idiopathic facial palsy. Persistent weakness is observed in 30–50% of patients and only 10% recover completely after complete loss of function without treatment.[133] Regarding management, the same controversies exist as in idiopathic palsy. Most advocate a combination of steroids and antiviral agents, but for a longer period of time, 2–3 weeks. The largest retrospective Ramsay Hunt syndrome treatment study showed a statistically significant improvement in patients treated with prednisone and acyclovir within 3 days of onset.[134] The recommended regime is prednisone 1 mg/kg/day for 5 days followed by a 10-day taper, as well as intravenous acyclovir (250 mg three times daily), or oral acyclovir (800 mg five times daily). Robillard et al.[135] have shown that patients with Ramsay Hunt syndrome treated with prednisone were less likely to progress to complete facial paralysis than untreated patients. The combination of steroids and acyclovir also seems to reduce otalgia, vertigo and post-herpetic neuralgia. Surgical decompression is not indicated.

OTHER VIRAL CAUSES

A variety of viral diseases have been associated with facial nerve palsy. Guillain–Barré syndrome (acute inflammatory demyelinating polyradiculoneuropathy) presents typically 2–3 weeks after an upper respiratory infection probably caused by an abnormal T-cell response against myelin components. The most prominent feature is ascending symmetrical muscular weakness and autonomic involvement with a maximum effect 2–3 weeks after the onset of illness. Facial nerve paralysis may develop and is often bilateral. Supportive management is of the essence, with attention mainly focused on respiratory support and passive physiotherapy. Steroids have been shown to have no beneficial effect and may even delay recovery. The most effective form of treatment is considered to be intravenous immunoglobulin infusion. Epstein–Barr infection (infectious mononucleosis) is clinically characterized by generalized lymphadenopathy, fever and sore throat and may be associated with facial nerve palsy. The presence of at least 10% of atypical lymphocytes on peripheral tests and positive serology will confirm the diagnosis. Forty percent of the EBV-associated facial nerve palsy cases are bilateral (**Figure 112.18**).[136] Facial nerve paralysis during the course of human immunodeficiency virus (HIV) infection can present at any stage of the disease. The presumed mechanisms of paralysis include local infection of the facial nerve or geniculate ganglion by the HIV, inflammatory demyelinating neuropathy or secondary infection precipitated by immunosuppression with agents such as VZV, HSV or EBV.[137]

Figure 112.18 A young girl with a complete right-sided facial palsy caused by infectious mononucleosis.

FACIAL NERVE TRAUMA

As a general rule, management of facial nerve paralysis following trauma is generally deferred until the patient is both medically and neurologically stable as most cases are associated with more life-threatening injuries. This often delays treatment for a large proportion of patients and for many it dictates that a suboptimal management plan has to be adopted, for example when associated with severe head injuries.

Facial nerve paralysis can result from stab wounds to the face or mandibular fractures. If possible, it is advisable to explore the region within 3 days so that a nerve stimulator can be used to identify the distal segments of facial nerve branches. Transection of the cervicofacial or temporofacial primary divisions should be promptly repaired by end-to-end anastomosis. Mobilization to avoid unwanted tension may be necessary if a short segment of nerve is destroyed. Rarely, an interposition graft is necessary. Injuries to branches distal to the lateral canthus or nasolabial fold are too small for anastomosis and are better approximated and glued in position. This offers a better chance of some recovery without synkinesis. If the wound is dirty, it is advisable to identify and tag the facial nerve branches, clean the wound thoroughly and, in severely soiled cases, repair and close at a later stage. The major problem in knife wounds to the face is that damage to the facial nerve is often multi-segmental with transections at more than one level. With each transection the chance of a good functional outcome is diminished.

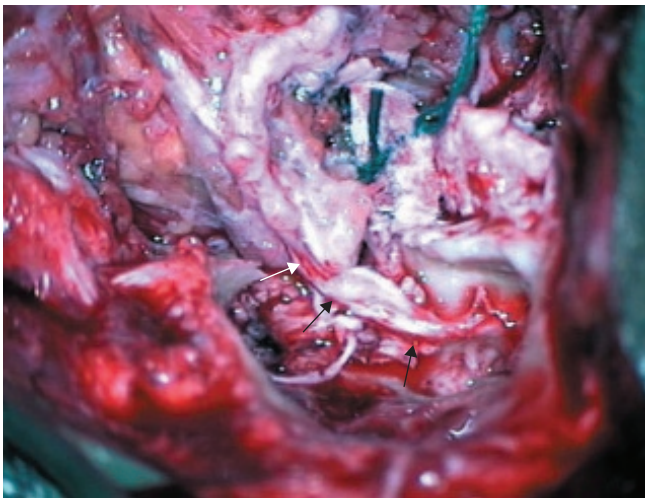

Figure 112.19 This man was shot in the ear and suffered a complete facial palsy. The nerve has been shredded over a significant distance (arrowed).

GUNSHOT INJURIES

Care must be taken when assessing facial nerve function in this type of injury as there is often significant facial oedema and both muscle tone and eye closure appear adequate when in fact they are not. This illusion can last for several days. The mastoid segment of the facial nerve is most commonly affected and often over a long segment. Low-velocity bullets may be found lodged in the mastoid tip.[138] Surgical exploration of the facial nerve should be performed as early as possible. Long delays make identification of the nerve more difficult because of granulation tissue and traumatic neuroma formation. If a segment of the nerve has been destroyed, the proximal and distal ends of the nerve must be trimmed back to a point where healthy fascicles can be seen and then an interval cable graft inserted. Good functional results are rarely achieved and other methods of reanimation should be considered.[139]

There is often considerable bony damage and the potential for subsequent cholesteatoma development should be kept in mind. Open mastoidectomy with a meatoplasty is the surgical technique of choice in this situation as there is a high risk of infection and it may not be possible to find and remove all fragments of skin and bullet (**Figure 112.19**).

FRACTURES OF THE TEMPORAL BONE

Temporal bone fractures are divided traditionally into longitudinal and transverse subtypes, although a significant proportion of these are mixed. Longitudinal fractures are associated with a 20% incidence of complete paralysis and the perigeniculate region is most commonly involved. Transverse fractures have a higher incidence of facial nerve paralysis (50%) and the labyrinthine and mastoid segments are most commonly involved (**Figures 112.12** and **112.13**). Longitudinal fractures are overwhelmingly more common than transverse fractures which is fortunate as outcomes are better. Some authors have recently proposed a different classification according to whether the otic capsule is involved or spared, as this correlates better with the incidence of complications.[140] Patients with otic capsule violating fractures are approximately twice as likely to develop facial nerve paralysis, four times more likely to have a CSF leak and seven times more likely to sustain a profound hearing loss.

The key issues to consider in the management of facial nerve paralysis following temporal bone trauma are (a) if there is an indication for surgical exploration, and if so, (b) when to operate; (c) which is the optimal surgical approach; and (d) which nerve repair technique to use. The use of high-resolution CT scans and ENoG are important in decision-making. If surgical exploration is indicated, the goals are (a) to decompress the nerve to prevent ischaemic injury; (b) to remove bony fragments that impinge on the nerve; and (c) to re-establish continuity in case of transection.

Management in the early post-injury stage

Patients with normal facial nerve function at presentation, regardless of whether they develop delayed palsy or even paralysis, or those with acute onset incomplete palsy without progression, have an excellent prognosis and do not require surgical exploration.[141] Similarly, follow-up with serial ENoG is probably not necessary, although this is not universally accepted. In cases of acute complete paralysis, surgical exploration is warranted if ENoG shows greater than 90% denervation within 6 days of the onset of paralysis and the patient is neurologically stable.[142] The same applies for incomplete palsy that progresses to complete paralysis over time with unfavourable ENoG recordings. In some patients, it is difficult to establish whether the onset of palsy was immediate as the patient may be unconscious at the time of presentation. However, ENoG can be performed on unconscious patients. Lambert and Brackmann[143] have suggested that the indication for surgery should be based on ENoG findings and that time from onset of paralysis should not be taken into account.

Timing of surgery will be dictated by the general condition of the patient: there is no general consensus on the optimal timing, although an early exploration is probably desirable. Chang and Cass[144] suggested decompression within 14 days of injury and May[145] has demonstrated superior results if nerve repair is performed within 30 days of injury. According to Quaranta et al.,[146] recovery of satisfactory facial nerve function can be achieved in more than 75% of cases treated 27–90 days after trauma. It should be noted that there are no studies reporting on the natural history regarding recovery of patients with unfavourable ENoG results.

Management in the late post-injury stage

Owing to trauma-related issues it is not rare to see a patient with facial nerve paralysis many months following injury. As discussed above, ENoG is not helpful after 3 weeks have elapsed. The decision to explore is therefore largely based on CT findings and electromyographic results. The rationale for late exploration is the

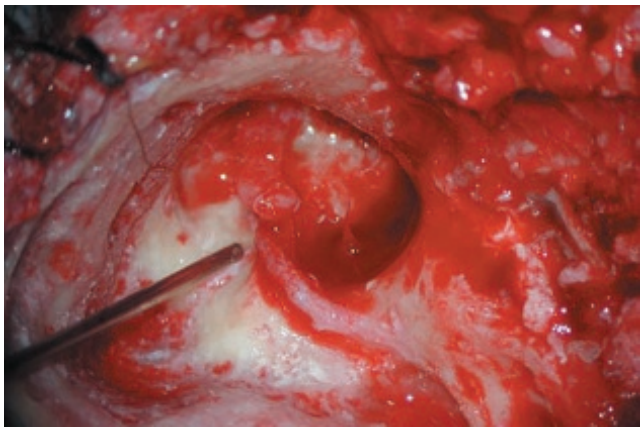

Figure 112.20 This fracture has transected the tympanic segment of the facial nerve. The proximal segment has become fibrotic as a result of organized intraneural haemorrhage and the bone shifts associated with the fracture have made approximation of the ends impossible. An interposition graft was necessary.

need to remove any fragments of bone and fibrosis that may impede regeneration. If no return of facial function is observed 6–12 months after the injury and there are no signs of polyphasic potentials that suggest reinnervation, exploration is indicated with a view to achieving nerve continuity either by end-to-end anastomosis, interposition grafting, rerouting or other reinnervation techniques. If, however, EMG findings suggest long-term denervation (no electrical output), static or dynamic facial reanimation procedures are indicated.

The surgical approach that will be used depends on the site of injury and the hearing status of the patient. In general, a middle fossa approach is preferred for longitudinal fractures in which hearing is preserved. In the very unlikely event of mixed or transverse fractures with serviceable hearing, the same approach may be employed in combination with a transmastoid exploration. In the presence of severe sensorineural hearing loss, a translabyrinthine approach is easier to use and results in less morbidity. Decompression is usually sufficient, although a severely crushed nerve is best resected and primarily anastomosed. If the nerve is transected and if it is possible, an end-to-end anastomosis without any tension on the cut ends is best. Otherwise an interposition nerve graft from the great auricular or sural nerve should be used (**Figure 112.20**). There are no controlled studies on the use of steroids in temporal bone fractures. Administration is based on the assumption that neural oedema is a contributing factor in the progression of nerve injury.

IATROGENIC INJURY

Middle ear and mastoid surgery

The incidence of facial nerve palsy has been reported to be between 0.6% and 3.6%.[146] In the Royal College of Surgeons audit it was found to be 0.8%.[147] The most common site of injury during middle ear or mastoid surgery is the distal tympanic segment including the second genu, followed by the mastoid segment.[148] If an injury to the facial nerve is recognized intra-operatively, exploration with decompression of proximal and distal segments of the nerve should be undertaken. If nerve fibres are found to be herniating, the epineural sheath should be opened with a neurotomy knife or Beaver blade. If more than 50% of the circumference of the nerve has been disrupted it should be repaired with either direct suture or inlay graft.

If facial nerve paralysis is observed immediately post-operatively, it is important to determine whether the facial nerve was identified or its integrity tested intra-operatively. If facial palsy is observed immediately after surgery and the nerve was identified or was not at risk during the operation, a few hours of observation will usually allow for any local anaesthetic-induced weakness to clear. The possibility of a tight mastoid dressing over an exposed nerve should also be considered and it is wise to remove the pack. If the paralysis is incomplete, the patient should be started on oral steroids and observed clinically. In cases of progression to full paralysis, exploration should be considered. Although immediate exploration was advocated in the past, this is no longer justified.[149] Green et al.[150] have not demonstrated a difference between early versus more than 7-day delayed exploration. HRCT imaging should be obtained even though it will probably be subject to artefact from iodine-containing compounds. Perhaps the most important thing is to make sure that a more experienced surgical colleague undertakes the re-exploration or that the patient be transferred to a regional centre where subspecialty expertise is available.

In rare cases, a delayed palsy is observed a few days after uneventful middle ear surgery with a reported incidence of 0.9–1.4%.[151, 152] The aetiology is unclear, although reactivation of HSV or VZV is postulated as the underlying mechanism. Combined use of prednisone and acyclovir should be considered and the overall prognosis appears to be good.

Parotid surgery

The likelihood of temporary facial weakness correlates with tumour location deep to the plane of the facial nerve, previous parotid surgery, previous sialadenitis and the addition of neck dissection to the parotidectomy. All parotid surgery is best undertaken with facial nerve monitoring and at the end of the procedure the main trunk should be stimulated to confirm continuity. If there is no response, the nerve and its branches should be closely inspected for areas of discontinuity. A reduced incidence of facial nerve palsy has been reported with the use of a harmonic scalpel.[153]

Cerebellopontine angle tumour surgery

Post-operative facial nerve function in CPA tumour surgery mainly depends on tumour size and surgical skill. When the facial nerve is lost during dissection, it may be possible to achieve an end-to-end anastomosis or place a cable interposition graft. Unfortunately, this is more often not the case and an expectant approach is probably best lest any fibres have been preserved. A subsequent reanimation procedure can be performed at a later date.

TABLE 112.8 Neonatal facial palsy

Developmental and inherited disorders	Clinical characteristics
Moebius syndrome	Agenesis of VI and VII cranial nerve nuclei. Bilateral facial nerve palsy, abducens palsy, possible involvement of other cranial nerves
Dystrophia myotonica	Progressive familial distal myopathy. Bilateral facial nerve palsy, without abducens palsy at birth. Muscle and extramuscular wasting, swan-like neck (wasting of muscles of mastication and sternocleidomastoids)
Alberg–Schoenberg's disease	Osteopetrosis of bony canals resulting in blindness, deafness and facial paralysis. Present later in childhood, not usually at birth
Melkersson–Rosenthal syndrome	Facial palsy, facial oedema, fissured tongue
CHARGE association	Colobomata, heart defects, choanal atresia, retarded growth, genital hypoplasia and ear abnormalities
Oculoauricular-vertebral syndrome	Abnormal formation of first and second arches
Congenital unilateral lower lip palsy	Hypoplasia of the depressor anguli oris muscle. Cardiac defects in 10%

Neonatal facial nerve injury

The frequency of neonatal facial nerve paralysis ranges from 0.05% to 0.23%.[154] Trauma is the main cause, but other rare congenital conditions should be excluded (Table 112.8). Forceps delivery is associated with a slightly increased incidence of paralysis. The superficial position of the facial nerve at the stylomastoid foramen and the softness of the temporal bone make it vulnerable to injury by this and other presumed mechanisms, such as compression against the infant's shoulder or maternal sacral prominence in cephalopelvic disproportion.[155] Facial nerve paralysis usually involves the entire distribution of the nerve and is usually unilateral. Other signs signifying trauma that may be present include Battle's sign and haemotympanum. EMG responses are present at birth with progressive decline in amplitude over time, as opposed to inherited or developmental disorders where they are absent. Unfortunately, they are rarely obtained and this leaves the surgeon with a diagnostic dilemma. Any child with facial paralysis at birth should also undergo brainstem response audiometry to test hearing as some developmental disorders are associated with cochlear nucleus abnormalities. The prognosis of neonatal facial nerve injury is excellent with more than 90% recovering completely. The indications for surgical intervention are similar to facial nerve paralysis in adults.

Facial nerve paralysis as complications of the ear infection

OTITIS MEDIA

Facial nerve paralysis may complicate both acute otitis media and CSOM. The presumed pathophysiological mechanisms include: direct involvement of the facial nerve by infection through Fallopian canal dehiscences or physiologic canaliculi for neurovascular connections; Fallopian canal osteitis with bone erosion and nerve involvement, inflammatory oedema leading to compression and secondary thrombosis of the vasa nervorum with consequential ischaemia and infarction of the facial nerve, and demyelination of the facial nerve caused by bacterial toxins. The mainstay of treatment of facial paralysis associated with acute otitis media is antibiotic therapy. Steroids may be used, although their efficacy is not supported by any studies. When spontaneous perforation is absent, myringotomy and the insertion of a ventilation tube is generally recommended. Mastoid exploration and facial nerve decompression is essential for patients with CSOM.

MALIGNANT OTITIS EXTERNA

Malignant otitis externa is an invasive *Pseudomonas* or *Aspergillus* infection of the ear canal which may lead to skull base osteomyelitis (Figure 112.21). It mainly afflicts immunocompromised patients, particularly the elderly, insulin dependent and poorly controlled diabetics. Facial palsy indicates advancing infection and invasion through the bony-cartilaginous junction and the fissures of Santorini, under the tympanic ring and posteriorly to the stylomastoid foramen. Ciprofloxacin (750 mg orally twice per day) seems to be the antibiotic of choice and prolonged treatment for a minimum of 6–8 weeks is recommended.[156] However, there are no comparative trials between antibiotics in the literature. Ciprofloxacin has also been safely administered to children with cystic fibrosis and is therefore indicated for treatment of malignant external otitis in the rare paediatric patient. In cases of resistance to ciprofloxacin, antipseudomonal β-lactam agents (ceftazidime, piperacillin, imipenem) with or without an aminoglycoside can be used. Cases attributed to *Aspergillus* infection need systemic antifungal therapy. Surgical management is currently not indicated other than diagnostic biopsies to exclude malignancy. Hyperbaric oxygen has been used on occasion with mixed results and may be considered as an adjuvant treatment for refractory cases although its efficacy remains unproven.[157]

Inflammatory disorders of the facial nerve

Sarcoidosis is an autoimmune systemic disease characterized by non-caseating granulomata mainly developing in the lungs. Facial nerve palsy is the most common otologic manifestation, which can develop either in isolation or with uveitis and parotitis as a component of Heerfordt's disease (uveoparotid fever). A raised angiotensin converting

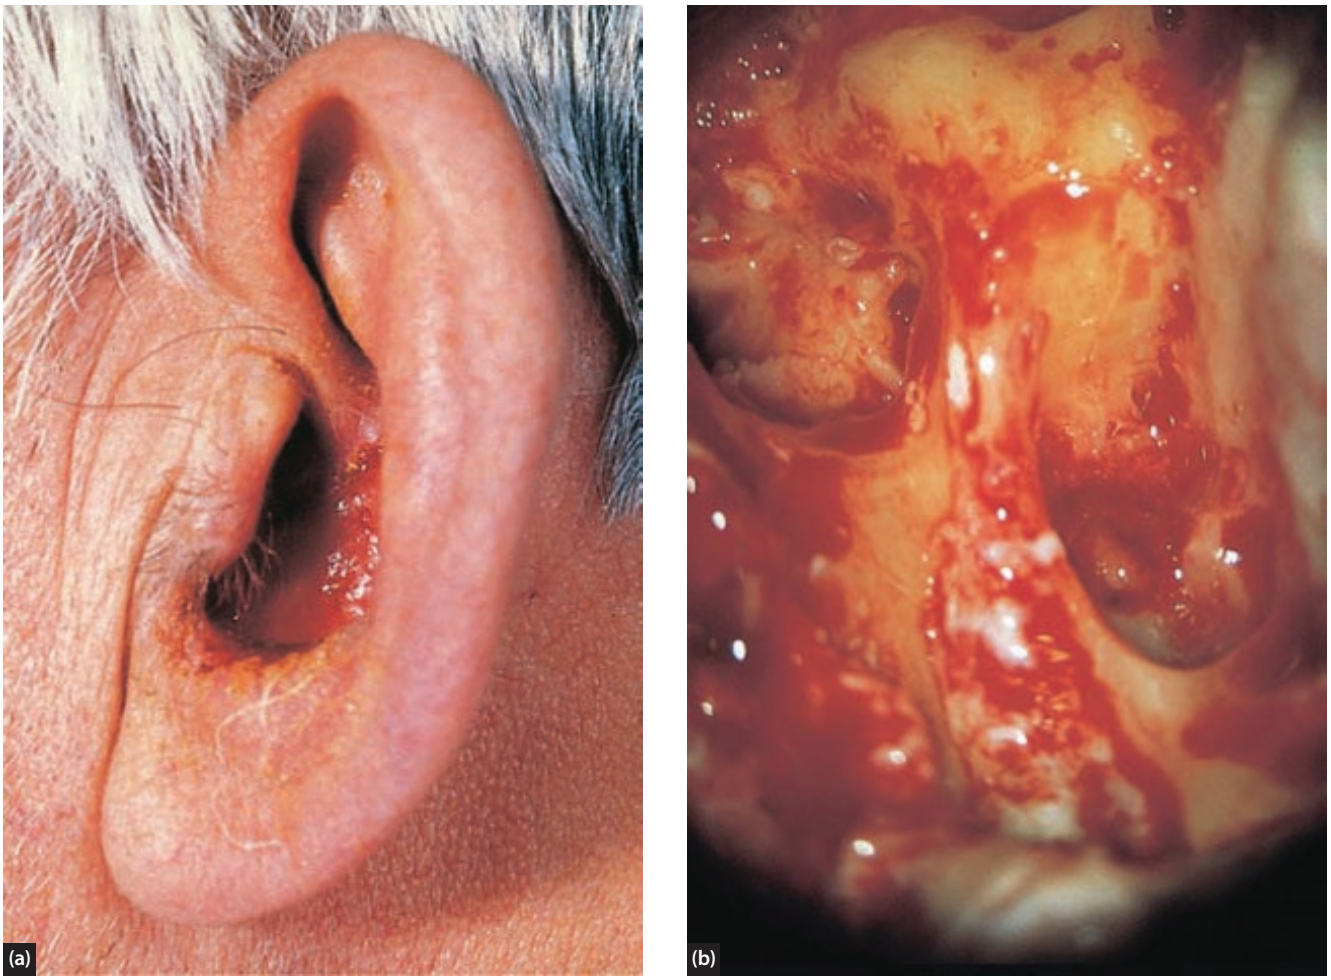

Figure 112.21 Malignant otitis externa. **(a)** discharge from left ear canal; **(b)** on opening at operation, pus was drained from the Fallopian canal. This patient's facial nerve was decompressed at a time well before the introduction of Ciproxin.

enzyme titre helps to confirm the diagnosis. Treatment with systemic corticosteroids is indicated.

Granulomatosis with polyangiitis, formerly known as Wegener's granulomatosis, is an autoimmune necrotizing vasculitis characterized by granulomata of the upper and lower respiratory tracts and kidneys. Facial nerve paralysis may be seen in this condition secondary to middle ear involvement in the presence of a dehiscent Fallopian canal. Clinical suspicion is raised by the synchronous presence of sensorineural hearing loss. Diagnosis is confirmed by elevated circulating antineutrophil cytoplasmic antigen test. Treatment of granulomatosis with polyangiitis includes a combination of cyclophosphamide and steroids. Mastoid exploration and facial nerve decompression is unrewarding and may often aggravate the problem.[158]

Lyme disease is a vector-borne, multisystem inflammatory disease caused by the spirochete *Borrelia burgdorferi*, transmitted to humans by the bite of *Ixodes ricinus* ticks. It is characterized by flu-like symptoms and erythema migrans. Facial palsy can be bilateral and should raise suspicion of the disease, especially in children. Serologic testing can confirm the diagnosis, although sero-conversion can take up to 6–8 weeks. Doxycycline or amoxicillin for 14–21 days is indicated for patients with facial nerve palsy with normal CSF findings. It should be remembered that doxycycline is contraindicated in patients younger than 8 years of age and in pregnant women. Macrolides are suitable alternatives in cases of penicillin allergy.

Multidisciplinary management of established facial palsy

In patients whose facial palsy has not resolved or when recovery is incomplete, the assessment of the degree of impairment and the impact on their physical and psychological well-being is best managed in the setting of a Multidisciplinary Facial Nerve Clinic.[159, 160] Although various models exist, most Facial Nerve MDT clinics comprise surgeons from otolaryngology and plastic surgery and highly specialized facial therapists (physiotherapy or speech and language therapy). Additional support from an oculoplastic surgeon, expert radiologist, clinical photography and psychological services is advised.[161] Patients seen in specialized clinics should expect not only a comprehensive assessment of their facial function and directed management to ameliorate the negative physical aspects of a paralyzed face, but also an attempt at securing

the diagnosis. It is not uncommon for the diagnosis to change once a patient has been seen and assessed under the auspices of the MDT clinic.

PHYSIOTHERAPY FOR INCOMPLETE RECOVERY OF FACIAL PALSY AND SYNKINESIS

Facial physiotherapy techniques for patients with facial palsy vary amongst professionals who specialize in this unique area of practice. A large proportion of the workload is devoted to patients with unresolved idiopathic palsies, although patients with other causes of unresolved facial palsy benefit from the expertise of the therapist.[162, 163] Idiopathic palsy patients may have tightness and shortening of the muscle fibres resulting in a 'frozen face' which may be associated with an aching pain which increases throughout the day. Specific guidance regarding muscle stretches allows the muscles to relax and facial symmetry to improve. Once the muscle length is restored, more active movement is usually achieved.

Given the lack of proprioceptive information from the facial musculature, patients have to relearn to make facial expressions that were previously natural. Facial therapists will spend time guiding the patient in front of a mirror in facial retraining. Novel technologies to engage patients, particularly children, have been developed to help in this regard.

CHEMODENERVATION WITH BOTULINUM TOXIN

Botulinum toxin is utilized as a second-line treatment to further release the over-tightened facial muscles and to facilitate the stretches advised above.[164] In patients with synkinesis, i.e. unwanted muscle contractions resulting from aberrent reinnervation, chemodenervation is helpful in reducing and weakening these unwanted movements.

Occasionally, chemodenervation can be judiciously used to weaken the more active 'normal' facial muscles in order to achieve a more balanced facial appearance and functional benefit for the patient.

FACIAL REANIMATION CONSIDERATIONS

The topic of facial reanimation is beyond the scope of this chapter but some basic principles exist which are considered here. It is generally accepted that a lack of recovery of facial function 12 months following the original insult is considered a permanent deficit. Throughout this period there is a steady loss of motor end-plate units and progressive muscle atrophy, such that after some months reinnervation techniques will have no beneficial effect. Therefore, techniques employing nerve grafting, or nerve transfer are only considered of value if carried out within that first 12-month period and the sooner the better. Historically, ENT surgeons have made use of a hypoglosso-facial anastomosis, providing tone and some active movement in patients with complete loss of ipsilateral facial function. Using an end-to-side neurorraphy or partially opening, rather than transecting, the hypoglossal nerve, it has been possible to preserve good tongue movement.[165] Other cranial nerves may be employed in nerve transfers including the contralateral facial nerve and the nerve to masseter (a branch of mandibular nerve). Whichever technique is employed the patient must expect a long period of rehabilitation and ongoing physiotherapy to achieve the optimum results.

Static reanimation

Given the inability to restore normal facial symmetry and achieve natural spontaneous movement, it is often appropriate for the Facial Nerve MDT to discuss simple small procedures to reduce the burden of facial weakness without the risk of larger more complex procedures. This is particularly the case in older and medically less-robust patient. Periocular surgery, including lower-lid tightening, lateral canthopexy, brow lift and upper eyelid positioning/weighting surgery may be performed under local anaesthesia and can provide benefit for the patient with troublesome eye symptoms.

Various face-lifting techniques can improve the static position of the face. These may be combined with soft-tissue procedures (e.g. wedge resection of the lower lip) to achieve a more balanced facial appearance and more importantly to improve facial function (oral competence).

Dynamic reanimation

In those patients where active movement is desired, particularly in terms of smile, it is usually necessary to bring new tissue to the area. This may be in the form of muscle transfer, for example a temporalis transfer – Labbé procedure[166] or free muscle graft using the gracilis muscle.[167] The latter is preferred in paediatric patients who have the necessary neural plasticity to achieve excellent results following physiotherapy. Depending on the aetiology of the facial nerve palsy, nerve grafting may also form an integral part of this surgery.

PSYCHOLOGICAL ISSUES IN FACIAL PALSY

Facial appearance and non-verbal communication are so central to human interaction that it is no surprise that patients who are unable to eat in public and communicate without embarrassment may suffer significant psychological distress. The development of support networks and groups has enabled patients to benefit from the experience of others and to reduce the isolation associated with living with the effects of facial palsy. Psychological support with counselling is provided in some specialist units and is available through primary care.

The over-arching principle in the management of patients with established facial palsy is to improve facial function, reduce the psychosocial consequences of the facial weakness and improve the overall quality of life for the patient.[168] These aims can be best achieved in a setting where all possible treatment modalities that might be employed in the management of a patient with facial palsy are available.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Dr Steve Connor, Consultant Neuroradiologist, King's College Hospital for his guidance with the radiology section of the chapter.

BEST CLINICAL PRACTICE

- ✓ Intra-operative facial nerve monitoring is a wise precaution for any surgery around the facial nerve regardless of the surgeon's experience. It is a standard of care in Vestibular Schwannoma surgery.
- ✓ Decompression of the facial nerve in the acute phase after trauma is indicated when paralysis is complete from the outset, there is ENoG evidence of rapid denervation and clear CT evidence of compression or wide displacement of the Fallopian canal.
- ✓ Late exploration of the facial nerve after cranial base trauma is indicated if there is no recovery after 9-12 months and CT evidence of a significant fracture.
- ✓ If a patient awakes from mastoid surgery with an unexpected facial palsy, remove the pack and obtain a CT scan. If no recovery ensues in the first few hours, the ear must be re-explored to establish the integrity of the facial nerve or correct any damage.
- ✓ Antibiotic therapy for malignant otitis externa must be prolonged, often for several months.

FUTURE RESEARCH

- ➤ Although there is some evidence to suggest that Bell's palsy is caused by HSV, definitive evidence is still lacking.
- ➤ Further knowledge regarding aberrant reinnervation and the role of facial therapy in preventing/reducing synkinesis may have a useful benefit for patients.

KEY POINTS

- The commonest cause of facial palsy in adults is an idiopathic palsy.
- Although electrophysiological testing may provide useful prognostic information and serve as a guide to the management of facial palsy, there are some important limitations: it provides no useful information in cases of incomplete facial paralysis and it fails to provide information on the immediate post-paralysis period.
- Ipsilateral recurrent facial nerve palsy or a paralysis with progressive or incomplete recovery should raise the suspicion of malignancy.
- Any facial palsy that does not recover or is recurrent needs further investigation and imaging.

CHAPTER 113

TUMOURS OF THE FACIAL NERVE

Patrick R. Axon and Samuel A.C. MacKeith

SEARCH STRATEGY

The data may be updated with a PubMed or MedLine search using the following keywords: facial nerve tumour, schwannoma and neuroma.

INTRODUCTION

Facial nerve tumours are rare. The most common histological type are facial nerve schwannomas (FNS) although facial nerve haemangiomas, malignant nerve sheath tumours and 'skip' lesions from parotid malignancies, amongst others, may also occur.[1] This chapter focuses on FNS, their presentation, diagnosis and management, but will also consider the differential diagnoses for these lesions.

PATHOLOGY

As with other schwannomas, FNS are benign, slow growing tumours arising from Schwann cells within the nerve sheath. Facial nerve neuroma, neurinoma and neurilemmoma are other terms previously used. The classic histology showing Antoni type A and B tissue is indistinguishable from vestibular schwannomas. As such, diagnosis requires correlation with imaging findings and/or intra-operative confirmation of the tumour arising from the facial nerve.

INCIDENCE

Facial nerve schwannomas are rare and thought to account for between 1% and 3% of all cerebellopontine angle (CPA) tumours although are not uncommonly seen as part of neurofibromatosis type 2.[2] A previously reported cadaveric temporal bone study found 5 FNS in 600 specimens, suggesting that these tumours may grow undetected without symptoms.[3]

CLINICAL PRESENTATION

Facial nerve schwannomas can arise from anywhere along the course of the facial nerve from the CPA to the ramifications within the parotid. The presenting symptoms will vary according to the segment involved. The relative frequency of occurrence at each site varies and has been reported to be most common at the geniculate ganglion (68%), labyrinthine (52%) and tympanic (43%) and mastoid segments.[4] In addition, FNS are commonly found to involve multiple segments.[1, 5, 6]

Intratemporal FNS most commonly present with progressive weakness or spasm, although less commonly may present with sudden onset or recurrent facial weakness.[7–8] Tumours affecting purely the internal auditory canal (IAC) or CPA are reported to represent less than 2% of FNS.[9] When isolated to this segment their presentation commonly mimics that of a vestibular schwannoma (VS) with symptoms of hearing loss, tinnitus and imbalance.[9] In these cases diagnostic confirmation of FNS may only occur at surgery thereby presenting an intra-operative management dilemma. This will be considered later in this chapter. Although rare, extra temporal FNS may present simply with a parotid mass.[10]

For FNS that continue to grow and extend intracranially either from the IAC into the posterior fossa or from the geniculate ganglion into the middle fossa, neurological sequelae may develop causing symptoms of brainstem compression/hydrocephalus or seizures.

The natural history of FNS is not as well studied or understood as for VS. However, there is a growing number of published series demonstrating that a significant proportion of FNS do not grow.[5, 11] A recent study of 21 patients with FNS managed with observation for a mean follow-up of 6.4 years (range 4–9) showed that, overall, 43% grew, which corresponded to 10% growth rate in FNS <10 mm in size and 73% growth rate in those >10 mm in size. Furthermore, 18 of 21 (86%) maintained facial function of HB grade III or better.[12]

INVESTIGATIONS

Radiological investigations

The mainstay of diagnosis is with high resolution cross-sectional imaging. A T1 weighted MRI with gadolinium will show an enhancing (often fusiform) lesion at the site of involvement, which may vary in appearance depending on the location. Multiple segment involvement is common and may give a 'beads on a string' appearance.[6,9] Facial nerve schwannomas are classically described as causing smooth bony expansion of the facial nerve canal, which helps to distinguish between contrast enhancement of the facial nerve as seen following a simple Bells palsy and a true facial nerve schwannoma.

Facial nerve schwannomas that are limited to the internal auditory meatus (IAM)/CPA can be difficult to differentiate from VSs (see **Figure 113.1**). However, the advantage of a T1-weighted MRI with gadolinium over other sequences (such as FIESTA) is that it may demonstrate a 'labyrinthine tail' with enhancement of the adjacent facial nerve (see **Figure 113.1**).[6] Involvement of the geniculate ganglion with extension along the greater superficial petrosal nerve makes radiological diagnosis of FNS more obvious (see **Figures 113.2 and 113.3**).

CT of the temporal bones may be helpful in demonstrating smooth bony expansion at the site of the FNS (see **Figure 113.4**). An exception to this well defined appearance has been described when the vertical mastoid segment of the nerve is involved and growth extends into adjacent mastoid air cells giving the suggestion of an aggressive tumour (especially on MR).[13]

Facial nerve schwannomas affecting the tympanic segment of the facial nerve have been described as appearing as a pedunculated mass on imaging but, again, enhancement of the adjacent nerve should help in distinguishing it from other middle ear masses.

Other investigations

Audiometry with a pure tone audiogram and speech audiometry is essential and may influence subsequent management decisions and surgical approaches.

Topographical assessment of facial nerve function (taste, lacrimation and stapedial reflexes) has largely been superseded by other diagnostic modalities and do not usually form part of a standard assessment.

Electroneurography (ENoG) has been advocated as a method for calculating the proportion of facial nerve motor neurons lost to tumour compression. It measures the compound muscle action potential (CMAP) to maximal bipolar stimulation of the facial nerve at the stylomastoid foramen. The investigation is used as an aid in the management of acute facial paralysis because it indicates the severity of Wallerian degeneration in the days after onset of facial weakness. ENoG, however, does have its drawbacks. It relies on comparison of the maximal CMAP derived from the muscles of the affected and normally functioning side and has a poor test–retest reliability. It is particularly inaccurate

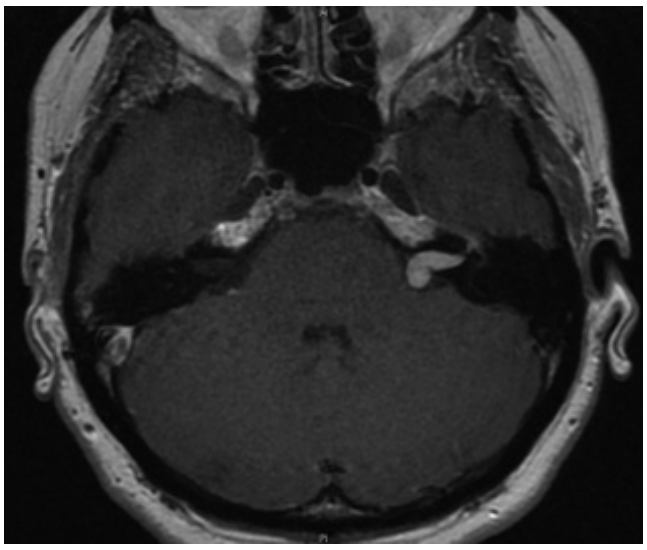

Figure 113.1 Axial T1 weighted MRI of patient who presented with facial weakness showing contrast enhancing tumour of the IAM/CPA with subtle enhancement of adjacent segment producing 'labyrinthine tail'.

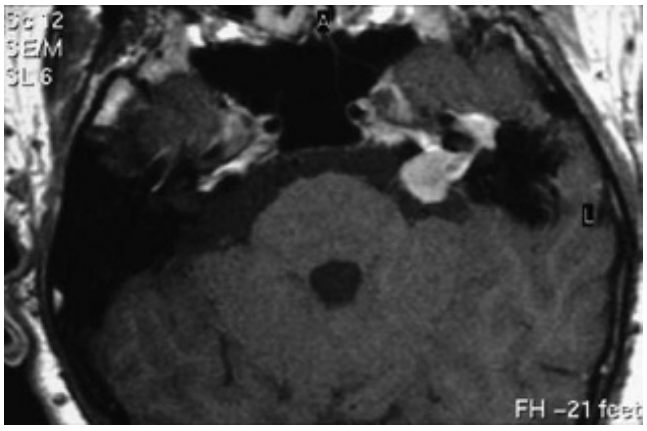

Figure 113.2 Axial T1 weighted MRI with contrast showing facial schwannoma filling the internal auditory meatus and extending along the greater superficial petrosal nerve into the middle fossa.

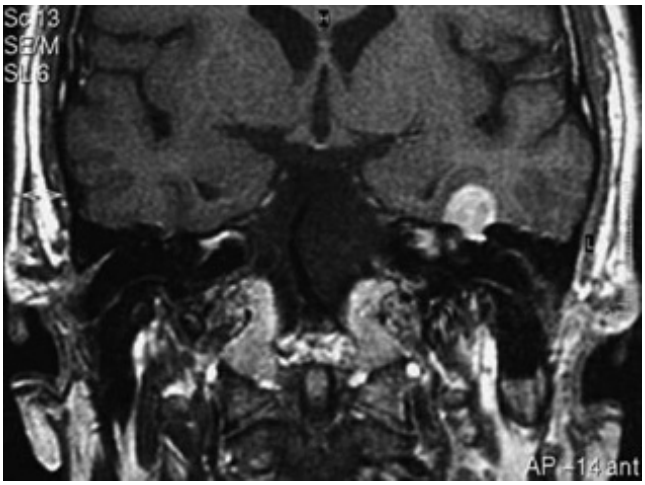

Figure 113.3 Coronal MRI showing a facial schwannoma arising from the geniculate ganglion and extending through the petrosal foramen into the middle fossa, pushing upwards into the temporal lobe.

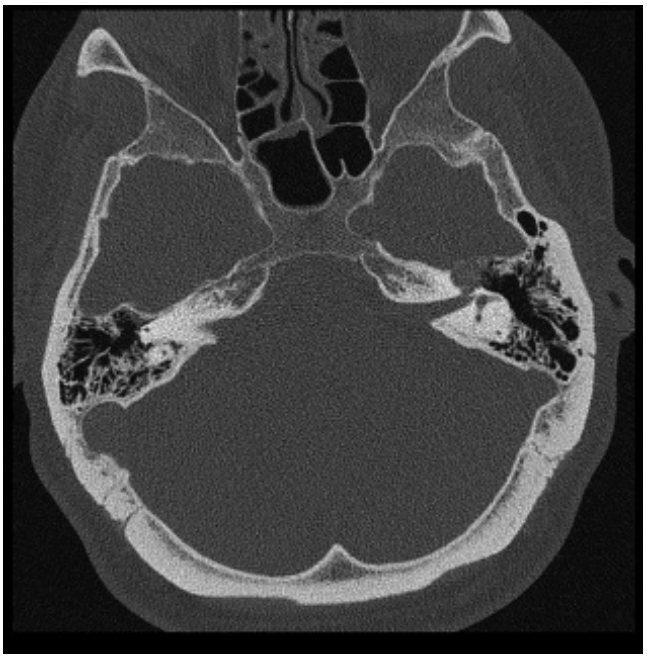

Figure 113.4 Axial CT of temporal bones at the level of the IAM/geniculate ganglion on the left with a round smooth bony expansion of the geniculate fossa caused by a facial schwannoma. (See **Figure 113.5** for corresponding MRI.)

for assessing longstanding or slowly progressive facial palsy, for two important reasons. First, it is unable to take into account terminal collateral sprouting in response to nerve injury, which increases the number of muscle fibres each motor neuron innervates. Second, it cannot differentiate between motor neurons that are functioning normally across the site of tumour compression and those in conduction block. As such, a clinical assessment of facial function using the House-Brackmann grading system provides a pragmatic assessment for guiding management decisions. Some units do advocate the use of ENoG to monitor for subclinical deterioration in nerve function as an additional factor when considering surgical intervention.[11]

Investigation of intraparotid FNS by fine needle aspiration cytology biopsy has been shown to be unreliable in retrospective analyses.[14–15]

MANAGEMENT

Due to the rarity and heterogeneity of FNS and the inherent problems of conducting prospective trials in this setting (as for VS), management of FNSs remains controversial and lacks good evidence to support any particular treatment algorithm. Overall, however, there does appear to be an evolving philosophy towards a more conservative approach with the paramount aim of preserving optimal facial nerve function for as long as possible.[5, 11] This is in contrast to the previously held wisdom that FNSs should be excised and grafted.[1, 16–17] An acceptance that facial nerve grafting can reach, at best, a House-Brackmann (HB) grade III, has lead to a reluctance to intervene surgically in patients with good facial function (HB I or II).

As for VS, the management options are: observation with serial scanning; radiotherapy (stereotactic or fractionated); and surgery. Management decisions are largely influenced by existing facial nerve function, hearing, tumour location and patient comorbidities.

For patients with an FNS and good facial function (HB I or II), unless there is evidence of significant intracranial extension with mass effect, observation with serial imaging is an appropriate initial strategy for most patients.

For FNSs that have demonstrated growth, the options include stereotactic radiation or surgery (or continued observation). In an effort to prevent deterioration in facial function in FNSs growing within a bony confine or with deteriorating facial function or ENoG, some units advocate bony decompression.[18]

STEREOTACTIC RADIATION

Published reports of stereotactic radiation (SR) treatment for FNS have increased significantly in recent years.[19–21] High tumour control rates of as high as 93% are quoted but these studies include all treated tumours and not just those that have demonstrated growth on serial MR imaging. In a recently published series from Manchester, tumours in only 2 of 11 patients that were managed conservatively with observation grew, giving a growth rate of only 18%.[5] Further larger long-term observational studies are needed to delineate the natural history of these tumours to better measure the true effect size of SR treatment. Nevertheless, given the poor surgical outcomes in terms of facial function, SR remains an attractive option for treating growing FNSs in patients who have good facial function (HB I or II).

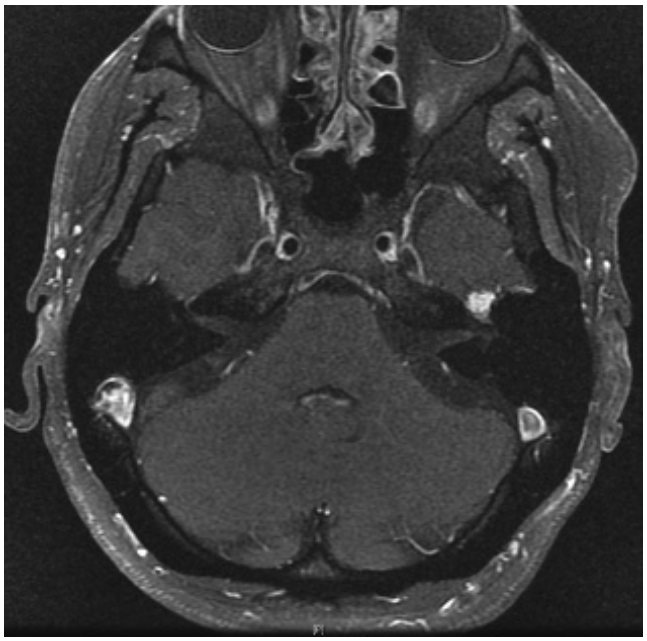

Figure 113.5 A T1 weighted MRI showing enhancing facial schwannoma of the geniculate ganglion from same patient as Figure 113.4.

SURGERY

Surgical intervention is often reserved for growing FNSs that have failed radiation treatment, tumours with significant intracranial extension with mass effect and tumours where facial function has already deteriorated to HB grade III or worse. There is, however, no consensus on the optimal time to intervene or the type of surgical intervention in this scenario. The options include:

- near total/subtotal excision in attempt to maintain nerve integrity with the option of SR treatment if the residual remnant grows
- fascicle preservation surgery/tumour stripping from intact facial nerve
- excision with primary anastamosis, grafting or other reanimation technique.

The choice of surgical approach varies depending on tumour location, levels of hearing and surgeon preference. An FNS involving the mastoid segment of the facial nerve extending through the stylomastoid foramen will require a combined transmastoid/parotidectomy approach, whereas involvement of the geniculate ganglion extending primarily along the superficial petrosal nerve will likely require a middle fossa approach. Tumours extending medially from the internal auditory meatus into the cerebellopontine angle will require a translabyrinthine or retrosigmoid approach depending on surgeon preference. For larger tumours involving multiple segments, combined approaches will be required.

Some units have adopted subtotal excision as a more conservative approach to reduce facial nerve dysfunction. Li et al. published a series demonstrating a regrowth rate of 27% for 15 FNS that had undergone subtotal or near total resection. They concluded that this was not a safe technique despite achieving HB of I or II for 93%.[22] Other centres would consider this acceptable and utilize radiation treatment for growing residual tumour. Fascicle preservation surgery (or tumour 'stripping') has been described as a surgical technique whereby a plane of cleavage can be found between the tumour and the facial nerve, thereby maintaining its integrity.[23,24] Sherman et al. described 5 patients in a series of 10 who had total macroscopic tumour removal leaving an intact facial nerve.[25] All patients achieved HB grade I or II post-operative facial function and one patient had tumour recurrence. O'Donoghue et al. maintained at least 50% facial nerve continuity in 11 of a series of 36 patients undergoing surgery; however, the post-operative results were no better than facial nerve resection and grafting.[26]

For growing FNS where the facial function has already deteriorated significantly, excision of the tumour and involved segment of the nerve offers the best chance of long-term cure. Primary end-to-end anastomosis has the highest success rate and can be performed by mobilization of the nerve when there has been minimal loss of length. More commonly a cable graft is required, such as using the great auricular (or sural nerve if longer length is required). Most would accept that the best outcome possible with this technique is an HB grade III. Techniques vary to achieve the tension free nerve anastomosis but include suturing the epineurium with 8.0–10.0 nylon, using fibrin glue[27] and the use of grafting conduits to aid coaptation such as with autologous vein, tubed fascia or collagen nerve tubules.[18] Clearly, there are many more dynamic and static facial nerve reanimation techniques utilized in this setting that cannot be covered in this chapter.

MANAGEMENT OF THE INTRA-OPERATIVELY DIAGNOSED FNS

As described earlier, the clinical presentation and radiology may not always give the diagnosis of FNS and only at surgery does it become apparent that the tumour is arising from the facial nerve. An index of suspicion in these cases may avoid inadvertent injury. During a translabyrinthine approach to a presumed VS, the finding of a normal superior vestibular nerve overlying a tumour antero-superiorly in the IAM presents a surgical dilemma. At this point the options include: abandoning the procedure; decompression; or some form of partial/total excision as described above. This decision will depend on the individual case, particularly the preoperative facial nerve function, as well as the surgical team's management philosophy.

A middle ear mass arising from the facial nerve identified intra-operatively should not be biopsied as this may cause a facial palsy. Appropriate imaging should be organized post-operatively, which is likely to aid diagnosis, with an FNS often identified on the horizontal facial nerve segment.

DIFFERENTIAL DIAGNOSIS

The main differential diagnosis of an intratemporal facial nerve schwannoma is a facial nerve haemangioma. Clinically these are associated with a significantly worse facial function at presentation, even when relatively small.[28] There may be similar appearances to FNS on imaging but with subtle differences. Bony erosion may not be smooth because haemangiomas do not have a capsule. They do not usually affect multiple segments as FNS do. Haemangiomas have been described as having a 'honeycomb' appearance on imaging.[29] Again, evidence to support management decisions is sparse but given the early loss of facial function and the possibility to resect these keeping the facial nerve intact, some advocate early intervention.[30, 31]

Malignant peripheral nerve sheath tumours can affect the facial nerve and occasionally occur in association with neurofibromatosis type 1. Treatment usually requires radical surgery, often with adjuvant radiotherapy. Other malignant tumours affecting the facial nerve include perineural spread from the parotid gland tumours as seen with adenoid cystic carcinoma and others.

CONCLUSION

FNSs are rare and usually present with disturbance of facial function, with or without audiovestibular dysfunction. Management decisions must be tailored to each patient based on existing facial and audiovestibular function and tumour location but management philosophy varies between units internationally. The primary aim of management is preservation of optimal facial function for as long as possible.

FUTURE RESEARCH

- ➤ Accurate long-term data on FNS managed with observation will provide a better understanding of the natural history of this condition, which will help better counsel patients.
- ➤ The results of long-term data assessing the efficacy of SR treatment are awaited, including the results of subsequent surgery and reanimation in those that fail radiotherapy.

KEY POINTS

- FNS should be considered in all patients with a presumed diagnosis of VS presenting with facial spasm or weakness.
- Surgical excision with facial nerve grafting can achieve a HB grade III facial function at best.
- Most surgeons avoid/delay excision of FNS whilst good facial function is maintained.

CHAPTER 114

OSTEITIS OF THE TEMPORAL BONE

Cheka R. Spencer and Peter Monksfield

SEARCH STRATEGY

Data presented in this chapter may be updated by a National Library of Medicine PubMed search of all medical literature using the keywords: skull base osteomyelitis, malignant otitis externa, necrotizing otitis externa, limited to human, English language and full text.

INTRODUCTION

Osteitis is defined as inflammation of bone. It can be due to a number of reasons, the most common of which is secondary to infection. Acute infection of the temporal bone known as acute mastoiditis and chronic mastoid infections coupled with middle ear disease and chronic otitis media are dealt with in other areas of this book.

Temporal bone osteomyelitis, more often called skull base osteomyelitis as it progresses to other bones of the skull base, is the more invasive form of temporal bone osteitis. It usually occurs as a result of otitis externa in immunocompromised individuals. It can cause neuropathy of cranial nerves and is resistant to treatment.

Other inflammatory conditions affecting the temporal bone are rare and much of the literature is limited to case reports rather than case series or larger studies.

SKULL BASE OSTEOMYELITIS

Definition

Skull base osteomyelitis is a rare complication of otitis externa. It is a vicious infection in which the soft tissue pathogens have spread to the periosteum and temporal bone of the skull causing necrosis. This may be associated with involvement of the facial nerve, carotid artery and jugular vein, including the bulbar and hypoglossal nerves. The infection may then progress to other bones of the skull base.

Nomenclature

The condition was first described in 1959 by Meltzer and Kelemen, who named it 'pyocutaneous osteomyelitis of the temporal bone'.[1] Subsequently, Chandler coined the term 'malignant external otitis' in 1968 when presenting his series of 13 patients with progressive osteomyelitis of the temporal bone.[2] He termed it malignant due to the aggressive clinical behaviour, poor treatment outcome and high mortality rate for the patients affected by this disease. This used to be as high as 50% but has significantly reduced with better antibiotic regimens. The term 'malignant' is controversial as many authors feel some may misconstrue the inflammatory process as neoplastic and advocate 'necrotizing otitis externa' instead.[3] It has been suggested that 'necrotizing otitis externa' be used for aggressive soft tissue infection without bony involvement.[4] Otogenic 'skull base osteomyelitis' refers to the more severe clinical entity following spread of infection through the soft tissue and cartilage with histological or radiological confirmed bony involvement.

Epidemiology

Skull base osteomyelitis most frequently affects the elderly and diabetic.[2, 5–18] The national incidence of skull base osteomyelitis, according to the Hospital Episodes Statistics (see **Figure 114.1**), is increasing significantly (from 67 in 1999–2000 to 421 in 2012–2013) out of proportion to the increase of hospital admissions in general[8, 12] This is thought to be due either to the increased number of elderly

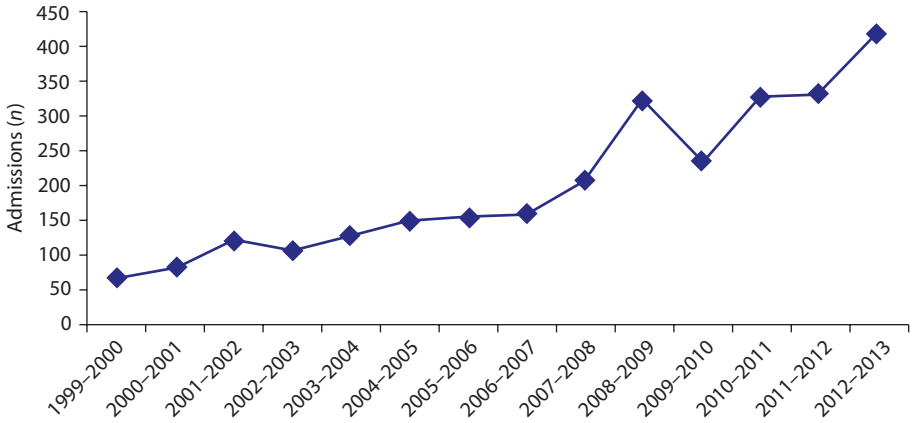

Figure 114.1 Cases of necrotizing otitis externa 1999 to 2013 according to the Hospital Episodes Statistics data.[8]

diabetics or to an increased index of clinical suspicion, and is likely to be both of these factors. The reported prevalence of diabetes in this condition ranges from 65% to 100% of patients.[2, 5, 13] It is postulated that endarteritis, microangiopathy and small vessel obliteration prevalent in the elderly diabetic in addition to their innate defects in humoral immunity, predispose them to this condition.[9, 15] Patients are usually older than 60 years of age and there is a male preponderance with a ratio of 2:1.[12, 17] Conditions causing immunosuppression such as HIV/AIDS, steroid usage, chemotherapy, anaemia, leukaemia, lymphoma, neoplasia and renal transplantation are also predisposing factors to skull base osteomyelitis.[5, 6, 8, 13] The epidemiology of skull base osteomyelitis is said to be changing, with more presentations amongst the immunocompromised.[12]

HIV-affected patients with skull base osteomyelitis tend to be younger than those with diabetes. They are also more likely to have a fungal infection (i.e. *Aspergillus sp.*), particularly when CD4 counts are less than 50 cells/mm.[5]

Skull base osteomyelitis in children is rare. It is most often seen in immunocompromised states such as immunoglobulin A (IgA) deficiency, acute monocytic leukaemia, iatrogenic neutropenia and bone marrow transplantation. Diabetes as a risk factor is not as common in children as in adults.[5, 12, 15]

Pathophysiology

Various factors are said to account for the susceptibility of diabetics to skull base osteomyelitis including their weakened immune response to *Pseudomonas aeruginosa* infection and the high pH of their cerumen.[5, 6, 9, 13–15, 17] In all cases, the infection spreads to the skull base from the external auditory canal through the fissures of Santorini. At the osteocartilaginous junction, the infection spreads medially to the tympanomastoid suture along venous canals and fascial planes invading connective tissue, cartilage, bone, nerves and blood vessels. The inflammatory process alters the morphology of the compact bone of the skull base, changing it to granulation tissue.[5, 9] As the infection progresses to the skull base foramina it causes cranial neuropathies. The facial nerve is most commonly affected due to its close relation to the external auditory canal. The disease can spread medially and subsequently affects nerves around the jugular foramen. Further spread of disease can affect abducens and trigeminal nerves around the petrous apex, and also the optic nerve. Septic thrombosis of the sigmoid sinus and internal jugular vein may also complicate skull base osteomyelitis should the infection spread there. Histologically, new bone formation is observed next to areas where bone has been destroyed. The otic capsule and middle ear structures are very resistant and are rarely, if ever, involved in the disease.[5, 9]

Diagnosis

The diagnosis of skull base osteomyelitis is based on the clinical features, microbiology for culture, radiological changes within the bone of the skull base and histology showing inflammation without neoplasia.[11] Fungal pathogens may also be identified on silver staining of histological sections.[5]

CLINICAL FEATURES

Patients with skull base osteomyelitis are usually elderly diabetics presenting with severe unremitting otalgia, unilateral otorrhoea and a hearing loss. There is usually a history of ear canal trauma, often after irrigation for wax removal.[13] Self-inflicted trauma has also been implicated and a strong relationship between laterarality of skull base osteomyelitis and handedness has been reported.[18] Otalgia that is nocturnal, deep, lancinating and disproportionate to the clinical signs is highly suggestive of osteomyelitis. It is often resistant to analgesics. It is the most common presenting symptom with a prevalence of 75–100%.[6, 7]

Purulent otorrhoea, the second most common symptom and sign, in an exquisitely tender and oedematous ear canal, is found on examination in more than half of the cases.[9] Inspection of the floor of the ear canal may reveal granulation tissue or exposed bone (see **Figure 114.2**). There may also be a polyp or granuloma in the canal obstructing the view of the tympanic membrane. The granulations should be sent for histological analysis to exclude malignancy, histiocytosis and tuberculosis.[6] Patients with HIV infection often lack granulation tissue.[13]

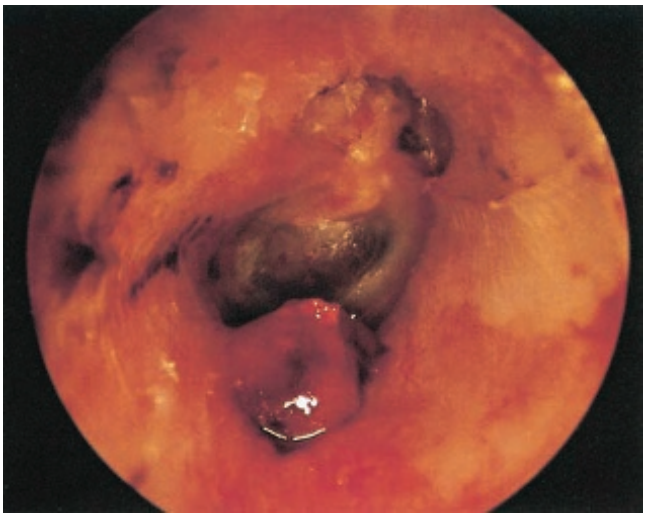

Figure 114.2 Necrotizing otitis externa with granulations of the floor of the right external auditory canal. Reproduced from Carney.[37]

The hearing loss is usually conductive due to external auditory canal obstruction by granulation or oedema. Sensorineural hearing loss is usually due to pre-existing presbycusis.[5]

As bony destruction and inflammation progresses medially through the skull base to the foramina, cranial neuropathies ensue initially with facial paralysis (in up to 25% of patients). This is followed by cranial nerves IX, X, XI, XII and then VI and II. Meningitis, cerebral abscess and sigmoid sinus thrombosis are late signs that are associated with a poor prognosis.[6, 9]

Children with skull base osteomyelitis usually develop facial nerve palsies earlier due to their more medial fissures of Santorini and their underdeveloped mastoid process.[13]

Parotitis and trismus due to masseter myositis and temporomandibular joint involvement is a rare clinical feature that has been described.[9]

A meta-analysis which sought to develop a clinically useful prognostic scoring system found the following factors to have a statistically significant negative effect on outcome: cranial neuropathies, external auditory canal granulations, bilateral symptoms and positive aspergillus cultures.[12]

BACTERIOLOGY

Pseudomonas aeruginosa, a Gram-negative obligate aerobe, is the most common bacteria species in skull base osteomyelitis.[5–7, 12–14] It is opportunistic and only a pathogen when the natural host defences are defective.[9] It has the ability to invade local vasculature and cause a focal coagulative necrosis of the surrounding tissue. Diabetics are susceptible to *P. aeruginosa* infection due to their poor phagocytosis of polymorphonuclear leucocytes. Virulent species have a mucoid surface layer that confers additional protection against phagocytosis. They may additionally produce lytic enzymes (for example, collagenases and elastases) and endotoxins, resulting in a necrotizing vasculitis.[6–9] Some strains also produce neurotoxins, which likely play a role in the development of cranial neuropathies.[6]

Staphylococcus aureus, *Staphylococcus epidermidis*, *Proteus mirabilis*, *Klebsiella oxytoca*, *Klebsiella pneumonia, Burkholderia cenocepacia, Enterobacter cloacae* and *Streptococcus constellatus* are other bacteria that have been implicated in the pathogenesis of skull base osteomyelitis.[5–7, 12]

Fungal infections are more commonly associated with the immunocompromised (e.g. HIV/AIDS) than with diabetics. In contrast to pseudomonal skull base osteomyelitis, these originate more often in the middle ear or mastoid. *Aspergillus fumigatus*, is the most common fungal organism isolated. It is associated with a worse prognosis than *Pseudomonas* when it is the causative agent. Others include *Aspergillus niger, Aspergillus flavus, Candida sp., Malassezia sympodialis* and *Scedosporium apiospermum*.[5–7, 9, 12–15, 17]

RADIOLOGY

All imaging modalities are reliant on the experience and confidence of the radiologist reporting the scans in order to help establish the diagnosis and guide treatment. A high-resolution computed tomography (CT) scan is valuable in diagnosing bony erosion and reduced density in the skull base. However, the value of CT scans is limited due to it only detecting bony demineralization of 30% or greater.[6, 9, 19] A negative CT scan must therefore be treated with caution as a potential false negative, as demineralization may take months to appear.[8, 13] A contrast-enhanced CT scan is useful in evaluating the extent and severity of extratemporal soft tissue involvement. Other features of complicated skull base osteomyelitis, such as abscess formation, mastoid and temporomandibular joint involvement, as well as progression of disease to the petrous apex and carotid canal, can also be demonstrated on CT scanning. However, CT scanning cannot reliably measure treatment response, distinguish between neoplasia and inflammation or show intracranial or bone marrow involvement.[8, 9, 14] It has been shown to depict persistent cortical changes 12 months after initiation of treatment.[11] It is nonetheless useful at the initial evaluation to outline the extent and location of the osteomyelitic process. Magnetic resonance imaging (MRI) is generally good at soft tissue differentiation and in skull base osteomyelitis can depict bone marrow oedema. Nonetheless, MRI is unable to assess response and resolution of disease and has also been shown to depict soft tissue and marrow abnormalities months after treatment has been completed.[6, 9, 11]

Nuclear imaging is useful in diagnosing skull base osteomyelitis, defining its extent and evaluating response to treatment and resolution of infection. Technetium-Tc ^{99m}-methylene-diphosphonate (^{99m}Tc-MDP) or Technetium-Tc 99-hydroxymethylene-diphosphonate (^{99m}Tc-MDP) scintigraphy has almost 100% sensitivity.[5] Its radiotracer accumulates in areas of high osteoblastic activity even in early cases of the disease. It has low specificity as it is also positive in malignancy; and so histological confirmation is important. As it

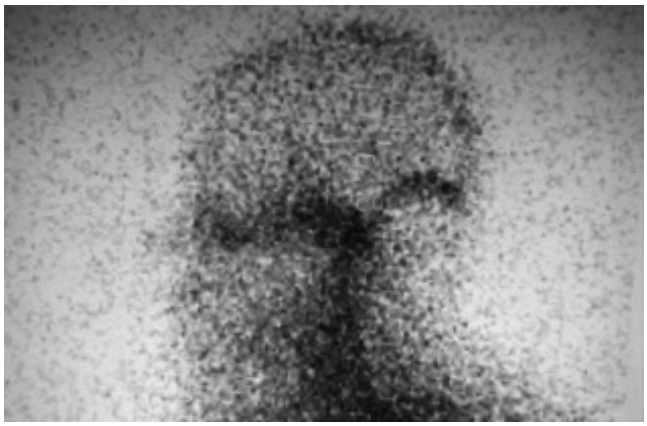

Figure 114.3 Indium labelled white cell scan of a patient with necrotizing otitis externa showing increased uptake in the left temporal bone. Reproduced from from Carney.[37]

cannot distinguish between active infection and bone remodelling, Gallium-67-citrate scanning is often utilized to monitor treatment response.[11, 14] It is based on the propensity of Gallium Ga 67 citrate to accumulate in areas of active inflammation in both soft tissue and bone. As Gallium uptake normalizes with disease resolution, unlike ^{99m}Tc MDP, it is a reliable tool to gauge response to treatment.[6, 9, 11] It should ideally be repeated every 4 weeks to monitor response to antibiotics until it is no longer positive.

Indium 111 (111 In) labelled leucocyte scintigraphy detects neutrophil mediated inflammation (see **Figure 114.3**). Single photon emission computed tomography (SPECT) creates 3-D pictures using Indium 111 or Gallium 67, which optimize anatomical localization.[5]

A meta-analysis of 23 studies seeking to determine which modality was most accurate found that fluorodeoxyglucose positron-emission-tomography (FDG-PET) was most accurate in confirming or excluding osteomyelitis but not significantly better than the combination of ^{99m}Tc bone and leucocyte scintigraphy or Ga67 scintigraphy.[11] Such modalities may not be available in most acute settings.

Treatment

AURAL TOILET

Aural toilet of the external auditory canal, as with uncomplicated otitis externa, is vital. It enables control of granulations and pain. Controversy surrounds the use of topical anti-microbial therapy in these cases as it may make culture of the pathological organism difficult.[4]

CONTROL OF DIABETES

Patients with poorly controlled diabetes are more susceptible to developing skull base osteomyelitis than diabetics with satisfactory control of serum glucose levels.[18] Aggressive glycaemic control in diabetic patients can be as crucial a management strategy as systemic antimicrobial therapy.[5, 13] Achieving good control of serum glucose may be difficult with invasive infection.

SYSTEMIC ANTIBIOTICS

Long-term systemic culture-directed antimicrobial therapy is the mainstay of treatment of skull base osteomyelitis. This is on average continued for at least 6–8 weeks depending on the resolution of symptoms,[5] but in advanced cases could be administered for months. In the ideal setting, antimicrobial therapy should be continued for as long as the gallium-67 scan remains positive. Fluoroquinolones have transformed the treatment of skull base osteomyelitis.[20] They are antipseudomonal, have good bone penetration and good oral bioavailability, and have fewer side effects than such alternatives as penicillins and aminoglycosides. Monotherapy with oral ciprofloxacin (750 mg twice daily) is the preferred initial regimen[5, 21–23] although some experts, with no conclusive evidence, still advocate parenteral antimicrobials converted to oral once the serum C-reactive protein (CRP) and/or the erythrocyte sedimentation rate (ESR) start to decline.[24] The addition of rifampicin (600 mg twice daily) has also been suggested, again with no direct evidence that it confers additional benefit.[25]

The incidence of *Pseudomonal* resistance to fluoroquinolones worldwide is increasing.[16] Cephalosporins active for pyocyanin (i.e. ceftazidime, cefepime), penicillins (i.e. ticarcillin, clavulanate) and aminoglycosides either in combination or as monotherapies are suitable alternatives in the context of resistance.[5, 7] Amphotericin B is the antifungal agent of choice for skull base osteomyelitis of fungal origin.[26] Oral itraconazole may be used after a successful course of amphotericin B.[27]

HYPERBARIC OXYGEN

The use of hyperbaric oxygen as an adjunct to systemic antimicrobial therapy has been debated with reports that it confers a beneficial effect.[27–29] It increases the partial pressure of oxygen, relieving hypoxia and enhancing the oxidative killing of microbes. A Cochrane review, however, found that there was no evidence from randomized controlled trials to support this treatment.[30]

SURGERY

In contrast to the era when the condition was first described, which saw radical debridement advocated to improve survival, surgery has a limited role in the management of skull base osteomyelitis. It is primarily performed to obtain specimens for culture, to locally debride granulation tissue and to exclude malignancy.[17] In selected cases it may be necessary to remove dead sequestra and drain associated abscesses.[5] Facial nerve decompression for complete facial palsies has unproven therapeutic benefit.[16]

OTHER INFLAMMATORY CONDITIONS AFFECTING THE TEMPORAL BONE

Sarcoidosis

Sarcoidosis is a granulomatous inflammatory condition that can affect several organs. It is thought to be due to an

autoimmune response by CD4 lymphocytes and mononuclear phagocytic cells against an unspecified antigen that evolves into a granuloma.[31] The vast majority of patients will have pulmonary involvement but other organs can be affected such as the eyes, spleen, mucous membranes and spleen.

In osseous sarcoidosis, which occurs in 1% to 13% of patients with sarcoidosis, the granulomatous inflammation is within the bone marrow. The petrous apex has been shown to be pneumatized in 30% of temporal bones,[31] with the remaining cases containing bone marrow, which could be a focus for sarcoidosis.

Clinical features have been reported to include otalgia, sensorineural hearing loss, aural fullness, tinnitus, disequilibrium and vertigo. Otomicroscopy is likely to be normal. Neurosarcoidosis, which occurs in 5% of cases, may cause cranial neuropathies with the facial nerve most commonly affected.[31]

Bony involvement exhibits threepatterns of radiographic appearance: lytic, permeative and destructive.[32] ^{99m}Tc-MDP scintigraphy and CT scanning are useful diagnostic tools in identifying bony lesions.[33] Biopsy of accessible lesions is useful when the diagnosis is unclear (e.g. suspected malignancy).[31, 33] There is no consensus on the length of time serial imaging should continue but annual surveillance scanning has been suggested.[31] Oral corticosteroids are the usual treatment modality in sarcoidosis.

Paget's disease

Osteitis deformans, also known as Paget's disease, is characterized by increased osteoclast activity, resulting in bony resorption, followed by osteoblast-mediated disorganized new bone formation. This results in a thickened, hypervascular, hypodense bone that is susceptible to fracture.[34]

It affects 3% of people aged over 40 years, with males more frequently affected.[34] The temporal bone is affected in 65–70% of cases.[35] Hearing loss occurs in 30–50% and vestibular dysfunction in 20–25%.[34] CT scanning demonstrates cotton wool appearance of involved bone due to replacement of marrow with hypodense bone. ^{99m}Tc-MDP scintigraphy is very sensitive in the early stage of the disease process as it is taken up by active osteoblasts.[34] Bisphosphonates that inhibit osteoclast activity are the mainstay of treatment. Zoledronate has been found to be the most potent bisphosphonate in suppressing disease activity.[36]

KEY POINTS

- Skull base osteomyelitis is a severe infection usually arising from otitis externa.
- The incidence of this infection is increasing.
- It affects the elderly, diabetics and immunocompromised individuals.
- Treatment comprises aural toilet, diabetic control and long term systemic antibiotics.

CHAPTER 115

SQUAMOUS CELL CARCINOMA OF THE TEMPORAL BONE

Liam Masterson and Neil Donnelly

SEARCH STRATEGY

Data in this chapter may be updated by a PubMed, EMBASE and CINAHL search using the keywords: squamous cell carcinoma, temporal bone, external auditory canal, lateral skull base and free tissue reconstruction. The evidence in this chapter is mainly level 3 or 4. The clinical recommendations are predominantly B and C.

HISTORICAL BACKGROUND

Schwartze and Wilde provided the first description of temporal bone carcinoma in 1775, but it was not until the 1880s that Kretschmann, Politzer and Zeroni confirmed the existence of this pathology.[1–3] In 1917, Newhart published the first accurate case series, which consisted of 34 patients with squamous cell carcinoma (SCC) affecting the middle ear cavity, all of whom died after a short period of observation.[4]

The principle of *en bloc* resection emerged in the 1950s after reports by Campbell et al.[5] Using this approach, 20 years later, Lewis published a 25% 5-year survival in a cohort of 100 patients.[6] Modern skull base and reconstructive surgery techniques have improved the treatment of SCC of the temporal bone. Surgery is now more effective due to a greater understanding of skull base anatomy. Imaging techniques such as magnetic resonance (MR) and computed tomography (CT) help produce accurate assessment of the disease extent with particular regard to soft tissue involvement and/or bone erosion. With this approach, recent case series have demonstrated improved control of local advanced (T4) disease with 5-year survival rates ~40%.[7–10]

EPIDEMIOLOGY

SCC is the most common tumour type to occur in the temporal bone. The reported incidence is <6 cases per million per year, which accounts for 0.3% of all cancers within the head and neck. There is a slight predisposition to the male sex and the median age at presentation is within the seventh decade.[11–17]

AETIOLOGICAL THEORIES

Established risk factors for SCC within the epithelium of the temporal bone are chronic suppurative otitis media (CSOM) and previous radiotherapy.[8, 18] Exposure to ultraviolet light may be a risk factor for SCC that originates in the external auditory canal (EAC).[11]

One theory, which may provide a connection for the various predisposing factors, is the establishment of a chronic inflammatory process leading to metaplastic or neoplastic change. No strong evidence exists for occupational exposure to radiation or chlorinated disinfectants.[19]

Chronic suppurative otitis media

Chronic otitis media and cholesteatoma are common in patients with SCC affecting the temporal bone.[8, 20] In recent years several studies[21–23] have suggested an aetiological role for high risk human papillomavirus; however, they are limited to archival samples with disparate methods of collection. As yet, no study has been conducted on a prospective basis with fresh tissue due to the infrequent nature of this condition. It is also not clear if this viral subgroup demonstrates an improved survival after treatment.

Radiation-associated tumours

A past medical history of radiotherapy is relevant and may serve as a red flag at presentation. Goh et al.[24] reported seven patients with temporal bone malignancy, all of whom were initially treated by radiotherapy for head and neck disease. The latency period before symptoms were detected ranged from 5 to 30 years.

Although radiation-associated tumours of the temporal bone occur with a low incidence, their prognosis can be poor.[25] This potential risk should be considered when deciding upon the most appropriate treatment for individuals with tumours of the head and neck – especially if the patient is young and/or the condition is benign (i.e. acoustic neuroma or vascular malformation).

Exposure to ultraviolet light

The most common type of primary cancer in the EAC is SCC. It is suggested that long-term ultraviolet light exposure to the pinna or lateral concha can lead to carcinogenic change that migrates medially.[11] This is more likely in Caucasians, who are more prone to non-melanomatous skin cancers in sun exposed areas. A genetic predisposition to skin cancer may also exist, manifesting as the development of skin cancers in sites not exposed to sunlight (in addition to the more conventional locations).

SURGICAL ANATOMY AND CLINICAL FEATURES

Tumour spread is difficult to predict due to the complex anatomy of the temporal bone. The cartilaginous portion of the EAC provides minimal resistance to malignant invasion and the foramen of Huschke and fissures of Santorini are a source of direct egress to the parotid and temporomandibular regions. Although the bony canal is more resistant to local disease spread, posterior involvement of the mastoid cavity may occur. Medial spread along the EAC can extend through the tympanic ring, allowing entrance to the middle ear cavity and increasing the probability of conductive hearing loss. Invasion of blood vessels of the EAC gives rise to bloody otorrhoea. Once in the middle ear cavity, involvement of the Fallopian canal may result in facial nerve palsy. Extension through the petrous apex and invasion of the internal carotid artery (ICA) is possible but less likely due to the resistant bone of the otic capsule. The Eustachian tube and local neurovascular structures provide a potential method of tumour spread beyond the temporal bone to the nasopharynx, infratemporal fossa or neck. Extension to the inferiorly based jugular foramen may cause dysphonia or dysphagia by involving the vagal, glossopharyngeal or hypoglossal nerves.

Superior invasion through the tegmen tympani is a frequent occurrence and will allow spread to the middle fossa dura and/or the temporal lobe. Less frequently, malignancy within the mastoid will allow direct spread to the posterior cranial fossa.

Node-positive disease is an infrequent finding for early stage tumours (T1–2) but may occur in 10–20% of cases of advanced disease (T3–4).[8, 26] The first echelon lymph nodes are often within the parotid gland and these drain into pre-auricular nodes en route to the jugulodigastric and deep cervical chain of lymph nodes.[27] The integrated pathway of the facial nerve through the temporal bone results in 10–30% of patients with suboptimal facial function at presentation.[7, 8, 14–16] Involvement of the nerve may be found at the stylomastoid foramen/mastoid tip, Fallopian canal, geniculate ganglion or intracranial pathway.

Distant metastases are rarely reported but when present will normally occur in the liver, lungs or bone.[28] Haematogenous spread from other sites to the temporal bone can be possible and should form part of the differential diagnosis.[29]

DIAGNOSIS AND INVESTIGATION

History

The clinical history is relevant if temporal bone malignancy is to be diagnosed at an early stage. Moody et al. showed that the average time from onset of symptoms to the time of primary treatment for cancer was 3.9 years.[26] Common presenting symptoms include otalgia, blood-stained otorrhea and hearing loss. As many patients have associated cholesteatoma or CSOM, a change in clinical pattern can point to the development of a more sinister pathology.[11] If cranial palsies are noted at presentation, skull base osteomyelitis is a more likely differential but a malignancy should be actively excluded.[30]

The frequency of reported symptoms for large contemporary series is reported in **Table 115.1**.

Examination

Clinical examination should include inspection of the pinna, external ear canal and middle ear for scars, ulcers,

TABLE 115.1 Frequency of presenting symptoms (%)

	Gidley[7]	Masterson[8]	Gillespie[16]	Nyrop[13]	Leonetti[15]	Pensak[14]
Otalgia	52	53	53	35	73	74
Otorrhoea	62	55	73	45	69	84
Hearing loss	44	n/a	33	25	69	62
Facial palsy	16	17	13	n/a	30	18

mass lesions or soft tissue swelling. In patients with chronic otitis externa or CSOM, it may be difficult to determine malignant change from inflammation and this fact alone can account for diagnostic delay. An endophytic or exophytic mass within the EAC is likely to be malignant and is a strong indication for an urgent biopsy (**Figure 115.1**). Facial nerve assessment should be meticulously documented along with all other cranial nerves. A complete head and neck examination is performed, looking in particular for enlarged nodes within level II, III and Va.[13] The patient's general medical condition should be evaluated as this may greatly impact treatment options and outcome.

Biopsy and histological confirmation

A trans-canal biopsy is required to determine whether the lesion is malignant or benign. A staging mastoidectomy is not appropriate as this may complicate definitive treatment once a formal diagnosis has been made. Clinically suspicious neck nodes should undergo ultrasound guided core biopsy to improve the diagnostic accuracy of clinical staging and facilitate treatment planning.[31]

Although the majority of neoplastic lesions of the temporal bone are due to SCC, it is important to be aware of a differential diagnosis that can include basal cell carcinoma, melanoma, chondrosarcoma, Ewing's sarcoma, verrucous carcinoma, adenoid cystic carcinoma and metastatic disease.

In view of the strong correlation of SCC with chronic inflammation, it is important to have a high index of suspicion in this group of patients to avoid unnecessary treatment delays caused by misdiagnosis. Deep biopsies are preferable due to the risk of misrepresentative sampling. The middle ear cavity may now also be accessible via CT-guided biopsy. Early results suggest this alternative to direct trans-canal biopsy may increase the probability of a positive biopsy result but at present the majority of the surgical community are sceptical.[32]

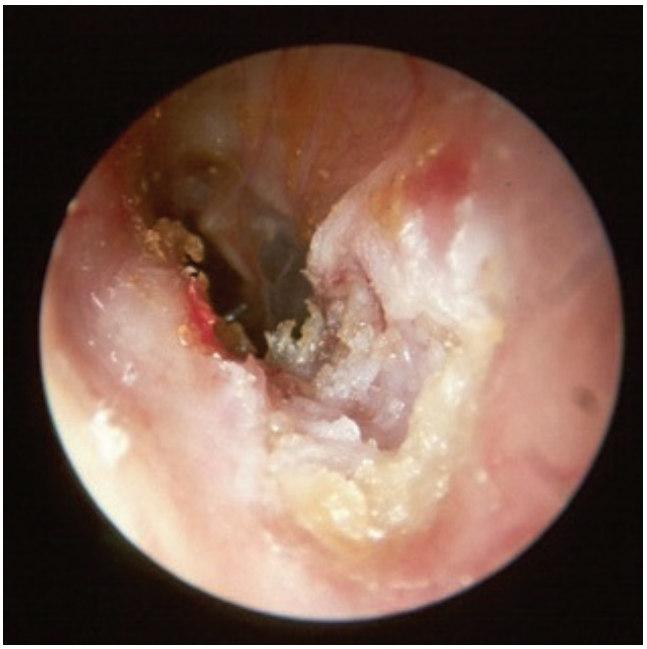

Figure 115.1 Early stage SCC right ear canal.

Audiometry

SCC temporal bone carcinoma rarely involves the sensorineural or balance system. However, an audiogram is mandatory before commencing any major ear surgery.[11] This will allow a baseline threshold for future comparison and also investigate the need for hearing rehabilitation as a result of the surgery.

This is important as Kwok et al.[33] identified poor communication in the post-surgical period as a major adverse influence on patient reported quality of life (ranked higher than cosmetic deformity).

Tumour staging

Staging systems are devised to aid classification of patients pre-operatively into groups with similar prognosis. There is now general consensus that the modified Pittsburgh staging system should be used to standardize comparison of outcomes between treatment centres and the differing surgical/non-surgical techniques undertaken.[7, 8, 10, 15, 17, 23, 26]

Arriaga et al. first conceived the Pittsburgh staging system to conform to the American Joint Cancer Committee's TNM classification system.[34] This staging system is based on clinical, pathological, and radiologic evidence. Tumours limited to the EAC are defined as early stage disease, and those that spread from the external canal to invade adjacent soft tissues, the mastoid, middle ear or cranial nerves indicate advanced disease. More recently, this scheme has been modified (**Table 115.2**) again to take into account facial nerve involvement as a prognostic indicator.[26, 35] Complete or partial facial nerve paresis would be classified as T4 regardless of the anatomical area of involvement.

It should be noted that the presence of metastatic lymph nodes in the neck are a poor prognostic indicator and consequently upstage the disease regardless of the T status.

Imaging

Physical examination alone cannot reliably characterize tumour beyond the external ear canal or middle ear cavity. Magnetic resonance imaging is the optimal modality for soft tissue analysis and can help differentiate tumour from fluid or inflammatory mucosa in the middle ear cavity, especially where bony erosion is not present.[32] MR scans with gadolinium DTPA enhancement are better for the assessment of soft tissue disease. Dural and brain involvement, infratemporal disease and perineural spread can be demonstrated when present, which may have great prognostic significance.[34]

High resolution CT (axial and coronal) portrays bone erosion accurately and when combined with MR imaging can improve pre-operative staging and give vital information to the surgical team (**Figures 115.2** and **115.3**).[36] A 1 mm fine-cut CT image is optimal for the temporal bone. The images should be carefully assessed with

TABLE 115.2 Modified Pittsburgh staging system[26,34]

Stage		Description
T Classification	T1	Limited to the EAC without bony erosion or evidence of soft tissue involvement
	T2	Limited to the EAC with bone erosion (not full thickness) or limited soft tissue involvement (<0.5 cm)
	T3	Erosion through the osseous EAC (full thickness) with limited soft tissue involvement (<0.5 cm), or tumour involvement in the middle ear and/or mastoid
	T4	Erosion of the cochlea, petrous apex, medial wall of the middle ear, carotid canal, jugular foramen, or dura; with extensive soft tissue involvement (>0.5 cm, such as involvement of the TMJ or styloid process); *or evidence of facial paresis*
N Classification	N0	No regional nodes involved
	N1	Single metastatic regional node <3 cm in size
	N2a	Single ipsilateral metastatic node 3–6 cm in size
	N2b	Multiple ipsilateral metastatic lymph nodes
	N2c	Contralateral metastatic lymph node
	N3	Metastatic lymph node >6 cm in size
Overall stage	I	T1N0
	II	T2N0
	III	T3N0
	IV	T4N0 and T1-4N1-3

regards to the EAC, middle ear, facial nerve, mastoid, tegmen, middle/posterior fossa dura, sigmoid sinus, jugular bulb and carotid canal. Extra features to review include the parotid gland, TMJ and infratemporal fossa.[37]

If CT or MR raises the possibility of ICA involvement, angiography with balloon occlusion should be considered, as sacrifice of the ICA may be necessary. Angiography with ipsilateral balloon occlusion testing is established to check the patency of cerebral blood flow from the other side. The venous phase is also important to determine the patency of the contralateral sigmoid/jugular system, in case surgery requires sacrifice of the sigmoid sinus or internal jugular vein. In view of the potential consequences of carotid ligation, the multidisciplinary team often makes the pre-operative decision not to sacrifice this major artery unless deemed absolutely necessary.[8, 16]

A staging scan of the neck and chest is routinely performed. CT scanning of the pelvis and abdomen is not required unless the biopsy result suggests an alternative diagnosis to SCC (e.g. lymphoma, melanoma or adenocarcinoma).[35, 36]

TREATMENT

The UK National Institute for Health and Care Excellence (NICE) document, *Improving outcomes in head and neck cancers* was first published in 2004 and subsequently revised in 2012.[38] It provided several recommendations to improve the quality of patient care, for example the establishment of a direct referral pathway and a multidisciplinary team approach (surgeon, oncologist, pathologist and radiologist) to reassess diagnosis and instigate

appropriate treatment plans. Other key recommendations included the provision of a specialist nurse service to enhance co-ordination of care, provide supportive counselling and improve opportunities for participation in clinical trials. The rehabilitation team (audiologist, speech and language therapist, occupational therapist, physiotherapist) is deemed essential to aid the anticipated hearing handicap, balance disorder and speech or swallowing problems.

At present, there is no consensus strategy for operative management of temporal bone tumours. The main surgical approaches are *en bloc* resection combined with adjuvant radiotherapy versus piecemeal resection or radical mastoidectomy with adjuvant radiotherapy.

There appear to be two underlying causes for this. First, a significant proportion of oncological procedures require a degree of piecemeal tumour removal as the main block of tissue is weakened or fragmented by the carcinoma. Second, in some patients the diagnosis is made during mastoid exploration for what seemed to be a routine cholesteatoma or another chronic inflammatory disease. A pragmatic approach entails post-operative radiotherapy alone without further surgical intervention; however, this may adversely affect patient survival.

Notwithstanding the above, recent results suggest that the most favourable survival rates are achieved with *en bloc* extended temporal bone resection and post-operative radiotherapy. This can be demonstrated by analysis of recent results from Yin, Gidley, Bacciu and Masterson et al., which all demonstrate improved survival figures despite treating a cohort of patients dominated by T3 and T4 disease.[7–10, 28]

It is useful to consider each stage or section of the operation separately to give an overview of the management that may arise in individual patients.

Surgical management of the neck

Although nodal metastases are uncommon in early stage disease, a neck dissection will allow accurate staging and provide access to the major vessels for free flap reconstruction. If suspect lymph nodes are found, these are sent for frozen section analysis and, where positive, a modified radical neck dissection is performed. Node-positive disease is associated with a poor prognosis, and neck dissection does not improve survival.[7–9, 26, 34]

Gidley et al. noted that the distribution of pathological nodes within their cohort was largely restricted to levels II/III/Va with the exception being level IV in < 10% of cases.[7] On this basis, a selective neck dissection should incorporate these anatomical zones when performed for node-negative disease. The parotid gland and intraparotid nodes are not only the anterior resection margin of the tumour but also the first echelon nodes draining the EAC. A superficial parotidectomy is routinely performed in early stage disease where a functional facial nerve is present. A total parotidectomy is reserved for advanced stage disease with sub-optimal facial nerve function.

LATERAL TEMPORAL BONE RESECTION

Tumours lateral to the tympanic membrane (T1 and T2) can be resected adequately by a lateral temporal bone resection.[39]

In view of the aggressive nature of this disease, the pinna is only preserved if a wide soft tissue margin (> 1 cm) exists between the lateral aspect of the tumour and the external auditory meatus. Pinna resection will impose a significant handicap to the patient, in terms of both aesthetics and function for those who wear spectacles.

An extended cortical mastoidectomy should be undertaken and the facial nerve identified and preserved as the medial limit of the dissection. The tegmen is followed anteriorly toward the zygoma to allow a suitable bony margin along the anterosuperior canal wall. The facial nerve is skeletonized along its inferior path towards the stylomastoid foramen. The mandibular head may also be transected and the tumour removed *en bloc*. All mucosa is removed from the middle ear cavity to optimize the flap repair and the Eustachian tube is obliterated by scarifying the mucosa and then plugged with muscle, fascia or bone wax.

The anterior border of the malignancy is the posterior limit of the temporomandibular joint (TMJ). The thin bone of the anterior canal wall can be difficult to assess pre-operatively and many studies recommend removal of the articular disc, or at least drill out the glenoid fossa. However, if the condyle is removed, this may give rise to significant dental occlusion deformity. Recent data from Cambridge (UK) would suggest no evidence of microscopic invasion into the condylar head for patients with T1-2 disease.[8] Finally, the primary tumour should be removed *en bloc* with the neck dissection and the superficial parotid gland. This is often not possible due to technical constraints, requiring the neck dissection and parotid to be detached separately.

EXTENDED TEMPORAL BONE RESECTION

An extended temporal bone resection is required when invasion extends medial to the tympanic membrane or into the mastoid (T3/T4 disease). With locally advanced disease, aggressive treatment is required due to the equally aggressive nature of the malignancy. The facial nerve is sacrificed in this procedure and the entire pinna is also removed.

The specimen includes the lateral temporal bone resection (as above) with additional dissection of the medial bony wall of the middle ear, extended mastoidectomy and removal of the otic capsule (**Figure 115.4**). The margins of resection are the ICA anteriorly, middle fossa dura superiorly, sigmoid sinus and posterior fossa dura posteriorly, petrous apex medially and the jugular bulb inferiorly.

In selected patients, resection of dura or brain may be required. A posterior and middle fossa craniotomy is achieved by resecting bone 3 cm above the sigmoid sinus and temporal line. Involved dura is removed with

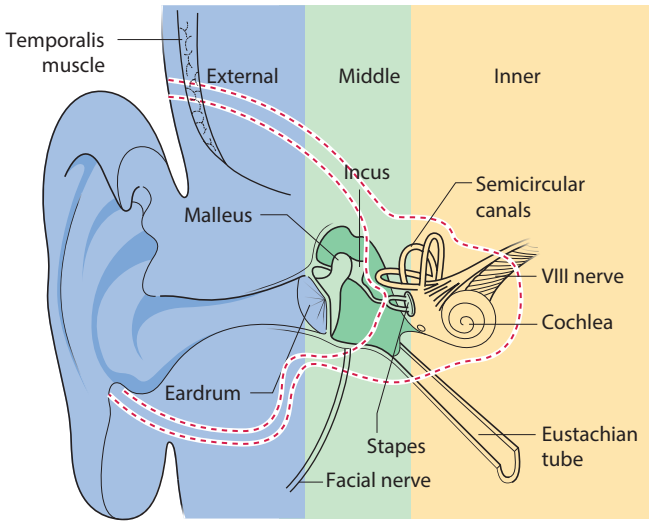

Figure 115.4 Anatomy of the left temporal bone in the coronal plane, showing the extent of a lateral temporal bone resection (outlined in red) and an extended temporal bone resection (outlined in green).

an adequate margin. The jugular bulb and sigmoid sinus are delineated as the resection extends medially. The bony labyrinth and the internal auditory canal are both resected and the intrapetrous portion of the carotid artery exposed. The middle fossa dura is retracted to allow further detailed inspection. Dura and brain, which have macroscopic tumour involvement, are removed as a separate specimen. Frozen sections from all margins of the dura are taken to ensure clear margins. The defect in the dura is then sealed with fascia lata and sutured carefully to avoid a potential cerebrospinal fluid (CSF) leak.

If a radical neck dissection has been performed, the next stage will be to divide and ligate the sigmoid sinus. Wherever possible, the lower cranial nerves (IX, X, XII) are conserved if macroscopic disease is not present. For some, removal of the condyle, coronoid process and the upper two-thirds of the ramus of the mandible together with surrounding soft tissue will be necessary after the masseter has been dissected away. This may allow greater exposure of the infratemporal fossa region to assess disease extension.

The anterior margin of the resection includes the entire parotid gland. Frozen section analysis is employed if there is concern that the surgical margin is not clear. After this stage, the whole temporal bone resection lateral to the ICA together with the neck dissection and parotid gland are removed.

RECONSTRUCTION

Free tissue transfer is routinely used to reconstruct the pyramidal defect that typically remains following ablative surgery. The anterolateral thigh flap is a common choice as it provides skin and fascial covering and can be taken with muscle if more bulk is required.[40, 41] The thigh donor site provides access for fascia lata if required for static slings for simultaneous facial palsy reconstruction. The distant flap donor site allows for concomitant flap harvest and oncological resection, minimizing the duration of surgery. Alternative free flaps, which are less commonly used, include the radial forearm and lateral arm flaps. Pedicled myocutaneous flaps and scalp transposition fasciocutaneous flaps have also been employed with good results, but are usually reserved for the minority of patients who are not good candidates for free tissue transfer due to microvascular disease (e.g. diabetic or peripheral vascular disease patients).[42]

In cases of pre-existing facial palsy or where the facial nerve has been sacrificed, simultaneous facial palsy work can be undertaken including upper eyelid gold weight insertion, browpexy, lateral tarsorraphy and static fascial slings. In patients aged <65 years, and depending on the integrity of the distal facial nerve branches, a nerve graft procedure may be possible (e.g. interposition neurorraphy or transposition of the nerve supplying masseter onto the distal stump of the facial nerve).

Following removal of the pinna and completion of post-operative treatment, patients are routinely offered a prosthesis or, less frequently, a staged autologous pinna reconstruction.

Adjuvant therapy

RADIOTHERAPY

The literature supports a beneficial effect of adjunctive radiotherapy on DSS, but as yet no well-controlled studies have been performed. Most studies report a dose ~60 Gy applied to the temporal bone and upper neck region.[7–10, 15, 43]

The effect of RT may also extend beyond adjuvant therapy based on some retrospective case series. Pemberton et al.[44] revealed a 45% 5-year DSS for 123 patients treated with 55 Gy radiotherapy alone; however, the survival benefit was significantly lower for patients who had advanced disease (T3-4), suggesting primary radiotherapy alone is not appropriate in this subgroup. In the most extreme cases in which contraindications to surgery are present, palliative radiation and/or chemotherapy may be offered.

In patients who have previously undergone treatment with radiotherapy, further doses may be given if the previously irradiated area has been resected and new vascularized tissue covers the defect.[42] Post-operative radiotherapy normally commences 6–8 weeks after surgical intervention to maximize flap viability.

CHEMOTHERAPY

Adjuvant chemotherapy was previously thought to provide little advantage. However, in 2006 Nakagawa et al.[45] reviewed series of patients all treated with either pre-operative chemoradiation or with chemoradiation alone. Four of eight patients treated with chemoradiation (5-Flourouracil + external beam radiation with a dose of 40 Gy), were free of disease at 24–47 months. The same

study also a reported a significant difference in 5-year survival for T4 patients with advanced stage disease treated surgically (75%) and non-surgically (16%). In a similar manner to radiotherapy above, the available evidence would not suggest a survival benefit for primary chemotherapy in advanced stage disease.

TREATMENT OUTCOMES AND PROGNOSTIC FACTORS

Early stage tumours generally have a favourable outcome, with most series reporting an 80–100% survival rate. However, T4 tumours have reduced survival rates even after adequate surgery and adjuvant radiation treatment (Table 115.3).

Prior surgical intervention is often a prerequisite towards making the diagnosis of malignancy, but this can complicate pre-operative staging, disrupt margins and require the surgeon to operate in an inflammatory region.[9] The literature is divided as to whether persistent/residual disease will result in significantly reduced survival when compared to patients who have not received prior treatment.[8, 14–16]

Although true *en bloc* resection is sometimes difficult to achieve because of the complicated three-dimensional nature of the temporal bone and anatomical spread of disease, more recent results confirm that it does offer the greatest chance of successful treatment.[7–10, 16, 28] Advanced stage of disease, node-positive status, dural/brain involvement, facial nerve palsy, poor histological differentiation, positive surgical margins and carotid invasion are all important adverse factors.[7, 8, 16, 17, 28, 36]

Stage of disease

The modified Pittsburg staging system predicts disease outcome by tumour size, local/distant metastatic spread and/or facial nerve involvement. Moody et al.[26] revised the University of Pittsburgh staging system in 2000 by suggesting that temporal bone SCC with evidence of facial nerve palsy should be categorized as T4. Multiple studies have since endorsed this new classification, the best evidence coming from Higgins et al.,[17] who produced a systemic review to determine the impact of facial palsy on survival outcomes. This study selected 21 articles containing information on 348 subjects and found that disease-specific survival (DSS) and overall survival in patients with facial palsy were significantly worse than for subjects without this deficit.

Dural and cerebral infiltration

Extension superiorly through the tegmen with dural and cerebral involvement is considered by some to be a particularly ominous feature. Moody et al.[26] reported that dural involvement was such a poor prognostic indicator that it may render curative surgery futile. This may directly contradict the findings in the larger study by Masterson et al., where 14/60 patients presented with brain involvement and the disease specific five-year survival was not significantly different from the rest of the group (37% versus 44% $p = 0.335$).[8]

Tumour differentiation

For this condition, most studies[7–9, 28] correlate poorly differentiated histology to an adverse prognostic outcome (Figure 115.5). Primary SCC affecting other sites in the head and neck behave in similar manner.

Surgical margins

In those patients with positive surgical margins, recurrent disease is more likely and survival reduced.[10, 16] The judicious use of intra-operative frozen sections can aid detection of safe margins.[8, 14, 18, 34]

Carotid involvement

Carotid involvement is fortunately rare, and also correlates strongly with a poor outcome.[7, 8, 28] Resection of the intrapetrous carotid artery can result in serious consequences and as such should only be attempted with appropriate caution. Malignant invasive disease may sometimes be limited to the adventitia and as a consequence the tumour can be dissected clear without need for ligation and division of the artery.

COMPLICATIONS OF TREATMENT

Complications of treatment depend on the extent of resection and the use of adjunctive radiation. Extended temporal bone resection will commonly cause or exacerbate a cranial nerve deficit. Facial palsy will cause both cosmetic

TABLE 115.3 Five-year disease specific survival stratified by stage of disease†

and functional disability. Prompt eye care is of vital importance to prevent exposure keratitis.

Post-operative vertigo, hearing loss and other cranial nerve deficits (e.g. V, VIII, IX, X, XI) may also occur. Vagal, glossopharyngeal or hypoglossal nerve palsies may enhance patient risk of poor nutritional input and aspiration pneumonia. Speech and language expertise can be helpful but ultimately some patients will require a gastrostomy and/or temporary tracheostomy.

If the dura was resected and repaired, the risk of meningitis due to a CSF leak can be ameliorated by the use of lumbar drains inserted for 24–72 hours.[46] The main complications of adjuvant radiotherapy include osteoradionecrosis, soft tissue fibrotic change that can mask future recurrent disease, destruction of salivary gland tissue and increased risk of iatrogenic malignancy within the central nervous system (CNS).[16]

CONCLUSION

The gold standard treatment for temporal bone SCC remains undefined because of continued debate regarding staging, adjuvant radiation and the extent and nomenclature of surgical procedures. It is clear that there is a survival advantage to be gained from being managed in a tertiary centre with multidisciplinary expertise in the condition. At present, the number of patients with this condition at each individual institution restricts definitive conclusions. Multi-institutional cooperation is now required to facilitate prospective clinical trials.

Surgery and adjuvant radiotherapy alone are currently insufficient for obtaining adequate survival rates for patients with advanced T4 disease. Induction or concurrent chemotherapy should be investigated as a means of achieving improved survival.

Finally, well-validated outcome measures of quality of life parameters need to be utilized and communicated in the literature. There has been restricted work on patient-perceived outcomes of what is often referred to as disfiguring and debilitating surgery.

BEST CLINICAL PRACTICE

- ✓ Early biopsy of a suspicious lesion in the EAC will avoid diagnostic delays for patients with temporal bone SCC and improve their survival.
- ✓ All patients should have both MR and CT scans to stage their disease and facilitate treatment planning.
- ✓ *En bloc* resection with post-operative radiotherapy is the current treatment of choice.
- ✓ Management by a multidisciplinary team is essential, for example the expertise of the plastic surgeon for reconstruction of the defect, and the skills of the speech and language therapist to overcome speech and swallowing problems.

KEY POINTS

- Temporal bone squamous cell carcinoma is a rare disease that may cause severe morbidity.
- Otitis externa that does not resolve mandates formal biopsy.
- The treatment plan should be informed by careful staging with MR and CT imaging.
- Optimal management involves a multidisciplinary team with specialist expertise in squamous cell carcinoma of the temporal bone.
- The multidisciplinary team should include an otolaryngologist, neurosurgeon, clinical oncologist, reconstructive surgeon, neuroradiologist and rehabilitation team to deal with hearing handicap, balance disorders, speech and swallowing problems.
- Palliative surgery may have a role in advanced cases.

CHAPTER 116

COMPLICATIONS OF SKULL BASE SURGERY

Abdul Karim Nassimizadeh and Chris Coulson

SEARCH STRATEGY

Data in this chapter may be updated by a Medline search using the keywords: randomized controlled trials, meta-analysis, evidence-based medicine, review literature, skull base (focusing on surgery and complications), skull base neoplasms (focusing on surgery and complications), postoperative complications, vestibular schwannoma (focusing on surgery and complications), cerebrospinal fluid rhinorrhoea (focusing on surgery, complications, prevention and control), cerebrospinal fluid otorrhoea (focusing on surgery, complications, prevention and control), CSF lumbar drainage, antibiotic prophylaxis, meningitis (focusing on surgery, complications, prevention and control), electromyography, intraoperative monitoring, facial nerve and facial nerve injuries (focusing on prevention and control), acetazolamide (focusing on adverse effects and therapy), papaverine (focusing on therapy), intracranial hypertension (focusing on therapy), hydrocephalus (focusing on therapy and drug therapy), CSF pressure, therapeutic embolization, meningioma, angiofibroma. In addition, the Cochrane database has also been searched.

INTRODUCTION

The evolution of skull base surgery has provided an intersection between various surgical specialities including neurosurgery, otolaryngology surgery, ophthalmology, oncology, radiology, head and neck surgery, as well as craniofacial and reconstructive surgery. In addition to this, the last decade has seen dramatic advances in surgical technique, neuronavigation and optics; including the triple chip cameras, endoscopic 3D systems and high-definition screens, providing both precise surgical resection, as well as preservation of surrounding neurovascular structures. Intra-operatively, nerve monitoring has further aided the modern day surgeon when managing varying pathologies within a delicate anatomical region. An improvement in surgical interventions has been coupled with accurate radiological imaging, allowing both appropriate visualization and management of anatomically remote and complex lesions to be safely resected. A collaborative multidisciplinary team, in conjunction with the dramatic advances in surgical technique and technology, has resulted in improved patient care and reduced post-operative complications.

Despite a constant evolution, skull base surgery remains a challenging field of surgery, with important risks. As with any surgical procedure, identification and minimization of complications is essential. Skull base tumours are intimately related to vital neurological structures, cranial nerves (CN), major arteries and venous sinuses, making surgical resection challenging. These problems may be compounded when large tumours directly invade important structures. Dural breaches predispose to cerebrospinal fluid (CSF) leakage and the close proximity to contaminated aero-digestive structures may expose the patient to an increased risk of infection.

In this chapter we will detail both intra-operative and post-operative complications of skull base surgery.

INTRA-OPERATIVE COMPLICATIONS

Vascular

ARTERIAL HAEMORRHAGE

Transection of a major artery is a disastrous but fortunately rare event. Inadvertent excessive manipulation or direct forceful suction of an intracranial artery may lead to vasospasm and cerebral infarction. Gentle handling of vessels using neurosurgical patties for protection with medium/low suction and frequent irrigation with isothermic saline

are mandatory operative techniques. Infiltration of vasoconstrictive agents prior to surgery, as well as local application of patties soaked in vasoconstrictive agents produce lower rates of morbidity intra-operatively.

The primary vessels at risk during lateral skull base surgery are the basilar artery and the anterior inferior cerebellar artery (AICA). The basilar artery may be injured during translabyrinthine or suboccipital approaches to very large vestibular schwannomas (VS). The AICA is frequently in the surgical field during VS surgery. Injury to the AICA may result in Atkinson syndrome – lateral tegmental pons infarction, which is often fatal.

Major vascular complications in anterior skull base surgery primarily affect the carotid within the sphenoid sinus, particularly in transphenoidal surgery for patients with acromegaly. The specific difficulties within this cohort include the sinus being deeper, characterized by more septa and a reduced intercarotid distance, resulting in potential intra-operative surgical difficulties.[1] The intrasphenoid carotid artery can further complicate matters both pre- and intra-operatively. Its presence can mimic a sinonasal mass with variations occurring in approximately 40% of patients, as well as aneurysms of the cavernous portion, which accounts for 2–9% of all intracranial aneurysms.[2, 3] In conjunction with this, there are high rates of dehiscence shown in literature, with multiple other papers finding only a mucoperiosteal covering the intrasphenoid carotid artery coursing through the sphenoid sinus.[3] Sethi et al. described rates of dehiscence as high as 93%, although this paper did not define their criteria.[4] As a result, if the surgeon is not aware of such common variations, a damaged intrasphenoid carotid artery can result in both vascular and neurological complications and potentially death.

Embolization of selected vascular tumours such as meningiomas, paragangliomas and nasopharyngeal angiofibromas may reduce the risk of intra-operative and post-operative bleeding and even the operative time. Unfortunately, studies have yielded contradictory results and, at present, there is no consensus on its use. The majority of studies have been retrospective, and the two prospective studies to date on the preoperative embolization of meningiomas have produced conflicting conclusions.[5, 6] Major complications of such neuroradiological procedures include cerebrovascular accident (CVA), subarachnoid haemorrhage, intratumoral haemorrhage, raised intracranial pressure and CN palsies due to tumour swelling or embolization of the vaso vasorum and even death.

VENOUS HAEMORRHAGE

Venous haemorrhage may be controlled using a variety of methods depending on location and quantity of bleeding. These include bone wax if the bleeding point has a bony perimeter, bipolar diathermy or repair using 6-0 or 7-0 monofilament suture if the vessel wall is easily visible, or placement of haemostatic agents such as oxidized cellulose (Surgicel), microfibrillary collagen (Avitene) or biological tissue glue, typically for more diffuse bleeding. Occasionally, large sinus perforations may require extraluminal packing to achieve haemostasis or even formal ligation. Anatomical studies have shown a unilateral non-functioning sigmoid sinus/jugular bulb is present in only 4% of normal subjects, so adverse post-operative sequelae, such as cerebral oedema or long-term benign intracranial hypertension following ligation, is infrequent.[7]

Air embolus

Air embolus is a rare complication that usually only happens when the patient is in the sitting position. This position leads to a reduction in intracranial venous pressure; if a defect in a venous sinus is created, a pressure gradient favouring the passage of air into the circulation is created.[8] The first sign is a sucking sound or venous crepitation at the site of entry. Later, hypotension, tachycardia, dysrhythmias and diminishing end-expiratory pCO_2 develop. When this complication is detected, inhalation anaesthesia is discontinued and 100% oxygen administered, while the bleeding site is controlled by direct pressure and the jugular veins are compressed in the neck. The patient is placed in the left lateral Trendelenburg position with the head lowered in order to trap the air embolus in the right side of the heart, preventing it entering the pulmonary circulation. The air can then be aspirated through a central venous catheter or, in its absence, needle aspiration of the right ventricle via a subxiphoid approach should be attempted.

Cranial nerve injury

Cranial nerve injuries are among the most debilitating complications encountered in skull base surgery. Most pre-operative CN deficits persist post-operatively if due to tumour invasion rather than compression. Unlike sensory CN deficits, there is a good prospect of some recovery of motor CN function if a primary reanastomosis or cable graft is performed. Microdissection techniques and electrophysiological nerve monitoring enhance the preservation of CN during tumour resection.

OLFACTORY NERVE

The olfactory nerve is at risk and often unavoidable in anterior skull base procedures, specifically ethmoidal tumours or meningiomas of the sphenoid ridge and those involving stripping of the dura from the cribriform plate treated through an open approach. This is due to the position of nerve within the subarachnoid space, with only a meningeal sheath covering.

The olfactory epithelium is present at the apex of the nostrils bilaterally, covering an area of approximately 2–3 cm^2. The epithelium consists of both trigeminal and olfactory nerve fibres, with trigeminal fibres sensitive to irritation and temperature rather than olfaction. Tumours involving the anterior fossa floor often lead to unilateral anosmia, which is usually not perceived; however, it can occasionally cause permanent bilateral anosmia.[9]

Management of patients with anosmia includes safety advice and dietary advice. Smoke and gas detectors should be installed in their homes and they will require advice on healthy eating, as many foods are unappetizing without the sense of smell and this can lead to an unbalanced diet.

OPTIC NERVE

The optic nerve is at risk in anterior skull base surgery, specifically pituitary tumours close to the optic chiasm. Blindness within tumour management may also be secondary to radiotherapy, leading to radiation keratitis, or direct radiation injury to the optic nerve. Visual-evoked potentials should be monitored during surgery. Sharp dissection around the nerve using the appropriate microscopic or endoscopic techniques will lower the risk of injury.

It is interesting to note there is a high level of protrusion and dehiscence of the optic nerve, with over 30% of the population having both protrusion and dehiscence, and various papers reporting rates of protrusion as high as 70%.[3] These differences in variations are attributed to ethnic background.[3] Without careful anatomical dissection it will lead to post-operative visual difficulties, with increased risk of blindness from optic nerve damage within the sphenoid sinus.[3]

CRANIAL NERVES III, IV AND VI

The cranial nerves III, IV and VI are at risk during operations of the petrous apex adjacent to the cavernous sinus and the anterior skull base. The trochlear nerve exits the posterior brainstem and has a relatively long intracranial course, but is well protected in the tentorium and is infrequently injured. Abducens nerve palsy has been reported after lumbar drain placement – it is not known whether this is through an ischaemic or traction injury. Abducens nerve palsy management tends to be symptomatic, with recovery tending to be slow and progressive. In paediatric patients occlusive patch therapy for eyes will help avoid amblyopia, until residual palsy improves. Monitoring of extraocular movements is important in recovery.

TRIGEMINAL NERVE

The trigeminal nerve is at risk during lateral skull base surgery, such as large VSs, temporal bone resection and approaches to the clivus, nasopharynx and parasellar–parasphenoid compartments, when intentional neural section may be necessary for anatomical access. Trigeminal nerve branches are also at risk during anterior skull base procedures. With sensory innervation of the head mainly covered by the trigeminal nerve, except the occipital and maxillary joint area, disorders may lead to severe discomfort for the patient. Various forms of rehabilitation have been hypothesized and researched. With regards to conservative therapy, vitamin B6 is traditionally used as a neurotrophic substance; however, there is little clinical evidence to support its use. Nerve growth factor is a similar neurotrophin, with local use following damage increasing expression of tyrosine receptor kinase A. However, it is currently not available for clinical use and is still within research phases for possible neural repair and reconstruction. Surgically, there have been positive outcomes following reconstructions of the inferior alveolar and lingual branches of the trigeminal nerve, with suggestions that the same theories can be utilized for sensory nerve reconstruction. Possible interposition grafts include the great auricular nerve or the sural nerve for longer graft requirements. Both of these have drawbacks, with permanent sensory deficits over the ear lobe and calf respectively. If reconstruction and rehabilitation is not a realistic option, typically carbamazepine or gabapentin are used as required to treat possible facial pain from trigeminal nerve dysfunction.[10]

FACIAL NERVE

Facial nerve damage frequently leads to decrease in a patient's quality of life, despite successful lesion removal.[11] Pre-operative dysfunction is independently linked to post-operative paralysis, with informed consent essential.[11] Important anatomical variations lead to higher intra-operative complications, with appropriate knowledge of the superficial location of the stylomastoid foramen in infants integral. Other anatomical variations include absence of chorda tympani, lateralization of the vertical portion, duplication in the tympanic segment of the nerve and common bony defects of the fallopian canal. It is, however, important to be aware that the majority of facial nerve injuries in mastoid surgery occur in the presence of an anatomically normal facial nerve.[12] Seventy per cent of iatrogenic injury is located in the pyramidal segment (between tympanic and mastoidal segment) at the second genu.[11]

Orbicularis oculi and orbicularis oris muscles are typically routinely monitored intra-operatively via electromyographic (EMG) monitoring during mastoid procedures. The introduction of intra-operative facial nerve monitoring has facilitated early identification and localization of the facial nerve and is of prognostic value in predicting functional outcome.[13] Feedback from monitoring probably shortens the learning curve, as the surgeon adapts his technique to avoid manoeuvres that produce excessive EMG discharges; however, this does not replace anatomical knowledge and surgical ability.

If the nerve is transected, a primary reanastomosis avoiding tension is the optimum management. If necessary the nerve may be mobilized from the fallopian canal to gain 0.8 cm of length. Removing a portion of the tympanic bone and retracting the parotid gland with a suture can add another 0.9 cm. In total, 1.7 cm of additional length is possible following complete mobilization of the facial nerve for a primary anastomosis.[14] Failing this, the next best option is cable grafting using the greater auricular nerve or the sural nerve. If there is poor or absent facial function one year post-operatively other facial reanimation techniques, such as gold weight upper lid implants, temporalis muscle transfer, cross-facial anastomosis or faciohypoglossal anastomosis techniques may be required. Despite advances, reconstruction techniques are not capable of restoring facial nerve function grade I or II, using the House Brackmann (HB) grading system.[15]

VESTIBULOCOCHLEAR NERVE

Surgical ablation or resection causes a complete loss of audiovestibular function, with symptoms differing depending on pre-operative function. Patients with pre-operative good or near normal auditory and vestibular function will have severe vertigo and noticeable hearing loss. Patients usually achieve satisfactory central vestibular compensation over several weeks, but for some vestibular exercises are invaluable. In addition, customized rehabilitation regimes in the pre-operative phase may facilitate earlier vestibular compensation. Those patients with poor auditory and vestibular function, which is typical in those undergoing nerve resection in VS surgery, or vestibular nerve section for Ménière's, often have a minimal change in symptoms post-operatively.

The auditory nerve has no perineurium, and is therefore prone to damage from mechanical trauma, as well as from vascular injury within the internal auditory canal during tumour resection. Hearing conservation in VS surgery is an option in those with small acoustic tumours and good pre-operative hearing (minimum mean pure tone audiometry 30 dB/70% speech discrimination). It can be performed by a middle fossa or retro mastoid approach depending on tumour location and may preserve useful hearing in 40–79% of cases.[16] The chance of hearing preservation is inversely related to tumour size, with 90% of tumours > 3 cm involving the auditory nerve pre-operatively.[11] Most techniques of intra-operative auditory monitoring only provide delayed feedback to the surgeon and have not improved hearing conservation results in the last decade. Unilateral hearing loss may be rehabilitated by a contralateral rerouting of the signal (CROS) hearing aid or a bone-anchored hearing aid.

LOWER CRANIAL NERVES

The glossopharyngeal and vagus nerves travel closely together throughout most of their course in the skull base and any injuries often happen simultaneously. This may result in a potentially life-threatening complication due to chronic aspiration and recurrent pneumonia. Satisfactory functional recovery often takes place with peripheral lower CN dysfunction, so a temporary tracheostomy and gastrostomy are frequently advisable. However, brainstem dysfunction, especially involving the lower CN nuclei, often results in long-term bulbar problems necessitating laryngeal airway protection. A gastrostomy and tracheostomy will not prevent contamination of the lower respiratory tract. Epiglottopexy and epiglottic plication techniques offer an alternative management option.[17, 18]

Cardiac dysrhythmia

Vagal stimulation can cause a sinus bradycardia and hypotension. Brainstem stimulation may cause tachycardia and hypertension. Fortunately, any adverse cardiac event is invariably transient, although it is usually advisable for the surgeon to switch attention to work on another part of the tumour to allow consolidation of the recovered cardiac status in the patient.

OPHTHALMOLOGICAL COMPLICATIONS

Due to the inherent close relationship of the eyes, as well as their neurovascular supply, to skull base surgery, there are clear risks to vision. Neurovascular injury is especially important in elderly patients with fragile periobital capillaries. In certain scenarios, surgical necessity can lead to visual symptoms, with orbital floor removal producing vertical dystonia, excision of the medical canthal area causing canthal drift, as well as diplopia if two or more extraocular muscles are removed. Rehabilitation for these defects is difficult, with some surgeons opting occasionally for exenteriation of the orbit subsequently or reconstruction following radiation therapy. If reconstruction is sought, the temporalis muscle is most commonly used.[11, 19]

Nasolacrimal duct blockage and the ensuing epiphora can usually be treated effectively with dacrocystorhinostomy. Ectropion and entropions can result from open surgery, with appropriate reconstructive methods extensively used for both cosmesis and corneal surface disorders. Corneal abrasion is the most common cause of post-operative blindness secondary to surgical drape position, foreign body injury or reduced tear production from intra-operative anticholinergic agents.

LATERAL SKULL BASE APPROACH COMPLICATIONS

Lateral skull base approaches require intimate anatomical knowledge, in conjunction with precise surgical exposure of the lesion. To obtain this, an approach through the middle and inner ear may be required, resulting in careful dissection of structures.

Hearing loss can be due to drill-generated acoustic trauma, caused either by direct contact of the burr with the ossicles or endosteal membrane of the cochlea. Avoiding contacting the ossicles and systemic and local application of corticosteroids are the mainstay of protecting the inner ear against trauma.[11] If the inner ear is advertently opened, recognition, repair and avoiding suction of perilymph/endolymph can preserve underlying function.

Whilst the ideal approach to CPA lesions is still debated and will be discussed in Chapter 105, Non-vestibular schwannoma tumours of the cerebellopontine angle, the differing approaches confer different potential complications. Ten to fifteen per cent of CPA surgery procedures are complicated by a post-operative CSF leakage, with the largest risk found in the translabyrinthine approach.[20] Tumour excision through the translabyrinthine approach can either be attempted to be total, with a 57% HB I–II facial nerve preservation rate, or surgeons can perform a functional resection, accepting they are leaving a thin rim of tumour on the nerve, achieving a 77% HB I–II facial nerve outcome.[21] In relation to the retrosigmoid approach, the CSF leak and facial nerve palsy rates are lower (approximately 9% and 6% respectively); however, there is a requirement of cerebellum retraction, which is related to its own complications, and furthermore there is compromised access to the internal auditory canal fundus due to the nature of this technique.[22, 23] Further, the retrosigmoid approach, when compared to

the translabyrinthine approach, is typically used for smaller tumours, which is an independent risk factor for facial nerve outcomes. In comparison the middle fossa approach has greater risks of facial nerve damage (16%), as the anatomical course of the facial nerve may compromise tumour exposure; however, it has higher hearing preservation rates.[23, 24] As a result, although the retrosigmoid approach would seem to provide the most versatile corridor for facial nerve preservation, the middle cranial fossa approach seems safest for hearing preservation for smaller tumours. The translabyrinthine approach would be reserved for larger tumours. Detailed knowledge of potential pitfalls of surgical technique is vital when assessing skull base lesion management, based on position and outcomes desired.

ANTERIOR SKULL BASE ENDOSCOPIC SURGERY RISKS

Within endoscopic surgery, unfavourable results are typically related to learning curve and time taken to adapt to a two-dimensional (2D) environment. With vision of vital importance in surgery, the 2D nature of surgery creates drawbacks, specifically with regard to a lack of stereopsis impairing depth perception. This may impair the surgeon's ability to recognize and manage anatomical structures. With the safety of skull base procedures largely dependent on precise anatomical knowledge, this remains a key concern. Experienced surgeons compensate for this difficulty through the use of visual and tactile feedback, dynamic movements of the scope, light and shadows and detailed anatomical knowledge. Image guidance is another recent advance, with recent studies highlighting a higher number of cases of incomplete resection when image guidance is unavailable.[19, 25, 26]

A further concern with endoscopic surgery is in relation to temperature during surgery. Bone drilling and cauterization within a narrow field delivers significant levels of thermal energy, which can continue despite suctioning and flushing. Incessant increase of the temperature in the intra-operative field can potentially harm neural structures, with temperatures over 42 degrees causing cerebral harm. Regular breaks are important during these procedures.

POST-OPERATIVE COMPLICATIONS

Haematoma

This potentially fatal complication is usually due to inadequate haemostasis. With intradural haematomas, the source of bleeding is invariably vessels adjacent to the tumour. Careful bipolar diathermy effectively controls most bleeding but cannot be used immediately adjacent to important CNs as dysfunction inevitably follows. Surgicel may be helpful in many situations, but many surgeons are reluctant to allow this material to come into direct contact with CNs as increased post-operative neural oedema is possible. On occasions, application of a biological glue such as Tisseal® provides very satisfactory haemostasis in these circumstances. Very occasionally, one will encounter a patient with a previously unknown bleeding diathesis. If the administration of drugs and appropriate blood coagulation products fail, a combination of Surgicel with FloSeal® is effective.

Extradural haematomas may result from failed middle meningeal artery cautery or ligation and more superficially from branches of the superficial temporal artery. They may also arise from haemorrhage at the craniotomy site and require the judicious application of bone wax.

The rate at which neurological deficits develop varies with the location and source of bleeding. Arterial haemorrhage produces a rapid collection of blood. In contrast, venous haemorrhage results in a gradual neurological deterioration, often due to subdural haematoma formation, and may result in secondary hydrocephalus. Depending on the severity and rapidity of the patient's neurological deterioration, management varies from immediate decompression by wound opening at the bedside to surgical exploration in the theatre or computed tomography (CT) imaging. Most haematomas are rapid and precious time should not therefore be wasted on imaging studies.

Cerebrospinal fluid leak

This is the most common complication after VS surgery. CSF leak rates of approximately 10% are reported in the immediate post-operative period. However, late leaks may develop many months or years after surgery and up to 35% of leaks develop 2 weeks after VS surgery.[27] It is likely that neither the surgical approach nor the tumour size affect the post-operative CSF leakage rate and transient post-operative rises in CSF pressure may be responsible.[11, 24, 25, 27] CSF leaks are also the most common anterior skull base complication with reported rates of occurrence between 3% and 19%.[28]

To prevent the development of CSF leaks a peri-operative lumbar drain to lower CSF pressure may be left in place for up to 5 days, during which time the patient is kept on strict bed rest, with the head of the bed elevated at 15–30 degrees. Unfortunately, patients often experience low-pressure headaches.[29] There is no evidence regarding the effectiveness of prophylactic lumbar drainage, but for established leaks it eliminates 50–90%.[29, 30] Known complications of continuous lumbar drainage include brainstem herniation (may present with vagal nerve paresis and vocal cord paresis), Chiari type 1 malformation, infection, pneumocephalus and subdural haematoma.[27, 28] A compression dressing is maintained over the wound to promote watertight healing.

Symptoms of CSF leak include pain or headache (especially positional), unexplained pyrexia and, more seriously, meningitis. Rhinorrhoea may present as a salty taste in the patient's mouth. High-flow CSF leaks lead to clear rhinorrhoea and, less frequently, otorrhoea or wound discharge. A sample should be sent for immunoelectrophoretic assay for beta transferrin, which is both highly specific and sensitive for CSF.

High-flow CSF leaks require surgical exploration and repair. Low-flow CSF leaks may be managed with bed rest and elevation of the head by 20–50 degrees. In addition, a lumbar spinal drain may be used for up to 5 days. Wound

leaks are managed by the insertion of further sutures and the application of a compressive head bandage. Acetazolamide is known to lower CSF pressure by inhibiting the enzyme carbonic anhydrase and by decreasing CSF production. Some units use this therapy but there is no evidence for its efficacy in the treatment of CSF leaks.[31] The use of prophylactic antibiotics remains uncertain. There is some evidence favouring the role of prolonged prophylactic antibiotics in patients with ventricular drains but no studies exist for lumbar drains.[32] Two large meta-analyses have produced conflicting conclusions over the role of antibiotic prophylaxis in the prevention of meningitis in patients with basilar skull fractures and CSF fistulae.[33, 34] The larger meta-analysis found no reduction in meningitis.[35] It is known that prolonged antibiotic use encourages the development of resistant organisms and prophylactic antibiotics in patients with CSF fistulae are probably best avoided, due to poor penetration of the meninges.[34, 36]

Infection

The incidence of wound infections is usually low. Recognized risk factors include tumour size, operative time and haematoma. Anterior skull base procedures performed in a cleaned but previously contaminated environment, where the wound is in close contact with the aerodigestive tract, have a rate of infectious complications of between 0% and 30%.[28, 37] Frontal bone flap osteomyelitis may complicate craniofacial resection for anterior skull base tumours in certain cases.[38] Wound infection may lead to meningitis or a brain abscess. Meningitis is usually associated with a CSF fistula.

The risk of infection is minimized by the liberal use of peroperative irrigation and prophylactic antibiotics (for clean non-implant procedures and for clean contaminated procedures). Prophylactic antibiotics should be given on induction of anaesthesia to ensure high tissue levels at the time of surgery. Antibiotics given more than 4 hours after the end of surgery are not effective, either experimentally or in clinical trials.[39] The Infection in Neurosurgery Working Party of the British Society for Antimicrobial Chemotherapy recommends that surgery for clean and clean-contaminated surgery should be administered as a single intravenous dose on induction of anaesthesia, with additional doses every 3 hours for long procedures.[39] In support of these recommendations, a systematic review in the Cochrane database of prospective randomized controlled trials of patients undergoing major pulmonary, gynaecological, obstetric, urological, pelvic or abdominal surgery, who had been given either single or multiple dose prophylaxis, found no difference in surgical site infection rates.[40] This confirms the findings from an earlier review of similar patient groups.[41] In addition, prolonged antibiotic prophylaxis increases the risk of hospital acquired infection.[40]

Pneumocephalus

Intracranial air is often present after craniotomy and may be seen on CT, but usually resorbs after 7–10 days. The presence of pneumocephalus is pathognomonic for the presence of a CSF leak, with risks of meningitis as high as 30%.[42] It is rarely seen after posterior fossa surgery and is usually associated with surgery at sites that include the aerodigestive tract, as in anterior skull base procedures. Clinically significant pneumocephalus presents in 2–12% of post-operative craniofacial patients.[28] Air accumulating under pressure may create a tension pneumocephalus, which if unrecognized is a potentially fatal condition. The use of positive pressure ventilation and a lumbar catheter drain are risk factors. The lumbar drain creates a vacuum effect by lowering intracranial pressure and drawing air in through the wound. Treatment with needle aspiration via a craniotomy burr hole may be adequate. Surgical exploration to decompress the brain and seal air leaks may sometimes be necessary. About one-third are associated with CSF leaks and a thorough search for a fistula is, therefore, also advisable.

Hydrocephalus

This presents in the early post-operative period with headache, impaired consciousness, gait disturbance and incontinence. It is secondary to cerebral oedema or intracranial haemorrhage. Normal pressure hydrocephalus is due to chronic obstruction of arachnoid villi function. It has been reported following jugular bulb resection in association with unrecognized contralateral cerebral venous drainage insufficiency. The presence of post-operative hydrocephalus is approximately 6% within anterior skull base tumour resection.[43]

Epilepsy

Post-operative seizures may herald the development of haematoma, oedema, infarction or any complication causing mass effect and cerebral irritation. Temporal lobe manipulation carries a special risk of the development of this complication, which is not encountered with posterior fossa surgery. Manipulation or resection of brain parenchyma can result in an irritable epileptic focus. For high-risk procedures, consideration should be given to the use of carbamazepine, phenobarbitone or phenytoin for antiseizure prophylaxis. For post-operative seizures these drugs and diazepam are indicated. One medication is initiated at a time and the dosage increased until the seizure is controlled or the maximum serum level of the drug is reached. Another drug may then be added if necessary.

Headaches

There is a higher incidence of headache with the retrosigmoid approach for VS surgery, which may be debilitating and intractable.[22, 23] This is a feature of VS surgery, with headache not as common using this approach in other posterior fossa tumours. It has been suggested that adherence of the dura to nuchal soft tissue, neck muscle spasm and aseptic meningitis from bone dust or fibrin glue is responsible.[44, 45] It is more common following VS surgery for small tumours, although this may reflect individual psychological

factors, causing patients of a 'sensitive disposition' with mild tumour symptoms to present early and also to be more likely to report local discomfort post-operatively. Intradural drilling of the internal auditory meatus deposits bone dust into the posterior fossa, and alternatively, it is postulated that larger VSs prevent wide distribution of bony debris. The use of cranioplasty techniques with bone or titanium mesh and acrylic reduces the incidence.[44, 45]

BEST CLINICAL PRACTICE

- ✓ **General practice:**
  - performing procedures in a multidisciplinary team, utilizing the strengths of each member
  - regular frequency of surgeries; minimum once every 2 weeks.
- ✓ **Pre-operative management:**
  - otological and audiological examination – pure-tone and speech audiometry
  - vestibular examination – 1/3 of patients with profound sensorineural hearing loss report subjective hearing loss, while twice as many show pathological vestibular signs in caloric testing and/or vestibular evoked myogenic potentials
  - imaging – temporal bone imaging revealed high riding bulb in 32% (which can lead to the presence of bony defects of the hypotympanon), anterior sigmoid sinus in 34%, a low riding dura in 26% and an aberrant carotid artery in 0.02%.
- ✓ **Vascular:**
  - discontinue aspirin and clopidogrel 7–10 days prior to surgery
  - warfarin discontinued 5 days pre-operatively, which is adequate time to reconstitute the coagulation factors. If at risk of thromboembolic event, use low molecular weight heparin 2 days after stopping warfarin or 3 days prior to operation, stopping 24 hours before surgery
  - pre-operative corticosteroid administration – to reduce inflammatory mediators which cause vasodilation, transduction and oedema
  - patient positioning should be reverse Trendelenberg, as head elevation reduces mean arterial pressure in the elevated area. Patient must be tilted in and out of position slowly to avoid sudden shift in blood
  - ventilation technique maintaining normocapnia or mild hypocapnia to minimize bleeding, with some centres using high-frequency jet ventilation
  - highly vascular tumours may require pre-operative embolization and ligation of feeding vessels. Should be performed 24 to 72 hours pre-operatively to provide adequate thrombosis and prior to re-formation of collateral blood supply
  - bleeding is controlled using bone wax, bipolar diathermy, placement of haemostaic agents such as oxidized cellulose (Surgicel), microfibrillary collagen (Avitene) or a biological glue and repair using 6-0 or 7-0 monofilament suture
  - occasionally, large venous sinus perforations require extraluminal or intraluminal packing or even ligation to achieve haemostasis
  - decrease bleeding with controlled hypotensive anaesthesia.
- ✓ **Air embolus:**
  - the first sign of this complication is a sucking sound or venous crepitation at the site of entry
  - later hypotension, tachycardia, dysrhythmias and diminishing end-expiratory pCO_2 develop.
- ✓ **Cranial nerve injury:**
  - microdissection techniques and electrophysiological nerve monitoring enhance the preservation of CN during tumour resection
  - if the facial nerve is cut, primary reanastomosis avoiding tension is best. Failing this, cable grafting using the greater auricular nerve or the sural nerve is the next best option, followed by facial-hypoglossal anastomosis.
- ✓ **Cardiac dysrhythmia:**
  - vagal nerve stimulation can cause a sinus bradycardia and hypotension
  - brainstem stimulation may cause tachycardia and hypertension.
- ✓ **Temperature:**
  - regular flushing of endoscope
  - site of bone drilling to be short and varied to avoid high temperature.
- ✓ **Haematomas:**
  - arterial haemorrhage produces a rapid collection of blood in the extradural space
  - venous haemorrhage results in a gradual neurological deterioration, owing to subdural haematoma formation
  - depending on the severity and rapidity of the patient's neurological deterioration, management varies from bedside wound opening to surgical exploration in the theatre or CT imaging.
- ✓ **Cerebrospinal fluid leak:**
  - immunoelectrophoretic assay for beta transferrin is both highly specific and sensitive for CSF
  - CSF lumbar drainage is effective in eliminating 50–90% of cases of CSF leaks after skull base surgery.
- ✓ **Infections:**
  - there is a good evidence base to recommend a single intravenous dose antibiotic prophylaxis, given at induction of anaesthesia for skull base procedures
  - meningitis is usually associated with a CSF fistula.
- ✓ **Pneumocephalus:**
  - air accumulating under pressure to create an acute elevation of intracranial pressure is potentially fatal.
- ✓ **Hydrocephalus:**
  - this presents in the early post-operative period with headache, impaired consciousness, gait disturbance and incontinence.
- ✓ **Epilepsy:**
  - post-operative seizures may herald the development of haematoma, oedema, infarction or any complication causing mass effect and cerebral irritation
  - temporal lobe manipulation carries a special risk.
- ✓ **Headaches:**
  - there is a higher incidence of headache with the retrosigmoid approach for VS surgery, which may be debilitating and intractable.

FUTURE RESEARCH

Despite the wealth of data on the pathophysiology of disease and our theoretical foundations for treatment, randomized trials have produced somewhat surprising results in the past. Prospective randomized controlled trials, which may need to be multicentred, are required to improve the evidence-base on the following issues:

- the efficacy of neuronavigation technology in reducing complications
- evaluation of newer tumour ablation techniques
- the value of pre-operative embolization of highly vascular tumours, addressing selection criteria, different materials and the timing in relation to surgery
- the efficacy of CSF lumbar drainage for prophylactic prevention of post-operative CSF leaks (How long should the drain remain *in situ*? Should it drain at a certain rate or would a lowered stable CSF pressure setting be more efficacious?)
- the role of antibiotic prophylaxis in clean contaminated skull base procedures, with lumbar drains and in patients with a post-operative CSF leak
- use of novel monitoring techniques, such as four contact adherent systems for glossopharyngeal and vagus nerve monitoring during surgery. Utilize compound muscle action potentials from posterior pharyngeal wall.

KEY POINTS

- The sound of crepitation at the site of a large perforation of a venous sinus and later cardiorespiratory distress should alert the surgeon to the possibility of an air embolus.
- Manipulation of the vagus nerve or brainstem may result in cardiac dysrhythmia and surgery should be halted until sinus rhythm returns.
- Cranial nerve injuries are among the most debilitating complications encountered in skull base surgery.
- Microdissection techniques and electrophysiological nerve monitoring enhance the preservation of CN during tumour resection.
- CSF leaks are among the most common post-operative skull base surgery complications.
- There is a good evidence base to recommend a single intravenous dose antibiotic prophylaxis, given at induction of anaesthesia for skull base procedures.
- Post-operative seizures may herald the development of haematoma, oedema, infarction or any complication causing mass effect and cerebral irritation.
- Most post-operative intracranial haematomas are rapid and require prompt surgical exploration, avoiding the delay of imaging studies.
- There is a higher incidence of headache with the retrosigmoid approach for VS surgery, which may be debilitating and intractable.
